Our data support only in part a purely syntax-based account such as Friedmann et al.'s (2009), or the similarity-/cue-based interference accounts of relative clause processing. While we do find that an embedded 1st-person pronoun facilitates OR processing, we also find that an embedded 3rd-person pronoun does not. It appears that OR processing is constrained not only by the syntactic complexity of the structure, but also by the referential properties of the involved constituents. Both require memory resources and might thus determine difficulties in processing the OR, as has been suggested for adults. The results suggest that both language and memory abilities play a role in modulating these syntactic and discourse accessibility constraints, and that they do so in an independent, additive fashion.

Acknowledgments

We thank: the participating children and their parents; Julia Billerbeck and Isabell Keßlau for their help with material preparation and data collection; the two reviewers for insightful comments and helpful suggestions. The research presented here was supported by a full scholarship granted to the first author from the *Ernst Ludwig Ehrlich Studienwerk* (Grant PF123) and by the SFB 632 "Information Structure" project, funded by the *Deutsche Forschungsgemeinschaft* (German Research Foundation). The publication of the paper was funded by the *Deutsche Forschungsgemeinschaft* and the *Open Access Publishing Fund* of the University of Potsdam, which are gratefully acknowledged.

Using the Visual World Paradigm to Study Retrieval Interference in Spoken Language Comprehension

Irina A. Sekerina[1, 2, 3]*, *Luca Campanelli*[4] *and Julie A. Van Dyke*[5]

[1] Department of Psychology, College of Staten Island, City University of New York, Staten Island, NY, USA, [2] Linguistics Program, The Graduate Center, City University of New York, NY, USA, [3] Neurolinguistics Laboratory, National Research University Higher School of Economics, Moscow, Russia, [4] Speech-Language-Hearing Sciences, The Graduate Center, City University of New York, NY, USA, [5] Haskins Laboratories, New Haven, CT, USA

The cue-based retrieval theory (Lewis et al., 2006) predicts that interference from similar distractors should create difficulty for argument integration, however this hypothesis has only been examined in the written modality. The current study uses the Visual World Paradigm (VWP) to assess its feasibility to study retrieval interference arising from distractors present in a visual display during spoken language comprehension. The study aims to extend findings from Van Dyke and McElree (2006), which utilized a dual-task paradigm with written sentences in which they manipulated the relationship between extra-sentential distractors and the semantic retrieval cues from a verb, to the spoken modality. Results indicate that retrieval interference effects do occur in the spoken modality, manifesting immediately upon encountering the verbal retrieval cue for inaccurate trials when the distractors are present in the visual field. We also observed indicators of repair processes in trials containing semantic distractors, which were ultimately answered correctly. We conclude that the VWP is a useful tool for investigating retrieval interference effects, including both the online effects of distractors and their after-effects, when repair is initiated. This work paves the way for further studies of retrieval interference in the spoken modality, which is especially significant for examining the phenomenon in pre-reading children, non-reading adults (e.g., people with aphasia), and spoken language bilinguals.

INTRODUCTION

Memory processes are crucial for language comprehension, especially the ability to store linguistic constituents and retrieve them later (perhaps much later) to combine with new information. For example, it is quite common for linguistically dependent information to be separated by a considerable distance. An example of such a construction is in (1), where a dependent constituent, *the girl,* is separated from the verb *smelled* by two relative clauses.

(1) The girl who walked with the cute little boy that wore the striped shirt smelled the flowers.

Consequently, a clear understanding of the memory processes that support accurate comprehension is critical to any psycholinguistic model of language use. In this paper, we

present a novel application of the Visual World eye-tracking Paradigm (VWP; Altmann, 2004; Trueswell and Tanenhaus, 2005) for studying these memory retrieval processes in spoken language comprehension. The particular novelty of the current study is to test the VWP against the logic of the dual-task paradigm, which has been used previously (Van Dyke and McElree, 2006, 2011) as a means of explicitly manipulating the contents of memory, and arguing specifically for retrieval interference (as opposed to encoding interference) in processing of spoken sentences with syntactic dependencies.

The Cue-Based Retrieval Theory (CBRT)

Several theories have been proposed to explain why establishing memory-dependent linguistic relationships as in (1) is challenging, even for monolingual adult speakers (see Levy et al., 2013 for a review). One of the most cited is *the Cue-Based Retrieval Theory* (*CBRT;* Gordon et al., 2002; McElree et al., 2003; Van Dyke and Lewis, 2003; Lewis et al., 2006; Van Dyke and McElree, 2006, 2011; Van Dyke and Johns, 2012; Van Dyke et al., 2014) which is grounded in a large body of empirical research pointing to a severely limited active memory capacity even for skilled monolingual readers, accompanied by a fast, associative retrieval mechanism that uses cues to access memory directly (reviewed in McElree, 2006). A central prediction of the CBRT is that interference effects will arise whenever retrieval cues necessary for identifying a distant dependent are ambiguous. It is this interference that creates comprehension difficulty. For example, in (1) the verb *smelled* selects for an animate subject, and there are two such NPs that fit these cues (*the girl* and *the cute little boy*). The second NP serves as a distractor for retrieving the target subject, resulting in longer reading times at *smelled* and lower accuracy to comprehension questions (Van Dyke, 2007).

In order to distinguish the retrieval account of the CBRT from accounts emphasizing costs associated with storing multiple similar items (e.g., Gordon et al., 2002). Van Dyke and McElree (2006) directly manipulated the relationship between the contents of memory and the cues available at retrieval. To do this, they utilized a dual task paradigm in which they asked participants to read written sentences like (2) in a phrase-by-phrase manner while performing a simultaneous memory load task.

(2) It was the button that the maid who returned from vacation spotted in the early morning.

On high memory load trials, participants were asked to remember a list of three words (i.e., KEY-PEN-EARRING) and then read the sentence in (2). The manipulation of interest was when the verb *spotted* was replaced with *sewed*; in the *spotted* case, all of the words from the memory list could serve as the verb's object, but only a *button* is *sew*-able. The authors observed increased interference effects from the words in the memory list in the form of longer reading times at the verb *spotted* (578 ms), but not at the verb *sewed* (540 ms). This difference disappeared when the memory list was not presented (564 vs. 567 ms, respectively), demonstrating that the reading time difference was *not* simply related to a difference in the semantic association between the verb and the clefted NP. Interference was due to the match between the distractors in the memory list and the semantic retrieval cues from the verb that specify the target referent (*the button*), i.e., an object that can be spotted.

This type of interference has now been demonstrated not only in measures of reading speed, but also in comprehension accuracy and grammaticality judgments, and in a variety of linguistic constructions; it takes place whether the intruders occur before (proactive interference) or after (retroactive interference) the retrieval target (Van Dyke and McElree, 2006, 2011; Martin and McElree, 2009); whether the intruder is syntactically, semantically, or referentially similar (Gordon et al., 2002; Van Dyke and Lewis, 2003); or even when the intruder is unlicensed in the grammatical construction (Van Dyke, 2007; Vasishth et al., 2008; Martin et al., 2012). Finally, sensitivity to interference appears to be modulated by individual differences in cognitive abilities (Van Dyke et al., 2014).

Written vs. Spoken Modality

The evidence associated with the CBRT is robust, but so far, it has been restricted to the reading modality. Hence, the role of retrieval interference in *spoken language comprehension* remains unknown. Speech contains a variety of spoken cues, but there is little evidence about how spoken cues are considered by the retrieval mechanism, and what priority they may receive vis-à-vis other cues (e.g., semantic, syntactic). This issue is critical because speech cues play a primary role in memory encoding (Baddeley, 1966, 2012; Liberman et al., 1972), creating the possibility that input modality may be an important means for modulating effects of retrieval interference.

Modality effects have been found elsewhere in the literature. Using a self-paced listening paradigm, contrasted with a self-paced reading paradigm, older adults have been found to take longer to read relative clauses than to listen to them (Waters and Caplan, 2005; Caplan et al., 2011). Further, a study with cleft sentences of the sort investigated here (DeDe, 2013) examined whether input modality and syntactic complexity interact in healthy younger and older adults and people with aphasia. As in the studies conducted by Caplan and colleagues, DeDe found that the processing time for healthy controls was longer in the self-paced reading experiment than in the self-paced listening one, and this effect was only observable on the verb. She concluded that "...listening may exert fewer processing demands because it is a more natural and over-practiced skill than reading" (p. 11).

In contrast, neuroimaging studies have found small, but consistent modality differences in word (Chee et al., 1999) and sentence processing (Michael et al., 2001; Rüschemeyer et al., 2006), with listening being more resource-demanding. For example, Michael and colleagues compared subject and object relative clauses and found increased hemodynamic response in listening to object relatives in the auditory modality, but not while reading. A possible explanation for this difference, offered by Chee and colleagues, points to the greater reliance on working memory in spoken language comprehension (but see Van Dyke et al., 2014 for an alternative view). Hence, examining retrieval interference in the spoken modality and the specific role of speech cues is an important means of advancing the CBRT.

APPLYING THE VWP TO STUDY RETRIEVAL INTERFERENCE IN SPOKEN LANGUAGE COMPREHENSION

In all of the aforementioned studies that tested the CBRT, sentences with filler-gap dependencies were presented to participants in the written form and, therefore, effects of distractors were indirectly inferred from differences in reading times at the verb (*spotted* took longer to read than *sewed*), contrasted with similar conditions containing no extra-sentential distractors. The current study seeks to determine whether retrieval interference effects can be found in the spoken modality.

The Visual World Paradigm

The Visual World eye-tracking Paradigm (VWP) is well-suited for addressing these questions because VWP experiments measure overt looking to multiple, clearly separable referents (represented as pictures or real objects) called *Target, Competitor*, and *Distractors*. Hence, it provides a straightforward measure of competition between referents while listening. For example in **Figure 1**, the key manipulation involves the relationship between the four pictures and the main verb in the spoken sentence. As in the original study (Van Dyke and McElree, 2006), we expect that the semantic properties of the verb will guide the search for a filler for the gapped object (trace position), so that when the verb is *sewed* there will be more looks to the button than to any other picture, whereas the verb *spotted* will support looks to any of the four pictures, which are all objects that could be spotted.

This prediction is similar to classic findings in the VWP literature, where properties of a verb enable participants to anticipate what will be referred to post-verbally (e.g., Kamide et al., 2003; Huettig and Altmann, 2005). For example, Altmann and Kamide (2004) presented participants with four pictures (i.e., a cake, toy train, toy car, and ball) while requiring them to listen to either of the two spoken sentences, (3a) or (3b):

(3) a. The boy will eat the cake.
b. The boy will move the cake.

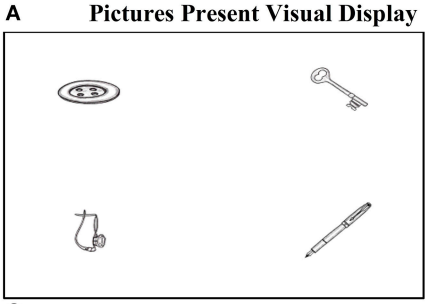
They found that the participants were much more likely to launch eye movements to the cake in (3a) than (3b) and that this happened before the onset of the word *cake*. They interpreted these results as evidence that semantic properties of the verb are used immediately (and incrementally) to guide subsequent integrative processing.

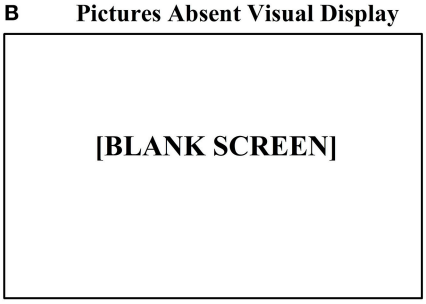
There are several previous VWP studies that investigated processing of memory-dependent linguistic relations in sentences with syntactic dependencies. In these studies, the visual display always included four pictures of the referents explicitly named in the preamble and experimental instruction. Sussman and Sedivy (2003) tested unimpaired adults and established that in oblique object *Wh*-questions (e.g., *What did Jody squash the spider with*?), the *wh*-filler *what* triggered an increase in anticipatory fixations to the potential argument of the verb (i.e., the spider) during the verb despite the fact that the gap was filled. At the preposition, the participants quickly switched to the correct referent (i.e., the shoe). Dickey et al. (2007) simplified the object *Wh*-questions used in Sussman and Sedivy's experiment by removing the oblique object (e.g., *Who did the boy kiss that day at school?*) and compared eye movements of control adults with those of people with aphasia who had difficulties with comprehension of sentences with syntactic dependencies. Based on eye-movement patterns of people with aphasia in the incorrectly answered questions, they argued that their comprehension errors were caused by late-arising competition between the target object referent (e.g., the girl) and the competitor subject (e.g., the boy).

However, neither Sussman and Sedivy (2003) nor Dickey et al. (2007) explained their results in terms of retrieval interference. In contrast, Sheppard et al. (2015) specifically tested *the intervener hypothesis* in search for an explanation of comprehension failure in people with aphasia when they process two types of object *Wh*-questions (e.g., *Who* vs. *Which mailman did the fireman push yesterday afternoon?*). To ensure the felicity of the *which*-questions, the 4-referent display was replaced with an action picture in which one fireman and two mailmen were depicted in two simultaneous pushing events. The results suggested that the more people with aphasia looked at the incorrect mailman (i.e., the intervener) the more likely they were to answer the question, in particular, the *which*-question, incorrectly. A similar explanation was proposed by Clackson et al. (2011) in accounting for eye movements of adults and children in sentences with referentially ambiguous personal pronouns (e.g., *He [Peter] watched as Mr. Jones bought a huge box of popcorn for him.*.). Children were especially prone to look more at the gender-matched referent (e.g., Mr. Jones) in the position intervening between the pronoun (e.g., *him*) and its accessible antecedent (e.g., *Peter*) even though this intervener is ruled out by the Binding theory.

Our current application of the VWP provides a more direct way of testing retrieval interference in processing of sentences with syntactic dependencies. All of the previous studies required referent selection based on a forced choice between two referents explicitly named in the spoken materials, i.e., the target and competitor. In the 4-referent set-up employed by Sussman and Sedivy (2003), Dickey et al. (2007), and Clackson et al. (2011), the remaining 2 referents (i.e., a distractor and a location) attracted very few looks, thus, effectively restricting referential choice to two. In addition to the fact that all 4 distractor referents were explicitly named in the spoken context, the intervener was placed in the sentence between the filler and gap which increased their salience and availability during retrieval of the filler at the verb.

The case study described in this article employed the dual-task paradigm (Van Dyke and McElree, 2006), in which every one of the three distractor referents was a legitimate semantic intruder that was *outside* the spoken sentence. Hence, any interference from the distractors suggests that information contained within memory, but not part of the sentence itself, impacts successful retrieval of the actual target. This has important ramifications for the specification of the type of retrieval mechanism (i.e., one that matches to all contents of memory simultaneously, as in a global matching mechanism (e.g., Clark and Gronlund, 1996) or else a retrospective serial search that entertains each item in memory individually. The former predicts that all distractors





C

a. Interfering:

It was the button that the maid who returned from vacation *spotted* in the early morning.

b. Non-Interfering:

It was the button that the maid who returned from vacation *sewed* in the early morning.

FIGURE 1 | Sample experimental conditions. (A) Visual display for Picture Memory List Present, **(B)** Visual display for Picture Memory List Absent, **(C)** Two types of spoken sentences.

should receive increased looks when they match retrieval cues from the verb, while the latter predicts that only the target referent (which is the most recent) would receive looks from the verb. In addition, interference effects from extra-sentential distractors suggest that sentence processing utilizes the same memory capacity as that used for short-term memory, contrary to accounts that would give sentence processing a separate memory capacity (e.g., Caplan and Waters, 1999).

Using the VWP for studying retrieval interference in spoken language comprehension brings an additional advantage in that this method removes potential confounds related to reduced reading skill or difficulty comprehending complex task instructions, concerns which are paramount when investigating comprehension ability in linguistically diverse populations, such as children, bilingual and second language learners, and participants with language impairments. Instead, the VWP provides a naturalistic way to assess language processing while participants listen to verbal input and look at visual arrays. In addition, it could be employed in a passive listening mode that does not require verbal, gestural, or motor responses, making it amenable for use with older individuals or persons with aphasia (Hallowell et al., 2002; Ivanova and Hallowell, 2012).

"The Blank Screen" Paradigm in the VWP

The classic VWP experiments with spoken sentences found anticipatory looks toward an object when the verb precedes it (Kamide et al., 2003; Huettig and Altmann, 2005) demonstrating that the verb's selectional restrictions activate its argument structure. The latter, in its turn, drives looks to the referent that is named by the noun in post-verbal position. However, looks could be crucially dependent on the co-occurrence of linguistic input and the overt presence of the referent's picture. To counter this argument, Altmann (2004) demonstrated that the physical presence of the pictures was not necessary. Listeners still moved their eyes to the location of a previously displayed object even when the object was no longer present while they listened to the spoken sentence. This method received the name of the "blank screen" paradigm. Although the proportion of looks using this method was relatively low in absolute terms (16%; Altmann and Kamide, 2004, Figure 11.1), Altmann and Kamide interpreted these results as evidence that it is the mental representations of the objects held in memory that are activated by the verb's semantics. Therefore, eye movements in the VWP were shown to reflect the mental world, and not just visual attention in the form of iconic memory.

Because this method has particular theoretical significance in the VWP literature, we chose to implement the blank screen paradigm as a potential analog of the Memory-Load condition of Van Dyke and McElree. We hoped this would allow us to determine the extent of interference from visually presented distractors: If interference from *absent* distractors were observed, this would suggest that semantic interference from present distractors is not merely contingent on the current visual scene, but related to accessing all matching memory representations, whether currently active or not. As it turned out, firm conclusions on this point were frustrated by a methodological confound. Hence, although we present these results, our conclusions are drawn primarily from the Pictures Present conditions in our design.

In what follows below, we present a VWP implementation of the Van Dyke and McElree (2006) study, which examined how semantic properties can be used to guide retrieval of previously occurring constituents. Specifically, in (2), the grammatical encoding of the clefted NP makes it unambiguously identifiable as the object of a later occurring verb however, there is no prospective information about the semantic relationship between that object and the verb. Thus, any difference in looks to the target in the Interfering (e.g., *spotted*) vs. Non-Interfering (e.g., *sewed*) conditions has to occur only once the verb is heard (or after) and must be attributed to interference driven by the verb's semantic cues. The prediction of fewer looks to the correct target picture (*button*) in the Interfering conditions compared to the

Non-Interfering conditions is analogous to the finding in Van Dyke and McElree, where semantically similar distractors *outside* the sentence produced inflated reading times at the point of integrating the verb with its direct object.

A CASE STUDY: RETRIEVAL INTERFERENCE IN SPOKEN LANGUAGE COMPREHENSION

Participants

Twenty-four undergraduate students from the College of Staten Island participated in this study for credit as one of the requirements for an introductory psychology class. All participants (7 men, mean age = 21.4) identified themselves as native English speakers. This study was carried out in accordance with the ethical principles of psychologists and code of conduct of the American Psychological Association and was approved by the Institutional Review Board of the College of Staten Island. All participants gave written informed consent in accordance with the Declaration of Helsinki.

Materials

Each experimental item was realized as one of four conditions in a 2 × 2 (Interference × Picture) factorial design. The interference manipulation was identical to that in the original study by Van Dyke and McElree (2006), but the objects from the memory set were presented as pictures, and not as words: in the interfering condition, all pictured items could serve as the object of the main verb (e.g., *spotted*) in the sentence. For the corresponding non-interfering condition, the same pictures were presented but the main verb was changed in the spoken recording (e.g., *sewed*) so that only the clefted NP made sense as its object (See **Figure 1**). Each picture occupied one of the four quadrants on the stimuli computer monitor, and the clefted NP picture was evenly rotated through each quadrant. For the picture manipulation, pictures remained on the screen while the sentence played (Present) or were removed (Absent, the blank screen paradigm) after the participant named them.

As in Van Dyke and McElree's (2006) Memory Load conditions, the picture memory list was always presented to participants first—prior to reading the spoken sentence, as in (2). The sentence was always followed by a *yes/no* comprehension question, and then, finally, they were asked to recall the four pictures from the memory list. The four steps of the procedure were each crucial to the implementation of the memory interference paradigm. The picture memory list established potential distractors in the comprehension context, the sentence presented the main language processing task, the comprehension questions ensured that participants would attend to the sentence (rather than ignore it in favor of focusing all their attention on the memory task), and the recall task ensured that they would work to keep the pictures from the memory list within their active memory. Participants were explicitly told to do their best on each of the individual tasks.

An important dimension of exploring retrieval interference in the spoken modality is the possible effect that prosodic cues may play in mediating retrieval difficulty. It is currently not known whether or not these cues are considered by the retrieval mechanism, and what priority they may receive vis-à-vis other cues (e.g., semantic and syntactic). Because of this, we decided to employ neutral prosody so as to establish a baseline for whether the expected effects would manifest in eye-movement patterns. Although clefted constructions such as (2) often occur with a stress contour, there is no information about whether individual readers assign such a contour when they read them silently. This is significant because the original study by Van Dyke and McElree (2006) employed self-paced reading, which may have discouraged the natural assignment of implicit prosody. Thus, we considered the use of neutral prosody to be the best approximation to the reading conditions in the original study.

The 28 sets of experimental items were selected from the original 36 object cleft sentences of Van Dyke and McElree's (2006) self-paced reading experiment based on how well the items in the memory lists could be depicted. There were also 56 filler items of two types: eighteen subject cleft sentences (e.g., *It was the son who was wild that smashed the lego tower that nearly reached the ceiling.*—Picture Memory List: ROSE, POMEGRANATE, SICKLE, VIOLIN), and 38 non-clefted sentences (e.g., *The sailors knew that the treasure enticed the pirate on the hijacked ship*—Picture Memory List: HOUSE, STAR, ROBE, FAIRY). Pictures for the filler sentences were selected randomly; one half was presented with pictures, and the other half was paired with a blank screen. There were also five practice items with feedback. Four lists were constructed using the Latin Square design consisting of five practice, 28 experimental (7 items per condition) and 56 filler items in such a way that each experimental item was both preceded and followed by one of the fillers. Thus, all experimental items were separated by two fillers. Six participants were randomly assigned to each of the four lists, containing 89 trials in total.

The 356 pictures (89 trials × 4 pictures) were selected from the electronic database of object and action pictures created in the Neurolinguistics Laboratory (head: Dr. Olga V. Dragoy) at the Higher School of Economics (Moscow, Russia). The database is available online free of charge (http://stimdb.ru/) and contains black-and-white pictures normed on many dimensions (i.e., naming agreement, visual complexity, age of acquisition, frequency, and familiarity; Akinina et al., 2015).

All spoken sentences (experimental and filler) were recorded by a female native speaker of American English at a sample rate of 22,050 Hz. Every effort was made to pronounce them with neutral prosodic intonation to eliminate the contribution of special prosodic cues associated with cleft sentences in English, i.e., a fall-rise pitch accent on the clefted NP (Hedberg, 2013) and a prosodic break after the clefted NP indicating phrasal boundary, during retrieval. However, after data collection we discovered that this goal was not met: experimental sentences were recorded in two different sessions, which resulted in subtle perceptual and prosodic differences between the interfering and non-interfering conditions. We discuss this methodological error later. Speaking rate was slightly slower than is heard in everyday casual speech, due to efforts to enunciate each word; see Appendix B in Supplementary Material for example recordings.

The comprehension questions were designed following the method of Van Dyke and McElree (2006). Two thirds of the questions for the experimental items (19 out of 28) were about the subordinate clause (e.g., Example 4: *It was the cigarette that the criminal who robbed the electronics store smoked/sought in the dark alley*. Question: *Did the criminal rob a liquor store?*) and one third (9 items) were about the main clause with the clefted NP (e.g., for Example 2 the question was, *Was it the maid who was on vacation?*).

The pictures, spoken sentences, and comprehension questions for all 28 experimental items and a sample of eight representative fillers, as well as the two auditory versions of example (2) in both the interfering and non-interfering conditions, are provided in Audios 1 and 2 in the Supplementary Material.

Procedure

The experiment was controlled by DMDX software (Forster and Forster, 2003), with the game pad serving as the interface device. Participants were seated in front of a 17-inch Dell laptop (resolution of 1024 × 768 pixels) at a viewing distance of ∼60 cm. On each trial, participants first saw the four-picture memory list (**Figure 1A**), with each picture centered in one of the four 350 × 350-pixel quadrants of the display. Each of the four images subtended about 11 degrees of visual angle. Participants were asked to label the pictures in any order using just one word and then press the "Yes" button on the game pad to listen to the auditory sentence (**Figure 1C**, a-b). Specific picture labels were not sought in this experiment, hence no feedback was given in this phase. In the pictures present condition, participants continued to look at the pictures while listening to the sentence (**Figure 1A**); in the pictures absent conditions, they looked at the blank screen (**Figure 1B**). An auditory comprehension question automatically followed the sentence (e.g., *Was it the maid who was on vacation?*) and was answered by pressing either the "Yes" or "No" button on the game pad. As soon as the response was provided, DMDX presented a written reminder for the participants to recall the four pictures from the memory list (i.e., *Now recall the four pictures*), and their voice responses were recorded with the help of a microphone connected to a digital SONY DSR-30 video tape-recorder. Participants were asked to recall all of the pictures in any order, but were encouraged not to belabor the recall if they couldn't remember them.

The video tape-recorder was connected to the ISCAN ETL-500 remote eye-tracking system that collected participants' eye movements. Eye movements were sampled at a rate of 30 times per second. Prior to the experiment each participant underwent a short calibration procedure. The experiment was conducted in one session and lasted ∼1 h.

Statistical Analysis

Mixed-effects logistic regression was used to examine three measures: picture recall accuracy, comprehension question accuracy, and eye movement data. Mixed-effects modeling allows us to account for the clustered nature of the data, with responses nested within participants and items; furthermore, it makes it possible to examine variability within and between participants and items and is flexible in handling missing data (Raudenbush and Bryk, 2002). All models included crossed random intercepts for participants and items (Baayen et al., 2008). Random slopes for the-within-subjects independent variables were examined but not retained in any of the analyses, either because of convergence failure or because the random slopes did not improve the model fit.

Between-subjects outliers were trimmed following a 2-stage procedure: first, for each experimental condition we excluded subjects with average proportion of fixations more than 2.5 SD below or above the grand mean. Second, for each model, we examined the level-2 residuals and we re-fitted the models without observations with absolute standardized residuals greater than 2.5. This 2-stage procedure never led to the exclusion of more than 3% of the data.

Missing values due to equipment malfunctioning and track loss constituted 0.4 and 4.6% of the data, respectively. Data were analyzed with R version 3.1.2 (R Core Team, 2014) using the glmer function from the *lme4* package, version 1.1-7 (Bates et al., 2014).

RESULTS AND DISCUSSION

Recall of Pictures

In the beginning of the trial, participants were asked to label each picture in the 4-item memory list using one word, but they were free to choose any appropriate word. For example, they could choose to label a picture depicting a rug as "*carpet*." No feedback or corrections were provided except in the practice trials. Accuracy of recall of pictures was scored based on the actual number of pictures recalled for each trial and ranged from zero (no pictures recalled) to 100% (all four pictures recalled). Any order of recall was allowed as long as the pictures were labeled the way the participant labeled them in the beginning of the trial (e.g., saying *rug* when the picture was labeled as *carpet* was counted as an error). The top row of **Table 1** shows the mean correct recall of the pictures as a factor of Interference and Picture.

Mixed-effects logistic regression analysis was used to examine the effect of Interference and Picture on accuracy of picture recall. Results showed a significant effect of Picture, such that the recall of the pictures was significantly better in the Pictures Present than in the Pictures Absent conditions, 91.6 vs. 85.8% (cf. **Table 2**, left panel). There was no effect of Interference and no interaction. Interestingly, the recall of the pictures in our experiment was higher than that for written word memory lists in Van Dyke and McElree's (2006) experiment (non-interfering condition: 80%, interfering condition: 78% in that study) and this was true even in the Pictures Absent condition. We interpret this as evidence that visually presented items have increased salience in memory as compared to verbally encoded memory words. This could possibly be explained by the difference in encoding modality: an auditorily presented sentence interferes less with memory for visually encoded stimuli. It is also possible that recall was increased because participants had both a visual and verbal encoding of the stimuli (Nelson and Brooks, 1973; Snodgrass and McClure, 1975; Paivio, 1986).

TABLE 1 | Accuracy of recall of pictures and comprehension questions, % (SD).

	Interfering, Pictures Present	Interfering, Pictures Absent	Non-Interfering, Pictures Present	Non-Interfering, Pictures Absent
Picture recall	91.4 (8.17)	86.3 (12.8)	91.7 (7.19)	85.3 (12.0)
Comprehension question	32.1 (20.3)	29.2 (25.8)	35.1 (17.4)	35.1 (17.4)

Comprehension Question Accuracy

Accuracy of responses to the comprehension questions as a factor of Interference and Picture was low overall, 32.9% (see **Table 1**, bottom row.) Results of mixed-effects logistic regression analysis of accuracy showed no significant effects (see **Table 2**, right panel). This is consistent with the results in Van Dyke and McElree (2006), however despite no significant effects the participants in that study had much higher accuracy levels (87% in the Non-interfering condition vs. 83% in the Interfering condition, a statistically significant difference). We note that this low accuracy was not due to our participants' overall level of performance in the experiment—their overall high picture recall (88.7%) confirms that they did pay attention. One possible explanation for the difference between the current results and the Van Dyke and McElree results is that the latter used the self-paced reading method which allows participants to read at their own pace. This self-controlled, and likely slower, presentation rate affords participants additional time for encoding and/or deciphering the meaning of the sentence, which in turn positions them to do better on the comprehension questions. In contrast, the spoken sentence passes quickly in the listening paradigm used here, and together with memorizing the pictures, this may have made the task more difficult. This is consistent with other findings showing less accurate comprehension in the auditory modality compared with comprehension of the same sentences in the written modality (Johns et al., 2015). Another possibility, suggested by our comparatively higher recall accuracy, is that participants traded off attention during sentence reading with attention to the recall task. We discuss this further below.

Eye Movements

The spoken sentences were divided into four regions for purposes of statistical analysis of eye movements: three sentence regions illustrated in (4) and one second of silence following the end of the sentence. The actual durations of each ROI in individual sentences varied because of differences in lexical items that constituted the experimental items. Each ROI was constructed around the specific onsets and offsets of individual items, but in the time course figures (**Figure 2**), the vertical dashed lines are aligned with the average onsets of the 4 ROIs.

(4)	Region 1 Clefted NP-that-Subject-Relative Clause (RC)	Region 2 Verb	Region 3 PP	Region 4 Silence
	It was the button that the maid who returned from vacation	sewed/ spotted/	in the early morning	

Eye movements were coded from the launch of a saccade to one of the 4 referent pictures present in the visual display and included a fixation that followed, as long as their combined duration was at least 100 ms. Looks in between the referents were coded as *else*, and looks off the screen were considered track loss and were removed from statistical analysis. Descriptive statistics and a graphical representation of the time course of the proportions of fixations to the target picture over all trials and all regions are reported in **Table 3** and **Figure 2**, respectively.

Region 1: Clefted NP-that-Subject-RC

Results of mixed-effects logistic regression analysis (**Table 4**; **Figure 3A**) showed a to-be-expected significant effect of Picture, such that the proportion of looks to the quadrant of the target picture was greater in the Pictures Present condition than in the Pictures Absent condition, where the eyes may be more apt to roam around the blank screen. Unexpectedly, we observed significant effects of Interference and an Interference × Picture interaction in this region, such that the proportion of looks to the target picture was greater in the Interfering than in the Non-Interfering condition when the pictures were present, and smaller in the Interfering than in the Non-Interfering condition when the pictures were absent. As both the linguistic and picture contexts were identical for all conditions prior to the verb, we trace this effect to the prosodic differences in the sentence recordings. *Post-hoc* analyses revealed that the average durations of the two

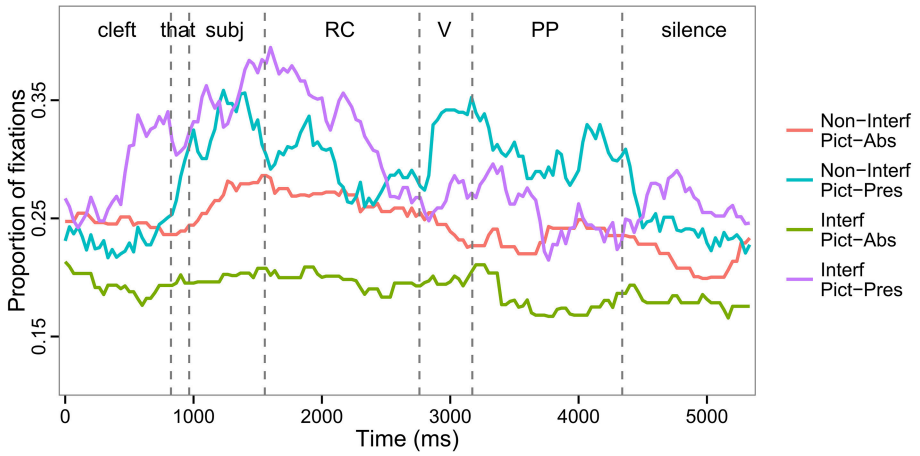

FIGURE 2 | Time course of fixation to the target picture as a function of Interference, Picture Memory List, and Region (all trials).

TABLE 3 | Proportions of looks to the target picture as a function of Interference, Picture, and Region, mean (SD).

Condition	Region 1	Region 2: V	Region 3: PP	Region 4: silence
Interfering, Pictures Absent	0.193 (0.131)	0.214 (0.166)	0.186 (0.130)	0.179 (0.144)
Interfering, Pictures Present	0.323 (0.118)	0.269 (0.162)	0.259 (0.115)	0.252 (0.151)
Non-Interfering, Pictures Absent	0.259 (0.127)	0.259 (0.170)	0.236 (0.132)	0.212 (0.139)
Non-Interfering, Pictures Present	0.281 (0.113)	0.294 (0.205)	0.306 (0.150)	0.243 (0.113)

components of the clefted NP—the cleft part (e.g., *it was the…*) and the target noun (e.g., *button*)—were consistently shorter in the Interfering than in the Non-Interfering condition, 309 ms vs. 343 ms [$t_{(26)} = 4.5496$, $p < 0.001$], and 323 ms and 346 ms, respectively [$t_{(26)} = 4.0341$, $p < 0.001$]. In addition, twice as many sentences in the Interfering condition (i.e., 15) than in the Non-Interfering condition (i.e., 8) had an extra prosodic break after the clefted NP (4) (// indicates a prosodic break). A representative pair of the actual recordings of the sentence types (e.g., Audio 1 and Audio 2) are available in the Supplementary Material.

(4) a. Interfering: It was the button // that the maid // who returned from vacation spotted…
b. Non-Interfering: It was the button // that the maid who returned from vacation sewed…

We speculate that despite the fact that we avoided pitch contours in an effort to keep prosody neutral, these differences created unintended prosodic cues that served to direct looks to the target noun in the Interfering, Pictures Present condition. The fewer looks to the target in the Interfering, Pictures Absent condition may also have resulted from the increased saliency of the target item, so that looking to the now-empty location of the target referent was not as necessary as it was for remembering the other, less salient referents[1]. Whether or not this account is correct, we emphasize that with respect to the Pictures Present condition, whatever bias drove these results went in the *opposite* direction to that predicted for the critical region (Region 2), where we expected looks to the target to *decrease* in the Interfering condition as compared to looks to competitors, which should increase in response to retrieval interference. Moreover, we conducted additional *post-hoc* analyses of the region after the target noun and found no additional prosodic differences between conditions. Hence, we are confident that results in Regions 2-3 are interpretable despite this methodological error. As for the Pictures Absent condition, this is a true confound. In order to better assess the presence of the Interference effect in relation to the Picture manipulation, we report the results of pair-wise comparisons for all future analyses.

Regions 2–3: Verb-PP

These two regions—Region 2 (Verb) and Region 3 (PP)—revealed the predicted pattern of results for the Interference manipulation. Region 2 is the critical region containing the verb that determines whether the pictured items are distractors or not (**Figure 3B**). We found a significant main effect of Interference, such that there were fewer looks to the target in the Interfering condition, where all of the pictured items could serve as the object of the main verb (e.g., they are all fixable in the example

[1]An alternative account is that the increased salience may reduce the need to look back during retrieval, perhaps because the target was already in a state of increased activation. Existing eye-movement evidence is not consistent with this interpretation however, as pre-activation of a target (greater looks to the target before hearing it) has not been related to reduced looks to the target upon hearing it or later (Altmann and Kamide, 1999; Coco et al., 2015). For example, Kukona et al. (2014) manipulated initial activation through making the target more or less predictable based on its relation to the verb. In the High Predictable condition ("eat cake") looks to the target were never less than looks to the target in the Low Predicable conditions ("move cake").

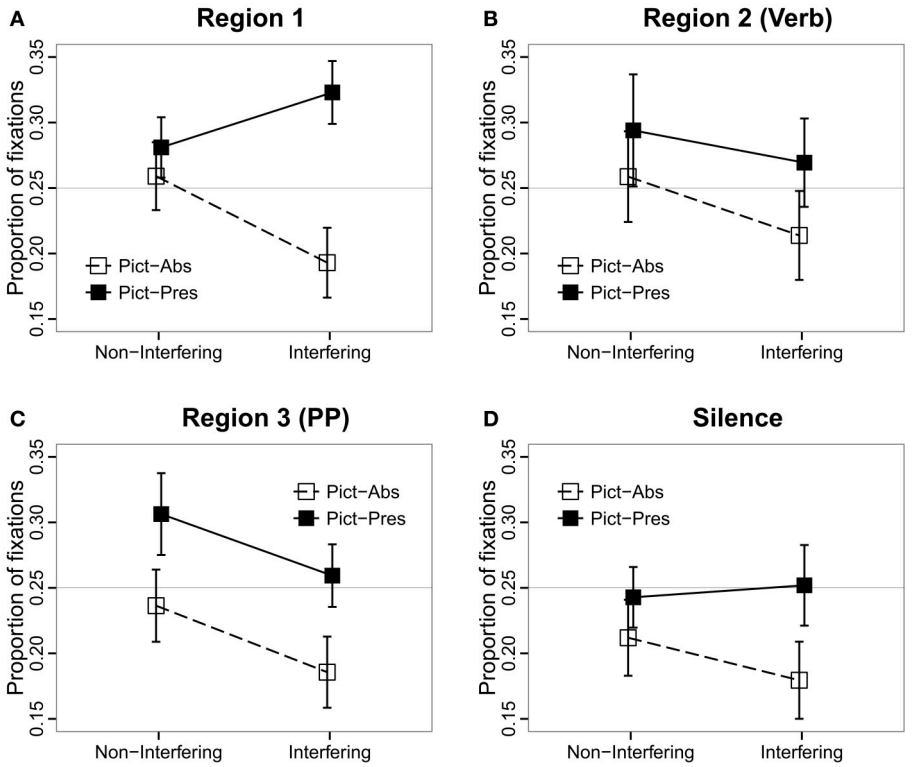

FIGURE 3 | Proportions of fixations to the target picture as a function of Interference, Picture Memory List, and Region. (A) Region 1 (Clefted NP-that-Subject-RC), **(B)** Region 2 Verb, **(C)** Region 3 (PP), **(D)** Region 4 Silence.

in **Figure 1**). We performed pair-wise comparisons to make sure that the main effect of Interference was not driven by the Pictures Absent condition. We found that the effect was significant in both the Pictures Present conditions (Tukey test: $z = -2.34, p < 0.05$) and in the Pictures Absent conditions (Tukey test: $z = -12.93$, $p < 0.001$). We also observed a significant effect of Picture, with a greater proportion of looks to the target picture in the Pictures Present condition as compared to the Pictures Absent condition. The interaction was not significant.

In Region 3, which contained the prepositional phrase, (**Figure 3C**) we observed the same pattern of results as in Region 2 (see **Table 4**). The proportion of looks to the target was greater in the Non-Interfering condition than in the Interfering condition. This effect obtained in the pairwise comparisons in both the Pictures Present conditions (Tukey test: $z = -6.88$, $p < 0.001$) and in the Pictures Absent conditions (Tukey test: $z = -6.36$, $p < 0.001$). Inspection of eye-movements in this time window (see **Figure 2**) suggests that this result was driven by looks to the target at the end of the sentence, and may reflect end-of-sentence wrap-up effects in which the participant is verifying his/her interpretation of the subject-verb dependency. As in the previous region, a significant effect of Picture was also observed, with more looks to the target in the Pictures Present condition.

