About Frontiers

Frontiers is more than just an open-access publisher of scholarly articles: it is a pioneering approach to the world of academia, radically improving the way scholarly research is managed. The grand vision of Frontiers is a world where all people have an equal opportunity to seek, share and generate knowledge. Frontiers provides immediate and permanent online open access to all its publications, but this alone is not enough to realize our grand goals.

Frontiers Journal Series

The Frontiers Journal Series is a multi-tier and interdisciplinary set of open-access, online journals, promising a paradigm shift from the current review, selection and dissemination processes in academic publishing. All Frontiers journals are driven by researchers for researchers; therefore, they constitute a service to the scholarly community. At the same time, the Frontiers Journal Series operates on a revolutionary invention, the tiered publishing system, initially addressing specific communities of scholars, and gradually climbing up to broader public understanding, thus serving the interests of the lay society, too.

Dedication to Quality

Each Frontiers article is a landmark of the highest quality, thanks to genuinely collaborative interactions between authors and review editors, who include some of the world's best academicians. Research must be certified by peers before entering a stream of knowledge that may eventually reach the public - and shape society; therefore, Frontiers only applies the most rigorous and unbiased reviews.
Frontiers revolutionizes research publishing by freely delivering the most outstanding research, evaluated with no bias from both the academic and social point of view.
By applying the most advanced information technologies, Frontiers is catapulting scholarly publishing into a new generation.

What are Frontiers Research Topics?

Frontiers Research Topics are very popular trademarks of the Frontiers Journals Series: they are collections of at least ten articles, all centered on a particular subject. With their unique mix of varied contributions from Original Research to Review Articles, Frontiers Research Topics unify the most influential researchers, the latest key findings and historical advances in a hot research area! Find out more on how to host your own Frontiers Research Topic or contribute to one as an author by contacting the Frontiers Editorial Office: **researchtopics@frontiersin.org**

ENCODING AND NAVIGATING LINGUISTIC REPRESENTATIONS IN MEMORY

Successful speaking and understanding requires mechanisms for reliably encoding structured linguistic representations in memory and for effectively accessing information in those representations later. Studying the time-course of real-time linguistic dependency formation provides a valuable tool for uncovering the cognitive and neural basis of these mechanisms. This volume draws together multiple perspectives on encoding and navigating structured linguistic representations, to highlight important empirical insights, and to identify key priorities for new research in this area.

Table of Contents

07 ***Editorial: Encoding and navigating linguistic representations in memory***
Claudia Felser, Colin Phillips and Matthew Wagers

Section 1: Anaphor resolution

13 ***Reflexive anaphor resolution in spoken language comprehension: structural constraints and beyond***
Kaili Clackson and Vera Heyer

22 ***Retrieval interference in syntactic processing: the case of reflexive binding in English***
Umesh Patil, Shravan Vasishth and Richard L. Lewis

40 ***Retrieval interference in reflexive processing: experimental evidence from Mandarin, and computational modeling***
Lena A. Jäger, Felix Engelmann and Shravan Vasishth

64 ***Local anaphor licensing in an SOV language: ilmplications for retrieval strategies***
Dave Kush and Colin Phillips

76 ***Teasing apart retrieval and encoding interference in the processing of anaphors***
Lena A. Jäger, Lena Benz, Jens Roeser, Brian W. Dillon and Shravan Vasishth

94 ***The structure-sensitivity of memory access: evidence from Mandarin Chinese***
Brian Dillon, Wing-Yee Chow, Matthew Wagers, Taomei Guo, Fengqin Liu and Colin Phillips

110 ***The relationship between anaphor features and antecedent retrieval: comparing Mandarin* ziji *and* ta-ziji**
Brian Dillon, Wing-Yee Chow and Ming Xiang

126 ***Processing the Chinese reflexive "ziji": effects of featural constraints on anaphor resolution***
Xiao He and Elsi Kaiser

145 ***Wh-filler-gap dependency formation guides reflexive antecedent search***
Michael Frazier, Lauren Ackerman, Peter Baumann, David Potter and Masaya Yoshida

164 ***A fan effect in anaphor processing: effects of multiple distractors***
Kevin S. Autry and William H. Levine

179 ***Backward- and forward-looking potential of anaphors***
Petra B. Schumacher, Jana Backhaus and Manuel Dangl

193 ***Immediate sensitivity to structural constraints in pronoun resolution***
Wing-Yee Chow, Shevaun Lewis and Colin Phillips

209 ***The online application of binding condition B in native and non-native pronoun resolution***
Clare Patterson, Helena Trompelt and Claudia Felser

225 ***Structural constraints on pronoun binding and coreference: evidence from eye movements during reading***
Ian Cunnings, Clare Patterson and Claudia Felser

243 ***Active search for antecedents in cataphoric pronoun resolution***
Leticia Pablos, Jenny Doetjes, Bobby Ruijgrok and Lisa L.-S. Cheng

256 ***Interference in the processing of adjunct control***
Dan Parker, Sol Lago and Colin Phillips

269 ***On the shallow processing (dis)advantage: grammar and economy***
Arnout Koornneef and Eric Reuland

Section 2: Filler-gap dependencies

286 ***The localization of long-distance dependency components: integrating the focal-lesion and neuroimaging record***
Maria M. Piñango, Emily Finn, Cheryl Lacadie and R. Todd Constable

309 ***Cross-linguistic evidence for memory storage costs in filler-gap dependencies with wh-adjuncts***
Arthur Stepanov and Penka Stateva

328 ***An fMRI study dissociating distance measures computed by Broca's area in movement processing: clause boundary vs. identity***
Andrea Santi, Angela D. Friederici, Michiru Makuuchi and Yosef Grodzinsky

340 ***Discourse accessibility constraints in children's processing of object relative clauses***
Yair Haendler, Reinhold Kliegl and Flavia Adani

357 ***Using the visual world paradigm to study retrieval interference in spoken language comprehension***
Irina A. Sekerina, Luca Campanelli and Julie A. Van Dyke

372 ***The processing of raising and nominal control: an eye-tracking study***
Patrick Sturt and Nayoung Kwon

387 ***Structure modulates similarity-based interference in sluicing: an eye tracking study***
Jesse A. Harris

405 ***Filling the silence: reactivation, not reconstruction***
Dario L. J. F. Paape

423 ***Working memory differences in long-distance dependency resolution***
Bruno Nicenboim, Shravan Vasishth, Carolina Gattei, Mariano Sigman and Reinhold Kliegl

439 ***When high-capacity readers slow down and low-capacity readers speed up: working memory and locality effects***
Bruno Nicenboim, Pavel Logačev, Carolina Gattei and Shravan Vasishth

463 ***Hyper-active gap filling***
Akira Omaki, Ellen F. Lau, Imogen Davidson White, Myles L. Dakan, Aaron Apple and Colin Phillips

481 ***Thematic orders and the comprehension of subject-extracted relative clauses in Mandarin Chinese***
Chien-Jer Charles Lin

494 ***Filling predictable and unpredictable gaps, with and without similarity-based interference: evidence for LIFG effects of dependency processing***
Kimberly Leiken, Brian McElree and Liina Pylkkänen

510 ***Task-dependency and structure-dependency in number interference effects in sentence comprehension***
Julie Franck, Saveria Colonna and Luigi Rizzi

525 ***Corrigendum: Task-dependency and structure-dependency in number interference effects in sentence comprehension***
Julie Franck, Saveria Colonna and Luigi Rizzi

526 ***Syntactic constraints and individual differences in native and non-native processing of wh-movement***
Adrienne Johnson, Robert Fiorentino and Alison Gabriele

543 ***Similarity of* wh*-phrases and acceptability variation in* wh*-islands***
Emily Atkinson, Aaron Apple, Kyle Rawlins and Akira Omaki

559 ***The D-linking effect on extraction from islands and non-islands***
Grant Goodall

570 ***Distinctiveness and encoding effects in online sentence comprehension***
Philip Hofmeister and Shravan Vasishth

583 ***Elaboration over a discourse facilitates retrieval in sentence processing***
Melissa Troyer, Philip Hofmeister and Marta Kutas

Section 3: Computing agreement and feature-based encoding

592 ***Representing number in the real-time processing of agreement: self-paced reading evidence from Arabic***
Matthew A. Tucker, Ali Idrissi and Diogo Almeida

613 ***Gender agreement attraction in russian: production and comprehension evidence***
Natalia Slioussar and Anton Malko

633 ***Minimal interference from possessor phrases in the production of subject-verb agreement***
Janet L. Nicol, Andrew Barss and Jason E. Barker

645 ***Language processing as cue integration: grounding the psychology of language in perception and neurophysiology***
Andrea E. Martin

662 ***Grammatical number processing and anticipatory eye movements are not tightly coordinated in English spoken language comprehension***
Brian Riordan, Melody Dye and Michael N. Jones

673 ***An interference account of the missing-VP effect***
Jana Häussler and Markus Bader

Section 4: Other phenomena

689 ***Listeners exploit syntactic structure on-line to restrict their lexical search to a subclass of verbs***
Perrine Brusini, Mélanie Brun, Isabelle Brunet and Anne Christophe

697 ***Dependency resolution difficulty increases with distance in persian separable complex credicates: evidence for expectation and memory-based accounts***
Molood S. Safavi, Samar Husain and Shravan Vasishth

712 ***Poor readers' retrieval mechanism: efficient access is not dependent on reading skill***
Clinton L. Johns, Kazunaga Matsuki and Julie A. Van Dyke

732 ***Processing implicit control: evidence from reading times***
Michael McCourt, Jeffrey J. Green, Ellen Lau and Alexander Williams

748 ***Dependency-dependent interference: NPI interference, agreement attraction, and global pragmatic inferences***
Ming Xiang, Julian Grove and Anastasia Giannakidou

Editorial on the Research Topic

Encoding and Navigating Linguistic Representations in Memory

MOTIVATIONS

We created this research topic to address two closely related needs: to support a rapidly growing area of language science, and to support the (predominantly young) scientists who are working in this area. Recent years have seen a rapid growth in the amount of psycholinguistic research being carried out in linguistics departments. This has created a venue for exploring new questions. Understanding structured mental representations and the relations within them is the bread-and-butter of much research in linguistics, but the traditional focus has been on theories at a level of analysis that assumes discrete, symbolic representations, and is agnostic about how those representations are constructed in real time, whether in comprehension, production, or acceptability judgment tasks. Now there is a community of researchers who are working to understand these phenomena in more fine-grained terms.

In the area of syntax, the growth in research at the intersection of linguistics and psychology has been fueled by a number of parallel developments.

First, by connecting linguistic representations with psychological theories of memory encoding and access. The literature on memory encoding provides only limited inspiration for theories of structured linguistic representations, because most memory research is based on unstructured lists. But the literature on memory access has served as a strong inspiration for theories of linguistic dependency formation. In particular, models of content-addressable memory (CAM) have been influential in psycholinguistics. In CAM, items in memory are accessed (or their activation-level is boosted) based on their match to a set of content-based retrieval cues, rather than based on their memory address, as in classical computational architectures. A hallmark of memory access in CAM is similarity-based interference effects. These effects have been widely documented in language processing (Gordon et al., 2001; Van Dyke, 2007) and they feature prominently in many of the papers in the current collection. A second hallmark of memory access in CAM is non-effects of structural or linear distance in retrieval times (McElree et al., 2003), and these effects are the focus of one article in this collection (Dillon et al.). The influence of CAM on psycholinguistics has been aided by an implemented CAM-based parsing model (ACT-R: Lewis and Vasishth, 2005). This model makes specific, testable predictions, and provides a useful framework for thinking about memory access in language processing.

Second, research on the time course of linguistic processes is now more accessible, due to portable and affordable technical resources. Many studies can be carried out on laptop computers or even via the internet. Free statistical software packages are widely used, aided by a supportive user community. And one should not underestimate the value of role models that show that linguists can do this kind of research.

Together, the theoretical and practical developments have opened up a playground of languages and linguistic phenomena that can be used to develop and test models of real-time linguistic processes. The scale and diversity of the research in this collection was not possible 10–15 years ago.

However, publication venues have not kept pace with the growth in research at the intersection of linguistics and psychology. Researchers in this area still need to choose whether to submit their work to journals with a traditional linguistics focus or journals with a traditional psychology focus. For example, the *Journal of Memory and Language* is one of the most highly regarded journals in psycholinguistics. As of the start of 2017 its editorial staff and editorial board include more than 50 individuals, and there is almost no representation from linguistics. The associate editorial board of *Linguistic Inquiry*, an influential linguistics journal, has 70 members and just a couple of psycholinguists (To its credit, the new open access linguistics journal *Glossa* has a more diverse editorial team). This polarization means that there are few hospitable outlets for research that is unapologetic in its use of both linguistic and psychological models and analyses. Psychology journals routinely tell authors that their work "will not be understandable to our readers," even for relatively basic linguistic notions, especially if not from English. Notice the quaint idea that people read journals rather than articles. Linguistics journals are more likely to ask authors, "But how does this bear on theory?," where "theory" is assumed to mean claims at the traditional level of linguistic analysis, as if psycholinguists don't build theories. Of course, a number of papers have made their way into prominent journals in either field (e.g., Sturt, 2003; Phillips, 2006), but there is limited appetite for ongoing debates that delve into the details of real-time grammatical processes.

An additional benefit of editing this research topic is that we have been pleasantly surprised by the effectiveness of the Frontiers editorial process, which departs from tradition in a number of respects.

(i) As research topic editors, we could request 1-page abstracts before inviting a full paper submission. This allowed efficient triage of unsuitable submissions, and allowed us to make suggestions to authors at an early stage in the process.
(ii) The focus in the review process on soundness rather than impact was liberating for authors and reviewers alike, as they could engage more candidly with one another about what the results did and did not show. There has been much recent hand-wringing about transparency and replicability in psychological science (Open Science Collaboration, 2015). Most discussions have focused on how to avoid problems by legislating pre-registration, data sharing, specific analyses, etc. But it's just as important to remove the unrealistic expectations that create pressure on authors to distort their claims (Nosek et al., 2012; Maner, 2014). Our experience with this research topic is that authors are refreshingly open when the system does not penalize them for that.
(iii) The interactive review process helped to keep reviewers and authors on target and on time. The discussion-like format also made the process more collegial.

The success of the research topic is also evident in various metrics. As of January 2017, the 48 articles in this collection are the largest Frontiers research topic under the heading Psychology (out of 482 research topics) and Language Sciences (out of 53 research topics). One hundred and fifty-five authors contributed, as did 74 reviewers. This leaves little doubt that there is a market for publication venues at the intersection of linguistics and psychology. Also, the publication cycles were dramatically faster than other journals in linguistics and psycholinguistics. The median time from manuscript submission through two rounds of review (independent + interactive) to online publication was just over 4 months (128 days). For traditional journals the norm is 1–2 years or more. Of course, rapid publication is particularly valuable for junior researchers whose careers are hurt by extremely slow publication cycles. The speed of publication had the unexpected consequence that articles in this collection were cited at rates that are competitive with leading journals in linguistics, although this was not part of our original goal. We refer interested readers to a fuller discussion of our editorial experience elsewhere (Phillips, 2016).

Although we were encouraged by the number and quality of the articles and by the success of the review process, there were a couple of areas where we were disappointed. We hoped to see more articles on populations other than young adult native speakers, and we hoped to see more computational contributions. In both of these areas the lower demand may reflect the availability of other accessible and fast outlets. We also hoped to see more articles focusing on theory and synthesis. If this new field of research is to be sustainable, then it will need more than a large body of findings about specific linguistic phenomena in diverse languages. Without theoretical debates that serve to organize and guide research, the field will quickly run out of steam.

TOPICAL REVIEW

To review the individual contributions in our research topic, we have divided our collection roughly by linguistic phenomena, and consider the (overlapping) subsets of articles that deal with *anaphor resolution, filler-gap dependencies*, and *agreement*. These subsets, particularly the first two, address questions of how structured, compositional information is used in online sentence comprehension, and what kinds of features or similarity relations can aid or hinder comprehension. These themes—particularly the latter two—also consider how forward-looking the parser is, both in terms of expectations it explicitly commits to, but also in terms of how it encodes present information for future retrieval.

ANAPHOR RESOLUTION

Nineteen of the articles in the collection focus on anaphor resolution (And that does not include the articles on different forms of ellipsis). Encountering an anaphoric expression is thought to trigger a memory search for a suitable antecedent. Of the linguistic phenomena represented in this collection, anaphor resolution seems the most obviously suitable one for testing theoretical assumptions about memory access and retrieval, and how different types of cue interact in guiding the search process. Linguistic constraints on anaphor resolution such as Conditions A and B of the binding theory (Chomsky, 1981; Sportiche, 2013) seem to be at odds with some of the assumptions of well-motivated retrieval models. Most of the studies on anaphor resolution in this collection focus on interference; that is, on the question of whether anaphor resolution is affected by the presence of feature-matching distractors, and whether this is the case even for distractors that are structurally illicit antecedents. Interference can serve as a probe for memory access mechanisms. Whilst earlier studies investigating the role and timing of binding constraints during anaphor resolution mostly focused on English or English-type reflexives and pronouns (e.g., Nicol and Swinney, 1989; Badecker and Straub, 2002; Sturt, 2003), the articles in the current collection considerably expand the empirical research base by examining other languages and types of anaphora, including bound variable and long-distance anaphora.

A number of articles investigate the processing of reflexives or reciprocals. Using the visual-world paradigm, Clackson and Heyer find evidence for similarity-based interference during the processing of English reflexives, with listeners being distracted by a discourse-prominent but syntactically inaccessible antecedent. Patil et al. observe interference effects during the processing of English reflexives using eye-movement monitoring during reading, and Jäger et al. report interference effects during the processing of reflexives in Mandarin. No interference effects were observed by Kush and Phillips in the processing of pre-verbal anaphors (reciprocals) in Hindi, however. Jäger et al. report a series of studies on German and Swedish reflexives, where their findings suggest that interference affects retrieval but not encoding.

Dillon et al. provide experimental and modeling evidence for a locality bias for Mandarin long-distance reflexives, using a speed-accuracy tradeoff (SAT) paradigm, and Dillon et al. show this bias to be reduced for morphologically complex reflexives. Also examining Mandarin reflexives, He and Kaiser provide reading-time evidence showing that person features can block long-distance referential dependencies. Frazier et al.'s eye-movement results show that syntactic gaps (*wh*-traces) interact with reflexive resolution in English.

Several other contributions focus on non-reflexive pronouns. Looking at pronoun resolution across sentence boundaries, Autry and Levine demonstrate that multiple distractors give rise to cumulative ("fan") effects. Schumacher et al. examine the inter-sentential resolution of German pronouns and demonstratives using ERPs. Their results suggest that both semantic and positional cues contribute to a potential antecedent's referential prominence.

Investigating the role of binding constraints during pronoun resolution, Chow et al. present reading-time evidence which indicates that the antecedent search is constrained by Condition B. This conclusion is further supported by the findings reported by Patterson et al., whose participants also included non-native speakers of English. Unlike the native group, the non-native speakers showed a bias toward matrix subject antecedents, regardless of whether or not local coreference was allowed. The eye-movement results reported by Cunnings et al. show that c-command constrains pronoun binding by a quantificational antecedent, but not coreference between a pronoun and a non-quantificational antecedent. These findings are in line with what Sportiche (2013: 196) has dubbed "Condition D" of the binding theory. Pablos et al. investigate the processing of Dutch cataphoric (rather than anaphoric) pronouns using ERPs. Their results indicate that binding Condition C constrains the search for a suitable referent. The contribution by Parker et al. provides evidence for similarity-based interference during the computation of adjunct control dependencies, showing that an overt pronoun is not necessary.

Finally Koornneef and Reuland's "hypothesis and theory" article draws largely on findings from anaphor resolution studies. The authors argue that "deep" or grammatically driven processing is not necessarily computationally more costly than "shallow" processing using extra-grammatical information sources.

The studies on anaphora in this collection ultimately present a mixed picture: On the one hand, there is clear evidence of structure-based constraints guiding the antecedent search, while on the other hand referential dependency formation has been shown to be vulnerable to similarity-based interference under specific conditions. These seemingly contradictory findings can possibly be accounted within CAM-based processing models capable of implementing structure-sensitive constraints, and the specific way of capturing them is a focus of current debate.

FILLER-GAP DEPENDENCIES

A large number of articles in this collection examine the processing of filler-gap dependencies, with most of them focusing on *wh*-movement or relative clauses. Filler-gap dependencies are mediated by hierarchical phrase structure representations, and successfully completing them involves both memory storage and retrieval (e.g., Gibson, 1998). Encountering a filler such as *which student* in a *wh*-interrogative sentence like *Which student did you say you met at the concert last night?* is thought to trigger the prediction of a corresponding gap to which the filler must be linked before it can be fully integrated into the emerging sentence representation. Piñango et al. present brain imaging evidence showing that gap search and gap completion processes can be distinguished at the neurocognitive level.

As a filler needs to be kept in memory until a suitable gap can be identified, processing filler-gap dependencies can incur measurable storage costs. The difficulty of retrieving a filler (or antecedent) at a gap site may be affected by the nature of the sentence material that intervenes between antecedent and

gap, giving rise to interference effects. Stepanov and Stateva report cross-linguistic reading-time evidence for memory storage effects during the processing of *wh*-adjunct dependencies in both English and Slovenian, and Santi et al. present brain-imaging results which show that *wh*-dependency formation is affected by the syntactic type of the intervening sentence material. Using the visual-world paradigm, Haendler et al. show that German-speaking children's ability to comprehend object relative clauses is affected by referential properties of the intervening subject. In their Methods article, Sekerina et al. demonstrate that items held in short-term memory can interfere with filler retrieval during the auditory processing of object clefts, replicating earlier findings from reading-based tasks in a different modality. Using eye-movement monitoring during reading, Sturt and Kwon show that the processing of both subject raising and nominal control dependencies is subject to facilitatory interference effects. Also taking into account Parker et al.'s findings of interference effects during the computation of adjunct control dependencies, these studies indicate that antecedent retrieval at gap sites is generally vulnerable to interference.

This conclusion is further corroborated by the two studies in this collection that have investigated sluicing, a special type of clausal ellipsis that involves fronting of a remnant *wh*-expression (as in *He lost his keys but didn't know where*). The eye-movement data presented by Harris provide evidence that antecedent retrieval during the processing of sluiced sentences is subject to similarity-based interference modulated by structural properties of the antecedent. The contribution by Paape examines how the presence of a temporary subject/object ambiguity in the antecedent affects the processing of sluiced sentences in German.

Two further studies have examined effects of individual differences in working memory (WM) capacity on the processing of filler-gap dependencies. Nicenboim et al. present reading-time evidence for such effects from Spanish, and Nicenboim et al. report further evidence showing that locality effects in Spanish and German are modulated by WM capacity.

Several contributions focus on the nature of the gap search and how this search is constrained, or on the question of how dependency formation interacts with other grammatical computations. Omaki et al.'s findings show that the gap search process is highly predictive, with direct object gaps being postulated independently of verb transitivity even in a verb-medial language like English. The contribution by Lin focuses on the role of expectation during the processing of different types of subject relative clauses in Chinese, showing that canonical thematic ordering facilitates processing. Leiken et al. investigate the role of gap predictability in the processing of English object relatives (in comparison to verb-phrase ellipsis and right-node raising structures) using magnetoencephalography. Their results suggest that the left-anterior frontal gyrus (LIFG), a brain region previously found to be involved in dependency formation, subserves memory retrieval at gap sites regardless of whether or not the gap was predictable. Franck et al. use the phenomenon of agreement attraction to demonstrate that computing filler-gap dependencies involves the creation of abstract hierarchical phrase-structure representations, and Frazier et al. demonstrate that *wh*-gaps interact with the processing of reflexives. Engaging in an active gap search does not mean that gaps are postulated freely, however. The reading-time results reported by Johnson et al. suggest that neither native English speakers nor native Korean-speaking learners of English postulate gaps in so-called "island" environments.

Other studies examine how properties of the filler affect the processing of filler-gap dependencies. Atkinson et al. report a series of acceptability judgment experiments showing that morphosyntactic and semantic features interact in ameliorating *wh*-island violations, and Goodall shows that one of the factors known to ameliorate island violations ("d-linking") also improves the acceptability of non-island sentences. Hofmeister and Vasishth's reading-time results indicate that more complex fillers are easier to retrieve at gap sites than less complex ones, and the findings reported by Troyer et al. show that elaboration also facilitates filler retrieval across short pieces of discourse.

Taken together, the above studies provide strong evidence that retrieval at gap sites is vulnerable to similarity-based interference, that more complex or elaborate fillers are easier to retrieve than less complex ones, and that both gap postulation and filler retrieval are sensitive to information encoded in hierarchical phrase-structure representations.

COMPUTING AGREEMENT AND FEATURE-BASED ENCODING

Several articles in our collection address the phenomenon of agreement attraction. Agreement attraction is a robust perceptual illusion that mirrors a speech error in production (Bock and Miller, 1991). For example, speakers are prone to produce sentences like *The **dogs** [that the shelter **rescue** in the winter] eventually got adopted*. In our example, the agreement on the verb *rescue* should be controlled by its singular, grammatical subject, *the shelter* but instead it is attracted to agree with another nearby phrase *the dogs*—the attractor. Not only are such examples easily found in natural speech and elicited in the lab, but they are also routinely missed by language perceivers: speakers experience an illusion of grammaticality.

The illusion turns out to be very sensitive to the relationship between the features on the grammatical subject, the attractor noun, and the verb. For this reason, it has served as a productive system for probing issues around linguistic encoding: what are the features with which comprehenders represent partial linguistic information in their working memory? A common, well-motivated view about how nouns are encoded relies on feature markedness. Along any feature scale, certain values are more marked than others, like plural is more marked than singular: for example, plural nouns are less common than singular nouns and are usually signaled by more complex morphological forms (*dog-s* vs. *dog-Ø*). And it appears that these marked values are more visible in the comprehension system, in terms of how they are encoded during language processing (Eberhard, 1997). But several papers in our collection demonstrate that a more nuanced view is necessary, and they do so by looking at feature systems in under-investigated languages with grammars that have more complicated syntax/morphology

mappings, ones that are more amenable to investigating this question.

Tucker et al. show that in Modern Standard Arabic (MSA) the morphological exponence of a marked feature also matters. MSA expresses the plural feature in two ways, the so-called suffixed plural and the broken (or ablaut) plural. The suffixed plural causes more attraction and with a different time-course than the ablaut plurals in MSA. Slioussar and Malko examined a more complex feature system—gender—in Russian. The Russian gender system has three values, called masculine, feminine, and neuter. This three-way distinction makes it possible to demonstrate that, in determining whether attraction will occur, the visibility of the attractor alone is insufficient, and the visibility of the head is crucial. Nicol et al. also reinforce the conclusion that the head-attractor relationship matters, but from the perspective of hierarchical relatedness. Attractors that are closer to the head noun in the sentence's phrase structure induced more attraction effects. Moreover, how saliently a noun was marked as non-nominative mattered (e.g., *women's* generated less attraction than *dogs*'). Franck et al.'s paper on filler-gap dependencies likewise demonstrates that the relative syntactic prominence of the attractor is encoded.

Research on how plurals are encoded in real-time not only feeds-back into how plurality is represented in the grammar, but it also leads the way to broader questions of the relationship between *how* dependent elements are initially encoded and how retrieval cues are identified and integrated across time. These issues are taken up by Tucker et al. in their discussion of "feature-cue" algorithms in MSA. But Martin's Hypothesis article raises higher-level questions about how a theory of cue integration might relate different kinds of linguistic representation, such as how information signaled by distinct morphemes may be integrated into the percept of a phrase. Riordan et al. specifically consider the cue validity of Number in a broad variety of syntactic contexts; they demonstrate that number cues often generate quite weak predictions about numerosity, based on anticipatory looking in the visual world paradigm.

Hofmeister and Vasishth address the encoding/retrieval relation from a different angle: investigating the processing of relative clauses, they show that only syntactic and semantic elaboration of an left dependent (the RC head) affects retrieval at the right dependent (the RC verb)—but other differences experienced at encoding, like different text colors, do not. Troyer et al. show that such elaborative effects can happen as referents are processed over the span of a discourse, and not merely locally, i.e., not only when the elaboration occurs at the targeted retrieval position itself.

When there are evidently effects of similarity-based interference at a retrieval site, it is important to assess whether such effects derive from the process of retrieval itself or whether they might have arisen during the process of encoding. Along these lines, Häussler and Bader argue that interference at retrieval can explain the "missing VP" effect observed in the processing of center self-embedded relative clauses, even in languages like German which may benefit from highly predictive encoding mechanisms. Likewise, Jäger et al.'s paper on reflexives also takes up a phenomenon to argue that the culprit in any online fallibility is explicitly not encoding interference.

The remaining articles in this collection address issues relating to prediction, memory retrieval, or the role of linguistic structure in dependency formation by examining other linguistic phenomena. Brusini et al.'s contribution investigates verb prediction in French, providing evidence that syntactic cues constrain lexical access. In a series of reading-time experiments, Safavi et al. examine the processing of complex predicates in Persian, showing that dependency resolution difficulty is affected both by predictability and distance. Using an auditory speed-accuracy tradeoff paradigm, Johns et al. show that individual differences in reading skill do not affect memory retrieval during listening. McCourt et al. present reading-time evidence which challenges previous claims to the effect that the phenomenon of implicit control involves a silent syntactic argument. Xiang et al. show that susceptibility to interference during the processing of negative polarity items (NPIs) correlates with pragmatic reasoning as measured by an autism scale, whereas susceptibility to agreement attraction does not correlate. This indicates that NPI illusions have a different source than agreement attraction.

We report results from an eye-tracking during listening study examining English-speaking adults' online processing of reflexive pronouns, and specifically whether the search for an antecedent is restricted to syntactically appropriate positions. Participants listened to a short story where the recipient of an object was introduced with a reflexive, and were asked to identify the object recipient as quickly as possible. This allowed for the recording of participants' offline interpretation of the reflexive, response times, and eye movements on hearing the reflexive. Whilst our offline results show that the ultimate interpretation for reflexives was constrained by binding principles, the response time, and eye-movement data revealed that during processing participants were temporarily distracted by a structurally inappropriate competitor antecedent when this was prominent in the discourse. These results indicate that in addition to binding principles, online referential decisions are also affected by discourse-level information.

Keywords: binding principle A, reflexive resolution, discourse prominence, sentence processing, eye-tracking

INTRODUCTION

According to most theoretical accounts, the interpretation of a reflexive is determined solely by a structural constraint which identifies a unique referent (Chomsky, 1981, 1986; Levinson, 1987; Pollard and Sag, 1992; Reinhart and Reuland, 1993; Reinhart, 2000, Reuland, 2001; Burkhardt, 2005 among others). For example, Principle A requires that an English argument reflexive is bound by a local antecedent that falls within its governing category, so that the anaphor and its antecedent are co-indexed (i.e., have compatible number, gender and person features), and the anaphor is c-commanded by its antecedent. In (1) *Susan* is structurally accessible as an antecedent as *Susan* binds (i.e., c-commands and is co-indexed with) *herself* and falls within the governing category of *herself* (shown by square brackets). *Jane* falls outside the governing category of *herself* and so is not structurally accessible as an antecedent.

(1) Jane_1 says that [Susan_2 hurt $\text{herself}_{*1/2}$].

In recent years there has been considerable discussion about the role that such structural constraints play in online sentence processing. Of particular interest is whether the parser's search for a referent is guided principally by structural considerations, where each potential antecedent is assessed based on its structural position; or whether a more cue-based search is implemented, where a structurally illicit referent that is strongly supported by other cues (such as being of appropriate gender and number, and in a prominent position) might be briefly considered and so lead to interference effects [for further discussion see Van Dyke (2007), Phillips et al. (2010), and Dillon et al. (2013) among others]. As the referent for a reflexive can be identified on the basis of structural information alone (in contrast to pronouns where structural information rules out certain referents, but does not necessarily identify a single referent), reflexive resolution is often seen as a good test case in this debate. In the present study we ask whether a noun phrase in a position where co-reference with the reflexive would violate a constraint, henceforth termed "inaccessible," [such as *Jane* in (1)] is ever considered by the parser as a potential referent. Results from previous research have pointed to somewhat differing conclusions, leaving this question unresolved.

For example, early cross-modal priming studies (Nicol, 1988; Nicol and Swinney, 1989) suggested that during reflexive resolution, the structural constraint acts as an early filter so that the adult parser only considers structurally accessible antecedents but not structurally inaccessible ones[1]. Evidence to support this has also come from studies using more time-sensitive measures such as ERPs and eye-tracking during listening (Xiang et al., 2009; Clackson et al., 2011) where no effects of the inaccessible antecedent were found[2]. In contrast, using a self-paced reading task Badecker and Straub (2002) found that reading times on the second word following the reflexive were significantly longer when the gender of the inaccessible antecedent matched that of the reflexive compared to when it did not, suggesting that the parser briefly considered the inaccessible antecedent as a potential antecedent. Furthermore, although results from eye-tracking during reading experiments are somewhat mixed, a number of studies have found tentative evidence that the inaccessible antecedent is not fully ruled out by Principle A. For example, Cunnings and Felser (2013) found that the gender of the inaccessible antecedent affected

[1] It should be noted that priming effects were only tested for at the point of the reflexive, not shortly after where effects have subsequently been found.

[2] In both experiments numerical trends suggested an effect, but these were non-significant in the statistical analysis.

reading times both at the reflexive region and text downstream of the reflexive, while Sturt (2003) found an effect in second-pass reading times on the reflexive and later regions[3]. While a number of studies have not found evidence of interference effects (e.g., Felser et al., 2009; Dillon et al., 2013) it is possible that such null results are due to particular properties of the materials used (see Discussion section), or stem from a lack of power to detect a relatively small effect [see Chen et al. (2012) for further discussion on power].

One difficulty in interpreting previous results is that it is not certain whether participants interpreted the reflexive correctly. If previous studies included comprehension questions, they were usually not aimed at the interpretation of the critical reflexive in order to avoid drawing participants' attention to the purpose of the experiment. Therefore, in most experimental paradigms there is no offline measure of the interpretation of the reflexive, making it impossible to know whether the observed results reflect successful processing of the reflexive or not. Indeed, one offline study showed that participants incorrectly interpreted a reflexive as referring to a gender matching but structurally inaccessible antecedent in 17% of cases (Sturt, 2003). Furthermore, a number of the studies above rely on gender stereotype nouns (such as *surgeon* being assumed to be male) to create "gender match" and "gender mismatch" conditions, and again it is impossible to know if participants interpreted such nouns in the manner intended.

The present eye-tracking during listening study avoids such difficulties by only using proper names for potential antecedents and by using a "goal-directed" design. The advantage of such a design is that the participant is required to identify the referent for the reflexive for each trial, thus allowing for separate analysis of eye movements and response times for trials where participants did, and did not, interpret the reflexive correctly. Trueswell (2008) supports such designs, arguing that eye movements reflect "goal-directed behavior" and that it is only possible to infer referential decisions from eye movements when these decisions are necessary to achieve the task at hand. The "goal-directed" design was chosen because a naturalistic design, with participants simply looking at pictures while listening to auditory stimuli, can lead to less data relevant to the research question due to participants not paying attention to the pictures at critical points. For instance, Clackson et al. (2011) investigated reflexive resolution using eye-tracking during listening by asking participants to listen to stimuli and answer general comprehension questions which did not probe the referent of the reflexive. One effect of this naturalistic task was that participants' attention was in no way drawn to the non-salient reflexive. As a result, in approximately half the trials participants did not look at any potential antecedent on hearing the reflexive, considerably reducing the quantity of relevant eye movement data collected. Therefore, it is possible that the observed numerical trend showing an effect of the inaccessible antecedent soon after hearing the reflexive (i.e., fewer looks to the accessible antecedent and more looks to the inaccessible antecedent when the inaccessible antecedent matched in gender with the reflexive) did not turn out to be statistically reliable due to the limited data collected.

In the present study the participants' task was presented as a "Who is it for?" activity where participants were asked to identify as quickly as possible which character in a story received a particular object. In experimental trials the recipient was identified by a reflexive. Gaze direction across a scene which included the participants in the story was monitored, so that three responses were recorded: accuracy of identifying the recipient character, response time, and gaze direction at the point of the crucial reflexive. If manipulation of the gender of the inaccessible antecedent (matching or mismatching the gender of the reflexive) affects responses, this interference effect would suggest that the inaccessible antecedent was briefly considered as a potential antecedent in the early stages of processing.

MATERIALS AND METHODS

PARTICIPANTS

Forty-two native speakers of English (mean age: 23, range: 18–48, 16 males) were recruited at the University of Essex and were paid for their participation. All participants had normal or corrected-to-normal vision.

DESIGN AND MATERIALS

The auditory materials were taken from the reflexive conditions used by Clackson et al. (2011) consisting of spoken pairs of sentences, each involving two characters from the set of Susan, Peter, Mr. Jones, and Mrs. White. The first sentence introduced the first character and established a suitable context for the second sentence, which included the second character, an inanimate object, and the critical reflexive. In each trial, the object was for, or was given to, the second character (the recipient), referred to by a reflexive. The auditory stimulus set comprised 24 experimental items, each appearing in two conditions. In the Double-Match condition the gender of both characters matched that of the reflexive, and in the Single-Match condition only the gender of the accessible antecedent matched that of the reflexive, as illustrated in (2).

(2) *Double-Match*
Peter was waiting outside the corner shop. He watched as Mr. Jones bought a huge box of popcorn for himself over the counter.

Single-Match
Susan was waiting outside the corner shop. She watched as Mr. Jones bought a huge box of popcorn for himself over the counter.

The inaccessible antecedent [*Peter* or *Susan* in (2)] is in a discourse prominent position as it is the first-mentioned character and the subject of both main clauses (repeated as a pronoun in the second one). The accessible antecedent (here: *Mr. Jones*), in contrast, is less salient as the subject of the subordinate clause.

Auditory stimuli were recorded using splicing to ensure that each version of an item was identical except for the name and pronoun changes necessary for the experimental manipulation.

[3]A further study reporting significant interference from an inaccessible antecedent in the processing of reflexives used eye-tracking during listening to investigate the interpretation of picture noun phrases (Runner et al., 2003). However, the authors concluded that reflexives in such contexts are in fact "logophors" and thus exempt from Binding Theory [see also Runner et al. (2006)].

Experimental items from a separate pronoun experiment were presented together with those from the present reflexive study, so that in addition to the reflexive experimental trials, each participant heard 24 pronoun items which mirrored the structure of the reflexive items, and 48 filler trials comprising a range of different grammatical constructions and featuring some additional characters (Doctor, Nurse, King, and Queen). Filler trials were similar to the experimental items in that the recipient of an object was introduced by a preposition (*for*, *to*, *on*, or *at*), but other properties were manipulated to provide variety of structure: the number of characters introduced before the preposition varied from one to three and, in contrast to the experimental items, the majority of filler items identified the recipient by name. This meant that contexts in which the recipient was only introduced after the preposition could be created, thus preventing participants from assuming that the recipient would always be mentioned early in the sentence. Furthermore, the point at which it became obvious which character received the object was varied in the filler items so that participants did not know when to expect the information which provided the answer to the task. For example, the recipient of the object is mentioned quite early in (3) but fairly late in (4) (object is underlined and recipient is shown in bold).

(3) At the hospital the nurse got a glass of water for **the doctor** because he had bad hiccoughs and needed to see a patient.

(4) After the accident in the royal carriage the King and the Queen were very upset. The doctor visited them and put a plaster on **the Queen's** nose where she had cut it.

Each auditory trial was accompanied by two visual displays as shown in **Figure 1**. A picture of the inanimate object was shown in the centre of the screen prior to the start of the auditory stimulus, and this was followed by the main visual display comprising four pictures: the inanimate object and three animate characters, which was viewed while the auditory stimulus was heard. For experimental trials, two of these characters were mentioned in the auditory stimulus and one (mismatching the gender of the reflexive) served as a distracter.

The four pictures were positioned in the corners of the screen, with a small cross in the center, and the positioning of the pictures of the characters and the inanimate object was counterbalanced across items. All pictures were black-and-white line drawings, of approximately the same size, and were not noticeably different in terms of visual saliency. All pictures were selected from a set of 520 pictures from the International Picture Naming Project (http://crl.ucsd.edu/~aszekely/ipnp/) for which various normed measures are available[4]. Experimental trials were arranged in four lists according to a Latin Square design (due to the similarity between the two reflexive conditions and two pronoun conditions from a separate experiment) so that each participant saw each trial in only one condition (Double-Match or Single-Match). The same set of filler trials was used with each list, and trials were presented in a pseudo-randomized order such that no more than two experimental trials occurred consecutively. To counteract any effects of fatigue, the four lists were then reversed to create eight lists in total so that items heard early in the experiment by one participant were heard late in the experiment by another. The study received ethical approval from the University of Essex ethics committee.

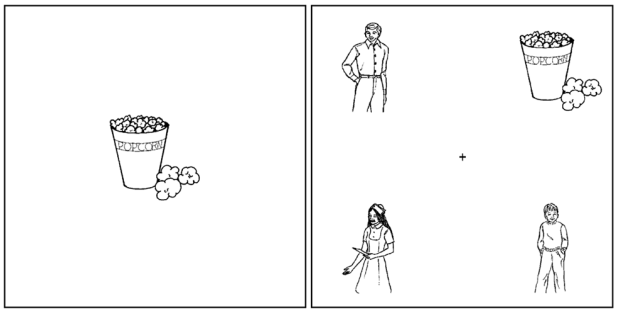

FIGURE 1 | Example visual displays for auditory stimuli shown in (2) (Double-Match condition).

PROCEDURE

Participants sat two meters away from a projection screen where the visual display measured 170 × 120 cm, and during the experiment their eye movements were recorded by a digital camcorder recording 25 frames per second (i.e., one frame every 40 ms) which was placed below the projection screen and trained on the participant's face. This set-up ensured that when the video was played back, participants' eye movements between pictures were distinct enough to be clearly interpreted. The presentation of visual and auditory stimuli was programmed using DMDX (Forster and Forster, 2003), and the sound output from the computer was split, going directly to both the headphones worn by the participant, and to the video camera so that the sound recorded by the video camera was exactly synchronized with what the participant heard. Participants were provided with full details of the procedure and gave written consent before the testing session started.

At the start of each trial, a cross appeared on screen for 1 second, followed by a picture of the object mentioned in the story, which remained in the centre of the screen for 3 seconds. The participant's task was to play a game of "Who is it for?," identifying the recipient of this object while listening to the story which followed. Following the picture of the object, the main visual display for that item was shown on screen for 1 second before the auditory stimulus began, and remained on screen until the next trial began. Participants were asked to listen carefully to the story and respond as quickly as possible once they knew who the object was for, by pressing the button on the gamepad which corresponded with the position of the selected character on the screen. For example, if the recipient was identified as being the character in the top left quadrant of the screen, the participant would press the top left button. If participants answered incorrectly the word "OOPS!" was displayed on the screen to encourage participants to pay closer attention and to discourage hasty responses before the recipient had been identified in the story. There was no feedback for correct responses. The next trial was initiated automatically, independent of the participant's response. Participants were introduced to all the characters and their pictures at the start of the session, and in order to get

[4]The selected picture stimuli could be easily recognised, as shown by their mean "visual recognisability" score of 97% (SD: 6%, range: 80–100%).

used to the pictures and the process of selecting the recipient of the object on the gamepad, the experiment was preceded by six practice trials. For these trials the stories were presented over loudspeakers to allow for immediate questions by the participant as well as to enable the experimenter to check that participants responded shortly after the key word and did not wait until the end of the story. If a participant was not completely confident with the procedure after this, the practice session was repeated. During the main experiment, participants listened to stimuli through headphones and were offered three breaks, one after every 18 items. The entire session took approximately 35 minutes.

Three dependent measures were taken and analyzed: response accuracy (the accuracy with which participants correctly interpreted the reflexive to identify the recipient of the object), response times, and eye movements. For statistical analyses, response accuracy was recorded as either correct or incorrect. Reaction times were calculated as the delay between the onset of the reflexive and when the response button was pressed. Video footage of participants' eye movements was analyzed using ELAN annotation software (Brugman and Russel, 2004), and gaze direction was recorded every frame for 2000 ms (50 frames in total) from the onset of the critical reflexive. The still image for each frame (every 40 ms), was inspected to determine the direction of gaze (toward one of the four pictures, the center of the screen or off-screen), and a target was counted as "fixated" for every frame where eyes were directed toward that picture[5]. Off-screen looks (which accounted for 2.2% of the total dataset) were treated as missing data.

RESULTS

All analyses were carried out on raw data using mixed-effects regression modeling in "R," version 3.0.1 (Baayen et al., 2008; R Development Core Team, 2010). Models included participant and item random effects, and to account for the fact that gaze direction in consecutive frames is not independent (gaze direction in any particular frame is heavily influenced by gaze direction in the previous frame), random effects of Trial were also included for analyses of eye movement data. Maximal random effects structure was used so that as well as random intercepts, all fixed effects and interaction terms had corresponding random slopes by participant, item, and trial as appropriate (Barr et al., 2013). Best fitting models were identified by adding predictors incrementally to an empty model, with those that resulted in a significant improvement of the fit of the model being retained. In the analysis of eye movements, the fixed factor of Time was added to the model in order to test for differences between conditions over time (i.e., proportions of looks increasing or decreasing differently across the two conditions). Due to the non-linear relationship between looks and Time, second and third order polynomials of Time were also tested as predictors. The response accuracy and eye movement data were analyzed using logistic regression due to the categorical nature of the data. For eye movement data the binary dependent variable encoded whether the picture of a particular antecedent was, or was not, fixated for each of the 40 ms frames. Tables/graphs show grand mean results as participant and item differences are accounted for in the mixed-effects analysis.

As the offline measure allows for the identification of trials in which the final interpretation of the reflexive was incorrect, and as response times and eye movements in trials where the inaccessible antecedent (or another incorrect answer) was selected do not reflect successful processing, incorrectly answered trials (comprising 3.6% of the total data set) were not included in the analysis of response times or eye movements.

RESPONSE ACCURACY

As shown in **Table 1**, response accuracy was high (above 95%) in both conditions. In the Double-Match condition the majority of errors were due to the selection of the inaccessible antecedent.

Table 1 | Offline button press responses.

	Correct responses	Incorrect responses	
	% Accessible antecedent	% Inaccessible antecedent	% Other erroneous responses
Double-Match	95.2	4.4	0.4
Single-Match	97.6	0.4	2.0

Analysis of accuracy scores (with each response coded as correct or incorrect) showed no effect of Condition (adding Condition as a fixed factor did not improve the fit of the model over an empty model).

RESPONSE TIMES

Table 2 shows the mean response times for correctly identified recipients. Participants took more time to identify the referent when both antecedents matched the reflexive in gender.

Table 2 | Mean response times (and standard deviation) for correctly answered trials.

	Response time
Double-Match	1155 (688)
Single-Match	1043 (687)

Statistical analyses confirmed that response times were significantly longer in the Double-Match condition [Condition (Double-Match): $\beta = 101.28$, SE $= 44.83$, $t = 2.259$].

EYE MOVEMENTS

Figure 2 shows fixations of the two potential antecedents in the two experimental conditions (Double-Match/Single-Match)

[5]To avoid gaze direction coding being influenced by coders' expectations, coding was initially done "blind," so that gaze direction was coded as being toward the top left, top right, bottom left, bottom right, center, or off-screen (i.e., participant blinking or not looking at screen), without the coder knowing the arrangement of the pictures in the visual display the participant was viewing. Gaze directions were then re-coded with reference to the visual display to show whether the participant was looking at the accessible antecedent, the inaccessible antecedent, the object, the distracter character, the center, or off-screen.

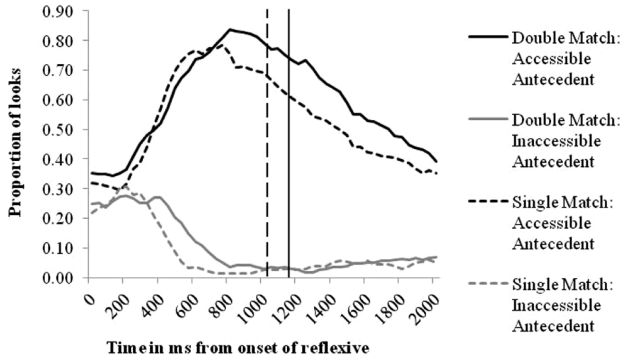

FIGURE 2 | Proportions of looks to potential antecedents.

during the 2 seconds following the onset of the critical reflexive. The *x*-axis displays the time in milliseconds from the onset of the reflexive, and the *y*-axis depicts the proportions of looks to the two potential antecedents, i.e., the number of trials in which a participant fixated on a particular picture for each 40 ms video frame as a proportion of the total number of trials in which they were looking at the screen. As it takes approximately 200 ms to program an eye movement (Rayner et al., 1983), only changes in proportions of looks after 200 ms can be attributed to participants hearing the reflexive. Note that while the graph shows grand mean data plotted on a proportional scale for ease of interpretation, the statistical analysis uses a logistic scale (as analysing data on a proportional scale can lead to inaccurate estimation of effects) and takes into account the clustering of data for each participant, item, and trial.

From 200 ms after hearing the reflexive, the proportion of looks to the accessible antecedent (black lines) increases sharply in both conditions, and looks to the inaccessible antecedent (gray lines) fall. The vertical lines in **Figure 2** indicate the mean response time for each condition (solid line = Double-Match, broken line = Single-Match). Proportions of looks to the other areas of the screen not shown in the graph (object picture, distracter picture and center of the screen) were low throughout the time window (typically between 0 and 0.15), with looks to the object gradually increasing to 0.30 after 1200 ms. The proportion of looks to each of these screen areas was similar across conditions, but slightly higher in the Single-Match condition than the Double-Match condition.

In order to investigate the time course of effects, in the statistical analysis models were fit to 400 ms time windows (200–600 ms, 600–1000 ms, 1000–1400 ms, and 1400–1800 ms). These time windows were selected following visual inspection of the data.

It is important to note that differences between conditions may be seen in two different ways: it may be that in any particular time window the average proportion of looks to an antecedent is higher in one condition than another, or it may be that the rate of increase/decrease in looks (shown by the slope or curve) differs. To investigate the first possibility, models were fit to test for an interaction between Antecedent (Inaccessible/Accessible) and Condition (Single-Match/Double-Match). To explore the second possibility, models also tested for an interaction between Antecedent, Condition, and Time. Thus findings of an Antecedent × Condition interaction, or an Antecedent × Condition × Time interaction each signify (in slightly different ways) that participant performed differently across the two conditions. In later discussion of results, the general term *effect of the inaccessible antecedent* will be used to cover both types of effect.

As shown in **Table 3**, statistical analyses revealed significant interactions between Antecedent, Condition, and Time, in the 200–600 ms and 600–1000 ms time windows. These results show that gaze direction was affected by the gender of the inaccessible antecedent until at least 1 second after the onset of the reflexive.

In order to further investigate the source of the interactions, looks to each antecedent were analyzed separately for the 200–600 ms and 600–1000 ms time windows, as shown in **Table 4**.

From 200 to 600 ms looks to the accessible antecedent increased more slowly in the Double-Match condition than in the Single-Match (shown by the negative slope for the Time × Condition interaction), while, in contrast, from 600 to 1000 ms there was a greater increase in looks to the accessible antecedent in the Double-Match condition (shown by the positive slope for the Time × Condition interaction). While the lack of significant effects in the looks to the inaccessible antecedent shows that there is not

a direct relationship between looks to the two antecedents (i.e., a lower proportion of looks to the accessible antecedent does not directly correspond with an increase in looks to the inaccessible antecedent – recall that gaze was distributed over five screen regions), it is nevertheless the case that the presence of a gender matching inaccessible antecedent leads to slower initial identification of the correct antecedent, and then to prolonged looking at the accessible antecedent prior to giving a response to identify the recipient.

SUMMARY OF RESULTS

While offline accuracy in determining the referent for the reflexive was not affected by the gender of the inaccessible antecedent, response times were significantly longer when the gender of the inaccessible antecedent matched that of the reflexive (Double-Match condition).

The analysis of eye movements also showed that the gender of the inaccessible antecedent significantly affected looks to the accessible antecedent over the first 1000 ms following the onset of the reflexive. When a gender matching competitor was present (i.e., in the Double-Match condition) participants were initially slower to identify the correct antecedent (200–600 ms), and then more likely to look at the correct antecedent as they prepared to respond to the task (600–1000 ms).

DISCUSSION

Results showed that adults are significantly distracted by a gender matching but structurally inaccessible competitor antecedent. Eye movement data revealed a two-phase pattern, with early interference effects leading to faster identification of the accessible antecedent in the Single-Match condition, and a later effect whereby participants looked more at the accessible antecedent in the Double-Match condition.

One advantage of eye-tracking during listening over reading-based measures is the ability to focus more precisely on the nature of the effect. While reading-based measures can tell us whether the presence of a gender matching inaccessible antecedent has an effect on the processing of the reflexive, eye-tracking during listening experiments allow us to investigate the origin of that effect more precisely. In this case, we have seen not only that the gender of the inaccessible antecedent has an effect, but specifically that it affects looks to the accessible antecedent. This leads to two possible interpretations of our findings[6]. Firstly, it may be (as is traditionally assumed by studies finding effects of the inaccessible antecedent) that the gender-matching inaccessible antecedent is briefly considered as a potential referent by the parser, before being discarded on the grounds of structural position. If this were the case, one might expect significant effects in the looks to both the inaccessible antecedent and the accessible antecedent (more looks to the inaccessible and fewer to the accessible antecedent). Alternatively, it may be that a gender matching inaccessible antecedent has the effect of slowing down identification of the accessible antecedent, but is not specifically considered as an antecedent itself. Since it is not clear why the gender of the inaccessible antecedent should affect processing of the reflexive unless the inaccessible antecedent were being considered as a competitor, and bearing in mind offline results showing that a gender matching inaccessible antecedent is frequently incorrectly interpreted as the referent for a reflexive

[6]We thank a reviewer for pointing out these two subtly different interpretations.

(Sturt, 2003), we are inclined to support the former interpretation (arguing that there is clearly a numerical, though non-significant, trend toward increased looks to the inaccessible antecedent in the Double-Match condition). However, we acknowledge that the latter interpretation is possible, and that future research probing this distinction is needed. Under either interpretation, it is clear that processing the reflexive involves accessing the inaccessible antecedent, thus arguing against theories which claim that the early application of structural constraints makes inaccessible antecedents "invisible" to the parser.

Our results differ from those reported by Clackson et al. (2011) who used the same materials as the present study but a naturalistic listening task and found no significant effects of the inaccessible antecedent. However, visual inspection of their results shows a numerical effect between 200 and 600 ms similar to the early effect observed here, with a slower increase in looks to the accessible antecedent, and increased looks to the inaccessible antecedent in the Double-Match condition. In order to make a direct comparison between the present study and Clackson et al.'s (2011), data from the latter was re-analyzed using the same analysis methods as presented here (400 ms time windows, maximal random effects structure and including random effects of Trial), however, results showed no significant effects of the inaccessible antecedent[7]. Nevertheless, since early differences between conditions were seen in both experiments (although not significant in Clackson et al., 2011), this suggests that this effect is task-independent, i.e., similar results found using naturalistic and goal-directed designs. In contrast, the later effect appears to be task-specific: in the goal-directed task where participants are aware that the right or wrong response depends on the correct interpretation of the reflexive, we see more looks to the accessible antecedent in the Double-Match condition from 600 to 1000 ms, whereas when participants are required only to listen to auditory stimuli with no emphasis put on processing the reflexive, no such later effect is seen.

The suggestion that later effects may be more affected by the participant's task is supported by evidence from ERP experiments where early and late ERP components differ with regard to their susceptibility to experimental variations. Both the early left anterior negativity (ELAN; occurring around 100–300 ms) and the P600 (occurring around 600–1000 ms) are associated with syntactic violations, but while the early effect is not affected by changes to the task, the later effect has been shown to be dependent on task manipulations such as the expected frequency of syntactic violations (Hahne and Friederici, 1999) and the specific instructions given to participants (Hahne and Friederici, 2002). Such results have led to the suggestion that the early effect reflects highly automatic processes, while the later effect reflects processes that are under the participant's strategic control. Friederici (2002) identifies the P600 component with a process of "reanalysis and repair." Since our participants were more likely to look at the picture of the accessible antecedent in the more challenging Double-Match condition immediately prior to responding, this may reflect a similar process of overcoming any earlier confusion and "checking" the answer. Logically, such a checking process would be absent when the task did not require the participant to give a response identifying the referent of the reflexive.

The cross-task differences in results observed for studies using the same auditory stimuli highlight the importance of identifying and separating task-independent and task-related effects. In eye-tracking during listening studies, the naturalistic listening method avoids participants adopting behavioral strategies to complete the task (as there is no task), but leaves questions about whether participants actually processed the linguistic element under investigation, and if so, whether their interpretation was in fact correct. In contrast, the goal-directed method forces participants to process the required language and gives a clear indication of the participant's interpretation, although the results may also reflect the conscious processes involved in attaining the goal. It is only by systematic comparison of results from experiments using the same materials but differing designs that the role of the task can be identified. More studies of this sort are needed to confirm which effects are truly task-independent, and in the case of eye-tracking during listening studies, to further explore how cross-condition differences between looks to the target and looks to the competitor might be interpreted.

It might be suggested that a potential explanation for the early effect is that in the Double-Match condition participants initially interpret the first syllable of "himself/herself" as the pronoun "him/her," leading to early eye movements toward the gender matching non-local antecedent before participants hear "... self." However, acoustic comparison of the first syllable of "himself/herself" and the pronouns "him/her" carried out by Clackson et al. (2011) showed that the unstressed syllable in the reflexive was significantly reduced in duration and intensity compared to the pronoun. While pronouns often occur in phonologically weak forms, in the materials used here any pronoun occurring in the position of the reflexive would naturally be pronounced as a strong form, making it unlikely that participants would interpret the weak first syllable of the reflexive as a pronoun.

As outlined in the introduction, results from previous experiments using different methodologies differ with regard to the existence and timing of interference effects. In particular, eye-tracking during reading studies have revealed conflicting patterns of results (even when the materials were very similar), and where interference effects are reported, these are usually in "later measures" corresponding with Sturt's (2003) "defeasible filter" theory, which proposes that although the inaccessible antecedent is initially blocked by the syntactic constraint, the parser may consider it at a later point in processing. In contrast, the results from the current study suggest that the interference caused by the gender matching inaccessible antecedent occurred relatively early in processing. While this apparent timing difference is still to be fully explained, it may be related to differences between auditory and visual processing or the fact that the two methodologies measure very different things, making it questionable whether reading times on the reflexive and following words can be directly compared with the probability of looking at a

[7]Perhaps because the low salience of the reflexive in the naturalistic design meant that in a large number of trials participants did not look at any potential antecedent on hearing the reflexive, thus reducing the number of valid data points and leading to a low-power analysis.

particular referent. Another contributing factor may be that the low salience of the reflexive affects reading designs in the same way that it can lead to participants failing to look at a potential antecedent in naturalistic listening designs. Specifically, the null effects in early reading measures could be due to high skipping rates and the resulting smaller amount of data points, i.e., a lack of power to detect small effects. For instance, Felser and Cunnings (2012) and Cunnings and Felser (2013) report skipping rates in the reflexive region of 11.2–15.6%, considerably higher than in the spill-over region (5.1–8.2%), raising the possibility that the reported null effect in early measures is due to a lack of power.

Connected to skipping rates, a further potential explanation for a lack of consistent effects in reading studies is the preview benefit in written texts. While orally presented sentences are presented one phoneme after the other, readers can visually inspect several letters at a time, both in the fovea and the parafovea. The fact that the reading span in English generally extends 14–15 letters to the right of the fixation allows readers to "look ahead" in the sentence [for reviews of research on parafoveal processing see Rayner (1998) and Schotter et al. (2012)]. Therefore, it is likely that in reading studies participants processed the reflexive parafoveally before actually fixating on it. With spaces and length information being very salient, the distinction between English reflexives (6–10 letters) and pronouns (2–4 letters) can easily be made on the basis of this formal information available in the parafovea. This might provide participants with a "head-start," reducing potential surprise effects which lead to longer reading times when a reflexive does not refer to the gender matching and discourse prominent, but structurally inaccessible, antecedent.

Even across methodological boundaries, it is clear that the discourse prominence of the inaccessible antecedent plays a role in determining the extent to which it can interfere with processing of the reflexive. In the present study and previous research reporting interference effects, the materials used were constructed such that the inaccessible antecedent was promoted in the discourse by being both in first-mentioned position and the matrix subject (Badecker and Straub, 2002; Sturt, 2003; Cunnings and Felser, 2013). In contrast, studies using materials where the inaccessible antecedent was not in first mentioned or matrix subject position (Xiang et al., 2009; Dillon et al., 2013), or where the prominence of the inaccessible antecedent relative to that of the accessible antecedent was reduced (Felser et al., 2009) have found no reliable effect of the inaccessible antecedent. This is consistent with recent findings showing that while sentences presented in isolation provide evidence for a syntax-based account of sentence processing, structural parsing mechanisms are influenced by discourse factors when sentences are placed in a more natural context (Yang et al., 2013).

In conclusion, our findings support a multiple constraint or cue-based retrieval approach to reflexive resolution whereby each potential antecedent is promoted by a variety of factors (both structural and discourse related), and while strong weighting is given to the structural constraint, non-structural cues or constraints (such as discourse prominence) can also affect online reflexive resolution. Furthermore, we suggest that behavioral measures may be influenced by the specific task participants are given and particularly that later occurring effects may reflect more conscious/controlled processes, as has also been reported in previous ERP research.

ACKNOWLEDGMENTS

This research was supported by an ESRC postgraduate studentship awarded to Kaili Clackson by the Department of Language and Linguistics at the University of Essex and a Ph.D. scholarship from the Potsdam Research Institute for Multilingualism awarded to Vera Heyer. We are grateful to Loay Balkhair for sharing participants and to Harald Clahsen and members of the Psycholinguistic Research Group for useful discussions.

Retrieval Interference in Syntactic Processing: The Case of Reflexive Binding in English

Umesh Patil[1,2]*, *Shravan Vasishth*[1] and *Richard L. Lewis*[3]

[1] Department of Linguistics, University of Potsdam, Potsdam, Germany, [2] Computational Linguistics, Institute of Cognitive Science, University of Osnabrück, Osnabrück, Germany, [3] Department of Psychology, University of Michigan, Ann Arbor, MI, USA

It has been proposed that in online sentence comprehension the dependency between a reflexive pronoun such as *himself/herself* and its antecedent is resolved using exclusively syntactic constraints. Under this *strictly syntactic search* account, Principle A of the binding theory—which requires that the antecedent c-command the reflexive within the same clause that the reflexive occurs in—constrains the parser's search for an antecedent. The parser thus ignores candidate antecedents that might match agreement features of the reflexive (e.g., gender) but are ineligible as potential antecedents because they are in structurally illicit positions. An alternative possibility accords no special status to structural constraints: in addition to using Principle A, the parser also uses non-structural cues such as gender to access the antecedent. According to cue-based retrieval theories of memory (e.g., Lewis and Vasishth, 2005), the use of non-structural cues should result in increased retrieval times and occasional errors when candidates partially match the cues, even if the candidates are in structurally illicit positions. In this paper, we first show how the retrieval processes that underlie the reflexive binding are naturally realized in the Lewis and Vasishth (2005) model. We present the predictions of the model under the assumption that both structural and non-structural cues are used during retrieval, and provide a critical analysis of previous empirical studies that failed to find evidence for the use of non-structural cues, suggesting that these failures may be Type II errors. We use this analysis and the results of further modeling to motivate a new empirical design that we use in an eye tracking study. The results of this study confirm the key predictions of the model concerning the use of non-structural cues, and are inconsistent with the strictly syntactic search account. These results present a challenge for theories advocating the infallibility of the human parser in the case of reflexive resolution, and provide support for the inclusion of agreement features such as gender in the set of retrieval cues.

1. INTRODUCTION

Sentence comprehension involves, among other things, recovering hierarchical structure from an input string of words (e.g., Frazier, 1979). Such recovery requires the online application of grammatical constraints that delimit the possible relationships between various elements of the sentence. For example, to understand a sentence like (1), the pronoun *himself* has to be resolved

to a referent of an earlier noun *surgeon*; the reflexive cannot be associated with *Jonathan* due to Principle A of the binding theory (Chomsky, 1981)[1].

(1) The surgeon who treated Jonathan had pricked himself.

Establishing a relationship between two non-adjacent elements in a sentence requires maintaining some memory of the immediate past. The question we are concerned with here is: what role do grammatical and non-grammatical constraints play in the access to the immediate past? The binding of English reflexive pronouns is a particularly informative case, because the configurational and agreement constraints are relatively clear, and the structure admits manipulations of distance and distracting candidate antecedents (Sturt, 2003).

One proposal for how structural constraints are implicated in dependency resolution is motivated by the experiments reported in Nicol and Swinney (1989), Sturt (2003), and Xiang et al. (2009). Using different experimental methodologies, these studies found that a grammatically incorrect antecedent [e.g., *Jonathan* in (1)] does not interfere in the process of binding a reflexive pronoun by a grammatically correct antecedent [e.g., *surgeon* in (1)], at least in the early stages of processing a reflexive.

Nicol and Swinney (1989) presented evidence from a series of experiments that employed the cross modal lexical priming paradigm. Participants listened to sentences similar to those shown in (2) and responded to visually presented probe words that was presented immediately following the reflexive *himself*. The probe word was either semantically related or unrelated to one of the three previously occurring nouns in the sentence (*boxer*, *skier*, or *doctor*). Participants judged whether the probe word was a word or non-word. A significant priming effect was observed when probe words were related to grammatically accessible as antecedents [e.g., *doctor* in (2)], but not when they were related to grammatically inaccessible antecedents [e.g., *boxer* and *skier* in (2)]. Nicol and Swinney (1989) concluded that no priming was observed for words related to grammatically inaccessible antecedents because they had not been considered during co-reference resolution.

(2) The boxer told the skier that the doctor for the team would blame himself for the recent injury.

Sturt (2003) reported eye tracking studies using materials such as (3). He found that first fixation duration and first pass reading time on the region containing the reflexive were longer when the gender of the reflexive did not match the stereotypical gender of the grammatically accessible antecedent than when it matched (e.g., *herself* and *surgeon* vs. *himself* and *surgeon*). Early reading times were *not* affected by gender match between the reflexive and the grammatically inaccessible antecedent (*Jonathan* or *Jennifer*). Second pass reading time at the reflexives showed an interaction for gender match between the reflexive and the two antecedents suggesting that in later interpretation stages (but, crucially, not in earlier processing stages)[2] the inaccessible antecedent is part of the candidates being considered as antecedents. There was also an effect of the inaccessible antecedent in second pass reading time in the pre-final region, but this effect was observed only when the accessible antecedent matched the gender of the reflexive. However, these late effects of the inaccessible antecedent were not observed in the second experiment [with design as in (4)], but he pointed out that the absence of any effect of the inaccessible antecedent in Experiment 2 could have been due to the fact that the inaccessible antecedent did not c-command the reflexive and it was also not as prominent as in Experiment 1.

To gain further insight into this late-stage interpretation of the sentences, Sturt (2003) also ran a follow-up study, where a sentence-by-sentence self-paced reading task was followed by a question that directly probed for the antecedent of the reflexive. This study showed a significant interference effect, with more ungrammatical interpretations when the grammatically inaccessible antecedent matched the gender of the reflexive; the effect was bigger when the accessible antecedent did not match the gender of the reflexive. Sturt (2003) concluded that grammatical constraints are applied very early in processing, but interference from the grammatically inaccessible antecedent occurs during later processes that are related to recovery strategies, rather than during processes related to the initial interpretation of the reflexive.

(3) {Jonathan/Jennifer} was pretty worried at the City Hospital. {He/She} remembered that the surgeon had pricked {himself/herself} with a used syringe needle. There should be an investigation soon.

(4) {Jonathan/Jennifer} was pretty worried at the City Hospital. The surgeon who treated {Jonathan/Jennifer} had pricked {himself/herself} with a used syringe needle. There should be an investigation soon.

Dillon et al. (2013) reported two eye tracking studies with English reflexives using material with syntactic structure similar to Experiment 2 in Sturt (2003). They also did not find any effect of the inaccessible antecedent, but reported effects of the accessible antecedent. Xiang et al. (2009) reported similar results in an ERP study, where they found that a P600 is elicited by a reflexive that mismatches the stereotypical gender of the grammatically accessible antecedent, and is not attenuated by the presence of a matching antecedent in a grammatically inaccessible position.

Based on results from these studies, Phillips et al. (2011) suggests that:

> "*…argument reflexives are immune to interference from structurally inaccessible antecedents because antecedents are*

[1]Principle A specifies a structural constraint on the interpretation of reflexives in English: a reflexive must be bound by an antecedent in the local domain (the current clause). An antecedent X can bind a reflexive Y, if X and Y are coindexed, and X c-commands Y. The term c-command defines a hierarchical relationship between two constituents in a syntax tree. A constituent c-commands its sister constituent and every constituent *below* the sister constituent in the syntax tree. In (1), the reflexive *himself* is bound by *surgeon*; the noun *Jonathan* cannot bind the reflexive because it does not c-command it.

[2]In this paper, we follow the literature (see e.g., Sturt, 2003) in assuming that so-called early and late measures in eye tracking data map onto processes that occur (respectively) in early and late stages of parsing.

retrieved using only structural cues. In effect, we are suggesting that the person, gender, and number features of reflexives like himself, herself, and themselves play no role in the search for antecedents . . . "

An alternative possibility accords no special status to the structural constraints: in addition to using Principle A, the parser also uses non-structural cues such as gender to access the antecedent. For example, in (1), it is possible that the parser considers a relation between *Jonathan* and *himself*, due to a gender-feature match, and perhaps also due to the relative proximity of *Jonathan* compared to *surgeon*. Under at least one cue-based retrieval theory (Lewis and Vasishth, 2005; Lewis et al., 2006), this should result in interference from grammatically inaccessible antecedent while resolving the reflexive-antecedent dependency[3]. Some evidence for this account comes from studies reported in Badecker and Straub (2002), Choy and Thompson (2010), and Cunnings and Felser (2013) among others.

Badecker and Straub (2002) reported an interference effect from gender-matched distractors in a self-paced reading experiment using sentences as in (5). They found that reading times two words beyond a reflexive were slowed by the presence of a gender matching NP in a grammatically inaccessible position.

(5) {Jane/John} thought that Bill owed himself another opportunity to solve the problem.

More evidence for early retrieval interference in reflexive binding comes from the study reported in Cunnings and Felser (2013). In two eye tracking studies they tested how application of Principle A varies between low and high working memory span readers. In the first study they found a late effect of inaccessible antecedent, emerging only at regions following the reflexive region. However, in the second study where the inaccessible antecedent was closer in the surface string to the reflexive, the effect of inaccessible antecedent was observed in an early eye movement measure, namely first fixation duration, at the reflexive itself, although this effect was limited to low span readers. Consequently, Cunnings and Felser (2013) conclude that "lower span participants were more likely to consider both potential antecedents of the reflexive early on during processing, before converging on the structurally accessible antecedent later on."

Further evidence for the effect of interference from grammatically inaccessible antecedent comes from an eye tracking study in a visual world paradigm reported by Choy and Thompson (Thompson and Choy, 2009; Choy and Thompson, 2010). Although this study was targeted at aphasics' processing deficits with binding constructions, for present purposes we consider data only from unimpaired participants. Choy and Thompson (2010) recorded eye movements while the participants listened to a story as in (6), with the critical sentence containing a pronoun or a reflexive (e.g., *him* or *himself*). The visual stimuli consisted of pictures of two persons, one of which was grammatically accessible and the other inaccessible (e.g., *soldier* and *farmer*); a human-referring distractor; and an inanimate-referring noun mentioned in the story (e.g., *glasses*). The data for the reflexive condition from unimpaired participants showed an increase in the proportion of fixations to the inaccessible antecedent in the reflexive and post-reflexive regions compared to the pre-reflexive region. Although the proportion of fixations to the accessible antecedent was higher than the fixations to the inaccessible antecedent in most of the regions, the increase in fixations to the inaccessible antecedent from the onset of the reflexive indicates that participants considered the inaccessible antecedent as the potential antecedent of the reflexive, albeit less often than the accessible antecedent.

(6) Some soldiers and farmers were in a house. The soldier told the farmer with glasses to shave {himself/him} in the bathroom. And he did.

In summary, the effect of interference from a grammatically inaccessible antecedent is sometimes observed in early processing and sometimes in late processing, and in some studies the effect is completely absent.

In the remainder of this paper, we first apply an existing computational model of cue-based parsing (Lewis and Vasishth, 2005) to an empirical paradigm well established for testing the processing of reflexives in English. The model generates qualitative predictions and demonstrates that these predictions are robust against substantial variation in the quantitative parameters. We then use the theoretical perspective provided by the model to formulate conjectures for why some of the existing empirical work may have failed to detect evidence for the use of non-structural cues. Based on this analysis we advance a new experimental design which is intended to be more sensitive, and demonstrate that for many of the predictions the modified design yields larger effects in modeling simulations. We next present an eye tracking study based on the modified design, yielding several results that confirm the early use of non-structural cues in a manner consistent with the model. The paper concludes with discussion of the implication of these new results for some current theoretical approaches to dependency resolution.

2. MODELING REFLEXIVE BINDING IN THE CUE-BASED RETRIEVAL FRAMEWORK

The cue-based retrieval architecture provides a natural characterization of the retrieval steps triggered in the process of reflexive resolution. We begin by presenting a model of Experiment 1 and its follow-up in Sturt (2003), which will provide insight into the predicted effects and their robustness against parametric variation, and provide motivation for the modified design used in the eye tracking study reported here.

[3]We will follow the literature in referring to the correct antecedent as stipulated by Principle A as the *grammatically accessible* antecedent and the antecedent that is incorrect following Principle A as the *grammatically inaccessible* antecedent. Occasionally, we abbreviate these terms to *accessible* and *inaccessible* antecedents. It is important to keep in mind that under the model we advocate in this paper, the grammatically inaccessible antecedent is in fact "accessible" for memory retrieval; a more appropriate term would have been "incorrect antecedent," since this does not presuppose that the non-c-commanding antecedent is inaccessible.

The emphasis of the model described here is not on parsing the entire sentence, but on detailed modeling of the retrieval process carried out at the reflexive.

Experiment 1 in Sturt (2003) included an eye tracking experiment in which participants were required to read short texts consisting of three sentences. An example is given in (7), showing the four experimental conditions. A named referent (*Jonathan* or *Jennifer*) is introduced in the first sentence, and this referent is subsequently referred to using a pronoun (*he* or *she*) in the second sentence. The second sentence also introduces a second referent *the surgeon*, and includes a reflexive anaphor (*himself* or *herself*). The first named referent is not a grammatically accessible antecedent for the reflexive in terms of binding theory, while the second referent (*the surgeon*) is a grammatically accessible antecedent. Accessible and inaccessible antecedents either matched or did not match the gender of the reflexive. Note that even when the accessible antecedent doesn't match the gender of the reflexive, the sentences are still grammatical because a *surgeon* is only stereotypically masculine and hence a licit antecedent of *herself*.

In match-interference and match conditions [(a) and (b) in (7)] the accessible antecedent matches the gender requirement of the reflexive, and in mismatch-interference and mismatch conditions [(c) and (d) in (7)] it does not. Furthermore, in match-interference and mismatch-interference conditions the inaccessible antecedent matches the gender of the reflexive. Henceforth, we will refer to match-interference and match conditions simply as *match* conditions, and mismatch-interference and mismatch conditions as *mismatch* conditions, reflecting the fact that the accessible antecedent matches the gender of the reflexive for one pair and does not for the other. We will refer to match-interference and mismatch-interference conditions as the *interference* conditions because the gender of the inaccessible antecedent matches that of the reflexive—potentially causing interference.

(7) **Sentence 1:** {Jonathan/Jennifer} was pretty worried at the City Hospital.

Sentence 2:

a. *Accessible-match/inaccessible-match* (*Match-interference*)
He remembered that the surgeon had pricked **himself** with a used syringe needle.

b. *Accessible-match/inaccessible-mismatch* (*Match*)
She remembered that the surgeon had pricked **himself** with a used syringe needle.

c. *Accessible-mismatch/inaccessible-match* (*Mismatch-interference*)
She remembered that the surgeon had pricked **herself** with a used syringe needle.

d. *Accessible-mismatch/inaccessible-mismatch* (*Mismatch*)
He remembered that the surgeon had pricked **herself** with a used syringe needle.

Sentence 3: There should be an investigation soon.

This eye tracking study showed an early effect of the accessible antecedent (**Figure 1**). First fixation duration and first pass reading time were faster in the match conditions compared to the mismatch conditions. But no effect of the inaccessible antecedent was found in the early measures. The effect of inaccessible antecedent was found only in later measures—second pass reading time was shorter in match-interference condition compared to the match condition.

As mentioned above, Sturt (2003) also conducted a follow-up study to find out the participants' final interpretation of the reflexive. This was a sentence-by-sentence self-paced reading with the same sentences as in (7) but, instead of sentence 3, there was a question that explicitly probed for the antecedent of the reflexive [e.g., a question like *Who had been pricked with a used needle?* with possible answers, for example, for condition (a) as *Jonathan* or *surgeon*]. The follow-up study showed a main effect of accessible antecedent, inaccessible antecedent and also an interaction between these two factors (see (**Figure 1**). When the accessible antecedent did not match the gender of the reflexive, participants made a higher proportion of errors in selecting the correct antecedent. In addition, when the inaccessible antecedent matched the gender of the reflexive participants made more errors than when it did not. Moreover, the increase in error due to gender match with the inaccessible antecedent was larger when the accessible antecedent did not match the gender, resulting in the interaction between the two factors.

Thus, there are four major findings in Sturt's Experiment 1 and his follow-up study. First, gender mismatch with the default gender of the accessible antecedent resulted in lower question-response accuracies. Second, gender match with the inaccessible antecedent resulted in lower question-response accuracies. Third, early reading time measures (first fixation duration and first pass reading time) increased when the gender specification of the accessible antecedent mismatched that of the reflexive. Fourth, second pass reading time (re-reading time) was *shorter* when the gender of the inaccessible antecedent matched the gender of the reflexive (this occurred in the case where the accessible antecedent matched the reflexive in gender, i.e., in match conditions).

Interestingly, the first three of the four effects can be explained by simply assuming that the search for an antecedent includes a gender feature. Therefore, we begin our modeling by assuming that both grammatical knowledge about antecedent and gender matching is used when resolving antecedents in English. For simplicity, we model the grammatical constraint by assuming that the antecedent should be a noun and should be the subject of the clause containing the reflexive, albeit under some different implementation of this grammatical constraint, the predictions may turn out differently[4]. This choice of retrieval cues is motivated by the conjecture that including agreement features in general may be an adaptive feature of the parser, although attempting to establish this is not the purpose of the work reported here. As a result the set of retrieval cues for the

[4]There are more sophisticated ways to encode the c-command constraint but these implementation details are orthogonal to the present discussion. See Alcocer and Phillips (2012) which compares some alternatives of implementing the c-command constraint.

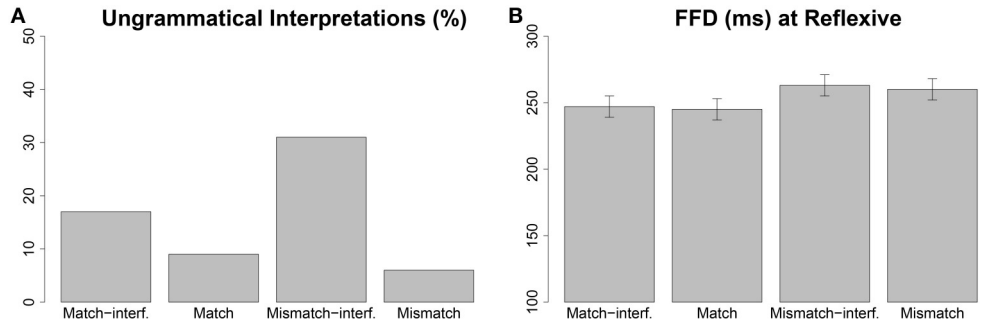

FIGURE 1 | The effects in Sturt (2003) Experiment 1: (A) proportions of ungrammatical interpretations of reflexives in the follow-up study; (B) first fixation durations in the eye tracking study. The error bars in the plot for first fixation duration show 95% confidence intervals.

TABLE 1 | The match of retrieval cues with the accessible and inaccessible antecedents for the four conditions in Sturt's experiments (cat=category).

Conditions	Accessible	Inaccessible
a (match-interference)	Gender, cat, role, clause	Gender, cat, role
b (match)	Gender, cat, role, clause	Cat, role
c (mismatch-interference)	Cat, role, clause	Gender, cat, role
d (mismatch)	Cat, role, clause	Cat, role

reflexives *himself* and *herself* are {gender = masculine/feminine, category = noun, role = subject, clause = current-clause}, differing only in the value of the *gender* feature. See **Table 1** for the list of cues matched by the two antecedents across the four conditions in Sturt's experiments.

The accessible antecedent matches all four cues in conditions (a) and (b) (the "match" conditions), but only three cues in conditions (c) and (d) (the "mismatch" conditions), since the stereotypical gender of *surgeon* is masculine, which does not match the gender retrieval cue at *herself* (gender = feminine). The inaccessible antecedent matches three cues (gender, category, role) out of a total of four cues in conditions (a) and (c), and in conditions (b) and (d) it matches two cues (category, role). As a result, interference for retrieving the antecedent will be higher in conditions (a) and (c) (the "interference" conditions) as compared to conditions (b) and (d). Note that the alternative possibility, as suggested by Phillips and colleagues, is that gender plays no role in retrieval; in that case, the cues for the match (a vs. b) and mismatch conditions (c vs. d) would be identical, leading to no interference.

The cue-based retrieval model predicts that similarity-based interference (SBI) arises at the moment of retrieval. SBI in reflexive binding is manifested in terms of delay in retrieval of the correct antecedent or an error in retrieving the correct antecedent. The delay in retrieval of the correct antecedent is a result of the fan assumption (see Equation 3 in Appendix A of Supplementary Material) that reduces the strength of association between a cue and a target as a function of the number of items associated with that cue. Reduced strength of association means reduced activation boost, which produces higher latencies. On the other hand, the error in retrieval of the correct antecedent is a combined result of activation fan and partial match. Reduction in activation boost of the accessible antecedent due to activation spreading, and partial matching between retrieval cues (the second summation component in Equation 1 in Appendix A of Supplementary Material) and any inaccessible antecedents can lead (probabilistically as a function of activation noise) to higher activation of the inaccessible antecedents. As a result, the probability of retrieving the inaccessible antecedent increases. The greater the partial match with inaccessible antecedents, the higher the percentage of errors in retrieving the accessible antecedent.

We model retrieval in sentence 2 from (7); this is the crucial sentence for generating predictions about the reflexive binding process. The predictions of the model are generated by running 1000 simulations for each condition. All model parameters are set to the values that have been used in the previous models from Lewis and Vasishth (2005), Vasishth and Lewis (2006), and Vasishth et al. (2008). A list of all the parameter values that we use is given in Table A1 in Appendix A of Supplementary Material.

The predicted retrieval error percentages accurately capture the pattern found in the Sturt (2003) follow-up study: There is a main effect of accessible antecedent, inaccessible antecedent, and an interaction between these two factors, exactly as in Sturt's follow-up study's response accuracies. First, when the accessible antecedent does not match the gender of the reflexive the model makes a higher number of errors in retrieving the correct antecedent (the mismatch effect in response accuracy). Second, when the inaccessible antecedent matches the gender of the reflexive the model makes more errors than when it does not (the interference effect in response accuracy). Third, the increase in error due to gender match with the inaccessible antecedent is greater in the mismatch conditions.

The retrieval times predicted by the model (shown in **Figure 2**) show a main effect of matching in the accessible antecedent: When the accessible antecedent does not match the gender of the reflexive, the retrieval times are higher than when it does. The model also predicts a match × interference interaction—retrieval times are predicted to be higher in the *match-interference* condition (198 ms) than in the *match* condition (194 ms); however, retrieval times are predicted to be

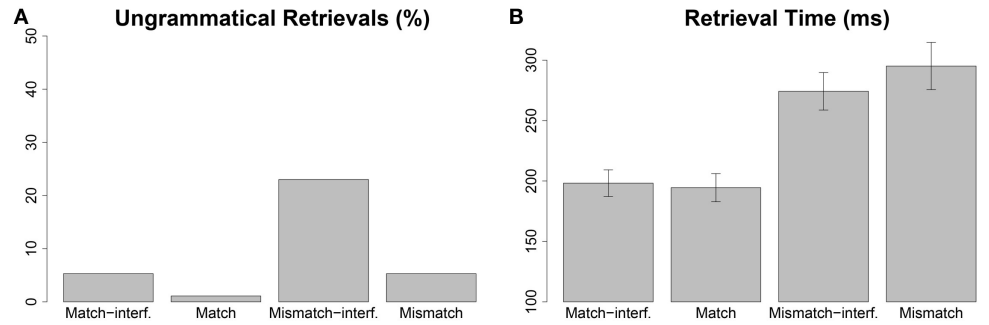

FIGURE 2 | The twofold predictions of the cue-based retrieval model for Experiment 1 in Sturt (2003), based on the parameter values listed in Table A1 in Supplementary Material. (A) Proportions of retrievals of the inaccessible antecedent; **(B)** retrieval times at the reflexive. The error bars in the plot for retrieval time show 95% confidence intervals

lower in the *mismatch-interference* condition (274 ms) compared to the *mismatch* condition (295 ms).

In order to compare the predictions to the data, we use the following terminology: the *mismatch effect* is the difference between the *match* conditions and the *mismatch* conditions; the *interference effect* is the effect between the two interference conditions and the other two conditions; the *match-interference effect* is the effect of interference in the two *match* conditions; and the *mismatch-interference effect* is the effect of interference in the two *mismatch* conditions.

The predicted ungrammatical retrievals accurately model the ungrammatical interpretations observed in the Sturt (2003) follow-up study. However, the predicted retrieval times accurately capture only the mismatch effect observed in the first fixation duration (FFD) in the eye tracking study. The interaction predicted between the *mismatch* effect and *interference* effect is not observed in the data. Thus, the model accurately captures the question-response accuracy data, but only partly characterizes the first fixation duration data.

The divergent patterns between the model's retrieval times and the first fixation durations in Sturt's study come from the differences in the patterns seen in the predicted match-interference effect and the mismatch-interference effect. The predicted match-interference effect is a consequence of spreading of activation of the gender cue which is matched by both the accessible and inaccessible antecedent. As described earlier, activation spreading reduces the strength of association between the cue and the target, causing longer retrieval latencies in the match-interference condition than the match condition. On the other hand, the mismatch-interference effect is a consequence of partial match between the cues and inaccessible antecedent: the inaccessible antecedent matches the gender cue which is not matched by the accessible antecedent (see **Table 1**), leading to higher probability of retrieving the inaccessible antecedent. This can be seen in the predicted retrieval error percentages in **Figure 2**. Moreover, in the *mismatch-interference* condition the inaccessible antecedent receives more activation from retrieval cues than in the *mismatch* condition as it matches more retrieval cues in the *mismatch-interference* condition. A substantially higher number of incorrect retrievals occur due to higher activation from the retrieval cues, and the retrieval times in the *mismatch-interference* condition are faster than the retrieval times in the *mismatch* condition, contrary to the findings in Sturt's study (see **Figure 1** vs. **Figure 2**). We return to this issue in the Section 3.6.

To summarize, the model predicts the following effects for retrieval errors (RE) and retrieval times (RT) at the reflexive:

E1. Mismatch effect (RE): the retrieval errors for the two mismatch conditions are higher than those for the two match conditions.

E2. Interference effect (RE): the retrieval errors for the match-interference and mismatch-interference conditions are higher than those for the other two conditions.

E3. Mismatch effect (RT): the retrieval times for the two mismatch conditions are longer than those for the two match conditions.

E4. Match-interference effect (RT): the retrieval times for the match-interference condition are longer than the match condition.

E5. Mismatch-interference effect (RT): the retrieval times for the mismatch-interference condition are *shorter* than the mismatch condition.

In Sturt's experiment, only the effects E1, E2 and E3 were observed. The interference effects E4 and E5 were missing in the early measures (first fixation duration and first pass reading time) of the eye tracking studies.

Here we assume that the RE translates to incorrect interpretation of the reflexive and RT translates to reading time in the experiment. We also make a simplified assumption about the lexical representation of nouns with stereotypical gender—as far as the gender feature is concerned, the representation of a stereotypically masculine or feminine noun (e.g., "soldier" or "nurse") is the same as that of an unambiguously masculine or feminine noun (e.g., "John" or "Jane"). It has been shown that the gender violation effects are stronger for definitionally masculine or feminine nouns than for stereotypically masculine or feminine nouns (Osterhout et al., 1997). This means that

our simplified assumption may lead to inflated predictions of various effects than what might be observed in an experiment. Finding out the precise difference in the representation of these two types of nouns is an important research question, but we think it lies outside the scope of this paper. We also assume that the first antecedent that is retrieved, is considered to be the correct antecedent of the reflexive in the final representation irrespective of its gender match with the reflexive; i.e., there is no reanalysis of the reflexive-antecedent dependency.

2.1. Parametric Variability in the Model

We did not estimate any parameter values for the current model. All existing parameters were set to the values that have been used in previous published versions of the cue-based retrieval model. It is possible, however, that the predictions of the model are valid only for the specific parameter values that we used here; this could be the reason behind the lack of effects E4 and E5 in the data—these effects might emerge only for a particular combination of parameter values. Conversely, the correct predictions of effects E1, E2, and E3 might depend on the specific values used by the model. To gain a better understanding of the range of possible predictions of the model, we ran the model for a range of values of three crucial ACT-R parameters: *noise*, *maximum associative strength* and *maximum difference*. The noise parameter controls the amount of instantaneous activation noise added to each chunk at retrieval; maximum associative strength is the constant "S" in Equation 3 in Supplementary Material; and the maximum difference parameter controls the penalty due to a mismatch between a retrieval cue and a feature value of a chunk. For each of these parameters, the range of values over which the predictions are generated is given in **Table 2**. The predictions are generated by running 1000 simulations for each combination of values of the three parameters. The total number of combinations of the three parameter values are 1287 (see **Table 2**). The predictions of effects E1–E5 across these sets of parameter values are plotted in **Figure 3**. Each effect is plotted against the parameter along which it varies the most. Effects E1 and E2 are influenced the most by noise, E3 and E5 are influenced the most by the maximum difference parameter, and E4 is influenced the most by the maximum associative strength parameter. Each point in the plots represents a mean over all values of the other two parameters. In short, **Figure 3** illustrates how the size of each effect varies across different parameter values.

The effect E1 varies from 0 to 23.9%, the effect E2 varies from 0 to 17.15%, the effect E3 varies from −1.55 to 228.4 ms, the effect E4 varies from −6.53 to 17.34 ms and the effect E5 varies from from −36.01 to 3.21 ms. The effects E1 and E2 are zero when the instantaneous activation noise is zero, which essentially means that the model does not make any mistake in retrieving the accessible antecedent when there is no noise added to the activations of chunks. But, in general, a non-zero value for noise parameter is necessary for modeling memory errors and response time distribution. Overall, although all effects show variation across different parameter combinations, they all remain mainly non-zero and have the same numerical sign as the predicted effects with the predefined parameter values. These results show that the model's predictions for E1–E3 are not crucially dependent on the fixed parameter values we used.

TABLE 2 | The range of parameter values used for testing the parametric variability of the cue-based retrieval models.

Parameter	Range of values
Noise	0.05–0.4, in steps of 0.05
Maximum associative strength	1–4, in steps of 0.25
Maximum difference	−1 to 0, in steps of 0.1

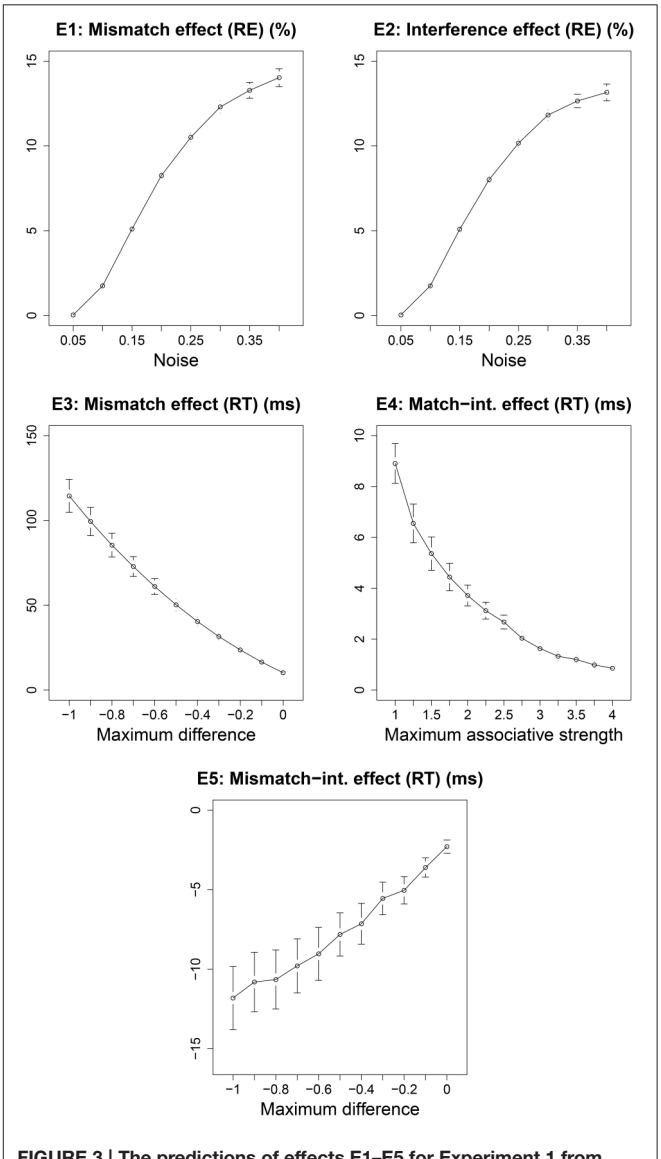

FIGURE 3 | The predictions of effects E1–E5 for Experiment 1 from Sturt (2003) across a range of parameter values. Each effect is plotted against the parameter that affects it the most.

2.2. An Alternative Explanation for the Absence of Interference Effects (E4 and E5) in Sturt (2003)

Although the lack of an interference effect in Sturt (2003) Experiment 1 could imply that non-structural cues like gender are not used in retrieval, Sturt noticed that the absence of an effect could be due to the non-local linear position of the interferer (inaccessible antecedent) with respect to the reflexive [see (7) above]. The accessible antecedent was introduced later in the string than the inaccessible antecedent, and was therefore closer to the reflexive. In his Experiment 2, Sturt (2003) modified this design by using stimuli as in (8), where the linear positions of the binding accessible and inaccessible antecedents are reversed with relation to Experiment 1, while their accessibility with respect to the binding theory is kept constant. However, this experiment also did not show any interference effect.

(8) {Jonathan/Jennifer} was pretty worried at the City Hospital. The surgeon who treated {Jonathan/Jennifer} had pricked {himself/herself} with a used syringe needle. There should be an investigation soon.

In addition to surface-string locality, we consider now another possibility for the apparent lack of interference: the degree of overlap between potential distractors and retrieval cues. We hypothesized above that reflexive binding uses grammatical category (noun, verb etc.), grammatical role (subject, object etc.) and gender as the retrieval cues to retrieve the correct antecedent. In the cue-based retrieval model, the overlap of these cues with grammatically inaccessible antecedents leads to an interference effect in both retrieval latency and retrieval errors. This formulation in the model leads to the following alternative explanation for the lack of interference effect in Sturt's Experiment 2: the interfering antecedent was the object of the relative clause [see (7) above], and hence did not match the grammatical role cue for retrieval at the reflexive. In fact, Van Dyke and McElree (2011) have recently proposed that although distractors with matching semantic cues exert interference, cues like grammatical role are weighted heavily in the retrieval process. They found that the interference effect due to the semantic match was present only when the distractors matched the grammatical cues as well. These results can also explain the lack of interference effect in Sturt's Experiment 2.

In terms of activations of memory elements, the probability of retrieving an incorrect element is higher if it has a higher activation value at the time of retrieval. The activation value of a memory element is directly dependent on its creation time, retrieval history, and its match with the retrieval cues—the more recently an element is created or retrieved, and the higher feature overlap it has with the retrieval cues, the better chances it has of being retrieved. Consequently, in Sturt's Experiment 1 the interferer has less chance of getting retrieved due to its less recent creation time with respect to the accessible antecedent, and in Experiment 2 the interferer has less chance of getting retrieved because its overlap with the retrieval cues is lower in comparison to the overlap of the accessible antecedent with the retrieval cues. In other words, in Sturt's experiments the inaccessible antecedents may not be strong enough interferers to detect their effect on the retrieval process. If this reasoning is correct, then the effect, or rather the lack of an interference effect, might be a false negative (a type II error). Concluding that an absence of an interference effect is evidence that no interference occurs has important consequences to the theory of retrieval processes in sentence comprehension. No interference in processing argument reflexives implies that the retrieval mechanism for reflexive binding is different from other retrieval mechanisms in sentence processing, e.g., subject-verb agreement, and agreement attraction. On the other hand, finding an interference effect simplifies the theory of retrieval processes considerably, since no exemption is granted to antecedent-reflexive resolution processes.

2.3. A Modified Design

In order to increase the strength of the interference effect, we can use an object relative clause [see (9)] where the inaccessible antecedent has the subject role in the clause. It is also closer to the reflexive in terms of linear distance. Under the cue-based retrieval account, the inaccessible antecedent would be more likely to interfere in the retrieval process than in the two experimental designs in Sturt (2003)—but under the structurally-constrained approach, this manipulation should not matter to the reflexive binding process. In fact, Xiang et al. (2009) used this design in their ERP study, but they did not have the crucial *match* condition. Cunnings and Felser (2013) also used this design to test the interaction of reflexive processing and memory capacity. They do find effect of inaccessible antecedent, but they did not evaluate their findings in terms any specific memory retrieval mechanism. See Section 4 for more details. Note that our design also uses the manipulation of stereotypical gender of the accessible antecedent, as in Sturt (2003), but all sentences are grammatical despite the gender mismatch between the reflexive and the stereotypical gender of the accessible antecedent.

c. *Accessible-mismatch/inaccessible-match (mismatch-interference)*
The tough soldier that Katie treated in the military hospital introduced herself to all the nurses.
d. *Accessible-mismatch/inaccessible-mismatch (mismatch)*
The tough soldier that Fred treated in the military hospital introduced herself to all the nurses.

We implemented a cue-based retrieval model for the modified design described in (9) as well as for Experiment 2 in Sturt (2003). The goal of this modeling is to compare the predictions of the cue-based retrieval theory for the five effects (E1–E5) across three designs—Experiment 1 (including the follow-up study; we

count the eye tracking study and the follow-up study as one experiment, following Sturt), Experiment 2 from Sturt (2003), and the modified design. The modeling assumptions are the same as in the model described above.

Figure 4 compares the predictions for effects E1–E5 across the three experimental designs. The predictions are generated for the range of parameter values listed in **Table 2**. The pattern of effects E1–E5 for Experiment 2 and the modified design are similar to that for Experiment 1. Across a range of parameter values, the predictions for effects E1, E2, and E5 are clearly stronger (higher numerical value) for the modified design than for Experiment 1 and 2 in Sturt (2003). Although the predictions for effect E3 are almost identical for the modified design and Experiment 2, they are nevertheless stronger than for Experiment 1. In contrast, the predictions for effect E4 are not distinguishable across the three designs. To gain better insight into the predictions for E4, we compared effect E4 across variations of the other two parameters (noise and maximum difference); see **Figure 5**. For the maximum difference parameter, effect E4 is stronger in the modified design and Experiment 2 than in Experiment 1 when the difference penalty is high (more negative), and it is weaker when the maximum difference penalty is low. For the noise parameter, effect E4 is stronger in the modified design and Experiment 2 than in Experiment 1 when the noise is low, and it is weaker when the noise is high. These patterns show that the predicted strength of effect E4 is dependent on the specific value or a range of values that are selected for these parameters. The noise parameter is a frequently modified parameter across various models (Wong et al., 2010), which is suggestive of uncertainty regarding its value across diverse cognitive tasks (cf. the decay parameter, which is usually kept fixed). The best way to estimate or, at least, restrict the noise parameter's value would be to empirically validate predictions of various models. In contrast to noise, the maximum difference penalty parameter is seldom modified, and is set to its default value of −1. For the default value of this parameter, the model clearly predicts a stronger E4 effect for the modified design and Experiment 2.

In sum, the predictions for the modified design and Experiment 2 show stronger effects than Experiment 1 across a range of parameter values. For the most part—and as expected—the effects for the modified design are much stronger than the other two designs. Next, we report an eye tracking study that we ran with the modified design (9). The goal of this study is to evaluate the predictions of our model that diverge from Sturt's findings (specifically, effects E4 and E5), as well as to replicate the effects E1–E3 that Sturt (2003) found.

3. EYE TRACKING EXPERIMENT

3.1. Participants

Forty English native speakers residing in Berlin, Germany participated in the eye tracking study. Data from one participant was excluded due to less than 40% accuracy on the sentence comprehension questions on all trials including experimental

and filler trials. The remaining 39 participants included 20 female participants and had a mean age of 29.5 years. The 39 native English speakers consisted of 14 British, 13 American, 8 Australian, 3 Canadian, and 1 New Zealander. All participants had normal or corrected-to-normal vision and were paid 10 Euros for their participation. The experiment had a duration of approximately 45 min, including set-up time. This study was carried out in accordance with the Helsinki declaration with written informed consent from all participants.

3.2. Design and Materials

Twenty-four stimuli were selected from the Xiang et al. (2009) study and constructed as per (9) by adding an extra *match* condition (see Appendix B in Supplementary Material for the list of stimuli). Of these 24 stimuli, 12 used stereotypically male nouns and 12 used stereotypical female nouns for the binding-accessible antecedent. There were 4 lists that comprised different item-condition combinations according to a Latin Square. Each list contained 54 filler sentences. Two-third of the target items and all fillers contained a comprehension question, and these were equally distributed across yes and no answers. In all, each participant answered 70 comprehension questions.

3.3. Procedure

Participants were seated 60 cm from an NEC Multisync 2080UX screen color monitor with 1600 × 1200 pixel resolution. They were asked to sit comfortably in front of an EyeLink 1000 eye tracker (SR Research) running at 500 Hz sampling rate (0.01° tracking resolution, and $< 0.5^{\circ}$ gaze position accuracy). Though the viewing was binocular, only the participant's right eye was tracked. The distance between the camera and the eye was 50 cm.

Participants were asked to position their head in a frame that stabilized their forehead and chin. They were asked to avoid large head movements throughout the experiment and to avoid blinking while reading the sentences. A 7-button Microsoft Sidewinder game pad was used to record button responses. The presentation of the materials and the recording of responses was controlled by two separate PCs, one running internally developed software (this is called EyeScript, and was originally developed in Richard Lewis' lab by Mason Smith, and later in Shravan Vasishth's lab by Felix Engelmann, Titus von der Malsburg, and Tobias Günther; the software is open source and available at https://github.com/tmalsburg/EyeScript) and the other running SR Research's proprietary software.

Each participant was randomly assigned one of four different stimulus lists. The list was randomized for every subject. At the start of the experiment, a standard calibration procedure was performed which involved participants looking at a grid of 13 fixation targets in random succession, in order to validate their gazes. Calibration and validation were repeated if the experimenter noticed that measurement accuracy was poor, and if participants took a break during the experiment.

Each trial consisted of the following steps: First, a fixation target in the same position as the first character of the text display was presented; two 200 ms fixations followed by one 400 ms fixation on this target triggered the presentation of the sentences (this procedure ensured that the participants always started reading in the left-most character position and helped the experimenter ensure the accuracy of calibration). Participants were instructed to read the sentence at a normal pace and to move their gaze to a dot at the bottom right of the screen after finishing the sentence. This triggered the presentation of a comprehension question in two-thirds of the trials, and in the rest it triggered the presentation of the next trial. The comprehension questions were included in order to ensure that the participants attended to the content of the sentences.

3.4. Data Analysis

All data processing and analyses were carried out in GNU-R (R Development Core Team, 2009). Fixations were detected using the algorithm described by Engbert and Kliegl (2003); an open source R package, *saccades*, developed by Titus von der Malsburg was used to carry out this step (the package is available at https://github.com/tmalsburg/saccades). Fixation and regression-based measures were extracted using another open source R package, *em2*, developed by Pavel Logačev (the package is available at: https://cran.r-project.org/src/contrib/Archive/em2/). All fixations 30 pixels above and below the sentence were included in the sentence. Fixations in the blank spaces between words were also counted; fixations in the first half of the space were included in the fixations on the preceding word and fixations in the second half were included in the fixations on the following word. All other fixations outside these regions were excluded.

Effects of accessible antecedent gender match (henceforth, *match*) and inaccessible antecedent gender match (*interference*) with the gender of the reflexive were evaluated across various eye movement measures. Data analysis was carried out using linear mixed models (Bates and Sarkar, 2007; Gelman and Hill, 2007). Linear mixed models were fit for the following eye movement measures at the reflexive. *First Fixation Duration* (FFD), the time spent during the first fixation during the first pass; *First Pass Reading time* (FPRT), the sum of all fixations during the first pass; *Re-reading Time* (RRT), the sum of all fixations in a region that occurred after first pass; *Total Reading Time* (TRT), the sum of all fixations in a region, *First Pass Regression Probability* (FPRP), the probability of regressing from a region after fixating in that region during first pass; and Re-reading Probability (RRP), the probability of reading a region during the second and subsequent passes. In the linear models, we used nested contrast coding and defined three contrasts that correspond to the three effects that we are interested in—mismatch effect, match-interference effect, and mismatch-interference effect. The interference effects were nested within the mismatch effect. The contrasts were coded such that having a positive coefficient meant that the effect was in the predicted direction. Apart from these three contrasts, trial number was used as a (centered) predictor. All linear mixed models were fit with by-participant and by-item random intercepts, and by-participant and by-item random slopes for the three contrasts. For FPRP and RRP, only random intercepts were used, since otherwise the models failed to converge. All reading times were log transformed before fitting the linear models. For FPRP and RRP, generalized linear mixed models were fit with a binomial link function.

TABLE 3 | Mean reading times at the reflexive with standard errors, percentages of first pass regressions from the reflexive, percentages of re-readings of the reflexive, and comprehension question response accuracies across four conditions.

3.5. Results

All mean reading times at the reflexive along with standard errors, FPRP from the reflexive, RRP at the reflexive and comprehension accuracy percentages are summarized in **Table 3**. The results of the statistical analysis are summarized in **Tables 4, 5**.

3.5.1. Question-Response Accuracy

Overall average accuracy for trials that included a comprehension question was 88% and average accuracy for target items was 84%. Accuracy values for comprehension questions across four conditions are listed in **Table 3**, but are not theoretically interpretable because the questions targeted different parts of the critical sentence, not just the antecedent-reflexive relation as in the Sturt follow-up study. We present these mean accuracies only for completeness.

3.5.2. Eye Tracking Dependent Measures

A statistically significant mismatch effect was observed in TRT and RRP, i.e., the conditions in which the stereotypical gender of the accessible antecedent did not match the gender of the reflexive were read more slowly and had higher probability of re-reading than the conditions where it matched. A statistically significant match-interference effect was observed in FPRP, with the high interference condition showing more regressions than the low interference condition.

3.6. Discussion

3.6.1. Early Effects

The results outlined above show an early effect of match-interference (E2) from the inaccessible antecedent in first pass regression probability, such that a gender match between the reflexive and the inaccessible antecedent leads to a higher number of first pass regressions from the reflexive (see **Figure 6**). The occurrence of a regression from a word reflects some difficulty in integrating the word when it is fixated and hence it is plausibly an early effect (Clifton et al., 2007). We are assuming that higher number of retrieval errors should reflect in higher probability of regression. First pass regressions cannot reflect the late processes triggered at the end of a sentence or the processes reflected by late measures such as second pass reading time. Assuming that first pass regressions reflect processing difficulty triggered relatively early during the first contact with the critical word, the interference effect is inconsistent with the conclusion of Sturt (2003), that the online application of Principle A is not affected by interference from the inaccessible antecedent at early stages of processing. Conclusions derived in Nicol and Swinney

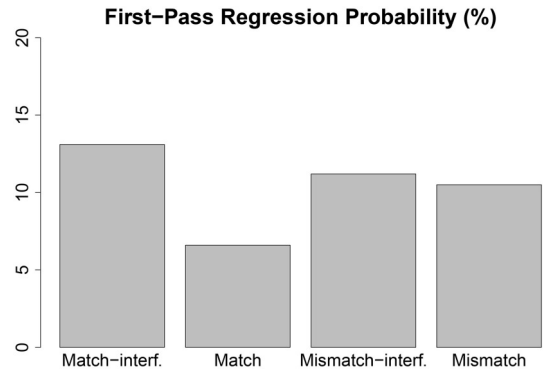

FIGURE 6 | Early effect of *interference*. Effects that are observed in "early" eye tracking measures are considered to be early effects. Usually measures like FFD, FPRT, and FPRP are considered to be early measures since they are associated with reader's first exposure to a region.

(1989) and Xiang et al. (2009) are also not compatible with these results. As a result, this study challenges the claim from Phillips et al. (2011) and Dillon et al. (2013) that an antecedent for a reflexive is retrieved using only structural cues without considering the gender feature. Our findings are consistent with those of Badecker and Straub (2002), Choy and Thompson (2010), Cunnings and Felser (2013), Thompson and Choy (2009).

3.6.2. Late Effects

The effect of accessible antecedent gender match (E1 and E3) was also observed in the RRP and TRT (see **Figure 7**) such that reading times were elevated and there were higher number of re-readings when the accessible antecedent did not match the gender of the reflexive (we are assuming that E1, the mismatch effect predicted in retrieval errors, should reflect in elevated reading times). The absence of an early effect of accessible antecedent is different from the finding of Sturt (2003), where the effect appeared at FFD. We also observed a marginal effect of mismatch-interference (E5) ($p = 0.063$) in the RRP. Although the effect doesn't reach conventional significance level, it corroborates the patterns we observe in our exploratory data analysis with cumulative progressions (see Section 3.6.4).

3.6.3. Regression Contingent Effects in FFD

As an exploratory data analysis, we analyzed FFD contingent on the first pass regressions—separate analysis for FFD followed by regressions and FFD not followed by regressions. The two patterns are plotted in **Figure 8**. FFD followed by regressions show a pattern consistent with the retrieval times predicted by the model. Although the match-interference effect (E4) ($t = 1.77$) and mismatch-interference effect (E5) ($t = 1.70$) do not quite reach conventional significance levels, they show the trend of interference effect as predicted by the model. These FFDs also show the main effect of mismatch (E1 and E3) ($t = 2.78$) which is consistent with the early mismatch effect in Sturt (2003). FFD not followed by regressions did not show this effect.

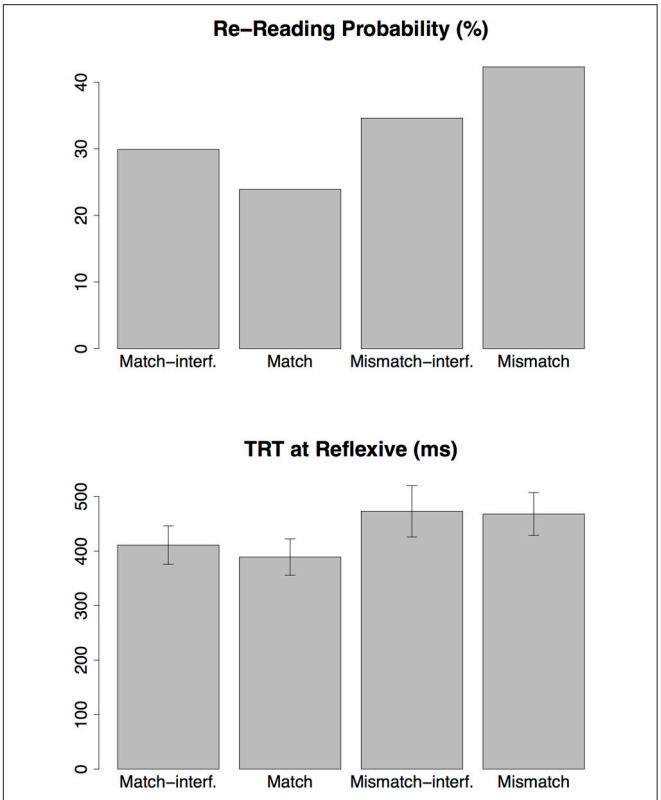

FIGURE 7 | Late effect of *match*. Effects that are observed in "late" eye tracking measures are considered to be late effects. Usually measures like RRP and TRT are considered to be late measures since they involve reader's second and possibly subsequent exposures to a region.

3.6.4. Effects Revealed in Cumulative Progressions

As another way of exploratory data analysis, we examined an eye movement measure called the cumulative progression, which has been used earlier by Kreiner et al. (2008) and Cunnings and Sturt (2014). The cumulative progression quantifies how far a reader's eyes have traveled from the region of interest. The assumption with analyzing cumulative progressions is that the further away, in the direction of reading, a reader progresses from a region (in one condition compared to another), the easier the information in that region is for processing. It is a measure of continuous eye movements, in the sense that it assigns a numeric value, the distance, at each point in time that can be recorded by an eye tracker. This makes it possible to compare the processing cost between two conditions over a continuous period of time. For example, in our case, we could examine if participants consistently progress further away from the reflexive region in the match conditions compared to the mismatch conditions after entering the reflexive region for the first time. And if they do, then, by assumption, it implies that the reflexives are easier to process in the match conditions than in the mismatch conditions. Effectively, we are assuming that faster retrievals at the reflexive will result (in faster processing, and hence) in progressions that are further away from the reflexive.

Cumulative progressions are computed by measuring the distance between the position of the first fixation in the region

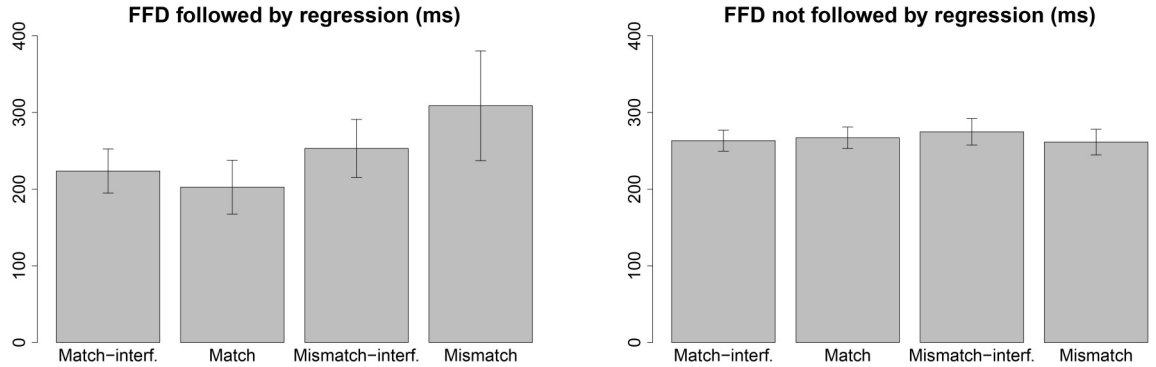

FIGURE 8 | Regression contingent FFD.

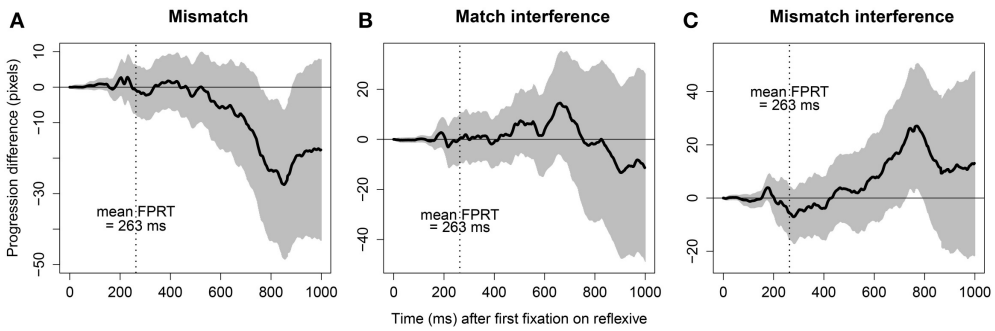

FIGURE 9 | Progression differences plotted against timestamps starting at the first fixation in the reflexive region. Each curve represents an effect and the gray area around it represents the 95% confidence interval. The dotted vertical line denotes the position of the mean FPRT for the reflexives. **(A)** The mismatch effect is obtained by subtracting the mean progressions in the two mismatch conditions from the mean progressions in the two match conditions, **(B)** the match-interference effect is obtained by subtracting the mean progressions in the match condition from the mean progressions in the match-interference condition, and **(C)** the mismatch-interference effect is obtained by subtracting the mean progressions in the mismatch condition from the mean progressions in the mismatch-interference condition.

of interest and the subsequent eye positions, ignoring word boundaries. In the earlier studies mentioned above the distance was calculated in terms of characters (the number of characters by which the current eye position is separated from the position of the first fixation in the region of interest). Only forward eye movements change the value of the measure; regressive eye movements or no eye movements, as in fixations, do not change the value of the measure. This means that the sequence of cumulative progressions for one trial is a monotonically increasing sequence—every subsequent number (representing the distance) is greater than or equal to the previous number (hence the name cumulative). Unlike in earlier studies, where the distance was calculated in terms of characters, we calculate the distance in terms of the number of screen pixels a participant has progressed, which gives a more fine-grained measure of distance. As in Cunnings and Sturt (2014), we evaluate various effects by comparing the numerical *differences* in mean cumulative progressions for different conditions.

Figure 9 plots cumulative progression differences. Each panel represents one of the three effects in reading times that we are considering here. Each point on curve is obtained by first averaging cumulative progressions across participants and items for one condition at one timestamp, and then calculating the difference between the averages across two conditions that are compared. For the mismatch effect curve, the averaging is done for two pairs of conditions and then the difference between them is calculated. The x-axis represents timestamps starting with the first fixation in the reflexive region and extends till the next 1000 ms; two consecutive timestamps are 2 ms apart since the eye tracker sampled every 2 ms (which means each curve is composed of 501 points). The y-axis represents the difference in pixels between averaged progressions of conditions that are compared. It is crucial to note here that this is an analytic approach, and it is only an exploratory data analysis. Since each data point in this figure is averaged across participants and items, it underestimates variance between participants and items. Moreover, the 95% confidence intervals are underestimates, and with more conservative approach the plots may look consistent with noise. Overall, we need a more rigorous statistical analysis to do justice to the conclusions we are drawing based on cumulative progressions.

The curve representing the mismatch-interference effect diverges at 434 ms from the x-axis on the positive side and remains on the positive side. This implies that after the

first fixation in the reflexive region, from 434 ms onwards, participants speed up in the mismatch-interference condition compared to the mismatch condition. This, in turn, is consistent with the mismatch-interference effect (E5) predicted by the model. The curve representing the mismatch effect diverges at 528 ms from the x-axis on the negative side and remains on the negative side. This implies that the two mismatch conditions are read slower than the two match conditions from 528 ms onwards, after the first fixation in the reflexive region, which is consistent with the mismatch effect (E3) predicted by the model. However, the match-interference effect curve diverges from the x-axis, initially on the positive side at 420 ms and then switches to the negative side at 754 ms and then predominantly remains on the negative side. The diversion in the positive direction is opposite to what the model predicts, but the later diversion to the negative side is consistent with the predictions of the model. Effectively, if we assume that faster cumulative progressions from the reflexive region reflect faster retrievals at the reflexive, the mismatch-interference effect (E5) and the mismatch effect (E3) are visible in the cumulative progressions. Interestingly, the mismatch-interference effect also starts earlier than the mismatch effect.

3.6.5. Timing of Mismatch and Interference Effects

It is important to note that the predictions of the model are not specific to early or late measures, but we expect that both mismatch and interference effects should occur during the same time frame in an experiment because, in the model, both the effects take place during the same (sub)process. Moreover, the absence of early mismatch effect in our experiment (and also in Cunnings and Felser, 2013 and Cunnings and Sturt, 2014) does not support the argument in Sturt (2003) that binding accessible antecedents influence early stages of processing, albeit it need not necessarily speak *against* Sturt's argument either, because early effects don't always show up in early measures (Vasishth et al., 2013).

In sum, the eye tracking study, through various measures, supported the predictions of the cue-based retrieval model of reflexive binding that assumes gender of the reflexive as one of the retrieval cues. The mismatch effects E1 and E3 were observed in total reading time, re-reading probability and in cumulative progressions from the reflexive. The interference effect E2 was observed in first pass regression probability. The interference effect E4 was observed in first pass regression probability and a trend of this effect was observed in the regression contingent first fixation duration. The interference effect E5 was observed in re-reading probability, cumulative progressions from the reflexive, and there was also a trend of this effect in first fixation durations that were followed by regressions. Along with replicating the mismatch effects, observed in Sturt's experiments, the presence of interference effects (E4 and E5), which were absent in Sturt's experiments, makes the results consistent with the model's predictions.

4. GENERAL DISCUSSION

In this paper, we investigated the question: what kinds of cues are used initially by the parser when resolving antecedent-reflexive relations? The two positions on this question are: early use of only structural cues (Nicol and Swinney, 1989; Sturt, 2003; Xiang et al., 2009; Phillips et al., 2011; Dillon et al., 2013), or early use of structural as well as other cues such as gender marking (Badecker and Straub, 2002). We framed the theoretical question within a computational model of sentence processing, the cue-based retrieval model proposed in Lewis and Vasishth (2005) and Lewis et al. (2006), and showed that if we assume that cue-based retrieval involves structural as well as non-structural cues, the model makes five predictions, repeated below:

E1. Mismatch effect (RE): the retrieval errors for the two mismatch conditions are higher than those for the two match conditions.

E2. Interference effect (RE): the retrieval errors for the match-interference and mismatch-interference conditions are higher than those for the other two conditions.

E3. Mismatch effect (RT): the retrieval times for the two mismatch conditions are longer than those for the two match conditions.

E4. Match-interference effect (RT): the retrieval times for the match-interference condition are longer than the match condition.

E5. Mismatch-interference effect (RT): the retrieval times for the mismatch-interference condition are *shorter* than the mismatch condition.

Effects E1–E3 are attested in Sturt's studies; but effects E4 and E5 are not. We hypothesized that Sturt failed to find effect E4 because the inaccessible antecedent had a different grammatical role (object) than the accessible antecedent (subject); i.e., it was distinct enough from the accessible antecedent to be rejected successfully during search. We predicted that if both the accessible and inaccessible antecedents had the subject role, then a match-interference (E4) effect would occur. Moreover if grammatical cues are weighted heavily in the retrieval process (Van Dyke and McElree, 2011), a subject distractor will induce a higher interference effect. We then conducted an eye tracking study in which both the accessible and inaccessible antecedents had the subject role, thereby increasing their similarity. We showed that in first pass regression probability a match-interference effect is indeed seen, as predicted by the model. In addition, as an exploratory data analysis, when we separately analyzed the first fixation duration contingent on regressions, the first fixation durations that were followed by regressions showed marginal effects consistent with the two interference effects E4 and E5. These first fixation durations also confirmed the effect E3. The effect E3 was observed in re-reading time and total reading time as well. This result is consistent with the model's predicted mismatch effect in retrieval times, and the predicted mismatch effect in retrieval errors. Further, in another exploratory data analysis with an eye tracking measure called cumulative progressions, which has been claimed to capture processing difficulty on a continuous time scale, we found that the interference effect E5 and the mismatch effect E3 are realized; with E5, in fact, occurring earlier than E3. Though the analysis with cumulative progressions involved only visual inspection, the

visual patterns are consistent with these two effects predicted by the model.

In sum, the eye tracking study provided empirical evidence for all the effects predicted by the model, including the interference effects that were not observed in the earlier studies such as Sturt (2003) and Xiang et al. (2009). There was clear support for the mismatch and match-interference effect predicted by the model. Although the support for the mismatch-interference effect was not equally clear—it was only marginally significant in two of the eye tracking measures, and there was some evidence in the exploratory data analysis with cumulative progressions—the two interference effects have important theoretical implications for the generality of the retrieval mechanisms in sentence processing, and so should not be ignored.

The interference effects and the mismatch effect have also been observed in some other studies[5]. The mismatch effect E3 has been found in the reading studies (eye tracking and/or self-paced reading) such as Cunnings and Felser (2013) (Experiment 1 and 2), Cunnings and Sturt (2014) (Experiment 1), Dillon et al. (2013) (Experiment 1 and 2), King et al. (2012), Parker and Phillips (2014) (Experiment 1, 2, and 3), and Sturt and Kwon (2013) (Experiment 3 and 4) with a design comparable to Sturt's experiment 1. The interference effect E4 has been found in the reading studies such as Badecker and Straub (2002) (Experiment 3 and 4) and Mansbridge and Witzel (2012), and the interference effect E5 has been found in the reading studies such as Cunnings and Felser (2013) (Experiment 2 in high working memory span readers), King et al. (2012), Parker and Phillips (2014) (Experiment 2 and 3) Sturt and Kwon (2013) (Experiment 3 and 4). In the visual world paradigm, an effect equivalent to the interference effect E4 has been reported in Choy and Thompson (2010), Clackson et al. (2011), Runner and Head (2014), and Thompson and Choy (2009). Overall the pattern appears to be that the mismatch effect has been observed robustly, although there are at least a handful of studies reporting the two interference effects as well.

4.1. Why Were the Interference Effects Found Less Often in Earlier Studies?

Apart from the reasons mentioned in the motivation for the design of the experiment reported here, namely the proximity of the inaccessible antecedent to the reflexive and it being the subject of the clause, there could be other reasons for the absence of the interference effect. The absence of the effect could just be a failure to find an effect that in fact exists, which may happen due to low power of the experiment. For example, the effect could be masked by other confounding variables. Indeed, Cunnings and Felser (2013, p. 23) found that participants with high working memory spans show (in first fixation duration) an effect in exactly the direction predicted by the cue-based retrieval model (though they didn't interpret the effect as an interference or intrusion effect). It is participants with low working memory span who show longer first fixation durations in the interference condition in the mismatch cases. If one were to ignore the working memory span in the Cunnings and Felser data, the two differently-signed effects by span would cancel out, showing no difference between the interference and no-interference condition in the mismatch cases, exactly as found in the literature. Thus, since our data and all previous experiments (except, of course, Cunnings and Felser's) do not take working memory capacity into account as a variable, it is quite possible that we are missing an effect that is correctly predicted by the model. Of course, this raises the question that the ACT-R model as currently implemented does not explicitly model high working memory capacity participants. In future work, we intend to explore the role of working memory capacity in triggering the mismatch interference effect.

Another possibility could be that the interference effects are not as strong as the mismatch effect. The model, in fact, predicts numerically smaller interference effects compared to the mismatch effect (see **Figure 4**). Recently, Parker and Phillips (2014) using sentences as in (10), found that the mismatch-interference effect is visible when the reflexive mismatches two features, such as the number and gender (e.g., herself and schoolboys), with the accessible antecedent, but not when it mismatches only one feature. King et al. (2012) using sentences as in (11), found that the mismatch-interference effect is visible when the reflexive is not adjacent to the verb [condition (b) in (11)] allowing the information about the verb's argument structure, and hence the information about the accessible antecedent, to decay. These results possibly corroborate the model's prediction that the mismatch-interference effect is weaker than the mismatch effect, and hence difficult to detect.

(10) The {librarian/janitor} said that the {schoolgirl/schoolboy/schoolboys} reminded herself about the book.

(11) a. *Verb-adjacent:* The mechanic who spoke to {John/Mary} sent {himself/herself} a package.
b. *Verb-non-adjacent:* The mechanic who spoke to {John/Mary} sent a package to {himself/herself}.

Effectively, our results are not only in line with the results from Cunnings and Felser (2013), King et al. (2012), and Parker and Phillips (2014), among others, but also provide convincing evidence for the model's predictions with manipulations independent of the memory span of the participants, with a configuration involving verb-adjacent reflexives, and with lowest possible (= single) mismatch of retrieval cues with the accessible antecedent.

4.1.1. Strictly Structured Access as an Alternative

Here, we discuss the strictly structured retrieval approach proposed in Dillon et al. (2013) and Phillips et al. (2011) for resolving reflexive-antecedent dependency, and examine its claims in the light of existing experimental and modeling findings. Although Phillips and colleagues refers to the

[5]In this paper we are considering only argument reflexives and only in English. But interference effects have also been reported for Mandarin reflexives (Jäger et al., 2015b; Chen et al., 2016) and for non-argument positions such as English reflexives inside picture noun phrases (Runner et al., 2006). On the other hand, for the pronoun-antecedent dependency (which is subject to different grammatical constraints than the reflexive-antecedent dependency), Chow et al. (2014) failed to replicate the interference effect observed in the pronoun experiments reported in Badecker and Straub (2002).

mechanism as structured access, we refer to it as a *strictly* structured access to emphasize the point that the approach suggested in this paper does not ignore the structural constraints, but it includes other constraints as well.

Dillon et al. (2013) supported evidence for the strictly structured access with a set of computational and experimental studies involving English reflexives and subject-verb agreement. This experiment essentially replicated the *interference asymmetry* effect from Wagers et al. (2009) and the absence of interference effect in processing English reflexives from Sturt (2003). Based on these results, they concluded that agreement dependency and reflexive dependency employ different retrieval mechanisms for resolving the dependencies—agreement dependencies are resolved using morphological features of the target noun phrase whereas the antecedent for a reflexive is retrieved using *only* structural constraints. They further compared the predictions of a strictly structural cue based retrieval model of reflexives to a model utilizing mixed cues—structural as well as agreement. The mixed cue model predicted an interference effect in retrieval errors (similar to E2 above) and a mismatch-interference effect in retrieval times (similar to E5 above). The prediction of the match-interference effect (E4) was not reliably non-zero, in the sense that for some parameter combinations the model didn't predict any difference between the match and match-interference condition. The structural cue based model predicted no interference effect in either retrieval errors or retrieval times. The mismatch effects in retrieval errors and retrieval times (E1 and E3), as predicted by the mixed cue model, were not discussed in Dillon et al. (2013). On the basis of these predictions, Dillon et al. (2013) concluded that the strictly structured access model captures the reflexive binding data from their Experiments better than the mixed cue model.

Although Dillon et al. (2013) replicated the findings in Sturt (2003), the lack of interference effect is subject to the same alternative explanation that we suggested for Experiment 2 in Sturt (2003): we hypothesized that reflexive binding uses the grammatical role *subject* as one of the retrieval cues for retrieving the correct antecedent. The absence of the interference effect could be due to (apart from power concerns) the fact that the interfering antecedent had an *object* role in the experiments above, which does not match one of the retrieval cues, reducing the strength of interference. Badecker and Straub (2002) also reported that the interference effect is found when the interferer is in the subject position. Moreover, Van Dyke and McElree (2011) found that, in thematic binding, the interference effect due to the semantic match was present only when the distractors matched syntactic cues along with semantic cues. If the retrieval process gives higher weight to syntactic cues than semantic cues, the absence of interference effect could simply be due to the absence of matching a grammatical role in the inaccessible antecedent.

The predictions of the structured access model hold only for a limited set of experiments and a limited set of effects in those experiments. The mismatch-effects (E1 and E3) that have been replicated in various studies like Sturt (2003), Cunnings and Felser (2013) and also the one reported in this paper cannot be explained by this model. The structured access model predicts

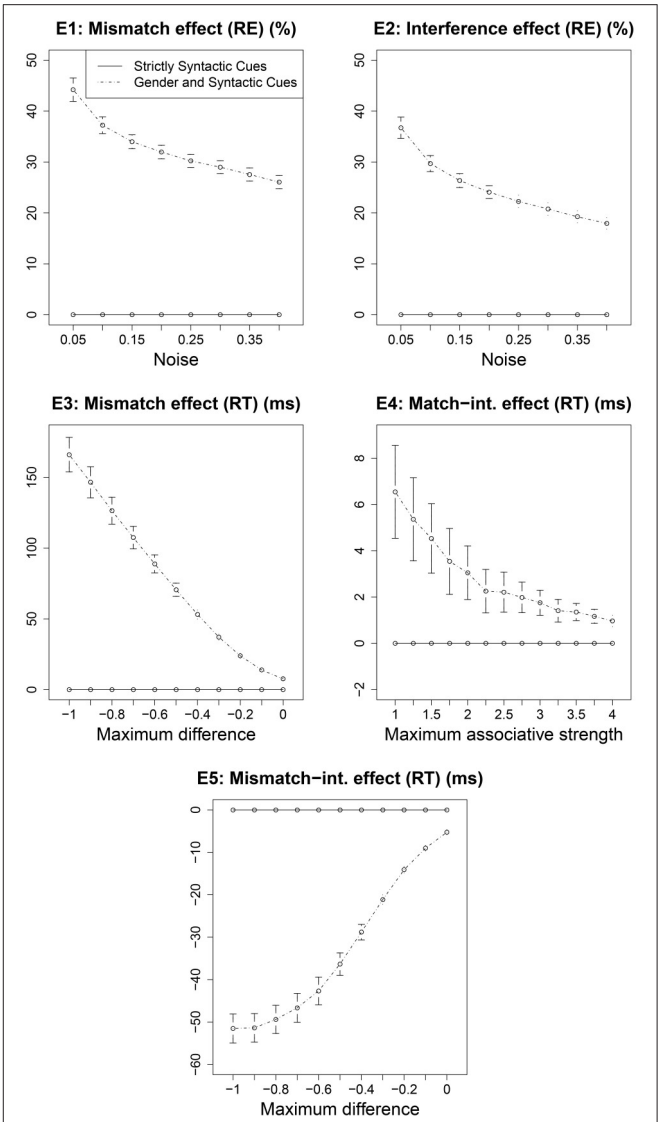

FIGURE 10 | The predictions of a strictly structural cue-based model and a model with structural and agreement feature based cues. The predictions are for the new experimental design and are generated across a set of parameter values.

no difference between match and mismatch conditions (see **Figure 10**). Furthermore, the interference-effects (E2, E4, and E5) observed in various reflexives studies like Badecker and Straub (2002) Experiment 3, Sturt (2003) follow-up study, Cunnings and Felser (2013) Experiment 2 and the one reported here cannot be explained by this model. Consequently, a model assuming structural as well as agreement features as retrieval cues predicts a broader range of data than a strictly structured access model.

Dillon et al. (2013) further claimed that the match-interference effect (E4)—higher reading times when the inaccessible noun matches gender or number of the reflexive—is not reliable evidence for interference from the grammatically inaccessible antecedent, for mainly two reasons: (1) The cue-based retrieval model doesn't predict any difference in retrieval

times between the match and match-interference conditions for certain parameter combinations, since on the one hand the cue-overlap (gender and number) between accessible and inaccessible antecedents leads to an inhibitory effect, and on the other hand the retrieval of the inaccessible antecedent leads to a facilitatory effect; (2) The match-interference effects can be explained in terms of feature-overwriting (Nairne, 1990; Gordon et al., 2001, 2004, 2006; Oberauer and Kliegl, 2006) instead of interference at the time of retrieval. Consequently, Dillon proposed that only a facilitatory effect in mismatch-interference can be considered as evidence for retrieval interference.

As far as the first argument is concerned, we, in fact, show that the cue-based retrieval model with mixed cues consistently predicts a positive match-interference effect across a set of parameter values for Sturt's two experiments (see **Figures 4**, **5**). Although the effect for the modified design is not predicted to be positive for all combinations of parameter values, for a certain set of combination of values the effect is non-zero and positive, and only for a very small set of parameter values is the effect predicted to be zero.

The second argument, in fact, applies to the mismatch-interference effect as well—the mismatch-interference effect (for this particular design) can also be explained in terms feature-overwriting or encoding interference. Encoding interference is a consequence of the feature overlap between the accessible and inaccessible antecedents. In the design discussed here, the feature overlap between the accessible and inaccessible antecedents is, in fact, higher in the mismatch condition compared to the mismatch-interference condition ("soldier" and "Fred" have the same gender in the mismatch condition whereas "soldier" and "Katie" have different genders in the mismatch-interference condition). This means between these two conditions, the interference conditions are reversed for encoding and retrieval interference. Retrieval interference predicts faster reading time for the mismatch-interference condition while encoding interference predicts *slower* reading time for the *mismatch* condition, leading to exactly the same pattern of retrieval times between the two mismatch conditions. Effectively, this configuration makes it impossible to tease apart the two types of interference theories using the experiment design considered in this paper or in similar earlier studies including Dillon et al. (2013). However, Jäger et al. (2015a) using self-paced reading and eye-tracking studies with German and Swedish reflexives, compared the predictions of the two interference theories. They could not find any evidence for encoding interference and concluded that "invoking encoding interference may not be a plausible way to reconcile interference effects with a structure-based account of reflexive processing." If we assume that the retrieval process for reflexives in German, Swedish and English are similar (especially because these are closely related languages) then we can safely conclude that, even though our design does not have the possibility of disentangling the two retrieval theories, the effects that we see in our experiment are driven by retrieval interference.

In summary, we have presented a theory and computational model of the access of antecedents for reflexive pronouns in English, and used this theory to gain insight into empirical studies that have yielded mixed results concerning the putative role of non-structural cues. We used this analysis and the results of further modeling to motivate a new empirical design that formed the basis of an eye tracking study. Many of the results of the eye tracking study are consistent with the model's assumptions concerning the early use of non-structural cues. These results present a challenge for theories advocating the infallibility of the human parser in the case of reflexive binding in English, and provide support for the inclusion of agreement features such as gender in the set of retrieval cues. In general, the results provide further support for the deployment of a rapid, parallel cue-based access mechanism in service of sentence parsing (McElree, 2000; McElree et al., 2003; Lewis and Vasishth, 2005; Lewis et al., 2006), and help to sharpen deeper explanatory questions concerning the utility and selection of cues.

AUTHOR CONTRIBUTIONS

UP wrote the model, SV and RL supervised the process. UP conceived, setup, and carried out the experiment. UP and SV analyzed the data. UP, SV, and RL wrote the manuscript.

ACKNOWLEDGMENTS

We would like to thank William Badecker, Brian Dillon, Sol Lago, Colin Phillips, Rukshin Shaher, Ming Xiang, and the two reviewers for their helpful comments, and to Felix Engelmann, Pavel Logačev and Titus von der Malsburg for their technical help at various stages of the eye tracking study. The eye tracking experiment reported here was run at the ZAS in Berlin; many thanks to Manfred Krifka for providing space to run this study. Thanks for the support of the Deutsche Forschungsgemeinschaft (Project No. BO 2142/1-1) to UP, and the National Science Foundation under Grant BCS-1152819 to RL.

Retrieval interference in reflexive processing: experimental evidence from Mandarin, and computational modeling

*Lena A. Jäger *, Felix Engelmann and Shravan Vasishth*

Department of Linguistics, University of Potsdam, Potsdam, Germany

We conducted two eye-tracking experiments investigating the processing of the Mandarin reflexive *ziji* in order to tease apart structurally constrained accounts from standard cue-based accounts of memory retrieval. In both experiments, we tested whether structurally inaccessible distractors that fulfill the animacy requirement of *ziji* influence processing times at the reflexive. In Experiment 1, we manipulated animacy of the antecedent and a structurally inaccessible distractor intervening between the antecedent and the reflexive. In conditions where the accessible antecedent mismatched the animacy cue, we found inhibitory interference whereas in antecedent-match conditions, no effect of the distractor was observed. In Experiment 2, we tested only antecedent-match configurations and manipulated locality of the reflexive-antecedent binding (Mandarin allows non-local binding). Participants were asked to hold three distractors (animate vs. inanimate nouns) in memory while reading the target sentence. We found slower reading times when animate distractors were held in memory (inhibitory interference). Moreover, we replicated the locality effect reported in previous studies. These results are incompatible with structure-based accounts. However, the cue-based ACT-R model of Lewis and Vasishth (2005) cannot explain the observed pattern either. We therefore extend the original ACT-R model and show how this model not only explains the data presented in this article, but is also able to account for previously unexplained patterns in the literature on reflexive processing.

1. Introduction

One major task the human parser has to accomplish is to syntactically link together two or more linguistic elements that are not adjacent to each other. For example, when a reflexive is being processed, it has to be somehow linked to its antecedent even if there is intervening material. Therefore, one central question in psycholinguistics is what mechanisms the human parser uses to identify and retrieve the previously processed part of a dependency. Theoretically, there are different options how this identification and retrieval of a linguistic constituent from working memory might be accomplished: different kinds of search mechanisms on the one hand (Sternberg, 1966, 1969) and cue-based, i.e., content-addressable, retrieval on the other

hand (McElree and Dosher, 1989; Anderson and Lebiere, 1998; Anderson et al., 2004).[1] In general, a search mechanism checks certain items in memory based on their location in order to find the target. Cue-based retrieval, in contrast, assumes that retrieval targets are content-addressable and can be accessed directly by the use of certain features as retrieval cues. Over the last decade, evidence favoring a content-addressable memory underlying human sentence processing has accumulated (McElree, 2000, 2003; McElree et al., 2003; Van Dyke and McElree, 2006; Martin and McElree, 2008).

In the case of English reflexives, retrieval cues used in a content-addressable memory might be non-structural cues like gender or number along with structural cues like local c-command. Note that a reflexive's binding domain varies between languages (Büring, 2005; Reuland, 2011). Whereas in English it can be approximated by the local clause, in Chinese the reflexive *ziji* can be bound across clause boundaries (non-local binding; for a brief overview of the syntactic properties of Chinese *ziji* see below). For the sake of simplicity, we will refer to the structural feature of *c-commanding the reflexive and being contained in its binding domain* briefly as the *c-command* feature.

However, within the framework of cue-based retrieval, it is still an open question which features the parser uses as retrieval cues. On the one hand, it has been proposed that all available cues are used for retrieval with equal weights being applied to all cues (Lewis and Vasishth, 2005). We will refer to this account as the *standard cue-based retrieval account*. On the other hand, Van Dyke (2007) and Van Dyke and McElree (2011) and others argue that syntactic cues (being in a certain tree-configurational position) have some kind of priority over non-syntactic cues. In particular, it has been proposed that for the processing of reflexive-antecedent dependencies, the set of features used for retrieving a reflexive's antecedent is limited to syntactic cues such as c-command within the reflexive's binding domain (Nicol and Swinney, 1989; Sturt, 2003; Xiang et al., 2009; Phillips et al., 2011; Dillon et al., 2013; Kush and Phillips, 2014). We will refer to this proposal as *structure-based account*.

If a structure-based retrieval is applied, a noun phrase that is in a structural position that disqualifies it from being the reflexive's antecedent should not have any effect on the processing of the reflexive-antecedent dependency, no matter whether it matches non-structural features of the reflexive such as gender or number. Thus, in a sentences like (1), the gender of *Jonathan* or *Jennifer* should not affect processing times of the reflexive since they do not c-command it and hence cannot syntactically bind the reflexive.

(1) a. **Antecedent-match; distractor-match**
The *surgeon* who treated *Jonathan* had pricked *himself* …

b. **Antecedent-match; distractor-mismatch**
The *surgeon* who treated *Jennifer* had pricked *himself* …

c. **Antecedent-mismatch; distractor-match**
The *surgeon* who treated *Jennifer* had pricked *herself* …

d. **Antecedent-mismatch; distractor-mismatch**
The *surgeon* who treated *Jonathan* had pricked *herself* …

The parsing architecture developed by Lewis and Vasishth (2005), which is based on Anderson et al. (2004)'s cognitive architecture ACT-R (Adaptive Control of Thought–Rational) assumes a cue-based retrieval mechanism without syntactic constraints. This model has been used to explain interference effects in sentence processing and in reflexives in particular (e.g., Dillon et al., 2013; Parker and Phillips, 2014; Patil, Vasishth, and Lewis, "Retrieval interference in syntactic processing: The case of reflexive binding in English," unpublished manuscript). According to the ACT-R model, both latency and probability of retrieving a certain target item are determined by (i) the quality of the match between retrieval cues and target features and (ii) similarity-based mutual inhibition between the target and other matching items. Retrieval speed and probability increase with the number of cues matching the target. If, however, certain cues match the features of multiple memory items, similarity-based interference leads to a higher retrieval latency, i.e., inhibitory interference effects. The latter is the case in (1a) as compared to (1b), because in (1a) both the target *surgeon* and the distractor *Jonathan* share the feature *+masculine*. In the antecedent-mismatch conditions (1c) vs. (1d), in contrast, the target *surgeon* and the cue-matching distractor *Jennifer* in (1c) do not share the feature *+feminine*, hence, no similarity-based interference arises. Consequently, no inhibition is predicted in (1c) vs. (1d). On the contrary, because both target and distractor only partially match the retrieval cues in (1c), they are equally likely to be retrieved. Compared to (1d), this predicts a higher proportion of incorrect retrievals and a lower average retrieval latency, which is usually referred to as *facilitatory interference* or *intrusion*.

In sum, a major prediction that distinguishes standard cue-based retrieval from models assuming a limitation of the retrieval cues to structural features is that the former entails interference effects from non-target items that match (some of) the cues used for retrieval.[2]

In order to tease apart structure-based from standard cue-based retrieval, interference effects from feature-matching but syntactically illicit antecedents in the processing of reflexive-antecedent dependencies have drawn considerable attention in recent years. Several studies used a feature-match/mismatch

[1] Note that the different models of content-addressable memory differ with respect to their assumptions about the exact nature of similarity-based retrieval interference. While the model proposed by Anderson et al. (2004) predicts similarity-based retrieval interference to be observed in retrieval probabilities as well as in retrieval latencies, the model proposed by McElree (2000) predicts that similarity-based retrieval interference only affects retrieval probabilities and not retrieval latencies. In this article, we will focus on cue-based retrieval in the sense of Anderson et al. (2004).

[2] It should be noted that cueing for a c-command feature is a simplification since it actually is a tree-configurational relation between items. There is no straightforward way to attribute a feature like that in an incremental parsing mechanism in content-addressable memory. In this paper, we do not provide a detailed account of how the attribution of a c-command feature could be implemented. As an example, Patil, Vasishth, and Lewis, "Retrieval interference in syntactic processing: The case of reflexive binding in English" (unpublished manuscript) in their ACT-R model for English reflexives approximated a c-command relation by cueing for a subject in the local clause. For a discussion of possible ways to encode tree-configurational information such as c-command in content-addressable memory see Alcocer and Phillips, "Using relational syntactic constraints in content-addressable memory architectures for sentence processing" (unpublished manuscript).

design, where a non-syntactic feature (e.g., gender or number) was manipulated at the antecedent and at a structurally inaccessible distractor (see Example 1 for typical sentence material). In **Table 1**, we provide an overview of the studies examining interference effects in reflexives (including reflexives inside a prepositional phrase and possessive reflexives) and reciprocals using a feature-match/mismatch design. Studies on the processing of reflexives in so-called picture noun phrases have not been included in our review since their binding properties differ from other reflexives (Büring, 2005; Reuland, 2011). Moreover, experiments investigating specific populations such as children or L2 learners are not considered in the review. **Table 1** summarizes whether or not inhibitory (i.e., a slowdown due to the presence of a cue-matching inaccessible distractor) or facilitatory (i.e., a speed-up due to the presence of a cue-matching inaccessible distractor) interference was observed in (i) conditions with an accessible antecedent that matched the feature under examination and (ii) conditions with an accessible antecedent that mismatched the feature under examination (i.e., sentences that are either ungrammatical or at least violating the stereotypical gender of the accessible antecedent). Some studies manipulated other factors in addition to the feature-match/mismatch manipulation. In these cases, we split the respective experiments into two entries in **Table 1**, with one entry for each level of the additional factor. In particular, for Felser et al. (2009), who manipulated feature type (gender vs. c-command) as additional within-participants factor and language proficiency (native speaker vs. L2 learner) as between-participants factor, one row in **Table 1** refers to the manipulation of the c-command feature in native speakers and another row refers to the gender manipulation in native speakers. The results of the non-native group are not included in the table because this review concerns adult native speaker populations. For Chen et al. (2012), who manipulated whether the Chinese reflexive *ziji* was locally or non-locally bound, one row in **Table 1** refers to the interference effect observed in conditions with a local antecedent and a second row refers to the conditions with a non-local antecedent. Similarly, in the case of King et al. (2012), who manipulated whether the reflexive directly followed the verb or a preposition intervened, one table entry refers to the former configuration (labeled as *adjacent*) and another entry refers to the latter configuration (labeled as *non-adjacent*). In the review of Clackson et al. (2011), who primarily investigated the processing of reflexives in children, we only report the results of the adult control group. For the reviewed experiments, we report effects observed at the region containing the reflexive (labeled as *crit*) and the following regions (labeled as *crit*+*x*). Although the size of the interest areas in terms of number of words contained in one region differs between studies, which reduces the comparability of the time course of the observed effects to a certain extent, we keep the sectioning of the interest areas as in the respective publication.

In accessible antecedent-match conditions, previous studies found inhibitory interference in six cases (Badecker and Straub, 2002, Experiments 1 and 2; Felser et al., 2009, c-command manipulation in native speakers; Chen et al., 2012, non-local reflexives; Clackson and Heyer, 2014; Patil, Vasishth, and Lewis, "Retrieval interference in syntactic processing: The case of reflexive binding in English," unpublished manuscript). Statistically significant facilitatory interference in antecedent-match conditions was found in two experiments (Sturt, 2003, Experiment 1; Cunnings and Felser, 2013, Experiment 2). However, Sturt found the effect only in re-reading time two words after the reflexive and this effect could not be replicated by Cunnings and Sturt (2014), who used similar stimuli. Cunnings and Felser found the effect for readers with low working memory span (*lWM*), but not for high-span readers. In the majority of the experiments, in contrast, no interference effect was observed in antecedent-match conditions (Nicol and Swinney, 1989; Clifton et al., 1999; Badecker and Straub, 2002, Experiments 5 and 6; Sturt, 2003, Experiment 2; Felser et al., 2009, gender manipulation in native speakers; Clackson et al., 2011, adult control group of Experiment 2; Chen et al., 2012, conditions with local reflexive binding; King et al., 2012, adjacent conditions; Cunnings and Felser, 2013, Experiment 1; Dillon et al., 2013; Kush and Phillips, 2014; Cunnings and Sturt, 2014, Experiment 1; Parker and Phillips, 2014).[3]

For conditions with a feature-mismatching accessible antecedent, two studies report significant effects of facilitatory interference (King et al., 2012; Parker and Phillips, 2014) and two studies report a marginal facilitatory effect (Cunnings and Felser, 2013, Experiment 1; Patil, Vasishth, and Lewis, "Retrieval interference in syntactic processing: The case of reflexive binding in English," unpublished manuscript)—however, the latter effect was only found in a *post-hoc* analysis of regression-contingent first-fixation durations, and thus might be spurious. Marginal effects of inhibitory interference have been reported for participants with low working memory span (Cunnings and Felser, 2013, Experiment 2), in the processing of reciprocals (Kush and Phillips, 2014), and in Experiment 1 of Cunnings and Sturt (2014). The latter only report a marginal main effect of the distractor, but their reported means suggest that the effect was driven by the antecedent-mismatch conditions. This does, however, not seem very reliable because they used similar stimuli as Sturt (2003), Experiment 1, who, in contrast, had not found an effect in antecedent-mismatch conditions but a facilitation in antecedent-match conditions. A general pattern is that interference effects in antecedent-match conditions are less frequently observed than effects in antecedent-mismatch conditions.

To summarize, the literature on reflexive interference contains a mixture of results, not favoring one particular of the retrieval models in question. Studies showing a general absence of interference support structure-based accounts (Nicol and Swinney, 1989; Sturt, 2003; Xiang et al., 2009; Phillips et al., 2011; Dillon, 2011; Dillon et al., 2013; Kush and Phillips, 2014). On the other hand, observations of significant interference effects have been interpreted as evidence against purely structure-based retrieval (Badecker and Straub, 2002; Chen et al., 2012; Clackson and Heyer, 2014; Parker and Phillips, 2014). Crucially, however, taking into account the direction of the effects, there are patterns that cannot be explained by either account without

[3] King et al. (2012) report different results in their CUNY 2012 abstract and their final conference poster. We refer here to the results presented on the poster.

TABLE 1 | Overview of interference effects at reflexives categorized for feature-match/mismatch of the accessible antecedent and direction of the effect (inhibitory vs. facilitatory interference).

Experiments are sorted by effect pattern (effect in antecedent-match first, effect in antecedent-mismatch second). Marginal effects are in parentheses. The experiments are classified by language (English EN, Mandarin Chinese CN, Hindi HI), experimental method (self-paced reading SPR, eye-tracking while reading ET, visual world eye-tracking VW, event-related potentials ERP, cross-modal priming Primg), retrieval cues that are examined (gender, number, animacy, c-command), dependency type (reflexive, prepositional reflexive, possessive reflexive, reciprocal), interference type (proactive vs. retroactive), and by syntactic position of the distractor (subject, object, genitive attribute, sentence external memory load, and discourse topicality in parenthesis). For reading studies, the interest area (AOI) labeled crit refers to the region containing the reflexive/reciprocal. For eye-tracking experiments, Measure indicates the dependent variable in which the effect was observed (first-fixation duration FFD, first-pass reading time FPRT, total-fixation time TFT, regression-path duration RPD, right-bounded reading time RBRT, re-reading time RRT, first-pass regression probability FPRP, first-fixation duration in regression-contingent trials reg.-cont. FFD). Effects in parentheses are only marginally significant. The entry "—" means that the respective conditions were not tested in the experiment while "n.s." means that no significant effect was observed. IWM *refers to participants with low working memory capacity.*

employing additional assumptions: The cue-based retrieval account as implemented by Lewis and Vasishth (2005) and employed by Dillon (2011), Dillon et al. (2013), Kush and Phillips (2014), Parker and Phillips (2014) and Patil, Vasishth, and Lewis, "Retrieval interference in syntactic processing: The case of reflexive binding in English" (unpublished manuscript) is unable to explain facilitatory interference in antecedent-match conditions or inhibitory interference in antecedent-mismatch conditions.

The present article (i) provides further experimental evidence relating to the current debate about the use of non-structural retrieval cues and (ii) proposes two extensions to the standard cue-based retrieval architecture in order to account for the seemingly contradictory patterns of experimental results observed across studies.

We first present two eye-tracking experiments examining interference effects in the processing of the Mandarin Chinese reflexive *ziji*. There is a wide range of competing syntactic or pragmatic approaches of how to analyze *ziji* (for formal accounts see Yang, 1983; Manzini and Wexler, 1987; Pica, 1987; Kang, 1988; Tang, 1989; Huang and Tang, 1989, 1991; Cole et al., 1990, 1993; Cole and Sung, 1994; Cole and Wang, 1996; for pragmatic and non-uniform accounts see Huang et al., 1984; Yu, 1992, 1996; Xue et al., 1994; Pan, 1997; Pollard and Xue, 1998; Huang and Liu, 2001; Liu, 2010). We will restrict the following summary of the syntactic behavior of *ziji* to its properties that are relevant for the present experimental design. In contrast to English reflexives, *ziji* does not have any gender or number marking, but requires its antecedent to be animate (Tang, 1989).[4] Thus, animacy might be used as a non-structural cue to retrieve *ziji*'s antecedent. Similar to reflexives of many other languages including English, *ziji* needs to be c-commanded by its antecedent.[5] Moreover, the antecedent is required to be a subject (Huang, 1984). In contrast to English, the antecedent does not have to be contained in the local clause of the reflexive, but can also be contained in a superordinate clause (non-local binding). The processing of locally vs. non-locally bound *ziji* has been investigated by Gao et al. (2005), Liu (2009), Li and Zhou (2010), Dillon (2011), Chen et al. (2012), and Dillon et al. (2014).

The present experiments examine whether animate nouns that are in a structurally inaccessible position (i.e., not c-commanding the reflexive) induce interference effects on the processing of *ziji*. So far, the literature on interference effects in reflexives has focused on morphologically marked phi-features (gender, number). Thus, the examination of animacy in the processing of Mandarin *ziji* does not only add cross-linguistic evidence to the debate that, so far, has been centered on English, but also extends the range of investigated retrieval cues to a purely semantic feature.

Both experiments have relatively large sample sizes in order to increase statistical power. Given that the prediction of the structure-based account is that no effect should be seen (i.e., a null result), it is particularly important to conduct high power studies.

2. Experiment 1

In Experiment 1, we tested whether locally bound *ziji* is subject to interference from a structurally inaccessible distractor that fulfills the animacy requirement of *ziji*. In a 2 × 2 design we manipulated animacy of the structurally accessible antecedent (henceforth labeled as *antecedent-match* vs. *antecedent-mismatch*) and of a structurally inaccessible distractor noun that intervened between the accessible antecedent and the reflexive (henceforth labeled as *distractor-match* vs. *distractor-mismatch*). This design extends the study reported by Chen et al. (2012), who were the first to test interference effects in Mandarin *ziji*, in several respects. In contrast to Chen and colleagues, in the present experiment, *ziji* was in object position rather than being a possessive modifier and we included antecedent-mismatch conditions which Chen et al. did not test. Moreover, we used the more time-sensitive eye-tracking method rather than self-paced reading.

The ACT-R model as implemented by Lewis and Vasishth (2005) predicts an inhibitory interference effect in antecedent-match conditions and a facilitatory interference effect in antecedent-mismatch conditions at the reflexive. The structure-based account (Nicol and Swinney, 1989; Sturt, 2003; Phillips et al., 2011; Dillon, 2011; Dillon et al., 2013; Kush and Phillips, 2014), in contrast, predicts the absence of an interference effect in both antecedent-match and antecedent-mismatch conditions. Moreover, the Lewis and Vasishth ACT-R model predicts incorrect retrievals of the animate distractor (misretrievals) in both antecedent-match and antecedent-mismatch conditions, but the proportion of misretrievals is predicted to be higher in antecedent-mismatch conditions. The structure-based account predicts no misretrievals of the animate inaccessible distractor.

2.1. Materials and Method

2.1.1. Materials

We tested 48 experimental sentences which contained an either animate (antecedent-match) or inanimate (antecedent-mismatch) accessible antecedent in subject position (*yundongyuan* "athlete" vs. *pihuating* "kayak" in 2) and the reflexive as direct object. Due to the animacy requirement of *ziji*, the conditions with an inanimate accessible antecedent were ungrammatical. Between the main clause subject and the main clause verb, an adverbial clause intervened that contained an either animate (distractor-match) or inanimate (distractor-mismatch) inaccessible distractor (*lingdui* "team leader" vs. *meiti* "media" in 2). This distractor was also a subject, but did not c-command the reflexive and was therefore not a legal antecedent. The reflexive was followed by a frequency phrase or a durational phrase consisting of four characters, which was analyzed as a spillover region.

[4]There are some exceptions under which the animacy constraint can be violated, see (Tang, 1989; Pan, 1995) for a discussion. Crucially for our experimental design, in the syntactic literature, there is no example of non-emphatic, mono-morphemic *ziji* in argument position bound by a clearly inanimate NP.

[5]The c-command constraint might be violated in case of animate sub-commanding antecedents (Tang, 1989; Xue et al., 1994; Pollard and Xue, 1998), psychological verbs (Huang and Tang, 1991), passives and *ba*-constructions (Yu, 1992, but cf. Cole and Wang 1996), and in case of cataphoric binding by the subject of a matrix clause that is preceded by an adjunct clause containing *ziji* (Huang and Liu, 2001). Moreover, *ziji* can refer to the speaker of the utterance (Li, 1991), the addressee, or even a third person salient in the discourse (Pan, 2000).

(2) **Animate/Inanimate antecedent; Animate/Inanimate distractor**

运动员$_i$/*皮划艇$_i$			在	领队$_j$/媒体$_j$	施加	巨大	压力	的	情况	下

When the team leader/media excerted great pressure, the athlete/kayak outperformed himself/itself three times in total…

The experimental items were complemented with 72 filler sentences (48 grammatical, 24 ungrammatical) with varying syntactic structures including sentences containing the bare reflexive *ziji* as well as the bi-morphemic reflexive *ta-ziji* and pronouns in different syntactic positions.

Each sentence was followed by a multiple choice comprehension question that probed for the correct retrieval of the antecedent. Participants could choose between the antecedent, the distractor, an unrelated noun taken from a previous trial and the option "I am not sure." This design allowed us to examine not only whether the antecedent was retrieved correctly, but also to assess the proportion of misretrievals of the distractor. To ensure that participants also fully parsed the intervening adverbial clause containing the distractor, a second multiple-choice question targeted the adverbial clause. The same options were provided as in the first question. The questions following the filler sentences targeted various syntactic positions in the sentence.

Pretest. Since the exact binding properties of *ziji* are still subject to discussion in the syntactic literature, we conducted a paper-based questionnaire study to test our assumption that the main clause subject in the experimental items binds the reflexive. Forty native speakers of Mandarin recruited at Beijing Normal University participated in this study against payment of 25 RMB (approximately 3 EUR). None of them would participate in either of the eye-tracking experiments. Participants were presented with the antecedent-match conditions of the experimental items together with 90 filler sentences containing *ziji* in various syntactic positions and were instructed to circle the word in the given sentence *ziji* referred to or to explicitly write down the referent in case of an unbound interpretation of *ziji*.

Results. In 97.2% of all trials, participants selected the main clause subject as antecedent for the reflexive (97.0% and 97.3% when the distractor was animate or inanimate, respectively). This shows that in the experimental materials, Mandarin speakers indeed choose the main clause subject as antecedent for the reflexive.

2.1.2. Participants and Procedure

The experiment was conducted in the eye-tracking lab of the State Key Laboratory of Cognitive Neuroscience and Learning at Beijing Normal University. One hundred fifty students from different universities located in Beijing participated in the experiment against payment of 40 RMB (approximately 5 EUR). All participants were native speakers of Mandarin and had normal or corrected to normal vision.

Eye movements (right eye monocular) were recorded using an SR Research Eyelink 1000 eyetracker at a sampling rate of 1000 Hz. Participants' head was stabilized using a forehead- and chin-rest. The screen-to-eye-distance was 82 cm, the camera-to-eye-distance 75 cm. Stimuli were presented in Simplified Chinese characters (font type SimSun, black font, font size 25) on a 22 inch monitor with light gray background using SR Research Experiment Builder software. Re-calibrations were performed between trials if necessary. Each experimental session began with 6 practice trials in which feedback to the comprehension questions was provided. In the experimental trials, no feedback was given. Short breaks were given according to the participants' individual needs. The sentences were presented according to a standard Latin Square. Items were pseudo-randomized such that at least one filler sentence intervened between two experimental sentences. Each sentence was followed by two multiple choice comprehension questions as described above.

2.2. Results

All statistical analyses were carried out in R using linear mixed effects models provided by the lme4 package version 1.0-6 (Bates et al., 2014). Binary dependent variables were analyzed using a logistic link function. For both, the analysis of response accuracies and eye movements, two sets of contrasts were applied. We first ran a model testing for a main effect of antecedent (animate antecedents coded as $+0.5$; inanimate antecedents coded as -0.5), a main effect of interference (animate distractors coded as $+0.5$; inanimate distractors coded as -0.5) and the interaction between the two main effects. Second, we applied nested contrasts testing for an interference effect within antecedent-match and antecedent-mismatch conditions separately. All models were fit with a full variance-covariance matrix for participants and items (Gelman and Hill, 2007); in case the model failed to converge or the variance-covariance matrix was degenerate, random slopes for items or participants were removed.

2.2.1. Comprehension Questions

Comprehension questions targeting the reflexive-antecedent dependency were analyzed. We analyzed response accuracies and the proportion of incorrect selection of the inaccessible distractor. An overview of participants' answers is provided in **Table 2**. In the statistical analysis of response accuracies, only the main effect of antecedent reached marginal significance (estimate $= 0.34$, $SE = 0.18$, $z = 1.84$, $p = 0.07$). The antecedent (i.e., the correct option) was chosen more often in antecedent-match conditions. This effect was expected since

TABLE 2 | Experiment 1: Chosen answer to the comprehension question by condition in percentages.

Antecedent	*Distractor*	Chosen answer			
		Antecedent	Distractor	Unrelated	"Not sure"
match	*match*	82.3	5.1	0.9	11.7
	mismatch	81.6	3.6	2.4	12.4
mismatch	*match*	75.9	4.8	1.1	18.2
	mismatch	75.7	4.9	0.8	18.5

in the antecedent-mismatch conditions, no fully grammatically correct answer to the comprehension question was available (the antecedent was coded as "correct" answer, but the option "not sure" was provided as one response option in order to account for the ungrammaticality of the sentence). The analysis of the proportions of incorrect selection of the distractor revealed a main effect of antecedent: participants chose the distractor more often in antecedent-mismatch conditions than in antecedent-match conditions (estimate $= -0.45$, $SE = 0.18$, $z = -2.48$, $p < 0.05$). However, the size of this main effect was very small. We will therefore not base any conclusions on this effect. Moreover, the interaction between antecedent and distractor was significant (estimate $= 0.56$, $SE = 0.15$, $z = 3.61$, $p < 0.001$). Pairwise comparisons revealed that, within antecedent-match conditions, the distractor was chosen more often erroneously as answer to the comprehension question in case the distractor was animate (estimate $= 0.83$, $SE = 0.31$, $z = 2.70$, $p < 0.01$). But, as can be seen from **Table 2**, the animate distractor did not cause a decrease in selection probability of the antecedent but rather attracted selections from the unrelated noun. In antecedent-mismatch conditions, no interference effect was observed.

2.2.2. Eye Movements

Eye movements were analyzed at the reflexive, the pre-critical region (verb) and the spillover material consisting of the frequency/durational phrase (post-critical). In order to provide a comprehensive picture of our data, and to make our results comparable to other studies we report the whole range of eye-tracking measures common in psycholinguistic research, although some of these measures are correlated by definition. As first-pass measures, we report first-fixation duration (FFD), i.e., the duration of the first fixation in first-pass reading, and first-pass reading time (FPRT, also called gaze duration), i.e., the sum of all first-pass fixations on a word before leaving it. As regression-related measures, we report regression-path duration (RPD, also called go-past time), i.e., the sum of all fixation durations starting from the first first-pass fixation on a word including regressive fixations to previous material until a region to the right of this word is fixated, right-bounded reading time (RBRT), i.e., the sum of all fixations on a word before another region to the right of this region is fixated, and first-pass regression probability (FPRP), i.e., the proportion first-pass regressions initiated from a word. As a later-pass measure, we analyzed re-reading time (RRT), i.e., the sum of all fixations on a word that are not contained in FPRT. In addition, we analyzed total-fixation time (TFT), which is defined as the sum of FPRT and RRT. In order to achieve close to normally distributed model residuals, we log-transformed reading times (Box and Cox, 1964) and excluded all trials in which the respective continuous dependent variable was zero. First-fixation probability of the pre-critical region, the reflexive and the spillover region was 90, 62, and 87%, respectively. Re-readings occurred in 60, 33, and 45% of the trials at pre-critical region, the reflexive and the spillover region, respectively. In all models, centered log-frequencies of the antecedent and the distractor taken from the SUBLETEX-CH database (Cai and Brysbaert, 2010) were included as covariates because items had not been matched for frequencies of the antecedents and distractors. Mean raw reading times with standard errors for the pre-critical, critical and post-critical regions are provided in **Table 3**. The results of the statistical analyses of participants' eye movements are summarized in **Tables 4**, **5**.

The main effect of antecedent (longer reading times or a higher proportion of regressions in antecedent-mismatch conditions) was significant across regression-related measures (RPD, RBRT, FPRP) and late measures (TFT, RRT). In RPD and RBRT, the effect of antecedent started already at the pre-critical region and remained significant at the reflexive and the post-critical region. In FPRP, the effect was significant at the reflexive only. In TFT, the effect also started at the pre-critical region and continued to be significant at the reflexive. In RRT, the effect reached significance only at the pre-critical region.

The main effect of interference (longer reading times or higher proportion of regressions in distractor-match conditions) reached significance across first-pass, regression-related and late measures. In RPD and FPRP, the effect reached significance at the reflexive itself, in FPRT and RBRT at the post-critical region and in TFT at the pre-critical region.

The interaction between antecedent and interference reached significance at the reflexive across first-pass and regression-related measures (FFD, FPRT, RBRT). In RBRT, this interaction was already present at the pre-critical region. Pairwise comparisons revealed that the interference effect was driven by the antecedent-mismatch conditions: Within antecedent-mismatch conditions, an inhibitory interference effect was observed across first-pass, regression-related and late measures (FFD, FPRT, RBRT, RPD, TFT).[6] In FFD, FPRT, RBRT,

[6]In RPD, the effect predicted by the linear-mixed model is also an *inhibitory* one, although the opposite pattern is present in the raw means (cf. **Table 3**). This discrepancy is driven by a few very long (i.e., > 6000 ms) regression-path durations in the antecedent-mismatch/distractor-mismatch condition of one particular item. Because of the concave nature of the log-function, the log-transformation of the data reduces the impact of these extremely high values. As all of these extreme values stem from the same experimental condition, the difference in means of the log-transformed RPDs even switches the sign in antecedent-mismatch conditions (log-transformed means in antecedent-mismatch conditions: distractor-match = 5.85 log-ms; distractor-mismatch = 5.80 log-ms). This explains why the linear-mixed model estimates an inhibitory rather than a facilitatory interference effect. Removing the item which caused the extreme values yields similar results as log-transforming the data, i.e., the sign of the interference effect also switches from negative to positive (raw means in antecedent-mismatch conditions with the item causing extremely long RPDs being removed: distractor-match = 476 ms; distractor-mismatch = 469 ms).

Statistically significant ($\alpha = 0.05$) effects are marked with an asterisk and highlighted in bold.

Moreover, the models revealed that the higher frequency of the antecedent led to a significant slowdown at the reflexive in regression-based measures (RPD: estimate = 0.03, $SE = 0.01$, $t = 2.12$; RBRT: estimate = 0.02, $SE = 0.01$, $t = 2.00$) and RRT (estimate = 0.05, $SE = 0.02$, $t = 2.76$). Frequency of the distractor, in contrast, did not affect reading times at the reflexive in any measure.

One potential issue with the data analysis reported here is the so-called multiple-testing problem, that is, testing more than one dependent variable but keeping the significance threshold α unchanged at 0.05. Although in the field of psycholinguistics it is uncommon to apply an α-level correction when multiple eye-tracking measures are analyzed, we applied a Bonferroni correction to the α-level (Bonferroni, 1936; Dunn, 1959, 1961) and checked whether the effects reported above remained significant under this more conservative analysis. This is important in order to reduce the Type I error probability because, as has been noted for example by Ioannidis (2005), false positives are a serious issue in empirical science and in psychological science in particular (Simmons et al., 2011). With respect to reading studies, von der Malsburg and Angele, "The elephant in the room: False positive rates in standard analyses of eye movements in reading" (unpublished manuscript) recently showed by means of Monte Carlo simulations that testing multiple eye-tracking measures leads to a more dramatic increase of Type I errors as compared to what had been generally believed in the field. Von der Malsburg and Angele therefore recommend to apply a Bonferroni correction to the α-level. Given that we have analyzed seven dependent variables, the Bonferroni correction yields a corrected α-level of 0.007, which corresponds to an approximate t-value of $\pm$ 2.69.[7] With this adjusted α-level, the main effect of antecedent remained significant in RBRT at the pre-critical region and in RPD at the reflexive and at the post-critical region. The main effect of interference reached significance in FPRT at the post-critical region and in TFT at the pre-critical region. The interaction between antecedent and interference was significant in FPRT at the reflexive. In pairwise comparisons, the interference effect in antecedent-mismatch conditions in FPRT at the reflexive and at the post-critical region remained significant. The antecedent-frequency effect reached the Bonferroni-corrected significance threshold in RRT, but not in RPD and RBRT. In sum, although the Bonferroni correction and the considerable loss in statistical power that goes along with it makes some effects lose statistical significance, the overall pattern of results remains unchanged: An early interference effect at the reflexive present only within antecedent-mismatch conditions, an effect of antecedent in regression-related dependent variables starting already at the verb preceding the reflexive and an effect of antecedent-frequency at the reflexive.

2.3. Discussion

Comprehension questions required participants to correctly identify the reflexive's antecedent and to select it from four response options. Although participants could choose the option "not sure," they were highly likely to choose the antecedent even

[7] This t-value was approximated by using a normal distribution.

if it was inanimate and hence a semantically illicit antecedent. This shows that in their final interpretation of the reflexive they gave structural information a higher priority than semantic information. In antecedent-match conditions only, the distractor was chosen more often in case it was animate. But, crucially, this higher proportion of distractor choices was at the cost of choices of the unrelated noun, not of the antecedent. From this pattern we conclude that the observed effect reflects *offline* interference, i.e., an effect driven by meta-linguistic considerations at the moment of answering the comprehension question. If, in contrast, the effect reflected retrieval interference during the actual sentence reading, i.e., online effects, it would be expected to manifest itself in a higher proportion of misretrievals of the distractor leading to a lower proportion of choosing the *antecedent*, not the unrelated noun, because the latter is only introduced in the question.

The analyses of eye movements firstly showed that the presence of an animate distractor led to a processing slowdown (i.e., inhibitory interference) in antecedent-mismatch conditions. This slowdown was observed across first-pass, regression-related and late measures. In the more conservative analysis with Bonferroni-corrected significance threshold, this slowdown remained reliable in FPRT. In antecedent-match conditions, this interference effect did not reach significance. This pattern cannot be explained by either of the two accounts under discussion: The parser's sensitivity to the presence of an animate distractor cannot be accounted for by a structure-based retrieval mechanism. ACT-R cannot explain the results either since, in its current implementation, ACT-R predicts facilitatory rather than inhibitory interference in antecedent-mismatch conditions caused by a higher proportion of misretrievals of an animate distractor. Kush and Phillips (2014) also found inhibitory interference in antecedent-mismatch conditions in a self-paced reading experiment on Hindi reciprocals. They explain this effect in terms of interference that occurs during a later repair process of the ungrammatical sentence rather than at the moment of retrieval. Crucially, in Kush and Phillips (2014)'s experiment, the interference effect reached marginal significance only two words after the reciprocal. For the present experiment, their explanation seems implausible since the interfere effect reaches significance already in first-pass measures at the reflexive.

Second, we did *not* find any interference effects in the antecedent-match conditions. Although these results are statistically inconclusive, it is worth mentioning that this is consistent with the findings of Chen et al. (2012), who found interference effects in non-locally bound *ziji* but failed to find effects in locally-bound *ziji*.

Third, we observed a slowdown due to an inanimate antecedent in regression-related and late measures. This grammaticality effect is in line with both structure-based retrieval and the ACT-R model. In contrast to the interference effect, this effect is most pronounced at the pre-critical region. We will discuss possible explanations for this early appearance of the effect in the Discussion of Experiment 2.

Fourth, we found that lower frequency of the antecedent led to faster reading times at the reflexive. This effect might be explained by a low-frequency encoding advantage. It has been shown that the lower frequency of a word leads to a better memory encoding which results in a faster retrieval at a later point in time (Diana and Reder, 2006). Thus, low frequency antecedents might be better encoded in memory leading to a facilitated retrieval when reaching the reflexive, which shows the more prominent role of the antecedent in the retrieval process. Indeed, this facilitation due to infrequent antecedents replicates findings from English pronouns. In an eye-tracking-while-reading experiment, Van Gompel and Majid (2004) found faster FFD and FPRT at the region following the reflexive as a function of lower frequency of the antecedent.

One potential concern with the present results might be that task-related influences on interference cannot be ruled out. One of the two comprehension questions following the experimental sentences targeted the reflexive-antecedent dependency, which—in particular in the ungrammatical conditions—might have caused readers to spend some additional reading time to rule out the animate distractor. This would explain the observed inhibitory interference in the target-mismatch conditions. In the design of the experiment, we had addressed this potential issue by including ungrammatical fillers containing *ziji* with questions that did not target the reflexive-antecedent dependency. Moreover, participants had the option to answer "not sure," which allowed them not to assign any meaning to an ungrammatical sentence. If task-specifics had been an influential factor, they would most probably be reflected in repair attempts that are triggered by unexpectedly retrieving an inanimate antecedent. However, the interference effect reached significance already in FFD and FPRT. Based on a large-scale review of eye movements in reading, Clifton et al. (2007) have suggested that early measures like FFD or FPRT are unlikely to reflect repair processes since across studies, repair or reanalysis effects are typically observed in regression-related or later-pass reading measures. To the extent that Clifton et al. (2007)'s claim is correct, we can conclude that repair processes caused by the task-demands are unlikely to explain the observed results.

3. Experiment 2

This experiment extended Experiment 1 in several aspects. First, it examined proactive rather than retroactive interference; second it examined the influence of distractor items that are not a syntactic part of the sentence itself but presented as memory load; third, we tested the influence of syntactic locality on the retrieval and its interaction with interference. Previous studies report a processing slowdown in case *ziji* is non-locally bound compared to locally bound *ziji* (Gao et al., 2005; Li and Zhou, 2010; Dillon, 2011; Chen et al., 2012; Dillon et al., 2014). In the present experiment, we aimed at replicating this locality effect and investigating whether interference effects are modulated by locality of the reflexive binding.

In a dual-task paradigm, similar to Van Dyke and McElree (2006), participants were asked to remember three animate or three inanimate distractor nouns while reading a sentence

containing an either locally or non-locally bound reflexive. This resulted in a 2 × 2 design, with locality (local vs. non-local) and the distractors' animacy (animate vs. inanimate) as factors. Conditions with animate distractors are labeled as *distractors-match* and conditions with inanimate distractors as *distractors-mismatch*.

The structure-based account predicts no effect of animacy of the distractor nouns held in memory. In contrast, the standard ACT-R cue-based retrieval model predicts an inhibitory interference effect due to animacy of the distractors: retrieval times at the reflexive are predicted to be longer in distractors-match conditions. Moreover, ACT-R predicts a main effect of locality with non-local conditions being read slower. This prediction does not follow from the cue-based nature of the retrieval mechanism but rather from the ACT-R assumption of decay: The more recent, i.e., the local, antecedent has a higher level of activation than the non-local antecedent when reaching the reflexive. This difference in activation is predicted to be reflected in both, retrieval times and comprehension accuracies. Since this predicted locality effect is unrelated to the set of cues used for retrieval, the structure-based cue-based retrieval account (i.e., the ACT-R model with only structural features used as retrieval cues) makes the same prediction. Moreover, a structure-based serial search mechanism that first checks the local subject position and subsequently the non-local subject as proposed by Dillon (2011) and Dillon et al. (2014) for the processing of Mandarin *ziji* also predicts a processing slowdown in non-local conditions.

3.1. Materials and Method

3.1.1. Materials

We tested 36 experimental sentences[8] which consisted of a super-ordinate clause and an embedded clause containing the reflexive *ziji* as direct object. The locality factor of the antecedent-reflexive dependency was achieved by manipulating animacy of the local subject (i.e., the subject of the embedded clause) and the non-local subject (i.e., the subject of the superordinate clause): in the local conditions, the local subject was animate and the non-local subject was inanimate (see 3a) while in the non-local conditions, the local subject was inanimate and the non-local subject was animate (see 3b). Since *ziji* requires its antecedent to be animate, this design ensured that in the local conditions, *ziji* was bound by the local subject whereas in the non-local conditions it was bound by the subject of the superordinate clause. Similar to Experiment 1, the reflexive was followed by a spillover region consisting of four characters that formed a frequency phrase or a durational phrase. Each sentence was followed by a yes/no-comprehension question that probed for the correct binding of the reflexive. Seventy-two filler sentences containing reflexives and pronouns in varying syntactic positions were presented with memory load words of varying part-of-speech.

Pretest. In order to verify that speakers of Mandarin indeed bind the reflexive to the local subject/the superordinate subject in the local/non-local condition, respectively, we presented 40 native speakers of Mandarin recruited at Beijing Normal University with the experimental sentences in form of a paper-based questionnaire against payment of 25 RMB (approximately 3 EUR). Ninety filler sentences containing *ziji* in various syntactic positions were included. Participants were instructed to circle the word in the sentence *ziji* referred to, or, in case they found that no antecedent was available in the sentence, to write down which entity *ziji* referred to.

Results. Overall, 90.4% of all trials were answered as we had expected: In the local conditions, the animate local subject was chosen as antecedent and in the non-local conditions the animate matrix subject was selected. In the local conditions, accuracy was lower (85.1%) than in the non-local conditions (95.6%). A syntactic classification of the incorrect answers is provided in the Appendix.

3.1.2. Participants and Procedure

This experiment was conducted in the same laboratory as Experiment 1. One hundred thirty native speakers of Mandarin with normal or corrected-to-normal vision participated in the experiment against payment of 60 RMB (approximately 7 EUR). The general experimental set-up was the same as in Experiment 1. The experiment was split into two experimental sessions (40–70

[8]Originally, we had 48 items, but 12 of these were excluded based on low acceptability judgments of native speakers.

minutes per session) conducted on two subsequent days. At the beginning of each trial, the three distractors were shown on the screen one below another for 3 seconds. When the words disappeared, the test sentence was displayed. After having finished reading the sentence, the comprehension question was presented. After having answered the comprehension question, participants were asked to serially recall the distractors: The three distractors together with three unrelated items (similarly animate or inanimate nouns) were displayed simultaneously on the screen as a numbered list in randomized order. Participants were asked to choose the distractors in their correct order from this list.

3.2. Results

For all dependent variables, we fit two sets of contrasts; the first tested for main effects of locality (local conditions coded as -0.5; non-local conditions coded as $+0.5$) and interference (animate distractors coded as $+0.5$; inanimate distractors coded as -0.5) and their interaction; in the second model pairwise comparisons of memory load nested within each level of locality were applied. In addition, experimental session (first vs. second session) was coded with sum-contrasts and its interaction with the other effects were included as predictors. All models were fit with random intercepts for items and participants, no random slopes were fit since they led to convergence failure in most of the models.

3.2.1. Comprehension Questions

Mean accuracy scores by experimental condition are shown in **Table 6**. None of the comparisons reached statistical significance.[9]

3.2.2. Memory Recall

Mean serial and non-serial recall accuracies for each of the three distractors and total serial and non-serial recall accuracy (i.e., all distractors recalled correctly) are presented in **Table 7**. In the statistical analyses of total serial recall accuracy none of the comparisons reached significance. In the analyses of total non-serial accuracies, the interaction between animacy of the distractors and locality was significant (estimate = -0.22, $SE = 0.10$, $z = -2.21$, $p < 0.05$). Pairwise comparisons revealed that this interaction was driven by a significant effect of distractors (lower recall accuracy of animate distractors) that was present only in local conditions (estimate $= -0.30$, $SE = 0.14$, $z = -2.25$, $p < 0.05$).

3.2.3. Eye Movements

The same log-transformed dependent variables as in Experiment 1 were analyzed at the reflexive, the verb preceding it (pre-critical), and the spillover material (post-critical). As in the analysis of Experiment 1, trials were excluded when the continuous variable on which the analysis was carried out was zero. First-pass fixations occurred at the pre-critical region, the reflexive, and the spillover region in 86, 50, and 85% of the trials, respectively. Re-readings were recorded in 55, 25, and 36% of the trials at pre-critical region, the reflexive, and the spillover region, respectively. Mean reading times with standard errors for each dependent variable are provided in **Table 8**.

The output of the linear-mixed models is summarized in **Tables 9** and **10**. The effect of experimental session was significant across regions and measures: Participants read faster in their second experimental session.[10] The main effect of locality reached significance across regression-based and later-pass measures (RBRT, RPD, FPRP, RRT, TFT) at the pre-critical region only. The main effect of interference was significant only in RRT at the post-critical region (longer RRTs when distractors were animate, i.e., inhibitory interference). The interaction between locality and interference was significant across first-pass, regression-based, and later-pass measures (FFD, FPRT, RBRT, RPD, TFT) at the reflexive. The pairwise comparisons revealed that the interaction was driven by a slowdown for animate distractors at the reflexive that was present only in local conditions. This inhibitory interference reached significance across first-pass, regression-based, and later-pass measures (FPRT, RBRT, RPD, TFT). For non-local conditions, a similar slowdown was observed only in RRT at the post-critical region.

As we did for Experiment 1, we checked which of the observed effects remained significant with a Bonferroni-corrected significance threshold. Given seven dependent variables, the corrected α-level is 0.007, which corresponds to an approximate t-value of $\pm$ 2.69.[11] The significance of the main effect of locality was not affected by this correction in any dependent variable, it remained significant at the pre-critical region in RBRT, RPD, FPRP, TFT, and RRT. The main effect

[9]In response accuracies the proportion of correctly answered yes-questions was strikingly higher than the proportion of correctly answered no-questions. We can exclude the possibility that this pattern can be explained by a general tendency of the participants to answer "yes" since no such difference was observed in filler sentences. We also excluded the hypothesis that this pattern might be related to the difficult nature of the dual-task paradigm by running a follow-up eye-tracking experiment ($N = 14$) with the same experimental set-up but without memory load that yielded a similar response pattern. As the pre-test on the materials had shown that native speakers indeed do the correct binding of the reflexive, we hypothesized that the response pattern was intrinsically related to the nature of the comprehension questions rather than to the experimental sentences themselves. We therefore ran another experiment ($N = 52$) in which the experimental and filler sentences appeared on the computer screen together with the respective comprehension question. Again, we observed a similar response pattern as in the online experiments. We thus conclude that the observed tendency to answer "yes" on the experimental comprehension questions reflects an offline effect, i.e., an effect which occurs at the moment when participants meta-linguistically think about how to answer the question, rather than an effect of online reflexive binding.

[10]The effect of experimental session is not of theoretical interest to our research question, therefore it is not presented in the results tables and will not be discussed further.

[11]This t-value was approximated by using a normal distribution.

of interference at the post-critical region in RRT did not reach the adjusted significance threshold. The interaction between locality and interference remained significant at the reflexive in RBRT and TFT, but did not reach significance anymore in FFD, FPRT, and RPD. In pairwise comparisons, the interference effect in local conditions at the reflexive remained significant in RBRT and TFT, but did not reach the significance threshold anymore in FPRT and RPD. The interference effect in non-local conditions that was observed at the post-critical region did not reach the adjusted significance threshold. In sum, the main effect of locality as well as the interference effect in locally bound *ziji* remained significant in various dependent variables even with an adjusted α-level. The interference effect in non-local conditions, in contrast, was not reliable under the corrected α-level.

3.3. Discussion

In the comprehension questions, no evidence for an interference effect was found. In the memory recall task, in contrast, we found that, in local conditions only, animate words were more difficult to recall than inanimate words.

First, we found evidence for a processing slowdown associated with the non-local binding of the reflexive. This locality effect replicates findings from SAT (Dillon, 2011; Dillon et al., 2014), ERP (Li and Zhou, 2010; Dillon, 2011), cross-modal priming (Liu, 2009), and self-paced reading (Chen et al., 2012), and is accounted for by the ACT-R model, no matter whether the set of retrieval cues is unconstrained or limited to structural cues. The structure-based serial search as proposed by Dillon (2011) and Dillon et al. (2014) is also in line with the observed locality effect. However, it is not fully clear why this locality effect appears at the verb preceding the reflexive rather than at the reflexive itself. One explanation would be a preview effect. Alternatively, it might be the case that the observed effect does not reflect locality of the reflexive binding but rather the verb's preference for an animate subject since the locality manipulation is achieved by having the local subject either animate or inanimate. Along the same lines, one could explain why in Experiment 1, the effect of animacy of the antecedent becomes significant already at the verb preceding the reflexive. A strong indication that the observed effect at the verb indeed reflects the verb's preference for an animate subject comes from a re-analysis of the self-paced reading data reported by Chen et al. (2012), where the locality manipulation was also achieved by varying the animacy of the local and non-local subjects, and the main clause verb also directly preceded the reflexive *ziji*. Chen et al. (2012) analyzed only the region containing the reflexive and the regions *following* the reflexive, but not the verb *preceding* the reflexive. Re-analyzing their data at the verb region revealed that the locality effect in their

data was already significant at the verb ($t = 2.5$). As preview effects are ruled out as an explanation in self-paced reading, and given the high structural similarity of our experimental materials to the ones used by Chen et al. (2012), we conclude that the effect observed at the verb in Experiment 2 is most likely due to an animacy preference of the verb. Given this—admittedly unforeseen—confounding animacy preference of the verb, we cannot draw any conclusions about the actual locality manipulation. A potential locality effect might have been masked by the stronger effect of animacy preference: when reaching the verb in the non-local conditions, readers are highly likely to re-read the previous material to overcome the difficulty associated with the verb's inanimate subject, as indicated by the highly significant effects in FPRP, RPD, and RBRT. This leads to activation of the preceding materials in the non-local conditions *directly before* reaching the reflexive, which, in turn, might have canceled out a locality effect at the reflexive. Therefore, we conclude that our data is inconclusive with respect to the locality manipulation.

Second, we found clear evidence for inhibitory interference, but the time-course of this effect was different for local and non-local conditions. In local conditions, animate distractors led to a slowdown across first-pass, regression-based, and late eye-tracking measures at the reflexive itself. Even with a Bonferroni corrected significance threshold of $\alpha = 0.007$, this effect remained significant in RBRT and TFT. In FPRT and RPD, the inhibitory interference effect did not survive Bonferroni correction. However, since these measures numerically pattern with other measures—especially with RBRT, which is closely related—it could reflect a real effect. In non-local conditions, the interference effect appeared only later in processing (in RRT at the post-critical region). However, with Bonferroni adjusted significance threshold, this effect was not reliable. In sum, the observed interference pattern extends the findings of Experiment 1 in two respects. First, Experiment 2 shows that locally bound *ziji* is subject to early interference even in case a fully cue-matching antecedent is available. The difference to Experiment 1, where the interference effect did not reach significance in antecedent-match conditions, might be explained by the different experimental paradigms: rehearsal of the distractors during reading might cause stronger interference than the sentence-internal manipulation of Experiment 1.

TABLE 10 | Experiment 2: Interference effect nested within each level of locality (local vs. non-local) at the pre-critical (*ziji*−1), critical (*ziji*), and post-critical (*ziji*+1) regions for the dependent variables (DVs) first-fixation duration, first-pass reading time, right-bounded reading time, regression-path duration, first-pass regression probability, total fixation time, and re-reading time.

Statistically significant ($\alpha = 0.05$) effects are marked with an asterisk and highlighted in bold.

Second, the interference profile in non-locally bound *ziji* differs from the one in locally bound *ziji* in the sense that in non-local conditions no early effect was found, but there is weak evidence for a late effect. Although the late effect in non-local conditions was not significant under Bonferroni correction, there is reason to believe in this effect when viewed against the background of previous findings by Chen et al. (2012), who found an inhibitory interference effect in non-local *ziji*.

The observed interference effects are not compatible with a structure-based retrieval mechanism since no effect of the distractors is predicted. The ACT-R model, in contrast, can account for the inhibitory interference effect. However, ACT-R is unable to explain the delayed appearance of the effect in non-local conditions.

A possible explanation for the different interference patterns in local vs. non-local conditions could be that qualitatively different mechanisms are involved in the processing of locally and non-locally bound *ziji*. In the syntactic literature, it has been proposed that only the locally bound *ziji* should be regarded as a reflexive pronoun whereas non-locally bound *ziji* should be regarded as a logophoric pronoun which is subject to pragmatic and discourse constraints rather than to purely syntactic binding principles (Huang and Liu, 2001; Huang, 2002). One prominent argument favoring this idea of two lexically different instances of *ziji* are blocking effects observed in long-distance *ziji* but not in local *ziji* (Huang, 1984, 2002; Tang, 1989; Huang and Tang, 1991; Xue et al., 1994; Pan, 2000). A qualitative distinction between locally bound *ziji* and non-local *ziji* has also been proposed in the psycholinguistic literature. Based on previous work by Gao et al. (2005), Liu (2009) conducted a cross-modal priming experiment using sentences in which both a local and a non-local animate antecedent were present (i.e., globally ambiguous sentences in terms of binding) and manipulated stimulus-onset asynchrony (0 ms, 160 ms, 370 ms). When the probe was presented directly after the offset of the reflexive (SOA = 0 ms), a semantic priming effect for probes related to the local antecedent but not for probes related to the non-local antecedent was observed. At an SOA of 160 ms, in contrast, the pattern was reversed: There was a priming effect for probes that were semantically related to the non-local antecedent, but no priming effect for probes related to the local antecedent. At an SOA of 370 ms, both the local and non-local antecedent elicited a semantic priming effect. Liu (2009) interpreted these results as evidence for *ziji* being bound by the local subject in a first stage of processing and by the non-local subject in a second stage of processing, whereas in the final stage, both bindings are possible. Along the same lines, Dillon (2011) and Dillon et al. (2014) suggested that the parser tries to first access the local subject and only at a later stage accesses non-local antecedent positions. Such a temporal delay for the triggering of the retrieval of a non-local antecedent would indeed predict the pattern observed in Experiment 2: In the local conditions, the retrieval is triggered immediately at the moment when the reflexive is first encountered. The interference effects associated with this retrieval therefore appear already in early measures at the reflexive. In non-local conditions, in contrast, the retrieval of the non-local antecedent is triggered only after a certain delay,

which causes the interference effects to occur only in RRT at the spillover region.

4. An Extended Cue-Based Retrieval Model

As has been pointed out in the experimental discussions, the interference effects observed in the experiments presented here are not compatible with structure-based accounts. The current implementation of the standard cue-based retrieval model in ACT-R (Lewis and Vasishth, 2005) cannot explain the observed patterns either. In particular, standard cue-based retrieval is unable to explain (i) why there is an effect in antecedent-match conditions in Experiment 2 but not in Experiment 1, and (ii) why there is inhibitory interference observed in antecedent-match conditions in Experiment 1. We propose an explanation of the observed patterns by adding two independently motivated assumptions to standard cue-based retrieval: that (i) similarity-based interference is modulated by *distractor prominence* and that (ii) *cue confusion* can lead to similarity-based interference between non-similar items. As discussed earlier, the difference in the interference profiles of local and non-local *ziji* might be due to a qualitative difference in processing mechanisms and was therefore not included in our modeling.

4.1. Principle 1: Prominence

In Experiment 1, we found an interference effect in antecedent-mismatch conditions but not in antecedent-match conditions. According to Wagers et al. (2009), this is an expected prediction of cue-based retrieval and, in the context of subject-verb number attraction phenomena, the authors named it "grammatical asymmetry." Their intuitively plausible explanation was that a perfectly matching antecedent (as is the case in antecedent-match conditions) must clearly outcompete a partially matching distractor, while more interference is caused when both antecedent and distractor are only partially matching candidates.

Simulations with the current ACT-R implementation (Lewis and Vasishth, 2005) revealed that the latter does not predict such asymmetry (for details, see Engelmann et al., 2015, and our forthcoming paper Engelmann, Jäger, and Vasishth, "Confusability of retrieval cues in dependency resolution: A computational model," manuscript in preparation)—at least not in a principled way: It is possible to adjust ACT-R's parameters to permanently reduce similarity-based interference. However, this would leave unexplained why in some cases effects in antecedent-match conditions do appear (see the General Discussion for details). Standardly, ACT-R predicts interference effects in match and mismatch conditions. We therefore extended the ACT-R model with a *prominence principle* that scales similarity-based interference in relation to the difference in activation between antecedent and distractor.

In standard ACT-R, a memory item i receives an amount of spreading activation S_{ji} for each retrieval cue j it matches. This activation is reduced relative to the number of distractors that match the same retrieval cue j (this number is called the fan_{ji}):

$$S_{ji} = S - \ln(fan_{ji}) \tag{1}$$

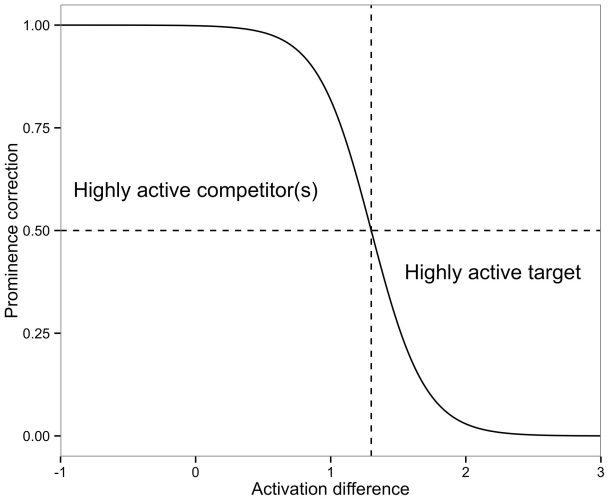

FIGURE 1 | Prominence correction by activation difference *Diff* (target − distractors) with $C = 5$ and $x_0 = 1.3$.

where S is the *maximum associative strength* parameter (*MAS*), which defaults to 1.

In our model, the fan_{ji} is transformed into fan'_{ji} by a *prominence correction*, that takes into account the distractors' relative activation:

$$fan'_{ji} = \begin{cases} \frac{1}{1+e^{-C(x_0-Diff)}} \times fan_{ji}, & \text{if } C > 0 \\ fan_{ji}, & \text{otherwise} \end{cases} \tag{2}$$

where *Diff* is the difference $A_i - \bar{A}_{Competitors}$ between the target activation A_i and the mean activation of all competitor items associated with cue j. The *prominence correction factor* C scales the steepness of the logistic *prominence correction* function and should not vary within the same model. In our simulations, we set it to 5. The function's *offset* x_0 is fixed at 1.3, which means that fan'_{ji} is $0.5 \times fan_{ji}$ at an activation difference between target and distractor of 1.3.

Figure 1 shows the change in the multiplicative term (the *prominence correction*), that determines the relation between *fan* and its transformation fan'. When the target has lower activation than the mean activation of its competitors, *Diff* is negative and the prominence correction approaches 1, which implies that the fan will correspond to the standard calculation in ACT-R, and the activation of the target will be reduced by some amount. This is the case when there are highly activated distractors present: similarity-based interference occurs in this case. *Diff* will be positive when the mean activation of the competitors is relatively low. In this case, the prominence correction will be a value less than 1, and as a consequence the second term in Equation (1) will approach 0, leading to a relatively larger amount of spreading activation to the target. In other words, there will be less interference.

This implementation of a prominence principle adds two predictions to the standard cue-based retrieval model: First, there

is generally less interference in antecedent-match conditions due to the presence of a highly activated fully matching antecedent. Second, similarity-based (inhibitory) interference in antecedent-match conditions is *increased* for distractors that are highly activated or when there are multiple distractors as in our Experiment 2.[12] Distractor base-level activation could be influenced by its grammatical role (subjects are more salient or accessible than objects, Chafe, 1976; Keenan and Comrie, 1977; Brennan, 1995; Grosz et al., 1995) and by its discourse topicality (Chafe, 1976; Givón, 1983; Du Bois, 1987, 2003; Ariel, 1990; Gundel et al., 1993; Grosz et al., 1995). Other factors contributing to the salience of the distractor and hence to its base-level activation might be first mention (Gernsbacher and Hargreaves, 1988), thematic role (Arnold, 2001), contrastive focus (Cowles et al., 2007) or animacy (Fukumura and van Gompel, 2011). In effect, the prominence principle accounts for both the absence of an effect in antecedent-match conditions of Experiment 1 and the presence of an inhibitory effect in Experiment 2. Furthermore, the prominence principle predicts greater interference effects in antecedent-match conditions for distractors in more salient positions. We will relate this prediction to the literature in the General Discussion.

4.2. Principle 2: Cue Confusion

As explained in the introduction and resulting from Equation (1), similarity-based (inhibitory) interference (or the fan effect) in ACT-R only arises when multiple memory items match the same retrieval cues. Since this is not the case in the antecedent-mismatch conditions of Experiment 1, the observed inhibitory interference is incompatible with ACT-R theory. At least this seems to be the case. We argue that this assumption of incompatibility might not be justified.

In the application of cue-based retrieval to sentence comprehension, it is generally assumed that retrieval cues perfectly distinguish matching features from non-matching ones. For instance, a *+plural* cue always activates plural items and not singular items. For our first experiment, this means that *+animate* is perfectly different from *+c-com* and no similarity-based interference is predicted in antecedent-mismatch conditions where the antecedent only matches *+c-com* and the distractor only matches *+animate*. However, the language processor might not differentiate between features categorically but rather on a continuous scale of similarity. In fact, in the general ACT-R framework, features are memory items just like the items they belong to and, therefore, could be confused with each other if they have a sufficient degree of similarity. If we assume that cue-feature associations have to be learned from language experience, it follows that these associations would somehow reflect co-occurrence statistics in the language input. Consequently, cues in a retrieval specification could, depending on the retrieval-relevant context, be associated with several features to different degrees.

A co-occurrence-based account would predict differences between English reflexives and Mandarin *ziji* in the following way: *Ziji* invariably requires its antecedent to match {*+ c-com*, *+animate*}, meaning that these two features frequently co-occur in the specific task of processing the Mandarin reflexive. English reflexives, on the other hand, have several alternative forms like *himself*, *herself*, *itself*, and *themselves*. All of these forms have the same structural requirement toward their antecedent but their non-structural retrieval cues vary in gender and number. The benefit of distinguishing features for number, gender, and structural relation in English reflexives results in a stronger one-to-one association between a cue and the corresponding feature. In the case of Mandarin *ziji*, however, there is no benefit from distinguishing *+ c-com* and *+animate* for the task of finding the appropriate antecedent. In consequence, retrieval cues might in this case be associated with both features to some degree in a kind of *crossed association*. In relation to the retrieval specification, antecedent and distractor would appear similar in this case, although they theoretically do not share any features. This confusion-induced similarity can cause similarity-based interference as of Equation (1), predicting inhibitory effects in conditions where they would not be expected in terms of standard cue-based retrieval assumptions.

We implemented cue confusion by further adjusting the measure of similarity-based interference (the *fan*) from Equation (1) to take into account all features and their strength of association with a certain cue:

$$fan_{ji} = 1 + \sum_k (1 + Q_{jk}) \tag{3}$$

where Q_{jk} is the *associative strength* between cue value j and feature value k on a scale of $[-1, 0]$, with -1 meaning no association and 0 representing maximum association. We assume that this association is dynamically adaptive to individual dependency environments. Equation (3) predicts that the stronger a cue-feature association the more this feature will contribute to similarity-based interference related to that cue. For example, if $Q_{c\text{-}com;anim}$ for *ziji* is -0.5, the resulting fan for the *+c-com* cue would be 1.5 instead of 1 as original ACT-R would predict. This increases similarity-based interference in comparison to English reflexives, where, say, $Q_{c\text{-}com;gend}$ would be standardly assumed -1, hence having a fan of 1 for each cue.

Another example of increased feature-co-occurrence are reciprocals like *each other*. In this case, the feature combination {*+ c-com*, *+plural*} is invariably required. Hence, our account predicts an increased cue-confusion level in the case of English reciprocals just like in Mandarin reflexives, possibly leading to inhibitory interference in antecedent-mismatch conditions.

With the cue confusion account, we propose that task requirements (frequent co-occurrence of certain features in similar retrieval contexts) dynamically influence how cues are treated during a retrieval request. Cue confusion therefore predicts that inhibitory interference effects in antecedent-mismatch conditions should preferably be observed

[12]Note that, for the case of multiple distractors, the original model, too, predicts increased interference. This, however, only explains the difference in effect size between Experiment 1 and 2, but neither the discrepancy between antecedent-match and antecedent-mismatch conditions in Experiment 1 nor the differences between other experiments that did not use multiple distractors.

in constructions where cues frequently co-occur. An evaluation of these predictions beyond our own experimental results will be provided in the General Discussion.

4.3. Simulation Results

We report model predictions for the full range of cue confusion values. ACT-R parameters were fixed to their defaults or to values used in previous simulations (Lewis and Vasishth, 2005): latency factor $LF = 1.5$, activation noise value $ANS = 1.5$, mismatch penalty $MP = 1.5$. We compare the model predictions with empirical FPRT on *ziji* of Experiments 1 and 2. We refer to FPRT in Experiment 2 although it was not significant under Bonferroni correction. It however patterned with an effect in RBRT, which had a similar magnitude. **Figure 2** plots the prediction space of a cue-based retrieval model that implements cue confusion and prominence (values represent the means of 2000 simulations each). For comparison, the predictions of a model without prominence are plotted in gray. The cue confusion level is plotted on a percentage scale, with 100% confusion meaning that both features, +*c-com* and +*animate*, are maximally associated with both the *c-com* and *animate* cues ($Q_{c\text{-}com;anim} = 0$ and $Q_{anim;c\text{-}com} = 0$). With *prominence correction factor* at 0 and *cue confusion level* at −1, the current model is equivalent to the original ACT-R model. The original model's predictions are therefore represented by the left-most points of the gray lines. The left panel shows the predictions for Experiment 1. With increasing cue confusion, the interference effect for the antecedent-mismatch conditions increases. At a confusion level of about 55% (indicated by the dotted vertical line), the model predicts an effect of the observed size in local conditions (19 ms in FPRT, indicated by the dashed horizontal line). In contrast to the original model, the prominence model predicts an interference effect close to zero for antecedent-match conditions in Experiment 1 for all cue confusion levels. This is in line with the absence of an effect in the data.

The right panel of **Figure 2** shows the predictions for a similar model as the left panel, but with three distractors instead of one, simulating the conditions of Experiment 2. The inhibitory effect for antecedent-match conditions increases with cue confusion in this scenario. An effect of about the observed size (15 ms in FPRT) is predicted at the same cue-confusion level as for Experiment 1.

To summarize, the extended model with cue confusion and prominence predicts the observed data of both experiments with fixed parameters at a cue-confusion level of about 55%. More specifically, the model predicts two patterns that the original ACT-R model does not predict: (i) the absence (or near absence) of an inhibitory interference effect in the antecedent-match conditions of Experiment 1 in spite of an effect present in Experiment 2 and (ii) an *inhibitory* interference effect in antecedent-mismatch conditions in Experiment 1.

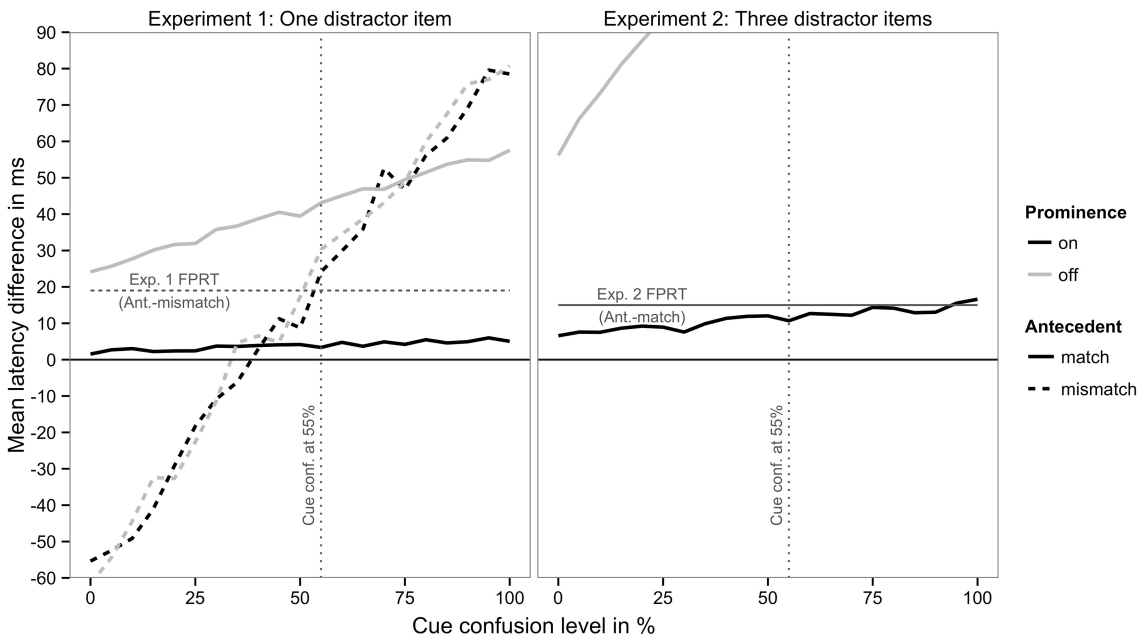

FIGURE 2 | Predicted interference effect (distractor-match − distractor-mismatch) by cue confusion level for the default model (gray lines) and the prominence model (black lines). The left panel shows the predicted interference for a single distractor (Exp. 1); the right panel for three distractors (Exp. 2). Solid lines represent the conditions where the antecedent matches the semantic cue, mismatch conditions are represented by dashed lines. The gray horizontal lines indicate the observed effect size in antecedent-mismatch conditions in Exp. 1 (left panel) and local antecedent-match conditions in Exp. 2 (right panel)—both in first pass reading time FPRT. The gray dotted vertical line intersects the x-axis at the estimated cue confusion value (55%) in both panels.

5. General Discussion

We conducted two eye-tracking experiments in which we investigated whether the reflexive *ziji* is subject to interference effects from structurally inaccessible distractor nouns that fulfill the animacy requirement of *ziji*. In Experiment 1, where only a single distractor was present in the sentence, we found inhibitory interference in antecedent-mismatch conditions but no effect in antecedent-match conditions. In Experiment 2, where three distractors were presented as memory load, we found interference effects also in antecedent-match configurations.

These results are clear evidence against a structure-based mechanism underlying memory retrieval in human sentence parsing. The interference effects observed in Experiments 1 and 2 are incompatible with a purely structure-based retrieval mechanism. However, Sturt (2003) and Kush and Phillips (2014) have proposed a potential explanation for interference effects within the structure-based account. These authors hypothesize that, in the case of retrieval failure, a later repair process might employ a retrieval with relaxed structural restrictions, giving rise to late interference effects. This late-interference account is a plausible explanation for the effect observed in the non-local conditions of Experiment 2, where the effect occurred only in RRT at the post-critical region. However, for the effects observed in locally bound *ziji* (Experiments 1 and 2), the late-interference account appears implausible given that the effects occur already in first-pass eye-tracking measures and at the critical region.[13] Also note that the effect reported in Kush and Phillips (2014) does not necessarily reflect late processes, since in self-paced reading experiments, it is very common that effects triggered at the critical region appear several words downstream.

The standard ACT-R model of cue-based retrieval (Lewis and Vasishth, 2005) does predict immediate interference effects but is not fully compatible with our results either. First, it predicts facilitatory rather than inhibitory interference in antecedent-mismatch conditions and, second, it cannot explain the absence of an effect in the antecedent-match conditions of Experiment 1. In fact, in the literature on reflexive processing, hardly any study can be found that reports the exact pattern predicted by the standard ACT-R model, namely inhibitory interference in antecedent-match conditions and facilitatory interference in antecedent-mismatch conditions.[14] An approach of extending the ACT-R model in favor of a structure-based mechanism has been taken by Parker and Phillips (2014). They have proposed that structural cues are weighted higher than semantic or morphological cues, so that interference effects occur only in case of an abnormally poor match of the accessible antecedent. This is a plausible explanation for their data and offers an account for the fact that interference is hard to find in reflexives. However, with respect to our results, it neither explains the inhibitory interference in antecedent-match conditions nor the difference in effect sizes in antecedent-match vs. antecedent-mismatch conditions.

In order to account for our results and the diverse patterns in the literature, we have introduced two concepts as an extension of the standard cue-based retrieval model. The *prominence principle* implements the idea that a perfectly matching or otherwise highly activated antecedent is only marginally affected by similarity-based interference from comparably poorly matching distractors. This explains the discrepancy between Experiments 1 and 2 (absence of an effect in antecedent-match conditions in Experiment 1 vs. an inhibitory interference effect in Experiment 2). With the concept of *cue confusion*, we proposed that the retrieval cues can be associated with several features of memory items and that the strength of these associations depends on experience with a specific linguistic context. For special cases, this can cause similarity-based interference between items that do not match the same retrieval cues. We argued that *ziji* is such a special case, which would explain the observed inhibitory interference in antecedent-mismatch conditions of Experiment 1.

In the following, we compare the predictions of the extended ACT-R model with the literature on reflexives. Prominence predicts that interference in antecedent-match conditions is generally low compared to antecedent-mismatch conditions but increases as a function of distractor activation. If we assume that distractor position (grammatical role and discourse topicality) affects its base-level activation in memory, the literature summary in **Table 1** seems to conform with these predictions: Among the studies which tested both antecedent-match and antecedent-mismatch conditions, about 75% report an interference effect (including marginal effects) in antecedent-mismatch conditions while only 50% of the studies found an effect in antecedent-match conditions. All studies that did report an effect in antecedent-match conditions had the distractor either in subject position (Badecker and Straub, 2002; Chen et al., 2012; Patil, Vasishth, and Lewis, "Retrieval interference in syntactic processing: The case of reflexive binding in English," unpublished manuscript), in topicalized subject position[15] (Felser et al., 2009; Cunnings and Felser, 2013; Clackson and Heyer, 2014), or had multiple distractors (Experiment 2 reported here). On the other hand, only half of the studies reporting no interference effect in antecedent-match conditions had the distractor in subject position. Obviously, not all studies that have the distractor in subject position report an effect, but the literature review suggests that subject position increases the probability of finding one. For the absence of an antecedent-match interference effect in our Experiment 1, there might be a specific reason: Dillon et al. (2015) have shown that items within restrictive relative clauses

[13]This is assuming that the pre-critical effects in Experiments 1 and 2 are due to difficulty with an inanimate subject, as discussed above, rather than reflecting an early application of binding during the parafoveal preview of the reflexive.

[14]It should be noted that the (marginal) facilitatory interference in antecedent-match conditions reported by three studies presented in **Table 1** (Sturt, 2003; Cunnings and Felser, 2013) is compatible with the ACT-R model although this may not be intuitively obvious. An exceptionally highly activated distractor (in all three of these experiments, the distractor is a discourse prominent subject) can lead to facilitatory interference (see Engelmann et al., 2015, and our forthcoming publication Engelmann, Jäger, and Vasishth, "Confusability of retrieval cues in dependency resolution: A computational model," manuscript in preparation).

[15]With distractors in "topicalized subject position" we here refer to distractor nouns in subject positions which appear as the current discourse topic in the test sentence because they were introduced in a preceding context sentence.

cause more interference as compared to items in appositive relative clauses. They attribute this difference to the idea that, in contrast to restrictive relative clauses, appositive relative clauses constitute a speech act separate from the one of the main utterance (Potts, 2005; Arnold, 2007). More generally, their results suggest that the embedding environment containing a distractor influences the strength of interference caused by this distractor. In terms of ACT-R, one might think of this as different base-level activations as a function of the type of embedding environment. It might be possible that the interposed adverbial structures which contain the distractor in our materials belong to those embedding environments which cause a relatively low degree of interference. This seems a plausible assumption since in our materials, the adverbial clause can simply be ignored by the parser without affecting the grammaticality or plausibility of the whole sentence.

For antecedent-mismatch conditions, cue confusion predicts stronger inhibition the higher the crossed association between cues and features is assumed to be, that is, in contexts with frequently co-occurring cue combinations. However, note that cue confusion is compatible with both facilitatory and inhibitory effects, and even with the absence of an effect, as all this is part of the effect continuum that is illustrated in **Figure 2**. This raises the concern of how to determine a sensible confusion level in each case, since a model allowing arbitrary predictions is not useful. Currently, the model prediction can only be treated as a predicted difference between two conditions in one or the other direction along the effect continuum. In other words, a prediction should be stated in terms of whether the antecedent-mismatch interference effect of one dependency tends more toward inhibition or toward facilitation in comparison to another dependency like, e.g., English reflexives. In the reasoning we apply here, we refer to English reflexives as a baseline with zero cue confusion and spot special cases where a different feature-co-occurrence rate can be assumed that would motivate a higher confusion level. We have argued that inhibitory interference was observed in antecedent-mismatch conditions in our Experiment 1 because *ziji* is a special case in the sense that the feature combination {+ *c-com*, +*animate*} is constant compared to the variable combinations in the different forms of English reflexives. The same logic with respect to {+ *c-com*, +*plural*} would apply to reciprocals. In the literature there is one study by Kush and Phillips (2014) that tested the Hindi equivalent of the reciprocal *each other* and indeed found the predicted inhibitory interference in antecedent-mismatch conditions.

Although the *post-hoc* nature of our proposals here is an important limitation that needs to be addressed with new empirical tests, theory development necessarily is data-driven, and the existing data suggest that our proposal constitutes one possible explanation. Indeed, currently it is the only computational account of the patterns of findings discussed here. In order to empirically test the predictions of cue confusion, it is necessary to experimentally manipulate feature-co-occurrence within a minimal pair. A potential experiment could use stimuli like in Example (4) to compare the interference effect in antecedent-mismatch conditions for *themselves* and *each other*. Cue confusion predicts a smaller facilitation or even an inhibition for *each other*. Furthermore, it should be possible to derive a numerical metric of cue confusion for a range of dependencies by computing co-occurrence frequencies in a treebank that contains dependency information as well as information about retrieval relevant features such as gender, number, and animacy.

(4) a. **Reflexive; distractor-match**
The *nurse* who cared for the *children* had pricked *themselves* . . .
b. **Reflexive; distractor-mismatch**
The *nurse* who cared for the *child* had pricked *themselves* . . .
c. **Reciprocal; distractor-match**
The *nurse* who cared for the *children* had pricked *each other* . . .
d. **Reciprocal; distractor-mismatch**
The *nurse* who cared for the *child* had pricked *each other* . . .

A more thorough test of the extended model's predictions will be presented in a forthcoming publication (Engelmann et al., "Confusability of retrieval cues in dependency resolution: A computational model," manuscript in preparation) that includes quantitative simulations of a range of previous studies on reflexive processing and subject-verb dependencies.

As a rather speculative point we want to add that the cue confusion level of a certain dependency might not only be influenced by feature-co-occurrence but also by task demands and individual differences. If cue-feature associations are subject to an adaptive learning process, they might also be affected by resource-preserving strategies. An example where strategic adaptation of comprehension processes has been found are relative clause attachment ambiguities. Swets et al. (2008) and Logačev and Vasishth (2015) have found that processing effort in ambiguity resolution was adapted to the type of comprehension questions. Also, effects of individual differences in working memory span have been found by Traxler (2007) and von der Malsburg and Vasishth (2012) for the processing of attachment ambiguities. If analogously to task- and resource-related underspecification in attachment ambiguities, cue-feature associations are affected by resource-preserving strategies in the sense of *good-enough processing* (Ferreira et al., 2002), we would expect that low-span readers tend to have greater cue confusion and, thus, exhibit interference effects further toward inhibition in the continuum than high-span readers. The marginal inhibitory effect for low-span readers in antecedent-mismatch conditions of Experiment 2 by Cunnings and Felser (2013) would fit with this expectation. However, more experimental data is needed in order to evaluate effects of individual differences and task-demands on cue-feature associations.

6. Conclusion

We have presented experimental evidence that is incompatible with structure-based accounts of reflexive processing and also inconsistent with the original cue-based ACT-R model of

sentence processing. In order to account for the observed pattern, we have proposed to add two new principles, prominence and cue confusion, to the ACT-R model. This extension to the ACT-R model is not only able to explain the pattern observed in the data presented in this article, but can also account for a range of previously unexplained patterns reported in the literature on reflexive processing. Naturally, this proposal needs to be evaluated with novel experimental data.

Acknowledgments

We thank Prof. Hua Shu and the State Key Laboratory of Cognitive Neuroscience and Learning at Beijing Normal University, China, for allowing us to conduct our experiments in their eye-tracking lab. We are grateful to Dr. Ming Yan, Dr. Jing'er Pan and Wei Zhou for their kind assistance and their very helpful comments on the experimental materials. We thank Prof. Reinhold Kliegl for his valuable advice on the statistical analyses and Dr. Zhong Chen and Maja Stegenwallner-Schütz for constructive discussions. We thank the audience at AMLaP 2012 and 2014 for comments. This work was partly funded by the Studienstiftung des deutschen Volkes and the Potsdam Graduate School by awarding a scholarship to the first and the second author, respectively. Publication of this article was funded by the Deutsche Forschungsgemeinschaft and the Open Access Publishing Fund of the University of Potsdam.

Because morphological and syntactic constraints govern the distribution of potential antecedents for local anaphors, local antecedent retrieval might be expected to make equal use of both syntactic and morphological cues. However, previous research (e.g., Dillon et al., 2013) has shown that local antecedent retrieval is not susceptible to the same morphological interference effects observed during the resolution of morphologically-driven grammatical dependencies, such as subject-verb agreement checking (e.g., Pearlmutter et al., 1999). Although this lack of interference has been taken as evidence that syntactic cues are given priority over morphological cues in local antecedent retrieval, the absence of interference could also be the result of a confound in the materials used: the post-verbal position of local anaphors in prior studies may obscure morphological interference that would otherwise be visible if the critical anaphor were in a different position. We investigated the licensing of local anaphors (reciprocals) in Hindi, an SOV language, in order to determine whether pre-verbal anaphors are subject to morphological interference from feature-matching distractors in a way that post-verbal anaphors are not. Computational simulations using a version of the ACT-R parser (Lewis and Vasishth, 2005) predicted that a feature-matching distractor should facilitate the processing of an unlicensed reciprocal if morphological cues are used in antecedent retrieval. In a self-paced reading study we found no evidence that distractors eased processing of an unlicensed reciprocal. However, the presence of a distractor increased difficulty of processing following the reciprocal. We discuss the significance of these results for theories of cue selection in retrieval.

Keywords: memory retrieval, anaphor resolution, Hindi, self-paced reading, computational modeling

INTRODUCTION

In order to establish grammatical dependencies between words across a distance during routine sentence processing comprehenders rely heavily on their ability to encode and retrieve items from memory. For example, processing of a local anaphor such as the reflexive *themselves* or the reciprocal *each other* in (1) requires recalling the previously seen noun phrase (NP) *the people* from memory so that it may be interpreted as the antecedent.

(1) The people talked to *themselves/each other*.

The mechanism by which previously encountered items are retrieved for subsequent processing has been the subject of recent research. A number of recent studies have motivated a processing model that exploits a cue-based access mechanism to retrieve items from content-addressable memory (e.g., McElree, 2000; McElree et al., 2003; Lewis et al., 2006; Van Dyke, 2007; Martin and McElree, 2008, 2009; Van Dyke and McElree, 2011).

A hallmark property of cue-based retrieval is that it is susceptible to interference (Nairne, 1990). Task-irrelevant items in memory whose features overlap with a probe's retrieval cues (distractors) can exert influence on the retrieval of a target item. In the context of sentence processing retrieval interference is said to occur when grammatically inappropriate distractors influence the processing of a phrase that must enter into a dependency with a previously encountered head. The influence of distractors can be *inhibitory*: a distractor may increase the difficulty of retrieving an appropriate item. Van Dyke (2007) found that distractor NPs increased the difficulty of retrieving a grammatically appropriate subject for the purposes of thematic integration with a verb (see also Van Dyke and McElree, 2006, 2011). A distractor's influence may also be *facilitatory* if its presence decreases the difficulty of processing an otherwise ungrammatical or unlicensed element. Comprehenders have repeatedly showed signs of facilitatory interference during the processing of subject-verb agreement (e.g., Pearlmutter et al., 1999; Wagers et al., 2009). Wagers and colleagues found that reading times immediately following the plural verb *were*, which mismatched the features of the singular subject *key*, were decreased when an intervening distractor [*cabinet(s)*] was plural, compared to when the distractor was singular.

(2) The key to the **cabinet(s)** unsurprisingly *were* rusty from years of disuse.

The authors argued that facilitation arose because comprehenders erroneously retrieved the plural distractor on some portion of trials when attempting to find a licensor for the plural marking on the verb. These kinds of facilitatory interference effects have also been observed in the processing of other grammatical dependencies such as negative polarity item (NPI) licensing (e.g., Drenhaus et al., 2005; Vasishth et al., 2008; Xiang et al., 2009; Parker and Phillips, submitted), and the retrieval of antecedents for null pronominal subjects (PRO) in adjunct clauses (Parker et al., 2012) and many authors have attributed these effects to misretrieval of a distractor under (partial) match with a set of retrieval cues.

Although facilitatory interference has been repeatedly observed in the processing of some dependencies, other dependencies that recruit retrieval have displayed virtual immunity to facilitation from distractors. Recent work has found that the processing of a local anaphor that lacks a grammatical antecedent is unaffected by the morphological feature-content of intervening distractors (e.g., Sturt, 2003; Dillon et al., 2013). For instance, Dillon et al. (2013) demonstrated that the processing of the unlicensed plural reflexive *themselves* in (3) is not influenced by plural-marking on the distractor *manager(s)*.

(3) The new executive who oversaw the manager(s) apparently doubted *themselves*...

The lack of facilitatory interference effects is unexpected on the assumption that the same cues as those used to find licensors for agreement dependencies (e.g., morphological features such as number) are used to identify potential antecedents of reflexives. As with agreement, reflexives must match their licensors in number and gender, so the use of morphological features as cue for retrieval of appropriate antecedents would appear to be motivated. On analogy to agreement licensing, the use of these morphological cues should in turn render antecedent retrieval subject to interference.

The results suggest that morphological features may play a different role in antecedent retrieval for local anaphors than they do in agreement licensing. One option, advocated by Dillon et al. (2013), is that antecedent retrieval forgoes the use of interference-prone morphological features, opting instead to exclusively use *positional* syntactic features to access the local subject. Another option is that antecedent retrieval preferentially weights syntactic cues over morphological cues instead of avoiding them altogether. This second account predicts a small but non-negligible interference effect that the first does not, but previous experiments may not have had sufficient power to find this effect, so they cannot distinguish between the two competing explanations.

Although the two accounts differ, they both assign priority to positional cues. This goes against the general assumption that retrieval identifies targets through the use of a maximal cue set that uniformly weights lexical, morphological, syntactic, and semantic features (see Van Dyke and McElree, 2011 for discussion).

As it stands the previous studies may not be sufficient to establish a preference for positional features. It is possible that the absence of facilitatory interference could be attributed to a confound that masks the contribution of morphological features that are weighted equally to syntactic cues. In almost all previous studies the critical anaphor immediately followed its verb, which could potentially play a role in reducing the incidence of facilitatory interference (see King et al., 2012 for a similar suggestion).

As Dillon et al. (2013) note, the post-verbal position can provide an anaphor with privileged access to the local subject by means of recent activation alone. If subjects are retrieved by their verbs for thematic integration, the local subject *the executive* in (3) should be recalled by the verb *doubted*. Retrieval of the local subject entails that it should have the highest baseline activation out of all other items in memory immediately following the verb. At the time that a verb-adjacent reflexive is encountered, this high degree of activation may be strong enough to guarantee retrieval of the local subject instead of the feature-matching distractor even if morphological cues were used.

Alternatively, it may be that previous studies on reflexives do not provide a measure of susceptibility to facilitatory interference because establishing a dependency between the local subject and a post-verbal anaphor might not require retrieval at all. Some theories assume that the most recently retrieved item is maintained in a state that the parser can access without retrieval. In some theories this state is referred to as the *focus of attention* (e.g., McElree, 2000), in others such as Lewis and Vasishth's (2005) parsing model it is the *problem buffer*. When an anaphor is encountered immediately following the verb, it is possible that it consults the contents of this buffer to find its antecedent rather than initiating a retrieval from memory.

In this study we address the extent to which the lack of facilitatory interference in anaphoric licensing depends on an anaphor's post-verbal position. If the absence of interference is a consequence of the target anaphor occupying an immediately post-verbal position, then in languages where anaphors uniformly precede their verbs, local anaphor licensing should display facilitatory effects that have not been seen in English. We tested this prediction by investigating the processing of Hindi reciprocals. Hindi is a language in which all arguments and adjuncts precede the verb in unmarked word order. In (4), for example, the subject *LaRkoN* ("boys"), the reciprocal object *ek-dusre* ("each other"), and the adjunct *kal* ("tomorrow") precede the verb *dekhaa* ("saw").

(4) LaRkoN-ne ek-dusre-ko kal dekhaa.
Boys-Erg each.other-Acc yesterday saw.
'(The) boys saw each other yesterday.'

Hindi reciprocals provide a minimal contrast to English reflexives because they are subject to nearly identical licensing conditions as English local anaphors. Their antecedent must have matching morphological features: in order to license the reciprocal in (5), the local subject must bear plural features. The reciprocal's antecedent must be contained in the same local clause as the reciprocal: the main clause subject in (6) cannot antecede the

reciprocal in the embedded clause, despite bearing correct number marking, because it is not local to the reciprocal. Finally, the reciprocal's antecedent must also c-command the reciprocal (cf. Dayal, 1994). In (7), the plural NP *boys* does not c-command the reciprocal because it is embedded inside the adjunct phrase *at the boys' party*. It is therefore ineligible to license the anaphor.

(5) *LaRk*-{*-e/oN}-ne *ek-dusre*-ko kal dekhaa.
Boy-{Sing./Pl.}-Erg each.other-Acc yesterday saw.
'(The) boy*(s) saw each other yesterday.'

(6) **LaRkoN*-ne kahaa ki Mary-ne *ek-dusre*-ko dekhaa.
Boys-Erg said that Mary-Erg each.other-Acc saw.
*'(The) boys said that Mary saw each other.'

(7) *Mary-ne [*larkoN*-ki parTi me] *ek-dusre*-ko dekhaa.
Mary-Erg boys' party in one-another-Acc saw
*'Mary saw each other at the boys' party.'

We test whether morphological number features engender facilitatory interference effects during the processing of Hindi reciprocals.

SIMULATIONS

We ran a series of computational simulations that modeled local anaphor resolution in Hindi using equally-weighted morphological and positional features as cues for retrieval. Modeling was carried out to obtain qualitative predictions about the character and direction of interference from the distractor's morphological features that could then be compared with empirical reading times in the self-paced reading experiment.

PROCEDURE

We implemented a modified version of Lewis and Vasishth's (2005) ACT-R model of sentence processing [using code originally developed by Badecker and Lewis (2007)]. ACT-R is a general cognitive architecture that has been used to model a wide range of phenomena in cognitive psychology (Anderson, 1990). In the model, items are stored as "chunks" in a content-addressable memory and are retrieved with a success proportional to their overall activation at the time of retrieval, which is in turn determined by the overlap of their features with those of a retrieval probe. Memory access is modeled as a rational procedure that employs a general retrieval mechanism that minimizes retrieval error in the limit (Anderson, 1989; Anderson and Milson, 1989; Anderson and Schooler, 1991). Although fully implemented ACT-R parsing models exist (e.g., Lewis and Vasishth's, 2005 ACT-R parser), the simulations here focus solely on modeling retrieval latencies, abstracting away from the contributions of other modules. Retrieval latencies do not exhaust the processes that must be carried out in order to advance to the next word in a parsing task (other operations include structural attachment and integration), but for current purposes we adopt the standard assumption that longer retrieval latencies entail longer RTs (Anderson and Milson, 1989).

In the model the probability of retrieving an item i is governed by its activation A_i, computed as in (8). B_i is chunk i's baseline activation. The weight assigned to the individual cue j is represented w_j. For the purposes of our simulations cues were assigned uniform weights, so this term can be effectively dropped. S_{ji} is the strength of association between cue j and chunk i. PM in the equation below is a term that penalizes partial matches. The term ε introduces stochastic noise.

$$(8)\quad A_i = B_i + \Sigma w_j S_{ji} + PM + \varepsilon_i$$

S_{ji} is calculated according to the Equation in (9), where S is a parameter that specifies the maximum strength of association allowed. The fan_j term reflects the number of items that bear cue j. The term provides a way of quantifying the distinctiveness of a particular cue. The fan serves to decrease the associative strength between item i and cue j as a function of the number of total cues in memory that bear j.

$$(9)\quad S_{ji} = S - \ln(fan_j)$$

Baseline activation is calculated according to (10), where d is the decay rate of a chunk's activation in memory at a given point since retrieval time t_m.

$$(10)\quad B_i = \ln[\Sigma_m\, t_m^{-d}]$$

The chunk with the highest activation has the shortest retrieval latency (T_i) as calculated according to the equation below, where *F* is a scaling parameter. The chunk with the shortest retrieval latency is the chunk that is retrieved in simulations.

$$(11)\quad T_i = Fe^{-A_i}$$

The model equations above contain a number of free parameters whose settings could impact the results of the simulation. We ran a series of simulations that systematically combined parameter values from across the range of those reported in previous work. Values of the *total source activation*, *activation noise*, *fan*, *decay rate*, and *match-penalty* parameters were manipulated[1]. The scaling factor (F) was held constant at 0.75 across all simulations. This resulted in the construction of 324 different models with unique parameter value combinations. As noted by Dillon et al. (2013), conducting such a sweep through the space of possible parameter values and combinations enables the identification of model predictions that are independent of idiosyncratic parameter combinations. 10,000 Monte Carlo simulations were run for each model, providing for each simulation a prediction of the most probable retrieval target and its retrieval latency.

MATERIALS

We simulated antecedent retrieval time-locked to a position corresponding to the critical reciprocal in a sentence that contained

[1]Total source activation took one of three values across our simulations: 1.0, 1.25, 1.5. Four values were possible for the activation noise parameter: 0.3, 0.4, 0.5, 0.6. Three values were used for the fan parameter: 1.0, 1.5, 2.0, centered at the default value of 1.5 (Lewis and Vasishth, 2005). Three decay rates were used: 0.5 (the default rate of decay; Lewis and Vasishth, 2005), 0.25, and.001. Finally, we used three values for the match-penalty parameter: −0.2, −0.4, and −0.6.

three preceding NPs. The first NP, the *subject*, corresponded to a structurally appropriate antecedent for the reciprocal. The second NP, introduced at a lag after the subject NP, corresponded to a structurally inappropriate distractor. A third NP (NP3) was also introduced to more directly model the materials in our self-paced reading (SPR) experiment, the design of which is discussed below. The three NPs were introduced at 300 ms, 900 ms, and 1500 ms after simulation onset. Retrieval of the critical reciprocal was scheduled at 2400 ms after simulation onset.

Each NP in the simulation was marked with three features relevant for retrieval: its *category*, *number*, and *clause index*. All NPs bore the NP category feature. Number features could be either *singular* or *plural*. The *clause index* feature was used as a proxy feature for encoding an NP's structural appropriateness for the purposes of binding the reciprocal: the local licensing requirement is assumed to be satisfied if the antecedent bears the same clause index as the reciprocal. This indexing scheme can be viewed as a feature-based implementation of the clause-mate constraint on local anaphor licensing (see Lasnik, 2002 for a review of such constraints, which can differ in formulation from the c-command constraints of Chomsky, 1981; Reinhart, 1983).

Models were run to simulate four distinct conditions, corresponding to different feature combinations on the subject and distractor. The number features on the subject and the distractor were manipulated, resulting in the 2 × 2 factorial design schematized in (12). In grammatical conditions the subject was plural-marked, in ungrammatical conditions the subject was singular. In *NoInterference* conditions the distractor was singular, while in *Interference* conditions it was plural-marked. The structurally appropriate subject NP was marked with the *main clause* feature, while both the distractor and NP3 were marked as *embedded* and were therefore ineligible to antecede the reciprocal.

Antecedent retrieval at the reciprocal was modeled as specifying *NP* as a category cue and *main clause* as the clause cue. The number feature *plural* was also used in the retrieval cue set, to measure the interference effect associated with morphological features.

RESULTS

We report three measures of interest from the simulations run for each condition: (i) predicted error rate, (ii) average predicted latency by condition, and (iii) predicted interference effect.

Predicted error rate corresponds to the percentage of the runs when the distractor, rather than the appropriate subject, was retrieved as an antecedent for the reciprocal. This measure is a relevant index of facilitatory interference in the ungrammatical conditions if facilitation stems from erroneous retrieval of the distractor instead of an appropriate target NP.

Predicted latency provides a measure of how long on average the winning retrieval should take in each condition. In simulations, the chunk with the shortest retrieval latency is the chunk that is retrieved from memory. According to the fully implemented ACT-R model, reading times on a particular word or phrase are the sum of the latency of retrieval triggered at that phrase and the amount of time associated with subsequent processing required by that word or phrase. Retrieval latencies should therefore map monotonically to reading times, with longer retrieval latencies corresponding to longer overall reading times, although the mental processes that intervene between retrieval and button-press may interact or contribute additional difficulty in such a way as to distort the underlying pattern of retrieval. Despite the possibility of later processing concealing underlying retrieval patterns, previous work has found a degree of relative transparency between the qualitative pattern of retrieval latencies furnished by the model and observed effects of facilitatory interference in self-paced reading or eye-tracking measures (see e.g., Wagers et al., 2009; Dillon et al., 2013).

The interference effect is a difference measure that compares average retrieval latencies between two conditions that differ on a single feature, as a way of estimating the magnitude and direction of interference contributed by the retrieval probe matching that one feature. We report two interference effects: the difference between the two grammatical conditions, as well as the difference between the two ungrammatical conditions. These comparisons provide a quantitative prediction of the effect of distractor plural marking when the features of the appropriate subject are held constant.

PREDICTED ERROR RATES

Error rates are reported in **Table 1**. The error rates are consistent with a profile of facilitatory interference. Between the *Ungrammatical* conditions, plural marking on the distractor is predicted to increase rates of erroneous retrieval compared to when there is no NP in the sentence that matches the reciprocal in features (26.1 vs. 6.5%). On some proportion of trials, the recency of the distractor is predicted to increase the NP's baseline level of activation enough to result in it being the most highly-activated NP at retrieval. In the *Ungrammatical-NoInterference* condition, the distractor does not share any features with the reciprocal's cue set, so the main subject is still more likely to be retrieved, as it matches the retrieval probe's clause index cue. Error rate is

Table 1 | Retrieval error rates by condition for retrieval using morphological and syntactic cues calculated as the percentage of trials on which the distractor was retrieved across 10,000 runs each of 324 different models with unique parameter combinations.

	NoInterference (%)	Interference (%)
Grammatical	2.0	7.4
Ungrammatical	6.5	26.1

expected to differ slightly between the two grammatical conditions: misretrieval of the distractor is 5.4% more common when it bears plural marking and the main subject matches the retrieval cues completely.

AVERAGE PREDICTED RETRIEVAL LATENCIES

In the simulations the presence of a feature-matching subject has a facilitative effect on retrieval latencies (see **Figure 1**). Overall, retrieval times should be faster in the grammatical conditions because the grammatical subject, which matches the reciprocal's morphological and syntactic retrieval cues completely, is highly activated. Increased activation due to greater feature-match with the probe results in faster retrieval latencies in accordance with Equation (11). In the *Ungrammatical* conditions, where the main subject matches only on syntactic cues, retrieval latencies should be longer because the retrieved chunk should never match the probe completely. The appropriate subject only matches the probe's category and positional cues. The distractor matches the category cue and, in the *Ungrammatical-Interference* condition, the reciprocal's number feature. A pairwise difference is also predicted between the average retrieval latencies in the *Ungrammatical-NoInterference* and *Ungrammatical-Interference* conditions, which can be linked to the presence of morphological plural marking on the distractor. On the proportion of trials where the distractor is retrieved in the *Ungrammatical-Interference* condition, latencies are reduced relative to when the main clause subject is retrieved. This results in a reduction of average latency across retrievals.

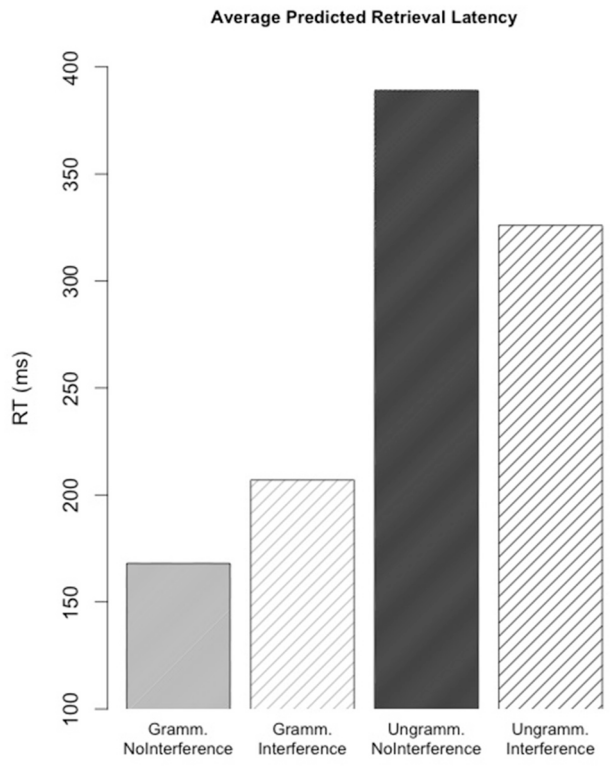

FIGURE 1 | Retrieval latencies by condition as predicted by the model in Experiment 1. Reported retrieval latencies represent the mean latency by condition across all simulations.

INTERFERENCE EFFECTS

Predicted interference effects are shown in **Table 2**. The grammatical interference effect was calculated by subtracting the average predicted latency in the *Grammatical-Interference* condition from the predicted latency in the *Grammatical-NoInterference* condition. The same difference was calculated for the two ungrammatical conditions. 95% confidence intervals represent the range of predicted interference effects across simulations.

The simulation results predict that a plural-marked distractor should cause facilitatory interference in the ungrammatical conditions. The *Ungrammatical-Interference* condition exhibits faster average retrieval latencies than the *Ungrammatical-NoInterference* condition. Though the size of the effect varies, a facilitatory effect was consistently observed across all parameter combinations.

A small effect of inhibitory interference is also predicted in the grammatical conditions. This inhibition can be attributed to the fan effect (see Equation 8). In the *Grammatical-Interference* condition, the strength of association between the appropriate subject and the plural retrieval cue is decreased relative to the *Grammatical-NoInterference* condition, due to the presence of another plural-marked NP (the distractor).

DISCUSSION

The goal of the simulations was to obtain predictions about the effect that a feature-matching but syntactically inappropriate distractor would have on the retrieval of an antecedent for a local reflexive if that retrieval used morphological features as cues that were weighted equally to syntactic cues.

The simulations show that when morphological cues are assigned the same weight as syntactic cues, the presence of a feature-matching distractor should decrease the parser's ability to retrieve a syntactically appropriate but feature-mismatching subject as an antecedent for a local anaphor. Some proportion of the time, the distractor is expected to be erroneously retrieved as a result of partial overlap with the retrieval cues. This misretrieval is predicted to have a facilitating effect on reading times in comparison to a case of retrieval when neither the distractor nor the local subject match the reflexive.

SELF-PACED READING EXPERIMENT

The modeling results predict that retrieval of a pre-verbal reciprocal's antecedent should display facilitatory interference effects from structurally inappropriate distractors, if morphological cues

Table 2 | Average interference effects across 10,000 runs each of 324 different models.

	Interference effect	Middle 95% of simulated distributions
Grammatical	+36 ms	+11, +82 ms
Ungrammatical	−63 ms	−18, −142 ms

such as number are assigned the same weight as syntactic cues in retrieval. The experiment below used the self-paced reading method to investigate whether evidence of the predicted facilitatory interference would be found.

MATERIALS

The experiment had a 2×2 factorial design that matched the simulated conditions. The design manipulated the factors GRAMMATICALITY and INTERFERENCE. The structure of the test items is schematized in (13) and an example item is given in (14). All conditions contained a critical reciprocal (*ek-dusre*) that required a plural-marked antecedent in the main clause. The reciprocal was contained in a post-positional phrase that preceded a manner adverbial (*gupt-rup-se,* "*secretly*") and the main clause verb (*baat kii,* "*chatted*" *lit.* "*chat did*").

GRAMMATICALITY was manipulated by changing whether the main clause subject was plural-marked [*Doctor(-oN),* "*doctor(s)*"]. Plural marking was unambiguously marked by the inflectional suffix *–oN*. In the grammatical conditions, the main clause subject was plural and could therefore act as a grammatical antecedent for the reciprocal. In the ungrammatical conditions, the local subject was singular and the reciprocal therefore lacked a clause-mate antecedent. The factor INTERFERENCE manipulated whether the distractor [*mariiz-(oN),* "*patient(s)*"] was plural-marked.

In previous studies on local anaphor licensing (e.g., Sturt, 2003; Dillon et al., 2013) distractors have been positioned within relative clauses (RCs) attached to the main clause subject. RC-modification of subjects is a marked construction in Hindi, so the present study embedded the distractor inside a locative phrase that preceded the critical reciprocal.

The locative phrase contained an NP denoting a location modified by an animate possessor (*nurse-ke steSan,* "the nurse's station"). The distractor was embedded as the object of a verb within a prenominal RC that was attached to this possessor. In this position the distractor was not a clause-mate of the reciprocal and was therefore ineligible to act as a potential antecedent.

Critical reciprocals were always followed by a case marking post-position, either the genitive *ke*, the objective *ko*, or the dative *se*. When followed by the genitive, reciprocals were embedded in a complex post-position that was an argument to the main verb (e.g., *ke bare-me* "about" in 14). In sentences with *ko* or *se*, adverbial material was introduced after the post-position to maintain consistent length across sentences.

Inside the pre-nominal RC the distractor bore either accusative or genitive case (according to the verb's requirements). Although this increased the contrast between the nominative grammatical subject and the distractor, it is unlikely that the case difference would play a role in distinguishing appropriate from inappropriate NPs, as accusative and genitive-marked NPs can serve as antecedents for local anaphors under the right structural conditions (see, e.g., Dayal, 1994; Mohanan, 1994; Bhatt and Dayal, 2007).

A second concern with the experimental materials is that there exists the potential for temporary misanalysis of the structural position of the distractor during incremental parsing. When it initially encounters the distractor, the parser has not yet encountered any information that indicates that the distractor is contained within an embedded clause. In the absence of this information, an incremental parser is likely to analyze the distractor as a constituent of the main clause. This type of temporary misparse is common in head-final languages where embedded arguments can be encountered prior to the verb that licenses them (Inoue, 1991; Mazuka and Itoh, 1995; Miyamoto, 2003). The misanalysis would be disconfirmed at the relative pronoun *wali*, at which point the object would be correctly reanalyzed as a constituent of the relative clause. This misparse should occur across all conditions, but it may have a greater impact on processing in the *Ungrammatical-Interference* condition. Under this misanalysis the RC-internal object would initially be analyzed as a suitable antecedent for an upcoming reciprocal. We return to the ability of such a misparse to affect later parsing decisions in the *Ungrammatical-Interference* condition in the discussion.

PARTICIPANTS

32 self-reported native speakers of Hindi were recruited from the student bodies of IIT, Delhi and Jawaharlal Nehru University in New Delhi (18 male, mean age = 20.1). Participants were compensated Rs. 300 for their participation, which lasted around 35 min.

PROCEDURE

Participants were run on one of two laptop PCs using the Linger software package (Doug Rohde, MIT) in a self-paced word-by-word moving window paradigm (Just et al., 1982). Each trial began with a sentence masked by dashes appearing on the screen. Letters and punctuation marks were masked, but spaces were left unmasked so that word-boundaries were visible. As the participant pressed the spacebar, a new word appeared and the previous word was re-masked. All text appeared in Devanagari font.

A yes/no comprehension question that probed its interpretation followed each sentence (experimental materials can be found at the first author's website). Participants were instructed to read sentences at a natural pace and to respond to the comprehension questions as accurately as possible. Participants responded to questions using the f-key for "yes" and the j-key for "no." If the question was answered incorrectly the word *galat* ("incorrect/wrong") appeared briefly in the center of the screen. Each participant was randomly assigned to one of the lists and the order of the stimuli within the presentation list was randomized for each participant.

ANALYSIS

Data from one participant were excluded due to failure to comply with experimental guidelines. Data from another participant were excluded because the participant's mean accuracy on comprehension questions was close to chance. This resulted in the data of 30 subjects being used for later analysis. Two items were excluded from analysis due to errors.

Statistical analyses were carried out on log-transformed reading times using linear mixed effects regression (Baayen et al., 2008). Reading times from both correct and incorrect trials were included in the analysis. Experimental fixed effects were the simple difference sum-coded factors GRAMMATICALITY and INTERFERENCE and their interaction. All models included random intercepts for both subjects and items. Models with a maximal random effects structure were fit whenever possible (Barr et al., 2013). If a maximal model failed to converge, a model was used that contained only by-subject random slopes for both fixed effects and their interaction.

RESULTS

Comprehension Question Accuracy

Comprehension question accuracy averaged 69.2%. No significant differences were found in average accuracy across conditions (logistic mixed effects model, all zs < 1).

Reading Time Results

Reading times from the post-reciprocal region are given in **Figure 2**.

Pre-reciprocal region. No significant effects were found in the pre-reciprocal region.

Reciprocal region. No significant effects were found in the reciprocal region.

Post-position region. Average reading times were reliably faster in the grammatical conditions than in the ungrammatical conditions (main effect of GRAMMATICALITY: $\hat{\beta} = -0.088$, s.e. $=$ 0.034, $t = -2.92$); see **Figure 3**. Although reading times in the *Ungrammatical-Interference* condition were numerically longer than those in the *Ungrammatical-NoInterference* condition, the GRAMMATICALITY $\times$ INTERFERENCE interaction was not significant ($t = 1.41$). No reliable pairwise differences were observed between ungrammatical conditions ($t < 1$).

Reciprocal+2 region. There were no significant main effects two regions after the critical reciprocal, but the model revealed a marginally significant GRAMMATICALITY $\times$ INTERFERENCE interaction ($\hat{\beta} = 0.105$, s.e. $= 0.054$, $t = 1.96$) two regions after the reciprocal. This interaction reflected the fact that the *Ungrammatical-Interference* condition was read more slowly than any other condition, including the *Ungrammatical-NoInterference* condition. The pairwise comparison between the two ungrammatical conditions revealed the numerical difference between the

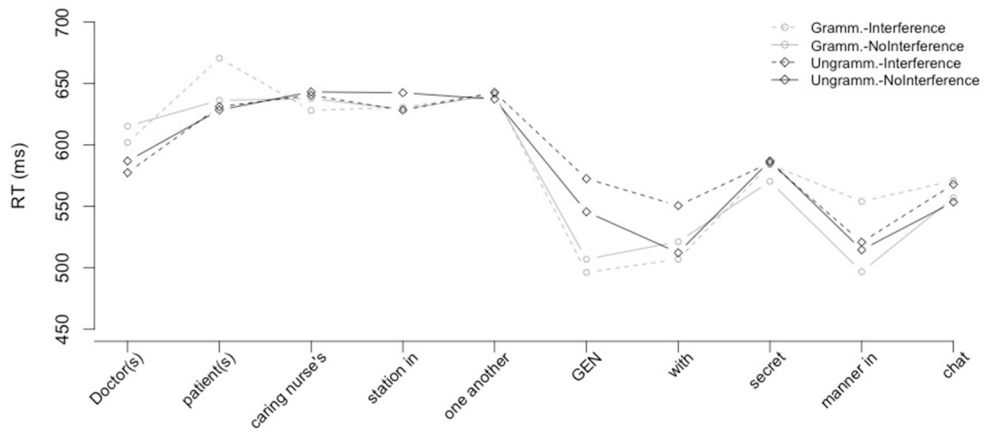

FIGURE 2 | Average word-by-word self-paced reading times for all items in Experiment 1.

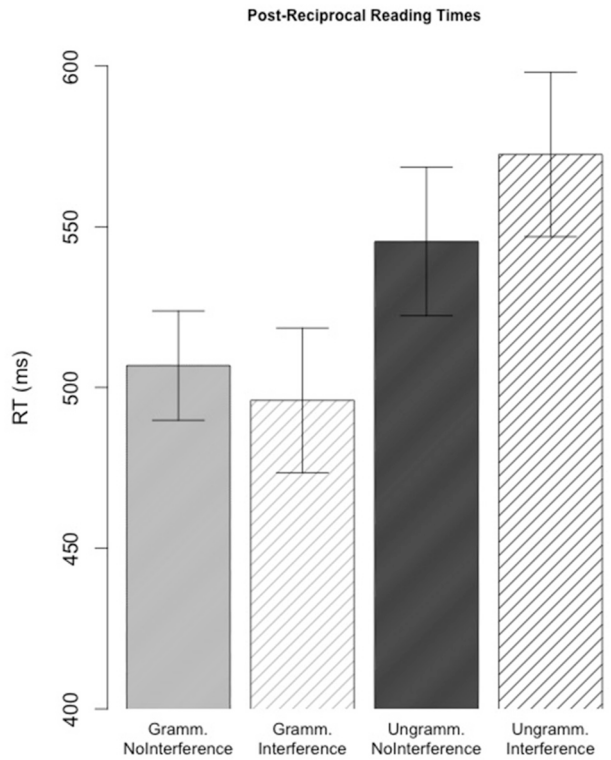

FIGURE 3 | Average post-reciprocal self-paced reading times in Experiment 1. Error bars indicate standard error of the participant mean.

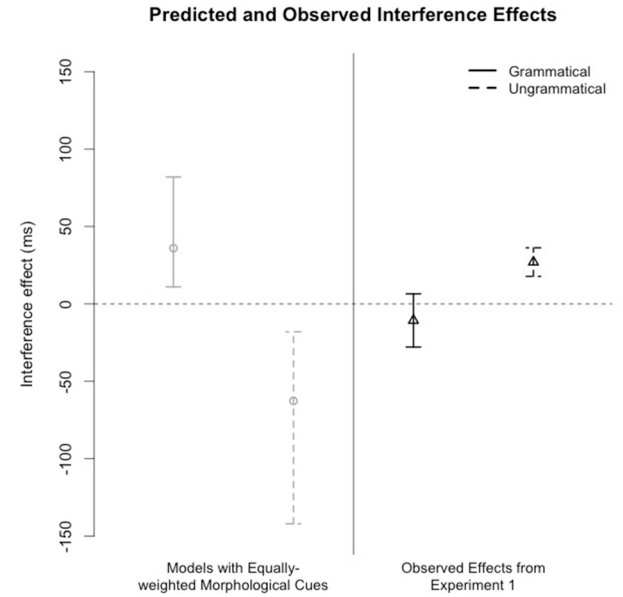

FIGURE 4 | Comparison of predicted interference effects from model simulations and observed interference effects from Experiment 1. Models simulated expected retrieval latencies if morphological and positional cues were assigned equal weights in antecedent retrieval. For the simulated data, error bars represent the middle 95% of the distribution of predicted interference effects. Error bars around the empirical means mark the 95% CI.

two conditions not to be significant ($t = 1.3$). However, given the relatively low power of the current study, it is possible that this interaction would achieve significance with higher power. We return to this interaction effect in the discussion.

Reciprocal+3 till Final region. No significant effects were observed in any subsequent region.

DISCUSSION

The SPR experiment sought to determine whether the processing of a pre-verbal reciprocal in Hindi was subject to facilitatory interference. The study manipulated the number features on a structurally appropriate antecedent for the reciprocal, as well as the features of the structurally inappropriate distractor, as a means of testing whether (equally weighted) morphological cues are used to access a local anaphor's antecedent.

When a structurally appropriate feature-matching antecedent was present to license the pre-verbal reciprocal the regions following the critical reciprocal were read more rapidly than when there was no feature-matching and structurally appropriate antecedent. In contrast to the prediction of the model simulations, we failed to find any evidence of facilitatory interference (see **Figure 4**). In fact, the empirical results trend in the opposite direction; there were clear inhibitory effects. The post-reciprocal region in the *Ungrammatical-Interference* condition was read at a comparable or slightly slower rate than the processing of the reciprocal in the *Ungrammatical-NoInterference* condition. Despite the fact that our study potentially lacks the power to observe an interference effect, we are more secure in our conclusion that there is a lack of facilitatory interference in light of the direction of the numerical trend toward an interaction in the post-reciprocal region.

Two words downstream from the reciprocal, reading times were longest when the local subject did not match the features of the reciprocal but the features of the distractor did match the reciprocal's number features.[2] We discuss this effect below because although it is inconsistent with the predictions of our simulations, it does potentially indicate that the distractor's morphological features may affect overall processing of the reciprocal.

The mechanism by which the distractor exerts inhibitory influence on reciprocal licensing is unclear. It is commonly assumed that inhibitory interference should occur when multiple items in memory match a retrieval cue (e.g., Badecker and Straub, 2002; Lewis and Vasishth, 2005; Van Dyke and McElree, 2011). Yet, we observed inhibition in the absence of a multiple-match configuration: the main subject matched the positional cue and the distractor matched the number cue. This suggests that the mechanism used to explain inhibition in multiple-match cases (e.g., the fan effect in Lewis and Vasishth's, 2005 model), is not the appropriate explanation for our finding. We consider three possible explanations of this inhibitory effect and the role

[2]We expect that this effect would be stronger with a larger sample.

that number features play in guiding initial retrieval under each scenario.

The first possible interpretation of the inhibitory effect links the slightly delayed slowdown to erroneous retrieval of the distractor during initial memory access. The increased reading times in our SPR experiment might reflect initial misretrieval of the distractor based on its morphological overlap with the probe, followed by the increased processing cost of inhibiting that distractor. This line of reasoning has been pursued by Patil et al. (2012) and Chen et al. (2012) to explain inhibitory effects in reflexive licensing. We consider this interpretation unlikely for the present data because we see no evidence of the erroneous retrieval on which the explanation is predicated. In light of subject-verb agreement and NPI licensing effects, we would expect initial misretrieval to result in some degree of facilitation, however fleeting, that would be observable in the self-paced reading times. These facilitatory interference effects consistently yield large effects on reading times in studies of other linguistic dependencies. No such facilitation was observed prior to the point of inhibitory interference in the current study.

The inhibitory effect might also be explained in terms of *cue-confusability*, as defined by Jäger et al. (2014). The proposal rests on the speculation that cues that reliably co-occur in specific retrieval contexts can be confused (less effectively deployed). In reciprocal licensing the clause and plural cues are reliably associated because both cues should be selected whenever a reciprocal is encountered. This contrasts with cue association in reflexive licensing where specific gender cues (e.g., masculine and feminine) and the clause-mate cue co-occur less reliably, e.g., it is not the case that reflexive licensing uniformly uses masculine gender. According to the proposal, confusion is more likely to occur in reciprocal licensing than in reflexive licensing. Although we note that this is a possibility in principle, we believe that the notion of cue-confusability or the mechanism by which confusion creates retrieval interference has not been sufficiently articulated to be thoroughly evaluated.

The third alternative interpretation of the effect connects the slowdown to the influence of an abandoned early garden-path parse that analyzed the distractor as a constituent of the main clause. The previous partial parse could provide an appropriately marked antecedent for the reciprocal, but would fail to provide a coherent global parse. There are no grammatical re-parses of the sentence that would allow the distractor to be reanalyzed as an appropriate antecedent for the reciprocal. We hypothesize that resolving the tension between attempting to license the reciprocal and building a globally grammatical parse of the sentence is the source of the observed interaction. The misparse is expected to intrude on the processing of the reciprocal in the *Ungrammatical-Interference* condition, where consideration of the reparse would result in a structurally appropriate, feature-matching antecedent for the reciprocal.

We favor the interpretation that this inhibitory effect reflects the influence of the mis-parse on repair strategies that are triggered by failure of initial antecedent retrieval (as proposed for similar effects by, Sturt, 2003; Chow et al., 2014). On this interpretation the failure to retrieve an appropriate antecedent for the reciprocal would initiate a more liberal search for a feature-matching phrase, or would attempt to find an alternative parse for the sentence under which the reciprocal could be grammatically bound. These repair procedures are argued to be less constrained by the structure of the previous parse (and therefore structural constraints), perhaps reflecting uncertainty in the structural analysis in light of the error signal. This scenario attributes the increase in reading times to interference, but not interference that occurs during antecedent retrieval. Rather, the locus of interference lies in retrievals associated with syntactic revision and reanalysis. It is also possible that the distractor in the mis-parsed sentence could contribute interference at retrieval time, a possibility that would be consistent with the numerical trend toward an interaction in the post-reciprocal region. We acknowledge that the present study cannot distinguish between these two options.

In sum, our SPR experiment failed to find the characteristic profile of facilitatory interference that has been found in other studies on the construction of subject-verb agreement, NPI-licensing, and control dependencies and is predicted under a cue-based retrieval model that uses morphological cues to access potential antecedents for a local anaphor. Instead, a feature-matching distractor triggered a delayed inhibitory effect when the local subject could not antecede the reciprocal in Hindi. We argued that this process was not an indication of interference during antecedent retrieval, but rather interference during a repair process subsequent to antecedent retrieval.

GENERAL DISCUSSION

The purpose of the present study was to assess whether syntactic cues are given priority over morphological cues in the retrieval of antecedents of pre-verbal reciprocals in Hindi. Investigating the processing of Hindi reciprocals helps to establish whether the absence of facilitatory interference effects from morphologically-matched distractors in previous experiments was due to a confound of anaphor position. We hypothesized that if the absence of interference were solely due to the post-verbal position of the anaphor, and not prioritization of syntactic cues, interference would be observable in the retrieval of an antecedent for a pre-verbal anaphor in Hindi.

In our self-paced reading study native Hindi speaking participants resolved a local reciprocal dependency more quickly when the main clause subject was plural than when no grammatical antecedent was present. The presence of a feature-matching distractor did not induce reliable effects of facilitatory interference when the local subject did not match the reciprocal in features. These findings are consistent with a general lack of facilitation in the licensing of local anaphors found in previous work (e.g., Sturt, 2003; Xiang et al., 2009; Dillon et al., 2013), and with lack of interference during local anaphor licensing more generally (e.g., Nicol and Swinney, 1989; Clackson, 2011). The presence of a feature-matching distractor produced a delayed inhibitory effect when an appropriate antecedent for the reciprocal could not be found. We reasoned that the inhibitory effect in our experiment might have arisen as a result of error-driven repair strategies, and not from participants accessing the distractor during initial antecedent retrieval.

The empirical results of our SPR experiment were compared against the results of a series of simulations that modeled latencies and error rates of a cue-based retrieval process that used equally-weighted morphological and positional cues to retrieve antecedents of a local anaphor. The empirical results did not align with the simulations' prediction that there should be facilitatory interference between ungrammatical conditions.

Overall, the results lend support to the hypothesis that the lack of facilitatory interference in local anaphor antecedent retrieval is not primarily determined by an anaphor's post-verbal position. In particular, the Hindi results appear to be incompatible with a number of the possible ways in which verbal adjacency could influence retrieval of antecedents for local anaphors discussed. The results cast doubt on explanations that rely on recent reactivation of the grammatical antecedent immediately before the reciprocal. In the Hindi materials there is no point at which retrieval of the subject is required between the distractor and when the reciprocal is encountered.

The results are consistent with models of cue-based antecedent retrieval that prioritize syntactic information in one manner or another. As noted in the introduction, a parser could be said to prioritize syntactic cues by assigning them greater weight than morphological cues, or by using syntactic cues exclusively.

Because some dependencies display facilitatory interference effects while others do not, it would appear that retrieval does not consistently prioritize positional cues. One question that arises is how the parser determines when it should prioritize syntactic cues. Rational models often assume that retrieval uses a set of cues and weights that maximizes the probability of retrieving the target, while minimizing the chances of interference. It is important to note that the optimal cue set for meeting both of these goals may change as a function of (i) the dependency being computed and (ii) the local syntactic context. Therefore, strategic considerations that take the local context into account may comprise an important part of the cue selection procedure. We term different solutions that the parser could adopt *retrieval strategies*.

The parser could adopt one of two strategies that make different use of morphological cues during local antecedent retrieval. First, the parser could uniformly prioritize syntactic cues for all instances of local antecedent retrieval regardless of syntactic context. Dillon et al. (2013) proposed that the parser implements such a retrieval strategy. According to these authors, local antecedent retrieval only uses structural cues.

An alternative to this proposal is that the parser could condition the use of morphological cues on the local syntactic context of the anaphor that triggers retrieval, as proposed by Kush (2013). The intuition behind this proposal stems from the observation that in certain environments structural cues alone may not suffice to identify a unique antecedent for a local anaphor. If the subject of the local clause is the anaphor's only co-argument, as it is in (15), then syntactic cues are sufficient to guarantee its retrieval. However, if there exists an additional co-argument that precedes the anaphor as in (16), a syntactic cue like the clause feature would not be able to distinguish the appropriate antecedent (*the boys*) from the structurally appropriate, but feature-mismatching NP *Mary*.

(15) *The boys* spoke with *each other*.
(16) Mary introduced *the boys* to *each other*

Kush (2013) proposed that a parser that could determine the number of clause-mates that preceded a local anaphor might use morphological cues to help guarantee retrieval of an appropriate antecedent. Determining whether the local subject is the anaphor's only clause-mate should be possible by consulting the local syntactic context. When processing English reflexives in direct object position, the anaphor's adjacency to the verb would be sufficient. In Hindi, verbal adjacency cannot be exploited to make such a determination. Kush (2013) proposed that the decision could be made if cue selection had access to the phrase structure rule being used to incrementally parse the input sentence. In cases where the anaphor is the first NP encountered during the incremental parse of the VP, the phrase structure predicted for the VP should not contain co-argument NPs. On the other hand, if the parser encounters a non-subject co-argument that precedes the reciprocal, the PS rule for the VP would reflect its presence and cue selection could determine that the clause index cue would no longer provide diagnostic access to the local subject.

If the parser adopts this retrieval strategy interference effects are predicted to emerge when there are non-subject clause-mates that precede a local anaphor. This proposal is consistent with recent findings from Wagers and colleagues, which suggest that that resistance to interference is, in fact, selectively conditioned on whether the anaphor is encountered after another co-argument (King et al., 2012). Under this interpretation, interference should emerge if a co-argument preceded the reciprocal in Hindi, as in (17). We leave testing this prediction to future work.

(17) *Larke-ne Mary-ko baccoN-ki party me ek-dusre ke-bare-me bataayaa.
Boy-Erg Mary-Acc kids' party in one-another about told.
*The boy told Mary during the kids' party about *each other*.

CONCLUSION

In this paper we asked whether the absence of intrusive licensing during local anaphor antecedent retrieval is restricted to post-verbal anaphors, or whether the lack of interference indicates a more general cross-linguistic state of affairs. We investigated the effect of a feature-matching distractor on the processing of unlicensed pre-verbal reciprocals in Hindi and found no indication of facilitatory interference. The results suggest that antecedent retrieval's ability to accesses the syntactically appropriate subject when licensing a local anaphor does not depend on direct verbal adjacency between the anaphor and its verb. The results appear to be better explained by a cue-based retrieval process that prioritizes, or exclusively uses, structural cues over morphological features. Finally, although we did not find evidence that a feature-matching distractor facilitates the processing of an unlicensed reciprocal, it did appear that a distractor might exert an inhibitory influence on some stage of reciprocal resolution. Future work should test whether this inhibition is a general effect, or whether its appearance is related to properties of the materials used here.

ACKNOWLEDGMENTS

The results from our SPR experiment were previously presented at the CUNY Sentence Processing and GLOW Conferences in 2012. We thank Usha Udaar, Karthik, Pritha Chandra and Ayesha Kidwai for their assistance in recruiting participants and providing space to run Experiment 1. We thank Ashok, Ambrish, and Manu Kush for helping to construct the materials for the SPR experiment. The code used for the simulations was generously provided by Rick Lewis. We thank Brian Dillon, Pedro Alcocer, and Dan Parker for their subsequent revisions and additions to this code. Shravan Vasishth and Umesh Patil also provided useful discussion. This work was supported by NSF IGERT DGE-0801465 to University of Maryland.

Two classes of account have been proposed to explain the memory processes subserving the processing of reflexive-antecedent dependencies. Structure-based accounts assume that the retrieval of the antecedent is guided by syntactic tree-configurational information without considering other kinds of information such as gender marking in the case of English reflexives. By contrast, unconstrained cue-based retrieval assumes that all available information is used for retrieving the antecedent. Similarity-based interference effects from structurally illicit distractors which match a non-structural retrieval cue have been interpreted as evidence favoring the unconstrained cue-based retrieval account since cue-based retrieval interference from structurally illicit distractors is incompatible with the structure-based account. However, it has been argued that the observed effects do not necessarily reflect interference occurring at the moment of retrieval but might equally well be accounted for by interference occurring already at the stage of encoding or maintaining the antecedent in memory, in which case they cannot be taken as evidence against the structure-based account. We present three experiments (self-paced reading and eye-tracking) on German reflexives and Swedish reflexive and pronominal possessives in which we pit the predictions of encoding interference and cue-based retrieval interference against each other. We could not find any indication that encoding interference affects the processing ease of the reflexive-antecedent dependency formation. Thus, there is no evidence that encoding interference might be the explanation for the interference effects observed in previous work. We therefore conclude that invoking encoding interference may not be a plausible way to reconcile interference effects with a structure-based account of reflexive processing.

1. Introduction

A central task the human sentence processing mechanism has to accomplish is to link two parts of a syntactic dependency, irrespective of how much linguistic material separates the two dependents. Many theories of sentence processing therefore assume that upon encountering the second dependent, the parser triggers a memory retrieval to access the first dependent in order to integrate it with the current node (Gibson, 2000; Lewis and Vasishth, 2005). Interference effects have recently come into focus in sentence processing research because they are taken to be

informative about the more precise nature of the retrieval mechanisms that subserve sentence processing. However, the relationship between empirically observed similarity-based interference effects and theories of retrieval is somewhat indirect, because there are multiple distinct mechanisms that could give rise to similarity-based interference effects in online processing. Indeed, whether or not the observation of interference effects can be interpreted as evidence favoring one or another account of sentence processing depends on the exact mechanisms causing the interference effects. In this article, we will present different mechanisms that have been proposed to account for interference effects in sentence comprehension and present three experiments with different methodologies and languages to tease them apart. We will first give an overview of two kinds of mechanisms, *cue-based retrieval interference* and *encoding interference*, which in the working memory literature have been proposed to underly similarity-based interference. Subsequently, we will turn to the implications for sentence processing and antecedent-retrieval in the processing of reflexives in particular.

Similarity-based interference has long been known to be a major cause of forgetting (Anderson and Neely, 1996). In memory models which represent items as bundles or vectors of features, similarity-based interference is assumed to arise as a function of the degree of overlap between an item's features with the features of other items in memory (Nairne, 1988, 1990; Anderson and Neely, 1996; Anderson and Lebiere, 1998; Anderson et al., 2004; Oberauer and Kliegl, 2006; Lewandowsky et al., 2008). However, the various memory models differ with respect to the mechanisms which they assume to underlie similarity-based interference. Generally speaking, one can distinguish between two kinds of similarity-based interference. On the one hand, similarity-based interference is assumed to affect the encoding or maintenance of an item (Nairne, 1988, 1990; Oberauer and Kliegl, 2006; Lewandowsky et al., 2008). We will refer to this proposal as *encoding interference*. On the other hand, similarity-based interference is assumed to arise during the retrieval of an item (Anderson and Neely, 1996; Anderson and Lebiere, 1998; Anderson et al., 1998, 2004; McElree, 2006; Oberauer and Kliegl, 2006). We will refer to this second proposal as *cue-based retrieval interference*.

Encoding interference is assumed to arise from the competition between the features of similar items that occurs at the moment of encoding or maintaining items in memory. Nairne (1990), for instance, proposed that whenever two items share a feature, they compete for this feature. In a certain proportion of cases, the memory representation of one of these items therefore loses this feature.[1] Hence, this item's memory representation becomes less distinct from other items and, as a result, retrieval probability decreases. An important, but subtle, point here is that even though encoding interference arises at the stage of encoding or maintaining an item in memory, it has an impact on the ease of this item's later *retrieval*. Oberauer and Kliegl (2006), who adopted Nairne (1990)'s concept of feature-overwriting, implemented the idea of an item's memory representation being degraded by decreasing this item's activation level. At the moment of later retrieval, this lower activation level leads to lower retrieval probability and a slow-down in processing times. In their model, the retrieval of an item from working memory is implemented as its gradual activation into the focus layer of the memory system. The processing speed of this gradual activation is defined as a function of this item's activation level prior to retrieval. Thus, if an item's activation level is decreased due to encoding interference from competitor items, a slow-down in the retrieval process is predicted. Note that Oberauer and Kliegl (2006) do not make any predictions about retrieval latencies. Their model is designed to explain data collected in speed-accuracy tradeoff experiments, where they experimentally controlled the time point when retrieval was supposed to happen. In their model, the slow-down in the retrieval process therefore is reflected in a higher proportion of retrieval failures rather than in increased retrieval latencies because participants are forced to interrupt the retrieval process after an experimentally defined time lag. Translating the Oberauer and Kliegl (2006) model to sentence processing, where the participant has more time to carry out retrieval, leads us to the assumption that the slow-down in the retrieval process is reflected in longer retrieval latencies. For the predictions of the experiments reported in this article, we will refer to encoding interference as implemented in the Oberauer and Kliegl (2006) model, with the additional assumption that a slow-down in the retrieval process leads to increased retrieval latencies. In sum, although encoding interference acts at the moment of encoding and maintenance rather than at retrieval, it indirectly affects the success and the speed of the retrieval process because it results in a representation that is more difficult to access.

Cue-based retrieval interference, in contrast, is assumed to arise due to cue-overload at the moment of retrieval. In a content-addressable memory architecture, cue-overload refers to a scenario when the cues used for retrieval do not point to a unique target, but rather match multiple items (Watkins and Watkins, 1975). This is assumed to lead to misretrievals of partially matching distractor items (Anderson and Lebiere, 1998; Anderson et al., 2004; McElree, 2006) and mutual inhibition between the distractors and the target resulting in a higher retrieval latency in case the target and the distractor have one or more retrieval relevant features in common (Anderson and Lebiere, 1998; Anderson et al., 2004).[2] To summarize, encoding interference is predicted to occur whenever items share features, no matter whether these features are used for retrieval or not. Cue-based retrieval interference, in contrast, is predicted to occur when more than one item matches the retrieval features. Inhibition between these items occurs only when they match the same retrieval features, otherwise cue-based retrieval interference

[1] Nairne (1990) did not use the term *encoding interference* but rather *feature-overwriting* to refer to his conception of interference.

[2] Note that the model proposed by McElree (2006) predicts that cue-based retrieval interference is reflected only in retrieval probability, not in retrieval latency. In contrast, the ACT-R architecture developed by Anderson and Lebiere (1998) and Anderson et al. (2004), on which the Lewis and Vasishth (2005) model of sentence processing is based, predicts retrieval interference to be reflected in both, retrieval probability and retrieval latency.

is reflected only in misretrievals (Anderson et al., 2004). Note that encoding interference and cue-based retrieval interference are not mutually exclusive concepts. Indeed, in Oberauer and Kliegl (2006)'s working memory model, both retrieval and encoding interference are assumed and the authors show that their interference model is indeed able to account for a large range of data.

In sentence processing research, early studies investigating interference effects point rather toward encoding than cue-based retrieval interference, but they were not designed to disentangle the two. For example, Gordon et al. (2002) conducted a self-paced reading experiment where participants held a set of nouns in memory while reading the target sentence. The authors report a slow-down in reading times when the noun type (common noun vs. proper name) of the memory load words matched the nouns in the sentence compared to when the memory load nouns and the nouns in the sentence were of different types. These results are further supported by Fedorenko et al. (2006), who also observed similarity-based interference in a memory-load paradigm. Gordon and colleagues report similar results for studies that manipulated similarity between sentence internal nouns rather than memory load (Gordon et al., 2001, 2004, 2006). An example item taken from Gordon et al. (2006) is shown in (1).

(1) **Interference/No interference**
The banker *that* ***the barber/Sophie*** *praised climbed the mountain . . .*

Since in all of these studies, similarity of the nouns was manipulated while the efficiency of the retrieval cues (i.e., the degree to which the retrieval cues uniquely identify the target) remained constant across experimental conditions, the data reported by Gordon and colleagues favor rather encoding than cue-based retrieval interference as an explanation. However, as Van Dyke and McElree (2006) noted, the above cited studies found interference effects only in the region where the critical noun phrase was retrieved (i.e., at the region containing the verb). This might indicate that the observed effect should rather be attributed to cue-based retrieval interference since encoding interference should also affect processing ease at the moment of encoding, i.e., at the moment when the second of the similar nouns is first being encountered. Van Dyke and McElree (2006) conducted a memory load experiment where, in contrast to the memory load experiments reported by Gordon et al. (2002) and Fedorenko et al. (2006), the memory load words were held constant across experimental conditions, but the retrieval cues at the verb were manipulated. The experimental items consisted of object-cleft sentences in which the main clause object preceded the main clause verb (the critical region where retrieval was triggered); for an example taken from Van Dyke and McElree (2006) see (2).

(2) **Interference/No interference**
It was the boat that the guy who lived by the sea ***sailed/ fixed*** *in two sunny days.*

Memory load: *table*, *sink*, *truck*

When the memory load words fit the semantic constraints of the verb, a slow-down in self-paced reading times was observed. These results cannot be attributed to encoding interference since the degree of similarity between the memory load words and the verb's object NP is constant across conditions. Van Dyke and McElree (2006)'s data are thus clear evidence for cue-based retrieval interference playing a role in sentence processing. However, note that the possibility that both retrieval and encoding interference affect sentence processing ease cannot be excluded by Van Dyke and McElree (2006)'s study since their data is clear evidence for cue-based retrieval interference but no evidence *against* encoding interference affecting sentence processing in general.

In recent years, interference effects in the processing of reflexive-antecedent dependencies have drawn considerable attention. The underlying research question was whether unconstrained cue-based retrieval, as proposed by Badecker and Straub (2002) and Patil, Vasishth, and Lewis (unpublished manuscript), or a structure-based access mechanism, as proposed by Nicol and Swinney (1989) and Sturt (2003), subserves the processing of reflexive-antecedent dependencies. Unconstrained cue-based retrieval assumes that all available cues are used to retrieve a reflexive's antecedent. Structure-based accounts, in contrast, assume that structural, i.e., syntactic tree-configurational, information guides the retrieval process. Interference effects in reflexive processing have been generally interpreted in terms of cue-based retrieval interference and taken as evidence for a cue-based retrieval mechanism since *retrieval* interference from syntactically inaccessible constituents is incompatible with the structure-based account. However, as pointed out by Dillon (2011) and Dillon et al. (2013), many of the observed effects—which we will describe more in detail below—can equally well be accounted for by *encoding* interference and hence are not necessarily incompatible with the structure-based account. Indeed, for the kind of materials commonly used to investigate the processing of reflexives (see 3; example taken from Sturt, 2003), encoding interference makes the same predictions for all experimental conditions as the unconstrained cue-based retrieval account implemented in the Lewis and Vasishth (2005) sentence processing model, which is based on the general cue-based architecture Adaptive Control of Thought-Rational (ACT-R) (Anderson and Lebiere, 1998; Anderson et al., 2004) and has been widely used for modeling the processing of reflexives (Dillon, 2011; Dillon et al., 2013; Parker and Phillips, 2014; Kush and Phillips, 2014; Jäger et al., 2015; Patil et al., unpublished manuscript).[3] Thus, for the question of structure-based vs. unconstrained cue-based retrieval in reflexives, it is crucial to disentangle encoding from cue-based retrieval interference. If evidence can be found showing that encoding interference plays a role in the type of materials generally used to investigate the processing of reflexives, this implies that the interference effects that have

[3]The Lewis and Vasishth (2005) model *per se* does not make any commitments with respect to the question which features are used as retrieval cues. Hence it is also possible to implement the structure-based account in this framework by restricting the set of retrieval cues to structural features.

been interpreted as evidence favoring unconstrained cue-based retrieval are equally well compatible with a structure-based account.

Studies investigating interference effects in the processing of reflexives mostly tested sentences in which the reflexive was bound by the local subject which c-commanded the reflexive (*surgeon* in Example 3; henceforth referred to as *antecedent*). We will express the antecedent's conformance to the structural requirements for binding the reflexive by attributing the feature {c-com:+} to it.[4] The interference manipulation was achieved by inserting another noun phrase in a structurally inaccessible position, i.e., not c-commanding the reflexive ({c-com:-}) and hence not qualifying as a binder for the reflexive (*Jonathan/Jennifer* in Example 3; henceforth referred to as *distractor*). A non-structural feature (e.g., gender or number in English reflexives) of this distractor was manipulated. Crucially, the feature which was manipulated might theoretically be used as a retrieval cue. For example, in the processing of English reflexives, the gender feature {gender:masc/fem} marked at the reflexive *himself* or *herself* might be used as a cue to retrieve the antecedent. Thus, if gender is used as a retrieval cue, a gender-matching distractor is predicted to cause cue-based retrieval interference as compared to a distractor which does not match the gender of the reflexive. Therefore, interference effects caused by a feature-matching distractor can be interpreted as evidence favoring an unconstrained cue-based retrieval account. If, in contrast, no effect of a feature-matching distractor is observed, this can be taken as evidence for a structure-based account. This experimental design (or a variation thereof) was used by a large number of studies which aimed to decide whether an unconstrained cue-based retrieval or a structure-based access underlies the processing of reflexive antecedent-dependencies (Nicol and Swinney, 1989; Badecker and Straub, 2002; Sturt, 2003; Xiang et al., 2009; Chen et al., 2012; King et al., 2012; Cunnings and Felser, 2013; Dillon et al., 2013; Clackson and Heyer, 2014; Kush and Phillips, 2014; Parker and Phillips, 2014; Jäger et al., 2015; Patil et al., unpublished manuscript). Some of the cited studies also manipulated feature-match of the structurally accessible antecedent (*surgeon* in Example 3).[5] An effect of antecedent match/mismatch can be accounted for by both unconstrained cue-based retrieval and structure-based accounts.

The results of the above cited studies are mixed. In antecedent-match conditions, increased processing difficulty due to the presence of a cue-matching distractor has been reported by Badecker and Straub (2002), Experiments 3, 4, Chen et al. (2012), Clackson and Heyer (2014), Jäger et al. (2015), Experiment 2, and Patil et al. (unpublished manuscript). By contrast, Sturt (2003), Experiment 1, and Cunnings and Felser (2013), Experiment 2 found a facilitation due to a cue-matching distractor. It should be noted that in Sturt (2003)'s experiment, the effect appeared only delayed and in Cunnings and Felser (2013)'s study, the interference effect was only observed in participants with low working-memory span. Importantly, in a large number of studies, no interference effect in antecedent-match conditions was observed (Nicol and Swinney, 1989; Badecker and Straub, 2002, Experiments 5, 6; Sturt, 2003, Experiment 2; King et al., 2012; Dillon et al., 2013; Kush and Phillips, 2014; Parker and Phillips, 2014; Jäger et al., 2015, Experiment 1). In antecedent-mismatch conditions, a significant processing speed-up due to a cue-matching distractor is reported by King et al. (2012) and Parker and Phillips (2014). The opposite direction of the effect was only observed in Jäger et al. (2015), Experiment 1. The absence of an effect in antecedent-mismatch conditions is reported by Sturt (2003), Xiang et al. (2009) and Dillon et al. (2013). For a literature review of interference effects in reflexives, see Jäger et al. (2015).

As mentioned above, unconstrained cue-based retrieval as implemented in the Lewis and Vasishth (2005) ACT-R model of sentence processing makes precisely the same predictions as encoding interference for sentences like the ones shown in (3). For conditions with a cue-matching antecedent (see 3a,b), the Lewis and Vasishth (2005) model predicts cue-based retrieval interference when the distractor matches the gender of the reflexive (3a). This retrieval interference is predicted to be reflected in inhibition between the antecedent and the distractor because in (3a), but not in (3b), the antecedent (*surgeon*) and the distractor (*Jonathan*) share the gender cue {gender:masc}. Thus, longer retrieval latencies (and hence longer reading times at the reflexive) are predicted in (3a) compared to (3b). Moreover, misretrievals of the partially cue-matching distractor (*Jonathan* in 3a) are predicted. These misretrievals are predicted to be reflected in response-accuracies if the comprehension questions target the reflexive-antecedent dependency. For conditions with a mismatching antecedent (see 3c, d), the unconstrained cue-based retrieval model (Lewis and Vasishth, 2005) also predicts cue-based retrieval interference due to a cue-matching distractor (3c). As in antecedent-match conditions, this retrieval interference is

[4]It should be noted that using {c-com:+} as a feature is a simplification since a tree-configurational relation is not as straightforward to code as a feature of an item as, e.g., gender or number. For a discussion of how tree-configurational information such as c-command could be encoded as an item's feature see Alcocer and Phillips (unpublished manuscript). On a theoretical basis, Kush (2013) argues against the representation of c-command as a feature and discusses how, in online sentence processing, the human parser might distinguish between c-commanding and non-c-commanding antecedents.

[5]In some experiments, only the stereotypical gender of the accessible antecedent was violated (as in 3c,d), whereas in other studies, real feature violations were used resulting in ungrammatical sentences in the antecedent-mismatch conditions.

predicted to be reflected in a higher proportion of misretrievals of the matching distractor. But, in contrast to antecedent-match conditions, no inhibition between the antecedent and the distractor is predicted because they do not share any of the experimentally manipulated retrieval relevant features (in 3c and d, the antecedent and the distractor neither share the gender cue {gender:fem} nor the structural cue {c-com:+}). Since ACT-R predicts faster retrieval latencies in the case of misretrievals as a result of a race-like configuration, the trials with misretrievals are predicted to lead to a decreased mean retrieval latency. Therefore, in the absence of inhibition between the distractor and the antecedent in antecedent-mismatch conditions, faster processing times are predicted when a feature-matching distractor is present.

Encoding interference predicts increased retrieval latencies and a higher proportion of misretrievals as a function of the number of features the target (here the antecedent) shares with other items in memory (Oberauer and Kliegl, 2006).[6] Thus, in conditions with a matching antecedent (see 3a,b), a slow-down and a higher proportion of misretrievals due to a feature-matching distractor (3a) is expected. By contrast, in conditions with a mismatching antecedent (see 3c,d), a slow-down and a higher proportion of misretrievals due to a *feature-mismatching* distractor (3d) is predicted since the mismatching antecedent and the mismatching distractor have the same gender feature {gender:masc}.[7]

To summarize, for materials as the ones presented in (3), both encoding interference and cue-based retrieval interference predict that a matching distractor leads to a processing slow-down in antecedent-match conditions and to a speed-up in antecedent-mismatch conditions. For online reading time measures, both accounts thus make precisely the same predictions and can account for the inhibitory effects in antecedent-match conditions reported by Badecker and Straub (2002), Chen et al. (2012), Clackson and Heyer (2014), Jäger et al. (2015) and Patil et al. (unpublished manuscript) as well as for the facilitatory effects in antecedent-mismatch conditions reported by King et al. (2012) and Parker and Phillips (2014). For retrieval probabilities (to be reflected in response accuracies of adequate comprehension questions), both accounts also make the same predictions for antecedent-match conditions but differ in their predictions for antecedent-mismatch conditions. Hence, if online evidence for encoding interference in reflexives can be found, we need to reconsider the theoretical implications of interference effects in reflexives with respect to the debate about structurally-guided vs. unconstrained cue-based retrieval. In the following, we present two experiments on German and one experiment on Swedish designed to disentangle encoding from cue-based retrieval interference.

[6]To be precise, the number of distractors sharing a certain feature with the target also affects retrieval latencies and retrieval probability because the more distractors share this feature with the target, the higher the probability that one of these distractors "robs" this feature from the memory representation of the target.

[7]Because we set out to determine whether invoking encoding interference is a way to reconcile interference effects with structure-based retrieval, for the predictions of encoding interference we are assuming that only structural retrieval cues are used. If, by contrast, one assumes that gender is used as a retrieval cue, the feature matching distractor (3c) is predicted to be misretrieved more often than the feature mismatching distractor (3d). This prediction is orthogonal to the question of encoding interference, but follows from the basic assumption that an item's retrieval probability depends on its features' match with the retrieval cues. This basic assumption is shared by models of encoding interference (Nairne, 1990; Oberauer and Kliegl, 2006). (Note that this point is unrelated to the cue-based retrieval interference component in the Oberauer and Kliegl, 2006 model which is assumed to cause inhibition between items sharing the same retrieval cues.)

2. Experiment 1: German Reflexives (Self-Paced Reading)

The German reflexive *sich* "himself"/"herself" is an interesting test case for teasing apart encoding from cue-based retrieval interference. The third-person singular reflexive *sich* is gender neutral and, roughly speaking, requires its antecedent to be a c-commanding noun phrase contained in the reflexive's local clause. For more details about the syntactic properties of German reflexives see Everaert (1986), Reinhart and Reuland (1993), Reuland and Reinhart (1995), Reuland (2001), Gast and Haas (2008) and Reuland (2011). Since *sich* is gender neutral and thus gender can be assumed to not be used as a retrieval cue, we do not expect any cue-based retrieval interference from a structurally inaccessible distractor that shares its gender with the antecedent. Encoding interference, in contrast, predicts that a distractor of the same gender as the antecedent leads to a degradation of the antecedent's memory representation resulting in longer processing times when retrieving the antecedent upon encountering the reflexive. Moreover, encoding interference predicts a lower retrieval probability of the antecedent when a gender-sharing distractor is present. We will use the term *gender-overlap* to refer to the situation where the antecedent and the distractor share their gender in order to reserve the term *gender-match* for the match of an item's feature with a retrieval cue as in Example (3) discussed above.

2.1. Materials and Method

2.1.1. Materials

The experimental items consist of a matrix clause whose subject is the antecedent of the third person singular reflexive *sich* (see 4 for an example). The reflexive is the first constituent of a conjoint determiner phrase (*sich und die Kollegen* in 4) which as a whole is the direct object of the matrix verb. The antecedent (*der Dieb/die Diebin* in 4) is modified by an object-extracted relative clause that intervenes between the antecedent and the reflexive. The subject of this relative clause (*der Hehler/die Hehlerin* in 4) does not c-command the reflexive and hence syntactically disqualifies as antecedent. We will refer to this noun phrase as *distractor*. Both the antecedent and the distractor were always animate common nouns with a definite article. King et al. (2012) have shown that interference effects in reflexives are more likely to be detected when the verb, which triggers the retrieval of its subject—which, in turn, is also the reflexive's antecedent—does not directly precede the reflexive. In order to increase the chances of detecting an effect, we chose perfective tense for our materials, because, as opposed to present tense or simple past,

the reflexive precedes the main verb in perfective sentences (for another study on interference effects using pre-verbal reflexives see Kush and Phillips, 2014). Moreover, we inserted a relatively long adverb between the perfective auxiliary *hat* and the reflexive. As in the classical gender-match/mismatch design, we manipulated the antecedent's and the distractor's gender. This resulted in a fully crossed 2 × 2 design with gender of the antecedent (masculine vs. feminine) and interference (gender-overlap vs. no gender-overlap between the distractor and the antecedent) as factors. For our research question, the gender manipulation of the antecedent was not of interest *per se*. It was included in order to experimentally control for lexical properties such as word length or frequency which, due to the nature of the German language, are inseparable from the gender manipulation. We will discuss this issue more in detail in the Results section.

(4) **Masc/Fem antecedent; Masc/Fem distractor**

Der Dieb$_i$***/Die Diebin***$_i$,	*dem/der*	***der Hehler***$_j$***/die Hehlerin***$_j$		*befohlen*	*hat*	*zu*	*stehlen,*	*hat*		
the thief-MASC/the thief-FEM	whom	**the dealer-MASC/the dealer-FEM**		obliged	has	to	steal	has		
überraschenderweise	***sich***$_{i/*j}$	*und*	*die*	*Kollegen*	*angezeigt,*	*berichtete*	*das*	*Hochglanzmagazin.*		
surprisingly	**self**	and	the	colleagues	denounced	reported	the	magazine		

'The thief whom the dealer obliged to steal surprisingly denounced himself/herself and the colleagues, reported the magazine.'

Each sentence was followed by a *yes/no* comprehension question targeting the reflexive-antecedent dependency. One half of the comprehension questions tested whether the antecedent was retrieved successfully (to be answered with *yes*) and the other half tested whether the distractor was misretrieved instead (to be answered with *no*). Question types were balanced across items and held constant within the four conditions of each item.

2.1.2. Participants and Procedure

144 undergraduate students from the University of Potsdam who were all native speakers of German participated in the study for credit or payment of 5 EUR. We chose a relatively large sample size in order to increase statistical power, i.e., reduce Type II error probability. For our research question, high statistical power is particularly important since if encoding interference in the processing of reflexives is absent, a null result is predicted. The number of participants was determined based on a statistical power test assuming an effect of 20 ms and a standard deviation of 75 ms. In order to achieve power of 90%, 149 participants would be needed. Due to the restricted nature of our participant pool, the actual sample size was slightly smaller, which yielded a statistical power of 0.89%. 16 test items and 32 filler sentences were presented in a moving-window self-paced reading paradigm (Just et al., 1982). Items were arranged according to a Latin Square with a different randomization for each participant. Each trial was followed by a *yes/no* comprehension question.

2.2. Results

Statistical analyses were carried out in GNU-R (R Development Core Team, 2011) using linear mixed effects models provided by the lme4 package version 1.0-6 (Bates et al., 2014). Binary dependent variables were modeled using generalized linear mixed models with a logistic link function. For the analyses of comprehension questions and reading times, we fit models testing for a main effect of gender of the antecedent, a main effect of interference (i.e., effect of whether or not the distractor overlapped in gender with the antecedent) and an interaction between the two. All models were fit with random intercepts and slopes for participants and items (Baayen et al., 2008). No correlations between random effects were estimated since in many of the models the correlation matrix of random effects was degenerate.

In German, the feminine form of a noun is usually generated by adding the suffix *-in* and in many nouns, the masculine form is more frequent than the feminine one. Therefore, a correlation between gender and word length and word frequency could not be avoided in the stimuli. More precisely, correlations between the main effect of gender and frequency/length of the antecedent as well as correlations between the interaction antecedent gender × interference and frequency/length of the distractor are expected. Crucially, including the gender manipulation of the antecedent as a fully crossed within-items factor in our design ensured a zero correlation between frequency/length of the antecedent or the distractor with the critical main effect of interference. Along the same lines, correlations between frequency/length of the antecedent and the interaction antecedent gender × interference as well as correlations between frequency/length of the distractor and the main effect of gender of the antecedent cancel out due to the fully-crossed factorial design. To test these assumptions and to obtain estimates for the expected correlations, we computed Pearson-correlations of each of the contrasts to be tested in the linear-mixed model with centered word lengths measured in number of characters and centered log-transformed lemma frequencies taken from dlexDB[8] (Heister et al., 2011) of the antecedent and the distractor (see **Table 1**). As expected, there was a positive correlation ($r = 0.63$) between the main effect of gender of the antecedent and frequency of the antecedent and a negative correlation ($r = -0.44$) between the main effect of gender of the antecedent and word length of the antecedent.

TABLE 1 | Experiments 1 and 2.

	Length antecedent	Frequency antecedent	Length distractor	Frequency distractor
Interference	0	0	0	0
Gender antecedent	−0.44	0.63	0	0
Gender ant. × Interf.	0	0	−0.24	0.39

Correlations (Pearson correlation coefficient) of word length and log lemma frequency of the antecedent and the distractor with the experimental manipulations (main effect of interference, main effect of gender of the antecedent and their interaction). Word length and log lemma frequencies were centered (z-scores).

TABLE 2 | Experiment 1.

Condition	Accuracy
Gender-overlap - masculine antecedent	71
Gender-overlap - feminine antecedent	73
No gender-overlap - masculine antecedent	75
No gender-overlap - feminine antecedent	77

Mean accuracy scores of question responses in percentage by experimental condition.

Similarly, there was a positive correlation ($r = 0.39$) between the frequency of the distractor and the interaction antecedent gender × interference and a small negative correlation between word length of the distractor and the interaction antecedent gender × interference. Thus, a main effect of gender of the antecedent and the interaction between the two main effects should not be interpreted since they might be confounded with the effects of antecedent/distractor length and frequency.

2.2.1. Comprehension Questions

Comprehension question response accuracies were analyzed using a linear mixed model with a logistic link function. Mean accuracy scores of question responses are provided in **Table 2**. Statistical analyses revealed a main effect of interference: accuracy was lower in conditions with a gender-sharing distractor (estimate $= -0.25$, $SE = 0.12$, $z = -2.02$, $p < 0.05$). Neither the main effect of gender nor the interaction were significant.

2.2.2. Reading Times

An overview of raw reading times for each region of the sentence is provided in **Table A1** in the Appendix. Reading times were analyzed at the reflexive, the following NP together with the preceding conjunction *und* "and" (n+1), the main clause verb (n+2) as well as at the two words preceding the reflexive as a sanity test of the baseline reading times. In order to achieve a close to normal distribution of the model residuals, we analyzed negative reciprocal reading times (Box and Cox, 1964). None of the comparisons reached significance at any region. Modeling log-transformed RTs instead of reciprocal RTs yielded similar results. The output of the linear-mixed models is provided in **Table 3**.

2.3. Discussion

In reading times, we did not find any effect of gender-overlap between the antecedent and the distractor. However, in comprehension questions, we observed lower response accuracies when the distractor overlapped in gender with the antecedent. This effect might be explained by misretrievals due to encoding interference during online processing which, critically, did not affect processing times. Alternatively, the lower response accuracies in the gender-overlap conditions might reflect an offline effect that arises at the moment of answering the comprehension question. Crucially for our research question, we could not find any evidence supporting the idea that encoding interference affects online processing times at the reflexive. With respect to previous studies on reflexives, we can therefore conclude that there is no indication that the interference effects observed in previous studies reflect encoding rather than cue-based retrieval interference.

3. Experiment 2: German Reflexives (Eye-Tracking)

Experiment 2 is a cross-methodological replication of Experiment 1. Already Ronald Fisher, the father of frequentist statistics, emphasized the importance of replication (Fisher, 1937, page 16). Indeed, non-replicable findings are a major problem in experimental psychology and psycholinguistics (Simmons et al., 2011; Asendorpf et al., 2013). Moreover, a potential concern about Experiment 1 is that our conclusions are based on a null result. Although we have addressed this issue by testing a large sample and thus gaining high statistical power, one could still argue that the self-paced reading method is not sensitive enough to detect a potential effect. We therefore tested the same materials as in Experiment 1 in an eye-tracking while reading paradigm, which presumably is a more sensitive method compared to self-paced reading (Staub and Rayner, 2007).

3.1. Materials and Method

3.1.1. Materials

The same stimuli (including fillers) were used as in Experiment 1.

3.1.2. Participants and Procedure

151 undergraduate students from the University of Potsdam with normal or corrected-to-normal vision who were all native speakers of German participated in the experiment against credit or payment of 7 EUR. None of the participants had participated in Experiment 1.

Participants' eye movements (right eye monocular tracking) were recorded with an SR Research Eyelink 1000 eyetracker at a sampling rate of 1000 Hz using a desktop mount camera system with a 35 mm lens. The participant was seated at a height-adjustable table with his/her head stabilized using a forehead/chin-rest. Stimuli were presented on a 22 inch monitor (resolution of 1680 × 1050 pixels) with an eye-to-screen distance of 62 cm and an eye-to-camera distance of 60 cm. As a response pad, a Microsoft Button Box was used. Stimuli were presented using Experiment Builder software provided by SR Research. The experimental items were presented on a light gray background

No gender-overlap - feminine antecedent	75

Mean accuracy scores of question responses in percentage by experimental condition.

in black font, font type Times New Roman, font size 14. They were arranged according to a Latin Square and were pseudo-randomized for each participant separately such that every experimental trial was preceded by at least one filler sentence. A nine-point calibration was carried out at the beginning of the experiment and repeated during the experiment, if needed. Each experimental session started with 6 practice trials. At the beginning of each trial, participants had to fixate a drift correction point at the left center of the screen where the first word of the sentence was to appear.

3.2. Results

Linear mixed-effects models were fit with the same predictors as for Experiment 1. As in the analysis of Experiment 1, all models were fit with varying intercepts and slopes for participants and items. No correlations between random effects were estimated since, as in the data of Experiment 1, the correlation matrix of random effects was degenerate in many of the models.

3.2.1. Comprehension Questions

Mean accuracy scores by experimental condition are provided in **Table 4**. We observed a marginal main effect of interference with lower accuracies in conditions where antecedent and distractor had the same gender (estimate $= -0.20$, $SE = 0.10$, $z = -1.95$, $p = 0.05$). This replicates the pattern found in Experiment 1. None of the other effects was significant.

3.2.2. Eye Movements

An overview of raw reading times at each word of the sentence is provided in **Table A2** in the Appendix. The same regions were analyzed as in Experiment 1. Raw fixation durations shorter than 20 ms or longer than 1000 ms (0.25% of the data) were excluded from all analyses. In eye-tracking data, the dependent measures can be partitioned into first-pass, regression-related (proportions of regressions and duration of regressive events) and later-pass measures. Since the exact mapping between syntactic effects and eye-tracking measures is still unclear (Clifton et al., 2007), we analyzed one representative measure from each group. As a first-pass measure, we analyzed first-pass reading time (FPRT, also referred to as gaze duration), which is defined as the sum of all first-pass fixations on a region. As regression related measures, we analyzed first-pass regression-probability (FPRP), i.e., a binary variable coded as 1 if a first-pass regression was initiated from a region, and regression-path duration (RPD), i.e., the sum of all fixation durations starting from the first fixation on a region until leaving this region to the right including all regressive fixations that fall into this time window. As a later-pass measure, we analyzed total-fixation time (TFT), i.e., the sum of all fixations on a region. Strictly speaking, TFT is not a pure late measure but rather the sum of FPRT and re-reading time. However, we chose to report TFT as a representative late measure since TFT is one of the most commonly reported measures in psycholinguistics; we do not analyze re-reading time because the critical region was re-read in only about 20% of the trials leading to very low statistical power. In order to achieve approximately normally distributed residuals, the continuous dependent variables were log-transformed (Box and Cox, 1964).

An overview of the output of the linear mixed-effects models is provided in **Table 5**. At the reflexive (n), the word preceding the reflexive and the region following the reflexive, none of the comparisons reached significance in any of the dependent variables. At region n+2 (i.e., the main clause verb), a significant effect of gender of the antecedent was observed in TFT (longer fixation times in conditions with a feminine antecedent). However, as we have argued in the Results section of Experiment 1, this effect should not be interpreted since it correlates with frequency and length of the antecedent. For our research question, only the main effect of interference is relevant.

Moreover, a *post-hoc* analysis of the region containing the relative clause verb (*zu stehlen* in Example 4) revealed a significant main effect of interference in TFT with longer fixation durations when the antecedent and the distractor overlapped in gender (estimate $= 0.05$, $SE = 0.02$, $t = 2.28$).

3.3. Discussion

Experiment 2 replicated the findings of Experiment 1. As in Experiment 1, no evidence for encoding interference due to gender-overlap between the reflexive's antecedent and a

Main effects of interference and gender of the antecedent and their interaction on the dependent variables log-first-pass reading time, log-regression-path duration, first-pass regression probability and log-total fixation time measured at the adverb preceding the reflexive (n−1), the reflexive (REFL), the coordinate NP following the reflexive (n+1) and the main clause verb (n+2). Statistically significant ($\alpha = 0.05$) effects are marked with an asterisk.

structurally inaccessible distractor was observed neither at the reflexive, nor at the pre- or post-critical regions.

At the relative clause verb, however, gender-overlap between the main clause subject, i.e., the antecedent, and the relative clause subject, i.e., the distractor, led to significantly longer total-fixation times. At this region, the relative clause subject needs to be retrieved. Hence, the observed effect, which appears in a similar region as the effects reported by Gordon et al. (2001), might reflect encoding interference. However, it is disconcerting that this effect was observed only in total-fixation time and was not present in Experiment 1, as a *post-hoc* analysis of the self-paced reading data showed. Thus, one might discount this effect as a possible Type I error. If one does not discount the effect, it raises the question why encoding interference affects argument-head dependency completion, but not reflexive-antecedent dependency formation. A possible explanation might be that the encoding interference effect (to the extent that it is not a Type I error) dies out by the time the reflexive is processed.[9] In any case, further replication attempts of this configuration are needed. In sum, it is possible that we are seeing encoding interference at the distractor, but, which is crucial for our research question, this encoding interference does not seem to have any effect at the reflexive.

Taken together, the results of Experiments 1 and 2 are a strong indication that in reflexive-antecedent dependency formation, the sharing of a non-structural feature such as gender does not lead to encoding interference reflected in a processing slow-down. More precisely, it indicates that in materials of the type used in this experiment, encoding interference does not affect retrieval latencies of the antecedent when processing the reflexive. However, the marginal interference effect in offline comprehension accuracies, which had been significant in Experiment 1, indicates that the antecedent was retrieved less often correctly when it shared its gender with the distractor. This can be interpreted as evidence for encoding interference affecting retrieval probability of the antecedent. In sum, neither experiment provides any evidence for the claim that encoding interference affects reading time at the reflexive. However, our offline results suggest that encoding interference might affect retrieval probability of the antecedent. Crucially, even if encoding interference affected retrieval probability of the antecedent or the offline interpretation of the sentence, there is no evidence that it affects the participants' online behavior at the reflexive measured in self-paced reading times or eye-movements. Hence, encoding interference is not a plausible explanation for the *online* effects previous studies have observed in eye-tracking or self-paced reading measures.

4. Experiment 3: Swedish Possessives (Eye-Tracking)

Experiments 1 and 2 yielded converging results: we found no evidence for encoding interference affecting the online processing speed of German reflexives. However, there are still two potential concerns with these results: (i) Our conclusion is based on two null-results, and (ii) we need to cross-linguistically validate our conclusion. In Experiment 3, we addressed these issues by examining the processing of Swedish possessives in an eye-tracking experiment. In

[9]A reviewer noticed that the effect at the relative clause verb occurs in total-fixation time, a measure which can reflect processing difficulty encountered further downstream in the sentence, and therefore might actually reflect processing difficulties at the reflexive which triggers re-readings of the previous materials. However, if this were the case, one would expect an increase in the proportion of regressions or increased regression-path durations at the reflexive. As this is not the case, it is difficult to conclude that the effect observed at the verb reflects processing difficulty associated with the reflexive.

Swedish, there are two kinds of possessives: reflexive possessives that are not gender-marked and pronominal possessives that need to agree in gender with their antecedent. The reflexive possessive *sin* "his"/"her" can only be bound by a c-commanding antecedent inside its local clause. In contrast, the pronominal possessive *hans* "his" must not be bound within its local clause, but requires an antecedent outside its clause domain (see Holmes and Hinchliffe, 1994 and Kaiser, 2003, p. 209). In a 2 × 2 factorial design, we manipulated anaphor type (pronominal possessive vs. reflexive possessive) and interference, i.e., whether or not a structurally inaccessible distractor shared the gender of the antecedent. For this design, encoding interference predicts increased processing difficulty in the gender-overlap conditions compared to the no-gender-overlap conditions, regardless of anaphor type. Cue-based retrieval interference, in contrast, predicts an interaction between anaphor type and interference: increased processing difficulty due to a gender-sharing distractor is predicted for the gender-marked pronominal possessives but not for the gender-unmarked reflexive possessives. This is because only in pronominal possessives, the gender-marked anaphor can trigger a retrieval process where gender is used as a retrieval cue. When both the antecedent and the distractor match the gender cue, cue-based retrieval interference predicts inhibition between the antecedent and distractor and a higher proportion of misretrievals of the distractor (Lewis and Vasishth, 2005). Thus, the present experiment allows us to directly pit encoding and cue-based retrieval interference against each other. In contrast to Experiments 1 and 2, cue-based retrieval interference predicts an interaction rather than a null-result.

(5) a. **Pronominal possessives; gender-overlap/no gender-overlap**

'Åke, whom Alf/Ann thanked, calls his cousins in the evening.'

4.1. Materials and Method

4.1.1. Materials

The conditions with pronominal possessives (see 5a for an example item) consist of a superordinate clause whose subject is the antecedent (*Åke* in 5a) and a subordinate clause containing the distractor (*Alf* or *Ann* in 5a) which either matches or mismatches the gender of the antecedent and the gender-marked pronominal possessive (*hans* "his" in 5a). The conditions with reflexive possessives (see 5b for an example item) consist of a main clause containing the antecedent (*Åke* in 5b) and the gender-unmarked reflexive possessive (*sina* "his"/"her" in 5b). The distractor (*Alf* or *Ann* in 5b) is the subject of an appositive relative clause intervening between the antecedent and the reflexive possessive. As Swedish does not code masculine and feminine as grammatical gender, and the number of nouns with inherent gender such as *boy* or *girl* is very limited, both the antecedent and the distractor were proper names in all experimental sentences. Indeed, it is crucial for our research question to extend the findings of Experiments 1 and 2 to proper names, which differ from common nouns with respect to their referential properties (Longobardi, 1994; Elbourne, 2005), since several of the studies reporting interference effects in reflexives actually employed proper names (e.g., Badecker and Straub, 2002).

The nouns used as antecedents and distractors are all highly frequent, gender unambiguous Swedish first names taken from Statistics Sweden, a database which contains the 100 most frequently given and used male and female first names in Sweden.[10] Antecedents and distractors are all matched for word length (numbers of characters) within each item. Half of the items have a feminine antecedent and the other half a masculine antecedent. The possessed noun phrase (*sysslingar* in 5) is always a plural noun.

Two types of comprehension questions were designed. The first type probed for the correct interpretation of the anaphor-antecedent dependency. 50% of these questions were to be answered with *yes*. The second question type targeted various parts of the sentence, but not the interpretation of the anaphor. Again, 50% of these questions were to be answered with *yes*.

4.1.2. Participants and Procedure

35 native speakers of Swedish currently living in Berlin or Potsdam with normal or corrected-to-normal vision participated in the experiment against payment of 5 EUR (plus 6.20 EUR to cover travel expenses). The sample size was smaller compared to Experiments 1 and 2 due to logistic limitations, but we tested a larger number of experimental items compared to Experiments 1 and 2. Participants' eye movements (right eye monocular tracking) were recorded while reading 48 experimental sentences

[10] http://www.scb.se/BE0001-EN; we used the data of 2012.

and 70 filler sentences. The general technical set-up was the same as in Experiment 2. Stimuli were arranged in a Latin Square and pseudo-randomized such that each experimental trial was preceded by at least one filler sentence. Each trial was followed by a comprehension question. Two thirds of the comprehension questions targeted the correct interpretation of the anaphor and one third targeted other parts of the sentence. The experiment started with 5 practice trials to familiarize participants with the procedure.

4.2. Results

On all dependent variables, we fit linear mixed-effects models with main effects of anaphor type (pronominal vs. reflexive possessive), interference (whether or not the distractor had the same gender as the antecedent) and their interaction as predictors. When the interaction reached significance, nested contrasts testing for an interference effect within each anaphor type were fit. All models were fit with varying intercepts for participants and items. No varying slopes were fit because the generalized likelihood-ratio test showed that they did not improve the model fit. The pattern of results was not affected by whether or not varying slopes were fit. For the interpretation of results, it should be kept in mind that the effect of anaphor type is not of theoretical relevance to our research question. As the two levels of anaphor type differ lexically at the pre-critical and the critical region, a main effect of anaphor type does not have any useful interpretation.

4.2.1. Comprehension Questions

Mean accuracy scores by experimental condition and question type (i.e., whether or not the comprehension question targeted the anaphor) are provided in **Table 6**. We ran a linear-mixed effects model with a logistic link function with main effects of anaphor type, interference and question type and their interactions including the three-way interaction between all main effects as predictors. The model output is summarized in **Table 7**. The main effect of interference and the interaction between interference and question type reached significance. Moreover, a marginal three-way interaction between interference, anaphor type and question type was observed. A second model in which we applied nested contrasts testing for an interference effect within each level of anaphor type and question type[11] showed that the interactions were caused by a highly significant interference effect that was present only in questions targeting the anaphor in pronominal possessives (estimate $= -1.16$, $SE = 0.25$, $z = -4.62$, $p < 0.0001$). In sum, in questions targeting the anaphor-antecedent dependency, the presence of a gender matching distractor led to lower response accuracies in sentences with pronominal possessives but not in sentences with reflexive possessives. In questions not targeting the anaphor-antecedent dependency, no effects were observed.

TABLE 6 | Experiment 3.

Condition	Accuracy	
	Anaphor	Other
Pronominal - gender-overlap	75	82
Pronominal - no gender-overlap	90	82
Reflexive - gender-overlap	85	80
Reflexive - no gender-overlap	86	81

Mean accuracy scores of comprehension questions in percentage by experimental condition and question type, i.e., whether the question targeted the anaphor-antecedent dependency or another element of the sentence.

4.2.2. Eye Movements

An overview of raw reading times at each region of the sentence is provided in **Table A3** in the Appendix. We analyzed the pre-critical region containing the verb (plus postposition), the critical region containing the pronominal or reflexive possessive and the post-critical region containing the possessed noun. The same dependent variables were analyzed as in Experiment 2. Continuous dependent variables were log-transformed in order to achieve approximately normally distributed residuals.

An overview of the output of the linear mixed-effects models is provided in **Table 8**. The effect of anaphor type reached significance across regions and dependent variables. However, as mentioned above, this effect was not of interest to our research question: conditions with pronominal and reflexive possessive differ from each other in syntactic structure, distractor position, lexicon, word length and number of words contained in the pre-critical region. At the pre-critical and the critical region, no other effect reached significance in any dependent variable. At the post-critical region, a significant interaction between anaphor type and interference was observed in FPRP. Pairwise comparisons revealed that this interaction was driven by a significant interference effect in pronominal possessives. When the distractor shared the gender of the antecedent and hence matched the gender-cue, less first-pass regressions were observed (estimate $= -0.44$, $SE = 0.18$, $z = -2.47$, $p < 0.05$). In order to test whether this facilitation due to a gender-matching distractor reflected misretrievals of the latter, we re-ran the models on comprehension question response accuracies for trials

TABLE 7 | Experiment 3.

Predictor	*coef*	*SE*	*z*

Main effects of interference, anaphor type and their interaction at the pre-critcal region n−1, the reflexive/pronominal possessive (REFL/PRON) and the post-critical region n+1. The dependent measures are log-first-pass reading time, log-regression-path duration, first-pass regression probability and log-total fixation time. Statistically significant ($\alpha = 0.05$) effects are marked with an asterisk.

with and without a first-pass regression from the post-critical region separately.

In trials without a first-pass regression from n+1, the interference effect in pronominal possessives in questions targeting the critical dependency (i.e., the effect observed in the overall data) was highly significant (estimate $= -1.19$, $SE = 0.28$, $z = -4.21$, $p < 0.0001$). By contrast, in trials with a first-pass regression initiated at n+1, this effect did not reach significance (estimate $= -0.94$, $SE = 0.57$, $z = -1.66$, $p = 0.09$). This *post-hoc* analysis clearly shows that the interference effect in response accuracies in pronominal possessives was driven by trials in which no first-pass regression was initiated, i.e., by the trials responsible for the facilitation observed in FPRP.

4.3. Discussion

We did not find any evidence for encoding interference affecting processing times of Swedish anaphor-antecedent dependencies. Together with the results of Experiments 1 and 2, this suggests that in materials with a classical gender-match/mismatch manipulation, encoding interference does not affect retrieval latencies of the antecedent. In comprehension questions, we did not see evidence for encoding interference affecting retrieval probability of the antecedent either. This is in contrast to the pattern observed in response accuracies of Experiments 1 and 2.

Evidence for interference occurring at the moment of retrieval was observed in online and offline measures. The lower proportion of first-pass regressions initiated at the region directly after the gender-marked pronominal possessive in conditions with a gender-matching distractor indicates a processing facilitation due to a cue-matching distractor. Such a facilitation can be explained in terms of misretrievals of the gender-matching distractor under the assumption that misretrievals go along with shorter retrieval latencies. The lower response accuracies in comprehension questions targeting the retrieval of the antecedent support this explanation. Indeed, the *post-hoc* analysis of response accuracies for trials with and without a first-pass regression from the post-critical region clearly shows that the facilitation observed in first-pass regressions is directly connected to misretrievals of the gender-matching distractor.

The cue-based ACT-R model of sentence processing (Lewis and Vasishth, 2005) predicts misretrievals of the gender-matching distractor. These misretrievals are predicted to lead to shorter retrieval latencies, i.e., a processing facilitation, in the respective trials. However, the ACT-R model also predicts inhibition between the gender-matching distractor and the antecedent leading to longer retrieval latencies of the antecedent. Overall, the predicted direction of the interference effect therefore depends on the concrete parameter setting of the model. With the default parameter setting, inhibitory interference (i.e., the opposite effect than the one in the data) is predicted. If one assumes a particularly high activation of the distractor, ACT-R predicts the observed pattern because the highly activated distractor is misretrieved in a considerable proportion of the trials, which leads to a speed-up in the observed mean retrieval latencies (Jäger et al., 2015). Indeed, facilitation in a configuration similar to our materials has been observed in previous studies (Sturt, 2003; Cunnings and Felser, 2013; Laurinavichyute et al., 2015; Patil et al., unpublished manuscript). An argument favoring the assumption that the distractor is highly activated in our materials is that, similar to the other experiments reporting facilitation, the distractor is in subject position. Moreover, the distractor has a recency advantage over the antecedent as it is linearly closer to the retrieval site. Indeed, ACT-R predicts a recency advantage which follows from the assumption that an item's activation level decreases as a function of the passage of time (decay) and intervening material (interference). In sum, under the plausible assumption that the distractor is highly activated in our materials, cue-based

retrieval interference as implemented in the ACT-R model can account for the observed pattern. Hence, the interference effect in pronominal possessives can be interpreted as evidence favoring a cue-based retrieval mechanism. However, it should be kept in mind that pronominal possessives are not subject to Binding Principle A (Chomsky, 1981). Hence, the observed effects cannot be interpreted as evidence against theories of sentence processing claiming that Principle A is immune to interference from structurally illicit antecedents (Nicol and Swinney, 1989; Phillips et al., 2011; Dillon et al., 2013).

An alternative explanation that can account for the facilitation leading to misretrievals of the gender-matching distractor in pronominal possessives but not in reflexive possessives builds on the fact that we are comparing reflexive possessives which are subject to Binding Principle A with pronominal possessives which are subject to Binding Principle B. As mentioned above, pronominal possessives must not be bound in their local domain (Binding Principle B, see Chomsky, 1981). In the syntax-semantic literature about the interpretation of pronouns, it has been proposed that in the presence of a local c-commanding noun phrase which matches the gender feature of the anaphor (as the gender-matching distractor in the pronominal possessives conditions of Experiment 3), local binding is preferred over a non-local antecedent (Fox, 1998; Heim and Kratzer, 1998). This leads to a temporary violation of Binding Principle B. Only after the local binder has successfully been inhibited, the actual search for the structurally licit antecedent is initiated (Grodzinsky and Reinhart, 1993; Reinhart, 2000; Reuland, 2011). If in our materials, the syntactically local binder of the pronominal possessive (i.e., the distractor) is accessed in a first stage of the retrieval process, in a certain proportion of the trials, this local binder might be misretrieved in case it matches the gender of the pronominal possessive and the search for the antecedent terminates already after this first stage. Such a scenario would explain the misretrievals reflected in response accuracies and also the speed-up in trials where misretrievals occurred. This model correctly predicts that facilitatory interference should be observed only with Principle B pronouns, not with Principle A reflexives since in reflexives, the local binder is the licit antecedent. Crucially, the absence of an effect in our reflexive possessive conditions is not explained by them being unmarked for gender but rather by their syntactic binding properties.

To summarize, we found no evidence for encoding interference affecting the processing of Swedish possessives. We did observe evidence for retrieval interference in gender-marked pronominal possessives. The presence of a gender-matching distractor led to facilitated processing, presumably as a consequence of misretrievals of the latter in a certain proportion of trials. Although this pattern can be explained in terms of unconstrained cue-based retrieval, it is also consistent with the view that comprehending a pronoun constrained by Principle B requires comprehenders to temporarily consider and inhibit coreference with the local subject (the distractor in our materials). However, it should be noted that recent evidence from English pronouns reported by Chow et al. (2014) is inconsistent with the idea of first accessing and subsequently inhibiting a local antecedent. In none of their five reading experiments did they observe a facilitatory effect on pronoun resolution from a feature-matching local antecedent.

5. General Discussion

We set out to find evidence for encoding interference in the processing of reflexives. With respect to the current debate about structure-based vs. unconstrained cue-based retrieval subserving the processing of reflexives, the question whether encoding interference can be observed in reflexives is crucial because, as has been argued by Dillon (2011), encoding interference provides an alternative explanation for interference effects in reflexives which originally have been attributed to cue-based retrieval interference and hence taken as evidence for unconstrained cue-based retrieval (Badecker and Straub, 2002; Chen et al., 2012; Jäger et al., 2015; Patil et al., unpublished manuscript).

In order to decide whether encoding interference is present in the processing of reflexives, we conducted two experiments on the German reflexive *sich*. In contrast to previous studies, where encoding and cue-based retrieval interference made the same predictions, the gender-unmarked *sich* allowed us to pit against each other the predictions of retrieval and encoding interference. Cue-based retrieval interference predicts no effect of gender of a structurally inaccessible distractor whereas encoding interference predicts a slow-down when the gender of the distractor matches the gender of the antecedent. Neither with self-paced reading nor with eye-tracking did we find any indication for an online interference effect caused by a gender-sharing distractor, although the statistical power of our experiments was considerably higher than the one of previous experiments reporting interference effects in reflexives. We conducted a third experiment on Swedish possessives to cross-linguistically validate our finding. The interaction between interference and anaphor type provided further support for the conclusion that sharing the gender feature with a distractor does not lead to encoding interference in the processing of reflexives. Although we did not find any evidence that encoding interference affected online processing ease, response accuracies in the comprehension questions of Experiment 1 indicate that encoding interference might have caused misretrievals of the gender-sharing distractor. However, this effect was only marginal in Experiment 2 and could not be replicated in Experiment 3. Critically, these supposed misretrievals observed in Experiment 1 are not reflected in online processing measures. In sum, there is no evidence for encoding interference affecting online processing measures. Therefore, there is no evidence for the proposal that online interference effects reported in previous studies on reflexives arise from encoding interference. This finding therefore provides support for the assumption that interference effects observed in reflexive processing arise at the moment of retrieval rather than at the encoding stage. In other words, encoding interference is not a plausible explanation for reconciling interference effects with a structure-based account of reflexive processing. Thus, taken together with the interference effects reported in previous studies on reflexive processing, our findings favor an unconstrained cue-based retrieval architecture.

Lastly, we want to emphasize that our results should not be interpreted as evidence for the absence of encoding interference in sentence processing *per se*. Indeed, the effect at the relative clause verb in Experiment 2 might reflect encoding interference. The presence of encoding interference *as such* is in principle not incompatible with a content-addressable architecture since content-addressability is an architectural mechanism concerning the *retrieval*, but not the *encoding* or the *maintenance* of an item in working memory.

More generally, our findings provide support for a content-addressable memory architecture subserving language comprehension. This adds to a growing body of evidence from various kinds of syntactic dependencies such as filler-gap (McElree et al., 2003) and subject-verb dependencies (Van Dyke and Lewis, 2003; Van Dyke and McElree, 2006, 2011; Van Dyke, 2007; Wagers et al., 2009; Dillon et al., 2013), the licensing of negative-polarity items (Vasishth et al., 2008) and verb-phrase ellipsis (Martin and McElree, 2008), suggesting that the parser uses a cue-based retrieval mechanism to process these dependencies. One fundamental question in sentence processing research is whether the human parser uses qualitatively different retrieval mechanisms in the processing of different kinds of dependencies. Indeed, proponents of the structure-based account of reflexive processing have argued that the retrieval mechanisms mediating the processing of reflexives differ qualitatively from the ones used, e.g., in the processing of subject-verb dependencies (Phillips et al., 2011; Dillon et al., 2013). Hence, evidence for cue-based retrieval subserving the processing of reflexives is one important piece of evidence toward a content-addressable model of working memory underlying sentence processing in general, which not only invokes qualitatively similar working memory mechanisms to explain the processing of different kinds of linguistic dependencies, but, even beyond that, locates the language processing system within a general cognitive architecture where independently motivated working memory mechanisms operate on linguistic representations.

The present study examined the processing of the Mandarin Chinese long-distance reflexive *ziji* to evaluate the role that syntactic structure plays in the memory retrieval operations that support sentence comprehension. Using the multiple-response speed-accuracy tradeoff (MR-SAT) paradigm, we measured the speed with which comprehenders retrieve an antecedent for *ziji*. Our experimental materials contrasted sentences where *ziji*'s antecedent was in the local clause with sentences where *ziji*'s antecedent was in a distant clause. Time course results from MR-SAT suggest that *ziji* dependencies with syntactically distant antecedents are slower to process than syntactically local dependencies. To aid in interpreting the SAT data, we present a formal model of the antecedent retrieval process, and derive quantitative predictions about the time course of antecedent retrieval. The modeling results support the *Local Search hypothesis*: during syntactic retrieval, comprehenders initially limit memory search to the local syntactic domain. We argue that Local Search hypothesis has important implications for theories of locality effects in sentence comprehension. In particular, our results suggest that not all locality effects may be reduced to the effects of temporal decay and retrieval interference.

Keywords: working memory, reflexive processing, speed-accuracy trade-off, Mandarin Chinese, sentence processing

INTRODUCTION

One fundamental question for models of sentence comprehension is the question of how comprehenders are able to construct long-distance linguistic dependencies reliably and rapidly in comprehension. Long-distance dependencies occur whenever two non-adjacent elements in a sentence must be syntactically and/or semantically integrated with each other. For example, in a sentence like "*William took a terrible yet interesting photo of himself*," the relationship between the reflexive anaphor *himself* and its antecedent *William* is constructed across multiple intervening words. Recent models of sentence comprehension have advanced the hypothesis that this sort of syntactic dependency formation minimally requires the use of memory retrieval mechanisms to access temporally distant syntactic encodings. On this view, to interpret the reflexive in the sentence above, comprehenders must retrieve a representation of the antecedent from memory. Moreover, it has been argued that the memory retrieval mechanisms that underlie sentence comprehension share a number of key features with domain-general retrieval mechanisms (McElree, 2000; McElree et al., 2003; Van Dyke and Lewis, 2003; Lewis and Vasishth, 2005; Lewis et al., 2006). This view receives support from mounting evidence that comprehenders rely on a cue-based, direct access retrieval mechanism during syntactic comprehension. Cue-based retrieval mechanisms allow direct access to syntactic encodings by matching retrieval cues to the features of all item representations in memory in a parallel fashion. Items whose features provide a close match to the retrieval cues are then retrieved for further processing (for a discussion of implementations of this idea, see Clark and Gronlund, 1996).

Despite the growing evidence in favor of cue-based retrieval in sentence comprehension, these models still face a number of difficult theoretical questions. One central question concerns the nature of the retrieval cues used to retrieve syntactic dependents during processing (Van Dyke and McElree, 2011; Dillon et al., 2013; Kush, 2013). Existing evidence suggests that comprehenders use both semantic and syntactic cues to guide retrieval (Van Dyke and McElree, 2006, 2011; Van Dyke, 2007). Furthermore, there is some evidence that syntactic cues may be given priority over semantic or morphological cues, although this may depend on the kind of dependency being formed (Van Dyke and McElree, 2011; Dillon et al., 2013). However, very little is known about the nature of the syntactic cues that guide retrieval operations. In the present paper, we address this question by asking whether syntactic cues refer only to the attributes of individual syntactic

encodings, such as their case or thematic role (*item information*), or whether syntactic cues distinguish constituents based on their hierarchical or linear distance from the retrieval site (*position information*). We hypothesize that the cues that guide memory retrieval during parsing do include positional syntactic information, and furthermore, that comprehenders use positional information as retrieval cues to prioritize retrieval of constituents within the local syntactic domain (what we will refer to as the *Local Search hypothesis*).

The goal of the present paper is to evaluate the Local Search hypothesis by examining the speed with which comprehenders process reflexive dependencies in Mandarin Chinese, where reflexive anaphors may be bound either inside or outside of their local clause. We then develop a formal model of a local search retrieval process, and derive quantitative predictions about the processing time necessary to recover *ziji*'s antecedent if the parser assumes a local search strategy. To preview our conclusion, the results of our investigation support the main predictions of the Local Search hypothesis. We argue that the Local Search hypothesis offers important insight into a widely-observed preference for local dependencies over distant dependencies in sentence comprehension (Kimball, 1973; Hawkins, 1994; Gibson, 1998; Bartek et al., 2011; *a.o.*). In particular, the results presented here support theories that attribute these *locality effects* to a substantive bias to search syntactically local domains at retrieval, rather than theories that attribute locality effects entirely to effects of decay or interference of items in working memory (MacDonald et al., 1994; Lewis and Vasishth, 2005; Lewis et al., 2006).

CUE-BASED RETRIEVAL IN SENTENCE PROCESSING

There are two main sources of empirical evidence that implicate the use of a cue-based retrieval mechanism in parsing. The first source of evidence comes from studies of interference effects in online processing. In a cue-based, direct access memory architecture, the process of matching the retrieval cues against all memory encodings allows rapid access to task-relevant encodings, but is susceptible to interference effects. If there is a good match between the retrieval cues and more than one item in memory, then access to the target memory can be impeded. Similarity-based interference effects have been widely documented in studies of sentence comprehension (Gordon et al., 2001, 2004; Van Dyke and Lewis, 2003; Drenhaus et al., 2005; Lewis and Vasishth, 2005; Lewis et al., 2006; Van Dyke and McElree, 2006, 2011; Van Dyke, 2007). In addition, cue-based retrieval architectures naturally account for the phenomenon of *illusory licensing*. Illusory licensing occurs when comprehenders appear to use a grammatically unavailable constituent to license a syntactically dependent element (negative polarity item licensing: Vasishth et al., 2008; Xiang et al., 2009; subject-verb agreement: Wagers et al., 2009; Dillon et al., 2013). In a cue-based retrieval architecture, this arises because a syntactically illicit constituent may be misretrieved during the search for a licensor, which in turn leads to illusory licensing of the dependent element that triggered the retrieval.

A second important line of evidence in favor of cue-based retrieval mechanisms comes from studies of the time course of memory access. In a cue-based, direct access memory architecture, only items that match the retrieval cues are contacted at retrieval, and so retrieval times are predicted to be constant over search sets of different sizes. This prediction has been supported by speed-accuracy tradeoff studies (SAT) of item recognition. In an SAT study, participants are trained to respond at a number of varying response deadlines. This allows the experimenter to derive an SAT function that tracks behavioral accuracy as a function of time. This function measures the complete time course of information processing. Importantly, SAT permits the experimenter to make separate measurements of processing speed and processing accuracy, two aspects of information processing that are confounded in simple reaction time (RT) paradigms (Wickelgren, 1977). SAT studies of recognition judgments in list memory tasks have provided support for direct access models of recognition memory by showing that the number of elements in the list does not affect processing speed (McElree and Dosher, 1989). This finding is not consistent with search models, which retrieve representations based on their location in memory. Search may proceed either in serial or parallel, but it crucially involves performing explicit comparison processes over a positionally defined search set (see Townsend and Ashby, 1983). For this reason, search models predict that memory access times should grow either as a function of the size of the search space, or as a function of the position of the target in a serial or ordered search. This prediction reflects the fact that the more sampling operations are necessary to recover the intended target, the longer time should be required for retrieval. In contrast to item recognition, the retrieval of explicit order information does appear to recruit this sort of iterative search process (McElree and Dosher, 1993; Gronlund et al., 1997).

In language comprehension, research using the SAT technique has demonstrated that memory access time does not grow with the size of the search space (McElree, 2000; McElree et al., 2003; Foraker and McElree, 2007; Martin and McElree, 2008, 2009). For instance, McElree et al. (2003) examined the processing of object cleft-constructions as in (1), in which the clefted object is separated from the associated verb by 1, 2, or 3 clauses:

a. It was the scandal that the celebrity relished.
b. It was the scandal that model believed that the celebrity relished.
c. It was the scandal that the model believed that the journalist reported that the celebrity relished. (1)

McElree and colleagues used the SAT paradigm to measure comprehension accuracy at various time points from the offset of the final verb in (1), manipulating the hierarchical (and linear) distance between the filler (*the scandal*) and the verb that hosts its gap (*relished*). The results suggested that the length manipulation impacted how accurately comprehenders were able to retrieve the *wh*-filler, as reflected in their asymptotic accuracy rates on a plausibility detection task, but that it did not impact the speed of this retrieval. McElree et al. argued that these results favor a cue-based direct access retrieval mechanism over search-based retrieval mechanisms, on the assumption that their length manipulation increased the size of the search set for the critical retrieval of the *wh*-filler. Similar results were observed for the

comprehension of verb phrase ellipsis (Martin and McElree, 2008, 2009), sluicing (Martin and McElree, 2011), and pronominal reference (Foraker and McElree, 2007).

Although previous SAT studies have consistently found that the structural distance between two elements in a dependency does not impact the speed of forming the dependency, the technique has been shown to have the power to detect other sorts of processing slowdowns that occur during sentence comprehension. For example, SAT studies have shown that processing slowdowns obtain in cases of syntactic reanalysis (McElree et al., 2003; Bornkessel et al., 2004), cases of potential lexical ambiguity (Foraker and McElree, 2007), and configurations that require multiple retrieval operations (McElree et al., 2003). Lastly, although length *per se* has not been shown to modulate processing speed, in certain cases the type of intervening material has been shown to contribute to slowed processing. McElree et al. (2003) also reported that the time necessary to process a subject-verb dependency is slowed by an intervening relative clause, but not an intervening prepositional phrase (see also Wagers and McElree, 2009).

LOCALITY EFFECTS IN A CUE-BASED ARCHITECTURE

The adoption of a cue-based, direct access architecture for syntactic processing requires a reexamination of existing theories of locality effects in sentence processing. It is widely observed that local syntactic dependencies are easier to process or, in cases of ambiguity, preferred over longer syntactic dependencies (Kimball, 1973; Frazier, 1978; Just and Carpenter, 1992; Hawkins, 1994; Gibson, 1998; Lewis and Vasishth, 2005; Lewis et al., 2006; Bartek et al., 2011; *inter alia*). Because cue-based, direct access mechanisms do not need to execute a serial search of a parse to retrieve a syntactic dependent or a pronominal antecedent, locality effects cannot emerge as a property of the access mechanism without making further assumptions. Instead, the advantage for local dependencies reflects two factors: time-based decay and interference processes (Van Dyke and Lewis, 2003; Lewis and Vasishth, 2005; Lewis et al., 2006; Bartek et al., 2011; see also Frazier and Clifton, 1998). Decay and interference both serve to degrade the availability of more distant syntactic constituents, thus making processing of longer dependencies more difficult. Decay does so by affecting the activation of constituents: more local constituents will have higher activation values by virtue of being accessed more recently. The effect of interference is more indirect. When dependencies are longer, then there are likely to be more constituent encodings in memory. When there are more items in memory, the degree of similarity-based interference is likely to be greater.

These explanations for locality effects in sentence processing stand in contrast to the explanation offered by accounts that attribute locality effects to a parsing strategy that preferentially attaches incoming constituents within a local syntactic domain (Kimball, 1973; Frazier, 1978; Berwick and Weinberg, 1984; Frazier and Clifton, 1989, 1996; Gibson et al., 1996; Gibson, 1998; Sturt et al., 1999, 2000). Although these accounts vary widely in their details, they might all be called *search-based* accounts of syntactic retrieval. The core claims of search-based accounts include (i) the parser distinguishes local vs. distant syntactic domains through positional syntactic information, and (ii) the search for a potential syntactic dependent proceeds by first searching within some local syntactic domain, the size of which may vary across theories.

Although it may appear that the claims of these search-based accounts are incompatible with the locality account advanced by cue-based parsing models, this is not so. The core claims of search-based accounts may in fact be integrated with cue-based retrieval models if we suppose that positional syntactic information is available to guide retrieval operations, and that at retrieval the parser uses this positional information to limit retrieval to a local syntactic domain. We call this the *Local Search* hypothesis:

> *Local Search hypothesis*: The parser uses positional syntactic information during the retrieval of syntactic dependents, and positional cues serve to restrict retrieval to constituents in some local syntactic domain. (2)

According to the Local Search hypothesis, locality effects in sentence processing reflect in part a parsing strategy that prioritizes the retrieval of syntactically local constituents. In other words, the Local Search hypothesis claims that locality effects in sentence processing do not merely emerge from effects of decay and interference, but instead they reflect a strategy for the retrieval of syntactic dependents.

Within existing cue-based parsing models, it is not generally assumed that positional syntactic information is available to guide retrieval. Lewis and Vasishth (2005) propose that positional syntactic information, either hierarchical or linear, plays no role in the memory retrieval operations that guide attachment operations (cf. the *no serial order* hypothesis; see also Lewis et al., 2006). For example, while the parser may be able to use item information such as case to identify the subject of a sentence, it cannot use positional syntactic information to distinguish the encoding of the local subject from a more distant subject. On this account, the inability to distinguish distant and local subjects on the basis of their syntactic position provides an explanation of the well-known center embedding difficulty in terms of retrieval difficulty: when the parser needs to retrieve a subject for an embedded verb, there are too many similar subject encodings in memory to permit the parser to retrieve the grammatically appropriate subject, and positional information cannot be recruited to help with this process (Lewis and Vasishth, 2005; Lewis et al., 2006). In contrast to the Local Search hypothesis, these models claim that locality effects in sentence processing are entirely reducible to the effects of interference and temporal decay.

This claim is compatible with the SAT results reviewed above, which suggest that neither the linear nor structural position of the retrieval target directly impacts retrieval times. It is tempting to conclude from this that positional syntactic information is not used to guide syntactic retrieval operations. However, this conclusion would be premature on the basis of these data alone. These studies largely investigated configurations where there was only one grammatically licit position that could serve as the target of the retrieval. For instance, when the verb initiates the retrieval for the clefted object filler in (1), *wh*-feature cues could unambiguously select the filler as the target of retrieval. For this

reason, they provide no direct test of whether syntactic position information plays a role in helping the retrieval mechanism to distinguish between multiple, syntactically accessible targets in different syntactic domains.

A potential exception is Martin and McElree (2011), who investigated the processing of sluiced sentences as in (3):

a. Distant VP: Michael drank coffee and typed something, but he didn't tell me **what**.
b. Recent VP: Michael typed something and drank coffee, but he didn't tell me **what**. (3)

Martin and McElree hypothesized that the processing of the sluiced *wh*-phrase *what* requires comprehenders to retrieve an antecedent VP from memory, which is then used to construct the elided clause (i.e., the IP) at the sluice site. Martin and McElree manipulated the distance between the antecedent VP (*typed something* in 3) and the sluiced *wh*-phrase. In addition, they attempted to manipulate the size of the antecedent search set by manipulating whether a competitor VP was present in a coordination structure (*drank coffee* in 3). Nonetheless, they observed that only accuracy, not processing speed, was negatively impacted by the presence of multiple VP antecedents. They additionally observed that the recency of the antecedent VP only impacted retrieval accuracy. They argued that this pattern of results provided a strong data point in favor of content-addressable retrieval operations over syntactically structured search operations. However, because the two candidate antecedents were coordinated, this study may not have effectively manipulated the syntactic locality of the antecedent VP. Both potential antecedents were in a structurally similar position in the preceding clause. For this reason, this study leaves unresolved the question of how structural locality impacts retrieval.

THE CURRENT STUDY

In the present study we evaluate the Local Search hypothesis by investigating the processing of the Mandarin Chinese long-distance reflexive *ziji*. The anaphor *ziji* is an example of the cross-linguistically well-attested class of long-distance reflexives, reflexive pronouns that may be bound outside of their local clause. Thus, unlike the English reflexives *himself* and *herself*, *ziji* does not require that its antecedent be in the same clause, as seen in (4), where subscript indices are used to indicate possible coreference:

Zhangsan$_j$ *shuo Lisi*$_i$ *nongshang-le ziji*$_{i/j}$
Zhangsan says Lisi harm-perf self
"Zhangsan says that Lisi harmed him/herself" (4)

In (4), it can be seen that *ziji* may be bound either by the local subject *Lisi* or the matrix subject *Zhangsan*. Like many long-distance reflexives, *ziji* imposes a number of constraints on potential antecedents (Büring, 2005; Huang et al., 2009). There are significant syntactic constraints placed on antecedents: they must be subjects whose clausal projection dominates the clause that contains *ziji* (Huang and Liu, 2001). In addition to these syntactic constraints, there are a number of discourse-pragmatic constraints on the use of *ziji*. Antecedents must be animate and sentient, and must be prominent in the current discourse (Xue et al., 1994; Huang and Liu, 2001). In the absence of an appropriate antecedent in the immediate sentential context, *ziji* has been claimed to refer to the speaker, presumably as a reflex of the prominent discourse status that is automatically afforded to the speaker (Kuno, 1972; Huang and Liu, 2001). Though there are ongoing debates about the exact nature of *ziji*'s licensing conditions (Huang et al., 2006), it is uncontroversial that resolving the antecedent-anaphor dependency requires the comprehender to systematically exclude structurally unacceptable referents from consideration.

Although *ziji* can in principle take either local or long-distance antecedents, previous research suggests that there is a preference for local antecedents over more distant antecedents in online comprehension. For example, Li and Zhou (2010) provide ERP evidence that long-distance binding of *ziji* elicits a larger P300/600 response relative to local or ambiguous binding of *ziji*, suggesting greater processing difficulty associated with recovering long-distance interpretations. In addition, cross-modal priming studies have shown that probes associated with local antecedents are recognized more quickly than probes to long-distance antecedents upon encountering *ziji* (Gao et al., 2005; Liu, 2009). Chen et al. (2012) also present self-paced reading evidence that comprehenders read local *ziji*-antecedent dependencies more quickly than long-distance dependencies. These studies establish a preference for local binding over long-distance binding in comprehension, but without any direct time course evidence it is unclear whether this preference reflects a difference in retrieval speed or retrieval accuracy for local antecedents.

In this study we investigate the processing of local and long-distance interpretations of *ziji* as in (5). We take the embedded and matrix clauses in (4) to constitute distinct syntactic domains for the purposes of finding *ziji*'s antecedent.

a. *Zhangsan*$_i$ *shuo fengbao*$_j$ *hai-le ziji*$_{i/j}$
Zhangsan says storm harm-perf *ziji*
"Zhangsan said the storm harmed him."
b. *Xiaoshuo*$_i$ *shuo Zhangsan*$_j$ *hai-le ziji*$_{i/j}$
novel says Zhangsan harm-perf *ziji*
"The novel said Zhangsan harmed himself." (5)

Because *ziji* requires an animate and sentient antecedent, only *Zhangsan* in (5a,b) is a grammatically licensed antecedent. Of critical interest is the long-distance configuration (5a), where the local subject is inanimate and thus semantically inappropriate as an antecedent for *ziji*. The critical empirical question in this comparison is whether comprehenders will show delayed access to the matrix antecedent in (5a). If the match on semantic cues outweighs the effect of dependency locality, and if it grants reliable direct access to the matrix antecedent, then the only difference between (5a) and (5b) should be the amount of time the antecedent has decayed in memory. Previous findings show that decay alone does not impact the speed of retrieval (see e.g., McElree et al., 2003). Thus, if semantic cue match outweighs the effect of locality in this configuration, we predict no difference

in retrieval speeds between local and long-distance interpretations of *ziji*. Instead, we should see only a difference in processing accuracy between the two configurations in (5), such that local antecedents are more accurately retrieved.

The Local Search hypothesis, however, does predict a difference in retrieval speeds. If the parser initially uses cues that limit retrieval to the local clausal domain, then on a significant portion of trials the comprehender should misretrieve the local subject in (5a) despite its poor fit to *ziji*'s semantic cues. This would require the comprehender to engage costly reanalysis processes to recover the more distant antecedent, leading to slowed retrieval times in (5a). In Experiment 1, we used a variant of the SAT technique known as multiple response SAT (MR-SAT) to estimate the speed of processing *ziji* in these two configurations to determine whether local and long-distance *ziji* dependencies are associated with different retrieval speeds.

EXPERIMENT 1

Experiment 1 employed the multiple-response speed-accuracy tradeoff procedure (MR-SAT; Wickelgren et al., 1980) to estimate the time course of retrieving an antecedent for *ziji* in sentences such as (5). MR-SAT is an attractive technique to use in studying language comprehension because it dissociates processing speed from processing accuracy (McElree, 2000; McElree et al., 2003; Foraker and McElree, 2007; Martin and McElree, 2008, 2009, 2011). In a MR-SAT paradigm, participants are required to make acceptability judgments at pre-specified response latencies. This provides a measure of how accuracy grows over time, and thus provides a direct measure of the time course of processing. In contrast, single RT paradigms are limited in how informative they are about time course of processing. Because participants can trade speed and accuracy in many standard judgment tasks (Wickelgren, 1977), merely estimating a point RT per condition (or a single RT/accuracy pair) can obscure differences between the probability of successfully completing a process and the speed with which that process reaches completion. In contrast, the full time course summarized in an SAT function allows the researcher to separately estimate the speed and the accuracy of memory retrieval. In the present case, we are concerned with the nature of any difficulty observed with non-local *ziji* interpretations as in (5a). Prior work suggests that retrieval difficulty associated with temporal decay or linear distance is associated with a decrease in retrieval accuracy, rather than retrieval speed (McElree, 2000; McElree et al., 2003; Foraker and McElree, 2007; Martin and McElree, 2008, 2009). Based on these results, we do not expect to observe differences in retrieval speed purely as a function of decay or recency.

METHOD

Participants

Twenty college students from Beijing Normal University participated in the experiment. Data from 3 participants were excluded for reasons that are detailed below. The remaining 17 participants included 10 females, and had a mean age of 23.5 years. Each participant completed six 1-h experimental sessions spaced at least a day apart, in addition to a 1-h practice session for familiarization with the MR-SAT procedure. All participants were native Mandarin Chinese speakers and had normal or corrected-to-normal vision. Following an IRB-approved protocol, all participants gave informed consent and were paid 35 RMB per hour for their participation in the experiment.

Materials

Our critical experimental materials were Mandarin sentences that contained a main clause verb that selects for a sentential complement (e.g., "*biaoshi*," say). The embedded complement clause was always transitive, and the embedded object was always the sentence-final word. Two features of the stimuli were manipulated orthogonally, in a crossed 3 × 3 experimental design. One was the position of a syntactically prominent animate subject; it was either the subject of the main clause (*long distance animate)*, the subject of the local (embedded) clause (*local animate*), or not present (*no antecedent*). In addition we manipulated the form of the embedded object NP, which was either the long-distance reflexive *ziji*, a contextually plausible definite NP, or a contextually implausible definite NP.

Four of the nine resulting conditions formed the critical experimental conditions (**Table 1**). Based on the position of the animate subject, *ziji* either took a long-distance antecedent (Long-distance animate, *ziji* condition) or a local antecedent (Local animate, *ziji* condition). In the control conditions *ziji* was replaced with a full NP that was a plausible object of the embedded verb (e.g., *the batsman*). The inclusion of these control conditions helps to ensure that any differences in processing speed or accuracy observed in the critical *ziji* conditions are specific to retrieval processes associated with *ziji,* rather than other properties of the sentence frame. In the critical experimental conditions, sentences were acceptable across all four conditions.

In the local *ziji* and the corresponding control conditions, the main clause subject NP was always an inanimate noun that described a form of written or spoken media (e.g., *book*, *documentary*, *memo*) to ensure compatibility with the meaning of the main clause verbs (e.g., *say*) while being an unacceptable antecedent of *ziji*. None of the inanimates used in any position could be construed metonymically; metonymic interpretations of inanimates (i.e., *the newspaper* being used to refer to the employees of the newspaper) may be used as antecedents for *ziji.* In order to ensure that participants do not have ceiling performance in our task (McElree, 2006), a temporal adverbial clause was interpolated between the embedded subject and the embedded verb. In all conditions, an animate NP was used as the subject of the temporal adverbial phrase. However, since it occupied a position that is not structurally higher than *ziji,* it is not a grammatical antecedent for *ziji*.

In addition to these critical four conditions, the implausible object conditions contained a contextually implausible embedded object (e.g., "The auto-biography says that the coach underestimated *the glasses* when the team was doing poorly.") and the no animate conditions did not contain an animate NP in either the matrix or embedded subject position (e.g., "The auto-biography says that the report underestimated *ziji* when the team was doing poorly."). These extra conditions provided unacceptable counterparts to the critical conditions, either because of a

Table 1 | Summary of the critical conditions in Experiment 1.