Region 4: Silence

In the 1-s interval of silence following the end of the sentence (**Figure 3D**) the effect of Interference interacted with Picture, such that the proportion of looks to the target picture was comparable in the Interfering and Non-Interfering conditions when the pictures were present (Tukey test: $z = 0.63$, $p = 0.78$), and smaller in the Interfering than in the Non-Interfering condition when the pictures were absent (Tukey test: $z = -4.2$, $p < 0.001$). Visual inspection of these effects (**Figure 2**) suggests that the absence of an Interference effect in the Pictures condition, as compared to the significant Interference effect detected in the previous sentence regions, could be attributed to a proportional increase in looks to the target picture toward the end of the sentence for the Interfering conditions. We suggest that this effect can be associated with a repair process invoked when listeners realize they have constructed an incorrect interpretation due to interference from distractors. Similar late effects of semantic interference vis-à-vis retrieval cues have been observed in reading times (Van Dyke, 2007) and in BOLD signal during fMRI (Glaser et al., 2013).

Correct vs. Incorrect Trials

We performed a secondary analysis in which we separated the trials for which the comprehension questions were answered correctly from the ones with the incorrectly answered comprehension questions to assess the role of low accuracy on our results. **Figure 4** presents the time course of fixations for both subsets of trials; **Table 5** presents results of mixed-effect modeling. We observed a total of 219 correct trials, resulting in 33,356 total fixations; there was an average of 2.3 items per

****p < 0.001.*

condition for each participant. We observed a total of 447 inaccurate trials, with a total of 69,374 fixations and 4.7 items per condition per participant. Inspection of the pattern of eye-movements in the two item subsets reveals two important observations (see **Table 5** for modeling results). First, the effect of the bias toward the target in Region 1, which was created by the unintentional prosodic cues in the Interference trials, was more pronounced in accurate trials. This is apparent from the larger beta estimates in accurate trials vs. inaccurate trials (see **Table 5** for main effect estimates). *Post-hoc* contrasts of the effect in the Pictures Present condition revealed a larger effect when pictures were present in accurate trials (Tukey test: $\beta = 0.45$, $z = 9.00$, $p < 0.001$) vs. inaccurate trials (Tukey test: $\beta = 0.12$, $z = 3.62$, $p < 0.005$). In particular, in the Non-Interfering, Pictures Present condition, there were more looks to the target in inaccurate ($M = 0.29$; $SD = 0.13$) than accurate trials ($M = 0.23$; $SD = 0.17$) in all 4 ROIs. As discussed in the analysis of overall results, the direction of the effect was reversed in the Pictures Absent condition, but the magnitude of beta was still larger in the accurate trials (Tukey test: $\beta = -0.35$, $z = -5.78$, $p < 0.001$) than for inaccurate trials ($\beta = -0.29$, $z = -7.72$, $p < 0.001$). This is consistent with the idea that prosodic cues in the Interfering condition served to distinguish the target, which enabled participants to more accurately comprehend the sentences. However, given that only 33% of trials were correctly answered, it appears that these prosodic cues were often not helpful for participants.

Secondly, and more importantly, the data suggest an interference effect regardless of trial accuracy, but with different time-course manifestations. For incorrectly answered trials (top panel, **Figure 4**), looks to the target in the Interfering condition are reduced compared to the Non-Interfering condition beginning at the critical Region 2 (Verb), and continuing on, until the end of the sentence. This main effect was significant in all regions (see **Table 5**); pairwise comparisons verify the finding for both Pictures Present contrasts (Region 2, Tukey test: $z = -2.29$, $p < 0.05$; Region 3, Tukey test: $z = -0.20$, $p < 0.001$; Region 4, Tukey-test: $z = -3.04$, $p < 0.005$) and Pictures Absent contrasts (Region 2, Tukey test: $z = -4.58$, $p < 0.001$; Region 3, Tukey test: $z = -3.59$, $p < 0.001$; Region 4, Tukey test: $z = -7.29$, $p < 0.001$. In contrast, for the correctly answered trials, the Interference effect seems not to arise until the later Region 3 (PP), where we observed more looks to the target in the Non-Interfering condition for both the Pictures Present and Pictures Absent conditions[2]. The reason for this later time-course seems likely related to the bias in the Interfering conditions created by prosodic cues, which encouraged more looks to the target just prior to the critical verb. For Pictures Present trials, **Figure 4** shows an immediate increase in looks to the target in Region 2 for the Non-Interfering conditions, however given the already inflated baseline for looks in the Interfering condition, the difference between the two took longer to manifest. It is especially notable that even with the bias toward looks to the target in the Interfering condition, a reduction in looks to the target in that condition compared to looks in the Non-Interfering condition was anyway observed. Moreover, in the Pictures Absent conditions, a substantial increase in looks to the target in the Non-Interfering condition compared both to the previous baseline for that condition as well as the Interfering, Pictures Absent condition is also apparent. This effect did reach statistical significance (Tukey test: $z = -6.22$, $p < 0.001$). Although these data patterns are not all confirmed statistically,

[2] Pairwise contrasts for accurate trials are inconclusive due to the low number of observations and corresponding high variability per condition. We discuss here only the apparent pattern of looks displayed in **Figure 4**. When pairwise effects do reach significance, they are noted in the text.

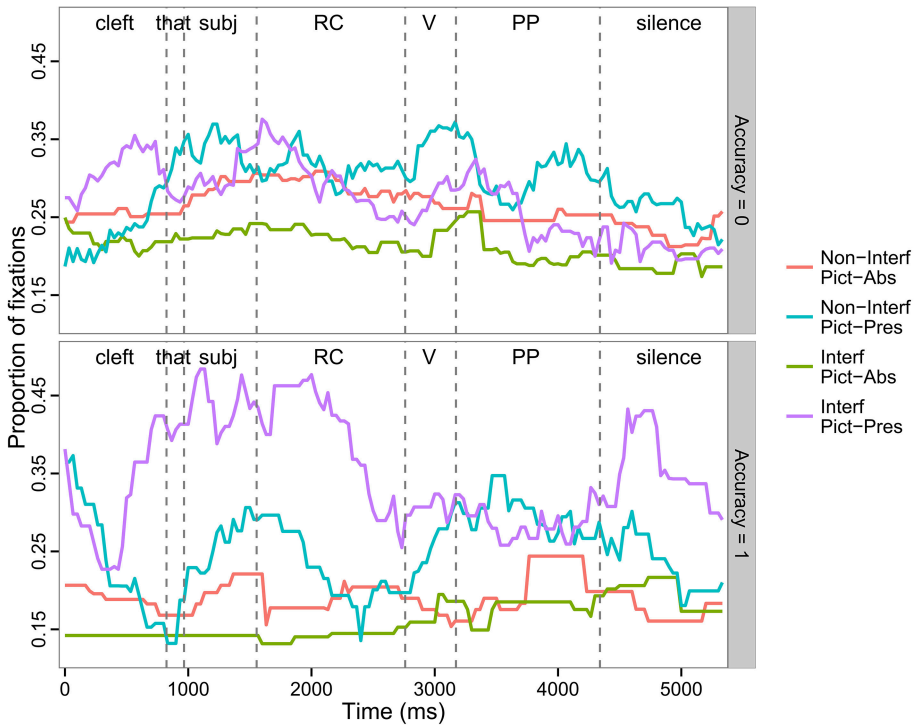

FIGURE 4 | Time course of fixation to the target picture as a function of Interference, Picture Memory List, and Region, separated by accuracy on comprehension questions. Top panel: Incorrectly answered trials (Acc = 0), Bottom panel: Correctly answered trials (Acc = 1).

they are consistent with the expected effect of the non-interfering verb as providing unambiguous cues for identifying the correct filler for the post-verbal gap.

Also of note in the accurate conditions, we observed a strong "correction" to the Interference effect in Region 4 (Silence), characterized by a steep increase in looks to the target in the Interference conditions. This effect was significant for both the Pictures Present contrast (Tukey test: $z = 4.47$, $p < 0.001$) and the Pictures Absent contrast (Tukey test: $z = 3.60$, $p < 0.001$). This is the same effect referred to in the overall analysis as a "wrap-up" or repair process. We conclude that this secondary analysis supports the repair interpretation of the Region 4 effect discussed above, as it was only the correctly answered trials that drove that late effect.

GENERAL DISCUSSION

The goal of the present experiment was to test whether the Visual World eye-tracking Paradigm can be extended to study retrieval interference in spoken language comprehension. We sought to determine whether the VWP could enable direct observation of online interference effects, through measuring overt looks to pictures of distractor referents held in memory, rather than needing to infer interference effects from reading times. The current study provides initial evidence—despite a methodological flaw—that indeed, retrieval interference effects do occur in the spoken modality, and the VWP provides a robust means of examining them. The key finding is of increased looks to extra-sentential competitors in the interference condition, which produced a concomitant *decrease* in looks to the target in this condition. This is consistent with the suggestion of Van Dyke and colleagues, that a cue-driven retrieval mechanism uses cues to query *all* of the contents of memory[3] . When the semantic cues from the verb also match the competitors, as in the Interference conditions, then this type of global matching will cause the competitors to affect processing (either by increasing reading times or engendering more looks to themselves), even though they are not in the sentence, or strongly related to each other or any other words in the sentence. The benefit of VWP paradigm is that we can directly observe the looks to the extra-sentential competitors, whereas in the original reading time studies a "No-Load" contrast condition was necessary to support the inference that the increased reading time at the verb in the interference condition was not due to a more difficult integration between the clefted NP and the verb. In what follows, we discuss our results further in relation to the original Van Dyke and McElree (2006) study.

Despite modality and methodological differences, the two studies are consistent in demonstrating effects of extra-sentential distractors on processes of argument integration. Although the dependent measures were different, i.e., eye-movement patterns

[3]We note that any effect of extra-sentential distractors is contrary to accounts that would give sentence processing a separate memory capacity (e.g., Caplan and Waters, 1999).

*$p < 0.05$, **$p < 0.01$, ***$p < 0.001$.

over pictures vs. reading times in self-paced reading, the locus of the effect was the same across paradigms—at and after the manipulated verb, which provided either discriminating or ambiguous retrieval cues for identifying the target direct object. In the current experiment, participants looked significantly less to the target picture in the Interfering conditions than in the Non-Interfering conditions beginning at the critical verb, while in the written modality they read this verb more slowly. In both cases, we hypothesize that these effects are due to the presence of the distracting referents, be they pictures or words, which matched the retrieval cues of the verb (e.g., *spotted*) in the Interfering condition, but not in the Non-Interfering condition (e.g., *sewed*).

Moreover, the VWP proved sensitive to dynamic processes associated with recovering from incorrect retrievals, as evidenced by the marked increase in looks to the target for Interfering conditions in the silence region for correct trials. This is similar to the sentence-final effect of semantic interference from distractors *within* a sentence observed by Van Dyke (2007), however the VWP has the added benefit of providing direct evidence that the increased reading times are associated with additional processing of the target in the Interfering conditions but not in the

Non-Interfering conditions. In both cases, we take this increased late effort to reflect repair processes, invoked when listeners realize they have constructed an incorrect interpretation.

Despite the weakness in the current study related to unintended prosodic cues, which may have created increased encoding opportunities for the target in the Interfering condition, the interference effect was clearly observed in the Pictures Present conditions. It attests to the robustness of both the VWP method for indexing integrative processes (e.g., Tanenhaus et al., 1995; Huettig et al., 2011) and the retrieval interference effect itself. One might have expected that the more salient target would have promoted correct integration of the clefted NP, however the eye-movement patterns suggest interference effects in both correct and incorrect trials (although low power yielded non-significant results in the latter category). This demonstrates that salience alone is not sufficient to override the immediate effects of ambiguous retrieval cues on argument integration.

We attempted to further validate this conclusion using the blank screen paradigm, where we expected the same pattern of results as in the pictures present condition. This would have replicated the Altmann and Kamide (1999) results and leant further support to the hypothesis that the looks to the target in the pictures present condition are not a mere epiphenomenon due to visual cues, but instead reflect integrative processing driven by a cue based retrieval mechanism. Unfortunately, as described above, results from the pictures absent condition were difficult to interpret. Nevertheless, there remains a significant body of research that has established that looks to target objects during sentence processing cannot be entirely attributed to visual cues, but instead reflect activation of mental representations at least partially guided by the parser (Spivey and Geng, 2001; Altmann, 2004; Altmann and Kamide, 2004; Johansson et al., 2006). Moreover, the current study replicates Van Dyke and McElree (2006) which used the exact same sentences to demonstrate interference effects in relation to retrieval of previously stored distractors. Based on these considerations we are confident in concluding that our findings in the pictures present condition reflect the memory retrieval mechanisms at work during sentence comprehension. However, we do acknowledge the need for future work to demonstrate the validity of this approach to examining interference effects in the spoken modality more generally.

A further unexpected outcome was the extremely low accuracy to comprehension questions. We believe the primary reason for low accuracy is that the dual process task is quite difficult. High scores in the picture recall suggests that participants traded off attention to that task, for attention to the sentence task, which impacted their ability to correctly answer questions. It is highly possible that answering offline comprehension questions, which require a meta-analysis of what was heard, may be difficult for these participants for reasons that are entirely unrelated to our manipulation (e.g., poor meta-analysis skills or difficulty querying the situation model). In addition, the dissociation between accuracy scores for picture recall (high) and comprehension questions (low), together with the significant effects of Interference observed in the Pictures Present conditions, suggests that performance on comprehension questions is a poor index of whether participants experienced online effects of interference. Even when the eye movement record shows evidence of interference effects, there is no guarantee that participants were able to *accurately resolve* the interference, leading to correct performance on the comprehension questions. Thus, we take the accuracy scores to be orthogonal to the main conclusion to be drawn from these data; namely, that the VWP can reliably index retrieval interference effects during spoken language comprehension. We interpret our observation of these effects in eye movements, despite low comprehension, as an even stronger indicator that the VWP is a sensitive method for these effects.

Finally, we note an additional contribution of the current study, which is to further the goal of determining which cues guide retrieval and how they are combined (Van Dyke and McElree, 2011). This study provides an initial indication that retrieval interference effects occur independently of prosodic cues. This will be an important area for future research, some of which is already occurring in our laboratories. This paper demonstrates that the VWP is a useful method for investigating these effects. In addition, the sensitivity of VWP to indexing effects of retrieval interference opens up new possibilities for evaluating predictions of the Cue-Based Retrieval Theory in non-reading populations, such as people with aphasia, children, and auditory second language learners.

The processing of raising and nominal control: an eye-tracking study

Patrick Sturt[1]* *and Nayoung Kwon*[2]

[2] Department of English Language, Konkuk University, Seoul, South Korea

According to some views of sentence processing, the memory retrieval processes involved in dependency formation may differ as a function of the type of dependency involved. For example, using closely matched materials in a single experiment, Dillon et al. (2013) found evidence for retrieval interference in subject-verb agreement, but not in reflexive-antecedent agreement. We report four eye-tracking experiments that examine examine reflexive-antecedent dependencies, combined with raising (e.g., "John seemed to Tom to be kind to himself…"), or nominal control (e.g., "John's agreement with Tom to be kind to himself…"). We hypothesized that dependencies involving raising would (a) be processed more quickly, and (b) be less subject to retrieval interference, relative to those involving nominal control. This is due to the fact that the interpretation of raising is structurally constrained, while the interpretation of nominal control depends crucially on lexical properties of the control nominal. The results showed evidence of interference when the reflexive-antecedent dependency was mediated by raising or nominal control, but very little evidence that could be interpreted in terms of interference for direct reflexive-antecedent dependencies that did not involve raising or control. However, there was no evidence either for greater interference, or for quicker dependency formation, for raising than for nominal control.

1. Introduction

Successful language comprehension requires the computation of grammatical dependencies between linguistic elements in each sentence. For example, the interpretation of (1) requires a dependency between the reflexive *himself* and its antecedent *John*:

1. Bill thought that John was kind to himself.

However, although a great deal of research has been directed at the factors that affect processing difficulty during sentence comprehension, it is only recently that researchers have begun to turn their attention to the actual mechanisms that are used in on-line dependency formation.

One important aspect of dependency computation that has recently been examined in a number of studies is *memory retrieval*. Given that linguistic input is sequential, the two end-points of a dependency (e.g., *John* and *himself* in 1) are necessarily separated in time. In cases like (1), this means that memory access is required to solve the dependency—in order to interpret *himself*, the antecedent *John* needs to be retrieved from working memory. Recent work in human

sentence processing has sought to examine the types of memory retrieval processes that best characterise linguistic dependency formation. According to a well-known view (e.g., McElree et al., 2003; Lewis and Vasishth, 2005; Lewis et al., 2006; Van Dyke and McElree, 2006), memory retrieval in sentence processing is a content-addressable process, in which potential targets in memory are activated in response to retrieval cues. For example, in (1), when *himself* is processed, the retrieval cues might include gender (the antecedent has to be masculine), as well as relevant structural information (the antecedent has to be in an appropriate local position relative to *himself*). According to such models, the activation of dependency targets is a parallel process, where multiple potential targets may be activated simultaneously through partial cue matching. This means that the retrieval of a grammatically licit retrieval target may be affected by the presence of other (grammatically illicit) items that partially match the retrieval cues, a phenomenon known as *interference*. For example, in (1), during the retrieval of the grammatically correct antecedent *John*, the grammatically illicit antecedent *Bill* may become partially activated, as it matches the *male* feature required by *himself*. This may affect the time taken to retrieve the correct antecedent *John*.

Computational models that make predictions concerning retrieval speed (e.g., Lewis and Vasishth, 2005; Lewis et al., 2006) predict that that interference can be either *facilitatory* (speeding up retrieval) or *inhibitory* (slowing down retrieval), depending on the contents of working memory at the point where retrieval takes place, and on the retrieval cues. These models assume a monotonic relation between retrieval times predicted by the model and reading times at the relevant point of the sentence where retrieval is assumed to occur. Below, we briefly describe two patterns of interference that have been reported in the literature. In this paper, we will refer to these as *facilitatory interference* and *inhibitory interference* respectively.

Facilitatory interference can be illustrated using the subject-verb agreement examples given in (2a,b), taken from the self-paced reading study reported by Wagers et al. (2009):

2a. The musician who the reviewer praise so highly will probably win a grammy.
2b. The musicians who the reviewer praise so highly will probably win a grammy.

Both (2a) and (2b) are ungrammatical, due to the number mismatch between the plural verb *praise* and the singular relative clause subject *reviewer*. However, Wagers et al. (2009) found that the reading time penalty was significantly reduced in (2b), which includes a plural distractor *the musicians*, relative to (2a), which does not. In this paper, we will use the term *facilitatory interference* specifically to refer to the reduction of processing difficulty (and thus faster retrieval) for a mismatching dependency, due to the presence of a partially matching distractor (see also Vasishth et al. (2008) and Xiang et al. (2009) for examples of facilitatory interference in other types of dependencies).

In the computational model proposed by Lewis and Vasishth (2005) and Lewis et al. (2006), facilitatory interference is explained in terms of mis-retrieval of the illicit retrieval target. For example, in (2a), the retrieval cues of the verb lead to activation of all potential targets in parallel, including both a licit and an illicit antecedent. However, the mismatching number feature on the licit antecedent, *the reviewer* in (2a,b) means that its retrieval takes a relatively long time. Similarly, in (2a), there is relatively little feature overlap between the distractor, *the musician* and the retrieval cues, leading to a lower activation of the distractor, and thus lower probability of misretrieval. On the other hand, in (2b) the distractor, *the musicians* partially matches the retrieval cues of the verb, sometimes leading to mis-retrieval of *the musicians* as the subject of *praise*. This "illusionary licensing" effect could lead to faster processing in (2b) relative to in (2a).

The second phenomenon that has been argued to follow from a content-addressable memory system is *inhibitory interference*. To illustrate this phenomenon, consider (3a,b), from Badecker and Straub (2002):

3a. John thought that Bill owed him another chance to solve the problem.
3b. John thought that Beth owed him another chance to solve the problem.

In both (3a) and (3b), the only grammatically licit antecedent for the pronoun *him* is *John*. However, in (3a), there is also a gender-matching (grammatically illicit) distractor (*Bill*), while (3b) contains a mismatching distractor *Beth*. Badecker and Straub (2002) found that the two words following the pronoun were read more slowly in (3a) than in (3b). In this paper, we use the term *inhibitory (retrieval) interference* to refer to processing difficulty (and thus slow retrieval) that occurs when the intended dependency target completely matches the retrieval cues (e.g., *John* in 3a), but where there is also a partial match with the distractor—for example, *Bill* in 3a is a distractor, as it is not a grammatically possible antecedent for *him*, but it partially matches the retrieval cue, as it bears the required *male* feature[1].

In the computational model of Lewis and Vasishth (2005) and Lewis et al. (2006), inhibitory interference effects can be explained in terms of the parallel activation of all partially matching retrieval targets; in (3a), the distractor *Bill* has a relatively high activation level during the retrieval of *John*, due to the fact that it partially matches the features of the retrieval cue (i.e., it is masculine), and this leads to competition, slowing down the retrieval of the intended referent *John*. In contrast, in (3b), the distractor *Beth* overlaps to a lesser degree with the retrieval cue, leading to a relatively low activation, and thus less competition.

To summarize, in this paper, we use the term *facilitatory interference* to refer specifically to facilitation in the retrieval of a *feature mismatching* retrieval target; and we use *inhibitory interference* to refer speficically to inhibition in the retrieval of a *feature matching* retrieval target. In both cases, this is due to a the presence of a distractor that partially matches the retrieval cue. The previous literature on interference effects in dependency formation has yielded a mixed picture—although both facilitatory and inhibitory interference effects have been found, neither of these have been found consistently across different dependency

[1]See Van Dyke (2007) and Gordon et al. (2006) for examples of inhibitory interference involving other types of dependencies. Gordon et al. (2006) argue that inhibitory similarity-based interference reflects feature-overlap or feature overwriting in the encoding stage, rather than multiple cue-overlap in retrieval.

types. For example, while Badecker and Straub (2002) found inhibitory interference for both pronoun-antecedent dependencies and reflexive-antecedent dependencies, these results have seldom been replicated. In fact, subsequent studies have failed to replicate inhibitory interference for both pronouns (Chow et al., 2014) and reflexives (e.g., Dillon et al., 2013, *inter alia)*.

Facilitatory interference is reliably found for subject-verb agreement (e.g., Wagers et al., 2009) and negative polarity licensing (Vasishth et al., 2008; Xiang et al., 2009) but has not been consistently found for reflexive-antecedent agreement. Indeed, one recent study (Dillon et al., 2013) has directly compared these two dependency types in a single experiment, and found facilitatory interference effects only for subject-verb agreement, but no evidence for interference for reflexive-antecedent agreement.

The correct explanation for this variability in interference effects is not currently known. Concentrating on the variability of facilitatory interference across dependency types, Phillips et al. (2011) suggest that the parser may make use of either a structure-sensitive search process, or a content-addressable retrieval process, depending on the certain features of the dependency that is being computed: Specifically, Phillips et al. (2011) suggest that the type of memory access that is used may depend on how quickly structural information becomes available relative to other information.

Another possibility, argued by Dillon et al. (2013), is that all dependency types involve a content addressable retrieval process, but that the cues used for retrieval differ between different dependency types. This idea predicts that different types of dependency may lead to different interference profiles, even though they may target the same item in memory, for example, the subject of the local clause. For example, Dillon et al. (2013) contrasted reflexive-antecedent dependencies with subject-verb dependencies, both of which involve the local subject as a retrieval target. Based on their finding of facilitatory interference only in subject-verb dependencies, they argued that, while both dependencies make use of structural cues targeting the local subject, only subject-verb agreement uses the featural cue of number. The use of number as a retrieval cue in the subject-verb dependencies predicts that number-matching distractors become activated during retrieval, leading to interference, as observed by both Dillon et al. (2013) and others such as Wagers et al. (2009). In contrast, Dillon et al. (2013) argue that reflexive-antecedent dependencies only make use of structural retrieval cues, but not featural cues such as number and gender. If number is not used as a retrieval cue for reflexive-antecedent dependencies, this predicts that number-matching distractors are not activated during retrieval, which in turn predicts a lack of interference effects, in contrast with subject-verb agreement[2].

The idea that different types of dependencies could involve different retrieval cues or processes, however, has not yet been tested using a wide range of dependencies. In particular, few studies have examined the retrieval processes of lexically-based dependencies, or compared them systematically with more structurally-based dependencies. Accordingly, it is not clear how retrieval processes would differ between these two types of dependencies. Thus, in this paper, we compared the retrieval processes of raising and nominal control constructions, which are illustrated in (4a,b) below.

4a. **Raising:**
It was surprising that John seemed Ø to be kind to himself.
4b. **Nominal control:**
I was surprised at John's agreement Ø to be kind to himself.

In (4a,b), the phonologically unexpressed subject of the infinitive (marked Ø in the above examples) participates in a dependency with its antecedent *John*. In (4a), the dependency is formed through raising, while in (4b), it is formed through nominal control. Raising and nominal control differ in many ways that could be relevant for processing. One important difference lies in the way that a dependency is motivated. That is, while the interpretation of raising is structurally constrained, the interpretation of nominal control depends crucially on lexical properties of the control nominal. For example, compare (5a) and (5b) below:

5a. John's agreement with Mary Ø to be kind to himself.
5b. John's order to Mary Ø to be kind to herself.

In (5a), the control nominal *agreement* is an instance of *giver control* (see Culicover and Jackendoff, 2001, for an overview of nominal control), meaning that Ø is interpreted as co-referential with the *giver* of the agreement (i.e., *John*)[3]. This leads to an interpretation in which *John* is kind to himself. In (5b), in contrast, *order* is an instance of *recipient control*, meaning that Ø is interpreted as co-referential with the *recipient* of the order (i.e., *Mary*). The interpretation is that *Mary* is kind to herself. In contrast with nominal control dependencies, raising dependencies, such as (4a) above do not exhibit lexically specific variability in the range of potential interpretations: if a raising verb (e.g., *seemed*) has a referential subject (e.g., *John* in 4a), then this must always be co-referential with the subject of the infinitive complement (i.e., Ø in 4a; cf. Hornstein, 1999). Thus, in (6) below, even though an "experiencer" distractor argument (i.e., *Mary*) intervenes, the raising construction still requires co-reference with *John*:

6. John seems to Mary Ø to be kind to himself.

These differences arguably have an analog in a representational distinction that syntacticians typically draw between raising and control. For example, in the Principles and Parameters framework (e.g., Chomsky, 1986) the empty subject in the raising example (6) is assumed to be an instance *NP-trace*, which participates in a strictly local and structurally constrained dependency with its antecedent. In contrast, the empty subject in all varieties of control, including nominal control (5), is assumed to be PRO, a pronominal element that is much less constrained, and whose choice of antecedent will depend on many factors, including the

[2]In addition to facilitatory interference and inhibitory interference, one other interference profile has been reported in the literature: in a study on the resolution of Spanish dependencies involving *otro* (similar to English "another"), Martin et al. (2012) reported processing disruption for grammatical dependencies where a distractor mismatched the retrieval cue.

[3]We used nominal control rather than verbal control because nominal control gives a wide range of control predicates that can be used in the *giver*-control condition (e.g., *vow oath*, *promise*). For verbal control, in contrast, there are very few control verbs that can be used in an analogous way.

type of control relation. In other syntactic frameworks, the representational difference between (5) and (6) is even more marked—for example, in certain varieties of Lexicalized Tree Adjoining grammar (LTAG), the raising example (6) would not be assumed to include an empty infinitival subject at all[4], while the control example (5) would include PRO, as in the Principles and Parameters framework (see the X-tag grammar of English, XTAG Research Group, 1998, for a framework that takes this approach). For the purposes of the present paper, we will continue to assume that both raising and nominal control involve an empty subject, but we will return to consider the predictions of the LTAG proposal where relevant below.

What types of cues might be used in retrieving the antecedent of the empty subject Ø in (5) and (6)? We assume that the empty subject is initially recognized around the point where *to be kind* is reached in the input, and we also assume that a retrieval process is launched around this point, to find the antecedent of Ø. Given the discussion above, it would make sense to assume that the retrieval cue for the raising dependency (6) would be structural in nature, (for example, targeting the subject of the next-highest finite clause). For nominal control (6), the retrieval cue would need to be represented in a more complex way, as it would need to refer to the control predicate (e.g., *agreement* or *order*), and locate the required target based on that predicate's control properties and argument structure.

In the studies reported in this paper, we examine the processing of sentences that are similar to (5) and (6), in that they combine a control or raising dependency with a reflexive-antecedent dependency. In both (5a) and (6), the dependency between the reflexive *himself* and its ultimate antecedent *John* is indirect—there is one (anaphor-antecedent) dependency between the reflexive and the empty subject, and another (raising or control) dependency between the empty subject and its antecedent. In other words, the dependency between the reflexive and its antecedent is mediated by nominal control (5) or raising (6). We therefore assume that the process of retrieval of the reflexive's antecedent is also mediated by nominal control or raising in cases like these (5) and (6). As a consequence, there are (at least) two retrieval events that involve raising or control in each of these sentences—the initial retrieval of the empty subject's antecedent around the infinitival verb, and a second retrieval, triggered by the reflexive. This second retrieval event, which is the focus of the experiments reported in this paper, has a wider range of cues that could potentially be relevant, because the reflexive provides gender and number information that is not available at the point where the empty infinitival subject is initially recognized—in the case of (5a) and (6), the reflexive requires its antecedent Ø to be male and singular, so Ø in turn must also require its antecedent to be male and singular. Whether each of these dependencies actually uses gender or number as retrieval cues is an empirical question. However, given that the nominal control dependency involves the element PRO, which is a species of pronoun, whose resolution is influenced by a wide range of factors, we believe that this dependency is more likely to use gender and number as a retrieval cue than the purely structural raising dependency.

In this paper, we test the hypothesis that nominal control dependencies would be (a) more prone to interference, and (b) processed more slowly, than raising dependencies. There are several reasons why nominal control dependencies might be expected to be more susceptible to interference than raising dependencies. One reason is that, as discussed above, the resolution of nominal control dependencies requires the use of complex constraints involving lexical information, while raising dependencies can be resolved through purely structural means. This might lead to more indeterminacy in the retrieval process for nominal control, leading to more interference, or it might mean that the two dependency types use qualitatively different retrieval mechanisms, for example, an interference-prone content-addressable mechanism for nominal control but a direct structure-based search for raising. A second possible reason is that, even if both dependency types use a content-addressable mechanism, nominal control dependencies may use a wider array of retrieval cues than raising dependencies, allowing more opportunity for a partial match with a distractor. In the present paper, we are particularly concerned with gender as a retrieval cue, as we use an experimental paradigm that manipulates gender agreement via reflexive-antecedent dependencies, allowing for the possibility of interference via a gender-matching distractor (see below for details). Under these circumstances, control dependencies would be expected to be susceptible to interference if they can use gender as a retrieval cue, while raising dependencies would be expected to be less susceptible, if their retrieval cues are purely structural. Finally, if nominal control and raising dependencies involve very different syntactic representations (e.g., if nominal control uses an empty infinitival subject, while raising does not, as suggested by the LTAG analysis, XTAG Research Group, 1998), then this could lead to different retrieval profiles for the two dependencies. We will postpone further discussion of this last point until the introduction to Experiment 4 below.

Our second hypothesis was that nominal control dependencies would be processed more slowly than raising dependencies. In order to examine this question, as well as retrieval interference, we used a *gender mismatch paradigm* (Sturt, 2003), combining raising or control dependencies with reflexive-antecedent gender agreement, as mentioned above. In this type of experiment, the matching between the reflexive and its antecedent is manipulated. For example, compare example (6) above, with the mis-matching variant in (7):

7. John seems to Mary Ø to be kind to herself.

In (7), the gender of the reflexive *herself* mismatches with the structurally appropriate antecedent *John*. Previous work, using eyetracking during reading, has shown that readers fixate for longer on a reflexive the when its gender mismatches that of its structurally licit antecedent (relative to matching controls) (see for example Sturt, 2003, inter alia).

In this paper, we refer to such processing difficulty as the *mismatch cost*, and we are particularly interested in the *onset* of the mismatch cost in the eye-movement record, in relation to the onset of the first fixation on the reflexive, as a measure of how

[4]Technically, *John* is substituted into the subject position of the elementary tree headed by *kind*, and the elementary tree headed by *seems* is adjoined (i.e., inserted) into the elementary tree headed by *kind*.

quickly the grammatically appropriate antecedent is identified. In previous studies using eye-tracking, the mismatch cost for reflexive-antecedent dependencies has been observed very early in the eye-movement record. For example, Sturt (2003) reported that the first fixation on a reflexive with a gender mismatching antecedent was reliably shorter than when the antecedent matched in gender. Since the average fixation duration in reading is around 250 ms, this implies that the structurally appropriate antecedent must have been recognized within 250 ms after the reader first started fixating the reflexive.

In fact, there is some evidence to suggest that the *onset* of the mismatch cost may differ depending on the structure of the sentence that contains the reflexive. For example, in a series of eye-tracking experiments, Cunnings and Sturt (2014) used the gender mismatch paradigm to examine the resolution of reflexive pronouns sentences like (8a,b):

8a. He heard that the soldier had positioned himself/herself in the middle of the mess hall.
8b. He heard that the soldier had a picture of himself/herself in the middle of the mess hall.

The design included reflexives that either matched (*himself*) or mismatched (*herself*) the stereotypical gender of the antecedent (*the soldier*). In separate experiments, Cunnings and Sturt (2014) found evidence of a mismatch cost for both (8a) and (8b)—in both cases, readers began to slow down after they had initially fixated a mismatching reflexive (relative to a matching one). However, the onset of this mismatch cost appeared earlier in (8a) (where the reflexive and its antecedent *the soldier* are co-arguments of the same verb *positioned*), relative to (8b) (where the reflexive is embedded in a picture noun phrase, and is thus not a direct co-argument of the antecedent)[5]. This difference in the onset of the mismatch cost may indicate that the speed of dependency formation for reflexives is affected by the structure of the sentence—for example, it may be that initial retrieval processes consider co-arguments as potential antecedents, leading to an earlier formation of the dependency in (8a), and thus an earlier appearance of the mismatch cost.

The present research aims to follow up on these results by examining whether the onset of the mismatch cost for a reflexive is also affected by whether its antecedent is accessed via a raising or a nominal control dependency. There are several reasons why this may be the case. As mentioned above, the raising dependency can be resolved using purely structural information, while the control dependency requires a more complex evaluation of the control nominal's argument structure[6]. A second reason is related to the possibility that nominal control and raising may involve different syntactic representations. For example, if raising does not involve an empty infinitival subject, as suggested by the LTAG view XTAG Research Group (1998), then the dependency between a reflexive and its antecedent in an example like (6) is direct. This would contrast with nominal control, where the dependency would be assumed to be mediated by an empty subject. It may therefore be plausible to assume that a direct dependency might be processed more quickly than an indirect one, leading to an earlier onset of the mismatch cost for raising, relative to control.

In the remainder of this paper, we report four experiments that were designed to examine the formation of raising and nominal control dependencies. Experiment 1 establishes a baseline by examining reflexive-antecedent dependencies that are not mediated by raising or control. Experiment 2 directly compares raising and nominal control dependencies, without distractors, thus allowing us to test for differences in the onset of the mismatch cost. Then, in Experiments 3 and 4, we include distractors, focusing on nominal control (Experiment 3) and finally raising (Experiment 4).

We believe that it is important to consider a wide range of dependency types in our search to understand memory access and dependency formation in sentence comprehension. Raising and control dependencies offer a potentially interesting domain of enquiry, because they differ in theoretically relevant ways, while sharing considerable surface similarity. We also believe that it is important to consider not only simple direct dependencies between overt linguistic elements within a sentence, but also indirect dependencies, such as the reflexive-antecedent dependencies that are mediated by raising or control, which we examine here. We hope that the four experiments that we report below add new data points that will increase our understanding of the factors that affect retrieval interference, and will also provide a first step toward gaining a picture of retrieval in indirect dependencies.

2. Experiment 1

In Experiment 1, we establish a baseline by examining the processing of a direct dependency between a reflexive and its antecedent, without incorporating raising or control dependencies. In all other respects, the sentences are very similar to those used in the other experiments.

2.1. Materials and Methods

2.1.1. Participants

Thirty-two participants from the University of Edinburgh community were paid to participate in the experiment. All were native speakers of English, with normal or corrected-to-normal vision, and none reported any reading disability. All of the participants in the four experiments reported in this paper gave informed consent to take part. The research protocol was approved by the Psychology Research Ethics Committee, of the University of Edinburgh.

2.1.2. Stimuli

The stimuli of Experiment 1 were similar to (9)[7]:

9a. **Accessible-match Inaccessible match:**
John didn't trust Tom but was kind to himself appropriately and very sincerely.

[5]Co-argumenthood is an important notion in certain theoretical treatments of anaphoric binding (see Reinhart and Reuland, 1993, for a well-known example of such a theory).

[6]However, we acknowledge that the extra complexity of the control nominal dependency might not necessarily result in slower access. As pointed out by a reviewer, it is possible that the richer lexical information would in fact make access faster.

[7]The stimuli for all experiments are available in the Supplemental Material.

9b. **Accessible-match Inaccessible mismatch:**
John didn't trust Amy but was kind to himself appropriately and very sincerely.

9c. **Accessible-mismatch Inaccessible match:**
Mary didn't trust Tom but was kind to himself appropriately and very sincerely.

9d. **Accessible-mismatch Inaccessible mismatch:**
Mary didn't trust Amy but was kind to himself appropriately and very sincerely.

Given this design, the main effect of *accessible antecedent* matching can be used to gauge the time at which the parser first becomes sensitive to the gender matching between the reflexive and its grammatically correct antecedent, and can thus, given the assumptions above, be used as a measure of how quickly the structurally appropriate antecedent is identified. For example, if this effect is initially found in first fixation duration it would suggest that the antecedent is identified very early (see the Section 2.2 below for details of the eye-movement measures). Moreover, the effect of *inaccessible antecedent* (or its interaction with *accessible antecedent*) is informative about any effect of interference. For example, if the mismatch cost for the accessible antecedent is reduced where the inaccessible antecedent matches (11d) relative to when it does not (11c), this could be indicative of a *facilitatory interference* effect. Alternatively, if we find evidence for extra processing difficulty when both potential antecedents match the reflexive (11a) relative to when only the accessible antecedent matches (11b), then this could be interpreted as *inhibitory interference*. Given the experimental design, either of these two patterns, or their combination, would result in an interaction between the two experimental factors. Specifically, *facilitatory interference*, on its own, would result in a difference between the two accessible mismatch conditions (i.e., a penalty for inaccessible mismatch relative to inaccessible match), with no difference among the accessible match conditions. *inhibitory interference*, on its own, would result in a difference between the two accessible match conditions (i.e., a penalty for inaccessible match relative to inaccessible mismatch), with no difference among the accessible mismatch conditions. Finally, a combination of these two interference profiles would result in a cross-over pattern of means.

2.1.3. Procedure

The experiment was carried out using an SR Research Eyelink 1000 eye-tracker, with a sampling rate of 1000 Hz. The tracker was used in tower mode. Only the right eye was tracked, although viewing was binocular. The eye-tracker was calibrated at the start of each participant's session, with recalibration being carried out as necessary through the experiment. At the start of each trial, a black box appeared at the left of the screen, in the position of the first character of text. When a stable fixation was detected in this position, the box disappeared, and the text appeared. The stimuli were presented in black on a white background, using Times Roman 16 point. The stimuli were presented in either one or two lines of text. In all cases, the critical reflexive was always placed at least two words before the end of a line.

The stimuli were combined with 102 filler sentences of varied sentence types. Thirty-six of the fillers were from an unrelated experiment on the processing of emotion words. A comprehension question followed around two thirds of all stimuli, including all of the experimental items (as an example, the question for (9) was "Was the kindness appropriate?"). The participant had to answer the question by pressing a button to select one out of two displayed answers. The stimuli were distributed into four lists, using latin square counterbalancing.

2.2. Data Analysis

The sentences were divided into regions for the purpose of analysis. Here, we will report data for the following regions:

- **pre-critical region:** kind to
- **critical region (reflexive):** himself
- **spillover:** appropriately and
- **final:** very sincerely

Eye-fixation data were screened and manually corrected for vertical drift. Fixations of less than 80 ms were incorporated into larger fixations within a distance of one character, and then we deleted any remaining fixations of less than 80 ms, as well as any over 1200 ms.

We will report data for five eye-movement measures. First fixation is the duration of the first fixation in a region, from the time the region is first entered from the left, until a subsequent fixation is made. First pass reading time is the sum of fixation durations within the region, from the time the region is first entered from the left, until the region is exited, either to the left or right. Go-past is the sum of fixation durations from the time the region is first entered from the left until it is exited to the right (including any fixations made to the left of the region). Total time is the summed duration of all fixations on the region. In the above measures, for any given trial, if the measure returned no data (e.g., if there were no fixations on the region), the trial was treated as a missing value in the analysis. Finally, Second Pass reading time is the summed duration of all re-fixations on the region, after it has already been fixated for the first time. As is customary, for Second Pass reading time, trials that do not include a relevant fixation are included in the analysis as zero millisecond data points. Note that the first fixation measure is most meaningfully applied to single-word regions, which can be assumed to be processable within a single fixation. Thus, we report first fixation durations only for the critical reflexive region.

The results for all eye-movement measures were submitted to 2×2 Analyses of variance, aggregating by subject (F_1) and by item (F_2). The factors in the analysis were Accessible antecedent matching (match vs. mismatch) and Inaccessible antecedent matching (match vs. mismatch), both of which were within item and within participant.

2.3. Results

Two items were excluded from analysis because of typographical errors. Therefore, the item analysis is based on 38 items, with a corresponding reduction in the degrees of freedom for the F_2 analysis. Means for Experiment 1 are presented in **Table 1**, and statistical results are presented in **Table 2**.

TABLE 1 | Means (and Standard Errors) for Experiment 1.

Region		Pre-critical	Critical	Spillover	Final

Match	Mismatch	329 (18)	271 (10)	500 (29)	465 (29)
Mismatch	Match	337 (19)	286 (14)	488 (32)	412 (27)
Mismatch	Mismatch	334 (21)	291 (13)	508 (31)	425 (30)
GO-PAST					
Match	Match	396 (26)	343 (22)	722 (64)	1482 (119)
Match	Mismatch	388 (21)	357 (19)	707 (54)	1463 (123)
Mismatch	Match	438 (42)	367 (18)	816 (61)	1667 (159)
Mismatch	Mismatch	403 (25)	378 (26)	914 (66)	1628 (167)
SECOND PASS					
Match	Match	224 (29)	153 (21)	298 (32)	126 (17)
Match	Mismatch	190 (24)	143 (19)	292 (30)	133 (20)
Mismatch	Match	244 (34)	176 (19)	360 (42)	139 (22)
Mismatch	Mismatch	223 (22)	179 (19)	392 (40)	159 (23)
TOTAL TIME					
Match	Match	525 (34)	404 (25)	813 (51)	533 (33)
Match	Mismatch	514 (32)	406 (23)	795 (47)	609 (38)
Mismatch	Match	565 (45)	447 (27)	845 (62)	560 (38)
Mismatch	Mismatch	548 (39)	457 (24)	898 (59)	600 (47)

As in previous work (e.g., Sturt, 2003), there was very early evidence for a mismatch cost for the accessible antecedent; the effect appeared in the first fixation duration on the critical reflexive (the earliest measurable point, given the eye-tracking methodology), and this was mirrored in first pass times in the same region. However, this early effect did not interact with the matching of the inaccessible antecedent. The inaccessible antecedent had a marginal effect on fixation times in the final region in Total Time and First Pass. The pattern was for the inaccessible mismatch condition to lead to longer reading times than the corresponding match condition. In First Pass, this effect in the final region interacted with the accessible antecedent, but only in the analysis by item—the reading time penalty for the inaccessible mismatch condition (relative to inaccessible match) was greater when the reflexive matched the accessible antecedent (465 vs. 397 ms; a relative cost of 68 ms; both F's > 6, both p's < 0.02) than when it did not (425 vs. 412 ms; a relative cost of 13 ms; both F's < 1).

2.4. Discussion

This experiment sets a baseline using direct reflexive-antecedent dependencies, for the following experiments, where the reflexive-antecedent dependency is mediated by raising and control. We find that an early main effect of accessible antecedent on the critical reflexive, indicating an early onset of the mismatch cost. There was little evidence of either inhibitory interference or facilitatory interference, at least in the early measures. Later effects suggest a difficulty for *mismatching*, relative to *matching* inaccessible antecedents. This pattern may possibly be interpreted in terms of facilitatory interference. However, this interpretation is not straightforward, as the effect of inaccessible antecedent appeared as a main effect rather than the interaction predicted by current memory models. In fact, the marginal interaction in First Pass in the final region shows, if anything, that the facilitatory effect was larger for the *grammatical* sentences than the ungrammatical sentences, which is not the pattern that is expected for facilitatory interference. In addition, we note that First Pass reading times are often hard to interpret in the final region of a sentence, due to the possibility of relatively short initial fixations preceding regressions out of the region (see Sturt, 2007; Sturt et al., 2010).

3. Experiment 2

Experiment 2 used reflexive-antecedent dependencies that are mediated by raising or nominal control, depending on condition, in simple sentences that do not contain distractor noun phrases. This allows us to determine whether there are any baseline differences in the time-course of processing of raising-mediated and control-mediated dependencies, over and above those that may be explained in terms of interference effects. If the dependencies are formed more quickly when they are mediated by raising than when they are mediated by control, then we would expect the onset of the mismatch cost to appear earlier in the eye-movement record in raising than in control.

4. Materials and Methods

4.1. Participants

Thirty-two participants from the University of Edinburgh community were paid to participate in the experiment. All were native speakers of English, with normal or corrected-to-normal vision, and none reported any reading disability.

4.2. Stimuli

There were 40 stimuli, which were similar to those given in (10):

10a. **Control Match:**
I was surprised at John's agreement to be kind to himself appropriately and very sincerely.

10b. **Control Mismatch:**
I was surprised at John's agreement to be kind to herself appropriately and verysincerely.

10c. **Raising Match:**
It was surprising that John seemed to be kind to himself appropriately and very sincerely.

10d. **Raising Mismatch:**
It was surprising that John seemed to be kind to herself appropriately and very sincerely.

The design manipulated sentence type (Raising vs. Control), and gender matching (Match vs. Mismatch).

As we mentioned in the introduction, we assume that the raising and nominal control dependencies are initially formed around the point where *to be kind* is received in the input, and that there is a second retrieval event that is triggered by the reflexive, which is also mediated by control (10a,b) or raising (10c,d). It is this second retrieval event that we are measuring in this experiment, using the gender-mismatch paradigm. It is important to recognize that this second retrieval event involves two dependencies, (a) a reflexive-antecedent dependency (between *himself* and its direct antecedent, the empty subject of the infinitival clause), and (b) a raising or control dependency (between the empty subject and *John*). The logic of the design is that, as the relevant aspects of the reflexive-antecedent dependency are essentially identical between the raising and control conditions, any differences that we might find in the onset of the mismatch cost must be due to processing differences related to raising or control.

4.3. Procedure

The sentences were divided into regions for the purpose of analysis as shown below.

- **pre-critical region:** kind to
- **critical region:** himself
- **spillover:** appropriately and
- **final:** very sincerely

The pre-critical region consisted of the two words immediately preceding the critical reflexive. The spillover region consisted of the two words immediately following the reflexive. The final region consisted of the last two words of the sentence.

4.4. Results

The means are given in **Table 3**, and statistical results in **Table 4**.

As in Experiment 1, there was an early effect of matching, indicating a cost for the gender mis-matching items. This effect is present in all eye-movement measures on the critical reflexive, and persisted into the spill-over region. As this includes measures indicative of early processing, such as first-pass reading time, and first fixation, this suggests that the antecedent was identified equally quickly, whether the dependency was mediated by raising or control. In fact, the timing was in line with the co-argument reflexive-antecedent dependencies examined in Experiment 1. This early mismatch cost did not interact with structure. In addition, a main effect of structure type suggested that the control sentences were harder to read than the raising sentences (see Total Time, pre-critical region, and First Pass, spill-over region). However, this overall difference is not the focus of the current investigation.

4.5. Discussion

In this experiment, we investigated sentences where raising and control dependencies were combined with reflexive-antecedent dependencies. The main effect of matching appeared in both first fixation and first pass on the critical reflexive. This is the earliest detectable point given the eye-tracking methodology, and is in line with the timing of the accessible mismatch effect in the co-argument reflexive-antecedent dependencies examined in

TABLE 3 | Means (and Standard Errors) for Experiment 2.

Raising	Mismatch	621 (52)	545 (41)	1023 (75)	633 (46)

Experiment 1. As the effect was not modulated by sentence structure, there is no indication of any difference in the time-course of antecedent identification, whether the dependency was mediated by raising or nominal control dependencies. However, the study was carried out as a baseline, and did not include distractor noun phrases. Thus, although the study suggests no clear difference in time-course between dependency types, it does not rule out that the two dependency types may be differentially susceptible to interference. In Experiments 3 and 4, we address this issue, by including distractor antecedents in Nominal control (Experiment 3) and Raising (Experiment 4) sentences.

5. Experiment 3

Experiment 3 was designed to test the susceptibility of nominal control dependencies to interference.

5.1. Materials and Methods

5.1.1. Participants

Thirty-two new participants from the University of Edinburgh community were paid to participate in the experiment. All were native speakers of English, with normal or corrected-to-normal vision, and none reported any reading disability.

5.1.2. Stimuli

There were forty experimental items similar to those in (11)[8]:

11a. **Accessible-match Inaccessible match:**
John's agreement with Tom to be kind to himself was surprising to everyone.

11b. **Accessible-match Inaccessible mismatch:**
John's agreement with Amy to be kind to himself was surprising to everyone.

11c. **Accessible-mismatch Inaccessible match:**
Mary's agreement with Tom to be kind to himself was surprising to everyone.

11d. **Accessible-mismatch Inaccessible mismatch:**
Mary's agreement with Amy to be kind to himself was surprising to everyone.

The items all used giver control nominals (exemplified by *agreement* in 11a–d; Culicover and Jackendoff, 2001), with the result that the accessible antecedent for the reflexive was always the genitive subject of the control nominal (e.g., *John's* in 11). The design orthogonally manipulated the gender matching of the reflexive with the accessible antecedent (e.g., *Mary* vs. *John*) and with the inaccessible antecedent (*Tom* vs. *Amy*).

5.1.3. Procedure

All relevant aspects of the procedure were identical to Experiment 1.

We will report analyses based on the following regions:

- **pre-critical region:** kind to
- **critical region (reflexive):** himself
- **spillover:** was surprising
- **final:** to everyone.

5.2. Results

The means are given in **Table 5**, and statistical results in **Table 6**.

The results show evidence of a mismatch cost for the accessible antecedent in go-past, total time and second pass in the critical reflexive region. Go-past and Total times on this region were not modulated by any interactions with inaccessible antecedent matching. There was some marginal evidence that reading was affected by the inaccessible antecedent, in measures of later processing. The effect of inaccessible matching was significant (in the subjects analysis only) in second pass in both the critical and spillover regions; as in Experiment 1, the tendency was for inaccessible mismatch conditions to be read more slowly than inaccessible match conditions.

There was a marginal interaction between accessible and inaccessible gender matching in go-past and first-pass reading time in the spill-over region. This interaction was examined using pairwise comparisons, to test the simple effect of inaccessible antecedent, within (a) the accessible match conditions, and (b) the accessible mismatch conditions. For first-pass reading times,

[8]The position of the control nominal in the sentence is different in Experiment 3 from Experiment 2. This is because Experiment 2 needed to use a sentence frame that allowed a comparison of nominal control with raising, while Experiment 3 only used nominal control, so could use a more naturally suited sentence frame.

neither of these pairwise comparisons was reliable (all p's > 0.1). However, for Go-Past time, pairwise comparison (b) (i.e., within the accessible mismatch conditions) showed significantly faster reading times for the inaccessible match (797 ms) relative to inaccessible mismatch (948 ms) [$F_{1(1,31)} = 5.72$, $p < 0.05$; $F_{2(1,39)} = 4.11$, $p < 0.05$], while comparison (a) (i.e., within the accessible match conditions) showed a non-significant difference in the opposite direction (794 ms vs. 768 ms) [both p's < 1].

5.3. Discussion

The first appearance of the mismatch cost for the accessible antecedent was in the Go-past measure on the critical reflexive. This shows that the ungrammatical dependency in the accessible mismatch conditions disrupted processing fairly quickly—soon after the participants initially fixated the reflexive, and before they moved on to fixate subsequent words.

The experiment did not show strong interference effects, but we believe that the results for Go-past in the spill-over region are highly suggestive, at the very least. Despite the fact that the interaction was marginal, the results of the pairwise comparisons are as predicted for facilitatory interference, since the cost for the accessible mismatch was significantly reduced when the inaccessible antecedent matched the gender of the reflexive, relative to when it did not.

6. Experiment 4

Experiment 1 showed no evidence that could be straightforwardly interpreted in terms of interference, for direct reflexive-antecedent dependencies that were not mediated by raising or control. Experiment 3 showed some marginal evidence for facilitatory interference, in the resolution of reflexive-antecedent dependencies that were mediated by nominal control. In Experiment 4, we examine reflexive-antecedent dependencies that are mediated by raising, using a design that is analogous to that of Experiment 3.

6.1. Materials and Methods

6.1.1. Participants

Thirty-two new participants from the University of Edinburgh community were paid to participate in the experiment. All were native speakers of English, with normal or corrected-to-normal vision, and none reported any reading disability.

6.1.2. Stimuli

There were 40 stimuli, which were similar to those in (12):

12a. **Accessible-match Inaccessible match:**
John seemed to Tom to be kind to himself appropriately and very sincerely.

12d. **Accessible-mismatch Inaccessible mismatch:**
Mary seemed to Amy to be kind to himself appropriately and very sincerely.

The items used a raising construction incorporating an experiencer argument (e.g., *to Amy*). The accessible antecedent for the reflexive was always the subject of the main clause (e.g., *Mary*), while the experiencer argument was always an inaccessible antecedent. The design orthogonally manipulated the gender matching of accessible and inaccessible antecedents.

Recall from the introduction of this paper that we expected raising-mediated dependencies to be less susceptible to interference than the control-mediated dependencies that we examined in Experiment 3. The introduction lists some reasons for this expectation, such as potential differences in access mechanisms, retrieval cues, or syntactic representation. Here, we will briefly elaborate on how differences in syntactic representation may lead to different retrieval profiles, using Lexicalized Tree Adjoining Grammar (LTAG) as an example grammatical framework. In LTAG, the matrix subject in (12) (e.g., *John*), would be assumed to occupy the subject position of a predicative elementary tree[9], projected by *kind*, without this relationship being mediated by an empty subject position in the infinitival clause (see XTAG Research Group, 1998, p.106–107). In contrast, in the nominal control stimuli (see 11 in Experiment 3), *John's* would be assumed to occupy the specifier position of *agreement*, while the infinitival clause would have an empty subject, occupied by the empty element PRO (see XTAG Research Group, 1998, p.97–101, for an analysis of verbal control)[10]. Thus, according to the LTAG proposal, *John* is effectively a co-argument of *himself* in the raising sentences, but is not a direct co-argument of *himself* in the nominal control sentences. Accordingly, this approach would predict that the interference profile for raising-mediated dependencies would pattern like the co-argument dependencies examined in Experiment 1, rather than like the control-mediated dependencies examined in Experiment 2.

6.1.3. Procedure

As the experiment was based on Experiment 3, the regions were defined identically:

- **pre-critical region:** kind to
- **critical region (reflexive):** himself
- **spillover:** appropriately and
- **final:** very sincerely

6.2. Results

The means are given in **Table 7**, and statistical results in **Table 8**.

As with Experiment 3, the first evidence of a mismatch cost for the accessible antecedent is in the go-past measure on the critical reflexive region, with a main effect of accessible matching. This main effect persists until the final region, and is found (in the critical and spill-over regions) also in the Total Time and Second Pass measures.

Second pass reading time shows a significant interaction between accessible and inaccessible matching in both the critical and spill-over regions. Pair-wise comparisons on both of these regions show a pattern consistent with facilitatory interference: there was a reliable difference between the two accessible mismatch conditions, with longer second pass times when the inaccessible antecedent also mismatches the reflexive than when it does not {critical region: 266 ms vs. 215 ms [$F_{1(1,\,31)} = 4.10$, $p = 0.052$; $F_{2(1,\,39)} = 5.66$, $p < 0.05$]; spill-over region: 519 ms vs. 398 ms [$F_{1(1,\,31)} = 6.92$, $p < 0.05$; $F_{2(1,\,39)} = 7.68$, $p < 0.01$]}. In contrast, the difference between the two accessible match conditions was in the other direction, but much smaller, and non-significant (critical region: 149 ms vs. 153 ms; spill-over region: 337 ms vs. 359 ms; all F's < 1).

On the final region, there were marginal interactions in both Second pass and Go-past (significant only by subjects for Go-past, and only by items for Second-pass). Pairwise comparisons revealed patterns of significance that were suggestive of

[9] An elementary tree can be thought of as a lexically-stored extended projection of a head word.

[10] The XTAG grammar does not treat nominal control, but we assume that the analysis would be analogous to that of verbal control.

inhibitory interference. Among the accessible match conditions, reading times were longer when the inaccessible antecedent also matched the reflexive, than when it did not {Go-past: 1741 ms vs. 1518 ms; [$F_{1(1,31)} = 4.63$, $p < 0.05$; $F_2(1, 39) = 1.60$, $p = 0.21$]; Second pass: 206 ms vs. 150 ms; [$F_{1(1,31)} = 4.32$, $p < 0.05$; $F_2(1, 39) = 5.54$, $p < 0.05$]}. Among the accessible mismatch conditions, the difference was in the opposite direction, but was not reliable (Go-past: 1832 ms vs. 1955 ms; both F's < 1.2, both p's > 0.3; Second pass: 208 ms vs. 221 ms; both F's < 1).

6.3. Discussion

As in Experiment 3, the first indication of a mismatch cost was the main effect of accessible matching in the critical reflexive region. There was also some clear evidence of facilitatory interference, in second-pass reading times in the critical and spill-over regions. Thus, the interference profile for this raising-mediated dependency resembled that of the control-mediated dependencies in Experiment 3, and differed from the the co-argument dependencies examined in Experiment 1, where no strong evidence of interference was found. Thus there is no evidence for the hypothesis that raising-mediated dependencies should show reduced interference effects relative to control-mediated dependencies, based on differences in the access mechanism, retrieval cues, or syntactic representation.

Unlike any of the previous experiments, there was also some evidence of inhibitory interference. However, this result is hard to interpret, as it comes from second-pass and go-past measures on the final region, and could thus be contaminated by wrap-up effects, or preparations for the comprehension question. Here, second pass time is based on the fixations that are made when the final region is re-fixated, following any initial regressions back to earlier points in the sentence, and before the button is pressed to indicate the end of the trial. Go-past time on this region also includes these fixations. Thus, if inhibitory interference is indeed present, it occurred very late in the trial, probably during sentence-final wrap-up.

7. General Discussion

The above experiments were designed to examine the interference profile, and speed of dependency formation, for raising and nominal control dependencies. We began with the hypothesis that nominal control dependencies would be more subject to interference, and processed more slowly, than raising dependencies. This prediction was not confirmed overall. In the following, we will discuss the issues of time-course and interference in turn.

Experiment 1 established a baseline using reflexive-antecedent dependencies without the involvement of raising or control, and it replicated previous work in showing that gender mismatching between a reflexive and its accessible antecedent can slow down processing as early as the first fixation on the reflexive. Experiment 2 further established that, in the absence of inaccessible distractor antecedents, dependencies that were mediated by raising and nominal control elicited an equally early onset of the gender mismatch difficulty. Experiments 3 (control) and 4 (raising) included inaccessible distractor antecedents. These experiments showed the accessible mismatching cost on the critical reflexive

in go-past, as well as in Total Time and Second pass, but, unlike in Experiments 1 and 2, not in first-fixation or first-pass.

Although we need to be cautious in interpreting between-experiment differences among first-pass measures, the control-mediated dependencies did not show an earlier onset for the mismatch cost than raising-mediated dependencies. Instead, the overall pattern of results is consistent with a slightly delayed onset of the mismatch cost for both the raising and control dependencies in Experiments 3 and 4 (go-past on the critical reflexive), relative to the co-argument reflexive-coargument dependencies tested in Experiment 1 (first-fixation and first pass on the critical reflexive). This delayed onset does not appear to be due to the involvement of raising or control dependencies *per se*, as Experiment 2, which used these dependencies (but without distractor phrases), showed an onset of mismatch difficulty in first-fixation, as early as that of Experiment 1. Rather, if anything, the delayed onset appears to be due to the presence of potentially interfering distractor phrases (whatever their gender marking), in conjunction with the use of raising and control dependencies. This should be interpreted as a preliminary finding, pending further investigation using more complex within-participant designs that have sufficient power to allow the statistical detection of potentially small differences in the onset of the mismatch cost. Such studies could also be supplemented by studies that allow a more direct measure of processing speed (e.g., Speed Accuracy Tradeoff; McElree et al., 2003).

Turning now to the discussion of interference, the results did not support the idea that dependencies mediated by nominal control would be more susceptible to interference than raising dependencies. On the one hand, assuming that the marginal interaction effect for Experiment 3 (control) reflects genuine interference, it may be the case that interference occurs earlier where the dependency is mediated by nominal control, compared with when it is mediated by raising. This is because the interference effect for Experiment 3 occurred shortly after readers had progressed forwards from the critical reflexive (i.e., in Go-past on the spill-over region), while in Experiment 4 (raising), the same region showed the effect only in second-pass. On the other hand, the interference effect seems to be stronger in Experiment 4 (raising) than in Experiment 3 (control). That is, in Experiment 3, the interaction between accessible and inaccessible gender matching was (marginally) significant only in go-past and first-pass reading time in the spill-over region, while in Experiment 4 it was fully significant in second-pass on the critical and spill-over regions (and marginal in two measures on the final region of the sentence). Thus, overall patterns of results do not support the hypothesis that the involvement of lexically-driven dependencies (control) leads to more interference than that of structurally-driven dependencies (raising), or that the access mechanism differs due to different retrieval cues or syntactic representations.

Both Experiment 3 (control) and Experiment 4 (raising) showed the profile expected for facilitatory interference. The pattern was such that when the reflexive did not match the gender of its structurally licit antecedent, the processing cost was reduced if there was an intervening distractor that matched the reflexive, relative to when the distractor did not match. The fact that interference was facilitatory, rather than inhibitory, accords with previous studies on subject-verb agreement (e.g., Wagers et al., 2009) and negative polarity licensing (e.g., Vasishth et al., 2008; Xiang et al., 2009), where interference was found only among ungrammatical (or otherwise degraded) conditions. Thus, like those earlier studies, our results do not tell us whether interference also affects grammatical, non-degraded dependencies. Moreover, our interference effect was found in measures that reflect fixation behavior after the reader has already progressed forwards from the critical reflexive, and thus, after the point where the mismatching of the accessible antecedent had started to cause a slow-down in reading. Because of this, we believe that the retrieval interference for these dependencies occurred, not during the initial retrieval of the antecedent, but during the repair process, possibly reflecting a *re-retrieval*, while readers searched for an acceptable interpretation of the ungrammatical sentences in the accessible mismatch conditions. In fact, the pattern of results can be summarized by saying that, while the *onset* of the accessible mismatch cost was unaffected by the gender of the distractor, the *duration* of this processing difficulty was affected by the distractor—i.e., the duration was shorter when the distractor matched the reflexive's gender.

Recall that the stimuli of Experiments 3 and 4 used dependencies that involved both reflexive-antecedent dependencies

and control (or raising) dependencies. However, Experiment 1 used co-argument reflexive-antecedent dependencies with superficially very similar materials, and it showed no reliable evidence that could be straightforwardly interpreted in terms of the facilitatory interference or inhibitory interference. We therefore interpret Experiments 3 and 4 as support for the claim that reflexive-antecedent dependencies that are mediated by raising or control are processed more slowly and are more susceptible to interference than the co-argument dependencies when there is a distractor. Below, we outline a possible sequence of events that, while admittedly speculative, might explain how our raising and control sentences are affected by interference. For expository reasons, we focus on the *accessible-mismatch inaccessible-match* condition for Nominal Control in Experiments 3, as exemplified in (13): but analogous remarks also apply to Experiment 4.

13 **Nominal Control: Accessible mismatch, Inaccessible Match**
Mary's agreement with Tom Ø to be kind to himself was surprising to everyone.

As discussed in the introduction of this paper, in (13), we assume that the control dependency is initially formed around the point where *to be kind* is read. Note that the retrieval is effectively triggered by a null element (i.e., Ø), so the retrieval cue cannot include gender information, so this retrieval is not expected to have been affected by gender-based interference. It is not possible to measure interference at this early point in the sentence with our design (and indeed, the experiment was not designed to detect this). In fact, our experiments investigated a second retrieval event, related to the processing of the reflexive, but so far, we have not discussed this second event in any detail. Accordingly, we now sketch a possible account, based on our experimental results.

In (13), we assume that, following the initial retrieval event at *to be kind*, the null element Ø is associated with information about its antecedent *Mary*, including the fact that the antecedent is female. At *himself*, the null element Øis retrieved, and the gender incompatibility with the reflexive is registered, causing processing difficulty, and triggering a repair process. During the repair process, a new retrieval process is launched for Øto find its antecedent. This now includes a male gender cue due to the fact that *himself* is male. It is at this point that *Tom* can be misretrieved as the antecedent of Ø, leading to processing facilitation. Note that, in order for this mis-retrieval to occur in the way that we have suggested, it would have to be possible for the reflexive to use gender as a retrieval cue (contra Dillon et al., 2013), as least during the repair process.

An alternative to the above account is that the interference that we observe in sentences like (13) is driven entirely by a repair process involving the reflexive-antecedent dependency in response to the gender mismatch, without a new control-related retrieval being launched. Thus, for example, the error at the reflexive might reduce confidence in the structural encoding, increasing sensitivity to other gender-matching items in the sentence. However, such an account would still need to explain the apparent lack of interference in the direct reflexive-antecedent dependencies examined in Experiment 1. In other words, if the reflexive triggered an error-based retrieval (without invoking control or

raising dependencies) in Experiments 3 and 4, then why did it not also trigger an analogous error-based retrieval in Experiment 1? While this may potentially be due to other differences between the stimuli of Experiment 1 and the other experiments, we believe that the most likely reason is the fact that the relation between the reflexive and its antecedent is direct in Experiment 1, but mediated by control (or raising) in experiments 3 and 4, and that the control (or raising) dependency plays a role in the observed interference.

A question for future research is whether indirect dependencies (such as the ones that we examined in Experiments 3 and 4) are in general more prone to interference than direct dependencies (such as the one that we examined in Experiment 1).

Author Contributions

PS Supervised the running of the experiments, conducted the statistical analyses, and drafted the article. NK Supervised the creation of stimuli, and participated in writing the article. Both authors contributed equally to the planning of the research, and to the theoretical interpretation of the results.

Funding

This work was supported by the National Research Foundation of Korea grant funded by the Korean Government (NRF-2014S1A2A2028232), and by a British Academy/Leverhulme Small Research Grant (SG120693).

Acknowledgments

We thank Oliver Stewart and Gloria Chamorro for assistance with data collection.

Structure Modulates Similarity-Based Interference in Sluicing: An Eye Tracking study

Jesse A. Harris *

Department of Linguistics, University of California, Los Angeles, Los Angeles, CA, USA

In cue-based content-addressable approaches to memory, a target and its competitors are retrieved in parallel from memory via a fast, associative cue-matching procedure under a severely limited focus of attention. Such a parallel matching procedure could in principle ignore the serial order or hierarchical structure characteristic of linguistic relations. I present an eye tracking while reading experiment that investigates whether the sentential position of a potential antecedent modulates the strength of similarity-based interference, a well-studied effect in which increased similarity in features between a target and its competitors results in slower and less accurate retrieval overall. The manipulation trades on an independently established Locality bias in sluiced structures to associate a *wh*-remnant (*which ones*) in clausal ellipsis with the most local correlate (*some wines*), as in *The tourists enjoyed some wines, but I don't know which ones.* The findings generally support cue-based parsing models of sentence processing that are subject to similarity-based interference in retrieval, and provide additional support to the growing body of evidence that retrieval is sensitive to both the structural position of a target antecedent and its competitors, and the specificity or diagnosticity of retrieval cues.

INTRODUCTION

The rapid formation of non-adjacent syntactic dependencies during online sentence comprehension offers intuitive evidence for the importance of an efficient retrieval system. Two well-studied cases are argument-verb dependencies, in which an argument must be related to its verb no matter the amount of intervening material (1a), and anaphoric dependencies, in which a pronominal element, like *him* or *one*, is associated with another co-referring expression, possibly from among multiple possibilities (1b). The noun phrase *the barber* must be retrieved from memory in each case: either in the subject-trace (gap) position t_1 (1a) or else as a co-referring expression (1b). Only in the former case is the dependency unambiguously determined by structure; the second case is simply the most plausible given the topicality of *the barber* and real world knowledge, as illustrated by fact that likely co-reference possibilities depend on the predicate (1c).

(1) a. The barber$_1$ (that John$_2$ wanted his son$_3$ to visit) t$_{1/*2,*3}$ died yesterday.
b. He$_{1>2>3}$ was 95 years old.
c. He$_{2>3,\#1}$ was saddened to hear the news.

Findings from both types of cases support recent cue-based parsing models of sentence processing in which all possible antecedents are activated in parallel through a fast, domain-general associative cue-matching procedure (for review of evidence and models see, e.g., Lewis et al., 2006; Van Dyke and Johns, 2012; Caplan and Waters, 2013). In such models, a retrieval cue—e.g., the verb *died* in (1a) or the pronoun *he* in (1b), initiates direct access to all possible targets (possible antecedents or dependencies) from memory. However, not all possible targets must be equally activated within memory: some targets might receive greater activation by virtue of sharing syntactic or semantic features with the retrieval cue, while other targets might receive less activation as a function of temporal decay (Van Dyke and Johns, 2012, for review, though a reviewer points out that decay as the primary source of forgetting is not strongly supported in the general memory literature, as demonstrated by Keppel and Underwood, 1962 and Waugh and Norman, 1965). Further, the allocation of attentional resources in memory is severely constrained, possibly limited to a single item within the focus of attention (e.g., McElree, 2001). Thus, the memory architecture employed in sentence processing strongly resembles the architecture thought to underlie domain-general tasks (e.g., McElree, 2000; McElree et al., 2003; Van Dyke and Lewis, 2003; Lewis and Vasishth, 2005; Lewis et al., 2006).

A major research question within the cue-based parsing literature addresses the extent to which domain-specific knowledge influences the retrieval process; in particular, whether syntactic constraints affect antecedent retrieval, and, if so, at precisely what stage of retrieval. Much of the research conducted thus far has examined whether syntactically inaccessible targets are considered viable candidates for retrieval. The two major schools of thought addressing this issue in the cue-based parsing literature are (i) structure-based accounts, and (ii) unconstrained-cue accounts. In the former, grammatical constraints filter the set of possible antecedents retrieved from memory by constraining the search set to grammatically permissible positions (e.g., Nicol and Swinney, 1989; Sturt, 2003; Xiang et al., 2009; Chow et al., 2014). Thus, items in structurally inaccessible positions would be effectively ignored in the retrieval process, though grammatically illicit items may feed repair processes triggered by retrieval failure (Chow et al., 2014). In contrast, the latter, unconstrained-cue, approach proposes that grammatical constraints are but one of the many possible factors guiding retrieval (e.g., Badecker and Straub, 2002; Lewis and Vasishth, 2005; Chen et al., 2012; Jäger et al., 2015). Badecker and Straub (2002), for example, propose that the set of possible antecedents are restricted not by tree geometry, but a number of other factors, such as attention or discourse importance. Elements in the focus of attention are often identified with discourse topics or a center, though details regarding how to define topics vary considerably (see, e.g., Chafe, 1976; Gundel, 1985; Gundel et al., 1993; Grosz et al., 1995). Under this type of account, syntactically inaccessible items might well interfere with retrieving a target, particularly if such items are highly salient in the discourse, though, of course, structure may be one of the factors that determines discourse salience. Although it should be clear that both viewpoints agree that structural information is a factor in retrieval, they permit very different types of mechanisms by which structure is utilized.

Unfortunately, results that would clearly arbitrate between the two camps are somewhat mixed. For example, while filler-gap dependencies are sensitive to syntactic islands (for review see, e.g., Sprouse et al., 2012), retrieving pronouns and reflexives has sometimes been found to be susceptible to interference from structurally inaccessible items (e.g., Badecker and Straub, 2002; Jäger et al., 2015; though see Chow et al., 2014 for a failure to replicate Badecker and Straub's results). The general finding is that syntactic information plays an important role in retrieval for at least certain types of dependencies (Van Dyke and McElree, 2006, 2011; Van Dyke, 2007; Dillon et al., 2014; Cunnings et al., 2015), even if it is currently unclear whether that role is to filter possible antecedents or provide weighted or probabilistic cues regarding their likelihood of matching the probe (Badecker and Straub, 2002; Cunnings et al., 2015). Further, it is unclear at this stage whether syntactic information should be treated as value in a feature bundle (e.g., Lewis and Vasishth, 2005), and if configurational relations like c-command inherently preclude such a treatment (see Alcocer and Phillips, 2012; Kush, 2013, for discussion).

The present research seeks to widen the empirical coverage of the issue of structural import by leveraging an independently established bias guiding the resolution of correlate-remnant pairs in clausal ellipsis (sluiced) structures. In (2), for example, the remnant *which (ones)* might be paired with either a subject correlate (*a few linguists*) or an object correlate (*some silly examples*), spelled out as (2a) and (2b), respectively.

(2) [A few linguists] gave [some silly examples], but I don't remember which (ones).

a. …I don't remember which linguists. (Subject correlate)
b. …I don't remember which examples. (Object correlate)

Although sluicing ellipsis permits correlates in both subject and object position above, it shows a strong preference for the latter (Frazier and Clifton, 1998). As mentioned, much research in content-addressable retrieval systems in language processing addresses whether grammatical restrictions govern the resolution of various types of anaphoric dependencies, especially the availability of syntactically illicit antecedents (e.g., Sturt, 2003; Martin et al., 2012, 2014; Cunnings et al., 2015; see also Phillips et al., 2011, for review). In contrast, correlates to sluiced remnants are merely heavily biased, rather than constrained grammatically. Thus, sluiced structures provide a potentially revealing counterpoint to studies investigating syntactic barriers to accessibility: if structurally defined preferences, in addition to grammatical restrictions, influence the retrieval process, the retrieval system may use structural information to privilege some products of memory over others. In which case, the retrieval system might be said to avail itself of domain-specific, linguistically defined structural preferences, in addition to hard-coded grammatical principles. In the remainder of the paper, I review the aspects of cue-based parsing that are most relevant for this study, along with the basic assumptions regarding the ellipsis structures explored here. I

then present two experiments which collectively support the idea that retrieving antecedents in sluiced sentences is subject to interference effects (congruent with Martin and McElree, 2011, discussed in detail below) and that the strength of such interference effects depends on the sentential position of possible targets and strength of the cue provided at retrieval.

Cue-based Parsing and Similarity-based Interference

Many models of how linguistic representations are encoded and retrieved during real-time language comprehension have been proposed (for review, see Van Dyke and Johns, 2012; Caplan and Waters, 2013). In contrast to cue-based retrieval systems, traditional models employ an operation that searches through items in memory, typically in a serial fashion (Dosher and McElree, 1992; McElree and Dosher, 1993), as developed for short-term memory in general (Sternberg, 1966, 1975). In these models, the path of the search varies according to whether the search queue starts with the first item encountered, as in forward search, or the most recent item, as in backward search. The basic prediction of search models is that retrieval time should increase as a function of search space within the path: the more items that must be searched through, the greater the search time required to do so. This prediction, however, has not been supported by Speed Accuracy Tradeoff (SAT) experiments which report that speed of reaching a stable judgment or interpretation is unaffected by the size of the putative search space, even though accuracy is (McElree and Dosher, 1989; McElree, 2000, 2006; McElree et al., 2003; Foraker and McElree, 2007, 2011; Martin and McElree, 2008, 2009, 2011). For example, McElree (2001) manipulated the amount of intervening material (underlined) between a relative clause filler *the book* and its object position gap t_1, shown in (3). Subjects were trained to make an acceptability judgment in response to tones at various post-sentence intervals. Measuring the rate at which responses achieved a stable interpretation (the asymptote) as a function of time, he found that while accuracy decreased as more material intervened between the filler and the gap, the speed at which the asymptote was reached did not (see also McElree et al., 2003).

(3) a. This was [the book]$_1$ that the editor admired t_1.
    b. This was [the book]$_1$ that the editor who the receptionist married admired t_1.
    c. This was [the book]$_1$ that the editor who the receptionist who quit admired t_1 married.

That accuracy, not the rate of reaching the asymptote, is affected by increasing items in memory not only provides an important argument against search models, it also suggests that the quality of the representations recovered is susceptible to interference from distractors. A content-addressable retrieval system is able to account for this tradeoff by proposing that all items are compared against the target in parallel, not by a search operation, but by an automatic associative cue-matching procedure which compares partial representations of items in memory (possibly encoded as bundles of semantic and grammatical features; Clark and Gronlund, 1996) against cues from the target (as in ACT-R models, Anderson et al., 2004; Lewis et al., 2006). Thus, linear or structural distance is irrelevant for retrieval times, but additional competitors interfere with the cue-matching process by introducing partial matches, thereby degrading the quality of the retrieved item. In other words, the greater the similarity or overlap between a target and its competitors, the greater the effect of interference (Crowder, 1976; Anderson and Neely, 1996).

Similarity-based interference, i.e., the failure to successfully distinguish a target from similar competitors in retrieval, has now been well documented both in general memory manipulations (Nairne, 2002; Öztekin and McElree, 2007) and in language processing contexts (Lewis, 1996; Gordon et al., 2001, 2002, 2004, 2006; Van Dyke and Lewis, 2003; Van Dyke and McElree, 2006, 2011; Van Dyke, 2011; Autry and Levine, 2014, among others). Dual task paradigms combine the two, so that a subject attempts to retain a list of words in working memory while processing a separate sentence for comprehension. When items in the memory set are similar to critical words in the sentence, performance decreases on both reading speed and comprehension accuracy (Fedorenko et al., 2006), especially if those items overlap with retrieval cues for long distance dependencies (Van Dyke and McElree, 2006).

What is less clear is the extent to which structural information modulates the accessibility of a target. On the one hand, grammatically illicit cues appear to license a syntactically dependent element in case of illusory licensing (including negative polarity items, NPI, Vasishth et al., 2008; Xiang et al., 2013, as well as agreement attraction, Wagers et al., 2009; Dillon et al., 2013). To illustrate, comprehenders often accept configurations in which an NPI licensor like *no* simply precedes, rather than c-commands, the NPI *ever*, as in *The restaurants that no newspapers have recommended in their reviews have ever gone out of business*, raising the possibility that configurational information may sometimes be ignored. On the other hand, several recent studies show that distractors within the same syntactic position more greatly interfere in the formation of long distance dependencies (Van Dyke and McElree, 2006, 2011; Dillon et al., 2013, 2014). For example, Van Dyke and McElree (2011) observed that syntactic constraints limit the amount of interference exerted by semantically similar distractors, without eliminating interference completely (also Van Dyke, 2007; Van Dyke and Johns, 2012). They attribute these results to greater disturbance from *retroactive interference*, in which retrieval is hampered by a distractor D that separates a cue C from its target T (schematically: T-**D**-C), than from *proactive interference*, in which retrieval is impeded by distractors processed before the target (**D**-T-C).

Similarly, Dillon and colleagues find an increased interference effect for structurally distant antecedents of a reflexive *ziji* in Mandarin Chinese—i.e., when a distractor intervened between a target and the reflexive. They propose that structurally local domains restrict the initial area for dependency formation.

(4) **Local search hypothesis:** The parser uses positional syntactic information during the retrieval of syntactic dependents, and

positional cues serve to restrict retrieval to constituents in some local syntactic domain.