Condition	Example
Long-distance animate, *ziji*	张教练 表明 那篇报导 [在 团队 未能 发挥 水准 的时候] 低估了 **自己** Coach Zhang say [that report (when team not perform well-time) underestimate **ziji**] "Coach Zhang says that that report underestimated ***self*** when the team was doing poorly."
Local animate, *ziji*	回忆录 表明 张教练 [在 团队 未能 发挥 水准 的时候] 低估了 **自己** Auto-biography say [coach Zhang (when team not perform well-time) underestimate **ziji**] "The auto-biography says that coach Zhang underestimated ***self*** when the team was doing poorly."
Long-distance animate, control	张教练 表明 那篇报导 [在 团队 未能 发挥 水准 的时候] 低估了 **那位击球手** Coach Zhang say [that report (when team not perform well-time) underestimate **that batsman**] "Coach Zhang says that that report underestimated ***the batsman*** when the team was doing poorly."
Local animate, control	回忆录 表明 张教练 [在 团队 未能 发挥 水准 的时候] 低估了 **那位击球手** Auto-biography say [coach Zhang (when team not perform well-time) underestimate **that batsman**] "The auto-biography says that coach Zhang underestimated ***the batsman*** when the team was doing poorly."

local implausibility, or because *ziji* did not have an antecedent available. There were two reasons for including these additional conditions, despite the fact that they were not part of the primary experimental manipulation. First, they provided unacceptable sentences that could be used in *d*-prime scaling. More importantly, the inclusion of the implausible object and no antecedent *ziji* conditions ensured that within the experiment neither the presence of *ziji* nor the acceptability of the sentence was predictable from the sentence context. Because it is typical for a subject in an SAT experiment to see all conditions of an experimental item, the inclusion of these additional conditions was critical to ensure that participants could not use familiarity with the sentence context to anticipate their response in advance of the sentence final word.

Forty sets of the 9 sentence types (5 acceptable and 4 unacceptable) were generated. The resulting 360 sentences were equally distributed in 6 presentation lists, one for each of the 6 sessions, to minimize the repetition of content material within a session. Thus, across the six sessions, each participant saw each experimental item in each of its 9 conditions. Crucially, no two instances of *ziji* sentences from the same item set were presented within the same session. Within a session, each participant viewed 206 sentences, of which 60 were drawn from the current study. Since only one third of target sentences contained *ziji*, the critical *ziji* conditions comprised around 10% of all sentences within and across sessions. The order of presentation within a session was randomized.

Procedure

Stimulus presentation, timing, and response collection were all carried out on a personal computer using the Linger software (Rohde, 2003). Each trial began with a 500 ms fixation cross presented in the center of the screen. Each word appeared in the center of the screen for 400 ms, followed by 200 ms of blank screen. All words were presented using simplified Chinese characters, and the last word of each sentence was marked with a period (。). At the onset of the final word, a series of 18 auditory response cues (50 ms, 1000 Hz tone) was initiated. The cues occurred every 350 ms, and the final word of the sentence remained on the screen. Participants were asked to decide for each sentence whether it was an acceptable, coherent sounding sentence or not (in Mandarin: *tōngshùn he héshì)*. Participants were trained to initially respond by pressing both response keys simultaneously to indicate an undecided response, and to respond at every tone. They were then trained to switch their response to either the "accept" or "reject" key as soon as they could. Importantly, they were also trained to modify their responses if their assessment changed. During the 1-h practice session, participants were told that some of the sentences were complex, but nevertheless were meaningful sentences, and explicit feedback was given about acceptable and unacceptable sentences in the experiment. Each participant performed six 1-h experimental sessions, and in each they saw one of the lists of materials. The order of lists was randomized across participants.

Data analysis

To derive the full time-course information, d' scores were calculated by comparing an acceptable and an unacceptable condition at each of the response tones. The resultant series of d'-values at each time point t was fit using a shifted exponential function:

$$d' = \lambda\left(1 - e^{-\beta(t-\delta)}\right), t > \delta,$$
$$d' = 0 \quad , otherwise \tag{6}$$

The SAT function in Equation (6) describes the growth of accuracy over time using three parameters: *asymptote* (λ), *rate* (β), and *intercept* (δ). By regressing the non-linear SAT function against the time course data collected in the experiment, we may make inferences about the effect of experimental manipulations on each of the parameters. The initial period of chance performance is described by the intercept parameter (δ), which indicates the point at which the SAT function departs from chance performance (0 in d' units). The next portion of the function is characterized by a period of increasing accuracy; the rate of growth in this portion of the SAT function is described by the

rate parameter (β). The last portion of the function reflects terminal accuracy in the behavioral judgment, and it is reflected in the asymptote parameter of the SAT function (λ). The intercept and the rate together index the speed of the process, while the asymptote indexes the terminal accuracy of the process. The processing speed may also be evaluated by considering a composite measure known as the *speed* of the SAT function ($\beta^{-1} + \delta$). By parameterizing the SAT function in this way, we can separately estimate the speed of processing (as reflected in the intercept, rate, or speed measures) and the accuracy of processing (as reflected in the asymptote). Differences in the intercept or rate parameters indicate a difference in processing speed between two conditions; differences in the asymptote parameter indicate a difference in processing accuracy.

d' is the standard measure of discrimination (assuming equal-variance Gaussian distributions): $d' = \Phi(\text{hits}) - \Phi(\text{false alarms})$ (Macmillan and Creelman, 2004; Φ represents the inverse of the cumulative distribution function of the standard normal). However, in the models reported below, we only report a *pseudo* d' measure that does not correct for the false alarm rate [$d' = \Phi(\text{hits})$]. We adopted this analysis because the somewhat high acceptability of the no antecedent condition (see below) made it inappropriate for the construction of a discriminative d' measure. For reference, a pseudo d' score of 2.5 represents perfect performance in our experiment, and a pseudo d' score of 0.84 represents a hit rate of 0.80.

It is important to note that our pseudo d' measure does not correct for any response bias that participants may have. In this respect, our analysis differs significantly from the approach adopted in previous SAT work, which has generally used d' as the dependent measure to ensure that any time course differences are not simply due to differences in response bias across conditions. However, we note that our critical conditions constitute a 2×2 crossed factorial design (presence of *ziji* by position of animate antecedent). This design allows us to account for any response bias introduced by two major features of our stimuli: the configuration of the sentence prior to the critical final word, and the presence of *ziji* in final position. If response bias varies as a function of the sentence context, then this bias should be shared by both *ziji* and control conditions. Likewise, if there is response bias associated with a sentence final *ziji*, as opposed to a sentence final lexical NP, then this bias should be shared by both *ziji* conditions. Thus, any interactions of *ziji* and position of the animate subject in our design cannot be the result of response bias introduced by either of these two configurations.

Data analysis proceeded in two steps: a model selection analysis and a parameter estimation analysis (Liu and Smith, 2009). In the model selection analysis, the best fit SAT model was determined using the adjusted R^2-statistic (in Equation 7) using a hierarchical model-testing scheme over the averaged data, an approach pursued in prior work on SAT in sentence comprehension (McElree, 2000; McElree et al., 2003; Foraker and McElree, 2007; Martin and McElree, 2008, 2009). However, we note that for multiple-response SAT, determining the number of independent data points n is not a trivial problem, because of the lack of independence between responses on any trial. Because of the uncertainty concerning the number of truly independent data points that underlie any one MR-SAT function, it is difficult to straightforwardly apply model fitting metrics such as adjusted R^2, the AIC, and the BIC. In the parameter estimation analyses, only fully saturated models that allow all parameters to vary by condition are considered, and any differences between the critical conditions on the parameters of interest are assessed using familiar hypothesis testing measures over individual parameter estimates. This analysis follows the recommendations of Lorch and Myers (1990) for dealing with regression analyses in the context of a repeated measures experiment. In order to obtain parameter estimates, we used the R statistical computing environment to fit non-linear regressions of the SAT function Equation (6) against the pseudo d' score (see McElree and Griffith, 1998; McElree, 2000; McElree et al., 2003; Martin and McElree, 2008, 2009, 2011). We used the `nls()` function with an adaptive non-linear least squares algorithm (Dennis et al., 1981) to determine the least squares fit of the SAT function to the data.

$$R^2 = 1 - \frac{\sum_{i=1}^{n} (d_i - \hat{d}_i)^2/(n-k)}{\sum_{i=1}^{n} (d_i - \bar{d})^2/(n-k)} \tag{7}$$

Prior to modeling the d' scores, analysis was performed on empirical pseudo d' measures by participants. This was obtained by taking the average rate of acceptance over the last four response points in each condition to determine the empirical hit rate, and calculating d' as described above. Hit rates that reflected perfect performance were smoothed by subtracting 0.0125 from the hit rate [1/(2N) smoothing (Macmillan and Creelman, 2004)].

Where appropriate, behavioral measures and parameter estimates from the SAT function in Equation (6) were further analyzed by entering them into a 2×2 repeated-measures ANOVA crossing dependency type (*ziji* vs. *control*) and the position of the animate argument (*long-distance* vs. *local*).

Of the twenty participants run, data from two participants were excluded due to unreliable dynamics estimates. The empirical d' scores from these participants appeared better fit by a sigmoidal rather than exponential function, leading to unrealistically large and unreliable differences in the critical conditions in the crucial intercept and rate parameters when fit with the SAT function in Equation (6). The data from one further participant were rejected due to lower than 60% correct responses on both critical *ziji* conditions. These participants' empirical d' were not included in any analyses below.

RESULTS

Accuracy and empirical d′ analysis

For the four critical experimental conditions, acceptance rates were high. Average acceptance was 87% for long-distance *ziji* conditions and 83% for local *ziji* conditions. The rates of acceptance for the long distance and local control conditions were 91 and 88%, respectively.

In contrast, the average acceptance was 47% percent for no antecedent *ziji* conditions, and the unacceptable control conditions each had an average acceptance rate of 2%. In addition, the rate of acceptance of the no antecedent acceptable control condition was 92%.

Table 2 presents the mean empirical pseudo d' for *ziji* and control conditions. The data were analyzed using a 2×2 repeated-measures ANOVA with dependency type and animate position as within-participant factors. This analysis revealed a marginal main effect of position of animate argument [$F_{(1,\ 16)} = 3.6$, $p < 0.1$], as well as a marginal effect of dependency type [$F_{(1,\ 16)} = 4.3$, $p < 0.1$]. The interaction of animate position and dependency type was not significant ($F < 0.1$). However, planned comparisons between the long-distance and local conditions within *ziji* and control conditions did not reveal any reliable effects [*ziji*: $t_{(16)} = 1.02$, $p = 0.32$; control: $t_{(16)} = 1.6$, $p = 0.12$].

Time course analysis

Competitive fits of the shifted exponential function in Equation (6) were conducted to assess differences in asymptotic accuracy, rate, and intercept across conditions for each participant. Model fits were conducted separately for control and *ziji* conditions. Because the empirical d' analysis revealed only marginal differences between conditions in accuracy, it is not clear whether competitive model fits are justified in allowing the asymptote parameter to vary freely between conditions. In light of this, we fitted two SAT functions to each data set: one model whose asymptote parameter was fixed to the empirical pseudo d' obtained by averaging over the final four response latencies, and one where the asymptote parameter was allowed to vary. We report results from the free parameter models, but we note that fitting the models with fixed asymptotes did not yield qualitatively different results.

Model-fitting analyses pitted nested models against each other on adjusted R^2 Equation (7), following McElree et al. (2003) and Liu and Smith (2009). Fits to the across-participants average for the critical *ziji* conditions revealed a small advantage for models that allocated separate intercept parameters (δ) for local and long-distance conditions (2λ-1β-2δ, R^2:0.986) and models that models that posit separate rate (β) parameters (2λ-2β-1δ, R^2:0.985) over models that posited shared rate and intercept parameters for the two conditions (2λ-1β-1δ, R^2:0.982). This difference reflected a small rate advantage for local *ziji* condition over long-distance *ziji* condition (LD β: 0.96 s^{-1}, Local β: 1.26 s^{-1}; LD δ: 0.75 s, Local δ: 0.58 s). These models were in turn a better fit to the data than any model that contained only a single asymptote for both conditions (max $R^2 = 0.974$). Control conditions showed no improvement in fit for additional rate or intercept parameters (2λ-1β-1δ, R^2:0.996; 2λ-2β-1δ, R^2:0.996; 2λ-1β-2δ, R^2:0.996). The average data for *ziji* and control conditions, along with best-fit models on the adjusted R^2 metric, are presented in **Figure 1**.

Of critical interest is whether the fits to the average data reflect a reliable trend across individuals. It is possible that the SAT function reflected in the average is not in fact representative of a pattern observed in any individual subject (Liu and Smith, 2009), and in the present case, there was a very small difference between models with different dynamics parameters and those without. In order to assess the reliability of parameter estimates across participants, each individual's d' data were fit with the SAT function separately for each of the four critical conditions. As before, fits were conducted both with fixed and free asymptote parameters, and these two types of models did not yield qualitatively different results. Thus, we report only the results from models

Table 2 | Mean empirical pseudo d'-values, obtained by averaging accuracies over final four response latencies.

	ziji	Control
Long-distance animate	1.26 (±0.12)	1.53 (±0.12)
local animate	1.11 (±0.13)	1.33 (±0.13)

with free asymptote parameters. Fits to individual participants revealed differences in whether dynamics differences between the critical conditions were reflected in the SAT function's rate, its intercept, or both. Because of these differences, here we additionally present and analyze the speed measure ($\beta^{-1} + \delta$). This composite measure allows us to quantify processing speed in a uniform way across individuals in the face of this variation. The results of this analysis for the critical *ziji* conditions are presented in **Table 3**.

The individual parameter estimates were entered into a 2 × 2 repeated-measures ANOVA with dependency type and animate position as within-participant factors. ANOVAs revealed an interaction of dependency type and animate position both for rate parameters β [$F_{(1,\ 16)} = 4.8,\ p < 0.05$] and for the composite speed measure $\beta^{-1} + \delta$ [$F_{(1,\ 16)} = 8.2,\ p < 0.05$]. In addition, there was a main effect of dependency type on speed measures [$F_{(1,\ 16)} = 6.1,\ p < 0.05$] and on rate parameters [$F_{(1,\ 16)} = 3.6,\ p < 0.1$], reflecting faster processing of *ziji* conditions. Additionally, a significant effect of dependency type was observed for the asymptote parameter λ [$F_{(1,\ 16)} = 4.9,\ p < 0.05$]. There were no significant effects on the intercept parameter δ for either fixed or free asymptote models.

Planned pairwise comparisons revealed that these interactions were driven by differences in the *ziji* conditions in the speed measure $\beta^{-1} + \delta$ [$t_{(16)} = -2.6, p < 0.05$]. This analysis revealed only marginal effects on the rate parameter β [$t_{(16)} = 1.9,\ p < 0.1$]. There were no effects of antecedent position in the control conditions for either speed [$t_{(16)} = 1.6, p = 0.12$] or rate [$t_{(16)} = -0.1$, $p = 0.89$]. On average, the speed measure for local *ziji* condition was 294ms faster (95% CI: 52–538 ms) than long-distance *ziji* condition.

DISCUSSION

Both individual and average data suggest a time-course advantage for local *ziji* conditions compared to LD *ziji* conditions. In competitive model fits to the average time course data, there was a slight advantage for models that allocated different rate parameters to long-distance and local *ziji* conditions; no such difference was observed for control comparisons. An analysis of the parameter estimates for individual participants showed that for the critical *ziji* comparison, the local condition was processed significantly faster than the long-distance condition, as reflected in the rate parameter (β) and the composite speed measure ($\beta^{-1} + \delta$). No difference was observed in control conditions. In ANOVA analyses of empirical d' scores, there was no significant difference for either *ziji* or control comparisons in asymptotic accuracy.

Follow-up experiment

One unexpected finding in Experiment 1 was the high acceptance rate of the no antecedent *ziji* condition, which participants accepted on 47% of trials. It has been claimed that in the absence of an overt, syntactically prominent antecedent, *ziji* can refer to the speaker (Huang and Liu, 2001). However, post-experiment debriefing suggested that some speakers also interpreted *ziji* as coreferential with an implicit author of the inanimate main clause subjects such as *book* or *speech*. It is also possible that the subject contained in the temporal adjunct in our experimental sentences contributed to retrieval interference, and was misinterpreted as

an antecedent for *ziji* on some trials. We conducted a follow-up experiment to determine the interpretations that comprehenders might assign to each of our three conditions.

The follow-up experiment used the three *ziji* conditions from Experiment 1. Twenty-four of the original 40 item sets were selected at random, and were distributed in a Latin Square fashion into three experimental lists. Each list was presented as a short questionnaire on the online experimental platform IbexFarm (Drummond, 2011). Each sentence was presented on the screen, and participants were instructed to choose their preferred interpretation of *ziji*'s antecedent from five options: the *main clause* subject, the *local* subject, the *interfering* subject contained inside the temporal adjunct, the *speaker* of the sentence, or *none*. When the main clause subject was inanimate (e.g., *book*), the main clause subject response option referred to the implicit author (e.g., *the book's author*).

Seventeen native Mandarin speakers were recruited via the Internet. The results are presented in **Table 4**. In order to test for differences across conditions in the proportion of responses, each response category was converted into a binary variable that was 1 if a response was in the category, and 0 otherwise. Each response category was analyzed using logistic mixed effects models with crossed random intercepts for subjects and items and random slopes of condition for subjects. Two Helmert contrasts were employed for the condition factor: a *locality* contrast that compared local and LD conditions, and an *antecedent* contrast that contrasted the no antecedent condition with the average of the LD and local conditions.

This analysis revealed that the *no antecedent* condition had significantly more *none* responses ($\beta = 0.64$, Wald's $z = 3.4$, $p < 0.05$) and *interferer* responses ($\beta = 1.53$, Wald's $z = 6.1$, $p < 0.05$) than the other two conditions. The LD condition had significantly more matrix subject responses than the local conditions ($\beta = -3.5$, Wald's $z = -8.0$, $p < 0.05$), and the local condition had significantly more embedded subject responses than the LD condition ($\beta = 3.4$, Wald's $z = 8.8$, $p < 0.05$). In addition, there was a significant effect of *antecedent* on embedded subject responses ($\beta = -0.9$, Wald's $z = -5.2$, $p < 0.05$), reflecting the low proportion of local subject responses in the no antecedent condition. No other effects were significant.

The follow-up experiment confirms that participants overwhelmingly select a structurally prominent, animate antecedent for *ziji* when there is one available. This replicates the judgments reported in the literature on Mandarin long-distance reflexives. Additionally, the results show that in the absence of a semantically appropriate and syntactically accessible antecedent, comprehenders nonetheless ultimately prefer a sentence-internal antecedent: the interfering subject is selected on 31% of trials, and on 35% of trials participants coerce an animate antecedent from the matrix subject.

Table 4 | Average proportion of interpretations reported on critical ziji comparisons in the follow-up experiment.

	Long-distance	Local	Interfering	Speaker	None
LD antecedent	0.87	0.06	0.03	0.00	0.04
Local antecedent	0.03	0.91	0.03	0.00	0.03
No antecedent	0.35	0.12	0.31	0.04	0.18

DISCUSSION

The results of the follow-up experiment confirm that comprehenders prefer to select syntactically prominent, animate antecedents for *ziji* in our materials. The results of Experiment 1 show that comprehenders are measurably slower to access long-distance antecedents for *ziji* than local antecedents. The fact that dependency distance impacted retrieval speed in our SAT experiment contrasts with previous SAT findings. Previous work on SAT in language comprehension suggests that distance does not affect the dynamics parameters in the SAT function (McElree, 2000; McElree et al., 2003; Foraker and McElree, 2007; Martin and McElree, 2008, 2009). This makes it unlikely that the faster access times we observe to local antecedents reflect a simple effect of temporal distance or recency.

Another way that long-distance and local antecedent configurations differ is in the type of interference contributed by the semantically inappropriate antecedent. In long-distance conditions, the semantically inappropriate antecedent intervenes between the target antecedent and the anaphor, and so generates retroactive interference (RI) in the process of retrieving the target antecedent. Conversely, in local antecedent configurations, the long-distance antecedent precedes the target, and so generates proactive interference (PI) that may disrupt the anaphor's retrieval of its antecedent. The difference in the type of interference created by the semantically inappropriate antecedent may be critical: Öztekin and McElree (2007) observed that in recognition memory tasks, the presence of PI has an effect on retrieval dynamics, leading to slower retrieval times. However, recent SAT work has directly investigated the effects of PI and RI on retrieval processes in language comprehension (Van Dyke and McElree, 2011). Van Dyke and McElree (2011) suggest that RI contributes more difficulty in dependency completion in sentence comprehension than does PI, but crucially, they show that the type of interference (PI/RI) does not impact retrieval speeds in multiple-response SAT. Instead, they observe only that RI configurations lower asymptotic accuracy relative to PI configurations. In light of these results, it appears unlikely that the speed differences that we observed were due to the type of interference generated by the inappropriate antecedent.

A MODEL OF THE LOCAL SEARCH HYPOTHESIS

We have suggested that neither recency alone nor the type of interference (RI/PI) was the source of the observed differences in retrieval times in Experiment 1. Instead, we argue that these results suggest that comprehenders consider or misretrieve the local subject position when the target antecedent is syntactically distant, which then leads to slowed retrieval of long-distance antecedents. We propose that this arises because locality outweighs semantic cues when retrieving an antecedent for *ziji*. There are two potential explanations of this locality effect in our data. According to the Local Search hypothesis, this effect reflects the use of cues that restrict retrieval operations to a local syntactic domain. However, it is possible that this locality effect reflects more misretrievals of a semantically inappropriate local subject

simply because it has a relatively high resting activation. There are two reasons to suspect that the local subject might have higher resting activation prior to reaching the anaphor *ziji*. First, it is more recent, and so will have undergone less temporal decay. Second, the embedded subject forms a dependency with the verb that precedes *ziji*. The process of retrieving the subject to form this dependency may boost the embedded subject's resting activation prior to encountering the anaphor.

To distinguish between a Local Search account and an account that attributes the slowed processing of LD *ziji* to the heightened activation of the local subject, we formalize the predictions of both accounts with a simple quantitative model of the antecedent retrieval process for *ziji*. Our model incorporates the declarative memory component of the ACT-R framework (Anderson and Lebiere, 1998), which implements a direct access cue-based retrieval process that is subject to temporal decay and retrieval interference. An attractive feature of this model is that it has been used in a number of successful models of cue-based parsers (Lewis and Vasishth, 2005; Lewis et al., 2006; Vasishth et al., 2008). Our goal in modeling the antecedent retrieval process using ACT-R is to estimate the effect of a local search strategy on SAT retrieval dynamics above and beyond the effects of interference and decay.

We define our retrieval models in terms of the set of cues (the retrieval probe) used to retrieve an antecedent from memory. The *unrestricted* retrieval model limits the probe to item information only. In our implementation, this includes category identity (*NP*), a case feature (+*Nominative*), which serves to identify subjects, and an animacy feature (+*Animate*). The latter two cues implement the syntactic and semantic constraints on *ziji*'s antecedent. The *local search* retrieval model includes these features plus a feature (+*Local*) that distinguishes the local clause from other clauses. In terms of our stimuli, this feature is used to distinguish the embedded clause from both the matrix clause and the adjunct clause. This feature implements the core claim of the Local Search hypothesis: that the parser uses positional information to restrict search to the local syntactic domain at retrieval, creating a retrieval process that explicitly prioritizes retrieval within a local syntactic domain (here taken to be the local clause).

Our model assumes that the process of finding *ziji*'s antecedent involves a series of serially executed, cue-based retrievals from a content-addressable memory store (consistent with the processing assumptions of Lewis and Vasishth, 2005). Once an item is retrieved, it is evaluated as the antecedent of *ziji*. If the retrieved item is rejected as an antecedent for *ziji*, then the processor samples another potential antecedent from the linguistic context, without replacement. We assume that the processor samples antecedents in this way until an appropriate antecedent is found. Under this model, cue match, temporal decay, and interference all influence the average number of sampling operations that are required to recover the correct antecedent for *ziji*. The more sampling operations are executed during the retrieval of an antecedent, the slower the speed of the SAT function that tracks this process.

To fit this model to the empirical data, we first determine the probability of successfully retrieving the target antecedent on each successive sampling operation. We determine these probabilities by simulation, using the equations that define declarative memory in ACT-R. The ACT-R component of the simulations reported below was developed by Badecker and Lewis (2007) using the R programming language (R Core Team, 2013). Under this model, the parser retrieves the item in memory with the highest activation value, where activation is a function of the match to retrieval cues and the resting activation of all items in memory. Formally, the activation of a memory item i (A_i) is the sum of its resting activation B_i, the match between the item and each of the J retrieval cues in the probe (S_j), and random noise (ϵ):

$$A_i = B_i + \sum_j W_j S_{ji} + \epsilon \tag{8}$$

The weight associated with each retrieval cue W_j is the total amount of goal activation available G divided by the number of retrieval cues. The resting activation of item i is a function of temporal decay (controlled by the decay parameter d) over all M intervals t_m since the item was last retrieved or created:

$$B_i = ln\left[\sum_m t_m^{-d}\right] \tag{9}$$

The match of an item i to the retrieval probe is the sum of a weighted associative boost for each cue S_j in the retrieval probe that matches the features of item i. The weight of a feature W_j is assumed to be equal across all cues in the probe. The associative boost that a given cue adds to an item it matches is reduced by the *fan* of that cue, or the number of items in memory that match that cue:

$$S_{ji} = S - \ln(fan_j) \tag{10}$$

Lastly, a small amount of stochastic noise is added to every item's activation level. On any given trial a noise value is drawn from a logistic distribution with a mean of zero and a variance that is controlled by a noise parameter s.

$$\epsilon \sim logistic(0, \sigma^2) \tag{11}$$

$$\sigma^2 = \frac{\pi^2}{3} s^2 \tag{12}$$

For all predictions reported below, we simulated the model's predictions on a range of parameter settings, and report the mean predicted values across all parameter settings (following the approach in Dillon et al., 2013). Our choices of possible parameter settings were based on the settings reported in Lewis and Vasishth (2005)[1]. One exception was the scaling parameter F, which was set to yield a mean retrieval time of 90 ms. This was chosen because it provided a close fit to the estimated retrieval time of 85 ms in the SAT paradigm found by McElree et al. (2003). The times between the creation

[1]The parameter settings considered were: $F = \{0.08, 0.10, 0.12\}$; $d = \{0.4, 0.5, 0.6\}$, $S = \{0.75, 1.0, 1.25\}$; $G = \{0.75, 1.0, 1.25\}$. Crossing all possible parameter settings resulted in 81 unique parameterizations of the model.

of antecedent representations and the retrieval associated with *ziji* were calculated directly from the experimental presentation parameters. In addition, an intermediate retrieval of the local subject at the embedded verb was simulated, which provided a boost in the embedded subject's resting activation prior to the point when *ziji* was encountered.

For both retrieval models, the probability of retrieving the target and each of the distractor NPs under these conditions was estimated using Monte Carlo simulation and averaging across all parameter settings considered. From this distribution we simulated the average number of sampling operations necessary to recover the target antecedent for both retrieval models. The resulting distributions are presented in **Table 5**. Under local search models, the local target is reliably retrieved after only one sampling operation on 56% of trials, whereas the modal number of sampling operations required to access the long-distance antecedent under the search model is 3 (occurring on 55% of trials). In the unrestricted search models, there is a lower probability of success with a single retrieval: local antecedents are retrieved on the first trial in 35% of trials for unrestricted models, and long distance antecedents are retrieved on 27% of trials. The lower probability of success for unrestricted models reflects the additional interference from the syntactically illicit distractor NP that occurs without positional cues to retrieval. On unrestricted models the number of sampling operations necessary to recover the target antecedent does not appear to differ substantially for local and long-distance antecedents. This pattern suggests that the increased resting activation of the local subject does not by itself lead to a substantially increased rate of retrieval errors during the retrieval of a long-distance antecedent. Instead, the search model results suggest that a semantically inappropriate local subject is most likely to be misretrieved when the search probe contains positional cues that select the local subject.

Next, we calculated the distribution of finishing times for the search process under the serial sampling model we have proposed. We simulated the distribution of finishing times for a retrieval process with n sampling iterations by simulating the sum of n retrievals from the ACT-R model given above. For retrievals beyond the first, an additional 50 ms was added, reflecting the additional processing necessary to evaluate the retrieved item[2]. In ACT-R, the retrieval latency T_i is a function of activation and a scaling parameter F (see Footnote 1):

$$T_i = Fe^{-Ai} \tag{13}$$

Table 5 | Probability distribution over the average number of sampling operations necessary to recover ziji's antecedent for the critical experimental conditions, for each of the candidate retrieval models.

P (number of samples = *X*)	1	2	3
LD antecedent, unrestricted	0.270	0.385	0.345
Local antecedent, unrestricted	0.353	0.437	0.210
LD antecedent, local search	0.190	0.258	0.552
Local antecedent, local search	0.560	0.351	0.089

[2]Fifty milliseconds is the time necessary to execute a single production step in ACT-R.

Inspection of the resulting finishing time distributions showed that they were well-fit by gamma distributions. Therefore, we modeled the overall predicted finishing time distribution for a given retrieval model as a mixture of gamma distributions, with each component reflecting the distribution of finishing times for a process with n sampling iterations. The mixing probabilities on each component were provided by the distribution in **Table 5**. With this mixture distribution, we could then follow the modeling approach advanced by McElree (1993). To do this, we used the resulting mixture to model the probability that the retrieval process will have completed by any time t as the cumulative distribution of this mixture, offset by a constant base encoding time δ (McElree, 1993):

$$P(T \leq t) = \frac{\beta^\alpha}{(\alpha - 1)} \int_0^{t-\delta} e^{-\beta t'} t'^{\alpha-1} dt' \qquad t > \delta, \text{ else } 0. \tag{14}$$

This cumulative distribution was then used to estimate the probability of responding with a hit at each time point t. This was calculated following the method described in McElree (1993). In particular, we assumed that all unfinished processes at time t contributed a hit 50% of the time, reflecting a guess on the part of the participant. We additionally assumed that on 5% of trials the target antecedent was rejected, leading to a miss response. The predicted proportion of hits at each time point was then transformed using the inverse cumulative normal distribution. Finally, the SAT function was fit to the predicted curves for each retrieval model and parameter setting, and the speed measure $\beta^{-1} + \delta$ was estimated for each predicted curve. We define the *locality advantage* as the predicted speed to access a long-distance antecedent minus the predicted speed to access a local antecedent, given a set of model parameters and a retrieval probe. The predicted locality advantages were calculated for both retrieval models, under all parameter settings. The predicted locality advantages were then compared to the empirical locality advantage in speed observed in Experiment 1.

Figure 2 provides a comparison of the empirical locality advantage with the predicted locality advantages for unrestricted and local search models. It can be seen that the local search model provides a good fit to the SAT data. On average, local search models predicted a locality advantage of 143 ms, approximately half of the observed empirical estimate of 294 ms from Experiment 1. However, the unrestricted search model predicts a much smaller speed advantage for local antecedents (39 ms). We tested the fit of each candidate retrieval model to the data by comparing the distribution of predicted locality advantage effects to the distribution of the mean locality effect estimated in Experiment 1. From these distributions, we calculated Bayes factors using the model comparison approach advocated by Gallistel (2009). This comparison gives 5:1 odds in favor of the local search model over the unrestricted model, providing "substantial" evidence in favor of the Local Search model (Jeffreys, 1961).

The modeling results suggest that the local search model provides a better explanation of our experimental data than does an account in which the locality advantage is simply attributed to the heightened activation of the local subject. We note that the model

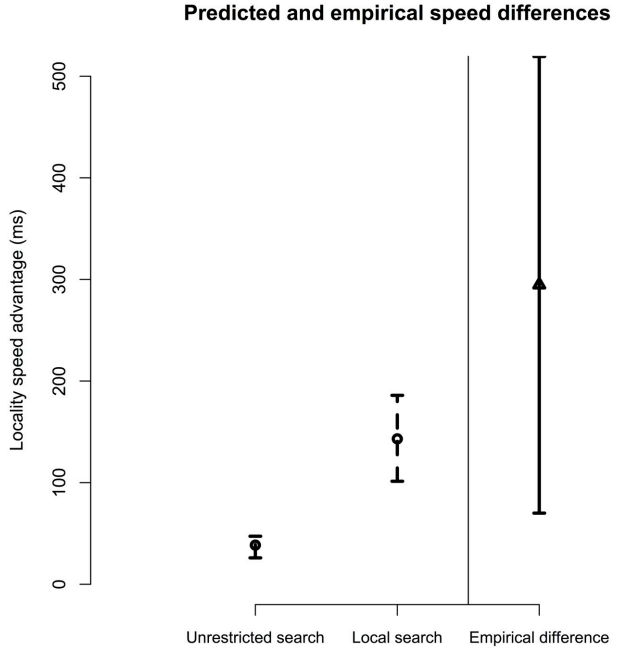

FIGURE 2 | Comparison of empirical speed advantage for local *ziji* antecedents and search model's predictions, given both unrestricted and local search retrieval probes. For model predictions, error bars represent the 95% central range of predicted locality advantage over parameter settings. For empirical data, error bars represent 95% confidence interval of true speed advantage for local antecedents by participants.

does confirm that an unrestricted model of antecedent retrieval does predict a small speed difference in the SAT function, due to the interaction of temporal decay, RI, and reactivation of the local subject prior to the anaphor. However, given the modeling assumptions here, these factors alone were not sufficient to allow the model to capture the findings of Experiment 1. By providing evidence against these plausible alternative explanations for the results of Experiment 1, the findings from the computational simulations lend additional support to the Local Search hypothesis.

DISCUSSION

SUMMARY OF RESULTS

The current study presented time-course data from the MR-SAT paradigm on the processing of the Mandarin Chinese long-distance reflexive *ziji*. Non-linear regressions using the SAT function revealed that the parameters that describe the speed of processing (specifically, rate and speed) were significantly faster for sentences containing a local antecedent for *ziji* than for sentences with a long-distance antecedent for *ziji*. Control conditions without any anaphoric dependency showed no difference in speed or rate parameters. We observed only marginal differences in accuracy. Sentences with long-distance animate subjects were accepted at slightly higher rates for *ziji* and control conditions alike, and control conditions were accepted at a higher rate than *ziji* conditions. A follow-up experiment evaluated the interpretations that comprehenders assigned to *ziji* to a subset of our experimental materials. These results confirmed that participants overwhelmingly interpreted a local animate subject as the preferred antecedent for *ziji* when it was present, and likewise when there was a long-distance animate subject present. However, when there was no syntactically licit animate subject in the sentence, participants either rejected *ziji* as antecedentless, interpreted *ziji* as coreferent with an implicit possessor argument in the highest subject position, or interpreted it as coreferent with an animate subject embedded inside a temporal adjunct clause.

To aid in interpreting these data, we fit the predictions of two retrieval models to the SAT data. The Local Search model implemented a retrieval process that used positional syntactic cues to restrict retrieval to the local clause. The Unrestricted model used only item information to access potential antecedents. We showed that the Local Search model provided a closer fit to the empirical data than the Unrestricted model, using plausible parameter estimates.

LOCALITY IN RETRIEVAL

The slower time course to access the matrix subject suggests that comprehenders initially access the local subject position when retrieving an antecedent for *ziji*, even if that position does not contain an acceptable antecedent. The results of our simulations suggest that this misretrieval of the local subject is not merely due to a higher resting activation for local subject positions compared to more distant subject positions. Instead, the models suggest that comprehenders attempt to use retrieval cues to limit search to the local syntactic domain. This supports the key claims of the Local Search hypothesis: comprehenders attempt to limit retrieval to the local clause, even for dependencies that are not strictly clause-bounded. This suggests that in at least some cases, locality effects in processing do not simply reflect decay and interference processes. In some cases, they additionally reflect a search strategy that favors the retrieval of syntactically local dependents.

One interesting finding from Experiment 1 is the individual variation in the retrieval dynamics observed across participants. Four of the 17 participants showed substantially faster retrieval of the long-distance antecedent than the local antecedent. For these participants, the average speed advantage seen for long-distance antecedents was 343 ms. This variation raises the possibility that the positional cues used to retrieve an antecedent are under strategic control, such that these four participants were able to prioritize retrieval of the highest subject over the local subject. Additionally, two of the remaining 13 participants showed a substantial rate advantage for the local conditions, driven by extremely fast retrieval speeds for local *ziji* conditions. The extremely rapid growth of these participants' SAT functions suggests that they may have adopted a distinct strategy for determining whether *ziji* was licensed in our experiment, perhaps one based on familiarity with an animate referent rather than full retrieval of an antecedent. Although we believe it is important to understand the variation observed across our participants, we caution that these suggestions are for the moment highly speculative. Further research is necessary to determine the exact ways in which memory search strategies are subject to strategic and individual variation.

We presented a model of the Local Search strategy that relies on a direct access memory architecture. On this model, the slowdown for retrieving the matrix antecedent reflects the fact that comprehenders must execute multiple retrieval operations to recover the distant antecedent in the face of a substantive locality bias in retrieval. However, the data are also compatible with a serial scan mechanism that operates over syntactic structures. This is compatible with previous claims about the mechanisms that allow the recovery of order or positional information in retrieval (McElree and Dosher, 1993; Gronlund et al., 1997). On this model, the present results do not reflect misretrieval of the local subject, but rather a backwards process of traversing the parse until an acceptable antecedent is encountered. Although existing SAT data provide evidence against the use of serial search processes for a number of linguistic dependencies, it is possible that a serial search process is applied uniquely to syntactic binding dependencies. Indeed, Berwick and Weinberg (1984) make an argument on computational grounds for just such a serial, backwards search process for the retrieval of a bound anaphor's antecedent. However, our present results do not distinguish between these two distinct mechanisms.

Although we have argued that our simulations point to a role for a Local Search strategy in memory access, it is true that this argument rests on a number of modeling assumptions that we made. It is possible that the SAT results reflect an overwhelming activation advantage for the local subject that is not captured in our implemented retrieval model, which might lead to slowed access to the distant subject even without the use of positional cues. One way this might occur is if the local subject were available in the focus of attention at the point of processing the anaphor, thus obviating the need for any retrieval process (McElree, 2006; Jonides et al., 2008). This interpretation seems less likely in light of findings that indicate that the focus of attention is extremely limited in size and scope, possibly corresponding to just one task-relevant encoding (McElree and Dosher, 1989; McElree, 1998). If only one element occupies focal attention before *ziji* is processed, it is likely to be the verb, although it is difficult to generalize from findings about the scope of attention in recognition memory tasks to sentence processing. The data on the capacity of the focus of attention is somewhat sparser for connected linguistic representations, which have considerably richer structure than lists. However, it has been shown that opening a new clause displaces the contents of focal attention (McElree et al., 2003; Wagers and McElree, 2009), and so the adverbial clause that intervened between the subject and the verb in Experiment 1 is likely to have displaced the local subject from active memory.

A second possibility is that the local subject is reactivated at the verb that precedes *ziji.* Although our model accounted for a process of local subject reactivation prior to the anaphor, it is possible that the boost given to the local subject due to this reactivation is substantially larger than our model allows for. At present we cannot rule out this possibility, but we believe that it is unlikely on empirical grounds. In particular, data from the cross-modal lexical priming paradigm show that a subject is not strongly activated above baseline while processing its verb (Nicol and Swinney, 1989, 2003). Studies that have contrasted activation of the local subject position before and after reflexive anaphors demonstrate that reactivation of the local subject is contingent on the construction of an anaphoric dependency; processing the verb alone is not sufficient to boost activation, nor is activation observed in post-verbal positions that do not contain a reflexive anaphor (see a review in Nicol and Swinney, 2003).

Finally, it should be noted that our model assumes that all retrieval cues are equally diagnostic. Although this is a plausible assumption that is common in ACT-R modeling and elsewhere (see also Clark and Gronlund, 1996; Lewis and Vasishth, 2005), recent research into how retrieval cues are combined in sentence processing does raise the possibility that syntactic and semantic cues are not equally weighted. In particular, Van Dyke and McElree (2011) argue that syntactic cues are more highly weighted than semantic cues in comprehension, and Dillon et al. (2013) argue that cue weight may vary as a function of grammatical dependency. Further work is necessary to determine whether different cues to antecedent retrieval for *ziji* are in fact differentially weighted, and if so, how differential cue weighting would influence the conclusions of the present research.

CONCLUSION

The present study examined the time-course of antecedent retrieval for the Mandarin Chinese long-distance anaphor *ziji*. It was found that *ziji* is processed more quickly with a local antecedent than with a long-distance antecedent. A computational model of the retrieval process supports the conclusion that the locality advantage observed when retrieving *ziji*'s antecedent reflects an explicit local search strategy: when retrieving an antecedent, comprehenders prioritize retrieval of items within the local clause. These results suggest that locality effects in sentence processing cannot be entirely reduced to the effects of temporal decay and interference in memory.

In the present study we report two self-paced reading experiments that investigate antecedent retrieval processes in sentence comprehension by contrasting the real-time processing behavior of two different reflexive anaphors in Mandarin Chinese. Previous work has suggested that comprehenders initially evaluate the fit between the morphologically simple long-distance reflexive "ziji" and the closest available subject position, only subsequently considering more structurally distant antecedents (Gao et al., 2005; Liu, 2009; Li and Zhou, 2010; Dillon et al., 2014; cf. Chen et al., 2012). In this paper, we investigate whether this *locality bias* effect obtains for other reflexive anaphors in Mandarin Chinese, or if it is associated specifically with the morphologically simple reflexive *ziji*. We do this by comparing the processing of *ziji* to the processing of the morphologically complex reflexive *ta-ziji* (lit. s/he-self). In Experiment 1, we investigate the processing of *ziji*, and replicate the finding of a strong locality bias effect for *ziji* in self-paced reading measures. In Experiment 2, we investigate the processing of the morphologically complex reflexive *ta-ziji* in the same structural configurations as Experiment 1. A comparison of our experiments reveals that *ta-ziji* shows a significantly weaker locality bias effect than *ziji* does. We propose that this results from the difference in the number of morphological and semantic features on the anaphor *ta-ziji* relative to *ziji*. Specifically, we propose that the additional retrieval cues associated with *ta-ziji* reduce interference from irrelevant representations in memory, allowing it to more reliably access an antecedent regardless its linear or structural distance. This reduced interference in turn leads to a diminished locality bias effect for the morphologically complex anaphor *ta-ziji*.

INTRODUCTION

Anaphoric expressions such as pronouns (e.g., *him*, *he*), reflexives (e.g., *himself*), and anaphoric definite descriptions (e.g., *the boy*) have been widely studied in both linguistic and psycholinguistic traditions. Linguists have long been concerned with how the interpretation and syntactic distribution of referring expressions are determined (Chomsky, 1981; Heim, 1982; Elbourne, 2008; *a.o.*). Psycholinguists have studied anaphoric expressions both as a window into how

comprehenders organize a text, and as a window into the working memory mechanisms that support sentence-level and discourse-level language comprehension (Kintsch, 1975; Gernsbacher, 1989; Greene et al., 1992; Myers and O'Brien, 1998; Foraker and McElree, 2011; Kush, 2013; Sturt, 2013; Dillon, 2014; *a.o*).

In the present work, we pursue a research question at the intersection of these two traditions. We ask how the form of a referring expression is related to the processing mechanisms that comprehenders use to assign it a referent. To this end, we contrast the processing of two closely related reflexive anaphors in Mandarin Chinese. Specifically, we compare the processing behavior of the morphologically simple reflexive *ziji* to that of the morphologically complex reflexive *ta-ziji*. In two self-paced reading experiments, we investigate the degree to which each anaphor exhibits a *locality bias*, a processing advantage (or preference) for syntactically local antecedents over more distant ones. Our empirical goal is to investigate the effect of morphological complexity on the processing of an anaphoric expression, with special attention to how morphology modulates the degree to which an anaphor will exhibit locality biases in processing. We interpret our results with respect to a theoretical model of anaphoric processing developed in other work (Dillon et al., 2014). To foreshadow our empirical and theoretical conclusions: our experimental findings suggest that morphologically complex anaphors in Mandarin Chinese show a diminished locality bias in comparison to morphologically simple ones, a finding that we attribute to how the processor makes use of the richer morphological feature content of morphologically complex anaphors in retrieving an antecedent from memory.

LONG DISTANCE REFLEXIVES AND LOCALITY EFFECTS

In recent years, there have been a number of experimental investigations into the real-time processing behavior of the Mandarin Chinese long-distance reflexive *ziji*. *Ziji* is a morphologically simplex reflexive, literally meaning *self* (Huang et al., 2009). *Ziji* is a *long-distance* reflexive, unlike English reflexives which must be bound within their immediate tensed clause (their *binding domain*; Chomsky, 1981). Long-distance reflexives are so called because their binding domain is larger than their immediate tensed clause, although the exact size of their expanded domain varies across languages (see Büring, 2005). For Mandarin *ziji*, it appears that the binding domain is the entire root clause in which *ziji* is found (Tang, 1989; Xue et al., 1994; Huang and Liu, 2001; Büring, 2005; Huang et al., 2006, 2009). To take one example, in (1) *ziji* may be bound either by the subject of its immediate clause *Lisi*, or by the subject of the higher (root) clause *Zhangsan* (subscripts are used to indicate acceptable coindexation):

(1) 张三 说 李四 弄伤了 自己
Zhangsan$_j$ shuo Lisi$_i$ nongshang-le ziji$_{i/j}$
Zhangsan say Lisi harm-PERF self
"Zhangsan says that Lisi harmed him/herself"

Ziji requires an animate antecedent (Tang, 1989; Xue et al., 1994; Huang and Liu, 2001), and receives an interpretation analogous to English reflexive forms. *Ziji* does not bear any overt morphological features, however, and so may take antecedents regardless of their gender, number, or person features.

Given the possibility of long-distance binding, it is interesting to note that many experimental studies have shown that comprehenders show a locality bias when processing *ziji*, preferring or more easily processing antecedents in their local clause over antecedents found in more distant clauses. For example, Li and Zhou (2010) conducted an ERP experiment in Mandarin, measuring the electrophysiological response to the anaphor "ziji" in examples like (2):

(2) a. 小李 让 小张 不要 伪装 自己
Xiaoli$_i$ rang Xiaozhang$_j$ buyao weizhuang ziji$_{?i/j}$.
Xiaoli ask Xiaozhang not disguise ziji.
"Xiaoli asked Xiaozhang not to disguise himself."

b. 小李 让 小张 不要 牵连 自己
Xiaoli$_i$ rang Xiaozhang$_j$ buyao qianlian ziji$_{i/?j}$.
Xiaoli ask Xiaozhang not embroil ziji.
"Xiaoli asked Xiaozhang not to embroil him."

Li and Zhou observed a larger positivity (P300/P600) at *ziji* when the semantics of the verb created a bias toward a long-distance reading of the reflexive, as in (2b), compared to when the meaning of the verb biased comprehenders toward a local reading of the reflexive, as in (2a).

Cross-modal priming studies point to a similar advantage for local antecedents over long-distance antecedents. Gao and colleagues (Gao et al., 2005; Liu, 2009) presented participants with spoken sentences of the form in (1). Upon reaching the sentence-final *ziji*, participants were presented with a visual probe word. When the probe was presented immediately after the anaphor, participants recognized probes that were semantic associates of a local antecedent more quickly than they did probes associated with long-distance antecedents; this locality advantage disappeared or reversed at slightly longer SOAs (160 and 370 ms).

Using a different experimental paradigm, Chen et al. (2012) showed using self-paced reading that locally bound *ziji* was read more quickly than long-distance bound *ziji*. These authors leveraged the observation that *ziji* requires an animate antecedent to create the pair of experimental sentences in (3) (brackets are used to indicate tensed clause boundaries):

(3) a. 反对派 领袖 表示 这个 声明
Fanduipai-lingxiu$_i$ biaoshi [zhe-ge shengming$_j$
在 抗议 失控 的 时候 告诫了 自己 的
[zai kangyi$_k$ shikong de- shihou] gaojie-le ziji$_{i/*j/*k}$
党员
de dangyuan]
opposition-leader say [this- cl announcement [at protest out.of.control time] warn- PERF ziji de party.member]
"The opposition leader said that this announcement warned his party members when the protest was out of control"

b. 这个 声明 表示 反对派 领袖
Zhe-ge shengming$_i$ biaoshi [fanduipai- lingxiu$_j$
在 抗议 失控 的 时候 告诫了 自己 的
[zai kangyi$_k$ shikong de-shihou] gaojie-le ziji$_{*i/j/*k}$
党员
de dangyuan]
this-CL announcement say [opposition-leader [at protest out.of.control time] warn-PERF ziji de party.member]
"The announcement said that the opposition leader warned his party members when the protest was out of control"

In these examples, *ziji* is the possessor of the direct object NP and it appears immediately after the embedded verb. In (3a), the only animate, c-commanding antecedent is *fanduipai-lingxiu*, "opposition leader." Thus, in this example, *ziji* must take a long-distance antecedent in the immediately higher clause. In contrast, the embedded subject in (3b) is the only animate and c-commanding antecedent, and so *ziji* must take a syntactically local antecedent. In this paradigm, the difference in reading times between *ziji* in (3a) and (3b) is taken to indicate the difficulty of constructing a long-distance *ziji* interpretation in (3a). Chen and colleagues observed a small but reliable RT slow-down in reading times at the region following *ziji* (*de*) in (3a) relative to (3b), suggesting more difficulty in constructing a long-distance than local interpretation of *ziji*. This result was subsequently replicated in an eye-tracking while reading study, using direct object *ziji* in place of possessive *ziji*, and without an adverbial clause intervening between the subject and the verb (Jäger et al., 2015; Experiment 2).

Dillon et al. (2014) asked whether the locality bias associated with *ziji* reflected a difference in processing *speed* for accessing long-distance antecedents, or simply a difference in processing *accuracy* associated with long-distance antecedents. For example, it is possible that the memory trace of a distant antecedent is of relatively poor quality compared to that of a local antecedent, perhaps due to memory decay processes. Such a difference in the representational quality of the antecedent could have given rise to the locality bias effect observed in previous studies, without any difference in processing speed. Alternatively, it may be that comprehenders simply take more time to access a long-distance antecedent, such that local antecedent positions have a temporal advantage compared to more structurally or linearly distant positions. Simple response time measures cannot tease these possibilities apart (see McElree, 2006). In order to ask this question, Dillon and colleagues used the multiple-response speed-accuracy tradeoff (MR-SAT) technique to investigate sentences similar to those in (3). The (MR-)SAT technique involves eliciting behavioral responses at a series of pre-defined response deadlines. This allows the researchers to chart how accuracy on a response measure grows as a function of time, giving a full picture of the time-course of processing. Importantly, the resulting SAT function may be separated into independent measures of processing speed and processing accuracy. Dillon et al.'s results indicated that the difference between local and long-distance binding was reflected in the rate parameter of the SAT function, suggesting that comprehenders took longer to retrieve long-distance antecedents for *ziji* than local antecedents.

Thus, a growing body of evidence suggests that despite the formal possibility of long-distance antecedents for *ziji*, comprehenders experience relatively more processing difficulty when *ziji*'s antecedent is not local. Furthermore, this locality bias seems to reflect a temporal advantage for local antecedents over long-distance antecedents: comprehenders more rapidly access local antecedent positions than long-distance positions.

ZIJI AND *TA-ZIJI*

Although previous research on *ziji* provides much evidence for a locality bias associated with *ziji*, it is not known how general this locality bias is. It is possible that a locality preference is a general property of long-distance reflexive anaphors. This might be expected if *ziji*'s locality bias was simply a reflection of the temporal or linear proximity of a local antecedent. In this case, we might expect all reflexive forms that can find an antecedent outside of their immediate clause to show comparable locality bias. On the other hand, it may be the case that the locality bias is rooted in some other specific property of *ziji*. For example, it may be the case that *ziji*'s lack of overt morphological features causes comprehenders to rely more heavily on positional cues when identifying an antecedent, which could lead to a preference for structurally local antecedents. If this is true, then we might expect the presence of locality bias effects to vary from anaphor to anaphor, depending on the surface form of the anaphor.

Mandarin grammar allows us to ask this question, because reflexive anaphors in Mandarin come in two forms: the morphologically simple, "bare" reflexive *ziji*, and morphologically complex anaphors. An example of a morphologically complex anaphor is *ta-ziji*, which consists of a third singular pronoun along with the bare reflexive (e.g. "he-self"). Other morphologically complex reflexives may be formed by combining other pronouns with *ziji* (e.g., *wo-ziji*, myself; *ni-ziji*, yourself), although here we focus on the third person singular form *ta-ziji*. *Ta-ziji* has a distribution that partially overlaps with *ziji*. For instance, when the antecedent of the anaphor is in the local clause, *ta-ziji* and *ziji* are interchangeable:

(4) 李四 弄伤了 自己 / 他自己
Lisi$_i$ nongshang-le ziji$_i$/ta-ziji$_i$
Lisi harm-PERF self / 3sg-self
"Lisi harmed himself"

The morphological differences between *ziji* and *ta-ziji* could lead to processing differences, because there are reasons to suspect that the addition of an overt pronoun to form a morphologically complex anaphor will yield richer cues for purposes of identifying an antecedent. First, the orthographic representation of the pronoun overtly provides gender and personhood cues: 他 (tā) is used for human male referents, 她 (tā) is used for human female referents, and 它 (tā) is reserved for non-human or gender-neutral referents. These forms are

distinguished orthographically, but they are not distinguished phonologically. In addition, the use of an overt pronoun is statistically more likely for gendered human antecedents than for non-human or gender neutral antecedents. A search of the Google Books corpus for simplified Chinese in the last 50 years reveals that approximately 73–80% of tokens of the third person singular pronoun refer to explicitly gendered human antecedents.

If this is correct, then we might say that *ta-ziji* has more features that can be used as cues to identify an antecedent when processing the reflexive. In particular, the addition of a pronominal form contributes humanness cues (i.e., [+human]) and gender cues. In contrast, the reflexive form *ziji* may only contribute animacy cues, because this is the only restriction that it places on potential antecedents. An interesting question to ask is whether the relatively more specified feature content of *ta-ziji* will lead to diminished locality bias for *ta-ziji* compared to *ziji*. If the locality bias associated with *ziji* reflects solely the influence of standard memory variables, such as decay or interference, then we might not expect the size or magnitude of the effect to vary with the surface form of the anaphor. If, on the other hand, the surface form of the anaphor contributes additional cues to identifying an antecedent, then locality bias might be diminished or eliminated for anaphors whose surface form bears more overt features. Thus, in the present study we aim to provide a head to head comparison of the locality bias associated with morphologically simple and morphologically complex anaphors, in an attempt to determine how generally locality bias is in the processing of anaphors in Mandarin.

Unfortunately, a direct comparison of the locality effects for *ziji* and *ta-ziji* is somewhat complicated by the fact that they do not have identical syntactic distributions. In contrast to *ziji*, the size of *ta-ziji*'s binding domain is a matter of some controversy. Huang et al. (2009) reported that it must be bound within its immediate tensed clause, like English *himself*. However, Pan (1998, 2000) argued that the binding domain of *ta-ziji* is fixed by the closest accessible animate antecedent, such that *ta-zij* can be bound outside of its local clause if the local subject is inanimate. What is clear is that *ta-ziji* places greater restrictions on long-distance antecedents than does *ziji*, and for this reason it is sometimes classified as a purely local reflexive in Mandarin (Huang et al., 2009). Because of the lack of clarity in the binding domains associated with these two reflexives, it is not ideal to compare these reflexives in the same embedding configurations used in previous studies (Chen et al., 2012; Dillon et al., 2014; Jäger et al., 2015).

Instead, we compared the behavior of *ziji* and *ta-ziji* in environments where they do have reliably overlapping distributions. For both *ziji* and *ta-ziji* the c-command relation that regulates binding in English (Chomsky, 1981) appears to be too restrictive. Instead, antecedents that do not strictly c-command these anaphors may be grammatically available, as in (5) (Tang, 1989):

(5) 张三 的 骄傲 害了 自己 / 他自己
Zhangsan$_i$ de jiao'ao$_j$ hai-le ziji$_{i/*j}$/ ta-ziji$_{i/*j}$
Zhangsan de arrogance harm-PERF ziji / 3sg-ziji
"Zhangsan's arrogance harmed him."

In (5), the antecedent *Zhangsan* is embedded inside the subject, and hence does not c-command the anaphor. Nonetheless, in this configuration it is available to bind the reflexive. The structural relationship between Zhangsan and *(ta-)ziji* in (5) is referred to as *subcommand* (Tang, 1989; Huang and Tang, 1991). An NP is said to subcommand the anaphor if it is contained within an NP in subject position that c-commands or subcommands the anaphor (Tang, 1989).

However, it is important to note that subcommanding antecedents are not freely available. Instead, a subcommanding antecedent is only available when no animate c-commanding or subcommanding antecedent is structurally closer to *ziji*. Thus, when the subject head noun is animate, subcommanding antecedents are grammatically blocked as in (6):

(6) 张三 的 小孩 害了 自己 / 他自己
Zhangsan$_i$ de xiaohai$_j$ hai-le ziji$_{*i/j}$/ ta-ziji$_{*i/j}$
Zhangsan de son harm-PERF ziji / 3sg-ziji
"Zhangsan's son harmed himself."

As *ziji* and *ta-ziji* distribute similarly in subcommanding environments, we may compare the processing of *ziji* and *ta-ziji* in configurations like (7):

(7) a. 张 太太 经常 光顾 的 那个
[Zhang taitai$_i$ jingchang guanggu de] na-ge
时装店 上个星期 把 自己 /她自己
shizhuangdian$_j$ shang-ge-xingqi ba ziji$_{i/*j}$ / ta-ziji$_{i/*j}$
不小心 弄伤了
bu xiaoxin nongshang-le.
Mrs. Zhang often visit DE that-CL boutique last-week ba self / 3sg-self not careful harm-PERF.
"The boutique that Mrs. Zhang often visits carelessly harmed her last week."

b. 媒体 报道 的 那个 女裁缝 上个星期
[Meiti$_i$ baodao de] na-ge nü-caifeng$_j$ shang-ge-xingqi
把 自己 / 他自己 不小心 弄伤了
ba ziji$_{*i/j}$ / ta-zij$_{*i/j}$ bu xiaoxin nongshang-le.
Media report-on DE that-CL seamstress last-week ba self / 3sg-self not careful harm-PERF.
"The seamstress that the media reported on carelessly harmed herself last week."

These examples have an object extracted relative clause (e.g., "that the media reported on") modifying a subject noun (e.g., *na-ge nü-caifeng* "that seamstress"). This structure creates two subject positions that could in principle bind an anaphor: the *local* subject position inside the matrix clause, and a *distant* subject position inside the relative clause. Given the licensing constraints on *ziji* and *ta-ziji*, we expect that both the local subject *na-ge nü-caifeng* "that seamstress" in (7b) and the long-distance subject *Zhang taitai* "Mrs Zhang" in (7b) should be grammatically accessible antecedents. However, these two antecedents differ in their structural and linear distance from the reflexive. The subcommanding antecedent *Mrs. Zhang* in (7a) is a long-distance antecedent because it is linearly and structurally more distant from the anaphor than the local antecedent *na-ge nü-caifeng* in

(7b). For this pair of conditions, then, a locality effect should present as increased reading times on the anaphor in (7a) compared to (7b).

We now present two experiments that investigate *ziji* and *ta-ziji* in Mandarin Chinese. Our goal in these experiments was to compare the processing profile of these two anaphors on a number of different dimensions. First, and most importantly, we ask whether both *ziji* and *ta-ziji* show locality effects of comparable magnitude in online sentence comprehension. In addition, we ask whether the processing of both *ziji* and *ta-ziji* is equally affected by the presence of multiple feature-matched antecedents. Previous research suggests that the presence of multiple, feature-matched antecedents may cause processing difficulty (the *multiple match effect* of Badecker and Straub, 2002), although this effect has not be observed in all studies (e.g., Clifton et al., 1999).

EXPERIMENT 1

Participants

Forty-one students from the University of Maryland community participated in the experiment. One participant was removed prior to analysis due to low comprehension question accuracy (see below). All participants were native Mandarin Chinese speakers from mainland China, and all had normal or corrected-to-normal vision. They were paid $10 for their participation in the experiment. Experimental sessions lasted approximately 45 min. Participants gave informed consent under an experimental protocol approved by the University of Maryland Institutional Review Board.

Stimuli

We created stimuli with the sentence structure in (7). We orthogonally manipulated the animacy of the local subject position and the embedded subject position, yielding four experimental conditions. These conditions are summarized in (8).

a. *LOCAL MATCH:*

媒体 报道 的 那个 女裁缝 上个星期 把

shang-ge-xingqi/ ba/ ziji/ bu xiaoxin/ nongshang-le.
Mrs. Zhang/ often visit DE / that-CL / boutique/ last-week/ BA/ self/ not careful/ harm-PERF.
"The boutique that Mrs. Zhang often visits carelessly harmed her last week."

c. *MULTIPLE MATCH:*

张 太太 经常 光顾 的 那个 女裁缝
Zhang taitai/ jingchang guanggu de/ na-ge/ nücaifeng/
上个星期 把 自己 不小心 弄伤了
shang-ge-xingqi/ ba/ ziji/ bu xiaoxin/ nongshang-le.
Mrs. Zhang/ often visit DE / that- CL/ seamstress/ last-week/ BA/ self/ not careful/ harm-PERF.
"The seamstress that Mrs. Zhang often visits carelessly harmed her/herself last week."

d. *NO MATCH:*

媒体 报道 的 那个 时装店 上个星期
Meiti/ baodao de/ na-ge/ shizhuangdian/ shang-ge-xingqi/
把 自己不小心 弄伤了
ba/ ziji/ bu xiaoxin/ nongshang-le.
Media/ report-on DE/ that-CL/ boutique/ last-week/ BA/ self/ not careful/ harm-PERF.
"The boutique that the media reported on carelessly harmed her last week."

The paradigm employed here thus followed Chen et al. (2012), Dillon et al. (2014), and Jäger et al. (2015) in using animacy to manipulate the binding possibilities for *ziji*. In the *LOCAL MATCH* and *DISTANT MATCH* conditions, the antecedent of *ziji* is the animate subject. In the *NO MATCH* condition, there is no intra-sentential antecedent for *ziji*. In the *MULTIPLE MATCH* condition, the local subject *na-ge nü-caifeng* "that seamstress" is the only grammatically available antecedent of *ziji*. In this condition, the animate local subject blocks access to the distant subject Mrs. Zhang; therefore, the interpretation of *ziji* is not ambiguous in the *MULTIPLE MATCH* condition (see Tang, 1989).

The primary comparison of interest for the present purposes is the difference in reading times between the *LOCAL MATCH* and *DISTANT MATCH* conditions at the anaphor. The *MULTIPLE MATCH* and *NO MATCH* conditions were included for two reasons. First, the factorial manipulation of the animacy of the two subject positions allows us to dissociate effects of interest from simple effects of local or distant subject animacy. Second, the inclusion of the *MULTIPLE MATCH* conditions allows us to estimate any reading time effects associated with multiple feature-matched antecedents (the multiple match effect, Badecker and Straub, 2002). The inclusion of the *NO MATCH* condition serves as a control. This allows us to evaluate whether readers were indeed attempting to find an antecedent for *ziji*; if this is the case, then the failure to find an appropriate antecedent in this condition should lead to longer reading times.

The distant (sub-commanding) antecedent position was always the subject of an object relative clause that modified the main clause subject. Owing to the head-final order of noun phrases in Mandarin Chinese, this embedded subject (distant antecedent) is both structurally and linearly further away from

the anaphor than the main clause subject (local antecedent). The local antecedent always followed the relative clause verb and the relativizing particle *de*. In order to construct plausible and natural sentences, the predicate inside the relative clause was different for animate (8a-c; e.g., "that Mrs. Zhang often visits") and inanimate (8b-d; "that the media reported on") relative clause subjects. The main clause predicate was constant across conditions.

In order to avoid having the critical word (the anaphor) in sentence-final position, the *ba* construction was used, because this construction has an S-ba-O-V word order (in contrast to the canonical SVO word order of Mandarin). A temporal adverbial was placed between the main clause subject (the local antecedent) and the *ba*-marked *ziji* to ensure that they were not adjacent to each other. A manner adverbial was placed between *ziji* and the main clause verb in order to provide an extra spillover region.

Eighteen sets of experimental items were produced, and distributed into four lists in a pseudo-Latin square fashion. They were combined with 77 fillers, including materials from an unrelated experiment, for a total of 95 sentences. The ratio of acceptable-to-unacceptable sentences varied slightly from list to list due to the pseudo-Latin square procedure, but remained between 83 and 85% acceptable. The fillers included 10 sentences that contained *ba* followed by non-anaphoric NPs in order to prevent participants from associating *ba* with *ziji* within the experiment.

Procedure

Sentences were presented using a moving-window self-paced reading paradigm, using the Linger software (Rohde, 2003). Each sentence was presented in black characters on a white screen, and no sentence was more than one line long. All sentences were presented using simplified Chinese characters. The sentences were segmented into 9 regions according to native speaker intuitions about where best to insert boundaries [regions are indicted by slashes in (8)]. This procedure resulted in regions that ranged from one character (e.g., *ba*) to 6 characters (e.g., *yishuticaoguanjun*, "gymnastics champion").

Sentences initially appeared as a series of dashes that obscured the entire sentence. Participants pressed the space bar to present the first region, and each subsequent space bar press masked the current region and triggered presentation of the subsequent region. Reaction times between button presses were recorded. After approximately 50% of the filler sentences, a Yes/No comprehension question was presented in its entirety on the screen, and participants were instructed to press one of two buttons to indicate their response. Feedback was given for incorrect responses. The critical *ziji* sentences never were followed by comprehension questions.

In the analyses below we refer to the region containing *ziji* as the *critical region*, and the region that follows (e.g., *bu xiaoxin*) as the *spillover region*.

Statistical Analysis

We performed a single statistical analysis over the pooled data in Experiments 1 and 2, which we present after Experiment 2. Reaction time data from both experiments were analyzed using linear mixed effects models with three critical experimental contrasts. Taking the *LOCAL MATCH* condition as the baseline, we defined the *Locality contrast* as the difference between the *DISTANT MATCH* condition and the *LOCAL MATCH* condition. As in previous studies (Chen et al., 2012; Dillon et al., 2014; Jäger et al., 2015), this contrast is interpreted as the penalty associated with long-distance binding of the anaphor. We further defined the *Multiple Match contrast* as the difference between the *MULTIPLE MATCH* condition and the *LOCAL MATCH* condition; this contrast is interpreted as the penalty associated with having multiple NPs that matched the features of the anaphor. Lastly, we defined the *No Antecedent contrast* as the difference between the *LOCAL MATCH* condition and the *NO MATCH* conditions. Each of these contrasts was coded with treatment coding, treating *LOCAL MATCH* as the baseline. These experimental contrasts were shared across Experiments 1 and 2. In addition to these fixed effects, we further included *Experiment* as a fixed effect with treatment coding, treating Experiment 1 as the baseline. Lastly, to test for differences in our experimental contrasts across experiments, we included terms for the interaction of *Experiment* with each experimental contrast.

Because our linear mixed effects models assume a normally-distributed response, we applied the Box-Cox procedure to reaction times at the regions we analyzed to determine a transformation that would yield a normally distributed response variable (Box and Cox, 1964). This procedure suggested a transformation in-between a negative reciprocal transform and a logarithmic transformation. Exploratory data analyses revealed that the qualitative pattern of results did not change under different transformations, and so we present the results of linear mixed effects models fit to logarithmically transformed reading time data. We adopted a "maximal" random effects structure, including random intercepts and random slopes for all fixed effect parameters within both subject and item grouping factors where possible (Barr et al., 2013). If the full model failed to converge, we removed random correlations but retained random slopes for all fixed effects.

Because of the pseudo-Latin square procedure, the number of sentences within each condition was not balanced within subjects. To test for any effects this imbalance may have had, we performed log-likelihood ratio tests of models with and without a fixed effect for experimental list. If log-likelihood tests indicated an effect of *list*, we performed further model comparisons to determine if the effect of *list* interacted with our experimental fixed effects.

In constructing the materials, we did not attempt to control the length or frequency of the subject noun phrases within items. However, as it has been shown that antecedent frequency is inversely correlated with reading times on anaphoric expressions (Van Gompel and Majid, 2004), we included antecedent frequency and antecedent length for both embedded and matrix subject positions as fixed effect control predictors in all mixed effects models. Antecedent frequency was estimated using the SUBTLEX Chinese corpus (Cai and Brysbaert, 2010). Many of our antecedent phrases were noun-noun compounds that were unattested in the corpus (e.g., *laladuiyuan*, "cheerleading squad member"). If the entire compound phrase was unattested, we

used frequency of the head noun. Length was entered into the model as the number of characters of the head noun in the subject phrase. Both antecedent frequency and length were centered before being entered into the model.

Analysis was performed for three regions of the experimental sentences: the pre-critical region *ba*, the critical region *ziji*, and the spillover region [e.g., *bu xiaoxin* in (8)].

Results

Offline Judgments

Prior to Experiment 1, we gathered offline acceptability judgments of all experimental materials. All experimental stimuli, including fillers, were entered into the online experimental platform IbexFarm (Drummond, 2011). Twenty-two native Mandarin speakers were recruited from Beijing Normal University. They were directed to a web address that hosted the offline naturalness judgment questionnaire and they were asked to rate each experimental stimulus on a scale from 1 (not natural) to 7 (very natural).

The results of this offline judgment study are presented in **Table 1**. These data were analyzed using linear mixed effects modeling, with fixed effects for matrix subject animacy, distant subject animacy, and their interaction. This analysis revealed a main effect of local NP animacy (Est $= -1.09 \pm 0.25$, $t = -4.3$), and an interaction of local and distant NP animacy (Est $= -1.29 \pm 0.38$, $t = -3.45$). There were lower acceptability ratings for both conditions with a local inanimate subject (*DISTANT MATCH* and *NO MATCH*). However, a *post-hoc* comparison between these two conditions revealed that average ratings were significantly lower in the *NO MATCH* condition than in the *DISTANT MATCH* condition ($\bar{x} = -0.9$, 95%CI: $[-1.4, -0.4]$).

Comprehension

One participant was removed from further analysis due to low accuracy (less than 70% accurate). After this exclusion, accuracy on the comprehension questions in Experiment 1 averaged 87% across participants, indicating that the participant attended to the stimuli. Across participants, accuracy ranged from 73 to 98%.

Reading Times

Raw mean reading times in Experiment 1 are presented in **Table 2** and in **Figure 1**.

Discussion

The results of the offline judgment experiment revealed that raters assigned lower ratings to sentences where there was not a local antecedent for *ziji*. The lowest ratings were given to the *NO MATCH* condition, presumably reflecting the unacceptability that results from the lack of an intra-sentential antecedent. Interestingly, the *DISTANT MATCH* condition was rated lower than the *LOCAL MATCH* and *MULTIPLE MATCH* conditions. This penalty is consistent with the presence of a locality effect. This conclusion is supported by independent evidence that the acceptability of grammatical sentences is reliably modulated by the length of a binding dependency (Sprouse et al., 2011). However, it is also possible that this reflects relative unacceptability that results from having an inanimate matrix subject. Critically for the present purposes, the *DISTANT MATCH* condition was rated as more acceptable than the *NO MATCH* condition, consistent with the claim that the distant subject is grammatically accessible as an antecedent for *ziji* (Tang, 1989; Huang and Tang, 1991).

The results of the self-paced reading experiment suggest a locality effect in the reading times, with the *DISTANT MATCH* condition being read 41 ms more slowly than the *LOCAL MATCH* condition at the critical region, and 215 ms more slowly in the spillover region. If reliable, this finding would extend the locality bias effect observed in previous experiments to the subcommanding configuration tested here (Chen et al., 2012; Dillon et al., 2014; Jäger et al., 2015). The data also suggest numerically smaller effects of the *Multiple Match contrast* and the *No Antecedent contrast*: in the spillover region, reading times were 81 ms longer in the *MULTIPLE MATCH* condition than in the *LOCAL MATCH* condition, and 84 ms longer in the *NO MATCH* condition than in the *LOCAL MATCH* condition.

Before further interpreting the data in Experiment 1, we present the results of Experiment 2.

EXPERIMENT 2

Experiment 2 was identical to Experiment 1 in all major respects, except that Experiment 2 investigates the processing of the complex anaphor *ta-ziji*.

Participants

Seventy students from the University of Maryland community participated in the experiment. All participants were native Mandarin Chinese speakers from mainland China, and all had normal or corrected-to-normal vision. They were paid $10 per hour for their participation in the experiment. Participants gave informed consent under an experimental protocol approved by the University of Maryland Institutional Review Board.

Stimuli

The materials were largely identical to those from Experiment 1. Two important changes were made to these materials. First, all instances of *ziji* were replaced with *ta-ziji*. The materials were additionally modified so that within an experimental item set, the animate nouns in each position were of the same gender. This was done to ensure that both NPs in the *MULTIPLE MATCH* condition matched the features of the reflexive. This change was necessary because *ta* orthographically marks gender. Half of the revised materials had male nouns, and the other half had female nouns.

All other aspects of the stimuli, including the fillers and comprehension questions, were identical to Experiment 1.

Procedure

The experimental procedure was identical to Experiment 1.

Offline Judgments

As in Experiment 1, we gathered offline naturalness judgments of all experimental materials prior to running Experiment 2. Collection of judgments and recruitment of participants proceeded in the same fashion as the offline pre-test for Experiment 1. Twenty-six native Mandarin speakers were recruited from Beijing Normal University.

The results of the offline judgment study are presented in **Table 3**. Linear mixed effects modeling revealed only an interaction of local and distant NP animacy (Est $= -1.88 \pm 0.38$, $t = -4.15$). This interaction was driven by low ratings in the *NO MATCH* and *MULTIPLE MATCH* conditions. There was no appreciable difference between the ratings of the *LOCAL MATCH* and *DISTANT MATCH* conditions.

Comprehension

As in Experiment 1, one participant was removed from further analysis due to low accuracy (less than 70% accurate). Accuracy on the comprehension questions averaged 84% across participants, indicating that the participant attended to the stimuli. Across participants, accuracy ranged from 71 to 100%.

Reading Times

Raw mean reading times are presented in **Table 4** and **Figure 2**. Visual inspection of the means suggests a weaker locality effect in Experiment 2 than in Experiment 1: the difference between the *LOCAL MATCH* and *DISTANT MATCH* conditions was 57 ms at the critical region, and 53 ms at the spillover region (compared to 215 ms in Experiment 1). The reading times suggest a numerically an effect of the *No Antecedent contrast* (109 ms at the critical region, 148 ms in the spillover region), and a small effect for the *Multiple Match contrast* (10 ms at the critical region, 50 ms in the spillover region).

The results of the statistical modeling of the reaction times at the pre-critical, critical, and spillover regions are presented in **Tables 5**–**7**. Analysis revealed no significant effects of counterbalancing list, and so we report models that do not include list as a fixed effect predictor.

At the pre-critical region, *ba*, we did not observe any statistically significant effects. This pattern suggests any early differences in the materials between conditions—such as the

animacy of the subject, or the different relative clauses used in different conditions—had returned to a neutral baseline prior to the critical region. We examined this observation further by performing an additional analysis of the region that immediately preceded the pre-critical region (e.g., *shangge xingqi*, "last week"). As in the pre-critical region, we failed to observe any statistically significant effects, providing further evidence that pre-critical differences in the materials across conditions did not have durable or long-lasting effects on reading times preceding the critical region.

In the critical region, we observed only a fixed effect of *Experiment*. Reading times in the anaphor region were significantly longer in Experiment 2 compared to Experiment 1, presumably reflecting the fact that *ta-ziji* is longer than *ziji*.

In the spillover region, we observed a statistically significant effect of the *Locality contrast*, and a statistically significant effect of the *No Antecedent contrast*. We did not observe any significant effects of antecedent frequency or length. Critically, we observed an interaction of *Experiment* with the *Locality contrast*. The direction of this coefficient indicates that the locality contrast was significantly smaller in Experiment 2 than it was in Experiment 1. To further investigate the interaction of *Experiment* with the *Locality contrast*, we fit a second model in which the critical *Locality contrast* was nested within individual levels of

Experiment. This model revealed that there was a significant *Locality contrast* for Experiment 1 (0.29 (0.05), $t = 6.31$). In Experiment 2, the estimated size of this effect was much smaller than in Experiment 1, and it was only marginal for Experiment 2 (0.07 (0.04), $t = 1.95$). The magnitude of the *No Antecedent contrast* was comparable between Experiments 1 and 2, and it reached statistical significance in both Experiments [Experiment 1: 0.14 (0.04), $t = 3.05$; Experiment 2: 0.17 (0.03), $t = 4.85$]. The *Multiple Match contrast* did not reach significance in either Experiment, although the magnitude of the observed effect and its sign were comparable across experiments [Experiment 1: 0.05 (0.05), $t = 1.08$; Experiment 2: 0.06 (0.04), $t = 1.56$]. The estimates of the fixed effects contrasts by *Experiment* yielded by this model are presented in **Figure 3**.

Discussion

The offline judgments for sentences containing *ta-ziji* revealed that the *DISTANT MATCH* and *LOCAL MATCH* conditions were considered equally acceptable, and that both were considered more acceptable than the *NO MATCH* condition. This pattern confirms that the distant subject position is accessible as an antecedent for *ta-ziji* in our materials. Furthermore, this pattern gives no indication of a locality bias in the offline judgments for *ta-ziji*. This contrasts sharply with the clear offline locality bias observed for *ziji* in Experiment 1.

Note furthermore that our *DISTANT MATCH* and *LOCAL MATCH* conditions differed in whether the main clause subject was animate. As the *DISTANT MATCH* condition was rated equally highly as the *LOCAL MATCH* condition in this experiment, one may infer that the inanimate main clause subjects in the *DISTANT MATCH* condition did not impact the naturalness of the sentences. This further suggests that the difference we observed between *DISTANT MATCH* and *LOCAL MATCH* in the judgments and reading times in Experiment 1 reflect aspects of the processing of *ziji*, rather than unacceptability that results from the presence of inanimate main clause subjects in the *DISTANT MATCH* condition.

Turning to the reading times, statistical modeling of the results yields several important insights. First, although both the *Locality contrast* was significant at the spillover region for both *ziji* and *ta-ziji*, there was a significant interaction of *Locality* and *Experiment*: the magnitude of the locality effect was much smaller for *ta-ziji* than for *ziji*. Although the locality effect was several times smaller for *ta-ziji* than for *ziji*, *post-hoc* analysis revealed that the *Locality contrast* was significant for both anaphors.

However, apart from this crucial difference, the processing of both anaphors was qualitatively similar. Our analysis revealed a significant *No Antecedent contrast* that did not differ in magnitude across studies. This indicates that comprehenders did indeed try to assign a referent to the anaphor upon encountering it, and moreover, it suggests that comprehenders experienced a similar amount of processing difficulty when there was no sentence-internal antecedent for both *ziji* and *ta-ziji*. Likewise, the magnitude of the *Multiple Match contrast* was similar across the two experiments, although it failed to reach statistical significance either in the omnibus analysis, or in the *post-hoc* analyses by experiment.

GENERAL DISCUSSION

In two self-paced reading experiments, we investigated the processing of two reflexive anaphors in Mandarin: the bare monomorphemic reflexive *ziji*, and the morphologically complex reflexive *ta-ziji*. In both offline acceptability rating and online reading time results, we observed that *ziji* was associated with a robust locality bias. Non-local interpretation of *ziji* was associated with lower naturalness ratings and longer reading times. In contrast, we observed a significantly smaller locality effect for *ta-ziji* in reading times, and no locality effect in offline acceptability judgments. Interestingly, this was the only difference we observed between *ziji* and *ta-ziji*. For both anaphors, we observed reliable reading time slowdowns when there was no licit antecedent in the sentence, and the size of this *no match* penalty did not reliably differ between anaphors in reading time measures. Likewise, for both anaphors we observed a trend toward a multiple match penalty. This effect did not reach statistical significance, although the consistency of the effect in sign and magnitude across experiments raises the possibility that the failure to observe this effect reflects a lack of statistical power. We take up each of these effects in turn.

Feature Richness and Antecedent Search

Our findings suggest that the locality bias that is associated with *ziji* does not generalize to other Mandarin reflexives that can take antecedents outside of their immediate tensed clause. Specifically, the morphologically complex anaphor *ta-ziji* shows a much diminished locality bias in online processing measures. One plausible hypothesis about this difference is that the overt morphological feature content on *ta-ziji* leads to faster or more reliable access to structurally distant antecedents. In contrast, *ziji* has fewer overt morphological cues to its antecedent, and so comprehenders may need to rely more heavily on positional cues to isolate its antecedent in memory, leading to relatively more pronounced locality bias.

This hypothesis is plausible given existing theories of how comprehenders access information in working memory during sentence comprehension. For a wide range of linguistic dependencies, there is evidence that the processor makes use of a content-addressable retrieval mechanism to form syntactic and referential dependencies between temporally distant phrases (McElree, 2000, 2006, 2014; McElree et al., 2003; Lewis and Vasishth, 2005; Lewis et al., 2006; McElree, 2006; Van Dyke and McElree, 2006, 2011; Foraker and McElree, 2011). A content-addressable retrieval mechanism accesses a representation in memory using the inherent features of the representation as cues to guide memory retrieval process. For example, a pronoun like *him* may be said to retrieve its antecedent by using gender features as cues to locate an antecedent in memory (e.g., Foraker and McElree, 2007). These cues are said to provide *direct access* to the desired representation, obviating any need to search through irrelevant representations at retrieval. This mechanism has the benefit of granting extremely rapid access to information in memory, making this an attractive mechanism for memory access in the human sentence processor (Lewis et al., 2006). In general, models that posit a content-addressable retrieval mechanism predict that an increase in structural or linear distance between the retrieval site (e.g., the anaphor) and the target of retrieval (e.g., its antecedent) may lead to reduced retrieval accuracy, but that structural or linear distance *per se* should not result in longer retrieval times. On some theoretical proposals, the speed of retrieval may be modulated by variables such as retrieval interference and temporal decay (Lewis and Vasishth, 2005; Lewis et al., 2006); on others, these variables primarily impact the probability of successfully recovering a target representation (McElree, 2006). Although cue-based models have the advantage of offering rapid access to representations in memory when they are required for sentence comprehension, they encounter difficulty if multiple representations in memory match the retrieval cues used at retrieval. If this occurs, it may be more difficult to isolate the *target* representation in memory, a phenomenon known as *retrieval interference*. Retrieval interference has been shown to be a primary cause of difficulty in sentence comprehension (Lewis, 1996; Van Dyke and Lewis, 2003; Lewis and Vasishth, 2005; Lewis et al., 2006; Van Dyke and McElree, 2006; Van Dyke, 2007; see also Gordon et al., 2001, 2002, 2004; for a recent review, see Van Dyke and Johns, 2012).

Several distinct hypotheses that draw upon this basic framework have been proposed to explain the locality bias associated with *ziji*. Chen et al. (2012) and Jäger et al. (2015) offered an account that draws on the ACT-R model of Lewis and Vasishth (2005). This model explains the locality bias as the result of decay and interference reducing the activation level of the distant subject, which in turn leads to longer antecedent retrieval times when the antecedent is distant from the anaphor. An alternative explanation is offered by Dillon et al. (2014), who proposed that the locality effect arises because comprehenders tend to initially retrieve the local subject as an antecedent for *ziji*. On this view, comprehenders must reject the local subject as a plausible antecedent and execute additional memory retrievals to access a distant antecedent for *ziji*. On this view, more retrieval operations are necessary to access distant antecedents, and so it is predicted that processing times should increase whenever *ziji* needs to take an antecedent other than the most local one.

One finding that distinguishes these two accounts is the MR-SAT study reported by Dillon et al. (2014). Dillon and colleagues observed that *ziji* with distant antecedents led to significantly slower processing rates in the speed-accuracy tradeoff function than *ziji* with local antecedents. Standard memory variables such as temporal decay and interference alone have not been shown to modulate processing speed in the speed-accuracy tradeoff functions associated with linguistic processing (McElree, 2000; McElree et al., 2003; Foraker and McElree, 2007, 2011; Martin and McElree, 2008, 2009, 2011; Van Dyke and McElree, 2011). However, processing speed as measured in the speed-accuracy tradeoff function has been shown to be slowed down by increasing the number of required retrieval operations, and in situations where syntactic reanalysis is required (McElree et al., 2003; Bornkessel et al., 2004; Foraker and McElree, 2007). Thus, the MR-SAT data lend support to the view that the locality effect arises because comprehenders are tempted to initially retrieve and evaluate the local subject as an antecedent when processing *ziji*.

This account also offers some insight into how the overt feature content of *ta-ziji* may allow comprehenders to overcome locality bias in comprehension. Many different implementations of cue-based retrieval mechanisms predict that the more highly specified a retrieval probe is in terms of the cues used, the less likely it is that partially matching (*distractor*) items in memory will cause retrieval interference, and compete with other representations at retrieval (Lewis and Vasishth, 2005; Van Dyke and McElree, 2006; Van Dyke, 2007). These models hold that retrieval probes that contain a greater number of retrieval cues will see a corresponding increase in the probability of recovering a target item in memory, because more numerous and specific retrieval cues will in general decrease the probability of retrieving a distractor that only matches a subset of the retrieval cues.

To illustrate how these models would account for the difference in the magnitude of the locality effect for *ziji* and *ta-ziji*, consider again the critical configuration in (9):

(9) 张 太太 经常 光顾 的那个时装店
Zhang taitai$_i$ jingchang guanggu de na-ge shizhuangdian$_j$
上个星期 把自己 不小心 弄伤了
shang-ge-xingqi ba ziji$_{i/*j}$ bu xiaoxin nongshang-le.
Mrs. Zhang often visit DE that-CL boutique last-week BA self not careful harm-PERF.
"The boutique that Mrs. Zhang often visits carelessly harmed her last week."

Upon reaching the anaphor, comprehenders will, by hypothesis, recruit a mixture of syntactic cues (e.g., cues to subjecthood, such as syntactic case) and semantic or morphological cues (e.g., animacy in the case of *ziji*; animacy, humanness, and perhaps gender in the case of *ta-ziji*). Although these cues form a perfect match to the target antecedent, the inappropriate local subject *shizhuangdian* (boutique) matches only the syntactic cues. Thus, it is possible for the local antecedent to be mis-retrieved some proportion of the time, because it partially matches the syntactic cue content of the retrieval probe. Although we might reasonably expect the semantically appropriate long-distance antecedent to outcompete the local subject at retrieval in many cases, the competition contributed by the local subject may be exacerbated by its recency or its structural proximity to the anaphor (Dillon et al., 2014). If the retrieval probe contains relatively few semantic cues, the likelihood of mis-retrieving the local subject may be relatively high. On the account offered by Dillon et al. (2014), this is precisely what happens when comprehenders process *ziji*: although *ziji* contains animacy cues, these are not enough to overcome interference from the local subject, and so the local subject is retrieved some proportion of the time. When this occurs, comprehenders must attempt additional retrievals in order to arrive at an acceptable interpretation of the anaphor.

In the case of *ta-ziji*, the addition of humanness and gender features into the retrieval probe ensures that the local subject *na-ge shizhuangdian* "that boutique" matches fewer retrieval cues in the probe. This decreases the probability of retrieving the partially matching local subject, resulting in a greater proportion of trials when comprehenders are able to access the desired antecedent without sampling multiple antecedent representations from memory. Thus, if the locality bias reflects a tendency to mis-retrieve and consider the local subject, rather than decay of the distant antecedent *per se*, then the locality bias is predicted to be smaller for *ta-ziji* than for *ziji*. Put simply, *ta-ziji*'s additional feature content decreases the attractiveness of the local subject as a distractor and makes it more likely that comprehenders will successfully retrieve the long-distance antecedent on their first attempt.

Although, we have offered an explanation of our results in terms of the likelihood that the local subject will be (mis-)retrieved when processing the anaphor, it remains to be seen whether accounts that explain the locality bias effect as decreased activation of the distant antecedent can account for the difference between *ziji* and *ta-ziji*. The contrast between these anaphors rules out the simple hypothesis that the locality bias associated with *ziji* is due to recency or temporal decay alone. This is because this hypothesis would predict an equal locality effect for both anaphors. However, it may be possible to capture the present finding in more sophisticated models where the activation of an item in memory is partially a function of the retrieval cues used to access memory, such as the ACT-R model of Lewis and Vasishth (2005). It is difficult to evaluate the predictions of these models without the aid of an implemented computational model. The predictions of this account vary substantially with specific modeling assumptions that one makes. For example, if one assumes that the distant antecedent in examples like (9) is a perfect match to the retrieval probe of *ziji* and *ta-ziji* alike, then the activation of the distant antecedent should not be modulated by the number of retrieval cues in the retrieval probe[1] . This is because the total activation boost that a retrieval probe gives to an item in memory is constant in ACT-R. Adding more retrieval cues to the probe therefore does not increase the amount of activation afforded to a perfectly matching item in memory; it instead diminishes the amount of activation boost that is contributed by any one cue on its own. Under these conditions, availability of the distant antecedent is not predicted to differ between *ziji* and *ta-ziji*, all else being equal. However, if one relaxes these assumptions, it may be possible to capture this result. Thus, although we cannot claim that the present results are incompatible with the explanation of the locality bias effect offered by Chen et al. (2012) and Jäger et al. (2015), more research and modeling work is necessary to determine the specific circumstances under which these models can capture the contrast between *ziji* and *ta-ziji*.

Ziji vs. *Ta-ziji*

The explanation we offer for our findings posits that overt morphological features provide retrieval cues for recovering an antecedent for an anaphoric expression. However, the precise relationship between overt morphological form and the cues used to retrieve an antecedent remains unclear. Indeed, the problem of specifying the nature of the retrieval cues that support language processing is a key theoretical issue for cue-based approaches, and remains an area where much further work is needed (Van Dyke and McElree, 2011; Dillon et al., 2013). Previous research suggests that the link between overt morphological feature content and retrieval cues may be rather indirect, such that there is not a one-to-one mapping between overt morphological features and retrieval cues. For example, Dillon et al. (2013) presented a series of studies that investigated the processing of English reflexive *himself*. On the basis of a comparison between computational retrieval models and online reading time data, they suggest that *himself* does not use gender and number features as cues to retrieve its antecedent, instead relying on a mixture of structural and locality cues (Dillon et al., 2013; Dillon, 2014; but see Jäger et al., 2015, for a critical view of this conclusion and an alternative analysis of these findings). Put differently, Dillon et al. (2013) proposed that the morphologically complex English reflexive *himself* deploys a cue set that is fundamentally similar to the cue set proposed for Mandarin *ziji*, despite the fact

[1]We are grateful to Lena Jäger for this observation.

that *himself* is morphologically more similar to Mandarin *ta-ziji* than it is to *ziji*. This contrast suggests that the simple hypothesis that overt morphological features are recruited as retrieval cues may not be correct, but we presently lack a theory of how morphological and semantic features of anaphoric expressions are used during antecedent retrieval.

Resolving this tension is beyond the scope of this paper, but there are several possibilities that suggest themselves. It may be that the direct link between morphology and retrieval cues that we offer as an explanation for the present findings is misguided, and some other difference between *ziji* and *ta-ziji* is responsible for the difference in their processing behavior. One plausible alternative explanation of our result could leverage the observation that *ta-ziji* may be readily interpreted as a contrastive reflexive, analogous to *he himself* in English (Pan, 1998; what Baker, 1995 calls an *intensive pronoun*). Baker (1995) suggests that the interpretive constraints on these intensive pronouns are best understood in terms of discourse prominence and contrastiveness of potential antecedents, rather than their syntactic positions. It is possible that the diminished locality effect for *ta-ziji* reflects a preference to construe *ta-ziji* as an intensive pronoun in our experiment. This could have caused readers to weight discourse cues more heavily than syntactic cues when retrieving an antecedent for *ta-ziji*, leading to a smaller locality effect. While we find this an interesting possibility, we cannot confidently endorse it on the basis of the present data because it is at present unclear whether readers understood *ta-ziji* as an anaphor or an intensive pronoun in our experiment. Another possibility is that the difference in locality bias reflects a difference in the frequency with which each anaphor takes antecedents beyond its local clause. Although we cannot rule out this possibility, we find it unlikely: the number of syntactic environments where *ta-ziji* can find an antecedent outside of its tensed clause is much smaller than the number of environments where *ziji* can, making it unlikely that *ziji* more often takes a local antecedent than *ta-ziji* in a Mandarin speaker's language experience. Nonetheless, corpus work would be necessary to secure this conclusion, and at present we must regard it as a possible, but unlikely, explanation of the present finding.

Multiple Match Effects

A further prediction of cue-based retrieval models is that the presence of multiple antecedents that match the retrieval cues of the anaphor should create retrieval interference, which should in turn create processing difficulty. For example, consider our *MULTIPLE MATCH* condition:

(10) 张 太太 经常 光顾 的 那个 女裁缝
Zhang taitai$_i$ jingchang guanggu de na-ge nücaifeng$_j$
上个星期 把自己 不小心 弄伤了
shang-ge-xingqi ba ziji$_{*i/j}$ buxiaoxin nongshang-le.
Mrs. Zhang often visit DE that-CL seamstress last-week ba self not careful harm-PERF.
"The seamstress that Mrs. Zhang often visits carelessly harmed her last week."

This sentence is not ambiguous, as the animate head noun *nücaifeng* ("seamstress") blocks access to the embedded subject *Zhang taitai* ("Mrs. Zhang"; see Tang, 1989). In other words, *Zhang taitai* is a grammatically inaccessible distractor in this example, even though this syntactic position would have been grammatically accessible if the relative clause's head noun were inanimate. Nonetheless, because the distant subject *Zhang taitai* matches the retrieval cues of the anaphor, it is predicted to create retrieval interference. Because there are multiple antecedents that match the animacy cues associated with *ziji*, it should be more difficult for comprehenders to isolate the correct antecedent *nücaifeng* in memory. In terms of our experimental manipulations, cue-based parsing models broadly predict that the *MULTIPLE MATCH* condition should be more difficult than the *LOCAL MATCH* condition at the reflexive, because the *MULTIPLE MATCH* condition contains more representations that match the retrieval cues, contributing to retrieval interference in the *MULTIPLE MATCH* condition that should inhibit access to the target antecedent. Moreover, it is predicted that the size of the multiple match effect should be greater for *ta-ziji* than for *ziji*, because the distractor matches a greater proportion of the retrieval cues for the complex anaphor.

Our experiments failed to provide clear evidence to support or disconfirm these predictions. In both Experiments 1 and 2, we observed numerically longer reading times on the *MULTIPLE MATCH* condition than in the *LOCAL MATCH* condition, but this contrast did not reach statistical significance in either experiment alone, and we failed to observe any trend toward a larger multiple match effect for *ta-ziji*. The interpretation of the present findings, and their relationship with previous findings, must therefore be treated with caution. We note that the size and magnitude of the multiple match effect was consistent, and in the predicted direction, in both experiments. This pattern suggests that our failure to find an effect may reflect a lack of statistical power.

Although a multiple match penalty has been observed in previous reading time studies (Badecker and Straub, 1994, 2002; Kennison et al., 2003; Felser et al., 2009; Chen et al., 2012; Jäger et al., 2015; see also Rigalleau et al., 2004; Stewart et al., 2007), the empirical generalization has remained unclear, especially for reflexive pronouns. Although some studies have presented evidence that feature-matched, but structurally inaccessible antecedents create processing difficulty for reflexive pronouns (Badecker and Straub, 2002; Felser et al., 2009; Chen et al., 2012; Jäger et al., 2015), many more studies have failed to find reliable evidence for such an effect in reading time measures, or found it only in limited contexts (Clifton et al., 1999; Sturt, 2003; Xiang et al., 2009; Cunnings and Felser, 2013; Dillon et al., 2013; Cunnings and Sturt, 2014; Kush and Phillips, 2014; Jäger et al., 2015). It is notable that Chen and colleagues reported that reading times on *ziji* were longer in the presence of a grammatically inaccessible, but semantically appropriate antecedent (c.f., Jäger et al., 2015). On balance, however, the repeated failures to find multiple match effects suggest that grammatically illicit antecedents do not create substantial interference effects, and so our failure to find

any multiple match effects in the present study may not be surprising. Dillon (2014) and Sturt (2013) offer reviews of the empirical landscape, and suggest that grammatical constraints act as strong filters on antecedent retrieval, allowing for very little (if any) retrieval interference from grammatically illicit antecedents.

A similar pattern emerges for studies that have focused on the processing of direct object pronouns in English. Chow et al. (2014) reported five experiments that sought to find multiple match effects with direct object pronouns in English, and failed to find any evidence of such an effect (including a near direct replication of Badecker and Straub, 2002). On the basis of this finding, Chow and colleagues argued that, in line with the processing of reflexives, structural constraints acted immediately to help rule out grammatically inaccessible antecedents for object pronouns as well (see also Clifton et al., 1997; Lee and Williams, 2008; Patterson et al., 2014).

On the basis of the non-significant multiple match effects in the present studies, very little can be concluded about whether the inaccessible antecedent in our *MULTIPLE MATCH* conditions created retrieval interference. However, inconsistent with claims that grammatical constraints rule out inaccessible antecedents, we did find clear trends in the predicted direction in both experiments. We thus regard it as an open empirical question whether an animate distant subject interferes with the retrieval of the correct local subject when processing *ziji* and *ta-ziji*.

CONCLUSION

In our Experiment 1, we observed that the morphologically simple long-distance reflexive *ziji* showed a robust locality bias in reading time measures. Experiment 2 revealed that the morphologically complex, local reflexive *ta-ziji* showed a much reduced locality bias in processing. We proposed that this contrast was due to the number of morphological and semantic features each anaphor uses during the process of retrieving an antecedent. Morphologically simple anaphors like *ziji*, which have relatively fewer retrieval cues, are more likely to access non-target antecedents at retrieval. This requires comprehenders to sample multiple antecedents in order to achieve an interpretation for the anaphor, leading to locality effects. In contrast, the relatively more specified *ta-ziji* has more cues for antecedent retrieval, which makes it less susceptible to interference from non-target representations. For this reason, complex anaphors like *ta-ziji* show diminished locality effects in comprehension.

ACKNOWLEDGMENTS

We would like to thank Lyn Frazier, Lena Jäger, and Dave Kush for comments on and discussion of an earlier version of this work, and Colin Phillips for extended discussion of the experiments presented here. This work was supported by a University of Maryland Fellowship to BD and WC. Experiments 1 and 2 were initially presented as part of Dillon (2011).

Processing the Chinese Reflexive "ziji": Effects of Featural Constraints on Anaphor Resolution

Xiao He[1] *and Elsi Kaiser*[2]*

[1] *ProSearch Strategies, Inc., Los Angeles, CA, USA,* [2] *Department of Linguistics, University of Southern California, Los Angeles, CA, USA*

We present three self-paced reading experiments that investigate the reflexive *ziji* "self" in Chinese—in particular, we tested whether and how person-feature-based blocking guides comprehenders' real-time processing and final interpretation of *ziji*. Prior work claims that in Chinese sentences like "John thought that {I/you/Bill} did not like ZIJI," (i) the reflexive ziji can refer to the matrix subject John if the intervening subject is also a third person entity (e.g., Bill), but that (ii) an intervening first or second person pronoun blocks reference to the matrix subject, causing *ziji* to refer to the first or second person pronoun. However, native speakers' judgments regarding the accessibility of long-distance antecedents are rather unstable, and researchers also disagree on what the exact configurations are that allow blocking. In addition, many open questions persist regarding the real-time processing of reflexives more generally, in particular regarding the accessibility (or lack thereof) of structurally unlicensed antecedents. We conducted three self-paced reading studies where we recorded people's word-by-word reading times and also asked questions that probed their off-line interpretation of the reflexive *ziji*. People's answers to the off-line questions show that blocking is not absolute: Comprehenders do allow significant numbers of non-local choices in both the first and the second person blocking conditions, albeit in small numbers. At the same time, the reading time data, particularly those from Experiments 2 and 3, show that comprehenders use person feature cues to quickly filter out inaccessible long-distance referents. The difference between on-line and off-line patterns points to the possibility that the interpretation of *ziji* unfolds over time: it seems that initially, during real-time processing, person-feature cues weigh more heavily and constrain what antecedent candidates get considered, but that at some later point, other kinds of information are also integrated and perhaps outweigh the person-feature constraint, resulting in consideration of referents that were initially "blocked" due to the person-feature constraint. In sum, in addition to the structural constraints identified in prior work, person-featural cues also play a key role in regulating the on-line processing of reflexives in Chinese.

He X and Kaiser E (2016) Processing the Chinese Reflexive "ziji": Effects of Featural Constraints on Anaphor Resolution. Front. Psychol. 7:284. doi: 10.3389/fpsyg.2016.00284

INTRODUCTION

In real-time language comprehension, a major challenge faced by comprehenders is the need to resolve dependency relationships, where the interpretation of one linguistic element depends on another. One such case is the interpretation of reflexive pronouns (e.g., *himself/herself*), which is traditionally argued to depend on a set of structural constraints. In English, for example, reflexives are constrained by a set of rules termed Binding Principle A (Chomsky, 1981, 1986). According to this principle, a reflexive [*himself* in (1)] can only refer to a referent within the local clause (*Bill*) and not a referent outside the local clause (*John*).

(1) John_1 said that Bill_2 disliked $\text{himself}_{*1/2}$.

While structural constraints seem to adequately capture the patterning of reflexives in many contexts, their influence on the real-time processing of reflexives is the subject of an ongoing debate. Specifically, researchers disagree on whether or not structural information has an immediate effect on what referents are considered potential antecedents. Early work by Nicol and Swinney (1989) and Sturt (2003), among others, showed that comprehenders' consideration of potential antecedent candidates is immediately determined by structural constraints. More recent evidence in the same direction comes from Xiang et al. (2009), Dillon et al. (2013) and others. Hence, according to these studies, structurally-incompatible/inaccessible referents [such as *John* in (1)] do not cause interference during the processing of reflexives.

However, other studies found that comprehenders do not fully abide by structural rules, at least in the early stage of processing (e.g., Badecker and Straub, 2002; Runner et al., 2006; Kaiser et al., 2009; Clackson and Heyer, 2014). These findings suggest that initial consideration of possible antecedents can be influenced by featural properties of potential referents (which can act as retrieval cues), such as person, animacy, and number, and that comprehenders at least temporarily consider feature-compatible but structurally inappropriate referents before they eventually reach the correct interpretation. Thus, opinions diverge regarding the role of structural constraints in the real-time interpretation of reflexives.

This situation is complicated by the fact that reflexives in non-English languages are not necessarily constrained by the same principles that govern English reflexives (e.g., Kuno, 1972; Sells, 1987; Iida and Sells, 1988; Jayaseelan, 1999; Sohng, 2004, for crosslinguistic examples in Japanese, Malayalam, Korean, etc.). In particular, the phenomenon of long-distance reflexivization, where reflexives are bound by antecedents outside the local domain, has attracted considerable attention and poses challenges for the traditional definition of Binding Principle A[1]. Long-distance reflexives exist in many languages, including Chinese, Japanese, Korean and Icelandic. For example, the Chinese reflexive *ziji* can be long-distance bound in configurations such as (2a):

(2a) John_1 juede Bill_2 bu xihuan $\text{ziji}_{1/2}$.
John$_1$ thought Bill$_2$ NEG like SELF$_{1/2}$
'John$_1$ thought that Bill$_2$ did not like him$_1$/himself$_2$' [*ziji* = ambiguous]

Here, the reflexive *ziji* can refer to either the local subject Bill or the long-distance matrix subject John[2]. It has often been noted that, cross-linguistically, long-distance reflexives are subject to various language-specific constraints, such as the kinds of clause types that allow long-distance binding (e.g., infinitivals, subjunctive clauses, indicative clauses), the animacy of the antecedent, the type of verb in the matrix clause, and the person features of the referents in the sentences (see Huang, 2000, for an overview).

In this paper, we present three self-paced reading experiments on the processing of the Chinese long-distance reflexive *ziji* "self," in order to enrich our understanding of the real-time processing of reflexives from a cross-linguistic perspective. Looking at *ziji* allows us to see what happens in a language where the accessibility of potential antecedents is governed by referents' person features: More specifically, while *ziji* could potentially refer to any subject-position referent (local or non-local), *the person feature* of intervening referents plays a key role in determining the accessibility of a long-distance referent.

Long-Distance Reflexives in Chinese: Blocking Effects

Here, we take a closer look at the Blocking Effects that have been claimed to guide the interpretation of long-distance reflexives in Chinese. Let us consider (2b). If the local subject is the first person pronoun *wo* "I" or the second person pronoun *ni* "you," the widespread claim in the theoretical literature is that *ziji* is bound by this local subject (*wo*/*ni* "I/you") and "blocked" from reaching the matrix/non-local subject ("John" in 2b) (see Xu, 1993; Pan, 1997, 2001; Huang and Liu, 2001). In contrast, if the local subject is a third person referent ("Bill" in 2a), *ziji* can refer to either the local subject or the matrix subject. Hence, there is an *asymmetric* Blocking Effect: An intervening first or second person pronoun blocks long-distance binding whereas a third person referent does not.

(2b) John_1 juede wo_2/ni_2 bu xihuan ziji_2.
John thought I/you NEG like SELF
'John thought that I/you did not like myself/yourself'

Various theoretical analyses have been proposed for this Blocking Effect. One widely used syntactic strategy is to argue that apparent long-distance binding effects can be derived from local dependencies. For example, Tang (1989) (see also Cole et al., 1990; Cole and Sung, 1994; Cole and Wang, 1996, etc.) analyzed long-distance binding as involving a series of movements at the level of logical form such that each movement satisfies the requirement of local binding. Under this view, long-distance

[1]It is important to note that alternative approaches to Chomsky's Binding principles have also been proposed. For example, some researchers argue for predicate-based theories, e.g., Reinhart and Reuland (1993).

[2]Example (2a), like our experiments, uses a proper name in the subject position of the embedded clause. This is because a pronoun in that position would allow for coreference between the embedded subject and the matrix subject (e.g., $John_i$ thought that he_i did not like SELF). This would make it impossible to tell whether people interpret *ziji* as referring to the embedded subject or the matrix subject.

binding in Chinese underlyingly satisfies Chomsky's Binding Principle A.

In addition to syntactic accounts, semantic accounts have been proposed. The most prominent of these attributes blocking to a perspectival conflict, and is based on the "direct discourse complementation" analysis of Kuno (1972). According to Kuno, when a third-person pronoun in an embedded clause refers to the matrix subject who is the speaker/thinker of the embedded clause, the embedded clause can underlyingly be a direct speech event so that the third person pronoun in the surface form is directly derived from an underlying first person pronoun. A sentence like "John$_i$ said he$_i$ hated pancakes" is derived from the underlying form "John said, 'I hate pancakes'."

Building on this, Huang et al. (1984) argued that when *ziji* is in an indirect/reported speech event inside an embedded clause and used as a long-distance reflexive, the embedded clause is derived from a direct speech event. Consider (2a). When *ziji* refers to the matrix subject *John*, the underlying form of the sentence is represented of (2a′) where *ziji* is replaced with the first person *wo* in the direct quote. Here, the first person pronoun *wo* refers to the matrix subject *John*. Hence, a long-distance co-referential interpretation is established. On the other hand, if *ziji* refers to the local subject *Bill*, (2a) is derived from the underlying form in (2a″).

(2a′) John$_1$ juede Bill$_2$ bu xihuan wo$_1$.
John$_1$ thought Bill$_2$ NEG like I$_1$
'John$_1$ thought: "Bill$_2$ doesn't like me." '

(2a″) John$_1$ juede Bill$_2$ bu xihuan ziji$_2$.
John$_1$ thought Bill$_2$ NEG like SELF$_2$
'John$_1$ thought: "Bill$_2$ doesn't like himself$_2$." '

Huang et al. (1984) argued that this approach explains the Blocking Effect. Consider (2b). Based on Huang et al., if *ziji* in (2b) is long-distance bound, the sentence is represented as (2b′), with the original *ziji* in (2b) being represented as the second occurrence of *wo* "I" in (2b′). This second instance of *wo* is intended to refer to the matrix subject *John*, but such a co-referential relationship is not allowed because it results in a conflict in perspectives: The two occurrences of *wo* in (2b′) refer to different referents: the first one refers to the external speaker of the sentence, and the second one to the matrix subject John. Hence, there is a conflict in perspectives. According to Huang et al. (1984), this perspectival conflict is the cause of blocking. In contrast, if *ziji* is locally bound, the underlying form is as in (2b″), and there is no perspectival conflict.

(2b′) ∗ John$_1$ juede wo$_2$ bu xihuan wo$_2$.
John thought I NEG like I
*'John thought: "I(=external speaker) don't like me(=John)".'

(2b″) John$_1$ juede wo$_2$ bu xihuan ziji$_2$.
John thought I NEG like SELF
'John thought: "I do not like myself."'

What about second person blocking? Huang et al. (1984) capture this in a similar way. In (2b), if the embedded subject is *ni* "you" and if *ziji* refers to the matrix subject (*ziji* = John), the underlying direct speech representation of (2b) would be (2c′) where *ziji* is replaced by first person *wo*. Note, however, that inside the direct speech, the second person pronoun *ni* refers to an addressee from the perspective of the *speaker of the entire sentence*, and not from the perspective of the matrix subject John—although, inside the direct speech, the first person pronoun *wo* is anchored to the matrix subject John (me=John). Hence, within the direct quote, we have two different perspectives, which cause a perspectival conflict. According to Huang et al., this again blocks long-distance binding.

(2c′) * John$_1$ juede ni$_2$ bu xihuan wo$_1$.
John thought you NEG like I
*'John thought: "you(=addressee) don't like me(=John)".'

(2c″) John$_1$ juede wo$_2$ bu xihuan ziji$_2$.
John thought I NEG like SELF
'John thought: "I do not like myself".'

Building upon Huang et al. (1984), Huang and Liu (2001) analyzed *ziji* by using a combination of structural and semantic principles. They argued that (i) locally bound *ziji* is a true reflexive and is governed by Binding Principle A and that (ii) long-distance bound *ziji* is a logophor and not subject to Binding Theory.

In sum, these kinds of approaches attribute the Blocking Effects of intervening first and second person pronouns to a perspective conflict that stems from the embedded clause being underlyingly represented as direct speech. Both first and second person pronouns cause a perspective clash when realized in the embedded subject position—unlike third person referents—and thus first and second person referents trigger a Blocking Effect[3].

However, this characterization of blocking is not universally agreed upon. Native speakers' judgments vary regarding the ability of intervening *third* person referents to block long-distance binding. For example, Tang (1989) and Pollard and Xue (1998) treat blocking as a symmetric process whereby a *difference* in person feature between a local referent and a long-distance referent suffices to induce blocking (regardless of the person feature of the intervening referent). Based on this view, the matrix subject *wo* ("I") in (3) cannot antecede the reflexive *ziji*, even though the intervening referent is third person. In other words, some claim that Blocking Effects arise not just with first and second person pronouns, but instead occur in any context where the person features of the local and the long-distance referent are different.

(3) wo$_1$ juede Bill$_2$ bu xihuan ziji$_{?1/2}$.
I thought Bill NEG like SELF
'I thought that Bill did not like SELF.'

In light of the divergent native speaker judgments, it would seem that a psycholinguistic approach could help clarify the situation.

[3]It is also worth noting that a situation where first and second person behave differently from third person may also be related to their different positions on the extended animacy hierarchy ((Dixon, 1979), see also (Croft, 2003)), which ranks first and second above third person.

However, while there exists a large body of experimental work on English reflexives, experimental research on *ziji* has only recently become more frequent. The work that has been done has led to mixed results. For example, Dillon et al. (2009) showed that non-c-commanding subjects did not cause immediate interference in the real-time processing of *ziji*. Based on this finding, Dillon et al. argued that comprehenders only search for structurally compatible referents—c-commanding subject-position referents. Hence, structural constraints play an immediate role. In contrast, Chen and Vasishth (2011) and Jäger et al. (2015b), using self-paced reading and eye-tracking respectively, found that intervening feature-compatible (animate) non-c-commanding subjects caused reliable interference. (For recent work on interference effects and a cue-based retrieval mechanism in German and Swedish, see Jäger et al., 2015a). Based on these findings, they argued that consideration of potential antecedent candidates also relies on featural cues (e.g., animacy). In related work that also points to featural effects, Schumacher et al. (2011) conducted an ERP experiment which found that self-directed verbs exhibit different ERP responses with first- and third-person interveners than with second person interveners.

Aims of the Present Work

The three self-paced reading experiments presented here aim to broaden our understanding of *ziji* by looking at whether and how person-feature-based blocking guides comprehenders' real-time processing and final interpretation of *ziji*.

We have three main aims: First, we want to test to what extent first person and second person interveners block access to long-distance subjects. Even before we turn to the debate regarding third person interveners, it is worth emphasizing that although it is often claimed that long-distance antecedents are not possible in the presence of an intervening first or second person pronoun, judgments seem to actually be rather murky. For example, in our experience, explicitly eliciting judgments from native speakers yields a mixed set of responses. Indeed, when we probed this in an off-line pilot study with 30 Mandarin speakers, we found that people would accept the supposedly impossible long-distance antecedent for *ziji* in a first-person blocking condition [like (2b)] 36.2% of the time. This seems like a rather high number for an interpretation that is supposed to be unavailable/ungrammatical. In order to be able to make progress on this issue, we feel that an experimental investigation of large groups of native speakers is an important step.

Second, given the debate on whether blocking is asymmetric, the present experiments are intended to test whether intervening third person referents block long-distance antecedents like their first and second person counterparts. Thus, in addition to our observations and off-line data which suggest that blocking by first and second person interveners may not be as absolute as some claim, there also exists a fundamental debate—both theoretical and empirical—about what exactly can act as a blocker.

Lastly, while previous experimental work on *ziji* focused primarily on the effect of structural constraints on non-c-commanding subjects, the current experiments examine the real-time effect of a different kind of constraint, namely person-feature cues. (Related work by Schumacher et al., 2011 on person features is discussed in more detail below.) We look at whether in real-time, person-feature cues can immediately reduce interference from blocked/inaccessible long-distance c-commanding subjects.

The three experiments presented in this paper investigate both the on-line processing and the final off-line interpretation of the reflexive *ziji* in the presence of potential first person, second person and third person interveners. Experiment 1 focuses on first person and third person interveners, whereas Experiment 2 tests second person and third person interveners. Furthermore, by changing the type of verb used in the matrix clause in Experiment 3, we test what happens when it is no longer possible to interpret the embedded clause as a direct speech act produced by the matrix subject.

EXPERIMENT 1: FIRST PERSON BLOCKING

Experiment 1 is a self-paced reading study that investigates the effects of intervening first-person pronouns on the real-time processing and off-line interpretation of the reflexive *ziji*. Specifically, we look at whether the presence of an intervening first person pronoun can fully block access to the long-distance matrix subject, as predicted by Blocking. If an intervening first person pronoun acts as an absolute blocker, the reflexive *ziji* should not trigger any consideration of the matrix subject—i.e., we should not see any sign of interference from the matrix subject, either in participants' on-line reading times or off-line interpretations. In addition, given the debate about the (a)symmetry of blocking, we also test whether a *difference* in person feature between a local referent and a long-distance referent suffices to induce blocking. In other words, can an intervening third person referent block access to a matrix subject with a different person feature, such as a first person subject? If yes, this would be evidence in favor of symmetric analyses of blocking and against asymmetric analyses.

Methods

Participants

Twenty adult native speakers of Mainland Mandarin Chinese (graduate students at the University of Southern California at time of testing) took part in Experiment 1 in exchange for USD 10. All of them had normal or corrected-to-normal vision and reported no known learning disabilities or hearing impairments. All studies reported in this paper were reviewed and approved by the University of Southern California University Park Institutional Review Board, which is fully accredited by the Association for the Accreditation of Human Research Protection Programs (AAHRPP). Due to the nature of the experiments, the Institutional Review Board determined that written consent was not needed.

Materials

We used a 2 × 2 design by manipulating the form of the matrix subject and the embedded subject (first person pronoun vs. third person pronoun). Sample sentences of the four conditions are in (4).

(4) Sample sentences for the four conditions
1st-1st 我告诉别人我觉得自己明年可以考进好大学。

wo gaosu bieren **wo** juede ***ziji*** mingnian keyi kaojin
I tell others **I** think **SELF** next year able get-in
hao daxue.
good college.
"I told others that I thought SELF could get into a good college next year."

1st-3rd 我告诉别人李四觉得自己明年可以考进好大学。

wo gaosu bieren **Lisi** juede ***ziji*** mingnian keyi kaojin
I tell others **Lisi** think **SELF** next year able get-in
hao daxue.
good college.
"I told others that Lisi thought SELF could get into a good college next year."

3rd-1st 张三告诉别人我觉得自己明年可以考进好大学。

Zhangsan gaosu bieren **wo** juede ***ziji*** mingnian keyi
Zhangsan tell others **I** think **SELF** next year able
kaojin hao daxue.
get-in good college.
"Zhangsan told others that I thought SELF could get into a good college next year."

3rd-3rd 张三告诉别人李四觉得自己明年可以考进好大学。

Zhangsan gaosu bieren **Lisi** juede ***ziji*** mingnian keyi
Zhangsan tell others **Lisi** think **SELF** next year able
kaojin hao daxue.
get-in good college.
"Zhangsan told others that Lisi thought SELF could get into a good college next year."

We created 32 target items, all of which contained 11 words[4]. (See Supplementary Materials for a full list of targets used in the experiments reported in this paper). The first and the fourth words were the matrix subject and the embedded subject, separated by a verb (*gaosu* "tell") and an object (*bieren* "others") both of which remained the same across all target items. The embedded subject was followed by a verb and then the reflexive *ziji*. In this study as well as the other studies reported in this paper, the verbs (and other lexical items) used in the embedded clauses were designed to be semantically neutral, i.e., to allow *ziji* to be interpreted as referring to either the matrix subject (e.g., Zhangsan) or the embedded subject (e.g., Lisi). [For work on the effects of self- vs. other-directed verbs on *ziji*, see Schumacher et al. (2011), He (2014) and others.]

Following the critical word *ziji* were five words (spillover region). This spillover region is important, because it is well known that in self-paced reading studies, effects many not be detectable until one, two or even three words after the critical word (e.g., Badecker and Straub, 2002, and many others). Our target items used *ziji* in the subject position of an embedded clause, because this allowed us to have a spillover region without a clause boundary *inside* the spillover region. (Clause and sentence boundaries are known to result in "wrap-up" slowdowns, e.g., Warren et al., 2009, which could potentially mask other effects. Indeed, we find signs of wrap-up slowdowns on the last word in our items, but this final word is not relevant for our analyses).

We employed a Latin Square design, resulting in four lists. Each participant saw 32 targets (8 per condition) and 72 fillers, described below. Each target item appeared once in each list but in a different condition in each list. (All experiments reported here used a Latin Square design.)

In addition to the 32 targets, 72 filler items were created. None of the fillers contained *ziji*. In this experiment, as in the other two experiments reported in this paper, the filler items were similar in length to the targets, and also contained multiple clauses (e.g., "Little An suggested that I go to a very renowned seafood restaurant by the seaside" and "Little Zhang heard from others that Little Liu's brother made Little Xiao very depressed").

All targets and fillers were followed by a forced-choice question with two possible answer choices shown on the screen. Target questions probed participants' interpretations of *ziji*, as shown in (5). Because antecedent choice questions could not be used in the 1st-1st condition, we included a referent unmentioned in the sentence as one of the two antecedent choices (6). The forced-choice questions after fillers asked about referents mentioned in the filler items (e.g., "Who recommended a seafood restaurant?" (Little An/I), "Who was very depressed?" Little Xiao / Little Zhang). Positions (left vs. right) of the answer choices for the forced-choice questions were counterbalanced.

(5) Sample comprehension question:
Sentence: Zhangsan gaosu bieren **Lisi** juede ***ziji*** mingnian keyi kaojin hao daxue.
'Zhangsan told others that Lisi thought SELF could get into a good college next year.'

Comprehension question: Shui mingnian keyi kaojin hao daxue?
'Who can get into a good college next year?'
(A) Zhangsan (B) Lisi

(6) Sample comprehension question for the 1st–1st condition:
Sentence: wo gaosu bieren **wo** juede ***ziji*** mingnian keyi kaojin hao daxue.
'I told others that I thought SELF could get into a good college next year.'

Comprehension question: Shui mingnian keyi kaojin hao daxue?
'Who can get into a good college next year?'
(A) Wangwu (B) I

Procedure

We used a moving-window word-by-word self-paced reading paradigm (Just et al., 1982; see also Badecker and Straub, 2002). Participants were tested individually on a laptop computer, using the *Linger* software (D. Rohde, MIT; Rohde, 2010). They first read the instructions and then proceeded to the practice items. The experimental trials started after the practice items. Participants

[4]The 11 words are as shown in the pinyin transliteration and the English word-by-word glosses in (4). Some of the words consist of more than one character in Chinese.

read sentences word-by-word by pressing the spacebar. When a sentence was finished, a comprehension question with two answer choices appeared at the center of the screen. Participants responded by pressing the F key for the answer on the left side or the H key for the answer on the right side.

Predictions

Antecedent Choices

If the blocking effect of the first person pronoun is absolute, long-distance antecedents should be available in the 3rd-3rd Condition but crucially not in the 3rd-1st Condition due to the first person intervener. We should also keep in mind that researchers disagree about whether intervening third person referents can induce blocking: While some argue that only first and second person interveners lead to blocking, others claim that any person-feature mismatch between long-distance and local referents leads to blocking. Hence, antecedent choices data from the 1st-3rd Condition allow us to obtain a clearer picture of the status of third person interveners.

Reading Times

Reading time slowdowns are taken to indicate competition or interference (e.g., Badecker and Straub, 2002). We follow Badecker and Straub (2002) in assuming that if a reflexive has two "candidate antecedents," then additional processing is required to select a unique antecedent, and this increase in processing load is reflected in slower reading times. In other words, competition/interference results in a reading time slowdown, relative to a situation where only one antecedent is being considered. Thus, the 1st-1st Condition should be read rapidly as it has only one referent, the first person pronoun. The 3rd-3rd Condition, on the other hand, should exhibit slowdowns at the reflexive and/or beyond, due to the third person matrix subject competing with the third person embedded subject.

What about the 3rd-1st Condition? If the first person intervener immediately excludes the long-distance matrix subject from the set of possible antecedents, the matrix subject should not cause interference, and this condition should not be read more slowly than the 1st-1st Condition. Alternatively, if the first person pronoun is not an absolute blocker, interference reflected in reading time slowdowns should arise. Predictions for the 1st-3rd Condition are similar to the 3rd-1st Condition. If this condition exhibits blocking as some have argued, no interference should be expected from the first person matrix subject. Otherwise, this condition should also exhibit interference from the matrix subject as reflected in significant reading time slowdowns.

Data Analysis

We used participants' accuracy on the unambiguous filler comprehension questions to check whether they were attending to the task. Since all participants correctly answered at least 90% of the questions, all participants' data were included in subsequent trimming and analyses.

Reading times smaller than 100 ms or above 4000 ms were excluded first. Then, data points were log-transformed to reduce the non-normality of residuals. Afterwards, reading times more than 2.5 standard deviations away from the mean by word and by condition were removed, resulting in the exclusion of approximately 2.7% of data points. Statistical analyses were conducted in R (Baayen et al., 2008; R Core Team, 2015, see also Baayen, 2008). Data for each of the first 10 word positions in the target items were analyzed using linear-mixed effects regression implemented in the R package *lme4* (Bates et al., 2014). Main effects and interaction effects were computed with the R package *car* (Fox and Weisberg, 2011).

Unless otherwise mentioned, logistic mixed-effects regression implemented in *lme4* was used to analyze antecedent choices data due to their binary nature (see Jaeger, 2008, for discussion). In the analyses of antecedent choices, we excluded the data from the 1st-1st Condition because the sentences in this condition only contained the first person pronoun *wo* "I," and one of the two options for the comprehension questions in this condition was a referent unmentioned in the sentence [see (6)]. Participants chose the unmentioned referent on 1.25% of trials in this condition, presumably by mistake.

To specify the random effects in each mixed-effects model, we started with fully crossed and fully specified random effects, testing whether the model could converge. If the model did not converge, we then reduced the random effects until the model reached convergence (see Jaeger at http://hlplab.wordpress.com). We then used likelihood ratio tests to test each random effect and removed those that did not contribute significantly to the model.

Results

Antecedent Choices

As **Figure 1** shows, there was an overall preference for the local (embedded) subject in all conditions (1st-3rd: 95.92%; 3rd-1st: 73.12%; 3rd-3rd: 85.67%). This locality bias is expected based on earlier work (e.g., Chen et al., 2012; Dillon et al., 2014; Jäger et al., 2015b). Furthermore, we see a striking pattern in the 3rd-1st Condition: Although blocking predicts the 3rd-1st Condition to have the lowest rate of non-local choices, in this condition participants opted for the matrix subject and violated blocking on 26.88% of trials. The 3rd-3rd Condition, which—prior research agrees—permits non-local choices, actually had fewer non-local choices than the 3rd-1st Condition. Lastly, the 1st-3rd Condition numerically exhibited the fewest non-local antecedent choices (4.08%).

Antecedent choices were compared using logistic mixed-effects regressions. Participants chose the matrix subject significantly more in the 3rd-3rd and the 3rd-1st Conditions than in the 1st-3rd Condition (**Table 1**). Although the 3rd-1st Condition numerically produced more matrix subject choices than the 3rd-3rd Condition, this difference was not significant (**Table 1**). The higher-than-expected rate of matrix subject choices in the 3rd-1st Condition goes against the prediction of blocking. The low rate of matrix subject choices in the 1st-3rd Condition goes against the claim that third person interveners do not cause blocking.

Lastly, we conducted Bonferroni-corrected one-sample t-tests to check whether the number of non-local, matrix subject choices in each condition was significantly above zero. (Here and elsewhere, we multiplied the *p*-values by the number of comparisons, instead of dividing the alpha level by the number of

3rd-1st vs. 1st-3rd	3.2087	2.732	<0.01*
3rd-3rd vs. 1st-3rd	3.1997	3.160	<0.005*
3rd-1st vs. 3rd-3rd	0.0090	0.016	1.0000

comparisons. These two options are mathematically equivalent.) The results showed that the amounts of non-local choices were significantly above zero in the 3rd-1st Condition [$t_{1(19)} = 3.849$, $p < 0.010$; $t_{2(31)} = 6.294$, $p < 0.0001$] and the 3rd-3rd Condition [$t_{1(19)} = 5.511$, $p < 0.001$; $t_{2(31)} = 4.776$, $p < 0.0001$]. For the 1st-3rd Condition, only the by-item test reached significance [$t_{1(19)} = 1.926$, $p = 0.104$; $t_{2(31)} = 2.239$, $p = 0.4870$]. Hence, the 3rd-1st Condition and the 3rd-3rd Condition and to a lesser extent the 1st-3rd Condition allow some amount of non-local choices.

Reading Times

Reading time patterns are shown in **Figure 2**, and results of omnibus tests in **Table 2**. In the five word positions prior to the critical word *ziji*, significant effects of MATRIX SUBJECT were observed, suggesting that conditions with third person matrix subjects were read more slowly than those with first person matrix subjects. At the embedded subject and the following verb, significant effects of EMBEDDED SUBJECT emerged, indicating that conditions with third person embedded subjects were read more slowly. Existing work suggests that third person names are generally read more slowly than first and second person pronouns (Warren and Gibson, 2002), so these patterns are expected but are not central to the aims of this experiment, namely the processing of *ziji*.

Starting from *ziji* (Word 6) and onward, a significant effect of MATRIX SUBJECT was observed at Word 7 ("next year"), but this effect was qualified by a MATRIX SUBJECT × EMBEDDED SUBJECT interaction. At *ziji* and several spillover words that followed, significant interaction effects were observed. To assess these interactions more closely, we compared the three two-referent conditions with the single-referent 1st-1st Condition. At word 7, all three double-referent conditions show significant slowdowns compared to the single-referent (1st-1st) condition (see **Table 3**). In fact, the 3rd-1st condition shows slowdowns relative to 1st-1st on *ziji* (word 6), word 7 as well as word 10. The 1st-3rd condition shows slowdowns relative to 1st-1st on *ziji* (word 6), word 7, and word 9.

Discussion

One of the goals of Experiment 1 was to look at whether the intervening first person pronoun constrains comprehenders' off-line interpretations of *ziji*. The **antecedent choices** in this experiment showed a higher-than-expected rate of matrix subject choices, indicating that blocking is not an absolute principle and that comprehenders sometimes do interpret *ziji* as referring to long-distance antecedents, even (or especially) in the presence of first person interveners. The current experiment also aimed to examine comprehenders' judgments of the 1st-3rd configuration. Researchers diverge regarding whether third person interveners can block access to person-feature mismatching long-distance referents (e.g., the 1st person matrix subject). Our data indicate the intervening third person referent in the 1st-3rd condition can "block" access to the long-distance subject in comprehenders' off-line judgments, in sense that we find less than 5% matrix-subject choices. This finding suggests that it is not accurate to analyze first person interveners as being "better" blockers than third person interveners, and supports previous research that treated third person referents as possible blockers as well (Tang, 1989; Pollard and Xue, 1998).

For the **reading time data**, the single-referent 1st-1st Condition and the double-referent 3rd-3rd Condition patterned as expected. The former was read fast, and the latter, in comparison, was read more slowly due to the two competing antecedents. This finding confirms the prediction that multiple accessible referents can cause competition, reflected in reading time slowdowns.

For the 3rd-1st Condition, if the intervening first person pronoun immediately constrains participants' consideration of antecedent candidates, the matrix subject should not be accessible and thus should not cause an interference (slowdown) effect. However, as we have seen, this condition gave rise to reading time slowdowns at *ziji* and in the spillover region, suggesting that the first person pronoun does not block the accessibility of the matrix subject in real-time and that the presence of two competing referents leads to an interference effect. This finding goes against theoretical claims which regard blocking as a categorical principle. However, it is in line with our off-line data which show that participants violated blocking on an unexpected high rate of trials in this condition.

Additionally, the 1st-3rd Condition, which produced the *fewest* non-local choices and hence exhibited a more stable blocking effect in the offline data, also showed reading time slowdowns. These slowdowns indicate that the "blocked" inaccessible matrix subject in sentences with this kind of configuration can still interfere with the local subject. The results from this condition are in line with existing work (e.g., Kaiser et al., 2009) that suggests comprehenders' off-line judgments do not always coincide with their real-time processing pattern. our case, even though the off-line judgments suggest a stable blocking effect, in real-time, comprehenders can still briefly consider those "blocked" referents.

EXPERIMENT 2: SECOND PERSON PRONOUNS

In Experiment 1, we found a higher-than-expected rate of matrix-subject choices in the first person blocking condition, suggesting that first person blocking is not absolute and that comprehenders sometimes interpret *ziji* as referring the long-distance, matrix subject despite the presence of intervening first person pronouns. Additionally, the results also suggest that in terms of comprehenders' off-line judgments, the intervening third person subject can also serve as a blocker if the long-distance subject has a different person feature, such as first person in Experiment 1. To further examine the interpretation of *ziji* and the blocking effect, Experiment 2 looked at second person blocking. Based on existing theoretical work, we do not expect the first person pronoun and the second person pronoun to differ in their effectiveness as blockers. However, ERP work on Chinese by Schumacher et al. (2011) found that blocking configurations with first- vs. second-person pronouns triggered

different brain responses. This brings up the question of whether first- and second-person pronouns could actually differ in their effectiveness as blockers. This idea receives preliminary (but indirect) support from Brunyé et al. (2009) work on English, which suggests that first- and second-person differ in their ability to induce perspective-taking (see also Ditman et al., 2010; Brunyé et al., 2011). This is especially interesting in light of claims by Huang and Liu (2001) and others that the Blocking effect in Chinese results from a perspective-taking process. In sum, there is (i) a need to better understand the strength of the Blocking effect, given the controversial judgments in this domain, and (ii) a need to better understand whether first- and second-person pronouns differ in their Blocking behavior. Answers to these questions can enrich our understanding of how reflexives are processed.

Methods and Data Analysis

Twenty-eight adult native speakers of Mainland Mandarin Chinese (graduate students at the University of Southern California at time of testing) participated in exchange for USD 10. None of them took part in the previous experiment. All had normal or corrected-to-normal vision and reported no known learning disabilities or hearing impairments. The experimental design, materials, and procedure were identical to those used in Experiment 1, except that all the first person pronouns in the experimental items were replaced by second person pronouns (*ni* "you"). Like Experiment 1, this study also used a Latin Square design.

All participants were highly accurate on the comprehension questions for filler items (90% and above); thus, all participants' data were included in subsequent analyses. The trimming criteria were identical to Experiment 1, resulting in the exclusion of approximately 3.3% of data points. The same statistical methods used in the previous experiment were used here.

Results

Antecedent Choices

In line with the pattern observed in Experiment 1, there was an overall preference for local antecedent choices (**Figure 3**). In the 2nd-3rd, the 3rd-2nd, and the 3rd-3rd conditions, participants chose the embedded subject on 96.88%, 90.18%, and 87.05% of the trials, respectively (As in Experiment 1, we excluded the 2nd-2nd condition from this analysis because this condition only contained one referent, the second person pronoun *ni* "you"). We can also see that the 2nd-3rd Condition and the 3rd-3rd Condition in this experiment were numerically comparable to their counterparts in Experiment 1. However, long-distance choices were relatively rare in the 3rd-2nd Condition (9.82%), compared to the relatively high rate of long-distance choices in the 3rd-1st condition in Experiment 1 (26.88%). We conducted logistic mixed-effects regression to compare these three conditions. The results (**Table 4**) showed that the 3rd-3rd Condition produced significantly more long-distance choices than the 2nd-3rd Condition and the 3rd-2nd Condition. The 2nd-3rd Condition and the 3rd-2nd Condition did not differ significantly from each other.

Bonferroni-corrected by-subject and by-item one-sample t-tests were used to check whether the average number of non-local choices in each condition was significantly above zero. The results show that the number of non-local choices was significantly above zero in all three conditions [2nd-3rd: $t_{1(26)} = 3.017$, $p < 0.010$; $t_{2(31)} = 3.950$, $p < 0.0010$; 3rd-2nd: $t_{1(26)} = 4.837$, $p < 0.001$; $t_{2(31)} = 6.428$, $p < 0.0001$; 3rd-3rd: $t_{1(26)} = 4.416$, $p < 0.001$; $t_{2(31)} = 2.234$, $p = 0.0492$]. Hence, all three conditions allow non-local interpretations of *ziji* to a certain extent.

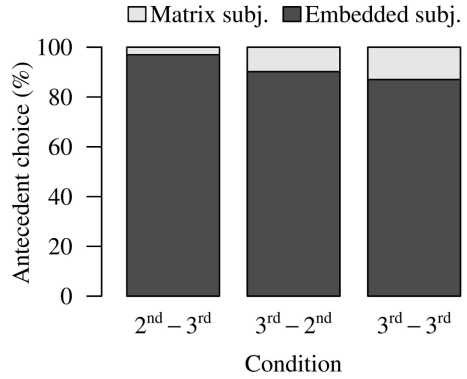

FIGURE 3 | Experiment 2 antecedent choice data.

TABLE 4 | Experiment 2: Comparing the numbers of non-local antecedent choices in the 2nd-3rd, the 3rd-2nd, and the 3rd-3rd Conditions ("*": $p < 0.05$; ".": $p < 0.1$).

Contrast	β	Z	Pr(>|z|)
3rd-2nd vs. 2nd-3rd	0.1675	0.198	0.8433
3rd-3rd vs. 2nd-3rd	1.4281	3.199	<0.0100*
3rd-3rd vs. 3rd-2nd	1.8285	2.788	<0.0100*

Comparing Antecedent Choices in Experiments 1 and 2

In Experiment 1, with first person interveners, participants chose long-distance interpretations of *ziji* in the presence of first person blocking (3rd-1st Condition) on a considerable subset of trials (26.88%). In contrast, in Experiment 2, the 3rd-2nd Condition showed a numerically lower rate of matrix-subject choices (9.82%). Logistic mixed-effects regression was used to directly compare the antecedent choices in Experiment 1 (first person intervener) and Experiment 2 (second-person intervener). We found that the 3rd-1st Condition in Experiment 1 had significantly more matrix subject choices than the 3rd-2nd Condition in Experiment 2 ($\beta = 2.0946$, $z = -2.444$, $p < 0.05$). This difference suggests that relative to the first person pronoun, the second person pronoun constrains comprehenders' final interpretations of *ziji* more consistently. No significant differences were observed between the 1st-3rd Condition and the 2nd-3rd Condition ($\beta = 0.3152$, $z = 0.572$, $p = 1.000$) or between the 3rd-3rd Condition from Experiment 2 and the 3rd-3rd Condition from Experiment 2 ($\beta = 0.1637$, $z = 0.509$, $p = 1.000$).

Reading Times

The reading time patterns for Experiment 2 are shown in **Figure 4**, and the results obtained from omnibus statistical

tests are presented in **Table 5**. The five words preceding *ziji* show a pattern similar to Experiment 1. Significant main effects of MATRIX SUBJECT and EMBEDDED SUBJECT were observed, indicating that third person matrix and embedded subjects elicited longer reading times than their second person counterparts (**Table 6**). A significant interaction was also found at the embedded subject. A closer look at this interaction effect revealed that the 2nd-3rd Condition and the 3rd-3rd Condition were significantly slower than the single-referent 2nd-2nd Condition (2nd-3rd: $\beta = 0.116$, $z = 2.301$, $p < 0.05$; 3rd-3rd: $\beta = 0.377$, $z = 6.90$, $p < 0.001$) and that the slowdown in the 3rd-2nd Condition was marginally significant ($\beta = 0.0703$, $z = 1.716$, $p = 0.087$). As we already mentioned when discussing Experiment 1, which shows a very similar pattern at this point, these results are in line with existing work showing that third person names are generally read more slowly than reduced nouns such as first and second person pronouns (Warren and Gibson, 2002).

At the reflexive *ziji*, a significant main effect of EMBEDDED SUBJECT emerged, suggesting that the two conditions with third person embedded subjects (1st-3rd and 3rd-3rd Conditions) were read more slowly. The word immediately following *ziji* showed a significant interaction effect. Planned comparisons showed that the 2nd-3rd Condition and 3rd-2nd Condition were marginally slower than the 2nd-2nd Condition (2nd-3rd: $\beta = 0.0691$, $z = 2.080$, $p = 0.096$; 3rd-2nd: $\beta = 0.0742$, $z = 2.23$, $p = 0.0672$).

Discussion

Building upon Experiment 1, Experiment 2 aimed to examine whether and how the intervening second person pronoun constrains comprehenders' interpretation of *ziji* both in real-time and off-line. The antecedent choice data provide additional insights into comprehenders' interpretations of the reflexive *ziji*. The results show that the second person blocking condition (3rd-2nd) exhibited a low rate of blocking violations. Direct

Exp 1: "{I/Zhangsan} told others that {I/Lisi} thought ZIJI could get into a good college next year."
Exp 2: "{You/Zhangsan} told others that {you/Lisi} thought ZIJI could get into a good college next year."

comparisons of antecedent choice patterns between Experiments 1 and 2 confirm that the second person pronoun is indeed a more consistently effective blocker than the first person pronoun. The low rate of long-distance interpretations in the 2nd-3rd Condition, on the other hand, provides additional support for the claim that intervening third person referents can also cause blocking if the long-distance referent has a different person feature.

Using the reading time data, we aimed to examine whether the intervening second person can immediately constrain participants' consideration of potential antecedent candidates in real-time. If the effect of the second person intervener is similar to that of the first person intervener observed in Experiment 1, then an interference effect from the matrix subject should arise in the 3rd-2nd Condition. The results in Experiment 2 showed that the 3rd-2nd Condition was marginally slower than the single-referent 2nd-2nd Condition at the word immediately following *ziji*, but not at any of the subsequent spillover words. This contrasts with Experiment 1, which found significant slowdowns with first person interveners. This suggests that the second person can immediately determine what antecedent candidates get considered, i.e., that the matrix subject can be immediately excluded from consideration.

As a whole, the results from Experiment 2 show hints of the second person pronoun being a stronger blocker than the first person pronoun, given (i) the significantly *fewer* long-distance choices in the 3rd-2nd Condition compared to the 3rd-1st Condition in Experiment 1 and (ii) the absence of competition (i.e., absence of reading-time slowdowns) in the 3rd-2nd Condition.

In related ERP work, Schumacher et al. (2011) found differences between first person and second person interveners with self-directed verbs in constructions like "Wangwu asked me/you to examine myself/yourself." They found a more pronounced early positivity with self-directed verbs with second person interveners than first or third person interveners. Self-directed verbs like "examine" tend to have objects that corefer with their subject/agents (Xi examined Xi). Schumacher et al. (2011) also note that sentences with the second person pronoun report a directive/imperative speech act whereas sentences with the first person pronoun report an assertive speech act. They suggest that, due to the imperative interpretation, the second person is higher on the person hierarchy than the first or the third person. Schumacher et al. (2011) also tested other-directed verbs and found no clear differences between first and second person interveners. Their results for self-directed verbs constitute the first published discussion of differences between first and second person interveners (to the best of our knowledge). However, our stimuli are different in a number of ways. Our target sentences used largely neutral verbs in the embedded clause (to allow *ziji* to refer to either the local or the matrix subject), and the matrix sentence used the verb "told others" (e.g., *Zhangsan told others that I/you/Lisi thought SELF could get into a good college next year.*) Thus, the addressee of "told" in our sentences is "the others," and as a result an imperative interpretation is not possible, in contrast to Schumacher et al. (2011), who derive the different behavior of first and second person interveners from a hierarchy ranking related to the directive/imperative vs. assertive distinction.

As we will see below in Experiment 3, the apparent difference in the blocking strength of first and second person pronouns may in fact be a side effect having to do with participants' (mis)representing the embedded clauses in the test sentences as direct/quoted speech, rather than an intrinsic difference in the blocking behavior of these two forms.

EXPERIMENT 3

Experiments 1 and 2 looked at the effects of first and second person blocking on the real-time processing and off-line interpretation of *ziji*. We saw that the first person pronoun did not seem to show a persistent blocking effect either off-line or in real-time. The second person pronoun, however, exhibited a more reliable blocking effect, significantly reducing interference from the matrix subject. This stronger blocking effect of second person interveners is not predicted by the majority of the existing literature on *ziji*—but see Schumacher et al.'s (2011)—and seems to point to a systematic difference in the blocking strength of the two pronouns.

However, let us take a careful look at the stimuli in Experiments 1 and 2, to see if there could be another reason for the asymmetry we observed. Target items had the sentence

structure shown in **Table 6**: In both experiments, the main-clause verb (Word 2: *gaosu* "tell") was a speech verb. Thus, the embedded clause (Words 4–11) following *gaosu bieren* "tell others" was indirect/reported speech.

For example, in (7), the embedded clause *wo juede ziji...* "I thought SELF..." is a reported speech event: Here, the person who uttered this sentence (the speaker) was reporting what Zhangsan said about the speaker's thoughts. Thus, the embedded subject *wo* "I" refers to the speaker of the entire sentence and not the matrix subject *Zhangsan*.

(7) Zhangsan gaosu bieren [wo juede *ziji* mingnian keyi
Zhangsan tell others [I thought SELF next-year can
kaojin hao daxue].
get-in good college]
"*Zhangsan told others that* [$I_{speaker}$ *thought SELF could get into a good college next year*]."

(8) Zhangsan gaosu bieren: "wo juede *ziji* mingnian keyi
Zhangsan tell others: "I thought SELF next-year can
kaojin hao daxue."
get-in good college"
Zhangsan told others: "$I_{Zhangsan}$ *thought SELF could get into a good college next year."*

However, we suggest that encountering a sentence like (7) may also activate, in people's minds, something similar to (8), which is direct/quoted speech. Crucially, if the embedded clause is direct/quoted speech spoken by Zhangsan, then *wo* "I" refers to Zhangsan and not the speaker of the sentence. (This idea differs from the earlier "transformation-based" approach of Kuno (1972) and Huang et al. (1984). We suggest that a sentence like (7) is, in some sense, ambiguous between reported speech and direct speech—or at least ambiguous enough that it at least partially activates a direct speech representation in participants' minds.) Let us now consider why we think that an example like (7) might partially activate a direct/quoted speech representation like (8).

First, Chinese lacks (overt) complementizers and hence a clause following a speech verb is (in terms of its lexical items) ambiguous between direct/quoted speech and indirect/reported speech. This is unlike English: Compare "*John said (that) I am tired*" with "*John said, 'I am tired'*." English does not use complementizers before direct speech, but optionally uses them before indirect speech. This probabilistic cue is entirely missing in Chinese. This ambiguity in Chinese may result in a sentence like (7) activating a direct speech representation (perhaps in parallel with an indirect speech representation or perhaps stochastically).

Second, the word-by-word self-paced reading paradigm may create the impression of potential "pauses" between words, which may make direct speech interpretations more likely. Given that the start of a direct/quoted speech event in spoken speech is typically characterized by a longer pause (Klewitz and Couper-Kuhlen, 1999), it could be that the boundaries between words created by the self-paced reading method led participants to activate a direct speech representation of the embedded clause. For example, it could be that the break between *bieren* "others" and *wo* "I" in (7) led participants to mentally represent (7) as (8) on some trials. (Like English, Chinese normally uses quotation marks to denote directed/quoted speech, but such cues—or the absence thereof—may be less salient in self-paced reading than normal reading which allows preview and regressions.)

In sum, we suggest that in Experiments 1 and 2, participants may have been partially activating direct speech representations, alongside indirect/reported speech representations. If participants are activating direct speech representations in addition to reported speech, this would lead precisely to the asymmetry between first and second person interveners that we found (i.e., first person pronouns seemingly acting as weaker blockers than second person pronouns):

In Experiment 1, with first person pronouns, under a direct speech representation, on blocking trials (3rd-1st Condition), the first person pronoun *wo* refers to the matrix subject [e.g., *wo* "I" = Zhangsan, as shown in (8)]. Then, if the reflexive *ziji* refers to *wo*, it also refers to the matrix subject [e.g., *Zhangsan* in (8)]. This might explain the apparent violations of blocking that occur on almost 30% of trials in the 3rd-1st condition of Experiment 1: The reflexive *ziji* only *seems* to skip the local subject in favor of the matrix subject: Actually, under a direct speech interpretation, *ziji* is bound by/refers to the local subject and thus also refers to the matrix subject, since local subject is coreferential with the matrix subject. So, according to this line of reasoning, the apparent long-distance interpretation is an *illusion* made possible by a direct speech interpretation, and *ziji* underlyingly refers to the local/embedded subject. Thus, if participants are partially activating direct speech representations alongside reported speech representations, on some proportion of the trials, the activation of the direct speech representation will presumably be sufficiently high to result in selection of the matrix subject.

In Experiment 2, with second person pronouns, the situation is different. In the blocking condition (3rd-2nd), whether or not comprehenders represent the embedded clause as direct speech, the second person pronoun *ni* "you" cannot refer to the matrix subject and can only refer to the addressee in both cases [see (9) and its direct speech counterpart (10)]. Thus, regardless of whether the embedded clause is interpreted as direct or indirect speech, the reflexive *ziji* in sentences with the second person pronoun *ni* "you" cannot use the same means to get to the matrix subject as in sentences with "I." Therefore, the "escape hatch" that is possible with first person embedded subjects in direct speech is not possible with second person embedded subjects in direct speech.

(9) Zhangsan gaosu bieren [ni juede *ziji* mingnian keyi
Zhangsan tell others [you thought SELF next-year can
kaojin hao daxue].
get-in good college]
"Zhangsan told others that [$you_{addressee}$ *thought SELF could get into a good college next year]."*

(10) Zhangsan gaosu bieren: "ni juede *ziji* mingnian keyi
Zhangsan tell others: "ni thought SELF next-year can
kaojin hao daxue."
get-in good college"
"Zhangsan told others: "You$_{addressee}$ thought SELF could get into a good college next year."

This difference between first and second person pronouns fits with our results in Experiments 1 and 2, i.e., the finding that first person pronouns apparently fail to fully block reference to the matrix subject whereas second person pronouns are significantly stronger blockers. In sum, then, this line of reasoning explains the seemingly weaker blocking ability of first person pronouns as "illusory." Under the direct-speech idea, the apparent weakness of first person pronouns as blockers stems from the fact that, with a speech verb in the matrix clause, first person pronouns can be coreferential with the matrix subject whereas second person pronouns cannot.

Experiment 3 aimed to investigate the validity of this idea. Instead of using speech verbs such as *gaosu* "to tell," we used the serial verb structure *ting bieren shuo* "hear others say." The use of the perception verb *ting* "hear" should eliminate the possibility that the embedded clause can be represented as the quoted direct speech of the matrix subject. Thus, Experiment 3 will allow us to see whether (i) the first person pronoun really is a weaker blocker than the second person pronoun, or whether (ii) the weakness of the first person pronoun as a blocker is actually due to direct speech representations.

Methods

Participants

Forty-two adult native speakers of Mainland Mandarin Chinese from the Hunan Normal University in China participated in this experiment in exchange for 60 RMB (equivalent to 10 USD). All had normal or corrected-to-normal vision and reported no known learning disabilities or hearing impairments.

Design and Stimuli

A 2 by 3 design was used. The first factor was PRONOUN TYPE, with two levels—first person and second person. The second factor was REFERENT COMBINATION, with three levels—pronoun-pronoun (or PRO-PRO) vs. pronoun-name (or PRO-NAME) vs. name-pronoun (NAME-PRO). This created a total of 6 conditions. The target sentence structure and examples of the 6 conditions are in **Table 7**.

A total of 42 target items were created, each with 13 words (**Table 7**). The first and the fifth words were the matrix subject and the embedded subject, respectively. The two subjects were separated by a serial verb—*ting biren shuo* "hear others say"[5]—that was constant across all target items. The reflexive was the eighth word and was in the possessive NP position (e.g., *ziji de chengji* "SELF's grade"). Finally, *ziji* was followed by five spillover words (Words 9–13). (The grammatical role of *ziji* in Experiment 3 is different from Experiments 1 and 2. This was necessitated by the change of verb from "tell others" to "hear others say," because we wanted to ensure that the sentences were felicitous and that *ziji* could, in principle, be interpreted as referring to either the matrix or the embedded subject.)

Crucially, the use of the perception verb *ting* "hear" should eliminate the possibility of interpreting the embedded clause (Words 5-13) as the quoted direct speech of the matrix subject. In (11) for example, the embedded clause *wo keyi...* "I could..." cannot be the quoted speech of the matrix subject *Zhangsan*, and can only be what *Zhangsan* heard. Hence, the first person pronoun *wo* "I" refers to the person who uttered the entire sentence and cannot refer to the matrix subject (unlike Experiment 1).

(11) **Zhangsan** ting bieren shuo [wo keyi ba ziji de
Zhangsan heard others say [**I** could BA **ZIJI** DE
chengji gei bieren kan.
grade let others see].
'Zhangsan heard others say [I could let others see SELF's grade].'

Like Experiments 1 and 2, this study also used a Latin Square design. Experiment 3 had six lists, due to its 2 by 3 design. Each participant saw 42 targets (seven per condition), and 68 fillers. The fillers were similar to those in Experiments 1 and 2 (see Section Materials). Similar to the previous two experiments, all items were followed by a forced-choice question. Left-vs.-right positions of the answer choices were counterbalanced.

Procedure

The experimental procedure in this experiment was identical to those in Experiments 1 and 2.

Predictions

Antecedent Choices

If the intervening first person pronoun indeed has a weaker blocking effect than the second person pronoun, we should observe a relatively high rate of blocking violations—i.e., matrix subject choices—in the conditions with first person interveners (3rd-1st) when compared to the conditions with second person interveners (3rd-2nd). Alternatively, if the weakness of the first person pronoun as a blocker (as in Experiment 1) is an illusion due to the "escape hatch" provided by direct speech representations which are ruled out in Experiment 3, then we expect the rate of blocking violations in conditions with first and second person interveners to now be comparable (a low number of blocking violations in both conditions).

Reading Times

If the first person pronoun has a weaker blocking effect than the second person pronoun, then in conditions with first person interveners, we should see reading time slowdowns from *ziji* and onwards as a result of competitions between the matrix subject and the embedded subject. In particular, the reading times in the first person blocking condition should be slower compared to those in the second person blocking condition, if the first person pronoun is weaker blocker (i.e., allows more competition from the matrix subject) than the second person pronoun. On

[5]In Chinese, there is no construction equivalent to the English structure *hear + embedded clause* (e.g., I heard Peter went to Costa Rica). The closest structures are *hear-say + embedded clause* and *hear-others-say + embedded clause*.

TABLE 7 | Sentence structure for target items and sample target sentences in Experiment 3.

Condition	1	2	3	4	5	6	7	8	9–13
1st-1st	**wo "**I"				**wo "**I"				
1st-3rd	**wo "**I"				**Lisi**				
3rd-1st	**Zhangsan**	ting "hear"	bieren "others"	shuo "say"	**wo "**I"	keyi "can"	BA	**ZIJI** "SELF"	de chengji rang bieren kan "DE grade let others see"
2nd-2nd	**ni "**you"				**ni "**you"				
2nd-3rd	**ni "**you"				**Lisi**				
3rd-2nd	**Zhangsan**				**ni "**you"				

1st-1st:* "I** *heard others say* **I** *could give* **ZIJI's score to others to look at."*
1st-3rd:* "I** *heard others say* **Lisi** *could give* **ZIJI's score to others to look at."*
3rd-1st:* "Zhangsan** *heard others say* **I** *could give* **ZIJI's score to others to look at."*
2nd-2nd:* "You** *heard others say* **you** *could give* **ZIJI's score to others to look at."*
2nd-3rd:* "You** *heard others say* **Lisi** *could give* **ZIJI's score to others to look at."*
3rd-2nd:* "Zhangsan** *heard others say* **you** *could give* **ZIJI's score to others to look at."*

the other hand, if the blocking violations in Experiment 1 (first person interveners) were actually "illusions" due to direct speech, then in Experiment 3, we should not observe competitions between the blocked matrix subject and the local subject.

Data Analysis

All participants were highly accurate on the comprehension questions for filler items (90% and above); thus, all data were included in subsequent analyses. The trimming criteria were identical to those used in Experiments 1 and 2 and resulted in the exclusion of 2.59% of data points. The same statistical methods were used to analyze data in the present experiment. The reading time data for the first 12 words of the target items were analyzed.

Results and Discussion

In this section, we present the results of Experiment 3 and discuss them briefly. We postpone an in-depth discussion of Experiment 3 until the General Discussion, because the full import of this third study is best appreciated when it is compared to the results of Experiments 1 and 2.

Antecedent Choices

As shown in **Figure 5**, matrix subject choices were numerically relatively rare (1st-3rd: 1.70%; 3rd-1st: 6.46%; 2nd-3rd: 4.08%; 3rd-2nd: 13.95%). However, the first person blocking condition (3rd-1st) and the second person blocking condition (3rd-2nd) had somewhat higher percentages of matrix subject choices than the other conditions. Surprisingly, the 3rd-2nd Condition actually had numerically the *highest* rate of matrix subject choices. (As in the preceding studies, we excluded the data from the two single-referent conditions, 2nd-2nd and 1st-1st, from analysis the antecedent-choice analyses.)

Logistic mixed-effects regression was used to test the effects of PRONOUN TYPE and REFERENT COMBINATION on antecedent choices. The results showed significant main effects of pronoun type [$\chi^2 = 13.069$, $df = 1$, $p < 0.001$] and referent combination [$\chi^2 = 21.071$, $df = 1$, $p < 0.001$] but no interaction [$\chi^2 = 0.0349$, $df = 1$, $p = 0.852$]. Hence, conditions with second person pronouns were more likely to elicit matrix subject choices than conditions with first person pronouns, and the two blocking configurations were more likely to produce matrix subject choices than the other two conditions.

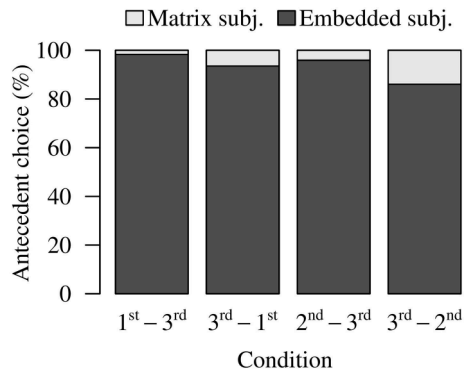

FIGURE 5 | Experiment 3 antecedent choice data.

Although the omnibus test reported above did not yield a significant interaction, a set of four planned comparisons was carried out. The results (**Table 8**) showed that the 3rd-1st Condition elicited more matrix subject choices than the 1st-3rd Condition, and that the 3rd-2nd Condition elicited more matrix subject choices than the 2nd-3rd Condition. In addition, the 3rd-1st Condition actually had *fewer* matrix subject choices than the 3rd-2nd Condition. This result is different from what we saw in Experiments 1 and 2 where the opposite pattern was observed. That is, the 3rd-1st Condition in Experiment 1 led to significantly more matrix subject choices than the 3rd-2nd Condition in Experiment 2. The finding that in Experiment 3 (when direct speech interpretations are blocked), the 3rd-1st Condition resulted in *fewer* matrix subject choices than the 3rd-2nd Condition clearly argues against the idea that the first person is an inherently weaker blocker than the second person.

As with the first two experiments, we used Bonferroni-corrected one-sample *t*-tests to check whether the number of non-local, matrix subject choices in each condition was significantly above zero. The results showed that the numbers of matrix subject choices in the two blocking conditions were significantly above zero, and were marginally above zero in the 1st-3rd condition and significantly above zero in the 2nd-3rd condition [1st-3rd: $t_{1(41)} = 2.354$, $p = 0.094$; $t_{2(41)} = 3.950$,

TABLE 8 | Experiment 3: Planned comparisons for antecedent choice data ("*": $p < 0.05$; ".": $p < 0.1$).

Contrast	β	z	Pr(>|z|)
3rd-1st vs. 1st-3rd	2.0751	2.975	0.0107*
3rd-2st vs. 2nd-3rd	2.4489	4.618	<0.001*
3rd-1st vs. 3rd-2nd	−1.2112	−3.604	0.0012*
1st-3rd vs. 2nd-3rd	−0.8374	−1.051	0.6672

$p = 0.094$; 3rd-1st: $t_{1(41)} = 2.953$, $p = 0.021$; $t_{2(41)} = 6.428$, $p < 0.001$; 2nd-3rd: $t_{1(41)} = 3.106$, $p = 0.014$; $t_{2(41)} = 3.950$, $p = 0.007$; 3rd-2nd: $t_{1(41)} = 3.683$, $p = 0.003$; $t_{2(41)} = 6.428$, $p < 0.001$].

In sum, we find that the 3rd-1st and the 3rd-2nd Conditions, which are often regarded as the prototypical blocking conditions, allow rates of blocking violations (matrix subject choices) that are significantly higher than 0, and in fact higher than the 1st-3rd and 2nd-3rd Conditions respectively. This indicates that blocking is not a strict, categorical phenomenon. Furthermore, we find no evidence that first person pronouns are weaker blockers than second person pronouns. In fact, in this study, the 3rd-2nd Condition results in more matrix subject choices than the 3rd-1st condition. This suggests that the high rate of matrix subject choices in Experiment 1 may indeed have been due to participants activating direct speech representations, which function as an "escape hatch" to allow *ziji* to refer to the matrix subject in the presence of an intervening first-person subject.

Reading Times

The reading time patterns are presented in **Figure 6** (conditions with first person pronouns) and **Figure 7** (conditions with second person pronouns). Linear mixed-effects regression was used to analyze log-transformed reading time data.

At the 7 words prior to *ziji*, a persistent effect of REFERENT COMBINATION was observed (**Table 9**), reflecting an increased processing effort involved in reading third person names (compared to first and second person pronouns). This pattern is similar to what we observed in Experiments 1 and 2 and is also expected based on existing research (Warren and Gibson, 2002). From *ziji* and onwards, marginally significant effects of REFERENT COMBINATION were observed at Words 9 and 10. However, planned comparisons did not yield any significant differences at these positions. A significant REFERENT COMBINATION × PRONOUN TYPE interaction was found at word 12, but planned comparisons did not reveal any significant contrasts at this position.

In sum, we find no clear evidence for reading-time slowdowns (i.e., competition between multiple referents) after *ziji*. This suggests that in this experiment, when direct speech representations are not possible, participants are not considering the matrix subject as a potential referent—or not sufficiently for it to result in a reading-time slowdown—for the reflexive *ziji*. In the General Discussion, we take a closer look at how these results relate to the outcomes of Experiments 1 and 2, and what the implications of these comparisons are.

GENERAL DISCUSSION

The experiments reported here tested whether and how person-feature-based blocking guides comprehenders' real-time processing and final interpretation of the Chinese reflexive *ziji* "self." Our work was motivated by three main aims. First, we wanted to test experimentally to what extent native speakers' judgments fit with the view often presented in theoretical work that first person and second person interveners block access to long-distance subjects. Second, there is debate in existing work concerning the configurations that can result in blocking—in particular, whether blocking only occurs with intervening first and second person pronouns, or whether it can also occur with third person pronouns as long as there exists a mismatch in the featural make-up of the matrix subject and the embedded subject. We tested whether intervening third person referents block long-distance antecedents like their first and second person counterparts. Third, we complement prior on-line work by testing whether person-feature cues can immediately reduce interference from blocked / inaccessible long-distance c-commanding subjects.

Absence of Absolute Blocking Effects, and Potential Asymmetries between First and Second Person Pronouns

Regarding the first and third questions mentioned above, Experiment 1 found that first person interveners in the purported blocking condition (3rd-1st) resulted in a higher-than-expected rate of matrix subject choices, as well as reading-time slowdowns. This suggests that when comprehenders encounter sentences with third person matrix subjects, first person embedded subjects, and a reflexive *ziji* in the embedded clause (3rd-1st), both the embedded and matrix subject compete as potential antecedents for the reflexive. This argues against claims that blocking is categorical, since under that view, we should see no matrix subject choices and no slowdowns. Interestingly, Experiment 2 found that second person interveners in the purported blocking condition (3rd-2nd) exhibited a low rate of matrix subject choices and only short-lived, marginal reading-time slowdowns.

In light of these results, one might be tempted to conclude that second person pronouns are stronger blockers. Such a conclusion might in fact be expected, in light of earlier claims that blocking in Chinese is related to perspective taking (Huang and Liu, 2001). Let us combine this idea with other work on perspective in cognitive psychology which found that in English (at least in some contexts), the second person induces stronger perspective-taking than the first person (Brunyé et al., 2009; Ditman et al., 2010, see also Brunyé et al., 2011). If this stronger perspective-taking effect with the second person pronoun also holds in Chinese and if blocking is indeed related to perspective taking, then we may expect to see a stronger blocking effect with the second person pronoun. However, as we will see below, Experiment 3 shows that this conclusion is too hasty, because the use of a verb of saying as the embedding verb in Experiments 1 and 2 allows first-person pronouns an "escape hatch" that seems

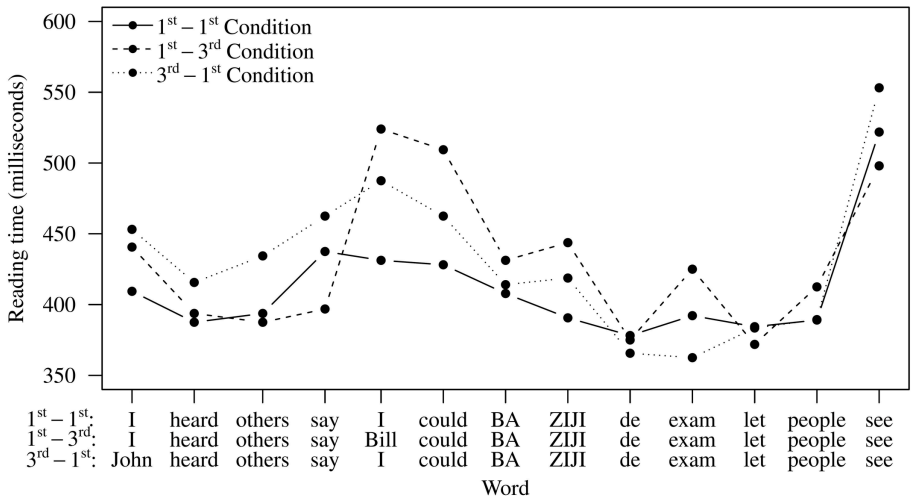

FIGURE 6 | Reading times for conditions with the first person pronoun in Experiment 3.

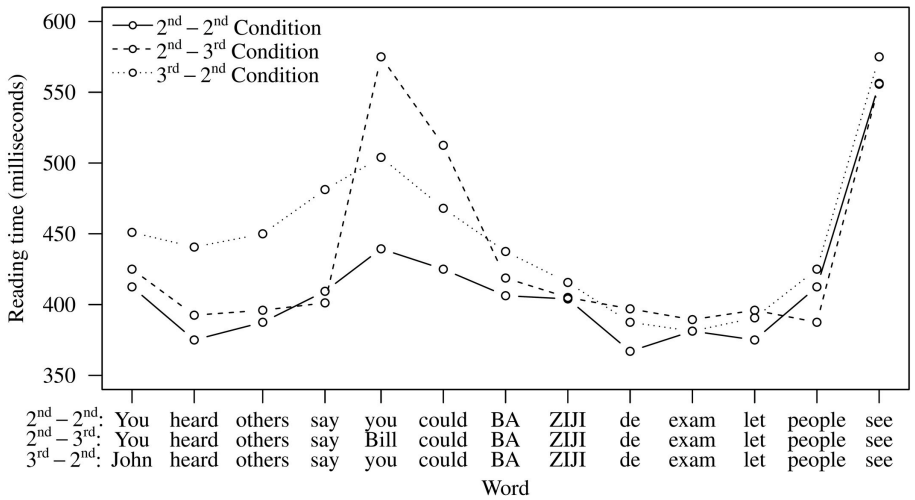

FIGURE 7 | Reading times for conditions with the second person pronoun in Experiment 3.

to be boosting the rate of matrix subject choices without violating blocking.

Evidence for Blocking in Asymmetrical Environments, Even Without First or Second Person Blockers

Regarding the second question above, namely whether blocking (even if it is not absolute) only occurs when the embedded subject (the blocker) is first or second person or whether blocking phenomena can also occur in configurations where the two subjects have different person features (e.g., 1st-3rd or 2nd-3rd, so the blocker is third person), our results argue for the second view. In all three experiments, an intervening third person referent in the 1st-3rd and 2nd-3rd conditions can block access to the long-distance subject in off-line judgments (i.e., we find relatively lower rates of matrix subject interpretations in those conditions than in 3rd-3rd conditions).

However, the reading time patterns in Experiments 1 and 2 are less clear: In Experiment 1, in the 1st-3rd Condition still showed reading time slowdowns (relative to the baseline 1st-1st condition), which could be taken as an indication that the "blocked" inaccessible matrix subject can still interfere with the local subject. In Experiment 2, the 2nd-3rd Condition showed only marginal reading time slowdowns relative to the 2nd-2nd Condition. Thus, even though the off-line judgments suggest a stable blocking effect, in real-time comprehenders may still briefly consider the "blocked" referents. In Experiment 3, the intervening third person referent seems to exclude the first and second person matrix subject from the initial set of

TABLE 9 | Experiment 2: Reading time results ("*": $p < 0.05$; ".": $p < 0.1$).

	Words	Main effect						Interaction

11	Let	0.189	2	0.910	0.761	1	0.383	3.633	2	0.393
12	People	1.248	2	0.546	3.917	1	0.048	8.371	2	0.015*

antecedent candidates, as we find no significant reading time slowdowns. Given that Experiments 1 and 2 allow direct speech interpretations, as discussed above, we assume that the results of Experiment 3 are more reliable in this regard.

As a whole, we interpret these results as supporting theoretical claims that blocking is symmetric and third person interveners can also serve as blockers (Tang, 1989; Pollard and Xue, 1998). However, the finding that in Experiment 3, the third person intervener actually exhibited a stronger blocking effect than first or second person interveners, hints that maybe blocking is not fully symmetric. Perhaps first and second person blocking involves a different mechanism than third person based blocking. We leave this as a question for future research.

Taking a Closer Look at Whether First Person Pronouns are Weaker Blockers

Experiment 3 was designed to test (i) whether the first person pronoun and the second person pronoun differ in their effectiveness as blockers, or (ii) whether the high rate of violations of first person blocking in Experiment 1 could be due to comprehenders treating the embedded clauses as quoted direct speech. As described above, a direct speech interpretation would allow "apparent" blocking violations even when the reflexive is actually bound by the local subject. In Experiment 3, we ruled out potential direct speech interpretations by using a verb of hearing (*heard from others* rather than *told others*).

We did not find any evidence in Experiment 3 that first person pronouns are worse blockers than second person pronouns. Interestingly, although both first and second person blocking conditions triggered matrix-subject choices at above-zero rates, the second person blocking condition actually allowed a *higher* rate of matrix subject choices than the first person blocking condition—contrary to the results of Experiments 1 and 2. Thus, after eliminating the possibility of participants representing the embedded clause as direct speech, the first person pronoun seems to create a more stable configuration than the second person pronoun in determining comprehenders' judgments of *ziji*. This finding was unexpected, and merits further investigation.

As a whole, the antecedent choice data in Experiment 3 provide additional evidence for our conclusion that blocking is not a strict, categorical phenomenon. In fact, the first and second person blocking configurations produced *more* matrix subject choices than the two conditions with third person interveners (1st-3rd and 2nd-3rd). However, the reading time data, particularly those from Experiments 2 and 3, show that comprehenders seem to use person feature cues quickly during real-time processing to filter out inaccessible long-distance referents. For example, in Experiment 3, the 3rd-1st Condition had a reading time pattern comparable to that of the 1st-1st Condition at *ziji* and onwards—in other words, we see no signs of a slowdown in the 3rd-1st condition, suggesting that the matrix subject is not competing as a potential antecedent when direct-speech interpretations are ruled out.

Thus, there seems to be a mismatch between comprehenders' on-line performance and off-line antecedent choices: Participants' final responses suggest that, although the local subject is the preferred antecedent for *ziji*, participants still interpret *ziji* as referring to the non-local subject at rates significantly higher than 0. However, at the same time, reading times suggest that when participants process *ziji,* they do not experience slowdowns/competition effects, i.e., reading time patterns suggest that only one antecedent is being considered at the point where *ziji* is processed. This difference between on-line and off-line patterns points to the possibility that the interpretation of *ziji* unfolds over time: it seems that initially, during real-time processing, person-feature cues weigh more heavily and constrain what antecedent candidates get considered. However, participants' off-line interpretations suggest that at some later point, other kinds of information are also integrated and perhaps outweigh the person-feature constraint, resulting in consideration of referents that were initially "blocked" due to the person-feature constraint.

Implications for Models of Reference Resolution

Our results highlight the role that person features play in guiding the interpretation of reflexives. This contrasts with most existing psycholinguistic models of reflexive processing, which have tended to focus on structural information. For example, Dillon et al. (2009) hypothesize that because *ziji* can be potentially bound by all c-commanding subjects in a discourse, comprehenders should use the c-commanding subjecthood information to search for potential antecedent candidates. Our experiments shed new light on the types of information that guide the interpretation of *ziji*. The finding that comprehenders quickly use person feature cues to guide the search for potential antecedents in real-time suggests that structural information is not the only type of constraint that regulates the real-time processing of *ziji*. In addition, the results from our experiments also suggest that the real-time interpretation of *ziji* can be subtly influenced by comprehenders' mental representations of written texts (i.e., direct vs. indirect speech representations of embedded clauses). These findings are in line with work by Patil et al. (2011), Chen and Vasishth (2011), and Jäger et al. (2015b), who showed that non-structural information also affects the real-time processing of referential forms. The results from Experiments 1–3 also lend support to studies such as Kaiser et al. (2009) that show that comprehenders' antecedent choices do not necessarily follow structural constraints strictly.

AUTHOR CONTRIBUTIONS

XH and EK conceptualized and designed the experiments. XH collected the data and conducted the statistical analyses. Both XH and EK interpreted the data and wrote the manuscript.

ACKNOWLEDGMENTS

We would like to thank the audiences at the 35th Penn Linguistics Colloquium, the 4th Conference on Quantitative Investigations in Theoretic Linguistics and the 23rd North American Conference on Chinese Linguistics, where earlier versions of some of this work were presented. Preliminary analyses of some of the data presented here appear in the University of Pennsylvania Working Papers in Linguistics Vol. 18, and in the dissertation of the first author (He, 2014, University of Southern California). Thanks are also due to the Frontiers reviewers, as well as to Maria Luisa Zubizarreta, Roumyana Pancheva, and Rand Wilcox for useful comments and feedback on many aspects of this work.

Wh-filler-gap dependency formation guides reflexive antecedent search

Michael Frazier, Lauren Ackerman, Peter Baumann, David Potter and Masaya Yoshida*

Department of Linguistics, Northwestern University, Evanston, IL, USA

Prior studies on online sentence processing have shown that the parser can resolve non-local dependencies rapidly and accurately. This study investigates the interaction between the processing of two such non-local dependencies: *wh*-filler-gap dependencies (WhFGD) and reflexive-antecedent dependencies. We show that reflexive-antecedent dependency resolution is sensitive to the presence of a WhFGD, and argue that the filler-gap dependency established by WhFGD resolution is selected online as the antecedent of a reflexive dependency. We investigate the processing of constructions like (1), where two NPs might be possible antecedents for the reflexive, namely *which cowgirl* and *Mary*. Even though *Mary* is linearly closer to the reflexive, the only grammatically licit antecedent for the reflexive is the more distant *wh*-NP, *which cowgirl*.

(1). Which cowgirl did Mary expect to have injured herself due to negligence?

Four eye-tracking text-reading experiments were conducted on examples like (1), differing in whether the embedded clause was non-finite (1 and 3) or finite (2 and 4), and in whether the tail of the *wh*-dependency intervened between the reflexive and its closest overt antecedent (1 and 2) or the *wh*-dependency was associated with a position earlier in the sentence (3 and 4). The results of Experiments 1 and 2 indicate the parser accesses the result of WhFGD formation during reflexive antecedent search. The resolution of a wh-dependency alters the representation that reflexive antecedent search operates over, allowing the grammatical but linearly distant antecedent to be accessed rapidly. In the absence of a long-distance WhFGD (Experiments 3 and 4), *wh*-NPs were not found to impact reading times of the reflexive, indicating that the parser's ability to select distant *wh*-NPs as reflexive antecedents crucially involves syntactic structure.

Keywords: reflexive antecedent search, filler-gap dependency resolution, structure-sensitivity, gender mismatch effect, eye-tracking, text-reading

1. Introduction

In order to interpret sentences of natural language, the human parser must establish non-local dependencies between elements received in the input. Two such kinds of dependencies are wh-dependencies and reflexive-antecedent dependencies. The former is the dependency between a *wh*-word such as *who* or *which* and the empty argument position (e.g., subject, direct object, indirect object) where it is interpreted, which we refer to throughout as a "*Wh*-filler-gap dependency" or "WhFGD." The latter is the dependency between a reflexive pronoun such as *himself* or *herself* and the antecedent noun phrase on which it is referentially dependent, which we refer to as a "reflexive dependency" or "RD."