The Local Search Hypothesis contrasts with content-addressable retrieval models that would explain putative effects of Locality in terms of activation decay (see comments in Lewis et al., 2006). Lewis and Vasishth (2005), for example, sharply discriminate items within the focus of attention from those outside of it, which are subject to decay, unless they are reactivated during retrieval processes. A model of this type need not rely on structural information, or even serial order, for retrieval cues. To the extent that syntactic information is utilized, it is established through encoding of morphosyntactic features like [±Theme] or [±Object] in their feature bundles, which collectively identify appropriate structures for retrieval. Thus, such models are entirely domain-general in the sense that the memory operations active during retrieval of linguistic material are the same as those that are active during other types of retrieval. If correct, this uniformity would be a powerful virtue—why postulate specialized retrieval procedures for linguistic structures when the unique aspects of language parsing could be captured simply in terms of specialized features comprising the representations that form the products of memory? In other words, what would be distinctive about language processing would be not so much the *mechanisms* involved in retrieval as how objects over which such mechanisms operate would be *encoded* in memory.

Nevertheless, the following study lends further support to the general finding that the sentence position for an antecedent is relevant during the retrieval process as linguistic dependencies are resolved, though it cannot by itself resolve whether it is best to conceive of such information as structural in nature over sequential or temporal orderings. The study capitalizes on key properties of sluicing ellipsis, as introduced in the following section.

Sluicing and the Locality Bias

Sluicing describes focus-sensitive clausal ellipsis after a *wh*-question (Ross, 1967, 1969; Chung et al., 1995; Merchant, 2001, among others), such as (5a) below. Following Merchant (2001) and others, I assume an account of sluicing which derives the overt structure through movement of the *wh*-element who_1 from its base-generated, clause-internal position to a fronted position followed by optional ellipsis <~~he is meeting~~ t_1> of the remainder of the clause. Thus, the unelided sentence (5b) is the source for the sluice (5a).

(5) a. John is meeting {someone/a friend} for dinner, but I can't tell you who_1 <~~he is meeting~~ t_1>.
b. John is meeting {someone/a friend} for dinner, but I can't tell you who_1 he is meeting t_1.

Sluicing places restrictions on the types of nouns that can serve as correlate to the remnant, though these restrictions depend on the type of *wh*-element and its restrictor residing in the remnant (Chung et al., 1995; Romero, 1998). For example, proper names and definite nouns are often unacceptable correlates for a *who*-remnant unless it is followed by *else* (6a). In select cases, the *wh*-element may co-refer with an adjunct (6b) or argument (6c) correlate that did not appear in the antecedent clause overtly, in an operation that Chung et al. (1995) call "sprouting."

(6) a. John is meeting Mary/the president for dinner, but I can't tell you who *(else).
b. John is meeting Mary/the president for dinner, but I can't tell you where/why/with who.
c. John ate, but I can't tell you $what_1$.

Sluicing, along with other forms of ellipsis, has received much attention in recent processing literature (Frazier and Clifton, 1998, 2005, 2011; Carlson et al., 2009; Martin, 2010; Poirier et al., 2010; Dickey and Bunger, 2011; Martin and McElree, 2011, among others). Previous results from processing ellipsis support the expectations of content-addressable retrieval systems, in that retrieval of antecedent material at the ellipsis site appears not to be affected by the size or complexity of the recovered material, an effect explained as either a cost-free copying mechanism (Frazier and Clifton, 2001, 2005; Frazier, 2008) or as a direct pointer in memory (Martin and McElree, 2009). In addition, Martin and McElree (2011) find that increasing the distance to a correlate in sluiced sentences affects retrieval accuracy, not retrieval speed, as predicted by content-addressable systems in which retrieval speed is held constant (as various models of retrieval propose, e.g., McElree, 2000; McElree et al., 2003; Lewis and Vasishth, 2005; Lewis et al., 2006). More detailed comparison to previous studies on sluiced sentences and cue-based parsing is delayed until the General Discussion.

Another important general result is that sluices show a structural preference to associate the remnant with the most local correlate in the antecedent clause, a principle formalized as the Locality bias below (see also Harris and Carlson, 2015, for a similar preference with *let alone* ellipsis).

(7) **Locality bias:** Associate the remnant of clausal ellipsis with a correlate occupying the structurally most local position.

Initial evidence for the Locality bias came from Frazier and Clifton (1998), who manipulated whether a sluiced sentence contained one or more possible correlates (8). In a self-paced reading study, they found that cases with multiple possible antecedents (8b) were read faster than unambiguous structures (8a). The penalty for (8a) can be attributed, in effect, to a violating the preference for Local correlates[1].

(8) a. Somebody claimed that the president fired someone but nobody knows who.
b. Somebody claimed that the president fired Fred but nobody knows who.

[1]Fully ambiguous sentences also show a strong Locality bias in silent reading, as explored in the controls for a different study (Harris, 2015). Subjects saw four ambiguous sluiced sentences like "An editor called a journalist, but I can't say which one it was any more" and were asked how they interpreted the sentences. There was an 86% bias toward the most local, object-correlate interpretation. In addition, the vast majority of the subjects ($N = 48$) displayed a complete or majority Locality bias for the items: 3 subjects were at chance, and only 1 subject had a consistent preference for non-local correlates.

Carlson et al. (2009) provide additional support for the Locality bias for sluiced sentences in an auditory questionnaire. They observed that unless the subject was focus-marked by a pitch accent or an *it*-cleft, sentences with object correlates were rated higher than alternatives.

A similar Locality bias has been observed for sluices with sprouted antecedents. Frazier and Clifton (2005) report a naturalness rating and reading time advantage when a verb with an implicit object (*studied*) appeared in second conjunct position (*slept and studied*) as compared to first conjunct position (*studied and slept*), as in *Michael (slept and studied/studied and slept), but he didn't tell me what*[2]. The basic result coheres with the expectations of the Locality bias in that near antecedents confer a processing advantage over far antecedents (see also Martin and McElree, 2011), though it does complicate the prediction that antecedent distance or complexity is not relevant to retrieval. As an aside, the Locality bias is not unique to sluiced sentences. It has been observed in other move-and-delete types of ellipsis, such replacives (Carlson, 2013) and *let alone* ellipsis (Harris and Carlson, 2015), as well as ambiguous gapping structures (Carlson et al., 2005).

The locus of the Locality bias is open to multiple possibilities. One such possibility derives from the assumption that the processor must ultimately recover elided material for interpretation, presumably by employing default biases and cues from information structure. Another, perhaps not mutually exclusive, possibility suggested by Frazier and Clifton (1998) and Carlson et al. (2005, 2009) is that the most likely correlate is determined by default-focus marking on the most embedded constituent (Selkirk, 1984; Cinque, 1993). In canonical English SVO sentences, the most deeply embedded constituent happens to be the object. For whatever reason, the preferences guiding remnant resolution in sluicing ellipsis appear to diverge from the first-mention bias established for third person pronouns, in which a pronoun is preferentially associated with the subject of a preceding clause (Arnold, 1998, among others).

In any event, there seems to be good evidence that sluiced sentences prefer the most local correlate as the antecedent for the remnant. We now turn to how the expectation for Local correlates might affect content-addressable retrieval systems, as outlined above.

The Current Study

An important advantage of using sluicing ellipsis to address the questions above is that the retrieval cues may be explicitly manipulated by modifying the inner restrictor of the *wh*-element. In example (2), for instance, the correlate-remnant pair can be disambiguated simply by repeating the nominal phrase directly, as in *A few linguists gave some silly examples, but I don't remember which linguists*. Such cases determine which noun functions as the correlate to the remnant by completely specifying the relationship: in such cases, there is *total overlap* between remnant and correlate. The eye tracking experiment below exploits this possibility by manipulating whether the restrictor is completely specified by a nominal like *which tourists/wines* (cue-rich probe) or partially specified by a pronoun like *which ones* (cue-poor probe), along with whether the indefinite (assumed to be the preferred correlate) appears in the preferred object location (9a) or not (9b). In addition, it manipulated whether a definite noun distractor appeared in the plural, thereby providing partial cue overlap with the indefinite.

(9) a. The tourists sampled some wine(s), but I don't know which wines/ones.
b. Some tourist(s) sampled the wines, but I don't know which tourists/ones.

Sluiced sentences like (9) conceivably involve two instances of retrieval: first, the recovery of the elided IP after the remnant, and, second, the pairing between the remnant and the correlate. Regarding the recovery of the elided IP, I adopt an approach in which a syntactic representation is recovered through some sort of cost-free mechanism, such as syntactic copying or recycling (Frazier and Clifton, 2001, 2005) or a pointer in memory (Martin and McElree, 2009), such that the size and complexity of the antecedent clause is essentially irrelevant for retrieval speed (Martin and McElree, 2009, 2011).

Regarding the pairing of the remnant with the correlate, there are several theoretical options to consider, especially with respect to the different types and strengths (diagnosticity) of cues in the remnant. First, we might imagine that the parser forms a dependency between the remnant and correlate selectively, that is, only when the remnant contains a pronoun, as in *ones*, but not when its inner restrictor is fully specified, as in *tourists* or *wines*. In this case, a fully specified restrictor could be interpreted via straightforward composition, without retrieving a correlate. However, this approach is unlikely given results from sprouting in sluicing ellipsis, which show a penalty when there is no overt correlate in antecedent clause (Frazier and Clifton, 1998; Dickey and Bunger, 2011).

The two remaining options would require that a dependency be formed between all types of correlates and remnants, but differ in what type of mechanism establishes it. One option to consider is one in which the nominal in the restrictor obviates the associative cue-matching procedure by forming a direct link to the previous instance of the noun, trivially avoiding cue overload effects altogether. Another option is that establishing a dependency between correlate and remnant evokes an associative cue-matching procedure, as proposed for anaphoric dependencies in general, but mitigates cue overload effects by virtue of the total overlap in cues between the remnant probe and the target correlate. In either case, we would expect the strength of the cue at the remnant to modulate the retrieval process. For concreteness, I adopt the latter approach, acknowledging that the experiments below do not depend on or arbitrate between these two possibilities.

As observed by a reviewer, it may be important that the two types of dependencies are not independent: if a comprehender resolves the remnant to an object-position correlate in (9), she is also committed to a particular syntax for the IP ellipsis, e.g., *[which wines]$_1$ they sampled t_1/[which tourists]$_1$ t_1 sampled them.*

[2]Frazier and Clifton (2005) argued that this asymmetry indicates the presence of syntactic structure within the ellipsis site, as the restriction on accessibility follows from their "conjunction domain hypothesis," an independently motivated syntactic constraint on extraction. See Martin and McElree (2011) for commentary.

While this dependency should be explored in depth, we will not do so here[3]. I will simply assume that however recovery of the IP ellipsis impacts retrieval of the remnant, the effects will be comparable across conditions.

An important conceptual issue for cue-based parsing models in general is what types of information constitute cues for retrieval. In such models, it is conceivable that any information coded as a feature value in a feature bundle is qualified to serve as a cue for retrieval, though some types of information, especially relational information, might be less amenable to representation by features than others (Kush, 2013). Following recent literature (e.g., Lewis and Vasishth, 2005), I assume that retrieval is driven, at least in part, by features from lexical (gender and number) and morphosyntactic (grammatical roles and case) information derived from context, and that what is retrieved are partial representations of constituents. Further, retrieval occurs whenever an item has to be associated with another item in memory for complete interpretation, including better-studied cases of anaphora resolution, verbal agreement, NPI licensing, and variable binding, although different kinds of dependencies might attend to distinct types of information. I remain largely agnostic about the internal organization of retrieval with respect to other interpretive processes, e.g., whether retrieval is discrete, continuous, or cascaded, as the study was not designed to address these issues, and the results below are consistent with any number of possibilities.

Assuming an associative cue-matching procedure and a preference for local antecedents, the reading experiment below was designed to test the following two basic predictions:

P1. Locality: The most local antecedent, in this case the object noun, is favored for retrieval.

P2. Nominal Advantage: Nominal restrictors (*which tourists*/*which wines*) include a rich set of cues specifying retrieval, and thus facilitate retrieval over cue-poor probes like *which ones*.

The most important prediction, however, is one in which distractors outside the local (object) domain are subject to varying degrees of interference; a strong effect of interference is predicted only in case of partial overlap, as fully specifying the inner restrictor with a nominal should eliminate the effects of cue overload, either by delivering the appropriate correlate directly, or via total overlap between the remnant and the target correlate.

P3. Structure-Dependent Interference: A retrieval penalty for violating Locality

i. arises when a distractor in the preferred (object) position shares features with the remnant, and
ii. increases if retrieval is initiated by cue-poor probes (*ones*).

Prior research investigating the effect of structural constraints on retrieval has often used the gender feature in a feature mismatch paradigm (e.g., Clifton et al., 1999; Badecker and Straub, 2002; Sturt, 2003; Chow et al., 2014). Manipulating gender agreement between the remnant and the antecedents was not possible here, given that English does not encode gender for impersonal pronouns like *ones*. Therefore, we must first show that plural definite nouns are viable correlate competitors for unambiguous *which* remnants, like *which tourists* or *which wines*, the central task of the following experiment. An affirmative finding will support the assumption that the plurality feature sufficiently induces similarity-based interference effects in the formation of correlate-remnant pairs with pronouns like *ones* in the next experiment. In addition, it will address the assumption regarding whether the indefinite determiner *some* marks the preferred correlate for sluices with *which*-remnants as opposed to the definite determiner.

As a final terminological note, the present use of "interference" diverges somewhat from a common use in the literature, in which the distractor is not a grammatical antecedent, or otherwise inaccessible (e.g., Van Dyke, 2007; Phillips et al., 2011). If both nouns in the matrix are acceptable as antecedents, the manipulation might be best cast in terms of a "fan effect" in which multiple non-referents interfere with dependency resolution (Anderson, 1974; Anderson and Reder, 1999; Autry and Levine, 2014). However, as the effects in either case would ideally be driven by the same underlying types of retrieval mechanisms, I retain the use of interference here, in hopes of expanding the empirical range of strongly biased, though not strictly speaking ungrammatical, structural preferences.

EXPERIMENT 1

A forced-choice completion test was first conducted over the Internet in order to determine the extent to which a plural definite noun competes with a plural indefinite as a correlate. I take such cases to be indicative of similarity-based interference effects, although they may differ in kind from other types of interference. A further question is whether the extent to which plurality makes a definite noun an appealing correlate is affected by its structural position.

Method

Participants

Twenty-nine subjects were recruited using Amazon Mechanical Turk, an Internet-based service where individuals complete

[3]The dependency between retrieval of a correlate and the syntax of the ellipsis site raises a number of pertinent issues regarding the relationship between the Locality Bias and parallelism between the matrix and the second conjunct. The interpretation of sluicing is known to be sensitive to parallelism (Carlson, 2002; Dickey and Bunger, 2011), as is conjunction generally (Frazier et al., 1984). If the processor takes the remnant phrase to be an object, perhaps on the basis Minimal Attachment (Frazier, 1978), the processor might prefer an object correlate to create structural parallelism between clauses. In an unpublished auditory forced-choice completion study ($N = 48$), Katy Carlson and I manipulated the surface position of the remnant to appear either as a subject (*A waiter talked to a guest, but . . . which waiter/which guest isn't clear*) or as an object (*A waiter talked to a guest, but . . . it's not clear which waiter / which guest*), along with the location of a pitch accent (subject or object). In addition to a general 66% bias for local object-position correlates, we found that subject position remnants (*which guest / which waiter isn't clear*) failed to elicit more subject responses than object position remnants did, and that pitch accent placement was the primary determinant of continuation choice. Further, accenting the object resulted in 8% more object continuations with a surface subject remnant, suggesting that linguistic focus (manifested here in the form of pitch accent), not syntactic parallelism, is the driving force behind the bias for local correlates in standard sluicing constructions.

short tasks online for payment. One subject self-identified as a non-native English speaker, and was removed from analysis. A pretest evaluated subjects' competency with three difficult to interpret questions. Three subjects were removed for answering one or more of these questions incorrectly. Four catch items were included to identify inattentive subjects, but no subject was removed on this basis. However, an additional subject was removed for counterbalancing purposes, leaving 24 subjects in the final data set. All subjects were compensated $4 for their participation, regardless of native language or performance. This experiment, along with the following, were carried out with prior Internal Review Board approval from Pomona College. All subjects gave written informed consent before starting the experiment, and were permitted to remove themselves at any time from the procedure without penalty.

Materials

The 2×2 experimental design crossed Indefinite Location (Object indefinite, Subject indefinite) with Definite Number (Plural, Singular). The levels of the Indefinite Location condition were determined by its syntactic position in the matrix clause. In other words, there were two sequences of determiner in the matrix clause: either (i) a definite subject (singular or plural) followed by a plural indefinite object, or (ii) a plural indefinite subject followed by a definite object (singular or plural). The Plural condition was created from the Singular condition simply by adding the plural marker to the definite noun phrase, e.g., *tourist* ∼ *tourists* or *wine* ∼ *wines.* All critical nouns except one (*fireman* ∼ *firemen*) were regular plurals. Twenty-four quartet fragments like (10) were constructed below. Items are reported in Appendix A of Supplementary Material.

(10) Object indefinite

a. *Plural definite:* The tourists sampled some wines, but I've forgotten...
b. *Singular definite:* The tourist sampled some wines, but I've forgotten...

Subject indefinite

c. *Plural definite:* Some tourists sampled the wines, but I've forgotten...
d. *Singular definite:* Some tourists sampled the wine, but I've forgotten...

Two forced-choice completions (11) were provided under the fragments in (10). The response options always agreed in plurality with the preceding sentence fragment, e.g., *tourists*/*wines* in (10a,c), *tourist*/*wines* in (10b), and *tourists*/*wine* in (10d). Answers were presented in a different random sequence for each subject.

(11) Forced-choice options

i. Subject correlate response: which tourist(s).
ii. Object correlate response: which wine(s).

After a short guided practice consisting of three sample sentences, subjects were presented with an additional 52 items from unrelated experiments with various structures, 12 non-experimental fillers, in which both responses were acceptable, and four catch items permitting only a single correct answer, for a total of 92 items.

Procedure

Items were presented in an individually randomized and fully counterbalanced order, so that subjects saw one and only one sentence fragment from each quartet. Subjects were instructed to rely on their intuitions to select whichever response would make "the resulting sentence sound the most natural." Subjects were given an hour to complete the task, but all subjects finished within 40 min, with an average of 25 min per subject. In addition, encrypted versions of IP addresses were recorded to identify subjects who may have taken the experiment more than once. No such cases were observed.

Results

One item (item 1 in Appendix A of Supplementary Material) contained a typo and was removed from analysis. Data analysis was conducted in R version 3.1.2 (R Development Core Team, 2014). Mean percent and standard deviations for *subject completion* responses by condition are presented in **Table 1**.

Conditions were given sum (deviation) coding so that the hypothetically simplest condition, the Object Correlate—Singular condition, was treated as the statistical baseline. The response data was modeled as a logistic linear mixed effects regression model using the lme4 package (Bates and Maechler, 2009) with by-subjects and by-items random slopes and intercepts, shown in **Table 2**.

As expected, the choice between Subject and Object correlate response closely corresponded to the location of the indefinite *some*: subject position indefinites garnered greater overall Subject correlate responses ($M = 71\%$, $SE = 3$) than object position indefinites ($M = 24\%$, $SE = 3$), $z = 6.77$, $p < 0.001$. The result confirms the intuition that language users prefer indefinites as correlates to remnants in sluiced structures, though

TABLE 1 | Experiment 1: percent *subject* response selected.

Indefinite location	Definite number		Correlate mean	Attraction effect
	Plural	Singular		
Object	28% (4)	19% (3)	24% (3)	−9%
Subject	67% (4)	75% (4)	71% (3)	8%

Standard errors are in parentheses.

TABLE 2 | Experiment 1: results of linear mixed effects regression model.

	Estimate	Std. error	Wald *Z*	*p*-estimate
(Intercept)	−0.179	0.362	−0.494	0.621
Correlate location	**1.661**	**0.285**	**5.834**	**< 0.001**
Definite number	−0.038	0.208	−0.183	0.855
Correlate × Definite number	**−0.473**	**0.199**	**−2.376**	**< 0.05**

Significant effects are printed in bold.

we should note that the preference is not absolute; see also the Discussion Section of Experiment 2, which acknowledges several complications.

While there was no main effect of Definite Number in this model, there was an interaction between Indefinite Location and Definite Number. In the case of a subject indefinite, more subject completions were observed when the object noun was singular (10d) than plural (10c); in the case of an object indefinite, more subject completions were elicited when the subject noun was plural than when it was singular (10b) than plural (10a), $z = 3.67$, $p < 0.001$. This reversal is to be expected if the indefinite provides the preferred candidate for the correlate, but a plural distractor interferes with the distinctiveness of the indefinite target.

These patterns are consistent with the theoretically-motivated assumption that *which*-remnants in sluicing prefer the antecedent with the most accessible set of individuals. In this case, the indefinite description *some* makes a set of alternatives salient in the discourse, as opposed to a definite description, which arguably introduces a plural sum of individuals that can be interpreted as a single entity (Link, 1983). Accordingly, responses were transformed to reflect the pairing in which the remnant forms a contrast with the indefinite, as depicted in **Table 3**. The transformed response data was modeled as a logistic linear mixed effects regression model using the lme4 package (Bates and Maechler, 2009) with by-subjects and by-items random slopes and intercepts and deviation coding as before. The result is shown in **Table 4**.

The model supports a sole effect of Definite Number, in that a plural definite noun (*the wines/the tourists*) resulted in fewer responses that co-referred with the indefinite target ($M = 69\%$, $SE = 3$) than singular definite distractors ($M = 78\%$, $SE = 3$), $t = -2.38$, $p < 0.05$, although the indefinite is still generally preferred.

TABLE 3 | Experiment 1: responses by the percentage of cases in which the indefinite was selected as the correlate.

Correlate choice	Plural interference		Correlate mean	Interference difference
	Interference	No interference		
Object	72% (4)	81% (3)	76% (3)	9%
Subject	67% (4)	75% (4)	71% (3)	8%
Interference mean	69% (3)	78% (3)		

Standard errors in parentheses.

	Estimate	Std. error	Wald *Z*	*p*-estimate
(Intercept)	1.661	0.285	5.835	< 0.001
Correlate location	−0.177	0.361	−0.49	0.624
Definite number	**−0.474**	**0.199**	**−2.38**	**< 0.05**
Correlate × Definite number	−0.038	0.208	−0.181	0.857

Significant effects are printed in bold.

Discussion

The results suggest that the structures are not fully ambiguous: there is a strong preference to associate the remnant with an indefinite correlate. The transformed results also show clear support for general similarity-based interference, in that plural definite distractors, which shared the plurality feature with an indefinite correlate, attracted more remnant resolutions than singular definite distractors.

EXPERIMENT 2

A second experiment was conducted to test the central predictions outlined above. First, by *Locality*, subject position indefinite nouns should elicit an online processing penalty over their more local, object position counterparts. Second, by *Nominal Advantage*, *wh*-restrictors with a fully specified nominal should facilitate the retrieval of their correlates compared to pronominal restrictors like *ones* by virtue of providing a richer feature set for cue-matching. Lastly, by *Structure-Dependent Interference*, plural definite nouns should exert a greater interference effect on retrieval when occupying object position, and, further, that such effects should manifest predominantly when the cues for retrieval are poor.

Method

Participants

Fifty-six native English speaking college students with normal or corrected-to-normal vision were recruited for the experiment, and were compensated $10 for participation. Nine students were excluded due to excessive blinks leading to extreme data loss, as detailed below, resulting in a final dataset of 47 subjects.

Materials

Twenty-four sextets were constructed from the items in Experiment 1, modified so that there were three animate subject correlate (12a–c) and three inanimate object correlate (12d–f) conditions. In both cases, there was a condition with a definite plural distractor and a fully-specified nominal in the *wh*-restrictor, e.g., *tourists* or *wines* (12a,d), a definite plural distractor and the plural pronoun *ones* (12b,e), and a definite singular distractor and the plural pronoun *ones* (12c,f). Note that in (12a–c) the indefinite noun appears in the object, and so by hypothesis the local and preferred, position. The pipe symbol "|" indicates how materials were later divided into seven regions for analysis. All conditions were identical after the remnant region

(12) a. |The tourists |sampled |some wines, |but I've forgotten |which wines, …
b. |The tourists |sampled |some wines, |but I've forgotten |which ones, …
c. |The tourist |sampled |some wines, |but I've forgotten |which ones,
d. |Some tourists |sampled |the wines, |but I've forgotten |which tourists, …
e. |Some tourists |sampled |the wines, |but I've forgotten |which ones, …
f. |Some tourists |sampled |the wine, |but I've forgotten |which ones, …
|since they all |seem the same to me.

Lexical level characteristics of length and frequency were computed for nouns in subject and object position. Subject (M = 6.83; SE = 0.27) and object nouns (M = 6.96, SE = 0.41) did not differ on number of characters, $t_{(23)} = -0.24$, $p = 0.82$. Two measures of frequency were obtained from the English Lexicon Project (Balota et al., 2007). Subject (M = 8.12; SE = 0.32) and object nouns (M = 8.86, SE = 0.42) did not differ on log HAL frequency, $t_{(23)} = -1.56$, $p = 0.13$. Further, subject (M = 2.26; SE = 0.15) and object nouns (M = 2.50, SE = 0.14) match on frequency calculated from SUBTLEX, $t_{(23)} = -1.22$, $p = 0.23$. In addition, the length of the remnant region was always included as a predictor in models of that region.

A reviewer notes that the spillover regions may not have been informative with respect to the intended interpretation. However, items were intentionally designed so that properties of the inner restrictor of the remnant provided the only disambiguating information. Further, spillover regions were consistent within an item across all conditions, and thus are unlikely to explain any effects. However, as noted above, it may be fruitful to explore the influence of the structure in unelided counterparts, as in *I don't know which ones (they sampled/were sampled*). Not all interesting contrasts could be presented in a single experiment, for fear of reducing statistical power or saturating readers with too many similar constructions. Another concern was that the example above contains the ambiguous pronoun *they* after the remnant. However, the item above is unique in that respect. As shown in the Appendix of Supplementary Material, no other item contains a pronoun of any sort.

Procedure

The experiment was presented using EyeTrack, the UMass Amherst presentation software (http://www.psych.umass.edu/eyelab/). Materials were presented in a sound isolated room on a 32-bit Dell Optiplex tower, running Windows 7, with peripheral programs and the Internet connection turned off. Text was presented as a single line in black 11pt monospaced font against a white background. The monitor was situated such that approximately three characters subtended 1° of visual angle. Eye movements were recorded on an SR Research Eyelink 1000 eye tracker, mounted on the table approximately 50 cm away from a 19" Mitsubishi Diamond Pro 900u flat-screen CRT monitor running at 170 Hz. Sampling rate was set to 1000 Hz. Drift correct was performed between each trial. Subjects were instructed to read naturally and for comprehension, and were encouraged to take breaks as often as needed.

All items were followed by comprehension questions probing the subject's interpretation (13). Questions were presented in CAPS to clearly differentiate comprehension questions from experimental materials.

(13) WHAT DID I FORGET?

i. Subject response: WHICH TOURIST(S)
ii. *Object response:* WHICH WINE(S)

Subjects selected the answer from among two possible choices on a Microsoft USB Sidewinder gamepad. Question responses were not considered in the analysis below. Experiments lasted approximately 40 min on average.

Results

Individual trials were removed if the participant blinked once or more during the first pass on the remnant region. No trials were removed if blinks occurred in another region or during re-reading of the remnant. Individual trials were also removed if excessive blinking led to significant track loss, or if track loss occurred for some other reason during the experiment (<4% of total trials).

Additionally, short (under 80 ms) and long (over 1200 ms) fixation times were removed from the data, as were trials with blinks on the remnant and track losses using the program EyeDoctor (http://www.psych.umass.edu/eyelab). Several standard eye tracking measures were used in the analysis (Rayner, 1998), computed with the DOS version of EyeDry analysis software: first *pass durations* (also known as gaze duration), the sum of all fixation durations within a region before leaving that region in any direction, *go past time*, the time spent after first entering a region to first moving past the region to the right, *percentage of regressions out* of and *percentage of regressions into* a region, second *pass time*, the time spent rereading a region once the region has been exited to the right including zero times indicating failure to re-read, and *total time*, the sum of all fixation times in a region during any point in reading (see, e.g., Staub and Rayner, 2007, for a concise review of these measures). Means and standard errors for these measures are presented in **Table 5** below.

Linear mixed effects regression models were used for all statistical analyses. Fixation and reading time measures (first pass, go past, second pass, and total times) were analyzed with linear regression models, whereas proportion data (regressions in and out of a region) were analyzed with logistic regression models. As models with maximal random effects error structures (as recommended by Barr et al., 2013) typically failed to converge, all models reported here were specified with by-subject and by-items random intercepts, but not with random slopes. Fixed effect predictor contrasts were assigned deviation coding that best cohered with the conceptual aims of the study. To assess the presence of a Locality bias, object noun correlates were coded as the baseline for the Correlate position predictor. To evaluate the effect of Interference, cue-poor probes (*which ones*) without plural interference were treated as the baseline for the Interference predictor, so that the model tests for similarity-based interference effects for nominal and pronominal cues over a no interference condition with a pronominal cue.

Instead of reporting the statistical results of each measure individually, the results are discussed in terms of the predictions of interest, noting when other effects were present. All significant effects for the measures of interest are reported.

Locality

Evidence for the Locality bias was observed in multiple measures of the eye movement record. The earliest evidence was found in first pass times immediately at the remnant (Region 5). indefinite subject correlates (M = 274 ms, SE = 5) elicited longer first pass times than indefinite object correlates (M = 249 ms, SE = 5), t = 3.88. No other effects were observed in first pass times. Additional evidence for the Locality bias appears in later eye movement measures, as well. Indefinite subject correlates elicited

longer go past times than object correlates on the remnant region ($M_{Subject}$ = 328 ms, SE = 10; M_{Object} = 295 ms, SE = 9), t = 2.72, and on the sentence final region, ($M_{Subject}$ = 960 ms, SE = 43; M_{Object} = 860 ms, SE = 38), t = 2.12. Fixed effects of models substantiating the above effects are provided in **Table 6**.

Further, violating Locality manifested in a persistent penalty for total times, as indefinite subject correlates were significantly longer in the sentential subject region ($M_{Subject}$ = 337 ms, SE = 40; M_{Object} = 265, SE = 11), t = 4.65, the remnant ($M_{Subject}$ = 324, SE = 9; M_{Object} = 287, SE = 8), t = 3.40, and the final region ($M_{Subject}$ = 524 ms, SE = 15; M_{Object} = 491 ms, SE = 14), t = 2.20. Models computed for total times are provided in **Table 7**. In addition, there was a marginally significant penalty for indefinite subject correlates (M = 147 ms, SE = 10) compared to indefinite object correlates (M = 125, SE = 10) on the spill-over region in second pass re-reading times, t = 1.95. A summary of the main effects on the remnant is provided in **Figure 1**.

However, a few measures showed a cost for indefinite object correlates. There were more regressions into the sentential subject region for items with indefinite object correlates (M = 70%, SE = 3) than indefinite subject correlates (M = 60%, SE = 3), t = 2.64, $p < 0.01$. The increased rate of regressions into the subject region may correspond to increased global re-reading for indefinite object correlates, as opposed to regressing back into a specific region. In addition, indefinite object correlates elicited longer total times than indefinite subject correlates did in the region containing the object noun (M_{Object} = 471 ms, SE = 13; $M_{Subject}$ = 401 ms, SE = 13), t = −4.73. This effect could be explained if total times corresponded to additional re-reading of the correlate. However, it is unclear whether such an explanation can be strongly maintained without supporting evidence from regressions in and second-pass reading measures, of which there is little evidence.

Nominal Advantage

For the second prediction, we expect that nominal restrictors (*which wines/tourists*) should receive a processing benefit over pronominal restrictors (*which ones*), due to greater specificity of the retrieval cue (also known as "cue diagnosticity"; see Martin and McElree, 2009, 2011; Van Dyke, 2011). Indeed, we find the expected advantage for nominal probes in a variety of measures. In go past times, there was a 117 ms advantage for nominal restrictors over pronominal ones on the final region, t = −2.42; see the *Interference nominal* row in **Table 6**. There were fewer regressions into the object region when a nominal cue in the remnant followed (M = 5%, SE = 1) as compared to a pronominal cue in the restrictor (M = 11%, SE = 2), t = −2.93, $p < 0.01$.

Further, the advantage for nominal cue conditions was considerable in second pass re-reading times of every region of the matrix clause. Nominal restrictors elicited shorter second pass times in the subject region ($M_{Nominal}$ = 87, SE = 9; $M_{Pronominal}$ = 119, SE = 11), t = −2.61, the verb region ($M_{Nominal}$ = 103, SE = 12; $M_{Pronominal}$ = 145, SE = 14), t = −3.21, and the object region ($M_{Nominal}$ = 34, SE = 6; $M_{Pronominal}$ = 80, SE = 10), t = −4.31; see **Figure 2**. There

were also shorter total times for nominal probes in total times for the subject region ($M_{Nominal}$ = 423 ms, SE = 17; $M_{Pronominal}$ = 485 ms, SE = 20), $t = -2.60$.

One region witnessed effects other than were expected: there were more regressions into Region 4 for Nominal than Pronominal conditions ($M_{Nominal}$ = 19%, SE = 2; $M_{Pronominal}$ = 15%, SE = 1), $t = -2.28$, $p < 0.05$. There is no ready explanation of this small effect, as the content of the region was identical in all conditions.

Structure-Dependent Interference

The central prediction of an interaction between similarity-based interference and structural position of the correlate was supported by later eye movement measures. Importantly, a penalty was predicted only for pronominal probes in the remnant like *ones*, but not when the cue was fully specified, as in the case of nominal probes. As expected, there was a greater penalty for second pass times for definite plural object nouns (*the wines*) and a subject correlate (*some tourists*) when the *wh*-restrictor was a pronominal. In the subject region, the penalty for conditions with pronominal restrictors was significantly greater for indefinite subject correlates (d = 70 ms) than for indefinite object correlates ($d = -18$ ms), t = 3.54. Similar effects obtained in the verb region, with a 57 ms penalty for subject correlates over object correlates ($d = -17$ ms), t = 2.26. Both of these effects are shown in the final row in **Table 8**.

On the remnant region, there was again a greater penalty for indefinite subject correlates (d = 33) than for indefinite object correlates (d = 8), t = 2.11; see **Table 9** and **Figure 3**. What's more, nominal restrictors showed a small 13 ms second pass time advantage for indefinite subject correlates and plural distractor objects, $t = -2.08$ in second pass times; **Table 9**. Finally, in the verb region, there was a greater total times penalty for indefinite subject correlates and plural distractors with pronominal retrieval cues (d = 72 ms) than the no interference baseline (d = 44 ms), t = 2.62.

Discussion

Results from the reading experiment support all three predictions of interest. There was early and sustained support for violating the Locality bias, and an advantage for Nominal cues that manifested in go past and second pass measures. These two effects interacted with respect to interference and cue-specificity: there were greater interference effects when the distractor occupied the preferred object position, such that the effect was enhanced when cues for retrieval at the remnant were partial. The results are thus compatible with previous findings of retroactive interference (e.g., Van Dyke and McElree, 2006; Van Dyke and Johns, 2012), but also adds support to the growing body of evidence that retrieval is modulated by the position of the antecedents (e.g., Van Dyke and McElree, 2011; Chow et al., 2014; Dillon et al., 2014; Kush and Phillips, 2014, among others). While the results are clearly consistent with the central predictions of a cue-based parsing system in which the location of targets in the sentence is not ignored during retrieval, the issue of how precisely to utilize such information within cue-based parsing models is far from settled. I return to this question the General Discussion.

As noted by a reviewer, evidence for the central predictions manifested at somewhat different time courses, although we should exercise caution when assigning linking assumptions to eye movement measures (Clifton et al., 2007). Whereas,

evidence for Locality and Nominal Advantage appeared in various measures, support for Structure-Dependent Interference was only observed in the "late" measure of second-pass times, as subjects re-read portions of the sentence. This delayed effect is compatible with multiple interpretations, including a multiple stage model of anaphoric processing in which measures occurring later in the eye movement record could reflect processing at a secondary stage of discourse integration, perhaps along the lines of Garrod and Sanford's (1990, 1994) bonding and resolution model. If this were the case, Structure-Dependent Interference might reflect difficulty interpreting the link between a poorly specified remnant and a correlate, rather than retrieval difficulty. Alternatively, that the effect appears relatively late in the eye movement record could be attributed to a lag resulting from poor quality matches. In this case, the integration difficulty would directly reflect increased interference from distractors in structurally preferred positions. The results do not arbitrate between these, or any number of, additional possibilities, which must instead be resolved through careful experimental design.

A reviewer proposed that several of the sentences in (12) are ambiguous, in that *which ones* may also co-refer with definite plural nouns. The above design depended on the assumption that definite nouns fail to provide an appropriate antecedent, as discussed in connection with examples (5–6). Yet, there may be a few systematic exceptions to the generalization that the remnant cannot correspond to a definite correlate. Discussion in the literature centers around contrasts like (13) below, which shows that a d-linked *which* remnant can take a definite noun as a correlate, but a simple *wh*-phrase like *what* cannot (Chung et al., 1995; Dayal and Schwarzschild, 2010).

(13) a. John announced he had eaten the asparagus. We didn't know which asparagus.
b. * John announced he had eaten the asparagus. We didn't know what.

These cases have been given various analyses. Chung et al. (1995) suggest that definite nouns are available as correlates whenever they are compatible with the pragmatic contribution of the remnant. They attribute the contrast in (13) to an intuitive conflict in familiarity between the definite *the asparagus* and the novelty imposed by *what* in (13b), a conflict that (13a) avoids.

In contrast, Dayal and Schwarzschild (2010) identify several cases in which presumed speaker knowledge, rather than familiarity, is the distinguishing factor. In their account, (14a) is infelicitous because the speaker has contradicted herself: the knowledge state that permits the speaker to assert that John talked to the detective places the speaker in a sufficient epistemic position to answer the question embedded under the sluice, i.e., *which detective did he talk to*? The corresponding assertion with an indefinite (14b) does not place the speaker in such a specific knowledge state as to warrant a self-contradiction (though see Barker, 2013; Barros, 2013, for recent commentary).

Interference pronominal × Locality	**12.313**	**5.836**	**2.110**

Effects with t-values above |2| are shown in bold.

(14) a. * John talked to the detective. I don't know which detective (he talked to).
b. John talked to a detective. I don't know which detective (he talked to).

They also observe that a definite correlate is sometimes available when it does not carry a uniqueness presupposition, as illustrated by the examples in (15) where there is no requirement that there is a singular, identifiable train or particular hospital in the context (akin to so-called weak definites, e.g., Carlson and Sussman, 2005; Aguilar Guevara, 2014).

(15) a. John is going to take the train, but he doesn't know yet which train (he is going to take).
b. They took him to the hospital. She wouldn't tell us which hospital (they took him to).

As would be predicted, a definite that corresponds to a unique individual within a given context, as in *the Chief of Police* in (16), cannot serve a correlate to the remnant.

(16) *Ed reported the matter to the Chief of Police but Joe couldn't figure out which chief of police (he reported the matter to).

Although it is unclear whether these examples are as acceptable when fully elided, e.g., *John is going to take the train, but he doesn't know which*, the experimental items were reviewed to determine whether the definite noun could sensibly be interpreted as a correlate to the remnant[4]. Two possible types of cases were observed. The first case involved collective nouns whose members could perform an action on behalf of others in the group (the ? mark reflects my judgment that these sentences are somewhat degraded):

(17) a. ? The trustees donated 10 million to the university, but I don't know which ones.
b. ? The professors wrote a letter to the dean, but it doesn't matter which ones.

For example, (17a) could be interpreted so that some of the trustees but not others were responsible for the donation. Here, the definite *the trustees* is interpreted as a collective entity, in which the donation was performed on behalf of the entire group. Although not many items in the experiment permit such a reading, one contender is *The nurses threatened to strike over some contracts, but I'm not sure which ones.*

The second case was one in which the remnant *which ones* does not refer directly to the definite noun phrase. Instead, co-reference appears to be coerced through a partitive interpretation taking the plural definite as the maximal set in order to derive a salient subset (a refset) from it (see Moxey and Sanford, 1993, for terminology). For example, such a reading might paraphrase (12d) as *Some tourists sampled the wines, but I don't know which (ones) of the wines they sampled.* The coercion process could posit a silent or elided partitive phrase, as proposed for bare determiner phrases like *Many (of them) sat down* (Gagnon, 2013). Again, very few plausible cases were found in the experimental items. Two possible cases include the example used as illustration throughout the paper (12), and *Some workers loaded the trucks, but I'm not certain which ones.* Such cases are perhaps strengthened by a distributive semantics of the verb, e.g., a sampling wine involves trying some, but not all, of it.

To assess empirically whether ambiguity could explain the effects observed above, I conducted a *post-hoc* by-items analysis of the results from Experiment 1. Averaging across conditions, no item was biased toward the definite noun completion. However, splitting the data by position of the indefinite revealed that eight items were either biased toward (definite subject: 13, 18, 21; definite object: 12, 24) or on par with (object definite: 2, 10, 18) the indefinite as a correlate. For most measures, there were no differences in the overall statistical effects when these items were removed[5]. However, removing potentially ambiguous items did weaken the interaction between Locality and Interference in second pass times: although the penalty for non-local correlates was still significantly greater for remnants with pronominal restrictors in the sentence-initial region, the interaction did not persist in following region, even though the interaction was still apparent in other measures, including total times. Thus, even though a plausible definite distractor could have engendered a longer lasting interference penalty from the indefinite, it is unlikely to be the primarily source of the effects reported here.

As a final note, ambiguity only becomes a genuine confound if it could otherwise explain the effects attributed to another variable. The only sentences that could have been ambiguous are those with cue-poor (*which ones*) remnants and plural definite distractors, i.e., (12b, d). Several other studies of pronominal ambiguity suggest that competing interpretations do not always result in processing penalties (e.g., attachment ambiguity explored in van Gompel et al., 2001, 2005), especially cases involving pronouns (e.g., Greene et al., 1992). Indeed, in the present case of sluicing, Frazier and Clifton (1998) report that ambiguity between subject and object position correlates did not slow readers down, provided that there was an indefinite correlate in the preferred, object position, like *someone* in (8a). Therefore, it is not yet clear how ambiguity would explain the effects I hope to attribute to interference.

Additionally, although the possibility of ambiguity might challenge whether we can truly interpret the effect of a plural definite as interference *per se*, it cannot fully account for the interaction between the plurality of the definite and its structural location. That is, irrespective of whether or not a definite noun is a possible correlate to *which* remnants, ambiguity does not explain why a plural definite in object position would elicit greater reading penalties than in subject position. Nevertheless, potential ambiguities could be more tightly controlled or even exploited (as in Harris, 2013, 2015) in future studies.

GENERAL DISCUSSION

The central question explored in the experiment above was whether positional information modulates similarity-based interference effects in sluicing structures. There was clear evidence that it does. The central manipulation capitalized on the unique syntactic properties of sluices in two ways. First, the Locality bias was employed to impose a preference for structural position of the correlate to a remnant in the elided clause. Second, the lexical content of the inner restrictor of the remnant was manipulated to examine the role of cue-strength in retrieval.

As previously mentioned, this study is not the first to exploit sluiced sentences in an argument in favor of content-addressable retrieval systems. Martin and McElree (2011) utilized two main properties of an object position correlate in sluiced sentences like (14) in SAT and eye tracking. The correlate appeared on its own

[4]Thanks to Colin Phillips for discussion of this issue and for providing some of the examples that appear in this section.

[5]Other changes were that the slowdown on the Interference pronoun condition in first pass times was marginal, and the penalty for violating the Locality Bias disappeared for go past and total times in the final region, as well as for second pass times in the spill over region. Several other effects were significant once potentially ambiguous items were removed, including an interaction supporting Structure-Dependent Interference in the verb region on second pass times, a slowdown for nominal restrictors in go past times at the remnant, and a previously marginal advantage for nominal restrictors reached significance for total times in the sentence-final region.

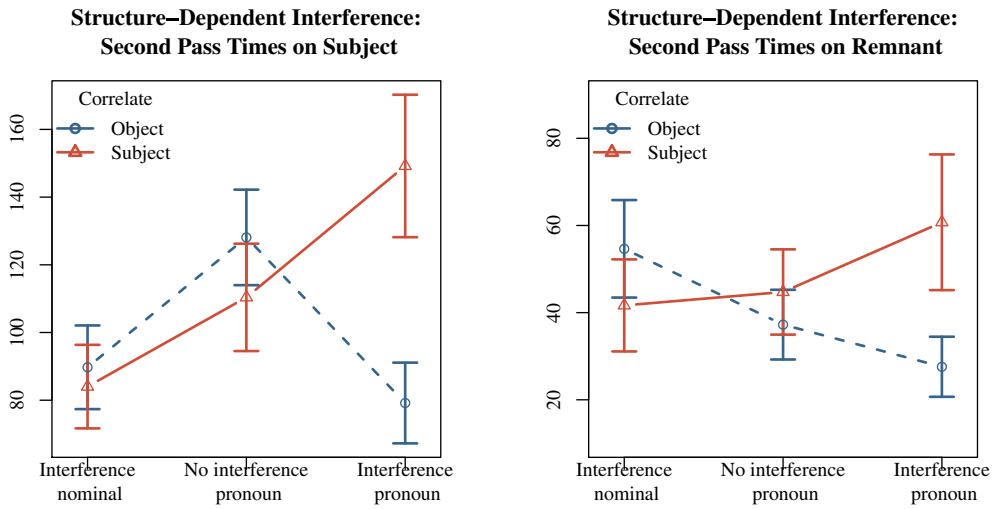

FIGURE 3 | Experiment 2: Structure-Dependent Interference effects on subject and remnant regions. Times presented in ms.

or within a conjunct in object position, and when the correlate was contained within a conjunct, which position of the conjunct it occupied (first or second conjunct position). The verbal syntax of only one member of the conjunct, *typed (something)*, provides a correlate, which varied according to whether the object was overt or not, to associate with the remnant *what*.

(14) a. Michael (slept and) studied (something), but he didn't tell me what$_1$ <~~he typed~~ t$_1$>.
b. Michael studied (something) (and slept), but didn't tell me what$_1$ <~~he typed~~ t$_1$>.

The design varied the distance between the correlate and remnant, along with the size of the elided material that was to be recovered. In keeping with the findings above, they found that readers spent longer re-reading distant antecedents (14b) than local ones (14a), and suggested, as I have, that interfering antecedents degrades the quality of a match with potential antecedents in memory. However, the materials of their study are quite different from the ones above in three respects. First, as only one conjunct provided a proper correlate (which sometimes had to be sprouted) to the remnant, the experiment lacks the conditions for fully investigating similarity-based interference from other noun phrase distractors. Second, the correlate was always in the object position, thereby satisfying the Locality bias, at least in a broad sense. Third, while the remnant varied according to *wh*-element type (*what*, *which*, and *where*), they did not manipulate the properties of the inner restrictor of the remnant to provide explicit cues to guide the dependency formation. The study above therefore contributes very different, yet congruent, evidence in favor of interference effects in retrieving correlates for sluiced sentences.

It is worth comparing Martin and McElree's study to the present one for another reason, as well. They found that the presence of a conjunct over a single noun in object position did not affect retrieval in either reading time or a SAT task, and concluded that retrieval processes access the material for ellipsis directly on the basis of its content via a cost-free pointer mechanism, in line with studies on verb phrase ellipsis (Frazier and Clifton, 2001, 2005; Martin and McElree, 2008, 2009). However, it is possible that the mechanisms responsible for retrieving a correlate for the remnant are distinct from those responsible for recovering the elided IP material. Given the previously discussed dependency between resolving the remnant and determining the appropriate syntax of the ellipsis, it stands to reason that the former might be prioritized over the later, rather than attempting to solve two retrieval problems at once. Although it is theoretically possible that the ellipsis site lacks an explicit syntactic representation (Chung et al., 1995), there is good evidence for syntactic structure in sluicing ellipsis from both theoretical (e.g., Merchant, 2001; van Craenenbroeck, 2010) and experimental (e.g., Frazier and Clifton, 2001, 2005; Poirier et al., 2010) literature, in which case retrieving the ellipsis site is unlikely to reduce to simply pairing a correlate to the remnant of ellipsis.

Finally, one might be concerned that increased temporal distance, and thus decay, between the subject and the remnant might sufficiently explain the Locality bias, thereby eliminating structural information *per se* as a factor in the retrieval process. However, this explanation is unlikely given the results of Poirier et al.'s (2010) cross-modal priming study, in which printed targets related to the subject (*the handyman*) and dative object (*the programmer*) distractors were presented at two probe points in an auditory sentence: immediately after the offset of the remnant $*_1$ or 500 ms downstream $*_2$.

(15) The handyman threw a book to the programmer but I don't know which book $*_1$ and no one $*_2$ else seems to know.

There was no difference between decision times for targets related to subject and dative object nouns until position $*_2$ (which showed a priming effect for the object), suggesting that subject

and the dative object nouns were equally active at the remnant of the ellipsis. Crucially, these effects do not contradict the results of the reading study, since probes related to the indefinite target *a book* could not be tested, given that they were repeated in the inner restrictor of the *wh*-phrase *which book*. If the restrictor were replaced with a cue-poor probe like *which ones*, we would expect an advantage for more local antecedents at, or soon after, the remnant.

Several models of sentence processing could in principle accommodate the findings reported above, models which diverge on how to account for the differences observed between subject and object position correlates. Naturally, the results of a single study cannot determine whether the effect of position reflects temporal precedence, linear distance, or, as I have suggested, structural information. Although various interpretations are possible, structural information has been shown independently to impact the earliest stages of retrieval in several related domains. It stands to reason that retrieval might privilege items located in preferred structural positions, even when the preference is not grammatically controlled. Of course, the nature of the mechanisms that underlie this putative advantage will remain unsettled until an effect of structural privilege is replicated in a design that dissociates structure from other factors, like linear order. Fortunately, sluicing ellipsis offers just the right sort of flexibility to tease such issues apart in the future.

Moreover, uncovering how the processor resolves the multiple dependencies required for interpreting sluiced sentences has only just begun. The configurational possibilities of sluicing ellipsis provide a rich testing ground for disentangling the retrieval processes that are charged with recovering linguistic antecedents and integrating them into a representation as it unfolds during real-time comprehension. While numerous questions remain, one major challenge is the stage at which semantic and discourse information informs dependency formation in ellipsis, and whether information structural cues or strongly biased contexts can favor potential antecedents in the same way that structural information can. At the minimum, the present study provides additional support for converging evidence for cue-based parsing, and that the mechanisms underlying such retrieval are not wholly blind to the structural location of products in memory.

FUNDING

The author gratefully acknowledges financial support from Pomona College.

ACKNOWLEDGMENTS

This research benefited from conversations with Lyn Frazier, Carson Schütze, Sarah VanWagenen, and the audiences at the 28th Annual CUNY Conference on Human Sentence Processing held at the University of Southern California, as well as at a psycholinguistics lab meeting at the University of Maryland. Many thanks to Brian Dillon, Colin Phillips, and the two reviewers for their generous comments on previous drafts. Any mistakes or errors should be attributed to me alone. I thank Karin Denton for her assistance in running subjects for Experiment 2.

SUPPLEMENTARY MATERIAL

Filling the Silence: Reactivation, not Reconstruction

Dario L. J. F. Paape *

Department of Linguistics, University of Potsdam, Potsdam, Germany

In a self-paced reading experiment, we investigated the processing of sluicing constructions ("sluices") whose antecedent contained a known garden-path structure in German. Results showed decreased processing times for sluices with garden-path antecedents as well as a disadvantage for antecedents with non-canonical word order downstream from the ellipsis site. A *post-hoc* analysis showed the garden-path advantage also to be present in the region right before the ellipsis site. While no existing account of ellipsis processing explicitly predicted the results, we argue that they are best captured by combining a local antecedent mismatch effect with memory trace reactivation through reanalysis.

Keywords: ellipsis processing, garden-path effect, German, retrieval, reconstruction, self-paced reading

1. INTRODUCTION

Besides verb-phrase ellipsis, sluicing (Ross, 1969) is probably the most-studied ellipsis variety in both theoretical linguistics (e.g., Chung et al., 1995; Merchant, 2001; Potsdam, 2007) and psycholinguistics (e.g., Poirier et al., 2010; Dickey and Bunger, 2011; Yoshida et al., 2013). In sluicing, an entire clause is left out and a wh-element remains behind, as in (1).

(1) John saw Mary, but I don't remember when ____.
____ = John saw Mary

Sluicing is anaphoric: to interpret (1), the semantics of the antecedent (*John saw Mary*) must somehow be inserted into the gap behind the word *when* to derive the meaning *I don't remember when John saw Mary*. We write "meaning" because deriving an interpretation is the fundamental goal of sentence processing, not because it is necessarily clear that the relevant representation of the antecedent is semantic in nature. There is an ongoing debate as to whether syntactic structure is also present at ellipsis sites (cf. Cai et al., 2013, and references therein), or whether one should adopt a more discourse-centered approach to the gap-filling process (e.g., Hardt, 1993; Kehler, 2000). Since the evidence to date, at least in our view, does not unequivocally favor any of these views, we will not take a stance with regard to the representation question. We will, however, use syntactic terminology throughout the article for ease of reference.

Even with the question of *what* is inserted into the gap set aside, another point of debate has been *how* it ends up there. Ross (1967) was perhaps the first to explicitly propose a deletion approach to ellipsis (in this case, verb-phrase ellipsis): the missing bit of structure is assumed to be underlyingly present, but its phonological representation is erased under identity with the antecedent.[1] Under the approach taken by Williams (1977), ellipsis involves copying. Like Ross (1967), Williams assumes invisible syntax at the gap, but the terminal symbols of this structure are null elements

[1]There is no condition of strict identity, however, as several kinds of mismatch can be observed, as in *The car was supposed to be washed but nobody did* (e.g., Kertz, 2000; Merchant, 2013, submitted).

(Wasow, 1972). The ellipsis is interpreted by copying the terminals (that is, words) from the antecedent to the appropriate positions within the gap.

From a processing perspective, it is not enough to claim that the syntax is there in the silence: the processor must have some way of creating it. A reader of (1) would have to first infer that deletion has applied, then identify the antecedent and finally reconstruct it at the gap. The main aim of the current study is to investigate how this "reconstruction" is to be conceived of: does the parser rebuild the antecedent's structure at the ellipsis site, or does it come to be there by virtue of some other mechanism?

One might think of dispensing with the idea of invisible structure altogether. The approach of Hardt (1993) is explicitly non-syntactic in nature and treats ellipsis as an unstructured proform that refers to a stored meaning in a discourse model. The notion of copying does not enter into the picture; ellipsis acts rather like a pointer or a hyperlink into memory than as an entity of its own. This conception can be related to the processing of other types of anaphors: It is not commonly assumed that in a sentence such as *The man from England drank tea, but he didn't drink coffee*, the pronoun *he* will contain the syntactic structure of the NP *the man from England* at any level of representation. Instead, an identity of *reference* between the two expressions seems to obtain (cf. Grinder and Postal, 1971, p. 269).

Note that the opposition between copying and the "memory pointer" approach is orthogonal to that between syntactic and semantic/discourse representations (cf. Phillips and Parker, 2014). Semantic representations could also be copied, just as syntactic representations could be pointed to. The processing literature has focused mainly on the copying/pointing dichotomy, even though some studies have also tested whether there is syntactic priming from ellipsis sites, with mixed results (Cai et al., 2013; Xiang et al., 2014). Murphy (1985) appears to have been the first to systematically look for effects of antecedent length on reading times for elliptical clauses, in this case the sentence *Later, his uncle did too* in (2).

(2) a. Jimmy swept the floor. Later, his uncle did too.
b. Jimmy swept the tile floor behind the chairs free of hair and cigarettes. Later, his uncle did too.

Despite being concerned with verb-phrase ellipsis, we assume that this study is informative with regard to sluicing as well, since the most parsimonious hypothesis would be that all types of ellipsis are processed in the same way. The reasoning behind Murphy's manipulation was that "[l]onger antecedents would be expected to affect a copying process, since the longer the string that must be copied onto the anaphor, the longer it should take to understand the anaphor" (p. 293). If there was no copying, so the argument goes, then reading times for the second sentence should not differ between (2a,b). Murphy found that reading times for the elliptical sentence were increased by about 260 ms when the antecedent was long rather than short. Interestingly, this difference disappeared when another sentence was inserted between antecedent and ellipsis[2].

[2]Murphy was concerned that the observed complexity effect was simply due to processing spillover from the antecedent sentence into the ellipsis sentence, but the intervening sentence did not show any effects either.

The system Murphy proposes is one in which there are two processes, namely copying and discourse-based "plausible reasoning," which operate in parallel, with the process that finishes first supplying the antecedent. When the antecedent is far away, the speed and/or availability of copying suffers and readers fall back on plausible reasoning, which by assumption is not influenced by complexity effects. Tanenhaus and Carlson (1990, p. 261) remain unconvinced by Murphy's (1985) evidence for copying, arguing that the length manipulation "also introduced potential scope and attachment ambiguities"[3]. The authors favor a pointer-based approach, while allowing for the possibility that there are both a syntax- and a discourse-based process at work.

Two additional important findings come from an experiment by Frazier and Clifton (2000) and a series of experiments by Martin and McElree (2008), all on verb-phrase ellipsis.

(3) Frazier and Clifton (2000), Experiment 1 B
a. Sarah left her boyfriend last May. Tina did too.
b. Sarah got up the courage to leave her boyfriend last May. Tina did too.

(4) Martin and McElree (2008), Experiment 3
a. The history professor understood Roman mythology, …
b. The history professor understood Rome's swift and brutal destruction of Carthage, …

…but the principal was displeased to learn that the over-worked students attending summer session did not.

Frazier and Clifton's study used self-paced reading and found no difference in reading times between (3a,b) for the sentence *Tina did too*. Martin and McElree's Experiment 3, which used sentences such as (4a,b), employed a speed-accuracy trade-off paradigm with end-of-sentence acceptability judgments. No effect of antecedent complexity on processing times was observed in this study and two further experiments, which the authors interpret as evidence for a pointer-based approach.

Here is where terminology becomes an issue, as Frazier and Clifton (2001) explain their earlier results by means of a mechanism called Copy α. Copy α becomes available when the scope of an ellipsis can be uniquely identified and serves as a shortcut to syntactic structure: instead of being built step-by-step, which would be computationally costly, the silent syntax is copied from the antecedent. As this process is assumed to be "cost-free," the complexity of the copied structure has no influence on processing time. Frazier and Clifton's use of the copying metaphor is not very intuitive (cf. Martin and McElree, 2008, p. 882f.), as it should take more time to copy a larger amount of information, in concordance with Murphy (1985) prediction[4].

[3]It is not obvious which ambiguities the authors are referring to, or how they would impact processing under an approach without copying. It should be pointed out, however, that interpreting the ellipsis with the long antecedent in (2) requires an additional assumption, namely that the floor became dirty again between the first and the second sweeping.

[4]A possible analogy would be the copying of a file from one location on a hard drive to another, which becomes more time-consuming as file size increases.

Indeed, Frazier and Clifton (2001, p. 17) themselves explain that a pointer would be a possible implementation of Copy α and in a later paper (Frazier and Clifton, 2005) describe Copy α as equivalent to "sharing" one structure between antecedent and ellipsis (cf. also Murguia, 2004). We will thus treat pointer-based approaches, Copy α and "sharing" as variants of one and the same idea, namely that the antecedent's structure is available in memory and can be retrieved from there as-is, without any additional costly computations.

Phillips and Parker (2014, p. 91) make note of several methodological problems in both of the above studies. Frazier and Clifton's (2000) experiment used only a small number of experimental items, all of which had the ellipsis at the very end of a sentence, where wrap-up effects might mask an influence of antecedent complexity. Additionally, comprehension questions were not asked after every trial and never targeted the interpretation of the ellipsis[5]. The ungrammatical sentences in Martin and McElree's (2008) study replaced the subject of the elliptical clause by an inanimate NP (*the overly worn books*), thus making the judgments fairly easy and possibly leading subjects to engage in superficial processing. Given these concerns, Phillips and Parker judge the results to be inconclusive, but also point out that it would be difficult to design an experiment that would provide convincing evidence for or against complexity effects.

Given this state of affairs, we think it worthwhile to look back at Frazier and Clifton's (2001) distinction between a syntactic structure that is computed step-by-step and one that is retrieved from memory. What happens when the antecedent is structured in a way that is known to fool the "normal" incremental parsing mechanism, that is, if it contains a garden path? Assuming a serial parsing architecture, recovering from a syntactic misanalysis involves reanalyzing the ambiguous region and assigning the same structure that would be computed for an unambiguous control sentence. Since the final memory representations for ambiguous and unambiguous sentences are the same, pointer-based approaches and Copy α would predict that there should be no difference in processing times at the ellipsis site. If, on the other hand, ellipsis is not resolved by linking the gap to a complete structure in memory, different scenarios are possible. One would be that the antecedent is accessed in memory as a word string, and that syntax and semantics are assigned to this string in the usual way, that is, incrementally. However, as verbatim memory is known to be highly fallible even in recognition tests (Sachs, 1967; Murphy and Shapiro, 1994), it may be unrealistic to assume that strings are *recalled* literally for ellipsis processing. The account of Kim et al. (2011) proposes that not the words themselves but their features are accessed by the parser at the ellipsis site, and that "derivations in an initial conjunct [are allowed] to do double-duty in a second conjunct" (p. 346). Their account states that "once [...] an appropriate antecedent is found, [its derivation] becomes available to the parser, just as if it were located at the elision point in the input string" (p. 346), essentially claiming that the derivation is carried out twice. Now, if the sentence processor has no way of "remembering" that it was garden-pathed by the antecedent, there is a chance that it will be garden-pathed again at the ellipsis site.

A model that is, in principle, compatible with both the pointer/sharing approach and the "reparsing" account is the cue-based retrieval parser of Lewis and Vasishth (2005). In this model, syntactic phrases are stored in working memory as chunks than can be retrieved if needed. For complex phrases, both the phrase itself and its constituent parts, such as the subject of a verb phrase, are stored, along with their grammatical relations. When an ellipsis site is encountered, the parser would thus have the opportunity to retrieve either the whole antecedent as one chunk, as under a pointer-based account, or to retrieve whatever chunks are contained within the antecedent and build a new structure, as under the "reparsing" view. The latter possibility may become especially attractive in cases of antecedent-ellipsis mismatch, where a strict isomorphism condition cannot be upheld (e.g., Merchant, 2001). As in the case of Kim et al. (2011) chunks are conceived of as feature bundles and thus no verbatim memory of the antecedent is required for retrieval. In fact, both Kim et al. (2011) and Lewis and Vasishth (2005) explicitly assume that the linear order of constituents is not represented in the syntax.

The "parse twice" approach might seem counterintuitive, but is in fact no less parsimonious than Frazier and Clifton's Copy α, given that it needs no special machinery besides access to grammatical features inside the antecedent structure. One would not expect the garden-path effect at the ellipsis site to be of the same strength as the one observed for the antecedent, just as one would not expect the reading time for *when* in (1) to be equal to that of *John saw Mary*. Several steps involved in lexical access can be omitted during ellipsis processing. Simner and Smyth (1999) suggest that instead of using lexemes, ellipsis targets word lemmas, which would be compatible with the "feature bundle" view described above. Additionally, ellipsis normally occurs in environments that feature a high amount of syntactic parallelism. If a parallel structure is expected, the relevant routines may be activated beforehand or at least be assigned a higher rank when the parser decides which structure to build at the ellipsis site, which can be seen as an instance of syntactic priming (Dubey et al., 2008; Dickey and Bunger, 2011). Given this assumption, however, it might be that in case of a garden path the preferred but incorrect structure will feature into the calculation, making the ellipsis more difficult to process than in cases where the antecedent's structure is unambiguous. While Arai et al. (2014) found evidence that resolving an ambiguity in a prime sentence makes processing of the same ambiguity in the target sentence easier when the same verb is repeated (see also Branigan et al., 2005), it is unclear whether ellipsis constitutes "repetition."

In our experiment, we used a known garden-path structure in German to test the—equivalent—predictions of pointer- and sharing-based approaches against those of a reconstruction-based approach of ellipsis processing. The former two predict that garden-pathing within the antecedent clause should have no

[5]An anonymous reviewer suggests that this might have been in order not to risk making the subjects aware of the experimental manipulation. While this is a fair point, it has been shown that subjects adapt their processing strategy to task demands, trying to minimize effort through underspecification (e.g., Foertsch and Gernsbacher, 1994; Swets et al., 2008). If one intends to investigate "deep" processing, we believe that the latter risk outweighs the former, being aware that the opposite stance is equally tenable.

effect at the ellipsis site while the latter predicts that the pattern observed at the point of disambiguation will reappear, although the effect size may be significantly smaller. To anticipate the results, we found an unpredicted pattern that was inconsistent with a reconstruction approach, but compatible with pointer- and sharing-based accounts if additional assumptions are made.

2. MATERIALS AND METHODS

2.1. Stimuli

It is known that German readers prefer to assign a subject interpretation to a sentence-initial NP that is ambiguous between a subject and an object reading, which results in a garden path when it is disambiguated toward an object role (cf. also Hemforth, 1993, among others). Different explanations for the subject preference have been proposed. For instance, Gorrell's (1996) approach assumes that the parser favors structural simplicity; under his analysis, deriving an OVS structure requires more movement operations (and thus more traces) than deriving an SVO structure, where the object presumably remains in the position at which it is base-generated. Schlesewsky et al. (2000) consider the possibility that the subject preference is due to a frequency-based "tuning" effect (e.g., Mitchell et al., 1995), reporting over 90% nominative-initial main clauses in a corpus study. Still other possibilities are that subject-first is a default parsing assumption, as has been proposed for English (e.g., Bever, 1970; Grodzinsky, 1986; Fishbein and Harris, 2014). If one follows the current standard analysis of German clause structure, where S(O)V word order is assumed to be basic and all other word orders are derived through movement (e.g., Schwartz and Vikner, 2007), the reanalysis of an object-initial structure will minimally involve removing co-indexation between an assumed trace position for the subject and the initial noun phrase, as well as postulating a trace position for an object.

The garden-path effect incurred by the non-canonical structure is stronger when disambiguation is achieved through agreement on the finite verb rather than through case marking on another NP (Meng and Bader, 2000). As shown in (5), we used indefinite NPs instead of the wh-marked NPs employed by Meng and Bader. Case marking on the *sympathizer* NP is either ambiguous (5a/b) or unambiguous (5c/d). The auxiliary *hatte(n)*, "had," agrees either with the singular *sympathizer* or with the plural *rebels* NP, thereby signaling either OVS (5a/c) or SVO word order (5b/d). The result is a 2 × 2 design with the factors word order and case marking. Diamonds indicate the boundaries of presentation regions in the experiment, subscripts indicate region coding for the statistical analysis.

struggled

"The rebels had supported a sympathizer (OVS, a/c)/A sympathizer had supported the rebels (SVO, b/d), but the government could not substantiate how, no matter how hard the investigative commission tried."

The antecedent clause ends at *unterstützt*, "supported." It is conjoined with a second clause by *aber*, "but," which contains a sluicing site (or "sluice") at *wie*, "how." All wh-phrases in the experiment were "sprouted" (Chung et al., 1995), that is, they had no explicit correlate in the antecedent. We only used adjunct wh-phrases since argument wh-phrases are case-marked in German, which would have introduced a potential confound. The other wh-phrases used were several expressions meaning "why" (*warum*, *weshalb*, *wieso*), *wo*, "where," *wann*, "when," *womit*, "with what," *wozu* "to what (end)," and *wobei*, "at what" (combined with the verb *unterstützen*, "to support"). The part of the sentence following the sluicing site was intended as a spillover region. We could have used only conditions (5a) and (5c) to look for an effect of reanalysis, but decided to also include (5b) and (5d) as control conditions since otherwise reanalysis would be completely confounded with the gender of the initial NP. Additionally, even though condition (5b) is initially ambiguous, there should be no reanalysis as readers will assume SVO order by default (cf. Meng and Bader, 2000); we can thus control for temporarily ambiguous antecedents being processed differently from unambiguous ones. Thirty-two sentences were created according to this schema for use in the experiment. A complete list of the experimental materials is given in the appendix. The

stimuli were combined with ninety-six filler sentences featuring various constructions.

We expected a garden-path effect to occur at the auxiliary of the antecedent clause in the form of a word order × case marking interaction. Meng and Bader (2000) observed longer reaction times in a grammaticality judgment task for OVS than for SVO sentences, indicating that OVS order is overall more difficult to process. In (5a), however, the *sympathizer* NP presumably has to be reanalyzed from subject to object, which should further increase processing time. If ellipsis acts as a pointer into memory, no interaction between the experimental factors should appear at *wie*, "how," as neither the scope of the ellipsis nor the availability of a completely analyzed antecedent structure vary between conditions. If, however, the syntax of the ellipsis site has to be constructed by normal parsing routines, the garden-path effect should reappear at this position, though most likely with reduced magnitude.

We had no specific predictions as to possible effects of OVS vs. SVO word order at the ellipsis site, but a *post-hoc* hypothesis will be developed in the discussion section. A complication concerning the predictions of both accounts that did not become apparent to us until after the experiment is that inserting a verb-second antecedent into the ellipsis site verbatim is impossible in our stimuli, as German subordinate clauses are generally required to be verb-final. The predictions outlined above are valid for well-formed antecedents, but should pertain to mismatched antecedents as well if certain additional assumptions are made, as will be explained shortly.

2.2. Participants

Sixty students from the University of Potsdam were recruited for the study. All subjects were native speakers of German and were either paid 6 € or received course credit for the participation. Informed consent was obtained from all participants prior to testing.

2.3. Procedure

The sentences were presented using the moving window self-paced reading technique (Just et al., 1982), which was implemented using the Linger software (Rohde, 2003; http://tedlab.mit.edu/~dr/Linger/). Participants sat in front of a PC in a quiet room and were instructed to read silently and at their own pace. Sentences were presented in 20 pt Courier New font according to a latin square procedure. At the beginning of each trial, all characters were masked with underscores. Participants completed two practice trials before the experiment proper. The order of fillers and experimental sentences was randomized at runtime. Each trial was followed by a comprehension test which took one of two forms: either a statement about the preceding sentence had to be judged as true or false, or a gap in a statement had to be filled by selecting one out of four options. Some test statements targeted the argument structure of the antecedent (*Rebels had supported a sympathizer of the opposition. [Yes/No]*), while others targeted other kinds of information from the sentence. The ratio of true to false statements for the judgment test was balanced. For a subset of fill-in-the-gap statements appearing after experimental sentences, participants had to supply the critical wh-pronoun[6].

3. RESULTS AND DISCUSSION

3.1. Data Analysis

After 15 participants had completed the experiment, it was noticed that three experimental items contained a typographical error in one condition each. The errors were removed and data from the corresponding trials were excluded from the statistical analysis. The remaining data were analyzed using the `R` software environment (R Core Team, 2015) by fitting linear mixed-effects models to individual regions of interest with the `lme4` package (Bates et al., 2014). The models included varying intercepts and slopes by subjects and by items. The code and data will be released with the publication of this paper. When the estimate for a slope adjustment was zero, the random effect was dropped from the model, along with any associated higher-order effects. When a model failed to converge, random effects were removed, starting with the effect that accounted for the smallest amount of variance, until convergence was obtained. Sum contrasts were defined for the experimental factors word order and case marking and entered into the models as fixed effects. For word order, the OVS conditions were coded as 1 and the SVO conditions as −1, respectively. For case marking, the ambiguous conditions were coded as 1 and the unambiguous conditions as −1. Since processing spillover is a known concern in self-paced reading, the reading time for the immediately preceding region was also entered into all models after being appropriately transformed (see below) and subsequently centered. The addition of this parameter improved model fit for all regions of interest[7], but the method is by no means guaranteed to eliminate spillover entirely, for instance if subjects postpone processing and keep "tapping" the button at fixed time intervals (Witzel et al., 2012).

An underlying assumption in linear modeling is that the residuals are approximately normally distributed. As this was not the case when raw reading times were used as the dependent variable, we applied the Box-Cox procedure (Box and Cox, 1964; Venables and Ripley, 2002), which suggested a reciprocal transformation (1/RT). Reciprocal reading times were multiplied by −1000 to make the parameters easier to interpret. Additionally, all data points corresponding to reading times below 150 ms were removed, which resulted in a loss of less than one per cent of data in all cases. Effects were judged as significant if $t \geqslant 2$. Model output is shown in **Table 2**.

3.2. Comprehension Accuracy

Participants' overall comprehension accuracy was at 90%, though accuracy for experimental items was somewhat lower at 82%. Overall, subjects were most accurate at supplying the wh-pronoun (92% accuracy) and least accurate at verifying

[6]Though the specific example in (5) was not accompanied by this kind of test, a possible fill-the-gap statement could have been *The government could not substantiate ____ rebels had supported a sympathizer of the opposition. [why/how/when/if]*.

[7]Improvement of fit was assessed through likelihood ratio tests comparing models with and without the spillover predictor.

statements about the argument structure of the antecedent (72% accuracy), with the rest of the comprehension tests falling in between (86% accuracy). All further analyses were conducted without distinguishing between question types, unless otherwise noted. A linear mixed-effects model was fit to question response times using the same procedure described above for reading times. The analysis revealed no significant effects of the experimental manipulation. An analogous model with reciprocal response time as an additional predictor was fit to response accuracies using a logit link function. The fit showed an effect of response time such that accuracy dropped with increased delay ($\hat{\beta} = -0.13$, $se = 0.03$, $t = -5.18$), as well as a significant word order × case marking interaction ($\hat{\beta} = -0.18$, $se = 0.07$, $t = -2.74$), which nested contrasts[8] revealed to be driven by the OVS/ambiguous condition eliciting more incorrect responses than the SVO/ambiguous condition ($\hat{\beta} = -0.27$, $se = 0.13$, $t = -2.09$). To investigate further, we created a new contrast between questions that queried the role of the arguments in the antecedent and questions that did not. When this distinction was entered into the model[9], it turned out to be highly predictive of accuracy ($\hat{\beta} = -0.66$, $se = 0.16$, $t = -4.24$), indicating that questions about argument structure were more difficult to answer than other question types. At the same time, the word order × case marking interaction was significant ($\hat{\beta} = -0.17$, $se = 0.07$, $t = -2.63$), but there was no three−way interaction. There was thus no indication that comprehension failure for questions targeting argument structure was limited to garden-path sentences. Why answering questions about garden-path sentences should be difficult even when the temporary ambiguity is not targeted remains mysterious for the time being.

3.3. Reading Times

Table 1 shows the mean raw reading times for the analyzed regions of interest. **Figure 1** shows residual mean reading times for each region of the antecedent. Residualization was carried out by fitting a linear mixed-effects model with region length as a fixed effect and random slopes by subject. Unresidualized reciprocal reading times (see above) were used in the statistical analysis. A main effect of word order appeared at the auxiliary ($\hat{\beta} = 0.03$, $se = 0.01$, $t = 2.07$), such that OVS was processed more slowly than SVO, which is likely due to the additional plural suffix in the OVS conditions. On the second NP, there were main effects of word order ($\hat{\beta} = 0.04$, $se = 0.01$, $t = 3.02$) and case marking ($\hat{\beta} = 0.04$, $se = 0.01$, $t = 3.3$), such that SVO was read faster than OVS and unambiguous sentences were read faster than ambiguous ones. There was also a significant interaction between the factors ($\hat{\beta} = 0.02$, $se = 0.01$, $t = 2.12$), which nested contrasts revealed to be driven by OVS clauses taking longer to read in the presence of ambiguous case marking ($\hat{\beta} = 0.07$, $se = 0.02$, $t = 3.68$). The preverbal adjunct again showed a main effect of word order ($\hat{\beta} = -0.02$, $se = 0.01$, $t = -2.38$); at this position, OVS clauses were read faster than SVO clauses[10].

Figure 2 shows the mean reading times from the region right before the ellipsis site to three words after the ellipsis site, again in residualized form. No significant effects appeared at the wh-pronoun or in the immediately following region. In the next region (wh+2), there was a main effect of word order ($\hat{\beta} = 0.03$, $se = 0.01$, $t = 2.02$), such that OVS clauses took longer to read than SVO clauses. For this position, closer inspection of the model revealed one very short reading time (177 ms) to be highly influential in the fit, and removing this value resulted in the effect merely approaching significance ($\hat{\beta} = 0.02$, $se = 0.01$, $t = 1.89$). In the third region after the wh-pronoun (wh+3), a word order × case marking interaction reached significance ($\hat{\beta} = -0.03$, $se = 0.01$, $t = -2.02$), due to the OVS/ambiguous condition being read faster than the OVS/unambiguous condition, with no single condition driving the interaction. During data analysis we noticed that five experimental sentences featured gender-marked pronouns at position wh+2, which presents a possible confound. Adding the presence vs. absence of a pronoun as a sum-coded predictor did, however, not change the results found at regions wh+2 and wh+3.

One might think that the interaction found at position wh+3 stemmed from occasional processing breakdowns in the OVS/ambiguous sentences. We assume that these would be due to failures in processing the antecedent, which would leave the parser without an adequate retrieval target for the ellipsis. To test this hypothesis, we added the reading time for the second NP, which is expected to reflect the difficulty of the garden path, to the reading time model for position wh+3 on the same trial. While this measure turned out to be a highly significant predictor ($\hat{\beta} = 0.13$, $se = 0.02$, $t = 5.51$), the word order × case marking interaction also stayed significant and indeed became stronger ($\hat{\beta} = -0.03$, $se = 0.01$, $t = -2.21$). This suggests that while the time spent processing the garden-path influences retrieval

[8]For this analysis, case marking was treated as nested within word order. One sum contrast compared the two ambiguous conditions, one compared the two unambiguous conditions, and a third one the OVS vs. SVO conditions.

[9]The fixed effect of reciprocal response time was removed from this model as it consistently led to convergence failure.

[10]Speculatively, this effect may be due to readers trying to make up for lost time after having been slowed down.

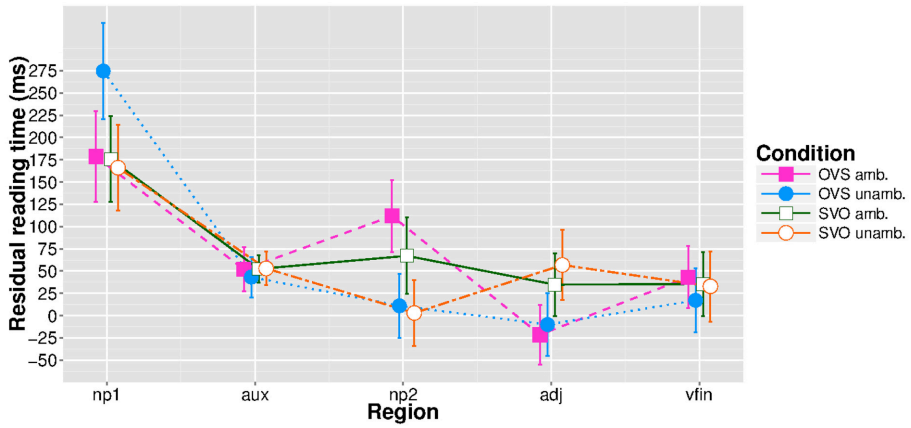

FIGURE 1 | Residual reading times for the antecedent regions, extreme values removed. Error bars represent 95% confidence intervals.