WhFGDs and RDs differ from one another in a number of ways. While in a WhFGD the presence of a *wh*-word at the left edge of a clause can provide evidence for the existence of an empty NP position later on, such as the empty direct object position in a sentence like *What did Mary eat?*, a RD cannot be recognized until later. This is because in a RD, it is typically the later-occurring element in the dependency that contains bottom-up evidence of the need for a reflexive-antecedent relation. That is, in a sentence like *Mary saw herself*, there is no indication that *Mary* will need to be associated with a reflexive later in the sentence until the reflexive *herself* is actually encountered. Evidence from many psycholinguistic studies, discussed below, indicates that both of these dependency resolution processes occur quite rapidly in online reading. If the presence of a WhFGD affects the online operation of a subsequent RD resolution, this would constitute evidence that the antecedent retrieval process is sensitive to syntactic structure, namely to the presence and location of the WhFGD.

In this paper, we investigate the interaction between the processes of the parser that establish these two kinds of dependencies in on-line sentence comprehension. In particular, we examine whether resolving a WhFGD establishes a new candidate antecedent in the representation that is searched during the resolution of a RD. Converging evidence from the psycholinguistic sentence processing literature indicates that the process of WhFGD resolution is an active process. In particular, upon encountering a *wh*-word, the parser does not wait to receive bottom-up information determining the location of the tail of the WhFGD, but actively posits or hypothesizes the dependency tail whenever it detects an incoming position at which resolving the dependency would be grammatically licit (Stowe, 1986; Traxler and Pickering, 1996; Phillips, 2006). Likewise, reflexive resolution is known to be rapid and grammatically sensitive (Nicol and Swinney, 1989; Sturt, 2003; Jäger et al., 2015): upon encountering the reflexive, the parser tries to link the reflexive to grammatically licit antecedents in the early stages of online processing.

Considering RDs like 1, a reflexive normally co-refers with its closest potential antecedent. In (1), *himself* is understood to co-refer with *the man*, not with *Jane*[1]. In (2), however, the *wh*-phrase *which man* is interpreted as the subject of the non-finite embedded clause *to have injured himself*, just as *the man* is in (1), but it is displaced from the canonical embedded subject position after *expect*. In a context such as this, the *wh*-phrase *which man* must be the antecedent of *himself*, instead of the linearly closer noun phrase *Jane*. If *Jane* were chosen as the antecedent of the reflexive in either (1) or (2), the example would be predicted to be unacceptable due to the gender mismatch between the feminine name *Jane* and the masculine reflexive *himself*, contrary to fact.

(1) Jane$_i$ expected the man$_j$ to have injured himself$_{*i/j}$.

(2) Which man$_i$ did Jane$_j$ expect to have injured himself$_{i/*j}$?

[1]Here and throughout, subscript indices are used to indicate possible and impossible coreference relations: NPs bearing the same subscript index indicate an interpretation under which these NPs refer to the same entity, and impossible interpretations [e.g., *himself* = *Jane* in (1)] are prefixed with an asterisk.

Examples such as these, with nonfinite embedded clauses associated with sentence-initial *wh*-phrases, allow us to investigate whether the result of WhFGD resolution influences RD resolution. Without WhFGD resolution, in an example like (2) the closest potential candidate antecedent (*Jane*) for the reflexive mismatches with it in gender. If reflexive resolution operates over a representation that does not include information about WhFGDs, then in the course of finding the antecedent for the reflexive *himself* in (2) the parser may (at least transiently) attempt to associate *himself* with *Jane*, leading to processing difficulty and a possible slowdown due to the gender mismatch (Sturt, 2003).

If, however, the active process of WhFGD resolution alters the representation over which reflexive resolution operates, it may establish a new candidate antecedent for the reflexive that is closer to the reflexive than the ungrammatical antecedent *Jane*, by co-indexing the sentence-initial *wh*-phrase *which man* with the position of the gap (3)[2]. In this case, the closest candidate antecedent for the reflexive in (2) will be the gap linked to the (masculine) *wh*-phrase. We would thus not expect the parser to attempt to associate *himself* with *Jane* even temporarily, because there is a closer, grammatically acceptable antecedent. The parser should therefore experience no gender-mismatch effect when the reflexive mismatches in gender with an ungrammatical but linearly close candidate antecedent such as *Jane* in (2).

(3) Which man$_i$ did Jane expect /gap/$_i$ to have injured himself?

Thus, whether or not the parser experiences gender-mismatch effects from a linearly close but ungrammatical candidate antecedent like *Jane* in examples like (2) can tell us whether the process of reflexive resolution is sensitive to the presence of a WhFGD.

The plan for this paper is as follows. In the remainder of Section 1, we discuss the theoretical and empirical background of this line of research, focusing in turn on WhFGD resolution (Section 1.1), and reflexive antecedent search (Section 1.2). In Section 2 we report the results of four experiments to test whether the tail of a WhFGD is treated online as a potential antecedent for reflexive resolution. Section 3 discusses the implications of these results for theories of sentence-processing, and Section 4 concludes.

1.1. Active *wh*-dependency Resolution

The term *WhFGD resolution* refers to the process by which the parser interprets a left-peripheral *wh*-question element such as *what*, *who*, or *which NP* to correspond to appropriate sentence-internal material—approximately, to correspond to the position in which the *wh*-element's correlate would appear in an answer to the *wh*-question. The end result of this process is that the *wh*-element in a *wh*-question like (4-a) is interpreted as corresponding to the empty direct object position, such that an answer to (4-a) would include an element filling this position, as in (4-b).

[2]Whether *position* here is defined structurally, or in terms of verbal selection frames, or at the level of predicate-argument relations, is immaterial at this early point in the discussion.

(4) a. What did Mary devour?
b. Mary devoured fish.

Upon encountering a position in the input string in which a grammatically obligatory element is missing, [in the case of (4-a), the object position immediately after *devour*] the parser has bottom-up evidence that this is the position to be affiliated with the left-peripheral *wh*-word. In what follows, we refer to this empty position in the input corresponding to the *wh*-element's answer and to the variable in the sentence's interpretation as the *gap*.

Converging evidence from the psycholinguistic sentence processing literature, however, indicates that the parser is not as conservative in resolving WhFGDs as the above would suggest: instead the process of *wh*-dependency resolution is an *active* process (Frazier, 1987). In particular, upon encountering a *wh*-word, the parser does not wait to receive bottom-up information determining the location of the gap (viz. a position in the input string in which a grammatically obligatory element is missing), but actively posits or hypothesizes the existence of a gap whenever it detects an incoming position at which such a gap would be grammatically licit (Traxler and Pickering, 1996; Phillips, 2006; Omaki et al., 2015).

The principle line of evidence that *wh*-dependency resolution is an active process in this sense comes from the so-called filled-gap effect (FGE, Stowe, 1986 *et seq.*). The FGE is a reading-time slowdown observed at the positions of an overt NP in a sentence with a *wh*-element, such as the position of *the sushi* in (5). The object position after *eat* is a potential gap site, but not an actual gap site, the actual gap site being in the complement of the preposition *with*. The fact that reading-time slowdowns are observed at such positions is interpreted as an indication of the parser's having hypothesized a gap in the position occupied by the overt NP and subsequently, upon finding this prediction falsified, having to take time to correct its mistake[3].

(5) What did Mary eat the sushi with?

Precisely how active or predictive the process of WhFGD resolution may be is not directly relevant to the present study, because in all experiments reported here the WhFGD occurs substantially before the measurement regions of the reflexive and its spillover region. However, the general finding that gap-filling is an active, rapid process is strong evidence that this process will have completed by the time RD resolution is triggered, when the parser encounters the reflexive in examples like (3). This enables us to study whether reflexive resolution is sensitive to the presence of a WhFGD without the danger that the WhFGD has not been recognized by the parser at the point when RD resolution occurs.

1.2. Antecedent Retrieval

Because *wh*-words in English are under normal circumstances located at the left edge of the clause with which they are associated, *wh*-dependency resolution is in the general case a forward process in the sense that the cue to the existence of a long-distance dependency between two linguistic elements is encountered at the leftmost element. Reflexive antecedent search is quite different, because while a reflexive is overtly marked with the morpheme *self*, it generally occurs after its antecedent, which does not bear any marking indicating that it is the antecedent of an upcoming reflexive. Trivially, in example (6) below, *John* occurs in the same form whether it is the antecedent of a reflexive (6-b) or not (6-a). That is, while the presence of *wh*-morphology triggers an active search through subsequently-processed linguistic material for the tail of the *wh*-dependency, the presence of reflexive morphology (English *-self*) must instead trigger a backwards search through previously-processed material for its antecedent.

(6) a. John_i dislikes $\text{him}_{*i/j}$.
b. John_i dislikes $\text{himself}_{i/*j}$.

Additionally, the possibility of a RD is constrained in two ways. The first constraint, typically referred to as Condition A of the Binding Theory (Chomsky, 1981), states that reflexives must be locally bound, so non-clausemate NPs and those that do not c-command[4] the reflexive are illicit antecedents, as indicated by the unacceptability of the examples in (7). Second, in English, a reflexive must match its antecedent in number and gender, so that e.g., masculine NPs are illicit antecedents of feminine reflexives and vice versa, as indicated by the unacceptability of the examples in (8).

(7) a. *John hopes that the police won't find himself.
b. *Rumors about John bothered himself.

(8) a. *John injured herself.
b. *Mary injured himself.

Although the aim of this study is principally to determine how structure-sensitive the reflexive antecedent retrieval process is, rather than to distinguish between different mechanisms of antecedent retrieval, the parser's behavior in this context still has the potential to be informative about the retrieval mechanism itself, and so some discussion of different models of the retrieval of linguistic antecedents from memory bears inclusion here.

In cue-based models of antecedent retrieval like Lewis and Vasishth (2005), the antecedent retrieval mechanism is not crucially constrained by syntactic structure. Instead, upon encountering a word that requires an antecedent (in the present case, the reflexive), the parser performs a feature-matching operation in parallel on all the elements in a content-addressable memory store—roughly, all the words it has recently encountered. In a model like this, cues indexing the syntactic position of potential antecedents can interact with non-structural cues like agreement features, allowing ungrammatical

[3]While (Stowe, 1986) observed FGE-related slowdown only in the position of non-subjects, not of subjects, since then, other researchers, for example Lee (2004), have found that subject-FGEs do appear under slightly different experimental settings.

[4]C-command (Reinhart, 1976) is a notion of relative syntactic prominence; formally, in a tree structure, α c-commands β iff α does not dominate β and the node immediately dominating α also dominates β. For our purposes here, it suffices that subjects c-command their associated verb phrases and all the contents of their associated verb phrases, including subordinate clauses. Note also that additional NPs contained inside an NP subject do not c-command anything out of the NP subject, as in (7-b) below.

antecedents to potentially be retrieved. On such an account, both candidate reflexive antecedents are predicted to impact the reading-time measures of the reflexive in our experiments, because both of them will be simultaneously checked against the features (in particular the gender feature) of the reflexive when the parser encounters it.

Precisely how the candidate antecedents should affect reading-time measures of the reflexive depends upon the details of the cue-based model adopted. A simple possibility is that the parser should experience extra difficulty when no candidate antecedent is found in its memory store, leading to an interaction effect such that the reflexive regions of sentences like (3) but containing no gender-matching antecedent for the reflexive, such as (9), are read most slowly.

(9) Which woman did Jane expect to have injured himself?

More complex patterns are also possible, however. In the model of Lewis and Vasishth (2005), two distinct interference effects are predicted between the match/mismatch of the *wh*-NP and the linearly local NP. First, when both candidate antecedents match the feature specification of the reflexive, similarity-based interference is predicted, such that the reflexive regions of sentences like (3) but containing two gender-matching antecedent for the reflexive, such as (10), will exhibit reading-time slowdowns.

(10) Which man did John expect to have injured himself?

This is due to the mutual inhibition between the featurally similar candidates. Second, facilitation should occur where the accessible antecedent mismatches and the inaccessible antecedent matches the features of the reflexive. This would manifest as faster reading times. More complex models such as the one in Jäger et al. (2015) also predict that the gender congruency of the candidate antecedents should interact in modulating reading-times at the reflexive. In general, cue-based retrieval models that are not constrained by syntactic structure make the prediction that both candidate antecedents should affect reading times.

Cue-based models commonly incorporate a decay parameter, such that items that have been in memory longer are less salient and harder to retrieve, but a decay parameter does not predict effects of the *wh*-NP in the absence of effects of the more local candidate antecedent NP, since the *wh*-NP will have been in memory slightly longer. Even if the *wh*-NP is re-activated (and thus boosted) in memory at the position of the verb in the lower clause as Lewis and Vasishth (2005)'s model predicts, it should still be the case that the activation of the more local candidate antecedent remains strong enough to induce some effect at the reflexive. For this reason, theories of cue-based retrieval would predict an interference effect from the matrix subject NP *Jane* in (3).

Dillon et al. (2013) did not observe an interference effect of this kind in their experiments on sentences like (11), and performed computational simulations of the level of memory activation of the competing reflexive antecedents in order to determine whether such a reactivation-based account could explain the lack of interference effects. They compared the predictions of a cue-based system that was restricted to consider only syntactic information in reflexive antecedent retrieval with one that could consider all cues, including agreement information, where both systems incorporated memory reactivation of the grammatical antecedent [in (11), *the new executive*]) at the matrix verb (*doubted*), a point after the competing antecedent (*the middle managers*).

(11) *The new executive who oversaw the middle managers apparently doubted themselves …

They concluded, however, that a formal model of antecedent activation that was restricted to consider only syntactic cues in reflexive antecedent search provided a closer fit to their empirical findings than one that considered all cues (including morphological ones) and depended only upon relative activation level to modulate which candidate antecedent was retrieved. That is to say, cue-based models that were not restricted to consider only syntactic structural cues in reflexive antecedent retrieval predicted more interference than observed, even after accounting for reactivation of the grammatical antecedent.

While the sentences studied in Dillon et al. (2013) involve somewhat different long-distance dependencies, in both their sentences and ours the grammatical antecedent is reactivated after the ungrammatical candidate antecedent [at *doubted* in their (11) and at or around *have injured* in our (3)], and so a model such as theirs plausibly predicts no effect of the ungrammatical candidate antecedent in our experiments as well.

Many previous studies have investigated whether the antecedent retrieval process, whether cue-based or otherwise, is constrained by syntactic relations: namely, where a potential antecedent is located in the syntactic tree (e.g., Badecker and Straub, 2002; Sturt, 2003; Felser et al., 2009; Xiang et al., 2009; Cunnings and Felser, 2013; Dillon et al., 2013; Clackson and Heyer, 2014; Cunnings and Sturt, 2014).

Sturt (2003) investigated the on-line application of Condition A of the Binding Theory in sentence processing by cross-manipulating the (stereotypical) gender match/mismatch and structural accessibility/inaccessibility (in terms of c-command relations) of prior discourse referents. In his Experiment 1, two candidate antecedents, both c-commanding a reflexive, were cross-varied for gender congruency with the reflexive, as in (12). As expected, when the linearly closer and structurally accessible antecedent mismatched the anaphor in stereotypical gender, reading times on the anaphor/spill-over region were slower.

(12) He/she remembered that the surgeon had pricked himself/herself with a used syringe needle.

On the other hand, in Sturt (2003)'s Experiment 1, a significant effect of inaccessible-match/mismatch was found in later measures, such that mismatching inaccessible antecedents slowed down subsequent reading times on the anaphor. Sturt (2003) interpreted this result as evidence that the antecedent retrieval process is structurally constrained such that grammatical constraints act as a filter on interpretation during on-line reading, which can subsequently be violated by more general comprehension processes. Cunnings et al. (2015) and Kush et al.

(2015) found similar patterns in the case of pronoun binding, and both interpret them as evidence of later comprehension processes attempting to coerce an antecedence relation when none is permitted by the grammar, though the explanation offered by Kush et al. (2015) involves a number of additional complications.

Sturt (2003)'s Experiment 2 is similar in some ways to the present study in that it also tests reflexive resolution in configurations where a grammatically inaccessible antecedent is linearly closer to the reflexive than the grammatically accessible antecedent.

(13) The surgeon who treated Jonathan/Jennifer had pricked himself/herself with a used syringe needle.

The fact that Sturt found no result of the inaccessible antecedent in his Experiment 2, in contrast with his Experiment 1 where late interference effects were found, may indicate that such interference effects are confined to configurations in which the inaccessible antecedent c-commands the reflexive. If this is the case, interference effects similar to those in Sturt's Experiment 1 may be found in the present study. However, in this study, unlike in Sturt's Experiment 2, both the accessible and inaccessible antecedent c-command the reflexive. This difference allows the present study to serve as a kind of follow-up to Sturt (2003), distinguishing whether the parser's reflexive antecedent resolution system is sensitive to structural (rather than linear) locality of a potential antecedent separately from c-command.

Substantial additional evidence indicates that at least the structural relation of c-command affects dependency formation. Cunnings et al. (2015) and Kush et al. (2015), for example, both investigated the retrieval of antecedents of bound pronouns which, like reflexives, are referentially dependent upon other NPs. Both groups of researchers found evidence that the c-command relation constrains the antecedent search process, such that bound pronouns only trigger antecedent retrieval of possible binders in c-commanding positions.

However, theories taking account of only c-command do not predict that the parser should be able to effectively distinguish between the grammatical and ungrammatical antecedents in our experiments, since both candidate antecedents c-command the reflexive. For these accounts to make different predictions about these sentences, a notion of locality is needed as well—reflexives in English are more restricted than bound pronouns because their antecedents must c-command the reflexive *and* must be contained in the same immediate clause. If the retrieval system can take advantage of both of these structural properties (c-command and clausemate-hood), it should fail to exhibit interference effects from the linearly more local candidate antecedent in sentences like (3).

That is to say, the possible grammatical sensitivity of the parser investigated here is somewhat finer grained than that investigated in e.g., Cunnings et al. (2015), who investigated whether antecedent retrieval is sensitive to the c-command constraint on anaphora. Correctly resolving sentences like (3) requires the parser to attend to two grammatical constraints–the clausemate condition on reflexives, and the necessity of a WhFGD tail in the embedded clause in examples like (3)–and not merely retrieve a c-commanding antecedent, since both *which man* and *Jane* c-command the reflexive in sentences like (3). In our case, if the reflexive is linked to the c-commanding linearly local antecedent, a gender mismatch effect is expected based upon the gender match/mismatch of this NP with the reflexive. On the other hand, if the reflexive is linked to the tail of the WhFGD, due to the parser's respecting the structural constraint on the WhFDG, we should observe a gender mismatch effect due to the *wh*-NP's match/mismatch with the gender of the reflexive.

Dillon et al. (2013) directly compared reflexive antecedent retrieval with a somewhat similar dependency, subject-verb agreement, that also requires feature congruency between words that may be linearly distant from one another. They investigated whether the interference effects found in subject-verb agreement, where an illicit potential antecedent can cause the verb to mistakenly bear incorrect agreement morphology, were also found in reflexive antecedent retrieval, and did not find evidence that they were. Dillon et al. (2013) proposed that, unlike in subject-verb agreement, the antecedents of reflexives are retrieved using solely syntactic cues, with other kinds of cues, such as grammatical gender, being checked against retrieved antecedents only later. On their account, the retrieval system has access to information about which NP in its memory store is the local subject, thus enabling it to be sensitive to c-command as well as locality. On an account of this kind, we would not expect to see an effect of the inaccessible antecedent on reading times of the reflexive.

However, there is a caveat to the preceding discussion. Even if the retrieval system is able to track the identity of the current local subject, it is possible for it to be misled by examples like (3). The grammatically accessible antecedent for the reflexive in (3) is the *wh*-phrase, which is not located inside the immediate local clause containing the reflexive, *to have injured himself*. No local subject is overtly present in this clause at all. The sentences in our experiments thus probe one further level of syntax-sensitivity on the part of the antecedent retrieval system: whether it is able to access the result of the WhFGD resolution process, a posited gap in the subject of the infinitive clause, as a potential reflexive antecedent. There are at least two reasons it might fail to do so.

First, it is possible that the results of WhFGD resolution are simply not represented in a way that is accessible to the reflexive resolution process. This might be the case if the gap/tail of the WhFGD was simply not present in its memory store. Second, it might be the case that the parser is susceptible to what are known as *local coherence effects*, where a parse is adopted that is suitable for only a substring of the input. Note that in examples like (3), if the *wh*-NP is disregarded, the result is the possible sentence *did Jane expect to have injured himself*, in which *Jane* must be the antecedent of the reflexive, contrary to gender congruency. There is evidence that in some contexts the parser can be misled by local coherence effects (e.g., Ferreira et al., 2002; Tabor et al., 2004; Konieczny et al., 2010), and if the result of WhFGD formation is not accessible to the reflexive antecedent retrieval system, it may exhibit such effects in this context as well.

Prior research on reflexive antecedent retrieval in configurations similar to WhFGDs in that they involve an NP associated with a subsequent, unpronounced position

similar to a gap has found mixed results. Kwon and Sturt (2015) investigated reflexive antecedent retrieval in the context of nominal control constructions like (14). Control constructions of this kind resemble WhFGDs in that they can involve a dependency between a displaced NP [*Luke* in (14-b)] and a position in an embedded clause [the subject position of *to photograph himself* in (14-b)].

(14) a. Luke's order to Sophia to photograph *himself/herself . . .
b. Luke's promise to Sophia to photograph himself/*herself . . .

Kwon and Sturt (2015) found an effect of antecedent-reflexive gender mismatch both in nominal control constructions like (14-a), where the accessible antecedent (*Sophia*) was closer to the reflexive than the inaccessible candidate, and in nominal control constructions like (14-b), where the accessible antecedent (*Luke*) was more distant, though the former effect was reliable for more reading-time measures. They interpret this result to indicate that the control relation is processed early on and used to constrain subsequent RD formation.

For our purposes here, the fact that an effect was observed in the control constructions most similar to WhFGDs, those like (14-b) where the antecedent is distant from the embedded clause, suggests that the antecedent retrieval system may be sensitive to agreement mismatch in resolving reflexive-antecedent dependencies even when the antecedent is related to the reflexive via the mediation of a long-distance dependency.

Sturt and Kwon (2015) presented additional results on reflexive antecedent retrieval in nominal control as well as the related construction of *raising*, illustrated in (15).

(15) John seemed to Amy to be kind to himself . . .

They found evidence of retrieval interference by grammatically inaccessible antecedents for both raising and nominal control, casting further doubt on the possibility that reflexive antecedent search can find an antecedent online whose relation to the reflexive is mediated by a long-distance dependency. Like Sturt (2003)'s early measures, however, they did not find evidence for interference from grammatically inaccessible antecedents in reflexive-antecedent configurations not involving raising or control.

1.3. Summary

The resolution of a WhFGD is an active process by which the parser posits the tail of a *wh*-dependency upon encountering grammatically licit positions for it in the input. Similarly, the application of binding conditions in reflexive resolution occurs rapidly in on-line reading. Because of this, sentences containing a *wh*-dependency whose tail constitutes the grammatically-licit antecedent for a reflexive pronoun are an ideal environment for a test for the time course of structure-sensitivity in on-line sentence processing. In particular, these kinds of sentences allow us to test whether backward antecedent search processes are sensitive to fine-grained details of the grammatical representation containing the candidate antecedent NPs. Furthermore, if the timing of effects of accessible and inaccessible antecedents differs, they may may be informative about whether grammatical sensitivity constrains the antecedent search process itself or whether the antecedent search process is itself insensitive to fine-grained syntactic details and syntactic knowledge becomes operative only later as a supplementary cue to filter out impossible antecedent-reflexive relations generated by the antecedent search process. The experiments described below constitute such a test.

2. Experiments

2.1. Experiment 1

2.1.1. Introduction

Experiment 1 is the principal experiment of this study and serves to test whether reflexive resolution is sensitive to the result of WhFGD resolution. Experiments 2–4, which are reported in subsequent sections below, serve as follow-up experiments to Experiment 1, intended to clarify the interpretation of Experiment 1's results. Like all of the experiments in this study, Experiment 1 tests sentences in which a *wh*-NP occurs at the left edge of a complex sentence involving a matrix clause and an embedded clause, the latter of which contains a reflexive pronoun. In Experiment 1, these sentences look like (16), and all follow the basic template in (17).

(16) [Which cowgirl did Mary/David expect [to have injured herself/himself due to negligence?]]

(17) [Which NP_1 did NP_2 VERB [to have VERB-ed him-/herself SPILLOVER REGION]]

By independently varying the reflexive's gender congruency with the linearly local, grammatically inaccessible candidate antecedent NP on the one hand, and with the grammatically accessible (but linearly more distant) *wh*-NP on the other, we use on-line eye-tracking reading measurements of sentences like (16) to investigate whether reflexive antecedent search is immediately sensitive to the presence of a WhFGD or whether it initially considers linearly local but grammatically impossible antecedents.

Much previous work using the gender-mismatch effect as a probe for the parser's establishment of a long-distance dependency has utilized gender-stereotypic nouns like *doctor* and *nurse*. In contrast to this, the experiments reported here all use gender-categorical nouns like *cowgirl* or *uncle* and strongly gendered personal names like *Mary* or *Steven*. The reason for this design decision is that in piloting work, the subject population (Northwestern University undergraduates) was not found to exhibit a measurable gender-mismatch effect in response to gender-stereotypic nouns associated with (stereotypic-)gender mismatched reflexives. We do not speculate here as to the reason for this difference from previously studied populations except to say that it may be connected to changing social attitudes about the appropriateness of different professions for individuals of one or another gender. For our purposes it is sufficient that the study population *does* exhibit a gender-mismatch effect in response to gender-categorical nouns and strongly

gendered personal names associated with gender-mismatched reflexives[5].

2.1.2. Participants

Forty English speaking undergraduates from the Northwestern University community volunteered to participate in this experiment in return for course credit or a small monetary compensation. This experiment, and all experiments reported below, were approved by the Northwestern University Institutional Review Board as compliant with ethical standards for research on human subjects and were run under the protocol *Meaning in Language: Words, Sentences and Inferences (STU00025908)* or *Clausal Ellipsis: Its Structure and Online Processing (STU00082465)*.

2.1.3. Design and Materials

Materials consisted of 24 sentences like (18), with a complex *wh*-NP at the left edge associated with the subject position of an embedded non-finite clause, plus 140 filler sentences from unrelated, non-competing experiments. Comprehension questions were asked after 25% of trials in order to motivate the participants to attend to the experiment. This procedure is used in all following experiments as well. The gender match of the reflexive with the *wh*-NP and the linearly closer matrix-clause subject was independently varied in a two-by-two factorial design.

(18) Sample Stimuli

a. Which cowgirl did Mary expect to have injured herself due to negligence? // *wh*-NP match, local NP match.

b. Which cowgirl did David expect to have injured herself due to negligence? // *wh*-NP match, local NP mismatch.

c. Which cowgirl did David expect to have injured himself due to negligence? // *wh*-NP mismatch, local NP match.

d. Which cowgirl did Mary expect to have injured himself due to negligence? // *wh*-NP mismatch, local NP mismatch.

In this experiment, the embedded clause is non-finite (marked with the infinitival marker *to* and without agreement or independent tense-marking) and the tail of the *wh*-dependency headed by the *wh*-NP terminates in the embedded clause, after the position of the subject of the matrix clause. Although the embedded verbs were not formally normed for transitive or reflexive frame probabilities, they are all judged by the consensus of the native English speaking authors to be obligatorily transitive or highly transitively biased, and none are inherently reflexive. The subject of the matrix clause is thus the closest overt NP to the reflexive, and will consequently be referred to as the *linearly local* candidate antecedent, but because of the long-distance WhFGD between the *wh*-NP and the subject position of the embedded clause (17), only the *wh*-NP can be adopted as the antecedent for the reflexive in the final interpretation of the example[6]. For this reason the *wh*-NP is a *grammatically accessible* antecedent in the terminology we adopt here, and likewise the linearly local NP (the subject of the matrix clause) is a *grammatically inaccessible* antecedent.

In conditions (a) and (c), the reflexive matches the gender of the linearly closer but grammatically inaccessible matrix-clause subject. In conditions (a) and (b), the reflexive matches the gender of the linearly more distant but grammatically accessible *wh*-NP. Full experimental materials for this and all subsequent experiments are available in the online Supplementary Materials.

2.1.4. Predictions

If the process of antecedent search involved in reflexive resolution is sensitive to the output of WhFGD resolution, an early gender-mismatch effect should be observed when the gender of the grammatically accessible *wh*-NP mismatches that of the reflexive [i.e., in conditions (c) and (d)], and no gender-mismatch effect should be observed when the grammatically inaccessible, linearly local NP mismatches the gender of the reflexive, at least in early reading-time measures.

In contrast, if reflexive antecedent search is not sensitive to the output of WhFGD resolution and consists of a retrieval system that is not constrained to consider only grammatical antecedents, early gender-mismatch effects should be observed when the gender of the grammatically inaccessible, linearly local NP mismatches the gender of the reflexive. Depending upon the naive retrieval model adopted, several patterns of effects from the grammatically accessible *wh*-NP might be observed. Effects of gender mismatch with the *wh*-NP may be predicted to be observed only in later measures, if subjects select the linearly closest candidate antecedent on their initial parse. This might be the case if subjects are initially misled into a locally-coherent but globally ungrammatical parse (Ferreira et al., 2002; Tabor et al., 2004; Konieczny et al., 2010) in which the *wh*-phrase is not assigned an interpretation, as discussed above. In this case effects of the *wh*-NP would be expected to follow those of the linearly local candidate antecedent. On the other hand, if the reflexive antecedent retrieval system is a cue-based system that is not constrained to consider only grammatical antecedents, an effect of gender mismatch with the linearly local but grammatically inaccessible candidate antecedent should interact with that of the grammatically accessible *wh*-NP. In particular, the slowdown effect due to gender mismatch with the *wh*-NP should be ameliorated in the presence of a gender-matching inaccessible antecedent, because a cue-based retrieval system that is not restricted to consider only syntactically accessible candidate

[5]Note that a consequence of this experimental manipulation is that conditions in which the only grammatically-accessible antecedent for the reflexive mismatches it in gender are prima facie ungrammatical because, for example, *The cowgirl injured himself* or *Steven injured herself* may not be grammatical reflexive-antecedent dependencies. However, it is arguable whether examples like *The cowgirl injured himself* or *Steven injured herself* are genuinely ungrammatical, rather than simply unacceptable in the majority of contexts: it is not unimaginable that a woman might be named *Steven*, merely very unexpected, and likewise in the context of a costume party, the individual picked out by the referring expression *the cowgirl* could conceivably be male.

[6]Modulo dispreferred intensifier readings of the reflexive which will be addressed in the discussion below.

antecedents should be able to retrieve the gender-matching but grammatically inaccessible candidate antecedent.

Importantly however, a linguistically-naive antecedent retrieval process, whether cue-based or otherwise, should always show effects of the grammatically inaccessible, linearly local NP if any gender-mismatch effects are measurable at all. This is because such a process can by definition not distinguish potential candidate antecedents based upon the syntactic configurations in which they occur. For this reason, an effect of the grammatically accessible *wh*-NP in this experiment in the absence of an effect of the grammatically inaccessible, linearly local NP should be a clear signal of structure-sensitivity in the reflexive antecedent search mechanism.

2.1.5. Data Analysis

Using a tower-mounted EyeLink1000 eye-tracker, gaze was recorded and manually corrected for vertical drift. Fixations shorter than 80 ms were incorporated into adjacent fixations, and fixations longer than 2000 ms were excluded from analysis. The following analysis is based on four eye-tracking measures: first fixation duration, first pass duration, regression path duration, and re-read time. First fixation measures are based on the duration of the first time a fixation occurs within the region. First pass times include all time spent within the region before the first instance of the gaze exiting the region, either to the left or the right. Regression path duration is calculated by summing the times spent within the region and all time after exiting the region to the left until the first instance that the gaze exits to the right of the region. Re-read time is the sum of time spent within the region after the first time the gaze exits the region.

For the purposes of this study, we will concentrate on two regions of interest: the critical region containing the reflexive anaphor [e.g., *herself* in (19)], and the spillover region containing the remaining words on that line before the carriage return [e.g., *for unimportant* in (19)]. The stimuli were all displayed on two lines, due to character length limitations of the presentation software. The carriage returns were all in the same location and included in the post-spillover region, which is not analyzed in this study due to the complexity of interpreting fixations in regions that contain line breaks.

(19) Which saleswoman did Margaret presume to have excused herself for unimportant reasons?

In line with discussion in Barr et al. (2013), analyses were conducted by comparing a converging maximally inclusive linear mixed effects regression (LMER) model to a reduced model, i.e., a model with the same structure as the maximal model but with a single effect of interest removed from the fixed effects structure. Intercepts (β) and standard error (S.E.) were calculated from the maximal model. Maximal and reduced models were then compared by ANOVA to calculate the χ^2 and significance ($\alpha = 0.05$), reported in **Table 2**. The ideal maximal model for the critical region consisted of two independent factors (gender congruency with the *wh*-phrase; gender congruency with the local NP), and one additional fixed factor (presentation order).

TABLE 1 | Means (and Standard Errors) for Experiment 1.

Region		Critical region	Spillover region
Wh-phrase	**Local NP**		
FIRST FIXATION			
Match	Match	207 (6)	199 (5)
Match	Mismatch	203 (5)	214 (6)
Mismatch	Match	212 (5)	209 (7)
Mismatch	Mismatch	221 (6)	212 (7)
FIRST PASS			
Match	Match	221 (7)	312 (14)
Match	Mismatch	225 (7)	338 (15)
Mismatch	Match	238 (8)	335 (16)
Mismatch	Mismatch	247 (9)	343 (15)
REGRESSION PATH			
Match	Match	314 (23)	666 (64)
Match	Mismatch	293 (17)	680 (63)
Mismatch	Match	331 (25)	757 (57)
Mismatch	Mismatch	404 (34)	931 (78)
RE-READ TIME			
Match	Match	395 (28)	434 (42)
Match	Mismatch	297 (23)	391 (28)
Mismatch	Match	376 (28)	463 (37)
Mismatch	Mismatch	397 (25)	457 (31)

Intercepts were allowed to vary across subjects and items. We also allowed for the slopes of the following effects to vary across subjects and items: gender congruency of the *wh*-phrase, gender congruency of the local antecedent, the interaction of these two factors, and the presentation order. In cases where the maximal model failed to converge, the random effects correlation parameters were removed from the random effects structure (thus necessitating removal from reduced models as well). All models converged with either the ideal maximal model[7], or with the random effects correlations removed, as suggested in Bates et al. (2015). Data were contrast coded with conditions summing to 0 (i.e., *wh*- and local congruency conditions were coded as 0.5 or −0.5, respectively.) This coding scheme and analytical method is used for all experiments in this study. **Table 1** contains the means and standard errors in milliseconds of reading times. These measures were calculated after manual vertical alignment of fixations. For statistical analysis, converging maximal linear mixed effect models were compared via ANOVA to depleted models of the same structure, but with a term of interest removed. χ^2-values and their corresponding *p*-values are reported in **Table 2**, alongside the estimates and standard errors calculated from the corresponding maximal model. Bold values indicate that the comparison reached significance.

[7] For example: $lmer(rt \sim wh{*}lc + ord + (1 + wh{*}lc + ord|subj) + (1 + wh{*}lc + ord|item), data = data)$, where *rt* is the reading time, the predictors *wh* and *lc* are the gender match/mismatch of the *wh*-NP and the local candidate antecedent NP, respectively, and *ord* is the presentation order.

TABLE 2 | Combined ANOVA and LME results for Experiment 1.

Region	Effect	Estimate	Std error	χ^2 (df)	*p*-value

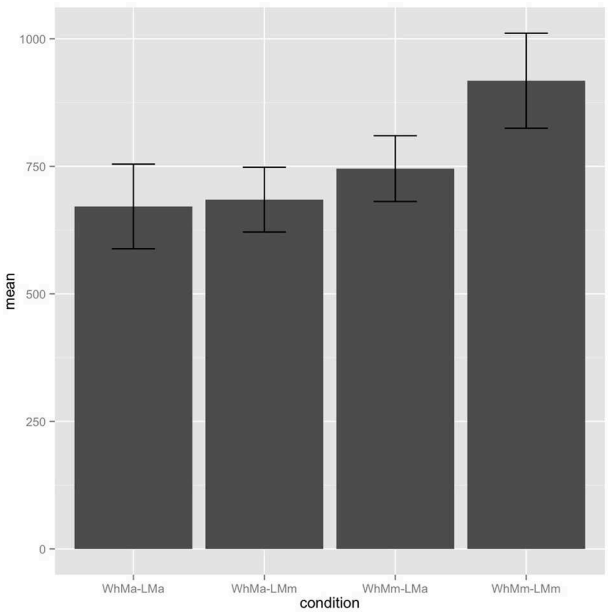

FIGURE 1 | Experiment 1 spillover region regression path durations.

2.1.6. Results

In the critical region, i.e., at the reflexive pronoun, we found a significant main effect of gender congruency between the *wh*-phrase and the reflexive, with matched gender read faster than mismatched gender, for first pass reading time [$\beta = -19.55$, S.E. $= 8.32$, $\chi^2(1) = 6.65$, $p = 0.010$]. This suggests that the parser is trying to form a dependency between the *wh*-phrase and the reflexive pronoun. When it successfully forms the dependency in the *wh*-phrase gender match condition, the reading time at the critical region is faster than when it is unsuccessful in the *wh*-phrase gender mismatch condition.

In the spillover region, we observe a significant main effect of gender congruency between the *wh*-phrase and the reflexive, with matched gender read faster than mismatched gender for regression path duration [$\beta = -159.70$, S.E. $= 72.40$, $\chi^2(1) = 4.33$, $p = 0.037$], (**Figure 1**). No other effects reached significance.

There were, however, marginal interactions of *wh*-phrase gender congruence with local NP congruence in the regression path duration and re-reading time in the critical region, such that the mismatch-mismatch condition was read more slowly. Although this interaction was not statistically significant it is consistent with the predictions of some unconstrained cue-based models of antecedent retrieval. On an explanation of this kind, the parser would attempt to associate the reflexive with all possible candidate antecedents in parallel and experience extra difficulty when no gender-congruent antecedent is found in its memory store. In the absence of a significant effect, this is of course a purely speculative suggestion.

The main effect we observe in the spillover region is consistent with the effect at the critical region and supports the hypothesis that the parser represents the tail of the *wh*-dependency and is thus able to connect the *wh*-phrase and the reflexive pronoun. This suggests that the presence of the WhFGD is accessible to the process of RD resolution. In other words, since the parser has already linked the *wh*-phrase with the gap, the search for the RD does not allow the parser to consider the interpretation in which the linearly closest antecedent (i.e., the proper name) is linked with the gap. The effect of gender mismatch of the *wh*-phrase in the absence of an effect of the linearly local but grammatically inaccessible candidate antecedent supports the hypothesis that the reflexive antecedent retrieval system is constrained to consider only grammatically accessible antecedents. However, the marginal interaction with the gender-match/mismatch of the linearly local candidate antecedent suggests a possible signature of a cue-based retrieval system that is not constrained to consider only grammatically accessible antecedents, which forms much of the motivation for Experiment 2.

In addition to the reflexive interpretation proper, the English pronouns ending in *-self* have at least two other interpretations which are subject to different syntactic constraints[8]. In an *emphatic* reading of a *-self* -type pronoun in English, the pronoun, though formally reflexive, does not have a properly reflexive

[8]Thanks to Dave Kush (*personal communication*) for pointing out the possibility of this reading for the stimuli in Experiment 1.

reading (roughly, indicating that the object of the verb refers to the same entity as the subject). Emphatic reflexives instead have a focus-related meaning emphasizing that some entity referred to by an NP associated with the reflexive was involved in the event described by the sentence, rather than any other entity that might have been involved in the event. So in (20-a), the emphatic reflexive *himself* is associated with the matrix subject *John* and serves to emphasize that John's expectation was that he himself, and not someone else, would have injured the cowgirl.

(20) a. John expected to have injured the cowgirl himself.
b. *John expected had injured the cowgirl himself.

In an *anti-assistive* reading of a *-self*-type pronoun, the *-self*-type pronoun serves to indicate that the agent of the sentence performed the action in question *without help*, so in (20-a), such a reading would mean that John expected to have received no assistance in injuring the cowgirl. Because control into finite embedded clauses is impossible in English (20-b), emphatic and anti-assistive reflexive readings for sentences like the stimuli for Experiment 2 (discussed below), with finite embedded clauses, are not possible.

2.2. Experiment 2

2.2.1. Introduction

In order to demonstrate that the effect of the *wh*-NP observed in Experiment 1 is, in fact, a consequence of the *wh*-dependency and not some other factor, we should replicate these results in a syntactically different context, but one that is similar in all respects that this account predicts to be relevant for the pattern of results observed in Experiment 1: namely, the presence of a dependency tail associated with the sentence-initial *wh*-NP after the linearly closest candidate antecedent. This is the primary purpose of Experiment 2.

Experiment 2 also serves to distinguish the possibility that the marginal interactions with the gender congruence of the local NP result from retrieval difficulty from the possibility that they result from the parser's later consideration of the dispreferred non-reflexive readings for the *-self* pronoun.

2.2.2. Participants

Forty English speaking undergraduates from the Northwestern University community volunteered to participate in this experiment in return for course credit or a small monetary compensation.

2.2.3. Design and Materials

Materials for Experiment 2 consisted of 24 target sentences, plus 90 filler sentences from unrelated experiments. The target stimuli used in Experiment 2 are based upon those used in Experiment 1, with one relevant difference. While the target stimuli from Experiment 1 include non-finite embedded clauses, those in Experiment 2 use finite embedded clauses, as exemplified in (21).

(21) Sample Stimuli
a. Which cowgirl did Mary expect had injured herself due to negligence? // *wh*-NP match, local NP match.
b. Which cowgirl did David expect had injured herself due to negligence? // *wh*-NP match, local NP mismatch.
c. Which cowgirl did David expect had injured himself due to negligence? // *wh*-NP mismatch, local NP match.
d. Which cowgirl did Mary expect had injured himself due to negligence? // *wh*-NP mismatch, local NP mismatch.

This difference has two related effects on the possible behavior of the parser in these sentences. First, because finite complement clauses in English do not permit control readings (22), there is no potential locally coherent substring of these examples in which the grammatically inaccessible, linearly local candidate antecedent NP is a grammatical antecedent for the reflexive. Given that effects of the linearly local candidate antecedent were not observed in Experiment 1, this difference is not expected to influence reading time measures.

(22) *Susan expected had injured herself.

A related but more important difference is that, precisely *because* a control reading is not possible for examples like those in (21), these examples do not admit of intensifier readings for the reflexive. For this reason, then, there is no grammatical possibility of linking the reflexives in the embedded clause with the matrix subject.

It is not clear how the possibility of an intensifier reflexive reading might have contaminated the primary results of Experiment 1, given that the observed effects were not compatible with such a reading (i.e., they did not indicate that participants were attempting to associate the reflexive with the matrix subject rather than with the *wh*-NP). However, because intensifier reflexives are subject to somewhat different syntactic constraints than reflexives proper, it was deemed worthwhile to ensure that a similar pattern of results obtained in the absence of any possibility of such a reading. Moreover, if the marginal interactions reported above do result from the parser's consideration of an intensifier reading for the reflexive, they should disappear in a context where this is not possible. In contrast, if they arise from interference in the antecedent retrieval process proper, they should be expected to persist.

2.2.4. Predictions

The results of Experiment 2 are predicted to be broadly similar to those of Experiment 1: namely, if reflexive resolution is sensitive to presence of a WhFGD and constrained to consider only grammatically accessible antecedents, a gender-mismatch effect should be observed when the gender of the grammatically accessible *wh*-NP mismatches that of the reflexive [i.e., in conditions (c) and (d)], and no gender-mismatch effect should be observed when the grammatically inaccessible, linearly local NP mismatches the gender of the reflexive. If reflexive antecedent search is not constrained to consider only grammatically accessible antecedents, gender-mismatch effects should be observed when the gender of the grammatically inaccessible, linearly local NP mismatches the gender of the

reflexive. If this is because of the antecedent search process's susceptibility to linear closeness, gender mismatch effects from the linearly local candidate antecedent should precede any from the *wh*-NP. If instead antecedent retrieval consists of a cue-based retrieval system that is able to consider ungrammatical reflexive antecedents, gender mismatch effects of both candidate antecedents should interact in such a way that the slowdown effect induced by mismatch with the *wh*-NP is ameliorated in the presence of a gender-matching ungrammatical candidate antecedent.

However, because in the finite embedded clauses used in Experiment 2 no control reading is possible, it is not possible to interpret the reflexive in the examples used in Experiment 2 as an intensifier reflexive linked to the matrix subject, so this experiment may constitute a cleaner test of the role of the binding constraints in reflexive antecedent search. It is not expected that the pattern of effects in this experiment will differ from that in Experiment 1; if it does, this would cast doubt upon an explanation of the effect of the *wh*-NP in Experiment 1 in terms of the parser's online sensitivity to find-grained syntactic constraints.

2.2.5. Data Analysis

The analysis of the data gathered in this experiment was carried out in much the same way as in Experiment 1. The critical region corresponds to the reflexive pronoun (*herself*) and the spillover region corresponds to *for unimportant* in the example below. Since the stimuli used in this experiment are adapted from Experiment 1, the same limitations on region size due to line breaks constrained the spillover region.

(23) Which saleswoman did Margaret presume had excused herself for unimportant reasons?

Table 3 contains the means and standard errors in milliseconds of reading times. These measures were calculated after manual vertical alignment of fixations. For statistical analysis, converging maximal linear mixed effect models were compared via ANOVA to depleted models of the same structure, but with a term of interest removed. χ^2-values and their corresponding p-values are reported in **Table 4**, alongside the estimates and standard errors calculated from the corresponding maximal model. The ideal maximal structure contains the same terms as in Experiment 1, and in cases where a maximal or depleted model did not converge, additional terms were removed in the order specified above.

2.2.6. Results

In the critical region, the only observed effects are in re-read time. We observe a significant main effect of the *wh*-phrase, with the gender matched condition read faster than gender mismatched conditions [$\beta = -129.22$, S.E. $= 31.34$, $\chi^2(1) = 12.43$, $p < 0.001$]. This is consistent with the observations in Experiment 1, that the local NP is not considered as a candidate antecedent for the reflexive pronoun, despite its linear proximity. No other effects reached significance.

The spillover region displays a similar pattern of effects, with the addition of significant main effects of *wh*-phrase observed in first pass reading time, regression path duration (**Figure 2**), and re-read time, with gender match between the *wh*-phrase and the reflexive pronoun read faster than gender mismatch [first pass: $\beta = -42.53$, S.E. $= 13.92$, $\chi^2(1) = 8.21$, $p = 0.004$; regression path: $\beta = -831.51$, S.E. $= 140.41$, $\chi^2(1) = 21.11$, $p < 0.001$], as in the case for re-read time [$\beta = -107.00$, S.E. $= 43.43$, $\chi^2(1) = 5.13$, $p = 0.023$].

As before, this indicates that the gender of the *wh*-phrase is somehow represented at the tail of the WhFGD, which is then being accessed during the reflexive antecedent search. These results are compatible with our observations in Experiment 1. As such, we can confirm that the gender mismatch effects observed in the critical region and spillover region in both Experiments 1 and 2 are due to the ability of the parser to form a dependency between the reflexive and the gap, although for different reasons. There were no marginal effects of the linearly local candidate antecedent NP in this experiment, unlike in Experiment 1, suggesting that the intensifier reading explanation for those effects in Experiment 1 may be on the right track, rather than an interpretation in terms of failed cue-based retrieval. This is of course merely speculation, given that the effects in question do not reach statistical significance.

2.3. Experiment 3

2.3.1. Introduction

Experiment 3 (as well as Experiment 4, discussed below) serves as a check to ensure that the difference observed in Experiments 1 and 2 between the effect of gender match/mismatch of the reflexive and the *wh*-NP and of the reflexive and the linearly closer NP is not due to some difference between the way *wh*-NPs

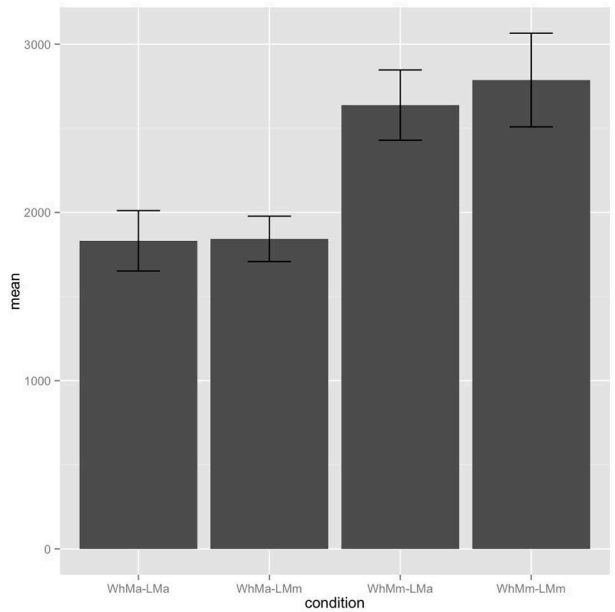

FIGURE 2 | Experiment 2 spillover region regression path durations.

and personal names are processed in general. For example, the results of Martin and McElree (2011) indicate that *wh*-NPs may have a higher prominence in memory, inasmuch as they are candidates for antecedent retrieval, than other categories. Therefore, there is a possibility that the results of Experiments 1 and 2 are not demonstrating grammar-sensitivity on the part of the parser's reflexive antecedent search process, but are instead merely demonstrating that *wh*-NPs are treated differently in memory than other NPs in some way that causes them to induce gender mismatch effects on subsequently encountered reflexives.

For this reason, in Experiment 3, the WhFGD originating in the sentence-initial *wh*-NP does not span across the linearly local NP but terminates before it, in the matrix clause, as in (24).

(24) Which cowgirl expected Mary to have injured herself due to negligence?

This has the effect that the *wh*-NP, though equally distant from the reflexive, is not its grammatical antecedent. If the effect of the *wh*-NP observed in Experiments 1 and 2 is due to a general high salience of *wh*-NPs in memory, the pattern of effects in this experiment should be largely the same here. On the other hand, if the effect of the *wh*-NP on RTs at and following the reflexive in Experiments 1 and 2 is due to the parser's sensitivity to the presence of a WhFGD intervening between the more linearly local candidate antecedent and the reflexive, the linearly local candidate antecedent should modulate RTs at the reflexive in this experiment rather than the *wh*-NP.

2.3.2. Participants

Forty English speaking undergraduates from the Northwestern University community volunteered to participate in this experiment in return for course credit or a small monetary compensation.

2.3.3. Design and Materials

Materials for Experiment 3 consist of 24 target sentences and 88 filler sentences from unrelated experiments. Experiment 3 (as well as Experiment 4, discussed below) serves as a check to ensure that the difference observed in Experiments 1 and 2 between the effect of gender match/mismatch of the reflexive and the *wh*-NP and of the reflexive and the linearly closer NP is not due to some difference between the way *wh*-NPs and personal names are processed in general. That is, there is a possibility that the results of Experiments 1 and 2 are not demonstrating grammar-sensitivity on the part of the parser's reflexive antecedent search process, but are instead merely demonstrating that *wh*-NPs are treated differently in memory than other NPs in some way that causes them to induce gender mismatch effects on subsequently encountered reflexives. For this reason, in Experiment 3, the WhFGD originating in the sentence-initial *wh*-NP does not span across the linearly local NP but terminates before it, as in (25).

(25) Sample Stimuli

a. Which cowgirl expected Mary to have injured herself due to negligence? // *wh*-NP match, local NP match.

b. Which cowgirl expected David to have injured herself due to negligence? // *wh*-NP match, local NP mismatch.
c. Which cowgirl expected David to have injured himself due to negligence? // *wh*-NP mismatch, local NP match.
d. Which cowgirl expected Mary to have injured himself due to negligence? // *wh*-NP mismatch, local NP mismatch.

If the effect of the gender match of the *wh*-NP in Experiments 1 and 2 is to be attributed to the parser's sensitivity to the WhFGD between the *wh*-NP and the embedded clause, this effect should go away when the WhFGD is not associated with the embedded clause but instead with the matrix clause, as in (25). On the other hand, if the role of the *wh*-NP in modulating reading times of the reflexive is due to a high overall salience of *wh*-NPs in memory, it should persist in this experiment.

2.3.4. Predictions

If the patterns of effects observed in Experiments 1 and 2–broadly, effects of the *wh*-NP's gender match/mismatch with the reflexive on the reading times of the reflexive–is due to the parser's grammatical sensitivity to the presence of a long-distance WhFGD between the sentence-initial *wh*-word and the embedded clause, the result in this experiment should be very different. In particular, because no such long-distance WhFGD between the sentence-initial *wh*-word and the embedded clause is present in the stimuli used in Experiment 3, no effect of the *wh*-NP's gender match/mismatch with the reflexive should be observed in this experiment. On the other hand, if the effect of the *wh*-NP on the reading time of the reflexive in Experiments 1 and 2 is due, in whole or in part, to a difference between the way that the parser treats previously-processed *wh*-NPs and the way it treats previously-processed personal names, an effect of the gender match/mismatch of the *wh*-NP should be observed in this experiment as well. If the results of Experiments 1 and 2 are due entirely to a difference between the behavior of previously-processed *wh*-NPs and personal names, then, the results of this experiment should be the same as those of Experiments 1 and 2. If a difference between the behavior of previously-processed *wh*-NPs and personal names is a contributor to the pattern of results in Experiments 1 and 2 but not the sole driver of the effect, with grammar-sensitivity of the parser also being implicated, then an effect of the gender match/mismatch of both candidate antecedent NPs, the *wh*-NP and the linearly local NP, should be observed. As above, if the antecedent retrieval system is a cue-based retrieval system that is not constrained to consider only grammatical antecedents, an interaction effect should be observed such that the gender mismatch effect due to the grammatically accessible antecedent (in this case, the linearly local antecedent rather than the *wh*-NP) should be ameliorated provided the other candidate antecedent is gender-matched with the reflexive.

2.3.5. Data Analysis

The analysis of the data gathered in this experiment was carried out in much the same way as in the previous two experiments. The critical region corresponds to the reflexive pronoun (*herself*) and the spillover region corresponds to *for unimportant* below. The stimuli used in this experiment are again adapted from Experiment 1 and the same limitations on region size due to line breaks constrained the spillover region. The critical difference between the stimuli in Experiments 1 and 2 and the current set is that the *wh*-phrase is no longer accessible to the reflexive pronoun. Rather, the local antecedent is the globally coherent and accessible antecedent.

(26) Which saleswoman presumed Margaret to have excused herself for unimportant reasons?

Table 5 displays the means and standard errors in milliseconds of reading times, calculated after manual vertical alignment of fixations. For statistical analysis, converging maximal linear mixed effect models were compared via ANOVA to depleted models of the same structure, but with a term of interest removed. χ^2-values and their corresponding *p*-values are reported in **Table 6**, alongside the estimates, and standard errors calculated from the corresponding maximal model. The ideal maximal structure contains the same terms as in previous experiments, and in cases where a maximal or depleted model did not converge, additional terms were removed in the order previously specified.

2.3.6. Results

In this experiment, we observe the expected reverse in effect source, now with the gender of the local NP influencing reading times in the critical region. Here, we observe a main effect of local NP in the critical region's re-read time, with the gender matched conditions read faster than gender mismatched

condition [$\beta = -100.51$, S.E. $= 35.59$, $\chi^2(1) = 6.62$, $p = 0.010$]. We also observe a main effect of gender mismatch in the regression path duration (**Figure 3**) and re-read time) in the spillover region [regression path: $\beta = -844.80$, S.E. $= 117.30$, $\chi^2(1) = 27.58$, $p < 0.001$; re-read time: $\beta = -164.91$, S.E. $= 69.38$, $\chi^2(1) = 4.97$, $p = 0.026$]. No other effects reached significance. Note however that all marginal effects are of the local NP, consistent with the parser only considering this NP as a potential reflexive antecedent. Thus, this supports the hypothesis that the results of Experiments 1 and 2 are due to the RD resolution process being sensitive to the presence of the WhFGD, rather than being due to some general property of *wh*-NPs as candidate antecedents.

2.4. Experiment 4

2.4.1. Introduction

Experiment 4 serves primarily to complete the paradigm explored in Experiments 1–3, so that over the course of all four experiments all combinations of *finite vs. nonfinite embedded clause* and *matrix interpretation of wh-word vs. embedded WhFGD tail* are investigated. The results of this experiment are not expected to differ from those of Experiment 3 except that, because of certain differences between finite and non-finite embedded clauses, as discussed below, the effect of the local candidate antecedent may be stronger in Experiment 4 than in Experiment 3.

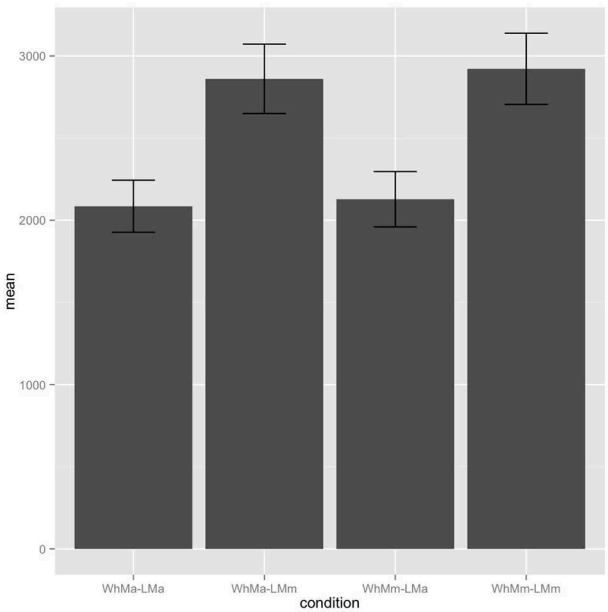

FIGURE 3 | Experiment 3 spillover region regression path durations.

2.4.2. Participants

Twenty English speaking undergraduates from the Northwestern University community volunteered to participate in this experiment in return for course credit or a small monetary compensation[9].

2.4.3. Design and Materials

The design of Experiment 4 is substantially the same as that of Experiment 3. The materials consist of 24 target sentences, plus 144 filler sentences from unrelated experiments. Like in Experiment 3, the sentence-initial *wh*-word is associated not with the embedded clause but with the matrix clause, and consequently it is not associated with a dependency tail intervening between the linearly local candidate antecedent and the reflexive. The difference between Experiments 3 and 4 is that in Experiment 4, as in Experiment 2, the embedded clause is finite rather than non-finite, as in (27).

(27) Sample Stimuli

a. Which cowgirl expected Mary had injured herself due to negligence? // *wh*-NP match, local NP match.

b. Which cowgirl expected David had injured herself due to negligence? // *wh*-NP match, local NP mismatch.

[9]The smaller number of participants in this experiment is due to accidental exclusion of the target stimuli during compiling for experimental presentation in half of the presentation orders. Fortunately, the conditions remain properly counterbalanced.

c. Which cowgirl expected David had injured himself due to negligence? // *wh*-NP mismatch, local NP match.
d. Which cowgirl expected Mary had injured himself due to negligence? // *wh*-NP mismatch, local NP mismatch.

2.4.4. Predictions

Because the only difference between Experiments 4 and 3 is the finiteness of the embedded clause, the result of this experiment is not expected to differ from that of Experiment 3. In particular, in this experiment as well, no long-distance WhFGD between the sentence-initial *wh*-word and the embedded clause is present in the stimuli used. Therefore, no effect of the *wh*-NP's gender match/mismatch with the reflexive should be observed in this experiment if the effect of the *wh*-NP's gender match/mismatch with the reflexive observed in the results of Experiments 1 and 2 is due to the parser's grammatical sensitivity to the presence of a long-distance WhFGD whose tail intervenes between the linearly closer NP and the reflexive. Likewise, if the effect of the *wh*-NP's gender match/mismatch with the reflexive is due to a general processing difference between *wh*-NPs and other NPs, it should be observed in this experiment as well. As in the preceding experiments, if the antecedent retrieval system is a cue-based retrieval system that is not constrained to consider only grammatical antecedents, an interaction effect should be observed such that the gender mismatch effect due to the grammatically accessible antecedent should be ameliorated provided the other candidate antecedent is gender-matched with the reflexive.

However, one possible small difference may be observed because of the similarity of embedded finite clauses to matrix clauses in English. Note that in example (27), if the initial words *which cowgirl expected* were omitted, the example would be the entirely grammatical matrix declarative sentences *Mary/David had injured himself/herself due to negligence*, until the presence of the question mark. It is conceivable that in these examples, for this reason, the association of the reflexive with the linearly local NP may be easier for the parser to detect, because of the similarity of these examples to simple matrix sentences in which there is only one candidate antecedent. If something like this is the case, we might expect the effect of the local candidate NP to reach significance for more reading-time measures than in Experiment 3.

2.4.5. Data Analysis

The analysis of the data gathered in this experiment was carried out in much the same way as in the previous three experiments. The critical region corresponds to the reflexive pronoun (*herself*) and the spillover region corresponds to *for unimportant*. Using the same design as in Experiment 3, the *wh*-phrase (i.e., *Which saleswoman*) is inaccessible to the reflexive pronoun as an antecedent, while the local antecedent (i.e., *Margaret*) is accessible. The limitations on region size due to line breaks constrained the spillover region, as in the previous experiments.

(28) Which saleswoman presumed Margaret had excused herself for unimportant reasons?

Table 7 displays the means and standard errors in milliseconds of reading times, calculated after manual vertical alignment of fixations. For statistical analysis, converging maximal linear mixed effect models were compared via ANOVA to depleted models of the same structure, but with a term of interest removed. χ^2-values and their corresponding *p*-values are reported in **Table 8**, alongside the estimates and standard errors calculated from the corresponding maximal model. The ideal maximal structure contains the same terms as in previous experiments, and in cases where a maximal or depleted model did not converge, additional terms were removed in the order previously specified.

2.4.6. Results

The results of Experiment 4 reveal a significant effect in regression path duration and re-read time, consistent with Experiment 3. This main effect of local NP in the critical region reveals that gender incongruency between the local NP and the reflexive pronoun led to an increased duration than when the gender matched [regression path: $\beta = -81.82$, S.E. $= 38.71$, $\chi^2(1) = 3.95$, $p = 0.047$; re-read time: $\beta = -222.01$, S.E. $= 44.71$, $\chi^2(1) = 13.25$, $p < 0.001$].

The pattern of increased durations in local mismatches is also observed in the spillover region [regression path: $\beta = -251.72$, S.E. $= 96.04$, $\chi^2(1) = 6.19$, $p = 0.013$, (**Figure 4**); re-read time: $\beta = -137.90$, S.E. $= 56.17$, $\chi^2(1) = 4.68$, $p = 0.031$]. This result is consistent with our claim that the parser

searches a sophisticated structural representation during reflexive antecedent dependency formation. That is, the presence of an effect from the local NP supports the results of Experiment 3 in demonstrating that the parser is sensitive to the tail of the WhFGD as well as other rich, phonologically null representations in the parse tree.

3. Discussion

The current study sought to investigate the interaction of the resolution of two non-local dependencies, *wh*-filler-gap dependencies (WhFGD) and reflexive-antecedent dependencies (RD). In particular, we investigated the time course of the online resolution of a RD in the context of grammatically accessible and inaccessible possible antecedents. Experiments 1 and 2 examined whether the RD resolution process would target a linearly closer but grammatically illicit antecedent, or whether instead the grammatically licit tail of a WhFGD would be selected as the reflexive antecedent. Experiments 3 and 4 examined whether a possible antecedent that was both grammatically illicit and linearly more distant from a grammatically licit antecedent would influence the reflexive antecedent search. Results from these four eye-tracking text-reading experiments indicates that the RD

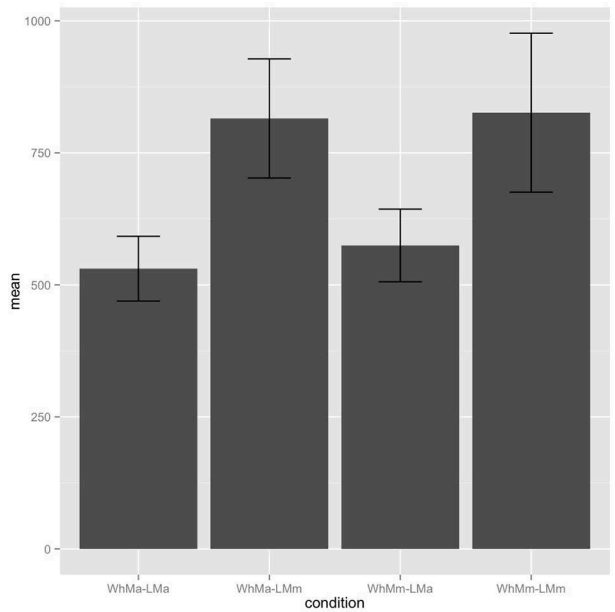

FIGURE 4 | Experiment 4 spillover region regression path durations.

resolution process is sensitive to grammatical structure, not local linear order.

Experiment 1 examined the time course of online reading of examples from the paradigm illustrated in (16). Crucially, such sentences are locally ambiguous; the string subsequent to the *wh*-phrase could be a coherent, grammatical utterance in which the antecedent for the reflexive would be a proper name. Globally, however, such a parse, with the proper name serving as antecedent for the reflexive, is unavailable; the only globally coherent parse is one in which the *wh*-phrase serves as the reflexive antecedent. Thus, if the search for reflexive antecedence is insensitive to syntactic structure, selecting either any feature-matching possible antecedent without regard to its structural position or the linearly closest possible antecedent, the proper name should be identified as the antecedent. Consequently, if such a theory is true, we expected to find a reading time slowdown at the reflexive if the gender of the reflexive and the proper name mismatched. Conversely, if the search for the reflexive antecedent is sensitive to grammatical configuration, we expected to see a reading time slowdown just in case the gender of the reflexive mismatched with that of the grammatically licit antecedent, the *wh*-phrase.

Results support the hypothesis that the parser is sensitive to global structural information during the reflexive antecedent search process. At or immediately after the reflexive, conditions in which the gender of the reflexive mismatched with that of the *wh*-phrase were read slower than those conditions in which the genders matched. At the spillover region the same effect of reflexive gender congruence with the *wh*-phrase was found, with the match condition read faster than the mismatch condition, in the regression path measure. We conclude that the parser attempts to form the RD with the grammatically accessible

antecedent, the *wh*-phrase, and not with the grammatically inaccessible antecedent, consistent with the findings of Sturt (2003). This is despite the fact that in the configuration in question the grammatically inaccessible antecedent is linearly closer to the reflexive.

Furthermore, in Experiment 1, the string including the grammatically inaccessible antecedent and the reflexive is locally coherent if the initial *wh*-phrase is disregarded as indicated in (29-a). Theories of sentence processing where the parser builds the structure based on the information available within a linearly local span (e.g., Ferreira et al., 2002; Tabor et al., 2004; Konieczny et al., 2010) would predict that the parser could be subject to confusion in these contexts and select the linearly closer candidate antecedent, but we do not find evidence for this behavior. Given the experimental support for the existence of local coherence effects of this kind elsewhere, a possible explanation for why they do not occur in this context is that the parser operates over a representation containing the unpronounced tail of the WhFGD after the linearly local candidate antecedent. If the RD formation process operates over such a representation, local coherence effects may be blocked here because the true closest candidate antecedent is the tail of the WhFGD, i.e., there is no actual locally coherent substring in the examples because the WhFGD tail disrupts the potential local coherency (29-b).

(29) a. …did Mary/David expect to have injured herself/himself…
b. …did Mary/David expect /gap/$_i$ to have injured herself/himself…

In addition to the main effect of *wh*-phrase gender congruence found in Experiment 1, marginal interactions of *wh*-phrase gender congruence with local NP congruence were found in the regression path duration and re-read time in the critical region, such that the mismatch-mismatch conditions were read more slowly. This interaction, while not statistically significant, could be consistent with the predictions of an unconstrained cue-based model of antecedent retrieval under which the parser attempts to associate the reflexive with all possible candidate antecedents and experiences extra difficulty when no gender-congruent antecedent is found in memory.

Another interpretation for this interaction relies upon the observation that the examples used in Experiment 1 have another, less easily accessible parse in which the reflexive receives a non-argument, intensifier interpretation. Such a parse can be paraphrased with the intensifier reflexive located in another position possible for such intensifiers: *Which cowgirl did Mary herself expect to have injured due to negligence?*. It is possible that the marginal interaction with the local NP is due to the parser considering this alternative parse. Experiment 2 is an attempt to distinguish these explanations by testing configurations in which this alternative parse is unavailable.

Experiment 2 examines the reading time course of examples from the example paradigm in (21). These examples are similar to those used in Experiment 1, with the exception that the embedded clause is finite. The consequence of this change is that the examples are no longer locally ambiguous in the substring subsequent to the *wh*-phrase. However, as in Experiment 1, these examples include a grammatically accessible antecedent for the reflexive, the *wh*-phrase, and a grammatically inaccessible, but linearly closer possible antecedent, the proper name. Consequently, the gender mismatch manipulation yields the same two sets of predictions in this experiment: if the search for the reflexive antecedent is structure-insensitive, we would expect to see a gender mismatch effect on the linearly closer but grammatically inaccessible antecedent, the local NP. Conversely, if the reflexive antecedent search is sensitive to grammatical structure, we would expect to see the gender mismatch effect on the grammatically accessible but linearly further *wh*-phrase.

The results again support the hypothesis that the parser only considers the grammatically accessible *wh*-phrase when attempting to identify the reflexive antecedent. On the critical region, in regression path duration and re-read times, we saw a main effect of gender congruence with the *wh*-phrase, with the match conditions read faster than the mismatch conditions. In the spillover region, we see the same effect in first pass, regression path and re-read times. Additionally, here we failed to see any effect, even marginal, of the grammatically inaccessible antecedent. As this alternative parse is unavailable for the stimuli used in Experiment 2, this suggests that the marginal interaction with the local NP in Experiment 1 may indeed have been due to the alternative *intensifier reflexive* parse discussed above, rather than being evidence for a cue-based retrieval system experiencing difficulty in the absence of a gender-congruent candidate antecedent.

In Experiments 1 and 2, we saw that the parser considered just the grammatically licit anaphor antecedent, despite the presence of another possible antecedent intervening between the grammatically licit *wh*-phrase antecedent and the anaphor. One may wonder, however, whether these results are the result of the *wh*-phrases having a special status in working memory, or having a particularly high prominence relative to other potential antecedents (Martin and McElree, 2011). If this were the case, the results from Experiments 1 and 2 might simply be the result of this high prominence; the parser attended to the *wh*-phrase as a potential antecedent not because it was a grammatically licit antecedent and the local NP an illicit antecedent, but rather because the *wh*-phrase was the most prominent possible antecedent.

Experiments 3 and 4 were designed to test this alternative hypothesis through the examination of the reading time-course of examples from the paradigms illustrated in (25) and (27). In these examples, the *wh*-phrase is no longer a grammatically accessible antecedent for the reflexive. Instead, the local NP serves as the sole grammatically licit antecedent. Thus, if the parser considered the *wh*-phrase as an antecedent regardless of whether it is a grammatically licit antecedent, we would expect that a mismatch in gender between *wh*-phrase and anaphor would induce a slowdown in reading times.

The results of Experiments 3 and 4 do not support this alternative hypothesis. In both experiments, the conditions in which the local NP mismatched in gender with the reflexive

were read slower than the conditions in which the local NP and reflexive matched in gender. In Experiment 3, this effect was found on the critical region in the first fixation, first pass, regression path, and re-read durations. In Experiment 4, the effect was found on the critical region in the regression path reading times.

The combination of Experiments 1 and 3 shows that merely having a *wh*-NP present in a sentence does not automatically cause it to be considered as the antecedent of a reflexive—that is, a general notion of the prominence of a potential antecedent, such that a *wh*-NP is checked as a potential antecedent of any dependency encountered in later processing, is insufficient to explain the observed pattern of results.

If the prominence of a potential antecedent were the source of the interference effects, we would expect to observe the same pattern in Experiments 1 and 3. But instead the observed pattern is that, when the tail of the WhFGD intervenes between the linearly local embedded subject NP and the reflexive, the *wh*-NP's gender congruency with the reflexive modulates the presence or absence of gender mismatch effects, whereas when the the *wh*-NP is not associated with a tail intervening between the subject and reflexive, the linearly local embedded subject NP's gender congruency with the reflexive modulates the presence or absence of gender mismatch effects. Thus, while it is plausibly true that *wh*-NPs are highly "prominent" candidate antecedents, the parser still appears to be guided by syntactic structure in the course of reflexive resolution and is not "confused" by the presence of an irrelevant *wh*-NP.

The principal significance of this set of findings is to provide evidence for quite sophisticated structure-sensitivity on the part of the antecedent retrieval system. Whatever mechanism subserves reflexive antecedent retrieval, whether cue-based or otherwise, must be able to exhibit online sensitivity to fine-grained syntactic structure of at least two kinds. First, it must be able to respect the clausemate condition on anaphora: that reflexives are unable to find their antecedent outside of their immediate clause. Second, it must be sensitive to the presence and location of WhFGD tails: the presence of a WhFGD must be visible to the antecedent retrieval system, whether in the form of reactivation of a previously processed NP upon gap-detection or via the positing of gaps/dependency tails as candidate antecedents in the representation over which reflexive antecedent retrieval operates. For this reason, this study constitutes evidence against unrestricted versions of cue-based retrieval, and in favor of models like that in Dillon et al. (2013) that constrain the antecedent retrieval process to respect syntactic structure.

Why might the reflexive antecedent retrieval system fail to experience interference from grammatically inaccessible antecedents in WhFGD contexts, while showing evidence of such interference in reflexive antecedent retrieval mediated by the related long-distance dependencies of raising and control studied in Kwon and Sturt (2015) and Sturt and Kwon (2015)? We speculate that the active nature of the WhFGD formation process may provide an explanation for this difference. Encountering a *wh*-NP triggers the parser to initiate an active search for its corresponding gap site, while control and raising dependencies cannot be identified until later in a sentence. If active search behavior on the part of the parser involves positing a WhFGD dependency tail within the local domain of the reflexive, this element may be an accessible retrieval candidate for a syntactically constrained antecedent retrieval system. Future research could address this question by investigating reflexive antecedent retrieval in the context of other long-distance dependencies whose leftmost element is a strong cue to the existence of the long-distance dependency, perhaps topicalization.

4. Conclusion

In this study we have investigated whether the process of reflexive-antecedent resolution is sensitive, in on-line measures, to the presence of a WhFGD dependency whose tail is the grammatically licit antecedent of the reflexive. The fact that Experiments 1 and 2 found gender mismatch effects between the *wh*-NP and the reflexive, and not between a linearly local NP and the reflexive, strongly supports the position that the tail of a WhFGD can be accessed rapidly online as a candidate antecedent in reflexive antecedent search.

This effect of the *wh*-NP is not compatible with an account where *wh*-NPs are simply highly prominent candidate antecedents regardless of the grammatical possibility of such an antecedent-reflexive relationship because, if this were the explanation for the effect of gender mismatch between *wh*-NP and reflexive in Experiments 1 and 2, Experiments 3 and 4 should have shown the same pattern. Instead, in Experiments 3 and 4, gender mismatch effects of the linearly local non-*wh*-NP and the reflexive were observed, consistent with an account on which the parser's reflexive antecedent search is grammatically guided. In general, then, we conclude that the parser's reflexive antecedent search is rapidly sensitive to such fine-grained syntactic details as the presence and location of a WhFGD. We take this to be evidence that, whatever mechanism is implicated in reflexive antecedent retrieval, it must be able to exhibit online sensitivity to the binding constraints and to treat the tail of a WhFGD as a potential candidate antecedent.

Acknowledgments

We would like to thank two reviewers for their detailed and helpful discussions. We are in debt to the following colleagues for their helpful discussion: Brian Dillon, Dave Kush, Nina Kazanina, Colin Phillips, Martin Pickering, Lars Konieczny, Patrick Sturt, and Whitney Tabor. Research suggests that the presence of a non-referent from the same category as the referent interferes with anaphor resolution. In five experiments, the hypothesis that multiple non-referents would produce a cumulative interference effect (i.e., a fan effect) was examined. This hypothesis was supported in Experiments 1A and 1B, with subjects being less accurate and slower to recognize referents (1A) and non-referents (1B) as the number of potential referents increased from two to five. Surprisingly, the number of potential referents led to a decrease in anaphor reading times. The results of Experiments 2A and 2B replicated the probe-recognition results in a completely within-subjects design and ruled out the possibility that a speeded-reading strategy led to the fan-effect findings. The results of Experiment 3 provided evidence that subjects were resolving the anaphors. These results suggest that multiple non-referents do produce a cumulative interference effect; however, additional research is necessary to explore the effect on anaphor reading times.

Keywords: comprehension, memory, fan effect, reading, anaphor resolution, antecedent, distractor

INTRODUCTION

Many theorists have argued that language comprehension processes can be explained in large part by appealing to general memory processes (e.g., Lewis, 1996; Gerrig and McKoon, 1998; Myers and O'Brien, 1998; Lewis and Vasishth, 2005; van den Broek et al., 2005); this hypothesis has been widely supported by empirical evidence. For example, general theories of memory processes have been shown to provide explanations for linguistic tasks such as establishing common ground between multiple parties (Horton and Gerrig, 2005) and resolving anaphors (O'Brien et al., 1990; Almor, 1999). Anaphor comprehension (often called anaphor resolution) in particular appears to rely heavily upon memory to determine co-reference between an anaphor and antecedent. Even within a sentence, limitations on working memory capacity induce the need for retrieval of referents (McElree, 2000). There are also instances, such as pronouns that refer to implicit referents (Greene et al., 1994) and bridging inferences (Garrod and Sanford, 1981), where anaphors are resolved even though the intended referent has not been explicitly mentioned. Such processes clearly rely on memory to produce an acceptable referent. Further evidence for the relationship between memory and anaphor resolution is provided by the findings that many factors affecting memory also affect anaphor resolution, including distance and elaboration (O'Brien et al., 1990), salience of the anaphor (Klin et al., 2004), salience of the referent (Foraker and McElree, 2007), and frequency (van Gompel and Majid, 2004). In the research reported here, we focus on anaphor resolution across sentences. Nevertheless, models of retrieval processes both across (Myers and O'Brien, 1998) and within (e.g., Lewis and Vasishth, 2005) sentences have many commonalities, which we highlight below.

Of particular interest for the current research are studies that have examined the effects of multiple potential referents on anaphor resolution (e.g., Corbett and Chang, 1983; Corbett, 1984; Mason, 1997; Levine et al., 2000; Wiley et al., 2001; Badecker and Straub, 2002; Klin et al., 2004, 2006; Ditman et al., 2007; Levine and Hagaman, 2008). In one of the first studies examining the effect of multiple potential referents, Corbett found longer reading time for an anaphoric noun phrase (e.g., *the frozen vegetable*) that included a category label when a text contained two members of that category (e.g., *fresh corn and frozen asparagus*) than when there was only a single category member (e.g., *frozen asparagus*). Badecker and Straub similarly found an increase in reading time shortly after subjects read reflexives when multiple gender-matched referents had been mentioned (e.g., *John thought that Bill owed himself another opportunity to solve the problem*). Levine et al. (see also Klin et al., 2004, 2006) found evidence suggesting that under some conditions anaphors (e.g., *the dessert*) appear not to be resolved at all when a text contains two potential referents from the same category (e.g., *tart* and *cake*), likely due to the increased difficulty in identifying a unique referent. The increased difficulty in processing anaphors in these studies suggests that readers engage in additional processing when a distractor (i.e., a non-referent) is present. Presumably this occurs because the both nouns are considered as potential referents, a process that is initiated by simple memory matching and that leads to retrieval-based interference. This explanation follows straightforwardly from global memory models (e.g., Ratcliff, 1978; Gillund and Shiffrin, 1984; Hintzman, 1986), which assume that stored memory representations that are related to a memory cue are activated in parallel and to the degree that they share features with the memory cue. Somewhat surprisingly, this

additional processing appears to occur regardless of disambiguating material that should identify the proper referent, such as a prenominal adjective like *frozen* or the grammatical constraints that govern interpretation of reflexives (e.g., Reinhart, 1983). The reliability and time course of distractor interference, especially for within-sentence retrieval, is a matter of debate. Recent evidence is consistent with a very early role for grammatical constraints in retrieval. For example, Chow et al. (2014) were unable to replicate Badecker and Straub's results, and they found evidence that grammatical constraints prevent distractor interference (see also Dillon et al., 2013). Across sentence boundaries, some features, such as parallel structure (e.g., *Josh criticized Paul. Then Marie insulted him.*), may play an early role in limiting referent search (Chambers and Smyth, 1998). Nevertheless, for definite noun-phrase anaphors like *the dessert*, reported findings suggest that retrieval processes rely on semantic matching between an anaphor and potential referents, with no evidence as yet indicating that there are grammatical constraints on this process.

Whereas results like those from Badecker and Straub (2002), Corbett (1984), and Klin and colleagues (Levine et al., 2000; Klin et al., 2004, 2006) illustrate indirectly that distractors are considered during anaphor resolution, direct evidence that distractors are activated during anaphor resolution comes from results reported by O'Brien et al. (1990). O'Brien et al. had subjects read passages with two potential antecedents (e.g., *train* and *plane*), which appeared early and late in a passage and were sometimes described elaborately. At the end of a passage, a sentence (e.g., *Mark's neighbor asked him how he had traveled to his parent's*) appeared that required retrieval of only one of the antecedents. Following this sentence, subjects had to name aloud one of the potential antecedent nouns. Relative to a no-anaphor control condition, referent nouns were named more quickly, replicating findings that suggest that referents are activated by anaphor resolution processes (e.g., Dell et al., 1983). Of perhaps greater interest was the finding that non-referent concepts were also activated relative to a control condition, especially when they were elaborated and appeared in the late position in the passage, between the anaphor and the correct antecedent. These results are consistent with the hypothesis that an anaphor acts like any other memory cue, activating related information in parallel. The finding that non-referent concepts were activated, especially when they occurred late and were elaborated, again fits very well with well-established findings from the memory literature that recency and elaboration lead to easier memory access.

Taken together, these studies demonstrate that people consider multiple potential referents when resolving anaphors, and further, that the resolution of the anaphor increases activation for the referent. However, studies involving distractors have typically been limited to situations with a single distractor. Therefore, the effect of additional distractors remains an open empirical question. A yet-stronger case that general memory processes govern anaphor resolution can be made if there is a cumulative effect of additional distractors. Both Myers and O'Brien's (1998) resonance model and Lewis and Vasishth's (2005) implementation of ACT-R (e.g., Anderson, 2005) as a theory of memory-retrieval in sentence-processing make similar predictions about the effect of multiple distractors. The resonance model states that elements in the mental representation resonate to signals from retrieval cues. In the case of anaphor resolution, the retrieval cue is the anaphor and the resonating elements are related items in the mental representation. Critically, the signal (i.e., resonance strength) of any item in the representation is divided among receiving elements, and only a subset of the elements with the strongest signal enter working memory (WM). Thus, the strength of a referent will be reduced in the presence of related distractors, reducing the probability that the correct referent will be selected into WM. Similarly, Lewis and Vasishth's model states that the activation that a chunk in memory will receive is reduced as there are more chunks in memory associated with a particular cue. Given the assumption that activation determines retrieval latency and the probability of the retrieval of a memory chunk, there should be greater difficulty in retrieving the correct referent with every additional distractor.

We can also draw on the memory literature to provide empirical guidance about the possible effects of multiple distractors. Specifically, research has shown that reading sentences that pair a person with multiple locations (or a location with multiple people) slows later recognition of the sentences (Anderson, 1974; Radvansky, 1998; Anderson and Reder, 1999). This result, known as the fan effect, is hypothesized to occur because of interference among competing associations in memory. Unlike the anaphor literature, which has focused on single distractors, the fan effect literature has explored situations with more than two associations and has demonstrated a cumulative effect, such that additional associations cause additional interference.

In the original demonstration of the fan effect (Anderson, 1974), subjects studied sentences in which a person was paired with a location (see 1–4 below).

(1) A hippie is in the park.
(2) A hippie is in the church.
(3) A policeman is in the park.
(4) A sailor is in the park.

Importantly, some people were associated with more than one location and some locations were associated with more than one person. For example, the sailor was associated only with the park (i.e., a fan of one), the hippie was associated with both the park and the church (i.e., a fan of two), and the park was associated with hippie, the policeman, and the sailor (i.e., a fan of three). Thus, the nouns varied in the number of associations with other nouns. After the study phase, subjects read another set of sentences, some of which were the same as those studied previously and some of which were novel pairings of people and locations that the subjects had not seen. For each sentence, subjects indicated whether it was the same as one they had read during the study phase or not. Consistent with the hypothesis that multiple associations interfere with one another, subjects were slower to recognize sentences with nouns that were associated with more nouns compared to sentences with nouns associated with fewer nouns. That is, subjects were slower to respond as the size of the noun's fan increased.

If anaphor resolution relies on general memory processes, and increasing the number of associations with a noun increases

interference, then we can predict that increasing the total number of potential referents for an anaphor should also show a cumulative retrieval-interference effect (i.e., a fan effect). The present study tested this prediction across five experiments by exploring the effects of multiple distractors on anaphor resolution and the subsequent activation levels of referents and distractors. In particular, we used a probe recognition task after anaphor sentences to measure the relative activation of an anaphoric referent when there were a variable number of distractors. We also used the probe task to measure activation of those distractors as a function of the number of distractors. Our results demonstrate evidence of a fan effect in anaphor resolution.

EXPERIMENT 1A

In Experiment 1A, subjects read pairs of sentences. The first provided an antecedent and one or more distractors in a serial list, and the second included an anaphoric noun phrase that co-referred with the antecedent; these were followed by a probe recognition task that was used to measure the activation of the referent concept (see **Table 1** for a sample passage and Appendix A in Supplementary Materials for a full list of experimental passages). In particular, the first sentence ended with a list of two, three, four, or five potential referents from the same taxonomic category, and the second sentence referred with a disambiguating adjective and categorical anaphor to a single item mentioned in the list. Following each sentence-pair, subjects completed a probe recognition task to measure the activation level of the referent following the anaphor. For example, the first sentence in the example in **Table 1** describes a person looking through a toolbox with a number of tools in it. The last tool mentioned in the sentence, a saw, is the antecedent concept. The second sentence then describes the person fixing a table using *the cutting tool*. The latter noun phrase serves as an unambiguous reference to the entity introduced by the antecedent. After the second sentence was completed, the word *saw* was presented in an old-new recognition task, the correct response for which is "old." We assume that reaction time and accuracy in responding to the probes will reflect the ease or difficulty the subjects have in selecting the correct referent (cf. Dell et al., 1983; Levine et al., 2000) from the list of potential referents, including the distractors and the referent.

Table 1 | Sample passage.

List sentence	Amelia's new table was wobbling, so she looked in her toolbox and found . . .
Two-noun	. . . a hammer and a saw. (all experiments)
Three-noun	. . . a screwdriver, a hammer, and a saw. (Experiments 1A and 1B only)
Four-noun	. . . a level, a screwdriver, a hammer, and a saw. (Experiments 1A and 1B only)
Five-noun	. . . a wrench, a level, a screwdriver, a hammer, and a saw. (all experiments)
REFERENCE SENTENCE	
Anaphor	She fixed it with the cutting tool before it broke. (all experiments)
No anaphor	She fixed the table all by herself before it broke. (Experiment 3 only)
PROBE WORD	
Referent	SAW (Experiments 1A, 2A, 2B, and 3)
Distractor	HAMMER (Experiments 1B, 2A, and 2B)
Comprehension question	Did Amelia use the saw? (all experiments)

We hypothesized that increasing the number of distractors would lead activation from the anaphor to spread among the referent and distractor concepts (Kintsch, 1988; Myers and O'Brien, 1998; Lewis and Vasishth, 2005). It was expected that the spread of activation from the anaphor to all conceptually-related potential referents would cause the referent to be less active following anaphor resolution as the number of distractors increased (i.e., a monotonic increasing trend in reaction time and decreasing trend in accuracy was expected), resulting in lower probe accuracy and longer probe recognition times. Additionally, this spread of activation should interfere with the selection of the appropriate referent during anaphor resolution, thus slowing reading of the reference sentence, replicating several findings (e.g., Corbett and Chang, 1983; Corbett, 1984; Mason, 1997; Badecker and Straub, 2002). Alternatively, it is possible that a backward, parallel-search process occurs such that the earlier-occurring distractors have little or no detectable impact on anaphor resolution (O'Brien, 1987). A backward, serial, self-terminating search would also predict no impact of early distractors on resolution of later referents. This latter strategy seems attractive especially in short passages with a list-like first sentence (cf. Townsend and Fific, 2004).

METHOD

Subjects

Ninety-five students enrolled in a general psychology course at the University of Arkansas participated in the experiment to partially fulfill a research requirement. All subjects were native-English speakers. Informed consent was obtained from all subjects in this and all subsequent experiments.

Materials and design

There were 31[1] experimental sentence-pairs that appeared in one of four conditions (see **Table 1**). Each sentence-pair began with a list sentence that introduced a character by proper name (half stereotypically male, half stereotypically female) and ended in a list of either two, three, four, or five nouns from the same taxonomic category. The nouns were all single words, common, and were selected to be roughly equal in typicality as judged by the first author and several research assistants. Furthermore, each of the last two nouns in the list was able to be distinguished from the other nouns by means of an adjective (e.g., saws can be distinguished from the other tools in the list using the adjective *cutting*). The list sentence was followed by a reference sentence that unambiguously referred to the final item in the list using an adjective and a categorical anaphor (e.g., *cutting tool*) that was the same for all conditions. The anaphor always occurred three words prior to the end of the reference sentence to ensure that there was enough time for the anaphor to be resolved by the time the sentence was fully read (i.e., by the time the probe-word task was presented).

[1]Experimenter error resulted in an odd number of experimental items in this experiment and in Experiment 1b.

In addition, there were 68 filler sentence-pairs that each included a list sentence with two to five nouns but that were not limited by the same restrictions on nouns in the experimental lists (e.g., the nouns could be proper or multiple words). As with the experimental sentence pairs, the filler reference sentences also included a categorical anaphor modified by an adjective; however, the referent of the anaphor was not always completely unambiguous. Moreover, the referent of the anaphor was not always the last item in the list. These two features of the fillers were expected to encourage subjects to put forth more effort in resolving anaphors across all trials.

Each experimental and filler sentence-pair also had a corresponding recognition probe and comprehension question. Following the reference sentence, subjects completed a probe recognition task in which they indicated whether a word on the screen had occurred in the previous sentence-pair. For experimental sentence-pairs, the probe word was always the final noun from the list, which required a "yes" response. To ensure an equal number of "yes" and "no" responses across the experiment, the majority of the filler probe tasks presented a word that did not occur in the sentence pair and therefore required a "no" response. Other fillers presented a probe word that was not the final noun from the list, requiring a "yes." Finally, a comprehension question was presented following the probe recognition task, half of which required a "yes" response and half of which required a "no" response. Comprehension questions frequently, but not always, focused on correct resolution of the anaphor (e.g., *Did Amelia use the saw?*).

Subjects saw each experimental sentence-pair in one of the four conditions along with all filler sentence-pairs. Four counterbalanced lists were created with the following constraints: one quarter of the list sentences had two nouns, one quarter had three nouns, one quarter had four nouns, and one quarter had five nouns. Furthermore, a second set of materials[2] was created that reversed the order of the final two nouns in the list, such that final noun in the first set of materials (e.g., *saw*) became the penultimate noun and the formerly penultimate noun (e.g., *hammer*) became the final noun. This also required a change in the disambiguating adjective in the reference sentence (e.g., *cutting* changed to *pounding*) such that the referent of the categorical anaphor was always the final noun. The manipulation of these factors resulted in a design that was 4 (nouns: 2, 3, 4, 5) × 2 (noun order: order 1, order 2).

Procedure

The experiment began with three practice blocks of five trials each, which were intended to familiarize the subject with the yes/no response keys, the probe recognition task, and the comprehension question, respectively. For all practice trials, feedback about the correctness of subjects' responses was provided.

Subjects then began the experimental session. Subjects were instructed to read the sentences as they normally would for comprehension and to respond to the probe words as quickly and accurately as possible. Each trial consisted of a list sentence, a reference sentence, a probe word, and a comprehension question. At the beginning of each trial, subjects were given the instruction "PRESS THE SPACEBAR WHEN READY" centered on a computer monitor. When they pressed the spacebar, the list sentence appeared left-justified in the middle of the screen. Subjects pressed the spacebar to indicate when they had finished reading the list sentence, which removed the list sentence from the screen and replaced it with the reference sentence. Subjects pressed the spacebar again to indicate when they had finished reading the reference sentence, which removed the reference sentence from the screen and replaced it with a probe word in all capital letters in the center of the screen. Subjects used the left and right arrow keys labeled "Y" and "N" for yes and no, respectively, to respond to the probe task. This removed the probe word and replaced it with a comprehension question in the center of the screen; no feedback about correctness was provided for probes or questions. Subjects again used the yes and no keys to respond to the comprehension question, which ended the trial.

The experimental session consisted of 99 trials (31 experimental and 68 fillers) in three blocks of 25 trials and one block of 24 trials. The order of the blocks, as well as the order of the trials within each block, was randomized with the restriction that the first sentence-pair of each block was always a filler sentence-pair, to allow time for the subjects to fully return their attention to the task after a mandatory 10 s break between blocks. Subjects were free to take breaks between trials. The experiment lasted approximately 30 min. The procedure for this and all subsequent experiments were approved by the University of Arkansas Institutional Review Board.

RESULTS

Data exclusion and general analytic considerations

A subject's data were excluded from further analysis if they met any of the following criteria: (1) they had more than 30% of reading times less than 1000 ms or greater than 7500 ms; (2) they had lower than 70% probe recognition accuracy; (3) they had more than 30% of probe reaction times less than 500 ms or greater than 2500 ms; (4) they had no non-outlying probe recognition observations in at least one condition; or (5) they had less than 70% comprehension question accuracy. Based on these criteria, the data from eight subjects were excluded from further analysis. Additionally, two experimental items were removed from further analysis due to counterbalancing errors. Therefore, the reported analyses include 85 subjects and 29 items.

For all experiments reported in this paper, subject and item condition means were analyzed separately; a subscript of 1 indicates that subjects were treated as a random-effects variable, whereas a subscript of 2 indicates that items were treated as a random-effects variable. For all significance tests, an alpha level of 0.05 was used. Predictions about monotonic increasing and decreasing trends were tested using polynomial contrasts. For all repeated-measures effects with more than one numerator *df*, Huynh-Feldt adjusted *p*-values are reported to correct for sphericity violations. Effect-size measures that are reported are based on the subject analyses, and all within-subject standard

[2]Probe length and frequency was similar for the two sets of materials (length: Set 1 $M = 6.5$ letters, $SD = 1.5$; Set 2 $M = 6.4$ letters, $SD = 1.7$; log frequency (Lund and Burgess, 1996; Balota et al., 2007): Set 1 $M = 7.4$, $SD = 2.4$; Set 2 $M = 7.2$, $SD = 2.9$).

errors in figures and tables were computed using the method recommended by Loftus and Masson (1994).

Comprehension

In general, the number of nouns did not affect comprehension (see **Table 2** for comprehension results across all experiments). The linear trend was non-significant, $F_{1(1,\ 84)} = 0.34$, $p = 0.56$, $F_{2(1,\ 56)} = 0.07$, $p = 0.79$, with no significant higher-order trends. (See Appendix C in Supplementary Materials for the results of the noun-order factor in this experiment and Experiment 1B.)

Probe accuracy

Figure 1 presents mean probe word accuracy and reaction times along with mean reference-sentence reading times as a function of the number of referents. In general, accuracy decreased as the number of nouns in the list sentence increased. The linear trend was significant, $F_{1(1,84)} = 9.63$, $p = 0.003$, $F_{2(1,28)} = 9.99$, $p = 0.004$, $\eta_p^2 = 0.10$, with no significant higher-order trends.

Probe reaction times (RT)

Only correct probes were analyzed. Outliers were first classified as RTs that were less than 400 ms or greater than 3000 ms. Remaining reaction times more extreme than 1.5 times the interquartile range above the 75th percentile or below the 25th percentile for each subject were classified as outliers (Tukey, 1977), resulting in 8.6% of the data being excluded from further analyses. In general, reaction time increased as the number of nouns in the list sentence increased (see **Figure 1**). The linear trend was significant, $F_{1(1,\ 84)} = 8.03$, $p = 0.006$, $F_{2(1,28)} = 6.68$, $p = 0.02$, $\eta_p^2 = 0.09$, with no significant higher-order trends.

Table 2 | Mean comprehension for all experiments (with standard errors of the mean).

	Two-noun	Three-noun	Four-noun	Five-noun
Experiment 1A	0.88 (0.014)	0.86 (0.014)	0.87 (0.014)	0.87 (0.014)
Experiment 1B	0.89 (0.014)	0.87 (0.015)	0.83 (0.017)	0.86 (0.016)
Experiment 2A				
Referent	0.95 (0.012)	–	–	0.92 (0.015)
Distractor	0.93 (0.012)	–	–	0.91 (0.014)
Experiment 2B

Distractor	0.92 (0.015)	–	–	0.91 (0.015)
Experiment 3				
Anaphor	0.88 (0.019)	–	–	0.90 (0.014)
No anaphor	0.96 (0.011)	–	–	0.91 (0.015)

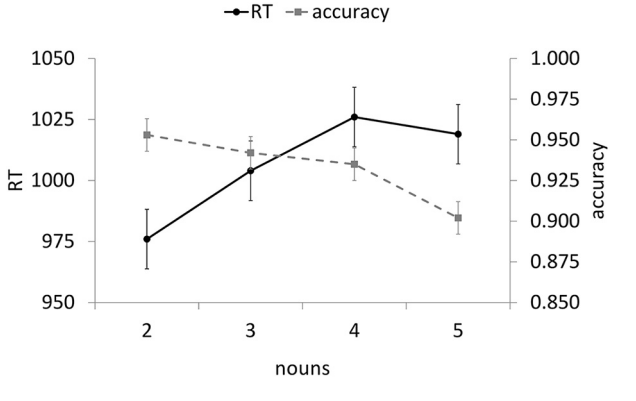

FIGURE 1 | Experiment 1A antecedent probe reaction times and accuracies by noun condition (error bars indicate SE of the mean).

Reference-sentence reading times

Reference-sentence reading times were transformed to per-character reading times by dividing the full-sentence reading time by the number of characters in the sentence, not counting spaces and punctuation (see **Table 3**). Outliers were first identified as trials with less than 15 ms/char or more than 150 ms/char. Outliers among the remaining reading times were then identified within each subject based on Tukey's (1977) criteria. 7.6% of the trials were excluded from further analysis. In general, reading time on the reference sentence *decreased* as the number of nouns in the list sentence increased. The linear trend was significant, $F_{1(1,84)} = 19.55$, $p < 0.001$, $F_{2(1,30)} = 10.87$, $p = 0.003$, $\eta_p^2 = 0.19$, with no significant higher-order trends.

DISCUSSION

The results of the probe word analyses were consistent with the fan-effect hypothesis and generally favor models of anaphor resolution that posit a parallel-search mechanism in retrieval of the correct referent. As predicted, the presence of distractors interfered with the probe recognition task. Increasing the number of distractors in the list sentence decreased recognition accuracy and increased reaction times for referents, which suggests that the activation level of referents decreased as the number of distractors increased. The existing literature has shown via a variety of measures and paradigms that the presence of one distractor interferes with anaphor resolution (e.g., Corbett and Chang, 1983; Corbett, 1984; Mason, 1997; Levine et al., 2000; Wiley et al., 2001; Klin et al., 2004, 2006; Ditman et al., 2007; Levine and Hagaman, 2008). The present results extend this finding by demonstrating a cumulative effect of distractors.

The effect of additional nouns on the subsequent reference-sentence reading times, however, was unexpected. It was predicted, based on previous research (e.g., Corbett, 1984), that anaphor resolution would be slowed by the presence of distractors, resulting in longer full-sentence reading times as the number of distractors increased. However, the results were exactly the opposite, indicating that the subjects actually read the reference sentences more quickly as the number of distractors

Table 3 | Experiment 1A mean per-character reading times in ms (with standard errors of the mean).

	List sentence	Reference sentence
Two-noun	73.2 (0.9)	58.3 (0.7)
Three-noun	74.0 (0.9)	57.5 (0.7)
Four-noun	76.8 (0.9)	55.4 (0.7)
Five-noun	77.4 (0.9)	53.9 (0.7)

increased. Assuming this is not a Type I error, one plausible explanation for this result is that subjects adopted a strategy of speeding through the reference sentence to reduce the time between the referents and the probe recognition task when there were more distractors. A similar finding was reported by Van Dyke and McElree (2006), who had subjects reading sentences of variable complexity while holding or not holding a memory load and found that reading was faster for more-complex sentences with a memory load than without one. This speeded-reading strategy as a potential alternative explanation for the fan effect was explored in further detail in Experiments 2A and 2B; we defer discussion until the presentation of those experiments.

EXPERIMENT 1B

Experiment 1A established that referents were less active following anaphor resolution when there were more potential referents available in the discourse. Experiment 1B replicated Experiment 1A but used distractors as the probe words to test the effect of multiple distractors on the activation level of a distractor. As in Experiment 1A, it was hypothesized that additional distractors would decrease probe accuracy and slow probe recognition times. If anaphors act like any other cue to memory, the activation of the referent and distractors should be split (Kintsch, 1988; Myers and O'Brien, 1998; Lewis and Vasishth, 2005), resulting in less activation to go around (i.e., a fan effect) as there are more related concepts in the list sentence. Because the anaphor contains two cues (i.e., adjective plus noun) to retrieve the referent but only one (i.e., the noun) that matches the distractors, referents should become more active and experience less interference (i.e., a reduced fan effect) than distractors following anaphor resolution. Moreover, later items may overwrite or displace earlier items, leading to degraded representations of the referent and especially earlier-occurring distractors (Nairne, 1990; Lewis, 1996). We examine these predictions in a cross-experiment comparison after presenting the results of Experiment 1B, and then examine them more directly (i.e., in a completely within-subjects design) in Experiments 2A and 2B.

METHOD

Subjects

Seventy-eight students enrolled in a general psychology course at the University of Arkansas participated in the experiment to partially fulfill a research requirement. All subjects were native-English speakers.

Materials, design, and procedure

Experiment 1B was identical to Experiment 1A except that the probe words in the probe recognition task for experimental trials were distractors (i.e., the penultimate word in the list).

RESULTS

Data exclusion and general analytic considerations

Based on the data exclusion criteria detailed in Experiment 1A, the data from eight subjects were excluded from further analysis. Sixteen more subjects were removed from further analysis for a systematic misunderstanding of the instructions. These subjects consistently responded "no" to distractors on the probe task when they should have been responding "yes." This pattern of responding suggests that these subjects were correctly identifying the correct referent of the anaphor, but misunderstanding that this identification was unrelated to the probe task. Therefore, the comprehension accuracy, probe accuracy, and reading time analyses included 54 subjects and 31 items.

Comprehension

In general, comprehension (see **Table 2**) decreased as the number of nouns increased. The linear trend was significant in the subject analysis, $F_{1(1,\ 53)} = 5.36$, $p = 0.025$, $\eta_p^2 = 0.09$, but non-significant in the items analysis, $F_{2(1,\ 60)} = 2.91$, $p = 0.093$, with no significant higher-order trends.

Probe accuracy

Figure 2 presents mean probe word accuracy and reaction times along with mean reference-sentence reading times as a function of the number of referents. In general, accuracy decreased as the number of nouns in the list sentence increased. The linear trend was significant, $F_{1(1,\ 53)} = 39.08$, $p < 0.001$, $F_{2(1,\ 30)} = 45.28$, $p < 0.001$, $\eta_p^2 = 0.42$, with no significant higher-order trends.

Probe reaction times

Based on outlier exclusion criteria, 9.6% of the data were excluded from further analyses. In general, reaction time increased as the number of nouns in the list sentence increased (see **Figure 2**). The linear trend was significant, $F_{1(1,\ 53)} = 16.79$, $p < 0.001$, $F_{2(1,\ 30)} = 6.59$, $p = 0.01$, $\eta_p^2 = 0.24$. There was also an unexpected cubic trend, $F_{1(1,\ 53)} = 12.81$, $p = 0.001$, $F_{2(1,\ 30)} = 3.13$, $p = 0.09$. There was no theoretical expectation of this effect, and it did not appear in Experiment 1A, so we did not try to interpret it.

Reference-sentence reading times

Based on outlier exclusion criteria, 5.2% of the data were excluded from further analyses. In general, as in Experiment 1A, reading time (see **Table 4**) on the reference sentence decreased as

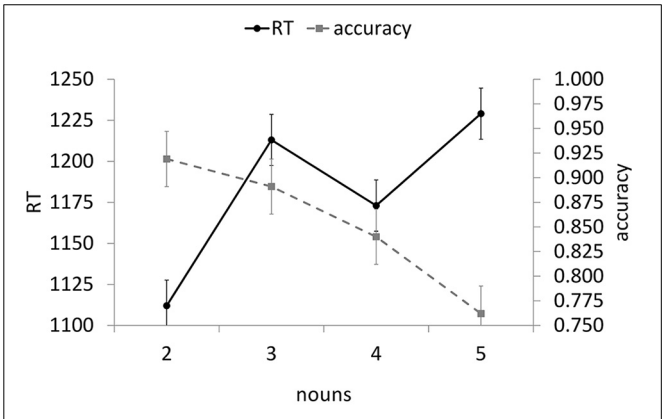

FIGURE 2 | Experiment 1B distractor probe reactions times and accuracies by noun condition (error bars indicate SE of the mean).

Table 4 | Experiment 1B mean per-character reading times in ms (with standard errors of the mean).

	List sentence	Reference sentence
Two-noun	77.0 (1.11)	60.9 (0.88)
Three-noun	80.3 (1.11)	59.8 (0.88)
Four-noun	80.3 (1.11)	58.3 (0.88)
Five-noun	82.5 (1.11)	57.4 (0.88)

the number of nouns in the list sentence increased. The linear trend was significant, $F_{1(1,53)} = 11.74$, $p = 0.001$, $F_{2(1,\ 30)} = 11.52$, $p = 0.002$, $\eta_p^2 = 0.18$, with no significant higher-order trends.

DISCUSSION

The probe word results were again consistent with the fan-effect hypothesis. As predicted, the presence of distractors interfered with the probe recognition task. Increasing the number of referents in the list sentence decreased recognition accuracy and increased reaction times for distractors similar to the effect found for referents in Experiment 1A. This result extends the findings of Experiment 1A to show that distractors also decrease in activation as the number of referents increases.

As in Experiment 1A, the reading-time results did not support the fan-effect hypotheses. Subjects again read the reference sentence more quickly as the number of distractors increased. This replication provides additional confidence that the unexpected results were not occurring due to chance. This issue was explored in further detail in Experiments 2A and 2B.

EXPERIMENTS 1A AND 1B COMBINED ANALYSIS

As noted in the introduction to Experiment 1B, the effect of fan size should be different for referents (Experiment 1A) and distractors (Experiment 1B). To compare the magnitude of the effect of the number of nouns on referents and distractors, an additional analysis was conducted for the probe reaction times from Experiments 1A and 1B. Probe reaction times for each subject in both experiments were first linearly regressed on the number of nouns (cf. Lorch and Myers, 1990), and the slopes were then examined in an independent-samples t-test with experiment (i.e., probe: referent vs. distractor) as a between-subjects variable. This analysis revealed a non-significant effect of probe in the expected direction, with a substantially smaller mean slope among subjects responding to referents in Experiment 1A ($M_{\text{slope}} = 15.2$ ms/noun, $SE = 5.4$) than among subjects responding to distractors in Experiment 1B ($M_{\text{slope}} = 31.3$ ms/noun, $SE = 7.6$), $t_{(137)} = 1.77$, $p = 0.08$, $d = 0.30$.

A similar analysis performed on the accuracy data revealed a large and significant effect of probe, with a substantially smaller mean slope among subjects responding to referents in Experiment 1A ($M_{\text{slope}} = -0.014$ accuracy/noun, $SE = 0.0046$) than among subjects responding to distractors in Experiment 1B ($M_{\text{slope}} = -0.052$ accuracy/noun, $SE = 0.0084$), $t_{(137)} = 4.33$, $p < 0.001$, $d = 0.74$. Although referents likely gained an advantage in both accuracy and speed of responding due to having appeared more recently than distractors, these analyses focused on the linear trends in which distance from the probe were equal. Therefore, these results provide evidence that the interference effect is greater for distractors than referents; this effect was tested more directly in Experiments 2A and 2B.

EXPERIMENT 2A

The procedure for Experiment 2A was modified from that in Experiments 1A and 1B such that subjects read the reference sentence one word at a time. This allowed for a more detailed analysis of the reading times, which was necessary to help understand the unexpected reference-sentence reading time results of Experiments 1A and 1B. The prediction that additional distractors should slow reading of the reference sentence was based on the hypothesis that multiple distractors would interfere with anaphor resolution. This means that the expected slowdown should occur specifically on the anaphor or immediately after the anaphor during spillover processing. According to this hypothesis, it was expected that there should be no difference in reading times on the reference-sentence until subjects reach the anaphor and post-anaphor regions, where they were expected to read more slowly as the number of distractors increased. However, if the results of Experiments 1A and 1B are reliable, then there should be longer reading times when there are more distractors at some point in the reference sentence prior to the anaphor.

In addition, Experiments 1A and 1B demonstrated that the presence of multiple distractors made recognition of both referents and distractors more difficult, as indexed by both reaction time and accuracy. Experiments 2A and 2B were designed to manipulate the probe word within subjects to address potential concerns about comparing results across experiments. Thus, in these experiments, probe word (referent vs. distractor) and number of distractors (two vs. five) were manipulated within subjects. The fan-effect hypothesis predicts that additional distractors would slow recognition and decrease accuracy for both referents and distractors. Moreover, to the extent that anaphor resolution focuses activation on the referent, thereby minimizing interference, the degree of interference should be greater for distractors than for referents.

METHOD

Subjects

Seventy-five students enrolled in a general psychology course at the University of Arkansas participated in the experiment to partially fulfill a research requirement. All subjects were native-English speakers.

Materials and design

Thirty of the experimental materials from Experiment 1 were used and appeared in only the two- and five-noun list conditions. This also required some modification of the list length in the filler sentences to maintain an equal distribution of list lengths across the entire experiment. In addition, the probe words were manipulated within subjects, such that each subject saw an equal number of referent and distractor probes following experimental items.

Subjects saw each experimental sentence pair in one of the four conditions along with all filler sentence pairs. Four

counterbalanced lists were created with the following constraints: approximately (i.e., 7 or 8 items) one quarter of the list sentences had two nouns followed by a referent probe, approximately one quarter had two nouns followed by a distractor probe, approximately one quarter had five nouns followed by a referent probe, and approximately one quarter had five nouns followed by a distractor probe. Because counterbalancing order did not have any important effects in Experiments 1A and 1B, order was no longer manipulated, resulting in a 2 (nouns: 2, 5) × 2 (probe word: referent, distractor) completely within-subjects design.

Procedure

The experiment was conducted using Linger (Rohde, 2003) to present the materials using a moving window (Just et al., 1982). Before starting the experiment, subjects completed three practice trials to familiarize themselves with the procedure. Each trial began with two rows of dashes, centered on the left-hand side of the screen, with each dash replacing a character or space in the sentences. Subjects pressed the spacebar to initially present the list sentence in its entirety. When they finished reading the list sentence, subjects pressed the spacebar again which replaced the list sentence with dashes and revealed the first word of the reference sentence. Subjects continued to press the spacebar to advance from one word to the next, with each press replacing the previous word with dashes and revealing the next word in the sentence. Pressing the spacebar after the final word of the reference sentence removed all of the dashes from the screen and presented a probe word in all capital letters in the center of the screen. Subjects responded to the probe word using the F key for yes and the J key for no. The response removed the probe word from the screen and replaced it with a comprehension question. Subjects again responded using the F and J keys, which advanced the screen to the next trial.

The experimental session consisted of 98 trials (30 experimental and 68 fillers) in two blocks of 49 trials each with the order of the trials completely randomized. Subjects were instructed to read the sentences as they normally would for comprehension and to respond to the probe words as quickly and accurately as possible. Subjects were free to take breaks between trials. The experiment lasted approximately 30 min.

RESULTS

Data exclusion and general analytic considerations

Based on the data exclusion criteria, the data from six subjects were excluded from further analysis. Therefore, the reported analyses included 69 subjects and 30 items.

Comprehension

In general, comprehension (see **Table 2**) decreased as the number of nouns increased. A 2 (nouns: 2, 5) × 2 (noun probed: referent, distractor) repeated-measures ANOVA revealed a main effect of nouns that was non-significant in the subject analysis, $F_{1(1,\ 68)} = 3.38$, $p = 0.07$, $\eta_p^2 = 0.05$, but significant in the items analysis, $F_{2(1,\ 29)} = 4.82$, $p = 0.04$. The main effect of noun probed was non-significant, $F_{1(1,\ 68)} = 2.62$, $p = 0.11$, $F_{2(1,\ 29)} = 1.07$, $p = 0.31$, and the interaction between number of nouns and noun probed was also non-significant, $F_{1(1,\ 68)} = 0.01$, $p = 0.92$, $F_{2(1,\ 29)} = 0.14$, $p = 0.71$.

Probe accuracy

Table 5 presents mean accuracy and probe reaction times as a function of the number of nouns and the noun probed. In general, accuracy was higher for referents than for distractors and when there were two nouns in the list sentence than when there were five. A 2 (nouns: 2, 5) × 2 (noun probed: referent, distractor) repeated-measures ANOVA revealed a significant main effect of the number of nouns, $F_{1(1,\ 68)} = 28.34$, $p < 0.001$, $F_{2(1,\ 29)} = 25.46$, $p < 0.001$, $\eta_p^2 = 0.29$, as well as a significant main effect of the noun probed, $F_{1(1,\ 68)} = 17.62$, $p < 0.001$, $F_{2(1,\ 29)} = 28.98$, $p < 0.001$, $\eta_p^2 = 0.21$. There was also a significant interaction between the number of nouns in the sentence and the noun being probed, $F_{1(1,\ 68)} = 4.51$, $p = 0.04$, $F_{2(1,\ 29)} = 4.37$, $p = 0.05$, $\eta_p^2 = 0.06$, with a greater 2- vs. 5-noun difference for distractors than for referents, replicating the effect seen in the between-experiments comparison presented above. Planned pairwise comparisons revealed a significant effect of the number of nouns for both the referent probes, $t_{1(68)} = 3.04$, $p = 0.003$, $t_{2(29)} = 3.69$, $p = 0.001$, $d = 0.37$, and the distractor probes, $t_{1(68)} = 4.53$, $p < 0.001$, $t_{2(29)} = 4.17$, $p < 0.001$, $d = 0.55$.

Probe reaction times

Based on outlier exclusion criteria, 7.8% of the data were excluded from further analyses. Like the accuracy results, reaction time tended to be shorter for referents than for distractors and when there were two nouns in the list sentence than when there were five. A 2 (nouns: 2, 5) × 2 (noun probed: referent, distractor) repeated-measures ANOVA revealed a significant main effect of the number of nouns, $F_{1(1,\ 68)} = 4.20$, $p = 0.04$, $F_{2(1,\ 29)} = 5.99$, $p = 0.02$, $\eta_p^2 = 0.06$, as well as a significant main effect of the noun probed, $F_{1(1,\ 68)} = 12.73$, $p = 0.001$, $F_{2(1,\ 29)} = 19.18$, $p < 0.001$, $\eta_p^2 = 0.16$. Despite the pattern of means replicating the cross-experiment interaction seen in Experiments 1A and 1B, there was not a significant interaction between the number of nouns in the sentence and the noun being probed, $F_{1(1,68)} = 0.28$, $p = 0.60$, $F_{2(1,\ 29)} = 2.64$, $p = 0.12$. Planned pairwise comparisons revealed a non-significant 46 ms effect of the number of nouns for the antecedents, $t_{1(68)} = 1.35$, $p = 0.18$, $t_{2(29)} = 0.80$, $p = 0.43$, but the 73 ms effect of the number of nouns

Table 5 | Experiments 2A and 2B mean probe word responses (with standard errors of the mean).

	Experiment 2A			
	Accuracy		Reaction time (ms)	
	Referent	Distractor	Referent	Distractor
Two-noun	0.97 (0.013)	0.92 (0.013)	1553 (25.1)	1632 (25.1)
Five-noun	0.93 (0.013)	0.83 (0.013)	1599 (25.1)	1705 (25.1)
	Experiment 2B			
	Accuracy		Reaction time (ms)	
	Referent	Distractor	Referent	Distractor
Two-noun	0.95 (0.017)	0.92 (0.019)	1151 (21.5)	1273 (21.5)
Five-noun	0.94 (0.013)	0.72 (0.022)	1245 (21.5)	1403 (21.5)

for distractor probes, though not significant by subjects, $t_{1(68)} = 1.73$, $p = 0.09$, was significant by items, $t_{2(29)} = 3.00$, $p = 0.005$, $d = 0.21$. For the sake of comparison with Experiments 1A and 1B, in Experiment 2A the slope of the number of nouns among the referents was 15.4 ms/noun, whereas the slope of the number of nouns among the distractors was 24.2 ms/noun. These values were 15.2 and 31.3, respectively, in Experiments 1A and 1B.

Reference-sentence reading times

Outliers were first identified as words read for less than 150 ms or more than 700 ms; different criteria were used in this experiment to try to approximate in a per-word measure the per-character measures used in the previous experiments. Outliers among the remaining reading times were then identified within each subject based on Tukey's (1977) criteria. This resulted in 8.1% of the trials being excluded from further analysis[3].

The individual-word reading times were combined into three regions of three words each. The pre-anaphor region consisted of the three words prior to the anaphor; the anaphor region consisted of the three-word noun phrase involving the determiner, adjective, and anaphor (e.g., *the cutting tool*); and the post-anaphor region consisted of the three words following the anaphor. Although some items had more than three words prior to the anaphor noun phrase, the analysis was restricted to this point because there was a dramatic drop in the number of observations starting four words prior to the anaphor region. The post-anaphor region was always the final three words of the anaphor sentence. Thus, each region consisted of three words, making their reading times roughly comparable.

In general, reading time on the reference sentence decreased as the number of nouns in the list sentence increased (see **Figure 3**); this effect occurred most strongly in the pre-anaphor region. A 2 (nouns: 2, 5) × 3 (region: pre-anaphor, anaphor, post-anaphor) repeated measures ANOVA revealed a significant main effect of the number of nouns only in the items analysis, $F_{1(2,\ 68)} = 2.68$, $p = 0.11$, $F_{2(1,\ 29)} = 4.66$, $p = 0.04$, $\eta_p^2 = 0.04$. There was also a significant main effect of region, $F_{1(2,\ 136)} = 29.9$, $p < 0.001$, $F_{2(1,\ 58)} = 16.8$, $p < 0.001$, $\eta_p^2 = 0.31$, but the interaction between the number of nouns and region was non-significant, $F_{1(2,\ 136)} = 0.65$, $p = 0.53$, $F_{2(1,\ 58)} = 1.03$, $p = 0.36$. Planned pairwise comparisons revealed that subjects read the pre-anaphor region significantly faster in the five noun condition compared to the two noun condition ($p = 0.02$ by subjects, $p = 0.05$ by items), but this effect was non-significant in the anaphor region (p =0.26 by subjects, $p = 0.16$ by items) and the post-anaphor region ($p = 0.51$ by subjects, $p = 0.21$ by items).

DISCUSSION

As predicted by the fan-effect hypothesis, and consistent with Experiments 1A and 1B, probe word accuracy was higher and responses were made faster in the two-noun condition than in the five-noun condition for both referents and distractors. Moreover, the cross-experiment interaction of number of nouns and probe type was replicated; the fan effect is larger for distractors. The reading time results replicated those from Experiments 1A and 1B: subjects read the reference sentence faster in the five-noun condition than in the two-noun condition. However, measuring reading time per-word enabled a more detailed analysis of the reference-sentence reading times and revealed that the faster reading primarily occurred in the pre-anaphor region. Because this region was identical across conditions and made no reference to the list sentence, there is no theoretical reason to expect this difference based on anaphor resolution processes. Instead, these results support the speeded-reading explanation suggested in the discussion of Experiment 1A, that subjects may have adopted a particular strategy in order to mitigate the increased difficulty of the probe-word task in the five-noun condition by reaching the probe word task and comprehension questions more quickly. Furthermore, per-character reading times on the list sentence (see Appendix B in Supplementary Material) increased as the number of nouns increased, suggesting that the speeded-reading strategy was adopted only on the reference sentence after subjects became aware of the increased difficulty imposed by the longer lists.

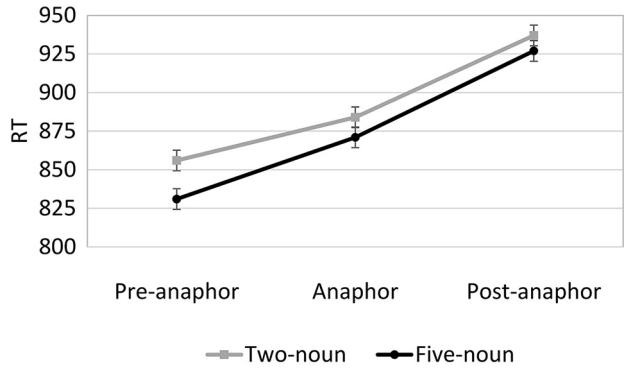

FIGURE 3 | Experiment 2A mean anaphor sentence reading times per region (error bars indicate SE of the mean).

EXPERIMENT 2B

Because subjects appeared to be adjusting their reading speed to accommodate the difficulty of representing multiple referents, it was important to assess whether the probe word results were dependent on this apparent strategy. Experiment 2B was thus a replication of Experiment 2A using a fixed-rate presentation of the passages. By controlling the pace of reading, any effects found on the probe recognition task can be assumed to reflect processes that occurred independent of subjects' variable reading speed. Holding reading-rate constant was not expected to change the probe-word results, so it was expected that responses to both referents and distractors would be faster and more accurate when there were two referents in the list sentence than when there were five referents. Moreover, this experiment provided one more opportunity to examine the prediction that the effect of fan would be greater among distractors than among referents. In the accuracy data, the fan effect has been reliably much stronger for distractors than it has been among referents. In the reaction-time data, between Experiments 1A and 1B, this effect was significant

[3]The pattern of results remained similar using a less-strict cutoff of 1500 ms/word.

only in a one-tailed test, and in Experiment 2A, the same pattern emerged but it was not reliable.

METHOD

Subjects

Sixty-six students enrolled in a general psychology course at the University of Arkansas participated in the experiment to partially fulfill a research requirement. All subjects were native-English speakers.

Materials, design, and procedure

The materials, design, and procedure were identical to Experiment 2A except that the materials were presented at a fixed pace of 450 ms per word[4].

RESULTS

Data exclusion and general analytic considerations

Based on the data exclusion criteria, the data from 10 subjects were excluded from further analysis. Four more subjects were removed from further analysis for a systematic misunderstanding of the instructions. Therefore, the analyses included 50 subjects and 30 items.

Comprehension

In general, comprehension (see **Table 2**) decreased as the number of nouns increased. A 2 (nouns: 2, 5) × 2 (noun probed: referent, distractor) repeated-measures ANOVA revealed a main effect of nouns that was significant in the subject analysis, $F_{1(1,\ 49)} = 4.59$, $p = 0.04$, $\eta_p^2 = 0.09$, but non-significant in the items analysis, $F_{2(1,\ 29)} = 2.53$, $p = 0.12$. The main effect of noun probed was non-significant, $F_{1(1,\ 49)} = 0.20$, $p = 0.66$, $F_{2(1,\ 29)} = 0.23$, $p = 0.63$, and the interaction between number of nouns and noun probed was also non-significant, $F_{1(1,\ 49)} = 1.50$, $p = 0.23$, $F_{2(1,\ 29)} = 1.31$, $p = 0.26$.

Probe accuracy

Table 5 presents mean accuracy and probe reaction times as a function of the number of nouns and the noun probed. In general, accuracy was higher for referents than for distractors and when there were two nouns in the list sentence than when there were five, once again replicating the pattern seen in Experiments 1A, 1B, and 2A. A 2 (nouns: 2, 5) × 2 (noun probed: referent, distractor) repeated-measures ANOVA revealed a significant main effect of the number of nouns, $F_{1(1,\ 49)} = 53.9$, $p < 0.001$, $F_{2(1,\ 29)} = 27.9$, $p < 0.001$, $\eta_p^2 = 0.52$, as well as a significant main effect of the noun probed, $F_{1(1,\ 49)} = 53.0$, $p < 0.001$, $F_{2(1,\ 29)} = 31.8$, $p < 0.001$, $\eta_p^2 = 0.52$. Additionally, there was a significant interaction between the number of nouns in the sentence and the noun being probed, $F_{1(1,\ 49)} = 29.2$, $p < 0.001$, $F_{2(1,\ 29)} = 23.1$, $p < 0.001$, $\eta_p^2 = 0.37$, with a greater 2- vs. 5-noun difference for distractors than for referents, the third time this pattern has been replicated.

[4]Due to limitations of the Linger program, words were presented at a fixed rate instead of using a variable rate dependent on the length of each word (cf. Gernsbacher, 1989).

Probe reaction times

Based on outlier exclusion criteria, 8.7% of the data were excluded from further analyses. Like the accuracy results, reaction time tended to be shorter for referents than for distractors and when there were two nouns in the list sentence than when there were five. A 2 (nouns: 2, 5) × 2 (noun probed: referent, distractor) repeated-measures ANOVA showed that there was a significant main effect of the number of nouns, $F_{1(1,\ 49)} = 25.8$, $p < 0.001$, $F_{2(1,\ 29)} = 19.4$, $p < 0.001$, $\eta_p^2 = 0.35$, as well as a significant main effect of the noun probed, $F_{1(1,\ 49)} = 44.1$, $p < 0.001$, $F_{2(1,\ 29)} = 31.9$, $p < 0.001$, $\eta_p^2 = 0.47$. Once again, the pattern of means replicated the cross-experiment pattern seen in Experiments 1A and 1B as well as that seen in Experiment 2A, with the effect of number of nouns being larger for distractors than for referents. Despite this, there was not a significant interaction between the number of nouns in the sentence and the noun being probed, $F_{1(1,\ 49)} = 0.70$, $p = 0.41$, $F_{2(1,\ 29)} = 2.03$, $p = 0.17$. The effect of the number of nouns was significant among the referents, $t_{1(49)} = 2.86$, $p = 0.006$, $t_{2(29)} = 2.54$, $p = 0.02$, as well as among the distractors, $t_{1(49)} = 4.55$, $p < 0.001$, $t_{2(29)} = 4.87$, $p < 0.001$; this effect was numerically smaller for referents (94 ms, $d = 0.40$) than for distractors (130 ms, $d = 0.64$). The slopes corresponding to these effects, 31.2 ms/noun for referents and 43.2 ms/noun for the distractors, were substantially larger than the respective slopes seen in the previous experiments, possibly due to the change in the presentation of the passages to experimenter-paced.

DISCUSSION

The results confirmed the predictions of the fan-effect hypothesis, and the probe-word results were conceptually identical to Experiment 2A. Although subjects in the previous experiments seemed to be adopting a special strategy of reading the reference sentence more quickly when there were more distractors, the results of Experiment 2B indicate that this strategy was not necessary for the emergence of the probe-word results we had previously observed because subjects did not have the opportunity to employ it. The replication of the finding that the activation level of nouns decreases as the number of distractors increases therefore appears to be the result of a diffusion of activation to all potential referents.

However, this conclusion relies on the assumption that subjects were resolving the anaphor and that the anaphor processing affected the activation level of the referents. There is some evidence, however, that anaphor resolution may not always occur during reading (Greene et al., 1992; Levine et al., 2000; Klin et al., 2004, 2006; Love and McKoon, 2011), making it possible that the present results could be occurring independent of anaphor resolution. The effect of nouns may have been caused by the increasing memory demands incurred as the number of referents increased regardless of whether the subjects attempted to resolve the anaphors. It is possible that as the amount of information in the subjects' mental representations increased, the probability of the correct referent being activated even by the probe word itself, independent of anaphor resolution processes, decreased, resulting in slower reaction times as the number of referents.

EXPERIMENT 3

Experiment 3 was designed to address the possibility that anaphors were not being resolved in the prior experiments. To do so, the reference sentence was modified such that it contained an anaphor or not (see **Table 1**), a manipulation that has been used many times in the anaphor resolution literature (e.g., Dell et al., 1983; Levine et al., 2000). As in Experiments 2A and 2B, there were either two nouns (i.e., a referent and one distractor) or five nouns (i.e., a referent and four distractors) in the list sentence that preceded the reference sentence. The referent was used as the probe word to provide an index of the activation of this concept at the end of the anaphor or no-anaphor sentence. According to the fan-effect hypothesis, it is activation from the anaphor as a memory cue that is divided among the referent and the distractors that is the source of the effect of the number of nouns. Thus, when there is an anaphor, the fan-effect hypothesis predicts an effect of the number of nouns like that seen in the previous experiments. Whatever pattern emerges for the effect of the number of nouns in the anaphor condition, because anaphor resolution involves reactivation of the correct referent (e.g., Dell et al., 1983), there should be an overall accuracy and reaction time advantage in the anaphor over the no-anaphor control condition.

METHOD

Subjects

Seventy students enrolled in a general psychology course at the University of Arkansas participated in the experiment to partially fulfill a research requirement. All subjects were native-English speakers.

Materials and design

Experiment 3 used the same set of materials as Experiments 2A and 2B with the exception that the reference sentence was manipulated (see **Table 1**) such that it included an anaphor (i.e., Anaphor condition) or not (i.e., No Anaphor condition), while equating for length (i.e., the mean length for both the anaphor and no anaphor conditions was 61.5 characters). Finally, the probe words were limited to referents only, as in Experiment 1A. The manipulation of these factors resulted in a 2 (nouns: 2, 5) × 2 (reference: anaphor, no anaphor) completely within-subjects design.

Procedure

The procedure of Experiment 3 was identical to that of Experiments 1A and 1B, except that it included only 98 trials (30 experimental and 68 fillers), as in Experiments 2A and 2B.

RESULTS

Data exclusion and general analytic considerations

Based on outlier identification and comprehension and probe accuracy, the data from 5 subjects were excluded from further analysis. Therefore, the reported analyses included 65 subjects and 30 items.

Comprehension

In general, comprehension (see **Table 2**) decreased as the number of nouns increased and accuracy was greater in the anaphor condition than in the no anaphor condition. A 2 (nouns: 2, 5) × 2 (reference: anaphor, no anaphor) repeated measures ANOVA revealed a non-significant main effect of nouns, $F_{1(1,\ 64)} = 0.62$, $p = 0.44$, $F_{2(1,\ 30)} = 0.90$, $p = 0.35$, and a significant main effect of reference, $F_{1(1,\ 64)} = 9.28$, $p = 0.003$, $F_{2(1,\ 30)} = 6.15$, $p = 0.019$, $\eta_p^2 = 0.13$. In addition, there was a significant interaction between the number of nouns and reference, $F_{1(1,\ 64)} = 4.83$, $p = 0.032$, $F_{2(1,\ 30)} = 5.23$, $p = 0.029$, $\eta_p^2 = 0.07$, with a 7.3% accuracy advantage for the 2-noun condition compared to the 5-noun condition in the anaphor condition but only a 1.3% accuracy advantage in the no anaphor condition. However, the comprehension questions differed between the anaphor and no anaphor conditions, making this the likely cause of the observed effect.

Probe accuracy

Table 6 presents mean probe word accuracy and reaction times along with mean reference-sentence reading times as a function of the number of referents and whether the reference sentence contained an anaphor. In general, subjects responded more accurately in the anaphor condition than in the no anaphor condition and when there were two nouns in the list sentence than when there were five nouns. A 2 (nouns: 2, 5) × 2 (reference: anaphor, no anaphor) repeated measures ANOVA revealed a significant main effect of the number of nouns, $F_{1(1,\ 64)} = 8.43$, $p = 0.005$, $F_{2(1,\ 29)} = 14.14$, $p = 0.001$, $\eta_p^2 = 0.12$; however, the simple effect of the number of nouns for the anaphor condition was not significant, $t_{1(64)} = 1.11$, $p = 0.27$, $t_{2(29)} = 1.21$, $p = 0.24$. There was also a significant main effect of reference, $F_{1(1,\ 64)} = 7.53$, $p = 0.008$, $F_{2(1,\ 29)} = 6.56$, $p = 0.02$, $\eta_p^2 = 0.11$, but the interaction between the number of nouns and reference was non-significant, $F_{1(1,\ 64)} = 2.70$, $p = 0.11$, $F_{2(1,\ 29)} = 2.84$, $p = 0.10$.

Probe reaction times

Based on outlier exclusion criteria, 7.5% of the data were excluded from further analyses. Reaction times (see **Table 6**) tended to be faster in the anaphor condition than in the no anaphor condition and when there were two nouns in the list sentence than when there were five nouns. A 2 (nouns: 2, 5) × 2 (reference: anaphor, no anaphor) repeated measures ANOVA revealed that the main effect of nouns was non-significant, $F_{1(1,\ 64)} = 1.26$,

Table 6 | Experiment 3 mean probe word responses and per-character reading times (with standard errors of the mean).

	Anaphor condition			
	Probe word responses		Per-character reading time	
	Accuracy	Reaction time	List sentence	Reference sentence
Two-noun	0.96 (0.01)	976 (9.9)	70.7 (1.32)	55.7 (0.64)
Five-noun	0.94 (0.01)	997 (9.9)	73.7 (1.32)	54.0 (0.64)
	No anaphor condition			
	Probe word responses		Per-character reading time	
	Accuracy	Reaction time	List sentence	Reference sentence
Two-noun	0.95 (0.01)	1009 (9.9)	–	51.2 (0.64)
Five-noun	0.89 (0.01)	1013 (9.9)	–	50.1 (0.64)

$p = 0.27$, $F_{2(1, 29)} = 0.24$, $p = 0.63$. Because of the prediction of the fan-effect hypothesis, the effect of the number of nouns was examined for the anaphor condition. The noun-effect was 23 ms but was also not significant, $t_{1(64)} = 1.26$, $p = 0.21$, $t_{2(29)} = 0.80$, $p = 0.43$. The main effect of reference was nearly significant in the subjects analysis, $F_{1(1, 64)} = 3.38$, $p = 0.07$, $\eta_p^2 = 0.05$, but non-significant in the items analysis, $F_{2(1, 29)} = 2.32$, $p = 0.14$, and the interaction between reference and nouns was not significant, $F_{1(1, 64)} = 0.65$, $p = 0.42$, $F_{2(1, 29)} = 1.09$, $p = 0.31$.

Reference-sentence reading times

Based on outlier exclusion criteria, 6.5% of the data were excluded from further analyses. In general, reading time (see **Table 6**) was longer when the sentence contained an anaphor than when it did not. A 2 (nouns: 2, 5) × 2 (reference: anaphor, no anaphor) repeated measures ANOVA revealed a significant main effect of reference, $F_{1(1, 64)} = 23.29$, $p < 0.001$, $F_{2(1, 29)} = 13.01$, $p = 0.001$, $\eta_p^2 = 0.27$. The main effect of nouns was not quite significant, $F_{1(1, 64)} = 3.08$, $p = 0.08$, $F_{2(1, 29)} = 1.56$, $p = 0.22$, although the pattern observed in Experiments 1A, 1B, and 2A appeared once again, with shorter reading times when there were more nouns. There was not a significant interaction between reference and nouns, $F_{1(1, 64)} = 0.23$, $p = 0.64$, $F_{2(1, 29)} = 0.55$, $p = 0.46$.

DISCUSSION

The results from Experiment 3 provided some evidence that subjects were in fact resolving the anaphors when reading the passages. Probe accuracy was better after reading a sentence with an anaphoric reference than after reading a sentence that did not make an anaphoric reference. Additional evidence that subjects were resolving the anaphors comes from the reading-time data. Controlling for length, the reference sentences were read more slowly when they contained an anaphor than when they did not, consistent with the hypothesis that subjects were engaging in additional processing to resolve the anaphor. This conclusion is tentative, though, as there were more explicit references[5] (e.g., pronouns, specifiers, definite noun phrases) to entities in the prior sentence in the reference sentences in the anaphor condition ($M = 2.8$, $SD = 0.8$) than in the no-anaphor condition ($M = 1.6$, $SD = 0.8$), $t_{(29)} = 6.27$, $p < 0.001$. In most cases (25 of 30 passages), these additional references were not to any of the list items; excluding the five passages with a second reference to list items does not change the pattern of results for probe accuracy or reaction time reported above.

The results of this experiment's anaphor condition were less consistent with the fan-effect hypothesis than the results from prior experiments, although the general pattern of degraded recognition performance with more nouns persisted; we return to this issue in the General Discussion.

GENERAL DISCUSSION

Explanations of how anaphoric expressions are understood have frequently appealed to general memory processes. Consistent with theories of comprehension that place memory at their center (e.g., Kintsch, 1988; Myers and O'Brien, 1998; Lewis and Vasishth, 2005), anaphor resolution is more difficult when factors are present that make retrieving a unique item from memory more difficult, such as when there is similarity between a desired target and some distractor. Prior research that has produced findings that are consistent with this hypothesis (e.g., Corbett and Chang, 1983; Corbett, 1984; O'Brien, 1987; O'Brien et al., 1990; Greene et al., 1992; Levine et al., 2000; Badecker and Straub, 2002; Klin et al., 2004, 2006) have used stimuli with one distractor and one antecedent, and by a variety of measures anaphor resolution has been shown to be more difficult because of the distractor. In five experiments, we examined the hypothesis that a greater number of distractors would lead to a fan effect (Anderson, 1974) in anaphor resolution, that is, if with each additional distractor there would be additional difficulty in identifying the correct referent of the anaphor. We also examined the effect of additional distractors on the activation of those distractors. Our subjects read pairs of sentences, the first of which provided a variably-long list of concepts from the same taxonomic category and the second of which made unambiguous reference to one of the items in the list with an adjective-modified definite noun phrase; this was followed by a probe recognition task that should provide an index of how active the probed concept is in the text representation.

Collectively, the probe word results from the present experiments supported the hypothesis that distractors have a cumulative effect on antecedent activation levels. Although the effect of the distractors on reaction time varied in size and significance from experiment to experiment, it is overall a robust effect. The two- and five-noun conditions with a referent probe were present in Experiments 1A, 2A, 2B, and 3. The subject data from these four experiments were combined and submitted to a 2 (nouns: 2, 5) × 4 (Experiments: 1A, 2A, 2B, 3) mixed-factor ANOVA with repeated-measures on the first factor. The effect of nouns was significant, $F_{(1, 265)} = 15.56$, $p < 0.001$, and the interaction was not, $F_{(3, 265)} = 1.18$, $p = 0.32$, suggesting that there was not significant variability in the effect of nouns across experiments. Cohen's d for the effect of nouns was 0.24 (95% confidence interval: 0.12, 0.36; Smithson, 2003), demonstrating a small but reliable effect. Whereas previous research has shown that the presence of a single distractor interferes with the activation of the antecedent, the present research extends this finding by demonstrating that each additional distractor further reduces the activation level of the antecedent and other distractors. This effect is akin to a set size effect (Sternberg, 1966), with larger lists leading to longer reaction times; however, the difference in the size of the effect for referents and distractors suggests that an additional process related to anaphor resolution is also occurring.

The present results are conceptually similar to the fan effect where delayed recognition [i.e., the recognition task occurring after the presentation of all of the materials as in Anderson (1974)] slows as the number of facts associated with a noun increases. This effect is generally attributed to the reduction in the probability of the correct item in memory being activated at the time of retrieval, thus slowing responses. The present experiments demonstrate an earlier effect, with the number of distractors affecting the activation level of nouns immediately after each

[5]Associative anaphora (e.g., referring to *the test* after a sentence mentioning studying) were not counted.

trial. In this case, the categorical anaphor (e.g., *tool*) acts as a retrieval cue, with activation being split among all of the concepts associated with the category (i.e., the referent and distractor[s]). Increasing the number of distractors should therefore increase the time required to resolve the anaphor. This increased retrieval time effect was not observed in the present experiments, although this was likely due to subjects adopting a speeded-reading strategy (see the discussion of the reading-time results below). As a consequence of multiple potential antecedents, activation should be divided among the concepts, limiting the activation for each one (see spreading activation theory; Collins and Loftus, 1975; Anderson, 1983). This prediction was supported by the slowed reaction times and the reduced accuracy resulting from increasing the number of distractors. The present results further demonstrate that activation does not spread equally to all category members when there is disambiguating information (e.g., an adjective modifier like *cutting* in *the cutting tool*). Increasing the number of nouns led to a consistently greater reduction in probe accuracy and increase in reaction time for distractors than for referents in the Experiments 1A and 1B combined analysis and Experiments 2A and 2B, suggesting that activation was spreading disproportionately to the referent.

We have framed the current results as primarily being an effect that occurs at the time of retrieval (i.e., upon reading the anaphor). It is possible that these effects are also influenced by encoding or storage interference. Upon reading multiple items with many shared features, like our list-sentence items, the mental representation of these items may be overwritten (Nairne, 1990) or degraded due to repeated reactivation by similar items (Estes, 1997). The methodology used in the current research does not allow for delineation between a storage-based and a retrieval-based explanation. Ferreting out the relative contributions of storage- and retrieval-interference processes would likely require careful parametric manipulation of feature overlap among distractors and the referent as well as precise control over not only timing of reading and probes but also time elapsed between storage and retrieval, as well as manipulation of serial position of distractors and referents. Attempting to work out these details is a promising avenue for future research.

Turning to the reading-time results, we found no evidence that additional distractors led to more difficulty processing anaphoric reference. By contrast, we consistently found that our subjects read faster as there were more distractors. We believe that this is the result of subjects adopting a speeded-reading strategy on difficult trials (i.e., trials with longer lists of nouns), which counteracted the predicted increase in anaphor reading time. This is similar to Van Dyke and McElree's (2006) finding that, while reading grammatically-complex sentences, subjects read faster and had worse comprehension while holding a memory load (i.e., a list of three words) than when not holding a memory load, suggesting a dual-task strategic trade-off. Our subjects also had lower comprehension with greater list length (see **Table 2**), suggesting that there was possibly a task demand that shifted attention somewhat from the comprehension aspect of the task to the memory aspect of the task. In no case, however, was comprehension lower than about 83%. Moreover, there is no theoretical reason to expect anaphor resolution to take less time as the number of candidate antecedents increases unless subjects were giving up on trying to identify the correct antecedent (Levine et al., 2000). There are a few arguments consistent with the notion that subjects were in fact resolving the anaphors in the current research. First, correctly answering a large majority of the comprehension questions required the anaphors to be resolved, which some have suggested is necessary to get subjects to resolve anaphors in anaphor resolution research (Foertsch and Gernsbacher, 1994). Second, some subjects, especially in Experiment 1B, spontaneously adopted the strategy of labeling distractors as new in the probe recognition task, which suggests that they had selected the referent as the "correct" answer and distractors as the "incorrect" answer to the probe task. Third, Experiment 3 provides tentative evidence that subjects were resolving the anaphor, even on five-noun trials. Given these arguments and findings, we believe that our subjects were resolving anaphors even when it was difficult to do so. Therefore, the speeded-reading strategy appears to be the most parsimonious explanation of these unexpected results. Furthermore, the fixed-pace presentation of the sentence in Experiment 2B prevented subjects from engaging in the speeded-reading strategy, demonstrating that the probe word effects do not rely on such a strategy. Future research should attempt to prevent the speeded-reading strategy while maintaining naturalistic reading (e.g., introducing a substantial delay between the passages and the probe task or eliminating the probe task entirely) in order to better evaluate the anaphor reading time hypothesis.

Finally, returning to the fan-effect hypothesis, the original explanation offered for the fan effect by Anderson (1974) was based on Anderson and Bower's (1973) theory of memory, which assumed that memory retrieval was based on search cues being used to identify, in parallel, matching elements in memory, which were then serially examined, resulting in an increase in reaction time with each additional matching element. In the former detail (i.e., a parallel matching), this theory is in the same family as other global-matching memory theories like those of Ratcliff (1978), Gillund and Shiffrin (1984), and Hintzman (1986), upon which memory-based text processing frameworks like Myers and O'Brien's (1998) resonance model are based. In this sense, the results of our experiments are confirmation of both theories of memory search and the hypothesis that at least some aspects of comprehension may be explained by general memory processes. However, other research into the fan effect has shown that there are circumstances under which there is no fan effect despite there being multiple associations with a single memory cue (Myers et al., 1984; Radvansky, 1998; Radvansky et al., 1998). Myers et al. found no fan effect when memory elements could be integrated causally. For example, reading the elements *the doctor went to the racetrack*, *the doctor studied the odds*, and *the doctor made a selection* may be readily integrated into a causally-coherent narrative representation about events occurring at a racetrack. Similarly, Radvansky and colleagues showed that the fan effect is reduced or even eliminated when potentially-competing memory elements can be readily integrated. One feature that makes elements easy to integrate is if they can occur at the same time (e.g., the grocer was folding a towel; the grocer was clearing his throat), whereas elements that are in different locations may not be integrated (e.g.,

the welcome mat is in the cocktail lounge; the welcome mat is in the office building). Radvansky et al. observed a fan-effect in recognition of hard-to-integrate elements, but not for easy-to-integrate elements. Given that there are boundary conditions for the fan-effect in memory experiments, a natural question to ask is if there are circumstances under which the search process in anaphor resolution might occur without interference. Across sentences, one such circumstance might be if the items in a list occur in more-naturalistic texts, allowing for an integrated situation model to be constructed, as suggested by both Myers et al. (1984) and Radvansky (1998; Radvansky et al., 1998). By contrast, within sentences, one condition that has been shown to limit the search for referents is when there are strong grammatical constraints on reference. Recent evidence from Dillon et al. (2013; see also Chow et al., 2014) suggests that syntactic principles may guide retrieval in a constrained manner for some linguistic dependencies, such as reflexives (but see Badecker and Straub, 2002; Kennison, 2003 and Sturt, 2003, for further complexities), leading to retrieval without interference from distractors; syntactic constraints may play an especially critical role in directing the retrieval processes that occur within a sentence. These types of findings are representative of two distinct research literatures have arisen over the past few decades, one focused on retrieval across sentences, and the other focused on retrieval within sentences. Integration of these theories and findings holds out the promise of yet further integration of theories of memory and comprehension.

AUTHOR NOTE

Portions of these data were presented at the 52nd Annual Meeting of the Psychonomic Society, 2011, Seattle, Washington, and at the 22nd Annual Meeting of the Society for Text and Discourse, 2012, Montreal, Canada.

ACKNOWLEDGMENTS

We thank Katie Berghorn, Willie Curry, Justin Dollman, Audrey Dunn, Alisha Foster, Samantha Herrera, Kelsey Lovewell, Mollie Price, Alicia Small, Colby Thompson, Jessica Turner, and James Wages for their assistance with stimulus preparation and data-collection, and Celia Klin for her comments on a previous draft of this paper. Two anonymous reviewers provided excellent constructive feedback on an earlier draft of this paper.

Backward- and Forward-Looking Potential of Anaphors

Petra B. Schumacher, Jana Backhaus and Manuel Dangl*

Department of German Language and Literature I, University of Cologne, Cologne, Germany

Personal pronouns and demonstratives contribute differently to the encoding of information in the mental model and they serve distinct backward- and forward-looking functions. While (unstressed) personal pronouns are the default means to indicate coreference with the most prominent discourse entity (backward-looking function) and typically mark the maintenance of the current topic, demonstratives are used to refer to a less prominent entity and serve the additional forward-looking function of signaling a possible topic shift. In Experiment 1, we present an ERP study that examines the time course of processing personal and d-pronouns in German (*er* vs. *der*) and assesses the impact of two prominence features of the antecedent, thematic role and sentential position, as well as neurophysiological correlates of backward- and forward-looking functions of referential expressions. We tested the comprehension of personal and d-pronouns following context sentences containing two potential antecedents. In addition to the factor pronoun type (*er* vs. *der*), we varied the verb type (active accusative verbs vs. dative experiencer verbs) and the thematic role order (canonical vs. non-canonical) in the context sentences to vary the antecedent's prominence. Time-locked to pronoun-onset, the ERPs revealed a general biphasic N400-Late Positivity for d-pronouns over personal pronouns with further subtle interactions of the prominence-lending cues in the early time window. The findings indicate that the calculation of the referential candidates' prominence (backward-looking function) is guided by thematic role and positional information. Thematic role information, in combination with initial position, thus represents a central predictor during referential processing. Coreference with a less prominent entity (assumed for d-pronouns) results in processing costs (N400). The additional topic shift signaled by d-pronouns (forward-looking function) results in attentional reorienting (Late Positivity). This is further supported by Experiment 2, a story continuation study, which showed that personal pronouns trigger topic maintenance, while d-pronouns yield topic shifts.

Keywords: pronoun resolution, prominence, agentivity, position, ERP, N400, Late Positivity, topic shift

INTRODUCTION

When a language makes available different forms to refer to entities in the world, these forms typically indicate discrete cognitive states in the mental representation of the interlocutors (cf. Gundel et al., 1993). Accordingly, personal pronouns, demonstrative pronouns, definite noun phrases (NPs) or indefinite NPs serve distinct discourse pragmatic functions. In the following, we will focus on the contribution of personal and demonstrative pronouns to reference tracking.

While (unstressed) personal pronouns are the default means to indicate coreference with the most prominent entity in the current discourse, demonstrative pronouns are used to refer to a less prominent entity or exclude the most prominent entity (cf. Comrie, 1997). We refer to this as the "backward-looking function" of referential expressions. In addition, personal pronouns signal the maintenance of the current topic, while demonstratives suggest that the respective referent is likely to be promoted to topic status in subsequent discourse and thus indicate a topic shift (cf. e.g., Abraham, 2002). This is what we call the "forward-looking function."

Demonstratives come in pronominal (*this, that*) or adnominal form (*this teacher, that book*) and represent deictic expressions that mark the relative distance of the respective referent to the speaker, the hearer or both. Languages vary with regard to how many distance contrasts they encode and whether they only consider the speaker as the deictic center or allow for perspectival centers associated with other protagonists as well; for example English distinguishes the near *this* and the distant *that*, Spanish has a three-way contrast (proximal: *este*, medial: *ese*, distal: *aquel*), Hausa a four-way contrast (near speaker: *nân,* near hearer: *nan*, away from speaker and hearer: *cân*, far away from speaker and hearer: *can*), and some systems encode even more contrasts (e.g., Navajo, Malagasy; Diessel, 2013). German, the language under investigation in this study, employs the demonstrative pronouns *dieser, diese, dieses* (masculine, feminine, neuter) and the d-pronoun *der, die, das*. The former is more restricted in its referential choice and is claimed to prefer the last mentioned entity as its referential candidate, while the d-pronoun does not have such a local restriction (cf. e.g., Zifonun et al., 1997). A less commonly used form to mark distance is *jener, jene, jenes*, but German more frequently uses a modifying adverbial (*hier* "here," *da* "there") to mark distance contrasts.

In the current investigation, we compare the comprehension of the d-pronoun *der* with that of the personal pronoun *er* in contexts with two potential antecedents. The resolution preferences are generally discussed with reference to the notion of referential prominence, which assumes that referents that are accessible in the mental model are ranked in a particular order (cf. e.g., Grosz et al., 1995). But what is prominence? In the literature on pronoun resolution many different factors have been discussed as prominence-lending cues and in the following we provide a brief overview over possible candidate features assumed in the processing literature.

The most influential accounts that investigated personal and demonstrative pronoun resolution considered syntactic function and topicality to be prominence-lending features. Bosch and colleagues initially proposed that personal pronouns in German show a subject preference, while d-pronouns have an anti-subject preference (Bosch et al., 2003). Based on examples with clear discourse topics, they subsequently suggest that personal pronouns favor topical entities and d-pronouns follow an anti-topic interpretation strategy (Bosch and Umbach, 2007; Hinterwimmer, 2015). These accounts assume complementary interpretation preferences for personal and d-pronouns. By contrast, on the basis of data from Finnish, where the personal pronoun was preferably interpreted to refer to the subject while the demonstrative elicited a last-mention preference, Kaiser proposed a non-complementary form-specific distribution of interpretation preferences (Kaiser and Trueswell, 2008). Research on pronoun resolution has identified numerous other candidate factors, including among others linear order, animacy, focus, coherence relations and verb semantics (Stevenson et al., 1994; Chambers and Smyth, 1998; Järvikivi et al., 2005; Kehler et al., 2008; Ellert, 2010).

An alternative account of pronoun resolution is the Bayesian model which promotes a tight relationship between pronoun interpretation and production (Kehler et al., 2008; Kehler and Rohde, 2013). In this framework, interpretive preferences are not merely a function of the prominence structure of previous discourse but arise from the combination of prior expectations for subsequent mention and the production bias for a particular form. Behavioral research within this framework suggests that grammatical function or topichood influence the production bias while coherence relations impact which referent is expected. This approach thus assumes that prominence-lending cues feed into an intricate system of predictive processing that shapes expectation for a particular referent and considers production biases for a particular form. This line of research is promising, but in the current research we do not tease apart production biases and prior expectation. We assess the mechanisms underlying pronoun processing but future research should follow up on the Bayesian predictions within our experimental design.

The current research asks the question whether thematic function is a high ranked candidate for referential prominence. This is motivated by claims that agentivity is part of core cognitive architecture and shapes our thinking and cognitive development in fundamental ways (Leslie, 1995). According to this view, agents are cognitive attractors that hold certain causal properties, initiate actions, pursue goals, have sentience. This is reminiscent of the feature-based characterization of agentivity in semantic theories that attributes causation, volitionality, sentience, self-propelled movement and independent existence to prototypical agents (Dowty, 1991; Primus, 1999). These theories have proposed thematic role hierarchies on the basis of proto-roles, with the highest thematic role being the "proto-agent" and the lower one the "proto-patient." According to this view, agents are the prototypical exemplar of proto-agent because they hold many of the properties listed above but experiencers also satisfy features of proto-agents. Previous research on pronoun resolution has already pointed to the contribution of thematic role information by looking at verb semantics and animacy, and subject or topic preferences may be explained by agent preferences as well, since these features are often aligned.

To disentangle the effect of thematic role from grammatical function, we investigate reference resolution in the context of antecedent clauses with dative experiencer verbs, which critically cross these two predictors for prominence and have an agentive object (i.e., the experiencer) and a non-agentive subject. Example (2) illustrates this construction. In this example, the boxer is the experiencer and the one who must be sentient

based on possible verbal entailments about the argument; hence the object holds more proto-agent properties than the subject.

(1) Der Feuerwehrmann will den Jungen retten … Aber er/der hat …
The firefighter-NOM wants the boy-ACC rescue … But he/D-Pro has …
"The firefighter wants to rescue the boy … But he has…"

(2) Dem Boxer hat der Musiker imponiert … Aber er/der hat …
The boxer-DAT has the musician-NOM impressed …. But he/D-Pro has …
"The boxer was impressed by the musician … But he has …"

Different prominence-lending features of the referents introduced in the context sentences may be responsible for pronoun resolution preferences in these two examples. Crucially, the context sentences differ with respect to the adherence and alignment of the following prominence cues: (i) agentivity (proto-agent > proto-patient), (ii) grammatical function (subject > object) and (iii) topicality. Note that for topicality we assume that the initial argument of a sentence represents the aboutness-topic (cf. Reinhart, 1981). Thus, rather than considering first vs. second mention effects, we pursue a functional approach according to which first mentioned referents serve as topics. **Table 1** illustrates the prominence-lending features incorporated by the initial argument in the active accusative context (1) and the dative experiencer context (2) for canonical and non-canonical argument order. The possible candidate features agent, subject and topic are fully aligned in the canonical active accusative case. The dative experiencer conditions represent an alignment of two of these features and will help to disentangle the contribution of agentivity and subjecthood. Finally, the non-canonical active accusative condition shows even less alignment at the initial argument. If harmonic alignment at the initial position is a key to pronoun resolution, this condition should yield less clear preferences.

As an alternative to alignment of prominence-lending cues, one feature or a combination of features may affect pronoun resolution. For instance if thematic function is a decisive feature during pronoun resolution, this may be reflected in interpretive preferences irrespective of verb type and canonicity. If two or more features act jointly, fine differences should be observable when testing different verb types and canonicity effects. For example, if agentivity and topicality act together, the pronoun following the canonical dative-experiencer construction should link with its antecedent more easily than that following the non-canonical dative-experiencer context; if subjecthood and topicality collaborate, the non-canonical dative-experiencer antecedent clauses should yield clearer interpretive preferences than the canonical dative-experiencer contexts; etc.

Previous behavioral studies indicate a combination of partial feature alignment and the role of thematic function information. In offline tasks, agentivity has been shown to be a stronger predictor than subjecthood for pronoun resolution in German (Schumacher et al., 2016). Sentence completion and referent identification tasks with stimuli that contained either an antecedent clause with active accusative verbs ["rescue" in (1) where topic, subject and agent are aligned] or dative experiencer verbs ["be impressed" in (2) where the proto-agent, the xperiencer, is the object] revealed a proto-agent bias for the personal pronoun and an anti-agent bias for the d-pronoun in the canonical argument order of (1) and (2). When the argument order in the context clause was reversed, the active accusative verbs still registered an agent (or subject) preference—contra first mention or topic preference accounts of personal pronoun resolution—and an anti-agent (anti-subject) bias for the d-pronoun. Argument reversal of (2) resulted in chance performance for both types of pronouns suggesting that in this case the calculation of the relative ranking of the referential candidates was hampered. These data indicate that in a task in which participants are not under time pressure agentivity outweighs subjecthood when it is aligned with topic and/or subject—i.e., in the canonical accusatives (where all three cues are aligned), the canonical dative experiencers (where agent and topic are aligned), and the non-canonical accusatives (where agent and subject are aligned). This suggests that alignment of certain prominence-lending features is beneficial for pronoun resolution. In the case where the agent is not aligned with either topic or subject (the non-canonical dative experiencer contexts), the relative ranking of the referents seems to be too weak to generate an interpretive preference for either of the referential candidates. This reveals that interpretive preferences are not just a consequence of (partial) alignment of prominence-lending cues but that the weighting of these cues is also of relevance.

In the current research, Experiment 1 was designed to investigate the real-time consequences of the verb type × canonicity manipulation for pronoun resolution through event-related brain potentials (ERPs). We hypothesize that prominence-lending cues are used for the generation of fine-tuned predictions about upcoming entities. Personal pronoun resolution as a potential means to signal topic maintenance may thus proceed relatively effortless but could be encumbered in cases in which prominence cues are difficult to process, for example due to certain types of misalignment (as illustrated in **Table 1** and by the behavioral data). D-pronouns in turn require the exclusion of the most prominent referential candidate, which should result in processing costs. Based on previous ERP research, prediction errors—here assumed to be guided by prominence cues—should be reflected in a negative brain potential (N400; for an overview see Bornkessel-Schlesewsky and Schumacher, 2016). N400 effects have for instance been

TABLE 1 | Prominence features of first argument in context sentence.

	Active accusative verbs	Dative experiencer verbs
Canonical order	Agent and Subject and Topic	Agent and Topic
Non-canonical order	Topic	Subject and Topic

observed for referents of differing degrees of givenness—with given entities being more predictable than inferrables and new entities being the least expected (Burkhardt, 2006)—or as an indicator of the distance between anaphor and antecedent—with effects of first mention and recency across multiple sentences (Streb et al., 2004). Negative deflections have also been reported for referential ambiguity during pronoun resolution, which may indicate that a disambiguating referential form is expected in such cases (Nieuwland and Van Berkum, 2006).

With regard to the forward-looking function of demonstrative pronouns, psycholinguistic investigations have been sparse. It has been claimed that demonstratives have the potential to initiate a topic shift and promote their referent to topic status in later discourse. For example, Abraham (2002) explicitly describes the demonstrative as a topic shifter. Empirical evidence comes from the comparison of indefinite *this* ("this egg") and regular indefinites ("an egg"; cf. e.g., Gernsbacher and Shroyer, 1989; Chiriacescu, 2011). Using text continuation tasks, in which participants were instructed to continue a story with five sentences, these studies found that indefinite *this* elicited more mentions of the referent in the continuations, with less marked forms, and had a higher topic shift potential than the regular indefinite. The function of a demonstrative is thus not only to draw the attention to a less prominent discourse entity but also to signal the comprehender that the respective referent may become more prominent in subsequent discourse. Experiment 2 was conducted to investigate the topic shift potential of d-pronouns (and topic maintenance potential of personal pronouns) using a text continuation task. The assumed shift in attention furthermore is predicted to have consequences for discourse representation. Previous research on Japanese and Chinese, in which the notion of topic is crucial for sentence processing, suggests that topic-marked entities that trigger a shift in the ranking of discourse referents and hence require the updating of discourse representation structure evoke a Late Positivity (Hirotani and Schumacher, 2011; Hung and Schumacher, 2012, 2014; Wang and Schumacher, 2013). We therefore predict a Late Positivity for discourse updating due to the topic shift potential of d-pronouns in Experiment 1.

EXPERIMENT 1

The current experiment was designed to assess the online processing of d-pronouns and personal pronouns with a particular focus on contexts in which subject and agent were not aligned. We therefore tested active accusative and dative experiencer antecedent clauses with canonical and non-canonical argument order (see **Table 2** for sample stimuli). As described above, dative experiencer constructions were chosen because they allow us to disentangle the contribution of thematic and syntactic function to pronoun resolution. These verbs come with a dative experiencer (proto-agent in the frameworks of Dowty, 1991 and Primus, 1999) and a subject that represents the lower ranked role and have already shown robust effects of agentivity in behavioral tasks (Schumacher et al., 2016). Note also that we assume that the canonical argument order for these constructions is object before subject (cf. e.g., Haider, 1993; but see Footnote 1 in the Discussion for an alternative view).

Concerning backward-looking, the core function of a pronoun is to refer to an entity available in the mental representation. Hence upon encountering a pronominal expression, a dependency relation between the pronoun and its antecedent must be established. This is guided by the prominence structure of the referents from prior discourse, resulting in a ranked set of referential candidates. Accessibility theories suggest that the personal pronoun prefers the most prominent entity or the entity in focus, which has been attested by corpus research and psycholinguistic experiments (cf. e.g., Gordon et al., 1993; Gundel et al., 1993). Accordingly, personal pronoun resolution should generally proceed rather effortlessly. By contrast, resolution of the d-pronoun has been described to exclude the highest ranked referential candidate (cf. Comrie, 1997; Abraham, 2002). Such an operation should be resource-consuming. All other things being equal, processing the d-pronoun should thus be more costly than processing the personal pronoun. With respect to ERP signatures, we hypothesize that the backward-looking function is first of all closely tied to this form-function correlation interacting with predictive referential parsing reflected in an N400 effect. For predictive parsing, the d-pronoun as the more marked form should be generally more costly than the personal pronoun because it requires the exclusion of the most prominent referent.

This process may be further affected by the misalignment or weighting of prominence features that may encumber the establishment of a ranked set of referential candidates. The experimental design allows us to investigate the organization of the possible set of prominence-lending features and its impact on real-time processing. We thus predict subtle interactions of the factors verb type (varying the combination of grammatical and thematic roles) and canonicity (assigning different topics) on pronoun resolution. If alignment of topic, subject and/or agent is a key force during online pronoun resolution, the different alignments illustrated in **Table 1** may result in processing effort reflected by the N400 amplitude. Likewise the weighting of the different prominence-lending features may affect the processes underlying the N400.

With regard to the forward-looking function, the literature assumes that d-pronouns are topic shifters, which we argue has consequences for discourse updating. We therefore expect a Late Positivity effect for the d-pronoun relative to the personal pronoun. Previous research has not considered the role of prominence cues on forward-looking processes but misalignment of prominence features may result in failure to rank the referential candidates, which may well encumber forward-oriented processing.

TABLE 2 | Example stimuli for the ERP experiment.

Argument order	Sentence	Stimuli
VERB TYPE: ACCUSATIVE VERB		
Canonical	Context sentence	Der Feuerwehrmann | will | den Jungen | retten, | weil | das Haus | brennt. The firefighter-NOM wants the boy-ACC rescue because the house-NOM burns. *The firefighter wants to rescue the boy, because the house is burning.*
	Target sentence	Aber | **er/der** | ist | viel | zu | aufgeregt. But he/D-Pro is way too nervous. *But he is way too nervous.*
Non-canoncial	Context sentence	Den Jungen | will | der Feuerwehrmann | retten, | weil | das Haus | brennt. The boy-ACC wants the firefighter-NOM rescue because the house burns. *The firefighter wants to rescue the boy, because the house is burning.*
	Target sentence	Aber | **er/der** | ist | viel | zu | aufgeregt. But he/D-Pro is way too nervous. *But he is way too nervous.*
Verification Question	Correct answer "Yes"	Brennt das Haus? *Is the house burning?*
	Correct answer "No"	Wackelt das Haus? *Is the house shaking?*
VERB TYPE: DATIVE EXPERIENCER VERB		
Canonical	Context sentence	Dem Boxer | hat | der Musiker | imponiert, | und | zwar | schon | lange. The boxer-DAT has the musician-NOM impressed, in fact already long. *The boxer was impressed by the musician for a long time.*
	Target sentence	Aber | **er/der** | wollte | das | nicht | wahr | haben. But he/D-Pro wanted that not true have. *But he didn't want to accept it.*
Non-Canonical	Context sentence	Der Musiker | hat | dem Boxer | imponiert, | und | zwar | schon | lange. The musician-NOM has the boxer-DAT impressed, in fact already long. *The boxer was impressed by the musician for a long time.*
	Target sentence	Aber | **er/der** | wollte | das | nicht | wahr | haben. But he/D-Pro wanted that not true have. *But he didn't want to accept it.*
Verification question	Correct answer "Yes"	Imponierte der Musiker dem Boxer? *Has the musician impressed the boxer?*
	Correct answer "No"	Imponierte der Musiker dem Fechter? *Has the musician impressed the fencer?*

Methods

Participants

Twenty-seven right-handed, monolingually raised native speakers of German (14 women; mean age: 22; range 19–32) from the University of Mainz participated in this study after giving written informed consent. Participants had normal or corrected-to-normal vision and had no history of neurological or psychiatric disorders. The study was performed in accordance with the Declaration of Helsinki and with the national and institutional recommendations of the Neurolinguistics Lab at the Johannes Gutenberg-University Mainz. Data from three candidates were excluded from the ERP analysis due to excessive artifacts.

Materials

Sample stimuli for the eight conditions can be found in **Table 1**. The first sentence included two NPs that were masculine, animate and definite. In the accusative contexts, the canonical argument order was subject–object, and in the dative experiencer contexts, it was object–subject. Each of the context sentences was followed by a subordinate clause, which contained at most one gender-incongruent referent, to ensure that there was a proper distance between the NPs and the critical pronoun. The target sentence was always introduced by "but," followed by either the personal pronoun "er" or the d-pronoun "der." Sentence completions were kept referentially ambiguous. The material consisted of 60 accusative sets and 60 dative experiencer sets. Additionally, 60 filler sentence pairs were constructed, which included a masculine and feminine antecedent thus eliminating the ambiguity of the pronoun. Each participant was presented with 300 quasi-randomized test items: 240 critical items, consisting of 120 sentences with accusative verb and 120 with dative-experiencer verb, and all 60 fillers. Comprehension questions for each item served to assure that participants were paying attention to the stimuli. Correct and incorrect responses were evenly distributed across the stimuli. The incorrect comprehension questions targeted either an NP from the main clause, the action of the main clause or an element in the subordinate clause of the context sentence. For the filler items, the questions also referred to the content of the target sentence. See **Table 1** for example comprehension questions.

Procedure

During the experiment, each participant was seated in a dimly lit, sound-proof booth. Stimuli were presented visually on a computer screen placed about 100 cm in front of the participant with yellow letters against a dark blue background. Each trial began with a fixation star that was displayed for 500 ms in the center of the screen and followed by a blank screen for 150 ms. Each stimulus was presented in segments as indicated by the horizontal bars in **Table 1**. Single word segments were presented for a duration of 350 ms; phrases containing two or three words were presented for 400 or 450 ms, respectively. An interstimulus interval (ISI) of 150 ms was applied between segments. To verify that the participants had read and understood the sentences, each stimulus was followed by a yes/no verification question. After a blank screen of 150 ms, three question marks occurred for 500 ms, followed by the verification question which was presented in its entirety for 4000 ms. Participants were required to respond as quickly and accurately as possible by pressing a "yes" or "no" button on a gamepad. The assignment of the left and right response buttons was counterbalanced across participants. After the question, a blank screen was presented for 400 ms, followed by the next trial. Prior to the experimental run, participants completed a brief practice session to get acquainted with the experimental procedure.

EEG Recording and Preprocessing

The electroencephalogram (EEG) was recorded from 24 Ag/AgCl scalp electrodes and mounted in an elastic cap (*Easycap*, Munich, Germany). Electrode placement adhered to the international 10–20 system. The ground electrode was positioned at AFz. Electrodes were referenced to the left mastoid and re-referenced offline to linked mastoids. To account for artifacts resulting from eye movements, horizontal, and vertical eye movements were monitored by means of two sets of electrode pairs placed at the outer side of each eye for the horizontal electrooculogram (EOG) and above and below the participant's right eye for the vertical EOG. Electrode impedances were kept below 4 kΩ. All EEG and EOG channels were amplified with a *BrainAmp DC amplifier* (Munich, Germany) and digitized with a rate of 500 Hz.

Before averaging, the EEG data were band pass filtered offline with 0.3–20 Hz to remove unsystematic pre-stimulus differences caused by slow signal drifts. This filter has been identified as an appropriate filter for language-related research that overcomes certain drawbacks arising from baseline correction and has been applied by a number of research groups in previous years (e.g., Wolff et al., 2008; Schumacher and Hung, 2012; Kulakova et al., 2014). Next, automatic (set to ±40 μV for the EOG rejection criterion) and manual rejections were performed to exclude trials containing ocular, amplifier saturation, and other artifacts. Trials with incorrect answers or time-outs to the comprehension question were also excluded from the ERP data analysis. The application of all of these rejection criteria amounted to the exclusion of 12.55% of the data points. Average ERPs were time-locked to the onset of the critical pronoun in the target sentence.

Data Analysis

Statistical analyses were carried out by means of repeated measures analyses of variance (ANOVAs) and were performed with the factors PRONOUN (personal vs. d-pronoun), VERB (TYPE) (active accusative vs. dative experiencer) and CANON(ICITY) (canonical vs. non-canonical). Additionally, REGION OF INTEREST (ROI) entered the analysis as a factor. The analysis was carried out separately for midline and lateral electrode sites. The lateral electrodes were grouped by topographical ROIs which entered the analysis with four levels: left anterior (F3, F7, FC1, FC5), left posterior (CP1, CP5, P3, P7), right anterior (F4, F8, FC2, FC6), right posterior (CP2, CP6, P4, P8). The midline analysis included the six midline sites as levels (Fz, FCz, Cz, CPz, Pz, POz). All statistical analyses were based on the mean amplitude value per condition and were carried out in a hierarchical order. Huynh–Feldt adjustment was applied when the analysis involved factors with more than one degree of freedom in the numerator. The analyses were performed using the ez-package (Lawrence, 2013) in R (R Core Team, 2015).

Results

Figure 1 shows ERPs time-locked to the onset of the personal pronoun (in red) and the d-pronoun (in blue) collapsed over conditions. The plot reveals a negative maximum for the d-pronoun peaking around 300 ms after pronoun onset and a subsequent positive deflection for the d-pronoun between 450 and 600 ms. In addition, there were fine-grained differences arising from the contextual manipulation of verb type and canonicity. This is illustrated by **Figure 2** which shows that while the main effect of pronoun—i.e., a negativity around 300 ms followed by a positivity around 500 ms—is found for the two canonical conditions (top row), the non-canonical conditions (bottom row) diverge from the general picture. The non-canonical active accusatives shows no negativity for the d-pronoun over the personal pronoun and the non-canonical dative experiencer contexts seem to have evoked no positivity difference. With the exception of the last comparison, these observations were supported by statistical analyses. After visual inspection, two time windows were determined for the statistical analysis: 275–400 ms for the negativity effect and 450–600 ms for the positivity.

The statistical analysis for the 275–400 ms time window registered a main effect for PRONOUN over lateral electrode sites [$F_{(1,\ 23)} = 20.65, p < 0.001$] as well as over the midline electrodes [$F_{(1,\ 23)} = 211.43, p < 0.001$] and a four-way interaction for PRONOUN × VERB × CANON × ROI [lateral regions: $F_{(3,\ 69)} = 3.64, p < 0.05$; midline electrodes: $F_{(5,115)} = 3.86, p < 0.05$], reflecting the more pronounced negative deflection for the d-pronoun in comparison to the personal pronoun. Separate resolutions of these interactions for lateral and midline regions by region registered no topographical difference for the midline electrodes (and only main effects of PRONOUN over all midline electrodes) but the lateral ROI analysis indicated that the interaction was strongest over right anterior electrode sites [$F_{(1,\ 23)} = 4.60, p < 0.05$]. Subsequent resolution by the factor VERB within this ROI produced the following pattern: for the accusative verbs there was an interaction of PRONOUN ×

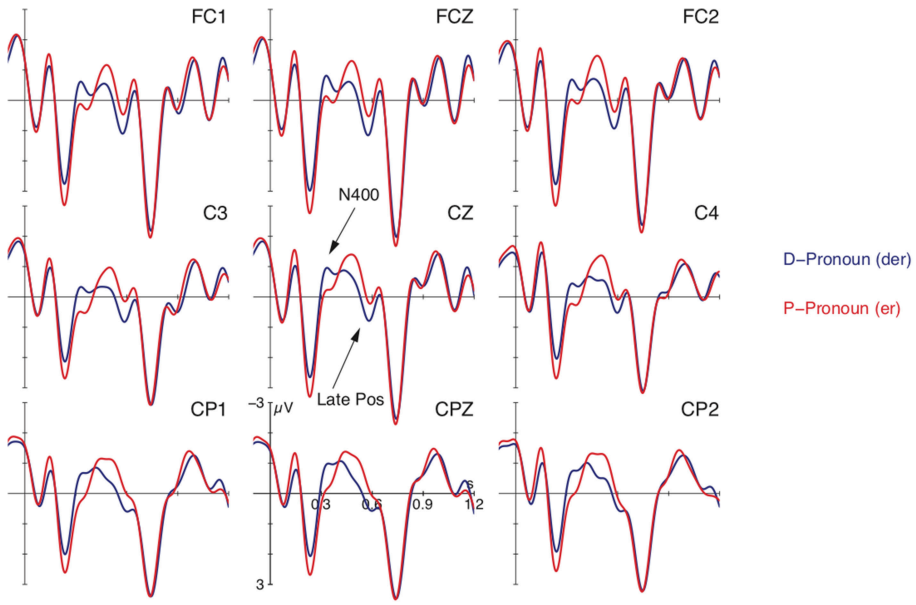

FIGURE 1 | Grand average ERPs at selected electrodes time-locked to the pronoun for the d-pronoun (blue) and the personal pronoun (red) averaged over both verb types and argument orders. Pronoun onset is at vertical bar. Negativity is plotted upwards.