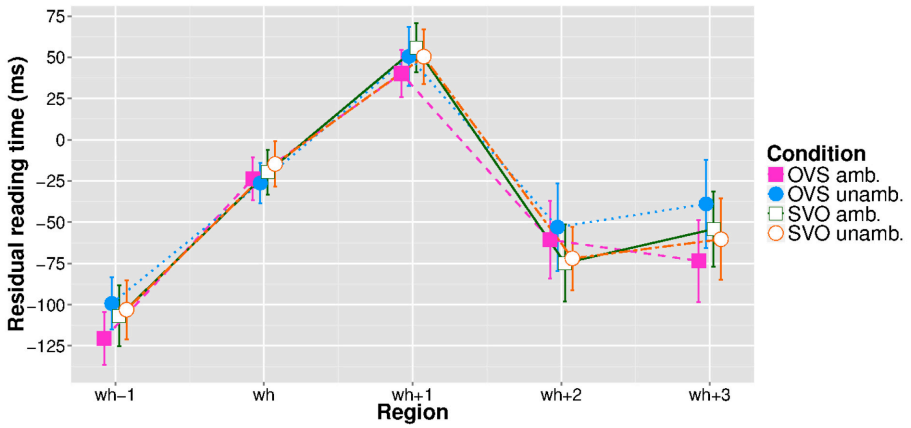

FIGURE 2 | Residual reading times for the pre-ellipsis, ellipsis, and spillover regions, extreme values removed. Error bars represent 95% confidence intervals.

difficulty, there are factors above and beyond this measure which determine processing effort at the ellipsis site. In a further test, we added reading times for both the second NP and position wh+3 to the response accuracy model reported above. The reasoning behind this was that processing failure at either position could lead to incorrect responses. Adding these parameters did, however, not change the result. We also compared the median reading time in the OVS/ambiguous condition for position wh+3 with the overall median reading time for the experimental items. The difference lay within reasonable bounds (439 ms, *se* 18 ms vs. 473 ms, *se* 2 ms), indicating that very short RTs from processing failures were not pushing down the median. Congruently with this, a visual inspection of a density plot of RTs at position wh+3 did not indicate a mode or tail of fast reading times, nor did Hartigan's Dip Test (Hartigan and Hartigan, 1985) yield any evidence for bimodality. Finally, we removed all trials with incorrect responses to the comprehension test, which amounted to 18% of the data for position wh+3, and refit our model. Note that an incorrect answer does not necessarily mean that parsing failed; misinterpretations could, for instance, arise from fragments of discarded analyses in memory (see below). Nevertheless, the results of the comprehension test are the only pertinent measure available to us. With one fifth of data removed, the word order × case marking interaction stayed near the significance threshold ($\hat{\beta} = -0.02$, $se = 0.01$, $t = -1.62$) and became marginally significant when antecedent reading time was added as a predictor ($\hat{\beta} = -0.03$, $se = 0.01$, $t = -1.86$). The loss of significance is not particularly unexpected given the loss of statistical power incurred by removing data. To our minds, these results do not indicate that processing failure was a factor in decreasing reading times for the OVS/ambiguous condition.

3.4. Discussion

The expected garden-path effect for the antecedent appeared one region later than predicted, at the second NP, showing that the experimental manipulation was successful. While no effects were found at the ellipsis site itself, OVS antecedents led to longer reading times two regions downstream from the wh-pronoun.

Note that this cannot be explained by a "global spillover effect" from the antecedent: earlier regions did not show the pattern, and there is no reason to assume that antecedents in the OVS/unambiguous condition were extremely difficult to process. Furthermore, an interaction between the experimental factors appeared at position wh+3, albeit in a surprising form: sentences in the OVS/ambiguous condition were read faster than those in the OVS/unambiguous condition, with the two SVO conditions lying in between. We assume that the observed pattern reflects delayed processing of the ellipsis, either as the consequence of subjects "tapping" the space bar at fixed time intervals (Witzel et al., 2012; see Discussion below) or as spillover that was not factored out by the statistical model. As the OVS/ambiguous condition was responsible for the garden-path effect within the antecedent clause, the processing advantage is unexpected with regard to the reconstruction hypothesis, which had predicted the same pattern to reappear at the ellipsis site. The result is also not straightforwardly explained by a pointer-based approach, which would have predicted no differences between the conditions. We will argue below that what we are observing at positions wh+2 and wh+3 is the interaction of two factors: antecedent-ellipsis mismatch and memory trace reactivation through reanalysis.

3.4.1. German Word Order and Antecedent-Ellipsis Mismatch

As we've pointed out in the introduction, German subordinate clauses are required to be verb-final[11] while main clauses invariably have the finite verb in second position. As the sluicing structures in the present study appeared in subordinate clauses, all antecedent clauses would therefore have had to be verb-final instead of verb-second to be compatible with the gap. Given that sluicing is still perfectly acceptable in all of our stimuli, we seem to be seeing a case of "acceptable ungrammaticality" (Frazier, 2008). Both SVO and OVS antecedents were, to use the terminology of Arregui et al. (2006), "flawed," but possibly not in the same way.

OVS order in German main clauses can be derived through topicalization, with the object occupying the so-called *Vorfeld* ("prefield," e.g., Müller, 2005)[12]. As this strategy is not available in subordinate clauses, non-canonical word orders must be derived via *scrambling*, which moves constituents within the so-called *Mittelfeld* ("middle field," e.g., Hinterhölzl, 2006). The slightly simplified examples in (6) illustrate this. SOV order in (6a) is unproblematic, but scrambled OSV in (6b) is, at the very least, highly marked[13].

[11]The only exception to this rule occurs when the verb takes a sentential complement, which was not the case in our experiment.

[12]The *Feldertheorie* of German sentence structure was first developed by Drach (1937), and is also known as the *Topological Model*.

[13]Apart from not being licensed by information structure, moving the object in (6b) also violates a constraint dictating that definite noun phrases should appear before indefinite ones (see Müller, 1999 for an optimality-theoretic account).

b. **OSV subordinate clause**

… ?? wie einen Sympathisanten$_i$ die Rebellen t$_i$
how a sympathizer.acc the rebels
unterstützt hatten.

The Recycling Hypothesis proposed by Arregui et al. (2006) predicts that ellipses are more difficult to process the more the antecedent mismatches the ellipsis site. Arregui et al. assume "repair" operations as the source of the difficulty. Assuming the verb-second antecedents have already been partly repaired by moving the verb to the end, (6b) would still need to be transformed into an SOV structure like (6a), presumably be reversing the movement operation. The increased reading times for sentences with object-initial antecedents observed at position wh+2 would be expected under the assumption that the mismatch between an OVS antecedent and an SOV sluice is greater than for SVO antecedents, where the repair process does not need to change the order of the arguments.

Two alternative suggestions made by an anonymous reviewer merit discussion. One is that the processor simply fills the ellipsis site with a verb-second clause, deriving a structure that would have no grammatical surface equivalent. There would be no reason to invoke the Recycling Hypothesis in this case, and the OVS disadvantage would need to be explained either by constraints on topicalization or possibly by invoking working memory factors. Both of these possibilities present problems. It has been found that surprising or unusual stimuli lead to better recall performance (Hirshman et al., 1989), which would lead us to expect that the more uncommon OVS antecedents should be easier instead of more difficult to retrieve. Additionally, the claim that ungrammatical structures can be derived during ellipsis processing seems extreme given that the observed effects can be explained through other means. The reviewer's second suggestion is that garden-pathing in the antecedent might result in its memory representation being more difficult to access, allowing a slower discourse-based mechanism like Murphy's (1985) to dominate during processing. However, seeing that *unambiguous* OVS antecedents also led to longer reading times at position wh+2, this does not seem like a plausible alternative to us.

3.4.2. Antecedent Reactivation through Reanalysis

A reviewer points out that there is some evidence that initial misinterpretations of garden-path sentences persist beyond the point of disambiguation, leading to structural priming, (van Gompel et al., 2006) systematic errors during paraphrasing (Patson et al., 2009) and in comprehension tests (Christianson et al., 2001), as well as competition effects when late-arriving plausibility information contradicts the initial parse (Slattery et al., 2013). One explanation for these effects is that the initial parse of the sentence remains active in memory to some degree even after it has been discarded. In the case of our experiment, if a remnant of the discontinued subject-initial analysis remains behind in the OVS/ambiguous condition, it might be conceivable that this memory trace is considered as a possible antecedent for the ellipsis, possibly blocking access to the "real," reanalyzed antecedent. Research on agreement processing, reflexives and subject-verb dependencies has shown that such memory interference may turn out to make processing easier or more difficult, depending on the phenomenon under study and the exact setup of the experiment (see Engelmann et al., submitted for a review). While the observed speedup in the current study may, in principle, be explained through facilitative interference, the results of Martin and McElree (2009) suggest that the availability of multiple candidate antecedents does not influence the time-course of ellipsis processing in any way. As it is unclear why the interference effect should visible in our experiment but not in theirs, we will present an alternative explanation of our results.

We suggest that the pattern at position wh+3 should be analyzed in terms of a reactivation of the antecedent's memory trace that outweighs the mismatch penalty created by the word order manipulation. As explained in the introduction section, the cue-based retrieval parser of Lewis and Vasishth (2005) incorporates the assumption that syntactic phrases are stored in working memory as chunks. If a chunk is retrieved in order to make an attachment, its activation level increases, which makes subsequent retrievals easier. A reanalysis such as the one required for sentences in the OVS/ambiguous condition should reactivate the antecedent's memory chunk as its structure needs to be changed. Later, at the ellipsis site, it should thus be retrieved faster than the other types of antecedents, to which reanalysis has not applied[14]. The mismatch effect explained above can also be accounted for through an extension of the Lewis and Vasishth (2005) model: If the wh-pronoun sets retrieval cues for a verb-final antecedent in order to match the local clausal configuration, there will be no matching chunk in memory. In order to be able to complete the retrieval, the processor may then attempt to retrieve chunks which do not match the cues perfectly, such as the main clauses in the current study. Due to the matching relative order of subject and object, an SVO chunk may resonate more strongly with the SOV cue than one with OVS word order, as schematized in (7).

(7) a. **OVS antecedent, resonates weakly with SOV cue (O-S $\neq$ SO)**

[Einen Sympathisanten hatten die Rebellen
A sympathizer had.pl the rebels
unterstützt]$_{OVS}$ …
supported

b. **SVO antecedent, resonates more strongly with SOV cue (S-O $\sim$ SO)**

[Ein Sympathisant hatte die Rebellen
A sympathizer had.pl the rebels
unterstützt]$_{SVO}$ …
supported

[14]This presupposes that trace decay has not reduced the activation of the antecedent to zero in any case by the time the ellipsis is processed. The model of Lewis and Vasishth (2005) assumes that the activation of chunks than have been reaccessed is higher even after complete decay.

***wie* in subordinate clause sets SOV cue**

… aber die Regierung konnte nicht nachweisen,
but the government could not substantiate
wie [ ]$_{SOV}$ …
how

A lower retrieval latency would then be expected for SVO chunks, thereby predicting the observed OVS disadvantage at position wh+2[15]. The reactivation/mismatch approach is thus able to account for the observed pattern of results, but due its status as a *post-hoc* argument is in need of further empirical validation.

One might think of yet another explanation for the result, namely that reconstruction *is* taking place and that syntactic priming is responsible for the advantage in the OVS/ambiguous condition. However, such an approach would not fit with the fact that the antecedent's structure is, strictly speaking, incompatible with the word order required at the gap: As the derivations of main and subordinate clauses involve different steps, it is not obvious what exactly would be primed. One would have to make a very specific set of assumptions: First, the parser would need to blindly reconstruct the syntax of the antecedent at the ellipsis site *before* checking for possible mismatches, similarly to the anonymous reviewer's suggestion that was discussed earlier. Secondly, garden-path sentences would need to prime their final structure more strongly than unambiguous controls, which to our knowledge has not been demonstrated to date. Ambiguous/OVS antecedents would then initially gain an advantage through increased priming while both kinds of OVS antecedents would be disadvantaged during the mismatch checking phase.

3.4.3. Sluicing and Predictive Processing

We believe that one additional result is worth mentioning, even though it was only arrived at *post-hoc*. It fits with the proposal by Yoshida et al. (2013) that predictive processing may be involved in the interpretation of sluicing structures. Yoshida et al. compared sentences in which it was either possible or impossible to analyze a specific wh-phrase as part of a sluice. The evidence suggested that as soon as the wh-phrase in question was encountered, the parser started building a sluicing structure, presumably because it is preferred over other possible continuations.

We took the implication of predictive processing as an incentive to analyze reading times for the region directly *preceding* the wh-pronoun in our own experiment: If sluicing is the preferred continuation after a wh-pronoun has been encountered, it is not unlikely that it will also rank fairly highly before that point. This is especially likely given that subordinate clauses in German require a comma, which was thus present in the pre-wh region in all of our stimuli, excluding a vast range of alternative continuations that would have been likely in Yoshida et al.'s materials.

The fitting of a linear mixed-effects model (see above) at position wh-1 revealed a significant interaction between word order and case marking ($\hat{\beta} = -0.03$, $se = 0.01$, $t = -2.3$) which had the same sign as the one observed at position wh+3[16]. **Table 3** shows the model output. However, unlike at the later position, nested contrasts showed that the interaction was driven by the OVS/unambiguous condition being read more slowly than the SVO/unambiguous condition ($\hat{\beta} = 0.04$, $se = 0.02$, $t = 2.24$), even though the numerical pattern in raw reading times was the same as for position wh+3. We have no ready explanation for this finding. Speculatively, a heuristic may be used to estimate the fit between the sluice and the antecedent. Such a heuristic might work better when case is overtly marked, and might operate more quickly when word order is canonical. In our opinion this kind of predictive strategy makes it unlikely that processing proceeds according to the priming-based account described above, in which local constraints do not influence the initial structure assignment for the ellipsis.

TABLE 3 | Coefficient estimates, standard errors and *t*-values for the linear mixed-effects model fit to reciprocal reading times at region wh-1.

	wh-1		
	Estimate	**Std. Error**	***t*-value**
(Intercept)	−2.10	0.06	−35.17
Case marking	−0.02	0.01	−1.60
Word order	0.01	0.01	0.93
Spillover	0.36	0.02	15.21
Case marking: word order	−0.03	0.01	−2.30

To further investigate the notion that a sluice was the expected structure in our materials, we ran a sentence completion study with thirty-five new participants. It has been suggested that the speech production system may be responsible for generating linguistic expectations in comprehension (Pickering and Garrod, 2007). As sentence continuation preferences have been shown to be predictive of processing difficulty in self-paced reading (Smith and Levy, 2011), we assume that a preference for sluicing continuations in our reading study should translate into a corresponding preference in sentence completions. The stimuli consisted of the 32 sentences used in the current reading study, along with 32 sentences from a different experiment and 96 fillers. Sentences were presented using a modified version of Linger's masked auto-paced reading (otherwise known as rapid serial visual presentation or RSVP). The stimuli from the current study were cut off right before the ellipsis site and participants were asked to complete the sentences using the first continuation that came to mind. Due to the nature of the presentation, participants could not reread the sentences while they were typing their continuation. Results showed a total of only five per cent sluicing continuations. Another 54% of continuations were non-sluiced wh-clauses, followed by *if*-clauses at seventeen per cent and *that*-clauses at seven per cent. Assuming that this pattern is not due to idiosyncrasies of the production system, the observed outcome casts some doubt on the assumption that a sluicing continuation was, in fact, highly expected in

[15]In order to derive grammatical structures, repair processes that change the word order to verb-final would still need to apply after retrieval.

[16]As a sanity check, we also analyzed reading times at position wh-2, finding no significant effects.

our stimuli. However, subjects in the production experiment could choose their preferred continuation freely, which may conceivably have led to more conscious deliberation on their part. It is entirely possible that sluicing is only one of several possible continuations which are pre-activated during reading, which might be enough to explain the findings of Yoshida et al. (2013) and the interaction we observed at position wh-1 in the self-paced reading study. Despite the limited scope of the production experiment, given the earlier findings by (Smith and Levy, 2011), we feel that it was important to investigate whether the predictive processing seen in comprehension maps directly onto language users' preferences in production. This is apparently not the case under the conditions tested here.

4. GENERAL DISCUSSION

The current experiment investigated the processing of a sluicing construction in cases where the antecedent is a garden-path structure, in this instance a clause with a subject/object ambiguity. We observed reduced reading times for sentences with garden-path antecedents three regions downstream from the ellipsis as well as directly before the ellipsis. Furthermore, there was an overall pattern of elevated reading times in the spillover region for antecedents that mismatched the canonical word order of the ellipsis site. Our results are best compatible with accounts of ellipsis resolution that can be implemented in the form of a memory pointer mechanism (Frazier and Clifton, 2001, 2005; Martin and McElree, 2008), which would need to be augmented to account for reactivation assumed by the cue-based retrieval parser of Lewis and Vasishth (2005). The evidence for a mismatch effect is in line with the predictions of the Recycling Hypothesis proposed by Arregui et al. (2006). However, given that we have observed no evidence for reconstruction in our experiment, we do not subscribe to Arregui et al.'s assumption that "flawed" antecedents are "repaired" in a way that is similar to syntactic reanalysis (p. 242). The mismatch effect may be better approached along the lines of the wh-pronoun setting a retrieval cue for an antecedent that matches the word order requirements of the local clause, opting for the closest candidate upon failure. Alternatively, one could follow the proposal of Kim et al. (2011), in which ellipses with non-canonical antecedents violate parsing heuristics that are based on construction frequency and expectation. Under an approach without reconstruction, we would claim that it is not a parsing heuristic that is violated, but a local expectation as to what an antecedent targeted by retrieval should look like. If the expectation were global, no mismatch effect would be expected, given that the antecedent has already been encountered in the input. The local expectation account fits with the pattern observed by Yoshida et al. (2013) as well as with the effect found in the pre-sluice region (wh-1) in the current study.

Still, why did we observe a pattern in which the experimental manipulation seemed to have an effect before and after, but not *at* the ellipsis site? We assume that this is due to either insufficient statistical power, to our subjects' reading strategies, or both. Power is always an issue when effect sizes are as small as in the current study: the mean reading time difference between the unambiguous/OVS and the ambiguous/OVS conditions at position wh+3 was only 30 ms. Given this value and the associated standard errors, the *post-hoc* power to detect a real effect was at 45%, which is comparable to Frazier and Clifton's (2000) study, where the computation yields 43% *post-hoc* power[17]. The bottom line is that sample size needs to be significantly increased in order to convincingly argue that there really is *no* effect of the manipulation, even though this might be construed as trying to "force significance."

The concern related to reading strategies comes from the fact that while non-cumulative self-paced reading more closely resembles data from natural reading than the cumulative variant does (Just et al., 1982), it is by no means certain that subjects will not adopt a "wait and see" strategy at least on some trials, meaning that they will press the button at a fixed rate and only then start processing. Witzel et al. (2012), suspecting such rhythmic "tapping" in their data, tried to remove its influence by calculating the standard deviation of the response time by subject and excluding the participants with the smallest variability, which did, however, not change their statistical result. The authors conclude that either 'tapping' was not a factor in their data or their method was not suitable to account for it, leaving the issue for future research. We will do the same here.

There is also a slightly different explanation for the delay we observed, namely that subjects *did* process the words the words as they were revealed, but postponed the processing of the ellipsis until they had more information. Such a strategy might make sense considering that an embedded question (i.e., an interrogative clause that serves as a complement, as in *. . . , but the government could not substantiate how, . . .*) in itself usually imparts no relevant information apart from the fact that some piece of information is missing. As the contents of the spillover region put this information in context (*. . . , because/so that/even though/until . . .*), the relevance may have become apparent, causing the observed processing pattern.

A final objection to our study would be that there was no control condition without ellipsis. It should be noted that it is extremely difficult to create closely matched controls for our sentences, given that possible continuations are limited to complement clauses, which usually feature more than one word. Other studies on ellipsis processing also lack controls [e.g., Frazier and Clifton, 2000, 2005 (except Experiments 2 and 3), Poirier et al., 2010], leaving open the possibility that any observed effects do not actually stem from the antecedent being recovered due to a perceived gap in the sentence but from some other mechanism. While this criticism can be met by pointing to the localization of the effects, as well as to the unavailability of a plausible alternative explanation, it would be desirable to include controls in future studies to strengthen the conclusions drawn from the data.

Further investigations into the interaction between antecedent ambiguity and ellipsis processing are already underway in our laboratory. We are currently aiming to find further evidence for the reactivation effect using different kinds of temporary

[17]Note that this is not the *true* power of the experiments, which depends on the unknown true effect size.

ambiguities and ellipses, as well as experimental procedures other than self-paced reading (e.g., eye tracking).

FUNDING

This research was funded by the University of Potsdam.

ACKNOWLEDGMENTS

To author wishes to thank Shravan Vasishth, Lena A. Jäger, Barbara Hemforth, the Vasishth Lab team, and the audience at CUNY 2015 for helpful comments and suggestions, as well as Johanna Thieke for assistance with data collection.

There is a wealth of evidence showing that increasing the distance between an argument and its head leads to more processing effort, namely, locality effects; these are usually associated with constraints in working memory (DLT: Gibson, 2000; activation-based model: Lewis and Vasishth, 2005). In SOV languages, however, the opposite effect has been found: antilocality (see discussion in Levy et al., 2013). Antilocality effects can be explained by the expectation-based approach as proposed by Levy (2008) or by the activation-based model of sentence processing as proposed by Lewis and Vasishth (2005). We report an eye-tracking and a self-paced reading study with sentences in Spanish together with measures of individual differences to examine the distinction between expectation- and memory-based accounts, and within memory-based accounts the further distinction between DLT and the activation-based model. The experiments show that (i) antilocality effects as predicted by the expectation account appear only for high-capacity readers; (ii) increasing dependency length by interposing material that modifies the head of the dependency (the verb) produces stronger facilitation than increasing dependency length with material that does not modify the head; this is in agreement with the activation-based model but not with the expectation account; and (iii) a possible outcome of memory load on low-capacity readers is the increase in regressive saccades (locality effects as predicted by memory-based accounts) or, surprisingly, a speedup in the self-paced reading task; the latter consistent with good-enough parsing (Ferreira et al., 2002). In sum, the study suggests that individual differences in working memory capacity play a role in dependency resolution, and that some of the aspects of dependency resolution can be best explained with the activation-based model together with a prediction component.

1. Introduction

Long-distance dependencies (also called non-local, filler-gap, or unbounded dependencies) have been investigated since Fodor's (1978) work on parsing strategies, but many questions remain

unanswered or only partially answered. It is uncontroversial that the distance over which a dependency is resolved, shown in (1) with an arrow, is a primary determinant of the speed and the accuracy of the dependency resolution (among others: Gibson, 2000; McElree et al., 2003; Lewis and Vasishth, 2005; Levy, 2008). It is controversial, however, how increasing this distance affects the speed and the accuracy of the resolution.

(1) What do different theories predict?

1.1. Memory-Based Explanations

There is a wealth of evidence showing that increasing the distance between an argument and its head hinders underlying memory processes in some way. This is supported by research that shows that longer dependencies produced (i) locality effects, that is, a slowdown (or increase of regressive saccades) at the region of the dependency resolution when the distance between dependent and head or subcategorizing verb (or gap) is increased (either in self-paced reading, eye-tracking experiments, or both; among others: Gibson, 2000; Grodner and Gibson, 2005; Demberg and Keller, 2008; Bartek et al., 2011; Vasishth and Drenhaus, 2011); (ii) Event Related Potential (ERP) measures associated with difficulty (Kluender and Kutas, 1993; Fiebach et al., 2002; but see: Phillips et al., 2005); and (iii) deterioration of response accuracy in speed-accuracy trade-off (SAT) experiments (McElree, 2000; McElree et al., 2003). The underlying memory process that is adversely affected when distance is increased is subject to debate. Here we discuss two theories that account for the memory-based locality effects: dependency locality theory (DLT; Gibson, 2000) and the activation-based model (Lewis and Vasishth, 2005).

DLT posits two separate components of a sentence's processing cost: storage and integration costs. Storage cost is argued to depend on the number of syntactic heads required to complete the current input as a grammatical sentence (Gibson, 2000) and seems to be independent of the amount of time that an incomplete dependency is held in memory (Gibson et al., 2005). On the other hand, integration cost is locality-based, that is, the cost is based on the distance between the dependent and its head; this distance is based on the number of new intervening discourse referents (Gibson, 2000).

In contrast to DLT, which is a theory specific to sentence comprehension processes, the activation-based model is based on a general cognitive model. In the activation-based model, linguistic items in memory are represented as feature bundles that suffer from decay and interference from the features of other linguistic items. Under this model, locality effects can be explained in terms of difficulty in the retrieval of a non-local argument; retrieval is driven by cues that are set at the moment of dependency resolution. Since the access to the argument involves a match of retrieval cue features against candidate memory items (Lewis et al., 2006), this access is adversely affected when (i) more time has passed from the encoding of the argument (decay); and (ii) when there are other items with similar features that serve as distractors (similarity-based interference). The activation-based model excludes the possibility of storage costs as proposed by DLT, but stored memories have their observable effects through interference (Van Dyke and Lewis, 2003; Lewis et al., 2006).

Thus, in cases such as (2), both DLT and the activation-based model predict that as the distance between the displaced argument *who* and the subcategorizing verb *supervised* increases, the retrieval of the argument will be harder. This is supported by the evidence of locality effects in relative clauses (Grodner and Gibson, 2005; Bartek et al., 2011).

(2) From Experiment 2 of Grodner and Gibson (2005)
   a. The administrator **who** the nurse **supervised**...
   b. The administrator **who** the nurse from the clinic **supervised**...
   c. The administrator **who** the nurse who was from the clinic **supervised**...

In spite of the evidence for locality effects, there is a growing body of evidence showing the opposite effect: antilocality. Studies on SOV structures (in Hindi: Vasishth, 2003; Vasishth and Lewis, 2006; and in German: Konieczny, 2000; Konieczny and Döring, 2003; Levy and Keller, 2013) showed that increasing distance can produce a speedup at the site of the dependency completion. In many cases the speedup can be accommodated in the activation-based model since the interposed material can help to strengthen the representation of the upcoming head by activating it through modification (Vasishth and Lewis, 2006). This would entail that the processing of the head will be facilitated since it has already been generated; we will express that here by saying that the VP has been *preactivated*. This is specially relevant for SOV languages, where the arguments of the VP appear preverbally, modifying the VP before the head is parsed. So, in cases such as (3), where the extra material belongs to the VP, the activation-based account will predict that increasing distance should, in fact, result in a speedup (but only if the decay does not offset the benefit of activation; Lewis et al., 2006).

(3) From Vasishth and Lewis (2006)
   a. Vo kaagaz **jisko** us laṛke-ne **dekhaa** bahut puraanaa thaa.
      that paper **which** that boy-ERG **saw** very old was
      'That paper which that boy saw was very old.' (Object relative, no intervening discourse referents)

   b. Vo kaagaz **jisko** us laṛke-ne mez-ke piiche gire.hue **dekhaa** bahut puraanaa thaa.
      that paper **which** that boy-ERG table-GEN behind fallen **saw** very old was
      'That paper which that boy saw fallen behind a/the table was very old.' (Object relative, two intervening discourse referents)

1.2. Expectation-Based Explanations

As in other aspects of cognition, predictions play an important role in language, and evidence from different sources supports the view that language processing does not only depend on bottom-up processes (for a review of prediction in language see: Kutas

et al., 2011). It has been shown that a syntactically constraining context can lead to facilitation when a word is predicted either (i) because of local syntactic constraints related to characteristic of verbs, as proposed by Trueswell et al. (1993), and Konieczny (2000); or (ii) because the parser is able to build structure in a top-down manner, using grammatical or probabilistic information, as proposed by Jurafsky (1996) and Hale (2001). The latter idea was developed further in an expectation-based theory of processing (Levy, 2008) where the main source of difficulty is determined by the surprisal (negative log of the conditional probability) of a word given its context (as proposed by Hale, 2001). The surprisal metric proposed by Hale (2001) formalizes the idea that a more surprising lexical content is also less predictable.

Long-distance dependency resolution is a situation where the comprehender knows that a subcategorizing verb has to appear, but does not know exactly when. Since each constituent of a given category that is integrated after the dependent (a wh-element in this case) eliminates most of the expectation for seeing another constituent of the same type next, each constituent that is read increases the expectation for seeing a constituent of one of the remaining types. Because the subcategorizing verb is one of the remaining types, the expectations of finding it will increase monotonically, and being more expected it will also be processed more easily. In other words, given that the clause has a finite length, the probability that the next word will be the subcategorizing verb rises as the number of words after finding the wh-element increases (in a similar way to an increasing hazard function as proposed for visual search by Peterson et al., 2001, and for the anticipation function of environmental cues in macaques by Janssen and Shadlen, 2005).

Thus, also in the cases where memory-based accounts will predict locality effects (due to integration or retrieval costs), the expectation-based account of dependency resolution will predict the opposite effect: antilocality. The predictions of the expectation-based account for non-local dependency resolution were borne out specially in studies using languages with SOV structures, which showed antilocality effects. However, as mentioned before, in many cases the predicted antilocality effects could also be explained either with local syntactic constraints (Konieczny, 2000) or with an activation-based account (Vasishth, 2003; Vasishth and Lewis, 2006). Independent support for the expectation-based account of antilocality in dependency resolution would come from cases where the length manipulation is independent of material that belongs to the VP and appears preverbally. Cases like this can be found in length manipulations such as (4): object wh-questions where the dependency crosses over a sentence boundary. This is examined in more depth in the experiments of this paper.

(4) a. **Who** has John **called**?
b. **Who** does Mary think that John has **called**?

1.3. Individual Differences

1.3.1. Working Memory Capacity and the Parsing of Unbounded Dependencies

Memory-based accounts of locality effects assume, either implicitly or explicitly, that if more working memory capacity (WMC) is required for processing than is available, longer processing times and/or a higher proportion of errors will result during retrieval or integration. This prediction is implicit in DLT, where the upper limits on storage and integration cost (Gibson and Thomas, 1999; Gibson, 2000) should depend on WMC; and it is explicit in the activation-based model, where low capacity is argued to result in hindered ability to complete a retrieval (Daily et al., 2001). One plausible implication is that low-capacity readers may be more affected by locality effects, showing stronger effects than high-capacity readers.

However, the effect of individual differences in WMC influencing dependency resolution processes has been neglected in the literature (but see: Van Dyke et al., 2014). This absence of work is surprising given that there is considerable evidence for the interaction of individual differences with syntactic and semantic processes (Just and Carpenter, 1992; Pearlmutter and MacDonald, 1995; Traxler et al., 2005, 2012; von der Malsburg and Vasishth, 2013), and there is also evidence for a reduction in performance during long-distance dependency resolution and memory dual-tasks (Fedorenko et al., 2006, 2013).

Regarding the influence of working memory on expectation-based parsing, the predictions are less clear. The studies showing that expectations may play a dominant role only when working memory load is relatively low (Levy, 2008; Levy and Keller, 2013; Husain et al., 2014) suggest that the processes involved in the anticipation of upcoming material may also depend on working memory. This is so because comprehenders' expectations depend on the accumulating information (Levy, 2008). Low-WMC readers, who have a reduced ability to temporarily store and manipulate information, may then be less able to adequately expect upcoming lexical material, relative to high-WMC readers. To our knowledge, the only evidence for this claim, however, comes from Otten and Van Berkum's (2009) ERP study where low-WMC participants showed an additional later negativity (900–1500 ms) to unexpected content.

1.3.2. WMC and Reading Skills

Differences in WMC can successfully explain individual differences in comprehension performance (Daneman and Carpenter, 1980); and this measure of individual differences seems to be the right candidate to account for differential effects in processes related to dependency resolution. There is ample evidence showing that lower WMC reflects higher limitations in attention allocation for goals (Engle, 2002), and several studies have shown the predictive power of WMC for language comprehension ability (for a meta-analysis of 77 studies till the mid-nineties: Daneman and Merikle, 1996). Furthermore, some studies have shown that individuals with lower capacity are less successful in integrating information over distance in a text (Daneman and Carpenter, 1980; Yuill et al., 1989), and have greater comprehension deficits, in part, because they are less able to maintain on-task thought (McVay and Kane, 2011). Moreover, low-capacity participants seem to have a greater disadvantage than high-capacity participants when they face difficult sentences (for garden-path vs. non-garden path sentences: Christianson et al., 2006; for comprehension reaction times in subject- vs. object-relative clauses: King and Just, 1991; Vos et al., 2001). The reason for differences in WMC may be rooted in the variability in either a limited amount

of activation (Just and Carpenter, 1992; van Rij et al., 2013), computational resources available or processing efficiency (among others: Daneman and Carpenter, 1980; Daneman and Carpenter, 1983), the ability to overcome interference (Hasher and Zacks, 1988; Unsworth and Engle, 2007), or the efficiency of retrieval cues present in the active portion of working memory (Ericsson and Kintsch, 1995).

It is possible, however, that individual differences in capacity only reflect experience and not intrinsic capacity differences (MacDonald and Christiansen, 2002; Wells et al., 2009). Readers characterized as high-capacity may indeed be more sensitive to the semantic cues available to them, as proposed by Pearlmutter and MacDonald (1995), but mainly because these readers also have more language experience. In fact, recent work by Traxler et al. (2012) raises the concern that WMC correlates with many other reader characteristics. According to Traxler et al., fast readers, who read more often than slow readers, will have greater experience with language; this would in turn make them more sensitive to semantic cues in the syntactic analysis. In a new set of analyses based on Traxler et al.'s (2005) data set, Traxler and colleagues found that WMC interacted with sentence-characteristic variables only when reading speed was not included in the model (since they assumed that reading speed was a measure of reading skills).

In order to obtain a reliable measure of working memory that is not correlated with reading speed and experience, we chose to use the operation span task (Turner and Engle, 1989; Conway et al., 2005). In addition, we adopted the rapid automatized naming task (Denckla and Rudel, 1976), since it has been shown that it predicts reading speed, comprehension, and other characteristics associated with reading skills (among others: Kuperman and Van Dyke, 2011). The inclusion of both tasks can therefore help to determine whether it is WMC and/or reading experience that account for differences in dependency resolution processes.

2. Experiments

The experiments have two main objectives. The first objective is to disentangle memory- and expectation-based explanations on the processing of long-distance dependencies. While both the expectation and activation accounts may predict antilocality effects, the activation-based model predicts that facilitation should occur when intervening material modifies an upcoming head, whereas the expectation account predicts facilitation regardless of what the intervening material modifies. Even though this is an oversimplification of the expectation account as defined by Hale (2001) and Levy (2008), it should hold for the type of sentences we included in our stimuli.

The second objective is to examine the effect of individual differences in dependency resolution: if working memory constraints are involved, participants with different WMC should show differential locality or antilocality effects.

In order to address these objectives, we measured WMC and reading skills of (Argentinean) Spanish native speakers, and we used both self-paced reading and eyetracking methodologies to provide converging evidence. The use of Spanish stimuli allowed us to investigate antilocality effects in an SVO language. In addition, because of the relatively free order and long sentences permitted by Spanish, we could do a manipulation that is more common in studies that investigate antilocality in *SOV* structures: increasing the dependent-head distance by interposing material that belongs to the verbal phrase (VP) but appears prior to the verb.

The design of the stimuli is exemplified by (5). The distance between the wh-element and the head verb (*had fired*) was manipulated by including an adverbial phrase (AdvP; *before some days*) that attaches to the different VPs in the sentence. Hence there are two different aspects of the manipulation to consider for each condition: (i) the attachment site of the adverbial phrase (main VP, intermediate VP, and last VP where the dependency is completed) and (ii) the length of the dependency between the wh-word (who.ACC) and the head verb. In (5a), the length of the dependency is the shortest one, since the AdvP is attached to the main clause VP *asked* (henceforth condition VP1). This entails that by the time the dependency is started at the wh-element, the AdvP has already been interpreted. In this condition, the action that was performed *before some days* was the "asking." In both conditions (5b) and (5c) the dependency length is larger than in (5a), since the the AdvP is interposed between the dependent and head verb. However, while in (5b) the AdvP modifies an intermediate VP (henceforth condition VP2), in (5c) it modifies the third VP, which contains the head verb, where the dependency is completed (henceforth condition VP3). So while in condition VP2 the "saying" happened *before some days*, in condition VP3 the "firing" of the dependent "who.ACC" was *before some days*. All the items had as a second verb either *comentar* or *decir* "to say." Even though these two verbs are ditransitive, the ditransitive construction is extremely uncommon in Argentinean Spanish without a clitic. This means that the reading that would allow an indirect object such as *a quién* completing the dependency is very unlikely (for a similar construction in Spanish with clitic left-dislocation, see Pablos, 2006). Since this type of verbs appears in all conditions, and they are not in the region of interest, they should not affect the experiment. Notice, as well, that the head verb position is kept fixed across conditions in order to avoid word-position effects (Ferreira and Henderson, 1993). The characteristics of the stimuli are summarized in **Table 1**.

(5) a. ATTACHMENT AT VP1

Hace algunos días, José preguntó **a quién**
Before some days José asked **who.ACC**
comentaron que el gerente **había despedido**
they-said that the manager **had fired**
por equivocación.
because-of mistake

"Some days ago, José asked who they said that the manager had fired by mistake."

b. ATTACHMENT AT VP2

José preguntó **a quién**, hace algunos días,
José asked **who.ACC** before some days
comentaron que el gerente **había despedido**
they-said that the manager **had fired**
por equivocación.
because-of mistake

"José asked who they said some days ago that the manager had fired by mistake."

c. ATTACHMENT AT VP3

José preguntó **a quién** comentaron que,
José asked **who.ACC** they-said that
hace algunos días, el gerente **había despedido**
before some days the manager **had fired**
por equivocación.
because-of mistake

"José asked who they said that the manager had fired some days ago by mistake."

2.1. Predictions

Predictions for the critical region (head verb) are summarized in **Table 2**. When the dependency length is increased (VP2 vs. VP1 and VP3 vs. VP1), DLT predicts increased processing effort, that is, locality-effects. In contrast, the expectation account predicts facilitation at the head verb, that is, antilocality effects. The activation-based model predicts, similar to DLT, increased processing effort for both VP2 and VP3 due to the decay of the wh-element. However, in contrast to DLT, the activation-based model also predicts that in VP3 this difficulty should be counteracted by the preactivation of the VP that contains the head verb. According to the activation account, while VP2 should display locality effects, the effect displayed by VP3 should depend on which underlying process is stronger: activation or decay (which in turn should depend on WMC).

It should be noted that while for self-paced reading experiments stronger locality effects imply longer reading times (Gibson, 2000; Grodner and Gibson, 2005; Bartek et al., 2011) and stronger antilocality effects imply shorter ones (Konieczny, 2000; Vasishth and Lewis, 2006; Levy, 2008), for eye-tracking studies these effects have been associated with different measures. Locality has been associated with the increase in the duration of first pass reading times in Staub (2010), total reading times and second pass reading in Bartek et al. (2011) and Levy and Keller (2013), and higher re-reading probabilities in Vasishth and Drenhaus (2011); and antilocality with the reduction of the duration of total reading times and second pass reading in Levy and Keller (2013), regression-path durations in Konieczny and Döring (2003), and lower first-pass regression probabilities in Vasishth and Drenhaus (2011).

Since the processing efforts of DLT and the activation account are associated with working memory constraints, according to these memory-based theories, participants with different WMC should show differential effects: the parse of the critical region will require more processing effort for low-WMC readers than for high-WMC. Thus, DLT predicts that as WMC increases, locality effects should decrease; and for high WMC (compared to low WMC) there should be the smallest difference between long and short conditions (see **Figure 1A**). For the expectation account, it is not clear whether WMC plays a role at all. If WMC is not relevant, there should not be a differential effect depending on the WMC of the readers (as in **Figure 1C**). It may be the case, however, that readers with more WMC are able to predict upcoming material better, then they should also display stronger antilocality effects (till a certain limit: either a minimal duration of the fixations or reading times or virtually no re-reading, as it is seen in **Figure 1D**). Regarding the activation-based account, its prediction for condition VP2 should be the same as the one of DLT: as WMC increases, locality effects should decrease; however, for condition VP3 the locality effects should be counteracted with facilitation due to preactivation, and given enough WMC, readers should offset the processing efforts and display antilocality effects (**Figure 1B**).

However, expectation and memory-based theories are not mutually exclusive; recent research supports the idea that insights from both types of theories are needed (Staub, 2010; Vasishth and Drenhaus, 2011; Levy and Keller, 2013; Levy et al., 2013; Husain et al., 2014). If DLT acts together with the expectation account (either the type that does not depend on memory, see **Figure 1C**, or the one that does depend on memory, see **Figure 1D**), locality effects should decrease as WMC increases until they become increasing antilocality effects, but, as before, the facilitation should not exceed a certain lower limit (see **Figure 1E**). As it is the case with each of these two accounts independently, the combination of DLT with the expectation account does not predict any difference between VP2 and VP3. If the activation-based model acts together with the expectation account, locality effects should also decrease together with an increase of WMC till they become increasing antilocality effects. However, processing efforts should be weaker and facilitation stronger for VP3 in contrast to VP2, since the facilitation of VP3 has two sources: expectations and preactivation, while the source of facilitation in VP2 is only expectations (see **Figure 1F**).

TABLE 1 | Summary of the conditions.