CANON [$F_{(1, 23)} = 7.31$, $p < 0.01$] reflected in an effect of PRONOUN for the canonical subject-before-object order [$F_{(1, 23)} = 9.24$, $p < 0.01$] and no difference between the two types of pronouns in the non-canonical object-before-subject order [$F_{(1,23)} < 0.41$]. The dative experiencer verbs showed a main effect of PRONOUN [$F_{(1, 23)} = 4.87$, $p < 0.05$] and no interaction of PRONOUN × CANON [$F_{(1,23)} < 0.58$]. These patterns are illustrated by the pairwise comparisons in **Figure 2**.

For the time window between 450 and 600 ms, the analyses showed main effects for PRONOUN [lateral sites: $F_{(1, 23)} = 31.28$, $p < 0.001$; midline electrodes: $F_{(1,23)} = 23.87$, $p < 0.001$] and an interaction of PRONOUN × CANON [lateral: $F_{(1, 23)} = 8.06$, $p < 0.01$; midline: $F_{(1, 23)} = 4.69$, $p < 0.05$]. Resolution of this interaction by CANON showed an effect of PRONOUN for the canonical orders [lateral: $F_{(1, 23)} = 37.36$, $p < 0.001$; midline: $F_{(1, 23)} = 28.61$, $p < 0.001$] and a weaker effect of PRONOUN for the non-canonical orders [$F_{(1, 23)} = 7.65$, $p < 0.05$; midline: $F_{(1, 23)} = 5.67$, $p < 0.05$]. The effects reflect the more enhanced positivity for the d-pronoun over the personal pronoun.

Before turning to the discussion of how these findings inform pronoun resolution, we would like to address one further issue. We want to show that the observed effects for d-pronouns are not due to the ambiguity between the pronoun and the definite determiner in German. According to this, the processing costs registered for the demonstrative could also be caused by the ambiguity between the d-pronoun and the masculine definite determiner (both "der" in German). If costs were due to form ambiguity or anticipation of a noun following the determiner (for a sustained negativity for definite vs. indefinite determiners in German see Schumacher, 2009), additional (reanalysis) processes should be observable in the segment following the critical region. **Figure 3** spans until 2000 ms after pronoun onset and illustrates that no effects occurred in spill-over regions. The segment-wise presentation mode chosen in the current investigation may have been conducive to this as well because NPs were always presented in their entirety. We thus exclude form ambiguity as a potential explanation for the observed differences between personal and d-pronouns.

Discussion

In the discussion of the ERP study, we first focus on the general effects of pronoun in the two time windows before looking at the subtle interactions with the other factors in more detail.

Main Effect of Pronoun

Averaged over canonicity and verb type, the d-pronoun in comparison to the personal pronoun displayed a biphasic pattern with a more pronounced negativity in the early time window between 275 and 400 ms and an enhanced positivity in the later time window between 450 and 600 ms (see **Figure 1**). We propose that these two effects reflect backward- and forward-looking operations respectively.

The backward-looking function represents a core characteristic of a pronoun, which is referentially deficient and depends on an antecedent. We take the observed negativity (N400) for the d-pronoun as an indication for the more demanding processing of such a dependency relation on the basis of the instruction to exclude the most prominent referential candidate. The N400 for the d-pronoun patterns well with other findings from reference resolution that indicate that more computationally demanding anaphor-antecedent relations engender a negativity, including surface distance, semantic distance or referential ambiguity to name a few (Streb et al., 2004; Burkhardt, 2006; Nieuwland and Van Berkum, 2006).

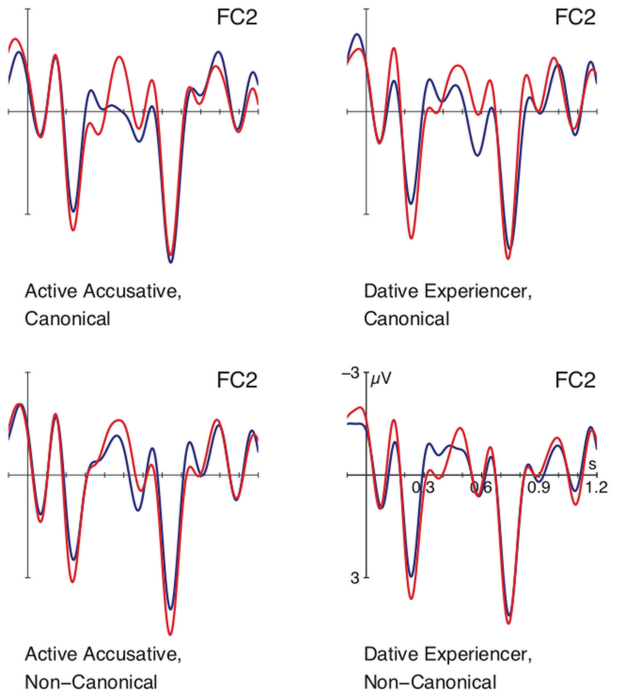

FIGURE 2 | Grand average ERPs for paired comparisons between the d-pronoun (blue) and the personal pronoun (red) at a selected right anterior electrode site (in which the four-way interaction was resolved). Pronoun onset is at vertical bar. Negativity is plotted up.

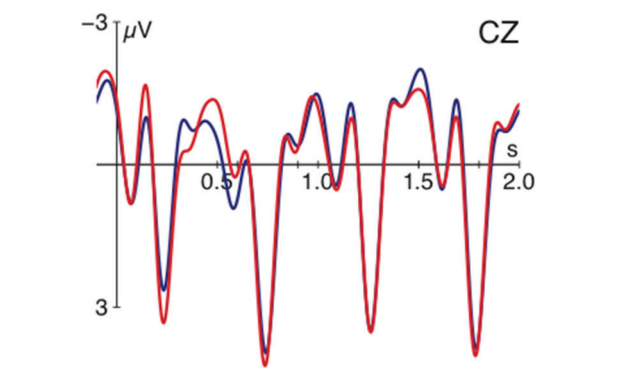

FIGURE 3 | Grand average ERPs at a selected electrode time-locked to pronoun-onset (at vertical bar) and spanning until 2000 ms later for the d-pronoun (blue) and personal pronoun (red) averaged over the factors verb type and argument order. Negativity is plotted upwards.

The current data with an enhanced N400 for d-pronouns over personal pronouns add to this view.

An alternative account for the observed cost would be that the d-pronoun is less expected than a personal pronoun (as a result of the information structural topic maintenance preference) and counters the particular prediction for an upcoming referent formed on the basis of prominence structure. Along these lines, the N400 has more generally been described as an expectation-driven process that is enlarged whenever a processing expectation is not met. However, the next section demonstrates that there are subtle interactions of the different prominence-lending cues manipulated in this study. Such findings indicate to us that the N400 for the d-pronoun reflects aspects associated with the prominence structure underlying the set of referential candidates (i.e., backward-looking operations). We assume that coreference relations depend on certain prominence features that govern the ranked set of referential candidates in the mental representation. Coreference with a less prominent entity (assumed for d-pronouns) results in processing costs.

The subsequent positivity (Late Positivity) for the d-pronoun over the personal pronoun is taken to reflect mental model updating costs. While a personal pronoun typically indicates the continuation of the current discourse topic, a d-pronoun signals a possible shift in attention toward a non-topical referent and therefore has a forward-oriented potential in providing cues about the changing (prominence) structure of the upcoming discourse (cf. e.g., Abraham, 2002). The d-pronoun further occurs in the topic position of the target sentence marking an interruption of the referential coherence. The processing of such forward-directed information exerts costs associated with the organization of discourse referents and the maintenance of the mental representation. Previous research on information structural influences on referential processing reported a Late Positivity for topic shift as well as contrastive focus (e.g., Hirotani and Schumacher, 2011; Wang and Schumacher, 2013; Hung and Schumacher, 2014). These information structural phenomena have in common that they can promote the cognitive status of their referents and direct the addressee's attention to a previously less attended referent. Behavioral data substantiate this role of topic and focus constituents (cf. Almor, 1999; Kaiser and Trueswell, 2004; Cowles et al., 2007). For the mental representation this implies that the prominence level of referents may shift dynamically and that any change may result in discourse updating costs. To substantiate these claims and assess whether d-pronouns affect the topic structure of subsequent discourse, we carried out Experiment 2 below.

Prominence Cues

When we look at the interaction of pronoun type with the two verb types and canonicity, subtle differences occur in particular with respect to processes in the N400 time window. Resolution of the four-way interaction revealed a more pronounced negativity for the d-pronoun over the personal pronoun in all conditions but the non-canonical active accusative antecedent contexts (see **Figure 2**). We take this to reflect processing differences associated with the computation of prominence, which seems to be most severely encumbered in the latter condition. This is best explained by the alignment based hypothesis (see **Table 1**): The four antecedent contexts differ with respect to their alignment of a number of potential prominence features, as illustrated by **Table 1**: (i) proto-agent > proto-patient, (ii) subject > object, and (iii) topic > non-topic (which we take to be a matter of sentence position). In the two canonical argument order cases, in which the proto-agent precedes the proto-patient, the underlying processes look much alike. As **Table 1** illustrates, all three prominence-lending cues are aligned to the first argument in the

canonical accusative contexts. The canonical dative experiencer contexts differ in that the initial topical argument is the agent but not the subject. This suggests that in this case of partial alignment, the absence of subjecthood does not have a negative impact on computation. And it indicates—in line with previous behavioral data (Schumacher et al., 2016)—that thematic role information represents a more highly ranked constraint during pronoun processing than grammatical function. Yet, grammatical function information still seems to contribute to pronoun comprehension to a certain extent because an N400 difference between personal and d-pronouns is still observed following the non-canonical dative experiencer contexts. In this case, the subject is aligned with the first position. Critically, in the non-canonical conditions, the active accusative condition diverges, which is the condition in which neither thematic role nor grammatical function information is aligned with the initial argument. This constellation apparently has real-time consequences for both personal and d-pronoun comprehension since the N400-morphology of both pronouns following the non-canonical active accusative contexts looks rather different from the other contexts. This suggests to us that the prominence-lending features made available by this particular context are not powerful enough to feed into prominence computation, encumbering coreference dependencies at this point in time.

Prominence computation—i.e., the calculation of a ranked set of referential candidates—thus seems to rely on the combination of weighted constraints over referential candidates. When agent or subject arguments occur in sentence-initial position, the resolution instruction ("corefer with the most prominent referential candidate" for the personal pronoun and "exclude the most prominent referential candidate" for the d-pronoun) can be executed, reflected in more computational demands for the exclusion of a referential candidate in the case of demonstratives. In situations in which the initial position is not aligned with either agent or subject (i.e., the non-canonical active accusative case), processing is hampered for both resolution instructions. This indicates that agents in first position are ideal candidates for referential prominence, regardless of grammatical function. When the first argument does not carry the highest thematic role, subjecthood of this argument enhances its referential status. This also indicates that initial position is one of the crucial cues contributing to referential processing (see e.g., Gernsbacher and Hargreaves, 1988). The first position typically hosts information structurally prominent entities, such as topics in German, which has led to proposals for topic and anti-topic pronominal resolution strategies, adding this feature to the prominence candidate set (Bosch et al., 2007; Hinterwimmer, 2015). One caveat arises from the unlicensed non-canonical argument order utilized in the current context sentences, which might well benefit from a richer context with an established discourse topic that paves the way for a marked argument linearization. In contextually enriched cases, prominence computation in non-canonical active accusative contexts may then be eased after all (cf. the research on information structural influences on argument linearization, e.g., Kaiser and Trueswell, 2004; Schumacher and Hung, 2012; Burmester et al., 2014).

Following our claim that the N400 reflects initial processes of executing the pronoun-specific linking instruction, one might ask how these data connect with the interpretive preferences obtained in previous offline studies (Schumacher et al., 2016). Similar to previous offline data that also tested the factors verb type and canonicity, the statistical analyses indicate more pronounced patterns for the canonical argument order (proto-agent > proto-patient) than for the non-canonical order. Yet the ERP data also differ partially from previous offline data in that the offline measures registered more interpretive insecurity in the non-canonical dative experiencer constructions, while the N400 patterns suggest that the non-canonical active accusative constructions are hampered. Certainly offline preferences may be influenced by additional factors and reflect more conscious and controlled operations. However, the differences between online and offline measures may also point out that the observed N400 effect reflects a more automatic process of prominence computation, which is calculated prior to referent selection[1]. A close look at **Figure 2** may even suggest a link between the Late Positivity and the offline data, where the non-canonical dative experiencers showed no positivity for the d-pronoun between 450 and 600 ms. This may be reflected by the Pronoun × Canonicity interaction in this time window, which yielded weaker effects for the two non-canoncial vs. the two canonical orders. However, the hierarchical analysis of the ERP data that we adopted does not allow us to test the non-canonical dative experiencer constructions in isolation. Since the coreference process is a discourse-internal operation, final resolution may well occur within the discourse-updating stage (cf. the two phases of bonding and resolution in e.g., Sanford and Garrod, 1989; Garrod and Terras, 2000). Coreference of personal pronouns is resolved effortlessly because the most prominent entity is maintained, while d-pronouns are more computationally demanding. Misalignments in the earlier prominence computation stage may then result in disruptive processing during discourse updating.

EXPERIMENT 2

In this study we wanted to test, whether d-pronouns have the capacity to initiate a topic shift, which would strengthen our account of the Late Positivity in Experiment 1. We employed a text continuation study, in which participants are provided with context-target sentence pairs and are asked to continue the story by writing six additional sentences. We then determined the topic constituent of each continuation sentence and calculated the topic shift potential of each pronoun, i.e., is the topic of the initial sentence maintained in the story sentences or is the other

[1]The ERP data may also be informative for a debate in the theoretical literature about the status of the dative experiencer linearizations. While we followed Haider (1993) among others who takes the dative-nominative order to be canonical, Barddal et al. (2014) argue that the two available argument orders alternate because both arguments carry certain subject features. This claim is supported by patterns of subject-verb inversion, covert realizations in control infinitives or reflexivization. While previous behavioral data (with uncertainty in the case of the nominative-dative order) did not strengthen this latter view, the N400 data show no order difference for the dative experiencer constructions.

referent promoted to topic status in subsequent discourse. This ties in with research that previously attested a larger amount of topic shifts for indefinite *this* relative to a regular indefinite NP (cf. Gernsbacher and Shroyer, 1989; Chiriacescu, 2011). Based on the claim that demonstratives are topic shifters (Abraham, 2002), we predict that the d-pronoun should show a higher capacity of topic shifting as the story unfolds, while the personal pronoun should encourage topic maintenance (cf. Grosz et al., 1995 for topic continuity expressed by the personal pronoun). Such a main effect of pronoun would substantiate the claim that the Late Positivity is associated with additional demands due to topic shifting, and based on the findings from Experiment 1 as well as the research literature, we predict more topic shift potential for all d-pronoun conditions irrespective of verb type and canonicity. Note however that there was a pronoun × canonicity interaction in the Late Positivity window in the ERP experiment which resulted from more pronounced effects in the canonical compared to the non-canonical conditions. Accordingly, non-canonical antecedent clauses—and in particular the non-canonical accusative contexts—which show misalignment of topic and agent may impede the dynamic updating of the discourse representation structure.

Methods

In this survey, participants were presented with context-target sentence pairs and were asked to continue the story by writing down six additional sentences.

Participants

Thirty-two native speakers of German (16 women; mean age: 25; range: 18–33 years), all monolingual, from the University of Cologne participated in this online survey. The investigation was performed in accordance with the Declaration of Helsinki and with the national and institutional recommendations of the Empirical Linguistics Lab at the University of Cologne.

Materials and Procedure

Four active accusative and four dative experiencer constructions were selected from Experiment 1 and each was presented in the four (canonicity × pronoun) versions. To reduce the number of given referents, only the main clause was used from the context sentence, followed by a target sentence with either a personal or a d-pronoun. The 32 critical items were distributed across 16 lists, so that each participant finished two items. Pilot research had shown that presenting more than two continuations is not recommendable.

Data Analysis

We wanted to find out which referent served as sentence topic in the continuation sentences. To this end we assume that the sentence-initial position holds the sentence topic (cf. aboutness-topic, Reinhart, 1981) and therefore determined whether the initial argument of each continuation reflected a shift or maintenance relative to the story-initial topic.

Each sentence of a continuation was coded with respect to whether it referred to the first or second NP in the context sentence or to another (new) referent that was introduced as part of the continuation. We only analyzed the first five (out of six) continuations, since in this task the last sentence often encourages a summary or wrap-up of the story line. Since we are interested in how the two referents from the initial sentence are picked up in subsequent sentences, reference to newly introduced entities were discarded prior to the analyses. Reference to the initial argument was coded as topic maintenance and reference to the second argument as topic shift. We first calculated the absolute frequency of topic shift and topic maintenance for the eight conditions. We further ran regression analyses with the predictors PRONOUN (personal pronoun; d-pronoun), VERB type (active accusative; dative experiencer) and CANON(ICITY) (canonical; non-canonical).

Results

Figure 4 depicts the difference scores determined from subtracting tokens of topic maintenance from tokens of topic shift. It is based on the cumulative absolute frequency of topic maintenance and topic shifts for the eight conditions. Positive values indicate more topic shifts, negative values reflect more topic maintenance. The figure illustrates that personal pronouns (in red) are more likely to maintain the sentence-initial topic—with the exception of the non-canonical active accusative condition—while d-pronouns (in blue) show a small but stable tendency for topic shift.

The regression analysis produced a final model that retained the entire set of effects and interactions. A test of this full model against a model reduced of interactions was statistically significant [likelihood ratio: $\chi^{2(4)} = 20.37$, $p < 0.001$]. As predicted the d-pronoun triggered more topic shifts than the personal pronoun. The analysis also showed that non-canonical constructions triggered more topic shifts than their canonical counterparts. As **Figure 4** indicates this effect of canonicity as well as the two-way interactions involving

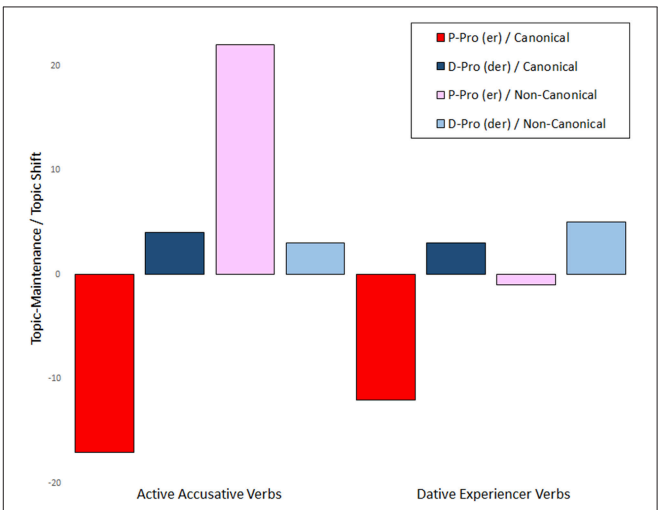

FIGURE 4 | Forward-directed potential of personal and d-pronouns in the eight conditions. Preference for topic shift is indicated by positive values (upwards) and for topic maintenance by negative values.

TABLE 3 | Regression analysis of Experiment 2.

Predictor	Beta	SE	*z*	*p*
Pronoun	1.47	0.55	2.66	0.008
Verb	0.31	0.60	0.53	0.598
Canonicity	3.10	0.69	4.51	0.000
Pronoun * Verb	−0.37	0.78	−0.48	0.633
Pronoun * Canonicity	−3.15	0.85	−3.70	0.000
Canonicity * Verb	−2.26	0.89	−2.55	0.011
Pronoun * Verb * Canonicity	2.46	1.14	2.16	0.031

canonicity (CANON × PRONOUN and CANON × VERB) and the three-way interaction CANON × VERB × PRONOUN are mainly driven by the unexpected pattern registered for the personal pronoun following the non-canonical active accusative condition. These interactions are reflected by the following patterns: While the d-pronouns show robust topic shift across conditions, personal pronouns in non-canonical antecedent clauses diverge from the topic maintenance observed in the canonical contexts. Active accusative contexts diverge immensely in this regard and even show a large amount of topic shift, while personal pronouns in non-canonical dative experiencer contexts registered only the smallest number of topic maintenance. **Table 3** reports the respective coefficients for the topic shift potential with the reference levels "er" for the factor pronoun, "accusative" for verb type and "canonical" for canonicity.

Discussion

The findings of this text continuation experiment confirm that the different pronouns serve discrete forward-looking functions. They show that the d-pronoun triggers more topic shifts in subsequent discourse than the personal pronoun. This supports previous research on the forward potential of indefinite demonstratives in English and German (cf. Gernsbacher and Shroyer, 1989; Chiriacescu, 2011). The personal pronoun in turn typically prompts topic continuations. The topic shift preference of the d-pronoun corroborates our proposal that the Late Positivity observed in the ERP study is associated with forward-directed signals that are encoded in discourse representation.

Based on these forward-oriented functions, the results for the personal pronoun in the non-canonical antecedent clauses suggest an interplay of prominence computation and discourse updating potential. In particular the pattern observed for the personal pronoun in the non-canonical active accusative constructions is surprising but it also emulates the exceptional role of this condition in Experiment 1, where we argued that the fact that neither proto-agent nor subject are aligned with the first position interferes with prominence computation. This seems to have far reaching consequences for subsequent discourse, where speakers possibly opt for an alternative strategy or even reset their mental representation and pick up the last mentioned referent making this the most prominent one (which results in topic shifts in Experiment 2).

GENERAL DISCUSSION

This research supports a dissociation of backward- and forward-looking functions for pronouns and reveals discrete patterns for personal and d-pronouns. The ERP data indicate a discrete time-course of the two functions and the text continuation data strengthen the account that d-pronouns are more likely to initiate a topic shift, while personal pronouns support topic maintenance.

Backward-looking Function

Overall, the current findings call for a resolution algorithm that considers multiple weighted prominence cues. Centering Theory (CT; Grosz et al., 1995) has served as a solid basis for numerous investigations of pronoun resolution. It assumes that certain referents of an utterance are more central than others, which, in turn, affects the processing of the subsequent utterance. Furthermore, personal pronouns are claimed to be preferably resolved toward the most central referential entity, which is understood as a means to establish coherence (Abraham, 2002). Within the CT framework, every utterance may contain several entities that have the potential to establish coherence with the following utterance. These referential expressions are called "Forward-looking Centers" (Cfs) and are ranked according to prominence features, whereby the highest ranked Cf of an utterance is referred to as "Preferred Center" (Cp). To determine if and how coherent two subsequent utterances are, CT offers an algorithm based on two parameters: the cognitive state of the "Backward-looking Center" (Cb), that is the element that picks up the highest ranked Cf from the previous utterance—ideally the Cp—and the current Cb's relation to the Cb of the previous utterance: either the Cb remains the same (Continue or Retain relations) or the Cb changes across two utterances (Smooth or Rough Shift relations; Brennan et al., 1987). Based on pronoun resolution in English, the ranking of the Cfs has been framed according to grammatical function (subject > object > other). Cross-linguistic comparisons however indicate that the setup of prominence cues is subject to language-specific constraints. Research on Japanese and German suggests that information structural notions contribute to the centering algorithm as well which has led to expansion of the grammatical function hierarchy (e.g., for Japanese: topic > empathy > subject > object > other; Kameyama, 1985; Walker et al., 1994, 1998; Di Eugenio, 1998; Abraham, 2002; Speyer, 2007).

While the application of the modified hierarchy may to a certain extent account for utterances with accusative verbs, it does not predict the proto-agent-preference observed for the dative experiencer verbs. We therefore propose to include proto-agentivity as a high-ranking constraint for the Cf ordering in German (proto-agent > proto-recipient > proto-patient; cf. e.g., Dowty, 1991; Primus, 1999). This shift from the grammatical function to the thematic role hierarchy does not affect the results for the canonical sentences with accusative verbs since the highest Cf is also the subject, but it serves to explain the preferences observed for the dative experiencer verbs in which subject and agent are assigned to distinct referents. Due to the non-canonical linearizations, we further

suggest to consider information structural notions as suggested previously on the basis of data from German and Japanese (cf. e.g., Walker et al., 1994; Abraham, 2002; Speyer, 2007). In particular, positional cues in the antecedent clause mark additional information status, with initial entities signaling topic status or contrast. In our case this information structural function may be weakened by the contextually unmotivated placement of a discourse-new object in initial position of the context sentence. But nevertheless first position in combination with other prominence-lending cues provides important information for prominence computation. The current data thus suggest an intricate interaction of agentivity, information structure, and subjecthood, which needs to be tested in more elaborate discourse contexts in future research. Furthermore, CT typically considers only the set of Cfs from the previous utterance; yet, larger discourse structure should be incorporated into CT algorithms. To summarize the backward-looking processes, the data indicate that the thematic role cue is tied to positional information, i.e., agents in initial position are the best candidates for prominence in the current study. In cases, where agents are not aligned with the initial position, grammatical function information collaborates with positional information to boost referential prominence.

Finally, a CT-like algorithm should also account for the resolution of demonstratives. In particular, resolution processes should exclude the Cp as a potential antecedent for the d-pronoun. In the absence of evidence to the contrary, this assumes that personal and d-pronouns in German make use of the same constraints over prominence structure (contra Kaiser's claims of form-specific constraints in Finnish, see Kaiser and Trueswell, 2008). In this regard, the Cp holds an important function within the referential space, which singles it out from the set of referential candidates.

Forward-looking Function

While demonstratives have been described as topic shifters, this forward-directed potential of referential expressions has been neglected in the research literature to a large extent (with the notable exceptions of Gernsbacher and Shroyer, 1989; Chiriacescu, 2011). To our knowledge, the continuation data from Experiment 2 represent the first test of the predictive potential of d-pronouns. They show that personal and d-pronouns influence the structure of subsequent discourse in different ways, yielding more topic maintenance and more topic shift respectively. This forward function of the pronouns can be regarded as a signal-driven cue whereby the d-pronoun promotes attention reorienting toward a new topic.

This finding thus strengthens our account of the Late Positivity in Experiment 1 as a marker of mental model updating triggered by the d-pronoun's inherent instruction to change the overall topic structure. Based on previous ERP research, we predicted a positive deflection for topic shift and attention orienting more generally, which is supported by the main effect of pronoun in the later time window with a more pronounced positive deflection for the d-pronoun relative to the personal pronoun. This suggests that the forward-looking function has real-time consequences during processing.

As far as the difficulties with the non-canonical active accusative contexts are concerned, the behavioral and ERP data converge. While the online data show no difference between the two pronouns in the N400 window—in contrast to all the other conditions—which we attributed to weak cues for prominence computation, this condition also diverges for the discourse continuation behavior by showing a surprising topic shift preference. This suggests that forward-oriented processing may be affected by the prominence structure of the preceding discourse. In the case where neither agent nor subject align with the first position, the relevant ranking of the referents seems to be destabilized hampering the typical forward potential of the personal pronoun.

CONCLUSION

The current investigation revealed differences in the time course of the resolution of personal and d-pronouns, reflected by a biphasic N400—Late Positivity pattern. We suggest that the N400 effect manifests an automatic operation of prominence computation that feeds into the pronoun-specific resolution instruction ("corefer with vs. exclude the most prominent referential candidate"). This early process is further influenced by verb specific information and word order, where the cooccurrence of agentivity and initial position yields an ideal candidate for referential prominence in German but prominence calculation may also be aggravated when particular prominence-lending cues are not aligned. The Late Positivity displays a discourse-internal updating process that provides cues for the possible change in prominence structure of the upcoming discourse, which is also supported by the story continuation task.

ACKNOWLEDGMENTS

We would like to thank Anika Joedicke and Flora Bastian for their assistance during data collection as well as Yu-Chen Hung and Hanna Weiland-Breckle for their support during data analysis.

† These authors have contributed equally to this work.

Real-time interpretation of pronouns is sometimes sensitive to the presence of grammatically-illicit antecedents and sometimes not. This occasional sensitivity has been taken as evidence that structural constraints do not immediately impact the initial antecedent retrieval for pronoun interpretation. We argue that it is important to separate effects that reflect the initial antecedent retrieval process from those that reflect later processes. We present results from five reading comprehension experiments. Both the current results and previous evidence support the hypothesis that agreement features and structural constraints immediately constrain the antecedent retrieval process for pronoun interpretation. Occasional sensitivity to grammatically-illicit antecedents may be due to repair processes triggered when the initial retrieval fails to return a grammatical antecedent.

Keywords: pronoun resolution, Principle B, memory retrieval, self-paced reading, eye-tracking

INTRODUCTION

This paper is concerned with how different kinds of linguistic constraints are used in memory retrieval processes in the course of real-time comprehension. We focus on third-person pronouns for two reasons. First, the interpretation of such pronouns almost always requires the identification of an antecedent from the previous discourse, so they reliably trigger memory retrieval processes in comprehension. Second, the dependency between a pronoun and its antecedent is subject to several kinds of linguistic constraints. Thus, the outcome of the antecedent retrieval process is potentially quite informative about whether the memory system is able to take advantage of different kinds of linguistic constraints to aid sentence processing.

We consider two broad types of constraints on pronominal dependencies. *Agreement* constraints require that the pronoun and its antecedent share certain features, such as number, person, gender, and animacy. For example, in (1), 'Mary' cannot be the antecedent for 'him' because it mismatches the pronoun in gender. *Structural* constraints require that the antecedent bear certain relations to the pronoun in the syntactic and discourse representations. We focus on the structural constraint known as Binding Principle B (Chomsky, 1981): roughly, a pronoun cannot be bound by an antecedent within its local clause. In (1), 'Peter' cannot be the antecedent for 'him' because it would bind the pronoun from within the local clause.

(1) Bill explained to Mary that Peter had deceived him.

Note that for the purposes of this paper, it is sufficient to understand Principle B as a descriptive generalization. We are only concerned with which elements are potential antecedents, and which are not. This approach therefore abstracts away from questions about how the distribution and interpretation of pronouns should be explained at the syntactic, semantic, and pragmatic level (Reinhart, 1983; Grodzinsky and Reinhart, 1993). We are also restricting ourselves to pronouns with intrasentential antecedents, and thus will not be considering the role of various discourse-level structural constraints on extrasentential antecedents.

The combination of agreement and structural constraints substantially narrows the field of potential antecedents for a pronoun. In (1), for example, three entities are mentioned before 'him,' but only 'Bill' is a possible antecedent. Thus, it seems that an efficient comprehension system would take advantage of all available constraints as soon as possible—in the initial retrieval of an antecedent. However, antecedent retrieval relies on memory processes, and it is by no means guaranteed that the human memory system is capable of using any and all linguistic constraints to restrict retrieval. It is therefore an open empirical question which kinds of constraints are used immediately in the initial retrieval, and which have their effect later, as "filters" on the results of the retrieval.

Previous research has demonstrated that comprehenders are sensitive to agreement constraints very early in the process of pronoun interpretation. They rapidly and accurately identify feature-matching entities in the discourse (Arnold et al., 2000)

and detect feature mismatches between a pronoun and its supposed antecedent (Osterhout and Mobley, 1995; Carreiras et al., 1996; Van Berkum et al., 2004). Based on these findings, we consider it uncontroversial that the initial antecedent retrieval process takes advantage of agreement features to restrict the set of candidates.

On the other hand, while many previous studies have examined the role of Principle B in real-time pronoun interpretation, their results have led to divergent conclusions (see Nicol and Swinney, 2003 and Sturt, 2013 for reviews). While existing accounts differ on many aspects, one critical point of contention among them concerns whether and how structural constraints impact the initial antecedent-retrieval processes. Some have argued that only structurally acceptable potential antecedents are considered during the early stages of processing (e.g., Nicol and Swinney, 1989; Clifton et al., 1997, 1999; Lee and Williams, 2008; Patterson et al., 2014), while others have contended that structurally unacceptable candidates can be retrieved initially if they match the pronoun in features (e.g., Badecker and Straub, 2002; Kennison, 2003; Runner et al., 2006). We hope to clarify the kind of evidence that would be necessary to support each of these alternatives by distinguishing different forms of sensitivity to structurally unacceptable potential antecedents. We argue that the apparently conflicting results from previous studies, as well as the results from our own studies, are all consistent with the simultaneous use of agreement and structural constraints in the initial antecedent retrieval process.

We abstract away from other differences among existing accounts and consider two competing hypotheses that differ minimally. The *Agreement First* hypothesis is that the initial retrieval process uses agreement features, but not Principle B, to restrict the set of potential antecedents for a pronoun. Under the *Simultaneous Constraints* hypothesis, the initial retrieval process uses both agreement and structural constraints simultaneously. Here we adopt the operational definition that, when the retrieval process "uses" or "implements" a constraint, the initial set of candidate antecedents does not contain any elements that would be ruled out by that constraint. The retrieval either returns all elements allowed by the constraint, or returns any one of those elements with equal probability. Let's return to our example in (1). Under the Agreement First hypothesis, the initial set of candidate antecedents would contain both 'Bill' and 'Peter' (or either one with some probability), since both match 'him' in agreement features. The structurally unacceptable 'Peter' would have to be ruled out later. Under the Simultaneous Constraints hypothesis, the initial candidate set would contain only 'Bill.'

This particular comparison reflects a slight change of perspective since the earlier studies on pronouns and the hypotheses considered here do not map directly onto any existing account. In particular, while earlier proposals asked whether structural constraints could preempt agreement features as an initial filter on the set of candidate antecedents (e.g., Nicol and Swinney, 1989; Clifton et al., 1997), we now take for granted that agreement features are used in the earliest stages of pronoun processing. The early sensitivity to agreement features fits naturally with models of sentence processing that incorporate cue-based retrieval in a content-addressable memory system (e.g., Lewis and Vasishth, 2005; Martin and McElree, 2008). What remains to be determined is when and how structural constraints play their role.

The Simultaneous Constraints hypothesis should be distinguished from previous accounts involving multiple weighted constraints, in which different constraints can be weighted and applied probabilistically (e.g., Badecker and Straub, 2002; Runner et al., 2006). For example, under Badecker and Straub's (2002) "interactive parallel constraints" hypothesis, a structural constraint can be outweighed by a discourse prominence constraint. As such, even evidence for the retrieval of a structurally unacceptable potential antecedent can be fully compatible with the immediate application of a structural constraint. In contrast, in the current formulation the simultaneously applied constraints are deterministic, so that the retrieval process cannot return an element that is ruled out by any one of them. Thus, we can falsify this hypothesis when we obtain evidence that an element that is ruled out by one (or more) of the constraints is retrieved initially.

To examine the effects of structural constraints on real-time pronoun interpretation, reading studies have generally used feature-mismatch paradigms (e.g., Clifton et al., 1999; Badecker and Straub, 2002; Lee and Williams, 2008). For example, the paradigm illustrated in (2) orthogonally manipulates the gender match between the pronoun and two potential antecedents: the structurally acceptable main clause subject ('John'/'Jane'), and the structurally unacceptable embedded clause subject ('Bill'/'Mary'). Reading times at and following the pronoun are considered indicative of the relative difficulty of resolving the reference of the pronoun (e.g., Carreiras et al., 1996; Clifton et al., 1997).

(2) a. John thought that Bill liked him a lot.
b. John thought that Mary liked him a lot.
c.Jane thought that Bill liked him a lot.
d. Jane thought that Mary liked him a lot.

In (2), the main clause subject is the only structurally acceptable potential antecedent for the pronoun 'him.' When this subject mismatches the pronoun in gender, as in (c) and (d), the sentences are considered ungrammatical. (Although an antecedent outside the sentence is technically possible, such sentences are initially perceived as ungrammatical when no context is provided. Presumably it takes some time to accommodate the lack of antecedent by inventing a potential context with an appropriate antecedent). Thus, sensitivity to the features of the structurally acceptable candidate in reading times at or following the pronoun is termed a *grammaticality effect*. On the other hand, since Principle B rules out the embedded clause subject as a potential antecedent for the pronoun, its features are irrelevant to the acceptability of the sentence. Thus (a) and (b) are equally acceptable, and (c) and (d) are equally unacceptable. Any sensitivity to the features of structurally unacceptable potential antecedents is broadly termed an *interference effect*.

Our predictions for each hypothesis depend on the assumption that some cost will be incurred if the context does not contain a potential antecedent that satisfies the constraints on the initial antecedent retrieval process. This assumption is compatible with most popular conceptions of memory retrieval mechanisms. On

the one hand, if retrieval is deterministic and exhaustive, returning all and only the candidates that satisfy all the constraints, then a lack of satisfactory potential antecedents in the context will result in retrieval failure. Since a pronoun cannot be interpreted without identifying its antecedent, retrieval failure would trigger an error signal or a repair or reanalysis process, either of which would be observable as increased reading times. On the other hand, if retrieval is probabilistic, returning a single candidate with greater or lesser likelihood depending on how fully it satisfies the constraints, then a lack of satisfactory potential antecedents in the context will result in the retrieval of partial matches. In this case, the additional cost arises from the need to rule out partial matches after they have been retrieved. Note that this "filter" would be separate from and prior to a filter based on constraints that were not active in the initial retrieval process.

Let us now consider the predictions of each of our alternative hypotheses. Under the Simultaneous Constraints hypothesis, agreement and structural constraints are both applied during the initial retrieval process, resulting in a set of feature-matching and structurally acceptable candidate antecedents. In (c) and (d), where the structurally acceptable noun phrase mismatches the pronoun in gender, the retrieval process will either—depending on one's preferred model of memory retrieval—fail to return any candidates, or return partial matches that must be ruled out. Either option would be costly. The Simultaneous Constraints hypothesis would therefore predict a grammaticality effect: longer reading times after the pronoun in (c) and (d) compared to (a) and (b). In fact, previous studies have consistently reported grammaticality effects (e.g., Clifton et al., 1999; Badecker and Straub, 2002; Lee and Williams, 2008).

Under the Agreement First hypothesis, structural constraints are not applied in initial antecedent retrieval, resulting in a set of feature-matching candidates that may or may not be structurally acceptable. In (2), (a) to (c) all contain at least one male name, matching the pronoun 'him' in features. The retrieval should only encounter difficulties in (d), which contains no feature-matching names. Thus, reading times after the pronoun in (a) to (c) should pattern together, contrasting with longer reading times in (d). Since reading times would differ between (c) and (d) based solely on the features of a structurally unacceptable potential antecedent, this is a type of interference effect. We will refer to this pattern as a *facilitative interference effect*, since the presence of a feature-matching but structurally unacceptable potential antecedent reduces reading times relative to (d).

Only a facilitative interference effect constitutes sufficient evidence to support the Agreement First hypothesis and rule out the Simultaneous Constraints hypothesis. It is therefore essential to emphasize that a facilitative interference effect has never been reported for pronouns. No existing evidence rules out the possibility that structural constraints restrict the initial antecedent retrieval process.

However, previous studies have occasionally reported *inhibitory interference effects*. These are of two types, distinguished by whether they arise in grammatical or ungrammatical sentences. Badecker and Straub (2002) observed a *multiple match effect*: when the structurally acceptable candidate matched the pronoun in gender (i.e., in grammatical sentences), reading times were longer when the structurally unacceptable candidate also matched, as in (2a), compared to when it did not (2b). Badecker and Straub interpreted this result as an effect of competition between the two feature-matching candidates. Crucially, however, since they also observed a grammaticality effect, not a facilitative interference effect, the results cannot be taken as evidence for the Agreement First hypothesis. At most, this pattern might support weakening the Simultaneous Constraints hypothesis, so that structural constraints interact with agreement constraints probabilistically, rather than deterministically restricting the initial set of candidate antecedents. To our knowledge, Badecker and Straub (2002) are the only authors to report a multiple match effect in a reading study. It is also worth noting that Clackson et al. (2011) found a similar effect in a visual world eye-tracking study.

A second type of inhibitory interference effect has also been reported. Kennison (2003) examined reading times in sentences like (3) where no structurally acceptable antecedent was available within the sentence. Reading times were longer when a structurally unacceptable potential antecedent matched the pronoun in features ('Carl'), compared to when it did not ('Susan'). We will call this type of pattern an *ungrammatical match effect*. Based on this finding, Kennison argued that structurally unacceptable potential antecedents are included in the initial set of candidate antecedents. Their presence delays the point when the comprehender can terminate the search for an antecedent and assume that the intended antecedent is an unmentioned discourse entity.

(3) {Carl/Susan} watched him yesterday during the open rehearsals of the school play.

Sturt (2003) observed a similar ungrammatical match effect in late processing measures in an eye-tracking study on reflexives. However, this study, unlike Kennison's, included a manipulation of the gender match of a structurally acceptable potential antecedent as well as the unacceptable one. There were early grammaticality effects: first-fixation and first-pass reading times on the reflexive were faster in sentences like (4), where the structurally acceptable potential antecedent ('the surgeon') matched the reflexive in stereotypical gender, compared to sentences like (5) where it mismatched. The ungrammatical match effect emerged later: in sentences like (5), second pass reading times on the pronoun were longer when the structurally unacceptable potential antecedent matched the reflexive in features ('She') than when it did not ('He'). Based on the combination of early grammaticality effects and late inhibitory interference, Sturt proposed that the initial set of candidate antecedents is structurally constrained (by Principle A, in the case of reflexives), but structurally unacceptable potential antecedents may be considered at a later stage if no acceptable candidates are retrieved initially.

(4) . . . {She/He} remembered that the surgeon had pricked himself with a used syringe needle. . . .
(5) . . . {She/He} remembered that the surgeon had pricked herself with a used syringe needle. . . .

In summary, different forms of sensitivity to structurally acceptable potential antecedents warrant distinct interpretations (cf. Sturt, 2013). Facilitative interference provides the only clear evidence for the Agreement First hypothesis. Other forms of interference are consistent with the Simultaneous Constraints hypothesis: they may reflect other properties of the processing system or later stages of processing. Thus, given our stricter interpretation of interference effects, the previous literature provides no positive evidence for the Agreement First hypothesis and is consistent with the Simultaneous Constraints hypothesis.

We had two goals for our experiments: to probe further for facilitative interference, and to investigate the causes of the other attested forms of interference. In Experiment 1 we show that comprehenders are immediately sensitive to the structural constraints on pronoun interpretation, regardless of the similarity between the candidate antecedents and their linear distance from the pronoun. We found robust effects of grammaticality, but no interference effects of any kind. In Experiment 2 we attempted to reconcile the discrepancy between our results and Badecker and Straub's (2002) findings in Experiment 2 by directly reproducing their experiment. We replicated our findings from Experiment 1, observing a clear effect of grammaticality but no interference effects. In three additional experiments, we never observed a multiple match effect. Thus, our results support the stronger version of the Simultaneous Constraints hypothesis: structural constraints immediately restrict the initial antecedent retrieval process.

EXPERIMENT 1

Experiment 1 had two goals. First, we wanted to investigate whether structural constraints immediately restrict the set of candidate antecedents for a pronoun. Second, we wanted to explore the possibility that superficial differences in experimental materials may have caused the discrepancies among previous findings.

The first goal of Experiment 1 was to examine whether structural constraints immediately restrict the set of candidate antecedents. We used the feature mismatch paradigm, manipulating the gender match between the object pronoun 'him' and two candidate antecedents: the structurally acceptable main clause subject and the structurally unacceptable embedded clause subject. According to the Simultaneous Constraints hypothesis, the initial retrieval process only returns candidate antecedents that satisfy both feature-match and structural constraints. We should observe only a main effect of grammaticality—gender match of the structurally acceptable candidate—in reading times at the pronoun and subsequent words. According to the Agreement First hypothesis, the initial retrieval process relies on feature matching alone and structural constraints only impact later stages of processing. Under this hypothesis, we should observe an interaction between the two factors in a pattern of facilitative interference. Specifically, reading times should be longer when neither potential antecedent matches the pronoun in gender, compared to the other three conditions where at least one of the potential antecedents matches the pronoun in features. The Agreement First hypothesis would also be consistent with a concurrent or subsequent multiple match effect, if retrieving multiple feature-matching candidates leads to competition-related costs.

The second goal of Experiment 1 was to explore the possibility that superficial differences in experimental materials may have caused the discrepancies among previous findings. We focused on two properties of the materials: (1) similarity between the structurally acceptable and unacceptable candidate antecedents; and (2) linear distance between the pronoun and the structurally acceptable candidate. Even if structural constraints can immediately restrict the set of candidate antecedents during the initial retrieval process (*Simultaneous Constraints* hypothesis), similarity-based interference (e.g., Gordon et al., 2001) and memory decay (Keppel and Underwood, 1962) may make it more difficult for comprehenders to distinguish between structurally acceptable and unacceptable potential antecedents during retrieval. As a result, when the potential antecedents are more similar or when the distance between the pronoun and the structurally acceptable potential antecedent is greater, comprehenders may be more likely to retrieve a feature-matching but structurally unacceptable candidate from a noisy memory representation and show facilitative interference. To explore the effects of these factors, we manipulated the properties of the embedded subject (the structurally unacceptable potential antecedent), as illustrated in **Table 1**.

Previous studies vary in the similarity between the potential antecedents in the sentence. For example, Badecker and Straub (2002) used sentences where both potential antecedents were proper names, and observed a multiple match effect. By contrast, Lee and Williams (2008) used a common noun as the structurally acceptable candidate and a proper name as the unacceptable candidate, and did not observe any interference effects. In our experiment, the main clause subject was always an unambiguously gendered proper name (e.g., 'Ethan' or 'Paige'). We manipulated the similarity between the structurally acceptable and unacceptable candidates by using either another unambiguously gendered proper name (e.g., 'Ronald,' 'Marissa') or a gender-biased common noun (e.g., 'the analyst,' 'the receptionist') as the embedded subject, as shown in **Table 1**.

Previous studies also vary in the distance between the pronoun and potential antecedents. A previous eye-tracking study by Ehrlich and Rayner (1983) found that reading times following a pronoun are longer when its antecedent is further away (cf. Walker et al., 1983). In our experiment, we increased the linear distance between the pronoun and the structurally acceptable candidate by modifying the common noun embedded subject with a subject relative clause or a prepositional phrase (e.g., 'the analyst who attended the office party'), as shown in **Table 1**.

METHODS

Participants

Thirty-six students (26 female, mean age = 20 years, range between 18 and 28) from the University of Maryland, College Park participated in this experiment. All participants were native speakers of English and had normal or corrected-to-normal vision. All participants gave informed consent and received course credit for their participation. Procedures for this experiment as well as Experiments 2–5 were approved by the Internal Review Board of the University of Maryland, College Park.

Table 1 | Experimental conditions and sample materials in Experiment 1.

	Embedded match	Embedded mismatch
COMMON NOUN		
Main clause match (grammatical)	Ethan discovered that the analyst had mocked him mercilessly for singing karaoke after drinking...	Ethan discovered that the receptionist had mocked him mercilessly for singing karaoke after drinking...
Main clause mismatch (ungrammatical)	Paige discovered that the analyst had mocked him mercilessly for singing karaoke after drinking...	Paige discovered that the receptionist had mocked him mercilessly for singing karaoke after drinking...
MODIFIED COMMON NOUN		
Main clause match (grammatical)	Ethan discovered that the analyst who attended the office party had mocked him mercilessly for singing karaoke after drinking...	Ethan discovered that the receptionist who attended the office party had mocked him mercilessly for singing karaoke after drinking...
Main clause mismatch (ungrammatical)	Paige discovered that the analyst who attended the office party had mocked him mercilessly for singing karaoke after drinking...	Paige discovered that the receptionist who attended the office party had mocked him mercilessly for singing karaoke after drinking...
PROPER NAME		
Main clause match (grammatical)	Ethan discovered that Ronald had mocked him mercilessly for singing karaoke after drinking...	Ethan discovered that Marissa had mocked him mercilessly for singing karaoke after drinking...
Main clause mismatch (ungrammatical)	Paige discovered that Ronald had mocked him mercilessly for singing karaoke after drinking...	Paige discovered that Marissa had mocked him mercilessly for singing karaoke after drinking...

Design and Materials

We crossed two levels of *main clause subject gender* (match/mismatch) and *embedded subject gender* (match/mismatch) with three levels of *embedded subject type* (proper name/common noun/modified common noun) to result in a $2 \times 2 \times 3$ within-participant design. The pronoun was always 'him,' since the feminine pronoun 'her' is ambiguous between an object pronoun and a possessive pronoun. We created 60 sets of experimental sentences. Each set included twelve variants, one in each condition. A sample set is shown in **Table 1**. A complete set of experimental stimuli are available in the Supplementary Materials.

The main clause subject was always an unambiguously gendered proper name. The embedded subject was either an unambiguously gendered proper name (e.g., 'Ronald,' 'Marissa'), a gender-biased common noun (e.g., 'the analyst,' 'the receptionist'), or a gender-biased common noun modified with a subject relative clause or a prepositional phrase (e.g., 'the analyst who attended the office party').

The gender-biased nouns were selected based on norming data from Kennison and Trofe (2003) and the intuitions of a native speaker. We collected gender bias ratings for all gender-biased nouns used in this experiment and Experiments 3–5 using Amazon Mechanical Turk. Twenty participants (9 female, mean age = 25 years, range between 21 and 28) rated each noun on a scale from 1 (most likely female) to 7 (most likely male). Overall the results support our choice of nouns. In Experiment 1, the female-biased nouns had an average rating of 2.5 (all of which had an average rating below 4) and the male-biased nouns had an average rating of 5.3 (57 out of 60 had an average rating above 4). The median rating difference between the female-biased and male-biased nouns within the same item was 2.6; 58 of the 60 pairs had mean differences of at least 1.

The 60 item sets were divided into 12 lists, such that each list contained exactly one version of each item and 5 items in each condition. Each list also contained 60 filler sentences, which varied in length and syntactic complexity and contained other referential expressions (e.g., proper names and gender-neutral nouns) and anaphors (e.g., feminine pronouns and reflexives). A third of the experimental and filler sentences were followed by a yes/no comprehension question to ensure that participants were attending to the stimuli. The comprehension questions never referred to the referential dependency between the pronoun and its antecedent. The order of experimental and filler sentences was randomized across participants.

Procedure

The experiment was conducted in a quiet room on a desktop PC. Participants read the sentences in a word-by-word, self-paced moving window task (Just et al., 1982) implemented with the Linger software package (Rohde, 2003). Each trial began with the sentence masked by underscores (___), with the words separated by spaces. Participants began a trial by pressing the spacebar, upon which the first word of the sentence appeared. They continued to press the spacebar to read each successive word. As each word appeared, the previous word was remasked. Participants were instructed to read at a natural pace and to make sure they understood what they were reading so that they could respond to comprehension questions accurately. Reaction times (RTs) were measured for each word from the time it appeared on the screen until the spacebar was pressed for the next word. In a third of the items, a comprehension question appeared after the last word in the sentence was read. Participants responded by pressing the "F" key for "Yes" and the "J" key for "No," and could then proceed to the next trial by pressing the spacebar. The experimental session was preceded by 6 practice trials to familiarize the participant

with the procedure. Testing sessions lasted approximately 35 minutes.

Analysis

Details of data analysis were consistent across all self-paced reading experiments (Experiments 1–4) and are presented for Experiment 1 only. In each experiment, only data from participants with at least 75% accuracy on the comprehension questions (and on the probe identification task in Experiment 2) were used in the analyses. No participants were excluded due to poor accuracy in Experiment 1. Trials containing RTs greater than 2000 ms were excluded from the analysis. This affected 3.4% of the data for Experiment 1.

Average reading times were compared across conditions in the following regions of interest: the pronoun itself (*pronoun*) and the two words immediately following the pronoun (*pronoun+1* and *pronoun+2*). Data for each of the regions of interest were entered into a $2 \times 2 \times 3$ repeated measures ANOVA with *main clause match*, *embedded match*, and *embedded subject type* as within-participant and within-item factors. ANOVAs were computed on the participant means collapsing over items (F1), and on the item means collapsing over participants (F2). Below we report comparisons that revealed a statistically significant difference in at least one of the by-participant and by-item analyses. Since the manipulation of embedded subject type resulted in superficial differences in the materials (e.g., sentence length), effects of embedded subject type are not interpretable unless they interact with the effects of main clause match and/or embedded match. Therefore, only effects involving main clause match or embedded match are discussed. Further, a 2×2 repeated measures ANOVA with *main clause match* and *embedded match* were conducted on each level of *embedded subject type* when it interacted with one or both of the other factors.

RESULTS

Participants answered the comprehension questions with an average of 87.8% accuracy.

Table 2 shows average reading times and standard errors in each region of interest (ROI) across all conditions. **Figure 1** shows average reading times starting from the word preceding the pronoun (the embedded verb) to one word following *pronoun+2* across conditions in each level of embedded subject type. The three-way repeated measures ANOVA in the *pronoun* region revealed a significant main effect of *embedded match* in the by-participant analysis [$F_{1(1,\ 35)} = 5.84$, $p < 0.05$; $F_{2(1,\ 59)} = 3.33$, $p = 0.07$]: reading times were longer when the embedded subject mismatched the pronoun in gender. A significant main effect of *main clause match* was observed in both the *pronoun+1* [$F_{1(1,\ 35)} = 16.12$, $p < 0.001$; $F_{2(1,\ 59)} = 30.57$, $p < 0.001$] and *pronoun+2* [$F_{1(1,\ 35)} = 12.24$, $p < 0.01$; $F_{2(1,\ 59)} = 21.35$, $p < 0.001$] regions: reading times were significantly longer when the main clause subject mismatched the pronoun in gender (i.e., a grammaticality effect). This main effect was accompanied by a significant interaction between main clause match and embedded subject type in the *pronoun+2* region [$F_{1(1,\ 35)} = 16.49$, $p < 0.001$; $F_{2(2,\ 118)} = 3.57$, $p < 0.05$].

Table 2 | Grand average reading times (with standard deviations) in each ROI across all conditions in Experiment 1.

	Pronoun	Pronoun+1	Pronoun+2
COMMON NOUN			
Main clause match, embedded match	372 (15)	406 (23)	374 (14)
Main clause match, embedded mismatch	391 (17)	401 (18)	399 (18)
Main clause mismatch, embedded match	377 (18)	465 (28)	412 (18)
Main clause mismatch, embedded mismatch	418 (20)	479 (26)	421 (21)
MODIFIED COMMON NOUN			
Main clause match, embedded match	348 (11)	354 (13)	376 (15)
Main clause match, embedded mismatch	359 (17)	380 (19)	376 (16)
Main clause mismatch, embedded match	341 (15)	405 (32)	414 (19)
Main clause mismatch, embedded mismatch	364 (20)	438 (26)	374 (16)
PROPER NAME			
Main clause match, embedded match	387 (16)	420 (23)	382 (13)
Main clause match, embedded mismatch	386 (15)	410 (22)	388 (16)
Main clause mismatch, embedded match	393 (23)	467 (33)	438 (25)
Main clause mismatch, embedded mismatch	407 (20)	497 (34)	471 (26)

To better understand the interaction involving embedded subject type, a two-way repeated measures ANOVA with *main clause match* and *embedded match* was conducted on each level of *embedded subject type* in the *pronoun+2* region. When the embedded subject was a common noun (e.g., 'the analyst'; **Figure 1A**), there was a significant main effect of *main clause match* in the by-item analysis [$F_{1(1,\ 35)} = 2.60$, $p > 0.1$; $F_{2(1,\ 59)} = 4.08$, $p < 0.05$]. When the embedded subject was a modified common noun (e.g., 'the analyst who attended the office party'; **Figure 1B**), the main effect of *main clause match* was not significant ($p > 0.1$), but there was an interaction between *main clause match* and *embedded match* that is significant in the by-participant analysis [$F_{1(1,\ 35)} = 5.59$, $p < 0.05$; $F_{2(1,\ 59)} = 1.91$, $p > 0.1$]: gender mismatch between the pronoun and the main clause subject led to longer reading times in the *pronoun+2* region only when the embedded subject matched the pronoun (i.e., an ungrammatical match effect). When the embedded subject was a proper name (e.g., 'Ronald'; **Figure 1C**), there was a significant main effect of *main clause match* [$F_{1(1,\ 35)} = 14.83$, $p < 0.001$; $F_{2(1,\ 59)} = 13.59$, $p < 0.001$]: reading times were significantly longer when there was a gender mismatch between the pronoun and the main clause subject (i.e., a grammaticality effect).

DISCUSSION

Experiment 1 had two main findings. First, we observed a robust grammaticality effect: reading times after the pronoun were

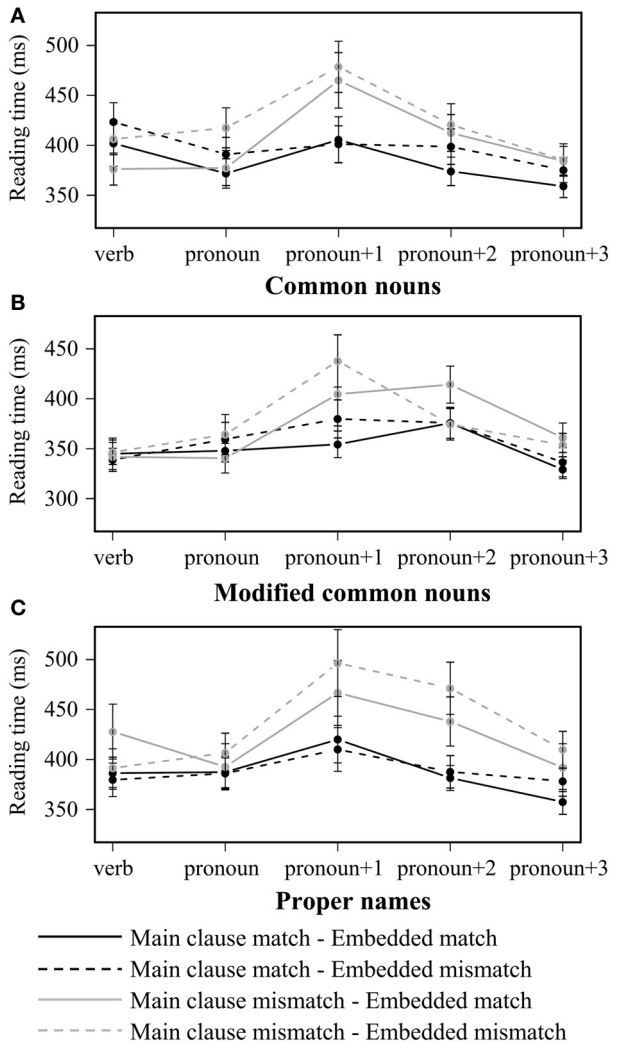

FIGURE 1 | Word-by-word reading times for (A) the common noun, (B) modified common noun and (C) proper name conditions in Experiment 1. Error bars indicate standard error of the participant mean.

significantly longer when the only structurally acceptable potential antecedent mismatched the pronoun in gender (a main effect of *main clause match* in both post-pronoun regions). This grammaticality effect was modulated by embedded subject type in the *pronoun+2* region: the effect of grammaticality was largest when both the main clause and embedded subjects were proper names.

Second, we never observed a facilitative interference effect. Overall three-way ANOVAs did not reveal a significant *main clause match* × *embedded match* interaction in any of the ROIs. Although a significant interaction was observed in the two-way ANOVA in the *pronoun+2* region in the modified common noun condition, it showed the opposite pattern: the presence of a feature-matching structurally unacceptable potential antecedent led to longer, rather than shorter, reading times in the absence of an acceptable antecedent. Therefore, neither similarity between the structurally acceptable and unacceptable candidates nor increased distance between the pronoun and the acceptable antecedent resulted in more retrievals of structurally unacceptable potential antecedents. Taken together, the robust sensitivity to the gender of a structurally acceptable potential antecedent and the absence of facilitative inference effects support the Simultaneous Constraints hypothesis. Structural criteria can immediately restrict the set of candidate antecedents during the initial memory retrieval processes.

An unexpected finding of this experiment is the observation of a significant main effect of *embedded match* in the *pronoun* region in the by-participant analysis. This effect did not interact with *embedded subject type* and was not predicted by either hypothesis. A closer inspection of the data suggests that it was mainly carried by the difference in the common noun condition (embedded mismatch: 404 ms vs. embedded match: 374 ms; **Figure 1A**), which showed a similar difference in reading times in the preceding region (415 ms vs. 389 ms). Therefore, this effect may be spurious and unrelated to pronoun processing.

Although the manipulation of *embedded subject type* never resulted in any facilitative interference effects, it did lead to an interesting interaction between *main clause match* and *embedded subject type* in the *pronoun+2* region. In particular, while main clause mismatch led to significantly longer reading times across all embedded subject types in the *pronoun+1* region, this effect continued to be observed in the *pronoun+2* region only in the proper name condition. That is, when the structurally acceptable and unacceptable potential antecedents were more similar to each other (both were proper names), the grammaticality effect lasted longer. This unexpected pattern could reflect either a more sustained processing disruption or greater variability in the onset time of the disruption.

When the linear distance between the pronoun and the structurally acceptable potential antecedent was lengthened (in the modified common noun condition), we observed a late-emerging ungrammatical match effect. Following the main effect of *main clause match* in the *pronoun+1* region, main clause mismatch led to longer reading times in the *pronoun+2* region only when the embedded subject matched the pronoun. Following Sturt's (2003) proposal for the processing of reflexives, we propose that this inhibitory interference reflects a repair process triggered by an initial failure to retrieve a feature-matching and structurally acceptable antecedent for the pronoun. We take the increased reading times in the *main clause mismatch, embedded match* condition to suggest that a feature-matching antecedent from a structurally unacceptable position may be retrieved when the initial retrieval fails. The observation of an ungrammatical match effect in the modified common noun conditions, but not in the common noun and proper name conditions, suggests that an initial retrieval failure may be more likely to trigger a repair process when the memory representation of the structurally acceptable potential antecedent is less activated due to decay over time. Note, however, that the embedded subject NP was heavier (and more complex) in the modified common noun condition than in the other two conditions. Since a heavier NP may require a more detailed memory representation, the heaviness (or complexity) of the structurally unacceptable potential antecedent may also impact the likelihood of triggering a repair process. More research will be needed to explore the effects of the heaviness of an NP

on memory representation and how it might impact memory encoding and retrieval more generally.

Finally, we never observed a multiple match effect: reading times were never longer when both subjects matched the pronoun compared to when only the main clause subject matched the pronoun. As shown in **Figure 1**, reading times in the multiple match conditions were short in every region, across all three levels of embedded subject type. We aimed to resolve this discrepancy between the current results and Badecker and Straub's (2002) findings in Experiment 2.

EXPERIMENT 2

In Experiment 1 we never observed any sensitivity to the presence of multiple feature-matching candidate antecedents. This contrasts with Badecker and Straub's (2002) repeated observations of a multiple match effect—longer reading times when both candidate antecedents matched the pronoun. We reasoned that, even though the proper name condition in Experiment 1 mirrored Badecker and Straub's (2002; hereafter B&S) Experiment 1, other differences between the experimental materials and procedures might have given rise to the discrepancy in the results. Thus, in Experiment 2, we attempted to directly replicate B&S's Experiment 1, using identical experimental materials and procedures.

We identified three main differences between the materials and procedures used in our Experiment 1 and B&S's Experiment 1. First, while we only used the masculine object pronoun 'him,' in order to avoid the ambiguity of the pronoun, B&S used the ambiguous feminine object pronoun 'her' in half of the sentences, and analyzed the results from sentences with feminine and masculine object pronoun together. Second, while our participants answered yes/no comprehension questions after a third of the items, B&S's participants performed a probe recognition task after each sentence and answered a yes/no comprehension only after a quarter of the sentences. Furthermore, B&S's participants received auditory feedback on their accuracy for both secondary tasks. Finally, while we presented sentences in a moving-window paradigm, B&S presented each word serially in the center of the screen. Since any of these differences may have contributed to differences in the results, we decided to begin our investigation by adopting all of the methods from B&S, in an attempt to replicate their original findings.

METHODS

Participants

Twenty-six students (25 female, mean age = 20 years, range between 18 and 22) from the University of Maryland, College Park participated in this experiment. All participants were native speakers of English and had normal or corrected-to-normal vision. All participants gave informed consent and received course credit for their participation. Data from two additional participants were excluded: one because accuracy on comprehension questions was too low (71%); the other because too many experimental items (25%) contained RTs greater than 2000 ms.

Design and Materials

This experiment had a 2 × 2 within-participant design in which *main clause match* and *embedded match* were fully crossed. We used the original 24 sets of sentences in B&S's Experiment 1. These materials contained an unambiguously gendered proper name in both the main clause and embedded subject positions and therefore resembled the materials used in the proper name condition in Experiment 1 (see **Table 3** for an example). In the original study half of the sentences used the feminine object pronoun 'her,' but sentences with feminine and masculine object pronoun were analyzed together. In order to increase the statistical power for examining the effects of the gender of the pronoun, we created 24 additional sets of sentences modeled after B&S's items, half of which used the feminine object pronoun. A complete set of experimental stimuli are available in the Supplementary Materials.

The 48 item sets were divided into four presentation lists, such that each list contained exactly one version of each item and 6 items in each condition. Each list also contained 100 filler sentences, which varied in length and syntactic complexity and contained other referential expressions (e.g., proper names and gender-neutral nouns) and anaphors (e.g., feminine pronouns and reflexives). Following B&S, a single word probe was selected for each experimental and filler item set. For half of the items, the probe word was selected from among the content words of the sentence—never the pronoun or either of the proper names.

Table 3 | Experimental conditions and sample materials in Experiment 2.

	Embedded match	Embedded mismatch
MASCULINE OBJECT PRONOUN 'HIM'		
Main clause match (grammatical)	Arthur believed that Ben owed him a second chance to solve the problem.	Arthur believed that Meg owed him a second chance to solve the problem.
Main clause mismatch (ungrammatical)	Sheila believed that Ben owed him a second chance to solve the problem.	Sheila believed that Meg owed him a second chance to solve the problem.
FEMININE OBJECT PRONOUN 'HER'		
Main clause match (grammatical)	Sheila believed that Meg owed her a second chance to solve the problem.	Sheila believed that Ben owed her a second chance to solve the problem.
Main clause mismatch (ungrammatical)	Arthur believed that Meg owed her a second chance to solve the problem.	Arthur believed that Ben owed her a second chance to solve the problem.

The location of the probe in the sentence (initial, medial, or final) was counterbalanced across items. For the other half of the items, words that did not occur in the sentence(s) were selected. Among these "no" probes, one third were semantic associates to a content word in the sentence (e.g., beach—ocean), one third were morphologically related to a word in the sentence (e.g., accepted—acceptance), and one third were neither semantically nor morphologically related to any content words in the sentence. Following B&S, comprehension questions were presented on one quarter of the trials. As in Experiment 1, responses to comprehension questions never required successful pronoun resolution. Finally, five additional complete trials were constructed to serve as practice trials.

Procedure

The procedure was similar to that of Experiment 1 with three critical differences. First, words were presented at the center of the screen. Second, at the end of each sentence, a probe word appeared at the center of the screen and the participant used the keyboard to indicate whether that probe word had occurred in the sentence. Finally, auditory feedback was provided to indicate accuracy on both of the secondary tasks. Testing sessions lasted approximately 30 min.

Analysis

As in Experiment 1, trials containing RTs greater than 2000 ms were excluded from the analysis. This affected 2.2% of the data. Initial statistical analyses were performed on data from all items, collapsing across pronoun gender. Data for each of the regions of interest were entered into a 2 × 2 repeated measures ANOVA with main clause match and embedded match as within-participant factors. We conducted two follow-up analyses to further examine potential differences between the present results and B&S's findings. We performed the same 2 × 2 repeated measures ANOVA on the subset of items taken from B&S to determine whether those items would show a different pattern. Finally, to examine the role of the pronoun gender, we added Gender as an additional factor to analyze all the items together. Data for each of the regions of interest were entered into a 2 × 2 × 2 repeated measures ANOVA with main clause match, embedded match and pronoun gender as within- participant factors.

RESULTS

Participants answered the comprehension questions and performed the probe recognition task with an average of 86.2 and 93.9% accuracy respectively.

All items

Main clause mismatch led to longer reading times across several regions (see **Figure 2**). The main effect of *main clause match* was significant in the by-items analysis in the *pronoun* region [422 ms vs. 400 ms; $F_{1(1,\ 25)} = 3.57$, $p = 0.07$; $F_{2(1,\ 47)} = 4.87$, $p < 0.05$], and in both analyses in the *pronoun+1* [447 ms vs. 392 ms; $F_{1(1,\ 25)} = 12.0$, $p < 0.01$; $F_{2(1,\ 47)} = 16.9$, $p < 0.001$] and *pronoun+2* [414 ms vs. 377 ms; $F_{1(1,\ 25)} = 8.82$, $p < 0.01$; $F_{2(1,\ 47)} = 16.8$, $p < 0.001$] regions. No other comparisons revealed a statistically significant difference (p's > 0.05).

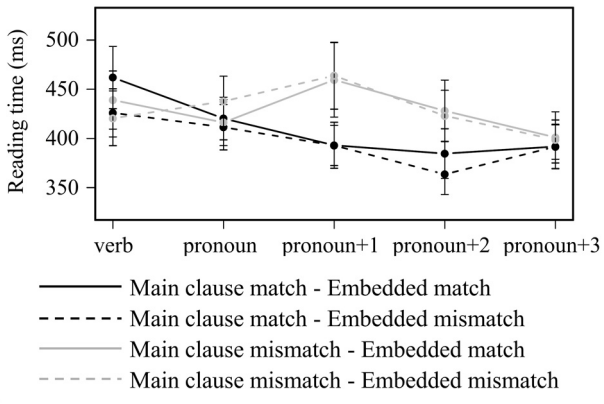

FIGURE 2 | Word-by-word reading times for all items in Experiment 2. Error bars indicate standard error of the participant mean.

Badecker and Straub's (2002) items

A similar pattern of results was observed in a separate analysis of just the subset of items from B&S. Main clause mismatch led to longer reading times at the pronoun and the three subsequent regions. this main effect of *main clause match* was statistically significant in the *pronoun* region [418 ms vs. 386 ms; $F_{1(1,\ 25)} = 5.26$, $p < 0.05$; $F_{2(1,\ 23)} = 7.25$, $p < 0.05$], and in the by-items analysis in the *pronoun+1* region [438 ms vs. 392 ms; $F_{1(1,\ 25)} = 3.89$, $p = 0.06$; $F_{2(1,\ 23)} = 4.81$, $p < 0.05$]. In the *pronoun+2* region, there was an interaction between *main clause match* and *embedded match* which was significant in the by-items analysis [$F_{1(1,\ 25)} = 3.57, p = 0.07; F_{2(1,\ 23)} = 5.72, p < 0.05$]. This interaction had the pattern of an ungrammatical match effect: when the main clause subject mismatched the pronoun, RTs were longer when the embedded subject matched (431 ms vs. 383 ms). No other comparisons revealed a statistically significant difference (p's > 0.05).

Pronoun gender

In a follow-up analysis which included pronoun gender as an additional factor, we continued to observe a main effect of *main clause match* across the *pronoun* [$F_{1(1,\ 25)} = 3.63$, $p = 0.07$; $F_{2(1,\ 47)} = 6.18$, $p < 0.05$], *pronoun+1* [$F_{1(1,\ 25)} = 12.1$, $p < 0.01$; $F_{2(1,\ 47)} = 15.8$, $p < 0.001$], and *pronoun+2* [$F_{1(1,\ 25)} = 8.89$, $p < 0.01$; $F_{2(1,\ 47)} = 14.3$, $p < 0.001$] regions. In addition, reading times were significantly longer for 'him' than for 'her' in the *pronoun* [426 ms vs. 396 ms, $F_{1(1,\ 25)} = 12.0$, $p < 0.01$; $F_{2(1,\ 47)} = 9.46$, $p < 0.01$] and *pronoun+1* [430 ms vs. 408 ms, $F_{1(1,\ 25)} = 7.70, p < 0.05$; $F_{2(1,\ 47)} = 3.27, p = 0.08$] regions. No other comparisons revealed a statistically significant difference (p's > 0.05).

DISCUSSION

In this experiment we adopted the experimental materials and procedures used in B&S's Experiment 1 in an attempt to replicate their observation of a multiple match effect. This attempt was unsuccessful, as we once again failed to observe any sensitivity to the presence of multiple feature-matching candidate antecedents. Instead we replicated the key findings from our

Experiment 1: a robust effect of grammaticality—longer reading times when the main clause subject mismatched the pronoun—and no facilitative interference effect or multiple match effect. When we looked at the subset of items taken from B&S's original study, we observed only a late ungrammatical match effect, similar to that observed in the modified common noun condition in Experiment 1. Across all cases, reading times were never modulated by the presence/absence of a feature-matching embedded subject when the main clause subject matched the pronoun in features.

EXPERIMENTS 3–5

Here we present three further attempts to explore the potential cause of comprehenders' sensitivity (or lack thereof) to the presence of multiple candidate antecedents when processing a pronoun. The design of these experiments was different from that of Experiments 1 and 2. To focus on potential multiple match effects, we removed the manipulation of the main clause subject—it always matched the pronoun in gender. We added a new manipulation of the *pronoun type*: object ('him') vs. possessive ('his'). In the possessive condition, both the main clause and embedded subjects are structurally acceptable, so the pronoun is referentially ambiguous. Thus, if the multiple match effect is possible, we should certainly expect to see it in the possessive condition.

We also added a manipulation of the referential status of the embedded subject: referential (e.g., 'the consultant') vs. quantified (e.g., 'every consultant'). This manipulation was originally motivated by the hypothesis that the multiple match effects observed by B&S could be related to the fact that local antecedents are acceptable in certain pragmatic contexts (Evans, 1980). Such effects might not be expected for quantified NPs (Reinhart, 1983). However, since we never observed a multiple match effect in any of our experiments, a full explanation of the theoretical motivation for this manipulation is beyond the scope of this paper. Here it serves only as a further test of the more basic questions about the structure sensitivity of the initial antecedent retrieval process across a wider range of sentences.

In Experiments 3 and 4 we used a moving-window self-paced reading paradigm. In Experiment 5 we used eye-tracking to examine comprehenders' eye movements while reading. In self-paced reading paradigms, reading must proceed in one direction, while in eye-tracking paradigms participants are free to skip or re-read parts of the sentence that they have previously read (or skipped). Thus, eye-tracking may be able to detect differences that only emerge in more naturalistic reading.

To preview, we never observed a multiple match effect in any of these experiments. In fact, comprehenders did not show increased reading times to a pronoun and its subsequent words, even in cases of genuine referential ambiguity, where multiple structurally acceptable and feature-matching candidate antecedents were available (in the possessive condition). Since the same design was used in all three experiments and they yielded minimally different results, below we report the methods and results of the three experiments together.

DESIGN AND MATERIALS

The same experimental design was used across Experiments 3–5. We manipulated *pronoun type* (object vs. possessive pronoun), the embedded subject's *referential status* (referential vs. quantified) and the *embedded subject gender match* (match vs. mismatch) in a $2 \times 2 \times 2$ within-participant design. A sample item set from Experiment 3 is shown in **Table 4**. The *pronoun type* determined the structural acceptability of the embedded subject as an antecedent for the pronoun: in the object pronoun condition ('him'), only the main clause subject is structurally acceptable as an antecedent, while in the possessive pronoun condition ('his'), both subjects are structurally acceptable. We only used singular masculine pronouns, as in Experiment 1, to avoid the lexical ambiguity of 'her.' The embedded subject, a stereotypically gender-biased common noun, was either quantified (e.g., 'every consultant') or referential (e.g., 'the consultant'). The main clause subject always matched the pronoun in gender, but the embedded subject was manipulated to either match or mismatch the gender of the pronoun.

There were minimal differences in the experimental materials across the three experiments. First, the main clause subjects were stereotypically male common nouns in Experiment 3, and unambiguously male proper names in Experiments 4 and 5. Second, to make the sentences more felicitous in the quantified condition, the embedded subject was modified by a relative clause or prepositional phrase in Experiment 3. In Experiment 4, the embedded subject was not modified; instead the experimental sentence was preceded by a context sentence. Finally, in Experiments 4 and 5, we added longer words (e.g., adverbs) immediately after the pronoun to reduce the likelihood of floor effects on reading times in the critical regions. The differences between the materials are illustrated in (6) and (7).

(6) *A sample item from Experiment 3:*
The lawyer believed that the stock broker who reported the fraud had deceived him about the extent of the illegal activity.

Table 4 | Experimental conditions and sample materials for Experiment 3.

	Embedded match (multiple match)	Embedded mismatch (single match)
Referential	The lawyer believed that the stock broker who reported the fraud had deceived him/his *boss* about the extent of the illegal activity.	The lawyer believed that the secretary who reported the fraud had deceived him/his *boss* about the extent of the illegal activity.
Quantified	The lawyer believed that every stock broker who reported the fraud had deceived him/his *boss* about the extent of the illegal activity.	The lawyer believed that every secretary who reported the fraud had deceived him/his *boss* about the extent of the illegal activity.

(7) *A sample item from Experiments 4 and 5:*
There appeared to be widespread fraud in the management of the hedge fund. Brian believed that the stock broker had deceived him repeatedly about the extent of the illegal activity.

A total of 80 sets of experimental sentences were used in Experiment 3; 64 sets were adapted and used in Experiments 4 and 5. A complete set of experimental stimuli are available in the Supplementary Materials. Gender bias of the common nouns was determined in an offline rating study (see Experiment 1, Design and Materials). On a scale from 1 (most likely female) to 7 (most likely male), female-biased nouns had an average rating 2.5 in Experiment 3 and 2.4 in Experiments 4 and 5. All female-biased nouns had an average rating below 4 (more likely to be female). Male-biased nouns had an average rating of 5.2 in Experiment 3 and 5.3 in Experiments 4 and 5. Most of them (76 of 80 main clause subjects and 75 of 80 embedded subjects in Experiment 3; 61 of 64 in Experiments 4 and 5) had an average rating above 4 (more likely to be male). The median rating difference between the female-biased and male-biased nouns within the same item was 2.6 points in both sets of stimuli.

In each experiment, experimental sentences were divided into 8 lists, each containing exactly one version of each item and the same number of items in each condition. A total of 80, 64, and 104 filler sentences of comparable length and structural complexity were used in Experiments 3, 4, and 5 respectively. Filler sentences contained other referential expressions (e.g., proper names and gender-neutral nouns) and anaphors (e.g., feminine pronouns and reflexives). In Experiments 3 and 5 every experimental and filler sentence was followed by a yes/no comprehension question; in Experiment 4 a yes/no comprehension question appeared following approximately one third of the trials (22 of 64 experimental and filler sentences respectively). The comprehension questions never referred to the referential dependency between the pronoun and its antecedent(s). The order of experimental and filler sentences was randomized across participants.

EXPERIMENT 3

Participants

Twenty-six students (15 female, mean age = 22 years) from the University of Maryland, College Park participated in this experiment. All gave informed consent and were paid $10 per hour for their participation. Data from two additional participants were excluded: one because accuracy on comprehension questions was too low (<70%); the other because too many experimental items (>20%) contained RTs greater than 2000 ms.

Procedure

The procedure was identical to that of Experiment 1. Testing sessions lasted approximately 45 min.

Analysis

Data for different pronoun types were analyzed separately. Data from each region of interest were entered into a 2 × 2 repeated measures ANOVA with *referential status* and *embedded match* as within-participant factors. As in Experiments 1 and 2, trials containing RTs greater than 2000 ms were excluded from the analysis. This affected 1.2% of the data.

Results

Participants answered the comprehension questions with an average of 86.7% accuracy.

Grand average reading times in each ROI across all conditions are presented in **Table 5**.

No significant differences were observed in the *pronoun* and the *pronoun+1* region in either object pronoun or possessive pronoun condition. In the *pronoun+2* region, there was a significant main effect of *referential status* in the object pronoun condition [$F_{1(1,\ 25)} = 5.05$, $p < 0.05$; $F_{2(1,\ 79)} = 4.12$, $p < 0.05$]: reading times were shorter when the embedded subject was quantified (300 ms) compared to when it was referential (312 ms). A reversed pattern was observed in the possessive pronoun condition [main effect of *referential status*: $F_{1(1,\ 25)} = 4.11$, $p = 0.05$; $F_{2(1,\ 79)} = 6.16$, $p < 0.05$]: reading times were longer when the embedded subject was quantified (347 ms) compared to when it was referential (326 ms). No other comparisons revealed a statistically significant difference (p's > 0.1).

EXPERIMENT 4

Participants

Thirty-eight students (30 female, mean age = 22 years) from the University of Maryland, College Park participated in this experiment. All gave informed consent and received course credit or $10 per hour for their participation. Data from one additional participant were excluded due to low accuracy on the comprehension questions (<70%).

Procedure

The procedure was identical to that of Experiments 1 and 3.

Analysis

The analysis method was identical to that of Experiment 3. Outlier rejection (RTs > 2000 ms) affected 2.5% of the data.

Table 5 | Grand average reading times in each ROI across all conditions in Experiment 3.

	Object pronoun (him)			Possessive pronoun (his)		
	Pronoun	**Pronoun+1**	**Pronoun+2**	**Pronoun**	**Pronoun+1**	**Pronoun+2**
Quantified, multiple match	331 (13)	319 (10)	300 (9)	325 (10)	328 (14)	343 (15)
Quantified, single match	330 (12)	329 (12)	301 (11)	322 (11)	335 (12)	351 (14)
Referential, multiple match	332 (14)	320 (12)	315 (13)	330 (14)	324 (13)	327 (12)
Referential, single match	332 (12)	322 (11)	309 (12)	327 (12)	330 (13)	325 (11)

Results

Participants answered the comprehension questions with an average of 90.0% accuracy.

Grand average reading times in each ROI across all conditions are presented in **Table 6**.

No significant differences were observed in any of the regions of interest in either of the pronoun conditions (all p's > 0.1).

EXPERIMENT 5

Participants

Twenty-four students (13 female, mean age = 22 years) from the University of Maryland, College Park participated in this experiment. All gave informed consent and received course credit or $10 per hour for their participation. Data collected from five additional participants were excluded due to problems with calibration.

Procedure

Participants were tested individually in a quiet room in one session lasting 45–60 min. Eye movements were recorded using an EyeLink 1000 eye-tracker (SR Research, Toronto, Ontario, Canada) interfaced with a PC computer. Participants were seated with their chin and forehead stabilized by the eye-tracker apparatus, 32 inches from an LCD monitor which displayed the stimuli. At this distance, 4.6 characters were displayed per degree of visual arc. The eye-tracker has an angular resolution of 0.25–0.5°. Viewing was binocular, but only the right eye was recorded. The sampling rate for recordings was 1000 Hz. Stimulus presentation and interface with the eye-tracker was implemented with the EyeTrack software suite (University of Massachusetts, Amherst).

Sentences were presented in 12-point fixed-width Courier font in two lines. The line break was located after the first word occurring at least 100 characters from the beginning of the line. Depending on the length of the first sentence, the line break generally fell around the fourth or fifth word of the second sentence—for example, between 'the' and 'consultant' in the sample item above. This location for the line break ensured that the pronoun and its following word appeared near the center of the second line. A calibration procedure was performed before the experiment, and re-calibration was carried out between trials as needed. Before the experiment began, each participant was instructed to read for comprehension as naturally as possible. Each trial began with only a gray square on the left edge of the display. The participant triggered the appearance of the sentences by fixating on the square, and pressed a button when they had finished reading to end the display of the item and trigger the presentation of the comprehension question.

Analysis

The initial stage of data analysis was carried out using EyeDoctor (UMass Amherst, http://www.psych.umass.edu/eyelab/software/). Trials with major tracker losses were excluded from the analyses. This resulted in the exclusion of 2.3% of all trials. Each trial was visually inspected to correct for small vertical drifts. Fixations of less than 80 ms in duration and within one character of the previous or following fixation were incorporated into this neighboring fixation. All remaining fixations shorter than 80 ms were excluded. Following Rayner and Pollatsek (1989), we assume that readers do not extract much information during such short fixations. We also excluded fixations longer than 800 ms.

We analyzed three regions, which corresponded to (i) the *pronoun* region, which included the pronoun and its immediately preceding word (i.e., the embedded verb), (ii) the *pronoun+1* region, which included the word immediately following the pronoun, and (iii) the *pre-final* region, which consisted of all words between the *pronoun+1* region and the sentence-final word (exclusive). Spaces between regions were included in the following region. Regions are indicated by brackets in the sample in (8).

(8) The international firm was to hold a press conference in the coming week. Patrick said that the consultant had [prepared him][sufficiently][to make a statement at the] meeting.

Standard eye-tracking measures (Rayner, 1998) were calculated for each region. We report three eye-tracking measures that are representative of early and late measures. *First-pass time* is the sum of all fixation times starting with the first fixation inside a region until the first fixation outside the region (either to the left or right) provided that the reader has not fixated subsequent text. For regions consisting of a single word, first-pass time corresponds to gaze duration (Rayner and Duffy, 1986). *Regression-path time* (e.g., Brysbaert and Mitchell, 1996) is the sum of all fixation times starting with the first fixation inside the region until the first fixation to the right of the region, again provided that the reader has not fixated subsequent text. Finally, *total time* is the sum of all fixations in a region. For all reading time measures, the data for a particular region were excluded if the reading time measure for that region was zero.

As in Experiments 3 and 4, data for different pronoun types were analyzed separately. Data from each region of interest were entered into a 2 × 2 repeated measures ANOVA with *referential status* and *embedded match* as within-participant and within-item

Table 6 | Grand average reading times in each ROI across all conditions in Experiment 4.

	Object pronoun (him)			Possessive pronoun (his)		
	Pronoun	**Pronoun+1**	**Pronoun+2**	**Pronoun**	**Pronoun+1**	**Pronoun+2**
Quantified, multiple match	380 (17)	373 (13)	371 (12)	374 (15)	424 (22)	385 (15)
Quantified, single match	383 (17)	385 (15)	383 (13)	357 (15)	406 (19)	408 (16)
Referential, multiple match	386 (18)	381 (15)	360 (11)	362 (16)	400 (19)	394 (14)
Referential, single match	406 (24)	370 (11)	375 (13)	367 (18)	404 (18)	382 (15)

factors. Below we report F1 and F2 statistics for data in the object pronoun condition and only F1 statistics for data in the possessive pronoun condition due to missing data in a small set of items in one of the regions or measures.

Results

Participants answered the comprehension questions with an average of 91.0% accuracy.

Grand average first pass time, regression path time, and total reading times in each ROI across all conditions are presented in **Table 7**.

Object pronoun condition (him). Repeated measures ANOVA revealed a significant main effect of *referential status* on first-pass time in the pronoun region [$F_{1(1,\ 23)} = 4.81$, $p < 0.05$; $F_{2(1,\ 63)} = 3.41$, $p < 0.1$]: reading times were longer when the embedded subject was quantified than when it was referential. No other comparisons revealed a statistically significant difference (p's > 0.05).

Possessive pronoun condition (his). In the *pronoun+1* region, there was a significant main effect of *referential status* on regression path time [$F_{1(1,\ 23)} = 7.77$, $p < 0.05$]: reading times were longer when the embedded subject was quantified than when it was referential. This effect was reversed in the *pre-final* region, in which regression path time was significantly shorter in the quantified conditions than in the referential conditions [$F_{1(1,\ 23)} = 6.27$, $p < 0.05$]. No other comparisons revealed a statistically significant difference (p's > 0.05).

DISCUSSION

In Experiments 3–5 we examined whether comprehenders are sensitive to the presence of multiple feature-matching candidate antecedents, in cases where both candidates are structurally acceptable ('his') and in cases where only one is ('him').

The results were largely the same across all three experiments, and consistent with the findings of Experiments 1 and 2. Comprehenders were not sensitive to the gender match of the embedded subject, regardless of its referential status. Surprisingly, this also held in the 'his' condition, where we expected to observe a multiple match effect due to the referential ambiguity. This suggests that resolving this referential ambiguity did not lead to any observable processing cost, or that comprehenders did not in fact resolve it online. We will return to discuss this in more detail in the General Discussion.

GENERAL DISCUSSION

Our goal in this paper was to investigate the role of structural constraints in the early stages of pronoun resolution—specifically, the initial retrieval of potential antecedents. We considered two hypotheses. Under the Simultaneous Constraints hypothesis, the initial retrieval would return a set of candidate antecedents constrained by both structural and agreement criteria. Under the Agreement First hypothesis, the initial retrieval would be constrained only by agreement features, while structural constraints would come into play later. Across all our experiments, the results supported the Simultaneous Constraint hypothesis.

In Experiments 1 and 2, we found that comprehenders are sensitive to structural constraints on antecedents as early as agreement constraints. Across all five experiments, we never observed any facilitative interference from the structurally unacceptable potential antecedent. Evidence for inhibitory interference was sparse: there were no instances of multiple match effects, and only one instance of an ungrammatical match effect, which emerged later than the initial sensitivity to structural constraints. Thus we have strong, consistent evidence for structure sensitivity in the earliest stages of pronoun resolution.

NO FACILITATIVE INTERFERENCE

The consistent lack of facilitative interference effects speaks against the Agreement First hypothesis. If the initial stages of pronoun resolution used only agreement features to identify a set of candidate antecedents, then reading times immediately

Table 7 | Grand average first pass time, regression path time, and total reading times in each ROI across all conditions in Experiment 5.

Referential, single match	533 (38)	428 (29)	1226 (99)	569 (45)	359 (24)	1591 (139)

following a pronoun should be sensitive only to the features of potential antecedents, not their structural position. The presence of a feature-matching (albeit structurally unacceptable) candidate would facilitate processing in sentences with no grammatical antecedent. We never observed such a pattern: reading times were always longer when the main clause subject mismatched the pronoun in gender, regardless of whether the embedded subject matched the pronoun in gender.

Some researchers have argued that studies may fail to observe interference effects due to a lack of power. If the predicted pattern of facilitative interference occurred with extremely small effect sizes, we could have failed to detect it even with multiple studies. We think this is unlikely, based on comparison with a case where facilitative interference is observed readily, without large numbers of participants and items: subject-verb agreement (production: Bock and Miller, 1991; comprehension: Staub, 2009, 2010; Wagers et al., 2009). For example, in ungrammatical sentences like (9), reading times on the verb 'praise' are shorter when a plural NP ('the musicians') is present in the context (as in 9b), compared to when only singular NPs are present (as in 9a).

(9) a. *The musician who the reviewer praise so highly will probably win a Grammy.
b. *The musicians who the reviewer praise so highly will probably win a Grammy.

There is good evidence that facilitative interference in subject-verb agreement arises because the retrieval of the subject triggered by the verb is guided primarily by agreement features, not structure (Wagers et al., 2009). If so, under the Agreement First hypothesis, we would expect facilitative interference effects for subject-verb agreement and pronoun resolution to look the same, all things being equal. Of course, all things are not equal. However, the sentences we tested do favor the possibility of facilitative interference: the structurally unacceptable potential antecedent (the embedded subject) is closer to the pronoun both linearly and structurally, so it should be more highly activated in memory than the structurally acceptable potential antecedent at the point when the pronoun triggers the retrieval process. Thus, if antecedent retrieval for pronouns were unconstrained by structure, like subject retrieval for verb agreement, we would expect effect sizes at least as large as those observed in studies of subject-verb agreement, which should therefore be observable in experiments with the same power.

The lack of facilitative interference effects aligns pronouns with reflexives, which also resist interference from structurally unacceptable potential antecedents. Thus, there seems to be a broad division between the processing of agreement dependencies, which show the hallmarks of Agreement First retrieval, and the processing of referential dependencies like pronouns and reflexive (Dillon et al., 2013; but see Parker et al., 2012). Future research will need to establish ways in which the processing of referential and agreement dependencies differ (or not). This will likely provide insights into how different kinds of linguistic information are represented and accessed in memory.

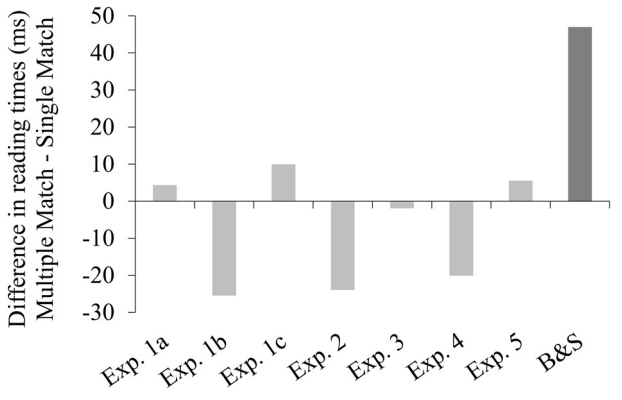

FIGURE 3 | Difference in reading times between the multiple match (main clause match/embedded match) and single match (main clause match/embedded mismatch) conditions in the *pronoun+1* region across Experiments 1–5, compared to Badecker and Straub's (2002) Experiment 1.

NO MULTIPLE MATCH OR REFERENTIAL AMBIGUITY EFFECTS

Another important finding of the current study is that we never observed the multiple match effect reported by Badecker and Straub (2002). In this case, we need not worry about a lack of power to detect the effect: all of our experiments had more participants and items than Badecker and Straub's, resulting in 1.5–5 times as many relevant data points in each experiment. **Figure 3** compares the lack of multiple match effect in the *pronoun+1* region across our five experiments to the rather sizeable effect observed in Badecker and Straub's Experiment 1.

In fact, the multiple match effect seems to be quite rare in the literature. Several other studies include the relevant comparison (Clifton et al., 1999, Experiment 3; Lee and Williams, 2008, Experiments 1 and 2; Patterson et al., 2014), but the effect has only been reported in one (Nicol, 1997; cited in Nicol and Swinney, 2003). In that study, the effect was driven by trials where the participant failed to identify the correct referent for the pronoun in a comprehension question. Nicol and Swinney (2003) therefore suggest that the presence of a multiple match effect depends on the participants' mode of reading.

We note, however, that the availability of more than one potential antecedent—even when they are all grammatically acceptable—does not necessarily lead to increased processing costs. In the possessive conditions of Experiments 3–5, the possessive pronoun 'his' was referentially ambiguous when it matched both the main clause and embedded subjects in features (e.g., 'The executive insisted that the consultant who worked on the project should prepare his client for the weekly press meeting'). This referential ambiguity was not associated with any observable processing cost: embedded subject match never impacted comprehenders' reading time profiles in the possessive pronoun condition.

Although the lack of cost for ambiguity may seem surprising, such effects are often absent in studies comparing ambiguous and unambiguous pronouns in reading comprehension (e.g., Caramazza et al., 1977; Lee and Williams, 2008; Cunnings and

Sturt, 2012; cf. MacDonald and MacWhinney, 1990; Garnham et al., 1995; Arnold et al., 2000; Nieuwland et al., 2007). The pronoun may be resolved using discourse constraints or heuristic strategies (e.g., first-mention bias: Corbett and Chang, 1983; implicit verb causality: Caramazza et al., 1977). Further, effects of referential ambiguity can also be modulated by other factors such as individual differences in working memory span (Nieuwland and Van Berkum, 2006), depth of processing (Stewart et al., 2007) and task demands (Yee and Heller, 2012). These factors might encompass the "mode of reading" idea suggested by Nicol and Swinney (2003).

Thus, even though both the main clause and embedded subjects were plausible antecedents for the possessive pronoun in the present experimental materials, various factors may have contributed to the lack of an ambiguity effect. Future work will be needed to determine how task and individual differences may explain the variation across studies. What is clear is that multiple match effects are far from being the dominant pattern in cases of multiple feature-matching intrasentential antecedents.

LIMITED UNGRAMMATICAL MATCH EFFECTS

We observed the "ungrammatical match" type of inhibitory interference in two cases: the *modified common noun* condition of Experiment 1, and the items in Experiment 2 drawn from Badecker and Straub's (2002) study. In these cases, the presence of a feature-matching but structurally unacceptable potential antecedent led to longer reading times when no grammatical antecedent was available.

Following Sturt's (2003) proposal, we suggest that initial failure to retrieve an acceptable antecedent for a reflexive or pronoun may trigger reanalysis processes leading to increased processing time when a structurally unacceptable potential antecedent matches the pronoun in features. Specifically, to recover an antecedent for the pronoun or reflexive, a feature-matching antecedent in a structurally unacceptable position may be considered. This consideration leads to increased processing time compared to the case when there are no feature-matching candidates at all to be considered. This account makes two predictions. First, sensitivity to a structurally unacceptable potential antecedent should be present only when no grammatical antecedents are available. Second, the effect should be delayed relative to the effect of grammaticality. Both of these predictions are compatible with the evidence available thus far. For instance, while Sturt (2003) observed an effect of grammaticality in first pass reading times, inhibitory interference in ungrammatical sentences was present only in second pass reading times. Correspondingly, in our Experiment 1, while there was an effect of grammaticality in the *pronoun+1* region, the inhibitory interference in ungrammatical sentences was observed only in the *pronoun+2* region.

Note, however, that this effect has only been observed in a subset of the existing studies that allowed the relevant comparison. It emerged in the modified common noun condition of our Experiment 1, but neither of the other embedded subject types, and in only half the items in Experiment 2. Other studies with similar designs have also failed to find any inhibitory interference in ungrammatical sentences (e.g., Clifton et al., 1999; Badecker and Straub, 2002; Lee and Williams, 2008). We take the inconsistency of the effect to suggest that initial failures to retrieve a structurally acceptable and feature-matching antecedent do not always trigger additional reanalysis processes, even when a feature-matching and structurally unacceptable potential antecedent is available. Future research will be needed to explore whether and how this effect may be modulated by factors such as task demands and the memory representation of the potential antecedents.

CONCLUSION

In the current study we examined whether structural constraints (Binding Principle B) impact the initial memory retrieval process alongside agreement constraints during pronoun interpretation. We argue that both the current results and previous evidence support the hypothesis that agreement features and structural constraints are used simultaneously in the process of pronoun interpretation.

ACKNOWLEDGMENTS

Earlier versions of this work have been presented at the CUNY Human Sentence Processing Conference in 2010 and at a GLOW workshop in 2012. We thank Bill Badecker for sharing experimental materials and for discussion. We would like to thank Sunyoung Lee-Ellis, Alex Drummond and Shayne Sloggett for their valuable help in carrying out these studies. We thank Chuck Clifton and Clare Patterson for helpful comments on earlier versions of this paper. This work was supported in part by NSF grant BCS-0848554 to Colin Phillips and NSF IGERT DGE-0801465 to the University of Maryland.

Previous research has shown that anaphor resolution in a non-native language may be more vulnerable to interference from structurally inappropriate antecedents compared to native anaphor resolution. To test whether previous findings on reflexive anaphors generalize to non-reflexive pronouns, we carried out an eye-movement monitoring study investigating the application of binding condition B during native and non-native sentence processing. In two online reading experiments we examined when during processing local and/or non-local antecedents for pronouns were considered in different types of syntactic environment. Our results demonstrate that both native English speakers and native German-speaking learners of English showed online sensitivity to binding condition B in that they did not consider syntactically inappropriate antecedents. For pronouns thought to be exempt from condition B (so-called "short-distance pronouns"), the native readers showed a weak preference for the local antecedent during processing. The non-native readers, on the other hand, showed a preference for the matrix subject even where local coreference was permitted, and despite demonstrating awareness of short-distance pronouns' referential ambiguity in a complementary offline task. This indicates that non-native comprehenders are less sensitive during processing to structural cues that render pronouns exempt from condition B, and prefer to link a pronoun to a salient subject antecedent instead.

Keywords: pronoun resolution, binding, sentence processing, eye-movement monitoring, bilingualism, English

INTRODUCTION

During language comprehension linguistic structure must be encoded, and rapid decisions about dependency formation such as pronominal reference need to be made. Whilst it is generally agreed that processing a pronoun involves the retrieval or reactivation of an antecedent (either explicit or understood from the context), there is no clear consensus on the precise role that structural constraints play in this retrieval process.

Much of the recent debate in this area has been around the memory processes involved in long-distance dependencies, with particular reference to reflexive processing and subject-verb agreement (see Dillon, 2011, for an overview). One view is that reflexive processing in particular involves a structure-sensitive search, so that the target of the retrieval is identified through its position in the linguistic structure (Dillon, 2011; Dillon et al., 2013). An opposing view is that retrieval for reflexives exploits the cues carried on prior representations, so that, for example, a singular, masculine reflexive triggers a search for representations carrying the features *singular* and *masculine*. Importantly, this second approach predicts that retrieval interference is possible from antecedents that are not structurally licensed (e.g., Patil, 2012).

As far as pronouns[1] are concerned, structure alone is not sufficient to uniquely identify a referent, and the interpretation of pronouns is subject not only to structural constraints but also a range of discourse constraints, distinguishing it from reflexive interpretation. Despite this, there is debate around the primacy of the structure-sensitive constraint known as condition B of the Binding Theory (Chomsky, 1981). Condition B restricts the interpretation of pronouns such that a pronoun cannot refer to a c-commanding antecedent within its local binding domain[2]. For example in (1), the direct object pronoun *him* cannot refer to *David* but it can refer to *Nick*. The embedded subject *David* is "inaccessible" as a binder for *him* because the two are coarguments of the same predicate.

(1) Nick$_i$ thinks that David$_k$ likes him$_{i,*k}$

Whether or not condition B can be defined in purely structural terms, though, is debatable. Binding Theory assumes an exclusion on the basis of structural position, but other views involve excluding the inaccessible antecedent on mainly pragmatic grounds (Huang, 1994) or by comparing two alternative semantic sentence representations (Reinhart, 1983; Reuland, 2001, 2011). In this paper, the term "condition B" will henceforth be used as a general

[1]For simplicity, reflexive pronouns will henceforth be referred to as reflexives and non-reflexive pronouns will be referred to as pronouns.

[2]The term "c-command" refers to a particular structural relationship between constituents that is defined in terms of hierarchical dominance (Reinhart, 1983). If, for example, a pronoun is contained within a category that is dominated by the same branching node that immediately dominates another NP, that NP is said to c-command the pronoun.

term to express the exclusion of inaccessible antecedents for pronouns, rather than endorsing a particular theoretical approach.

According to the *binding as initial filter* (BAIF) hypothesis by Nicol and Swinney (1989), condition B is used to exclude inaccessible antecedents from an early stage of processing. In the case of canonical condition B environments exemplified in (1), the local (inaccessible) antecedent would be immediately ruled out and would not influence the parse at any point. That is, condition B should prevent consideration of inaccessible antecedents even when they carry number or gender features that match those of the pronoun. Evidence for this hypothesis came from several cross-modal priming studies which found antecedent reactivation effects only for accessible but not for inaccessible antecedents (Nicol and Swinney, 1989). Further support for this hypothesis mainly comes from negative evidence in self-paced reading studies, i.e., a lack of a demonstrable effect from manipulating the gender or number features of an inaccessible antecedent. When no effect is found, the assumption is that the inaccessible antecedent is not being considered. Negative evidence of this kind has been found by Clifton et al. (1997, 1999).

A variant of the BAIF hypothesis is the idea that binding constraints may act as defeasible filters, with inaccessible antecedents potentially being considered at later processing stages. Evidence in support of this comes from an eye-movement study on English reflexives reported by Sturt (2003).

An alternative to both the BAIF and the defeasible filter hypotheses was put forward by Badecker and Straub (2002). They suggested that multiple cues or constraints that are relevant for pronoun processing (including structural constraints) all contribute in parallel, positively or negatively, to an antecedent's activation. Thus, positive activation from one constraint may be canceled out by inhibition from another. Due to this parallel activation/inhibition, the feature match or mismatch of an inaccessible antecedent will have an influence on processing, in direct contrast to the BAIF hypothesis. Badecker and Straub found that the reading times in regions following a pronoun were longer when both the accessible and inaccessible antecedents matched in gender with the pronoun, compared to when only the accessible antecedent matched. They suggested that all feature-matching referents, whether accessible or inaccessible according to Binding Theory, are evaluated. Further evidence that the inaccessible antecedent is not immediately excluded from consideration comes from Clackson et al.'s (2011) eyetracking-during-listening study. Adult participants' eye gaze patterns revealed that they experienced interference from a gender-matching but structurally inaccessible antecedent after encountering a pronoun. Such evidence can be characterized as supporting a feature-based antecedent search as proposed by Badecker and Straub.

Thus the current evidence bearing on the BAIF with respect to pronouns appears to point in two directions, and there is as yet no clear consensus on whether or not condition B gates access to certain potential antecedents during processing.

In order to establish a broader picture of the mechanisms behind pronoun processing, environments which are exempt from condition B should also be considered. While there are, of course, many syntactic environments in which condition B plays no role (because there is no inaccessible antecedent to exclude) the use of specific exceptions to condition B is more informative. In these cases, condition B *should* apply to rule out a local antecedent, but it does not. The exception that is made use of in the current study is the case of so-called "short distance pronouns" (SDPs). In certain structures such as (2) below, a local c-commanding noun phrase (NP) *can* be interpreted as the antecedent for the pronoun, and it seems that both reflexives and pronouns can appear in these positions (Lees and Klima, 1963, among others).

(2) Nick$_i$ saw David$_k$ put the cat beside him$_{i/k}$.

Possible reasons as to why SDPs seem exempt from condition B include proposals to the effect that prepositional phrases such as *beside him* in (2), or certain kinds of (verb phrase internal) aspectual phrases, can be binding domains (Hestvik, 1991; Tenny, 2004). Under this view, the local subject *David* in (2) is outside the pronoun's binding domain and is thus allowed to bind it without condition B being violated. More widely accepted is the proposal that the scope of condition B should be restricted to anaphoric dependencies involving coarguments (e.g., Reinhart and Reuland, 1993). This also allows for the pronoun *him* in (2) to enter into a referential dependency with the local subject *David* because the two are not in fact arguments of the same predicate. Alternatively, Rooryck and Vanden Wyngaerd (2011) have proposed that rather than being bound by the local subject NP, SDPs are variable-bound by a covert operator located at the left clausal periphery. Regardless of which of the above theoretical accounts is ultimately deemed preferable, recognizing syntactic environments in which local coreference is permitted requires sensitivity to the relevant structural differences between standard condition B environments such as (1) above and SDP environments such as (2).

Exceptions such as SDPs, then, make a good comparison point with canonical condition B environments because their structure is quite similar, but they can reveal how pronoun processing unfolds when condition B appears not to apply. This may, for example, shed further light on possible feature-driven processes, or reveal an underlying sensitivity to the linear ordering of antecedents, as has been found in certain syntactic environments (Cunnings et al., 2014). The online processing of pronouns in SDP environments has rarely been investigated. Experimental evidence for the referential ambiguity of SDPs has been reported by Sekerina et al. (2004). Using eyetracking-during-listening, they examined English-speaking children and adults' processing of questions such as (3) below.

(3) Which picture shows that the boy has placed the box behind himself/him?

Participants had to choose between two alternative pictures, one of which showed the box being located behind a boy (= the sentence-internal referent) and one in which it was located behind an adult male character (= the sentence-external referent). Participants' eye-gaze patterns showed a reduced proportion of looks to the picture corresponding to sentence-internal

reference resolution in the pronoun compared to the reflexive condition, suggesting that the alternative, sentence-external antecedent was more likely to be considered in the pronoun than in the reflexive condition. In a corresponding offline task, the adult participants showed a strong across-the-board preference for sentence-internal antecedents. The focus of Sekerina et al.'s study was on sentence internal vs. external antecedents, and possible differences between antecedent preferences for reflexives vs. pronouns. It does not give a broader picture of pronoun processing in environments with two potential sentence-internal antecedents, although it is interesting to note that pronouns appear to be more flexible in their interpretation than reflexives. In our current study, we use SDP environments such as (2) as a contrast to condition B environments. The crucial factor here is that both antecedents are thought to be accessible to the pronoun.

There are other environments which appear to be exempt from condition B; so-called "picture noun phrases" are a well-studied example (Runner et al., 2003; Kaiser et al., 2009, among others)[3] . The main finding from these studies regarding pronouns is that non-structural factors such as semantic role information are important. Most relevant to the current study, however, is that previous studies have shown that native English-speaking comprehenders are aware of the referential ambiguity of binding-theory exempt pronouns during processing.

NON-NATIVE PROCESSING OF PRONOMINAL ANAPHORS

It is not only exceptions to condition B that can provide a broader picture about the processing of pronouns. The processing profiles of different populations, in this case non-native speakers, can also be informative. Models of parsing, particularly those that are closely tied to aspects of general cognition, should be able to account not only for native language processing but also for processing in a non-native language. Additionally, non-native speakers have been shown in previous studies to take a more discourse-driven strategy than native speakers during the processing of, for example, reflexives (Felser and Cunnings, 2012), findings which appear to challenge the universal validity of serial or syntax-first models that were proposed on the basis of monolingual processing data.

Most previous research on non-native anaphor resolution has examined learners' knowledge of binding using offline judgment or antecedent choice tasks. Unlike the developmental delay of condition B that has been reported in the child language acquisition literature (e.g., Chien and Wexler, 1990), the application of binding condition B appears to be relatively unproblematic in the post-childhood acquisition of non-native speakers (henceforth L2s). White (1998), for example, reports that even intermediate-level L2 learners of English patterned with English native speakers in a truth-value judgment task in disallowing local antecedents for pronouns. Using a multiple-choice antecedent identification task, Bertenshaw (2009) found that native Japanese-speaking learners of English correctly rejected inaccessible antecedents for pronouns 92.8% of the time, a figure that compares favorably with the native speaker controls' correct rejection rate of 87.5%. Similarly high accuracy rates have been reported by Cook (1990).

Conversely, little is known about whether or when binding constraints are applied during online L2 processing. L2s have been claimed to show reduced sensitivity to syntactic information during processing compared to native speakers (henceforth L1s), and difficulty establishing structurally mediated discontinuous dependencies in a native-like way (Clahsen and Felser, 2006). However, a reduced ability to process syntactically mediated dependencies may affect L2 online interpretation of reflexives more than the ability to interpret pronouns, all other things being equal. This is under the assumption that binding of argument reflexives is contingent on mechanisms of syntactic computation, whereas non-reflexive pronouns can also be linked to an antecedent via discourse-based coreference assignment (e.g., Reuland, 2001, 2011).

While L1 speakers appear to respect condition A of the Binding Theory (which states that reflexives must be locally bound) from the earliest measurable point in processing (Sturt, 2003; Xiang et al., 2009), a different picture emerges in L2 processing. Felser et al. (2009) report evidence from timed grammaticality judgments and eye-movement monitoring showing that native Japanese speakers experienced competition from inaccessible antecedents for English argument reflexives during processing, despite demonstrating native-like knowledge of binding condition A in complementary offline tasks. Felser and Cunnings (2012) further explored the interaction of structural and discourse factors in non-native anaphor resolution by examining native German speakers' processing of English reflexives. Two eye-movement monitoring experiments were carried out using sentences such as (4a) and (4b) in a gender-mismatch paradigm (compare e.g., Sturt, 2003).

(4a) James has worked at the army hospital for years. He noticed that the soldier had wounded himself while on duty in the Far East.

(4b) James has worked at the army hospital for years. The soldier that he treated on the ward wounded himself while on duty in the Far East.

The L2s' reading-time patterns differed from the L1s' in that they initially showed unmodulated main effects of the inaccessible antecedent's gender only. This was the case both for sentences like (4a), in which the inaccessible antecedent (the pronoun *he*) c-commands the reflexive, and for sentences such as (4b), where it does not. Only in later measures and/or sentence regions did the L2 speakers pattern with the L1 controls in showing main effects of the accessible antecedent's gender. Taken together, these results indicate that unlike L1s, L2 speakers do not immediately apply binding condition A during processing but initially try to link argument reflexives to the most discourse-prominent antecedent via coreference assignment instead.

To our knowledge, the timing of binding condition B during L2 pronoun processing has never been investigated. L2 processing studies on pronoun resolution have focused on discourse anaphors rather than bound pronouns. The findings from these studies suggest that L2s can use information-structural cues such

[3] A typical example of a picture noun phrase is "Nick's picture of himself/him," where both the reflexive and the pronoun can be understood as referring to Nick.

as focus to guide pronoun resolution (Ellert, 2010) and may experience more competition than L1s in the presence of more than one feature-matching discourse antecedent (Roberts et al., 2008). Roberts et al. examined the role of contextual information in native Turkish and German speakers' real-time comprehension of ambiguous pronouns in L2 Dutch also using eye-movement monitoring. The two L2 groups patterned together in showing elevated total and second-pass reading times at the pronoun region when two (rather than only one) matching antecedents were present in the sentence-external discourse. The native Dutch controls, on the other hand, were not measurably distracted by the presence of another matching discourse antecedent.

Two experiments are described below which aim to explore the application and timing of condition B during L1 and L2 sentence processing using eye-movement monitoring during reading. To obtain information about participants' ultimate interpretation preferences, the two online reading experiments are complemented by an offline antecedent choice task (Experiment 1). Our first eye-movement experiment (Experiment 2) examines readers' processing of canonical condition B sentences such as (1) above, while Experiment 3 examines online pronoun resolution in SDP environments such as (2). Experiments 2 and 3 were run concurrently during the same experimental session. All experimental sentences contained one pronoun and two potential antecedents, local and non-local.

The following specific questions will be explored:

- Does condition B immediately exclude inaccessible antecedents from the candidate set?
- Does the order/timing of considering the two antecedents differ according to whether or not condition B applies?
- Are there any L1/L2 differences in the application of condition B?

We begin by reporting the results from the offline questionnaire study.

MATERIALS AND METHODS, EXPERIMENT 1

The purpose of Experiment 1, an offline antecedent choice task, was to examine the offline antecedent choices of L1 and L2 participants in the two different syntactic environments under investigation, in the absence of any time pressure. This is especially important for the SDPs because they are thought to be ambiguous.

PARTICIPANTS

The L1 group comprised 83 participants, all of whom reported that they were native speakers of English (33 males, mean age 40 years, range 19–72 years). They were recruited via email and word of mouth to people who were known to be native speakers of English, and through an advertisement on an English-language forum on the internet. The L2 group comprised 35 native German-speaking students at the University of Potsdam (10 males, mean age 22.2, range 19–37 years) who had learned English as their second language at school [4] . All L2 speakers participated in a subpart of the grammar section of the Oxford Placement Test (OPT; Allan, 2004). Their mean score was 39/50 (*proficient*), range 30–48 (*lower intermediate* to *expert user*).

MATERIALS

The materials were ten sentences in which pronoun interpretation was constrained by condition B such as (5) below, and ten sentences containing SDPs such as (6).

(5) The boy remembered that Matthew had bought him a new computer game.
(6) Harry heard William pull the curtain around him in the quiet hospital ward.

The critical sentences all contained a direct object pronoun and two potential antecedents which matched the pronoun in gender. In (5), the local antecedent *Matthew* is ruled out by condition B, whereas in (6), it should be possible for the pronoun to be linked to either the non-local antecedent (*Harry*) or the local one (*William*). Within each experimental condition an equal number of masculine and feminine pronouns was used. We also took care to create scenarios in which the local and the non-local antecedent were equally plausible as antecedents for the pronoun.

The experimental sentences were mixed and pseudo-randomized with 22 filler sentences containing ambiguous or unambiguous pronouns and reflexives in different syntactic environments, yielding a total of 42 items.

PROCEDURE

The questionnaire was administered via the internet using SurveyGizmo (surveygizmo.com). The L1 group completed the questionnaire remotely. The L2 participants completed the questionnaire as part of the experimental session for online Experiments 2 and 3, after they had finished the online element. Because the experimenters had less direct control over the conditions in which the L1 participants did the questionnaire, a larger number of L1 participants were included to increase the reliability of the responses[5] .

All participants were instructed to read each sentence carefully and decide who the pronoun probably referred to. The use of *probably* takes account of the fact that another interpretation is possible, although unlikely. After each sentence the same question appeared: "Who does [pronoun] refer to?" In each case participants were given three choices as in (7) below.

(7) The boy remembered that Matthew had bought him a new computer game. *Who does "him" refer to?*

- The boy
- Matthew
- Either

[4]The reason for the larger number of participants in the L1 group compared to the L2 group is discussed in the "procedure" section.

[5]Additionally, responses of both L1 and L2 participants to unambiguous filler items were checked to ensure that the participants had understood the task. The percentage of correct answers was 98% for the L1 and 93% for the L2 group.

The order of the two antecedent responses was varied throughout the questionnaire, and the *either* option always appeared at the bottom.

RESULTS, EXPERIMENT 1

One item was removed from the analysis of the condition B sentences because it could be construed as being ambiguous. **Figures 1**, **2** show the percentage of responses to the canonical condition B structures and the SDP structures, for each group.

For the canonical condition B structures (**Figure 1**), the preference for the non-local (accessible) antecedent is very clear in both groups; they both chose this option above 90% of the time (L1 98%, L2 91%). A 3 × 2 ANOVA with an appropriate logistic transformation (Agresti, 2002) of the response rates of each type (*non-local*, *local*, and *either*) showed a main effect of antecedent choice [$F_{1(2,\ 232)} = 2110.3$, $p < 0.0001$; $F_{2(2,\ 32)} = 349.2$, $p < 0.0001$] and an interaction between antecedent choice and group [$F_{1(2,232)} = 19.4$, $p < 0.001$; $F_{2(2,\ 32)} = 49.6$, $p < 0.001$]. The L1 group chose the *non-local* response more often than the L2 group [$t_{1(116)} = 5.3$, $p < 0.001$; $t_{2(16)} = 19.8$, $p < 0.001$]. Nevertheless, within-group *t*-tests confirmed that in both groups the percentage of *non-local* responses was significantly higher than that of *local* responses [L1: $t_{1(82)} = 55.8$, $p < 0.001$; $t_{2(8)} = 20.8$, $p < 0.001$; L2: $t_{1(34)} = 18.5$, $p < 0.001$; $t_{2(8)} = 12.2$, $p < 0.001$] and *either* responses [L1: $t_{1(82)} = 68.8$, $p < 0.001$; $t_{2(8)} = 21.4$, $p < 0.001$; L2:$t_{1(34)} = 26.9$, $p < 0.001$; $t_{2(8)} = 9.1$, $p < 0.001$].

Compared to the canonical condition B structures, for the SDP structures (**Figure 2**) there was more variability in the two groups' responses. There was a numerical preference in both groups for choosing the *either* response indicating that the pronoun was ambiguous (L1 60%; L2 43%). A 3 × 2 ANOVA showed a main effect of antecedent choice [$F_{1(2,\ 232)} = 24.0$, $p < 0.0001$; $F_{2(2,\ 36)} = 16.7$, $p < 0.0001$] and an interaction between antecedent choice and group [$F_{1(2,232)} = 6.6$, $p < 0.01$; $F_{2(2,\ 36)} = 4.1$, $p < 0.05$]. For the L1 group the *either* option was chosen significantly more often than both the *local* response [$t_{1(82)} = 7.3$, $p < 0.001$; $t_{2(9)} = 6.1$, $p < 0.001$] and the *non-local* response [$t_{1(82)} = 6.6$, $p < 0.001$; $t_{2(9)} = 4.3$, $p < 0.01$]. For the L2 group the *either* response was chosen significantly more often than the *local* response [$t_{1(34)} = 2.2$, $p < 0.05$; $t_{2(9)} = 3.9$, $p < 0.01$] but not significantly more than the *non-local* response [$t_{1(34)} = 0.4$, $p = 0.6$; $t_{2(9)} = 1.2$, $p < 0.2$]. When the *either* option was not chosen, the L1 group chose the local and non-local antecedent at roughly the same rate (18 and 22% respectively); a *t*-test showed no significant difference between these two response rates [$t_{1(82)} = 2.0$, $p = 0.5$; $t_{2(9)} = 0.3$, $p = 0.7$]. The L2 group, however, chose the non-local antecedent more often than the local antecedent (34 and 21% respectively), a difference which proved (marginally) significant in a *t*-test [$t_{1(34)} = 2.7$ $p < 0.01$; $t_{2(9)} = 2.1$, $p = 0.063$]. There was a significant negative correlation between participants' OPT scores and *non-local* antecedent choice rates for the SDP structures [$r_{(35)} = -0.35$, $p < 0.05$], however, no participant categorically chose *non-local* responses.

EXPERIMENT 1 SUMMARY

Participants' responses to the canonical condition B structures were highly consistent for both groups. While participants in the L1 group were overall more likely than those in the L2 group to choose the non-local antecedent, there was an overwhelming preference for the non-local antecedent in both groups, almost to the exclusion of any other response. This demonstrates that both L1 and L2 speakers are fully aware of the inaccessibility of the local antecedent, although the L1 group demonstrated more certainty than the L2 group. Participants' responses to the SDP structures were quite different, with the pronoun's ambiguity reflected in their antecedent choices. Both groups chose *either* at the highest

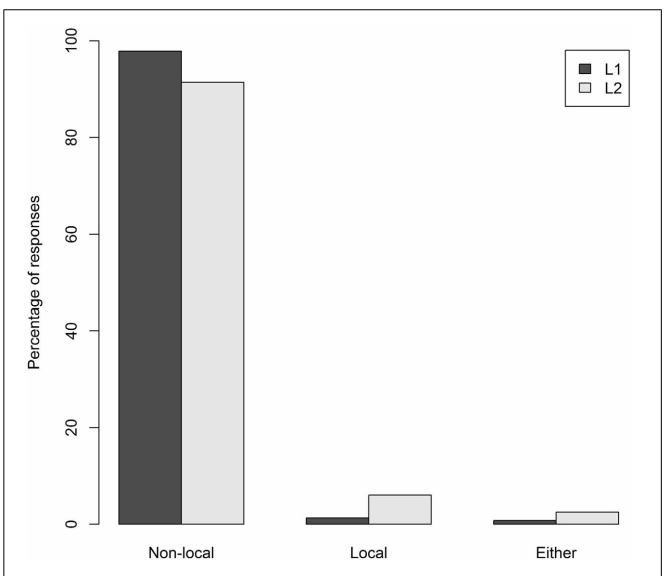

FIGURE 1 | Percentage of responses per group to the canonical condition B structures.

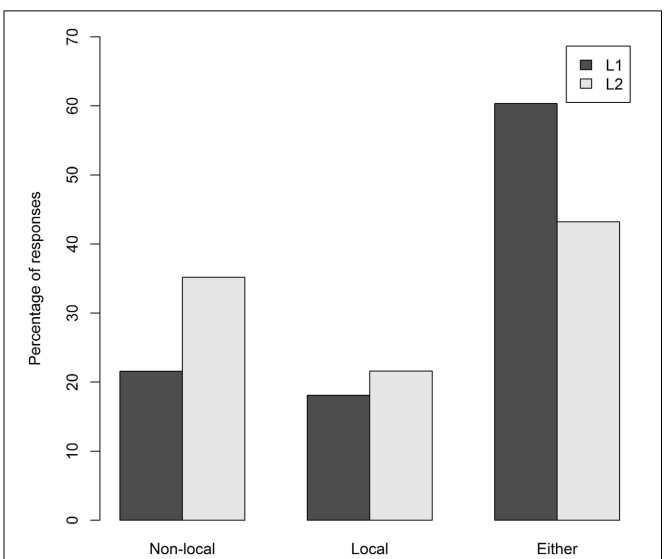

FIGURE 2 | Percentage of responses per group to the SDP structures.

rate, although the L2 group's rate of *either* responses was not significantly higher than their non-local responses. When choosing one particular antecedent (instead of the *either* option), the L1 group did not show a preference for either the local or non-local antecedent, whereas the L2 group displayed a slight preference for the non-local antecedent. This preference was related to OPT score; the lower a participant's OPT score, the more likely they were to choose the *non-local* referent. This may suggest that awareness of the ambiguity of SDPs increases with knowledge of English [6] . Taken together, the responses show that participants responded in line with condition B where appropriate, and displayed awareness of the ambiguity of SDPs.

MATERIALS AND METHODS, EXPERIMENT 2

Experiment 2 was designed to investigate the online application of condition B in sentences where only the local antecedent was accessible. We specifically sought to investigate whether L1 and/or L2 comprehenders would experience interference from the inaccessible antecedent at any point during processing.

PARTICIPANTS

The L1 participants were 34 native speakers of English (11 males) who were recruited from the University of Essex (UK) and the surrounding community. Their mean age was 25.9 (range: 18–54), and all confirmed that English was their first language. The L2 group consisted of 34 of the 35 native German speakers who took part in Experiment 1 (10 males, mean age 22.8, range 19–37), all of whom had learned English as their second language at school starting at the age from 5 to 13 (mean: 9.6, *SD*: 1.7). Their mean OPT score was 39/50 (*proficient*), range 30–48 (*lower intermediate* to *expert user*). All participants were paid for their participation, and all had normal or corrected-to-normal vision.

MATERIALS

Twenty-four experimental items were constructed. They were composed of three sentences: a lead-in sentence, a critical sentence that contained the pronoun and two potential antecedent NPs that were both proper names, and a wrap-up sentence. The gender match between the two names and the pronoun was manipulated to create three experimental conditions as shown in (8a–c) below[7] .

(8) Band practice was beginning to get rather dull.

(a) *Double match condition*
John remembered that Mark had taught him a new song on the guitar.

(b) *Local mismatch condition*
John remembered that Jane had taught him a new song on the guitar.

(c) *Non-local mismatch condition*
Jane remembered that John had taught him a new song on the guitar.
That really lifted everyone's spirits!

The names were matched in letter and syllable length, and were either typical male or typical female names (i.e., names that are not normally used for both genders). The names were counterbalanced across items to control for any potential frequency effects. The first name (the non-local antecedent) was always the main clause subject and was an accessible antecedent by virtue of being outside the local binding domain. The second name (the local antecedent) was always the subject of an embedded complement clause and a coargument of the pronoun. It was thus an inaccessible antecedent for the pronoun according to condition B. Half the pronouns were masculine and half feminine, and they were always object pronouns.

The experimental items were distributed across three presentation lists using a Latin-square design, and mixed and pseudo-randomized with 18 experimental items from Experiment 3 (described below) and 44 additional filler items, resulting in 86 items per list in total. The set of fillers included eight pseudo-fillers which were structurally similar to the experimental items but contained reflexive rather than non-reflexive pronouns, and another eight in which the structurally illicit antecedent for the pronoun was placed first. This was to ensure that participants were exposed to enough items that were similar to the experimental items but different in crucial factors (type of referring expression and position of the antecedent), to prevent them from developing expectations about the pronoun–antecedent relationships under investigation. Binary yes/no comprehension questions followed two thirds of the 86 items in each list, including the experimental items, to ensure that participants were paying attention and reading the items properly. A few of the comprehension questions following filler items directly probed the referent of a pronoun, to encourage participants to fully process the pronouns that they read. The experiment began with the presentation of six practice items to familiarize participants with the procedure, two of which were followed by a question.

PREDICTIONS

In the light of the different proposals regarding the primacy of condition B during processing, the following predictions can be made.

BAIF hypothesis

If structural information helps to rule out inaccessible antecedents at an early point, only the accessible (non-local) antecedent should be considered. This predicts that there will be a slow-down in reading times in condition (8c) (non-local mismatch) compared to the other two conditions. In addition, because the inaccessible antecedent is excluded from consideration on structural grounds, there should be no difference between condition (8a) (double match) and (8b) (local

[6] We remain cautious about this observation, firstly because of the limited range of the OPT scores, and secondly because the OPT gives placement scores (sufficient to demonstrate that all L2 participants were competent in English), rather than a direct and thorough measure of proficiency. Additionally, we did not set out to test the effect of proficiency here, and have made no specific predictions.

[7] A potential fourth condition in which neither name matched the pronoun in gender was not included in order to avoid presenting participants with too many unresolvable pronouns, which could have drawn their attention to the pronouns and encouraged strategic reading behavior. This is also the case for the materials of Experiment 3.

mismatch) because participants should not be sensitive to the gender of the inaccessible antecedent.

Defeasible filter hypothesis

Following Sturt's (2003) results for reflexives, it is possible that binding conditions act early to include or exclude certain antecedents, but the inaccessible antecedents are considered at a later point of processing. The defeasible filter account therefore predicts longer reading times for condition (8c), followed later by effects of the inaccessible antecedent which could manifest as either longer reading times in condition (8b) or as a competition effect with differences between condition (8a) and the other two conditions.

Feature-match hypothesis

If condition B does not immediately overrule other cues, then processing should also be sensitive to the gender features of the inaccessible antecedent initially. Readers may only home in on the accessible (i.e., the non-local) antecedent at later processing stages or sentence regions. Following Badecker and Straub (2002), if all antecedents with matching morphosyntactic or semantic features are activated on encountering the pronoun, regardless of the structural accessibility of the antecedents, participants might experience "retrieval interference" (Gordon et al., 2001; Lewis and Vasishth, 2005; Van Dyke, 2007) indexed as increased reading times when both antecedents match the pronoun in gender (condition 8a) compared to when only a single antecedent matches (conditions 8b and 8c).

PROCEDURE

The experimental and filler items were pseudo-randomized such that no two experimental items appeared adjacent to each other and were spread across three presentation lists in a Latin-square design. The experiment was divided into three blocks at which point participants could take a break if required. Forward and reverse orders of each list were constructed.

All items were presented in Courier New font (size 18), and displayed across up to three lines of text onscreen. Text was displayed in black on a white background. Eye movements were recorded using the EyeLink 1000 system (SR Research Ltd) at 500 Hz. Using the desktop system, the camera was located below the screen and participants placed their heads on a chin rest that was adjusted to allow a comfortable position. The distance between the eyes and the camera was 60 cm and the distance between eyes and screen 70 cm. Viewing was binocular but only the right eye was recorded. Each experimental session began with calibration of the eye-tracker on a nine-point grid. Calibration was repeated during the session if the experimenter noticed that measurement accuracy was poor. Before each trial, the screen displayed a marker positioned above the first word of the next trial. Participants were instructed to fixate upon this marker, and press a button to view the next trial, in order to control the placement of the initial fixations.

Participants read each text silently at their normal reading rate, pressing a button on a game pad once completed and after content questions requiring a yes/no push button response. The experiment session lasted approximately 30–45 min in total for L1 speakers. For the L2 participants the experiment took about 60 min because of the additional OPT, questionnaire (Experiment 1) and vocabulary test after the experiment. The vocabulary test consisted of a checklist containing all critical vocabulary items, and the learners were asked to read through the list carefully and circle any words that they were unfamiliar with.

The research was approved by the Ethics Committee of the University of Essex (L1, March 2011) and the ethics committee of the University of Potsdam (L2, application number 37/2011). Informed consent was obtained from all participants.

DATA ANALYSIS

Reading times for four regions of text are reported: the pronoun region, which contains the pronoun and the last three letters of the preceding word; the spillover region, which contains the two words following the pronoun [e.g., *a new* in (8a–c) above]; the next two words as the prefinal region [e.g., *song on* in (8a–c) above]; and the last two words of the sentence as the final region. For the statistical analysis, all reading time measures were log-transformed [$\log_e(x+1)$].

Five reading time measures will be reported for these regions. First fixation is the duration of readers' initial fixation within an interest area; first-pass reading time is the summed duration of fixations within an interest area until it is exited to either the left or the right for the first time; regression path time is the sum of all fixations on a region until this region is exited to the right; rereading time is the summed duration of all fixations in a region after it was first exited to either the left or right; and total viewing time is the summed duration of all fixations within a region. Reading times for trials in which track loss occurred, and reading times in regions which were initially skipped, were treated as missing data. For rereading time, trials in which a region was not refixated after the first-pass contributed a rereading time of zero to the calculation of averages.

Short fixations of 80 ms or below within one degree of visual arc of another fixation were automatically merged, and any other extremely short ($\leq$80 ms) or long ($>$1200 ms) fixations were removed. To explore whether the two participants groups patterned differently statistically, we carried out preliminary 3 × 2 ANOVAs with the factors Condition (*double match, local mismatch, non-local mismatch*) as within-subjects factor and Group (*L1, L2*) as a between-subjects factor, for each measure and interest region. Where interactions with the factor Group were found, the data from each group were analyzed separately[8].

RESULTS, EXPERIMENT 2

L1 participants answered 88% of the end-of-trial comprehension questions correctly and the L2 participants 86% overall, indicating that both groups paid attention to the task and read the stimulus items for meaning. Track loss accounted for 0.2% of the L1 and 0.13% of the L2 data. Skipping rates for the four reported

[8]Trials for which (L2) participants had indicated unknown vocabulary were not removed from the analysis reported here. A parallel analysis with unknown vocabulary trials excluded showed that excluding these did not affect the results.

regions were 25, 13, 11, and 6% in the L1 group and 9, 2, 4, and 0% in the L2 group.

Summaries of participants' reading times and of the ANOVA results are provided in **Tables 1**, **2** respectively. Results of subsequent pairwise comparisons are summarized in **Table 3**.

First-fixation durations, first-pass times and regression-path times in the region prior to the pronoun were also examined in order to check whether any effects of condition began before the pronoun was encountered. This precritical region consisted of the word before the pronoun (excluding the final three letters, which forms part of the pronoun region), and the previous word which was always an auxiliary verb. Skipping rates in this region were 11% for the L1 group and 2% for the L2 group. No effects of Condition, or Condition by Group interactions, were found in first-pass times or regression-path times. First-fixation durations did show a main effect of Condition (marginal in the F_2 analysis): [$F_{1(2,\ 132)} = 3.89$, $p < 0.05$; $F_{2(2,\ 46)} = 2.47$, $p = 0.09$.] Pairwise comparisons revealed that first-fixation durations were significantly longer in the local mismatch condition (8b) compared to the double match condition (8a) [$t_{1(67)} = 2.79$, $p < 0.05$; $t_{2(23)} = 2.26$, $p < 0.05$] and (marginally) longer than the non-local mismatch condition (8c) [$t_{1(67)} = 1.85$, $p = 0.07$; $t_{2(23)} = 2.12$, $p < 0.05$]. This effect is very fleeting, and is in a different direction from the effects seen at and beyond the pronoun region. It will therefore not be discussed any further.

PRONOUN REGION

Significant or partially significant main effects of Group were seen in all eye-movement measures, reflecting the fact that the L2 participants read the stimulus sentences generally more slowly than the L1 group. No main effects of, or interactions with, the factor Condition were found for first fixation durations or first-pass reading times. For both participant groups, regression path, rereading and total viewing times were longest in the non-local mismatch condition (8c), where the pronoun mismatched the accessible antecedent's gender, however. Significant main effects of Condition, unmodulated by the factor Group, were found for rereading and total viewing times. Subsequent *t*-tests on the collapsed L1 and L2 data confirmed that the pronoun region was reread significantly more slowly in the non-local mismatch condition (8c) compared to both the local mismatch (8b) and the double match condition (8a). The same statistical pattern was found for total viewing times.

SPILLOVER REGION

A similar pattern was seen at the spillover region. Main effects of Group were present in all measures other than rereading time. Both groups again showed the longest reading times in the non-local mismatch condition in regression path, rereading and total viewing times, giving rise to significant main effects of Condition unmodulated by the factor Group. Subsequent pairwise comparisons confirmed that in all three of these measures, the non-local mismatch condition elicited significantly longer reading times than the double match and local mismatch conditions.

The L2 group differed from the native readers in that the above reading-time pattern was also seen, numerically, in the L2 readers' first fixation durations and first-pass times at the spillover region. A Group by Condition interaction was found for first fixation durations that was significant by subjects only. To further explore this interaction, separate one-way ANOVAs for each group (L1 and L2) were carried out. These showed a significant effect of Condition for the L2 [$F_{1(2,\ 66)} = 3.81$, $p < 0.05$; $F_{2(2,\ 46)} = 5.02$,

$p < 0.05$] but not for the L1 group [$F_{1(2,\ 66)} = 0.76$, $p = 0.47$; $F_{2(2,\ 46)} = 0.29$, $p = 0.75$]. In the L2 group first fixation durations were marginally longer, by items, in the non-local mismatch condition (8c) compared to the double match condition (8a) [$t_{1(33)} = 1.69, p = 0.10$; $t_{2(23)} = 2.61, p < 0.05$] and significantly longer compared to the local mismatch condition (8b) [$t_{1(33)} = 2.56, p < 0.05$; $t_{2(23)} = 2.68, p < 0.05$].

PREFINAL AND FINAL REGIONS

Main effects of Group were again seen at the prefinal and final regions, alongside main effects of Condition not modulated by Group. In the prefinal region significant condition effects were found in regression path and total viewing times, with the effect significant by subjects only in rereading times. Pairwise comparisons once again revealed significant differences between the non-local mismatch condition (8c) and both the double match (8a) and the local mismatch condition (8b) for regression path, rereading and total viewing times. In the final region there was a main effect of condition in the regression-path times (also a main effect significant by subjects in rereading times). Pairwise comparisons again revealed significant differences between the non-local mismatch condition (8c) and both the double match (8a) and the local mismatch condition (8b) for regression path times, with marginal differences in the same direction for rereading times.

SUMMARY, EXPERIMENT 2

In Experiment 2 the two participant groups patterned largely alike. Participants showed sensitivity to gender-mismatching non-local (i.e., accessible) antecedents but not to mismatching local (i.e., inaccessible) antecedents. These non-local mismatch effects were generally restricted to later reading-time measures, including total viewing times, with the exception of the L2 group's first fixation durations at the spillover region. This relatively minor between-groups difference might be due to the non-native readers' generally more "serial" reading strategy (as reflected by their lower skipping rates). Participants showed no evidence of considering the local antecedent at any point during processing, a finding that is consistent with the BAIF hypothesis.

The accessible-mismatch effects we observed are also in line with the results from the offline antecedent choice task, where both participant groups consistently chose the non-local antecedent.

The predictions of the defeasible filter hypothesis are not borne out here, because there is no evidence that either group considered the inaccessible antecedent at a later point during processing.

Note, however, that it is theoretically possible that the non-local mismatch effects seen in Experiment 2 reflect a general preference for matrix subject antecedents rather than the application of condition B. Examining the processing of SDPs should be able to confirm or rule out this hypothesis. It also allows us to see whether feature matching plays a more important role in L1 and/or L2 processing in the absence of a structural constraint which rules out one of the antecedents.

MATERIALS AND METHODS, EXPERIMENT 3

Our second eye-movement experiment examined the real-time processing of pronouns believed to be exempt from condition B.

Recall that in the offline task (Experiment 1), both L1 and L2 participants showed awareness of the ambiguity of SDPs. However, in cases where one specific antecedent was chosen, L2s preferred the non-local antecedent whereas for L1s there was no preference. Online, will L1 and L2 participants show sensitivity to the gender of the local or non-local antecedent, or both antecedents?

PARTICIPANTS

These were the same as in Experiment 2.

MATERIALS

The materials for this experiment included 18 experimental items which were again composed of three sentences each, a lead-in sentence, a critical sentence that contained the pronoun and two potential antecedents, and a wrap-up sentence. The gender match between the two names and the pronoun was manipulated to create three conditions as illustrated in (9a–c).

(9) Suddenly the lights went on and there were police everywhere.

(a) *Double match condition*
Barry saw Gavin place a gun near him on the ground with great care.

(b) *Local mismatch condition*
Barry saw Megan place a gun near him on the ground with great care.

(c) *Non-local mismatch condition*
Megan saw Barry place a gun near him on the ground with great care.

The robbery was definitely over now.

The names were again matched in letter and syllable length, were either typical male or typical female names, and were counterbalanced across the items. Half the pronouns were masculine and half feminine. As in the materials for Experiment 2, the first name (the non-local antecedent) was always the matrix subject. The second name (the local antecedent) was always the subject of an infinitival complement of a perception verb. Unlike in Experiment 2, the pronoun here appeared inside a prepositional phrase and thus was not a coargument of the local antecedent.

PREDICTIONS

Since SDPs are thought to be ambiguous and exempt from condition B, the predictions for Experiment 3 differ somewhat from those for Experiment 2 above.

Matrix-subject preference

If the parser initially searches for the matrix subject (i.e., the non-local antecedent), longer reading times are expected in the non-local mismatch condition (9c) compared to the other two conditions, similar to the results from Experiment 2.

Feature-match hypothesis

Where condition B does not rule out the local antecedent, the parser may be sensitive to gender mismatches between the pronoun and either or both potential antecedents. Participants might experience interference or competition when both antecedents match the pronoun in gender (condition 9a) compared to when only a single antecedent matches (conditions 9b and 9c), which would be reflected in longer reading times for the double-match condition (9a) compared to the two mismatch conditions.

Previous research on SDPs suggests that L1s are sensitive to their ambiguity in online processing tasks (Sekerina et al., 2004). For L2s there is evidence from eye-movement experiments on reflexives which indicates that they prefer linking these to the most discourse-prominent antecedent initially (Felser and Cunnings, 2012). In the light of these findings, we may expect the L2 group to show a different processing pattern from the L1 group here. While L1s might fail to show a clear antecedent preference for SDPs, or may be slowed down by antecedent competition in condition (9a), the non-native group might try to link SDPs to the matrix subject, giving rise to non-local gender mismatch effects.

PROCEDURES

The experimental, data cleaning and data analysis procedures for Experiment 3 were the same as in Experiment 2.

RESULTS, EXPERIMENT 3

Responses to the comprehension questions are reported in the Results section for Experiment 2. As for Experiment 2, we will report statistical analyses for four sentence regions. The pronoun region contained the pronoun and the last three letters of the preceding preposition, the spillover region contained the two words (e.g., *on the*) immediately following the pronoun, the prefinal region two words (e.g., *ground with*) following the spillover region and the final region the final two words of the sentence. Skipping rates for these regions were 11, 20, 9, and 20% in the L1 group and 5, 4, 2, and 5% in the L2 group.

Table 4 provides an overview of the reading time data and **Table 5** shows the between-groups ANOVA results of the log-transformed data in Experiment 3.

As for Experiment 2, a precritical region was examined in order to check whether any effects of condition began before the pronoun was encountered. This consisted of the preposition preceding the pronoun (excluding the final three letters) and the previous one or two words forming the object of the second verb. Skipping rates in this region were 5% for the L1 group and 1% for the L2 group, No effects of Condition, or Condition by Group interactions, were found in first-fixation durations, first-pass times or regression-path times.

PRONOUN REGION

At the pronoun region the native readers showed the longest regression path, rereading and total viewing times for the local mismatch condition (9b) numerically, whereas the L2 group consistently showed the longest reading times for the non-local mismatch condition (9c). No significant main effects or interactions (other than main effects of Group in all measures except rereading times) were found at this region, however.

SPILLOVER REGION

At the two words following the pronoun, main effects of Group were once again seen in all measures except rereading times. The L2 group—but not the L1 group—again showed the longest reading times in the non-local mismatch condition (9c) in all

five eye-movement measures numerically. The initial omnibus ANOVA revealed a main effect of Condition in first fixation durations, as well as significant Group by Condition interaction in regression path times in the analysis by subjects. Marginal interactions, by subjects only, were also found for rereading and total viewing times. As the observed (marginal) interactions, in the presence of significant main effects of Group, are indicative of between-group differences, we went on to analyze each group's reading-time data for the spillover region separately. Whilst the L1 group showed no significant effects at this region, the L2 group showed a significant main effect of Condition for first fixation durations [$F_{1(2,\ 66)} = 4.82$, $p < 0.05$; $F_{2(2,\ 34)} = 5.41$, $p < 0.01$] and significant effects, in the analyses by subjects, for regression path [$F_{1(2,\ 66)} = 5.46$, $p < 0.01$; $F_{2(2,\ 34)} = 2.97$, $p = 0.06$] and total viewing times [$F_{1(2,\ 66)} = 5.67$, $p < 0.01$; $F_{2(2,34)} = 3.22$, $p = 0.05$]. Planned pairwise comparisons showed that the non-local mismatch condition (9c) was read significantly more slowly than both the double match (9a) [$t_{1(33)} = 3.08$, $p < 0.01$; $t_{2(17)} = 2.73$, $p < 0.05$] and the local mismatch (9b) conditions [$t_{1(33)} = 2.36$, $p < 0.05$; $t_{2(17)} = 2.57$, $p < 0.05$] in first fixation durations, significantly more slowly (by subjects) than the double match condition in regression path [$t_{1(33)} = 3.34$, $p < 0.01$; $t_{2(17)} = 2.06$, $p = 0.05$] and total viewing times [$t_{1(33)} = 3.10$, $p < 0.01$; $t_{2(17)} = 1.95$, $p = 0.07$], and significantly more slowly than the local mismatch condition in total viewing times [$t_{1(33)} = 2.87$, $p < 0.01$; $t_{2(17)} = 2.13$, $p < 0.05$].

PREFINAL AND FINAL REGIONS

No significant effects or interactions, other than main effects of Group, were found at the prefinal region. At the final sentence region, interactions between Condition and Group were observed for both rereading times (marginal by items) and total viewing times. Here the L1 group showed the longest reading times for the local mismatch condition (9b) in these measures, whereas the L2 group again had longer reading times for the non-local mismatch (9c) than for the other two conditions. Subsequent per-group analyses only yielded a marginally significant main effect of Condition for the L1 group's total viewing times [$F_{1(2,\ 64)} = 2.98$, $p = 0.06$; $F_{2(2,\ 34)} = 2.5$, $p = 0.09$], and a marginal one in the by-items analysis for the L2 group's rereading times [$F_{1(2,\ 66)} = 2.46$, $p = 0.09$; $F_{2(2,\ 34)} = 0.85$, $p = 0.43$], however.

CORRELATION OF READING TIMES WITH OPT SCORE AND OFFLINE CHOICES

To investigate whether, for the L2 participants, the slower reading times in the non-local mismatch condition in the spillover region (9c) originate from a lack of knowledge about SDP structures among those participants with lower OPT scores, both OPT score and offline antecedent choice rates from Experiment 1 were correlated against reading times[9]. The difference between mean total viewing time in conditions (9b) and (9c) in the spillover region was calculated per participant as a measure of an individual's processing difficulty on encountering a mismatching non-local antecedent. However, there was no significant correlation between this reading measure and either OPT score [$r_{(34)} = -0.14$, $p = 0.4$] or antecedent choice rates [$r_{(34)} = 0.03$, $p = 0.8$].

SUMMARY, EXPERIMENT 3

In Experiment 3 we saw differences between the L1 and L2 groups' reading-time patterns, in particular in the spillover region. In the

[9]We thank the reviewers for this suggestion.

pronoun region, the trend in the L1 data was for increased reading times in the local mismatch condition (9b) while the L2 trend was for increased times in the non-local mismatch condition (9c). Although these different patterns did not yield statistically reliable between-groups differences in the pronoun region, they gave rise to some interactions with the factor Group in later regions. In the spillover region the L1s showed no significant differences between the experimental conditions whilst the L2s showed increased reading times for the non-local mismatch condition (9c), indicative of trying to link the pronoun to the matrix subject. Analysis of the L1 data in the final region revealed a trend toward longer total viewing times in the local mismatch condition (9b). In the following section, the results from Experiment 3 will be discussed together with those from Experiments 1 and 2.

DISCUSSION

We set out to investigate the application and timing of condition B during L1 and L2 processing of English pronouns. Firstly, we discovered that both L1 and L2 groups were sensitive to the gender of the accessible antecedent online. There was an increase in reading times when the non-local (accessible) antecedent mismatched the pronoun's gender in canonical condition B environments. Secondly, we discovered that when both antecedents were structurally available (in SDP environments), L2s were again sensitive to the gender of the non-local antecedent (which was the matrix subject) while L1s experienced some difficulty with the local mismatch condition.

STRUCTURAL SENSITIVITY

Results from the offline questionnaire (Experiment 1) revealed that both the L1s and L2s ignored an inaccessible but gender-matching antecedent and instead chose the accessible antecedent almost exclusively, in line with condition B. This offline adherence to condition B was also reflected online in both groups, who showed longer reading times in the non-local mismatch condition in Experiment 2. This indicates a higher processing cost when the available antecedent mismatched in gender with the pronoun. No measurable processing cost was elicited by a mismatching inaccessible antecedent at any point, indicating that the inaccessible antecedent was not considered[10] . Furthermore, the results from Experiment 3 for the L1 group suggest that there may be no general preference for the first-mentioned antecedent, so it is unlikely that the Experiment 2 results were driven by such an underlying preference. These findings are line with the BAIF hypothesis, in which condition B gates access to the potential antecedents by filtering out structurally inaccessible ones. As such it adds to the evidence gained from the self-paced reading studies of Clifton et al. (1997, 1999), as well as self-paced reading and eye-tracking evidence from Chow et al. (in preparation). Because of the sensitivity of the eye-movement monitoring technique used in the current experiments, the evidence here suggests that previous support for the BAIF is not simply due to a less sensitive time measure which failed to pick up on short-lived, early effects.

The L1 data from Experiment 3 showed a trend for late processing difficulty in the local-mismatch condition, although this did not prove statistically reliable. This might nevertheless suggest that, while the native readers were largely unaffected by our manipulations of gender congruence between the pronoun and the potential antecedents, they had a weak preference for a local antecedent online. No such preference was visible in the L1 group's offline data, however. In the SDP environments both of the antecedents were accessible, and all experimental conditions contained at least one gender-matching accessible antecedent. This may explain the relative lack of any condition-specific processing difficulty in comparison to the condition B environments. The fact that the SDP items were processed differently despite being presented in same experimental session as the condition B items highlights that the L1 parser was sensitive to the subtle syntactic cues which distinguish SDP environments from those in which condition B applies.

TIMING

With respect to timing, it should first be noted that the L2 group showed sensitivity to our experimental manipulation in an earlier measure than did the L1 group in Experiment 2 (first fixation durations at the spillover region). In fact, the timing of the non-local mismatch effect in this experiment for the L1 group appears to be fairly late, appearing only in rereading times. The emergence of the L1 effect in rereading times could be due to a rapid reading strategy leading to fewer fixations and longer saccades, but increased regressive eye-movements in case of difficulty. In contrast, the L2s read more slowly, spending more time in each region. These differences in reading style might explain the seemingly earlier effects in the L2 group compared to the L1 group.

The timing of the effect in L1s, however, still stands in contrast to findings for inaccessible mismatch effects in previous (L1) studies with reflexives (e.g., Sturt, 2003). The comparison with reflexive studies is speculative because reflexives were not systematically tested in the current study. However some further consideration should be given to timing, since the study employs a method that is particularly sensitive to timecourse. It cannot be assumed that early and late reading measures are necessarily linked to distinct cognitive processes (see Pickering et al., 2004 for a discussion). As such, the effects in the rereading times could be behavioral echoes of much earlier processes. Even so, a later effect for pronouns fits in well with two considerations: first, pronouns are sensitive to a range of cues or information types which can help to determine their reference, so considering all these information sources may require more time; second, the nature of condition B, unlike condition A for reflexives, involves excluding rather than identifying an antecedent, and may require the generation of more than one semantic sentence representation (Reuland, 2001, 2011) or the consideration of pragmatic information (Huang, 1994).

[10]However, it should be noted that a previous analysis of the Experiment 2 data, in which the pronoun region contained only the pronoun itself, the L2 group did appear to be briefly distracted by a gender-matching, inaccessible antecedent. Following a reviewer's suggestion, this analysis was replaced due to high skipping rates and the resultant loss of data.

L1 vs. L2 PROCESSING

The L2 group showed a very similar pattern of results to the L1 group in Experiment 2, but a different pattern of results from the L1 group in Experiment 3. Although the results of Experiment 2 suggest that L2s do rule out the inaccessible antecedent in accordance with condition B (like the L1 group), results from Experiment 3 for the L2 group call this into question. In Experiment 3, the L2 participants were again sensitive to the gender of the non-local antecedent, despite their awareness of the ambiguity in the offline task (Experiment 1). This means that their sensitivity to the non-local antecedent in Experiment 2 may not be a result of applying condition B, but could instead be a general preference to link the pronoun to the matrix subject, even though offline the L2s show awareness of the ambiguity of the SDPs. This suggests firstly that L2s are less sensitive than L1s to the subtle syntactic cues that differentiate the SDP environments from the canonical condition B environments. Secondly, they appear to have a general preference for salient subjects, which may have driven the non-local mismatch effect for L2s in both Experiments 2 and 3. The discrepancy between L2s' offline knowledge and their use of this knowledge during online processing has been observed in previous studies, as well as a preference for (discourse-) salient antecedents (Felser and Cunnings, 2012 for reflexives). This finding is consistent with the hypothesis that L2 speakers tend to underuse structural information during processing and rely more on other cues such as discourse-level information instead (Clahsen and Felser, 2006).

A reviewer raises the question of whether the German participants' preference for non-local antecedents in Experiment 3 might reflect L1 transfer. Similar SDP configurations to those tested here also exist in German. To find out which, if any, antecedent native German readers might prefer online, we carried out a parallel eye-movement study on German (as yet unpublished). While L1 German readers showed an offline preference for the non-local antecedent, their reading-time patterns look similar to those of the native English group in the current study in that they did not show any measurable preference for either the local or non-local antecedent. The double-match condition tended to be the shortest one instead, a pattern that proved statistically significant only for total viewing times at the spillover region, however. This makes it unlikely that our Experiment 3 results reflect L1 transfer from German[11].

IMPLICATIONS FOR ANTECEDENT SEARCH MECHANISMS

The predictions of the BAIF hypothesis for pronouns appear to be very similar to those of a structured search mechanism for reflexives (Dillon, 2011; Dillon et al., 2013). If readers show sensitivity to the conditions governing both reflexives and pronouns, can they be assumed to exploit the same search mechanism? This makes the assumption that condition B is purely a structural constraint, a proposal which is contested by several theoretical accounts. A purely structured search to eliminate an inaccessible antecedent may therefore be inadequate. Nevertheless, a model of memory search for pronouns must incorporate (i) the ability to exclude an inaccessible antecedent from consideration even when it carries features that match the pronoun, and (ii) awareness of explicitly structural cues that distinguish, for example, canonical condition B environments from SDP environments. It is clear that native speakers make use of this information during processing, and that it plays a decisive role during the consideration of potential antecedents.

A slightly different question is whether there is a strict ordering of constraint application, as Nicol and Swinney imply in their original formulation of their hypothesis:

> "…the reactivation of prior referents is restricted by grammatical constraints. In the case where such information does not sufficiently constrain the list of potential antecedents to a single one, the pragmatic and other sentence/discourse processing procedures undoubtedly come into play, but, given the present evidence, only at a later point in processing."
>
> (Nicol and Swinney, 1989, p.18)

While the lack of interference from an inaccessible antecedent seems to imply that binding conditions are applied before other cues such as gender features are recruited, there is as yet no firm evidence that discourse cues, for example, are systematically withheld relative to binding constraints in the time-course of pronoun resolution. Given that discourse cues are increasingly found to act early and even predictively (e.g., Koornneef and Van Berkum, 2006; Cozjin et al., 2011), further research on the interaction between condition B and the discourse status of antecedents would be welcome, to confirm or disconfirm a strict ordering of constraint application.

In addition, any model of the retrieval process should be able to incorporate the profiles of both native and non-native comprehenders. As far as the L2 processing is concerned, the current study shows that the processing of pronouns may be driven by a search for a salient subject, rather than making use of a detailed structural analysis to distinguish condition B and SDP environments; this is not the case for L1 processing. This demonstrates a different sensitivity to structural cues in the two populations; generalizing a retrieval or processing model so that it applies equally well to L1 and L2 pronoun resolution could perhaps be achieved by assigning differing constraint weights in different populations.

CONCLUSION

Native English speakers appear to successfully apply condition B online so that they do not consider an inaccessible antecedent at any point during processing, which is in line with the BAIF hypothesis. They are also sensitive to syntactic cues that distinguish syntactic environments that either require, or do not require, the exclusion of a local referent. By contrast, non-native speakers do not appear to distinguish condition B environments from SDP environments online, appearing to opt for salient subject antecedents in both despite offline awareness of the difference. The different processing profiles of native and non-native speakers must be incorporated into models of retrieval, with particular reference to the relative importance of structural cues for different populations.

[11]Note that in order to draw any meaningful conclusions about possible L1 transfer, learner groups from different L1 backgrounds would need to be compared.

ACKNOWLEDGMENTS

Part of this research was completed as part of Clare Patterson's PhD dissertation at the University of Potsdam. She was supported by an ESRC postgraduate studentship awarded by the Department of Language and Linguistics at the University of Essex, and by an Alexander-von-Humboldt-Professorship to Prof. Harald Clahsen (Potsdam Research Institute for Multilingualism), which is gratefully acknowledged.

Structural constraints on pronoun binding and coreference: evidence from eye movements during reading

Ian Cunnings[1]*, *Clare Patterson*[2] *and Claudia Felser*[2]

A number of recent studies have investigated how syntactic and non-syntactic constraints combine to cue memory retrieval during anaphora resolution. In this paper we investigate how syntactic constraints and gender congruence interact to guide memory retrieval during the resolution of subject pronouns. Subject pronouns are always technically ambiguous, and the application of syntactic constraints on their interpretation depends on properties of the antecedent that is to be retrieved. While pronouns can freely corefer with non-quantified referential antecedents, linking a pronoun to a quantified antecedent is only possible in certain syntactic configurations via variable binding. We report the results from a judgment task and three online reading comprehension experiments investigating pronoun resolution with quantified and non-quantified antecedents. Results from both the judgment task and participants' eye movements during reading indicate that comprehenders freely allow pronouns to corefer with non-quantified antecedents, but that retrieval of quantified antecedents is restricted to specific syntactic environments. We interpret our findings as indicating that syntactic constraints constitute highly weighted cues to memory retrieval during anaphora resolution.

Introduction

The successful interpretation of anaphoric elements during language comprehension involves forming dependencies between constituents that may span several words or sentences. Anaphora resolution thus provides a key test case for studying the memory system that subserves language comprehension, as the correct interpretation of anaphoric constituents crucially relies on the retrieval of a particular item, the antecedent, from memory. A growing number of studies have investigated how syntactic and non-syntactic factors combine to cue the retrieval of an antecedent during the resolution of different types of anaphora (Badecker and Straub, 2002; Sturt, 2003; Xiang et al., 2009; Clackson et al., 2011; Cunnings and Felser, 2013; Dillon et al., 2013; Chow et al., 2014; Clackson and Heyer, 2014; Cunnings and Sturt, 2014; Patterson et al., 2014). Most previous research has investigated constraints on the resolution of reflexives and object pronouns, where syntactic constraints (e.g., binding conditions A and B; Chomsky, 1981) restrict memory retrieval to an antecedent in a particular syntactic domain. Research on real-time pronoun resolution has investigated the extent to which such syntactic constraints interact with other sources of information, such as discourse prominence and gender/number congruence, to guide the retrieval

of a particular antecedent. While some have claimed that syntactic constraints act as "hard constraints" that restrict memory retrieval to syntactically licit antecedents (e.g., Dillon et al., 2013; Chow et al., 2014), others argue that syntactic constraints are violable and interact with other sources of information to cue antecedent retrieval (e.g., Badecker and Straub, 2002).

While binding conditions A and B have been well studied, to date little research has investigated the time-course of the application of syntactic constraints on the interpretation of pronouns linked to quantified and non-quantified antecedents as in (1) and (2) respectively.

(1a) The man heard that every boy at school said that he was happy.
(1b) The man who every boy at school heard said that he was happy.
(2a) The man heard that the boy at school said that he was happy.
(2b) The man who the boy at school heard said that he was happy.

In (1a), the subject pronoun *he* can refer to either the matrix subject *the man* or the quantified antecedent *every boy*. In (1b) however, when *every boy* appears inside a relative clause, it is not possible for the pronoun to be bound by it. Note that this is not an absolute restriction on antecedents inside relative clauses however, as the pronoun can freely refer to the non-quantified antecedent *the boy* in both (2a) and (2b). This contrast between quantified and non-quantified antecedents thus provides a particular challenge for memory retrieval mechanisms during language processing. For example, if retrieval operations disfavored antecedents inside relative clauses this would ensure that syntactically illicit quantified antecedents, as in (1b), are not retrieved, but would also rule out perfectly licit non-quantified antecedents as in (2b). Conversely, if subject pronouns routinely trigger retrieval of antecedents inside relative clauses, syntactically illicit quantified antecedents may be retrieved. Instead, successful pronoun interpretation requires selective retrieval of antecedents inside relative clauses, but this is dependent on the properties of the to-be-retrieved material.

The aim of the current study was to investigate the retrieval of quantified and non-quantified antecedents during pronoun resolution to further examine how syntactic constraints on memory retrieval are implemented during real-time anaphora resolution. To this end, we conducted an offline judgment task and three online reading experiments investigating pronoun resolution with quantified and non-quantified antecedents. We begin below by discussing theoretical accounts of the contrast between quantified and non-quantified antecedents as exemplified in (1) and (2), before discussing implications of this contrast for models of memory retrieval during language processing in more detail.

Background

Variable Binding and Coreference Assignment

In linguistic theory, it has been claimed that pronoun resolution can be achieved in different ways. Although theoretical accounts differ in their precise nature, a core idea is that pronouns can be resolved either in the discourse representation, via coreference assignment, or in logical syntax, via variable binding (e.g., Evans, 1980; Bosch, 1983; Reinhart, 1983; Reuland, 2001, 2011). Coreference assignment involves linking a pronoun to a referential antecedent in the discourse, as in the case of linking the pronoun *he* to either of the antecedents (*the man* or *the boy*) in (2). Quantified phrases (QPs), as in (1), however do not refer to a single individual in the discourse, and a pronoun linked to a QP co-varies in interpretation with the quantifier. Pronouns linked to QPs are thus said to involve variable binding rather than coreference assignment.

A long-standing observation in the linguistics literature is that variable binding is only possible in certain syntactic configurations. This restriction has traditionally been characterized in terms of c-command. C-command refers to a relationship between constituents in the phrase structure representation of a sentence based on the notion of hierarchical dominance. In the standard definition, a constituent c-commands its sister constituents and any constituents that these dominate (Reinhart, 1983). Variable binding is only possible between a pronoun and an antecedent that c-commands it (see e.g., Reuland, 2001, 2011). As such, in (3a), when the QP *every boy* c-commands the pronoun, the pronoun can be bound by it, while in (3b), when the QP does not c-command the pronoun, variable binding between the pronoun and QP is not possible. Coreference assignment to non-quantified determiner phrases (DPs) is not contingent on c-command however, and as such the pronoun can corefer with the referential antecedent *the boy* in both (2a) and (2b).

Memory Retrieval during Language Processing

Recent psycholinguistic research has motivated a cue-based model of memory retrieval during language processing (McElree, 2000; McElree et al., 2003; Lewis et al., 2006). In cue-based content-addressable models, retrieval is achieved by matching a set of retrieval cues with the contents of all items in memory in parallel. The item in memory that provides the best match to these cues becomes most highly activated and will thus be retrieved. The distinction between variable binding and coreference assignment has a number of implications for models of memory retrieval during language processing.

One theoretical implication relates to how the c-command constraint on variable binding is implemented in content-addressable memory. Content-addressable models are well-suited to utilize feature-based cues that target intrinsic properties of to-be-retrieved material. For example, it is straightforward to implement a [+masculine] feature for masculine pronouns to cue retrieval of a masculine antecedent. However, the c-command constraint on variable binding may be more difficult to implement, as it involves access to information about the *relation* between two items in memory (the pronoun and antecedent), rather than accessing an intrinsic *feature* of the antecedent (for discussion, see Kush, 2013; Kush et al., 2015). The primary aim of the current study was to investigate *if* the c-command constraint on variable binding restricts antecedent retrieval, rather than the question of *how* it is implemented. We do however return to this issue in the General Discussion.

A second implication that the distinction between variable binding and coreference assignment has for models of memory retrieval during language processing relates to how pronouns that are ambiguous with regards to variable binding and coreference assignment are resolved. Research in theoretical linguistics has claimed that syntactic variable binding is preferred over coreference assignment. Reuland (2001, 2011), for example, proposed an economy principle which predicts that variable binding should be computed before coreference assignment is attempted (see also Koornneef, 2008). This predicts that variable binding antecedents should preferentially be retrieved before coreference antecedents. Cunnings et al. (2014) tested this prediction in two reading experiments. They manipulated gender congruence between a pronoun and two potential antecedents in the discourse, and monitored participants' eye-movements as they read sentences as in (3).

(3a) Every soldier who knew that James/Helen was watching was convinced that he/she should wave as the parade passed.
(3b) It looked to James/Helen that every soldier was completely convinced that he/she should wave as the parade passed.

In their Experiment 1, exemplified in (3a), gender congruence was manipulated between the pronoun and a c-commanding QP (*every soldier*), and between the pronoun and a non c-commanding but linearly closer proper name coreference antecedent (*James/Helen*). They hypothesized that if variable binding is computed before coreference assignment, when participants encounter the pronoun, the c-commanding QP antecedent should be preferentially retrieved. In this case, the gender of the c-commanding QP should affect reading times at a point in time before the gender of the proper name. However, in contrast to this prediction, they observed that reading times at and shortly after the pronoun were longer when the pronoun mismatched in gender with the proper name antecedent, and were not significantly affected by the gender of the QP. This suggests that the proper name antecedent, rather than the QP, was preferentially retrieved upon encountering the pronoun. In their Experiment 2 however, exemplified in (3b), when the QP was linearly closer to the pronoun than the proper name antecedent, reading times at and shortly after the pronoun were reliably longer when the QP mismatched in gender with the pronoun. Together, these results indicate there is no overall preference for either variable binding or coreference assignment. For variable binding antecedents to be retrieved additional factors, such as antecedent recency, need to favor the QP antecedent.

A third issue relates to how the c-command constraint on variable binding, however it is implemented, interacts with other cues to antecedent retrieval. Cunnings et al. only investigated cases in which variable binding antecedents were syntactically licit, and did not test sentences containing QPs that did not c-command the critical pronoun. A key prediction of cue-based models is similarity-based interference (see e.g., Lewis et al., 2006; Van Dyke and Johns, 2012). As retrieval involves the matching of a set of retrieval cues with all items in memory in parallel, a distractor item that partially matches the retrieval cues may sometimes be retrieved instead of the intended retrieval target. This leads to the possibility that a QP antecedent that does not c-command a pronoun may occasionally be retrieved even though this dependency is ungrammatical.

Attraction effects in subject-verb agreement are a key example of such interference effects during language processing. For example, Wagers et al. (2009) reported longer reading times for sentences containing ungrammatical compared to grammatical subject-verb agreement (e.g., *the key to the cabinet was rusty* vs. *the key to the cabinet were rusty*). This ungrammaticality effect was however reliably attenuated when the structurally illicit distractor matched the agreement marking of the critical verb (e.g., *the key to the cabinets were rusty*). This attraction effect provides good evidence that structural cues (e.g., [+phrasal head]) and agreement (e.g., [+plural]) are equally weighted cues that combine to guide retrieval during subject-verb agreement. When no item in memory fully matches the cues at retrieval, a partially matching distractor can sometimes be retrieved. We will refer to this pattern of results as *facilitatory* interference, as the processing of ungrammatical sentences is facilitated by a partially matching distractor.

Although facilitatory attraction effects are well attested for subject-verb agreement, a number of studies have failed to observe this specific pattern of interference during anaphora resolution (e.g., Sturt, 2003; Xiang et al., 2009; Dillon et al., 2013; Chow et al., 2014; Cunnings and Sturt, 2014). Sturt, for example, manipulated gender congruence between a reflexive and two antecedents in a piece of discourse (e.g., *Jonathan/Jennifer remembered that the surgeon had pricked himself/herself with a used syringe needle*) and observed that while first-pass reading times at the reflexive were reliably longer when the structurally licit antecedent *the surgeon* mismatched in stereotypical gender with the reflexive, the gender of the structurally illicit antecedent (*Jonathan/Jennifer*) did not affect reading times in this measure. Results such as these have led some to claim that while equally weighted syntactic and agreement cues combine to guide retrieval for subject-verb agreement, anaphora resolution is guided by syntactic "hard constraints" that restrict retrieval to syntactically licit antecedents (Dillon et al., 2013; Chow et al., 2014). Although the question of whether or not structurally illicit antecedents are always ignored during anaphora resolution is debated (e.g., Badecker and Straub, 2002; Cunnings and Felser, 2013; Clackson and Heyer, 2014), the contrast in attraction effects observed for agreement and anaphora suggests these dependencies implement agreement cues in different ways. For anaphora, syntactic constraints appear to be more strongly weighted cues to retrieval than gender/number congruence.

Syntactic constraints on reflexives could potentially be implemented as highly weighted cues that trigger retrieval of an antecedent within a particular syntactic domain (e.g., the same clause as the reflexive; see Dillon et al., 2013). However, constraints on quantified and non-quantified antecedents are difficult to implement in this way, as it is not the case that antecedents within a particular syntactic domain (e.g., a relative clause) are categorically ruled out. Rather, sensitivity to constraints on variable binding and coreference assignment require retrieval operations to be able to selectively retrieve antecedents that do not c-command pronouns depending on their quantificational status. The contrast between variable

binding and coreference assignment thus provides a unique challenge to memory retrieval operations during language processing, which may leave variable binding more susceptible to facilitatory interference than has been observed for other types of anaphora, such as reflexives.

We are aware of only one study that has investigated the potential for facilitatory interference during the resolution of bound variable anaphora. Kush et al. (2015) recorded participants' eye-movements as they read sentences as in (4).

(4a) The troop leaders that the boy/girl scout had no respect for had scolded her after the incident at scout camp.
(4b) The troop leaders that no boy/girl scout had respect for had scolded her after the incident at scout camp.
(4c) The troop leaders were sure no boy/girl scout was afraid that she would be scolded after the incident at scout camp.

In (4a), the only syntactically licit antecedent for the pronoun *her* is the coreference antecedent *the boy/girl*. In (4b), the pronoun has no syntactically licit antecedent as the quantified phrase (*no boy/girl*) does not c-command it. Kush et al. hypothesized that if the pronoun triggers retrieval of the coreference antecedent in (4a), a gender mismatch effect should be observed, with longer reading times for gender mismatching (*the boy*) than gender matching (*the girl*) antecedents. If antecedent retrieval respects the c-command constraint, this contrast between gender matching (*no girl scout*) and gender mismatching (*no boy scout*) antecedents should not be observed in (4b). If the c-command constraint does not restrict antecedent retrieval however, Kush et al. hypothesized that the gender mismatch effect should be observed in both (4a) and (4b), as evidence of facilitatory interference. During first-pass processing at the pronoun Kush et al. observed a gender mismatch effect in (4a) but not (4b), suggesting the c-command constraint on variable binding restricts the early stages of antecedent retrieval. They did observe gender mismatch effects in (4c) however, when the quantified phrase c-commanded the pronoun. Kush et al interpreted these results as indicating that pronouns trigger retrieval of both c-commanding quantified phrases and non c-commanding coreference antecedents, but not non c-commanding quantified antecedents, suggesting that the c-command constraint restricts antecedent retrieval.

Against this background, the aim of the current study was to further investigate the implementation of the c-command constraint on variable binding during anaphora resolution. While Kush et al. compared antecedent retrieval for c-commanding and non c-commanding quantified antecedents in different sentence structures with different (subject and object) pronouns, we investigated variable binding and coreference resolution in maximally similar sentences with identical (subject) pronouns across four experiments. We also tested the universal quantifier *every* rather than the negative quantifier *no*. Together with the study reported by Kush et al., the current experiments provide a systematic examination of how constraints on retrieving quantified phrases and referential antecedents during anaphora resolution are implemented during language processing. Experiment 1 was an offline task that tested the extent to which naïve participants are sensitive to the c-command constraint on variable binding in an untimed task. Experiments 2–4 were online reading studies in which participants' eye-movements were monitored. Experiments 2–3 contrasted the retrieval of quantified and non-quantified referential antecedents in order to test the extent to which variable binding and coreference antecedents are retrieved in c-commanding and non c-commanding configurations. Experiment 4 tested the extent to which the c-command restriction on variable binding acts as a "hard constraint" on antecedent retrieval.

Experiment 1

Experiment 1 used a sentence judgment paradigm to assess sensitivity to the c-command constraint on variable binding in an untimed offline task. The materials consisted of sentences as in (5), which manipulate the factor "c-command" to test whether participants are willing to link pronouns to QPs in different syntactic configurations.

(5a) *C-commanding QP*
The surgeon suggested that every man on the waiting list definitely realized that he needed some help.
(5b) *Non c-commanding QP*
The surgeon who every man on the waiting list suggested definitely realized that he needed some help.

In (5a), the QP *every man* c-commands the pronoun *he* and as such the pronoun can be bound by the QP via variable binding. In (5b) however, the QP appears inside a relative clause and as such does not c-command the pronoun. In this case, the pronoun can only refer to the matrix subject *the surgeon*. We expect native English speakers to be sensitive to the c-command constraint on variable binding in this offline task. That is, participants should consider the QP as a possible antecedent for the pronoun in (5a) but not (5b).

Methods

Participants

32 native English speakers (17 males, mean age 21; range 18–30) from the University of Edinburgh community either received course credit or a small payment for taking part in Experiment 1[1]. All participants in Experiment 1, and Experiments 2–4, provided written, informed consent before the experiment began. Ethical approval for all experiments was granted by the Department of Psychology Research Ethics Committee at the University of Edinburgh.

Materials

Materials consisted of 16 experimental items constructed as in (5). In each item, the pronoun matched in definitional gender with the QP antecedent. The pronoun also always matched in stereotypical gender with the matrix subject to ensure that the texts were felicitous. The materials manipulated the factor "c-command" in two conditions, such that the QP either c-commanded or did not c-command the QP. A full list of experimental items is provided in Appendix A. In addition to the

[1]The participants in Experiment 1 also completed Experiment 3. All participants completed Experiment 3 before Experiment 1.

experimental items, 24 filler items were also constructed, some of which also contained pronouns but others which did not.

Procedure

The experimental and filler items were presented to participants as a questionnaire in Microsoft Word. A question appeared under each text with two possible answers. For the experimental items, the question always probed the interpretation of the pronoun. In (4), for example, the question was "Who does 'he' refer to?" with "(A) the surgeon" and "(B) every man" as possible answers. Participants provided a response by selecting one of five options from a drop-down menu that appeared beside each text. Possible responses were "(A) strongly preferred", "(A) mildly preferred", "(A) or (B) equally likely", "(B) mildly preferred" or "(B) strongly preferred". Across the 16 experimental items, the matrix subject and QP antecedents each appeared as options "(A)" and "(B)" an equal number of times. Fillers that did not include pronouns consisted of complex (ambiguous and unambiguous) sentences containing elliptical gaps. Two paraphrases, (A) and (B), were provided as answers which participants had to choose between using the same scale as in the experimental items.

The experimental and filler items were pseudo-randomized such that no two experimental items appeared next to each other. Items were spread across two presentation lists in a Latin-square design. Forward and reverse orders of each list were presented to the same number of participants. Participants were instructed to simply read each sentence and provide an answer to the questions using the drop-down menu.

Results

Responses were coded from −2 to 2, with −2 meaning "QP strongly preferred" and 2 meaning "DP strongly preferred." A score of 0 indicated either antecedent was equally likely, while −1 and 1 indicated a mild preference for the QP and DP respectively. The average rating in the c-commanding QP condition was −0.16 (SD 1.62) and in the non c-commanding condition 1.38 (SD 1.14). A pairwise comparison indicated that scores were significantly higher in the non c-commanding QP condition than the c-commanding QP condition [$t_{1(31)} = 8.19$, $p < 0.001$; $t_{2(15)} = 11.80$, $p < 0.001$]. This indicates that the DP antecedent was chosen more often when the QP did not c-command the pronoun compared to when it did. One sample *t*-tests indicated that the average scores in the c-command condition did not differ significantly from 0 [$t_{1(31)} = 0.90$, $p = 0.374$; $t_{2(15)} = 1.23$, $p = 0.237$], but that the scores in the non c-command condition were significantly higher than 0 [$t_{1(31)} = 11.12$, $p < 0.001$; $t_{2(15)} = 16.46$, $p < 0.001$]. This indicates that when the QP c-commanded the pronoun, participants considered either antecedent equally likely, but that the DP was preferred when the QP did not c-command the pronoun.

Discussion

The results of Experiment 1 align with intuitions from the theoretical linguistics literature. When the QP c-commanded the pronoun, participants were equally likely to interpret the pronoun as referring to either the QP or the DP antecedent. When the QP did not c-command the pronoun, participants preferred to interpret the pronoun as being coreferential with the DP. Experiment 1 thus suggests that naïve participants are sensitive to the c-command restriction on variable binding[2]. Experiment 2 tested how this constraint is implemented during online sentence processing.

Experiment 2

The aim of Experiment 2 was to investigate the application of the c-command constraint on variable binding during real-time language processing. Participants read a series of texts as in (6) while their eye-movements were monitored. The gender-mismatch paradigm (Sturt, 2003; Kazanina et al., 2007) was used as a diagnostic of dependency formation.

(6a) *C-commanding QP, gender match*
Being in hospital can be quite difficult at times.
The surgeon saw that every old man on the emergency ward silently wished that he could go a little bit faster.

(6b) *C-commanding QP, gender mismatch*
Being in hospital can be quite difficult at times.
The surgeon saw that every old woman on the emergency ward silently wished that he could go a little bit faster.

(6c) *Non c-commanding QP, gender match*
Being in hospital can be quite difficult at times.
The surgeon who every old man on the emergency ward saw silently wished that he could go a little bit faster.

(6d) *Non c-commanding QP, gender mismatch*
Being in hospital can be quite difficult at times.
The surgeon who every old woman on the emergency ward saw silently wished that he could go a little bit faster.

In (6a,b) the pronoun *he* is c-commanded by the QP *every old (wo)man*. In (6c,d) the pronoun is not c-commanded by the QP, as it appears inside a relative clause. In (6a,c) the QP *every old man* matches the gender of the pronoun, while in (6b,d) the QP *every old woman* does not. If participants attempt to retrieve the c-commanding QP upon encountering the pronoun, we expect to observe a gender mismatch effect such that reading times at or shortly after the pronoun should be longer in gender mismatch condition (6b) than gender match condition (6a). If the c-command constraint restricts antecedent retrieval during processing (Kush et al., 2015), no gender mismatch effect should be observed when the QP appears inside a relative clause, as in (6c,d). If however participants violate the c-command constraint during processing, we can expect to see gender mismatch effects in both (6a,b) and (6c,d). Sensitivity to the c-command constraint

[2]A reviewer notes that the results of Experiment 1 on their own could equally be explained in terms of a dispreference for linking pronouns to antecedents inside relative clauses, irrespective of quantification, rather than a specific constraint on variable binding to QPs. While this is a possible explanation of the results in Experiment 1, the results of Experiments 2 and 3 suggest that the restriction on binding to QPs is best characterised in terms of the c-command constraint, rather than a general dispreference against antecedents inside relative clauses.

is thus diagnosed statistically by an interaction between the main effects of c-command and gender, while main effects of gender would indicate constraint violation.

Methods

Participants

Thirty two native English speakers (8 males, mean age 19; range 17–23) from the University of Edinburgh community with normal or corrected-to-normal vision, and who did not take part in any of the other experiments reported here, took part in Experiment 2.

Materials

Twenty four experimental items as in (6) were constructed. A full list can be found in Appendix B. Each item began with a short context sentence that took up one line onscreen. The critical second sentence appeared across two lines, with the line-break always appearing before the adverb [*silently* in (6)] that appeared before the verb preceding the critical pronoun. The matrix subject of the critical sentence always matched the pronoun in stereotypical gender to ensure that a felicitous interpretation of the pronoun was always possible. The critical gender manipulation between the QP and pronoun always involved definitional gender (e.g., *every old man/ woman*).

In addition to the experiment items, 60 filler texts were also constructed that included a variety of different constructions, some of which included different types of anaphors. The fillers took up between two and three lines of text onscreen.

Procedures

Experimental and filler items were pseudo-randomized such that no two experimental items appeared adjacent to each other and were spread across four presentation lists in a Latin-square design. A different random order of items was presented to each participant. The experiment began with five practice items to familiarize participants with the procedure. All items were presented in Consolas fixed width font and displayed across up to three lines of text onscreen.

Eye movements were recorded using the EYELINK 2000 system, sampling at a rate of 1000 Hz. While viewing was binocular, eye movements were recorded from the right eye only. Each experimental session began with calibration of the eye-tracker on a nine-point grid, and any drift in calibration was compensated for via recalibration between trials if required. Before each trial, participants fixated on a fixation marker above the first word of the trial to be displayed. Upon fixation on this marker, the trial text appeared. Participants read each text silently at their normal reading rate, pressing a button on a control pad once completed. To ensure participants paid attention to the content of the sentences, comprehension questions requiring a yes/no push button response followed two thirds of all trials. The entire experiment lasted approximately 30–45 min in total.

Reading times are reported for four regions of text. The critical *pronoun region* consisted of the subject pronoun and the preceding complementiser (*that he*). We extended the pronoun region to the left of the critical pronoun rather than the right to avoid effects of first-pass processing at the pronoun being mixed with spillover effects at the post-pronoun region. As the perceptual span in English is approximately eight characters to the right of fixation (Rayner, 1998), fixations on the complementiser are likely to involve foveal processing of the pronoun. The *spillover region* comprised the two words after the pronoun (*could go*) while the *prefinal region* consisted of the next two words (*a little*). The *final region* consisted of the rest of the critical sentence (*bit faster*).

Four reading time measures are reported for each region of text. *First pass reading time* is the summed duration of fixations within a region during its first inspection, until it is exited to the left or right, while *regression path duration* is calculated by summing the duration of each fixation, starting with the first fixation when a region is entered from the left, up until but not including the first fixation in a region to the right. In addition to these two *first-pass* processing measures, we also calculated *second pass times*, which included all fixations within a region *after* it has been exited following the first-pass. *Total viewing times*, which sum all fixations in a region, are reported as a global measure of processing load. All trials in which track loss occurred were discarded, and regions which were initially skipped during reading were treated as missing data in the two first-pass measures. For second pass times, trials in which a region was not refixated after the first-pass contributed a second pass time of zero to the calculation of averages. Prior to the calculation of reading time measures an automatic procedure merged short fixations of 80 ms or below that were within one degree of visual arc of another fixation. All other fixations of 80 ms or below, as well as those above 800 ms, were removed. Outliers that were above or below 3.5 standard deviations from a participant's mean reading time for each measure were also removed before analysis.

Analysis was conducted using linear-mixed effects models with crossed random effects for subjects and items (Baayen, 2008; Baayen et al., 2008). For each reading time measure, the analysis included deviation-coded fixed main effects of "c-command" (c-command vs. non c-command), "gender" (match vs. mismatch) and their interaction. Subject and item random intercepts, as well as subject and item random slopes for each fixed effect, were included using a "maximal" random effects structure (Barr et al., 2013). If this maximal model failed to converge, the random effects structure was simplified by removing the random correlation parameters, which for the analyses reported here always led to convergence. For fixed effects, p-values were estimated from the t distribution (Baayen, 2008, p. 248). In the case of reliable interactions, planned comparisons compared gender mismatch effects separately for the two c-command and two non c-command conditions.

Results

Overall accuracy to the comprehension questions was 88% (all subjects above 73%), indicating that participants paid attention to the content of the sentences. Track loss accounted for 0.1% of the data and skipping rates for the pronoun, spillover, prefinal and

final regions were 26, 5, 19, and 10% respectively[3]. A summary of the reading time data is provided in **Table 1**. **Table 2** provides a summary of the statistical analysis.

At the pronoun region, there was a significant main effect of c-command in first-pass reading times, with reading times being longer in the two non c-command conditions (6c,d) than c-commanding conditions (6a,b). This likely reflects spillover processing as a result of the extra layer of syntactic embedding from the relative clause that appears in conditions (6c,d) but not (6a,b). There were significant c-command by gender interactions in both second-pass and total viewing times. Planned comparisons in both measures indicated that when the QP c-commanded the pronoun, reading times were longer in gender mismatch condition (6b) than gender match condition (6a) (for second-pass times, estimate = 71, SD = 30, $t = 2.407$, $p = 0.017$; for total viewing times, estimate = 80, SD = 31, $t = 2.586$, $p = 0.010$). The same comparisons in the two non c-command conditions were not significant (for both measures, $t < 1$, $p > 0.651$). This pattern of results, with gender mismatch effects in the c-command conditions only, is illustrated for second pass times in **Figure 1**. These results indicate that readers attempted to link the pronoun to the QP when it c-commanded the pronoun but not when it did not.

[3]Skipping rates at the pronoun region were quite high in Experiments 2–4. We thus conducted an additional analysis in which the two first-pass measures at the pronoun were calculated using a leftward-shifting procedure (see Sturt, 2003, p. 548). In this analysis, if the pronoun was initially skipped during reading, fixations up to four characters to the left of the region boundary were included in the calculation of first-pass and regression path times. This reduced skipping rates at the pronoun to below 8% across experiments, but did not alter the overall pattern of results compared to the non-shifted analysis reported in the main text.

At the spillover region, there were significant main effects of gender in both second-pass and total viewing times that were modulated by significant c-command by gender interactions in both measures. Again, planned comparisons in the c-command conditions indicated significantly longer reading times for gender mismatch condition (6b) than gender match condition (6a) (for second-pass times, estimate = 111, SD = 33, $t = 3.403$, $p < 0.001$; for total viewing times, estimate = 134, SD = 35, $t = 3.920$, $p < 0.001$), but there were no significant differences between the two non c-command conditions (for both measures, $t < 1$, $p > 0.563$). These results further indicate that readers retrieved the QP upon encountering the pronoun, but only when the QP c-commanded it.

At the prefinal and final regions there were marginally significant c-command by gender interactions in the regression path times. At the prefinal region, regression path durations were again numerically larger following a gender mismatch in the c-command conditions only, but here neither of the planned comparisons was significant (both $t < 1.2$, both $p > 0.236$). At the final region, regression path durations were marginally longer following gender mismatches in the two c-command conditions (estimate = 405, SD = 225, $t = 1.801$, $p = 0.073$). The same comparison for the two non c-command conditions was not significant ($t < 1$. $p > 0.470$).

Discussion

The results of Experiment 2 clearly show that readers readily retrieved the QP upon encountering the pronoun, but only when it was a syntactically licit antecedent. At both the critical pronoun and spillover regions, second-pass and total viewing times were longer when the QP mismatched in gender with the pronoun,

TABLE 1 | Reading times in milliseconds for four eye-movement measures at four regions of texts in Experiment 2 (SDs in parentheses).

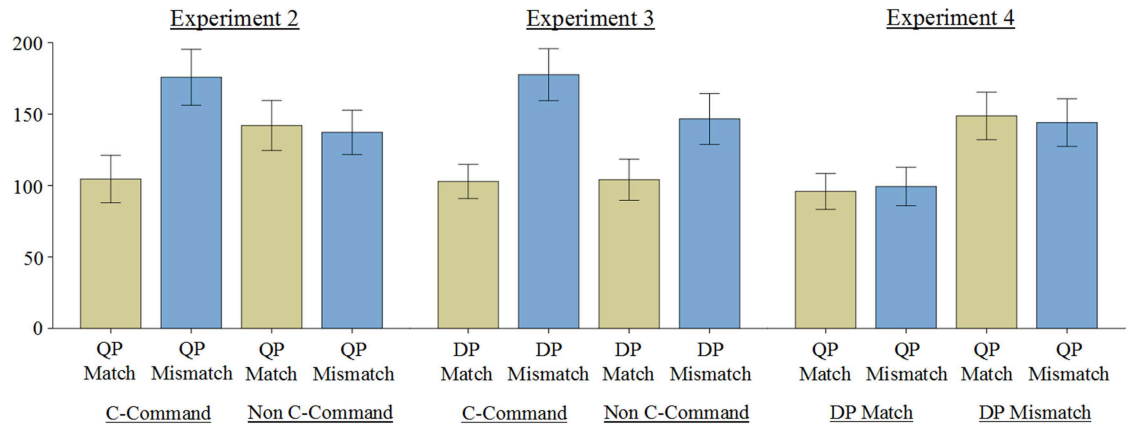

FIGURE 1 | Second pass times in milliseconds (with standard errors) at the pronoun region in Experiments 2–4.

but only when the QP c-commanded the pronoun. Similar trends were also observed in regression path times at later regions of text. At no point in time did we observe any reliable effect of the gender of the QP on participants' reading times when it did not c-command the pronoun. These results indicate that the c-command constraint on variable binding restricts antecedent retrieval during the resolution of subject pronouns.

One potential counterargument to this interpretation of our results is that the QPs inside relative clauses may have been ignored during retrieval not because of the c-command constraint on variable binding, but rather because antecedents inside relative clauses are comparatively non-discourse prominent. The results of Cunnings et al. (2014) however provide evidence against this interpretation. In their Experiment 1, they observed that readers would readily retrieve a non-quantified coreference antecedent inside a relative clause. This suggests that it is not the case that all antecedents inside relative clauses are ignored during retrieval, but rather they are readily retrieved only when syntactically licit.

However, it remains at least possible that there may have been subtle pragmatic differences between the texts used in Experiment 2 reported here and those used by Cunnings et al. (2014), which may have favored retrieval of the relative clause antecedent in Cunnings et al.'s study but not here. Note also that the coreference antecedent in Cunnings et al. was a proper name, which are known to be particularly discourse prominent (Sanford and Garrod, 1988). The aim of Experiment 3 was to investigate whether the selective retrieval profile observed in the

current experiment is truly a result of the c-command constraint on variable binding or results from differences in discourse prominence between c-commanding and non c-commanding antecedents in general.

Experiment 3

The aim of Experiment 3 was to investigate whether the c-command relationship between antecedent and pronoun affects the possibility of retrieval for non-quantified referential antecedents. The experimental materials used were identical to those from Experiment 2, except that the critical QP was replaced with a non-quantified referential DP as in (7).

(7a) *C-commanding DP, gender match*
Being in hospital can be quite difficult at times.
The surgeon saw that the old man on the emergency ward silently wished that he could go a little bit faster.

(7b) *C-commanding DP, gender mismatch*
Being in hospital can be quite difficult at times.
The surgeon saw that the old woman on the emergency ward silently wished that he could go a little bit faster.

(7c) *Non c-commanding DP, gender match*
Being in hospital can be quite difficult at times.
The surgeon who the old man on the emergency ward saw silently wished that he could go a little bit faster.

(7d) *Non c-commanding DP, gender mismatch*
Being in hospital can be quite difficult at times.
The surgeon who the old woman on the emergency ward saw silently wished that he could go a little bit faster.

As for QPs in Experiment 2, the DP c-commands the pronoun in (7a,b) but does not in (7c,d). In conditions (7a,c) the pronoun matches in gender with the DP, while in (7b,d) there is a gender mismatch. While variable binding between the pronoun and QP was syntactically illicit in conditions (6c,d) in Experiment 2, there is no constraint that restricts linking the pronoun to the DP in (7c,d) via coreference assignment. As such, if the results of Experiment 2 reflect application of the c-command constraint on variable binding, we expect to find different results with coreference antecedents in Experiment 3. That is, in contrast to the interactions observed in Experiment 2, in Experiment 3 main effects of gender should be observed such that reading times should be longer in gender mismatch conditions (7b,d) than gender match conditions (7a,c), irrespective of c-command.

However, if antecedents inside relative clauses are simply ignored during retrieval as they are not discourse prominent, we expect to observe similar results in Experiment 3 as were observed in Experiment 2. That is, we should observe reliable c-command by gender interactions, with gender mismatch effects being observed in c-command conditions (7a,b) but not non c-commanding conditions (7c,d).

Methods

Participants

32 native English speakers (17 males, mean age 21; range 18–30) from the University of Edinburgh community, none of whom took part in any of the other eye-tracking experiments reported here, took part in Experiment 3. All had normal or corrected-to-normal vision.

Materials

The 24 sets of experimental items from Experiment 2 were adapted as in (7). Experimental items were again interspersed with 60 fillers and pseudo-randomly distributed across four presentation lists in a Latin-square design.

Procedures

The procedure and data analysis were the same as outlined for Experiment 2.

Results

Average comprehension question accuracy was 90% (all subjects over 77%). There was no track loss and skipping rates for the pronoun, spillover, prefinal, and final regions were 32, 9, 16, and 12% respectively. Summaries of the reading time data and statistical analysis are provided in **Tables 3**, **4**.

At the pronoun region, there were significant main effects of gender in second pass and total viewing times, with reading times being longer in gender mismatch conditions (7b,d) compared to gender match conditions (7a,c). In contrast to Experiment 2, there was no hint of an interaction between c-command and gender in any measure at the pronoun region. This suggests that the DP was retrieved irrespective of whether or not it was inside a relative clause. This pattern of results for the second pass times at the pronoun region is shown in **Figure 1**.

The results of the spillover region replicated this pattern of results. In second pass times there was a marginal main effect of gender, with reading times again tending to be longer following a gender mismatch between the pronoun and DP compared to when there was a gender match. Total viewing times displayed the same pattern of results, with the main effect of gender being fully significant in this measure.

At the prefinal region, there was a significant c-command by gender interaction in first-pass reading times. Here, in the c-command conditions reading times were numerically longer in gender mismatch condition (7b) than gender match condition (7a). The planned comparison was however not significant ($t = 1.506$, $p = 0.133$). The opposite numerical pattern was observed in the two non c-command conditions, with gender match condition (7c) having numerically longer reading times than gender mismatch condition (7d). The planned comparison was however only marginally significant (estimate = 24, SD = 13, $t = 1.851$, $p = 0.065$). It is unclear what this numerical pattern might mean, and it is not replicated in any other measure. Indeed, in the regression path times at this region there was a significant main effect of gender, with reading times following the pattern observed at the pronoun and spillover regions, with reading times being longer following gender mismatches between the DP and pronoun compared to when there was a gender match.

There was also a marginally significant main effect of gender in the regression path times at the final region, with reading times again tending to be longer when the pronoun mismatched in gender with the DP compared to when there was a gender match.

Discussion

The results of Experiment 3 are in clear contrast to those from Experiment 2. Whereas we observed significant c-command by gender interactions at the pronoun and spillover regions in Experiment 2, in Experiment 3 we observed only significant main effects of gender at these regions. This suggests that, in contrast to Experiment 2, in Experiment 3 participants were equally likely to retrieve the DP antecedent in both the c-command and non c-command conditions. Indeed, the relative time-course of mismatch effects across both experiments is very similar (compare graphs from Experiments 2 and 3 in

Figure 1). The crucial difference between the two is that while mismatch effects were restricted to the c-command conditions in Experiment 2, they appear irrespective of c-command in Experiment 3. This provides good evidence that the results of Experiment 2 cannot be explained in terms of antecedents inside relative clauses simply being non-discourse prominent. Rather, while both antecedents that c-command a pronoun and those that do not are readily retrieved, quantified antecedents are only retrieved when variable binding is syntactically licit. It is this contrast between syntactically licit and syntactically illicit pronoun-antecedent dependencies that appears to best explain the contrast in results between Experiments 2 and 3.

Although the results of Experiments 2 and 3 indicate that the c-command constraint restricts antecedent retrieval during language processing, one issue that remains is how the c-command constraint and gender congruence combine during anaphora resolution. In Experiments 2 and 3, there was always at least one gender-matching and syntactically licit antecedent in the discourse, namely the matrix subject DP [*the surgeon* in (5) and (6)]. To fully test how the c-command constraint and gender congruence interact to guide antecedent retrieval, it is also necessary to investigate anaphora resolution when the only syntactically licit antecedent available in the discourse provides only a partial match to the cues at retrieval. Experiment 4 was thus conducted to test this issue.

Experiment 4

The aim of Experiment 4 was to investigate how the c-command constraint and gender congruence combine to guide antecedent retrieval. Materials in Experiment 4 contained the two non c-command conditions from Experiment 2, additionally manipulating the stereotypical gender relationship between pronoun and matrix subject DP as in (8).

(8a) *DP gender match, QP gender match*
Being in hospital can be quite difficult at times.
The surgeon who every old man on the emergency ward saw silently wished that he could go a little bit faster.

(8b) *DP gender match, QP gender mismatch*
Being in hospital can be quite difficult at times.
The surgeon who every old woman on the emergency ward saw silently wished that he could go a little bit faster.

(8c) *DP gender mismatch, QP gender match*
Being in hospital can be quite difficult at times.
The surgeon who every old woman on the emergency ward saw silently wished that she could go a little bit faster.

(8d) *DP gender mismatch, QP gender mismatch*
Being in hospital can be quite difficult at times.
The surgeon who every old man on the emergency ward saw silently wished that she could go a little bit faster.

In (8), the QP always appears inside a relative clause and as such is not a syntactically licit antecedent of the pronoun. In each condition, the only syntactically licit antecedent is the matrix subject DP *the surgeon*. In (8a,b), this DP matches in stereotypical gender with the pronoun, whereas in (8c,d) there is a stereotypical gender mismatch. In (8a,c) the non c-commanding QP additionally matches the gender of the pronoun, while in (8b,d) it does not.

Different predictions with regards to the time-course of antecedent retrieval can be made depending on how the c-command constraint and gender congruence combine. If syntactic constraints on anaphora resolution constitute "hard constraints" that gate retrieval to syntactically licit antecedents (Dillon et al., 2013; Chow et al., 2014; Kush et al., 2015), we should observe main effects of the gender of the DP only. Reading times should be longer in DP gender mismatch conditions (8c,d) than in DP gender match conditions (8a,b). The gender of the syntactically illicit QP should not influence reading times at any point in the sentence.

Alternatively, if the c-command constraint and gender congruence combine to guide retrieval, we expect to observe facilitatory interference (e.g., Wagers et al., 2009). In this case, we would expect reading times to generally be longer in DP gender mismatch conditions (8c,d) than DP gender match conditions (8a,b). However, the size of the gender mismatch effect should be reliably attenuated when the structurally illicit QP matches in gender with the pronoun. In this case, reading times should be shorter in condition (8c), when the QP matches the gender of the pronoun, in comparison to (8d), when neither antecedent matches. This result would indicate that when no syntactically licit antecedent is available in the discourse that matches the pronoun's gender, a gender matching but syntactically illicit antecedent may sometimes be retrieved.

Another possibility is that we may observe a difference in the time-course of effects for syntactically licit and illicit antecedents. Sturt (2003) proposed the "defeasible filter" hypothesis which predicts that initially only structurally licit antecedents are considered, but that structurally illicit antecedents can subsequently be retrieved during later stages of processing. Applying this logic to the current experiment, we may observe an initial attempt to retrieve only the syntactically licit DP, followed by subsequent effects of the syntactically illicit QP. In this case, we should observe main effects of stereotypical gender mismatch between the pronoun and DP antecedent only at or shortly after the pronoun, with any effects of the gender of the structurally illicit QP antecedent being in comparison delayed.

Methods

Participants

32 native English speakers (12 males, mean age = 24; range = 18–49) from the University of Edinburgh community with normal or corrected-to-normal vision, none of which took part in Experiments 1–3, took part in Experiment 4.

Materials

The 24 experimental items from Experiment 2 were adapted as in (8), and again pseudo-randomly interspersed with 60 fillers across four presentation lists in a Latin-square design.

The stereotypical gender manipulations included items that had previously been pre-tested to ensure they displayed the intended stereotypes (Cunnings and Felser, 2013; Cunnings et al., 2014).

Procedures

The procedure and data analysis were the same as in Experiments 2 and 3.

Results

Overall accuracy to comprehension questions was 89% (all subjects above 77%). Track loss accounted for 0.1% of the data. Skipping rates for the pronoun, spillover, prefinal and final regions were 21, 7, 14, and 7% respectively. Summaries of the reading times and statistical analyses are shown in **Tables 5**, **6**.

At the pronoun region, we observed significant main effects of the gender of the DP in both second pass and total viewing times. In both measures, reading times were longer when the DP mismatched in stereotypical gender with the pronoun, as in (8c,d) compared to when there was a stereotypical gender match, as in (8a,b). The gender of the QP did not significantly affect reading times in any measure at this region. These results suggest that participants attempted to retrieve the syntactically licit DP antecedent. This pattern of results is illustrated in **Figure 1**, which shows the second pass times at the pronoun region.

At the spillover region, there was a significant main effect of DP gender in first pass times. Here, reading times were again longer when the DP mismatched in stereotypical gender with the pronoun compared to when there was a gender match. There was also a significant main effect of the gender of the DP in both second-pass and total viewing times, with reading times again being longer when the DP mismatched in stereotypical gender with the pronoun. There was additionally a marginally significant main effect of QP gender in total viewing times only. Here, reading times tended to also be longer when the QP mismatched in gender with the pronoun. There was no hint of an interaction however, as this numerical trend for longer reading times following gender mismatching QPs was observed in both the DP match and DP mismatch conditions.

At the prefinal region, there was again a significant main effect of DP gender in total viewing times, with reading times being longer when the DP mismatched in stereotypical gender with the pronoun. No significant effects of the gender of the QP were found at this region.

At the final region there was a marginally significant interaction in first-pass times. Here, in the DP stereotypical gender match conditions, reading times tended to be longer in QP match condition (8a) compared to QP mismatch condition (8b), but the planned comparison was not significant ($t = 1.476$, $p = 0.141$). The opposite numerical pattern was observed in the DP stereotypical gender mismatch conditions, but again the comparison was not significant ($t = 0.779$, $p = 0.437$). In regression path times the main effect of the stereotypical gender of the DP was significant, the main effect of the gender of the QP marginal, and the DP gender by QP gender interaction significant. In this measure, while reading times in DP match conditions (8a,b) did not differ ($t = 0.381$, $p = 0.703$), for the DP stereotypical gender mismatch conditions, reading times were longer in QP match condition (8c) than QP mismatch condition (8d) (estimate = 569, SD = 220, $t = 2.591$, $p = 0.010$). While this reading time measure thus provides evidence of the QP's gender

significantly influencing reading times, the direction of the effect in the DP stereotypical gender mismatch conditions is in the *opposite* direction to that predicted by facilitatory interference. Total viewing times at the final region exhibited reading times similar to earlier regions of text, with reading times being significantly longer when the DP mismatched in stereotypical gender with the pronoun compared to when there was a gender match. The QP did not significantly influence reading times in this measure.

Discussion

The results of Experiment 4 indicate that readers readily retrieved the syntactically licit DP antecedent upon encountering the pronoun. In a number of measures across all regions of text reported, we observed significantly longer reading times when the DP mismatched in stereotypical gender with the pronoun compared to when there was a gender match. Effects of the gender of the QP antecedent were more elusive and the one significant effect that we did observe was delayed in comparison to the effects that were observed of the DP's gender. While DP stereotypical gender mismatch effects were first observed in second pass and total viewing times at the pronoun, and first pass times at the spillover region, the only reliable effect of the gender of the QP was observed in the regression path times at the final region. We leave discussion of this delayed effect of the QP's gender until the General Discussion, but overall interpret the relative time-course of effects as indicating that the c-command constraint on variable binding restricts the initial stages of antecedent retrieval during comparatively earlier stages of anaphora resolution. We discuss the implications of these results, along with the other experiments reported above, in more detail below.

General Discussion

The aim of this study was to investigate if the c-command restriction on variable binding restricts antecedent retrieval during anaphora resolution. The results of Experiment 1 indicate that native English speakers are sensitive to the c-command restriction on binding by quantified antecedents in an offline judgment task. Experiment 2, which investigated the extent to which QP antecedents are retrieved upon encountering a pronoun during online processing, indicates that participants readily retrieved the QP upon encountering the pronoun, but only when the QP c-commanded the pronoun. The results of Experiment 3 showed that retrieval of DP antecedents, which is not contingent on c-command, was equally likely irrespective of whether or not the DP c-commanded the pronoun. The results of Experiments 2 and 3 together confirm that it is not the case that non c-commanding antecedents are generally ignored due to their lower discourse salience. Instead, both c-commanding and non c-commanding antecedents are readily retrieved, but only when they are syntactically licit antecedents for a pronoun. Finally, the results of Experiment 4 indicate that when only one syntactically licit antecedent is available in the discourse, that antecedent is preferentially retrieved over a syntactically illicit QP, even when the syntactically licit antecedent mismatches in gender with the pronoun. This different pattern of results across the three eye-movement experiments is illustrated in **Figure 1**. Together, these data indicate that the c-command constraint on variable binding restricts antecedent retrieval during anaphora resolution. Below we discuss the implications of these results with regards to how the c-command constraint on variable binding may be implemented in models of memory retrieval, and the relative weightings of different cues to antecedent retrieval during anaphora resolution.

Implementing the C-command Constraint

One potential way to help ensure that only syntactically licit QPs are retrieved during anaphora resolution might be to restrict at least initial memory access operations to antecedents that c-command a pronoun. This proposal would be similar to claims in the linguistics literature that variable binding is computed before coreference assignment (e.g., Reuland, 2001, 2011; Koornneef, 2008). In the current study, c-commanding antecedents always appeared in the main clause of the critical sentence, while non c-commanding antecedents appeared in relative clauses. The preference for retrieving a c-commanding antecedent in the current study could thus potentially be achieved by postulating that pronouns preferentially cue retrieval of an antecedent carrying a [+main clause] feature. However, this would also predict that non c-commanding DPs, even though they can be linked to the pronoun via coreference assignment, should also initially be ignored. Note however that while we observed selective retrieval of QPs in Experiment 2 and retrieval of DPs irrespective of c-command in Experiment 3, the time-course of gender mismatch effects across the pronoun and spillover regions in both experiments was very similar. If an initial retrieval favors antecedents carrying the [+main clause] feature only, we would have expected to see a delay in gender mismatch effects for non c-commanding DP antecedents compared to c-commanding DP antecedents in Experiment 3 that was not observed. The results from Cunnings et al. (2014) also clearly indicate that there is no initial preference for c-commanding over non c-commanding antecedents. Thus, we believe the hypothesis that initial retrieval operations should always simply ignore non c-commanding antecedents can be rejected. Nor can the retrieval operation initially target *only* referential antecedents or quantified ones, considering that Cunnings et al. (2014) observed no overall preference for either variable binding or coreference assignment.

Sensitivity to the c-command constraint on variable binding thus requires a restriction that selectively retrieves antecedents based on the c-command relationship between the pronoun and QP. As noted in the introduction, some have claimed that this type of *relational* constraint may be difficult to implement in content-addressable memory architectures (Kush, 2013; Kush et al., 2015). Kush et al. propose that one way to implement the c-command constraint on variable binding would be to encode all potential antecedents with an ACCESSIBLE feature that the parser is able to dynamically update based on the current state of the parse during incremental processing. That is, antecedents are always initially marked as [+accessible], but retrieval operations at specific points during an incremental parse may deactivate this feature if need be. We believe this proposal could account for our results as follows. In Experiments 2–4, the critical QP/DP (*every old man/woman; the old man/woman*) will initially be encoded as being [+accessible]. In the c-commanding QP/DP conditions, this feature will always remain activated. In the non c-commanding QP/DP conditions, upon reaching the right-most edge of the relative clause, a retrieval operation will access all antecedents within the relative clause, deactivating the ACCESSIBLE feature for QPs to ensure that they are no longer possible targets for retrieval, but leaving it unchanged for DPs. In this way, well-known clause "wrap-up" effects may in part involve updating items in a particular clause as being either accessible or inaccessible to further retrieval operations. Upon encountering the pronoun, the ACCESSIBLE feature will be a highly weighted cue to retrieval, activating DPs irrespective of c-command, but activating c-commanding QPs only.

Cue Weighting during Anaphora Resolution

The results of the current study indicate that the c-command constraint on variable binding, perhaps implemented using the ACCESSIBLE feature as above, is a highly weighted cue to antecedent retrieval. The gender mismatch effects observed in Experiment 2 indicate that participants will readily retrieve a c-commanding QP during processing, but we found no evidence of the QP being retrieved when it did not c-command the pronoun. In Experiment 4, when the QP was always syntactically illicit, we found that a number of reading time measures were significantly affected by the stereotypical gender of the syntactically licit DP only. The earliest measures where we observed this effect were those including first pass processing at the spillover region and second pass processing at the pronoun region.

Some models of memory retrieval assume that cues combine in an equally-weighted fashion to guide retrieval during language processing (e.g., Lewis et al., 2006). Evidence from facilitatory interference effects during subject-verb agreement processing for example, suggest that for at least some dependencies syntactic constraints and agreement markers are equally weighted cues to retrieval (e.g., Wagers et al., 2009). More recently however it has been claimed that retrieval cues during language processing are not always equally weighted (Van Dyke and McElree, 2011; Dillon et al., 2013). For example, Dillon et al. claimed that syntactic binding constraints constitute "hard constraints" that restrict retrieval to syntactically licit antecedents. We argued that the most obvious kind of evidence that the c-command constraint and gender congruence combine equally to guide retrieval would be from facilitatory interference effects similar to those observed for subject-verb agreement. However, we failed to observe this pattern of results in Experiment 4.

Although we failed to observe facilitatory interference, Badecker and Straub (2002) reported a different type of *inhibitory* interference in a series of self-paced reading experiments. They observed longer reading times when multiple antecedents matched in gender with a reflexive or pronoun compared to when there was only one gender matching antecedent. Such effects could indicate that when there are multiple gender matching antecedents in the discourse, both syntactically licit and illicit antecedents compete for retrieval. The clearest evidence of this type of interference in the current study would have been from longer reading times in Experiment 4 in multiple gender match condition (8a) compared to the single match condition (8b). However, we also failed to observe this type of effect.

The clearest evidence of the gender of the QP significantly affecting reading times that we did observe was in the *opposite* direction predicted by facilitatory interference, and was also dissimilar to the effects observed by Badecker and Straub (2002). In the regression path times for the final region in Experiment 4, reading times were significantly longer when the syntactically illicit QP matched the gender of the pronoun, but only when

the grammatically licit DP antecedent itself mismatched in gender with the pronoun. Note also that this effect of the QP's gender appears delayed in comparison to the significant main effects of the stereotypical gender of the syntactically licit DP.

In line with recent proposals that not all cues to memory retrieval are equally weighted during language processing (Van Dyke and McElree, 2011; Dillon et al., 2013), we argue that the c-command constraint on variable binding, implemented with the ACCESSIBLE feature, is a more highly weighted cue to antecedent retrieval than gender congruence during anaphora resolution. Whether or not the c-command restriction acts as a "hard constraint" that imposes a categorical ban on the retrieval of syntactically illicit antecedents is difficult to conclude. However, the relative time-course of effects observed for DP and QP antecedents in Experiment 4 may bear on this issue. Recall that in the DP stereotypical gender mismatch conditions in the regression path times of the final region in Experiment 4, we observed *longer* reading times when the QP matched the gender of the pronoun compared to when it mismatched. We remain cautious in interpreting precisely what this effect may index, but it could potentially indicate that readers sometimes attempted to coerce an interpretation in which the pronoun was linked to a syntactically illicit but gender matching QP antecedent, with this coercion of a syntactically illicit interpretation leading to longer reading times. The time-course of this effect, appearing at the sentence final region and delayed in comparison to stereotypical gender violations between the DP and pronoun, may indicate that it reflects a relatively late interpretive process that tries to coerce an otherwise dispreferred interpretation for the pronoun. Similar to Sturt's (2003) defeasible filter hypothesis, we propose that the time-course of effects observed in Experiment 4 may indicate that initially, retrieval operations attempt to retrieve syntactically licit antecedents only. Readers may sometimes try to coerce syntactically illicit interpretations during comparatively later stages of processing however, perhaps during reanalysis after initially retrieving a syntactically licit, but gender-mismatching antecedent. We note also however that other interpretations of this delayed effect are possible. Kush et al. (2015) for example, found that non c-commanding QPs did not influence reading times during early stages of anaphor resolution in sentences like (4b), but did find some suggestive evidence of delayed effects of non c-commanding QPs influencing processing in measures that included second-pass processing. They claimed that such delayed effects might index coercion of an additional referential antecedent for the pronoun from the set of antecedents implied by the quantifier. In this sense, when the pronoun matches the gender of a non c-commanding QP in sentences like (8c), the delayed effect we observed may index coercion of a referential antecedent (*an old woman*) from the set of antecedents implied by the QP (*every old woman*). We do not attempt to tease apart these two interpretations here. Irrespective of how these effects are to be interpreted, as they appear delayed in comparison to effects of syntactically licit antecedents, we maintain that retrieval operations initially attempt to retrieve grammatically licit antecedents only.

Finally, we note that counterexamples in which variable binding appears to be possible between a pronoun and antecedent irrespective of c-command have been discussed in the linguistics literature. For example, in *Every boy's mother says that he is special* the pronoun can be bound by the QP *every boy* even though the QP does not c-command the pronoun under the standard definition. Barker (2012) discusses a number of such counterexamples and claims that the restriction on variable binding should be recast in terms of semantic scope rather than c-command. The relative clause manipulation tested in the current study is a relatively clear-cut case where both traditional accounts and Barker would predict that variable binding is not permitted. Our results show that variable binding is not attempted during processing in such cases, at least during early stages of antecedent retrieval (see also Kush et al., 2015). The extent to which pronouns may trigger retrieval of non c-commanding QPs in other constructions is less well understood. Some researchers have investigated whether pronouns are linked to QPs in non c-commanding configurations other than the relative clause manipulation in the current study (e.g., Carminati et al., 2002; Kush et al., 2015, Experiment 1c), but these experiments used different diagnostics for dependency formation and did not use interference paradigms as in Experiment 4 here. One question that arises is whether retrieval of QPs upon encountering a pronoun is always, at least initially, restricted to c-commanding quantified antecedents, or whether in exceptional cases, as in sentences like *Every boy's mother says that he is special*, quantified antecedents are always accessible. How the c-command constraint and gender/number congruence interact to guide anaphora resolution in other constructions will thus be an important avenue of further research to investigate the extent to which the current findings generalize beyond the relative clauses tested here.

Conclusion

Across four experiments we investigated how constraints on pronoun interpretation influence the retrieval of quantified and non-quantified antecedents in different syntactic configurations. We found that variable binding between a pronoun and quantified antecedent was only attempted if the quantifier c-commanded the pronoun. Retrieval of coreference antecedents, which is not contingent on c-command, was attempted irrespective of c-command. We interpret these results as indicating that syntactic constraints restrict memory retrieval operations during anaphora resolution. We conclude that the c-command constraint on variable binding constitutes a highly weighted cue during anaphora resolution that, at least initially, guides retrieval operations to access syntactically licit antecedents only.

Appendix A

The materials for Experiment 1 are provided below. The c-command manipulation is denoted in square brackets, delimited with a forward slash (/).

1 The soldier [suspected that every old man at the bar/who every old man at the bar suspected] suddenly wished that he had drunk a bit less that afternoon.
2 The footballer [observed that every salesman in the shop/who every salesman in the shop observed] secretly thought that he could offer some advice.
3 The butcher [heard that every boy in the street/who every boy in the street heard] loudly said that he could not lift the heavy box.
4 The farmer [saw that every schoolboy in the field/who every schoolboy in the field saw] truly feared that he would disturb the wildlife.
5 The pilot [knew that every waiter in the café/who every waiter in the café knew] really hoped that he would avoid getting ill.
6 The sailor [trusted that every prince at the royal celebration/who every prince at the royal celebration trusted] clearly understood that he should not join in the dance.
7 The surgeon [suggested that every man on the waiting list/who every man on the waiting list suggested] definitely realized that he needed some help.
8 The builder [noticed that every father at the school gate/who every father at the school gate noticed] openly stated that he should get back to work soon.
9 The nurse [noticed that every old woman in the hospital/who every old woman in the hospital noticed] genuinely expected that she would be allowed to leave very soon.
10 The secretary [saw that every saleswoman in the meeting/who every saleswoman in the meeting saw] obviously worried that she was not making a contribution.
11 The babysitter [observed that every girl in the house/who every girl in the house observed] thoroughly wished that she could reach the biscuit tin.
12 The kindergarten teacher [trusted that every schoolgirl in the class/who every schoolgirl in the class trusted] earnestly believed that she could improve during the term.
13 The housekeeper [knew that every waitress at the event/who every waitress at the event knew] rightly realized that she could create a good atmosphere.
14 The cleaner [suspected that every princess in the castle/who every princess in the castle suspected] truly thought that she could find the lost set of keys.
15 The typist [heard that every woman in the office/who every woman in the office heard] suddenly decided that she should leave early that day.
16 The florist [suggested that every mother on the committee/who every mother on the committee suggested] sincerely hoped that she could get the flowers in time.

Appendix B

The materials for Experiment 2 are provided below. Gender manipulations are shown in parenthesis and square brackets denote the c-command manipulation, delimited with a forward slash (/).

1 Being in hospital can be quite difficult at times. The surgeon [saw that every old man (woman) on the emergency ward/who every old man (woman) on the emergency ward saw] silently wished that he could go a little bit faster.
2 A fight had broken out at the celebration dinner! The footballer [noticed that every waiter (waitress) in the hotel/who every waiter (waitress) in the hotel noticed] quickly realized that he should move away from the table.
3 There was only one way to sneak into the palace party. The soldier [suspected that every prince (princess) outside the castle/who every prince (princess) outside the castle suspected] honestly doubted that he could climb over the high wall.
4 The company was spending a lot of money on a new building. The builder [suggested that every businessman (businesswoman) in the firm/who every businessman (businesswoman) in the firm suggested] sincerely thought that he could do the job much better.
5 There had been a big fire at the local high-school. The firefighter [heard that every father (mother) in the crowd/who every father (mother) in the crowd saw] quickly declared that he should be allowed to go back.
6 The tour of the new local airport was very enjoyable. The pilot [saw that every boy (girl) near the large plane/who every boy (girl) near the large plane saw] clearly expected that he would go up the steps first.
7 There was an uneasy atmosphere after the big match. The boxer [trusted that every policeman (policewoman) in the room/who every policeman (policewoman) in the room trusted] soon realized that he could reach the back exit safely.
8 Trading always starts very early during the morning. The butcher [suspected that every salesman (saleswoman) at the market/who every salesman (saleswoman) at the market suspected] secretly hoped that he could decide on the new price.
9 It was an extremely hot afternoon, even out at sea. The sailor [believed that every schoolboy (schoolgirl) on the boat/who every schoolboy (schoolgirl) on the boat believed] genuinely thought that he could jump into the cold water.
10 It's not very good to be selfish all of the time. The farmer [knew that every little boy (girl) in the small village/who every little boy (girl) in the small village knew] slowly realized that he must share the apples from the orchard.
11 Water had been pouring into the kitchen for a whole day. The plumber [suggested that every young man (woman) in the house/who every young man (woman) in the house suggested] seriously thought that he could stop the leak very easily.
12 It is unusual to talk openly about personal finances. The priest [heard that every man (woman) at the village church/who

every man (woman) at the village church heard] suddenly claimed that he should give more money to charity.

13 Modern life can be a little bit too busy at times. The cleaner [knew that every old woman (man) in the care-home/who every old woman (man) in the care-home knew] truly wished that she had much more time to talk.

14 There had been a lot of changes to the menu that night. The fashion model [heard that every waitress (waiter) in the restaurant/who every waitress (waiter) in the restaurant heard] incorrectly feared that she would get the wrong evening meal.

15 It was the beginning of another very important day. The housekeeper [trusted that every princess (prince) in the old castle/who every princess (prince) in the old castle trusted] clearly understood that she must make a very good impression.

16 There were going to be some big changes at the large company. The secretary [suspected that every businesswoman (businessman) at the meeting/who every businesswoman (businessman) at the meeting suspected] correctly realized that she could change the terms of the contract.

17 Life can get very tiring if you don't find time to rest. The babysitter [trusted that every mother (father) in the big group/who every mother (father) in the big group trusted] eventually realized that she needed to relax now and again.

18 The flower festival was always a very busy time of year. The florist [believed that every girl (boy) in the beautiful garden/who every girl (boy) in the beautiful garden believed] wishfully thought that she could smell all the lovely roses.

19 The carnival always seems to get bigger every year. The nurse [knew that every policewoman (policeman) at the annual event/who every policewoman (policeman) at the annual event knew] fully understood that she must help with any big emergency.

20 Working hard can sometimes bring great rewards. The typist [noticed that every saleswoman (salesman) in the firm/who every saleswoman (salesman) in the firm noticed] never doubted that she would get a big bonus payment.

21 The baseball match was due to start in 2 h. The cheerleader [noticed that every schoolgirl (schoolboy) in the team/who every schoolgirl (schoolboy) in the team noticed] quietly expected that she would stand in the front row.

22 It was yet another really hectic day at the theater in town. The beautician [saw that every little girl (boy) in the glamorous show/who every little girl (boy) in the glamorous show saw] mistakenly worried that she would mess up the expensive costumes.

23 There had been a lot of rumors going around for a while. The fortune-teller [believed that every young woman (man) at the fair/who every young woman (man) at the fair believed) unexpectedly claimed that she was not telling the whole story.

24 It can sometimes be very difficult to ask for assistance. The kindergarten teacher [suggested that every woman (man) in the village/who every woman (man) in the village suggested] wrongfully thought that she could manage without any extra help.

Active search for antecedents in cataphoric pronoun resolution

Leticia Pablos[1,2], Jenny Doetjes[1], Bobby Ruijgrok[1,2] and Lisa L.-S. Cheng[1,2]*

[1] Leiden University Center for Linguistics, Leiden University, Leiden, Netherlands, [2] Leiden Institute for Brain and Cognition, Leiden University, Leiden, Netherlands

Cataphoric dependencies where a pronoun precedes its antecedent appear to call on different mechanisms in language comprehension from forward dependencies where the antecedent precedes the pronoun. Previous research has shown that the resolution of cataphoric dependencies involves predictive processes such as the active search mechanism, which hypothesizes the automatic search for an antecedent immediately after encountering a cataphoric pronoun. The current study employs gender mismatch to investigate whether the active search for an antecedent of a cataphoric pronoun is restricted only to grammatically licit positions. We present results from an event-related potential experiment on the reading comprehension of cataphoric dependencies in Dutch. Results show that gender mismatch gives rise to an anterior negativity at grammatically licit antecedent positions only. We hypothesize that this negativity reflects the prediction failure for an antecedent after encountering a pronoun, rather than a gender mismatch. We discuss the timing, topography and functionality of this negativity with respect to previous studies and how this relates to the ERPs elicited in the processing of structural constraints on pronoun resolution.

Keywords: cataphora, active search, gender mismatch, anterior negativity, Principle C

INTRODUCTION

The on-line interpretation of pronominal dependencies has raised several questions within theories of sentence comprehension. Forward pronominal dependencies – where the antecedent precedes the pronoun – and backward pronominal dependencies – where the pronoun precedes the antecedent – appear to call on different mechanisms in language comprehension. In the case of forward dependencies, their resolution requires retrieving the information about the antecedent at the position of the pronoun, which is closely connected with memory-retrieval processes (Chow et al., 2014). On the other hand, the resolution of backward dependencies (also called cataphoric dependencies) requires the search for an antecedent, which is related to predictive processes.

One of such predictive processes is the active search mechanism (ASM), found initially for the interpretation of *wh*-gap dependencies (Crain and Fodor, 1985; Stowe, 1986; Clifton and Frazier, 1989). In the case of backward dependencies, the ASM hypothesizes that the human parser automatically starts a search for an antecedent in the upcoming sentence immediately after encountering a cataphoric pronoun. This has been shown in behavioral studies through gender mismatch effect (GMME) observations in experimental paradigms where possible antecedents for cataphoric pronouns are restricted by grammatical principles (Sturt, 2003; Van Gompel and Liversedge, 2003; Kazanina et al., 2007; Yoshida et al., 2014). This paper presents an event related potential (ERP) study where we confirm that a similar effect can also be observed in

neurophysiological data. Results support the presence of an ASM for cataphoric dependency resolution that respects grammatical principles. The topography and timing of the ERP component generated at the mismatching antecedent position in our study was an anterior negativity, while previous forward antecedent/pronoun dependencies studies have found a P600 (Osterhout and Mobley, 1995; Van Berkum et al., 2007; Xu et al., 2013). We postulate that the ERP component observed in cataphoric dependencies is related to a failure of a prediction by the parser, in line with the active search approach, while in the case of forward antecedent dependencies the effect can only be connected to a gender mismatch as no prediction is made (the pronoun is not required to interpret the antecedent).

Cataphoric Dependencies

Cataphoric pronouns are pronouns that occur linearly before their antecedent. In other words, they are instances of referential dependencies in which the antecedent follows the referentially dependent element, as illustrated in (1). The index *i* indicates that he_i and $Peter_i$ refer to the same person.

(1) While **he$_i$** had a broken arm, **Peter$_i$** could not ride his bike.

Pronouns such as *he* in (1) pose an interesting case for parsing theories. In order to resolve the interpretation of the pronoun with an antecedent in the same sentence, the parser needs to wait until the appearance of the antecedent. When the antecedent is found, the pronoun can establish a link with it for its own interpretation. However, this is only possible when the grammar allows the link between the cataphoric pronoun and the antecedent to be established. Consider the pronoun *he* in (2) and the pronoun *his* in (3). In contrast to the pronoun in (1), the pronoun in (2) cannot take the proper name *Peter* as its antecedent (as indicated by the starred index of *j* – *he* cannot have the same index/reference as *Peter*). However, *Peter* can be the antecedent of the pronoun *his* in (3).

(2) **He$_{i/*j}$** said that **Peter$_j$** is sick.
(3) **His$_i$** brother said that **Peter$_i$** is sick.

The restriction of the pronominal reference in (1), (2), and (3) can be captured under the principles of the Binding Theory (Chomsky, 1981) that indicates the configurations in which nominal elements can or cannot establish a coreferential relation. There are three Binding Principles, each of which concerns a different type of nominal elements. Binding Principles A and B are concerned with two different types of pronouns (*himself* vs. *him*), while Principle C restricts the distribution of Referential Expressions, including proper names such as *Peter*.

We focus on Principle C, which prohibits a Referential Expression (e.g., proper name) from being *bound* (Chomsky, 1981). The pronoun *he* in (1) does not bind the referential expression *Peter*, because the pronoun is embedded in an adverbial clause that does not contain *Peter*. Given that *he* does not bind *Peter*, the two can have the same reference. On the other hand, the pronoun *he* in (2) binds the referential expression *Peter* structurally and in such a case, coreference is excluded. *His* in (3) on the other hand is more deeply embedded in the structure (i.e., in the noun phrase *his brother*), and therefore, it does not act as a binder of *Peter*. Thus, similar to (1), a cataphoric dependency can be established in (3). Referential expressions, such as *John* or *the man*, independently refer and select a referent from the domain of discourse. Given that Referential Expressions have independent reference, they do not need and in fact cannot tolerate a binder. The binder would act as an antecedent for the Referential Expression, which is in conflict with the referential status of the latter.

In this study, we investigate whether Principle C of the Binding Theory is respected in cataphoric pronoun processing. As illustrated in (1), (2), and (3), whether a referential expression can be a potential antecedent for a cataphoric pronoun depends on the structural configuration. If a coreferential relation is established between a referential expression and a cataphoric pronoun and as a result, the referential expression is bound by the pronoun, Principle C of the Binding Theory would be violated. This paper examines how this type of violation affects parsing. In particular, it uses gender mismatch to investigate whether a search for an antecedent is restricted by structural constraints. Given that the parser respects structural constraints such as Principles B and C of the Binding Theory when interpreting pronouns on-line as shown by behavioral studies that have examined reading times (e.g., Kazanina et al., 2007; Chow et al., 2014; Yoshida et al., 2014), we expect these effects to be visible through electroencephalography (EEG) as well.

Active Search Mechanism [or Active Filler Hypothesis (AFH)]

The ASM claims that an active search is automatically initiated for each uninterpreted element A encountered in a sentence, to find the element B which can help interpret A. The main evidence for the existence of the active search comes from the so-called filled-gap effects involving *wh*-dependencies, which demonstrate that (a) a search for a gap starts as soon as a *wh*-phrase is processed and (b) filling the gap position where the *wh*-word could be interpreted with an overt element (thus blocking the parser from interpreting the *wh*-phrase in that position) results in a longer processing time compared to a sentence where no *wh*-dependency was initiated (Crain and Fodor, 1985; Stowe, 1986; Lee, 2004). Thus, the ASM hypothesizes that the parser anticipates a gap as soon as a *wh*-phrase is processed (Clifton and Frazier, 1989; Frazier and Clifton, 1989).

In the case of pronoun interpretation, the ASM predicts that a search is initiated for an antecedent as soon as a pronoun is encountered (Clifton and Frazier, 1989; Kazanina et al., 2007), in order to resolve the interpretation of the pronoun. Even though pronouns may have antecedents outside of the sentence that contains them, the ASM assumes that the search for an antecedent within the sentence is the default strategy in cases where there is no preceding discourse.

Studies on the processing of cataphoric pronouns have examined whether the parser indeed searches for an antecedent in the sentence once a pronoun has been processed and when the grammar allows the establishment of the binding relation (Sturt, 2003; Van Gompel and Liversedge, 2003; Kazanina et al., 2007;

Yoshida et al., 2014). In these behavioral studies, which used eye-tracking or self-paced reading methodology, the parser searches for an antecedent in the upcoming input in positions where the coreference between the pronoun and the antecedent is allowed (i.e., such coreference does not lead to a violation of the Binding Theory). In such cases, when the potential antecedent does not match in gender with the preceding pronoun, reading times are longer than when the potential antecedent and the pronoun match in gender (Sturt, 2003; Van Gompel and Liversedge, 2003; Kazanina et al., 2007; Yoshida et al., 2014). This reading slowdown effect, known as the GMME, has been taken to be a sign of the parser's active search for an antecedent to interpret the pronoun. Importantly, the data in these studies show that the GMME does not occur if the coreference between the pronoun and the referential expression yields a violation of the Binding Theory (in particular, Condition C), suggesting that in such cases, the referential expression does not count as a potential antecedent for the pronoun.

The main hypothesis of Kazanina et al. (2007) word-by-word self-paced reading experiments is that the parser respects Principle C of the Binding Theory when searching for an appropriate antecedent for a pronoun. This can be illustrated on the basis of the four different conditions in (4), which are from their third experiment: no constraint match in (4a), no constraint mismatch in (4b), Principle C match in (4c) and Principle C mismatch in (4d).

(4) **a. No constraint/Match**
His$_i$ managers chatted amiably with some fans while **the talented, young quarterback$_i$** signed autographs for the kids, but **Carol** wished the children's charity event would end soon so she could go home.
b. No constraint/Mismatch
Her$_i$ managers chatted amiably with some fans while **the talented, young quarterback** signed autographs for the kids, but **Carol$_i$** wished the children's charity event would end soon so she could go home.
c. Principle C/Match
He$_i$ chatted amiably with some fans while **the talented, young quarterback** signed autographs for the kids, but **Steve$_i$** wished the children's charity event would end soon so he could go home.
d. Principle C/Mismatch
She$_i$ chatted amiably with some fans while **the talented, young quarterback** signed autographs for the kids, but **Carol$_i$** wished the children's charity event would end soon so she could go home.

In the no constraint match condition in (4a), the possessive pronoun *his*, being further embedded in the nominal structure, does not bind the referential expression *young quarterback,* allowing it to be a potential antecedent. In other words, in (4a), Principle C does not block the coreference relation between the pronoun *his* and the referential expression (the antecedent *young quarterback*), and these two elements match in gender. Therefore the cataphoric pronoun should be interpreted at the antecedent position. The no constraint mismatch condition in (4b) differs from the no constraint match condition in (4a), in that the gender of the pronoun *her* and that of the potential antecedent *young quarterback* do not match, creating a GMME. In the Principle C match condition in (4c), on the other hand, the pronoun *he* binds the referential expression *young quarterback* in the embedded clause. Thus, *young quarterback* is excluded as a potential antecedent of *he* due to a Principle C violation. Furthermore, both the pronoun *he* and the referential expression *young quarterback* match in gender, as both are masculine. Finally, in the Principle C mismatch condition in (4d) the pronoun *she*, binds the referential expression *young quarterback* in the embedded clause, just like in (4c); however, in this case, they mismatch in gender. Importantly, the GMME is expected to be absent in the Principle C mismatch condition (condition 4d) at the position of the referential expression *young quarterback*, relative to the Principle C match condition (4c), as the coreference relation is barred from being established due to Principle C, preventing the GMME to occur. Conversely, the GMME is expected to be present at the referential expression *young quarterback* position in the no constraint mismatch condition (4b), relative to the no constraint match condition (4a). The main findings of Kazanina et al. (2007) confirm these expectations. Their reading time results thus suggest that the parser abides by Principle C when it attempts to resolve the interpretation of cataphoric pronouns in real-time in that they only find a reading time difference, or GMME, in the no constraint conditions, in which the referential expression in the no constraint mismatch condition in (4b) elicited longer reading times than the no constraint match condition (4a) at the same position (in particular, at the noun *quarterback*), whereas this reading time difference was absent at the referential expression in the Principle C conditions in (4c) and (4d). Furthermore, Kazanina et al. (2007) claim that the active search for an antecedent in cataphoric configurations only occurs when the Binding Principles allow it.

Yoshida et al. (2014) examine the formation of cataphoric dependencies across a relative clause island in a word-by-word self-paced reading experiment and they expect to obtain a GMME, or longer reading times, only in cases where coreference between the pronoun and the antecedent is licit (i.e., not obeying Principle C). Further, the GMME would only be expected to occur if cataphoric dependencies were not to be sanctioned across relative clause islands. Similar to Kazanina et al. (2007), Yoshida et al. (2014) manipulated the sentence initial pronoun [nominative vs. (possessive) genitive], the gender of the pronoun and the first referential expression. Their stimuli are shown in (5). In (5a) and (5b) the pronouns *his/her* can corefer with the referential expression *Jeffrey Stewart* (thus, *Jeffrey Stewart* can be a potential antecedent), but in (5c) and (5d) coreference is not licit due to Principle C of the Binding Theory.

(5) **a. No Constraint/Match**
His$_i$ managers revealed that the studio that notified **Jeffrey Stewart$_i$** about the new film selected a novel for the script, but **Annie** did not seem to be interested in this information.

b. No constraint/Mismatch
Her$_i$ managers revealed that the studio that notified **Jeffrey Stewart** about the new film selected a novel for the script, but **Annie$_i$** did not seem to be interested in this information.
c. Principle C/Match
He$_i$ revealed that the studio that notified **Jeffrey Stewart** about the new film selected a novel for the script, but **Andy$_i$** did not know which one.
d. Principle C/Mismatch
She$_i$ revealed that the studio that notified **Jeffrey Stewart** about the new film selected a novel for the script, but **Annie$_i$** did not know which one.

A GMME or reading slowdown is found at the antecedent position *Jeffrey Stewart* (in particular, at the last name *Stewart*) in (5b) relative to (5a), where the pronoun and the antecedent could corefer (the coreference does not violate Principle C). Moreover, the GMME or reading time difference occurs despite the fact that the potential antecedent is contained within a relative clause island. The GMME generated in the no constraint conditions (5a) and (5b) in the self-paced reading experiment by Yoshida et al. (2014) confirms that online formation of a cataphoric dependency is not affected by island constraints in that coreference is established in (5a) and (5b) conditions when the grammatical constraint of Principle C does not ban this coreference. If island constraints affected the generation of a cataphoric dependency we will not expect a GMME to occur in no constraint conditions, which it does. Furthermore, these results support the claim in Kazanina et al. (2007), that the processing of cataphoric dependencies is modulated by a grammatically constrained ASM, which respects grammatical principles such as Principle C.

The current study aims to replicate the GMME results from previous studies (Sturt, 2003; Van Gompel and Liversedge, 2003; Kazanina et al., 2007; Yoshida et al., 2014; a.o.) using ERP, to identify a neural correlate of the ASM found in the on-line interpretation of cataphoric dependencies. If an active-search is initiated for these dependencies (as shown by previous behavioral studies through the generation of the GMME effect, which is a slowdown in the gender mismatching conditions relative to the gender matched ones), it should be possible to identify an effect (i.e., an ERP component) comparable to the reading time differences shown in behavioral studies with the ERP methodology. In other words, we predict there to be a GMME in the no constraint mismatch conditions such as (4b) and (5b) above, relative to the no constraint match conditions in (4a) and (5a).

Event-related Potential (ERP) Studies on Gender Agreement/Mismatch

Since the current study examines gender agreement mismatches at the antecedent position in cataphoric configurations, a brief overview of the ERP studies that have tackled gender agreement issues is in order. Gender agreement mismatches have been examined in the ERP literature using different paradigms. Wicha et al. (2004) found a P600 for gender disagreeing nouns in determiner-noun combinations in Spanish, where the expected noun mismatched in gender with the preceding determiner. Van Berkum et al. (2005) on the other hand tested the prediction for the likely appearance of a specific noun based on the previous discourse. Their aim was to examine how listeners use their discourse knowledge to predict specific nouns. If listeners anticipate a noun with a specific gender by the time they encounter the indefinite article (not gender marked) in the story, a gender-mismatched adjective (i.e., mismatched in accordance to the gender of the noun that is expected) would be a surprise, leading to an ERP effect at the adjective position. They tested Dutch sentences where the sentence continuations had either an adjective consistently gender-marked with the upcoming predicted noun and its gender, or an adjective inconsistently gender-marked with respect to the prediction made for the upcoming noun and its gender. Their results again showed a P600 for gender-mismatched adjectives.

In a different set of studies, gender agreement violations between a determiner and a noun, or between an adjective and a noun, showed a left anterior negativity (LAN) followed by a P600 at the noun position for Spanish, Italian, and German (Demestre et al., 1999; Gunter et al., 2000; Barber and Carreiras, 2005; Molinaro et al., 2008; a.o.), a P600 for English and Dutch (Hagoort and Brown, 1999) and a N400 followed by a P600 for Hebrew (Deutsch and Bentin, 2001).

Finally, in a third set of studies, gender violations were tested in forward pronoun resolution dependencies, i.e., dependencies in which antecedents occur before pronouns. Osterhout and Mobley (1995) tested sentences such as (6) where a masculine or feminine pronoun matched or mismatched in gender with a previously encountered antecedent. They found a P600 at the pronoun *he* that mismatched in gender with the previously encountered feminine antecedent *the aunt*. Note that coreference between *he* and *the aunt* is only blocked by the gender mismatch and not by the Binding Conditions, as pronouns, contrary to referential expressions, may be bound by their antecedent if the antecedent is located in a different clause (cf. Principle B of the binding theory).

(6) **The aunt** heard that **she/he** had won the lottery.

Similarly, studies that tested gender violations in comparable forward pronoun configurations in Dutch (Van Berkum et al., 2007) and Chinese (Xu et al., 2013) found a P600 at the position of the pronoun when it mismatched in gender with the preceding antecedent.

Taking into consideration the results in these studies that have manipulated gender agreement, it is clear that a P600 component emerges constantly, regardless of whether the relation is one between (1) a determiner and a noun; (2) an adjective and a noun; or (3) an antecedent and a pronoun. While the P600 is preceded by a LAN or by a N400 in some cases in pure pronoun resolution cases more akin to the manipulation in the current study, only a P600 is obtained at the position of the gender-mismatched pronoun.

The Current Study

As indicated above, the present study examines processing of pronouns and their antecedents in a *cataphoric configuration*,

where the pronoun linearly precedes the antecedent. To summarize, the aim of this study is threefold. (i) First is to examine whether there is a GMME when the parser encounters the first potential antecedent of the cataphoric pronoun that does not match in gender. This would be an indication that the parser starts actively searching for a matching antecedent after encountering the cataphoric pronoun, even though the antecedent of the pronoun could, in principle, be found outside of the sentence. We predict the GMME to be present in the case of a mismatch, and absent in the matching condition. (ii) Second, we examine if the search mechanism is modulated by grammatical constraints such as Principle C of the Binding Theory. For cases where co-reference may lead to Principle C violations, we predict no difference between the match and the mismatch conditions. We predict that an ERP component is elicited only for referential expressions that can legitimately establish a co-reference relation with the cataphoric pronoun. (iii) Third, we examine if cataphoric pronoun dependencies generate the same kind of ERP components as forward pronoun dependencies. As discussed above, previous studies (e.g., Osterhout and Mobley, 1995; Van Berkum et al., 2007; Xu et al., 2013; a.o.) examined forward dependencies. However, no ERP study has examined cataphoric dependencies where the pronoun precedes the antecedent.

We aimed to search for the neuronal correlates of the ASM by means of a technique that has an excellent temporal resolution and where the effects of the active search can be examined by looking directly at brain behavior.

MATERIALS AND METHODS

Materials

Thirty-six experimental items were constructed in Dutch. These 36 items were distributed across four lists in a Latin Square design, which implies that each participant saw nine trials per condition. We decided on the relatively small number of trials per condition for a number of reasons: (a) The GMME effect has been quite reliable in the behavioral literature. Thus, we expect the size effect of the gender mismatch to be robust; (b) we would like to avoid reading fatigue as well as participant developing different processing strategies derived from the high number of proper names included in the items. Note that previous studies, which investigated the processing of coreference involving repeated nouns with the ERP technique, used a higher number of trials per condition for their experiments (i.e., 40 trials per condition; see for example, Swaab et al., 2004; Ledoux et al., 2007). However, the research questions of these studies and our initial question do not overlap, since these studies were examining word repetition-priming effects and the impact this factor had on the modulation of the N400 ERP component, whereas our interest lays in the process of coreference itself. The vast majority of ERP experiments in the field present every participant with 20–40 items per condition, but this is because the ERP effects that the experimenters are after are often rather small. Likewise, the use of a large number of trials is often connected to the fact that usually some trials are discarded due to artifacts or to the type of ERP component that the researchers are after, which might be different in size (see for example, Luck, 2005; Kaan, 2007 for further discussion of this specific issue).

We followed closely the set-up of the English word-by-word self-paced reading experiment by Kazanina et al. (2007) while creating our ERP experiment, since we were interested in seeing the time-course of the GMME using ERPs. There are four experimental conditions, as shown in (7). First, No-Constraint conditions, which contain a possessive pronoun, in masculine (7a) or feminine form (7b) that matches or mismatches, respectively, in gender with the linearly first antecedent *Lodewijk* (masculine). Second, Principle C conditions, which contain a cataphoric nominative pronoun in masculine (7c) or feminine form (7d) that cannot co-refer with the referential expression *Lodewijk* in the embedded clause due to Principle C.

In all conditions, the test sentences always contain a licit antecedent for the pronoun. For example, in the No-Constraint mismatch condition in (7b) and in Principle C conditions in (7c) and (7d), the pronouns corefer with an antecedent that appears toward the end of each sentence [i.e., *Mirjam* in (7b) and (7d), and *Thomas* in (7c)]. Relevantly, even if pronouns could have co-reference with an antecedent outside of the sentence, the availability of an antecedent in the same sentence (i.e., *Mirjam/Thomas*) guarantees that the pronoun-antecedent relation is resolved within the sentence. Feminine and masculine pronouns and referential expressions were counter-balanced. Previous reading time studies found effects at positions immediately following the antecedent (see Yoshida et al., 2014). Based on this, we included proper names with a surname (such as *Lodewijk Boer*) in our data to ensure that there could be a region immediately following the proper name that was still connected to the antecedent position. However, considering the superior time accuracy of the ERP technique, our prediction was that the effect should be observable at the target position rather than at immediately following regions. Participants read 36 target stimuli such as those in (7; see Data Sheet in Supplementary Material for a whole list of stimuli) randomly interspersed with 35 unrelated fillers that were part of a different experiment that examined the processing of backward negative polarity item dependencies (Pablos et al., 2012).

(7) **a. No-Constraint/Match**
Zijn$_j$ assistenten kwamen erachter dat **Lodewijk$_j$ Boer** geen prijswinnaar *His assistants found out that Lodewijk$_{masc}$ Boer no prizewinner* geselecteerd had, maar **Mirjam$_i$** had geen interesse in de roddel.
selected had but Mirjam$_{fem}$ had no interest in the gossip 'His assistants found out that Lodewijk Boer had not selected a prizewinner, but Mirjam had no interest in the gossip.'
(b) No-Constraint/Mismatch
Haar$_i$ assistenten kwamen erachter dat **Lodewijk$_j$ Boer** geen prijswinnaar *Her assistants found out that Lodewijk$_{masc}$ Boer no prizewinner* geselecteerd had, maar **Mirjam$_i$** had geen interesse in de roddel. *selected had, but Mirjam$_{fem}$ had no interest in the gossip.*

'Her assistants found out that Lodewijk Boer had not selected a prizewinner, but Mirjam had no interest in the gossip.'

c. Principle C/Match

He found out that Lodewijk$_{masc}$ Boer no prize winner
geselecteerd had, maar **Thomas$_i$** had geen interesse in de roddel.
selected had, but Thomas$_{masc}$ had no interest in the gossip.
'He found out that Lodewijk Boer had not selected a prizewinner, but Thomas had no interest in the gossip.'

d. Principle C/Mismatch

Zij$_i$ kwam erachter dat **Lodewijk$_j$ Boer** geen prijswinnaar
She found out that Lodewijk$_{masc}$ Boer no prize winner
geselecteerd had, maar **Mirjam$_i$** had geen interesse in de roddel.
selected had, but Mirjam$_{fem}$ had no interest in the gossip.
'She found out that Lodewijk Boer had not selected a prizewinner, but Mirjam had no interest in the gossip.'

Participants

Twenty-four students of Leiden University participated in this study, which was conducted at the EEG Laboratory in the Faculty of Social Sciences of Leiden University. They were all native speakers of Dutch. All participants had normal or corrected-to-normal vision, were right-handed, gave informed consent and were paid €12.50 for their participation, which lasted around 30 min, excluding set-up time. The experiment followed the Ethics Committee regulations of the Faculty of Social Sciences of Leiden University, which approved its implementation.

Procedure

Participants were comfortably seated in a dimly lit testing room around 100 cm in front of a computer monitor. Sentences were presented one word at a time in black letters on a white screen using the presentation software E-prime (Psychology Software Tools Inc.). Each sentence was preceded by a fixation cross ("+") which appeared at the center of the screen and remained there for 1000 ms. The fixation point was followed by a blank screen interval of 300 ms, and then the sentence was displayed word by word.

Each word appeared on the screen for 300 ms, followed by a fixation cross ("+") at the center of the screen that remained visible for 300 ms. Participants were instructed to read the sentences carefully for comprehension. The last word of each sentence was marked with a period, and 1000 ms later a comprehension question appeared and prompted the participant to press a button to continue. Every experimental item was followed by a comprehension question. The comprehension questions targeted different positions of the sentence and some of them targeted the referential expressions *Lodewijk Boer* or *Thomas/Mirjam*. The comprehension questions were counter-balanced for yes and no answers and, for some items, they differed across conditions (see Data Sheet in Supplementary Material). Four counterbalanced lists derived from a Latin Square Design were used for the experiment. Before starting the experimental phase, eight warm-up practice trials were presented to the participants, which had no similarity to any of the targets or filler items in the experiment. Participants were able to ask clarification questions to the experimenter about the task at the practice time. The experimental session was broken up by two break periods, with a different number of items distributed across each block, with 35 and 36 sentences per block.

EEG Recording

The EEG signal was continuously acquired at a sampling frequency of 512 Hz using a BioSemi (Active Two) system from 32 Ag/AgC1 electrodes distributed in the scalp following the extended 10–20 convention (Fp1/2, FC5/, AF3/4, Fz, CP5/6, CP1/2, Cz, F7/8, F3/4, T7/8, C3/4, Pz, FC1/2, P3/4, O1/2, Oz, P7/8, PO3/4). EEG data was referenced on-line to two auxiliary electrodes: common mode sense (CMS) and driven right leg (DRL) and re-referenced off-line to the mean activity at the two mastoids. A high-pass filter with a cut-off frequency of 0.1 Hz was applied online to eliminate DC drifts. Vertical and horizontal eye movements were monitored with two electrodes at the infraorbital and supraorbital, and electrodes at the outer canthus of the right and left eyes. Electrode impedances were monitored during installation to ensure a low level of electronic noise.

EEG Analysis

For every subject, recorded EEG waveforms were post-processed before analysis to reduce noise and artifacts as much as possible. After applying a high-pass filter to remove slow drifts and DC offsets, ocular correction was performed using an implementation of the Gratton et al. (1983) algorithm. Other artifacts were removed both by visual inspection and by performing an automated detection based on gradient change rate. The process resulted in the rejection of 6% of the trials (51 out of 864) distributed among the experimental conditions as follows: (7a) 1%; (7b) 1%; (7c) 2%; (7d) 2%. To confirm that these small differences between conditions were not significant and did not introduce biases in the results, we ran a repeated measures mixed-logit analysis with Match (match/mismatch) and Constraint (No Constraint/Principle C) as independent variable and Subject as random factor. Both main effects and interactions were considered, and no significant difference in likelihood ratio between the fitted model and a null intercept only model was observed.

As a final step, a low-pass filter with a cut-off frequency of 30 Hz was applied to remove noise and non-neurological signals. After the data cleaning, a few electrodes identified as noisy or with intermittent connection were replaced by an interpolation based on neighboring channel responses.

Electroencephalography recordings were then segmented from 200 ms before to 800 ms after the onset of the significant region being analyzed (*Lodewijk*). A baseline correction was applied based on the average of the 200 ms prior to the stimulus onset.

Previous studies that have examined gender mismatches consistently reported a P600 component. In order to evaluate the presence of a P600 in our experimental data, the 500–700ms time window was tested by means of a 4-way repeated-measure

ANOVA, considering four within-subject factors. Two to evaluate the signal scalp distribution: *Hemisphere* [Left *(Fp1, F3, F7, C3, P3, O1)* Central *(Fz, Cz, Pz)*, Right *(Fp2, F4, F8, C4, P4, O2)*], and *Position* [Frontal *(Fp1, Fp2, F3, F4, F7, F8)*, Medial *(C3, Cz, C4),* and Parietal *(P3, Pz, P4, O1, O2)*]; and two to examine effects between conditions: *Constraint* (No Constraint/Principle C), and *Match* (Match/Mismatch). Mean voltage-amplitude was considered as the dependent variable in the analysis, and p-values where corrected for sphericity where required.

RESULTS

Comprehension Questions

Average accuracy rates were high and no participants were rejected on the basis of accuracy ($M = 84.59\%$, $SD = 5.44\%$). The accuracy scores were similar across conditions ($M_{\text{NoConstraintMatch}} = 81\%$, $M_{\text{NoConstraintMismatch}} = 84\%$, $M_{\text{PrincipleCMatch}} = 87\%$, $M_{\text{PrincipleCMismatch}} = 86\%$). The difference in mean values was not significant as shown by a 2×2 repeated-measures ANOVA randomized by subjects with *Constraint* and *Match* as independent factors and Response Accuracy as dependent variable ($p > 0.5$ for all main effects and interactions).

Event Related Potentials

We investigated ERPs at the subject position of the embedded clause, *Lodewijk*, which is the first potential antecedent position in the sentence if there is no Principle C violation. Four-way ANOVA performed in the pre-selected P600 time window (500–700 ms) did not result in any significant main effect or interaction ($p \geq 0.1$ in all cases), as shown in the right most column of **Table 1**. However, visual comparison of the grand average time traces in the anterior electrodes for the No-Constraint Mismatch condition (7b) versus No-Constraint Matched (7a) condition shows an apparent sustained negativity in the 200–600 ms region (**Figure 1**). The anterior topography of the negativity can be observed in **Figure 2**. No such negativity is observed for Principle C Match/Mismatch conditions (**Figures 3** and **4**). The asymmetry observed in the No-Constraint with respect to the Principle C conditions supports the expectation of the experimental manipulation, therefore, an exploratory analysis was performed to investigate the reliability and nature of this apparent difference.

An omnibus ANOVA performed in the complete 200–600 ms time window shows a significant 4-way interaction of *Constraint, Match, Hemisphere,* and *Position* [$F(4,92) = 2.572$; $p = 0.043$]. Follow-up simple interaction analysis for each level of the *Constraint* factor reveals no significant interaction or main effect in Principle C conditions, while a significant 3-way interaction between *Hemisphere* × *Match* × *Position* is present in No-Constraint [$F(4,92) = 3.202$, $p = 0.016$]. A further breakdown of this interaction for every level of the *Position* condition shows a significant effect of *Match* factor at the Anterior sites [$F(1,23) = 4.82$, $p = 0.038$], and no dependence on *Hemisphere*. The *No-Constraint Mismatch* condition (7b) waveform average amplitude is more negative than (7a) [t-test nearly significant difference $t'(23) = 1.989$, $p = 0.057$].

The same analysis was repeated using sliding 200 ms long windows to localize the effect with respect to the onset time of the stimuli. **Table 1** summarizes the omnibus ANOVAs and **Table 2** provides the follow up simple interaction evaluation for those regions with significant interaction in the omnibus ANOVA. (Only significant comparisons and effects are shown for readability. Values are corrected for sphericity where required – corrected p-values are reported).

Finally, **Table 3** shows a summary of the main effects and *post hoc* pairwise comparisons observed in the two time windows (200–400 ms, 300–500 ms) in the breakdown of the interactions observed in **Table 2**, which in all cases reflect a significant anterior negativity of the *Mismatch* condition for the *No-Constraint* case when compared with the *matched* counterpart.

However, the results of the exploratory analysis above present the multiple comparison problem (MCP). To limit the Family Wise Error Rate (FWER) to a 5% level, the individual comparisons reported in **Table 1** should have a p-value lower than $0.05/4 = 0.0125$. In addition, an individual 2×2 ANOVA – to verify the interaction of the *Constraint* and *Match* factors in the topographical regions of interest defined by the *Position* and *Hemisphere* factors considered in the above analysis – did not yield a significant interaction in neither of the time windows ($p > 0.10$). This result is very likely due to the low statistical power provided by the small number of electrodes in each region of interest, and the limited number of trials.

To address the problem of MCP and verify if the differences observed were reliable, the ERPs measured were analyzed with a repeated measures two-tailed cluster mass permutation test (Bullmore et al., 1999; Maris and Oostenveld, 2007) using the Matlab Mass Univariate ERP Toolbox (Groppe et al., 2011). This test provides a better spatial and temporal resolution and weak control of the FWER. We included

all samples between 200 and 800 ms at all 32 electrodes. Electrodes within an approximate distance of 5.77 cm from each other were considered spatial neighbors for the cluster determination. Repeated measures *t*-tests were performed on the difference wave of the Match and Mismatch conditions for both *No-Constraint* and *Principle C* factor levels. *T*-test included the original data and 2500 random within-subjects permutations. With this technique, we tested separately the null hypothesis that the *Match* and *Mismatch* position do not differ in the No-Constraint and Principle C conditions. The maximum cluster-level mass procedure in the No-Constraint Match versus Mismatch comparison returned a cluster at the central-frontal electrodes extending temporally from 300 to ~420 ms with an alpha level $p = 0.07$ (see **Figure 2**). In contrast, the procedure in the Principle C conditions did not reject the null hypothesis to any level of significance ($p > 0.4$).

In conclusion, results show significant differences to an alpha level of ~0.07 between the *Match* and *Mismatch* conditions in the No-Constraint cases only, with anterior topographic distribution over a window around 300–420 ms. The observed difference is both in the direction expected based on the theoretical predictions, and with a coherent spatial and temporal localization. This reinforces that the effect is reliable even with the aforementioned reduced confidence level, compared to traditional 5% values. The presence of a positive result in an experiment with a relatively low power in terms of the number of trials observed per subject and condition (i.e., 9) suggests that the effect size is large and would be more prominent with an increased number of items [see Maxwell

et al. (2008) for a discussion on sample size and statistical power].

DISCUSSION

Active Search for Antecedents

We have shown that, in cases such as (7b) (No-Constraint Mismatch), where there is a gender mismatch between the pronoun and the first potential antecedent for this pronoun, an anterior negativity is generated at the potential antecedent position *Lodewijk*. This is not the case for (7a), where the potential antecedent matches in gender with the preceding pronoun. The anterior negativity could be interpreted as a result of the gender mismatch between a cataphoric pronoun and its antecedent, as well as the effect of failing to find an antecedent at the first potential position. However, for (7c) and (7d), where the cataphoric pronoun cannot corefer with the referential expression *Lodewijk* due to Principle C, no component is generated at the referential expression position. This confirms our predictions that (i) an active search for an antecedent is initiated as soon as a cataphoric pronoun is processed and that, (ii) although the ASM can be automatically initiated for every pronoun, which referential expression will be considered by the ASM is constrained by grammatical principles (in this case, Principle C). This result is in line with the behavioral results (e.g., Kazanina et al., 2007) that found a GMME at the potential antecedent.

Forward vs. Backward Antecedent/Pronoun Dependencies and Prediction Failure

The differences observed in ERP components generated between our results in the case of cataphoric dependencies (anterior negativity) and the forward pronominal dependency studies (Osterhout and Mobley, 1995; Van Berkum et al., 2007; Xu et al., 2013; P600) raise questions on the nature of the effect observed.

In the current experiment, we focus on the relation between a *cataphoric* pronoun and its potential antecedent. In the case of forward antecedent-pronoun dependencies [as in (6)], there is no need to search for a pronoun after encountering the antecedent (e.g., *the aunt*) since this referential expression can be independently interpreted. In other words, we do not expect an active search for a pronoun in the case of forward dependencies. The P600 component in these cases, therefore, must correspond to a gender mismatch between the referential expression and the pronoun.

In backward, cataphoric pronoun-antecedent dependencies, on the other hand, the processes underlying the generation and interpretation of these dependencies are different since the interpretation of the pronoun needs to be resolved. It is therefore reasonable to hypothesize that the parser prefers to start a search as soon as a pronoun is encountered. The anterior negativity in our experiment could be interpreted as related to the searching process itself, namely, a failure of a prediction and not so much to the gender mismatch. The GMME provides the evidence that the antecedent search is active in the no-constraint cases, but it might not be the primary reason for the generation of the anterior negativity. Nevertheless, after having examined previous literature on gender mismatches, we might still wonder why no P600 as well is generated for the gender mismatch at *Lodewijk* in (7b) after encountering the feminine pronoun *haar*. We hypothesize that, in forward dependencies, the parser needs to retrieve the gender of the antecedent from memory and check for gender matching. The P600 could be a reflection of the gender mismatch alone. Conversely, in backward dependencies, the parser anticipates the appearance of an antecedent in the upcoming sentence as soon as it processes the pronoun. Thus, when the parser encounters the first potential antecedent position, it expects to find a matched antecedent. When it fails, there is a negativity generated instead of a P600 because the failure of finding a matching antecedent prevails over the GMME. With this claim we do not intend to imply that the gender mismatch does not occur at all or that it does not precede the expectation failure (since the failure of the prediction cannot occur before the mismatch is detected) rather that the failure of finding a matching antecedent veils the presence of a P600.

In the second experiment in Osterhout and Mobley (1995), a negativity (at anterior and temporal sites in the left-hemisphere between 300 and 500 ms) is found for a dependency where a specific verb form that agrees with the subject is predicted and fails. In our experiment, a negativity is found for a dependency where an antecedent for the cataphoric pronoun is predicted

and this prediction fails because of a gender mismatch. These two types of dependencies are different in nature (one involves subject-verb agreement and the other a pronoun-antecedent coreferential relation), but the mechanism of prediction failure seems to be the same in that there is a negative component generated in both cases. Despite of the fact that the negativities in these two studies are different in distribution, we suggest that they are connected to the same basic process, and that they reflect the failure of a previously established expectation. However, we have to consider that the presence of a negativity in agreement violations is currently under debate since not all the studies observed it (see Nevins et al., 2007; Mancini et al., 2011; Molinaro et al., 2011; a.o.).

Potential Task and Stimuli Presentation Effects

One of the potential sources for the lack of P600 for the gender mismatch in our study might connect to issues that previous studies have discussed (Bornkessel-Schlesewsky et al., 2011; Molinaro et al., 2011; Sassenhagen et al., 2014), such as the influence of task and the modality of stimulus presentation. The current study used word-by-word visual presentation of the sentences in which subjects had to read the sentence and answer a Yes/No comprehension question afterward. Studies that have shown P600 effects for gender mismatches in forward antecedent/pronoun dependencies (Osterhout and Mobley, 1995; Van Berkum et al., 2007; Xu et al., 2013) have all used visual presentation, so the mode of presentation does not seem to have an impact in the results. Differences between our study and previous studies rest in the task that participants were required to complete. Van Berkum et al. (2007) do not require any task from participants besides reading the sentences, whereas Osterhout and Mobley (1995) and Xu et al. (2013) ask their participants to conduct an acceptability judgment after reading each sentence. Sassenhagen et al. (2014) discuss the idea that the generation of a P600 can be task-dependent and that consciously detected violations might differ with respect to non-consciously detected violations in that the detected or attentive violations elicit both an early negative component and a P600, whereas the non-detected ones do not necessarily elicit a P600 (Hasting and Kotz, 2008; Batterink and Neville, 2013). Results from our experiment seem to align with this idea since we only get an early negativity and the study does not implement a task that highlights the mismatch.

Temporal Characteristics and Scalp Distribution of Negativities in Previous ERP Studies

Previous studies that have elicited negativities have looked at agreement mismatches with personal pronouns and subject-verb agreement failures (Osterhout and Mobley, 1995), at noun phrases that ambiguously referred to two equally suitable referents (Van Berkum et al., 2003, 2007), at incorrect cases of noun ellipsis (Martin et al., 2012), at pronoun and verb-agreement violations (Coulson et al., 1998), at verb subcategorization violations (Rösler et al., 1993), at phrase structure violations (Neville et al., 1991; Osterhout and Holcomb, 1992) and at conditions of increased memory load (Kluender and Kutas, 1993; King and Kutas, 1995; Friederici et al., 1996; Müller et al., 1997; Münte et al., 1998; Fiebach et al., 2001).

All the negativities found in these studies reflect syntactic processes and in many cases they represent a response to syntactic violations. However, they do not always have the exact same scalp distribution or topography as the negativity in our study. Osterhout and Mobley (1995) tested agreement mismatches involving personal pronouns in forward dependencies in their first experiment (discussed under the section on ERP Studies on Gender Agreement/Mismatch in the introduction) and found that a small sample of participants ($N = 4$) who judged the sentence as grammatical (and thus considered that there was an antecedent outside the clause for the pronoun) showed a sustained negativity in frontal electrodes in the 500–800 ms. The referentially induced frontal negativity (Nref) elicited by Van Berkum et al. (2003, 2007) was a widely distributed and frontally sustained negativity, emerging at about 300–400 ms after their acoustic onset, whereas Martin et al. (2012)'s negativity had a broad central distribution and emerged between 400 and 1000 ms after word onset. In Coulson et al. (1998), the negativity elicited by ungrammatical pronouns was largest at left anterior sites while that elicited by ungrammatical verbs was centro-parietal and slightly larger over the right hemispheres. This effect was largest between 300 and 500 ms after stimulus onset. ERPs for syntactic violations in Rösler et al. (1993) were negative between 400 and 700 ms after target onset and were more pronounced at anterior sites and over the left hemisphere. In Neville et al. (1991), the phrase structure violations generated a negative response between 300 and 500 ms over temporal and parietal regions of the left hemisphere while in Osterhout and Holcomb, 1992, the negativity occurred between 300 and 500 ms post stimulus at left hemisphere anterior sites.

If we look at the studies with increased memory load, the sustained negativity in Fiebach et al. (2001) started at about 400 ms after the onset of the first prepositional phrase and was maximal at left-anterior electrode positions. Friederici et al. (1996) found a left anterior negativity for the syntactic-category violation condition in auditory and visual tasks in the time windows between 400 and 600 ms (for auditory) and 350 and 500 ms (for visual) after word onset. The ERPs to the verbs in Object relative clause sentences (i.e., *The reporter who the senator harshly attacked admitted the error*) in King and Kutas (1995) showed more prolonged negativity over left anterior regions of the scalp than those in Subject relative clause sentences (i.e., *The reporter who harshly attacked the senator admitted the error*), and in Kluender and Kutas (1993), a difference was seen in the ERP between 300 and 500 ms. post stimulus when wh-questions were compared to yes/no questions at a position early in the matrix clause. Finally, in Müller et al. (1997), there was a large fronto-central negativity beginning at the gap in the Object relative clause sentences and a left frontal negativity in Münte et al. (1998).

Referential Dependencies that Generated Negativities in Previous ERP Studies

Among the ERP studies that have generated negativities, Martin et al. (2012) report a centrally distributed negativity at a position that renders a gender-mismatch effect [i.e., the determiner *otro* 'another (MASC)'], which mismatches in gender with the antecedent *camiseta* ['t-shirt (FEM)'] in cases of noun ellipsis in coordinated sentences. In their study, the gender mismatch results in an ungrammatical sentence (its interpretation cannot be recovered, unlike in (7b) in our study where a second potential antecedent *Mirjam* can be used to resolve the interpretation of the pronoun *haar*) and the position in which the mismatch is detected is a determiner that allows nominal ellipsis within the second coordinated sentence. Both Martin et al. (2012) and our study examine the resolution of dependencies where a referential entity and an antecedent are involved and both concern gender mismatches. However, similar to the first experiment on the study in Osterhout and Mobley (1995) on forward pronominal dependencies, in Martin et al.'s (2012) study, the interpretation of a determiner that allows nominal ellipsis and whose antecedent sits in the previous coordinated clause might involve a completely different process from the process required in the dependencies examined within the current study, since the antecedent does not necessarily start a search for the determiner in the second conjunct.

A sustained negativity (largest at anterior sites) has additionally been found in cases of referential ambiguity under the name of referentially induced frontal negativity (Nref; Van Berkum et al., 2003, 2007), where participants had to choose among a set of equally plausible referents for a specific noun phrase. The fact that Van Berkum et al. (2003, 2007) and our study both cover the processing of dependencies that involve referential expressions, might have contributed to the overlapping characteristics of the ERP components that were found.

In short, we have argued that the anterior negativity in this study can be connected to negativities found in previous studies in that it involves (1) a gender mismatch; (2) a dependency that contains referential expressions in which coreference needs to be established, and (3) a dependency in which an expectation of the parser fails. Thus, even if the studies discussed thus far have looked at different phenomena, it seems that there are some common processes underlying all these negativities, such as building a referential dependency on-line and predicting a specific upcoming element in the sentence.

CONCLUSION

In our ERP study on the processing of cataphoric pronoun dependencies in Dutch, we replicated earlier behavioral findings (Sturt, 2003; Van Gompel and Liversedge, 2003; Kazanina et al., 2007; Yoshida et al., 2014) supporting that the parser actively looks for an antecedent for a cataphoric pronoun in the upcoming sentence (even when this pronoun could have coreference with an antecedent outside of the sentence), but restricts its choice to grammatically licit positions. This is evidenced by the fact that no ERP effect is elicited at the potentially mismatched referential expression in the conditions where Principle C of the Binding Theory bars coreference. The overall results show that the GMME connected to longer reading times in previous behavioral experiments is reflected in the current ERP study as an anterior negativity elicited at the potential antecedent in cataphoric dependencies. We postulate that this anterior negativity reflects the prediction failure for an appropriate antecedent after encountering a sentence initial pronoun.

ACKNOWLEDGMENTS

We would like to thank Niels O. Schiller for his advice and for discussion of the materials presented here. We are grateful to Nina Kazanina for sharing experimental materials, for discussion and for helpful comments on earlier versions of this paper. We thank Masaya Yoshida for useful discussion of the research presented here. We would like to thank Bastien Boutonnet for his assistance regarding the statistical analyses applied to the EEG data and, at an earlier stage, Guido Band and Kalinka Timmer for assistance in conducting the experiment at the EEG laboratory at the Faculty of Social Sciences (FSW) in Leiden University. Finally, we would like to thank the two reviewers for very helpful comments and suggestions and for fruitful discussions on the content of the article. Earlier versions of this work were presented at the Architectures and Mechanism of Language Processing Conference (AMLaP) in 2011, at the CUNY Human Sentence Processing Conference in 2012, at GLOW 35 in 2012, and at CNS in 2014. We thank the audiences of these conferences for their input.

Recent research on the memory operations used in language comprehension has revealed a selective profile of interference effects during memory retrieval. Dependencies such as subject–verb agreement show strong facilitatory interference effects from structurally inappropriate but feature-matching distractors, leading to illusions of grammaticality (Pearlmutter et al., 1999; Wagers et al., 2009; Dillon et al., 2013). In contrast, dependencies involving reflexive anaphors are generally immune to interference effects (Sturt, 2003; Xiang et al., 2009; Dillon et al., 2013). This contrast has led to the proposal that all anaphors that are subject to structural constraints are immune to facilitatory interference. Here we use an animacy manipulation to examine whether adjunct control dependencies, which involve an interpreted anaphoric relation between a null subject and its licensor, are also immune to facilitatory interference effects. Our results show reliable facilitatory interference in the processing of adjunct control dependencies, which challenges the generalization that anaphoric dependencies as a class are immune to such effects. To account for the contrast between adjunct control and reflexive dependencies, we suggest that variability within anaphora could reflect either an inherent primacy of animacy cues in retrieval processes, or differential degrees of match between potential licensors and the retrieval probe.

Introduction

Linguistic dependencies are subject to diverse structural and morphological constraints. Recent studies have examined how these constraints are applied in real-time comprehension in order to gain a better understanding of how we mentally encode and navigate linguistic representations. A comparison of the findings across studies shows a mixed profile of successes and failures of real-time constraint application: some constraints on dependency formation are accurately applied, whereas others are susceptible to errors. The reasons for these failures remain poorly understood, but the mixed profile of constraint application has been argued to reflect the way in which different linguistic processes engage memory retrieval mechanisms (Lewis and Vasishth, 2005; Vasishth et al., 2008; Wagers et al., 2009; Phillips et al., 2011; Lewis and Phillips, 2015).

In this paper, we focus on a specific type of memory retrieval error that leads to an effect called 'facilitatory interference' (also known as 'intrusion' or 'attraction'). Facilitatory interference arises when a structurally inappropriate but feature matching item facilitates the processing of an ill-formed linguistic dependency. This eased processing can trigger 'illusions of grammaticality,' which have been argued to reflect limitations of the memory retrieval mechanisms used to implement

linguistic constraints (Vasishth et al., 2008; Wagers, 2008). Such effects have been reported for subject–verb agreement and negative polarity item processing (Clifton et al., 1999; Pearlmutter et al., 1999; Drenhaus et al., 2005; Vasishth et al., 2008; Staub, 2009, 2010; Wagers et al., 2009; Xiang et al., 2009; Dillon et al., 2013; Tanner et al., 2014; Tucker et al., 2015). For instance, Wagers et al. (2009) used self-paced reading and speeded acceptability judgments to investigate interference effects in the comprehension of subject–verb agreement dependencies like those in (1). They varied the presence of a plural distractor noun in grammatical and ungrammatical sentences.

(1) a. The key to the *cell(s)* unsurprisingly was rusty from many years of disuse.
b. *The key to the *cell(s)* unsurprisingly were rusty from many years of disuse.

In grammatical sentences like (1a), Wagers et al. (2009) found that the plural number of the structurally inappropriate noun *cells* did not impact acceptability judgments or reading times after the verb, relative to the singular noun condition. However, in ungrammatical sentences like (1b) the presence of the plural distractor *cells* increased rates of acceptance and facilitated reading times after the verb, relative to the no distractor condition, giving rise to an illusion of grammaticality.

The profile of facilitatory interference effects in sentences like (1) provides important evidence about the source of these effects in comprehension. First, immunity to distractors in grammatical sentences suggests that facilitatory interference effects do not reflect misrepresentation of the subject number or the use of "good enough" representations (e.g., Ferreira and Patson, 2007). Misrepresentation of the subject phrase would lead comprehenders to misperceive grammatical sentences like (1a) as ungrammatical, triggering an 'illusion of ungrammaticality,' which rarely occurs. Second, if illusions of grammaticality are not due to problems in the representation of the subject, then facilitatory interference effects might instead be due to properties of the retrieval mechanisms used to resolve linguistic dependencies. For instance, under a view where both structural and morphological constraints guide memory access, facilitatory interference effects could reflect failure to apply structural constraints during retrieval, or they could reflect the outcome of a competition between structural and morphological constraints. Crucially, the finding that comprehenders are not misled by structurally inappropriate items in grammatical sentences provides good evidence that structural constraints are actively used to guide retrieval, and suggests that facilitatory interference reflects competing structural and morphological information[1].

Wagers et al. (2009) argued that facilitatory interference in subject–verb agreement is a consequence of competing constraints. Under their account, encountering the verb *were* in (1b) triggers a retrieval that probes previous items in memory to recover a noun phrase that is both the subject of the sentence and has plural number. In ungrammatical sentences, neither the target nor the distractor is a perfect match to the requirements of the verb, and the competition between the structural and morphological constraints is relatively even: the true subject is in the appropriate structural position, but it is not plural, and the distractor is plural, but it is in a structurally inappropriate position. On a significant portion of trials, the structurally inappropriate distractor is incorrectly retrieved, which facilitates processing of the ungrammatical verb and triggers an illusion of grammaticality. In grammatical sentences, by contrast, there is no competition between the structural and morphological constraints, and the full matching subject is almost always retrieved, as it easily out-competes a non-matching distractor[2].

Facilitatory interference is robust for subject–verb agreement, but not all linguistic dependencies are susceptible to it. For example, Dillon et al. (2013) directly compared the processing of subject–verb agreement and reflexive-antecedent dependencies using closely matched sentences like those in (2).

(2) a. The new executive who oversaw the middle *manager(s)* apparently doubted himself/*themselves on most major decisions.
b. The new executive who oversaw the middle *manager(s)* apparently was/* were dishonest about the company's profits.

Dillon et al. (2013) found that subject–verb agreement was susceptible to facilitatory interference from structurally inappropriate distractors (e.g., *managers*), but reflexive-antecedent dependencies were not. These findings are consistent with a growing number of studies that have concluded that direct object reflexives resist facilitatory interference (Nicol and Swinney, 1989; Clifton et al., 1999; Kennison and Trofe, 2003; Sturt, 2003; Xiang et al., 2009; Clackson et al., 2011; Jäger et al., 2015a). Specifically, these studies have found that structurally inappropriate distractors either do not impact the processing of the direct object reflexives or cause increased processing difficulty. The contrast between subject–verb agreement and reflexives is striking since retrieval for both dependencies targets the same structural position, i.e., the subject of the local clause. These findings are important because they cast doubt upon the claim that all linguistic dependencies are uniformly resolved using an error-prone retrieval mechanism, as suggested in previous research (McElree, 2000; McElree et al., 2003; Lewis and Vasishth, 2005).

The puzzle of why reflexives and subject–verb agreement show contrasting profiles with respect to facilitatory interference remains unresolved. One explanation that is often suggested is that the contrast may reflect differences in the interpretive status of reflexives vs. agreement (see Dillon, 2011, for discussion).

[1]Facilitatory interference cannot be simply a case of proximity concord (Quirk et al., 1985) or local coherence (Tabor et al., 2004), as the effect is also observed when the plural distractor does not intervene between the verb and true subject (cf. Wagers et al., 2009). The effect is also not merely due to dialectal variation, as speakers agree on the unacceptability of sentences like (1b) when they have ample time to make their judgment (see Dillon et al., 2013).

[2]More specifically, the account proposed by Wagers et al. (2009) predicts a bimodal response from the mixture of two distributions: either retrieval recovers the structurally inappropriate distractor, facilitating reading times and triggering an illusion, or the structurally appropriate target, slowing down processing. As a result, the average reading times across trials are reduced for ungrammatical sentences with a feature matching distractor relative to ungrammatical sentences where no matching distractor is present.

Reflexive licensing involves constructing an interpreted anaphoric dependency since the meaning of the reflexive depends on the semantic properties of its antecedent. By contrast, subject–verb agreement licensing might involve a morphological process without interpretive consequences (e.g., Lau et al., 2008; but cf. Patson and Husband, 2015). However, it is unclear why the interpretive status of a dependency should determine its susceptibility to facilitatory interference. One possibility is that all interpreted anaphoric dependencies that are subject to syntactic constraints might engage a more conservative retrieval strategy to avoid misinterpretation and interference from structurally inappropriate items. Under this hypothesis, reflexives and agreement could engage qualitatively different retrieval mechanisms, or use distinct sets of retrieval cues to access the local subject. For example, reflexive licensing might engage the same retrieval mechanism as agreement, but might only use structural retrieval cues, implementing morphological constraints only as a post-retrieval check (Dillon, 2011).

In this paper, we do not solve the problem of why reflexives and subject–verb agreement show differential susceptibility to facilitatory interference effects. Instead, we address a critical part of the puzzle by focusing on the status of anaphors and their reported immunity to such effects. Specifically, we test the hypothesis that all anaphoric dependencies that are subject to structural constraints avoid facilitatory interference during real-time comprehension. Our results challenge this hypothesis by showing that adjunct control dependencies, which involve an interpreted anaphoric relation between a null subject and its licensor, are susceptible to facilitatory interference. We then investigate the source of facilitatory interference in adjunct control dependencies, and conclude with a discussion of why anaphoric dependencies should vary with respect to facilitatory interference effects.

Adjunct Control Dependencies

In this paper, we focus on temporal adjunct control constructions like those in (3), which involve a phonetically null anaphoric subject (represented as Ø)[3]. Like reflexives, null subjects must establish a structural, item-to-item dependency with a licensor to receive an interpretation. Specifically, null subjects in temporal adjunct control structures are licensed by the subject of the immediately higher clause. For instance, in (3a,b), the phonetically null subject of the adjunct clause Ø receives its interpretation from the subject of the immediately higher clause *the little girl*, i.e., it is the little girl who played in the yard.

(3) a. The mother said [that *the little girl* fell asleep (after Ø playing in the yard)].
b. *The little girl* talked to her mother (after Ø playing in the yard).

[3]Our discussion does not rely on whether the missing subject is an empty category, e.g., PRO. See Hornstein (2003) for a discussion of the debate over how to formally represent control clause subjects.

However, there are several differences between reflexives and null subjects that might impact their susceptibility to facilitatory interference. For example, reflexives are licensed by the subject of the local clause, whereas null subjects in temporal adjunct control structures are licensed by the subject of the immediately higher clause. Another difference is that retrieval for reflexive licensing is triggered by an independent anaphoric element, whereas retrieval for null subject licensing is triggered by a gerundive verb preceded by a subordinator (e.g., "*after playing*"). Lastly, unlike reflexives, null subjects do not require overt gender or number agreement with a licensor. Instead, null subject licensing in adjunct control structures has been argued to be subject to an animacy constraint. For example, Kawasaki (1993) reported that adjunct control structures are judged to be more acceptable with animate licensors than inanimate licensors (4a vs. 4b; see Landau, 2001, for supporting judgments). The preference for an animate subject does not appear to be a general property of embedded clauses or a consequence of lexical verb biases, since the acceptability contrast between (4a) and (4b) is neutralized when the licensors are the overt subjects of the verb, as in (5).

(4) a. The doctor was certified after Ø debunking the hypothesis.
b. The discovery was certified after Ø debunking the hypothesis.

(5) a. The journalist was surprised that the doctor debunked the hypothesis.
b. The journalist was surprised that the discovery debunked the hypothesis.

The current study contributes to a growing body of research on the processing of control (e.g., Kwon and Sturt, 2014; Sturt and Kwon, 2015) by using the animacy preference for adjunct control structures to probe for facilitatory interference during real-time dependency formation. Animacy features are promising candidates to test for interference effects, as they have been shown to be used in memory retrieval during processing of various linguistic dependencies, including thematic binding and reflexive licensing (e.g., Van Dyke and Lewis, 2003, 2007; Van Dyke and McElree, 2006, 2011; Jäger et al., 2015b). Specifically, we contrast two hypotheses about the nature of retrieval for anaphoric dependencies. Under a view that posits that all anaphoric dependencies are immune to facilitatory interference, null subjects in temporal adjunct control structures should pattern like reflexives and show no susceptibility to facilitatory interference during retrieval for a licensor. In contrast, if anaphoric dependencies do not behave homogenously, then null subject licensing might show facilitatory interference effects similar to those observed for subject–verb agreement.

We report the results from three experiments. In Experiment 1 (untimed acceptability ratings) we confirmed the animacy constraint on null subject licensing. In Experiments 2 and 3 (self-paced reading), we directly compared the comprehension of null subjects and subject–verb agreement, and found that null subjects show a facilitatory interference profile that is qualitatively similar to the profile observed for agreement. These results imply that not all anaphoric dependencies resist facilitatory interference,

and suggest that differences in interpretative status cannot be uniquely responsible for the contrasting interference profiles reported for agreement and reflexives in previous studies.

Experiment 1

Experiment 1 used untimed acceptability ratings to confirm that temporal adjunct control sentences are more acceptable with animate than inanimate licensors, and that the preference for animate licensors is specific to adjunct control constructions, rather than a general property of embedded clauses or lexical verb biases (Kawasaki, 1993).

Participants

Twenty-four participants were recruited using Amazon's Mechanical Turk web-service[4]. All participants in this and the following experiments provided informed consent. Experiment 1 lasted approximately 10 min, and participants were compensated $2.

Materials

Twenty-four sets of items like those in (4–5) were constructed. Two experimental factors were manipulated: ANIMACY of the main clause subject (animate vs. inanimate) and CONSTRUCTION (adjunct control vs. overt subject). The 24 item sets were distributed across four lists in a Latin Square design. Within each list, the 24 target sentences were combined with 48 filler sentences of similar length and complexity, for a total of 72 sentences. The ratio of grammatical to ungrammatical sentences was 1:1, including the inanimate adjunct control sentences as ungrammatical. The ungrammatical filler sentences involved subject–verb agreement errors, unlicensed verbal morphology, and selectional restriction violations.

Procedure

Sentences were presented using Ibex (Alex Drummond[5]). Participants were instructed to rate the acceptability of the sentences along a 7-point Likert scale ('7' = most acceptable, '1' = least acceptable), according to their perceived acceptability in informal, colloquial speech. Participants could take as much time as needed to rate each sentence, as long as they finished the experiment within the 30 min restriction imposed by the Mechanical Turk session. Each sentence was displayed in its entirety on the screen along with the rating scale. Participants could click boxes to enter their rating or use a numerical keypad. The order of presentation was randomized for each participant.

Data Analysis

Data were analyzed using linear mixed-effects models, with fixed factors for experimental manipulations and their interaction. Models were estimated using the *lme4* package (Bates et al., 2011) in the R software environment (R Development Core Team, 2014). Experimental fixed effects and their interaction were set up using orthogonal contrast coding, and items and participants were crossed as random effects (following Baayen et al., 2008; Bates et al., 2011). To determine whether inclusion of random slopes was necessary, we compared a model that included random by-participant and by-item intercepts with a model that included a fully specified (i.e., maximal) random effects structure with random intercepts and slopes for all random effects and their interaction by-item and by-participant (Baayen et al., 2008; Barr et al., 2013). A log-likelihood ratio test revealed that the maximal model provided a better fit to the data [$\chi^2_{(2)} = 67.36$, $p < 0.001$]. Therefore, we adopted the maximal model. For all statistical analyses reported in this paper, an effect was considered significant if its absolute t-value was greater than 2 (Gelman and Hill, 2007).

Results

The results of Experiment 1 are presented in **Figure 1**. Adjunct control sentences with animate subjects were rated higher than those with inanimate subjects (means: 4.81 inanimate subject vs. 6.09 animate subject). By contrast, sentences with animate and inanimate overt subjects received similar ratings (means: 6.43 inanimate subject vs. 6.40 animate subject). The statistical analysis revealed a main effect of subject ANIMACY ($\hat{\beta} = -0.64$, SE = 0.19, $t = -3.40$), a main effect of CONSTRUCTION ($\hat{\beta} = -0.96$, SE = 0.18, $t = -5.08$), and an interaction between subject ANIMACY and CONSTRUCTION ($\hat{\beta} = -1.25$, SE = 0.30, $t = -4.08$). The interaction was driven by the fact that animacy significantly modulated ratings in the adjunct control conditions ($\hat{\beta} = -1.26$, SE = 0.29, $t = -4.32$), but not in the overt subject conditions ($t < 2$).

Discussion

Experiment 1 confirmed that adjunct control sentences are more acceptable with animate than with inanimate licensors. However, since sentences with inanimate licensors received relatively high ratings, we believe that the animacy constraint should be regarded as a weak constraint for adjunct control, or that it

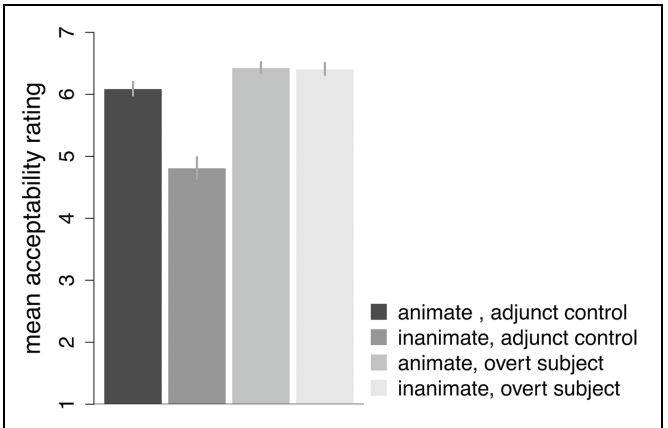

FIGURE 1 | Mean ratings and SE by participants for Experiment 1. Values are on a 7-point Likert scale, with '7' being most acceptable, and '1' the least acceptable. Error bars represent SEM.

[4]https://www.mturk.com

[5]http://spellout.net/ibexfarm

is a constraint that has a smaller impact on ratings because it does not block interpretability. Furthermore, the finding that the animacy manipulation did not impact ratings for sentences with an overt embedded subject implies that the animacy preference for adjunct control cannot simply reflect a general property of embedded clauses or lexical verb biases. Based on these findings, we conclude that comprehenders might use animacy as a cue to guide memory retrieval for null subject licensing, as has been reported for other linguistic dependencies, such as thematic binding (e.g., Van Dyke and Lewis, 2003; Van Dyke and McElree, 2006, 2011).

Experiment 2

The goal of Experiment 2 was to test the hypothesis that all anaphoric dependencies resist facilitatory interference during real-time comprehension. We used self-paced reading to investigate whether retrieval for null subject licensing is susceptible to interference from animate distractors in structurally inappropriate locations. Under the hypothesis that all anaphoric dependencies are immune to facilitatory interference, retrieval for null subject licensing should avoid facilitatory interference from structurally inappropriate animate distractors. Alternatively, if this hypothesis is incorrect, then we might observe facilitatory interference, yielding a profile similar to subject–verb agreement.

Participants

Thirty-two members of the University of Maryland community participated in Experiment 2. Participants were either compensated $10 or received credit in an introductory linguistics course. The self-paced reading task lasted approximately 40 min and was administered as part of a 1-hour session involving unrelated experiments.

Materials

The experimental materials consisted of 48 item sets, each containing eight conditions. The experimental conditions consisted of a 2 × 2 × 2 factorial design, which crossed the factors DEPENDENCY, GRAMMATICALITY, and DISTRACTOR. An example item set is provided in **Table 1**. The first factor, DEPENDENCY, varied the dependency of interest: adjunct control vs. subject–verb agreement. Subject–verb agreement conditions were included to provide an experiment-internal measure of facilitatory interference effects. Within each dependency type, the sentences were maximally similar and differed only in the manipulations of GRAMMATICALITY and DISTRACTOR.

All test items consisted of a passive main clause followed by an adjunct clause. Passive sentences were used because they naturally allow both animate and inanimate NPs in the main clause subject position, and provide a clear attachment site for the adjunct clause to the main clause VP, avoiding the possibility of an attachment ambiguity. In all conditions, the main clause subject was modified by an object relative clause that contained the distractor in subject position. The relative clause verb never overtly expressed agreement, and was always followed by an adverbial that signaled the end of the relative clause. The main clause verb phrase consisted of an auxiliary form of *be* (*was* or *were*) immediately followed by the main verb and an adjunct clause that consisted of a subordinator and gerundive verb.

In the adjunct control conditions, the adjunct clause contained an emphatic reflexive that was licensed by the subject of the adjunct clause, i.e., the null subject. This configuration provided two points to measure susceptibility to facilitatory interference in the adjunct control conditions. The earliest point to measure the impact of the distractor was the gerundive verb. The second point was the emphatic reflexive. Since the reflexive must access the properties of the adjunct clause subject, it was meant to provide a probe of the properties of the licensor retrieved for the anaphoric null subject. In the subject–verb agreement conditions, the earliest point to measure susceptibility to facilitatory interference was the main clause verb.

The factor GRAMMATICALITY was manipulated by varying the animacy of the main clause subject in the adjunct control conditions and the number of the agreeing verb in the subject–verb agreement conditions. In the grammatical adjunct control conditions, the main clause subject was animate and matched the animacy of the reflexive, which satisfied the animacy requirement of the adjunct control structures. In the ungrammatical conditions, the main clause subject did not satisfy the animacy requirement and mismatched the reflexive in animacy. In the grammatical subject–verb agreement conditions, the main clause subject and the agreeing verb were always singular, and thus matched in number. In the ungrammatical conditions, the agreeing verb was plural and mismatched the number of the main clause subject. Lastly, the factor DISTRACTOR was manipulated by varying the animacy of the distractor in the adjunct control

conditions and the number of the distractor in the subject–verb agreement conditions. In order to avoid spurious effects due to lexical differences, the lexical content of the main clause was held constant across dependencies.

Procedure

Sentences were presented on a desktop PC in a moving-window self-paced reading display using Linger (Doug Rohde). Sentences were initially masked by dashes, with white spaces and punctuation intact. Participants pushed the space bar to reveal each word. Presentation was non-cumulative, such that the previous word was replaced with a dash when the next word appeared. Each sentence was followed by a 'yes/no' comprehension question, and onscreen feedback was provided for incorrect answers. The order of presentation was randomized for each participant.

Data Analysis

Only data from participants with at least 70% accuracy on the comprehension questions were used in the analysis. No participants were excluded due to poor accuracy. Reading times greater than 2500 ms were excluded from the analysis (following Hofmeister, 2011; Vasishth and Drenhaus, 2011). This trimming method affected less than 1% of the data. Reading times were then log-transformed to reduce non-normality. For the adjunct control conditions average reading times were compared between conditions in four regions of interest: the subordinator (v−1), the gerundive verb (v), the emphatic reflexive (refl), and the word immediately following the reflexive (refl + 1). For the subject–verb agreement conditions, average reading times were compared between conditions in two regions of interest: the agreeing verb (v) and the main verb (v + 1).

Reading time data were analyzed using linear mixed-effects models. Experimental fixed effects and their interaction were set up using orthogonal contrast coding, and items and participants were crossed as random effects (Baayen et al., 2008). To determine whether inclusion of random slopes was necessary, we compared an intercept-only model to a model with a fully specified random effects structure, which included random intercepts and slopes for all fixed effects and their interaction by items and by participants. A log-likelihood ratio test revealed that the maximal model did not provide a better fit to the data in the critical regions [subject–verb agreement: $\chi^2_{(18)} = 4.39$, $p = 0.92$; adjunct control: $\chi^2_{(18)} = 9.98$, $p = 0.93$]. Therefore, we adopted the intercept-only model, and for consistency, we applied the same model to all regions of interest.

Results

Subject–Verb Agreement Conditions

Figure 2 shows average reading times starting from the region preceding the agreeing verb to five regions beyond the main verb. No effects were observed at the critical verb (v). The word immediately following the critical verb (v + 1) showed a main effect of DISTRACTOR ($\hat{\beta} = 0.06$, SE = 0.02, $t = -2.22$) and crucially, an interaction between GRAMMATICALITY and DISTRACTOR ($\hat{\beta} = -0.17$, SE = 0.05, $t = -2.96$). This interaction was driven by a significant effect of DISTRACTOR in the ungrammatical conditions ($\hat{\beta} = -0.15$, SE = 0.04, $t = -3.56$), reflecting faster reading times for sentences with a plural distractor, relative to sentences with no distractor. No such difference was observed in the grammatical conditions ($t < 2$).

Adjunct Control Conditions

Figure 3 shows average reading times starting from the subordinator to three regions following the reflexive. No effects were observed at the subordinator region (v−1). At the gerundive verb (v), there was an interaction between GRAMMATICALITY and DISTRACTOR ($\hat{\beta} = -0.11$, SE = 0.04, $t = -2.48$). This interaction was driven by a significant effect of DISTRACTOR in the ungrammatical conditions ($\hat{\beta} = -0.07$, SE = 0.03, $t = -2.03$), reflecting faster reading times for sentences with an animate distractor relative to sentences with an inanimate distractor. No such difference was observed for the grammatical conditions ($t < 2$). No effects were observed at the reflexive (refl). The word immediately following the reflexive (refl + 1) showed a main effect of GRAMMATICALITY ($\hat{\beta} = -0.06$, SE = 0.02, $t = -3.02$) and an interaction between GRAMMATICALITY and DISTRACTOR ($\hat{\beta} = -0.10$, SE = 0.04, $t = -2.23$). The main effect of GRAMMATICALITY was due to slower reading times in the ungrammatical conditions relative to the grammatical conditions. The interaction was driven by a significant effect

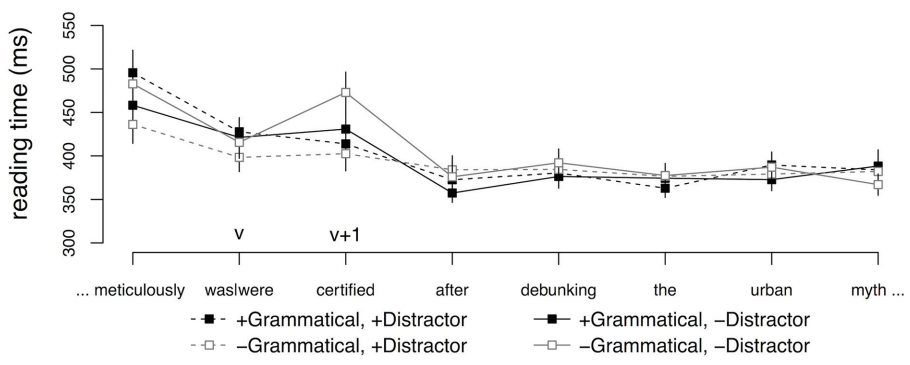

FIGURE 2 | Word-by-word reading times for subject–verb agreement conditions, Experiment 2. Error bars indicate SEM.

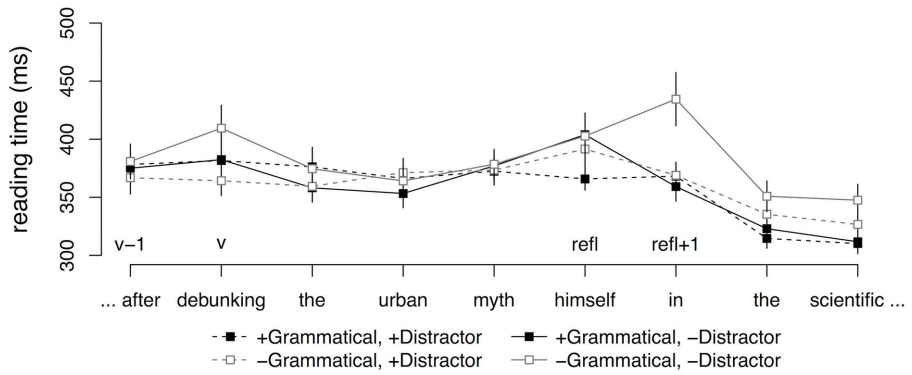

FIGURE 3 | Word-by-word reading times for adjunct control conditions, Experiment 2. Error bars indicate SEM.

of DISTRACTOR in the ungrammatical conditions ($\hat{\beta} = -0.07$, SE $= 0.03$, $t = -2.02$), reflecting faster reading times for sentences with an animate distractor relative to sentences with no distractor. No such difference was observed for the grammatical conditions ($t < 2$).

Discussion

Experiment 2 tested the hypothesis that immunity to facilitatory interference is a general property of anaphoric dependencies. Our results provide evidence against this hypothesis, since they show that adjunct control dependencies, which involve an anaphoric relation between a null subject and its licensor, are susceptible to facilitatory interference, similarly to subject–verb agreement. Facilitatory interference was observed at two different points in the adjunct control sentences. The first was at the gerundive verb, which was the earliest point where sensitivity to the structurally inappropriate distractor could be detected. At this region, reading times for ungrammatical sentences were facilitated by the presence of a structurally inappropriate animate distractor, leading to an illusion of grammaticality. The second region was the reflexive, which served as an additional probe of the properties of the licensor that was retrieved for null subject licensing. Reading times at this region showed a similar profile to the gerundive verb with respect to facilitatory interference. Taken together, these findings suggest that the structurally inappropriate animate distractor was sometimes retrieved as the subject of the adjunct clause, which licensed the reflexive without detection of the animacy violation.

The finding that null subject licensing exhibits facilitatory interference effects is striking, given that such robust effects have rarely been observed for anaphora before. Previous studies have consistently failed to find evidence of facilitatory interference in the comprehension of anaphoric dependencies, such as those involving direct object reflexives. In contrast, we found that null subject licensing shows an interference profile that is qualitatively similar to that observed for subject–verb agreement dependencies, which show strong interference effects.

The findings from Experiment 2 showed facilitatory interference for null subjects in adjunct control structures. However, our interpretation of the interference profile at the emphatic reflexive is based on the assumption that the reflexive was a faithful reflection of what was retrieved as the subject of the adjunct clause at the gerundive. This assumption is based on previous findings that reflexives generally only search for a licensor within the domain of their local clause (e.g., Sturt, 2003; Dillon et al., 2013). However, an alternative explanation of our results is that the interference effects observed at the gerundive and reflexive reflect independent effects, and that the profile observed at the reflexive is not predicated on the outcome of null subject licensing at the gerundive. For instance, the reflexive may not have tracked the interpretation of the subject of the adjunct clause but rather linked directly to one of the NPs in the higher clause (e.g., *the doctor*, *the report*). Since little is known about the processing of emphatic reflexives, it is possible that, unlike direct object reflexives, emphatic reflexives may trigger an error-prone retrieval that is not constrained to the domain of the adjunct clause, thus giving rise to an interference effect that is independent of the outcome of null subject licensing. We tested this possibility in Experiment 3.

Experiment 3

Experiment 3 tested the assumption that the reflexive in Experiment 2 tracked the interpretation of the subject of the adjunct clause, rather than linking directly to one of the NPs in the higher clause. We reasoned that if the reflexive accurately reflected the interference effect observed for null subject licensing, then eliminating interference for null subject licensing should also eliminate interference at the reflexive. To achieve this, we held constant the animacy of the target NP in the main clause and distractor NP in the relative clause, and manipulated their gender match with the reflexive instead, as shown in (6).

(6) The (harpist|drummer) that the (diva|guitarist) liked very much was congratulated after playing the beautiful song **herself** at the brand new recording studio.

As described earlier, reflexives require gender agreement with a licensor, but null subjects do not. Thus, the gender manipulation in (6) should not generate any interference effects at the gerundive in the adjunct clause, as only the correct licensor (*harpist*/*drummer*) should be retrieved for null subject licensing. Further, if the reflexive is a faithful reflection of what was retrieved for null subject licensing, then the reflexive should only be sensitive to the gender match of the structurally appropriate licensor (*harpist* vs. *drummer*), and thus pattern with the gerundive in the absence of interference effects. If, on the other hand, the reflexive links directly to either of the NPs in the higher clause, then different profiles might be obtained for null subject and reflexive licensing. In particular, although we do not expect interference at the gerundive, we might observe an interference effect at the reflexive when there is a structurally inappropriate but gender matching distractor in the relative clause (e.g., *diva*).

Participants

Thirty-two members of the University of Maryland community participated in Experiment 3. Participants were either compensated $10 or received credit in an introductory linguistics course. The task lasted approximately 40 min and was administered as part of a 1-hour session involving unrelated experiments.

Materials

The design of Experiment 3 was the same as Experiment 2, except that the animacy of the target and distractor NPs was held constant, and their gender match to the reflexive was manipulated. The experimental materials consisted of 48 item sets, each containing eight conditions. The experimental conditions consisted of a 2 × 2 × 2 factorial design, which crossed the factors DEPENDENCY, GRAMMATICALITY, and DISTRACTOR. An example item set is provided in **Table 2**. As in Experiment 2, the target NP appeared as the subject of the main clause, and was modified by an object relative clause that contained the distractor in subject position. The factor DEPENDENCY compared adjunct control conditions with subject–verb agreement conditions. The factor GRAMMATICALITY was manipulated by varying the stereotypical gender of the main clause subject in the adjunct control conditions and the number of the agreeing verb in the subject–verb agreement conditions. In the grammatical adjunct control conditions, the main clause subject was animate and matched the gender of the reflexive. In the ungrammatical conditions, the main clause subject was animate, but mismatched the gender of the reflexive. In the grammatical subject–verb agreement conditions, the agreeing verb was always singular and matched the number of the main clause subject. In the ungrammatical conditions, the agreeing verb was plural and mismatched the number of the main clause subject. The factor DISCTRACTOR was manipulated by varying the stereotyped gender of the distractor for adjunct control conditions and the number of the distractor for subject–verb agreement conditions. As in Experiment 2, the lexical content of the main clause was held constant across dependency types to avoid spurious effects due to lexical differences.

TABLE 2 | Example set of experimental items for Experiment 3.

Adjunct control conditions
Grammatical, distractor
The harpist that the diva liked very much was congratulated after playing the beautiful song herself at the brand new recording studio.
Grammatical, no distractor
The harpist that the guitarist liked very much was congratulated after playing the beautiful song herself at the brand new recording studio.
Ungrammatical, distractor
The drummer that the diva liked very much was congratulated after playing the beautiful song herself at the brand new recording studio.
Ungrammatical, no distractor
The drummer that the guitarist liked very much was congratulated after playing the beautiful song herself at the brand new recording studio.
Subject–verb agreement conditions
Grammatical, distractor
The harpist that the diva liked very much was congratulated after playing the beautiful song at the brand new recording studio.
Grammatical, no distractor
The harpist that the divas liked very much was congratulated after playing the beautiful song at the brand new recording studio.
Ungrammatical, distractor
The harpist that the divas liked very much were congratulated after playing the beautiful song at the brand new recording studio.
Ungrammatical, no distractor
The harpist that the diva liked very much were congratulated after playing the beautiful song at the brand new recording studio.

Procedure

The same self-paced reading procedure was used as in Experiment 2.

Data Analysis

The statistical analysis followed the same steps as in Experiment 2. Four participants were excluded from the analysis due to accuracy below 70% in the comprehension questions. Data trimming affected less than 1% of the data. Model comparisons revealed that a maximally specified random effects structure did not provide a better fit to the data in the critical regions than an intercept-only model [subject–verb agreement: $\chi^2_{(18)} = 11.16$, $p = 0.88$; adjunct control: $\chi^2_{(18)} = 14.53$, $p = 0.69$]. Therefore, we adopted the intercept-only model.

Results

Subject–Verb Agreement Conditions

Figure 4 shows average reading times starting from the region preceding the agreeing verb to five regions following the main verb. No effects were observed at the critical verb (v). The word immediately following the critical verb (v + 1) showed a main effect of GRAMMATICALITY ($\hat{\beta} = 0.18$, SE = 0.03, $t = -5.06$) and, crucially, an interaction between GRAMMATICALITY and DISTRACTOR ($\hat{\beta} = -0.21$, SE = 0.07, $t = -2.98$). This interaction was driven by a significant effect of DISTRACTOR in the ungrammatical conditions ($\hat{\beta} = -0.16$, SE = 0.05, $t = -2.97$), reflecting faster reading times for sentences with a

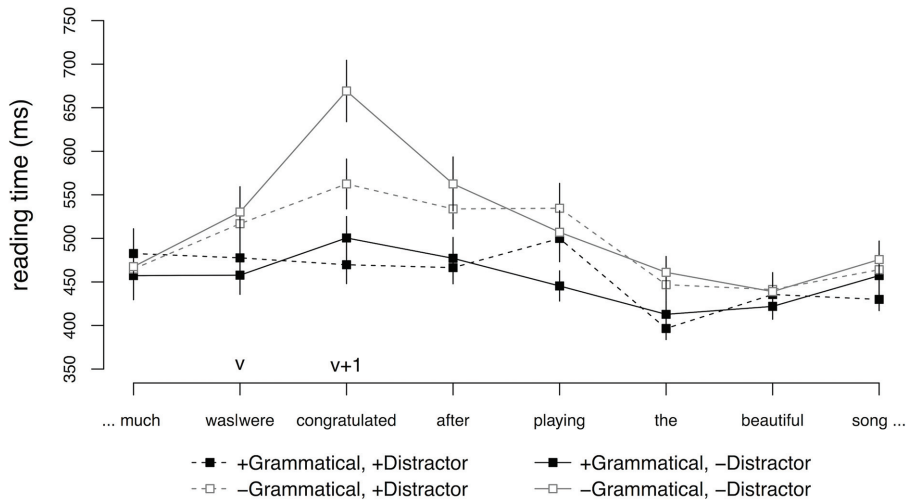

FIGURE 4 | Word-by-word reading times for subject–verb agreement conditions, Experiment 3. Error bars indicate SEM.

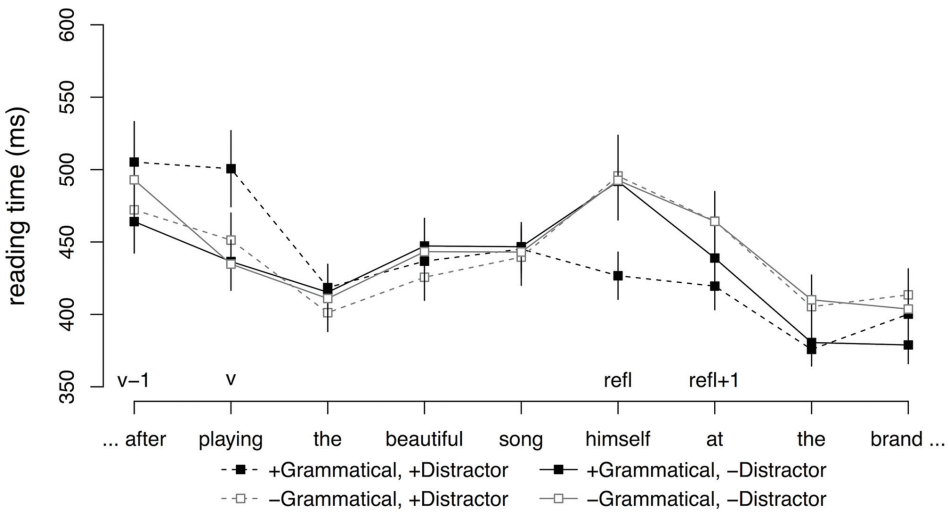

FIGURE 5 | Word-by-word reading times for adjunct control conditions, Experiment 3. Error bars indicate SEM.

plural distractor relative to sentences with no distractor. No such difference was observed for the grammatical sentences ($t < 2$).

Adjunct Control Conditions

Figure 5 shows average reading times starting from the subordinator to three regions following the reflexive. No effects were observed at the subordinator (v−1). At the gerundive verb (v), there was a main effect of distractor ($\hat{\beta} = -0.06$, SE $= 0.02$, $t = -2.31$). Pairwise comparisons revealed that this effect was due to a slowdown for grammatical conditions with an animate distractor ($\hat{\beta} = 0.10$, SE $= 0.04$, $t = 2.33$). No effect was observed in the ungrammatical conditions ($t < 2$). At the reflexive (refl), the grammatical condition with an animate distractor showed faster reaction times ($\hat{\beta} = -0.09$, SE $= 0.03$, $t = -2.41$). No other effects were observed at the reflexive (all *ts* < 2). The word immediately following the reflexive (refl + 1) showed a main effect of GRAMMATICALITY ($\hat{\beta} = -0.05$, SE $= 0.02$, $t = -2.09$), reflecting a slowdown for ungrammatical conditions relative to grammatical conditions. Crucially, and in contrast with Experiment 2, there was no effect of facilitatory interference at the word following the reflexive and no interaction was observed between GRAMMATICALITY and DISTRACTOR.

Discussion

Experiment 3 tested the assumption that the reflexive in the adjunct control constructions in Experiment 2 was a faithful reflection of what was previously retrieved as the subject of the adjunct clause. We reasoned that if the interference effect seen at the reflexive in Experiment 2 reflected the interference effect observed for subjects at the gerundive verb,

then eliminating interference at the gerundive verb should also eliminate interference at the reflexive. This outcome is not obvious, since different features are required to match to license the gerundive (animacy) and the reflexive (animacy, number, gender). As predicted, eliminating interference for null subject licensing also eliminated interference at the reflexive. These results provide preliminary evidence that the reflexive tracked the interpretation of the subject of the adjunct clause, rather than directly linking to one of the NPs in the higher clause. We discuss this further in the General Discussion.

Experiment 3 also revealed a main effect of distractor at the gerundive verb and the reflexive regions. Specifically, the presence of multiple gender matched licensors in the grammatical conditions (e.g., *The harpist that the diva... after playing... herself*) increased reading times at the gerundive verb, and later facilitated reading times in the same conditions at the reflexive. These effects were unexpected, and we believe that the effect of distractor at the gerundive might reflect a "fan" effect (Anderson, 1974; Anderson and Reder, 1999), which can arise in grammatical contexts when multiple items match the retrieval cues (Badecker and Straub, 2002; Autry and Levine, 2014; but cf. Chow et al., 2014).

In contrast with facilitatory interference effects at retrieval, fan effects have been argued to reflect interference at the encoding stage (Dillon, 2011). For example, encountering multiple items that overlap in morphological features can degrade the quality of memory representations for those items due to feature-overwriting (Nairne, 1988, 1990). Thus, the reading time slowdown at the gerundive for grammatical sentences with multiple match items may reflect impeded access to a degraded memory representation of the target at the point of retrieval for null subject licensing. Crucially, this effect does not entail that the structurally inappropriate licensor was retrieved during null subject licensing (see Dillon, 2011 for discussion). By contrast, the facilitation in the same conditions later at the reflexive could reflect a gender familiarity effect. After reading the gerundive verb, comprehenders might have been fairly confident that a gender matching item (*harpist* and *diva*) was present in the sentence, leading to facilitated processing (i.e., faster reading times) at the reflexive.

In sum, the critical finding from Experiment 3 is the absence of facilitatory interference effects in the ungrammatical conditions at the reflexive. These findings provide preliminary evidence that the reflexive in the adjunct control constructions from Experiment 2 tracked the interpretation of the subject of the same clause, rather than linking directly to one of the NPs in the higher clause. However, further research is necessary to better understand the source of the facilitation effect in the grammatical conditions.

General Discussion

Summary of Findings

The present study addressed one part of the puzzle of why reflexives and subject–verb agreement show contrasting profiles with respect to facilitatory interference effects. We tested the hypothesis that all anaphoric dependencies resist facilitatory interference from structurally inappropriate items during real-time comprehension. Specifically, we used an animacy manipulation to examine whether adjunct control dependencies, which involve an interpreted anaphoric relation between a null subject and its licensor, behave like reflexives in that they are immune to facilitatory interference effects.

In Experiment 1, we confirmed that null subject licensing in adjunct control structures obeys an animacy requirement, which we then used as a probe for interference effects in Experiment 2. In Experiment 2, we directly compared the reading time profiles of null subject licensing and subject–verb agreement dependencies. Our results revealed qualitatively similar profiles with respect to facilitatory interference, as illustrated in **Figure 6**. Specifically, we found reliable interference effects for null subject licensing at two points: at the gerundive verb and later, at a reflexive within the same clause, which served as an additional probe of what was retrieved as the subject of the gerundive verb.

The results from Experiment 2 challenge the hypothesis that all anaphoric dependencies resist facilitatory interference. Specifically, our results suggest that anaphors do not behave homogenously with respect to facilitatory interference, since null subject anaphors show interference, whereas reflexive anaphors typically do not. Thus, we believe that any account that claims that interference effects are linked to specific types of grammatical dependencies (e.g., anaphora vs. agreement) is unlikely to be successful. Furthermore, the results of Experiment 2 challenge the hypothesis that the contrast between reflexives and agreement seen in previous studies reflects differences based on their interpretive status. According to this hypothesis, anaphoric dependencies might engage a more conservative retrieval strategy to avoid misinterpretation and interference from structurally inappropriate items. Our results provide evidence against this hypothesis by showing that interpreted anaphoric dependencies involving null subjects are susceptible to facilitatory interference.

In Experiment 3, we tested the assumption that the reflexive in Experiment 2 tracked the interpretation of the subject of the same clause, rather than linking directly to one of the NPs in the higher clause. We tested a configuration that did not yield interference for null subject licensing, and found that the corresponding interference effect at the reflexive also disappeared, as shown in **Figure 6**. These results suggest that our assumption was justified.

However, there is an alternative explanation for the contrasting profiles at the reflexive between Experiments 2 and 3. Whereas in Experiment 2 the reflexive mismatched its licensor in both animacy and gender, in Experiment 3, the reflexive only mismatched its licensor in gender. This raises the possibility that the contrasting profiles at the reflexive between Experiments 2 and 3 may not reflect differences based on the outcome of null subject licensing. Rather, the contrast may have been caused by differences based on the degree of match between the reflexive and the candidate licensors (i.e., 2-feature mismatch in Experiment 2, but 1-feature mismatch in Experiment 3). Specifically, it is possible that the feature matching distractor was able to outcompete the target when the target mismatched the

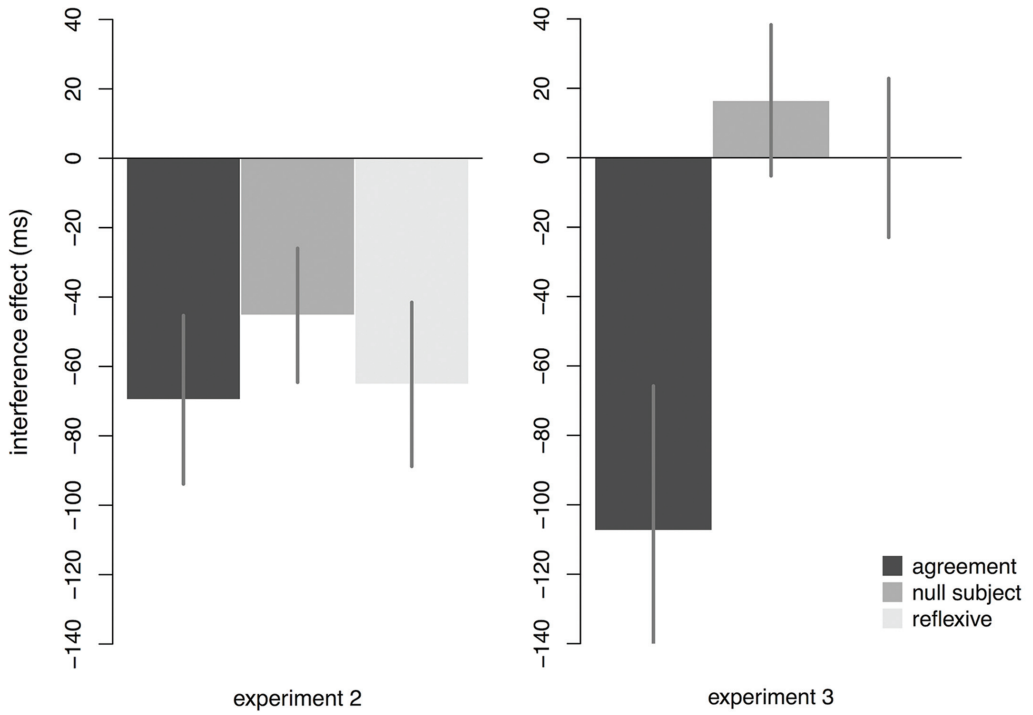

FIGURE 6 | Comparison of interference effects observed for subject-verb agreement (region: v + 1), null subject licensing (region: v), and reflexive licensing (region: refl + 1) in Experiments 2 and 3. Error bars indicate SEM. Interference effects (in ms) were estimated as the difference between the means of the two ungrammatical conditions.

reflexive in 2 features, but not when it mismatched the reflexive in only 1 feature. This difference could lead to interference in a 2-feature mismatch context (Experiment 2), but not in a 1-feature mismatch context (Experiment 3). We discuss this possibility further below.

Variability within Anaphora

The present study revealed that null subjects are susceptible to facilitatory interference in comprehension. These findings contrast with previous findings for reflexives, which typically resist interference. This raises the question of why anaphoric dependencies should behave differently at retrieval. We believe that there are two possibilities for why we should see variability within anaphora with respect to facilitatory interference.

First, previous studies on anaphora have failed to find evidence of facilitatory interference with designs that manipulated the gender or number match between the anaphor and its licensor. In contrast, we found evidence of facilitatory interference when we manipulated animacy. It is possible that the interference effects in our study reflect an inherent primacy of animacy information in anaphoric licensing. This could arise if animacy is a more reliable cue to the target subject in comprehension. For example, whereas a subject in a licensor position is typically animate, its gender and number may be more variable, leading comprehenders to prioritize animacy information at retrieval to access the target subject. This hypothesis aligns with recent findings on the psychology of memory, which suggest that animacy information is one of the most important dimensions in controlling memory retention (Nairne et al., 2013; Van Arsdall et al., 2013).

A second possibility is that the variability across studies could reflect the degree of feature match between the anaphor and its licensor (i.e., probe-to-target similarity). This possibility was raised earlier in our discussion of the contrasting profiles at the reflexive between Experiments 2 and 3. Specifically, we observed facilitatory interference at the reflexive when the target licensor mismatched the reflexive in two features (i.e., both gender and animacy), but failed to find evidence of interference when the target licensor mismatched the reflexive in only one feature (i.e., gender). These findings suggest that retrieval for reflexive processing might only be susceptible to facilitatory interference in configurations where the target mismatches the reflexive in more than one feature[6].

Our findings do not distinguish between the two possibilities discussed above, but they suggest some further directions. One avenue for future research would be to focus on the processing of direct object reflexives and to compare contexts in which

[6]A third possibility suggested by one of the reviewers is that retrieval involving animacy may be privileged over retrieval involving other features like gender or number, not because of the information-theoretic status of the antecedent, but because of the linguistic representation of feature hierarchies. Feature geometric approaches to agreement, e.g., Harley and Ritter (2002), propose that some features are represented as structurally higher than others, and we might expect that there are linguistic constraints on the order of feature access during retrieval.

the reflexive-antecedent dependency involves 1 vs. 2 feature mismatches. This test could help determine the source of the interference effects at the reflexive in Experiment 2 (see Parker and Phillips, 2014). Another avenue for future research would be to test the hypothesis that interference in anaphora is due to the privileged use of animacy information in retrieval. To achieve this, one could test languages where animacy and gender are not conflated, like Spanish or Polish. In these languages, gender is a syntactic property that is distinct from stereotypical or conceptual gender, such that a mismatch in animacy between an anaphor and its licensor does not entail a gender mismatch, like in English. Testing the impact of animacy independently of gender in these languages could help determine whether there is an inherent primacy of animacy in retrieval for anaphor processing.

Conclusion

This study explored the hypothesis that all anaphoric dependencies resist facilitatory interference during real-time comprehension. Our results challenged this hypothesis by showing that anaphoric dependencies do not behave homogenously with respect to facilitatory interference effects. Specifically, we found that adjunct control dependencies, which involve an anaphoric relation between a null subject and a licensor, are susceptible to facilitatory interference. In discussion, we explored several options for why anaphoric dependencies should vary with respect to facilitatory interference. We argued that variability within anaphora could reflect either an inherent primacy of specific content cues like animacy in retrieval processes, or the differential degree of match between the potential licensors and retrieval probe.

On the Shallow Processing (Dis)Advantage: Grammar and Economy

Arnout Koornneef[1*†] *and Eric Reuland*[2*†]

[1] *Brain and Education Lab, Institute for Education and Child Studies, Leiden University, Leiden, Netherlands,* [2] *Utrecht Institute of Linguistics OTS, Utrecht, Netherlands*

In the psycholinguistic literature it has been proposed that readers and listeners often adopt a "good-enough" processing strategy in which a "shallow" representation of an utterance driven by (top-down) extra-grammatical processes has a processing advantage over a "deep" (bottom-up) grammatically-driven representation of that same utterance. In the current contribution we claim, both on theoretical and experimental grounds, that this proposal is overly simplistic. Most importantly, in the domain of anaphora there is now an accumulating body of evidence showing that the anaphoric dependencies between (reflexive) pronominals and their antecedents are subject to an economy hierarchy. In this economy hierarchy, deriving anaphoric dependencies by deep—grammatical—operations requires less processing costs than doing so by shallow—extra-grammatical—operations. In addition, in case of ambiguity when both a shallow and a deep derivation are available to the parser, the latter is actually preferred. This, we argue, contradicts the basic assumptions of the shallow–deep dichotomy and, hence, a rethinking of the good-enough processing framework is warranted.

Keywords: anaphoric dependencies, good-enough processing, variable binding, coreference, (reflexive) pronouns, economy hierarchy

INTRODUCTION

The marriage between linguistic theory and experimental psycholinguistics is a tumultuous one. On the one hand the one cannot live without the other, on the other hand, their relationship is characterized by frequent quarrels and misunderstandings. The tension is nicely shown by the following two quotes on "deep" vs. "shallow" processing. One is from Marantz (class lectures, 2000):

(1) *Deep processing* (our label, borrowed from the literature)

> "The split between linguistics and psycholinguistics in the 1970's has been interpreted as being a retreat by linguists from the notion that every operation of the grammar is a mental operation that a speaker must perform in speaking and understanding language. But, putting history aside for the moment, we as linguists cannot take the position that there is another way to construct mental representations of sentences other than the machinery of grammar....There is no retreat from the strictest possible interpretation of grammatical operations as the only way to construct linguistic representations."

The other position is aptly illustrated by a quote from Ferreira (2003):

(2) *Shallow processing*

> "The results .... suggest that a comprehensive theory of language comprehension must assume that simple processing heuristics are used during processing in addition to (and perhaps sometimes instead of) syntactic algorithms. Moreover, the experiments support the idea that language processing is often based on shallow processing, yielding a merely "good enough" rather than a detailed linguistic representation of an utterance's meaning."

Over the last decade, Ferreira's and related positions prompted a substantial line of research examining the driving forces in language processing. The broad scope of Ferreira's claim becomes particularly clear in a recent elaboration of the shallow, or "good-enough," processing position in Karimi and Ferreira (2015). That is, from their comprehensive overview of the literature and their implementation of a general "online cognitive equilibrium" model of language processing, one must conclude that they intend the good-enough processing position to hold generally across linguistic domains, arguing that "algorithmic procedures for sentence processing are not only too costly but sometimes outright unnecessary."

Since the shallow processing position has become an influential one, it deserves careful scrutiny. Yet, if we want to fully understand it, we are facing the fact that the mechanisms for shallow processing have not been formulated explicitly: it remains unclear how, precisely, they do their work. For instance, in order to fully understand the quote in (2) it is important to have a clear understanding of what counts as a heuristic. However, as Karimi and Ferreira state themselves, "the nature of the simple rules that guide heuristic processing is unclear." They do, however, provide the following helpful characterization: "We believe that this (=heuristic, K&R) processing relies more heavily on top-down information from semantic memory, whereas algorithmic processing seems to rely more heavily on linguistic knowledge to derive meaning in a bottom-up way, by organizing and combining the unfolding input using well-defined, successive linguistic rules. "It this 'top-down' vs. 'bottom-up' characterization of the relevant contrast, we will rely on in our discussions in the current contribution.

Furthermore, we would like to submit that if one wants to argue that in a particular situation people only assign a shallow interpretation, there is no escape from the requirement to make precise what this interpretation is, and which processes are involved in its derivation. Also in this respect the good-enough approach leaves some fundamental questions open.

The Nature of Good-Enough Representations in Language Processing

To illustrate the issues raised above further, let's think more carefully about the basic question of what counts as a good-enough representation. Note, that this question relates to rather fundamental questions about meaning representation. But, for the purpose of the present contribution we will try to stay as concrete as possible. Consider, then, the utterance in (3):

(3) The girl pushed the boy.

We would take it that in order to be good enough the utterance should be interpreted as representing a pushing relation rather than a kissing relation or an injuring relation. But, suppose we know that the pushing resulted in an injury, would a representation as an injuring relation still not be good enough? Perhaps it is, perhaps it isn't. In any case, it seems to us that a representation in which the boy does the pushing and the girl is pushed would certainly not count as good enough.

Now consider a case with quantifiers as in (4):

(4) Some girl pushed every boy.

Which scopal relation should count as good enough? Suppose *every boy* scoping over *some girl* is intended (with each boy being pushed by a different girl), is then the alternative with *some girl* scoping over *every boy* (that is, all the boys are being pushed by the same girl) still good enough? It seems, then, that the notion "good enough" in isolation is problematic. And in fact this is already illustrated in Ferreira's (2003) discussion. As she shows, in a remarkable number of cases participants assign a wrong interpretation to sentences. Thus, the question to ask is what representation, given limitations on attention and processing resources, will have to make do for a particular hearer in a particular situation, and how it is derived.

One area that provides a simple illustration of the different perspectives and the problems associated with the notion good enough is the interpretation of reversible passives as in (5) (Grodzinsky, 1995; Ferreira, 2003). As is well-known, children, agrammatic aphasics, but also certain typical speakers with no known deficit (Ferreira, 2003), show problems interpreting reversible passives[1]. For instance, agrammatic aphasics may show above chance performance on the active (5a), but only chance performance on the passive (5b), allowing (5c) as a possible interpretation.

(5) a. The girl pushes the boy. (*Above chance performance*).
b. The boy is pushed by the girl. (*Chance performance*).
c. The boy pushes the girl.

One may then hypothesize (as did Grodzinsky) that agrammatic aphasics cannot link the surface position of *the boy* to the object position in which it is assigned its semantic role. As such, *the boy* cannot receive a theme role. Or, in a less explicit manner, hypothesize, as did Ferreira (2003) in a study of typical participants, that there is a cost in following the grammatical algorithms. Consequently, in this view, the participants in these tests resort to an extra-grammatical interpretation strategy, based on the idea that there is a hierarchy of semantic roles and that the *agent* role is the most prominent role in this hierarchy[2].

[1]See Dąbrowska (2012) for the claim that such differences in interpretation reflect differences in acquisition, but Reuland (2012) for a demonstration that this claim is unwarranted.

[2]Or, hearers may adopt a simple Noun-Verb-Noun heuristic based on frequency patterns (Townsend and Bever, 2001). But this again raises non-trivial questions. That is, even if one assumes that this heuristic could be obtained on the basis of

(6) Assign the *agent* role to the leftmost NP of the clause as a default role.

This simple rule of *agent first* is indeed a good example of a top-down heuristic involving an extra-grammatical principle. Participants use this strategy to assign a role to *the boy* and interpret (5b) as (5c). Thus, crucially, in such a case the meaning representation arrived at is certainly not good enough. In fact it is not good at all. But it is *the* representation the participant arrives at and for him or her has to make do.

From these and similar results Ferreira (2003; see also e.g., Karimi and Ferreira, 2015) concludes that the field of language comprehension should adopt an approach similar to that taken in the Fast and Frugal Heuristics models (Gigerenzer et al., 1999; Gigerenzer, 2000), who take the position that "Models of rational choice which assume 'unbounded rationality' are unrealistic because the computations that are assumed to take place are often far too burdensome for real creatures operating in demanding environments." In the context of our present discussion, this would imply that a complete syntactic parse of a sentence—i.e., demanding the application of a wide range of grammatical computations—often yields a situation that is too burdensome for real creatures.

A crucial assumption is, then, that shallow processing—by avoiding a full syntactic parse and applying extra-grammatical heuristics instead—is cheaper than deep processing—which is based on the application of all available syntactic algorithms. This assumption clearly embodies an empirical claim. Let's call this assumption the *shallow advantage*. A second assumption, crucial for a fast and frugal heuristic to be viable at all is that using shallow strategies can in principle yield a similar interpretive result as grammatical computations—at least roughly so, even if speakers don't always do so. That is, even if such representations may be "incomplete," "lacking in detail," "sketchy," or "imprecise," they have to be good enough to be used (cf. Karimi and Ferreira, 2015). Let's refer to this as the *shallow equivalence* assumption; a strategy that can only lead to representations that for principled reasons fail to be at least moderately equivalent to what would have been derived by grammatical computations in a particular domain (i.e., a representation that could *never* be good-enough), may be frugal, but not very fruitful for the creatures using it. It is the aim of this contribution to critically assess these assumptions, which so far received too little attention in the literature from this perspective.

In the latter sense our goals are on a par with those of Karimi and Ferreira (2015), who in their recent proposal elaborated on the core assumptions of the good-enough processing framework (e.g., Ferreira, 2003; Ferreira and Patson, 2007). They put forward two fundamental processing principles that, in fact, closely mirror the two assumptions formulated above. More specifically, Karimi and Ferreira specified that "the reason why sometimes only fast and frugal heuristics rather than deep and time-consuming algorithms are applied during comprehension could be because heuristics offer a faster route to equilibrium (Principle 1). Similarly, the reason why the system is sometimes satisfied with a good-enough representation and does not exert the extra effort to engage in deeper processing could be because heuristics often provides enough equilibrium for the system, causing it to stay in that state for as long as possible… (Principle 2)" (pp. 6). Furthermore, following Kuperberg's (2007) syntactic-semantic model, Karimi and Ferreira claim that the algorithmic route of their implementation of the good-enough approach is syntactic in nature. The alternative route, on the other hand, relies more heavily on top-down information from semantic memory, and is capable of generating more global meaning representations of a sentence (intrasentential) or discourse (intersentential)[3].

Hence, Karimi and Ferreira's Principle 1 is identical to the shallow advantage assumption. Moreover, even though their Principle 2 is perhaps formulated less specifically than the equivalence assumption we ascribe to the good-enough position, Principle 2 reflects a similar core idea. That is, during the initial stages of processing there should be a perceived—or at least anticipated—equivalence between the output of the heuristics and algorithmic routes—after all, why should a creature be bothered with the construction of a mental representation that he or she knows will not be a reasonable reflection of the associated linguistic input?

To further substantiate their claims, Karimi and Ferreira (2015) present a comprehensive overview of studies that, in their opinion, are best explained by adopting a fast and frugal approach to language processing. These studies examined shallow linguistic processing for a wide range of different phenomena, such as the Moses Illusion, local syntactic ambiguities in garden-path sentences, quantifier scope ambiguities, erroneous interpretations of syntactically complex sentences, and the resolution processes of referring expressions (for references and more discussion, see Karimi and Ferreira, 2015).

As becomes clear from the discussion of Karimi and Ferreira (and as pointed out to us by one reviewer), a problem that arises if we set out to evaluate the shallow processing position is that the term "shallow processing" (originally due to Carter, 1985) is being used to refer to two different types of "shallowness" that must be kept apart—although they are not entirely unrelated. One involves the *top down* use of information from semantic memory, as briefly mentioned above. The other involves what one may call *reduced processing*.

That is, in some of the processing literature (for instance Stewart et al., 2007), and also some of the cases discussed by Karimi and Ferreira, shallow processing comes down to simply not fully processing part of the input—or at least delaying its integration (cf. Von der Malsburg and Vasishth, 2013). As Stewart

frequency—i.e., note that most canonical sentences only match this pattern if much material is ignored—it raises fundamental questions like, how is it stored, and how is it retrieved, and crucially how does it contribute to interpretation? In fact, it can only do so if the pattern is interpreted as "Subject Verb Object." But these are not surface encoded notions, but in fact already presuppose non-trivial analysis.

[3]Note that this use of the term semantics is different from ours. Whereas semantics in the model we will present refers to logical form (LF) representations, the label semantics in Kuperberg (2007) and Karimi and Ferreira (2015) in part reflects lexical semantics, and in part would be classified as discourse representations in our model.

et al. argue, in processing an input like *Paul$_i$ lent Rick$_j$ the CD before he$_{i/j}$ left for the holidays* the processor my simply disregard the temporal clause initially, and only yield a representation for Paul lending the CD to Rick. This type of shallow processing does not involve extra-grammatical heuristics. There is no top-down use of information coming from semantic memory and, in fact, it is compatible with deep processing using standard grammatical algorithms of whatever has been admitted to the processing buffer. For want of a better term, we will refer to it as "shallow-by-reduction" or *shallow-R*, in order to avoid confusion.

Shallow-R processing in the Stewart et al.'s sense (i.e., as partial non-processing) is not what we primarily address in this contribution—although it still raises non-trivial questions about the representations that are being derived. Instead, we will be focusing on claims about the type of shallow processing that explicitly involves the use of top-down information—including the use of extra-grammatical *heuristics*. We will refer to this notion of shallowness as "shallow-by-top-down," briefly *shallow-TD*.

This brings us to our main concern with these latter type of heuristics, which is actually three-fold, and can be summarized as follows: (1) it is unclear how they actually do the job they are taken to perform; (2) it is unclear whether they are necessary at all; (3) it is unclear—if they exist—why/whether they would be cheaper than the use of syntactic algorithms. We will start the discussion of these concerns on the basis of the *agent first* heuristic in the (shallow) interpretation of passive sentences—i.e., before moving on to anaphoric dependencies, which will be the main test case in the current contribution for the shallow-by-top–down position.

The Agent First Heuristic in Passive Sentences

Linguistic theory moves forward at a considerable pace. Consequently, considerations from the past need no longer apply to the current state of affairs. For instance, if it is claimed, after Slobin (1966), that "nonreversible sentences can be understood by going directly to the semantic roles without an intervening syntactic structure," we can easily see this is overly simplistic. As we now know, thematic role assignment is not just a matter of an argument "encountering" a predicate—containing an empty slot—in the mental working buffer and "filling the hole." Rather, the process involved minimally depends on verb and role type as shown for the contrasts between the processing of different types of intransitive verbs demonstrated in Koring et al. (2012).

Thus, even simple intransitive predicates have more internal structure than meets the eye, and this carries over to our initial example of passives. It is important to see that—in order for there to be a meaning representation at all—*the boy* in (5b) must be assigned a position to be formally identified as a subject (checking agreement, and/or case), that is, to function as an argument of the verb and its associated functional material. Given that under this construal it receives—mistakenly—the agent role, it must be able to semantically integrate with the verb in this capacity. Furthermore, *the girl* must be construed as the object and interpreted accordingly as bearing the theme role associated with this position. There is no escape from the assumption that in assigning this interpretation to the sentence, the processor has to treat the passive verb form as the active entry to which it is lexically related (Reinhart, 2002; Reinhart and Siloni, 2005). This it can only do if it *disregards* function words, such as *by* and *is*, and morphology like—*ed*. Thus, when (5b) is in fact interpreted as (5c), the "active" computation still needs to take place, which is not necessarily shallow at all. Or to put it bluntly, also *deriving a "wrong" interpretation requires explicit computations unless one advocates resorting to magic*.

But there is a further question. Namely, is an auxiliary, heuristics-based, interpretation strategy in fact necessary in this case? Recall that (5b) can only be interpreted as (5c) if the processor disregards the relevant functional elements. But note, that if it does so, the active interpretation is the only one that can be assigned. So in fact, no recourse to auxiliary strategies is needed. It is enough to assume that under certain conditions some functional elements—here, those necessary for a passive construction—will not enter the buffer of the processing system, and the processor simply works with what is has. From the perspective of Marantz's thesis in (1), then, one may assume that in order to interpret (5b) as (5c) a sufficiently articulate structure will be projected and interpreted by the rules the grammar contains. Projecting a structure that ignores the functional material that is present to license the passive interpretation (e.g., since it does not fit in the buffer due to cognitive overload, time pressure etc.), and subsequently using the active base form of the verb, will be quite enough to derive the interpretation observed. Hence, the most parsimonious assumption is that, at least in this domain, no extra-grammatical heuristics—other than disregarding functional elements—are involved at all. In short, here, shallow-TD reduces to shallow-R[4].

[4]Note that even the simplicity of a principle like *Agent first* is in fact not obvious. Properly considered it hides a considerable number of hidden assumptions. Consider, therefore, semantic role assignment in more detail:
Task: Assign a semantic role to DP_1

(i) DP_1 .... [$_{VP}$ V ....]

Options:

1. Apply compositional interpretation procedure to V, VP, and DP_1
2. Go to extra-grammatical set of heuristics, find *Agent first* and assign Agent to DP_1

The leading idea in heuristic based approaches is that option 2 is less costly than option 1. But the simplicity of Agent first is misleading. Consider the fuller structure in (ii):

(ii) DP_1 was [$_{VP}$ V-ed by DP_2]

In order to get the relevant (wrong) interpretation the processor has to:

1. Leave grammar
2. Access list of heuristic principles
3. Find Agent first
4. Apply Agent first
5. Disregard functional material (was, -ed, by)
6. Apply the predication rule between DP_1 and VP

But this raises issues such as:

- What do these heuristic principles arise from?
- Why does searching the list carry no cost?
- For a proper interpretation a non-trivial amount of syntactic/semantic computation will still have to be carried out (DP_1 will have to be interpreted

Of course, one may argue that at least in some cases utterances are interpreted by truly shallow processing. In case of high running emotions people may focus on one or two words in an utterance, completely ignoring any nuance and complexity the utterance may carry. And it is true that so far little is known about the syntax and semantics of exclamations. On the other hand, there is a growing literature on headlines and other similarly reduced linguistic expressions, which shows that these are far from arbitrary, and reflect an articulate linguistic structure underneath (De Lange, 2008). Thus, even if emotions highly limit the amount of items that are admitted into the processing system's buffer, this does not imply that whatever is admitted into the system is not subsequently structured and processed with grammatical means.

The Current Contribution

The discussion on passives as presented above nicely introduces the assumptions underlying the fast and frugal heuristics model, in particular the assumption that a full syntactic parse is complex, and hence, often more costly than the extra-grammatical strategies the lazy language user has at his disposition—what we refer to as the shallow advantage. It also becomes clear that the interpretation of passives is perhaps not the best domain to further evaluate the issue of *top-down* vs. *bottom-up* strategies—since shallow-TD can be reduced to shallow-R.

In the present contribution we will focus on the domain of anaphoric dependencies instead. The underlying reason is twofold. First, in their recent overview of the literature Karimi and Ferreira (2015) explicitly state that an important case of shallow processing in discourse is reference processing, a topic that in their opinion has not received enough attention in the good-enough literature. Second, and more importantly, we will argue that the by now firmly established linguistic theories on anaphoric dependencies allow us to more directly compare shallow and deep processing. Or to frame it more in terms of a good-enough approach (and Karimi and Ferreira's remark on the cost of algorithmic procedures for sentence processing): since grammatical computations and heuristic top-down principles are taken to compete, the well-defined grammatical (deep/bottom-up) and extra-grammatical (shallow/top-down) processing mechanisms of anaphoric dependencies present the perfect testing ground to critically assess whether grammatical computations are indeed "too cumbersome for real creatures"—i.e., as compared to their extra-grammatical alternatives.

In the following sections, we will argue that they are not. That is, we will argue—primarily on theoretical grounds—that the *shallow equivalence* assumption does not hold, at least not in this specific domain (Section *The equivalence assumption for shallow and deep anaphoric dependencies*). In addition, the *shallow-TD advantage* assumption has been evaluated in several experimental studies and, as we will demonstrate, shown to be false in the domain of anaphoric dependencies (Sections *The shallow-TD advantage assumption: Preparing the ground* and *The shallow-TD advantage assumption: The issue of economy*). To us, it seems that this provides enough reason to be skeptical about the aforementioned assumptions and, hence, this particular good-enough implementation of the heuristic/top-down approach to language processing.

THE EQUIVALENCE ASSUMPTION FOR SHALLOW AND DEEP ANAPHORIC DEPENDENCIES

It is a fundamental property of language in its relation to the world around us—and its mental representation—that different nominal expressions may receive the same value. Although nothing forces it—i.e., putting pragmatics aside for the moment—also nothing prevents that *the old baron* and *the driver* in the following sentence are used to refer to the same person.

(7) The old baron was crossing the bridge in a ramshackle carriage. The driver was visibly tired.

In this process of valuation, a linguistic expression is assigned a value from an extra-linguistic domain. Or more specifically, which value it receives is not grammatically determined. This provides a nice case of a potentially shallow-TD operation: Take an expression and assign it a value; prima facie no deep grammatical computations involved, and neither much searching if the referent is prominent in the context (in any case not more than general heuristics may be expected to require). Perhaps Karimi and Ferreira (2015) most clearly articulated this idea, since they state that "the processing of unambiguous referring expressions is facilitated because the comprehension system quickly reaches equilibrium by establishing the referential link between the referring expression and the antecedent through a simple, quick, and heuristics-based coindexation process, leading to little if any processing difficulty."

Whereas in sentence (7) we are dealing with two lexical noun phrases, the same option is available for pronominals, as in (8).

(8) *This soldier* has a gun. Will *he* attack?

He in (8) can be interpreted as the same individual as *this soldier*. However, this option is not available for

as a generalized quantifier, VP will have to be interpreted as a property that is a member of the GQ), and functional material will have to be left out of the computation).

- Why is there no cost involved in the clash between the result of *Agent first* and the functional material that is present?
- How does *Agent first* apply in the case of subject experiencing verbs (hate, admire), or unaccusatives, whose subjects are not agents?

It seems then that the purported simplicity of *Agent first* is not clear from the steps the processor has to take. Now compare this to the derivation by computation:

1. Retrieve V (θ_1, θ_2)
2. Disregard *–ed* and *by*
3. Assign θ_2 to DP_2
4. Disregard *was*
5. Apply the predication rule between DP_1 and VP and assign θ_1 to DP_1

None of the further issues arises and, the procedure applies both to agentive and to subject experiencer verbs, without unwarranted outcomes for other verb classes.

all nominal expressions. The mini-discourse in (9) is infelicitous:

(9) *No soldier* has a gun. *Will *he* attack?

This is due to the fact that *he* and *no soldier* cannot be co-valued. *No soldier* is quantificational, and does not introduce an entity *he* can refer to (an observation leading to the canonical distinction between binding and coreference in Heim, 1982; Reinhart, 1983, and subsequent work; see also Partee, 1978; Bosch, 1980, 1983). This makes anaphoric reference such as in (8) impossible. The same holds true of expressions like *every soldier*. Note that these well-known examples have important implications for how one should interpret the notion "discourse entity." That is, possible discourse antecedents are as diverse as soldiers, water, beauty, head-aches, dissatisfaction, etc. In addition to these nominal expressions, also sentences, verb phrases, prepositional phrases, adjective phrases, and tenses, admit anaphoric relations. Thus, the notion discourse entity must be broad enough to capture all these cases of anaphora, yet be restrictive enough to separate them from quantificational cases such as *no soldier*, or *every soldier*.

Crucially, although *he* cannot be co-valued with *no soldier*, it can depend for its interpretation on the latter. This is shown in (10):

(10) *No soldier* who has a gun hopes *he* will shoot.

That is, in (10) *he* can be semantically bound by *no* soldier. The semantic structure of (10) can be represented as in (11) where *he* is translated as a variable—x:

(11) No soldier who has a gun (λx.(x hopes [x will shoot]))

Under this construal the dependency of *he* on *no soldier* makes perfect sense. Here we have the relation of argument binding (A-binding), defined in terms of "logical binding," as in (12):

(12) A-binding (Reinhart, 2006)
α is A-bound by β iff α is the sister of λ-predicate whose operator binds β

A crucial difference between coreference and A-binding is that the latter, but not the former is subject to a structural condition, namely c-command. Briefly, as indicated by the definition in (12), the A-binder must be the sister of a constituent containing the bindee, as in (13):

(13) A-binder [. . . . bindee. . .]

The role of c-command is clearly illustrated by the contrasts in (14):

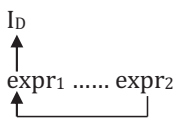
(14) a. The cop who found *the criminal* arrested *him*
b. *The criminal* found by the cop realized the latter would arrest *him*
c. *The cop who found *every criminal* arrested *him*
d. *Every criminal* found by the cop realized the latter would arrest him
e. *The cop who found *no criminal* arrested *him*
f. *No criminal* found by the cop realized the latter would arrest *him*

In (14a), *the criminal* does not c-command *him*, hence doesn't bind it, but since *the criminal* is referential and can have a discourse individual as its value, it can be co-valued with *him*, and there is no difference with (14b) where *the criminal* c-commands the pronominal; that is in both cases can *him* end up as covalued with *the criminal*. In (14c) *every criminal* does not c-command *him*, hence cannot bind it, hence the contrast with (14d). The same contrast is found between (14e) and (14f). Note, that one might argue that (14d) has a shallow counterpart that results by replacing *every criminal* by *all criminals*, and *him* by *them*, and possibly subjects might accept (14c) under such a construal (giving up on distributivity effects). But (14e,f) pose an insurmountable challenge to any such strategy; there is simply no alternative to a procedure in which *him* relates to the expression *no soldier*, and derives its interpretation from the instructions for interpretation this expression contains, since there is no discourse individual it could shallowly access instead[5].

In summary, these contrasts show that two different modes of interpretation must be distinguished: (1) (*shallow*), directly assigning two (or more) expressions the same discourse entity from the interpretation domain (I_D) as a value: *co-reference* as in (15a), and (2) (*deep*), interpreting one of the expressions first via another expression by grammatical—more specifically, semantic—means, as in (15b): *binding*[6].

(15) a. coreference:

b. binding:



It should be clear from these considerations that the contrast between co-reference and binding proves that a certain type of *bottom-up* (deep) dependency, namely binding, is plainly impossible to represent *top-down* (shallowly), without recourse to grammatical computation. Thus, the *equivalence* assumption underlying the shallow approach does not hold—i.e., in the domain of anaphora there is for principled reasons no extra-grammatical alternative to binding. This brings us to the discussion of the *shallow advantage* assumption—or more specifically, the *shallow-by-top-down (shallow-TD) advantage*—which cannot be refuted as easily on theoretical grounds alone, but requires recourse to an accumulating body of experimental evidence.

[5]Note, that it is crucial to distinguish between an expression and its value—for instance between the expression *John* and the individual John denoted by it. This distinction is often overlooked in the psycholinguistic literature, although clearly crucial if one wants to relate processing effects to the working of the memory system.

[6]One might think that such a two-route model is "uneconomical." However, clearly, each of these routes has its own independent motivation, and given their nature partial overlap between their effects is unavoidable.

THE SHALLOW-TD ADVANTAGE ASSUMPTION: PREPARING THE GROUND

While binding is subject to grammatical conditions, as we saw in (14), co-reference, by its very nature is not. Furthermore, binding is not only subject to the c-command requirement but elements to be bound can also be subject to a locality condition as illustrated in (16), with binding represented by co-indexing.

(16) a. Alice$_i$ expected [the King to admire her$_i$]
b. *Alice expected [the Queen$_i$ to admire her$_i$]

The upshot is that—as can be easily observed in the vast majority of languages—a pronominal may not be too close to its binder. In (16a) *Alice* is sufficiently far away from *her* to serve as its antecedent, but in (16b) *the Queen* is too close, matches in features, but yet is not allowed to bind *her*. This is one of the main patterns captured by Condition B of the Canonical Binding Theory (CBT, Chomsky, 1981, 1986)[7]:

(17) Condition B
A pronominal must be free (=not bound) in its governing category (=roughly, the domain of its nearest subject).

Condition B is a grammatical principle. But, one may wonder, why cannot the prohibition expressed by condition B be bypassed by using coreference? That is, even if *the Queen* in (16b) cannot bind *her*, why cannot the language system simply resort to the strategy (or top-down heuristic) in (15a), and assign the same individual to *the Queen* and to *her*? If this would be possible, we would never see the effects of condition B with referential antecedents, contrary to fact. This led to the postulation of what one may call a "traffic rule," reflecting an economy principle: *If a particular interpretation is ruled out by the grammar, this prohibition may not be bypassed* (see Reinhart, 1983; Grodzinsky and Reinhart, 1993; Reinhart, 2006; Reuland, 2011a, for discussion of this principle in various forms). In short, there are sentences where a binding and a coreference construal potentially compete, and when the binding dependency is rejected by the grammar, the coreference alternative is not considered. This is indicative of an economy ranking: *grammar* < *discourse*, reflected in Reinhart's Rule I and its successors[8].

The notion of an economy ranking plays an even more crucial role in the Primitives of Binding (PoB) model developed in Reuland (2001, 2011a), where the conditions on binding are derived from more elementary properties of the grammatical system. In its simplest form this economy measure is based on the assumption that the language system as whole is "lazy" and prefers to minimize the number of cross-modular steps, as in (15b) with one cross-modular step less than (15a)—i.e., in (15a) more information needs to be transferred from the grammar system to the interpretational system than in (15b).