Cond.	Constituent modified by AdvP	Dependency length
VP1	Main VP (head: asked)	Short
VP2	Intermediate VP (head: said)	Long
VP3	VP where the dep. is completed (head: had fired)	Long

VP3	Facilitation	Difficulty	Difficulty and Facilitation

2.2. General Procedure

Participants were tested individually using a PC computer. They got an overview of the whole experiment and then completed three tasks at their own pace: First, they performed a rapid automatized naming task; second, an operation span task; and

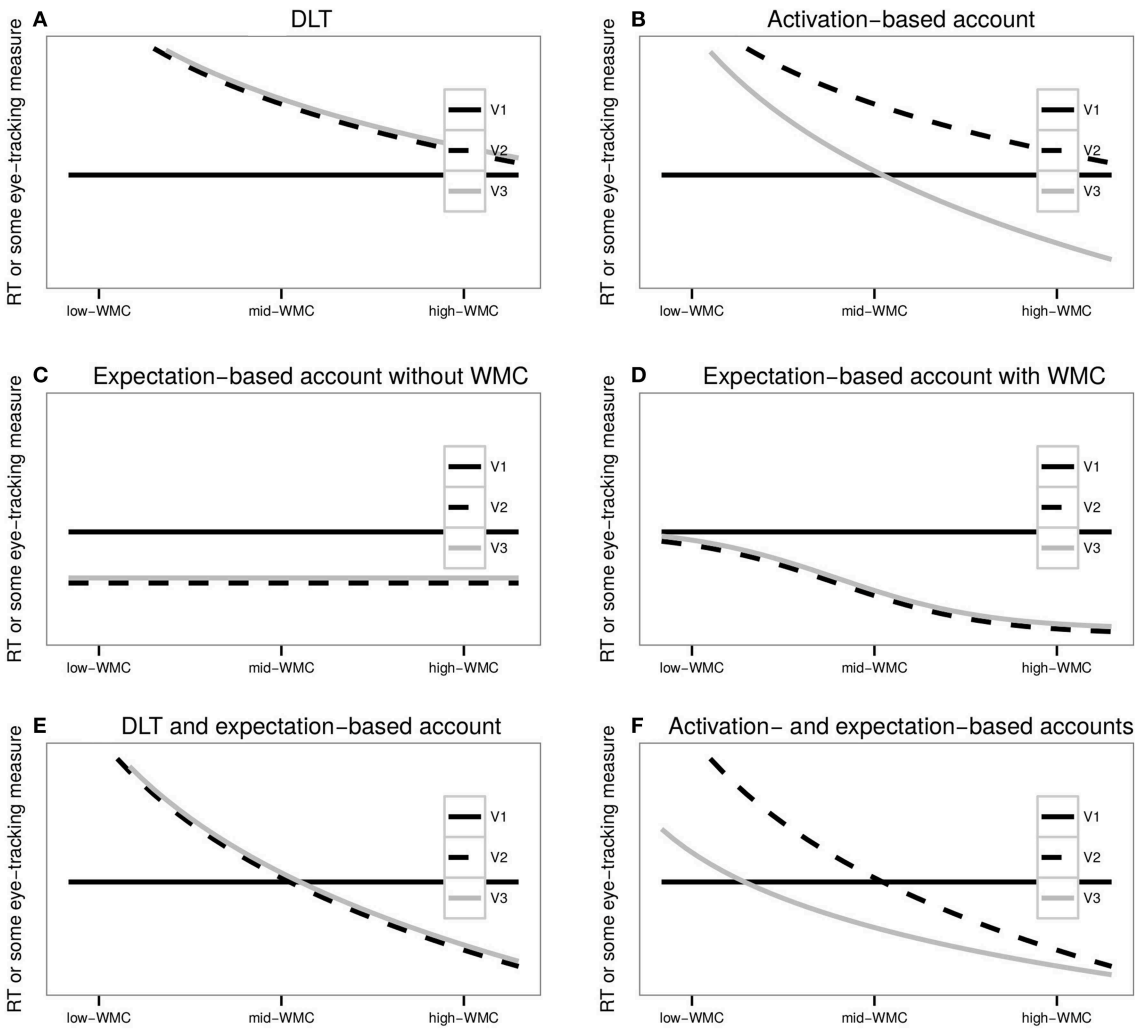

FIGURE 1 | The figure depicts the predictions of (A) DLT, (B) activation-based account, (C) expectation-based account unaffected by WMC, (D) expectation-based account affected by WMC, (E) the combination of the predictions of DLT and the expectation-based account, and (F) the combination of the predictions of the activation- and the expectation-based accounts.

finally, subjects performed an eye-tracking experiment in Experiment 1, and a self-paced reading task in Experiment 2.

2.2.1. Operation Span Task

Participants took part in the operation span task (Turner and Engle, 1989) using a software developed by von der Malsburg (https://github.com/tmalsburg/py-span-task) and used in von der Malsburg and Vasishth (2013) following the recommendations given in Conway et al. (2005). Even though variants of the reading span task by Daneman and Carpenter (1980) have been used in many psycholinguistic studies, it is likely that the reading span task measures verbal ability or reading experience as well as WMC (MacDonald and Christiansen, 2002; Conway et al., 2005). Since reading experience is also a good candidate for explaining differential effects in sentence processing, a solution is to include a nonverbal task to examine the domain-general aspects of cognition that may contribute to the individual differences (Swets et al., 2007). Since the operation span task probably measures mathematical ability as well as working memory (but not reading skills), if higher scores of the operation span task predict facilitation between experimental conditions, it would be unlikely that the result could be explained by the effect of reading experience alone.

The procedure of the operation span task test was similar to the one employed by von der Malsburg and Vasishth (2013) with some minor modifications: First, participants had to verify the correctness of 25 simple equations. At this stage, the reaction time of the Equations 10 to 25 was measured; the average reaction time plus two standard deviations was used as a time-out at the second stage. Calculating a time-out for every participant ensures that participants that are fast will not have time left to rehearse the items at the following stage of the test. Afterwards, participants had to carry out a dual task: check equations and memorize letters that were shown between the equations for

800 ms. After a group of equation-letter successions, participants were instructed to type in order the letters that had appeared before.

Before participating in the actual test, subjects practised with four trials of equation-letter successions. In the main test, successions of equation-letter had between three and seven elements, and there were eight sets for each size resulting in 32 trials. Presentation order of the sets was randomized and no feedback regarding the correctness of the judgments of equations or recalled items was given.

In all parts of the test, participants had to read the equations and letters aloud in order to prevent vocal rehearsal strategies. Only consonants were used as memory items to prevent participants from forming "words" with vowels and consonants, or "sentences," if words had been used.

Partial-credit unit scores, which indicate the mean proportion of correctly recalled items within the sets (Conway et al., 2005), were used as a numeric score of individual working memory.

2.2.2. Rapid Automatized Naming Tasks

Working memory-capacity correlates with other reader characteristics, which may in turn account for the variance in participants' reading behavior as well as or better than working memory capacity (Traxler et al., 2012). To determine whether working memory capacity correlates with reading times independently of reading skills, it is important to assess the effects of working memory capacity in the presence of some measure of reading skills.

Even though there are different ways to measure reading skills (among others: speeded naming abilities, oral language ability, vocabulary, attention), Kuperman and Van Dyke (2011) analyzed which tests from a broad battery of individual difference measures were predictive of eye-movement patterns associated with reading ability. They showed that rapid automatized naming was a robust predictor across the entire eye-movement record.

Participants with longer rapid automatized naming times tend to have lower reading comprehension scores, slower reading rates and their initial landing position when fixating tends to be further to the left (among others: Howe et al., 2006; Arnell et al., 2009; Kuperman and Van Dyke, 2011). Moreover, rapid automatized naming tasks seem to recruit a network of neural structures also involved in more complex reading tasks (Misra et al., 2004). In normal reading, readers must be able to disengage from one stimulus and move to another, rapidly programming saccades as the eyes move. Since this task involves speeded serial visual inspection and subsequent naming of items, the oculomotor component of this task is very similar to that required in natural reading.

In order to measure rapid automatized naming times, the first author developed a software that automatizes the test (https://github.com/bnicenboim/py-ran-task). In this task, participants saw a grid containing items (either letters or digits), and they were instructed to name them as fast as possible.

Each subject read a series of screens with 50 items; the items were the same set of letters or numbers that were used in Denckla and Rudel (1976): {o, a, s, d, p} and {2, 6, 9, 4, 7}. The first eight trials were composed of letters and the following eight had numbers. The items were displayed in five rows of ten columns and were listed in random order with the constraint that adjacent items were not the same. Before every trial, a screen with underscores instead of the items was displayed.

The participants were instructed to read aloud as fast as possible, and in case they misread, they were instructed to reread only the misread item. The test started with two practice trials to familiarize the participants with the task. Each trial started and ended with the spacebar: participants were instructed to start reading immediately after pressing the spacebar, and to press it again immediately after finishing reading aloud the last item.

Since the total reading times for letters and for numbers were highly correlated ($r = 0.88$ for Experiment 1 and $r = 0.87$ for Experiment 2), both were averaged together. The inverse of this averaged reading time was used as the *reading skills measure*; this way the measure furnishes an intuitive value associated with speed: a higher value represents a more skilled reader.

2.2.3. Data Analysis

The data analysis was conducted in the R programming environment (R Core Team, 2013), using either linear mixed-effects model (LMM; Pinheiro and Bates, 2000) or generalized linear mixed-effects models with a binomial link function to the response data (GLMM). Both are regression models that include both fixed effects (such as predictors) and random effects, and they are available in the package *lme4* (Bates et al., 2015). Since LMMs minimize the false positives when they include the maximal random effects structure justified by the design (Schielzeth and Forstmeier, 2009; Barr et al., 2013), both LMMs and GLMMs were fit following this guideline. However, the random effects structure was simplified by removing the correlations, since the models either did not converge or the correlation between variance components could not be estimated.

For large samples, the t distribution approximates the normal distribution and an absolute value of t larger than 2 indicates a significant effect at $\alpha = 0.05$. For all the models presented in the study, covariates such as WMC and reading skills were scaled and centered.

3. Experiment 1

3.1. Method

3.1.1. Participants

Seventy-six subjects aged between 17–42 years old (mean 24.1 years) participated in this experiment in Buenos Aires, Argentina. All participants were native speakers of Spanish and were naïve as to the purpose of the study. Five participants were excluded from the analysis: two participants had reading glasses that prevented an adequate calibration of the eye-tracker, two performed poorly in the mathematical task of the operation span test (with less than 70% accuracy), and another subject reported that she consciously re-read every sentence.

Partial-credit unit scores (Conway et al., 2005) for the operation span test measuring WMC of the remaining 71 participants ranged between 0.232–0.801 with an average of 0.543 (*SE*: 0.013).

Average character speed for the rapid automatized naming task for measuring reading skills ranged between 1.44–3.72 characters/second with an average of 2.54 (*SE*: 0.06) characters/second.

3.1.2. Stimuli

The stimuli for this experiment consisted of 48 items with three conditions (place of attachment) similar to example (5). Each participant read the 48 items together with 120 unrelated sentences (72 were experimental items of two unrelated experiments and 48 sentences were filler sentences) in an individually randomized order. The 144 experimental sentences (48 items in three conditions each) were presented in Latin square design. In order to ensure that participants had paid attention to the sentences, a true-or-false comprehension task was presented after half of all trials in the experiment, including fillers. Half of these statements were true and half false. For the sentences in (5), for example, the statement was false and it was the following: *El gerente fue despedido por equivocación.* "The manager was fired by mistake." The statements following other experimental sentences focused on different aspects of the stimuli: the participants (such as "Jose fired someone."), the action ("The manager hired someone."), the setting of the action (such as "Someone was fired on purpose."), etc. We chose to use true-or-false statements instead of yes-no questions in order to avoid long and unnatural questions.

3.1.3. Procedure

Participants performed the eye-tracking task after having completed a rapid automatized naming task and an operation span task. Before the eye-tracking experiment began, each participant was instructed to read for comprehension in a normal manner and had a practice session of seven sentences. Eye movements were recorded using an EyeLink 1000 eye-tracker, interfaced with a PC. Stimuli were displayed on an 21" monitor. Subjects were seated 65 cm from the computer screen. Viewing was binocular, but only the right eye was recorded. All sentences were displayed on a single line and were presented in twelve points Arial font. At the beginning of each trial, a dot appeared at the left edge of the screen and after participants fixated on this dot, the sentence appeared. Participants had to look at the bottom right corner of the screen to indicate they had finished reading. True-or-false statements appeared randomly for half of the stimuli at this point. No feedback was given as to whether the response was correct or not. After reading half of the sentences, participants took a 10-min break. A calibration procedure was performed at the beginning of the eye-tracking experiment, at the end of the break, and between trials as needed.

3.1.4. Data Analysis

Detection of saccades and fixations was done using a modification of the saccades package developed by von der Malsburg (https://github.com/tmalsburg/saccades), and eye-tracking measures were computed using *em2* package (Logačev and Vasishth, 2013). The appropriate transformation of the dependent variable was determined using the Box-Cox method (Box and Cox, 1964; Kliegl et al., 2010) with the boxcox function in the MASS package (Venables and Ripley, 2002). The log transformation was suggested as the most appropriate transformation.

3.2. Results

3.2.1. Comprehension Accuracy

Participants answered correctly on average 80% (*SE*: 1) comprehension probes of all trials, and 82% (*SE*: 1) of the trials belonging to the experiment. The comprehension accuracy for the experimental trials ranged between 58 and 100%, while the 25th, 50th, and 75th quartiles were 75, 83, and 90% respectively. In addition, a GLMM showed that WMC was a significant predictor of accuracy (higher capacity led to greater accuracy); Coef $= 0.21$, $SE = 0.10$, $z = 1.98$, $p = 0.048$.

3.2.2. Eye-Tracking Measures

Reading times were inspected at three regions of interest: the first critical region (auxiliary verb "había"), second critical region (participle form of the verb), and spillover region (P). We used successive differences contrast coding to test the predictions of the different accounts: VP2 (coded as 1) against VP1 (coded as -1) and VP3 (coded as 1) against VP2 (coded as -1). As in Vasishth and Drenhaus (2011), we found effects in the critical regions only in dependent measures related to re-reading; in the spillover region, we found effects only for total fixation time, consistent with Levy and Keller (2013). We provide the analysis of regions of interest for first-pass regression probability, re-reading probability and total fixation time. As defined in Vasishth and Drenhaus (2011), first-pass regression probability at a word is the probability of the eye moving leftwards after this word was fixated at least once; re-reading probability for a word is the probability of revisiting that word after having having made a first-pass.

After inspecting each LMM with total fixation time as dependent variable, we removed 0.12% of the data in order to keep the residuals normally distributed; the results of the model were virtually the same without this removal. Below we report only statistically significant effects.

3.2.2.1. First critical region (auxiliary verb "había")

We found a WMC and VP2-VP1 interaction for first-pass regression probabilities (Coef $= -0.38$, $SE = 0.17$, $z = -2.17$, $p = 0.03$) showing that as WMC increases, the probability of a regression at the auxiliary verb decreases for condition VP2 in comparison with VP1 (as shown in **Figure 2**).

Since we did not find evidence of more facilitation in VP3 in comparison with VP2, we also fitted a separate model that included the VP3-VP1 contrast. We found a decrease in re-reading probability for VP3 in comparison with VP1 (Coef $= -0.28$, $SE = 0.12$, $z = -2.40$, $p = 0.016$).

3.2.2.2. Second critical region (participle form)

As in the first critical region, we found a decrease in re-reading probabilities for VP3 condition in comparison with VP1 (Coef $= -0.20$, $SE = 0.10$, $z = -1.99$, $p = 0.047$).

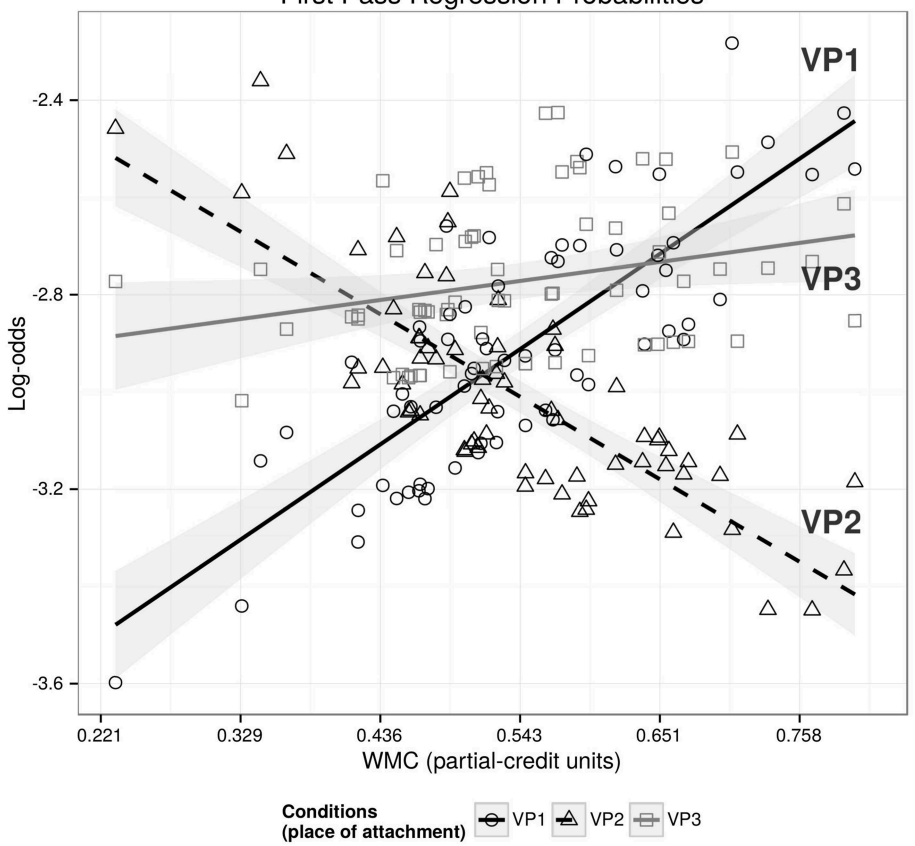

FIGURE 2 | The figure depicts the partial effects on first pass regression probabilities in log-odds scale for the contributing factors condition, WMC, and their interaction; random factors variance and effects due to reading skills were removed from the dependent variable using the remef function (Hohenstein and Kliegl, 2013).

3.2.2.3. Spillover (preposition)

We found a significant speedup for VP2 in comparison with VP1 for total reading time (Coef $= -0.06$, $SE = 0.03$, $t = -2.07$), and an unpredicted interaction between reading skills and VP2-VP1 (Coef $= 0.09$, $SE = 0.03$, $t = 2.86$) showing that as reading skills increases, total reading times at the spillover for condition VP2 increase in comparison with condition VP1.

3.3. Discussion

The central finding in the eye-tracking study is that individual differences associated with working memory have an impact in parsing sentences with long-distance dependencies. When the extra material modifies the intermediate VP (VP2), results for first pass regression probabilities for the critical region are consistent with the idea that expectations play a dominant role when the individual capacity of the participants is large enough to overcome the memory-driven locality effects (see **Figure 2**). That is, locality effects may become antilocality effects when WMC is large enough. This pattern can be explained by a memory account acting together with the expectation account. However, from this pattern alone it is not clear whether DLT or the activation-based model best explain the data. The predictions of DLT are based solely on dependency length, entailing that VP2 should be fully aligned with VP3 (see **Figure 1E**). The activation-based model predicts facilitation when the extra material is attached to the head verb, that is, facilitation for VP3 in comparison with VP2 (while sharing the same lower asymptote for extremely high WMC; see **Figure 1F**). At least for first pass regression probabilities for the critical region, it is unclear where VP3 condition stands: there is no significant facilitation in comparison with VP1 as all the described accounts would predict.

However, the study does provide some evidence for a differential effect that depends on *where* the extra material is attached, and not just on the linear distance of the dependency (as DLT and expectation account would predict). When the extra material is part of the same VP as the subcategorizing head verb (VP3), re-reading probabilities show facilitation compatible both with expectations and with the preactivation of the subcategorizing verb and similar to the evidence from SOV languages (Konieczny, 2000; Konieczny and Döring, 2003; Vasishth, 2003; Vasishth and Lewis, 2006; Levy and Keller, 2013). The fact that

facilitation occurs only for VP3 condition in comparison with the short dependency condition VP1, and not when the extra material modifies the intermediate VP (VP2), provides some indirect evidence indicating differential facilitation between VP2 and VP3 as predicted by the activation account.

As mentioned before, one of the main differences between the predictions depicted in **Figure 1** and our results is the status of VP3 condition: The facilitation of VP3 in comparison with the baseline VP1 appears in a different measure (re-reading instead of regression probabilities) than the facilitation of VP2 condition (in comparison with VP1), and it "spilled over" to the second critical region. In addition, and in contrast with VP2, the facilitation did not depend on the WMC of the participants.

Regarding the differences in the eye-tracking measures and spillover, the effect of adding preverbal material may have been more complex than hypothesized. The preverbal material may have added a new retrieval process at the head and thus overshadowed any facilitation caused by increased expectations. Furthermore, the appearance of the facilitation in different measures can be accounted for by assuming that facilitation due to preactivation, and facilitation due to increased expectations depend on different underlying mechanisms resulting in qualitatively different behavioral consequences in reading (Staub, 2010).

We can speculate that the difference in processing difficulty between VP3 and VP1 did not depend on WMC in our results because at VP3 condition, the facilitation has already reached a bottom asymptote (the minimum re-reading probability given the complexity of the stimuli; see **Figure 2F**). This lack of an effect of WMC on the facilitation might presumable be because of our relatively homogeneous pool of participants, who did not display a big enough variance in their WMC.

4. Experiment 2

This experiment is a replication of Experiment 1 using self-paced reading methodology. Even though eye-tracking experiments provide a more natural setting than self-paced reading, eye-tracking allows participants reading strategies that are absent in self-paced reading, such as skipping words and re-reading. Moreover, since it is possible to calculate many different eye-tracking measures, the chance of getting a false positive (a Type I error) goes up due to the multiple testing problem. Thus, one important motivation for the self-paced reading experiment was to determine whether the previous results were robust. A second motivation was to attempt a replication of the eye-tracking result using a different method. The absence of replication has been recognized as a major problem in psychology and related areas (Asendorpf et al., 2013).

4.1. Method

4.1.1. Participants

Eighty subjects aged between 18–44 years (mean age 25 years) participated in a self-paced reading experiment in Argentina. The first 34 subjects participated in Buenos Aires and the rest in Mendoza. All participants reported to be native speakers of Spanish and were naïve to the purpose of the study. Only one participant was excluded from the analysis, since s/he reported, after the experiment had been completed, that s/he suffered from a mental disorder related to memory.

Partial-credit unit scores for the operation span test measuring WMC of the remaining 79 participants ranged between 0.373–0.882 with an average of 0.631 (*SE*: 0.015). Average character speed for the rapid automatized naming task for measuring reading skills ranged between 1.60–3.45 characters/second with an average of 2.40 (*SE*: 0.05) characters/second.

4.1.2. Stimuli

The stimuli for this experiment consisted of 36 items similar to the items of Experiment 1, but with an extended spillover region. This extra region was included in case the self-paced reading task may delay the effects seen in the eye-tracking experiment.

Similarly to Experiment 1, each participant read the 36 items together with 176 unrelated sentences (120 were experimental items of three unrelated experiments and 56 sentences were filler sentences) in an individually randomized order after six practice trials; and the stimuli were presented in a Latin square design. A true-or-false comprehension task was presented after 65% of all trials in the experiment, including fillers. As in the previous experiment, the statements focused on various aspects of the stimuli, and the proportion of true and false statements was balanced.

4.1.3. Procedure

Subjects were tested individually using a PC. Participants completed the three tasks at their own pace: First, they performed a rapid automatized naming task, second, an operation span task, and finally, a self-paced reading task (Just et al., 1982).

Before the self-paced reading task began, each participant was instructed to read for comprehension in a normal manner and had a practice session of six sentences. All sentences were displayed on a single line and were presented in 18 pt Arial font using Linger software (http://tedlab.mit.edu/~dr/Linger/). In order to read each word of a sentence successively in a moving window display, participants had to press the space bar; then the word seen previously was masked and the next word was shown. At the end of some of the sentences, participants had to answer whether a certain statement related to the experimental item was true or false. No feedback was given as to whether the response was correct or not. Twice during the self-paced reading task, a screen announced the number of sentences read so far and invited the participants to take a break.

4.1.4. Data Analysis

The appropriate transformation of the dependent variable according to the Box-Cox method (Box and Cox, 1964) was the inverse transformation. We used $(-10^5/RT)$ to improve the readability of the models (a positive t-value for $-10^5/RT$ corresponds to a positive t-value of the untransformed measure RT).

4.2. Results

4.2.1. Comprehension Accuracy

Participants answered correctly on average 77% (SE: 1) comprehension probes of all trials, and 70% (SE: 1) of the trials belonging to the experiment. The comprehension accuracy for the experimental trials ranged between 46 and 88%, while the 25th, 50th,

and 75th quartiles were 62, 71, and 77% respectively. As in Experiment 1, a GLMM showed that WMC was a significant predictor of accuracy, with higher capacity leading to greater accuracy; Coef = 0.15, $SE = 0.07$, $z = 2.02$, $p = 0.043$.

4.2.2. Reading Times

We compared reading times at the same three regions of interest as in Experiment 1, using the same successive differences contrast coding. Since the effects appeared in the same regions as in Experiment 1, the added spillover regions were omitted from the analysis.

We removed 0.18% of the data in order to keep the residuals normally distributed; the results of the model were virtually the same without this removal.

4.2.2.1. First critical region (auxiliary verb "había")

For this region, including a quadratic term for WMC was justified according to a model comparison; an anova comparison of models based on a Chi-squared test yielded: $\chi^2_3 = 10.7$, $p = 0.013$.

The main results for this region are displayed in **Table 3**. Consistent with the indirect evidence in Experiment 1 (recall that for re-reading probabilities, we found significant facilitation in VP3 vs. VP1, but not in VP2 vs. VP1), we found a differential facilitation between VP2 and VP3: the critical region was read faster in VP3 in comparison with VP2. We also found a significant interaction between WMC^2 and VP2-VP1 showing an inverted U-shaped effect of WMC on reading times (see **Figure 3**), that is, shorter reading times in VP2 vs. VP1 for low and high-WMC than for mid-WMC. In other words, speedups were seen in low as well as high-capacity readers, but not in medium-capacity readers. An interaction between WMC and VP2-VP1, even though non-significant, suggests that the speedup may be stronger for high-WMC than for low-WMC. We also found significant interactions between WMC and VP3-VP2, and between WMC^2 and VP3-VP2. Due to these findings, we also fitted a separate model that included the VP3-VP1 contrast. This new model revealed that the effect of WMC was only relevant in relation to VP2 (as can be seen in **Figure 3**).

As expected, subjects with higher reading skills scores tended to have shorter reading times, but we also found an unpredicted interaction of reading skills with VP3-VP2 showing that as the reading skill score increases, reading times at the critical region get increasingly shorter for VP3 in comparison with VP2.

4.2.2.2. Second critical region

For these regions a quadratic term for WMC was not justified, so we report the main findings for the model including only linear terms for WMC and reading skills. As in the previous region, there was a speedup for VP3 in comparison VP2, which was independent of WMC (Coef = −7.17, $SE = 3.97$, $t = -1.81$). The results showed reading skills to be significant as well: subjects with a higher score tended to have shorter reading times (Coef = −30.11, $SE = 7.46$, $t = -4.03$).

TABLE 3 | Summary of the fixed effects in the LMM with a quadratic term of WMC for reading times at first critical region in Experiment 2.

Predictor	Coef	*SE*	*t*
VP2 vs. VP1	7.0	5.7	1.2
VP3 vs. VP2	−18.0	5.8	−3.1*
WMC	−2.5	6.6	−0.4
WMC^2	−5.6	6.3	−0.9
RS	−25.6	6.6	−3.9*
VP2 vs. VP1 : WMC	−7.3	4.2	−1.7
VP3 vs. VP2 : WMC	9.3	4.2	2.2*
VP2 vs. VP1 : WMC^2	−11.2	4.0	−2.8*
VP3 vs. VP2 : WMC^2	10.3	4.0	2.6*
VP2 vs. VP1 : RS	6.5	4.1	1.6
VP3 vs. VP2 : RS	−9.4	4.1	−2.3*

* *indicates a significant effect at* $\alpha = 0.05$.

4.3. Discussion

The main results of the self-paced reading study are an inverted U-shaped effect of WMC on reading times for the first critical region for the condition where the extra material modified the VP (VP2) in comparison with the condition with the short dependency (VP1), and a speedup at the two critical regions when the extra material modified the VP that contained the subcategorizing verb (VP3) in comparison with when it modified the intermediate VP (VP2).

The study thus shows that individual differences associated with working memory have an impact in reading strategies for processes associated with build-up of expectations and retrieval. Moreover, this study provides more evidence for a differential effect that depends on whether the VP that contains the head of the dependency is modified, as predicted by the activation-based model, but not by DLT and the expectation account.

We found that when the extra material modifies the VP where the dependency is completed (VP3), participants showed a speedup in comparison with the condition where the extra material modifies the intermediate verb (VP2). Since the dependencies in both conditions had the same length, this experiment provides further evidence for facilitation because of preactivation of the subcategorizing verb as predicted by the activation-based account (Vasishth and Lewis, 2006; and consistent with **Figure 1F**).

The data also showed a surprising inverted U-shaped interaction between WMC and VP2-VP1 conditions. An analogy to exam-taking may explain how two different underlying causes may lead to a process finishing early: students leave an examination hall early either because they do not have the resources (knowledge, skills, etc.) to complete the exam (i.e., they effectively give up), or because they have the resources in excess and can complete the exam quickly. Similarly, there may be two different reasons for the shorter RTs: Low-WMC subjects may read fast because they have done a shallow parse due to not having enough computational resources (probably using a good-enough parsing heuristic see: Ferreira et al., 2002; Ferreira and Patson, 2007), while high-WMC participants may read fast because they did a complete parse and still had enough resources to take advantage of the build-up of expectations (see the right part of **Figures 1E,F**). Medium-WMC participants, however, may have built a complete parse but either did not have enough resources

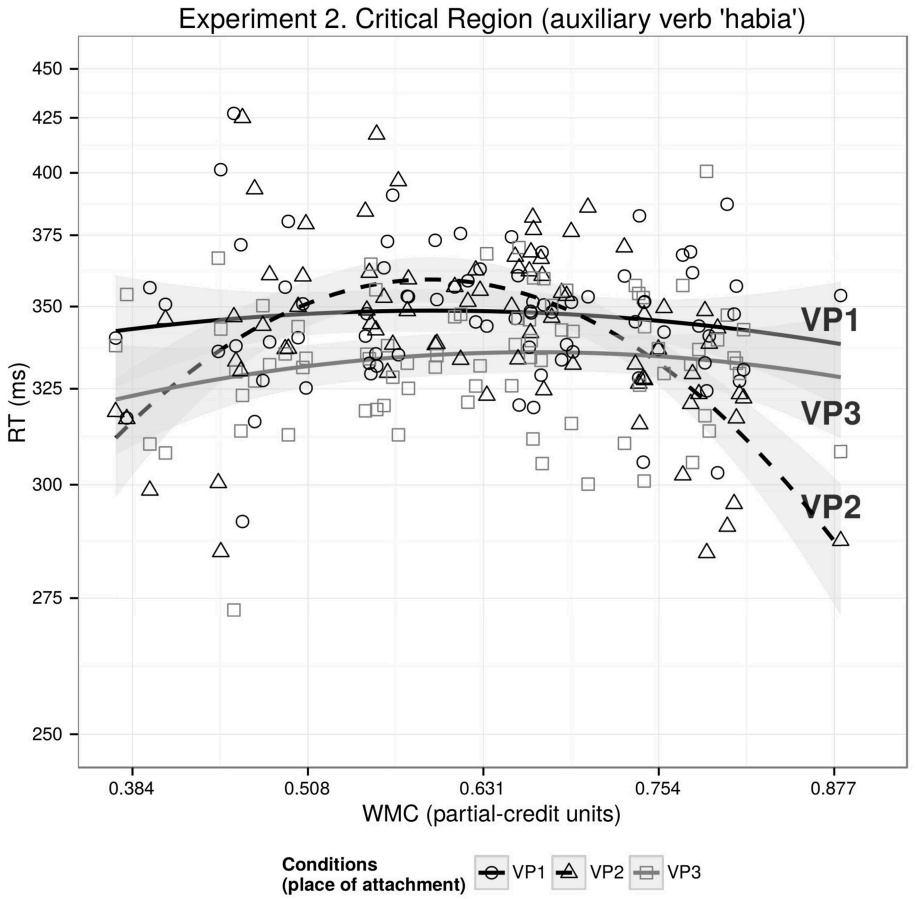

FIGURE 3 | The figure depicts the partial effects on the transformed -1/RT scale for the contributing factors condition, WMC, WMC^2 and their interaction; random factors variance and effects due to reading skills were removed from the dependent variable using the remef function (Hohenstein and Kliegl, 2013).

available for the build-up of predictions of the upcoming head, or the memory-driven locality effect offset the facilitation due to expectations. The difference between this study and the eye-tracking study may be due to the increased task demands of self-paced reading and the impossibility of making regressive saccades. This difference is also evident from the lower comprehension accuracy in self-paced reading in comparison with eye-tracking (70 vs. 82%).

As in the previous experiment, the speedup at the critical region depends only on WMC when the dependent-head distance is increased without a modification of the VP that contains the head (VP2-VP1), while the speedup is independent of WMC when distance is increased by a modification of the VP that contains the head (VP3-VP1). As it was shown in **Figures 1B,F**, it is expected that a facilitation that depends on WMC will have a bottom asymptote since the duration of the reading times cannot be zero and presumably there is a minimum time needed (for recognizing the word, pressing the space bar, etc). Since the activation-based model predicts stronger facilitation for VP3 in contrast to VP2, it also predicts that the effect of WMC on VP3 will reach the bottom asymptote earlier than on VP2 (and thus showing a "flat" WMC effect if all the participants have a relatively high WMC). It should be noted that for the extremely high values of WMC, however, the speedup of VP2 is stronger than of VP3, which is not predicted by the activation-based model (and neither by the expectation account or DLT). However, this is true for a few subjects, and it may be due to the lack of data for the extreme values of WMC.

In addition, the results showed that the facilitation due to preactivation (VP3 vs. VP2) "lasts longer." This is in some way parallel to the findings of Experiment 1, where the facilitation at VP3 condition (this time in comparison with VP1) appeared both in a different measure (re-reading instead of first pass regression probabilities) and it spilled over to the second critical region.

5. General Discussion

A major contribution of this paper is the finding that participants' WMC affects the processes involved in the dependency resolution. Even though recent research has shown that in some cases the relevant measure of individual difference to explain reading strategies is related to experience with language

rather than memory (vocabulary size in Prat, 2011; reading speed in Traxler et al., 2012), by taking into account the results of a rapid automatized naming task, which reflects experience with language, the current study showed WMC as measured by the operation span task to be a fruitful index of individual differences (at least for dependency resolution). Even though long-distance dependency completion is widely assumed to depend on the available working memory (but see Waters and Caplan's approach to working memory: Waters and Caplan, 1996; Caplan and Waters, 1999; Waters and Caplan, 2001), this is, to our knowledge, the first study showing that WMC modulates the reading times and regressions at the head of long-distance dependencies, as predicted by both DLT (Gibson, 2000) and the activation-based model (Vasishth and Lewis, 2006). The findings are consistent with the recent work of Caplan and Waters (2013). In this work, the authors argue that working memory supports retrieval in points of high processing load, which are identified by regressive saccades and longer self-paced reading times that enable better comprehension. In addition, our results show the added value of analyses that take individual variation into account instead of averaging over the data of participants (among others: Underwood, 1975; Brown and Heathcote, 2003; Traxler et al., 2005; and more recently Kliegl et al., 2011; Traxler et al., 2012; Payne et al., 2014).

The results of Experiments 1 and 2 together suggest that increasing the distance of the dependency affects the parsing of the head of the dependency in different ways, depending on whether the intervening material modifies the upcoming head or not. As predicted by the activation-based model (Vasishth and Lewis, 2006) but not by DLT or the expectation account, the facilitation is stronger when the intervening material modifies the upcoming head even when the length of the dependency is the same.

The increase of expectation-based facilitation at the subcategorizing head depends on adding lexical material that helps to sharpen predictions on the location of the upcoming head. However, the increase of lexical material also has its cost in memory processes, so expectation-driven facilitation seems to be noticeable as a speedup or as the decrease of regressions for participants with enough resources to overcome the difficulties caused by adding the extra lexical material (at least when the added facilitation due to the preactivation of the subcategorizing VP is absent). This predicts a monotonic effect of WMC, namely, when distance is increased, the difficulty for low-WMC is reduced as WMC increases, which turns into facilitation for high-WMC. While that was the case for our eye-tracking study (Experiment 1), this interaction was more complex than predicted for the self-paced reading task (Experiment 2).

Expectation-driven facilitation reduced the probability of regressions depending on the WMC of the participants of our eye-tracking study (Experiment 1), so that locality effects decreased as WMC increased until they became increasing antilocality effects. However, for the participants of the self-paced reading task (Experiment 2), the effect of WMC had an inverted-U shape, showing speedups in comparison with the short dependency condition for both high- and low-capacity readers. Since WMC predicted better comprehension accuracy, we assume that there are different underlying processes behind these two speedups, and only high-WMC readers are assumed to speed up because their WMC allowed them to parse the sentence and predict the upcoming lexical material. Since locality effects are assumed to be a response to either a memory overload (Gibson, 1998), the use of more computational resources (Gibson, 2000), or higher retrieval costs (Vasishth and Lewis, 2006), theories that predict locality effects would not predict that low-WMC participants would speed up in comparison with mid-WMC readers when the distance between head and argument is increased. In fact, there is ample evidence that proposes that individual differences in WMC reflect limitations in attention allocation for goals, especially in the face of interference or distraction (for a review see Engle, 2002).

There is independent evidence that high working memory load may lead to faster processing; this comes from the self-paced reading studies of Van Dyke and McElree (2006), who found that when subjects were presented with a memory load (a series of words to recall later) prior to reading a sentence, reading times were shorter and comprehension accuracy was lower in comparison with the conditions without the memory load. It seems that when the comprehender is parsing material while being engaged in processes that tax memory, a possible reading strategy is to disengage from the memory load sooner by reading faster. These results are in line with good-enough parsing (Ferreira et al., 2002; for a review: Ferreira and Patson, 2007), which states that the parser is not necessarily trying to achieve a fully specified representation of the sentence and that it might accept a partial or inconsistent representation. Furthermore, the findings converge with studies showing that low-WMC subjects may take less time when ambiguities are present (but they had worst accuracy) than high-WMCs (MacDonald et al., 1992; Pearlmutter and MacDonald, 1995; von der Malsburg and Vasishth, 2013), that they can read superficially enough to draw contradicting conclusions from a text (Oberauer et al., 2006); and that older adults' increase their reliance on heuristic-like good-enough processing to compensate for age-related deficits in WMC (Christianson et al., 2006).

Since this speedup for low-WMC readers is hypothesized to be a response to an incomplete parse of the more memory demanding condition, the speedup should appear together with a trade-off in the accuracy of the dependency completion. However, the true-or-false statements used for testing the participants' comprehension accuracy included many aspects of the stimuli in order to verify that they paid attention to the sentences, but they did not target exclusively whether the dependency was understood. Participants could in principle know whether the statement after the stimulus sentence was true or false, even without a complete understanding of the previous probe sentence. In addition, they could answer wrongly because they misunderstood other aspects of the sentences. The reason for this shortcoming is twofold: First, since most of the previous studies on locality effects examined only on RTs (except for McElree et al., 2003), the design of the experiment was not meant to explore the comprehension accuracy. Second, the nature of the stimuli

made it almost impossible to make short comprehension questions that could test only the dependency; this is so because the comprehension questions would ideally need to test whether sentences such as "it was commented that someone had fired who" are correct. Even though neglecting a deeper analysis of the sentence comprehension task is the normal state of affairs in psycholinguistics, it is a long-standing shortcoming in psycholinguistic research (but see: Christianson et al., 2001; Ferreira et al., 2001).

In sum, we have presented evidence that locality/antilocality effects are modulated by the participants' WMC. However, the exact relationship between WMC and expectations remains elusive. Two possible explanations are: (i) the prediction processes benefit from more WMC being available, as illustrated by **Figure 1D**, such that high-capacity readers may have a more precise expectation of the upcoming material, or they may be able to maintain the predictions for a head generated by the displaced argument (the wh-element in the experiments) for a longer time; or (ii) the prediction processes by themselves are unaffected by WMC (**Figure 1C**), while the stronger facilitation for high-WMC takes place due to the prediction processes being less affected by memory-driven locality effects.