The dependencies discussed so far were established in the "translation procedure" from syntactic representations to the interpretation system. But dependencies can also be pre-encoded by morpho-syntactic means. Quite characteristically, morpho-syntactic dependencies are obligatory. Whereas *him* in (14c) cannot depend for its interpretation on *every criminal*, nothing prevents it from being interpreted as some individual in the associated discourse. This is different from what we see with anaphors, like English *himself*, Dutch *zich(zelf)*, etc. Such expressions *must* be bound (at least in the core cases, see Reinhart and Reuland, 1993). Moreover, they must be bound in a very local domain, as illustrated for English by the contrast in (18), here again represented with the index notation:

(18) a. *Alice$_i$ expected [the King to admire herself$_i$]
b. Alice expected [the Queen$_i$ to admire herself$_i$]

In (18a) *Alice* is too far away from *herself* to serve as its antecedent, whereas *the King* is not a suitable antecedent due to a gender mismatch. As a result the sentence is ungrammatical. In (18b) *the Queen* is near enough, matches in features, and hence, binds *herself*. This is one of the main patterns captured by Condition A of the Canonical Binding Theory (CBT, Chomsky, 1981, 1986):

(19) An anaphor is bound in its governing category (=roughly, the domain of its nearest subject).

A characteristic property of the CBT is that it was based on a mix of syntactic and semantic properties. The notion of governing category is syntactic, the notion of binding itself is semantic, and the notion of an index—one of its key ingredients—was of a hybrid syntactic-semantic nature. This made it highly problematic as an ingredient of an explanatory theory (see Reinhart, 1983, for an initial discussion, and Reuland, 2011b, for a systematic overview of the problems with indices).

Minimalist approaches to grammatical structure (Chomsky, 1995, and subsequent work) introduced a strict separation between morpho-syntax and the interpretive system. Indices are not morpho-syntactic objects, hence, it was concluded, they have no place in syntax. Consequently, whatever there is syntactic in the binding conditions—such as locality—has to be derived with purely syntactic means. The means to do so in syntax are limited, just Movement and Agree (feature checking and valuation). This necessitated a thorough rethinking of binding and the binding conditions. A specific proposal to implement this was developed in Reuland (2001), and elaborated in Reuland (2011a). For reasons of space we will limit the discussion here to a few key issues, starting with condition A of the CBT.

In short, in Reuland (2011a) the locality property of *himself* is shown to follow from the semantic fact that *self* is an inherently reflexive relational noun. Given this property, *self* reflexivizes the predicate of which *himself* is an argument by—covert—head movement onto the verb (that is, it is interpreted as a reflexivizing operator). As we independently know, head-movement is strictly local (Travis, 1984). Hence, the locality of *himself* follows from

[7]For expository purposes we will ignore the subsequent modifications and explanations of Condition B in Reinhart and Reuland (1993); Reuland (2001, 2011a).

[8]Rule I: Intrasentential Coreference (Grodzinsky and Reinhart, 1993):
NP A cannot corefer with NP B if replacing A with C, C a variable *A*-bound by B, yields an indistinguishable interpretation.

the locality of head-movement. Thus, the relevant aspect of the representation of (18b) is as in (20):

(20) Alice expected [the Queen to SELF-admire her(self)][9]
….. the Queen (λx. (x admires SELF (x))

The upshot is, then, twofold. First, the interpretation of *himself*/*herself* involves a purely syntactic movement operation. Second, it is not just a matter of *himself*/*herself* 'looking for an antecedent' and being valued by the latter, but the process crucially involves the reflexivization of the predicate.

Indeed, there is independent experimental evidence that the processing of SELF-anaphors involves the verb in addition to whatever properties the antecedent may contribute. For example, Manika (2014), and Manika et al. (2014) using an information-theoretic approach (see Kostić, 1991, 1995 and subsequent work) show that the interpretation of a referentially dependent lexical item like Dutch *zichzelf* is modulated by the complexity of the verb—as quantified by the inflectional entropy of its paradigm—indicating that the interpretation of *zichzelf* involves an operation on the verb itself[10].

Also the binding of simplex anaphors like Dutch *zich* in (21) is encoded in the syntax (where SE stands for *simplex element anaphor*):

(21) *De klimmer* voelde [*zich* wegglijden]
The climber felt [SE slip away]

Here the encoding is brought about by the operation Agree: *zich* is deficient for gender and number, and is valued by Agree copying these features from the antecedent onto *zich*. The fact that (22) is ill-formed, again follows from economy (this contributes to deriving the canonical Condition B).

(22) **De klimmer* voelde [*hem* wegglijden]
The climber felt [him slip away]

To account for the fact that (22) is ruled out we apply the same logic as in the case of Rule I. The anaphoric dependency between *de klimmer* and *zich* in (21) can be encoded in syntax by Agree, but now consider the case where *hem* is selected, as in (22). Since *hem* is fully specified, it has no empty cells. Consequently, valuing it in the syntax by Agree is not an option. Hence, *zich* wins. But, crucially, this can only work if syntax cannot be bypassed by a derivation in which *hem* is directly interpreted as a bound variable by applying (12). So, syntax has to be considered before semantic binding can apply, and if syntax rejects the derivation, this is final. Since a syntactic operation such as Agree operates locally, we see this competition only when the dependent element is within the Agree domain of the element it is to depend on and not when it is further away[11]. Consequently, we arrive at the economy ranking in (23).

(23) syntax < semantics < discourse

We have by now prepared the ground for a discussion of the second assumption of good-enough interpretations: Are, deep—grammatical—operations indeed more costly for the processor than shallow-TD operations (i.e., in contrast to the economy ranking as depicted above)?

THE SHALLOW-TD ADVANTAGE ASSUMPTION: THE ISSUE OF ECONOMY

Interestingly, the issue of economy has received quite a bit of attention in the experimental literature, though not from the perspective sketched in the current contribution.

The Economy of Syntax

As is well-known, research on language acquisition shows an asymmetry between the performance of young children on condition A as compared to condition B. For instance, Chien and Wexler (1991) explored the question of whether children know Principles A and B from the outset or not. Their experiments show that children correctly require *local* antecedents for reflexives (Principle A) early on, whereas they are significantly delayed in disallowing *local* antecedents for pronouns (Principle B). As argued in Grodzinsky and Reinhart (1993) the computations involving the correct application of condition B are more costly than those involved in condition A. From the present perspective this indicates that the syntactic mode of encoding is indeed the least costly[12].

Although it is generally assumed in the psycholinguistic literature that condition A is a syntactic condition, it may be good to point out that in the PoB system condition A, as it is

[9]This analysis entails that locality is not an *intrinsic* property of *himself* qua being an anaphor. In fact, in positions from which *self* cannot move, there is no locality effect. This is what explains the fact that in (i), where *herself* is contained in a coordinate structure from which movement is prohibited there is no locality effect and *herself* can be bound by *Alice* (Reinhart and Reuland, 1991; Reuland, 2011a) despite the latter's distance:
(i) *Alice* was happy that the King invited the Rabbit and *herself* for tea

[10]This necessitates a rethinking of the conception of binding in the experimental literature, where it is mostly assumed that binding is just a matter of the anaphor looking for an antecedent.

[11]A simple illustration is provided by 1st person plural pronouns in Brazilian Portuguese. It has two forms: *nós*, which is both formally and semantically 1st person plural, and *a gente*, which is formally 3rd person singular, but semantically 1st person plural. *Nós* is free to semantically bind *a gente* and vice versa, but not when they are too close. In that case Agree causes a syntactic feature clash. But crucially, this clash cannot be bypassed by immediately going to the semantics. Note that this exposition is highly simplified. See Reuland (2011a) for the details.

[12]As brought up by one of the reviewers, since Chien and Wexler (1991) and Grodzinsky and Reinhart (1993) there has been considerable discussion about the status of the Delay of Principle B effect. For this discussion two issues must be distinguished. First, there is the question of whether there is a delay in the proper interpretations of pronominals at all. Second, as argued by both Chien and Wexler, and Grodzinsky and Reinhart, the delay shows up primarily with referential antecedents and not with quantificational antecedents. Elbourne (2005) expresses concerns about the adequacy of the experimental designs in these and subsequent studies that argue for such a difference between referential and quantificational antecedents. Conroy et al. (2009) present a number of new experiments that also call this contrast into question, coupled with an extensive overview of experiments discussed in the literature. Summarizing these contributions, it is clear that more factors have to be controlled for than previously assumed, not only involving the design but also the morpho-syntactic composition of the pronominal elements being studied (e.g., Baauw, 2002; Hartman et al., unpublished manuscript). However, even so, one can still maintain that children are more susceptible to Principle B violations than adults. Moreover, none of the literature cited calls into question that children behave quite adult-like with respect to condition A. Consequently, the general claim in the main text is not at issue.

reinterpreted, is indeed a purely syntactic operation (of course with semantic consequences). Hence, it is an ideal testing ground for the shallow vs. deep processing issue.

There are a number of experiments reported in the literature that test the status of condition A. Crucial for the present discussion, their results indicate that condition A applies early in the time course of processing and is, in addition, very robust. To illustrate this, in a well-known study Sturt (2003) carried out two eye-tracking experiments measuring (mis)match effects in sentences such as (24):

(24) *Jonathan/Jennifer* was pretty worried at the City Hospital. *He/She* remembered that *the surgeon* had pricked *himself/∗herself* with a used syringe needle. There should be an investigation soon.

In all the conditions only one character was structurally available (i.e., *the surgeon*, a profession with a stereotypically male gender). The distracting character (i.e., *Jonathan* or *Jennifer*) was highly prominent in the preceding discourse, yet not accessible as an antecedent for the reflexive. The results showed that if the reflexive and structurally available antecedent differed in gender, this immediately slowed down the reading process. Moreover, at this point during processing the distracting character (i.e., *Jonathan/Jennifer*) did not influence the resolution process. This suggests that the language system first attempts to link the reflexive to an antecedent that is structurally available—which will immediately fail when there is a gender-mismatch. In a follow-up experiment Sturt modulated the relative position of the distractor in the sentence, but the same conclusion was supported.

These finding are on a par with several other studies adopting a wide range of methodologies. For example, in an ERP experiment where the participants processed sentences such as (25), Xiang et al. (2009) investigate "intrusion effects" of potential, but non-commanding antecedents that appear—intrude—on the path between the SELF-anaphor and its antecedent.

(25) a. Congruent
The tough soldier that Fred treated in the military hospital introduced himself to all the nurses.
b. Intrusive
The tough soldier that Katie treated in the military hospital introduced herself to all the nurses.
c. Incongruent
The tough soldier that Fred treated in the military hospital introduced herself to all the nurses.

Furthermore, they compared these conditions to paired conditions in a second ERP-experiment in which intruders were present on the path between Negative Polarity Items and their licensers. Although they did find intrusion effects in the latter case, no significant intrusion effects were obtained in the case of the SELF-anaphor conditions as presented above (i.e., the ERP-waveforms revealed no difference between condition b and c). They concluded that during reflexive binding, syntactic constraints appeared to prevent intrusive antecedents from influencing the initial stages of anaphor resolution. In our view this points toward an early and robust application of the syntactic process establishing the dependency.

As a final example, Cunnings and Felser (2013) investigated the processing of SELF-anaphors in English, using the eye-tracking methodology. In their experiments they compared the performance of low working memory span with high working memory span readers. Here we will focus on one experiment—their Experiment 2—in which they measured the effect of a linearly intervening—but inaccessible antecedent (due to lack of c-command) using sentences as in (26):

(26) *James/Helen* has worked at the army hospital for years. *The soldier* that *he/she* treated on the ward wounded *himself/∗herself* while on duty in the Far East. Life must be difficult when you are in the army.

If Principle A would reflect a processing-based constraint this would lead to a different prediction than if it were a purely syntactic constraint. In the former case, particularly lower span readers may initially attempt to keep referential dependencies as short as possible. If so, main effects of the inaccessible antecedent should initially be observed. Higher span readers, on the other hand, would be less likely to find the creation of longer anaphoric dependencies difficult. It was found that for both lower and higher span readers the online application of Principle A could not be reduced to a (shallow-TD) memory-friendly "least effort" strategy of keeping anaphoric dependencies as short as possible[13]. All in all, the joint results of the two experiments they reported support, as they put it, a growing body of evidence showing that binding Principle A applies early during sentence processing to help guide reflexive anaphor resolution (e.g., Nicol and Swinney, 1989; Felser et al., 2009; Felser and Cunnings, 2012; Xiang et al., 2009; but see Badecker and Straub, 2002, for some conflicting evidence; see Dillon, 2014, for an excellent overview of all the relevant results).

Hence, a preferential position of syntactic encoding with respect to other strategies of anaphora resolution is warranted, which is in line with the PoB model (but not predicted by other approaches to binding). Or to put it slightly differently, a deep syntactic operation like binding of a SELF-anaphor is less costly for the processor than shallower operations, in contrast to what the "shallowness" approach predicts. In fact, this already is sufficient to establish our main point. There is *no clear support for a shallowness advantage*. Rather the opposite is the case: for the human processor *deep syntactic computations are preferred over shallow-TD interpretation processes*.

However, it will nevertheless be important to also assess the other members of the economy hierarchy as formulated in the PoB model: binding and coreference. This is what we will do next.

The Economy of Binding and Coreference

A well-known instantiation of the (economy) contrast between binding and coreference, introduced in (23) above, shows up in the interpretation of sentences with VP ellipsis, as in (27):

[13]Note that such a general least effort principle is highly implausible on other grounds, given the existence of long-distance anaphors in many languages, for instance, in Scandinavian.

(27) John fed his cat and Peter did too

Before we elaborate on this contrast in terms of economy, however, some facts and assumptions on VP-ellipsis should be discussed. First of all, it is clear that the second conjunct is about Peter feeding a cat, rather than about him combing a dog. This, uncontroversially, is a fact any theory of language will have to capture. A common idea is that for interpretation to obtain, the content of the VP in the second conjunct must somehow be recovered from the preceding context. As a first go one may assume a copying operation, as in (28).

(28) John fed his cat and Peter did <feed his cat> too.

As one can see, this gives rise to a puzzle, since the elided (i.e., covert) pronominal *his* in the second conjunct is ambiguous. More specifically, the interpretation of the full sentence can be either that John fed John's cat and *Peter fed Peter's* cat, as in (29a), or that John fed John's cat and that *Peter also fed John's cat*, as in (29b):

(29) a. John (λx. (x fed x's cat)) & Peter (λx. (x fed x's cat))
b. John (λx. (x fed a's cat) & a=J) & Peter (λx. (x fed a's cat) & a=J)

In (29a) *his* is interpreted as a variable, x, A-bound by Peter. This is what is generally referred to as the *bound variable* (BV), or "sloppy"[14] interpretation. In (29b), however, *his* is interpreted as a constant, here represented as *a*, which can receive the value of any individual in the discourse including John. That is, the occurrences of *his* in both conjuncts are *coreferential* (COR), yielding a "strict" interpretation.

Interestingly, the human processor is sensitive to this difference, and more importantly, it is a consistent finding in offline studies that in the interpretation of ambiguous VP-ellipses, BV-based interpretations are preferred over COR interpretations (see Frazier and Clifton, 2000, for an overview). This "preference" is reflected in the fact that typical subjects show longer reading times on COR in self-paced reading experiments (reported in Frazier and Clifton). In another experiment on the interpretation of VP ellipses that involved subjects with agrammatism, these subjects performed 80% correct on BV interpretations, but at chance on COR interpretations (Vasic et al., 2006). Curiously, then, what might seem to be the less sophisticated—more shallow—procedure, is the one that comes out as more costly in this case as well.

On the basis of such findings Frazier and Clifton (elaborating Reinhart, 1983; Avrutin, 1994, 1999) propose the following thesis as a hypothesis worth exploring:

(30) LF only/first hypothesis:
Bound-variable interpretations are preferred because the perceiver need only consult the LF representation (not the discourse representation) in order to identify the bound-variable analysis of the sentence.

[14]We use this term since it is so entrenched in the literature. But note that the "sloppy interpretation" is the one that does require grammatical operations. So, this is the one that is not shallow.

In order to do so they carry out a number of exploratory experiments and conclude that the hypothesis, though compatible with some of their results, is too problematic to be maintained.

However, as discussed by Frazier and Clifton (see also Koornneef, 2008; Koornneef et al., 2011) their results should be interpreted with some care, due to limitations of the experimental design and the statistical evaluation. In order to obtain more dependable results, subsequently, a number of full-size experiments using a more sensitive methodology were carried out, reported in Koornneef (2008, 2010), and Koornneef et al. (2006, 2011). Since the case is illustrative of the need to take theoretical advances into account we will briefly discuss Frazier and Clifton's interpretation of their findings before turning to the experiments of Koornneef and his colleagues.

One of the problems Frazier and Clifton note is of a *theoretical* nature. As they observed, a BV-preference also obtains across sentence boundaries, as in (31) (Experiment 1b). According to Frazier and Clifton this is incompatible with the nature of LF operations. That is, one would expect a grammatical operation like VP-copying to be limited to the domain of a sentence.

(31) Sarah left her boyfriend in May. Tina did [leave her boyfriend] too.

The other problem is *empirical* in nature. The choice between variable binding and coreference also shows up in the interpretation of *only*-sentences, illustrated in (32). Here it concerns the interpretation of the pronominal *he* in the complement clause of *think*. And again the pronoun shows an ambiguity. However, contrary to VP-ellipsis, Frazier and Clifton find a preference for a COR interpretation instead of the BV interpretation.

(32) Only Alfred thinks (that) he is a good cook.
a. Only Alfred thinks that Alfred is a good cook. (COR)
b. The only person who thinks of himself as a good cook is Alfred.
(BV).

On the basis of these findings, Frazier and Clifton conclude that the LF-only hypothesis (and equivalents) cannot be maintained. This, however, leaves a puzzle. Why would the case of VP-ellipsis be different from the *only*-case and what conclusions should we draw about the language processing system? Let's first address the theoretical issue Frazier and Clifton raise.

Theoretical Issue: What Mechanism Underlies Ellipsis?

The mechanism originally assumed in the literature on VP-ellipsis since Hankamer and Sag (1976) involved a copying operation (see Elbourne, 2008, for an overview and references). If so we would have to assume that the empty VP in the second sentence in (33a)—indicated by Δ—would be filled by a syntactic operation applying across sentences.

(33) a. Sarah left her boyfriend in May. Tina did Δ too.
b. Sarah (λx. (x left x's boyfriend)). Tina (λx. (x left x's boyfriend)) too.

This, Frazier and Clifton feel, violates the generally accepted idea that grammatical operations are limited to the sentential domain. Therefore, Δ cannot be interpreted by a grammatical copying operation. The question is, then, what kind of mechanism, is involved.

In recent years, however, independent evidence has been found that the theory of ellipsis should allow for greater flexibility (Merchant, 2001, 2008; Elbourne, 2008). This is illustrated by cases like (34) (Elbourne, 2008):

(34) Saskia, being a competitive type, has managed to acquire all the skills that Maaike and Brigitte possess. Maaike dances. Brigitte sings. Saskia does Δ too.

Here, Δ can be interpreted as the combined property of singing and dancing. In order to account for these and a variety of other cases, Elbourne proposes that ellipsis sites have internal—unpronounced—syntactic structure and are to be analyzed as silent "definite descriptions." In line with this, (33a) would be represented as (35), where the label TheP indicates that the complement of *did* is such a silent definite description (perhaps superfluously, we also indicate the silence by strike-through).

(35) Sarah left her boyfriend in May. Tina did [$_{\text{TheP}}$ ~~leave her boyfriend~~] too.

Then, to interpret the VP-ellipsis, the parser must somehow access the context (in this case "Sarah left her boyfriend in May") to retrieve the values for the constituent parts of TheP. Elbourne provides an elegant, yet fairly extensive and technical implementation whose details are beyond the scope of our present contribution. Relevant here is that, as he shows, the interpretation of the ellipsis site does not depend on a sentence-grammar "copy-and-paste operation," but rather reflects how a pronominal picks up its reference. That is, the elided VPs are treated as null pronouns, and under anybody's account, pronouns are able to pick up values from the preceding context. Hence, the relevant difference with the LF copying account is that under Elbourne's approach there is no theoretical reason to expect the context for the interpretation of VP-ellipsis to be limited to the same sentence.

What does the above mean for the explanation of a BV preference in VP-ellipsis like (34) in which the interpretation of the section "Tina did too" depends on retrieving information from a previous sentence? In fact, given that Elbourne's account obviates the same-sentence constraint, the same mechanisms are at work as in (28) where the elided site and the context clause *are* part of the same sentence. To illustrate this, in (35) the parser retrieves either "leave x's boyfriend" as value for the TheP (i.e., the preferred BV interpretation), or alternatively, it picks up "leave Sarah's boyfriend" as a COR alternative. More specifically, just like in the classic examples of VP-ellipsis—in which the ellipsis and context clause are part of the same sentence—any preference for a dependency type in the first sentence will be inherited by the second sentence in (35). No additional stipulations are necessary and in fact the theoretical problem as described by Frazier and Clifton does not arise—which illustrates yet again the fact that it is important to keep reassessing the interpretation of experimental results in view of theoretical advances[15].

Empirical Issue: Interpretational Preferences in Only-sentences[17]

In addition to a theoretical problem for the BV-preference in VP-ellipsis, Frazier and Clifton also report an empirical problem for so-called *only*-sentences. In order to understand what is at stake in *only*-sentences, consider again the pattern in (32), repeated here with additional material:

(36) Only Alfred thinks (that) he is a good cook.
  a. Only Alfred thinks that Alfred is a good cook (COR)
     Only Alfred (x thinks Alfred is a good cook)
  b. The only person who thinks of himself as a good cook is Alfred. (BV)
     Only Alfred (x thinks that x is a good cook)

Frazier and Clifton conducted a questionnaire study, which shows a strong preference for the (36a) interpretation among the respondents. However, there is a caveat about such off-line studies. They reflect an end-result, but don't give insight in the process itself. As it is, if we wish to interpret their results two questions come up. First, is it just a matter of BV vs. COR, or do other factors play a role? Second, what kind of information does

[15] One might wonder if perhaps even a simpler mechanism might work, namely a preference for an antecedent that is as local as possible. This, however, would not derive the parallelism the construction shows. One of the available options is a "3rd party" reading, as for instance in *John* loves his$_1$ *cat and Peter does love his*$_2$ *cat too*, where *his*$_1$ could be Charles given a suitable context. If *his*$_1$ is Charles, *his*$_2$ has to be as well. This shows that there is a dependency between the two occurrences of *his* that has to be represented in the licensing mechanism.

[17] Frazier and Clifton also discuss another empirical puzzle, based on their experiment 1a, a self-paced reading experiment. In this experiment they compare VP ellipsis internal to a sentence with VP ellipsis across sentences. Sentences (a) and (b) are neutral in the sense that they are easily compatible both with a BV and a COR interpretation, whereas (c) and (d) are biased in favor of a COR interpretation.

a. John thinks it's a good idea to shave himself before he goes to sleep and Andy does too. (Bound/Neutral, one sentence)
b. John thinks it's a good idea to shave himself before he goes to sleep. Andy does too. (Bound/Neutral, two sentences)
c. John thinks it's a good idea to shave himself before he goes to sleep and Anne does too. (Coreferential, one sentence)
d. John thinks it's a good idea to shave himself before he goes to sleep. Anne does too. (Coreferential, two sentences)

The puzzle this experiment raises is that the BV advantage seems to disappear across a sentence boundary as in the (b) and (d) cases. If so, this would suggest that whatever one sees in VP ellipsis is not the manifestation of a unified phenomenon. As already noted, the interpretation of their results is not entirely clear-cut due to the limitations of their design. In this case another complication arises.

In the contrast between these sentence types three factors are involved: i. Reflexivization of shave by himself; ii. Control: assigning a value to PRO in PRO to shave himself; iii. The interpretation of the implicit argument of good idea for x (PRO to shave himself) as either Andy, or John (assuming Anne to be ruled out due to the feature mismatch with himself). The latter constitutes a crucial independent factor, which should have been controlled for, in order for a proper interpretation of this result to be possible. The experiment, then, appears to bear on the interpretation of implicit arguments, rather than on VP ellipsis and the LF-first hypothesis directly.

the language processor have to draw together, to obtain either a BV or a COR interpretation in sentences with *only?*

For a proper understanding of these issues at least the following crucial fact should be taken into account: Across both interpretations the fact that Alfred is happy about his own cooking remains constant. Yet, a full interpretation requires the representation of some sort of "hidden" reference set consisting of everybody but Alfred, or in other words the *contrast set* (e.g., Rooth, 1985). The contrast set, implicitly introduced through the use of the term *only*, behaves differently in a BV reading than in a COR reading: whereas in the BV reading each individual member of the set is not that happy about his own cooking, the contrast set in the COR reading consists of members who think that Alfred's cooking is not very good. Given this, a possible additional factor in a BV or COR preference is how well the hidden contrast set fits the context overall.

Thus, a factor to take into account is that, possibly, the hidden set of the COR reading in the sentences tested by Frazier and Clifton just fits the context better. In fact, Frazier and Clifton presented their sentences without an explicit context. But, in order to interpret *only*-sentences, participants will have to set up a context. Thus, the question is what context they construe.

Crain and Steedman (1985) propose a *Principle of Referential Success,* reflecting that people choose the reading with the fewest "open ends." In view of this, it may well be the case that a strict interpretation is chosen more often in "*only* Alfred thinks he is a good cook" because it is more likely that the sentence is talking about Alfred's cooking, which is explicitly mentioned, than about the cooking of the "entire world." Hence, the lack of context could very well bias participants to a COR interpretation regardless of whether the language processor initially prefers a BV reading or not. It is therefore crucial to properly investigate the role of context, and, where necessary, control for its effects.

In summary, Frazier and Clifton (2000) reported both a theoretical problem and an empirical problem for the LF-only hypothesis—which incorporates the BV preference. We have shown that the theoretical problem with VP-ellipsis is in fact not problematic according to the most recent insights of linguistic theories. The second problem (a COR preference in only-sentences), we argued, required further testing. More specifically, as we will discuss in the next section, it generated the following hypotheses in (37) and a series of experiments testing them (e.g., Koornneef et al., 2006, 2011; Koornneef, 2008, 2010; Cunnings et al., 2014).

(37) Hypotheses
- The language processor initially prefers a BV interpretation.
- Context may then lead to a COR interpretation.
- This (mental) backtracking should be visible in the time course of the process.

Tracking the Time Course of Anaphora Resolution

The hypotheses presented in (37), and the issues raised by Frazier and Clifton regarding sentences containing the only-operator, were addressed by Koornneef et al. (2011) in a questionnaire (to assess the final interpretation of the participants) and an eye-tracking experiment (to track the mental processes preceding this final interpretation). In their study Dutch university students read a series of short texts in 4 versions about 2 story characters of the same gender (e.g., *Lisa* and *Anouk*, see ex. 38).

(38) Example of BV-biased/only-sentence condition
(S1)Lisa en Anouk zijn dol op de muziekzender MTV. (S2) Zij konden hun geluk niet op toen zij mee mochten doen aan het programma "Pimp My Room," waarin hun kamers werden opgeknapt. *(S3) Alleen Lisa vindt dat haar gepimpte kamer klasse heeft.* (S4) Smaken verschillen nu eenmaal.
"(S1). Lisa and Anouk love the music channel MTV. (S2) They were very happy when they were selected for the show 'Pimp My Room,' in which their rooms were redecorated. *(S3) Only Lisa thinks that her pimped room has a touch of class.* (S4) Oh well, each to his own taste."

Each story contained a critical third sentence (S3) that was ambiguous between a sloppy (BV) and strict (COR) interpretation. Moreover, two factors were manipulated in the stimuli. First, the critical sentence was an ambiguous only-sentence (e.g., "Only Lisa thinks that her pimped room has a touch of class.") or, alternatively, an ambiguous VP-ellipsis sentence (e.g., "Lisa thinks that her pimped room has a touch of class, but Anouk does not"). Second, by providing background information in the second sentence about both story characters ("Lisa and Anouk were very happy…") or, alternatively, about only one story character ("Lisa was very happy…"), the context either favored a BV interpretation or a COR interpretation of the ambiguous critical sentence, respectively.

The results of the questionnaire experiment, in which the participants presented their final interpretation of the ambiguous sentence (in addition to providing ratings of story-plausibility and -difficulty) showed that, while using a relatively, simple manipulation and exactly the same critical sentence, readers were more easily biased toward a BV interpretation than toward a COR interpretation. Moreover, contrary to the findings of Frazier and Clifton the context manipulation in the second sentence affected the interpretation of the only-sentences and ellipsis-sentences in the exact same way. Hence, these finding are consistent with the idea that the interpretation of the referential ambiguity in only-sentences and VP-ellipses is driven by the same constraints, which preferable single out a BV interpretation.

The eye-tracking data of the reading experiment of Koornneef et al. (2011) confirmed and extended these results. First of all, the stories in which the interpretation of the ambiguous sentence was biased toward a BV interpretation elicited shorter first pass reading times in the critical VP-ellipsis sections than the stories biased toward a COR interpretation[18]. Furthermore, the reading times for the second sentence (i.e., the sentence that contained the biasing information) also revealed a clear contrast between the COR- and BV-biased stories. In this case the second-pass durations—indicative of re-analysis and repair—were much longer for the COR-biased stories. Interestingly,

[18]Note that these results confirmed the findings of the self-paced reading experiments reported by Frazier and Clifton (2000). Hence, across methodologies and languages there is evidence that readers prefer to assign a sloppy identity to ambiguous elliptic structures.

this was observed for ellipsis- and only-sentences alike, which again suggests that the preference for BV interpretations is not restricted to ellipses, but a general property of the parser.

In all, the results of the offline questionnaire and in particular the online eye-tracking experiment were consistent with the hypotheses as formulated in (37). That is, the readers initially preferred a BV reading, since BV reflected the cheaper option in the processing hierarchy. However, when the larger context forced a COR reading instead, readers reanalyzed the story to change their initial BV reading into the more suitable COR reading. This (mental) backtracking surfaced in the eye-tracking data as longer first-pass reading times near the elided section of the ellipsis sentences and longer second-pass reading times at the biasing second sentence.

In a similar eye-tracking study examining the interplay between BV and COR, Koornneef et al. (2006) showed that the preference of the parser for BV dependencies generalizes beyond ambiguous ellipsis- and only-sentences. They observed that in sentences like (39) containing a quantified antecedent "iedere arbeider" (every worker) in a c-commanding position and a proper name "Paul" in a non-commanding position, readers more easily connected the ambiguous pronoun to the former than to the latter—even when the context preceding the critical sentence clearly mandated the COR reading in which "hij" (he) equaled "Paul."

(39) *Iedere arbeider* die zag dat *Paul* bijna geen energie meer had, vond het heel erg fijn dat *hij* wat eerder naar huis mocht vanmiddag.
"Every worker who noticed that Paul was running out of energy, thought it was very nice that he could go home early this afternoon."

In a more recent eye-tracking study, however, Cunnings et al. (2014) addressed some weaknesses in the stimuli of Koornneef et al. (2006) and failed to replicate the preference for quantified c-commanding antecedents over non-c-commanding proper names. More specifically, in the most relevant experiment of their study (i.e., Experiment 1) Cunnings et al. embedded sentences like (40) in a short discourse and manipulated the gender of the critical pronoun and the preceding proper name[19].

(40) *Every soldier* who knew that *James/Helen* was watching was convinced that *he/she* should wave as the parade passed.

At the critical pronoun and the region immediately following the pronoun they observed longer re-reading and total reading times when the proper name antecedent mismatched in gender with the pronoun. These results, according to Cunnings et al., indicated that readers preferred to connect the pronoun to the linearly closer, yet non-c-commanding antecedent. This would be inconsistent with the PoB framework, since "it fails to support the hypothesis that variable binding relations are computed before coreference assignment."

Although we agree with Cunnings et al. that these results do not provide strong evidence in favor of the PoB approach we disagree with the claim that the results are inconsistent with the approach, for the following reasons. First, in the experiment of Cunnings et al. the individuals [James/Helen in (40)] were not introduced previously—note that this was controlled for in the Koornneef et al. study (2006; see for a detailed discussion Koornneef, 2008). Therefore it is not unlikely that the readers were trying to get further information after the topic shift in the story, and thus tempted to consider a subsequent pronominal as a source of such information. This would be consistent with the fact that the reported differences show up in so-called "later" eye-tracking measures only. Which brings us to a second and arguably more important issue. That is, since the reading time differences become visible in later eye-tracking measures only, the non-c-commanding proper name does not seem to impact the interpretive costs of the pronoun immediately. Hence, instead of ruling out an early preference for BV dependencies over COR dependencies, the findings of Cunnings et al. indicate that COR distractors can influence the interpretive system during later stages of processing—i.e., not unlike the defeasible filter model concerning Principle A (e.g., Sturt, 2003). Crucially, this would be compatible with the PoB approach in which the choice between variable binding and coreference for an ambiguous pronoun is intrinsically free (e.g., Koornneef, 2008).

In all, we do not fully agree with the conclusions as presented by Cunnings et al. (2014), and hence, we maintain our position that there is sufficient evidence for a BV preference—and no convincing evidence against it. Hence, with respect to the good-enough approach (e.g., Ferreira, 2003; Karimi and Ferreira, 2015), the focus of our current contribution, we state that the empirical studies examining bound vs. coreferential dependencies confirm and extend our previous conclusion, where we reported that grammatical operations (such as binding of a SELF-anaphor) are less burdensome for the processor than shallower operations. Again in contrast to what the good-enough approach predicts, the experiments discussed above show that the same holds for binding of a pronominal; the deep variable binding algorithm is less costly than—and preferred over—the shallow top-down driven operation of coreference[20].

Before we present our final assessment of the good-enough approach in the domain of anaphoric dependencies, however, we should address some interesting suggestions of Cunnings et al. (2014) as to how their results can be related to more general architectural issues. First, they observe that a recurrent issue, highly relevant for the bound variable vs. coreferential (or grammatical vs. extra-grammatical) distinction, is the role of structure-based vs. unconstrained cue-based memory retrieval mechanisms (see e.g., Dillon, 2014; Jäger et al., 2015a, for recent overviews of this issue). Second (and somewhat related), they suggest that their results are more easily explained with a uni-modular approach as in Heim (2007), than with the multi-modular architecture assumed in the PoB model. These two architectural issues will be addressed in more detail below.

[19]The interpretation of their Experiment 2 is not entirely straightforward due to the presence of two c-commanding potential antecedents, but the findings of this experiment seem to be consistent with the predictions of the PoB model.

[20]Quite interestingly, many of the facts discussed in Karimi and Ferreira (2015) are consistent with the idea that there is a cost associated with accessing discourse. The essence of shallow-R processing of anaphoric dependencies appears to consist of foregoing or postponing the access to discourse, leaving pronominals unvalued.

Structure-Based vs. Unconstrained Cue-Based Retrieval

The PoB economy ranking in relation to shallow vs. deep processing is by no means the only issue that arises in the field of anaphor processing. For example, by now an important recurrent issue—although to some extent orthogonal to the economy issue—is what kind of retrieval mechanism promotes anaphor resolution. More specifically, based on a growing body of literature, Cunnings et al. (2014) distinguish two theoretically plausible ways in which the antecedent of a linguistic element can be retrieved from (working) memory. As a first possibility, a serial search mechanism is proposed in which the text representation is searched in a step-by-step manner until the proper antecedent for an anaphor has been located. A qualitatively different search (or retrieval) mechanism is based on the idea of a content-addressable memory (CAM) architecture (Lewis et al., 2006). In the latter type of memory systems, previously stored information can be accessed directly by the use of certain features as retrieval cues.

Cunnings et al. (2014; see also Jäger et al., 2015a,b) make the interesting conjecture that a specific instantiation of a serial search mechanism could be a structure-based retrieval mechanism in which syntactic tree-configurational information (e.g., c-command) guides the retrieval process. That is, in these type of systems "the priority in which antecedents are retrieved is dependent upon their relative position in the search path" (pp. 42) which would be compatible with an architecture assuming a BV preference. In contrast, CAM-like, unconstrained cue-based retrieval assumes that all available cues (e.g., gender, number, person, animacy, etc.) are used immediately (and in parallel) to retrieve an anaphor's antecedent. This system allows for more flexibility as structural constrains do not have a privileged status and, hence, COR interpretations of (reflexive) pronominals are also considered immediately—i.e., not subsequent to BV interpretations.

Cunnings et al. (2014) claim that the results of their eye-tracking experiments favor the latter cue-based approach, as recency (or linear proximity) of the antecedent seemed to guide the resolution process of a pronoun, rather than the structural notion of c-command. Indirectly, then, one could state that there is no solid experimental evidence to maintain a distinction between variable binding and coreference (cf. our discussion on uni-modular vs. multi-modular architectures below). Moreover, it would imply that the same cue-based memory mechanisms underlying the construction of a range of other (syntactic) dependencies—such as filler-gap dependencies (McElree et al., 2003), subject-verb dependencies (Van Dyke and Lewis, 2003; Van Dyke and McElree, 2006; Van Dyke, 2011, 2007; Wagers et al., 2009; Dillon et al., 2013), the licensing of negative-polarity items (Vasishth et al., 2008) and verb-phrase ellipsis (Martin and McElree, 2008)—are responsible for determining the proper antecedent for (reflexive) pronominals.

Whether cue-based memory retrieval, however, is indeed the most valid way to describe anaphoric processing is hotly debated still. For example, Dillon (2014) shows in a very systematic overview that reflexives are relatively immune to so-called retrieval interference, a property that would set them apart from superficially similar syntactic dependencies like subject–verb agreement. This conclusion in turn, is disputed by Jäger et al. (2015a) who conducted reading time experiments on German and Swedish reflexives, and *did* observe occurrences of retrieval interference as predicted by the cue-based approach—and as they claim, not by the structure-based approach.

Hence, at this point in time we are simply not in the position to single out a unique framework as the correct approach. In fact, in the case of anaphora it might well be true that both types of memory retrieval systems are somehow involved. For one thing, although binding dependencies are often discussed in terms of c-command, this certainly does not entail that the formation of logical form representations should be considered to be blind to cues such gender and number. Hence a possible, and in fact very plausible, outcome is that the antecedents for (bound) pronouns are determined by means of a system that combines structure- and cue-based search algorithms, with their respective roles depending on timing. For instance, one might expect intrusion effects at a stage before the final structure is established. In all, the precise nature of the interplay between c-command vs. morpho-syntactic cues is an important issue that must be left for future research (but note that coding a tree-configurational relation as a cue for a CAM-like system is not as straightforward as coding gender and number; see Jäger et al., 2015a, footnote 4).

Albeit in a different way, this latter question also surfaces in the second architectural issue raised by Cunnings et al. (2014). That is, incorporating c-command as a "normal" cue in a CAM retrieval system, or alternatively, setting it apart as a qualitatively different cue, can ultimately be interpreted as a debate on uni-modular vs. multi-modular approaches to anaphor resolution.

Uni-Modular vs. Multi-Modular Architectures

A very fundamental issue raised by Cunnings et al. (2014), concerns the (uni)-modular architecture of the anaphoric system. That is, in contrast to the PoB framework (in which at least three different modules/algorithms are assumed to underlie anaphora interpretation) they follow Heim (2007) who, they claim, puts forward a uni-modular approach. However, we feel that their interpretation of Heim's proposal on uni-modularity is less straightforward than they assume.

First, Heim's discussion is limited to condition B, and the status of Reinhart's Rule I. It does not address condition A, which uncontroversially is syntactic. So, even if Heim's endeavor works for condition B, binding theory as a whole would still minimally be "bi-modular."

Second, Heim does not include the interpretation of proper names and other referential expressions in her discussion. But, even in her system, one must assume that these are directly interpreted as some individual in the discourse—but of course, relative to context. This interpretation strategy, however, must also be available for certain uses of pronouns. Just like we can start a story with *Helen was watching the parade with a feeling of disgust. Suddenly* ….where we are introducing a discourse individual and slowly building a character while reading on, we can start a story with *She was watching the parade with disgust. Suddenly…* and again we will be introducing a discourse individual and slowly building a character. It seems to us that

there is no independent ground to treat the reference assignment differently in these cases. If so, not all cases of pronominal interpretation will fall under the binding strategy Heim proposes. Hence, whatever the division of labor in other cases, no truly uni-modular model for this domain will result in the end.

Heim doesn't discuss this issue. But if one looks carefully, one sees that what she achieves is tantamount to building Reinhart's Rule I into the binding conditions. Given that she set out to retain the core of Reinhart's insight, it is not surprising, then, that it surfaces in the details of the formulation of condition B. In fact what her system does is generalize over the "worst case scenario." The difference between binding and co-valuation shows up in the explicit role of context in the latter, but not in the former. This is interesting by itself, since from a processing perspective, this would make it quite unexpected for co-valuation to require fewer resources than binding. But it also shows that the core of the contrast between binding and co-valuation is in fact retained in her system.

Note furthermore that Heim's unification program is based on the idea that condition B is essentially semantic. However, as shown in Volkova and Reuland (2014), this idea cannot be maintained in view of languages with locally bound pronominals. Such cross-linguistic variation shows that there must be a syntactic component in condition B (see Reuland, 2011a, and Volkova and Reuland, 2014, for further evidence that condition B is in fact not a unified phenomenon). Pronoun resolution in such languages [as for instance Frisian, or (Tegi) Khanty] has not yet been studied experimentally to our knowledge. Such experiments could shed further light on the way interpretive dependencies are processed, and more specifically, on the contrasting economy rankings and its relation to shallow and deep processing as proposed in the good-enough and PoB frameworks.

This brings us back to the issue we started out with, and in fact to a conclusion[21]

CONCLUSION

As part of our more general goal of reassessing the interpretation of experimental results in view of the ongoing advances made in theoretical linguistics and psycholinguistics, the main focus of the current contribution was to evaluate the core assumptions of the good-enough framework as proposed by Ferreira and colleagues (e.g., Ferreira, 2003; Ferreira and Patson, 2007; Karimi and Ferreira, 2015). We structured our discussion around a recent elaboration of the good-enough approach (Karimi and Ferreira, 2015) in which an explicit distinction is being made between "deep" bottom-up syntactic algorithms and "shallow" top-down semantic/discourse operations. Crucially, given the presumed complexity of syntactic algorithms, the latter type of (extra-grammatical) heuristics should be preferred, thereby inducing good-enough representations of an utterance or text.

As it turned out, one of the key-notions in the discussion had to be reassessed. That is, we proposed that one must make a distinction between *shallow-TD* processing as a top-down process, and *shallow-R* processing as involving a reduced input (see e.g., Stewart et al., 2007). Taking this into account, the conclusion in terms of the *shallow equivalence* and the *shallow advantage* assumptions (cf. Principle 1 and 2 in Karimi and Ferreira, 2015) as formulated at the outset of this contribution are straightforward and simple. First, in the domain of anaphoric dependencies the equivalence assumption does not hold. There are binding dependencies whose interpretation cannot even be approximated by shallow-TD procedures. Second, and perhaps for current purposes more importantly, we reviewed a variety of experiments bearing on a purported shallow-TD advantage. None of the experiments provided support for such an advantage. Rather the opposite is the case: in the domain of anaphoric dependencies deep algorithmic computations are preferred over shallow-TD interpretational processes. Such a preference not only shows up in the comparison between syntax and what one may broadly call the interpretive system, but also *within* the latter system, i.e., between deep, structure-based (variable binding), and shallower context-based (coreference) interpretive procedures.

There is one important proviso: as becomes clear from the discussion (e.g., regarding Heim, 2007) context-based interpretive procedures may in fact require more computation than meets the eye. Hence, properly considered, they may not be as shallow as they prima facie appear to be. Perhaps, then, they are more costly because they, at least in some cases, require more sophisticated computations. But if this is so, this casts doubt on the very idea that there are truly shallow procedures. Such shallow procedures may well be no more than illusory effects that arise if some material is not admitted into the buffer. Therefore, we submit the bold claim that, until proponents of the existence of shallow procedures offer precise and falsifiable descriptions, Occam's razor requires us to treat them as just that: illusions.

[21]Many further interesting issues about the processing of interpretive dependencies arise. One factor that sets the processing of pronominals apart from the processing of SELF-anaphors, is that pronominals don't have to be bound, whereas SELF-anaphors in non-exempt positions and simplex anaphors must be bound. In argument positions SELF-anaphors and bound pronominals are in complementary distribution, but not in locative and directional PPs. It would be interesting to investigate the effect of such non-complementarity. Also non-local binding of simplex anaphors in Dutch, German, and Mainland Scandinavian languages raises interesting issues. They must be bound within the sentence – although their domain varies. Especially in Scandinavian they allow a choice of antecedents, and in the non-local domain they are not in complementary distribution with bound pronominals. The question is, then, how precisely these factors show up in the processing of these elements.

.

(Potsdam 2012) for their comments and to the editors for their patience. We are very grateful to the reviewers for their careful and constructive comments which stimulated us to considerably sharpen our argumentation. Above all we would like to thank Loes Koring for reading and commenting on an early draft, and extensive conversations that provided the impetus for choosing this particular focus.

[1] Language and Brain Lab, Department of Linguistics, Yale University, New Haven, CT, USA, [2] Interdepartmental Neuroscience Program, Magnetic Resonance Research Center, Yale University, New Haven, CT, USA

In the sentence "The captain who the sailor greeted is tall," the connection between the relative pronoun and the object position of *greeted* represents a long-distance dependency (LDD), necessary for the interpretation of "the captain" as the individual being greeted. Whereas the lesion-based record shows preferential involvement of only the left inferior frontal (LIF) cortex, associated with Broca's aphasia, during real-time comprehension of LDDs, the neuroimaging record shows *additional* involvement of the left posterior superior temporal (LPST) and lower parietal cortices, which are associated with Wernicke's aphasia. We test the hypothesis that this localization incongruence emerges from an interaction of memory and linguistic constraints involved in the real-time implementation of these dependencies and which had not been previously isolated. Capitalizing on a long-standing psycholinguistic understanding of LDDs as the workings of an active filler, we distinguish two linguistically defined mechanisms: *GAP-search*, triggered by the retrieval of the relative pronoun, and *GAP-completion*, triggered by the retrieval of the embedded verb. Each mechanism is hypothesized to have distinct memory demands and given their distinct linguistic import, potentially distinct brain correlates. Using fMRI, we isolate the two mechanisms by analyzing their relevant sentential segments as separate events. We manipulate LDD-presence/absence and *GAP-search* type (direct/indirect) reflecting the absence/presence of intervening islands. Results show a *direct GAP-search*—LIF cortex correlation that crucially excludes the LPST cortex. Notably, *indirect GAP-search* recruitment is confined to supplementary-motor and lower-parietal cortex indicating that *GAP* presence alone is not enough to engage predictive functions in the LIF cortex. Finally, *GAP-completion* shows recruitment implicating *the dorsal pathway* including: the supplementary motor cortex, left supramarginal cortex, precuneus, and anterior/dorsal cingulate. Altogether, the results are consistent with previous findings connecting *GAP-search*, as we define it, to the LIF cortex. They are not consistent with an involvement of the LPST cortex in any of the two mechanisms, and therefore support the view that the LPST cortex is not crucial to LDD implementation. Finally, results support neurocognitive architectures that involve the dorsal pathway in LDD resolution and that distinguish the memory commitments of the LIF cortex as sensitive to specific language-dependent constraints beyond phrase-structure building considerations.

Keywords: left inferior frontal cortex, Broca's and Wernicke's aphasia, supplementary motor area, precuneus, long-distance dependencies, sentence comprehension, working memory, attention

1. INTRODUCTION

A long-distance or filler-gap dependency (LDD) is a syntactico-semantic relation between a pronominal element and a syntactically licensed position, or GAP, in an embedded clause. The LDD is thus the linguistic device that allows the pronominal element to be interpreted within the embedded clause. In the English sentence "*The captain$_k$ [who$_{k/j}$ the sailor predicted that the weather would frighten (GAP)$_j$] smiled.*" the LDD is the connection between the relative pronoun and the object position of *frighten*, to which the semantic role of *frightenee* is assigned. LDDs have traditionally provided a window to explore the interaction between lexico-semantic and syntactic mechanisms involved in sentence composition, and have thus represented a rich space for neurolinguistic and psycholinguistic investigation. In LDDs, these mechanisms are specifically observed in the interpretation of the relative pronoun both as the object of the embedded verb (e.g., *the frightenee*) and as the coreferent to the head noun antecedent (e.g., *The captain*), mechanisms that are presumably grounded not only in fundamental properties of sentence composition such as argument structure licensing and discourse linking but also in the neurological properties of the linguistic subsystems that support those properties (e.g., Frazier et al., 1983; Frazier and Clifton, 1989; Grodzinsky, 1989; Swinney et al., 1989; Swinney and Zurif, 1995; Gibson, 1998; Grodzinsky, 2000; Phillips, 2003; Avrutin, 2006).

From a neurolinguistic perspective, LDD implementation also allows us to investigate how the interaction between sentence composition and memory should be understood, as well as what the cortical distribution of this interaction should be. Interpretation of the relative pronoun is, after all, expected to place significant demands on the memory system: the pronoun must be held in memory while the intervening syntactic and semantic material is parsed (in the present case "*that the weather would*"). The presence of intervening material taxes the processing system (e.g., King and Kutas, 1995; Cooke et al., 2002; Fiebach et al., 2002; Santi and Grodzinsky, 2012; Santi et al., 2015) and is subject to aging effects (Zurif et al., 1995). So, understanding the cortical distribution of these dependencies gives us insight into the basic commitments that any neurocognitive model of language must allow with respect to sentence composition in addition to the interactions of sentence composition with other components of cognition, most notably memory.

The record on LDD comprehension reveals a long-standing incongruence regarding the language processing commitments of the left inferior frontal (LIF) cortex: lesion studies show that in contrast to Wernicke's patients and patients with lesions in the right hemisphere homolog of Broca's area, Broca's patients fail to implement LDDs in a normal fashion during real-time comprehension. Specifically, these subjects fail to show normal implementation of the "GAP-filling" effect: the reactivation of the antecedent (i.e., the entity coreferent with the relative pronoun) at the position of the GAP (e.g., Zurif et al., 1993; Swinney et al., 1996; Grodzinsky et al., 1999; Grodzinsky, 2000; Burkhardt et al., 2003; Love et al., 2008). Given the localization value of Broca's and Wernicke's aphasia, this pattern of performance is taken to indicate that LDDs demand the workings of the LIF cortex and, crucially, do not depend on the workings of the left posterior superior temporal (LPST) cortex. By contrast, neuroimaging work has shown equal engagement of the LIF cortex *and* the LPST cortex for the implementation of the same dependencies (e.g., Stromswold et al., 1996; Cooke et al., 2002; Fiebach et al., 2002; Ben-Shachar et al., 2003, 2004; Friederici et al., 2003; Grodzinsky and Friederici, 2006; Santi and Grodzinsky, 2008).

We take both sets of results– lesion- and neuroimaging-based– to be valid and on that basis propose that together they provide complementary observations about LDDs and the neurocognitive resources that support them. Specifically, we hypothesize that one crucial property of LDD implementation–*GAP-search*–relies on the workings of the LIF cortex, as the lesion-based record shows. This leaves open the question of the role of the LPST cortex reported in the neuroimaging record. In this respect we test the hypothesis that such LPST cortical recruitment would not be connectable to the implementation of *GAP-search*; and may be instead implicated in *GAP-completion*, a local, lexically-driven process fundamental to all sentence composition. To this end, we isolate the neurocognitive factors underpinning LDD comprehension on the basis of an analysis of relative pronouns that connects to parallel, incremental left-to-right structure-building mechanisms with potential neurocognitive relevance. Using fMRI, we examine the timing and cortical commitments of the interaction of these mechanisms. We conclude with a discussion of the implications of these findings for the lesion vs. imaging "mismatch," and in the context of current neurocognitive models for our understanding of the LIF cortex as a "language" area.

1.1. The Structural and Processing Properties of Long-Distance Dependencies

The purpose of this section is to present the linguistic structure for long-distance dependencies (LDDs) that supports their real-time processing implementation. This structure is therefore the basis for the definitions of the processing mechanisms of *GAP-search* and *GAP-completion*, which operationalize the dependency in neurocognitive terms[1]. In English, long-distance dependencies prototypically emerge in relative clause and *wh*-question formation. In the case of relative clauses, they involve three main elements: the antecedent, the relative pronoun, and the GAP. The antecedent is the denotation of the head noun

[1]This linguistic description captures the consensus among a variety of syntactic approaches, e.g., Government Binding/Minimalism, Head-Driven Phrase Structure Grammar, Lexical Functional Grammar, and Simpler Syntax, among others, that LDDs are grounded on two organizational properties of language: (1) the possibility to "package" the semantic and syntactic local conditions of the relative pronoun as lexicalized content in the form of subcategorization and/or selectional restrictions, and (2) the possibility of a GAP, a phonologically empty lexico-syntactic entity whose purpose is to instantiate the lexical requirements of the embedded verb; requirements that are expressed in the form of argument structure and subcategorization specifications. These are fundamental and widely accepted properties of the language system. The description presented here is therefore compatible with any representational analysis of relative pronouns that incorporates these two properties (see Culicover and Jackendoff, 2005, for extensive discussion of the syntax-semantics interactions in LDDs and the assumptions that lead the various approaches in question to favor one specific implementation over another).

of the noun phrase containing the relative clause [*captain* in (1) below]. The RELPRO (which may be phonologically empty in English) is the entity that semantically links the antecedent and the GAP [*who* in (1) below]. The RELPRO occupies what we would call a "non-canonical" position, a position that does not receive direct semantic role assignment by a predicate, and therefore does not receive direct interpretation with respect to the proposition associated with the embedded clause. This interpretation is provided instead through the dependency it forms with the GAP. The GAP, in turn, is a hypothesized phonologically empty syntactically valid place-holder of the "displaced" relative pronoun which receives a semantic role by virtue of its grammatical function within the embedded clause. (1) below illustrates the relation between the GAP to which the semantic role of "experiencer" is assigned and the denotation of the head noun *captain* (the antecedent):

(1) The captain$_{antecedent}$ [who the sailor predicted that the weather would frighten ("the captain")$_{GAP}$] turned back to port.

The relation between the antecedent and the GAP is mediated by the relative pronoun (RELPRO). The RELPRO holds a coreference relation with the antecedent. And it is this coreference relation between the RELPRO and the antecedent that allows the antecedent to be interpreted as a participant in the proposition associated with the embedded clause, i.e., *the sailor predicted that the weather would frighten* ***the captain***. Establishing an LDD therefore means connecting, on the one hand, the antecedent and the RELPRO and, on the other, the RELPRO and the GAP. These two distinct links are identified by the (shared) indices in (2) below:

(2) The captain$_k$ [who$_{k/j}$ the sailor predicted that [the weather would frighten (GAP)$_j$]] turned back to port.

As can be seen, LDDs contain syntactic (construal of the relative pronoun as a grammatical relation in a"noncanonical" position) and lexico-semantic (semantic role assignment) mechanisms which are categorically distinct, and consequently subject to at least partially independent principles of composition. They also involve pronoun interpretation (the establishment of coreference between the RELPRO and the antecedent), which, at least for processing purposes, is identified as a discourse process (e.g., Grodzinsky et al., 1991; Avrutin, 1999; Piñango and Burkhardt, 2005). We take these mechanisms to be encoded in the lexical representation of the RELPRO itself as syntactic, discourse, and semantic selectional requirements respectively. The proposed representation is presented in (3) below:

(3) RELPRO "who"

{Syn:	[$_{NP}$ N$_{head}$	[$_{CP}$ **NP**$_{k/j/w}$	[$_{IP}$ NP$_j$	[V NP$_w$]]]]}
{Sem:	[argument$_k$	[**pronoun**$_{k/j/w}$	[predicate	[argument$_j$, argument$_w$]]]]}
{Discourse:	[antecedent$_k$	[**PRO**$_{k/j/w}$	[SUBJ$_j$	[OBJ$_w$]]]]}
{Phon:	[hu] }			

The representation in (3) specifies the syntactic, discourse, and lexico-semantic environments in which the RELPRO *who* may be licensed, thus capturing the main properties of its linguistic distribution in English. Retrieval of a RELPRO during comprehension therefore means the retrieval of this lexical *composite* with all the mutually constraining algorithms that determine the environment of its realization. In this way the lexical entry itself makes explicit the possible predictions by the parser regarding preceding and crucially, incoming lexical material.

This description thus represents the relevant lexico-syntactic characterization that we take to underlie both the filler-gap effect (e.g., Crain and Fodor, 1985; Stowe, 1986; Swinney et al., 1988; Frazier and Flores d'Arcais, 1989; MacDonald, 1989; McElree and Bever, 1989; Nicol and Swinney, 1989; Fodor, 1995) and its corresponding psycholinguistic generalization, the *Active Filler Hypothesis* (Frazier and Clifton, 1989). Specifically, in this linguistic articulation, the GAP is simply the realization of a coindexation relation between the relative pronoun and a phonologically unsupported [NP+semantic argument+grammatical relation] "triplet" in the embedded IP. The Active Filler Strategy therefore emerges as the implementation of the search to satisfy the RELPRO's requirements[2]. We conjecture that the explicitness of this lexically "packaged" parallel, multi-layer structure is what gives the LDD its seemingly unified processing implementation, what informs the parser as to the syntactic constituents where it can/cannot find a GAP (e.g., Stowe, 1986), and what so powerfully drives the RELPRO (the filler) to hypothesize a GAP even in constructions where it will ultimately be disallowed (e.g., Frazier et al., 1983; Hickok, 1993).

Having made explicit the necessary linguistic and psycholinguistic considerations, we turn to other non-linguistic real-time implementation requirements, specifically, memory requirements. We observe that there are in principle three "inflection points" in the LDD processing: the signaling by RELPRO retrieval that a GAP is incoming, the search for the GAP, and the actual instantiation of the GAP; that is, the point in the composition of the embedded clause where the RELPRO requirements are met (i.e., the GAP). We reason that whereas the antecedent-RELPRO coreference relation and GAP instantiation are unambiguous and local, the instantiation of the search for the GAP is, by contrast, multiply ambiguous due to the availability of multiple potential GAP positions that the RELPRO can be coindexed with and that are associated with all the possible grammatical relations in the embedded clause. This inherent ambiguity is presumably what forces the processor to closely track the syntactic and semantic structure of the incoming embedded clause until the GAP is reached, thus making it memory taxing. It is this basic difference what makes the gap search process a clearer candidate

[2]The index alignment shown across constituents in the syntactic, semantic, and discourse layers makes explicit the observation by most linguistic frameworks of a robust correlation between syntactic category/position, grammatical relation, and

for the probing of cortically localizable real-time linguistic processes.

On this basis, we articulate the LDD into two linguistically distinct stages, the search process itself vs. the licensing point of the GAP. These stages are in turn operationalizable as two mechanisms distinguishable by their differing memory demands. Those mechanisms are:

(i) *GAP-search*: triggered by the retrieval of the RELPRO. It is the language composition process where memory resources are maximally taxed: Upon retrieval of the RELPRO its lexico-syntactic requirements must be satisfied all while the phrase structure and semantic representations of the embedded-clause are being composed [e.g., *who*$_{k/j}$ *the sailor predicted that the weather*, in (2)]. *GAP-search* is the mechanism that effectively implements the Active Filler Strategy: the RELPRO's lexically-driven search within the embedded clause in order to meet its lexico-syntactic requirements.

(ii) *GAP-completion*: triggered by the retrieval of the embedded verbal predicate. It is the process whereby the RELPRO's lexico-syntactic requirements are satisfied. In (2) this process takes place when the embedded verb is retrieved: the earliest point at which the embedded predicate (e.g., *frighten*) can license the object grammatical relation/NP structure and assign to the RELPRO the corresponding semantic role (e.g., *frighten-ee*). This not only completes the interpretation of the RELPRO *who* within the embedded clause but "grounds it," as it were, into the composition of the rest of the embedded clause. It allows the interpretation of the coreferring antecedent (the denotation of the matrix subject head, *captain*) as a participant in the embedded proposition's semantic representation. Crucially, this process, like *GAP-search*, is compositional and therefore expected to require memory resources beyond lexical retrieval. However, given the locality of its resolution, the amount of memory resources *GAP-completion* demands should be significantly less than those demanded by *GAP-search*.

Here, we hypothesize that given their respective linguistic properties and correlated memory demands, these two mechanisms are potentially neurologically dissociable in a way that could shed light on the neurocognitive incongruence at issue. Notably, this kind of processing analysis finds direct support in previous findings by Phillips et al. (2005). That report presents two distinct electrophysiological components associated with long-distance dependency comprehension: a sustained anterior negativity subsequent to the initiation of the *wh*-dependency and a late posterior positivity (P600) associated with the completion of the dependency. We take that pattern to represent the electrophysiological correlates of *GAP-search* and *GAP-completion* respectively and thus take them as initial support for the analytical approach adopted here.

[2]semantic relation, such that if a predicate licenses, say, an agent argument, this argument will bear the subject function, which in English can be associated with NP category and SPEC;IP position (e.g., Chomsky, 1965, 1981; Bresnan, 1982, 2001; Fillmore, 1988; Goldberg, 1995; Van Valin and LaPolla, 1997; Culicover and Jackendoff, 2005).

Most crucially for our present purposes however, a closer look at the fMRI record also suggests the potential viability of this dissociation. We turn to that record directly below.

1.2. LDDs and the LIF Cortex in fMRI: Previous Experimental Record

In this section we discuss previous neuroimaging work that has also targeted either *GAP-search* or *GAP-completion* as we define them here in connection to the workings of the LIFG. Our search through the record was constrained by the requirement that the given report target one, the other, or both mechanisms in question as unified phenomena. The conclusions from that work together with the lesion-based evidence constitute the basis for the specific localizational predictions that we test[3]. Of the large body of neuroimaging work on LDD comprehension, four reports specifically deal with *GAP-search* as we have defined it: (Santi and Grodzinsky, 2007, 2010, 2012) and Matchin et al. (2014). Interestingly, we found no previous work on LDD comprehension targeting *GAP-completion*. In line with the focal lesion evidence these four reports converge on the observation that at least *GAP-search*, as we have defined it here, preferentially recruits the workings of the the LIF cortex. This is what unites them. In what follows we discuss for each of the reports the specifics of how these observations came to be.

Santi and Grodzinsky (2007) connect LDDs to the LIF cortex exclusively through what they call a "distance" effect. They test two phenomena. The one at issue involves object relatives in three conditions: one-NP embedded subject, two-NP embedded subject, and three-NP embedded subject. Crucially, these added NPs are irrelevant to the structure of the RELPRO-GAP dependency itself as the NPs have been added to the embedded subject phrase. Their function in the experimental design is to add material (specifically NP material which is syntactically identical to the RELPRO) between the RELPRO and the object-GAP. This material does not add to the complexity of the LDD but does increase the linear distance between the RELPRO and the GAP. In so doing, it increases the amount of structure the parser must build in order to get to the GAP. Such increase is coupled with an increase in number of nominals (one to three). Santi and Grodzinsky (2007)'s results show recruitment

[3]Our selectional criteria, necessary for our localizational purposes, had the unintended consequence of filtering out reports that have otherwise been valuable for our understanding of LDD processing. Fiebach et al. (2005), for example, connect (non-canonical) *GAP-search* to the LIF cortex, but report activation in other areas as well. For their Long > Short (obj.) contrast, they report in addition to the LIF cortex, right inferior frontal (RIF) cortex, junction of the left precentral sulcus, bilateral STS, MTG (21/22) and the left thalamus. By contrast, for their Long > Short (subj.) contrast, no LIFG is reported. Instead, they report activation in the bilateral inferior portion and left superior portion of the parieto-occipital sulcus (BA 17/30 and BA 7 respectively). So, this report relates the LIF cortex to *GAP-search* but not in a unified manner. Similarly, the results published in Makuuchi et al. (2009) address LDDs but are not directly relatable to our present objectives. Whereas they do report LIF cortex activation in connection to comprehension of double-center embedded clauses vs. single-embedded clauses akin to that reported by Santi and Grodzinsky (2007) and Fiebach et al. (2005), their report is based on a region of interest analysis exclusively, and not on a whole brain analysis. Whereas this approach makes sense given their specific interest in the internal articulation of the LIF cortex and not on localizing LDDs components, it prevents us from concluding whether the association they found targeted specifically the LIF cortex.

of the LIF cortex in the three vs. two nominal increment. We see this manipulation as addressing *GAP-search* as we have defined it (to the exclusion of *GAP-completion*) because in the three-NP condition, the minimal difference was the increase in distance between the RELPRO and the GAP, and this greater distance had to be tracked in order for the parser to get to the GAP[4].

More recently, Santi and Grodzinsky report in two separate papers, 2010 and 2012, an association between the LIF cortex and LDD processing which, given their respective designs, again target *GAP-search* to the exclusion of *GAP-completion*. Whereas in Santi and Grodzinsky (2010) the manipulation involves a comparison between *GAP-search* and embedding, connecting only *GAP-search* to the LIF cortex, Santi and Grodzinsky (2012) distinguishes general *dependency* from *predictability*, the ability of the parser to predict the need for a GAP. Their results show that *predictability* not *dependency* correlates with the LIF cortex effect, focused on BA 45[5].

Finally, Matchin et al. (2014) test the hypothesis that the LIF cortex supports a more general "antecedent-variable" dependency function, thus allowing the possibility to consider *GAP-search* as a member of a larger family of "search"-based processes. Such a hypothesis predicts an LIF cortex preferential activation for *pronoun-antecedent* relations (i.e., backward anaphora) which, like RELPRO-based LDDs, contain as a "variable" an element with an incomplete referential interpretation (pronoun) which must actively look for an "antecedent," the entity with which it must corefer. As with Santi and Grodzinsky (2007), the experimental design of Matchin et al. (2014) targets the *GAP-search* portion of the pronoun-dependency, as we have defined it. Their results show that only the subtractions involving backward anaphora (and not the RELPRO-based LDDs) yielded LIF cortex activation. And for these there was, in addition, activation in the right MTG, STC, bilateral SMA, bilateral occipital activation, and left STS. So, even though the observation is clearly made that the LIF cortex participates in predictive searches similar to *GAP-search*, it is also the case that other cortical regions also participate in this process, rendering the specific contribution of the LIF cortex in the processing of this kind of LDD inconclusive. This said, the presence of LIF cortex activation in this fairly different kind of dependency is suggestive of a deeper processing commonality, which so far has not been fully explored in the neuroimaging literature, and is one that we think may be captured by the generality of the *GAP-search* mechanism[6].

In sum, whereas the vast majority of fMRI research involving LDDs correlate them to cortical regions beyond the LIF cortex, some do provide exclusive or close to exclusive correlation with LIF cortex. Those that do, target *GAP-search* as we have defined it. By contrast, *GAP-completion*, the other major LDD mechanism capturing the more general properties of LDD composition, remains less explored. In light of this, and in order to further understand the factors involved in the neurocognition of LDDs we ask the following questions: What is the neurocognitive relation between *GAP-search* and *GAP-completion*? Do they rely on the workings of overlapping brain regions? And, could we associate *GAP-completion* to the LPST cortex, thus directly addressing the lesion-neuroimaging incongruence? In addition, a new question is revealed: if the effects reported reflect *GAP-search*, why are they observed mainly in the context of *object*-relative GAPs? The specifics of the study seeking to address these question are presented directly below.

1.3. The Study: Determining the Neurological Underpinnings of LDDs

Our analysis above shows that LDD comprehension can be organized into at least two processing mechanisms. We propose here that the existence of this dual mechanism infrastructure and the differential memory resources that it demands is the source of the disparity regarding the cortical recruitment of LDD processing. Moreover, we propose that the reason it has not been detected before has been due to a limitation inherent to the traditional data-analysis approach used in the past. We thus propose that the cortical localizational incongruence is the result of the interaction of two factors: one linguistic and one methodological. The **linguistic factor** refers to the previous analyses which collapse *GAP-search* with RELPRO interpretation at the GAP position, *GAP-completion*, thus conflating processes with potentially distinct neurocognitive demands. The **methodological factor** refers to the traditional approach to data analysis in language-related fMRI whereby

[4]We do observe, though, that this association is not unambiguous. An alternative interpretation to these findings could be that the reported LIF cortex effect results instead from the composition of a more complex meaning structure associated with a semantically more informative embedded subject. In this scenario, preferential activation of the LIF cortex emerges not from greater LDD distance, but from the semantic demands of processing an incrementally more elaborate embedded subject in composition with the embedded transitive verb and its complement. Indeed, this kind of effect is connectable to a similar LIF cortex recruitment found by Husband et al. (2011) and Lai et al. (2014), who independently show LIF cortex involvement in connection, this time, to the processing of complement coercion (e.g., *The girl began the book* vs. *The girl wrote the book*), a phenomenon also described as involving "enrichment" of the semantic representation.

[5]In another related paper, Santi et al. (2015) test a distinction similar to the one reported in 2007. In addition to the NP category, they introduce CP as potential intervening category. Their results show that for both conditions together (CP+NP), there is, in addition to LIF cortex activation, RIF cortex activation, again correlated with distance. The novel comparison here is the joint results involving the CP condition which, as the authors point out, suggest that the syntactic category of the intervening material is not relevant to *GAP-search*, a conclusion that contrasts with previous findings regarding Broca's poor performance in CP production, and fMRI results showing CP processing in connection to the LIF cortex (Shetreet et al., 2009). As in the case of Santi and Grodzinsky (2007), we believe that their results warrant consideration of an alternative interpretation: the possibility that the increased cost contributed by the CP distance be due instead to the possible garden-path created by the absence of complementizer in the lower CP. In the sentence "I knew [which porter the neurosurgeon said] CP_2 [the resident liked GAP] CP_1" two possible structural paths are possible at CP_2. Specifically, the CP_2 verb "said" subcategorizes for both an NP and a CP. When an NP is suggested (due to the absence of the complementizer), the CP possibility is discarded. But this soon proves to be the wrong decision both on semantic grounds (the neurosurgeon said [the resident]$_{NP}$) and on syntactic grounds (∗the neurosurgeon said [the resident liked]$_{*NP}$). Once the parser gets the lower verb "liked," it must revise its original decision in favor of the CP option, consequently incurring a cost.

[6]We find this kind of comparison to be right-minded and useful also because it connects with independent work on the neurology of anaphora resolution which notably reports an impairment in pronoun and logophor resolution in Broca's patients (e.g., Grodzinsky et al., 1993; Avrutin, 1999; Pinango, 2003; Piñango and Burkhardt, 2005; Schumacher et al., 2010).

subtractions take place at the *sentence level*, an approach which, in this case, prevents finer-grained exploration of the intra-sentential components of the dependency.

We address the linguistic factor by testing constructions that vary the degrees of linguistic compositional demands and in doing so allow us to examine the two mechanisms separately. These compositional demands range from a condition where an LDD is not required, as in (4):

(4) The captain **believed** the sailor's prediction yesterday **that** the weather would frighten$_{no-gap}$ **the crew** and turned back to port. (Condition D)

to one where an LDD is required and the link between the RELPRO and the GAP is syntactically direct, as in (2) above repeated here as (5):

(5) The captain$_k$ [**who**$_{k/j}$ the sailor predicted that the weather would frighten (GAP)$_j$] turned back to port. (Condition A)

to one where the syntactic connection between the RELPRO and the GAP is not direct [i.e., the intervening syntactic constituent does not contain the predicate licensing the GAP (6)][7]:

(6) The captain$_k$ [**who**$_{k/j}$ [the sailor's prediction yesterday about the weather] had frightened$_{gap}$, turned back to port. (Condition B/C)

Comparing these conditions allows us to observe the extent to which the memory-language interaction is sensitive to actual compositional linguistic mechanisms, and if so, which ones and with what cortical implications. In this respect, (5) > (4) and (6) > (4) in particular allow us to assess the cortical resources that must be recruited as the processor actively searches for the GAP [(5) > (4)] vs. those which must be recruited during the composition of sentence structure which the processor "knows" cannot contain a GAP, as in [(6) > (4)] (see Stowe, 1986; Kluender, 1998, respectively, for early evidence of the sensitivity of the processor to island constraints, and of how, and in contrast to widespread assumptions in linguistics, islands could in fact result from the interaction of processing factors).

With these contrasts in place, we are able to discuss our approach to the examination of the role of memory in the long-distance dependency construction. We do this through a data analysis manipulation whereby the two hypothesized processing mechanisms, *GAP-search* and *GAP-completion* are analyzed as separate *events*. Specifically, we use an intra-sentential event-related subtraction approach whereby subtractions are performed over the relevant non-overlapping segments of the sentence (see Data Analysis section below for technical details). This, in combination with the minimal contrasts in the linguistic manipulation between conditions, presence/absence of GAP and presence/absence of direct antecedent-GAP link, allows us to isolate simple phrase-structure building from active *GAP-search* and from *GAP-completion*, respectively. The details of the experimental design and data analysis are presented directly below (see Lai et al., in press for a similar use of event-related design in the context of semantic composition).

2. THE STUDY: INVESTIGATING *GAP-SEARCH* AND *GAP-COMPLETION*

2.1. Materials

The study contained a total of four conditions (A, B, C, and D) with 60 sentences in each of the conditions. Sentences were constructed as matching quadruples, thus controlling for non-relevant lexico-semantic and syntactic factors. This resulted in a final script of 240 sentences (60 quadruples). Test sentences for Conditions A and B were directly modeled from Gibson and Warren (2004), which introduces the ± direct RELPRO-GAP link manipulation. A sample of a quadruple is presented in **Table 1** below. As can be seen, whereas the conditions differ in the relevant syntactic properties (e.g., verbal vs. nominal: "sailor predicted" vs. "sailor's prediction") they share all other main lexico-semantic components, thus ensuring that they were as close as possible in terms of number of words, word frequency, and sense co-occurrence. Given our interest in separating activation related to *GAP-search* from that related to *GAP-completion* our unit of analysis was the *Event* which was a segment of the sentence. Accordingly, condition matching had to be implemented especially at the event level. For matching (and data analysis) purposes then each sentence was construed in terms of three events which in **Table 2** are observable in the internal bracketing of the sentences: **Event 0** contains the material before the brackets including head noun and relative pronoun/verb, **Event 1** corresponding to *GAP-search* contains the material in bold within brackets; and **Event 2** corresponding to *GAP-completion* contains the material after the brackets. As can be seen, for Event 1, all conditions match in terms of number of words. For Event 2, condition D, the control condition has in addition three words corresponding to the object NP (two words) and the conjunction (one word). We note that as this is the control condition any extra activation associated with the three extra words would be eliminated in the subtraction process.

[7]We call this condition "indirect *GAP-search*" and not "island" for the following reason: the term *island* refers to the perspective of the "moved" constituent *before* it has moved. This perspective states that such constituent cannot "leave" the larger constituent in which it is base-generated. To be sure, indirect *GAP-search* is a direct consequence of "movement"; but movement itself is only a metaphor, it has no processing status (i.e., the processor never carries out the movement; it only deals with its consequence). By contrast, the term indirect *GAP-search* is meant to refer to the perspective of the processor (left-to-right incremental composition). For the processor, what matters regarding any type of island is whether upon encountering a given constituent, it can hypothesize that the GAP is to be found within that constituent. If it can, then that constituent is searched for potential GAP positions, if it cannot, then the processor "waits," as it were, for that (local) constituent to end in order to continue the search. It is this situation that gives rise to the indirectness we refer to: the GAP is incoming, but not in the (minimal) constituent under construction. The "indirect *GAP-search*" label thus allows us to separate the linguistic intricacies of islands, which go well beyond the condition tested here, from one well-attested processing consequence of them. The label "indirect" therefore speaks to the fact that the subcategorized CP is not provided within the local constituent directly after the relative pronoun. So, from the perspective of the parser an "island" is simply a constituent that is not subcategorized and therefore it is not expected to contain the GAP.

TABLE 1 | Four experimental conditions.

	Sentence	Condition
A	The captain, who **[the sailor predicted yesterday that the weather]** would frighten$_{gap}$,turned back to port.	*GAP-search*/direct and *GAP-completion*
B	The captain, who **[the sailor's prediction yesterday about the weather]** had frightened$_{gap}$,turned back to port.	*GAP-search*/indirect and *GAP-completion*
C	*The captain, who **[the sailor's prediction yesterday about the weather]** had frightened the crew, turned back to port.	*GAP-search*/indirect and *GAP-completion* violation
D	The captain believed **[the sailor's prediction yesterday that the weather]** would frighten the crew and turned back to port.	No GAP-search and No GAP-completion

TABLE 2 | Experimental conditions by events.

Condition	Event 0	Event 1 (± ***GAP-search***)	Event 2 (± ***GAP-completion***)
A	The politician who	the journalist claimed that the government report	had bothered$_{gap}$ is calling a press conference
B	The politician who	[the journalist's claim about the government report]$_{island}$	had bothered$_{gap}$ is calling a press conference
C	The politician who	[the journalist's claim about the government report]$_{island}$	had bothered the people is calling a press conference
D	The politician believed	the journalist's claim that the government report	had bothered the people and is calling a press conference

TABLE 3 | Planned subtractions by events: single subtractions.

Subtraction	Event 1	Event 2
A > D	*GAP-search*$_{direct}$	*GAP-completion*
B > D	*GAP-search*$_{indirect}$	
A > B	*GAP-search* (*GAP-search*$_{direct}$ – *GAP-search*$_{indirect}$)	–
B > C	–	*GAP-completion*

(For further description of the analysis approach see **Table 3** in the Data Analysis section).

Table 1 presents the conditions with their respective dependencies. Figure S1 in the Supplementary materials presents the corresponding syntactic structures (Note that for Conditions A vs. B/C, the different syntactic structures determine the nature of the link between the RELPRO and GAP: *direct* for A and *indirect* for B). Asterisk (∗) in Condition C signals ungrammaticality.

In addition, the A, B, and D conditions were pre-tested for acceptability using a five-point likert scale. This pre-test allowed us to ensure that even though D would be more acceptable than A and B, there would be no difference in acceptability between A and B conditions. And this is what planned comparisons show. As expected Condition D [$D_{mean} = 3.79$ ($SD = 0.5$)] was deemed significantly more acceptable than conditions A [$A_{mean} = 2.66$ ($SD = 0.5$) ($t = -4.05$, $p < 0.001$)] and B [$B_{mean} = 2.67$ ($SD = 0.6$) ($t = -4.1$, $p < 0.001$)]. Also as expected no statistical difference in acceptability between A and B was found ($t = -0.03$, $p = 0.48$). This was calculated on the basis of responses from a sample of 13 native English speakers from the Yale undergraduate population, the same population from which the fMRI participants were selected.

Comprehension questions followed all condition A, B, and D sentences. No questions followed condition C sentences as the kind of ungrammaticality in that condition makes it difficult to ask questions that have an unambiguous yes/no answer. This said, we note that the ungrammaticality in Condition C appears toward the end-of the sentence, crucially, at the *GAP-completion* segment sentence. So, subjects could not know during the first part of the sentence up to the embedded verb whether they were in the presence of a grammatical or ungrammatical sentence. This motivated them to pay attention to all sentences equally.

In addition, questions probed different combinations of the matrix subject, embedded subject, matrix verb, and embedded verb. This variability was introduced intentionally to motivate participants to pay attention throughout the sentence as opposed to specific features of the sentence. To further minimize strategizing, the assignment of a given question to a given sentence was random, so even if the participants could realize that the matrix/embedded subject nouns and the matrix/embedded verbs mattered, for any given sentence they could not predict what specific element would be queried. So, they had to pay attention to all components of the sentences equally. For a sentence like *The captain, who the sailor predicted yesterday that the weather would frighten, turned back toward port.*, subjects would get one of these possible questions:

i. Did the sailor predict that the weather would frighten the captain? (expected answer: Y)
ii. Did the captain predict that the weather would frighten the sailor? (expected answer: N)
iii. Did the captain turn back toward port? (expected answer: Y)
iv. Did the sailor turn back toward port? (expected answer: N)

Coming back to the experimental sentences, this is what each condition probes:

Condition A examines *GAP-search*, triggered at *who* and *GAP-completion*. The distance between the RELPRO and the GAP is expected to reveal the workings of the memory system in a situation where finding the GAP is expected, given the

absence of intervening islands, as compared to Condition D, the no-GAP condition, and Condition B, the island condition where the GAP is not expected *within* the local constituent.

Condition B also combines *GAP-search* (triggered at *who*) and *GAP-completion*. However, in contrast to Condition A, in Condition B the search for the GAP must bypass the embedded subject (which is an island). Bypassing the embedded subject means that the processor needs to wait for that NP constituent to end to find the GAP. That is what the B>D contrast is intended to reveal.

For both A>D and B>D contrasts there is a clear interaction with the memory system in connection to *GAP-search*. So similarity in recruitment is expected. A difference in recruitment (A>D) and (B>D) would then be interpreted as a difference in the *quality* of the interaction with respect to *GAP-search*, one where the processor is not actively looking for the GAP (B>D), vs. one where it is (A>D).

Condition C is identical to Condition B except that the GAP position has been filled with an additional NP, which renders the sentence ungrammatical. The motivation for this condition focuses on the possible distinct cortical recruitment associated with *GAP-completion*. If, as we hypothesize, *GAP-completion* has distinct neurological commitments from *GAP-search*, this process will be observed as a unique activation pattern when comparing Conditions B>C, as these two conditions differ only with respect to the *GAP-completion* factor. B>C thus effectively brings us the closest to observing the preferential recruitment for *GAP-completion* alone.

Condition D represents the control condition. It has the same number of words and constituents as the Condition A and B counterparts, thus equally requiring full phrase-structure building and semantic composition. It lacks a long-distance dependency, so it is expected to tax the memory system the least in comparison to Conditions A or B.

2.2. Design

Each subject was presented with the 240-sentence script containing the 4 conditions, A, B, C, and D (60 items per condition). No additional fillers were included in the script. All 240 sentences were distributed in a pseudo-random fashion in 10 separate runs of 24 sentences each. The four experimental conditions were distributed in a counterbalanced fashion within each run such that no two sentences of the same quadruple would be included in the same run. Each subject was presented with a unique order of runs. So, in the end no two subjects saw the exact same sentence presentation order.

Each sentence presented had a maximum of 22 words. Each word in the sentence was visually presented at 500 ms per word. The 500 ms/word pace was chosen out of a variety of timings previously considered because it was the one that optimized ease of reading, speed, and accuracy in the comprehension of the sentence.

For 180 (75%) of the sentences, a query (yes/no question) about the sentence just read was presented for 4000 ms. The ISIs within and between (sentence+query) items were each 500 ms for a total of 16 s per item. Accordingly, the total time per run was 6 min 24 s (16 s × 24 sentences).

2.3. Procedure

The pre-scanning practice session was designed to familiarize the participants not only with the general procedure in the scanner but also with the length of the experimental sentences. In this practice session each participant was exposed to long embedded sentences similar to the ones they would be encountering in the study and at the same reading pace: one word at a time, paced at 500 ms per word, presented at the center of the screen and followed by a comprehension question.

Participants were instructed to read the sentences silently in the most natural way possible. To facilitate this, sentences were presented with punctuation marks (commas) supporting a native prosodic contour. Responses to the queried sentences were recorded with a yes/no button box. The total duration of the functional component of the study was about an hour, and the total duration of the testing session was 90 min.

2.4. Participants

Fifteen native speakers of English (8 female and 7 male) between the ages of 18 and 22 participated in this study. All except for one subject were right handed with normal or corrected-to-normal vision. By their own report, none had suffered a concussion nor were they under treatment for a neurological or psychological condition. All participants gave written informed consent in accordance with the guidelines set by the Yale University Human Subjects Committee and were compensated for their participation.

2.5. Data Acquisition

Head positioning in the magnet was standardized using the canthomeatal landmarks. In the scanner, cushions inside the head coil were used to reduce head movement and headphones were used to dampen the scanner noise and to communicate with participants. Conventional T1-weighted spin-echo sagittal anatomical images were acquired for slice localization using a 1.5T whole body imaging system with a quadrature head coil (Siemens, Erlangen, Germany). After a 3-plane localizer and a multiple-slice sagittal localizer, 28 T-1 weighted axial slices (TR = 485 ms; TE = 11 ms; bandwidth = 130 Hz/pixel; FA = 90°; slice thickness = 5 mm; FOV = 200 × 200 mm; matrix = 256 × 256) were obtained using flash spin-echo imaging parallel to the anterior and posterior commissure (AC–PC). Ten functional data series were then acquired with a single-shot gradient-echo echo planar imaging (EPI) sequence (TR = 2000 ms; TE = 30 ms; bandwidth = 1735 Hz/pixel; FA = 80°; slice thickness = 5 mm; FOV = 220 × 220 mm; matrix = 64 × 64; with 196 measurements) with same slice localizations as the T-1 anatomical. Stimuli were projected onto a semi-transparent screen at the head of the bore, viewed by the subject via a mirror mounted on the head coil. At the end of the functional imaging, a high resolution 3D Magnetization Prepared Rapid Gradient Echo (MPRAGE) sequence (TR = 24 ms; TE = 4.66 ms; bandwidth = 130 Hz/pixel; FA = 45°; slice thickness = 1.3 mm; FOV = 340 ×

340 mm; matrix = 256 × 256) was used to acquire sagittal images for multi-subject registration.

2.6. Data Analysis

All data were converted from Digital Imaging and Communication in Medicine (DICOM) format to analyze format using XMedCon (Nolfe et al., 2003). During the conversion process, the first three images at the beginning of each of the eight functional series were discarded to enable the signal to achieve steady-state equilibrium between radio frequency pulsing and relaxation leaving 193 images per slice per trial for analysis. Functional images were realigned (motion-corrected) with the Statistical Parametric Mapping 5 algorithm (www.fil.ion.ucl.ac.uk/spm/software/spm5) for three translational directions (x, y, or z) and three possible rotations (pitch, yaw or roll). Trials with linear motion that had a displacement in excess of 1.5 mm or rotation in excess of 2 degrees were rejected.

Individual subject data were analyzed using a General Linear Model (GLM) on each voxel in the entire brain volume with regressors specific for each task. For each of the four sentence types (A, B, C, D) there were four regressors (shown in **Table 2**): **Event 0** = onset of the first word up to the offset of "that/about," **Event 1, GAP-search** = onset of subject of relative/complement clause up to offset of word before lowest embedded verb; **Event 2, GAP-completion** = onset of lowest embedded verb up to end of the sentence, **Question** = onset of comprehension question up to the end of the question. We account for the hemodynamic delay within the General Linear Model used which includes the waver hemodynamic response function (hrf) from the AFNI software.

The resulting beta images for each task were spatially smoothed with a 6 mm Gaussian kernel to account for variations in the location of activation across subjects. The output maps were normalized beta-maps, which were in the acquired space (3.438 × 3.438 × 5 mm).

To take these data into a common reference space, three registrations were calculated within the Yale BioImage Suite software package (www.bioimagesuite.org, Papademetris et al., 2006). The first registration performs a linear registration between the individual subject raw functional image and that subject's 2D anatomical image. The 2D anatomical image is then linearly registered to the individual's 3D anatomical image. The 3D differs from the 2D in that it has a 1 × 1 × 1 mm resolution whereas the 2D z-dimension is set by slice-thickness and its x-y dimensions are set by voxel size. Finally, a non-linear registration is computed between the individual 3D anatomical image and a reference 3D image. The reference brain used was the Colin27 Brain (Holmes et al., 1998) which is in Montreal Neurological Institute (MNI) space (Evans et al., 1992) and is commonly applied in SPM and other software packages. All three registrations were applied sequentially to the individual normalized beta-maps to bring all data into the common reference space.

Data were corrected for multiple comparisons by spatial extent of contiguous suprathresholded individual voxels at an experiment-wise $p < 0.05$. In a Monte Carlo simulation within the AFNI software package and using a smoothing kernel of 6 mm and a connection radius of 6.97 mm on 3.44 × 3.44 × 5 mm voxels, it was determined that an activation volume of 197 original voxels (5319 microliters) satisfied the $p < 0.05$ threshold. Clusters were created for each of the four subtractions. Each cluster was identified with a region label, and then associated with additional numeral labels corresponding to Brodmann areas. Regional labels were assigned using the Yale Brodmann Area Atlas which is defined on the Colin27 Brain at 1 mm resolution.

2.7. Predictions

Table 3 presents the planned single subtractions isolating the two mechanisms in question and corresponding to the two (intrasentential) events: Event 1 and Event 2. Event 1-related subtractions target *GAP-search* and *direct vs. indirect GAP-search*: the correlates of a lexically driven search for the GAP in two contexts, direct vs. indirect, above and beyond phrase-structure building considerations. Event 2-related subtractions target *GAP-completion*: the satisfaction of the syntactic and lexico-semantic requirements of the RELPRO as comprehension unfolds. In addition, a series of *double subtractions* and three conjunction analyses were also performed to show whether or not any of the potential effects observed could be viewed as tapping a common cognitive process and if so which one. The specific double subtractions and conjunction analyses are presented further below in connection to the corresponding general predictions[8].

If *GAP-search*-which takes place during Event 1- and *GAP-completion*-which takes place during Event 2- place compositionally distinct linguistic demands with presumably different memory load implications, then they are likely to have distinct cortical recruitment commitments. The existence of distinct cortical recruitment is in turn hypothesized to be the root of the lesion-based/neuroimaging incongruence regarding LDD implementation. This distinction in recruitment should be observed between the two events across the relevant conditions (e.g., **Conditions A and B** vs. **Condition D** during Event 1 and **Conditions A and D** vs. **Condition D** during Event 2). Specifically:

2.7.1. Prediction for *GAP-search*: $GAP\text{-}search_{direct}$ and $GAP\text{-}search_{indirect}$

If the LIF cortex supports *GAP-search*, regardless of whether it locally leads to a GAP position or not, both the $GAP\text{-}search_{direct}$ and $GAP\text{-}search_{indirect}$ conditions (**Condition A**, Event 1 and **Condition B**, Event 1, respectively) should elicit the same pattern when a no-GAP condition is subtracted (**Condition D**, Event 1).

If, by contrast, the brain distinguishes between the situation where the memory system is actively *participating* in the *GAP-search* process, rather than simply *supporting* the phrase structure composition that happens to involve this process, we should observe a divergence in activation. In this case we expect that at least $GAP\text{-}search_{direct}$ - the condition that has been previously reported to be vulnerable in Broca's aphasia, is correlated with LIF cortex activation.

[8]We thank a reviewer for calling our attention to the importance of these two second-order analyses which as will be seen strengthened the quality of the evidence overall.

Three double subtraction analyses (1) *GAP-search* $A_1>D_1$ vs. *GAP-completion* $A_2>D_2$, (2) *GAP-search* $B_1>D_1$ vs. *GAP-completion* $B_2>D_2$ and (3) *GAP-search*$_{direct}$ $A_1>D_1$ vs. *GAP-search*$_{indirect}$ $B_1>D_1$ and one conjunction analysis *GAP-search*$_{direct}$ $A_1>D_1$ and *GAP-search*$_{indirect}$ $B_1>D_1$ are relevant for this prediction. The first two double subtractions test LIF cortex sensitivity to *GAP-search* once activation associated with *GAP-completion* has been eliminated. The third double subtraction and the conjunction analysis allows us to see the extent to which *GAP-search*$_{direct}$ and *GAP-search*$_{indirect}$ have common activation.

2.7.2. Prediction for *GAP-completion*

Our analysis confers *GAP-completion* a subordinate role in LDD composition as it is a strictly local process connecting *GAP-search* to the ongoing composition of the sentence. In terms of cortical localization, we have seen that the previous neuroimaging record does not isolate it. By contrast, the focal-lesion record gives us an important clue as to *GAP-completion*'s potential cortical distribution: For Broca's patients, the reactivation of the GAP, presumably involving *GAP-completion*, is not simply absent, it is *abnormal*. The GAP-filling effect is absent right after the licensing verb, but visible around 500 ms later (e.g., Burkhardt et al., 2003; Love et al., 2008). On the basis of our analysis, we interpret this comprehension pattern as the manifestation of a dissociation between *GAP-search* and *GAP-completion* such that the latter is evidently impacted by, but is not crucially dependent on, the workings of the LIF cortex.

Completing this picture, the lesion-based evidence also tells us that Wernicke's patients are able to implement gap-filling in a timely manner. Yet, *in offline tasks* such as sentence-to-picture matching, these very patients show impaired comprehension not only of object relative clauses, but also of subject relative clauses and non-embedded agentive matrix clauses, a behavior that has traditionally been rooted to a lexically-based deficit, and that accordingly confers Wernicke's area a generalized *compositional* role with direct semantic implications (e.g., Caramazza and Zurif, 1976; Shapiro and Levine, 1990; Piñango and Zurif, 2001, 2015).

Combining these pieces we reason that if there is a connection between LDD composition and the LPST cortex at all, it should be neither in connection to *GAP-search* nor to *GAP-completion* specifically, but in connection to a more general compositional process, involving the coupling of morphosyntactic and semantic composition, of which *GAP-completion* is but one manifestation. So, the localization prediction for *GAP-completion* is exploratory: *GAP-completion*—targeted in three Event 2-related comparisons (1) **Condition B** vs. **Condition C**, (2) **Condition B** vs. **Condition D**, and (3) **Condition A** vs. **Condition D**—should not activate the LIF nor the LPST cortices. But it should show an activation pattern that is instead neuroanatomically *connectable* to both LIF and LPST cortex associated with Broca's and Wernicke's aphasia respectively.

In terms of the double subtraction and conjunction analyses associated with this prediction, our objective is to determine whether or not, despite arising from different contrasts, the three activation patterns predicted to reveal *GAP-completion* indeed manifest the same preferential recruitment. Specifically, we compare $A_2>D_2$ and $B_2>D_2$ to each other and crucially to $B_2>C_2$, and look at how they differ (subtractions) and what cortical recruitment they have in common (conjunction).

In the strongest form of the prediction, if $A_2>D_2$ and $B_2>D_2$ are targeting the same process, subtracting them from each other and from $B_2>C_2$ should result in no difference. By the same token if the three subtractions are revealing the same cognitive process, the conjunction analysis with all three subtractions $A_2>D_2$ and $B_2>D_2$ and $B_2>C_2$ should show a high degree in overlap, one that is coherent with the single subtraction results.

3. RESULTS

3.1. Behavioral Task

Results from the post-sentential questions show an average accuracy rate of 87.6%, which was distributed across conditions as follows: Condition A: 90.57% (29.24), Condition B: 87.47% (33.1), Condition D: 84.82% (35.9). A mixed-model analysis revealed a marginally significant effect of condition [Chi-square $= 7.59$, ($df = 2$) $p = 0.083$]. Pairwise comparisons revealed a significant difference in A vs. D ($p = 0.001$) and a marginally significant difference in A vs. B ($p = 0.08$). There was no difference between B vs. D ($p = 0.1$) (all results corrected for multiple comparisons).

Given that all conditions show an accuracy rate higher than 80%, we interpret the A vs. D difference as the result of lapses in attention due to the relatively undemanding nature of the D condition which allowed the subjects to lose concentration and in turn miss some of the comprehension questions.

3.2. Isolating *GAP-search*: *GAP-search*$_{direct}$ and *GAP-search*$_{indirect}$

Figure 1A shows the pattern of activation, presented in radiological format, for the $A_1>D_1$ subtraction (Conditions A and D, Event 1). Two main regions of preferential activation are observed: the first one involves left BAs 45, 44, 47, 22 (inferior, medial), 38, and insula. The second one involves posterior cingulate, left primary and association cortex, and BAs 7 and 31 (both bilateral). **Figure 1B** shows the $B_1>D_1$ contrast. Interestingly, this pattern of activation appears as a non-overlapping recruitment involving one region connecting bilateral BA 6 (medial superior), bilateral BA 8, and bilateral BA 32 and right BA 24. **Table 4** below shows the significant differential volume by region for each of these comparisons.

The first double subtraction ($A_1>D_1$ vs. $A_2>D_2$) (**Figure 2**, **Table 5** below) shows a pattern almost identical to the one yielded by the original single subtraction: left BAs 47, 46, 45, 44, and 38, medial BA 7, BAs 17, 18, and 19, and the cerebellum. The second and third double subtractions ($B_1>D_1$ vs. $B_2>D_2$) and ($A_1>D_1$ vs. $B_1>D_1$) by contrast yielded no significant activation.

Finally, the conjunction analysis counterpart comparing direct vs. indirect search showed an empty intersect. This analysis which, crucially, is based only on the corrected maps, tells us that for this comparison the stronger more reliable activation is in terms of the *differences* in preferential activation between the two contrasts. This supports the possibility that for Event 1, any privileged association is not between LIF cortex and *GAP-search* but between LIF cortex and *GAP-search*$_{direct}$.

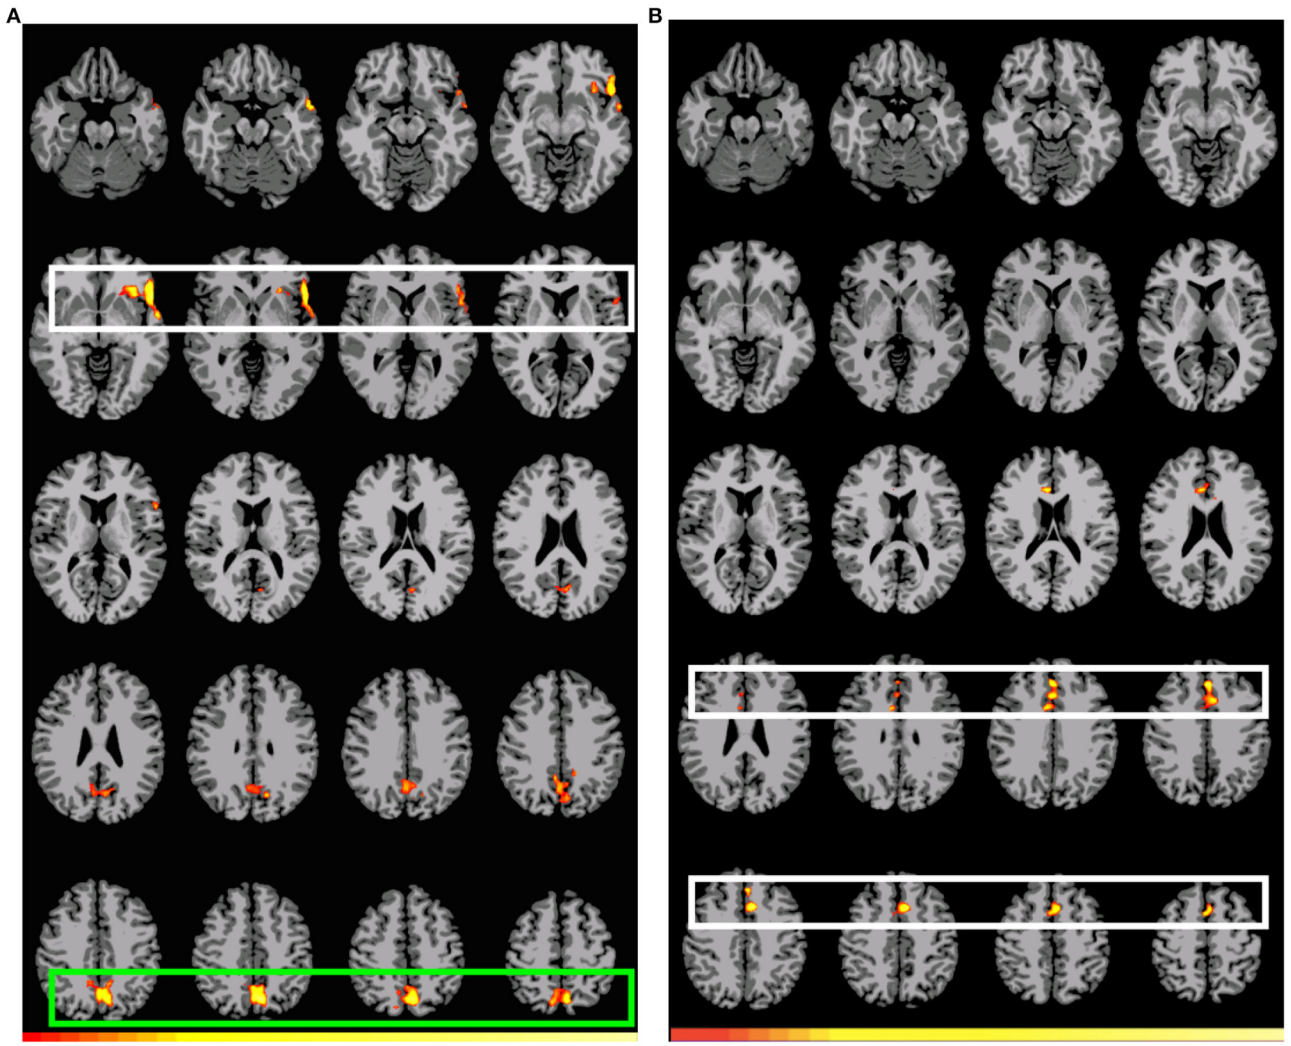

FIGURE 1 | Preferential activation for both *GAP-search* (Event 1) subtractions. Images are shown corrected at $p < 0.05$ in radiological format (LH is on the right). **(A)** *(Direct) GAP-search* (Event 1) subtraction: $A_1 > D_1$: "the journalist claimed that the government report" > "the journalist's claim that the government report." White: BAs 45, 44, and 47. Green: Posterior cingulate and sensory association cortex. Low thresholds ($p < 0.05$; $t = 2.14$) are indicated by red, while high thresholds ($p < 0.000007$; $t = 6.94$) are indicated by yellow. **(B)** *(Indirect) GAP-search* (Event 1) subtraction: $B_1 > D_1$: "the journalist's claim about the government report" > "the journalist's claim that the government report." White: SMA activation. Only positive activation reported. Low thresholds ($p < 0.05$; $t = 2.14$) are indicated by red, while high thresholds ($p < 0.00002$; $t = 6.42$) are indicated by yellow.

3.3. Isolating *GAP-completion*

Table 6 (**Figure 3**) shows the pattern of activation for all three contrasts involving *GAP-completion*: **Condition B > Condition C** (Event 2), **Condition A > Condition D** (Event 2), and **Condition B > Condition D** (Event 2), respectively. We interpret them together because the pattern of activation they each give rise to is by our hypothesis reflecting the same *GAP-completion* process. We present them separately because each emerges from different surface-level subtractions: a legitimately filled gap vs. an illegitimately filled gap ($B_2 > C_2$) and a filled gap vs. non-gap ($A_2 > D_2$ and $B_2 > D_2$).[9] Moreover, those segments come from different (non-local) sentential contexts (A and B, respectively). We reason that if *GAP-completion* is an isolable process, it should yield a similar activation pattern regardless

[9]A reviewer asks us about the meaningfulness of the B>C (event 2) comparison. The results from the B>C (event 2) subtraction reflect the preferential activation triggered by B (event 2) without the material that is represented by C (event 2). We infer that this preferential activation includes any process involved in the interpretation of the GAP that survives the violation which, by our analysis, includes the interpretation of the GAP by means of the dependency formation. Indeed, we take this to be the substance of the residual of the subtraction. This contrasts with the violation condition, where the GAP position has been independently filled thus preventing dependency from being completed. As we discuss here, what is interesting of this subtraction, B>C (event 2), is that despite emerging from a subtraction by a violation, the resulting pattern is comparable to the others in Event 2, particularly in terms of the SMA and parietal activation pattern, which the other two non-violation based contrasts also show.

TABLE 4 | Significant differential volumes by region for *GAP-search* subtractions.

(Direct) GAP-search (Event 1) subtraction, $A_1>D_1$				
Region	**Volume (mm^3)**	**Mean *T*-value**	**Max *T*-value**	**Max MNI Coords. (x, y, z)**
Region 1: left BA 45, left BA 44, left BA 47, left BA 22 (inferior, medial), left BA 38, insula	5571	2.94	5.83	−54, 18, −3
Region 2: posterior cingulate, left visual cortex (primary and association), bilateral BA 7 and 31	9516	2.82	6.94	−9, −66, 45
(Indirect) GAP-search (Event 1) subtraction, $B_1>D_1$				
Region	**Volume (mm^3)**	**Mean *T*-value**	**Max *T*-value**	**Max MNI Coords. (x, y, z)**
Right BA 24, bilateral BA 6 (medial superior), bilateral BA 8, bilateral BA 32	6262	2.80	5.56	−6, 15, 45

TABLE 5 | Significant differential volumes by region for *GAP-search* (Event 1) double subtraction ($A_1>D_1$) vs. ($A_2>D_2$).

Region	Volume (mm^3)	Mean *T*-value	Max *T*-value	Max MNI Coords. (x, y, z)
Region 1 left BA 47, left BA 46, left BA 45, left BA 44, left BA 38 (temporal pole)	9328	2.70	6.03	−51, 30, −6
Region 2: posterior cingulate, sensory (association)	7522	2.94	5.84	0, −63, 36
Region 3: cerebellum	7526	2.71	6.15	24, −69, −33

of non-local context. This is especially the case for $A_2>D_2$ and $B_2>D_2$ which share the same subtrahend.[10]

Figure 3 shows that there is indeed a very similar pattern of activation across the three subtractions. For all three contrasts, there are two main foci of preferential recruitment: BA 6 (left and bilateral) and visual cortex (primary/association). This said, type of subtraction also mattered: for the $A_2>D_2$ and $B_2>D_2$ contrasts, common preferential areas were revealed which did not emerge in the $B_2>C_2$ subtraction: anterior cingulate, BA 7 (precuneus), and BA 32. In addition, $B_2>D_2$ revealed activation of left BA 40. Finally, none of the contrasts showed overlap with BA 44 or BA 45–regions that were observed in the *GAP-search* condition. This finding was further confirmed in the double subtraction and conjunction analyses (see below). All results (from both Events 1 and 2) are summarized in **Table 7** below.

The two *GAP-completion*-related double subtractions yielded interesting results. We predicted that if all Event 2 subtractions are targeting the same process, subtracting one from the other should result in no difference. And indeed that is what we found for $A_2>D_2$ vs. $B_2>D_2$. When these two conditions were compared to $B_2>C_2$ a difference was observed not in terms of localization but in terms of *volume* of activation. As **Table 8** (see also **Figure 4**) shows, the activation pattern observed for these single and corresponding double subtractions is almost identical.

[10] The activation in blue associated with the violation C segment, C_2 vs. B_2, is addressed in the subsection "Other Patterns."

What we observe in the double-subtraction is a change in the volume for the SMA and which goes from 17,585 in the single $B_2>C_2$ subtraction down to 11,479 when subtracted by $A_2>D_2$ and to 13624 when subtracted by $B_2>D_2$. We compare these double subtractions to one where the *GAP-search* counterpart is subtracted: $B_2>C_2$ vs. $B_1>C_1$. We reason that if the previous two double subtractions are reflecting *GAP-completion* their results should converge with this one which isolates *GAP-completion* from *GAP-search*. And that is what we find. These results are summarized in **Table 9**. Finally, the conjunction analysis confirms these findings by showing again not only the primary and association visual cortex and connected posterior cortex, but crucially, BA 6 as a main area of overlap. These results are summarized in **Table 10** and shown in **Figure 5**.

3.4. Activation Beyond *GAP-search* and *GAP-completion*: Discourse-Composition and GAP Violation

In the Event 2 contrast, an additional pattern of activation is observed which results from the inverse subtraction $C_2>B_2$ and which is associated with a GAP violation. (The violation is caused by an expected GAP that already appears filled.) This contrast was not part of the main question the study seeks to address, but in light of the other results, it reveals a very interesting pattern which we believe is connectable to our main question. The $C_2>B_2$ segment, which reflects the violation proper, recruits no LIF, LPST, or parietal cortices. Instead, it recruits the *right hemisphere* BAs 45 and 46 and bilateral prefrontal cortex (BAs 9 and 10).

This pattern is interesting because it reflects cortical recruitment beyond the traditional language areas, suggesting that its impact is outside language composition strictly speaking. Indeed in connection to this observation a reviewer points out, correctly in our view, that this pattern of activation lines up with the so-called default mode network (DMN); a network traditionally associated with resting states or situations where subjects are left to carry out "undirected" thinking. Consequently, the reviewer suggests, these could be an indication that the parser most likely has simply halted the comprehension process.

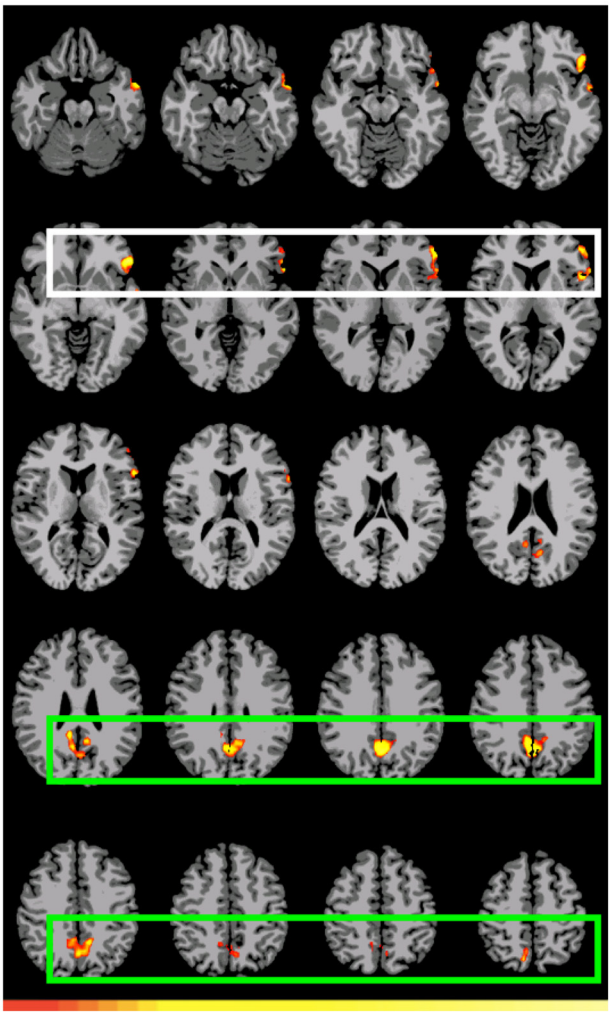

FIGURE 2 | Preferential activation for *(direct) GAP-search* (Event 1) double subtraction: (A_1>D_1) vs. (A_2>D_2). White: BAs 44, 45, 46, and 47. Green: Posterior cingulate and sensory association cortex. Images are shown corrected at $p < 0.05$ in radiological format (LH is on the right). Only positive activation reported. Low thresholds ($p < 0.05$; $t = 2.14$) are indicated by red, while high thresholds ($p < 0.000005$; $t = 7.20$) are indicated by yellow.

We agree with the reviewer that to the extent that we do not fully know the impact of ungrammaticality in the process of comprehension, the possibility remains that faced with ungrammaticality, the comprehension system stops tracking linguistic composition altogether, thus allowing the mind to direct thought away from the utterance in question. This said, we would like to propose an alternative interpretation which is connectable with our present aims: that the pattern of preferential activation observed, partially overlapping with the default mode network, directly reflects the specific *discourse-based* nature of the violation in Condition C; a possibility that complements the recruitment pattern involved in gap-search/completion. On our analysis, the violation in Condition C is caused by the inability of the parser to integrate the composed meanings of the embedded and matrix clauses. These clauses are each independently syntactically and semantically well-formed yet cannot be linked with each other. The ill-formedness is caused by the requirement that *GAP-completion* apply at a point in the sentence where it is not allowed to. *GAP-completion* is the process where the referent associated with the antecedent finds an interpretation as a participant in the semantic representation associated with the embedded clause, thus linking the proposition denoted by the embedded clause with that of the matrix clause. In the ungrammatical utterance, *The politician who the journalist's claim about the government report had bothered* ***the people*** *is calling a press conference*, *GAP-completion* cannot take place because the GAP is already occupied by another NP (*the people*). Consequently, not only is the antecedent (*the politician*) left without a (necessary) interpretation within the embedded clause, but a new and unexpected semantic interpretation (involving the participant *the people*) has been introduced, which is locally plausible but cannot be connected with the meaning of the matrix clause. These two locally coherent segments (matrix clause: *the politician is calling a press conference* and embedded clause: *the journalist's claim about the government report had bothered the people*) result in compositionally conflicting linguistic representations, which in turn yield a meaning incoherence for the sentence as a whole (i.e., two mutually exclusive individuals "the politician" and "the people" must be licensed as the experiencer of "bother"). The meaning of the embedded clause (containing the new participant) can no longer be incorporated into the meaning of the matrix clause (containing the antecedent). This incoherence cannot be resolved not because there is no one plausible interpretation to be obtained, but because there is one too many plausible interpretations.

We propose that the comprehension system is sensitive to this situation and it is the conflict that it represents what underlies the activation pattern observed for C>B event 2. This would suggest in turn that the thrust of the violation lies on higher level meaning-based structure, even though the violation itself is triggered by a local syntactico-semantic misstep[11].

If this were the case, it would make the non-linguistic regions in question relevant for language comprehension processes involving contextualization or integration of composed meaning. Early support for this possibility is found in fMRI reports suggesting a correlation of relevant right-hemisphere cortical areas with notions such as "discourse" level composition (e.g., Costello and Warrington, 1989; Devlin et al., 2003) and "aboutness" (Bornkessel-Schlesewsky et al., 2012). Specifically relevant to the DNM is the work on fMRI patterns relating the DMN to social cognition processes, in particular those connecting middle frontal cortex with theory of mind processes (see Mars et al., 2012 for a meta-analysis of this body of work in connection also to DMN processes in non-human primates). As noted, this interpretation is not intended to apply to syntactic violations across the board, but to activation

[11]This interpretation rests on a very specific assumption about the parser. The assumption is that the parser will attempt to build an interpretation even in the face of partial incoherence in the input as is the case in condition C. Yet as a reviewer correctly points out this assumption is not necessarily settled in the literature.

TABLE 6 | Significant differential volumes by region for all *GAP-completion* (Event 2) contrasts.

Contrast	Region	Vol. (mm^3)	Mean *T*-value	Max *T*-value	Max MNI (x, y, z)
$B_2>C_2$	Region 1: BA 6 (left, medial, bleeding into left BA 44), left primary motor/sensory	17,585	2.80	5.56	−39, −18, 57
	Region 2: visual cortex (primary/association)	28,691	2.80	5.56	15, −87, −6
	Region 3: caudate and putamen	7820	2.80	5.56	18, 21, 6
$A_2>D_2$	Region 1: BA 6 (bilateral, mostly medial/superior, bleeding into BA 8), anterior and dorsal cingulate, left primary motor/sensory	19,052	2.98	7.61	−24, −9, 57
	Region 2: BA 7, visual cortex (primary/association)	45,564	3.13	8.56	−18, −69, −9
	Region 3: caudate, left putamen, left BA 47, left insula	5829	2.63	4.51	−30, 21, 0
$B_2>D_2$	Connected region: BA 6 (bilateral, medial, superior), BA 8, anterior and dorsal anterior cingulate (right), left primary motor/sensory, BA 7 (bleeding into BA 39), left BA 40, visual cortex (primary/association)	72,530	2.97	9.07	−12, −87, −3

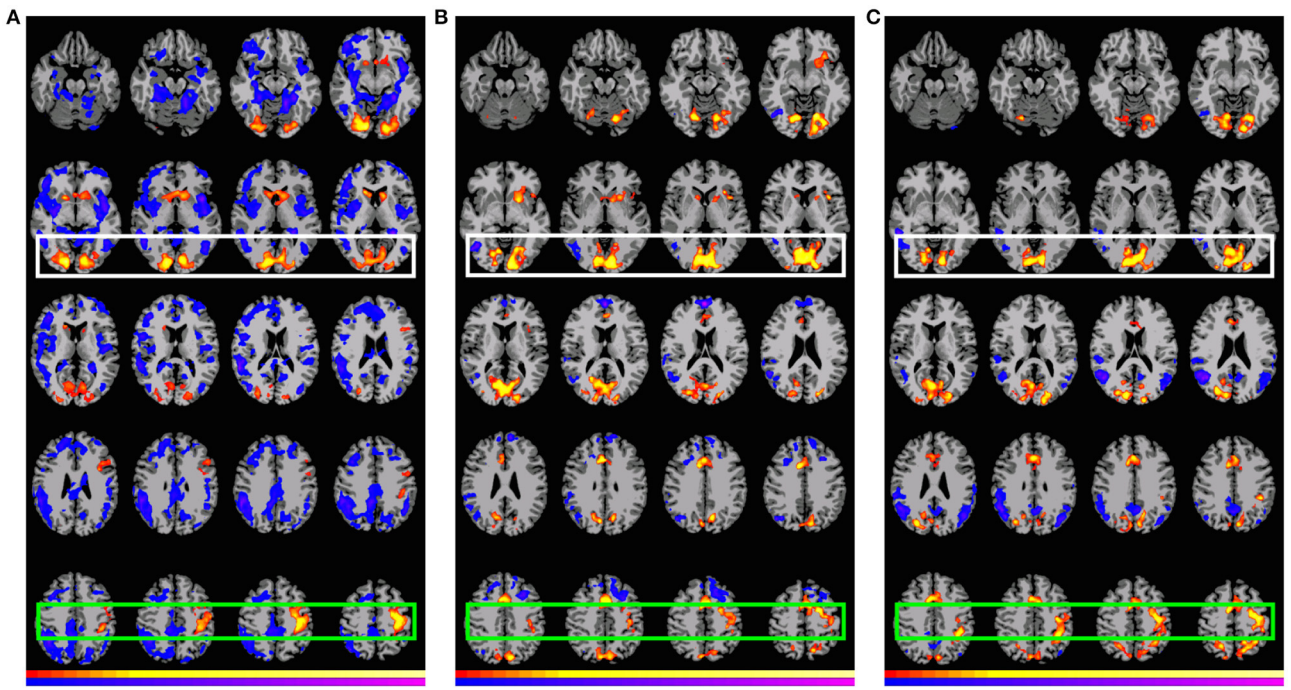

FIGURE 3 | Preferential (positive and negative) activation for *GAP-completion* (Event 2) subtractions. White: Visual cortex (association and primary), Green: SMA and parietal activation. Images are shown corrected at $p < 0.05$ in radiological format (LH is on the right). For **(A)**, low thresholds ($p < 0.05$; $t = 2.14$) are indicated by red and blue, while high thresholds ($p < 0.000000005$; $t = 12.6$) are indicated by yellow and purple. For **(B)**, low thresholds ($p < 0.05$; $t = 2.14$) are indicated by red and blue, while high thresholds ($p < 0.0000006$; $t = 8.6$) are indicated by yellow and purple. For **(C)**, low thresholds ($p < 0.05$; $t = 2.14$) are indicated by red (positive activation) and blue (negative activation), while high thresholds ($p < 0.0000003$; $t = 9.1$) are indicated by yellow (positive activation) and purple (negative activation). **(A)** $B_2>C_2$: "had bothered$_{gap}$ is calling a press conference." > "had bothered the people is calling a press conference." **(B)** $A_2>D_2$: "had bothered$_{gap}$ is calling a press conference." > "had bothered the people and is calling a press conference." **(C)** $B_2>D_2$: "had bothered$_{gap}$ is calling a press conference." > "had bothered the people and is calling a press conference."

patterns where the violation results in a larger discourse incoherence such as that created by a "doubly-filled" argument position. (For a more general discussion about brain patterns and violations, see Embick et al., 2000; Friederici et al., 2003).

4. DISCUSSION

Past neuroimaging work has shown that even though long-distance dependencies seem to recruit the workings of the LIF cortex, they also recruit the workings of the LPST cortex

TABLE 7 | Summary of cortical recruitment by Events: Single subtractions.

Subtraction	Event 1: GAP-search	Event 2: GAP-completion
B > C	–	BA 6 (lateral), BA 44 (edge), visual cortex (BAs 17, 18, 19), caudate and putamen. Activation is also observed in primary motor and primary sensory cortex.
A > D	Region 1: left BA 45, left BA 44, left BA 47, insula, left BA 22 (inferior, medial), BA 38 (temporal pole) Region 2: posterior cingulate, left primary visual cortex, left visual association cortex, bilateral BA 7, BA 31	Region 1: BA 6 (bilateral, mostly medial/superior, bleeding into BA 8), anterior and dorsal cingulate, left primary motor/sensory Region 2: caudate/putamen (left), BA 47 (left), insula (left) Region 3: BA 7 (bilateral), primary visual/association cortex (bilateral medial)
B > D	BA 6 (medial superior), BA 8, BA 24 (right), and BA 32.	BA 6 (bilateral, medial, superior), BA 8, anterior and dorsal anterior cingulate (right), left primary motor/sensory, BA 7 (bleeding into BA 39), left BA 40, visual cortex (primary/association)

	Region 2: right visual cortex (primary/association)	9155	3.35	8.91	18, −84, −12

and surrounding areas (e.g., Cooke et al., 2002; Fiebach et al., 2002; Amunts et al., 2004; Fiebach et al., 2005; Grodzinsky and Friederici, 2006; Santi et al., 2015). Moreover, while the lexical role of the LPST cortex has been well documented (see Wise et al., 2001; Hickok and Poeppel, 2004, 2007 for proposals regarding the role of the various subcomponents of the LPST cortex in long-term phonological encoding), no conclusive explanation has been given for why this area should be recruited in the instantiation of these dependencies. At the same time, whereas Wernicke's patients (with damage involving the left posterior temporal cortex, including parts of the angular and supramarginal gyri) show across-the-board impaired sentence comprehension including constructions containing dependencies, they are indistinguishable from matching controls in their ability to exhibit the gap-filling effect, thus indicating that whatever their linguistic impairment, it does not seem to involve *GAP-search* or *GAP-completion per se*.

Indeed, Wernicke's performance has been seen to reflect the capacity to implement the basic syntactic mechanics of the dependency, but showing, offline, an inability to put this knowledge to use, presumably due to an inability to properly access the necessary lexico-semantic information that makes the dependency meaningful (e.g., Caramazza and Zurif, 1976; Shapiro and Levine, 1990; see Piñango and Zurif, 2015 for a summary of the main findings). By contrast, Broca's patients, while unable to properly implement these dependencies (e.g., Zurif et al., 1993, 1994; Burkhardt et al., 2003; Love et al., 2008), show, offline, a selective pattern of impairment whereby canonical (subject) relative clauses result in above-chance performance and non-canonical (object) relative clauses reliably result in poor (chance-level) comprehension, a pattern of performance that appears to be linguistic in nature. So whereas the neuroimaging evidence tells us the brain regions that could be potentially participating in the implementation of the dependencies, the lesion-based evidence tells us of the possibility of an *asymmetry* in their participation.

The analysis of LDDs that we present here provides the basis for a potential reconciliation of these two sets of seemingly conflicting observations by invoking organizing principles that could give rise to such an asymmetry. Specifically, the model captures the main linguistic components of a dependency (phrase structure building, argument structure licensing, and pronoun resolution) as selectional/subcategorization constraints on the relative pronoun that separate the process of searching for the environment of argument licensing within the sentence (*GAP-search*) from the actual argument licensing (*GAP-completion*).

In the remainder of this section we discuss the specific activation patterns observed in connection to the hypothesized functional distinctions.

4.1. *GAP-search*: $GAP\text{-}search_{direct}$ vs. $GAP\text{-}search_{indirect}$

The hypothesis that LIF cortex is sensitive to *GAP-search* independently of the internal articulation of the dependency (direct vs. indirect) was not borne out. To the extent that *GAP-search* was reliably associated the LIF cortex it

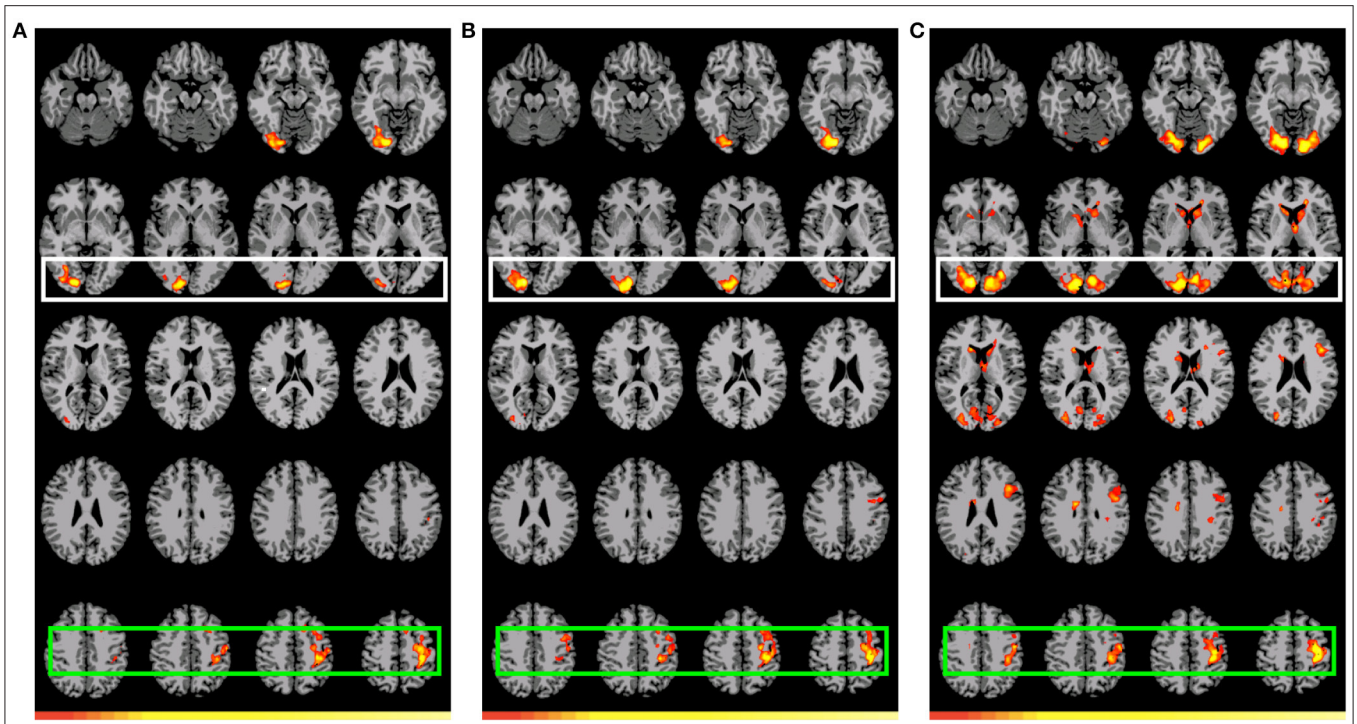

FIGURE 4 | Preferential positive activation for *GAP-completion* (Event 2) double subtractions. White: Visual cortex (association and primary), Green: SMA and parietal activation. Images are shown corrected at $p < 0.05$ in radiological format (LH is on the right). For **(A)**, low thresholds ($p < 0.05$; $t = 2.14$) are indicated by red, while high thresholds ($p < 0.00000001$; $t = 11.8$) are indicated by yellow. For **(B)**, low thresholds ($p < 0.05$; $t = 2.14$) are indicated by red, while high thresholds ($p < 0.000000009$; $t = 12.1$) are indicated by yellow. For **(C)**, low thresholds ($p < 0.05$; $t = 2.14$) are indicated by red, while high thresholds ($p < 0.000000009$; $t = 12.1$) are indicated by yellow. **(A)** ($B_2 > C_2$) vs. ($A_2 > D_2$): Residual preferential activation for *GAP-completion*. **(B)** ($B_2 > C_2$) vs. ($B_2 > D_2$): Residual referential activation for *GAP-completion*. **(C)** ($B_2 > C_2$) vs. ($B_1 > C_1$): Preferential activation for *GAP-completion* > preferential activation for *GAP-search*.

TABLE 9 | Summary of cortical recruitment for all *GAP-completion* (Event 2) double subtractions.

($B_2 > C_2$) vs. ($B_1 > C_1$)	Region 1: left BA 6, primary motor/sensory cortex, BA 8. Region 2: primary/association visual cortex. Region 3: caudate, putamen, thalamus

TABLE 10 | Significant differential volumes by region for conjunction of *GAP-completion* (Event 2) subtractions , ($A_2 > D_2$) + ($B_2 > C_2$) + ($B_2 > D_2$).

Region	Volume (mm^3)	Mean *T*-value	Max *T*-value	Max MNI Coords. (x, y, z)
Region 1 BA 6, motor (primary, supplementary), sensory (primary), anterior cingulate	5399	X	X	−2, −82, 5
Region 2: right visual (association), right angular/supramarginal gyri, fusiform	4422	X	X	49, −55, 19
Region 3: BA7, BA19, visual (primary, association), sensory (association)	15,869	X	X	−33, −16, 54

was only in connection to the *direct* condition (single and double subtractions). Within this pattern of activation two connected regions were involved: region 1 included BAs 45, 44, 47, bordering with the left insula and left temporal pole (anterior BAs 22 and 38). A second associated region connecting primary and associate visual cortex and BA7 and BA31 were also preferentially recruited. This second region of activation is interesting for two reasons; (1) it appears in $A_1 > D_1$ but not in the $B_1 > D_1$ contrast, and this is relevant because it involves the participation of BA7, a cortical region previously connected to CP embedding, precisely the kind of composition present in A_1 and absent in B_1, and (2) it

continues to appear in connection to *GAP-completion* for both $A_2>D_2$ and $B_2>D_2$ contrasts, thus suggesting that this area is sensitive to general composition such as that involved in *gap-completion*[12].

The results from the $A_1>D_1$ vs. $A_2>D_2$ double subtraction, support the importance of the LIFG for *GAP-search*$_{direct}$, an observation that replicates previous findings both from neuroimaging and lesion-studies. Those results further indicate that this cortical recruitment may at least be partly distinct from the cortical recruitment of *GAP-completion*.

Results also show that when *GAP-search* encounters a linguistic "obstacle"—as in Condition B (Event 1) *GAP-search*$_{indirect}$, and revealed in the B > D (Event 1) contrast - a different preferential activation pattern emerges involving BA 6 (medial superior), BA 8, right BA 24, and BA 32. At the same time, results from the double-subtraction $A_1>D_1$ vs. $B_1>D_1$ reveal no preferential activation suggesting that these two conditions are also very similar. So, in light of the ambiguous statistical results, we offer an interpretation constrained by previous neuroimaging and lesion-based observations. We propose here that these two sets of results indicate there may not be a categorical distinction between the cortical regions engaged in *GAP-search*$_{direct}$ vs. those engaged in *GAP-search*$_{indirect}$, instead the two reflect different patterns of activation within what is ultimately the same cortical network.

We thus interpret the LIF cortex preferential activation associated with *GAP-search*$_{direct}$ as resulting from an *interaction* of two factors involved in LDD resolution: (a) the prediction of a GAP, and (b) the possibility that the GAP be found within the syntactic and semantic contexts immediately after the RELPRO, that is, when nothing in the unfolding syntactic and semantic structure prevents the licensing of the GAP. These findings would thus represent independent neurological support for the existence of an active-filler (Clifton and Frazier, 1989; Frazier and Clifton, 1989; Fodor, 1995) that, crucially, is sensitive to the details of the linguistic context of the relative pronoun independently of the length of the dependency (Phillips et al., 2005).

Indeed, we take this pattern to reflect not necessarily a difference in search but a difference in quality of the search: when the parser is forced to use memory resources outside of the implementation of any specific linguistic mechanism -the delay caused by the parser's recognition that the expected GAP is *not* to be found in the current local constituent- those resources are recruited from cortical regions, most relevant BA 6 (SMA), which have been previously identified as participatory for language composition. The combined *GAP-search* pattern of results (direct plus indirect) would thus be reflecting the workings of two functional foci of the same linguistic *network*.

Support for this view is the observation that the LIF cortex and SMA have been traditionally connected, particularly in the focal-lesion literature (e.g., Benson, 1985; Tonkonogy, 1986; Vignolo, 1988; Naeser et al., 1989; Alexander et al., 1990; Goodglass, 1993). This would mean in turn that the LIF cortex is sensitive to the expedient resolution of the dependency, which will only happen when such resolution is allowed by the local linguistic context. If it is not, then the preferential activation shifts (or reduces) to pre-SMA–all, however, within the same pathway.

This interpretation is consistent with Santi and Grodzinsky (2012) regarding the connection between "prediction" and the LIF cortex. Yet, what our results show is that presence of "prediction" is not enough. For the LIF cortex to be fully engaged, it must continuously be tracking for "gap-viability" as composition unfolds[13].

Further elaborating on this issue, a reviewer suggests a perspective on the $B_1>D_1$ activation pattern that gives it a specific role—namely the suppression or inhibition of the direct *GAP-search* mechanism associated with the LIF cortex. In this view then, the monitoring action would presumably rely on the workings of the pre-SMA and in the situation where the *GAP-search* could not take place, due to the island, it would act on the LIF cortex to suppress or hold search activity. We agree that this possibility, though outside the scope of the present data, is interesting and consistent with all other roles independently attributed to the SMA (e.g., Schwartze et al., 2012). Moreover, it brings the debate not only to a discussion of networks but to the possible distinguishable roles that their individual components may play during real-time cognitive processing.

Indeed, we take the activation of the supplementary motor area (SMA) in the B>D (Event 1) contrast to be an important clue to the cortical recruitment of LDDs. Not only regarding *GAP-search*, but also *GAP-completion* as we will see below. Specifically, pre-SMA and SMA-proper (BA 6) have been independently shown to be involved in sensory-motor processing possibly manifested through a "gradient" in which sensory, nonsequential, suprasecond information is processed rostrally (recruiting pre-SMA cortex) while motoric, sequential, and subsecond information is processed more dorsally (Schwartze et al., 2012). Our present data are not fine-grained enough to reveal a dissociation between pre-SMA and SMA proper. However, the data do show the shared locus of activation to be on medial BA 6, suggesting the targeting of pre-SMA over SMA-proper. Such a locus would be consistent with the processing of non-motoric, non-sequential, suprasecond information such as that involved in the holding of the filler in memory, as it were,

[12]A reviewer asks us about our predictions for event 0. We note that no A/B > D difference was predicted and no difference was found at this segment. There are two reasons for this: (1) this early in the sentence, both A/B and D conditions show composition between the head noun and RELPRO, on the one case, and between the subject and the verb, on the other. Even though the nature of the composition that each carries is presumably different, we have no reason to expect that each will recruit visibly distinct cortical regions as a result. (2) Regarding the relative pronoun, even though it is true that by our definition *GAP-search* is triggered as soon as the RELPRO is retrieved, at this early point no structure has been built over which the search is to be carried out. So, even though *GAP-search* is triggered at event 0, it will not be visible until the embedded clause is beginning to be built. This is precisely what the event 1 contrast is intended to reveal.

[13]These findings also connect directly to the cause of the abnormally delayed gap-filling observed in Broca's real-time comprehension (e.g., Burkhardt et al., 2003, Love et al., 2008). The combined behavior of A>D and B>D suggests that Broca's impairment may not be rooted to a generalized problem in syntactic structure formation (brought about in turn to a slowing in lexical retrieval), as has been proposed, but instead to the inability to engage the filler in an active manner as composition progresses, that is, to keep track of the viability of the syntactico-semantic structure being built.

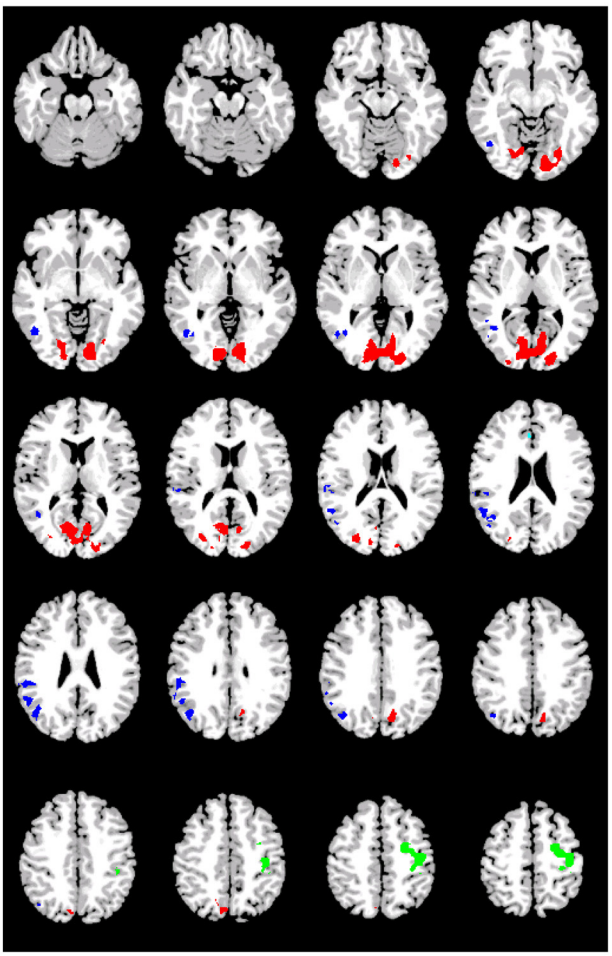

FIGURE 5 | Preferential activations for the conjunction of *GAP-completion* subtractions. Images are shown corrected at $p < 0.05$ in radiological format (LH is on the right). Green: BA6, primary motor and primary sensory connected with anterior cinculate (Acqua); Red: BA7, BA19, primary and association visual; Blue: right visual (association), right angular/ supramarginal gyri, and fusiform.

until the "GAP-unviable" segment has passed and active search can resume[14].

4.2. *GAP-completion*

Regarding *GAP-completion*, our findings from the simple subtractions show that this mechanism recruits the workings of a contiguous cortical region within the left fronto-parietal lobes (and non-overlapping with those associated with (direct) *GAP-search*) connecting supplementary motor area, precuneus, and portions of the left angular and supramarginal gyri and peristriate (BA 19). This observation is further supported by all relevant double subtraction and conjunction analyses. What emerges then is a coherent language "network," as all of these areas have been independently connected with related components of language processing. Most critically, they have been associated with lexically-driven composition, such as that involving subcategorization (Shetreet et al., 2009) and lexico-semantic selectional restrictions (e.g., Lai et al., 2014). Indeed, we conjecture that this pattern of preferential activation is part and parcel of the "Dorsal Stream" or "Dorsal Pathway" (Hickok and Poeppel, 2004, 2007; Friederici, 2009, 2012), which connects the frontal and left posterior cortices via the parietal lobe. To the extent that this network is seen to be involved in a mechanism such as *GAP-completion*, a mechanism that brings together syntactic, lexico-semantic, and discourse composition, it tells us that this cortical region is at least partly recruited during unification of interpretation. And this would also be consistent with a version of the Memory, Unification and Control model (e.g., Hagoort, 2005, 2014) whereby the true locus of *semantic* unification includes, most crucially, at least the pre-SMA. It is in this way that the LPST cortex is connected to LDD implementation: as a potential participating region in a larger network that supports real-time lexically-driven language composition which, by definition, also supports *GAP-completion*.

One additional advantage of the connection between *GAP-completion* with the dorsal pathway is that it affords a possible explanation for the long-standing observation regarding Conduction aphasia comprehension first reported in Caramazza and Zurif (1976). Specifically, Caramazza and Zurif (1976) report that patients with Conduction aphasia (a syndrome associated with damage to the arcuate fasciculus) exhibit *chance* performance in the comprehension of semantically reversible (object) relative-clauses. Such a pattern is indistinguishable from that shown for Broca's comprehension but claimed to emerge from different causes. Caramazza and Zurif (1976) further note that, like Broca's, the pattern shown by Conduction patients contrasts sharply with that exhibited by Wernicke's patients, who show performance that is not attributable to any one linguistic or processing factor. Here we reason that if *GAP-completion* is dependent on the workings of the dorsal pathway, presumably connected to the arcuate fasciculus, it explains why Conduction patients would be impaired in the interpretation of semantically reversible relative clauses, despite being able to carry out *GAP-search*[15]. In sum, we take the overall pattern accrued for all three Event 2, related double subtraction and conjunction contrasts to reflect components of this dorsal pathway, with BA 6 as a crucial area. This interpretation captures the normal-like performance by Wernicke's in online gap-filling constructions and suggests in turn that the LPST cortex activation from the imaging literature may not have been in connection to *GAP-search* proper.

In light of these findings, we are now able to address the questions posed in the introduction. What is the neurocognitive relation between *GAP-search* and *GAP-completion*? Answer: Their loci appears to be the LIF cortex and the (pre-)SMA, respectively. Do they rely on the workings of overlapping brain regions? Answer: The patterns we report show minimal overlap in recruitment. However, to the extent that at least the lower SMA

[14]Interestingly, BA 6 and supplementary motor cortex have both been associated to Broca's aphasia *and* Transcortical Motor Aphasia, indicating a potential connection between the two syndromes, whose functional implications are still not well understood (Naeser et al., 1989; Alexander et al., 1990).

[15]The authors thank Julius Fridiksson (p.c) for reminding us of this long-standing yet unexplained observation.

has been considered to be part of Broca's area, they are expected to functionally overlap. Our conjecture regarding the two areas [viable resolution (LIF cortex) vs. holding in memory (SMA)] is a proposal about how this overlap could take place. Can we associate *GAP-completion* to the LPST cortex, thus addressing the lesion-neuroimaging incongruence? Answer: we can if we understand Wernicke's area not as an isolated "language area" but as a part of a larger connectivity pathway "the dorsal stream" that connects Wernicke's area to the left fronto-parietal cortex including BA40, BA7 and the SMA. In line with the lesion-based literature, we conclude that LDD processing (defined in terms of *GAP-search* and *GAP-completion*) does not directly involve the preferential workings of Wernicke's area, but relies on areas that are functionally related to Wernicke's area.

Finally, if the effects reported reflect *GAP-search*, why are they observed mainly in the context of *object*-relative GAPs? Answer: what we find is that the effects reported reflect only an aspect of *GAP-search*, namely the requirement that the RELPRO be locally interpreted. But this only happens when *GAP-search* is being carried out over viable structure. So, it is as if the function of the LIF cortex is to monitor or keep track of the ability of the structure being composed to provide a GAP slot. In terms of our analysis, that amounts to keeping track of whether the selectional requirements of the RELPRO are being satisfied. As long as the composition signals that the GAP is incoming, the LIF cortex is fully engaged. From this perspective, then, the fact that this is observed mainly in object-GAP constructions is not a consequence of the grammatical feature *per se*, but of the fact that in these constructions, it takes longer for the RELPRO to be resolved as compared with subject-gap constructions, thus increasing the probability that the effect will be observed.

As a separate observation, our results also show that processing of memory-taxing sentential constructions (A and B) appear to systematically recruit the workings of the visual cortex (primary and association) areas (see Santi et al., 2015 and references therein for similar findings). We interpret this pattern separately for two reasons: (1) these areas are not traditionally associated with linguistic processing proper, and (2) this preferential activation was observed both during *direct GAP-search* and *GAP-completion*, suggesting that the areas in question are not showing sensitivity to a specific linguistic process.

In light of this, we connect these findings to independent observations regarding the visual system and linguistic load, particularly in relation to pupillometry measures (see Piquado et al., 2010 for a review and additional experimental evidence in relation to language processing load and the visual system). That observation has been shown not to be restricted to cognitive effort, but to extend even to physical effort (Zénon et al., 2014). Accordingly, we take the visual cortex activation pattern to reflect the increased attention (i.e., effort) that the implementation of the relevant linguistic tasks represents but whose source may not be strictly linguistic (see (Martínez et al., 1999; Posner and Gilbert, 1999; Petersen and Posner, 2012) for observations specifically regarding non-visually related attention load and its impact on the visual cortex). In this respect we note that the visual cortex activation was not observed during *indirect GAP-search* further supporting the possibility that during the building of structure that is non-viable for a GAP, no search is actually taking place. And this would make this segment of comprehension less cognitively taxing.

5. CONCLUSIONS: THE PRESENT RESULTS IN THE CONTEXT OF NEUROCOGNITIVE ARCHITECTURES

In this section, we connect our results to larger neurocognitive architecture models. In this respect, we consider three models which address syntactic and/or semantic composition, the sort presumably directly involved in *GAP-search* and *GAP-completion*. The first general observation is that whereas no one model accounts for the findings, each provides an insight into the larger pattern that the findings reflect. This gives us, then, the opportunity to focus on the common ground that each provides. This is what guides our discussion.

We start with Lau et al. (2008), who propose a model of semantic composition that could potentially involve LDD composition. In this model, the LIF cortex is connected to lexical retrieval. Interestingly our processing analysis of LDDs is lexically driven, and the key Event 1 contrast $A_1 > D_1$ does vary the presence of the relative pronoun. However, as we have seen, lexical retrieval differences alone do not account for the activation pattern: specifically, the results from $B_1 > D_1$, which also differ by the presence of the relative pronoun, do not show preferential LIF cortex activation. So, what is required in this model is a more precise treatment of the connection of lexical-retrieval to *GAP-search* in particular[16].

The second model we consider is Friederici (2012), which proposes that language composition, understood as the process of building a semantic representation through syntactic structure, recruits the workings of the LIF cortex. To the extent that *GAP-search* has been isolated from syntactic structure building through the subtraction process, the model predicts the LIF cortex will not be involved in this process, a prediction that is not supported by the evidence. For the same reasons, the model does successfully predict the absence of activation of BAs 44 and 45, particularly BA 44, in $B_1 > D_1$, which involves *GAP-search* but no hierarchical building. Friederici's (2012) model predicts no direct *GAP-search* in connection to the LIF cortex, because according to this model BAs 44 and 45 in particular are responsible for all syntactic structure building. Our results do not contradict this, but do point to the fact that BAs 44 and 45 must be additionally characterized as having specific compositional sensitivity, beyond generalized structure building. Finally, and as mentioned in the discussion, a most relevant aspect of Friederici's (2012) model (which also incorporates important insights from Hickok and Poeppel, 2004, 2007) involves the dorsal pathway, specifically,

[16]Relatedly, the more natural association with the workings of LDDs would be composition, since after all, the whole motivation for *GAP-search* is to compose the subject matrix nominal into the meaning of the embedded clause (and vice versa). But in the semantic model presented in Lau et al. (2008), this task is connected instead to the anterior temporal cortex (ATC) and angular gyrus, areas that are connectable instead to the ventral pathway and which, in our data, were only partly connected to *GAP-search* (in the form of the marginal activation of the temporal pole for $A_1 > D_1$).

Pathway I (also discussed in Friederici, 2009) and which connects the STG and BA 6 through the arcuate fasciculus. It is this pathway, we propose, that is responsible for compositional processes such as those represented by *GAP-completion*.

We reserve the end of this section for discussion of the Memory, Unification and Control (MUC) Model (e.g., Hagoort, 2005, 2014). To our knowledge, this is the only model that explicitly assumes lexically-driven processing and grammatical systems, a feature that our processing analysis of LDDs also assumes. The model also capitalizes on the notion of unification, which provides a processing-friendly approach to composition. Like the Friederici (2012) model, Hagoort's 2005, 2014 model proposes a divide within the LIF cortex separating BAs 45 and 47 from BAs 44 and 45 for semantic and syntactic unification/processing functions, respectively. Whereas our data do not speak to the functional articulation within the LIF cortex, they do reveal that both subregions can at least work in tandem, as in the case of the activation for direct *GAP-search*. This is a reasonable interpretation, given that direct *GAP-search* involves both semantic and syntactic computations. What is not clear at this point is how unification should be understood such that it will include *direct GAP-search* as a mechanism while simultaneously excluding *indirect GAP-search*; both processes that are on the one hand "dynamic" in nature, and on the other highly sensitive to the linguistic context of the GAP. Another pending question is the nature of the connection between the LIF cortex and SMA/lower parietal cortex. Under MUC, these two regions could be involved in the same larger processing network, and the SMA activation observed could be part of the dynamics of the network triggered in turn by the linguistic properties of the sentence. In this interpretation, LDDs allow us to localize not two regions, but a network with two foci reflected in these two mechanisms. Since our data cannot speak directly to this point, this proposal remains to be supported.

To conclude, the results presented here suggest a resolution of the imaging vs. lesion incongruence by showing the privileging of BAs 45, 44, and 47 (over BA 6 and parietal and parieto-temporal cortex, including the LPST cortex) in the process of *direct GAP-search* and by suggesting that the activation of LPST cortex reported in the neuroimaging literature is a manifestation of the workings of a network that supports other linguistic compositional processes associated instead with *GAP-completion*.

The results capture the inherent asymmetry between *GAP-search* and *GAP-completion* and explain why damage to the LIF cortex would dramatically impact the ability of the comprehension system to complete the dependency, even if the cortical regions involved in *GAP-completion* remained intact. By the same token, to the extent that the evidence presented here does *not* involve the left posterior superior temporal cortex at least directly, the results tell us why Wernicke's patients should not have issues in searching for and completing the GAP. Indeed, if our conjecture regarding the functional commitments of the SMA and the left lower parietal region (associated with *GAP-completion*) to compositional unification is correct, Wernicke's patients, who have been shown to have lexical retrieval problems, should not show problems in finding/completing the GAP but in unifying this information with the matrix clause into an interpretable string. Such a situation would lead to across-the board comprehension problems in these patients, a prediction that evidence from offline comprehension of these patients (in contrast to Broca's patients) consistently supports.

AUTHOR CONTRIBUTIONS

MP is responsible for the conception of the work and participated in each aspect of the project including experimental design, data acquisition and analysis, and drafting of the work. EF is responsible for stimuli generation and norming, subject recruitment, data acquisition, data analysis planning (e.g., timing file generation), interpretation and drafting of the work, and participated in the final approval of the version to be published. CL carried out all the data analysis and participated in the final approval of the version to be published. RC participated in the experimental design, data analysis and interpretation, drafting of the work, and in the final approval of the version to be published.

FUNDING

This project was funded by NSF BCS-0643266 awarded to MP and NSF-INSPIRE 1248100 awarded to MP, Ashwini Deo, Mokshay Madiman, and RC.

ACKNOWLEDGMENTS

We thank Jeetu Bhawnani and Hedy Sarofin for programming and technical support through the data acquisition stage. We also thank Emily Foster Hanson, Sara Sanchez-Alonso, and Muye Zhang for key assistance with aspects of the data analysis and data presentation. Finally, we are grateful to Edgar Zurif for much discussion on the gap-filling effect and the neurocognition of language composition; discussion that has directly impacted the approach taken here. All errors remain our own.

Cross-linguistic evidence for memory storage costs in filler-gap dependencies with wh-adjuncts

Arthur Stepanov and Penka Stateva*

Center for Cognitive Science of Language, University of Nova Gorica, Nova Gorica, Slovenia

This study investigates processing of interrogative filler-gap dependencies in which the filler integration site or gap is not directly subcategorized by the verb. This is the case when the wh-filler is a structural adjunct such as *how* or *when* rather than subject or object. Two self-paced reading experiments in English and Slovenian provide converging cross-linguistic evidence that wh-adjuncts elicit a kind of memory storage cost similar to that previously shown in the literature for wh-arguments. Experiment 1 investigates the storage costs elicited by the adjunct *when* in Slovenian, and Experiment 2 the storage costs elicited by *how quickly* and *why* in English. The results support the class of theories of storage costs based on the metric in terms of incomplete phrase structure rules or incomplete syntactic head predictions. We also demonstrate that the endpoint of the storage cost for a wh-adjunct filler provides valuable processing evidence for its base structural position, the identification of which remains a rather murky issue in current grammatical research.

Keywords: parsing, filler-gap dependency, thematic role, wh-adjunct, Active Filler Strategy, Slovenian

Stepanov A and Stateva P (2015) Cross-linguistic evidence for memory storage costs in filler-gap dependencies with wh-adjuncts. Front. Psychol. 6:1301. doi: 10.3389/fpsyg.2015.01301

Introduction

It has long been known that processing syntactic dependencies, in which two elements are syntactically related and linearly separated by intervening material, may be difficult for sentence comprehenders. An early study in Wanner and Maratsos (1978) showed that such difficulties arise, in particular, in processing incomplete filler-gap dependencies, in which a wh-phrase is syntactically related to the gap in the subcategorized position of the verb:

(1) Which book do you think that Colin recommended _ to the librarian?

Such long-distance dependencies are a source of syntactic complexity that the parser has to deal with over and above what is required for processing phrase structure and specific lexical items. One line of explanation for these difficulties faced by the human parser is that syntactic dependencies of this kind incur a tax on the working memory needed to temporarily store the antecedent or predictor, until a suitable element with which it can be associated is encountered in the partially processed input (Chomsky and Miller, 1963; Abney and Johnson, 1991; Gibson, 1991, 1998; Stabler, 1994; Lewis, 1996). Thus, in (1), the filler (*which* book) must somehow be temporarily stored in working memory until a suitable integration point is found. The working memory tax associated with storage cost leads to particular behavioral effects such as increased response times, or specific brain activity patterns at the neural level. Chen et al. (2005), in one of their self-paced reading experiments, manipulated the type of structure between a relative clause, where a wh-dependency is established, and a sentential complement, where it is not, as in the following examples:

(2) a. The announcement [that the baker from a small bakery in New York City received the award] helped the business of the owner.
b. The announcement [which the baker from a small bakery in New York City received ___] helped the business of the owner.

The critical region was the subject NP "the baker from a small bakery in New York City." By hypothesis, temporarily storing the wh-filler "which" initiates an incomplete syntactic dependency and a prediction of a subcategorizing or thematic-role assigning verb to complete the dependency. Thus, assuming that both conditions otherwise involve the same amount of lexical integrations, it is predicted that the critical region in (2b) should elicit greater reading times, showing a distributed slowdown effect, as opposed to (2a) where no wh-dependency is initiated, because of the storage effect[1]. Indeed, Chen et al. (2005) observed that reading times in (2b) were greater than in (2a) (see also Gordon et al., 2002; Grodner et al., 2002 for related studies).

In the Event Related Potentials paradigm, storage costs for wh-fillers appear as a modulation of left anterior negativity (a negative voltage deflection in the frontal, often left-lateralized, regions of the scalp) spread over the region between the filler and the gap (Kluender and Kutas, 1993; King and Kutas, 1995), followed also by a P600, a positive deflection effect at the gap or pre-gap position (Kaan et al., 2000). Phillips et al. (2005) also observed that the sustained negativity persisting throughout the wh-dependency until the point of its completion is independent of the length of a filler-gap dependency, appearing both in short-distance (single clause) and long-distance (multi-clausal) wh-dependencies. The authors interpret this sustained negativity as a reflection of the cost of holding the wh-phrase in working memory. A similar pattern of Event Related Potentials was also observed in German and Japanese (Fiebach et al., 2002; Ueno and Garnsey, 2007).

In the present study, we investigate whether wh-adjuncts like *how quickly, when* and *why* elicit a similar kind of storage cost as wh-arguments do. Wh-adjuncts are notably different from wh-arguments in ways that directly affect processing. Semantically, adjuncts can never have a basic semantic type: canonically, they may function as predicates of events in the sense of event semantics (Davidson, 1980), or proposition or event modifiers in the sense of compositional semantics (Heim and Kratzer, 1998). In that capacity, wh-adjuncts are special in that their base (that is, semantically and syntactically determined) position is not predicted by subcategorization and/or thematic role assigning properties of the verb. The absence of direct association with the verb raises an a priori possibility that wh-adjuncts do not instantiate a filler-gap dependency at all: rather, they could be simply processed in their surface position. This lines up with certain grammatical theories that do not postulate syntactic displacement or dependency in the case of wh-adjuncts, as opposed to wh-arguments, and assume that wh-adjuncts are base-generated in their surface position (see, e.g., Hukari and Levine, 1995 for an overview, and the discussion below). We can then ask the following:

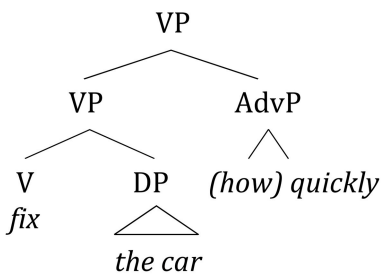
(3) a. Do wh-adjuncts instantiate filler-gap dependencies similar to wh-arguments, in the absence of thematic and/or subcategorization association with the verb?
b. Do all adjuncts incur similar storage costs?

As will become clear from the following discussion, we believe that the answer to (3a) is "yes," but the answer to (3b) is most likely "no." We do expect storage costs for (most) wh-adjuncts because their surface position must be syntactically linked to a base position linearly separated from it by intervening material. At the same time, recent advances in syntactic theory inform us that adjuncts differ with respect to their base positions. Consequently, we might expect different adjuncts to display different storage costs. The following section provides a basic overview of the major syntactic peculiarities that enter into processing considerations regarding filler-gap dependencies involving wh-adjuncts, and outlines the challenges presented by wh-adjuncts in light of the existing theories of storage costs and filler-gap dependencies in general.

Base/Integration Points of Wh-adjuncts

Syntactically, an adjunct is realized as a sister to an abstract syntactic node denoting the predicate that the adjunct modifies. An example of modifying an event predicate is shown in (4):

(4)



The actual attachment site of an adjunct may vary depending on the type of predicate that it modifies. Current theoretical research recognizes a multitude of positions in the syntactic structure of the sentence, where adjuncts of various semantic types may appear (e.g., Cinque, 1999). For the present purposes, we may adopt a simplified version of that typology and pinpoint at least four classes of adjuncts as in **Table 1** (cf. also Ernst, 2001; Rizzi, 2001).

The order of listing the adjunct types in **Table 1** roughly corresponds to their base structural position in the syntactic tree, or closeness to the root node. The attachment site of each adjunct type is determined by the corresponding phrase structure rule (e.g., S → AdvP S, or VP → VP AdvP) and corresponds to speakers' semantic intuitions. Structurally the "highest" are speaker oriented adverbs which we will not consider in this study. The next highest position is occupied by reason adjuncts and their corresponding *wh*-counterpart *why* (see also Experiment 2 for further details), placed above the sentential S node, in the domain of COMP (or Complementizer

[1] A reviewer points out that (2a) may be compatible with a filler-gap parse up to the item *the award*, which might affect comparison of storage costs between the two sentences. This potential confound is avoided in our design of Experiment 2 with the English materials (see below).

TABLE 1 | Grammatical typology of adjuncts and their wh-counterparts.

Adjunct types	Examples, non-wh-	Simplex wh-adjuncts	Complex wh-adjuncts
Speaker-oriented adjuncts, or evidentials	*Clearly, obviously, fortunately, in my opinion*	–	*How obviously, how fortunately*
Reason adjuncts	*Because*-adjuncts	*Why*	*For what reason*
Subject-oriented adjuncts	*Probably*, temporal, and spatial adjuncts	*When, where*	*In which room, after which holidays*
VP-oriented adjuncts	*Quickly, often, with a hammer* etc.	*How*	*How quickly, by what means*

Phrase in current syntactic terminology). This is followed by subject-oriented adjuncts that are adjoined to the S node (or Infl Phrase in many contemporary syntactic theories), not considered in this study either. Finally, VP-oriented adjuncts are adjoined to VP, thus are relatively "low" in the syntactic structure.

A major consequence of this diversity of the syntactic and semantic properties of wh-adjuncts is that, in contrast to arguments, the linear position of the adjunct in the sentence cannot be reliably predicted from the linear position of the corresponding verb and the information about the canonical word order in a language. Rather, the association of an adjunct to the verb in this case can only be *loose and indirect* [note that the lower VP constituent in (4) can syntactically be arbitrarily complex; other material can also be inserted by iterating the VP node]. In parsing, this translates into a state of affairs whereby a wh-filler cannot be reliably associated with a specific lexical stimulus, such as the verb. Rather, it may appear at an arbitrarily long distance from it[2]. With regard to VP-modifying wh-adjuncts, one can envision two possibilities as to where their integration point might lie.

The first possibility is that, despite the irrelevance of the thematic/subcategorization information, the parser follows some lexically-driven strategy to integrate the adjunct at or near the verb, similarly to wh-argument dependencies. Indeed, some grammatical models postulate a close syntactic relationship between (wh-)adjuncts and the verb outside the realm of the thematic relations. Such postulated relationship usually has a featural character: some morphosyntactic feature on the adjunct and a feature on its licensing head such as V or Infl must match or agree. In such approaches, different features may correspond to different adjuncts (Travis, 1988; Laenzlinger, 1996; Ernst, 2001). It is thus possible that the featural association of a wh-adjunct and the verb is reflected in the processing pattern, resembling or approaching the pattern of association of wh-argument fillers with corresponding verbs.

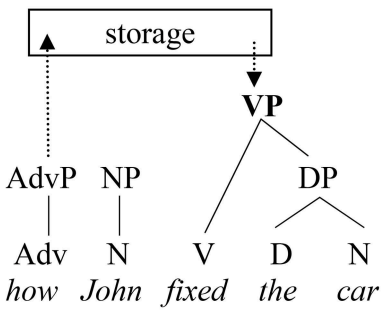
[2]Furthermore, there is an issue of *directionality*: some adjuncts may be left-adjoined or right-adjoined, following restrictions that may have syntactic, semantic or prosodic nature (for instance, prosodically heavy adjuncts tend to be right-adjoined, see Ernst, 2001). Even within the same class of VP-adjoined adjuncts, adverbs like *quickly* allow at least two grammatically acceptable positions compatible with the sisterhood to VP (with no easily discernible difference in meaning), while other manner adverbs like *poorly* do not allow such dual positioning (Bowers, 1993):

(i) a. John fixed the car quickly
b. John quickly fixed the car
(ii) a. John fixed the car poorly
b. *John poorly fixed the car

The second possibility is that the base position of the wh-adjunct (and, correspondingly, its integration point in a filler-gap dependency) requires online computation of an abstract syntactic node [cf. the lower VP in (4)] as a way of identification of the event-denoting predicate hosting the wh-adjunct, as well as some predictive information about its linear position with respect to that node. To illustrate schematically, let us assume a parsing algorithm with a storage component, using both bottom-up and top-down strategies and consulting the phrase structure module of the grammar. If such an algorithm is used to process the embedded part of a sentence like (5), the adverbial phrase *how* would be stored (possibly along with a pointer associating it with the relevant phrase structure rule; see also the discussion of the SLASH feature below) until the VP node is constructed online. Completion of the VP would trigger a subsequent application of the rule VP → VP AdvP, retrieving the stored phrase and integrating it at a grammatically permissible site [cf. (4)].

(5) I didn't know how John fixed the car

(6)



Formally, the difference between the two possibilities lies in the syntactic category of an element combining with an adjunct: a lexical head such as V^0 vs. a phrasal category such as VP, in the correspondent grammatical rule(s) guiding integration of the adjunct during online processing. In the absence of thematic and/or subcategorization criteria for integration, syntax seems to be a major relevant cue for predicting the integration site in this case (possibly supported by other cues such as plausibility). Consequently, no lexically-based strategy would be at issue; rather, the relevant integration algorithm would have to make reference to the syntactic category information in determining the integration point (see also Gibson, 1998, 2000 concerning processing costs of structural integrations). Similar considerations apply with respect to the processing costs of temporary storage of an wh-adjunct, as discussed below.

In sum, the grammatical distribution of (wh-)adjuncts in general is much more complex than that of (wh-)arguments.

Correspondingly, general processing predictions with respect to the base site of the filler-gap dependency headed by a wh-adjunct can hardly be formulated. Rather, gap predictions must be formulated item-specifically. In the absence of thematic/subcategorization information, such predictions have to take into account, at the very least, the semantic type of an adjunct, on the one hand, and the phrase structure rules generating it, on the other.

Storing Wh-adjuncts: Theoretical Predictions

From the storage perspective, investigating wh-adjunct dependencies is theoretically illuminating in at least two different respects. The first one concerns the role of the thematic factor in current theories of storage costs, and more generally, the role of lexically-based strategies of computation of these costs. The second regards the interaction and potential convergence of the processing and grammatical predictions concerning the endpoint of the storage costs, also in the context of the Active Filler Strategy. Below we consider these aspects in turn.

The Lexically-based vs. Syntactically-based Views on Storage Costs

Current processing theories of incomplete filler-gap dependencies focus, explicitly or implicitly, on the issue of the temporary storage of the wh-filler, its integration into the syntactic structure of the input, or both. For instance, the memory-based accounts of filler-gap dependencies (Gibson, 1998, 2000) assume that integration and storage incur separate memory costs, and the overall processing cost of a filler gap dependency is a function of both of these measures. These accounts are based on the general idea that integrations and storage share the same pool of memory resources and that this pool of resources is limited; consequently, exceeding the set limit at some point slows down performance (Baddeley, 1990; Just and Carpenter, 1992; Lewis, 1996)[3]. From the evidence accumulating from the previous psycho- and neurolinguistic studies (see Introduction), it can be conjectured that integration costs are associated with behavioral or neurophysiological markers showing up at certain discrete points of parsing, usually at or around the predicted gap site, whereas storage costs reveal themselves as extended intervals of specific behavioral or neural response over a range of input that coincides, or is very close to, the area between the filler and the gap, in the form of a reading slowdown or increased sustained voltage deflection in the ERP signal.

The theories of storage proposed to date differ with respect to the question as to what processing units may incur a memory storage cost (see Chen et al., 2005 for review). It has been proposed that storage be measured in units such as incomplete clauses (Kimball, 1973), incomplete phrase structure rules (Yngve, 1960; Chomsky and Miller, 1963), incomplete thematic role assignments (Hakuta, 1981; Gibson, 1991), incomplete Case dependencies (Stabler, 1994), and predicted syntactic heads (Gibson, 1998, 2000). For instance, under the theory taking incomplete phrase structure rules to be relevant storage units, a center-embedded structure as in *This is the malt that the rat that the cat that the dog worried killed ate* elicits storage costs quantifiable in terms of the number of the phrase structure rules such as S → NP VP that have to be kept in memory as more embedded material is processed. Similarly, under the predicted syntactic head theory, storage is quantified in terms of the number of syntactic heads expected to complete a dependency.

We believe that investigating wh-adjunct dependencies may reliably distinguish between these theories. In particular, the theories that take storage units to be incomplete thematic role assignments (Hakuta, 1981; Gibson, 1991) predict that wh-adjuncts should not elicit storage costs, simply because there are no thematic roles associated with them that need to be stored. A similar prediction is made by the theories that take the relevant storage units to be incomplete Case dependencies (Stabler, 1994): wh-adjuncts are usually adverbials or prepositional phrases; as such, they are not subject to the Case requirement, hence no Case information needs to be stored. Thematic roles, lexical head predictions and/or Case predictions are all part of the class of theories that take lexical factors as the cornerstone of relevance when it comes to computing storage costs.

On the other hand, theories that assume that incomplete phrase structure rules are stored during processing (see above) do predict storage costs for wh-adjuncts similarly to wh-arguments. As Chen et al. (2005) point out, these theories can be adapted to handle storage costs in filler-gap wh-dependencies utilizing the analytical tools of, e.g., head-driven phrase structure grammar (Pollard and Sag, 1994) and/or generalized phrase structure grammar (Gazdar et al., 1985). In these models, the mediation between the wh-filler and the verb is achieved via the SLASH feature which may propagate across syntactic nodes or rules down to the integration site thematically associated with the verb, and thus marks the path of the wh-dependency (Pollard and Sag, 1994; Sag and Fodor, 1994). The crucial point here is that the SLASH feature is insensitive to the syntactic category of the missing constituent. Thus, all else equal, it predicts the storage costs for wh-arguments, as well as for wh-adjuncts.

Similarly, theories that compute syntactic predictions in terms of expected syntactic heads (Gibson, 1998, 2000) predict storage costs for wh-adjuncts as well as wh-arguments. In contrast to the incomplete phrase structure rule theories, the expected syntactic head model does not make direct reference to hierarchical constituent structure, but only to its lowest level of representation, the level of syntactic heads. Let us assume for the moment that the gap expectation for *how* is at the point linearly following the lower VP constituent, as in (4). For concreteness, let us also assume the algorithm for quantitative estimation of storage costs based on predicted syntactic heads, as in Gibson (2000). Consider the relevant storage costs of the sentence in (7)

[3]Distinguishing the integration and storage costs empirically is not a trivial task. For instance, a classic explanation of the contrast in the parsing difficulty between center-embedded structures and the corresponding right-branching structures is that the former require a greater amount of storage space as opposed to the latter, and since the amount of memory resources available for sentence processing is limited (Miller, 1956), the difficulty arises at the point when the memory capacity is exceeded (Chomsky and Miller, 1963; Abney and Johnson, 1991; Lewis, 1996). But, as Gibson (1998) notes, there exists an alternative explanation that nested structures, by their nature, always require longer distance integrations between the respective syntactic heads, hence higher processing costs, than the right-branching structures. This caveat is obviously relevant to structures manifesting filler-gap dependencies as well.

(concentrating on the embedded clause) that can potentially be assigned in this model, with and without the wh-adjunct, all else being equal:

(7) I didn't know that/how you fixed the car yesterday

		Input word					
		…how	you	fixed	the	car	yesterday
(8)	Storage cost	3	2	2	2	1	0
		…that	you	fixed	the	car	yesterday
		2	1	1	1	0	0

Given the nature of adjuncts as event modifiers, the storage cost at the point when *how* is processed will be 3. This reflects, in addition to the associated gap position, two more heads to describe an event (e.g., *it happened* or *John arrived*). Upon encountering the subject *you*, the storage cost value is reduced to 2, expecting a predicate and (still) a gap. At the point when *the* comes, the parser expects the noun and a gap position. Finally, at *car*, only the gap position is expected. In the non-wh version, storage costs are correspondingly reduced.

To sum up, wh-adjuncts may provide important evidence to distinguish between theories that place crucial weight on the lexical properties of fillers and those that do not. If wh-adjuncts incur storage costs, that would argue in favor of the latter type of theories. The present study seeks to provide such evidence.

Endpoint of the Storage Costs

The second interesting aspect of storage costs has to do with understanding the way storage costs for wh-adjuncts are related to the two potential grammatical possibilities for the integration site considered above. The existing theories that take storage and integration both to be active components of the working memory, largely take it for granted that the integration site marks the retrieval of the wh-filler, hence the endpoint of the storage costs. For wh-arguments, the endpoint of the storage costs at the grammatically expected point (e.g., verb for the object filler) would not be particularly surprising. For wh-adjuncts, things are not that trivial. Current grammatical theories do not always offer reliable clues as to the end-/integration point of the wh-adjunct in the syntactic structure, due to their loose and mobile syntactic character that follows from the lack of thematic and/or subcategorizational anchors. The situation gets even more complicated considering that the integration site is different for different wh-adjuncts in the same language (see footnote 2 and Experiment 2). Naturally, wh-adjunct dependencies appear somewhat more elusive for tracking with current experimental methods than their wh-argument counterparts. The endpoint of the storage costs in this situation could then provide important processing evidence for grammatical theory, to the extent that it demarcates a likely integration site.

In this respect, it is also interesting to investigate the role of the Active Filler Strategy, a parsing strategy which assigns high priority to integrating the filler at the earliest point allowed by the grammar (see Fodor, 1978; Frazier and Clifton, 1989; de Vincenzi, 1991). The Active Filler Strategy bears on the "filled gap" effect of integrating a wh-argument like subject or object with its corresponding syntactic position in the input, as in the following sentences from the self-paced reading study in Stowe (1986):

(9) a. My brother wanted to know if Ruth will bring us home to Mom at Christmas.
b. My brother wanted to know $[\text{who}]_i$ G_i will bring us home to Mom at Christmas.
c. My brother wanted to know $[\text{who}]_i$ Ruth will bring $^*G_i$ us home to G_i at Christmas.

Longer reading times were reported at *us* in (9c) compared to (9a) and (9b). This is expected if the position of *bring* is the earliest potential position where the object wh-filler *who*, temporarily kept in the memory, can be integrated. That state of affairs causes reanalysis. In contrast, (9a) and (9b) involve no such reanalysis[4]. This and other studies investigating the Active Filler Strategy are usually based on processing verbal arguments. The interest in investigating the role of this strategy in processing wh-adjuncts consists primarily in determining (a) whether it is operative at all; and (b) if it is, what sort of evidence the parser uses in order to determine the earliest position, in the absence of thematic or lexically-oriented cues.

In the present study we report two self-paced reading experiments targeting wh-adjunct dependencies in Slovenian and English. Specifically, we focus on two examples of structurally low, VP-modifying adjuncts, as well as an example of a structurally high (reason) adjunct. Low or VP-modifying adjuncts offer a good source of evidence pertaining to research question (3a) above. Since the canonical word order in SVO languages presupposes some non-trivial distance between the occurrence of the filler and the VP in the linear representation of the interrogative sentence, a filler-gap dependency in this case can potentially be identified in parsing by a storage effect which extends across some part or all of the corresponding range in the input, much along the lines of the previous studies of storage costs incurred by wh-arguments. This is not the case with structurally high wh-adjuncts whose integration sites are likely to be close to their surface position or even identical to it (see also Section Storage Cost Predictions for *why*). Utilizing this idea, Experiment 1 aims at detecting a filler-gap dependency with the VP-modifying adjunct *kdaj* "when" in Slovenian, as well as investigating the endpoint of such dependency. Experiment 2, using English materials, addresses research question (3b) as well as (3a). It compares the storage cost patterns of the structurally low *wh*-adjunct *how quickly* and the structurally high *wh*-adjunct *why*, asking whether these processing patterns differ in a way that correlates with the syntactic and semantic properties of these two w*h*-items. This experiment also targets the endpoint of a filler-gap dependency in greater detail.

[4]Note that if *who* is ambiguous between subject and object, then the Active Filler Strategy also predicts increased reading times over the subject position (*Ruth*) in cases like (9b). In her study, Stowe found no increased reading times over the subject. However, Lee (2004) argues that a filled-gap effect appears when more material is added in between the filler and the (subject) gap, and thus sufficient time is available to the parser.

Inclusion of Slovenian in our study was justified on several grounds. Aside from the obvious benefit of expanding the empirical database of processing storage cost effects cross-linguistically, and the fact that Slovenian usually receives little attention in behavioral psycholinguistics, working with certain kinds of wh-adjunct dependencies in Slovenian turns out to be preferable as some wh-adjuncts in Slovenian are free of inherent lexical ambiguities typical of their counterparts in other languages, including English (as is the case of *when*, see below). This allows for a cleaner experimental design, avoiding potential confounds in the construction of stimuli. The present study is also the first, to our knowledge, comparing storage costs in filler-gap dependencies in two languages within the same experimental setup. Because of that, we show that storage costs elicited by wh-adjuncts are a language-independent phenomenon, a naturally expected result in the context of the general inquiry into the nature of the human parsing system.

Experiment 1: Slovenian *kdaj* ("when")

Experiment 1 is a self-paced reading study in which we investigate potential storage costs elicited by the structurally low, VP-modifying *wh*-adjunct *kdaj* "when" in Slovenian. If a wh-adjunct like *when* in the beginning of the sentence instantiates a filler-gap dependency as wh-arguments do, thus functioning as a filler, we may expect a storage cost effect extending across the range in the input which is commensurable with the structural distance between the filler and its corresponding gap in the VP area. The experiment tests this scenario.

In addition, Experiment 1 aims to shed light on the issue regarding the endpoint of the storage cost for *when*. As noted above, there are two main theoretical possibilities to consider with respect to this endpoint. One is that the dependency terminates at the verb, as is the case for wh-arguments. The other is that the dependency terminates at some point predicted by phrase structure rules for VP. Regarding the latter possibility, in a sentence with a transitive verb it makes sense to expect a gap at or after the relevant part of the argument structure, viz. verb plus object, is processed [cf. (4) above]. The working assumption, trivial for wh-arguments, but non-trivial for wh-adjuncts, is that the end of the storage costs (that is, a point where reading times are equalized compared to the input not involving a wh-dependency) signals the gap site. Based on the results in Chen et al. (2005) for wh-arguments, we thus expect to see a region of increased reading times to last until either the first or the second suspected gap site:

(10) a. I didn't know when John bought (G1?) the newspaper (G2?) in the kiosk
b. I didn't know that John bought the newspaper in the kiosk.

If the endpoint of the storage costs is at the verb, this would support the approach to storage costs based on the featural association of the verb and the adjunct (see above). On the other hand, if the endpoint of the storage costs is at or after the direct object, this would be consistent with the phrase structural theories, as well as with the predicted syntactic head theories of storage costs.

Note that *when* in English is ambiguous. It can be used in its truly interrogative sense (cf. *Peter asked when the parcel would arrive*) or in another, related, but non-interrogative, guise (cf. *Peter left when the parcel arrived*). When used in embedded contexts, the truly interrogative version of *when* is selected by a particular class of verbs such as *ask, wonder,* or *know*. When used in its non-interrogative sense, *when* does not need to be selected at all. It is often difficult to distinguish these two usages in English and other languages which use a single lexical item for both. In Slovenian, on the other hand, the two usages of *when* are lexically disambiguated: *kdaj* is used in the respective interrogative contexts, and *ko* in non-interrogative ones. Because of that, Slovenian is an excellent choice to study the online behavior of the interrogative *when* and rule out potential confounds caused by its non-interrogative usage (which may not trigger a wh-dependency at all).

We thus concentrated on *kdaj* in Slovenian, and compared performance over the region corresponding to the argument structure (in bold) in simple embedded wh-questions such as the following (further description of the items involved is discussed in the Section Materials below):

(11) a. Kritik je potrdil, da **je umetnik izdelal tisti**
Critic is confirmed that is artist created this
koš v svoji delavnici.
basket in his workshop
"The critic has confirmed that the artist created this basket in his workshop"
b. Kritik je potrdil, kdaj **je umetnik izdelal tisti**
Critic is confirmed when is artist created this
koš v svoji delavnici.
basket in his workshop
"The critic has confirmed (the date) when the artist created this basket in his workshop"

Since in (11a) the argument structure ends at the point ***koš***, this is the point where we expect the storage costs to equalize with those observed at the same point in (11b). Following the critical region was either a locative PP (e.g., *v svoji delavnici* "in his workshop") or a further optional specification of the object noun [e.g., (*koš*) *božičnih daril* "(basket) of X-mas presents"], which contained two to three words.

Methods

Participants[5]

Seventy-four monolingual speakers of Slovenian from the academic communities of the University of Nova Gorica and University of Ljubljana volunteered to participate in the experiment for no material compensation. All participants were naïve to the purposes of the study.

[5]The experiments in this study were carried out in accordance with the Declaration of Helsinki and the existing European and international regulations concerning ethics in research. All participants gave an informed consent prior to the beginning of testing.

Materials and Methodology

Twenty-four sets of sentences, each with the two conditions described above, were carefully constructed. Since we were interested in evaluating the actual "boundaries" of the filler-gap dependencies reflected in online storage costs, the sentences in the two conditions were exactly identical except for the value of the embedded clausal head, or Complementizer: this value was either a declarative *da* "that" or interrogative *kdaj*. To control for length of a wh-dependency, all sentences were made exactly 12 words long. Each sentence began with an introductory part involving a one-word subject, a past tense auxiliary and a main verb [cf. (11)]. The main verbs were carefully chosen so that they may embed either a wh-interrogative clause, or a declarative *that*-clause. In English, typical representatives of this class of verbs are *know* and *figure out* (e.g., *I know that the guests came* vs. *I know when the guests came*; see also Experiment 2). In general, at least for *when,* the set of such ambiguously embedding verbs is much larger in Slovenian than in English, so that there was no repetition of verb between the items. The fourth word is the embedded complementizer appearing in one of the two versions outlined above. Words five through nine represent the region of interest as they minimally describe an argument structure that can be modified by *when*. The sixth word is the embedded subject, the seventh is the embedded verb and the eighth and ninth words represent the direct object, where the eighth word was always a demonstrative determiner. This was done in order to make the object structurally "heavier," but not to the point when the complexity of its structure would potentially intervene with determination of the right boundary point. In choosing nouns used for embedded subjects and objects, as well as embedded verbs, we controlled for their plausibility and corpus frequency, for the latter using the FidaPLUS-JOS1M corpus (Erjavec et al., 2010).

The remaining three words always describe a location of the event in the form of a prepositional phrase compatible with the locative specification. The locational content of the prepositional phrase was chosen so that it would have a clear bias toward modification of the event, not of the last phrase (object). It should be also noted that Slovenian is a language where verbal clitics must always appear in the second position in the clause. The test sentences are all in past tense, whose grammatical manifestation in Slovenian requires a particular verbal clitic. That is why the second and fifth words in the test sentences are always verbal clitics, either singular or plural, depending on the grammatical number of the subject.

The target sentences were split into individualized lists balancing all factors in a Latin Square design, so that a different such list is activated for each participant. Each list was combined with 50 filler sentences of various syntactic types and of comparable length. The experimental items and fillers were thoroughly checked by a native speaker of Slovenian who is also a linguist. A complete list of target items along with their English glosses and translations is provided in Supplementary Material.

Subjects performed a self-paced reading task implemented by using the Ibex software (by Alex Drummond, http://spellout.net/ibexfarm/). We used a word-by-word centered-window presentation of stimuli. In this design, a subject initially sees two dashes in the center of the screen. By pressing the space bar, the first word in the sentence appears in place of the dashes. With each subsequent press of the space bar, the current word is replaced with the next word in the sentence, until the end of the sentence is reached. The reason we did not use the currently more popular moving window version of the self-paced reading task (see Just et al., 1982) was to rule out potential topological cues helping one to identify the left and right boundaries of a filler-gap dependency based on the positions of the relevant words or their placeholders (viz. dashes) in the linear representation of the sentence. Ruling out this possibility reinforces the scenario whereby processing filler-gap dependencies is based on the resources of working memory only, which is of primary interest from the point of view of evaluating storage costs. The order of stimulus presentation was pseudo-randomized for each participant by the experimental software and it was ensured that at least one filler intervenes between any two target items.

At the beginning of the experiment, participants were instructed to read the sentences at a natural pace and to be sure they understand what they read. To ensure that participants paid attention to the content of the reading task, half of the target items and one third of the fillers were followed by a yes-no comprehension question. Subjects were instructed to answer the question as quickly and accurately as possible. Feedback was provided when an incorrect response to a comprehension question was given, and subjects were told to take it into account as an indication to read more carefully. No feedback was given in cases of correct answer. Failure to respond within 4 s counted as an incorrect response. Before the start of the experiment, subjects read a short list of practice sentences and comprehension questions in order to familiarize themselves with the task. Each session lasted between 20 and 25 min per participant.

Statistical Procedures

We used the same statistical procedures for all experiments in this study. To control for differences in word length across conditions as well as overall differences in participants' reading speed, a regression equation predicting reading time from word length was constructed for each participant, on the basis of all filler and experimental items (see Ferreira and Clifton, 1986). At each word position, the reading time predicted by the participant's regression equation was subtracted from the actual measured reading time to obtain a *residual reading time*. The resulting residual reading times are the dependent variable used in all analyses (**Tables 2–4** also include raw reading times, to provide a more interpretable scale for the effects).

For all analyses of reading time data, we used linear mixed-effects models (Baayen et al., 2008), and for question-answering data we used a logistic mixed effects model for binary data (Jaeger, 2008). The only fixed effect in our analyses was COMP(lementizer), taking values corresponding to the respective [+interrogative] or [−interrogative] complementizers, with subjects and items entered as random

TABLE 2 | Mean (standard error) comprehension question performance in percent correct as a function of condition, by subject.

da	*kdaj*
82 (1.9)	85 (1.7)

effects. Our constructed models utilized the maximal random effect structure with random intercepts for subjects and items and random slopes for the fixed effect term in subjects and items (Barr et al., 2013). We report *p*-values based on the likelihood-ratio test, whereby a model containing the fixed effect of interest is compared to a model that is identical in all respects except the fixed effect in question. The *p*-values are computed by treating the *t* statistic resulting from linear mixed effects analysis as approximately normally distributed (justified for datasets of our size; see Baayen et al., 2008), as also supported by visual inspection of residual plots which did not reveal any obvious deviations from homoscedasticity or normality. Analyses were performed using the lme4 package (Bates et al., 2014) in R (R Development Core Team, 2011).

Results

Data from five participants were omitted from all analyses because of overall poor comprehension question performance (<67% accuracy overall). No subjects were removed on the basis of slow overall reading time (>4 standard deviations from the mean across subjects). Consequently, data from 69 subjects were used in subsequent analyses. For these subjects, reading time data from items with incorrectly answered comprehension questions were excluded from the analysis. In addition, residual reading time data points that were greater than three standard deviations from the subject mean were also excluded. This affected around 1.0% of the data overall for this experiment.

Comprehension questions

Overall, comprehension questions following the experimental items were answered correctly in 84% of the trials. The percentages of correct answers for each condition are presented in **Table 2**. A paired *t*-test revealed no significant effects [$t_{(357)} = -0.37$, $p = 0.71$]. To control for item (and subject) variability, we also fit a logistic mixed effects model and obtained similar results of COMP not being a significant predictor for the question response accuracy [$\chi^2_{(1)} = 0.07, p = 0.7935$].

Reading times

For the primary analyses, we treated each of the 12 words within each item as its own region, according to the following schema:

(12)

Kritik	je	potrdil	da/kdaj	je	umetnik	izdelal	tisti	koš	v	svoji	delavnici
critic	is	confirmed	that/when	is	artist	created	this	basket	in	his	workshop
MSubj	Cl1	MV	COMP	**Cl2**	**Subj**	**V**	**Det**	**Obj**	FU1	FU2	FU3

Figure 1 and **Table 3** show average residual reading times for each of the 12 primary regions per condition.

There was no significant effect of complementizer type in the COMP region [$\chi^2_{(1)} = 0.71$, $p = 0.3987$]. Since COMP is selected and/or subcategorized by the matrix verb, the absence of variation suggests that the parser is equally likely to expect a [−interrogative] and [+interrogative] complementizer after the selecting verbs. This is in line with the special properties of the verbs we used in our materials: they support both types of subcategorization. This result persists across each of the four verbs used in the stimuli validating the design in terms of balancing different types of subcategorization for the same verb.

As **Figure 1** and **Table 3** illustrate, the interrogative *kdaj* sentences were read slower than the declarative *da* sentences in the post-COMP area until region 9 (Obj). We have defined two aggregation regions in accord with the two different kinds of theoretical predictions considered above. Recall that the first class of theories predicts that the storage costs for wh-adjuncts are distributed more or less in conformity with those for wh-arguments, that is, they are bound to the verb. Thus the first region, indicated by the smaller circle on **Figure 1**, spans the range of stimuli between Cl2, the first post-COMP element, and V. The second type of theory predicts that the endpoint of storage costs extends beyond the verb, namely, across the VP domain generally. Thus the second aggregation domain, indicated by the larger circle on **Figure 1**, includes the first and extends further to the direct object phrase, until the first follow up word FU1.

In the first aggregated region spanning the area from Cl2 until V, linear mixed models revealed a main effect of COMP, which however shows up with a marginal significance [$\chi^2_{(1)} = 3.365$, $p = 0.0666$]. In the second, larger, aggregated region, there is a significant main effect of COMP [$\chi^2_{(1)} = 5.3896$, $p = 0.0203$], with the relevant portions of *kdaj* clauses being read about 10 ms/word ± 3.9 ms/word (standard errors) slower than *da* clauses. We also asked whether there is a main effect of COMP specifically in the direct object area (Det + Obj) differentiating our two aggregated regions. This turned out to be the case [$\chi^2_{(1)} = 4.427$, $p = 0.0353$], indicating that the slowdown in *kdaj* clauses persists across this particular area. Finally, regions FU1-FU3 following direct object showed no main effect of COMP, suggesting that there is no significant difference in reading times between the two conditions [$\chi^2_{(1)} = 0.08$, $p = 0.7795$].

Discussion

There were three main results of this experiment. The first result is that storage costs obtain for the wh-adjunct *kdaj* "when," similarly to wh-arguments. This result holds under the assumption that the resource-consuming memory processes relevant for sentence processing involve both storage and

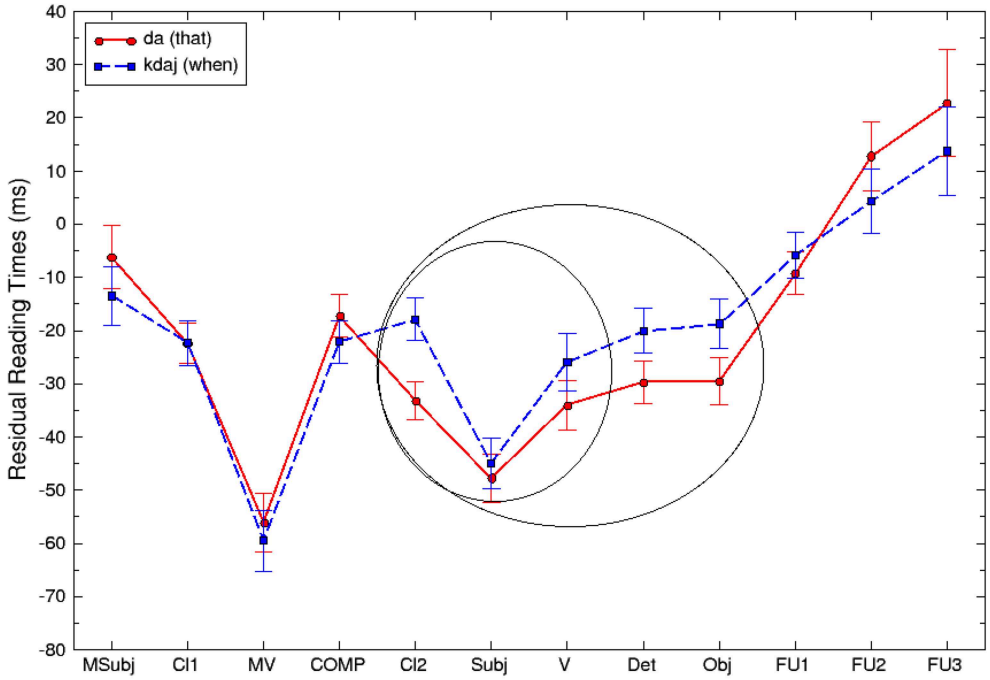


FIGURE 1 | Plot of mean (standard error) residual RTs per word by region in Experiment 1.

TABLE 3 | Mean residual RTs as ms/word by participants as a function of condition, for the post-COMP regions in Experiment 1, rounded to units (raw RTs in parentheses).

Region	*Da*	*Kdaj*
Cl2	−33 (421)	−18 (439)
Subj	−47 (443)	−45 (456)
V	−34 (459)	−26 (474)
Det	−30 (446)	−20 (459)
Obj	−29 (455)	−19 (473)
FU1	−9 (463)	−6 (469)
FU2	13 (502)	4 (499)
FU3	23 (520)	14 (504)

integrations into the partially processed structure, shared in some form by most theories of storage costs up to date. Since our compared conditions only differ in the COMP value, they involve the same number of integrations. Therefore, the increased reading times in the *kdaj*-condition is likely to be attributed to a storage effect. Furthermore, the temporal span of this effect suggests that it is related specifically to processing of *kdaj* which requires additional memory resources reflected in the reading slowdown.

The second result concerns the observed time-course pattern for the storage cost effect with respect to the predictions of the two classes of theories. If the first class of theories (the filler is associated with the verb) is correct, we should expect a significant difference across the first aggregated region, but not across the second. If the second class of theories (the gap is grammatically defined as following the lowest VP constituent) is correct, then we expect the storage cost effect across the second aggregated region, including the first region as well as the area differentiating the two regions. The results indicate that the latter is the case. We have seen that the difference in reading times persists until the end of the direct object area. Under the direct (feature-) association theories predicting association of the wh-adjunct with the verb, the continuing storage effect after the verb region would remain unexplained. At the same time the observed time-course pattern of the storage cost effect is consistent with the phrase structure theories predicting a gap, or the endpoint of the storage effect, after the direct object.

An alternative interpretation of this result, suggested by a reviewer, might be that the slowdown effect over the direct object area Det+Obj is due to (spill-over) integration costs, rather than storage costs *per se*. This interpretation would then be consistent with the theories which directly associate the gap with the verb, similarly to wh-arguments, and it would confine storage costs to the pre-V region only. While this possibility cannot a priori be ruled out given the design of Experiment 1, we believe it is unlikely to be the case. Such a scenario would imply that integration of a wh-adjunct filler is just too costly: it persists through a sequence of three items (V+Det+Obj) which takes considerable time (ca. 1.5 s; see **Table 3**). It is true that wh-adjunct fillers are semantically more complex than wh-arguments (see Section Base/Integration Points of Wh-adjuncts). However, the alleged difficulty appears incommensurable with the relatively simple semantics of *when* as well as with the general pattern of processing filler-gap dependencies generally. In particular, no spill-over effects have been reported in the previous studies

of filler-gap dependencies with wh-arguments (e.g., the ERP study of (Phillips et al., 2005) mentioned in Section Introduction observed a sustained P600 effect ending at the verb, interpreted by these authors as temporary storage cost). In addition, the fact that the post-V slowdown is restricted exactly to the entire direct object area (and not to some point before or after it) would be a suspicious coincidence under the spill-over scenario, whereas it is expected as a storage cost that conforms to the phrase structure-based theories (see above). Given these considerations, we continue to treat the direct object area as part of the relevant storage region.

The third result of Experiment 1, which stems from the second, suggests that the endpoint of the storage costs for a wh-adjunct can be a predictor of its potential gap position, or integration point. This result is important again in light of the grammatical theories that, due to excessive mobility of wh-adjuncts in the syntactic structure, often do not provide reliable diagnostics for their base position. The processing pattern is revealing in cases when the grammatical theory predicts more than one potential base position (see above), as well as in cases when it predicts a gap in a position different from the one found in a processing paradigm. An online processing study thus provides one with an efficient tool to carefully probe for the gap position in such non-trivial examples.

The results of this experiment are suggestive, but cannot be fully generalized because they are based on the processing of a single wh-item. It may be argued that the observed increased storage costs arise because of some specific lexical property of *kdaj* or, alternatively, because of some effect of interaction between this item and the syntactic structure independent of the storage cost effect. This experiment also raised an issue about the specific pattern of filler storage over the clausal subject regions. In particular, we would like to know whether the drop in the reading times is an idiosyncratic effect that occurs with specific wh-adjuncts, or representative of a more systematic pattern. Slovenian is a language whose grammar allows null/unexpressed subjects, so one could imagine a scenario where the storage cost effect expected over the subject would actually already be encoded over the preceding clitic (Cl2) region, given that this is a verbal clitic morphologically specified with the morphosemantic features of the subject (person, number, gender). Consequently, for instance, under the distance-based theory of storage costs reading the actual subject would not count toward calculating the overall storage costs for the wh-adjunct. Finally, not all wh-adjuncts are created equal. Unlike wh-arguments that are usually NPs with predicted syntactic behavior dictated by thematic considerations, wh-adjuncts may differ dramatically from each other from a syntactic point of view. There is thus an important question as to whether other wh-adjuncts elicit a similar kind of a storage cost effect, possibly correlating with their lexical, syntactic and semantic properties. Experiment 2 addresses these issues.

Experiment 2: English *how quickly* and *why*

Experiment 1 was concerned with the wh-adjunct *when* in Slovenian, which falls under the category of VP-modifying adverbs attached relatively low in the syntactic tree (see **Table 1**). Experiment 2 uses English materials in a self-paced reading task and takes the investigation of storage cost effects in wh-adjunct dependencies further. The goal of this experiment was threefold. First, we wanted to replicate the Slovenian pattern of storage costs in a language in which storage costs for wh-arguments have been previously investigated in reasonable detail and at present are better understood (see Section The Lexically-based vs. Syntactically-based Views on Storage Costs), with the aim to strengthen the cross-linguistic dimension of our inquiry. English is a natural choice in this regard. Second, now that there are reasons to believe that wh-adjuncts elicit storage costs as much as wh-arguments do, the main question we ask is whether these storage costs correlate with the syntactic base position of a particular wh-adjunct, along the lines outlined in Section Endpoint of the Storage Costs. Thus in Experiment 2 we focused on the comparison between the VP modifier *how quickly* and the wh-adjunct *why*. As shown in the syntactic literature, the syntactic behavior of *why* is quite different from that of VP-modifying adjuncts, and the most robust grammatical evidence for that again comes from English (see Section Storage Cost Predictions for *why*). Since we wanted to compare the patterns of storage costs for these two modifiers, our corresponding processing predictions can therefore be better grounded in this language.

Yet another goal of Experiment 2 was to more closely investigate the integration point of the wh-adjunct in light of the relevant storage costs. Experiment 1 showed that the parser may have to wait until the direct object is parsed in order to integrate the wh-adjunct. In this respect, we were interested in the role of the Active Filler Strategy as the parser's tendency to fill the adjunct gap as soon as possible. In particular, in cases of complex direct object phrases such as *a glass of water,* does the parser wait for bottom-up evidence that the end of the direct object constituent has been reached in order to discharge the wh-adjunct, or does it do it as soon as this becomes grammatically permissible - in our example, upon encountering *a glass* (and not waiting till the end of the direct object to determine whether the phrase is complete)? This question gains particular importance in light of the proposals in the literature that derive the Active Filler Strategy from a requirement to saturate a thematic role of the wh-filler as soon as possible (Pritchett, 1992; Gibson et al., 1994; Aoshima et al., 2004). If the Active Filler Strategy is indeed a thematic-oriented strategy, it should not be relevant in the case of wh-adjunct processing. On the other hand, if the Active Filler Strategy is, in principle, independent of the thematic factor (and may or may not interact with it), then it, or some version of it, should apply in the case of wh-adjunct dependencies also, and the gap should be filled on the first grammatically permissible occasion.

Storage Cost Predictions for *how quickly*

Syntactically, *how quickly* is a low, VP-modifying adjunct, and in this property it is similar to *kdaj* used in Experiment 1. Both items also have a comparable semantic status of event modifiers. Processing-wise, *how quickly* may be slightly more complex than

kdaj because it contains an additional word[6]. For the purposes of this experiment, we will, however, treat *how quickly* as a single unit (both words were presented simultaneously to participants). Given the results of Experiment 1 using the VP adjunct *kdaj*, we expect a storage cost effect for *how quickly* across a range of input extending between the filler and the syntactically determined gap site or endpoint, which would comport with the filler's VP-modifying syntactic status. The presence of a storage effect of *how quickly* would provide further evidence strengthening the empirical validity of storage costs incurred by VP-modifying adjuncts, both on a cross-item as well as on a cross-linguistic basis.

Storage Cost Predictions for *why*

Our particular interest in *why* in the present study is dictated by the growing consensus in grammatical research that the syntactic and semantic status of *why* is principally different from that of VP-modifying adjuncts like *how quickly* and *when*. Specifically, *why* has different scopal properties, different restrictions on co-occurrence with other wh-phrases, different behavior under syntactic ellipsis, sentential negation and other root phenomena (e.g., Subject-Aux inversion), compared to the other wh-adjuncts. *Why* also has semantic properties that make it different from the other *wh*-adjuncts. Whereas the latter are either event or predicate modifiers, *why* is a functor over an entire proposition (thus a question *Why did John leave the room?* has some sort of a proposition as the answer, e.g., *Because he was hurrying,* rather than a predicate modifier such as *quickly*). As an explanation for this differing behavior, it has been proposed in the syntactic literature that *why* is base-generated in its surface syntactic position in COMP at the left periphery of the sentence, or in a position very close to COMP (Bromberger, 1992; Rizzi, 2001; Stepanov and Tsai, 2008; Shlonsky and Soare, 2011). This amounts to the claim that *why* does not instantiate a filler-gap dependency in the usual sense of a long-distance dependency requiring encoding, storage and subsequent retrieval of the wh-filler. Under the standard compositional semantics approach, if *why* is a functor of propositions, *why* would then be interpreted as a sister of a syntactic node denoting a proposition, which is consistent with its base-generation at the clausal left periphery.

These syntactic and semantic accounts make a very clear prediction for a psycholinguistic study: if *why* does not initiate a filler-gap dependency, then there should be no storage effect in the case of *why*, as opposed to *how quickly*. All else equal, processing-wise, *why* is predicted to behave similarly to the complementizer *that* in a pair of sentences like (13): both expect a proposition afterwards.

(13) a. Peter knows that John fixed the car
b. Peter knows why John fixed the car

We thus expect that *how quickly* and *why* will show a contrast in terms of expected storage costs. While *how quickly* should elicit storage costs similarly to Slovenian *kdaj*, *why* is not expected to elicit any additional storage costs compared to the *that* control. Experiment 2 tests this prediction for English.

Methods

Participants

Eighty seven adult volunteers from the Glasgow community in the UK participated in this experiment voluntarily for no material compensation. All participants were recruited via email and social networking forums. All declared themselves as monolingual native speakers of English and were naïve to the purposes of the study.

Materials

Twenty-four sets of sentences with embedded clauses were carefully constructed[7]. Similarly to Experiment 1, the sentences in each set were exactly identical except for the value of the embedded COMP(lementizer). This time COMP takes one of the three possible values, each defining the respective condition: (1) *that*; (2) *why;* and (3) *how_quickly*. To control for the length of the wh-dependency, all sentences were made exactly 15 words long and matched by syllable structure to the best extent possible. An example is given in (14)[8]:

(14) The reporter didn't know *that/why/how_quickly* the soldier shot the panel of doctors in the hospital

Similarly to Experiment 1, each sentence begins with a four-word main clause including a two-word subject, a verbal modifier (e.g., negative *didn't* or an adverb) and a main verb in past tense. The main verbs were chosen so that they may embed either a wh-interrogative clause, or a declarative *that* clause. We chose four such ambiguously subcategorizing verbs: *know, forget*, *explain,* and *find_out*, which were equally represented among the set of experimental items (six instances each). The fifth word is the embedded Complementizer appearing in one of the three versions outlined above. Words six through twelve represent the main area of interest as they correspond to the verbal argument structure. The sixth and seventh words are always an embedded subject of the definite description type [the N], and the eighth is the embedded verb.

Words nine through twelve represent the direct object, which was always of the form [the N of N]. The first N is always

[6] As pointed out at the beginning of Section Experiment 1: Slovenian kdaj ("when"), using *when* in English can potentially be confounded by its lexically ambiguous status. Other simplex wh-adjuncts in English like *where* and *how* might be subject to similar concerns if used in embedded clauses, as in our study.

[7] Preparation of the English materials and subject recruitment for Experiment 2 was implemented by Calum Riach (see Riach, 2014, supervised by the first author).

[8] A reviewer raises a concern about potentially greater pragmatic oddity/implausibility of the *how quickly* sentences as compared to the *why* counterparts, which could then lead to an increase of reading times for the former in the post-verbal (direct object) region. Even though we controlled for general plausibility upon constructing the items, we conducted an additional norming-like evaluation with the aim to see if our items are biased in this direction. We asked two native speakers of English who were not involved in creating the items, to indicate, for each item, which version out of the two sounded more natural (plausible) to them, compared to the other. Both speakers preferred the *why* reading slightly more often (by 4 and 5 items out of 24, respectively) than the *how quickly* reading. We then fit mixed effects models entering preference as a fixed factor along with COMP, asking whether preference affects the reading times, in the direct object area. We found no main effect of preference ($p = 0.2246$ and $p = 0.6839$, respectively) and no interaction with the factor COMP. This suggests that the post-verbal reading times are not affected by pragmatics/plausibility, at least in obvious ways.

lexically ambiguous between a standard noun and a classifier, e.g., *glass*. The second N is either a mass noun (*water*) or bare plural (*doctors*). The reason why the direct object was intentionally made structurally more complex has to do with investigating the Active Filler Strategy. If this, or similar strategy requiring gap filling as soon as possible is in place also for wh-adjuncts, we would expect the end of storage costs to occur after the first N, given a possible gap site at this location in the context of the partially processed input. Conversely, if the Active Filler strategy is not operative in the case of wh-adjuncts, then, under the assumption that phrase structure (still) guides the integration point, the gap would be expected at or after the second N. In other words, in a sentence like *I don't know how quickly John finished the drink of beer* integration of *how quickly* may occur either after *drink,* or after *beer*. The remaining three words in the sentence (words 13–15) always describe a location of the event in the form of a prepositional phrase compatible with the specification expressed by *where*.

The target sentences were split into individualized lists balancing all factors in a Latin Square design, so that a different such list is activated for each participant by the experimental software. Each such list was combined with 50 filler sentences of various syntactic types and of comparable length. The order of stimulus presentation was also pseudo-randomized separately for each participant and it was ensured that the presentation begins with a filler and that at least one filler intervenes between any two target items. A complete list of target items is provided in Supplementary Material.

The procedure was identical to the procedure in Experiment 1, except that half of the filler sentences were accompanied with a yes-no comprehension question. Computation of residual reading times and the statistical analysis procedures all followed those used in Experiment 1. In addition, Tukey's pairwise comparisons were performed on our fitted models using the *glht()* function in R's "multcomp" package (e.g., Hothorn et al., 2008).

Results

Ten subjects were excluded because of coding errors that led to distorting stimulus presentation in several trials. In addition, six subjects were excluded due to low comprehension question accuracy (<67%) and/or low overall reading time (>4 standard deviations from the mean across subjects). This left the data from 71 subjects to be used in the analyses. Overall, comprehension questions were answered correctly in 88% of the trials. Residual RT data points (pooled across all regions and conditions) that were greater than three standard deviations from the mean were excluded from all analyses, affecting around 1.4% of the data overall for this experiment.

For the primary analyses, we treated each of the words as its own region (omitting the main clause area). **Figure 2** and **Table 4** show average residual reading times for each of the 11 primary regions per condition.

We have then defined four aggregated regions of interest, as shown in (15):

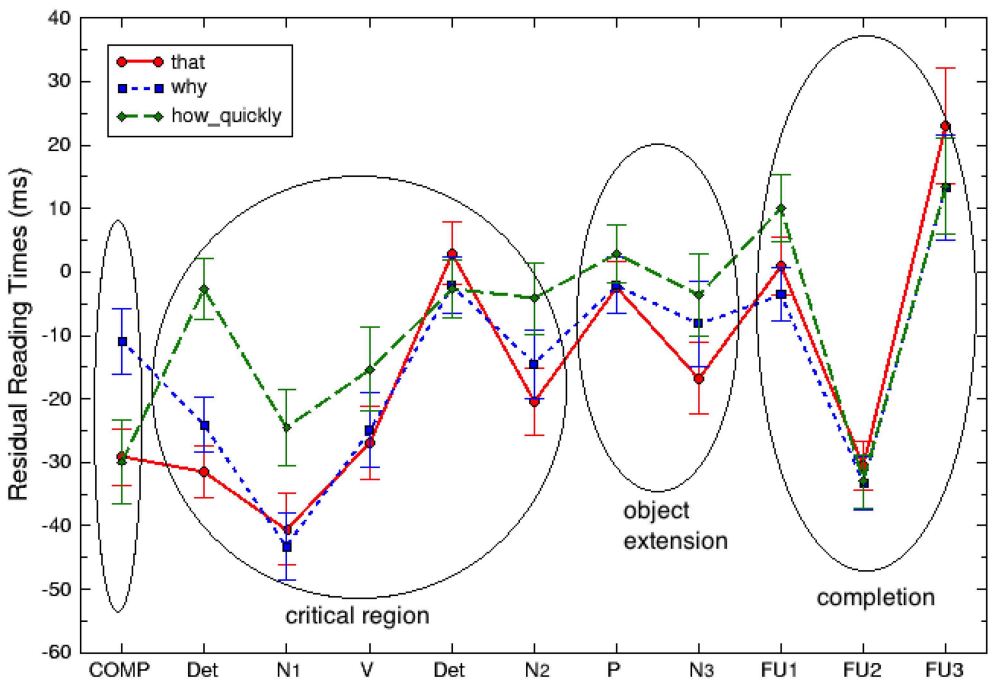

FIGURE 2 | Plot of mean (standard error) residual RTs per word by region in Experiment 2.

(15)

that / how_quickly / why	the	soldier	shot	the	panel	of	doctors	in	the	hospital
COMP	**Det**	**N1**	**V**	**Det**	**N2**	P	N3	FU1	FU2	FU3
	CRITICAL REGION					OBJECT EXTENSION		COMPLETION		

The first region includes embedded COMP which takes one of the three condition-defining values, *that, why* or *how quickly*. Following that is the critical region which represents components of the argument structure of the embedded verb. The object extension is always an *of*-phrase (see above). The final region is a locative PP including three follow-up words. **Table 5** includes estimated mean residual as well as raw reading times, illustrating a per region comparison among the three conditions.

At the leftmost COMP region, there is a significant variation in reading times [$\chi^2_{(2)} = 6.2785$, $p = 0.04331$]. *Post-hoc* Tukey estimations among the pairs of conditions indicate that *why* is read slower than both *that* and *how quickly* (pair *why/that*: $z = 2.157$, $p = 0.0783$; pair *why/how_quickly*: $z = -2.889$, $p = 0.0105$; pair *that/how_quickly*: $z = -1.146$, $p = 0.4844$). The tendency to read *why* slower than *that* and *how quickly* persists across each of the four subgroups of items defined by the respective embedding verbs (*know, forget, explain, find out*) calculated separately, though does not quite reach significance within any of the subgroups ($p > 0.05$). With respect to the *why*/*that* and *how_quickly*/*that* pairs, this result appears to contrast with Experiment 1 where there were no notable differences in the rate of reading *da* and *kdaj*.

Moving on to the critical region, linear mixed models revealed that COMP significantly affects reading times across the range until the first N of the direct object, the first suspected integration site of the wh-adjunct dependency [$\chi^2_{(2)} = 8.5873$, $p = 0.01365$], with the *how quickly* clauses being read about 12 ms/word ± 4.3 ms/word (standard errors) slower than the corresponding *that* clauses, and the *why* clauses virtually not affected at all with a difference of 0.3 ± 4.3 ms (standard errors) from the *that* clauses. Post-hoc pairwise Tukey comparisons confirm that the critical region of *how quickly* clauses was read significantly slower compared to *that* clauses ($z = 2.830$, $p = 0.01284$). *How quickly* clauses were also read slower than *why* clauses ($z = 3.335$, $p = 0.00241$). Finally, *why* clauses in the critical region were read with a rate similar to that of *that* clauses ($z = -0.459$, $p = 0.89048$).

In the context of estimating an endpoint of the storage cost effect and a possible impact of the Active Filler Strategy, we also asked whether the slowdown in the reading times for the *how quickly* clauses persists specifically over the part of the direct object area (Det+N2), similarly to Experiment 1. We found that, in that sub-region, *how quickly* clauses are read about 8 ms/word slower than the *that* clauses and about 5 ms/word slower than the *why* clauses. However, the effect does not reach significance [$\chi^2_{(2)} = 2.60$, $p = 0.27$].

As **Figure 2** demonstrates, *how quickly* clauses also tend to be read slower in the object extension region (the *of*-phrase), all the way up to the first follow-up word FU1. However, no main effect of COMP was estimated at the object extension region overall [$\chi^2_{(2)} = 2.1047$, $p = 0.3491$], or at each of the two word regions comprising it [region P: $\chi^2_{(2)} = 2.6271$, $p = 0.2687$; region N_3: $\chi^2_{(2)} = 2.2795$, $p = 0.3199$]. Finally, at the completion region (locative PP) no significant difference in reading times across the three conditions is observed either [$\chi^2_{(2)} = 0.6078$, $p = 0.7379$].

Discussion

There were three main results of this experiment. The first notable result was the replication of the pattern of reading times observed in Experiment 1. In particular, *how quickly* clauses were read slower than *that* clauses in the critical region. Since, as in Experiment 1, the number of structural integrations is the same, the slowdown is likely to be due to a storage effect.

Furthermore, since both *how quickly* and Slovenian *kdaj* ("when") share key syntactic characteristics typical for VP-modifying adjuncts, it can be concluded that such adjuncts elicit a storage effect similar to the one reported previously for wh-arguments, namely subjects and objects, and, furthermore, that this effect may be language-independent.

The second result of Experiment 2 was divergence of the patterns of the storage costs for *why* and *how quickly*. These diverging patterns would seem puzzling at face value, but they receive a natural explanation if grammatical considerations are taken into account. Since, *how quickly* needs to be kept in memory long enough to reach its integration point in the VP domain, storing it incurs a tax, much along the lines of the previous research on temporary storage of wh-arguments. At the same time, *why* does not need to be kept in memory (or it does for a very short time) because its integration site is more or less at the point where it is encountered. In this respect *why* behaves like a declarative complementizer. This result suggests that grammatical rules concerning base-generation of wh-adjuncts may serve as a reliable predictor of their storage costs, and, conversely, that observed storage cost effects provide processing evidence for the grammatical statements regarding the base position of specific (wh-)adjuncts in the syntactic structure of the sentence.

The third result, related to the second, concerns the endpoint of the storage costs for *how quickly*. Recall that inclusion of the *of*-phrase into the direct object region was motivated by our interest in the role of the Active Filler Strategy in wh-adjunct dependencies. In particular, if this or similar strategy is active, the endpoint should be observed at or around the right boundary of the critical region. If it is not active, then, under the phrase structural restrictions, we would expect the storage effect also over the object extension, the integration point then being at or right after that region.

We observed no significant difference in reading times in the direct object region, even though there is a tendency to read *how quickly* sentences slower than both *that* and *why* sentences, in that region. Thus, we did not fully replicate the result of Experiment 1 which revealed a reliable difference in the reading times between *kdaj* and *da* sentences in the direct object area. Based on the results of Experiment 1, we concluded that the parser consults the relevant phrase structural information while attempting to integrate the wh-adjunct. Given that, the reason why the English participants did not show a difference in the reading times in the direct object area following the verb could be because the grammatically permissible integration point of the adjunct *how quickly* is not the same as that for the wh-adjunct *kdaj* ("when") namely, following the direct object. As we saw in Section Base/Integration Points of Wh-adjuncts, the grammatically licensed base position of adjuncts may be either pre-verbal or postverbal. It might be, then, that the base position of *how quickly* is actually preverbal [cf. example (ib) in fn. 2], and if so, the parser would not have to wait until the direct object in order to integrate this wh-adjunct.

The materials in Experiment 2 contained complex object noun phrases such as *the panel of doctors*. We wanted to see if the storage cost effect ends after the first, or second noun, in order to determine whether the Active Filler Strategy is operative in the case of wh-adjunct dependencies. The results of Experiment 2, namely, the absence of a reliable effect both at the first noun (in the Det+N2 region) as well as across the entire direct object area, do not permit us at this point to make a definitive conclusion in one or the other direction. Thus the possibility that the Active Filler strategy applies also in the case of wh-adjunct dependencies, cannot be ruled out.

A somewhat surprising accompanying result of Experiment 2 was a slowdown in reading the embedded *why* item itself, compared to reading times for embedded *that* and *how quickly*. The relevance of this result lies in the domain of processing subcategorized information, in particular, subcategorized complementizers. With respect to the *why/that* pair, this contrasts with Experiment 1 where there were no notable differences in the rate of reading *kdaj* vs. *da* in Slovenian. It is not clear whether verbal subcategorization for a specific question word should lead to an increased processing effort reflected in reading times, or the observed difference in reading time is simply a baseline effect. Grammatically, the verbs selected for this experiment are equally likely to select for any wh-item, or for a declarative complementizer. Previous studies on filler-gap dependencies in embedded interrogatives (notably fewer than those that investigate filler-gap dependencies in relative clauses with an invariant relativizer such as *which*) did not report any difference in reading times at the embedded COMP, e.g., between wh-arguments vs. complementizer *if* (Stowe, 1986; Lee, 2004). A number of processing factors may in principle modulate expectations for a particular subcategorization frame. For instance, studies of garden path effects suggest that verb subcategorization frequencies have an immediate effect on sentence processing (Trueswell et al., 1993; Garnsey et al., 1997; Hare et al., 2003; Snedeker and Trueswell, 2004, see also Mitchell, 1987). One may also estimate predictability of a specific verbal subcategorization by calculating its conditional probability in the context of a subcategorizer, based on corpus data (cf. Levy, 2008). **Table 6** lists predictability of each of the three COMP items for each of the four embedding verbs. As **Table 6** indicates, for every verb with the exception of the *explain-why* bigram the predictability drops along the continuum *that-how-why* (we take the predictability of *how* to be representative for estimating the reading time for *how_quickly*). If predictability (negatively) correlates with reading times logarithmically (Hale, 2001; Levy, 2008), then it is in principle possible that the reading times increase past some critical threshold in predictability, thus making *why* read slower. It is also possible that *why* is read slower because it is different from other wh-adjuncts, as well as from the complementizer *that*: as pointed out above, it is a functor over propositions, as opposed to VP adjuncts that are

TABLE 6 | Co-occurrence of the target verbs with respective COMPs, calculated as conditional probability P(COMP |VERB) = P (COMP ∩ VERB)/P(VERB), where P (COMP ∩ VERB) is a probability of the respective bigram, based on the British National Corpus (Mark Davis/Brigham Young University, http://corpus.byu.edu/bnc/).

Context/COMP	*that*	*how*	*why*
know	0.083	0.033	0.011
forget	0.097	0.017	0.002
explain	0.082	0.047	0.078
find out	0.042	0.068	0.023
MEAN	0.076	0.04125	0.0285

predicate modifiers, and to *that* which is just a clause-introducer. Or, again, this could be just a baseline artifact. To further clarify this issue, the follow up Experiment 3 was conducted.

Experiment 3: *why* vs. *that*

Experiment 3 had the same design as Experiment 2. This time we concentrated only on the subcategorization aspects of COMP, asking whether reading the subcategorized *why* takes additional processing effort compared to reading the embedded *that*.

Methods

Participants

The procedure of subject recruitment was similar to Experiment 2. 26 English-speaking monolingual subjects volunteered to participate in this study for no material compensation.

Materials and Procedure

Experiment 3 used a subset of the English materials used in Experiment 2. We used the same 24 target items but this time COMP only had values *that* and *why*. The rationale for choosing these items was to control for the (absence of) possible filler-gap effects at COMP, given that neither of these items instantiate a filler-gap dependency proper, as Experiment 2 has demonstrated.

Subjects saw 24 items in a pseudo-randomized order, interspersed with 52 fillers. Similarly to Experiment 2, half of the filler items were accompanied by a comprehension question.

Results and Discussion

Overall, comprehension questions were answered correctly in 87% of the trials. No subject was excluded on the basis of comprehension accuracy or slow overall reading times (>4 standard deviations from the mean across subjects). Overall, comprehension questions were answered correctly in 87% of the trials. Residual reading time data points that were greater than three standard deviations from the mean were excluded from all analyses, affecting around 0.8% of the data for this experiment.

There was no main effect of COMP at the embedded complementizer [$\chi^2_{(1)} = 0.768$, $p = 0.3808$]. This suggests that subcategorization does not affect the reading times of complementizers *that* and *why*. Although with only 26 participants this experiment had less statistical power than Experiment 2, this result largely corroborated that of Experiment 1. However, there is still a tendency to read *why* slower than *that*, by about 5–20 ms depending on the matrix verb [mean overall RRT (*that*) = −11 ms; mean overall RRT (*why*) = −1 ms]. Thus, if a predictability effect of the kind outlined above exists, it is very weak and requires a substantially larger statistical sample than the population size in this study to reliably reveal itself.

General Discussion

In the beginning of this article, we viewed wh-adjunct interrogatives as an important and previously under-investigated empirical ground for testing theoretical predictions pertaining to the following aspects of storage costs in filler-gap dependencies: (1) the thematic factor and the role of lexically-based strategies of computation of online storage costs; and (2) the processing and grammatical predictions concerning the endpoint of the storage costs, also in the context of the Active Filler strategy. Below we evaluate the main results of this study in light of these aspects, and point to some further issues.

The Thematic Factor and the Lexically-based Strategies Revisited

Both Experiment 1 and Experiment 2 showed a reliable storage effect related to wh-adjuncts modifying a verbal phrase (VP), that is, Slovenian *kdaj* "when" and English *how quickly*. This effect is not predicted by the class of the theories that calculate temporary storage costs in terms of the number of unassigned/incomplete thematic roles (Hakuta, 1981; Gibson, 1991), as well as in terms of the number of unassigned/incomplete Case features (Stabler, 1994). The reason is that, being non-referential syntactic entities, wh-adjuncts do not receive a thematic role from the verb, and they generally do not need Case from the verb, their Case feature being satisfied either adjunct-internally (as in the case of wh-adjunct PPs such as *on which table*), or absent at all, as in the present study. On the other hand, our results support the class of storage cost theories that do not make reference to the thematic, Case or referential status of the filler. These include theories that estimate storage costs in terms of temporarily stored incomplete phrase structure rules or their close counterpart such as the SLASH feature of HPSG (see Section The Lexically-based vs. Syntactically-based Views on Storage Costs), as well as in terms of the number of incomplete syntactic heads (Gibson, 1998, 2000). These latter theories can thus be extended to wh-argument as well as wh-adjunct dependencies.

Note that the relevant principal distinction between these two classes of theories of storage cost metric lies in the amount of theoretical weight they place on a (lexicon-oriented) internal featural specification of the filler as opposed to its (syntax-oriented) structural environment. The Case/thematic role metrics of storage costs capitalize on the thematic argument and/or the NP status of the filler. Even though theta-roles, as well as Case, have always been commonly understood as part of the syntactic computation in the grammar, it was also clear that they have a strong lexico-semantic component. In contrast, the incomplete phrase structure and incomplete syntactic head metrics of storage costs capitalize on the syntactic status of the filler, that is, its structural relation with respect to other syntactic constituents specified at the level of syntax, as in the former case, or syntactic-head driven expectations, as in the latter. Our results thus support a more syntax-oriented and less lexicon-oriented view of temporary storage costs in filler-gap dependencies[9].

This view harmonizes with the grammatical status of (wh-)adjuncts. Since wh-adjuncts, unlike wh-arguments, are not grammatically associated with the verb directly, the integration point of a wh-adjunct in a filler-gap dependency, or its gap

[9]It should be noted that in phrase structure theories such as HPSG (see Section The lexically-based vs. Syntactically-based Views on Storage Costs) the distinction between the lexical and syntactic modules is not as clear cut as in other phrase structure theories (for instance, the transformational generative grammar). But even in that framework, the SLASH feature assigned to a lexical head (e.g., verb) is basically part of the syntactic computation establishing a relation between that head and other syntactic elements in the structure, thus the relevant processing predictions for a filler-gap dependency could arguably be made, again, on a syntactic basis.

site, is not signaled by the relevant stimulus encountered in the input (viz. the verb). Rather, it is determined on the basis of computing an abstract syntactic node [cf. (4)] with which the wh-adjunct can be associated, in the partially processed input. It is thus reasonable to suppose that the temporarily stored information associated with the syntactically constructed host, is itself of a syntactic nature, so that this kind of computation can be performed at the same, syntactic, level. This is consistent with the modular theory of parsing (Fodor, 1978), where storing and integration can potentially be performed during the first, syntactic, pass, as well as with the interactive theories, with a qualification that no access to non-syntactic (e.g., thematic) sources of information would be needed in the case of wh-adjuncts.

The Active Filler Strategy Revisited

The Active Filler Strategy (see Section Endpoint of the Storage Costs) was originally formulated independently from the subcategorization or theta-role assignment properties. A number of later works (e.g., Pritchett, 1992; Gibson et al., 1994; Aoshima et al., 2004) argued that the Active Filler Strategy in filler-gap dependencies reduces to the parser's need to satisfy thematic requirements of the fronted wh-phrase as soon as possible. The results of our study did not rule out the possibility that the Active Filler Strategy is operative also in wh-adjunct dependencies that are not thematically-based. If this possibility ultimately turns out to be true, that line of argument would be questioned. In this regard, we would like to briefly revisit some of the empirical evidence offered in the literature in support of recasting the Active Filler Strategy in thematic terms and consider an alternative, non-thematic interpretation of that evidence.

One empirical argument in favor of reinterpreting the Active Filler Strategy in terms of thematically-based statements comes from Aoshima et al. (2004) and is based on their experimental investigation of the Active Filler effect in Japanese, an SOV language where objects precede verbs. Aoshima et al. (2004) considered sentences with a left-scrambled wh-word that was an object of the verb in the embedded clause, as in (17) [their (7b)] which is interpreted as an embedded wh-question. Note the question word *–ka* marking the scope of that embedded question and appearing as a verbal suffix: this marker is obligatory in that context and is taken to be an interrogative complementizer:

(16) a. Dare-ni John-wa [Mary-ga sono hon-o
whom-dat John-top Mary-nom that book-acc
ageta-ka] itta.
gave-Q said
"John said to whom Mary gave that book."

The authors provide experimental evidence that the Japanese readers associate the scrambled wh-word with the most embedded clause of a multi-clause sentence (given the presence of the matrix subject). They argue that the wh-phrase *dare-ni* is already associated with the (bracketed) embedded clause even before the embedded verb is encountered, on the basis of a Japanese counterpart of the "filled gap" effect (Stowe, 1986, see also Section Endpoint of the Storage Costs). In particular, the readers show a surprise effect if instead of the marker–*ka* they encounter a different marker–*no* in the same context. The authors argue that if the parser's goal were simply to create a gap as soon as possible, then there would be no motivation to interpret the fronted wh-phrase inside the (most) embedded clause. Rather, the parser would posit a gap in the main clause (after the subject *John-wa*), and that gap would then be unaffected by further (embedded) structure. On the other hand, the embedded clause interpretation is expected, if the parser's objective is to satisfy thematic requirements of the verb or of the wh-phrase: the most embedded clause in an SOV language provides the first opportunity to accomplish that. In that case, the authors argue, the parser "repositions" the main clause gap as an embedded clause gap by reanalysis. On these grounds, they conclude that the Active Filler Strategy is a thematically-driven strategy (the authors also argue that the active search initiated by the parser in order to integrate the wh-phrase cannot be driven solely by the requirement to associate with the question marker; see this work for details).

The argument thus builds on the observed parser's tendency to search for the first available verb to associate with the wh-filler (see also Pritchett, 1992; Gibson et al., 1994 for similar arguments). A thematic association is indeed a natural explanation of this tendency, but, we believe, not the only one. Indeed, an association of the argument wh-filler with the verb can also be accomplished by a phrase structure rule such as V → NP V, whereby the verb is a right sister of the relevant phrase. From the perspective of the parser, a lexical strategy such as "this wh-phrase must be a thematic argument of some verb, let's go and find that verb as soon as possible" is equally plausible as a syntactic strategy such as "this wh-phrase must be a structural sister of some verb, let's go and find that verb as soon as possible." In the scenario of incremental structure building considered above, this amounts to storing the relevant phrase structure rule with an open slot (a verb in this case) in the working memory until a suitable candidate for filling in the slot is found, fully consistent with the theories of incomplete phrase structure rules. For the case of wh-arguments associated with verbs, the two strategies are virtually indistinguishable. They have the same empirical consequences, since the grammatical theory tells us that theta roles are assigned in a very local structural configuration, easily expressible with the usual machinery of phrase structure rules (e.g., Haegeman, 1994). Wh-adjuncts, however, provide a useful empirical ground for distinguishing the two strategies. The thematic/lexical strategy is not easy to restate in this case, precisely because thematic considerations are irrelevant here, whereas in the syntactic strategy, all that is needed is just to replace the relevant phrase structure rule (e.g., VP → VP Adj). The syntactic strategy additionally implies that the parser is sensitive to abstract syntactic nodes as well as to lexical items, but this is a common assumption made in the parsing literature which is simply reinforced here. A different version of a syntactically-oriented strategy is de Vincenzi's (1991) re-interpretation of the Active Filler Strategy in terms of his Minimal Chain Principle: "Avoid postulating unnecessary

chain members at S-structure, but do not delay required chain members" (p. 13).

Processing Evidence for the Base Position of Wh-adjuncts

The results from Experiment 1 and Experiment 2 are also relevant for grammatical theories regarding the base location of particular adjuncts. As mentioned in Section Base/Integration Points of Wh-adjuncts, the flexible phrase structural status of syntactic adjuncts makes it often difficult to pinpoint their base position for the purposes of explanatory syntactic analyses. This is in contrast with wh-arguments, whose base positions are usually trivially (modulo linear directionality of arguments as a parameter distinguishing, for instance, SVO from SOV languages) deduced on the basis of the linear positions of the respective predicates. With regard to wh-adjuncts, the endpoint of storage costs may provide a valuable, though admittedly indirect, processing evidence regarding these base positions. For instance, in Experiment 1 the object is a noun phrase. The end of the storage costs appears to be marked at or around the end of that noun phrase. Thus, by adjusting for the incremental character of online sentence processing, one may make an informed guess about the narrow structural area where the gap postulated by the mental grammar must lie, for each particular wh-adjunct under consideration. At the very least, the processing pattern provides us with a reasonable idea regarding directionality of the wh-adjunct gap relative to the verb. Furthermore, the absence of a continuing storage costs pattern for *why* observed in Experiment 2 is compatible with predictions of the grammatical theory regarding the non-postulation of the gap for this item. We thus have a reason to believe that the endpoint of storage costs may provide useful processing evidence for the grammatical theory of wh-adjuncts.

Overall, our results in Experiment 1 and Experiment 2 suggest that the role of the thematic factor in parsing should not be overestimated. While there is good evidence that the parser is generally sensitive to the argument structure of verbs (e.g., Rayner et al., 1983; Clifton et al., 1991; Friederici and Frisch, 2000), as far as filler-gap dependencies are concerned, the argument structure cannot be the (only) type of information that the parser makes use of during the temporary storage of the filler. Storage costs as a measure of complexity in parsing wh-adjunct dependencies suggest that phrase structure must play a role as well. In this respect, our results are consistent with the theories of integration costs employing complexity metrics of integration that do not take into account thematic information, but are based on different units of comparison, such as the number of intervening discourse referents. Our results are also consistent with the recent proposal that information from preverbal NPs may be sufficient to trigger active gap creation without having access to the verbal information including argument structure, in a kind of "hyper-active" manner (Omaki et al., 2015). In other words, the verb may not play an instrumental role in filler-gap dependencies even in the case of wh-arguments after all. In conjunction with our results on storage effects, this raises an interesting question as to whether the thematic factor can be dispensed with altogether in the processing theories of filler-gap dependencies, and replaced with the corresponding phrase structural statements. Note that in the case of wh-arguments, the thematic information is largely mirrored with the phrase structural information (this state of affairs is formalized in grammatical theory in various forms, such as "the Projection Principle," cf. e.g., Chomsky, 1986). Thus a direct object is usually a sister of the transitive verb, and a subject is a sister of the VP. Further relevant tests for probing the role of the thematic factor independently of phrase structure may potentially include thematic and non-thematic uses of *where,* as in *where did John V the book?* in conjunction with verbs like *put* (thematic) and *see* (non-thematic), and similar constructions for other wh-adjuncts.

Concluding Remarks

The present study provided converging cross-linguistic evidence from Slovenian and English, two languages belonging to different language families, that processing filler-gap dependencies with wh-adjuncts as fillers elicit storage costs across the range of the filler-gap dependency ending approximately at the points predicted by the grammatical theories for particular adjuncts. Our findings provide evidence to the class of storage cost models that are based on computation of the number of incomplete phrase structure rules or, alternatively, the number of incomplete syntactic heads. Our results underscore the non-thematic character of storage costs, and at the same time support the principle-based approach to parsing that draws on grammatical knowledge, specifically phrase structure, as a primary source of parsing decisions (Berwick and Weinberg, 1984; Pritchett, 1988, 1991, 1992; Gibson, 1991; Gibson et al., 1994; Weinberg, 1999).

Acknowledgments

This research was supported in part by the Heisenberg Fellowship of the German Research Foundation to the first author (STE-1851/1) and by the Slovenian Research Agency (program No. P6-0382). We are grateful to the two reviewers and Topic Editor Matthew Wagers for helpful comments and suggestions, and to Calum Riach, Petra Mišmaš, Jeremy Yeaton, Beth Phillips and Viviane Déprez for valuable assistance. Portions of this material were presented at AMLaP-2014 at the University of Edinburgh.

An fMRI study dissociating distance measures computed by Broca's area in movement processing: clause boundary vs. identity

Behavioral studies of sentence comprehension suggest that processing long-distance dependencies is subject to interference effects when Noun Phrases (NP) similar to the dependency head intervene in the dependency. Neuroimaging studies converge in localizing such effects to Broca's area, showing that activity in Broca's area increases with the number of NP interveners crossed by a moved NP of the same type. To test if NP interference effects are modulated by adding an intervening clause boundary, which should by hypothesis increase the number of successive-cyclic movements, we conducted an fMRI study contrasting NP interveners with clausal (CP) interveners. Our design thus had two components: (I) the number of NP interveners crossed by movement was parametrically modulated; (II) CP-intervention was contrasted with NP-intervention. The number of NP interveners parametrically modulated a cluster straddling left BA44/45 of Broca's area, replicating earlier studies. Adding an intervening clause boundary did not significantly modulate the size of the NP interference effect in Broca's area. Yet, such an interaction effect was observed in the Superior Frontal Gyrus (SFG). Therefore, the involvement of Broca's area in processing syntactic movement is best captured by memory mechanisms affected by a grammatically instantiated type-identity (i.e., NP) intervention.

Introduction

There is extensive evidence that Broca's area is taxed by sentences with *movement* both from neuropsychological studies of patients and neuroimaging studies of healthy adults (Just et al., 1996; Stromswold et al., 1996; Caplan et al., 1999; Ben-Shachar et al., 2003, 2004; Fiebach et al., 2005; Grewe et al., 2005). Less complex relations, such as simple phrasal composition and local agreement have also been shown to activate/depend on this region (Pallier et al., 2011; Carreiras et al., 2012), however, they have not done so as consistently across methods and populations, as movement (for lack of evidence for simple composition in imaging see Humphries et al., 2005; Brennan et al., 2012). Our goal in this paper is to push our understanding of this special relation between movement and Broca's area even further.

Recent work suggests that activation of Broca's area with syntactic movement may be specifically tied to memory interference, as activity appears to increase with each additional NP intervener within the movement dependency (Santi and Grodzinsky, 2007b; Makuuchi et al., 2013). In the current fMRI study we ask whether this interference effect is modulated by the number of intervening clause boundaries (0 vs. 1). As a clausal boundary increases the number of movements, this manipulation is particularly relevant to theories that place a special role for Broca's area in computing movement dependencies (Grodzinsky, 2000; Grodzinsky and Santi, 2008). Below we elaborate on the structural properties of movement that can be cashed-in as costly for processing mechanisms potentially located within this brain region. While many theoretical positions have been put forth in accounting for this effect, we will argue for the strength of an interference-based account, where interveners are of the same syntactic/semantic type as the moved phrase (type-identical interference henceforth), as opposed to others, for example the number of iterations of a local movement operation.

In sentences with *Movement* (2), a single Noun has (at least) two dependent positions that provide distinct interpretations (e.g., in (2) interrogative and thematic). Only one of these positions is pronounced (2,3), the other(s) copy is <bracketed>, silent and is where the noun is interpreted (thematically) as an argument of a predicate. In contrast, sentences without movement (1) have no silent copy and only one interpretive position for each noun.

1. The boy likes the girl.
2. **Who** does the boy like <***who***>?
3. **Who** <***who***> likes the boy?

Many investigations into movement processing have been based on the object vs. subject movement asymmetry. Object movement (2) unlike subject movement (3) has lexical material intervening between the pronounced position of the noun and where it gets thematically interpreted. Furthermore, the ordering of arguments is non-canonical in the case of object movement (Object-Subject-Verb, above).

The difficulty associated with processing object compared to subject movement has been largely attributed to the degree of referential similarity between the intervening argument(s) and the moved one (Gordon et al., 2001). In a behavioral study, Gordon et al. (2001) studied subject and object extracted relative clauses whereby the head of the relative clause was an NP that was a definite description (e.g., "the barber" in 4 and 5) and the NP within the relative clause was either also descriptive (e.g., "the lawyer") or a proper name (e.g., "Joe"). Reading times at the two critical words (those underlined in the example sentence in 4 and 5) demonstrated an interaction. Reading times were longer for object-extracted relative clauses compared to subject-extracted ones, when the NP within the relative clause was of the same type as the filler (i.e., descriptive). When a proper name was used there was little if any difference between object and subject extracted relative clauses.

4. The barber that **the lawyer/Joe** admired <*the barber*> climbed the mountain.
5. *The barber* that <*the barber*> admired the *lawyer/Joe climbed* the mountain.

This result demonstrates that the parser is sensitive to the syntactic and/or semantic similarity of features (e.g., +sing, +animate, +definite) between referential items.

Additional behavioral studies have reinforced the idea that long distance dependencies, more generally, are difficult to process when there is a similar intervener. These studies do not focus on referential features, but the syntactic position of the intervening material (Van Dyke, 2007). For example, a subject of a complement clause creates more interference within a subject-verb dependency than does the same NP within an object PP. Thus, a broad range of features (+nom, +animate, +singular, +definite, etc.) may contribute to similarity-based interference during dependency resolution, but their degree of contribution may depend on the particular dependency under investigation.

The finding that Broca's area is sensitive to object movement (Just et al., 1996; Stromswold et al., 1996; Caplan et al., 1999; Fiebach et al., 2005; Grewe et al., 2005) is reinforced by more sophisticated parametric fMRI studies. These studies quantified how taxing movement is by the amount of intervening units between the dependent elements, where units (i.e., "interveners") have most often been defined as animate, singular, descriptive NPs. Animate, singular descriptive NPs were selected, as they share syntactic and semantic features with the moved phrase, thereby introducing semantic/syntactic identity based interference in memory processes (Gordon et al., 2001). For an example of a parametric manipulation of number of similar interveners, see 6(a–d) from Makuuchi et al. (2013).

6. *a. Ich glaube, der Mann zeigte dem Kind den Onkel gestern Abend.*
   b. I think, the$_{NOM}$ man showed the$_{DAT}$ boy the$_{ACC}$ uncle last evening.
   c. I think, *the$_{DAT}$ boy* **the**$_{NOM}$ **man** showed <*the$_{DAT}$ boy*> the$_{ACC}$ uncle last evening.
   d. I think, *the$_{ACC}$ uncle* **the**$_{NOM}$ **man** showed **the**$_{DAT}$ **boy** <*the$_{ACC}$ uncle*> last evening.

The baseline sentence is presented in 6a in German and 6b presents the English gloss. In this baseline sentence all arguments are in their base position. In 6c, the direct object has moved in front of the subject (crossing 1 NP) whereas in 6d the indirect object has moved in front of the subject (crossing 2 NPs). Previous parametric studies investigated the neural reflections of the number of NPs crossed (i.e., interveners) by a *single* moved NP (Santi and Grodzinsky, 2007b; Makuuchi et al., 2013) *or* of the number of NPs displaced by syntactic movement (Friederici et al., 2006) across different languages (English, German) and movement constructions (Scrambling, Topicalization, Relative Clauses). Their results provide a neurocognitive generalization: Broca's area is sensitive to movement distance measured by the number of similar interveners (in this case type-identical NPs) that moved NPs cross. In conjunction with the results from additional fMRI studies, this interference appears to be occurring proactively rather than retroactively, given that dependencies,

which are not predictable until the tail of the dependency (e.g., reflexive binding and parasitic gaps), do not engage Broca's area (Santi and Grodzinsky, 2007a,b). Thus, it would seem that object movement is taxing due to maintenance of a prediction (i.e., gap for an NP) that crosses type-identical interveners (i.e., NP).

A recent fMRI study (Glaser et al., 2013) showed similarity of an NP intervener to the head of the dependency is critical in driving activation in BA44 and 45 (i.e., Broca's area). This particular study did not assess interference within a movement dependency, but a subject-verb (agreement) dependency. The high interference condition had an intervening subject NP (visitor)[1] within a complement clause (8), whereas the low interference condition had an intervening NP (that was not subject) within a PP (7). The greater activation within Broca's area for (8) than (7) was interpreted to reflect the main verb (i.e., was complaining) cueing for the retrieval of a subject NP whereby an intervening subject NP resulted in greater interference. Thus, unlike our conclusions above, they assume that similarity-based interference effects in Broca's area occur during a cue-based retrieval.

7. *The client* who had arrived after the important **visitor** that day *was complaining* about the investigation.
8. *The client* who implied that the **visitor** was important that day *was complaining* about the investigation.

Whether interference is occurring proactively or retroactively, conflict resolution can apply in recovering the correct representation (Thompson-Schill et al., 1997; Novick et al., 2005; Thothathiri et al., 2012). Thothathiri et al. (2012) specifically suggest that non-canonical structures activate Broca's area due to syntactic competition between an agent-first hypothesis and the actual syntactic representation, which is patient-first in the cases of object-relatives and passives. Conflict resolution is relied-on to distinguish the correct from the incorrect representation. Thus, conflict resolution may apply following interference and be the basis of the observed activation in Broca's area.

Although there is indication that Broca's area is engaged by interference generated by the number of NP interveners (whether affecting proactive, retroactive, or both aspects of processing) crossed by a movement dependency, movement may engage additional processing mechanisms within this region. However, the nature of the tests conducted thus far cannot address this. Multiple distinct computations within Broca's area is not unreasonable, given that it contains multiple anatomical subregions with presumably distinct functions (Amunts et al., 2010). Our goal in this study is to determine whether movement has effects in Broca's area above and beyond those imposed by the semantic/syntactic identity of intervening NPs within a movement dependency. Specifically, does the number of movements affect activation in any subregions of Broca's area or surrounding regions, as another neurolinguistic account of Broca's area has proposed it is involved in computing syntactic movement (Grodzinsky, 2000). We investigated this with sentences involving iterations of a movement operation (i.e., successive cyclic movement) as compared to sentences with a single movement (within a clause) but with an equal number of NPs crossed by that movement. The following provides a brief description of how movement proceeds successive-cyclically after which we will further elaborate on the complexity dimensions tested.

As discussed above, movement involves an interpretation of a phrase in a position that is not pronounced (i.e., silent copy). In those examples we were concerned with a single clause. By comparison, in sentences with multiple clauses, the wh-phrase (i.e., who) moves from a thematic (i.e., *doer* or *doee*), silent position which it "vacates" (gap) to a "filled" position (filler), in which it is pronounced, by stopping off at the left edge of *each* intervening clause and leaving behind a silent copy in each of them (10). Evidence that the wh-phrase moves through intermediate CPs (i.e., CP3 in 9) on the way to its final destination (i.e., CP2 in 10) comes from grammaticality contrasts, as in (9) vs (10). Both (9) and (10) are composed of 3 clauses (CPs). Note that in (9) the *wh*-phrase (i.e., who) crosses more words than in (10) along the path from thematic interpretation to its pronounced position, but (10) is ungrammatical and (9) is not. This grammaticality contrast can be explained by considering that in (9) the *wh*-phrase has an intermediate landing position available (left edge of CP3) that is not available in (10) because the intermediate position is already filled by another wh-phrase (*which boy*). It has thus been proposed that wh-phrases *must* move successively through each CP on the way to their final landing position, leaving traces or silent copies (identified by phrases in angled brackets) in these intermediate positions, because failure to do so results in ungrammaticality (10). This captures the successive-cyclic nature of *movement*.

9. [$_{CP1}$ I know [$_{CP2}$ *who* the teacher from Norway thinks [$_{CP3}$ <*who*> the boy likes <*who*>]]].
10. *[$_{CP1}$ I know [$_{CP2}$ *which girl* the teacher thinks [$_{CP3}$ which boy likes <*which girl*>]]].

Further, evidence for intermediate landing positions is provided by language acquisition studies, which show children produce wh-words in these intermediate positions (Thornton, 1995). Likewise, Psycholinguistic studies have provided support for intermediate positions (Gibson and Warren, 2004), through demonstrating that intermediate positions ease processing of a sentence-final silent copy relative to comparable length dependencies not involving embedded CPs, achieved through nominalization.

The current study had two design features: (1) we manipulated the number of NP interveners crossed by a

[1]Although note that in (7) the NP is modified by the adjective, "dangerous," whereas in (8) it is not. Thus type similarity between the intervening NP and the head of the dependency also differs across this contrast.

moved NP (Baseline:NP/CPS0, 1NP intervener:NP/CP/O1, 2NP intervener:NP/CPO2 in **Table 1**) and (2) compared successive cyclic movement to a single movement while controlling for number of intervening NPs (see **Table 1**). The first part of the design allowed us to relate the novel design/results to previous results that investigated a parametric manipulation in the number of intervening NPs. The second part allows us to test whether number of movements has an effect above the number of similar NPs crossed.

The baseline condition (CP/NPS0) involves a local subject (S) movement, hence crossing 0 similar NPs. This was compared to movement that crossed 1 similar NP (CP/NP O1); in order to accomplish this the object of the most embedded clause was moved across the subject of that same clause. Furthermore, this was compared to movement that crossed 2 similar NPs (CP/NP O2), which was accomplished again via object movement, either across the two subjects of the two most embedded clauses (CP condition) or across the direct object and subject in a single clause, containing a bi transitive verb (NP condition). This contrast of size to similarity addresses what form of information increases complexity of memory mechanisms in Broca's area. Thus, by comparing condition CPO2 to CPO1 we have a contrast in number of CPs crossed (2 vs. 1) and in contrasting NPO2 to NPO1 we have a contrast in number of NPs crossed (2 vs. 1). Furthermore, collapsing across the two types of interveners we can re-assess the parametric effect of number of similar interveners in comparing the current work to past results.

Although our primary interest was in investigating the effect of multiple movements, it is important to note that multiple movements have a couple of consequences that in and of themselves may increase processing complexity. The multiple movements coincide with a larger syntactic size of the "interveners" (i.e., CP) or put otherwise refers to movement that crosses a clausal boundary. In successive-cyclic movement we are crossing multiple clauses rather than a single one containing some multiple of NPs. CPs contain many more functional projections (i.e., CPs, and tense and agreement checking nodes) and as such are syntactically more complex[2]. Wagers and Phillips (2014) show that movement within a clause involves active maintenance of both coarse (e.g., category) and fine-grained (lexical semantic) information about the antecedent, but across clauses there is active maintenance of just the coarse-grained information, whereby fine-grained lexical information needs to be retrieved at the gap. Thus, a clause boundary manipulation should engage retrieval processes more than one without.

We can test whether crossing a clausal boundary of a wh-movement dependency has an effect on the fMRI signal above that of similarity of the intervener (i.e., NP) to the moved constituent by comparing crossing of 2CPs to 1CP with crossing 2NPs to 1NP (in a single clause). Note, in **Table 1**, the type contrast (CP, NP) does not differ in terms of dependency distance when there is either 1 or 0 intervener. Thus, one would only expect a difference between the intervener types when comparing 2 vs. 1 intervener (i.e., hence CPS0 is grayed out in **Table 1** to highlight the conditions contributing to the expected interaction effect). In summary, an enhancement of activation for crossing a clause could indicate 1 of 2 related processes: (1) number of movements or (2) taxing retrieval mechanisms more due to crossing a clausal boundary.

Any results from the current study that demonstrate an effect of number of CPs over NPs cannot distinguish between number of movements, syntactic size of the intervening material and crossing a clausal boundary. Nonetheless, the data will critically show whether or not Broca's area is sensitive to movement (and syntactic size or crossing clausal boundary) beyond similarity of the interveners to the head of the dependency. The potential complexity factors induced by successive-cyclic movement above type-identical based interference are interrelated (perhaps, reflections of different levels of analyses) and as such not easily disentangled, these include: (1) number of movements (and silent copies) (2) syntactic size of intervening material (between the pronounced and thematically interpreted NP), which involves the crossing of a clausal boundary.

TABLE 1 | Example Stimuli.

CP INTERVENER SENTENCES	
CPS0	I said the neurosurgeon knew *which resident* liked the porter
CPO1	I said the neurosurgeon knew [*which porter* **the resident liked** <which porter>]$_{CP1}$
CPO2	I knew [*which porter* **the neurosurgeon said**]$_{CP2}$ [<which porter> **the resident liked** <which porter>]$_{CP1}$
NP INTERVENER SENTENCES	
NPS0	I knew *which neurosurgeon* showed the resident to the porter
NPO1	I knew *which resident* [**the neurosurgeon**]$_{NP1}$ showed <which resident> to the porter
NPO2	I knew *which porter* [**the neurosurgeon**]$_{NP1}$ showed [**the resident**]$_{NP2}$ to <which porter>

The CP conditions include CPS0, CPO1, CPO2, and the NP conditions include NPS0, NPO1, NPO2. Subject movement conditions that cross 0 NPs (S0) conditions have an embedded wh-subject phrase that does not leave its clause. The object movement condition have an embedded wh-object phrase that crosses one (O1) or two (O2) interveners (defined as either CPs or NPs), respectively. CPS0 and NPS0 along with CPO1 and NPO1 are no different in terms of intervention across a movement dependency.

Methods

Subjects

Twenty one subjects participated in the study (after exclusion of two participants from the analysis due to low behavioral performance in the fMRI study (<65%)[3]. The average age of

[2]This is relevant given that Glaser et al. (2013) compared an intervening CP to an intervening PP in testing effects of (subject) NP interference, where the intervening CP condition was also the condition with "high-syntactic interference" and resulted in greater activation in Broca's area. The question remains whether this greater activation is due to greater syntactic structure intervening the dependency or the subject status of the NP within this structure.

[3]This level of accuracy is based on the fact that the sentences are quite complicated and additionally the offline comprehension questions were difficult, as they involved a thematic role reversal. Further, it is not necessarily the case that incorrect answers to an off-line comprehension question correspond to an incorrect parse online. Rather it may simply be the product of an incorrect memory of that parse. As will be discussed later on, in the lab prior to fMRI scanning, participants performed at 75% or higher in each condition and as is normal, performance became a bit worse in the peculiar environment of an fMRI machine.

participants was 19.90 years, and 12 were female. All subjects were right-handed according to the Edinburgh Handedness Inventory (Oldfield, 1971), had normal or corrected-to-normal vision, a score above 3 on the Daneman and Carpenter Reading Span Test (Daneman and Carpenter, 1980), and gave informed consent in accordance with the ethics committee of the Montreal Neurological Institute (MNI).

Stimuli

The design of the stimuli crossed NUMBER of intervener (0, 1, 2) with TYPE of intervener (CP, NP). Although as pointed out in the Introduction, the distinction across "Type" for our purposes only arises when the Number of interveners is 2. Each condition was made up of 40 sentences and every sentence was between 17 and 19 syllables in length. In the Intervening CP condition there were two embedded clauses allowing for two successive-cyclic movements from baseline. In the intervening NP condition, to allow for movement over multiple NPs, but not CPs, there was one embedded clause that contained a double-object verb. The following sections contain further detailed descriptions of the parameterization of distance for each intervener type (see **Table 1** for example stimuli and Supplementary Materials for full list of Stimuli).

Intervening CPs

All sentences started with a pronoun (I, we, he, she) followed by a verb that takes a sentential complement (thought, claimed, hoped, said). The sentential complement was composed of an NP and another verb (knew, learned, announced) that takes a sentential complement. This second embedded clause was composed of an NP, a verb and direct object NP. In CPS0 there is no movement over a clause but there is (or may be) movement into a CP (unless one does not assume string vacuous movement)[4]. From baseline there is movement of the second embedded object to the front of the second embedded clause (CPO1 in **Table 1**), or movement of the second embedded object to the front of the first embedded clause (CPO2).

Intervening NPs

Likewise in the NP condition the sentences began with a pronoun (I, we, he, she) followed by a verb that takes a sentential complement (knew, announced, learn), the sentential complement was made up of a subject NP, a double object verb (introduced, described, showed, recommend) and its direct object NP and indirect object NP. In the baseline condition, NPS0, there is no movement over an NP, but there is (or may be) movement of the subject into a CP (unless one does not assume string vacuous movement). From baseline there is movement of the direct object in front of the embedded subject (NPO1). The second parameterization moved the indirect object over both the direct object and embedded subject (NPO2).

Only two subjects had an individual condition with an average accuracy of 65%, but over all conditions each subject performed above 70% and typically above 80%.

[4]An alternative baseline with no movement, but rather a complementizer was considered. It was ruled out as problematic, given it would be the only condition without a wh-phrase. This confound would make interpretations of the data difficult.

Procedure

To assure the participants were processing and understanding the sentences a yes/no question about stimulus content followed 50% of the sentences. Half of these required a "yes" response and half a "no" response. Questions requiring a "no" response involved a thematic role reversal (see 7–8 below). Given the difficulty of the task, we wanted to be assured that there would be a low exclusion rate in the fMRI study. Thus we screened subjects before fMRI scanning for behavioral performance days to weeks before the actual fMRI session. During screening, participants performed the task on 50% of the stimuli and were included for the fMRI study if they performed at 75% or greater in every condition. We screened 52 people whereby 28 satisfied all requirements (including handedness, language and behavioral performance). Of the remaining 24 that did not satisfy the screening requirements, 14 of them did not satisfy the requirements for behavioral performance alone. Of those 14, 10 still scored above 75% on average across all conditions. Thus, many simply performed below the conservative threshold on 1 or 2 of the conditions. Half of the subjects were screened on one-half of the sentences and the other on the complementary set. Both groups of participants saw the complementary set of comprehension questions from their screening session in the actual fMRI study, and both saw the entire set of sentences (the full set of items across all conditions). Thus, the half they saw in practice they saw again during the fMRI study that was run days or weeks later. Therefore, comprehension sentences only appeared on 50% of the trials in the fMRI study.

7. I said the neurosurgeon knew which porter the resident liked.
8. Did I say the neurosurgeon knew which resident the porter liked?

The stimuli were programmed with Presentation software (Neurobehavioral Systems, Inc., Albany, California, USA) on a Windows PC. The stimuli were projected onto a screen at the back of the MRI and then reflected into a mirror attached to the head coil. The sentences appeared word/phrase by word/phrase (see **Figure 1**). Each word/phrase appeared for 700 ms with 100 ms between. The comprehension question was presented for 4000, 100 ms after the sentence. On trials without comprehension questions there were 3 scans (4.8 s) of blank screen inter-trial interval (ITI), whereas on trials followed by comprehension questions there were 2.5 scans (4 s) of ITI. Half of the stimuli were presented in each of two runs. See **Figure 1** for a depiction of the trial dynamics. Trial order and additional interspersed silence (10*12.8 + 10*9.6 s) for jittering stimulus onset was optimized by optseq (http://surfer.nmr.mgh.harvard.edu/optseq/) with the presentation of the trial being jittered by 0 or 800 ms from the onset of the scan. Run order was counterbalanced across participants. An MRI compatible response box for comprehension question responses was placed in the participants' left hand to avoid potential motor activation overlapping with typically left frontal language activation.

Image Acquisition

Functional and structural data were acquired on a 3T Siemens magnetom Triotim. Twenty-six slices, 4 mm thick oriented

AC-PC, with full coverage of the frontal, temporal, and occipital lobes and partial coverage of the parietal lobes were acquired (TR = 1.6 s, TE = 30 ms, Flip angle = 90°, FOV = 25.6 × 25.6 cm^2, 64 × 64 matrix). Superior aspects of the parietal lobe could not be included to maintain the desired functional and anatomical resolution. Voxels were 4 × 4 ×4 mm in volume. There were 176, 1 mm thick structural scans acquired with an MPRage sequence (TR = 2300 ms, TE = 2.98 ms, FOV = 256 ×240 mm, 256 × 240 matrix). During scanning, an air vacuum pillow and sponges were used to stabilize the head.

Analysis

Behavioral Data

Mean reaction times (RT) and accuracy for each subject and condition was entered into a 2 TYPE (NP, CP) by 3 Distance (0, 1, 2) Repeated Measures ANOVA (both by subjects and by items).

fMRI Data

The first 4 volumes of each fMRI run were removed from the analysis, in order to exclude magnetic saturation effects. The data were analyzed in SPM8 (available at http://www.fil.ion.ucl.ac.uk/spm/). Functional images were aligned to the first image and resliced in order to correct for motion. Then coregistration between functional and anatomical images was performed. Anatomical images were segmented and normalized to MNI space. The resultant transformation matrix was applied to the functional images that were subsequently spatially smoothed with an 8 mm FWHM Gaussian kernel. The data were modeled with regressors for each sentence condition and 1 regressor for all comprehension questions and convolved with a canonical model with a time derivative. The time derivative was applied to handle slice timing differences (Henson et al., 1999). A high pass filter with a cut-off of 128 s was applied to the data. The contrast images for each condition of each subject were submitted to a second-level (group) analysis: (1) 2TYPE(CP, NP) × 3Number(S0, O1, O2) within-subject ANOVA. F-test of the interaction was FWE corrected for multiple comparisons. T-tests were used to test for a linear effect of Number [-1 0 1 -1 0 1] (CP/NPO2>CP/NPO1>CP/NOS0) to replicate previous studies that have demonstrated an effect of number of NPs intervening a movement dependency. Main effects of Type (CP>NP) and (NP>CP) were coded as t-tests as well [1 1 1 -1 -1 -1] and [-1 -1 -1 1 1 1], respectively. These effects compare multiple syntactic factors (e.g., verb argument structure, number of clauses) so the interpretation of any such results need to be made with caution, but nonetheless provide further data considering syntactic differences in processing. Additionally, the interaction to test for an effect of syntactic size (CPO2-CPO1>NPO2-NPO1) was coded as a t-tests [0 -1 1 0 1 -1]. Again, this particular interaction test was to address whether an intervening clause modulates the effect of an intervening NP. The effect of an additional clause vs. NP is only provided by the 2 intervener condition (CPO2 vs. NPO2 condition). The t-test maps were thresholded at voxel-wise $p < 0.005$ for signal intensity and by a cluster size where only significant clusters ($p < 0.05$) were reported.

The anatomy toolbox (www.fz-juelich.de/ime/spm_anatomy_toolbox; Eickhoff et al., 2005) was used for the identification of cytoarchitectonic probability of cluster localization. The Marsbar toolbox (Available at http://marsbar.sourceforge.net) was used for extracting Percent Signal Change from clusters.

Results

Behavioral Results

The accuracy results demonstrated very high (>85%) accuracy rates (see **Figure 2**). A main effect of DISTANCE was nevertheless observed over subjects [$F_{1(2, 40)} = 15$, $p < 0.001$] and items [$F_{2(1.476, 57.55)} = 8.95$, $p < 0.001$]. Pairwise comparisons with a Sidak correction for multiple corrections showed that S0 was significantly more accurate than O1 ($p = 0.007$) and O2 ($p < 0.001$), but that O1 and O2 did not significantly differ from one another ($p = 0.251$) both in the subjects and items analysis. Although the conditions did not directly differ there was a significant linear decrease in accuracy (i.e., Linear effect) with DISTANCE in the subjects [$F_{1(1, 20)} = 37.60$, $p < 0.001$] and items [$F_{2(1, 39)} = 17.19$, $p < 0.001$]. This indicates that accuracy demonstrated a decreasing trend with increasing distance even though direct contrasts did not turn out significant. Neither the main effect of TYPE or the interaction of TYPE*DISTANCE were significant. The RT results (see **Figure 3**) likewise demonstrated a main effect of DISTANCE in the subjects [$F_{1(2, 40)} = 6.94$, $p < 0.003$] and items [$F_{2(2, 78)} = 6.35$, $p = 0.003$] and Linear Effect of DISTANCE in the subjects [$F_{1(1, 20)} = 10.66$, $p < 0.004$] and items [$F_{2(1, 39)} = 12.62$, $p = 0.001$]. The main effect of DISTANCE was due to a faster reaction time for S0 than O2 ($p = 0.012$) in the subjects analysis and due to a faster reaction for S0 than both O1 ($p = 0.03$) and O2 ($p = 0.001$). There was also a main effect of TYPE in the subjects [$F_{1(1, 20)} =$

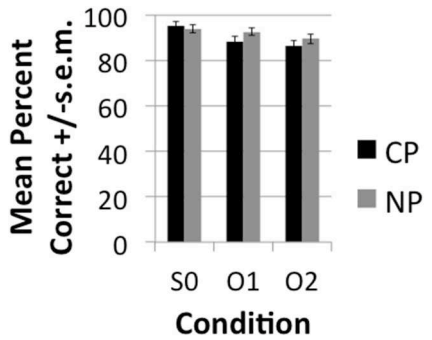

FIGURE 2 | Mean percent +/−s.e.m. correctly answered comprehension questions broken down by condition.

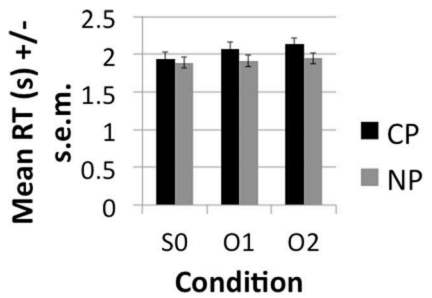

FIGURE 3 | Mean Reaction Time (RT) in seconds (s) ± s.e.m. to comprehension question broken down by condition.

19.23, $p < 0.001$] and items [$F_{2(1, 39)} = 28.9$] analyses and an interaction between TYPE and DISTANCE that was approaching significance in the subjects [$F_{1(2, 40)} = 3.22$, $p < 0.051$], but not the items [$F_{2(2, 78)} = 1.85$, $p = 0.164$] analysis. The trend of an interaction was due to CP interveners having a greater effect on slowing RT with increasing number of interveners than NP interveners. The main effect of TYPE was due to a slower RT for CP (mean = 2.05, SE = 0.084) than for NP (mean = 1.92, SE = 0.073).

fMRI Results

The current study tested whether an additional clause boundary within a wh-movement dependency has an effect on the fMRI signal above that of similarity of the intervener (i.e., NP) to the moved constituent. That is, it tested whether an additional clause boundary would have a greater effect on the fMRI signal than that of NP interveners.

Number of Intervener NPs

A significant linear effect of Number of interveners was observed bilaterally in the Inferior Frontal Gyrus (IFG) and in the Caudate Nucleus (see **Table 2** and **Figures 4**, **5**. for details). The anatomy toolbox, identified the peak LIFG activation (−40, 12 26) was within BA 44 with a probability of 30%. As can be seen in **Figure 5**, the LIFG activation is strongest in BA44 and spreads into the posterior portion of BA45. Across both the BA44 and 45

probability maps, thresholded at 30% (as in **Figure 5**), 404 voxels of the linear activation cluster are within the maps (i.e., 50% of the cluster overlaps with the maps). When using unthresholded probability maps (i.e., 10–100%), 590 voxels of the cluster are contained within the probability maps of BA44/45 (i.e., 73%). The activation that is not overlapping with the probability maps is mostly due to medial and posterior extension of the activation. In addition to LIFG activation, both the caudate and right Broca's area demonstrated activation, but this activation occupied a much smaller cluster (about half the size) then that on the left. Further, in fMRI it is difficult to know the necessity of the area(s) activated and from additional studies, it would appear that right Broca's area is often activated (amongst patients and healthy participants), but unlike LIFG, is not causally involved in language processes (Thiel et al., 2006).

Additional Clause Boundary

There was no interaction effect in Broca's area, either defined by a linear increase (0 to 1 to 2) that is greater for CP interveners than NP interveners or in terms of the (2–1 intervener) subtraction having a greater effect for CP compared to NP interveners. In the *t*-tests, a significant interaction effect defined by a greater effect of number of interveners (2 vs. 1) in the CP condition than the NP condition was, however, localized bilaterally in the Superior Frontal Gyrus (SFG; see **Table 3** and Supplementary Figure).

Effect of Syntactic Type

There was a significant effect of TYPE in the Superior Temporal Sulcus (STS) and the Inferior Occipital Gyrus (IOG, see **Table 4**; **Figure 6**). This effect was due to the CP condition producing greater activation than the NP condition. There were no significant clusters that demonstrated greater activation for the NP condition over the CP condition.

Discussion

The novel result that this study presents is that while Broca's area is sensitive to the number of type-identical interveners in long distance wh-movement, this effect is not augmented by **a clausal boundary**. Other less prominent areas of activation that demonstrated this same effect were found in the right homolog of Broca's area and the caudate nucleus. On the other hand, more

superior areas (i.e., SFG) were augmented by a clausal boundary (or the syntactic size of the intervener).

The result in Broca's area is consistent with psycholinguistic data that has demonstrated that the similarity of the interveners to the head of a movement dependency increases processing difficulty (Gordon et al., 2001). Our results further expand on these results in two ways: (1) by demonstrating that a syntactically similar intervener, but not an intervening clausal boundary, increases activation in Broca's area, its right homolog, and the basal ganglia, (2) a clausal boundary further increases complexity of a movement dependency, as evidenced by a marginally significant behavioral effect on offline RTs to verification questions and increased activation within the SFG and to some degree the left superior temporal cortex.

Broca's Area and Syntactic/Semantic Similarity Based Interference

Broca's area has been repeatedly reported to be engaged by object movement dependencies (Just et al., 1996; Stromswold et al., 1996; Caplan et al., 1999; Ben-Shachar et al., 2003, 2004; Fiebach et al., 2005; Grewe et al., 2005). Here we have explicitly framed movement distance in terms of number of

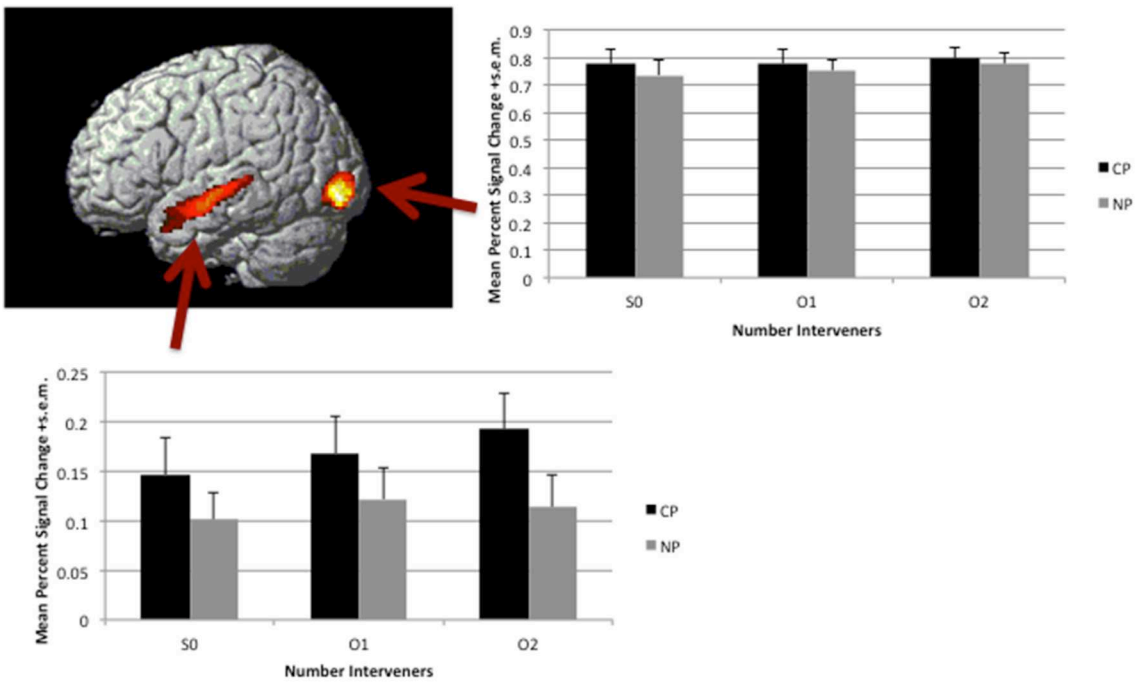

FIGURE 6 | Main effect of Type (CP>NP). Map is thresholded at voxel-wise $p < 0.005$ and corrected for multiple comparison through cluster size $p < 0.05$. Activation is overlaid on a rendered surface of the brain. The histogram to the right presents the mean percent signal change +s.e.m. over the entire Inferior Occipital Gyrus cluster broken down by condition (percent signal change was calculated in Marsbar per subject). type-identical interveners (NPs). This definition of distance not only holds of our results but also covers some other closely related studies (Santi and Grodzinsky, 2007b; Makuuchi et al., 2013). The cross-study consistency with Makuuchi et al. (2013) holds in terms of anatomical location but also in terms of experimental paradigm (reading word/phrase by word/phrase; comprehension questions assessing thematic role reversal) and methods for data analysis. The two studies differ in terms of the syntactic constructions tested. Makuuchi et al. (2013) investigated two types of movement dependencies in German, Scrambling and Topicalization. Here we studied embedded wh-movement. Similar to what is reported here, Makuuchi et al. (2013) found a linear effect of number of NP interveners on the fMRI signal with a peak in BA44, spreading into BA45.

A previous study by Santi and Grodzinsky (2007b) found the activation for increasing number of NPs within a movement dependency to be centered more anteriorly than the current study. This previous study differed from the current one in many ways. For one, intermittent scanning was used (thus the point of the scan may have been biased to BA45 processing, if BA45 has an earlier or later peak in processing relative to BA44), presentation modality was auditory, and the data analysis was slightly different (parametric effect was taken into consideration in the model). Nonetheless, these three studies are relatively similar and provide corroborating evidence for the role of Broca's area in being sensitive to movement distance defined over intervening constituents (i.e., NPs) that are similar to the head of the dependency.

Based on previous fMRI studies that find *unpredictable* syntactic dependencies (i.e., Reflexive Binding) do not activate Broca's area when NPs intervene, we suggest that the observed similarity-based interference effects are based on predictive processes. In particular, that there is storage of a prediction (NP gap) that is affected by similar, intervening NPs. The implication is that maintaining syntactic predictions increases activation in Broca's area and these predictions are affected by interveners that are identical in type. In the case of a movement relation, the parser is predicting a gap, which could involve storage of a category (i.e., NP) (Wagers and Phillips, 2014) or possibly an even more detailed feature profile (+sing, +animate, +nominal). When a *potential* gap site is reached this may cause reactivation of the entire lexical content of the filler or not (if maintained), but in either case the presence of another (type-identical) NP at a potential gap location will cause interference.

The behavioral data similarly shows that the number of intervening NPs affects both accuracy and RT. However, there is some indication that RT is primarily affected by CPs and not NPs (at least in the analysis by subjects but not the analysis by items). It is important to bear in mind that these are offline measures so how they directly relate to online measures of interference is more difficult to ascertain.

Our conclusions are consistent with Glaser et al. (2013) in showing that Broca's area is activated when there is interference by type-identical NP interveners in resolving syntactic dependencies. However, our conclusions differ in that Glaser et al. (2013) attribute this interference to occur during cue-based retrieval rather than along the prediction path. Remember that Glaser et al. (2013) do not investigate a movement dependency, but nonetheless one that is predictable, a subject-verb dependency (Van Dyke and McElree, 2006; Van Dyke, 2007). Trying to generalize across these two types of dependencies may not be the right approach. Further study is required to establish the degree of similarity in the memory mechanisms used to resolve these two dependencies and whether they are dependent on cue-based retrieval or maintenance of a prediction.

In general, the perspective that Broca's region engages in conflict resolution (Thompson-Schill et al., 1997; Novick et al., 2005; Thothathiri et al., 2012) is compatible with either interference during prediction or cue-based retrieval. In terms of prediction, it would attribute a conflict to wanting to release the filler as soon as possible and the actual representation, in which the "potential" gap site is already filled with a type identical NP. In resolving this conflict, the parser will need to maintain the gap prediction and do so for the correct NP. In terms of cue-based retrieval, this perspective would attribute conflict resolution to deciding between which of the type-identical NPs is the actual argument (head) of the verb or gap.

Lastly, it is worth noting that although about three-quarters of the activation lies within Broca's area (BA44/45), it also extends medially and posteriorly from Broca's area, including areas that connect Broca's area to other regions.

A Syntactic Working Memory

Given that the syntactic complexity effects observed in Broca's area depend on long distance dependencies, some have argued that its functional role is to provide a syntactic working memory (Caplan and Waters, 1999). The results from this study indicate that, if so, the size of the intervening structure is not as relevant as its similarity to the moved constituent. It appears that the critical dimension is the similarity of syntactic structure/features between the moved phrase and those intervening along the path of movement.

Phonological Working Memory

Some would argue that this linear effect of distance in Broca's are is related to a phonological working memory (Rogalsky et al., 2008) rather than syntactic/semantic similarity. However, contradictory evidence has been provided from various other studies (Caplan et al., 2000; Santi and Grodzinsky, 2007b). Even though Rogalsky and Hickok (2009) interpret their results to be due to phonological working memory, even their results demonstrate that there is activation in Broca's area during concurrent speech articulation. Thus, there is no clear evidence indicating that the observed syntactic complexity effect can be reduced to a phonological working memory.

Basal Ganglia, WM, and Syntactic Complexity

In addition to Broca's area (and its right homolog), a linear effect of interveners was observed in the basal ganglia. Makuuchi et al. (2013) also observed a linear effect of interveners within a movement dependency in the basal ganglia, however, there the activation was observed in the globus pallidus rather than the caudate nucleus. Further, a variety of related studies have found that the basal ganglia is sensitive to syntactic complexity (Prat and Just, 2011) and syntactic anomaly (Moro et al., 2001). Thus, this result is consistent with the region being engaged in the network that computes syntax.

Interaction Effect in MFG/SFG

The effect of syntactic size demonstrated an effect beyond type-identity interveners, bilaterally in the MFG/SFG, though most predominantly in the SFG. This was an unexpected finding, particularly with respect to the peak activation that lies anteriorly. The more posterior extent of the activation observed in the left hemisphere is similar to that seen in studies investigating the processing of Japanese scrambled sentences (Kinno et al., 2008) and one study that was interested in general distance effects within subject-verb agreement dependencies (Makuuchi et al., 2009). In fact, this posterior area is in very close proximity to the posterior end of the linear effect cluster (that is extending beyond Broca's area). Thus, this area seems to demonstrate some general engagement when Working Memory increases during sentence processing.

The bulk of the activation for the interaction, however, extends further anteriorly and is bilateral, thus demonstrating a distinction from these previous studies. Interpretations of the effect should, therefore, be made cautiously. Moreover, the plot of percent signal change by condition within this cluster provides a difficult picture to interpret. It seems as though there is activation for 1 intervening object in the double object construction, but no activation with 1 intervening object in the embedded clause structure. Then the pattern inverts for 2 intervening objects.

Auxiliary Brain Areas and Contrasts

Superior Temporal Cortex and CP>NP

In addition to examining the effect of distance (similarity and syntactic size) we looked at differences between the two Types of constructions. The results of this contrast need to be treated with care since many syntactic variables are concurrently manipulated (since this was not our primary interest). Although the CP and NP conditions contain the same number of NPs, the CP condition has an additional verb, whereas the NP condition has the preposition *to*. Furthermore, the argument structure of the verbs differ, the NP condition contains ditransitive verbs that the CP condition does not. Rather the CP condition contains more verbs that take sentential complements. Given these differences in verb argument structure, there is a consequent effect on the degree of syntactic structure building. The CP condition embeds clauses on each verb, thereby generating more syntactic structure. Having acknowledged the variety of differences across the TYPE contrast, the results of this contrast can be used to speak to current functional interpretations of the regions observed by this contrast that make reference to these syntactic variables. The anterior-to-posterior superior temporal gyrus activation is consistent with previous studies that have found the mid-to-superior posterior temporal gyrus sensitive to argument structure and syntax (Ben-Shachar et al., 2003, 2004; Friederici et al.,

2009; Santi and Grodzinsky, 2010) and the anterior temporal cortex to structure building (Humphries et al., 2005; Rogalsky and Hickok, 2009; Brennan et al., 2012). It is of interest to note, however, that the peak and focus of the activation is in the middle temporal cortex and not more anteriorly. In fact, in lowering the p-value ($p < 0.001$), the anterior temporal activation disappears and the mid-to-posterior activation remains. Thus, this contrast predominately depends on the mid-to-posterior superior temporal gyrus, rather than its anterior portion.

In looking at the percent signal change across conditions for this cluster, it is clear this effect is observed regardless of the number of intervening NPs. Additionally, it suggests a linear trend in activation with increasing number of NP interveners for the condition with multiply embedded CPs that is not observed for the condition with a ditransitive verb in a singly embedded CP. Similarly, the offline behavioral RT data demonstrate some evidence for increasing RTs with increasing number of interveners in the multiply embedded clause condition. This was observed in a marginally significant interaction effect (only in the by-subjects analysis, however). At appropriately thresholded levels, the fMRI data do not demonstrate such an interaction in the STS. However, when the voxel-wise p-value is dropped to $p < 0.05$ (voxel-wise and uncorrected for cluster size) the STS is observed in the interaction effect map. That is, a greater linear increase in activation with an increasing number of intervening NPs is observed in the multiply embedded clause condition over the single embedded clause one. Recall, in the two intervening object NP condition, the movement is occurring over a clausal boundary in the multiple clause condition, but is within a clause in the double object condition. Wagers and Phillips (2014) demonstrate that not all properties of the filler are maintained across a clause boundary, requiring their retrieval at the gap site. Thus the data, though not significant, show a trend for the STS to be sensitive to multiple movements or retrieval demands.

Inferior Occipital Gyrus and CP>NP

Not only was the superior temporal sulcus activated by the contrast in syntax type, but so was the inferior occipital gyrus. The location of activation is consistent with that observed by Makuuchi et al. (2013) in their contrast between Topicalization and Scrambling. The authors interpret this to be due to visual attention driven by the case-marked NP that appears sentence initial in wh-movement (topicalization), but in the embedded clause in scrambled structures. If the activation is due to increased attention, then in this study it must be for a different reason than the presence of an early case-marked NP that predicts the additional NPs. First there is no case-marking in the present study and, if anything, the filler appears earlier in the NP condition than the CP condition. A distinct potential syntactic factor that could be generating predictions and increasing visual attention in the CP compared to NP condition is that there are more open clausal phrases in the CP condition, leading to more predictions of verbs and arguments. Generally, these findings are consistent with other studies that demonstrated top-down effects in visual areas based on lexical predictions (Dikker and Pylkkänen, 2011).

Conclusions

The current parametric study manipulated the number of NP interveners in a movement dependency while also manipulating the presence of a clausal boundary across such a dependency. The results demonstrated a linear effect of number of interveners in Broca's area but no interaction between the number of interveners and the presence of a clausal boundary. More superiorly and bilaterally in the SFG there was an interaction due to the clausal boundary having a greater effect on the number of interveners than NPs. The STS demonstrated greater activation for the multiple clausal embedding condition than the single clausal embedding condition regardless of the number of interveners. As there were multiple distinctions across these conditions it is difficult to attribute the activation to a particular factor. Further, there was a trend within the STS in being sensitive to movement over a clause boundary, although not significant. In conclusion, Broca's area is sensitive to the number of interveners that are similar to the moved constituent and the activation is not augmented by an additional movement, or movement over a clausal boundary. Thus, type-identical interference rather than movement or crossing of a clausal boundary increases activation in Broca's area.

Discourse accessibility constraints in children's processing of object relative clauses

Yair Haendler[1], Reinhold Kliegl[2] and Flavia Adani[1]*

[1] Department of Linguistics, University of Potsdam, Potsdam, Germany, [2] Department of Psychology, University of Potsdam, Potsdam, Germany

Children's poor performance on object relative clauses has been explained in terms of intervention locality. This approach predicts that object relatives with a full DP head and an embedded pronominal subject are easier than object relatives in which both the head noun and the embedded subject are full DPs. This prediction is shared by other accounts formulated to explain processing mechanisms. We conducted a visual-world study designed to test the off-line comprehension and on-line processing of object relatives in German-speaking 5-year-olds. Children were tested on three types of object relatives, all having a full DP head noun and differing with respect to the type of nominal phrase that appeared in the embedded subject position: another full DP, a 1st- or a 3rd-person pronoun. Grammatical skills and memory capacity were also assessed in order to see whether and how they affect children's performance. Most accurately processed were object relatives with 1st-person pronoun, independently of children's language and memory skills. Performance on object relatives with two full DPs was overall more accurate than on object relatives with 3rd-person pronoun. In the former condition, children with stronger grammatical skills accurately processed the structure and their memory abilities determined how fast they were; in the latter condition, children only processed accurately the structure if they were strong both in their grammatical skills and in their memory capacity. The results are discussed in the light of accounts that predict different pronoun effects like the ones we find, which depend on the referential properties of the pronouns. We then discuss which role language and memory abilities might have in processing object relatives with various embedded nominal phrases.

Introduction

Relative Clause Processing in Children and Adults

The acquisition of relative clauses has been studied extensively and in a large variety of languages (Brandt et al., 2009; Arnon, 2010; Adani, 2011; Arosio et al., 2012; Belletti et al., 2012; Adani et al., 2014, among others). The existing research focuses mainly on the asymmetry between child performance on subject-extracted relatives (SRs) and object-extracted relatives (ORs), examples of which are provided in (1) and (2), respectively. In the examples, the head of the relative clause is the noun it modifies (*the bunny*). The underscore marks the position in the embedded clause from which the head noun is extracted: subject position in SRs and object position in ORs.

(1) The bunny that __ is chasing the horse
(2) The bunny that the horse is chasing __

In head-initial languages, it is a robustly attested finding that young children have difficulties comprehending and producing ORs, but not SRs (see Gutierrez-Mangado, 2011 for a reversed pattern in Basque). Children's errors with ORs are mainly expressed by the interpretation of these sentences as SRs. An account that aims to explain the SR–OR asymmetry in acquisition is proposed by Friedmann et al. (2009), following earlier work by Grillo (2005, 2009). This approach provides an explanation in terms of intervention locality, based on the syntactic principle of Relativized Minimality (RM; Rizzi, 1990 and subsequent work). We will refer to Friedmann et al.'s (2009) approach as the RM account.

Relativized Minimality is based on the configuration in (3), in which X is a constituent that moves from its original (gap) position Y crossing an intervening constituent Z.

(3) X . . . Z . . . Y

According to the RM Principle, a local relation between X and Y is impossible if Z is a potential candidate for that local relation. Such a case occurs when Z intervenes between X and Y and when Z is structurally similar to X. These two co-occurring conditions give rise to a locality intervention effect and, thus, to difficulties in parsing the structure. Friedmann et al. (2009) show how this configuration and the conditions that create intervention effects apply to the structure of SRs and ORs[1]. In the case of relative clauses, the authors identify the feature [+NP], or 'lexical restriction,' as the one that, when present on both X and Z, makes them structurally similar. In (1) and (2), repeated as (4) and (5), both X and Z are lexically restricted, or in other words: they are both full DPs. But only in the OR Z intervenes between X and Y. For this reason, according to Friedmann et al. (2009) ORs with two full DPs are difficult for children whereas SRs with two full DPs are not.

(4) [The bunny] that __ is chasing [the horse]
X Y Z

(5) [The bunny] that [the horse] is chasing __
X Z Y

The RM account predicts significant improvement in child comprehension of ORs when the head (X) is a full DP, whereas the embedded subject (Z) is not. Children are therefore predicted to perform more accurately on an OR with a full DP head and an embedded subject which is a personal pronoun, a DP that lacks the [+NP] feature. Friedmann et al. (2009, p. 75) tested this prediction examining child comprehension of Hebrew ORs with an embedded subject which is a null pronoun. The following example is taken from their paper.

(6) Tare li et ha-sus she- mesarkim oto
show to-me ACC the-horse that- *pro* brush-3rd-pl him
'Show me the horse that someone is brushing'
(literally, 'the horse that they are brushing')

The Hebrew *pro* subject in (6) is an impersonal subject that agrees with the 3rd-person plural form, as evidenced by the Person and Number agreement marking on the embedded verb *brush*. This impersonal, or arbitrary *pro* is used to describe the action of an unspecified agent. Friedmann et al. (2009) found that children understood ORs like (6) more accurately than ORs with a full DP head noun and a full DP embedded subject. They explained the improved comprehension as due to the attenuation of the intervention locality effect, caused by the fact that the head of the OR is a full DP but not its embedded pronominal subject. Crucially, the prediction is that any type of pronoun in the embedded subject position will improve comprehension, since what matters is the lack of lexical restriction, a property shared by all personal pronouns. This prediction receives further support from studies that find relatively accurate child performance on ORs whose embedded subject is an overt 3rd-person pronoun (Brandt et al., 2009), a 2nd-person pronoun (Kidd et al., 2007) or a 1st-person pronoun (Arnon, 2010).

Other accounts that explain OR processing based on adult performance make similar predictions. Warren and Gibson (2002, 2005) propose that sentence processing is determined by the number of new referents that intervene between a moved element (filler) and the gap site in which it is integrated into the structure. The greater the number of intervening referents (e.g., noun phrases, verbs) the harder it is to keep track of the filler until the gap site is encountered and the filler-gap dependency is resolved [a similar idea is advanced by O'Grady (2011)]. Under this view, an intervening pronoun reduces processing cost since it does not introduce a new discourse referent: it serves as a link to an already given one. Indeed, adults have less difficulty with doubly nested ORs and object clefts whose embedded-most DP is a pronoun, as compared to cases in which all the nominal phrases in the structure are full DPs (Warren and Gibson, 2002, 2005). Other accounts explain the difficulty with ORs in terms of similarity between the DP head and the embedded subject DP. It has been found that an OR becomes easier to parse when these two constituents are sufficiently dissimilar. For instance, ORs with two full DPs are more costly to process than ORs in which the head is a full DP and the embedded subject is a proper name (Gordon et al., 2004), or a 2nd-person pronoun (Gordon et al., 2001). Other studies define the difficulties with OR processing in terms of cue-based interference (Lewis and Vasishth, 2005; Lewis et al., 2006; van Dyke and McElree, 2006). Under this view, the similarity between the DP head and the embedded DP is defined by the cues that these two constituents bear. When a constituent (e.g., the DP head in an OR) is encountered it is encoded in memory. Later on, in the gap position, it has to

[1]The RM principle was first developed to explain intervention locality effects in extraction from weak islands (Rizzi, 1990). The approach was later extended to explain intervention effects in ORs, assuming a structural proximity between the latter and the original island phenomena (Grillo, 2005, 2009; Friedmann et al., 2009; Rizzi, 2013).

be retrieved from memory in order to be integrated into the structure. At this point, its (syntactic, semantic, or other) cues are analyzed in order to decide whether the filler-gap dependency can be resolved. If another constituent (e.g., the embedded subject DP in an OR) shares similar cues with those of the encoded constituent this second set of cues will interfere with the processing of the first one, increasing the overall processing cost of the structure. In an OR with an embedded pronoun, the cues of the intervening pronoun are sufficiently different from those of the encoded head noun, thus reducing the processing cost.

As can be seen, there is an affinity between the RM account and the accounts reviewed in the last paragraph, although the former is the only one whose predictions have been tested in experiments with children. All these accounts appear to share the prediction that an OR with an embedded pronominal subject is less costly for processing than an OR in which both the head noun and the embedded subject are full DPs. Moreover, at least some of these approaches (Gordon et al., 2001; Lewis et al., 2006), like the RM account, attribute the difficulties in OR processing to the (dis)similarity between the DP head and the embedded subject DP in terms of cues or features. Importantly, however, each of these studies tested the effect of only one pronoun type on OR processing. The only exception is Warren and Gibson's (2002) study with adults, to which we will return later. The present study is the first to assess the comprehension of ORs with different embedded pronominal subjects in children. That is, we will test the prediction that ORs with different pronouns in the embedded subject position should be equally easy for children, as compared to ORs with two full DPs. Comparing the effects of different pronoun types is particularly interesting given studies that show that pronouns with different referential properties affect sentence processing differently in adults (Warren and Gibson, 2002; Carminati, 2005).

We have recently shown (Haendler et al., 2015) that there is a relation between children's performance on ORs with different types of embedded referring expressions (full DP, different personal pronouns)[2] and their language skills, as measured by standardized tests for receptive grammatical abilities. These language or grammatical skills (we will use the two terms interchangeably) were defined as the average score on three subtests from Siegmüller et al. (2010). The tests assessed the comprehension of (a) canonical and non-canonical declarative sentences (SVO and OVS); (b) sentences containing reflexives and pronouns; (c) various types of relative clauses (right-branching and center-embedded; SRs and ORs). In the discussion, we will elaborate on what grammatical skills are assumed to underlie children's performance on these three language tests. Concerning the results, we found that children were most accurate on ORs with an embedded 1st-person pronoun (OR + 1pro; *The horse that I chase*), independently of their scores on the language tests. In ORs with an embedded 3rd-person pronoun (OR + 3pro; *The horse that it chases*) and ORs with a full DP head and an embedded full DP (OR + 2DP; *The horse that the bunny chases*), which were overall more difficult, children's performance interacted with their grammatical skills: children with higher scores on the language tests were more accurate on these conditions than children with lower scores.

In the present paper, we extend this picture by looking at memory skills and assessing whether they interact with language abilities in the modulation of children's performance on the three OR types. In other words, we want to see whether both language and memory have an impact on children's OR processing, and whether their effects are independent of one another or whether they interact. In the latter case, we want to see what kind of relation between language and memory skills emerges during OR processing. This kind of analysis will help distinguish between effects that are purely due to children's language skills, effects that are purely memory-dependent and effects that are caused by both types of cognitive abilities.

Memory and the Processing of Object Relative Clauses

The relevance of memory for the processing of relative clauses has been vastly investigated. To begin with, Friedmann et al. (2009) speculate that the difficulty with an OR containing two full DPs lies in children's limited memory capacity. During the processing of such a structure, one needs to hold in memory the featural specifications of the DP head and the embedded DP and compare them in order to determine their (dis)similarity (see also Adani et al., 2010). When the features of the DP head and of the embedded DP are similar, such as when they are both full DPs, the comparison of the features is more costly and memory capacity is overloaded. However, when the features on the DP head and on the embedded DP are sufficiently different, as in the case of an OR with an embedded pronominal subject, comparing the features becomes less demanding for memory resources and the comprehension of the OR is facilitated.

The reviewed accounts on adult processing similarly suggest that memory abilities constrain the processing of ORs (for a comprehensive review, see Wagers and Phillips, 2014). According to Gibson (1998, 2000) and Warren and Gibson (2002, 2005; see also O'Grady, 2011), the difficulty associated with keeping track of the filler while processing newly introduced discourse referents is related to available memory resources. The greater the number of new discourse referents that intervene between the filler and its gap site, the longer the filler has to be kept in memory until the filler-gap dependency is resolved. Therefore, people with strong memory capacity will be facilitated in maintaining the filler in memory while processing the sentence until the gap position is reached. Gordon et al.'s (2001, 2004) proposal that the processing cost of an OR is determined by the (dis)similarity between the DP head and the embedded DP is also related to memory capacity. The idea is that dissimilar DPs burden memory to a lesser extent, making the distinction of the two constituents during sentence processing easier. Finally, the processing mechanism assumed under the cue-based interference account (Lewis and Vasishth, 2005; Lewis et al., 2006; van Dyke and McElree, 2006) similarly draws on memory resources. If the set of cues of a previously encoded constituent (the DP head of an OR) and that of the

[2]We use the term 'referring expression' to mean any linguistic form that relates to some discourse referent. This term thus includes both definite noun phrases (full DPs) and pronouns (see Fukumura and van Gompel, 2012; Serratrice, 2013).

intervening DP are similar, memory capacity will be overloaded, resulting in an increased processing cost. If the two sets of cues are dissimilar, memory resources will be less burdened and the sentence will be easier to process.

The relation between children's memory abilities and their comprehension of syntactically complex sentences has been vastly studied. Different studies have used different kinds of tests to measure memory, yielding mixed results. Some studies found a relation between children's off-line response accuracy and their performance on listening span tasks (Montgomery et al., 2008; Montgomery and Evans, 2009; Weighall and Altmann, 2011), backward digit span tasks (Engel de Abreu et al., 2011; Boyle et al., 2013) and forward digit span tasks (Arosio et al., 2011, 2012; Engel de Abreu et al., 2011). An association has been found also between similar memory tasks and children's on-line sentence processing (Booth et al., 2000; Roberts et al., 2007). However, no systematic relation has been found between the score on any specific memory test and children's performance on any specific language task (Kidd, 2013). Particularly relevant for the present study is Arosio et al.'s (2012) work. Using a picture-selection task, they tested 7-years-old German-speaking children on the comprehension of SRs and ORs, disambiguated either by case-marking on the determiner of the embedded DP or by number-marking on the embedded verb. The authors found that children were more accurate on case-disambiguated than on number-disambiguated ORs. Also relevant is their finding that children's score on a forward span test was a reliable predictor of their comprehension of ORs (but not SRs).

In the present study, we administered to children both a forward and a backward digit span task. The memory measure was calculated as the average score on the two tests. As we have seen, both the forward and the backward span tests have been widely used in studies with children. Moreover, these tasks are typically assumed to reflect two kinds of memory components in Baddeley's classical model (Baddeley, 1986; Baddeley et al., 2009): the forward digit span task is believed to reflect the operation of the phonological loop, a short-term storage of phonological information; the backward digit span task is assumed to reflect the operation of the central executive, which is responsible for the coordination and elaboration of the stored information. The former is often referred to as *verbal short-term memory*; the latter as *verbal working memory* (Kidd, 2013). The fact that no systematic relation has been demonstrated between any of these two tests and a specific performance pattern on language comprehension led us to combine the scores on the two tasks into one, more general measure of memory capacity. The disadvantage in doing so is that we cannot look at separate effects caused by the two kinds of memory abilities (short-term memory and working memory). The advantage is that such a general memory measure is more robust and reliable for the analysis, since it combines data collected in two different tasks. The mixed findings in the literature regarding the relation between the two span tasks and certain language abilities leaves the qualitative analysis of the role of memory highly speculative. Hence, by using the composite score, we gain a stronger measure for the quantitative analysis of children's memory capacity.

Referential Properties and Discourse Accessibility

As we have seen, the prediction we are testing is that any type of embedded pronoun should facilitate children's performance on ORs to an equal extent. However, there is extensive literature focusing on differences between pronouns in terms of their referential properties. A case in point is the different way of establishing reference of 1st- and 2nd-person pronouns on the one hand, and 3rd-person pronouns on the other hand. When a participant in a linguistic act constructs a discourse model, 1st- and 2nd-person pronouns are directly integrated into that model since they refer, respectively, to the speaker and the interlocutor, two discourse referents which are always available and highly accessible (Recanati, 1993; Erteschik-Shir, 1997; Ariel, 2001). Moreover, the referents of these pronouns are derived from the lexical meaning of the pronouns themselves: 1st-person pronoun ('I,' 'we') = speaker; 2nd-person pronoun ('you') = interlocutor. This is similar to the way in which a regular noun phrase (e.g., 'the horse') establishes reference. The discourse referent of the noun phrase is derived from its lexical meaning, despite the fact that it is marked with 3rd-person (unlike 1st- and 2nd-person pronouns) and although it is not referring to a participant in the linguistic act (like 'speaker' or 'interlocutor'). By contrast, the referent of a 3rd-person pronoun ('it,' 'they,' and demonstratives such as 'this,' 'that') is derived from the discourse, in a process of pronoun resolution in which the pronoun relates to an antecedent in the linguistic or extra-linguistic context (Heim, 1991; Legendre and Smolensky, 2012).

There is experimental evidence that such differences in discourse accessibility of pronouns affect the processing of sentences in which they occur. Warren and Gibson (2002) found that adults perceive doubly nested ORs with an embedded 1st- or 2nd-person pronoun as less complex, as compared to such structures with an embedded 3rd-person pronoun. Moreover, adult on-line processing of pronoun resolution in infrequent circumstances (when the pronoun antecedent is a previously mentioned object, rather than subject) is facilitated when that pronoun is marked with 1st- or 2nd-person, rather than 3rd-person (Carminati, 2005). These effects, assumed to be caused by the referential properties of pronouns, have not been tested yet in children. But a number of studies suggest children are sensitive to discourse properties of pronouns as well. First, in line with the pronoun asymmetry described above, children acquire the ability to correctly interpret 1st- and 2nd-person pronouns before 3rd-person pronouns (Brener, 1983; Girouard et al., 1997; Legendre et al., 2011; Legendre and Smolensky, 2012). Moreover, there is substantial evidence indicating that children are sensitive to the discourse properties that determine pronoun usage and interpretation (Song and Fisher, 2005, 2007; Spenader et al., 2009; Pyykkönen et al., 2010; Koster et al., 2011; Hartshorne et al., 2015)[3]. For instance, Song and Fisher (2005) found that

[3]Some studies have tested children's comprehension of intra-sentential anaphora. These are sentences in which the referent of the pronoun is inside the same sentence in which the pronoun appears (e.g., Sekerina et al., 2004; van Rij et al., 2010; Clackson et al., 2011). Here we concentrate only on extra-sentential anaphora, where the referent of the pronoun is in the extra-sentential or extra-linguistic (visual) context. This is the relevant case for the present study.

3-year-olds, tested with a preferential-looking paradigm, looked more to the correct referent figure of a pronoun when it was made prominent in the discourse (in the preceding context it was the first-mentioned figure in a subject position and pronominalized once), than when the referent was not prominent. Children in Koster et al.'s (2011) study interpreted the pronoun as referring to the first-mentioned character in a context story, both when this character was consistently the discourse topic and when there was a shift in the topic of the story. Production studies also suggest that children are sensitive to referential properties of pronouns, as well as to the extra-sentential or extra-linguistic context, when they choose which referring expression to utter (see Serratrice, 2013 and references therein). Together, these studies suggest that, from early on, children are sensitive to discourse properties of pronouns such as topicality or order-of-mention. It appears that children can use these properties in order to construct a plausible discourse model and, based on that model, derive expectations regarding the usage of the referring expressions they encounter in the linguistic input (see a related discussion in Trueswell et al., 2011).

According to Goodluck (2010), who discusses data in contradiction with Friedmann et al.'s (2009) approach, children's performance on complex structures is determined by both syntactic and discourse accessibility operations (see also Goodluck, 1990, 2005 and Avrutin, 2000). Whereas the RM account predicts difficulties with object-extracted wh-questions in which both the moved constituent and the intervening one are full DPs (*Which lion did the zebra kick?*), Goodluck (2005) found that children perform more accurately when the moved constituent is a more generic name (*Which animal did the zebra kick?*). In explaining the data, Goodluck suggests that children's difficulty with object *which*-questions is related both to the syntactic factor of distance (*which lion/animal* is extracted from the more distant position as the object of the verb *kick*) and to the discourse factor of set-restriction (to interpret *which lion*, the child has to restrict the set of given lions and understand which one she is asked about; this operation is less costly when *lion* is replaced with the more generic *animal*). Although Goodluck's (2010, p. 1520) proposal is made in relation to structures that are slightly different from the ones dealt with here, the relevance of her work lies in the idea that "[. . .] children appear to have difficulty in general with grammatical phenomena that require access to discourse."

The Present Study

To summarize the goal of the present study, we test the prediction that ORs with different embedded pronominal subjects are easier than ORs with two full DPs. Moreover, no difference is predicted between the conditions with pronouns. We used right-branching ORs with various referring expressions in the embedded subject position. ORs with an embedded 1st-person pronoun (7) and with 3rd-person pronoun (8) were compared to a baseline condition of ORs in which both the head noun and the embedded subject are full DPs (9)[4]. Note that these ORs differ with respect to the referring expression that occupies the embedded subject position (in bold). Hence, we expect differences in performance on the ORs to reflect effects caused by these referring expressions.

(7) OR + 1pro: Welche Farbe hat der Hase, den **ich** jage?
what color has the bunny who **I** chase

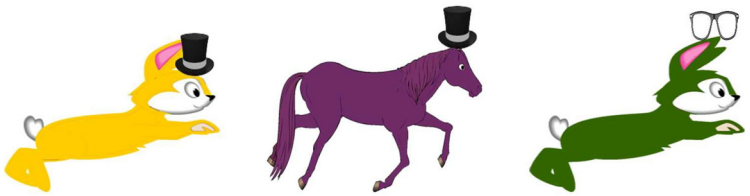
(8) OR + 3pro: Welche Farbe hat der Hase, den **es** jagt?
what color has the bunny who **it** chases

(9) OR + 2DP: Welche Farbe hat der Hase, den **das Pferd** jagt?
what color has the bunny who **the horse** chases

Previous studies on children's OR comprehension have used only off-line methods. Here, we designed a visual-world experiment (Tanenhaus et al., 1995) and measured both off-line response accuracy and on-line eye-gaze during the inspection of a visual scene that accompanied each test sentence. The off-line accuracy was collected as a measure of explicit comprehension; the on-line eye-gaze as a measure of implicit parsing strategies. Many studies using on-line measures (e.g., eye-tracking) have found evidence for early processing of complex structures and/or a more fine-grained performance pattern that usually remains hidden in the explicit response (Brandt-Kobele and Höhle, 2010; Adani and Fritzsche, 2015). Thus, on-line gaze measures are arguably more sensitive in testing child language, yielding results that suggest that children might implicity process a structure accurately even when their explicit response is inaccurate. For this reason, and since previous studies have found difficulties with ORs that persist until late in development (e.g., Friedmann et al., 2009; Arosio et al., 2012; Adani et al., 2014), we tested children at age 5. If the on-line eye-gaze measure is indeed more sensitive than the off-line response accuracy we might find evidence for correct processing of the harder condition(s) even as early as this age.

Let us now summarize the predictions regarding children's performance on the three conditions and the possible relation to language and memory abilities. The initial prediction is that children will be more accurate on OR + 1pro and OR + 3pro than on OR + 2DP, and there should be no difference between performance on OR + 1pro and OR + 3pro. However, if the different ways with which the 1st- and the 3rd-person pronouns establish reference influence children's performance, as found with adults (Warren and Gibson, 2002; Carminati, 2005), children should be more accurate on OR + 1pro than on OR + 3pro. We have already mentioned that stronger grammatical skills improve children's performance on two of the conditions. Given previous studies (Kidd, 2013), we might expect to find also an impact of memory that shows that stronger memory capacity improves performance on the task.

[4]In addition to these three conditions, we also tested a fourth condition in which the head noun was a demonstrative pronoun and the embedded subject was a full DP (*Welche Farbe hat der, den das Pferd jagt?* 'What color has that (the one) that the horse is chasing?'). The predictions regarding this condition are not straightforward, since existing literature is not explicit about whether such a demonstrative bears the [+NP] feature or not. Moreover, unlike this condition, all the others differed minimally by the referring expression in the embedded subject position. Upon suggestion from the two reviewers, we will neither present nor discuss the data from this condition.



Preamble: *Hier sind zwei Hasen. Der eine Hase ist gelb, und der andere Hase ist grün. Und hier ist ihr Freund, das Pferd. Das Pferd ist lila* ('Here are two bunnies. The one bunny is yellow and the other bunny is green. And here is their friend, the horse. The horse is purple').

Test sentence: *Guck mal! Welche Farbe hat der Hase, den das Pferd jagt?* ('Look! What color has the bunny who the horse chases?')

FIGURE 1 | Example of a visual scene, a preamble and a test sentence.

We might also find that language and memory abilities modulate children's performance differently. This would result in different patterns of interaction between language/memory and response accuracy/eye-gaze.

Regarding the specific pattern expected in the two kinds of data we have collected, a higher proportion of correct responses (i.e., naming the color of the correct figure) will express a more accurate off-line performance. With respect to the eye-gaze data, there are several possibilities. We measure the proportion of looks to the target figure in the visual scene that accompanies each test sentence, within a time window defined in advance for the analysis. Accurate processing of the sentence within the analysis window will be expressed either by earlier looks to the target figure, or by longer looks to the target (higher proportion of target looks), or both. Therefore, the initial predictions regarding the performance pattern in the accuracy data and the eye-gaze data roughly correspond. However, we might find evidence for correct processing of the sentences, or a more fine-grained performance pattern, only in the eye-gaze data.

Materials and Methods

Participants

Forty-seven 5-years-old children (24 females, age range 5.0–5.11, $M = 5.5$) participated in the study. All children are growing up as monolingual speakers of German and none has reported history of linguistic, hearing or other cognitive developmental disorders. Parents gave their consent for the participation of their children. The study, approved by the ethics commission of the University of Potsdam, was successfully piloted with a group of university students.

Material

Visual Stimuli

In a setup inspired by Arnon (2005, 2010) and Adani (2011) participants watched in each trial an animated video with two identical animals on the sides (target and distractor animals) and a third different animal in the middle (middle animal). Each of these three regions of interest had the same size of 436 × 400 pixels. An example of a visual scene is provided in **Figure 1**. Employing two verbs, 'chase' and 'tickle,' the three animals in the scene were chasing each other on half of the trials and tickling one another with a feather on the other half. Each of the animals in the scene was colored differently. The three colors were combined such that similar colors did not appear within the same video, in order to facilitate color distinction and recognition (Pitchford and Mullen, 2003). Each of the animals carried a small object (hat, glasses, flower or heart–all clip art images) that was relevant for the fillers, but not for the experimental items. The target animal (i.e., the referent of the OR head noun) could be one of four masculine nouns–bear, bunny, lion, or monkey–each of which appeared an equal number of times as target, and in a balanced manner across conditions. The middle animal was on some trials a neuter noun (horse, camel, zebra, or sheep) and on others a feminine noun (duck, cow, cat, or mouse). In the OR + 1pro condition, the middle animal was always the dog, established as referent for the 1st-person pronoun in an introduction story prior to the experiment (see Procedure). The direction of the scene was in half of the trials from left to right and in the other half from right to left. Depending on the action direction, the target animal was always either on the left or on the right side of the scene, but never in the middle. In the ORs, the target animal was always the last animal in the row; in the fillers, it was always the first animal in the row, to prevent participants from anticipating the side on which the target appeared.

Linguistic Stimuli

The design consisted of three experimental conditions [examples (7)–(9) in the Introduction], with seven trials in each condition, and 12 fillers (e.g., *Welche Farbe hat der Hase mit dem Hut?* 'What color is the bunny with the hat?'). Piloting the experiment before the actual testing revealed that, with this amount of items, the duration of the experiment (∼20 min) was adequate for 5-year-olds. The displayed videos were accompanied by the test sentences that were pre-recorded with a female German native speaker and integrated into the video file. These were questions about the color of one animal in the scene to be identified through a relative clause (in experimental items) or a small object (in fillers). Two lists were constructed, each containing a different pseudo-randomized order of the items. Half of the participants were exposed to the first list, and the other half were exposed

to the second list. The full list of items is provided in the online supplementary material.

Since all the target animals (i.e., the OR head noun) were singular masculine nouns, the relative pronoun in all the ORs was always unambiguously accusative case-marked (*den*, 'who$_{_ACC_MASC}$'). This way, the sentence is revealed to be an OR already upon encountering the relative pronoun and children might be facilitated in processing the sentence (Arosio et al., 2012). However, in order for children to be able to make use of this information, they have to be able to recognize the accusative case-marking on the relative pronoun. In particular, they have to be able to distinguish the accusative case-marked *den* from the nominative case-marked *der*. If children cannot tell apart the two minimally differing case-markings they might erroneously understand the sentence as a SR (e.g., *Welche Farbe hat der Hase, der das Pferd jagt?* 'What color has the bunny who$_{_NOM_MASC}$ the horse chases?'). This might mask the comprehension difficulties children typically have with the syntactic structure of the OR as such. In order to determine whether children were able to discern between the two case-markings, we looked at their performance on one of the language tests that were administered (from the TSVK battery, Siegmüller et al., 2010): the test on the comprehension of OVS sentences, which are grammatical but non-canonical in German. Successful performance on this test requires the distinction between nominative (*der*), accusative (*den*) and dative case-marking (*dem*), in order to understand that the pre-verbal noun is an accusative- or dative-marked object and that the post-verbal noun is a nominative-marked subject. When looking at the performance on this test it appears that 37 out of 41 children scored at or above 50% (answering correctly six or more out of the 12 questions in the test). Scatterplots showing the relation between individual performance on this test and the overall performance in the experiment (both in terms of off-line accuracy and on-line eye-gaze) are provided in the online supplementary material. Additional evidence that children in our study were able to tell apart nominative and accusative case-marking stems from independent studies that show that children as old as 4.6 can already distinguish nominative and accusative case-marking in German (Grünloh et al., 2011)[5].

Memory

We administered to the children a forward span test and a backward version of the same test. The sequences for the forward span test were taken from the Intelligence and Development Scales battery (Grob et al., 2009). The forward span test was used to measure verbal short-term memory. To measure verbal working memory, we used the same sequences in a backward span test which is typically taken to measure this type of memory capacity. The sequences in the two memory tasks were of increasing length, ranging from 2 to 7 items in each sequence, and containing either digits or letters (for instance, 5-3-8 or C-O-G). For each sequence length (of two items, three items, and so on) there was one sequence of digits and one sequence of letters.

Language

The language tests were three subtests from Siegmüller et al.'s (2010) standardized battery for receptive grammatical abilities in German: subtest 3 for the comprehension of SVO and OVS sentences (e.g., *Die kinder zeichnet der Mann* 'The$_{_ACC}$ children draws the$_{_NOM}$ man'); subtest 5 for the comprehension of sentences containing reflexives and pronouns (*Der Papa wäscht ihn* 'The$_{_NOM}$ father washes him$_{_ACC}$'); and subtest 6 for the comprehension of various types of relative clauses (right-branching SR: *Den Hasen schiebt der Esel, der weint* 'The$_{_ACC}$ bunny pushes the$_{_NOM}$ donkey that$_{_NOM}$ cries'; center-embedded OR: *Der Mann, den der Indianer trägt, liest* 'The$_{_NOM}$ man, that$_{_ACC}$ the$_{_NOM}$ Indian carries, reads'). In all these tests, the task is to point to one picture out of three that best corresponds to a sentence read aloud by the experimenter.

Procedure

The experiment was carried out at a university lab, in a quiet and child-friendly room. Participants were seated at a distance of 55–70 cm from a DELL laptop (screen resolution 1600 × 900, white background), connected to an SMI RED-m eye-tracker (sample rate 60 Hz). The experiment was run over the SMI Experiment Center software. An experimenter sat next to the participant, observing the tracking quality on a separate monitor and moving from one trial to the next, or repeating a trial if necessary, by pressing keys on an external keyboard. The experimenter also registered by hand the participant's verbal response in each trial.

In an introduction video, displayed prior to the experiment, Nellie the dog appeared and explained she would like to have the child's help in learning the color names. She explained the task and gave three example questions that served as warm-up trials. Participants received feedback on their responses to the practice trials, but not during the actual experiment. After the warm-up items, Nellie showed and named all the animals as well as the actions (chasing and tickling) that would appear in the game. The story teller also said she would appear every now and then and play with her friends. This, together with the appearance of the dog as the middle animal in the relevant trials, established the referent for the 1st-person pronoun and made its usage felicitous.

In the experiment, each trial started with a preamble video in which the animals of the scene were presented and their colors were named. The referent of the 3rd-person pronoun was stressed prosodically in the preamble, in order to make it more salient in the discourse. The test question followed the preamble video immediately (**Figure 1** shows an example of a visual scene with the preamble text and the test sentence accompanying it. An example of a preamble text and a test sentence for each of the conditions, as well as a video exemplifying a trial, can be found in the online supplementary material.). Upon hearing the question about the color of one of the animals, participants answered and the experimenter noted their response on a sheet. In case of no response the experimenter offered the participant to listen again to the question. In such cases, both the preamble and the

[5]To be sure, we performed all the analyses after excluding the four children who scored lower than 50% on the test for comprehension of OVS sentences. The results were qualitatively similar to those of the analysis in which these children are included. We therefore report the results from the analysis that includes all children.

test question were replayed and only the second response was counted in the analysis. A short break was taken after every 10 items. The entire duration of the experiment was approximately 20 min. Children, who were generally engaged and happy to participate, received stickers as a reward.

The forward and backward span tasks and the language tests were administered in a separate session, 1–3 weeks after the first appointment, at the same room at the university lab. The instructions for the forward span task were given following the protocol of this test (IDS, Grob et al., 2009). The instructions for the backward span task were based on those given in another such test that has norms from older children (HAWIK, Petermann and Petermann, 2008). In the forward span task, the experimenter read to the children the sequences of digits and letters and the child was required to repeat each sequence in the order in which the items had been presented. In the backward span task, the child heard the same sequences read by the experimenter and was instructed to repeat each sequence in the exact opposite order. The task was interrupted if the child failed to correctly repeat three consecutive sequences. The order of testing was the same for all children: the forward digit span test was administered first, then the backward digit span test, followed by the three language tests [comprehension of (a) OVS sentences; (b) pronouns and reflexives; and (c) relative clauses].

Results

We analyzed the data using the *lme4* package (Bates et al., 2014) in the R environment (R Development Core Team, 2014). The categorical accuracy data were analyzed with logit mixed models (Jaeger, 2008). The eye-tracking data were analyzed using linear mixed models with empirical logit as dependent variable (Barr, 2008). The eye-gaze plots present the data after having removed the individual differences from the dependent variable, based on the outcome of the linear mixed model. This was done using the *remef* function (Hohenstein and Kliegl, 2013). The plots therefore present the results on which the statistical inferences are based, that is, the ones that are derived from the statistical model. Importantly, in the case of the data presented here, plotting the partial effects yielded patterns qualitatively similar to those of the observed data. This means that removing the individual differences did not alter the general pattern in the data. For each of the eye-gaze plots, a corresponding figure showing the observed data is provided in the online supplementary material, for the sake of comparison. Memory Score (average score on the two span tests) and Language Score (average score on the three language tests) were inserted into the mixed-effects model analysis as continuous covariates, without splitting the group of participants. However, for the sake of presenting the data (either in a plot or in a table), the group was divided into children who scored higher vs. those who scored lower on the tests. This division was done with a median split. Scatterplots showing the individual performance pattern (for both the accuracy and the eye-tracking data) in relation to the average score on the memory and language tests can be found in the online supplementary material. In this section, we report the most relevant results of the analyses. The complete output of each model is listed in the online supplementary material.

The data from six children who did not do the memory and language tests were excluded, so the analysis of the accuracy data is based on 41 children. For two among these, eye-tracking failed due to technical problems during the testing session. Thus, the analysis of the eye-tracking data is based on 39 children. In the eye-tracking data analysis, we excluded 35 trials (2.2% of the total trials available) in which there was more than 50% data loss. The excluded items were distributed across all conditions and several participants. Prior to the analysis, we checked whether the participants performed similarly on trials with the verb *jagen* 'chase' and on those with the verb *kitzeln* 'tickle.' There was no substantial difference in the performance on trials involving these two actions, neither in terms of response accuracy nor in terms of eye-gaze. Hence, all trials were analyzed together.

Accuracy

Response accuracy was calculated based on the color named by the participants (Arnon, 2010). Naming the color of the target animal was scored as 1; otherwise as 0. Without taking into account the individual differences of language and memory abilities, children performed on the OR + 1pro condition 97% (SE = 0.03) accurately, on the OR + 2DP condition 47% (SE = 0.02) and on the OR + 3pro condition 44% (SE = 0.03). These accuracy percentages were compared to chance level using one-sample *t*-tests (chance level was set at 0.5 since, although there were three regions of interest in the visual scene, children never named the color of the middle animal, indicating that they never considered it a possible answer). Only performance on the OR + 1pro condition was significantly above chance ($t = 43.06$). On the OR + 2DP and OR + 3pro conditions, performance was at chance ($t = -0.59$ and $t = -1.16$, respectively).

The results look different when language and memory abilities are considered. **Figure 2** shows the pattern of relation between children's scores on the language and memory tests, and how it is manifested in their performance on each of the three conditions. The ceiling performance on the OR + 1pro condition was not influenced by language and memory abilities. The pattern that emerges in the OR + 2DP condition is similar to that in the OR + 3pro condition. A lower score on the language tests determined a below-chance performance on these two conditions, whereas a higher score on the language tests determined a more accurate performance on them.

The accuracy data were fit into a logit mixed model, including Condition as fixed factor, Language Score and Memory Score as two continuous covariates (without splitting the participant group) and intercepts for random effects of subjects and items. The OR + 1pro condition was excluded from the analysis to avoid the impact of extreme differences in task performance on the model outcome. All the terms that contain an interaction between Language and Memory were included, since these two covariates did not correlate significantly ($r = 0.08$, $t = 0.45$). A table of correlations between the language measure, the memory measure and response accuracy is provided in the online

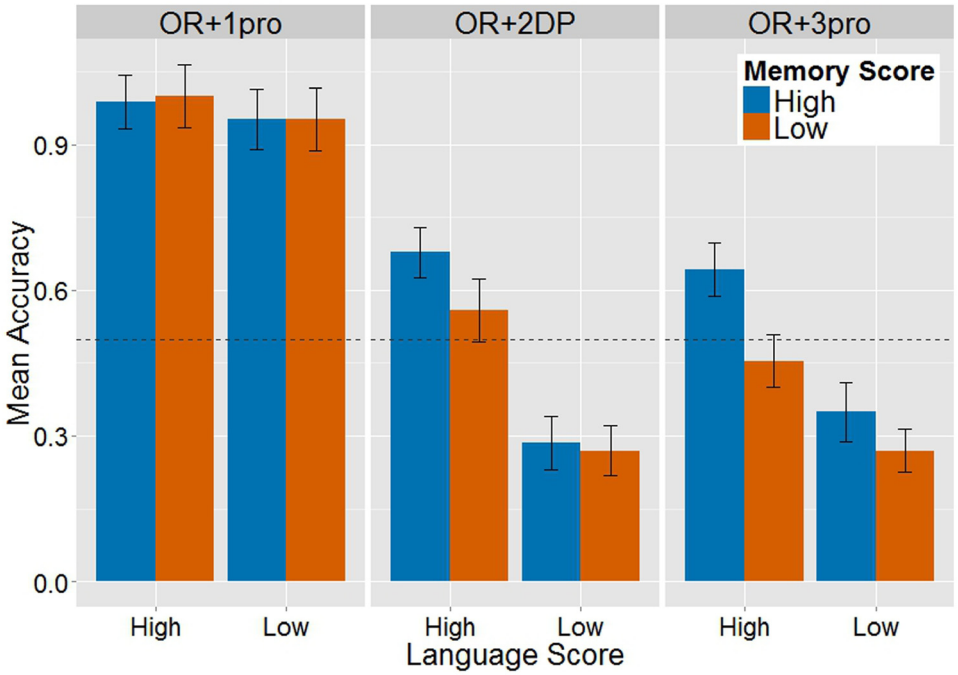


FIGURE 2 | Mean response accuracy (±1 SE) on the three conditions, in relation to children's scores on the language tests (on the *x*-axis) and on the memory tests (blue = High Score; orange = Low Score). The horizontal dashed line marks the chance level of 0.5.

supplementary material. The main effect Condition was not statistically significant (coef = −0.12, SE = 0.49, $z = -0.25$, $p = 0.81$), confirming that performance on OR + 2DP and OR + 3pro was overall similar. The main effect Language Score was significant (coef = 0.36, SE = 0.16, $z = 2.26$, $p = 0.02$), and so was the interaction Condition by Language Score (coef = −0.31, SE = 0.13, $z = -2.34$, $p = 0.02$). This interaction reflects the fact that, whereas performance on the OR + 2DP and OR + 3pro conditions was the same in children with lower language scores, children with higher language scores were significantly more accurate on OR + 2DP than on OR + 3pro. None of the terms that include Memory Score (main effect Memory and the interactions Condition by Memory, Language by Memory as well as Condition by Language by Memory) was statistically significant. Hence, we see that children's performance on OR + 2DP and OR + 3pro in the off-line data is modulated by language, but not by memory capacity.

Eye-Tracking

Figure 3 shows, for each of the three conditions, the proportion of target looks of children with high and low scores on the memory tests, broken by their scores on the language tests in order to see the relation between the two cognitive measures. The plot shows the data within the relevant time window, defined *a priori* for the analysis, rather than for the entire trial duration. This window starts at the offset of the relative pronoun *den* (plus 200 ms, the average time span necessary for programming and executing an eye movement; Trueswell, 2008). Note that the part that precedes the relative pronoun (*Welche Farbe hat der Hase,...* 'What color has the bunny...') is ambiguous about whether the sentence is a SR or an OR. However, based on the unambiguously accusative case-marked relative pronoun, it is already possible (and, indeed, very likely for adult speakers at least) to correctly predict that the sentence will turn out to be an OR. For these reasons, the beginning of the critical time window has been set at the beginning of the critical information in the sentence, that is, after the relative pronoun has been processed. This window ends after the 2-s long silence that followed the test question.

Within this time window, the effects we are interested in might start from the onset of the embedded subject DP onward, while the embedded full DP or pronoun and the verb are processed. Another (perhaps more plausible) possibility is that the effects emerge also in the 2-s long silence following the test sentence. In other words, children might continue to process the structure even after the sentence offset (Brandt-Kobele and Höhle, 2010; Adani and Fritzsche, 2015). Importantly, by including the post-sentential silence in the analysis time window we account for effects that might occur upon processing the verb, which is the very last word in the sentence. This is relevant in the light of studies with adults that predict the effect to occur at the verb, the point in which the filler-gap dependency is resolved (e.g., Gibson, 2000; Gordon et al., 2001, 2002; Warren and Gibson, 2002; Lewis et al., 2006; O'Grady, 2011).

Within the critical time window, which was approximately 2800 ms long, the dependent variable was the proportion of looks to the target figure, calculated as looks to the target animal

divided by looks to all the three animals in the visual scene. An accurate processing of the sentence in terms of eye-gaze might be expressed by faster looks to the target (earlier increase in proportion of target looks, or PTL), by more target looks (higher PTL), or by both. Note that, in the analysis procedure adopted here (Barr, 2008), Time is included in the model as a continuous covariate. Therefore, the analysis does not provide information about the specific point in which the effect occurs. For this reason, we will not be able to say how long exactly after the embedded subject DP or the embedded verb have been processed the effect starts. However, the advantage in such an analysis is that the time-related information is obtained in its entirety, without the necessity to cut time into chunks and lose information about the timely course of the gaze pattern. The time-related information is expressed here in the form of significant interactions with the Time covariate. For instance, a significant interaction Condition by Time would mean that, over time (without knowing where exactly during the analyzed window), target looks in one condition increase more than in another condition. For the analysis, each of the pronoun conditions was compared to the baseline condition with two full DPs, using sliding contrast specification (OR + 1pro vs. OR + 2DP vs. OR + 3pro). The plot and analysis of the eye-gaze data include all the trials in the experiment, independently of whether they were answered correctly or incorrectly.

Let us turn to the gaze pattern shown in **Figure 3**. In the OR + 1pro condition, the increase in target looks is faster and the PTL is higher (peaking around 1200 ms into the critical time window) than in the other two conditions, reflecting what we find in the accuracy data. Individual differences in language and memory skills do not appear to affect this pattern. In the OR + 2DP condition, children with a low score on the language tests look less to the target independently of their memory score (lower middle panel in **Figure 3**). Children with a higher language score (upper middle panel) look faster to the target when their memory score is high (culminating at about 1500 ms), as compared to when their memory score is low. These high-language but low-memory children eventually look to the target like their high-memory peers, but at a later point (around 1800 ms). In the OR + 3pro condition, children with a low language score again look less to the target independently of their memory score (lower right panel). However, a clear difference emerges between high-memory and low-memory children when their language score is high (upper right panel). Here, high-memory children look to the target faster and more than their low-memory peers.

Following Barr's (2008) procedure for the analysis of eye-tracking data in the visual-world paradigm, we performed only the by-subject analysis, aggregating the data across items. This was done due to the relatively small number of items per condition. The proportion of target looks was transformed to an empirical logit and used as the dependent variable in the model. Time, divided into 50 ms long bins, was centered around the point in which target looks started to increase when all conditions are collapsed together, based on a Grand Mean plot. We then fit a linear mixed model including Condition as fixed factor, Time as

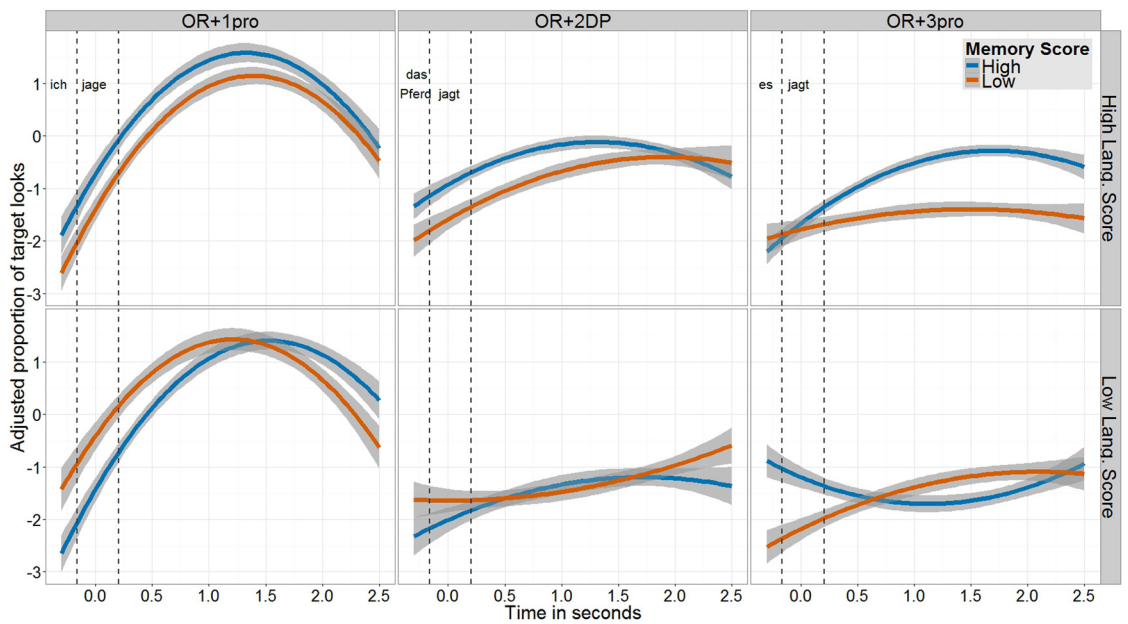

FIGURE 3 | Proportion of target looks (transformed to empirical logit and adjusted after the removal of individual differences) within the time window relevant for analysis, shown separately for each condition, divided by children's score on the memory tests (blue line = High Score; orange line = Low Score) and broken by their score on the language tests (top row = High Score; bottom row = Low Score). On the *x*-axis Time ranges from the offset of the relative pronoun until the end of the 2-s long silence that followed the sentence. Two vertical dashed lines mark the critical chunks in the analysis window: (1) embedded subject DP (*ich* 'I'; *das Pferd* 'the horse'; *es* 'it'); (2) embedded verb (*jage/t* 'chase/s'); (3) post-sentential silence. The analysis of the eye-gaze data was performed on the entire time window shown in the plot (chunks 1–3).

covariate with linear and quadratic polynomials, Language Score and Memory Score as additional continuous covariates (without group splitting) and an intercept for the random effect of subjects. As in the model for the accuracy data, all the terms that contain an interaction between Language and Memory were included as well, due to the lack of correlation between the two measures. The inclusion of a quadratic term for Time was justified by a comparison to a model with a linear term only ($\chi^2 = 726.3$, difference in Df = 12, $p < 0.001$).

The main effect Condition was significant for both comparisons, but in opposite directions: PTL in the OR + 1pro condition were significantly greater than those in the OR + 2DP condition (coef = −0.82, SE = 0.03, $t = -30.88$); PTL in the OR + 2DP condition were significantly greater than those in the OR + 3pro condition (coef = −0.25, SE = 0.03, $t = -9.46$). These effects mean that children looked to the target in OR + 1pro trials overall longer than in OR + 2DP trials, and in these longer than in OR + 3pro trials. The former effect reflects what we find in the accuracy data, but the advantage of OR + 2DP over OR + 3pro in terms of eye-gaze is absent in the accuracy data. Both the main effect of Language (coef = 0.06, SE = 0.03, $t = 1.98$) and the main effect of Memory (coef = 0.09, SE = 0.05, $t = 1.87$) were only marginally significant. Also the interaction Language by Memory was not statistically significant (coef = 0.07, SE = 0.04, $t = 1.73$). Most importantly, all the four-way interactions were significant. For the comparison OR + 1pro vs. OR + 2DP, the interaction Time by Condition by Language by Memory was significant (for the quadratic term of Time: coef = 3.88, SE = 1.82, $t = 2.13$). This effect reflects the pattern observed in the two middle and the two left panels of **Figure 3**. No individual differences in language and memory emerge in the performance on the OR + 1pro condition, whereas differences do emerge in the OR + 2DP condition depending on language and memory scores. Also for the comparison OR + 2DP vs. OR + 3pro, the interaction Time by Condition by Language by Memory was significant (for the linear term of Time: coef = 8.41, SE = 1.80, $t = 4.66$; for the quadratic term of Time: coef = −6.39, SE = 1.76, $t = -3.63$). This effect reflects what we see in the two middle and the two right panels of **Figure 3**. When language score is low, the gaze pattern in the two conditions is the same independently of the memory score. But when language score is high, the differences between high-memory and low-memory children are more pronounced in the OR + 3pro condition than in the OR + 2DP condition: only in the latter the low-memory children eventually look to the target like their high-memory peers, albeit later.

Looks to Distractor

Before discussing the results, let us examine the pattern of children's looks to the distractor animal. Recall that, in their off-line responses on incorrect trials, children named the color of the distractor animal, never that of the middle animal. **Figure 4** shows, for each of the three conditions, the proportion of distractor looks in children with high and low scores on the memory tests, broken by their language scores (again, we plot here the partial effects; the corresponding plot showing the

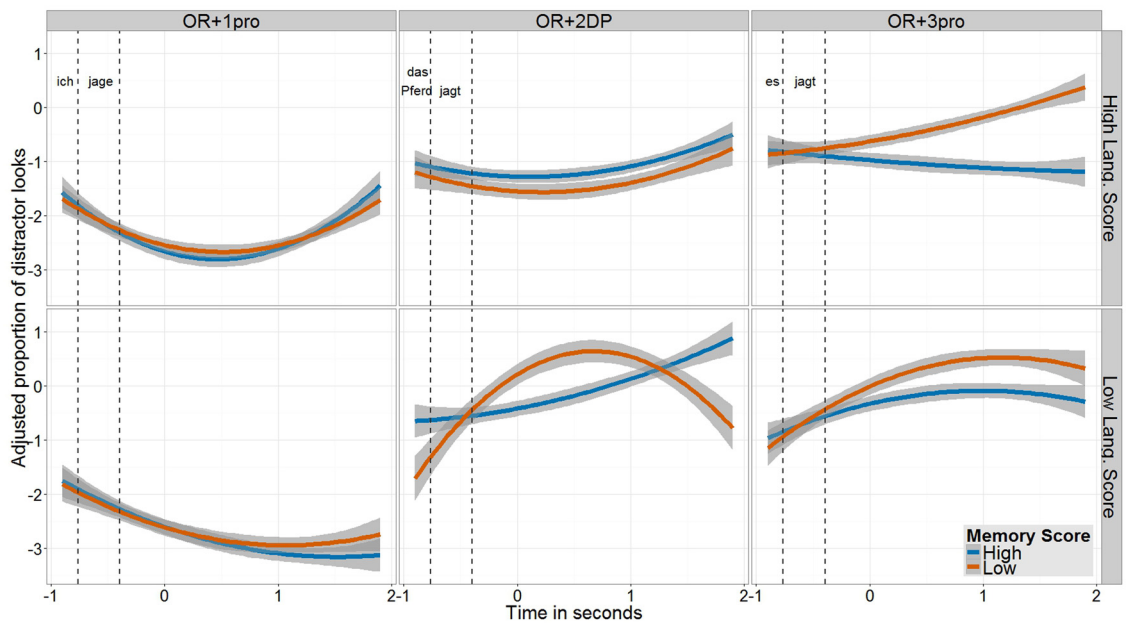

FIGURE 4 | Proportion of looks to the distractor figure (transformed to empirical logit and adjusted after the removal of individual differences) within the time window relevant for analysis, shown separately for each condition, divided by children's score on the memory tests (blue line = High Score; orange line = Low Score) and broken by their score on the language tests (top row = High Score; bottom row = Low Score). On the *x*-axis Time ranges from the offset of the relative pronoun until the end of the 2-s long silence that followed the sentence. Two vertical dashed lines mark the critical chunks in the analysis window: (1) embedded subject DP (*ich* 'I'; *das Pferd* 'the horse'; *es* 'it'); (2) embedded verb (*jage/t* 'chase/s'); (3) post-sentential silence.

observed data is provided in the online supplementary material). As expected, and reflecting children's off-line responses, on the OR + 1pro condition their looks to the distractor are very low. By contrast, on the OR + 2DP and OR + 3pro conditions, the proportion of distractor looks throughout the critical time window is very high, mostly for children with lower memory scores. That is, children's errors were expressed by their systematic (off-line as well as on-line) interpretation of the OR as a SR, treating the DP head as the subject rather than the object of the embedded clause. This pattern of error is typically found in studies on children's comprehension of relative clauses.

Discussion

The aim of the study was to test the effects of various pronoun types on children's processing of ORs. We took as reference condition ORs with a full DP head and an embedded full DP subject, which are typically hard for children, and manipulated the embedded subject using personal pronouns. The three OR types were structured with a masculine noun as DP head, which had the advantage of facilitating, at least potentially, children's comprehension. This was achievable due to the possibility to recognize the sentence as an OR rather early in the sentence, upon processing the accusative case-marking on the relative pronoun (*den*). There is evidence from previous studies on relative clause comprehension in German (Arosio et al., 2012) that children are facilitated when the relative clause (whether a SR or an OR) is disambiguated by case (as in our stimuli), as compared to when it is disambiguated by a singular or plural number-marking on the embedded verb (in our stimuli, the verb was always marked with singular). Another characteristic of the three conditions we tested is that they differ with respect to the referring expression in the embedded subject position–full DP, 1st- or 3rd-person pronoun. We therefore expect these referring expressions to trigger effects in task performance, if their referential properties play a role in determining OR processing. The initial prediction, as made by Friedmann et al. (2009) and by other accounts, is that ORs with embedded pronominal subjects are more accurately comprehended than ORs with two full DPs, independently of the pronoun type. Our findings support this prediction only partially.

First, we find that children are more accurate on ORs with an embedded 1st-person pronoun than ORs with two full DPs, both in terms of off-line accuracy and in terms of on-line eye-gaze, where we find more target looks in the OR + 1pro than in the OR + 2DP condition. This finding supports the initial prediction. It is also in line with other studies, both with children and with adults, showing that a 1st- or 2nd-person pronoun in the embedded subject position makes the OR easier to process (Gordon et al., 2001; Warren and Gibson, 2002, 2005; Arnon, 2010).

We also find that ORs with 1st-person pronoun are more accurately processed (again, both off-line and on-line) than ORs with 3rd-person pronoun. This result is not in line with the RM account, since the prediction is that different pronoun types in the embedded subject position facilitate ORs to an equal extent. The reason is that in both cases the full DP head, which contains the [+NP] feature, crosses an intervening pronoun, a constituent that lacks the [+NP] feature. This result appears to disagree also with other accounts that predict facilitated performance on ORs with an embedded pronoun, independently of the pronoun type (e.g., Gordon et al., 2001; Lewis et al., 2006). The pronoun asymmetry suggests that defining the (dis)similarity between the DP head and the embedded subject DP only in terms of 'lexical restriction,' that is, in terms of a full DP vs. a personal pronoun, is not sufficient. This pronoun asymmetry is in line, however, with theoretical accounts on referential properties of pronouns (Heim, 1991; Recanati, 1993; Erteschik-Shir, 1997; Ariel, 2001; Legendre and Smolensky, 2012) as well as with previous experimental studies with adults. Both Warren and Gibson (2002) and Carminati (2005) found that the presence of a 1st-person pronoun facilitates adults' sentence processing more than the presence of a 3rd-person pronoun. These studies explain such an asymmetry in terms of the different referential properties of the pronouns. Since discourse referents of 1st-person pronouns are accessed directly, these pronouns are less costly for processing than 3rd-person pronouns, which need to be resolved via an antecedent (in the sentential or extra-sentential context), before the discourse referent of the pronoun is accessed. This is also the case in the present study: the discourse referent of the 3rd-person pronoun is accessed only after the pronoun has been resolved via an antecedent, which had to be retrieved from the linguistic context provided in the preamble video before the trial. Hence, the presence of the pronoun in itself does not necessarily facilitate OR processing. It seems that only pronouns that relate to their discourse referents directly, like 1st-person pronouns, do so[6]. The facilitation found by Friedmann et al. (2009) with Hebrew ORs containing an embedded arbitrary *pro* subject (example 6 in the *Introduction*) can be explained on similar terms. The Hebrew arbitrary *pro* is used when the agent of the action remains unspecified. It might well be that the facilitation was due to the discourse properties of *pro*–the fact that it does not relate to any specific discourse referent, thus reducing processing cost–rather than to its property of lacking the [+NP] feature, as suggested by the authors.

A third pattern, that emerges in the eye-gaze data, is that ORs with a 3rd-person pronoun are actually harder for children than ORs with two full DPs. This finding is not in line with the prediction that any kind of pronoun in the embedded subject position facilitates OR comprehension (e.g., Gordon et al., 2001; Friedmann et al., 2009; Rizzi, 2013). It can be explained, again, if the referential properties of the referring expressions are taken

[6]Recall that the middle animal in the visual scenes accompanying the OR + 1pro condition was always the dog, the narrator. One reviewer pointed out that children's high performance on this condition might reflect their familiarity with this animal, rather than the effect caused by the pronoun itself. We have already addressed this issue in a follow-up study, yet to be published. Using similar material and methodology, we tested children on different types of relatives (SRs and ORs), in which the figure of the narrator appeared in various experimental conditions and in some fillers. In this setup, it was impossible to anticipate the type of sentence based on the visual presence of the narrator. Importantly, the results show that the 1st-person pronoun advantage over the 3rd-person pronoun persists, similarly to what we find in the present study.

into account. A 3rd-person pronoun can be interpreted only after it has been related to an antecedent, which needs to be located and retrieved from the linguistic or extra-linguistic context. This is not the case with a full DP, whose discourse referent is derived from its lexical meaning and accessed directly. Note that, just like in an OR with a 1st-person pronoun, also in an OR with 3rd-person pronoun the DP head crosses an intervening pronoun. The fact that the former condition is easier than the latter, compared to the baseline with two full DPs, supports further the claim that the presence of the pronoun on its own cannot account for children's performance. Rather, the type of pronoun–and more precisely, the referential properties of that pronoun–appear to play a major role in facilitating or not facilitating the processing of the OR.

Interestingly, Goodluck (2005, 2010) managed to separate intervention locality effects from complex discourse accessibility operations. Goodluck (2005) manipulated the discourse accessibility operation in object-extracted wh-questions by making it more demanding (*Which lion did the zebra kiss?*) or less demanding (*Which animal did the zebra kiss?*). Crucially, in both cases, the intervention locality effect was present (in both sentences, both the moved object DP and the intervening subject DP are lexically restricted). The fact that children were more accurate on the *which-animal* question than on the *which-lion* led the author to conclude that discourse accessibility determines children's performance on the structure independently of the syntactic complexity. This is reminiscent of what we find in the two pronoun conditions. Both in OR+1pro and in OR + 3pro, the (reduced) syntactic complexity is kept constant due to the embedded pronoun. Therefore, children' higher accuracy rate on OR + 1pro than on OR + 3pro is likely due to the different referential properties of the pronouns. In other words, the direct discourse accessibility in the case of the 1st-person pronoun makes this condition easier than the 3rd-person pronoun condition, in which discourse accessibility is indirect and therefore more demanding.

Note that the advantage of the OR + 2DP condition over OR + 3pro, in terms of main effect, is found only in the on-line eye-gaze data. An even more crucial finding is that the effects of memory only emerge in the on-line data, whereas they remain hidden when looking at the off-line accuracy data. These findings join a growing body of studies that show that children's performance sometimes appears different when tested by means of explicit or implicit responses. Specifically, measures of implicit processing (such as eye-tracking) often suggest that children accurately parse ORs even though their explicit performance on the same ORs remains poor (Adani and Fritzsche, 2015; see also discussion in Brandt-Kobele and Höhle, 2010). In the present study we show that children looked faster or longer to the target figure in conditions that they processed more accurately than in conditions that were harder for them. In other words, when children correctly processed a sentence their attention on the target figure was more stable in comparison to harder sentences.

These eye-gaze effects were found within the 2800 ms long time window defined *a priori* for the analysis. A widespread assumption, supported by evidence from on-line processing studies with adults, is that such effects occur upon processing the embedded verb of an OR, the site in which the filler-gap dependency is resolved (e.g., Gibson, 2000; Gordon et al., 2001, 2002; Warren and Gibson, 2002; Lewis et al., 2006; O'Grady, 2011). Although Friedmann et al. (2009) do not make specific predictions regarding the exact point in which intervention effects occur, it seems they do so in subsequent work (Belletti et al., 2012), suggesting that intervention effects are detectable only when the two relevant DPs (the head noun and the embedded subject in an OR) are similar in terms of morphological features that are overtly marked on the embedded verb. Hence, it seems that also according to the RM account intervention effects in ORs are expected to occur at the embedded verb. This idea is entertained also in Franck et al. (2015).

Analyzing the eye-gaze data in the entire time window from the offset of the relative pronoun until the end of the post-sentential silence does not allow the detection of time-locked effects. Nevertheless, it had several motivations and some evident advantages. First, the part of the sentence that precedes the relative pronoun, which was equal in the three conditions, is not informative enough to guide the participants toward the identification of the relevant referent. We therefore do not expect any gaze pattern prior to hearing the relative pronoun to be driven by the linguistic input. Second, processing the unambiguously accusative case-marked relative pronoun is virtually enough to be able to identify the sentence as an OR and thus the correct referent. Even though we do not expect to find evidence for such rapid processing in 5-year-olds, the crucial point is that the relative pronoun is the first informative point in the sentence. Third, young children might be slow in processing the OR, and effects stemming from their eye-gaze might well emerge after the critical information has been processed. Several visual-world studies have even found effects occurring after the sentence ended (e.g., Brandt-Kobele and Höhle, 2010; Adani and Fritzsche, 2015). Crucially, the embedded verb in our stimuli is the last word in the sentence. Thus, post-sentential effects might be driven (also) by the filler-gap dependency resolution at the verb, as predicted, for instance, by Gibson (2000), Gordon et al. (2001, 2002), Warren and Gibson (2002), Lewis et al. (2006), O'Grady (2011) and other account. Finally, following Barr's (2008) analysis procedure, the inclusion of Time as a continuous covariate appears to be more appropriate in a linear mixed-effects model analysis. The main reason is that the effect of time (the change in gaze pattern throughout the duration of the trial) is captured in its entirety, whereas by cutting it into chunks some information about the time course of the gaze pattern is lost.

Concerning language and memory abilities, we have looked at the role of children's memory capacity in their OR processing and at its relation to the role of their language skills. The goal was to test whether effects which are due to language and memory depend on each other or not and, if they do, in what manner. We had previously shown that, on the two harder conditions (OR + 2DP and OR + 3pro), children with stronger language abilities are significantly more accurate than children with weaker language skills (Haendler et al., 2015). Given the linguistic material used in the three administered subtests, we reasoned that

stronger language or grammatical skills meant a stronger ability to compute movement-derived structures (subtests on sentences with canonical and non-canonical word order) and a stronger ability in discourse accessibility operations (subtest on reflexives and pronouns). It is therefore not surprising that children who had a higher average score on these tests were more accurate on ORs that were more difficult in terms of computing the syntactic movement (OR + 2DP) and on ORs that were more difficult in terms of discourse accessibility (OR + 3pro). On the OR + 1pro condition, in which both the computation of the syntactic movement and discourse accessibility are facilitated, all children were accurate independently of their score on the grammatical tests.

In the present study, adding memory abilities to the picture reveals a more fine-grained pattern in the effects of language skills previously found. The analysis shows that language and memory have independent, additive effects that vary in relation to the experimental conditions. Children are most accurate on the OR + 1pro condition, but neither their response accuracy nor their eye-gaze are influenced by individual differences in language and memory abilities. Individual differences in language and memory do affect, however, performance on the OR + 2DP and OR + 3pro conditions, but the effects of memory are observable only in the eye-gaze data, as mentioned earlier. Whether children with weaker grammatical skills have stronger or weaker memory does not seem to affect their performance substantially. By contrast, the gaze pattern of children with stronger grammatical skills clearly changes depending on their memory capacity. In the OR + 2DP condition, low-memory (and high-language) children look to the target like their high-memory peers, but later, suggesting an accurate albeit delayed processing of the sentence. In the OR + 3pro condition, low-memory (and high-language) children look to the target less than their high-memory peers up to the end of the trial, showing no evidence of correct processing of the sentence. **Table 1** summarizes these findings in a schematic way.

To account for these results, we will now explain what might cause the qualitative differences among the conditions and how language and memory abilities might play a role in creating the effects we find. The three conditions are similar in their syntactic structure, in the sense that they are all ORs in which the DP head moves from the embedded object position. Processing this movement, and resolving the filler-gap dependency, is assumed to be facilitated in the two pronoun conditions. According to the RM account, the syntactic complexity of OR + 1pro and OR + 3pro is reduced due to the attenuation of the intervention locality effect, since the full DP head crosses an intervening pronoun rather than another full DP (Friedmann et al., 2009; Rizzi, 2013). The syntactic complexity of ORs with pronouns is reduced also from the perspective of the integration cost metric account (Gibson, 1998, 2000; Warren and Gibson, 2002, 2005) and according to the similarity-based and cue-based interference approach (Gordon et al., 2001, 2002, 2004; Lewis and Vasishth, 2005; Lewis et al., 2006; van Dyke and McElree, 2006, 2011). All these accounts argue that facilitated processing of ORs with embedded pronouns is due to reduced burden on memory resources (see also Sheppard et al., 2015). The three conditions differ, however, with respect to the referring expression in the embedded subject position: these referring expressions require different levels of processing cost in terms of discourse accessibility. The 1st-person pronoun and the full DP relate to their discourse referents directly, deriving them from their lexical meanings, whereas the 3rd-person pronoun relates to its discourse referent indirectly, deriving it from the meaning of the antecedent to which it relates. This implies that referring expressions (such as 1st-person pronouns and full DPs) whose discourse referent is accessed directly overload memory resources less than referring expressions (such as 3rd-person pronouns) whose discourse referent has to be retrieved from the previously encoded context (Warren and Gibson, 2002; van Rij et al., 2013).

These syntactic and discourse characteristics of the conditions appear to explain the pattern we find in the data. In particular, they might account for the role of memory capacity and its additive effects to those of language skills. Language skills, as defined by the average score on the three language tests, appear to be the underlying constraint on children's performance. If children score low on these tests–in other words, if they are less proficient in processing movement-derived structures and in accessing discourse (these are the two relevant operations assessed by the language tests, as we have seen)–then we find no evidence for accurate processing of the two conditions that are hard either due to syntactic movement (OR + 2DP, in which a full DP moves over another full DP) or due to discourse accessibility (OR + 3pro, in which accessing the discourse referent of the 3rd-person pronoun is more demanding). It seems that, in the case of low-language children, some basic grammatical skills are weaker and therefore their memory capacity does not make any difference. Not surprisingly, even low-language children succeed on the OR + 1pro condition, which is less demanding both in terms of its syntactic movement and in terms of discourse accessibility. But also here memory capacity does not make any difference: this condition is equally easy for all children independently of their memory skills. What happens in children who score high on the three language tests? Just like their low-language peers, they perform at ceiling on the easiest OR + 1pro condition, independently of their memory capacity. A different pattern, modulated by memory, emerges in the two harder conditions (OR + 2DP and OR + 3pro). In OR + 2DP, high-memory children correctly process the structure, whereas low-memory children do so as well, but rather late. In OR + 3pro, there is evidence that only high-memory children

TABLE 1 | A summary of the cases in which we find evidence for accurate processing (in terms of on-line target looks) of the different conditions, depending on language, and memory abilities.

		OR + 1pro	OR + 2DP	OR + 3pro
High-language	High-memory	YES	YES	YES
	Low-memory	YES	YES, but late	NO
Low-language	High-memory	YES	NO	NO
	Low-memory	YES	NO	NO

YES, there is such evidence; NO, there is no such evidence.

correctly process the structure, whereas low-memory children are substantially less accurate.

Thus, memory capacity appears to be crucial when discourse accessibility is demanding (as when 3rd-person pronouns need to be resolved), but only if general linguistic abilities, such as computing syntactic movements and accessing discourse referents of pronouns and reflexives, are sufficiently strong. In the OR + 2DP condition, in which retrieving the referent of a full DP is less costly, even low-memory children eventually look to the target, although later than their high-memory peers. In the OR + 3pro condition, in which the retrieval of the referent of the 3rd-person pronoun is more costly, low-memory children do not catch up with their high-memory peers and there is no evidence that they accurately process the structure.

Our findings resemble, at least partly, those of Warren and Gibson (2002), who elaborate on the idea that memory resources are crucial for processing structures that require both filler-gap dependency resolution and accessing discourse referents of various referring expressions. These authors found the same asymmetry between 1st-person pronouns and 3rd-person pronouns, with the former facilitating OR processing more than the latter, an asymmetry which is explained in the light of Gibson's (1998, 2000) integration cost metric. According to the authors, the processing cost of a certain structure increases with the number of discourse referents that intervene between the filler and the gap site in which it is integrated. The reason is that each of the intervening discourse referents has to be integrated as well, thus reducing the memory resources available to process the structure. When one of the intervening discourse referents is a 1st-person pronoun, whose integration is done straightforwardly, the available memory resources are less burdened than in the case in which the intervening constituent is a 3rd-person pronoun, whose integration is more costly. Note, however, that in Warren and Gibson (2002) adults judged ORs with an embedded 3rd-person pronoun as less complex than ORs with two full DPs. This pattern is unlike what we find with children. In the present study, OR + 3pro appears to be the condition on which memory has the strongest impact. Given that children's memory abilities are underdeveloped, compared to adults,' it is not surprising that children with weaker memory skills struggle while processing ORs with an embedded 3rd-person pronoun, even if their ability to perform on the language tests we used is already strong.

Conclusion