When High-Capacity Readers Slow Down and Low-Capacity Readers Speed Up: Working Memory and Locality Effects

Bruno Nicenboim[1]*, *Pavel Logačev*[1], *Carolina Gattei*[2] and *Shravan Vasishth*[1]

We examined the effects of argument-head distance in SVO and SOV languages (Spanish and German), while taking into account readers' working memory capacity and controlling for expectation (Levy, 2008) and other factors. We predicted only *locality effects*, that is, a slowdown produced by increased dependency distance (Gibson, 2000; Lewis and Vasishth, 2005). Furthermore, we expected stronger locality effects for readers with low working memory capacity. Contrary to our predictions, low-capacity readers showed faster reading with increased distance, while high-capacity readers showed locality effects. We suggest that while the locality effects are compatible with memory-based explanations, the speedup of low-capacity readers can be explained by an increased probability of retrieval failure. We present a computational model based on ACT-R built under the previous assumptions, which is able to give a qualitative account for the present data and can be tested in future research. Our results suggest that in some cases, interpreting longer RTs as indexing increased processing difficulty and shorter RTs as facilitation may be too simplistic: The same increase in processing difficulty may lead to slowdowns in high-capacity readers and speedups in low-capacity ones. Ignoring individual level capacity differences when investigating locality effects may lead to misleading conclusions.

Keywords: locality, working memory capacity, individual differences, Spanish, German, ACT-R

1. INTRODUCTION

When a reader or hearer is faced with a sentence containing a non-local dependency, (also called long-distance, filler-gap, or unbounded dependency) such as (1), the interpretation of the dependent (*what*) has to be delayed until the reader parses the head of the dependency (*did*). It has been argued that the delay taxes memory processes, and that processing difficulty increases with increasing distance (among others Gibson, 2000; Grodner and Gibson, 2005; Lewis and Vasishth, 2005; Vasishth and Lewis, 2006; Bartek et al., 2011; Husain et al., 2015). This increase in processing difficulty, which is reflected in longer reading times (RTs) at the head of the dependency, is known as a *locality effect* (Gibson, 2000; Lewis and Vasishth, 2005).

(1) Someone asked what the man did last summer.

While the underlying memory processes are subject to debate, theories that predict locality effects are based on the deterioration in *some* memory processes: either an increase in integration and storage costs in Dependency Locality Theory (DLT: Gibson, 2000); or decay and interference in the case of the activation-based theory (Vasishth and Lewis, 2006). Even though there has been evidence against online language processes drawing resources from a common working memory system (Waters and Caplan, 1996; Caplan and Waters, 1999; Waters and Caplan, 2001), in recent work, Caplan and Waters (2013) argue that working memory may support retrievals in points of high processing load. Locality effects may happen in these points of high processing load, which are identified by regressive saccades and longer self-paced reading times that enable better comprehension. The interaction between individual differences in working memory capacity (WMC) and dependency resolution can shed further light on memory-based explanations of locality effects: Differential effects for different capacities can support the assumption that locality-related processing difficulty may in fact be memory based. This is not explicitly stated in DLT, but it is implied since the upper limits on storage and integration cost (Gibson and Thomas, 1999; Gibson, 2000) should depend on WMC. Furthermore, Fedorenko et al. (2006, 2013) found a reduction in performance during long-distance dependency resolution and memory dual tasks, which they interpret as the integration of non-local dependents taxing memory resources.

The relationship between WMC and retrieval processes is more explicit in the activation-based model of sentence processing (Lewis and Vasishth, 2005; Vasishth and Lewis, 2006), which is based on the Adaptive Character of Thought-Rational framework (ACT-R; see for example Anderson et al., 2004). It is assumed that a head verb triggers the retrieval from memory of its non-local dependents using cues such as number, animacy, being a wh-element, and so forth. There is no assumption of serial search in memory, but there is instead a race between the stored items (i.e., the different encoded phrases), with the most highly activated item arriving to the threshold faster and being retrieved. The latency of a retrieval thus depends on the item's level of activation. While the activation of an item decreases with a certain decay rate from the moment of its encoding, retrieval cues are used to improve the chances to identify the "right item" from memory: matching cues boost the activation of an item (while mismatching cues are penalized).

WMC can be integrated into the activation-based model by assuming that it affects the activation of items in memory differentially. One possibility is that WMC affects the decay of information from memory. This has been modeled, for example, in Just and Carpenter's (1992) CAPS, by Byrne and Bovair (1997) to explain errors after an activity that has been completed (such as forgetting the credit card in an ATM); and it has been assumed in sentence processing by, for example, Cunnings and Felser (2013) to explain the differential processing of reflexives. However, it has long been believed that it is not mainly because time passes that information in memory erodes (for a recent example, see Berman et al., 2009). Some of the findings usually associated with decay can be accommodated within *interference-based decay* (Lustig et al., 2009), which is based on the idea that the passage of time increases the likelihood that the features of an item in memory will overlap with those of a noise distribution, making them increasingly difficult to distinguish (see also Oberauer and Kliegl, 2006).

Another possibility is that WMC differentially affects spreading activation, that is, the boost of activation due to matching cues. There are at least two ways in which this could happen. One way could be because WMC modulates the total amount of activation which is shared between matching cues (see for example Cantor and Engle, 1993 for the implementation in a predecessor of ACT-R, and Daily et al., 2001; van Rij et al., 2013 for the implementation in ACT-R of number recall and pronoun resolution respectively). Another way in which WMC could affect spreading activation was suggested by Bunting et al. (2004); in their view, WMC represents susceptibility to interference. Bunting et al.'s experiment showed that individual differences are better represented if low-capacity participants activate more irrelevant cues than high-capacity participants (recall that there is a total amount of activation that is shared between the cues).

If we assume, as ACT-R does, that decay and interference both play a role (and they may be functionally related, see, e.g., Altmann and Gray, 2002), we can schematize locality effects as follows: when a dependent is parsed, it is stored in memory (together with every other phrase parsed so far in the sentence). As the distance between dependent and head increases, the representation of the dependent decays, which translates to a reduction of its level of activation. Since more recent phrases will have a higher level of activation, the correct retrieval of a non-local dependent is possible by using retrieval cues that are derived from the word eliciting the retrieval (the head), together with context and grammatical knowledge (Lewis et al., 2006). Crucially, when the amount of activation available for boosting matching cues decreases or when this activation is shared between more cues, the role of decay due to the increased distance will dominate. This would entail that the role of decay will be more pronounced for low-capacity readers.

Thus, if the source of locality effects is memory based processes (such as the ones predicted by the activation-based model or implicit in DLT), low-capacity readers should show a stronger slowdown than high-capacity ones when dependent-head distance is increased. This prediction is also supported by the following findings: When faced with difficult sentences, the disadvantage of low-WMC readers seems to increase in comparison to high-WMC ones (for garden-path vs. non-garden path sentences: Christianson et al., 2006; for comprehension reaction times in subject- vs. object-relative clauses: King and Just, 1991; Vos et al., 2001). This is also supported by evidence showing that: (a) WMC influences the probabilities of success in integrating information over a distance in a text (Daneman and Carpenter, 1980); (b) WMC is associated with the ability to maintain on-task thoughts (McVay and Kane, 2011); and (c) there is a reduction in performance during long-distance dependency resolution and memory dual-tasks (Fedorenko et al., 2006, 2013). However, this prediction is also based

on the implicit assumption that RTs can be straightforwardly interpreted as indexing difficulty. We will argue that this is the case only when the retrieval of the dependent is successful. We will return to this topic and discuss the specifics of the role of WMC in the general discussion and modeling section.

Increasing dependent-head distance does not always have the same effect. Memory-driven explanations of locality effects are complicated by findings of so-called *antilocality* effects, that is evidence showing that increased distance can result in *faster* reading. For example, several studies on SOV structures (in Hindi: Vasishth, 2003; Vasishth and Lewis, 2006 and in German: Konieczny, 2000; Konieczny and Döring, 2003; Levy and Keller, 2013) showed that increasing the dependent-head distance can produce facilitation at the head of the dependency. However, such facilitation can be explained by increased expectations of the head (Levy, 2008; Levy et al., 2013; but for a memory-based explanation of facilitation see: Vasishth and Lewis, 2006; Nicenboim et al., 2015b). According to the expectation-based account, the primary source of difficulty incurred in processing a word is determined by the surprisal (negative log of the conditional probability) of a word given its context (Hale, 2001). Crucially for current purposes, this account suggests that when the distance of the dependency is increased, the appearance of the predicted head is delayed. As a consequence, the expectation of finding the head that will complete the dependency will increase monotonically. Thus, as the head is more expected, it will be processed more easily when it is encountered.

Importantly, memory- and expectation-based processes are theoretically not incompatible, and recent research (Staub, 2010; Vasishth and Drenhaus, 2011; Levy and Keller, 2013; Levy et al., 2013; Husain et al., 2014; Nicenboim et al., 2015b) shows that they may coexist. However, many of the experimental results in the literature are not easily interpretable, since increasing the distance by adding material between dependent and head systematically changes the sentences, resulting in confounding effects due to the different sentence structures engendered by the distance manipulation.

One aspect of the systematic difference between the sentences manipulated for dependency distance is the change in the linear position of the head. This is especially critical when the design argues for a speedup, since readers tend to speed up as the number of words increases (Ferreira and Henderson, 1993; Boston et al., 2008; Demberg and Keller, 2008); in (2), for example, distance is always confounded with position.

(2) a. SHORT Someone asked **what** the man **did** last summer.

b. LONG Someone asked **what** the man [words that should belong somehow to the sentence] **did** last summer.

The confound between word position and distance has been addressed (see for example: Vasishth and Drenhaus, 2011; Levy and Keller, 2013) by adding the same or similar *words that should belong somehow to the sentence* before the dependency in the short version; compare now (3a) with (3b).

(3) a. SHORT Someone [words that should belong somehow to the sentence] asked **what** the man **did** last summer.

b. LONG Someone asked **what** the man [words that should belong somehow to the sentence] **did** last summer.

Even though the word position confound is controlled, the new problem that arises is that the sentence structure is still consistently changed beyond the distance manipulation. If a difference is found at the head of the dependency *did* in (3), we cannot be sure whether it is a consequence of the distance manipulation or the change in the structure of the sentence. A slowdown (or a speedup) at the verb *did* in (3b) in comparison with (3a) could, in principle, have different alternative explanations. When lexical material is attached to a dependent to increase the dependent-head distance, the dependent that is retrieved in the longer version has also a richer semantic content that may produce a speedup at the verb (Hofmeister, 2007; Hofmeister and Sag, 2010; Hofmeister and Vasishth, 2014). This would be the case if *words that should belong somehow to the sentence* were, for example, a relative clause or a prepositional phrase in (3), so that the extra material is attached to *the man* in the long condition (and to *someone* in the short one). This is also exemplified in (4) from Grodner and Gibson (2005): when the distance is increased, the semantic content of the dependent also changes, namely, *the nurse from the clinic* is retrieved at the verb instead of just *the nurse*. Even though Grodner and Gibson did find locality effects, it does not rule out that the memory-driven locality effects were partially reduced by facilitation due to richer semantic content (and because of increased word position). But alternatively, the slowdown at the verb may have had independent reasons: When the dependent is more complex, it may include several nouns (*nurse* and *clinic* in the Experiment 4) that could cause encoding (Oberauer and Kliegl, 2006) and/or retrieval interference (Van Dyke and McElree, 2006), producing a slowdown at the head verb as well.

(4) Embedded verb conditions from Grodner and Gibson's (2005) experiment 2:

a. **The administrator** who the nurse **supervised** scolded the medic while ...

b. **The administrator** who the nurse from the clinic **supervised** scolded the medic while ...

In addition, there is evidence that preverbal material in the verbal phrase (VP) may cause a speedup at the verb, since the interposed material can help to strengthen the representation of the upcoming head by activating it through modification (as proposed by Vasishth and Lewis, 2006, and more recently Nicenboim et al., 2015b). This would be the case if *words that should belong somehow to the sentence* in (3) were an adverb such as *secretly*, so that the VP that contains the head in the long distance condition is *secretly did*, while it is only *did* in the short one (since *secretly* is attached to *asked* in the short condition). Furthermore, when the distance is increased by any manipulation, expectations may play a role (Hale, 2001; Levy,

2008): Once the reader starts parsing the embedded sentence at *what*, he or she will also start building expectations for the embedded verb; and these expectations will be different for the long and short conditions. In Levy's (2008) study, this is explained by assuming that the reader has knowledge about the grammar of the sentence, that is, he or she knows that the embedded sentence has some verb, but does not know when it will appear. The more constituents within the embedded sentence that have been integrated, the fewer possible choices there are for subsequent constituents. This means that the reader's expectation for the verb should increase as the number of integrated constituents increases. Thus, since the verb *did* in (3b) is assumed to be more expected than in (3a), it is also predicted to be processed faster.

One way to avoid many of the potential confounds and control for the differences in sentence structure is to compare each of the two experimental conditions, such as (5a) and (5b), to baseline conditions without an unbounded dependency, such as (5c) and (5d). Critically, in both short (5c) and long (5d) baseline conditions, a dependent of the verb (e.g., *something*) appears locally in the VP after the verb and remains at the same distance from the verb replacing the wh-element of the unbounded dependency conditions (5a) and (5b). In this experimental design, locality effects appear as an interaction between dependency type (unbounded vs. local, i.e., baseline), and the length of the material added immediately before the head verb (short vs. long). The sentences with local dependencies would act as baselines canceling out other effects that do not depend on the unbounded dependency. For example, if the extra material is attached to the subject of the embedded clause (*the man*), both long (unbounded and local dependency) conditions will have an argument with a richer semantic content that would require more encoding and trigger more expectations for a head verb (since the clause that starts either at the *what* or *that* is longer) than both short (unbounded and local dependency) conditions. Thus, locality effects at the critical region (*did*) would manifest as the difference between long-unbounded and short-unbounded (5b) − (5a) being larger than the difference between long-baseline and short-baseline (5d) − (5c) conditions.

(5) a. SHORT - UNBOUNDED DEPENDENCY
Someone [words that should belong somehow to the sentence] asked **what** the man **did** last summer.

b. LONG - UNBOUNDED DEPENDENCY
Someone asked **what** the man [words that should belong somehow to the sentence] **did** last summer.

c. SHORT - BASELINE (LOCAL DEPENDENCY)
Someone [words that should belong somehow to the sentence] asked if the man **did** *something* last summer.

d. LONG - BASELINE (LOCAL DEPENDENCY)
Someone asked if the man [words that should belong somehow to the sentence] **did** *something* last summer.

In the following experiments, we used this experimental design together with tasks that measure WMC and reading fluency in order to disentangle locality effects from potential confounds, and to find out whether locality interacts with individual differences. We used the operation span task (Turner and Engle, 1989; Conway et al., 2005) to obtain a reliable measure of WMC of our participants. We expected locality effects to be the strongest for readers with the lowest WMC readers, and we expected their magnitude to decrease with increasing WMC. One of the strengths of this type of design is that we can investigate locality effects without a priori commitments about the effect of the systematic change in the syntactic structure, that is, whether the long conditions will show a slowdown or a speedup at the critical region in comparison with the the short ones when we disregard the dependency manipulation.

It has been argued that differences in WMC may reflect differences in language experience or language skills, and not necessarily intrinsic capacity differences (MacDonald and Christiansen, 2002; Wells et al., 2009; Traxler et al., 2012), since WMC tends to correlate with many other reader characteristics.

In fact, while Traxler et al. (2005) found that WMC and syntactic complexity interacted in an eye-tracking experiment, a re-analysis of the data (Traxler et al., 2012) showed that reading speed accounted for more variation in individuals' responses than WMC. According to Traxler et al. (2012), fast readers, who read more often than slow readers, will have greater experience with language; this would in turn make them more sensitive to semantic cues in the syntactic analysis.

In order to obtain an independent measure of reading speed, we included an additional task called rapid automatized naming task (RAN: Denckla and Rudel, 1976). RAN has been shown to capture important variance associated with the processing of rapidly occurring serial information and it has been shown to predict reading speed, comprehension, and other characteristics associated with fluent reading (among others: Kuperman and Van Dyke, 2011; Araújo et al., 2015).

Norton and Wolf (2012) recently reviewed an extensive body of research that led them to consider RAN tasks "as one of the best, perhaps universal, predictors of reading fluency across all known orthographies" (p. 430). Norton and Wolf's view is that this task and reading are seen to require many of the same processes, such as eye saccade control, and the connecting of orthographic and phonological representations. By reading fluency, Norton and Wolf (2012) mean "fluent comprehension" (Wolf and Katzir-Cohen, 2001), that is, "a manner of reading in which all sublexical units, words, and connected text and all the perceptual, linguistic, and cognitive processes involved in each level are processed accurately and automatically so that sufficient time and resources can be allocated to comprehension and deeper thought" (Norton and Wolf, 2012, p. 215). Even though RAN tasks are usually used to study reading development and dyslexia, a few studies have shown that RAN is also predictive of some characteristics of reading fluency for non-college bound participants aged between 16 and 24 (Kuperman and Van Dyke, 2011), for undergrad students (Al Dahhan et al., 2014; Kuperman et al., in press), and for adults aged between 36 and 65 (van den Bos et al., 2002). In addition, some imaging studies performed in young adults have also shown that RAN and reading activate

similar neural networks of neural structures (Misra et al., 2004; Cummine et al., 2015). Even though RAN has been shown to be predictive of online processes associated with word recognition, a recent study (Kuperman et al., in press) argued that RAN may not be predictive of comprehension accuracy, at least for highly proficient population such as college students. However, it may be the case that in situations of high cognitive load, more fluent readers could show an advantage in comparison with less fluent readers. The inclusion of RAN can thus help us to determine whether some participants by virtue of being fluent readers have enough resources for a more efficient use of the retrieval cues and thus overcome more easily locality effects than less fluent readers.

Since most of the evidence from locality effects and most of the evidence from antilocality effects come from SVO and SOV structures respectively, our experiments also verify whether the same account has cross-linguistic validity.

2. EXPERIMENT 1

2.1. Methods

2.1.1. Participants

Seventy-nine subjects aged between 18 and 44 years old (mean 25.2 years) participated in the experiment in Argentina. All participants were native speakers of Spanish and were naïve to the purpose of the study. One additional participant was excluded from the analysis, since s/he reported that s/he suffered from a mental disorder related to memory after the experiment was conducted. Data from this experiment were collected in the same run as the self-paced reading experiment in Nicenboim et al. (2015b): the stimuli from one experiment served as filler sentences for the other experiment.

2.1.2. Stimuli

The stimuli for this experiment consisted of 48 items in Spanish with four conditions following the same logic as in (5) in a two-by-two design: embedded subject length × dependency, as illustrated in (6). The embedded subject length manipulation was created by converting the proper noun of the short condition into a PP that is attached to another NP: (6a vs. 6b, and 6c vs. 6d). The dependency manipulation was created by comparing conditions with an unbounded dependency vs. local dependency (baseline) conditions, so that only the conditions with the unbounded dependencies have shorter or longer dependencies, and the baseline conditions (6c-6d) have similar structures (shorter or longer subjects) but no unbounded dependencies.

(6) a. SHORT - UNBOUNDED DEPENDENCY

La hermana menor de Sofía preguntó **a quién**
The younger sister of Sofia asked **who.ACC**
fue que María **había saludado** en la puerta del
was that María **had greeted** at the door of the
colegio ayer a la tarde.
school yesterday at the afternoon

b. LONG - UNBOUNDED DEPENDENCY

Sofía preguntó **a quién** fue que
Sofia asked **who.ACC** was that
la hermana menor de María **había saludado** en la
the younger sister of María **had greeted** at the
puerta del colegio ayer a la tarde.
door of the school yesterday at the afternoon

c. SHORT - BASELINE

La hermana menor de Sofía preguntó si María
The younger sister of Sofia asked if Maria
había saludado a la prima de Paula en la puerta
had greeted to the cousin of Paula at the door
del colegio ayer a la tarde.
of the school yesterday at the afternoon

d. LONG - BASELINE

Sofía preguntó si la hermana menor de María
Sofia asked if the younger sister of Maria
había saludado a la prima de Paula en la puerta
had greeted to the cousin of Paula at the door
del colegio ayer a la tarde.
of the school yesterday at the afternoon

The 48 experimental items of the current experiment were presented together with 108 experimental items for other experiments and 56 filler sentences. The sentences presented included (i) 36 items with embedded object questions and adverbs in different positions from Nicenboim et al. (2015b); (ii) 48 items with embedded object questions from an unpublished study; (iii) 24 items with object and subject experiencer psychological verbs and different word order (SVO-OVS) from an unpublished study; and (iv) 56 filler sentences with a variety of saying verbs and embedded sentences.

2.1.3. Procedure

Subjects were tested individually using a PC. Participants completed three tasks at their own pace: tests to assess the individual differences in WMC (operation span task: Turner and Engle, 1989; Conway et al., 2005) and in reading fluency (rapid automatized naming: Denckla and Rudel, 1976), and a moving window self-paced reading task (Just et al., 1982).

2.1.3.1. Operation span

Participants took part in an operation span task (Turner and Engle, 1989) using a software developed by von der Malsburg (2015) and used previously in von der Malsburg and Vasishth (2013). Even though variants of the reading (or listening) span task by Daneman and Carpenter (1980) have been used in many psycholinguistic studies, we chose to use the *operation* instead of the *reading* span task, since the latter is likely to measure verbal ability or reading experience as well as working memory capacity (MacDonald and Christiansen, 2002; Conway et al., 2005). We elaborate on this point below.

Even though both reading span and operation span have been defined as measures of verbal working memory (Conway et al., 2005), we think that using the operation span task presents a methodological advantage. The reading span task measures

participants' abilities to do language-processing tasks, such as maintaining the phonological activation for the words in the face of competing demands from sentence processing, and thus it is not surprising that the reading span may be predictive of sentence processing phenomena (MacDonald and Christiansen, 2002). In contrast, the operation span task (described below) is further from language related tasks. And in fact, Turner and Engle (1989) motivation for the use of the operation span was that "A measure of WM should successfully transcend task dependence in its prediction of higher level cognitive functioning. That is, the memory span task could be embedded in a concurrent processing task that is unrelated to any particular skills measure and still predict success in the higher level task" (Turner and Engle, 1989, p. 129). Furthermore, a study of McVay and Kane (2011) showed some critical differences between reading and operation span task. McVay and Kane used among other measures of individual differences three complex span tasks, namely, operation, reading, and spatial span tasks. Even though the three tasks were highly correlated, the reading span task correlated with more reading comprehension tasks (and more strongly) than the operation span.

The procedure of the operation span task test was the following: At a first stage, participants had to judge the correctness of 25 simple equations. During this practice, the reaction time of Equations 10–25 was measured; the average reaction time plus two standard deviations was used as a time-out at the second stage. Having a time-out for every participant ensures that participants that are fast will not have time left to rehearse the items at the next stage of the test. At the second stage, participants had to verify equations and memorize letters (always consonants) that were shown between the equations. After each equation, a consonant was shown for 800 ms; and after a group from three to seven equation-letter successions, participants were instructed to type the letters that had appeared before in their order of presentation. During both parts of the test, participants had to read the equations and letters aloud in order to prevent vocal rehearsal strategies.

As a numeric score of individual working memory, we computed partial-credit unit scores, which indicate the mean proportion of correctly recalled items within the sets (Conway et al., 2005).

2.1.3.2. Rapid automatized naming

Participants' reading fluency was operationalized using rapid automatized naming speed. Subjects that perform this task faster tend to have better reading comprehension scores, faster reading rates and their initial landing position when fixating tends to be closer to the center (among others: Howe et al., 2006; Arnell et al., 2009; Kuperman and Van Dyke, 2011; Araújo et al., 2015). Rapid automatized naming times were measured using a software developed by the first author (https://github.com/bnicenboim/py-ran-task). The procedure of the test was the following: Each subject was instructed to read a series of trials with 50 items; the items were the same set of letters or numbers that were used in Denckla and Rudel (1976): {o, a, s, d, p} and {2, 6, 9, 4, 7}. The first eight trials were composed of letters and the following eight ones of numbers. The items were displayed in five rows of ten columns and were listed in random order. Participants were instructed to start reading aloud as fast as possible immediately after pressing the spacebar, and to press it again immediately after finishing reading aloud the last item. In case they misread, they were instructed to reread only the misread item. The test started with two practice trials to familiarize the participants with the task.

2.1.3.3. Self-paced reading

For the self-paced reading task all sentences were displayed in a single line and were presented in 18 pt Arial font using Linger software (http://tedlab.mit.edu/~dr/Linger/). A true-or-false comprehension task was presented after 65% of all trials in the experiment including fillers to ensure that participants had paid attention to the sentences. The statements focused on various aspects of the stimuli, and the proportion of true and false statements was balanced. For the sentences in the previous example (6) the statement was: *La hermana menor de Sofía preguntó algo.* "The younger sister of Sofía asked something," which was true for the short conditions but false for the long ones. The statements following other experimental sentences focused on different aspects of the stimuli: the participants, the action, the setting of the action, etc. As in Nicenboim et al. (2015b), we chose to use true-or-false statements instead of yes-no questions in order to avoid long and unnatural questions.

2.2. Results

2.2.1. Data Analysis

The data analysis was conducted in the R programming environment (R Core Team, 2015), using hierarchical models (also known as mixed effects or multilevel models) in Stan (Stan Development Team, 2015b) with the R package RStan (Stan Development Team, 2015a). We fit Bayesian rather than frequentist models, which are generally fit with lme4 (Bates et al., 2014; we provide, however, the results of the frequentist models in the Supplementary Material for comparison purposes). First, hierarchical models minimize false positives when they include the maximal random effects structure justified by the design (Schielzeth and Forstmeier, 2009; Barr et al., 2013). However, such maximal frequentist models did not converge for our data and therefore had to be simplified. In contrast, their Bayesian counterpart could be fit in Stan, by using appropriate weakly informative priors for the correlation matrices (so-called LKJ priors). Third, Bayesian hierarchical models solve the multiple comparisons problem since all relevant research questions can be represented as parameters in one coherent hierarchical model (Gelman et al., 2012). This puts more burden on the hierarchical models and shifts point estimates and their corresponding intervals toward each other via "shrinkage" or "partial pooling" (see Gelman et al., 2012, for more details). Fourth, Bayesian procedures provide credible intervals rather than confidence intervals. A 95% credible interval demarcates the range within which we can be certain with probability 0.95 that the true value of a parameter lies (given the data at hand). By contrast, a frequentist confidence interval (CI) is a property of the statistical procedure and not of the parameter. The CI indicates that when the procedure is used repeatedly across a series of hypothetical

data sets (i.e., the sample space), the procedure will yield intervals which contain the true parameter value in 95% of the cases (Hoekstra et al., 2014 and see Morey et al., 2016 for an extreme example of the difference between confidence and credible intervals). Thus, the frequentist CI cannot be used for inference because it tells us nothing about the uncertainty regarding the parameter's value. By contrast, the Bayesian credible interval expresses uncertainty about the parameter.

Another reason for using Bayesian models is that Bayesian procedures allow us to fit virtually any kind of distribution in a straightforward way. Residual RTs in self-paced reading are usually not normally distributed: They are limited on the left by some amount of time (i.e., the shift of the distribution), and they are highly right skewed. RTs can be reciprocal or log-transformed, but these transformations still assume that RTs are defined by their scale (mean) and shape (standard deviation), and they are unshifted (or have a shift of 0 ms). Rouder (2005) raises the concern that restricting the shift to be zero is unreasonable for response times. Unshifted distributions for *reading* times in SPR may also be unreasonable, since they do not take into account that there is a minimal amount of time that takes to read a word and press a button on the keyboard, typically around 150–250 ms. Evidence from distributional models similar to the shifted lognormal shows that shifts are nonzero and vary across participants (see, for example, Logan, 1992; Rouder et al., 2005). If distributions are shifted and analyzed as unshifted lognormal, with increasing shift, estimates of the mean artificially increase, and estimates of the standard deviation artificially decrease; and these artifacts may influence conclusions (Rouder, 2005). We decided to fit models with shifted lognormal distributions not only to avoid anti-conservative conclusions, but also to get more accurate estimates by fitting our data with a model that resembles the process that generates the data. Furthermore, when we compared the shifted lognormal distribution with unshifted distributions such as a reciprocal or a log transformation on the normal distribution, a model ranking according to the Watanabe-Akaike information criterion (or Widely applicable information criterion or WAIC; Watanabe, 2010; Vehtari and Gelman, 2014) favored the model with the shifted lognormal distribution. This may not be the only way to achieve a realistic fit to RTs; however, the shifted lognormal distribution has two key characteristics that are desirable of a RT distribution (Rouder et al., 2008): (i) it has a shift (which is absent in, for example, the ex-Gaussian distribution) and (ii) its error variance increases with mean RT (Wagenmakers and Brown, 2007). In addition, lognormal distributions are ubiquitous in nature, are well understood (Limpert et al., 2001), and are already used in psycholinguistics. We acknowledge that deeper research is needed to evaluate the advantages and disadvantages of different distributions in RTs in self-paced reading (similar to what was done for visual search by Palmer et al., 2011).

Thus we fitted a hierarchical model with a shifted lognormal distribution, allowing the shift to vary by participant. We present the posterior probability of the coefficients being positive given the data and its 95% credible interval. For all the models presented in the experiments, the predictors were sum coded (-1 and 1 for baseline and long dependency, and −1 and 1 for short and long), and covariates WMC and reading fluency were scaled and centered. In order to be able to compare the results across experiments (and regions), we report the estimates of the parameters $\hat{\delta_k}$ that quantify the effect size of each given coefficient k of the mixed model $\hat{\beta_k}$, such that $\hat{\delta_k} = \hat{\beta_k}/\hat{\sigma}$, where $\hat{\sigma}$ is the estimated standard error of the model (as recommended by Rouder et al., 2012). Effect sizes are a dimensionless quantity (Wagenmakers et al., 2010) and depend less on the methodology (self-paced reading, eye-tracking, EEG), the language, the type of participants (students or general population), etc, than the estimates. (We provide the code of the model in the Supplementary Material.)

We checked the convergence of the models after fitting them with eight chains and 2000 iterations, half of which were the burn-in or warm-up phase. In order to assess convergence, we verified that the $\hat{R}$s were close to one, and we also visually inspected the chains (Gelman et al., 2014).

2.2.2. Results of the Individual Differences Measures

2.2.2.1. Operation span

Partial-credit unit scores for the operation span test measuring WMC of the 79 participants had an average of 0.63 ($SE = 0.01$; range 0.37–0.88).

2.2.2.2. Rapid automatized naming

Average character speed for the rapid automatized naming task for measuring reading fluency ranged between 1.60 and 3.45 characters/second with an average of 2.40 ($SE = 0.05$) characters/second. The reciprocal of the averaged reading time was used as the reading fluency measure; this way a higher value represents a more skilled reader.

These two measures were not correlated for the participants of the experiment; $r = -0.04$, CrI (Credible Interval) $= [-0.26, 0.18]$. However, both were moderately correlated with the general accuracy for all the items; WMC: $r = 0.21$, $CrI = [0.00, 0.42]$; reading fluency: $r = 0.29$, $CrI = [0.05, 0.50]$. It should be noted that even though these two measures were not correlated for our subjects, who were mostly university students, it does not mean they are not correlated in the general population. The lack of correlation may be due to the so-called Berkson's paradox (Berkson, 1946), which arises when a specific part of the population is absent (in this case we can assume that people with not enough reading fluency or WMC would not attend college). However, the lack of correlation is informative in that the two measures may be tapping different underlying capacities or skills.

2.2.3. Results of the Self-Paced Reading Experiment

2.2.3.1. Comprehension accuracy

Participants answered correctly on average 77% ($SE = 1$) comprehension probes of the trials belonging to the experiment.

2.2.3.2. Reading times

We fitted a single model for our four regions of interest using Helmert contrasts; see example (7). This type of coding ensures the interpretability of the effects of interest (length, dependency type, WMC, reading fluency, and their interaction) and allows

us to detect a change in the pattern of the effects across the regions. We defined four contrasts that compare each region with the average of the preceding ones: (i) The first critical region (the auxiliary verb "había") is first compared with the precritical region (always a proper noun), then (ii) the second critical region (a participle form of the verb), (iii) the first spillover (a preposition), and finally (iv) the second spillover (a determiner) are compared with the average of their respective preceeding regions; see **Table 1**. In order to account for the correlations between the regions in a single sentence, we included random effects by sentence besides by participants and items as it is usual. We included random intercepts for participants, item and sentences, and by-participants and items random slopes for length, dependency and their interaction (with their correlations).

TABLE 1 | Helmert contrasts used for both experiments.

Precritical	−1	−1	−1	−1
Critical 1	1	−1	−1	−1
Critical 2	0	2	−1	−1
Spillover 1	0	0	3	−1
Spillover 2	0	0	0	4

Figure 1 shows mean RTs for high- and low-WMC readers at each comparable region, while **Figure 2** shows only the locality effects × WMC interaction.

(7) ... preguntó {a quién fue que; si} (la hermana menor
... asked {who.ACC was that; if} (the younger sister

de) | María | había | saludado | {a; en} |
of) | María | had | greeted | {to; in} |
| precritical | critical 1 | critical 2 | spillover 1 |
la | ...
the | ...
spillover 2 |

Observations with RTs under 150 ms and above 5000 ms were removed from the data (3.84%) after checking the residuals of the model. Values below 150 ms are too fast to be reading times, and they are likely to be erroneous taps on the spacebar. If RTs that are too fast are included, the model cannot estimate the appropriate shifts in the distribution (Rouder et al., 2005).

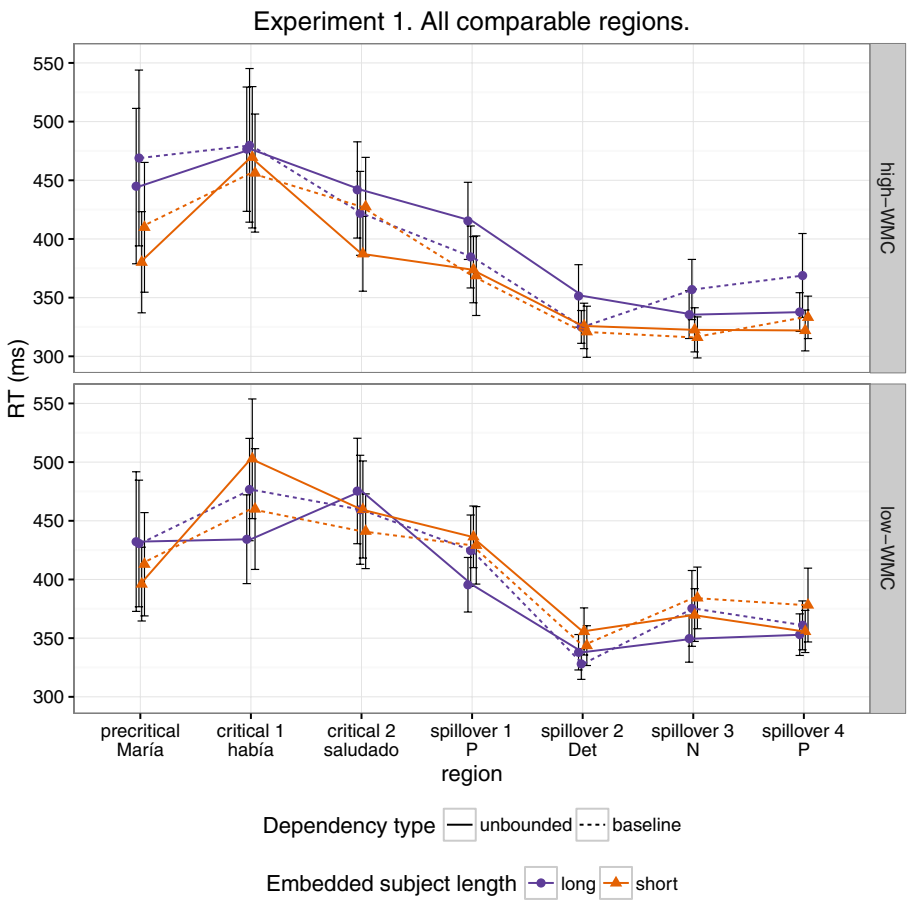

FIGURE 1 | Comparison of mean RTs for high- and low-WMC readers at each comparable region for every condition.

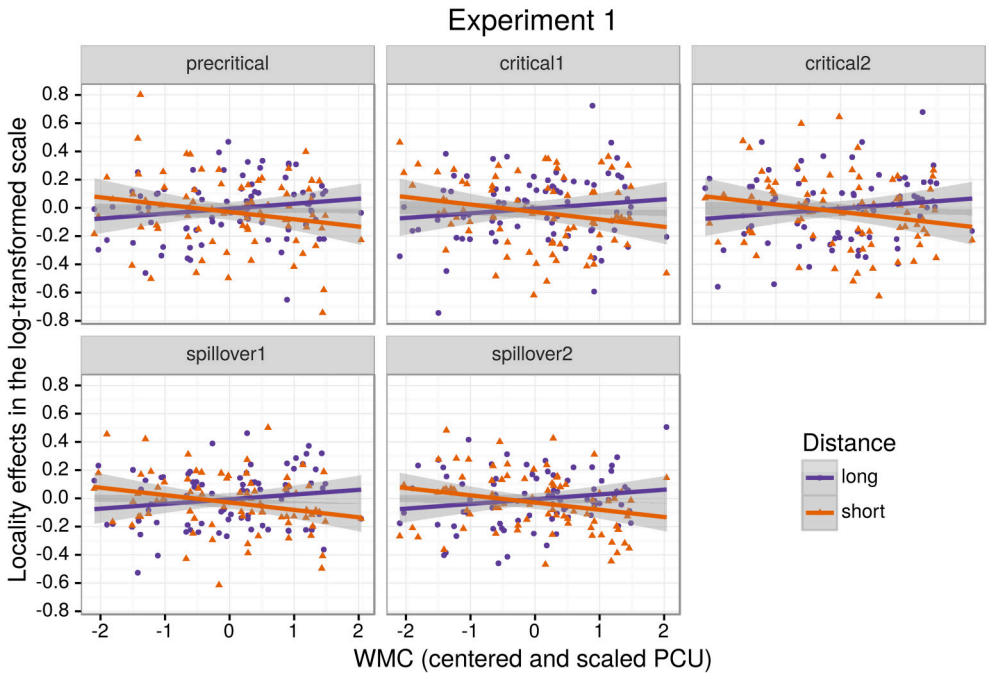

FIGURE 2 | The figure depicts the partial effect for the difference between unbounded conditions and baseline conditions, that is the (anti)locality effects, on the transformed scale of the analysis; random factors variance and effects due to reading skills were removed from the dependent variable (Hohenstein and Kliegl, 2013).

TABLE 2 | Main results for Experiment 1 (Spanish).

Predictor	$\hat{\delta}$	95% CrI		$P(\hat{\delta} > 0)$
Length	0.03	0	0.07	0.97
Dependency	−0.01	−0.04	0.02	0.17
WMC	−0.02	−0.2	0.17	0.42
RF	−0.16	−0.34	0.03	0.04
Length:dependency	0.01	−0.02	0.04	0.74
Length:dependency:WMC	0.04	0.01	0.06	1
Length:dependency:RF	−0.01	−0.04	0.01	0.15

WMC stands for working memory capacity and RF for reading fluency. The first column $\hat{\delta}$ shows the estimated effect size of the coefficients; the next two columns show the 2.5th and 97.5th percentiles of their posterior distribution, that is, where the effect size lies with 95% probability; and $P(\hat{\delta} > 0)$ indicates the posterior probability that each coefficient is positive.

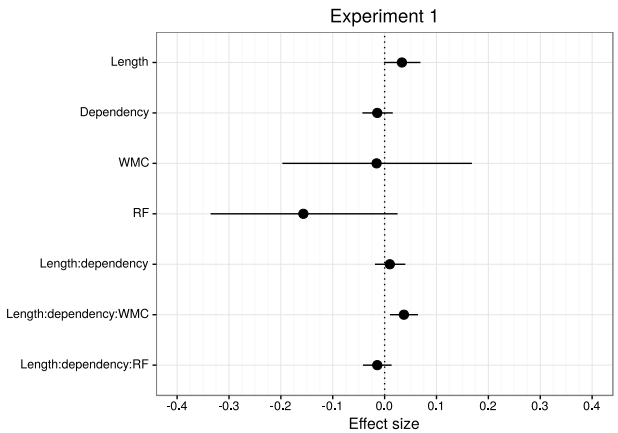

FIGURE 3 | Overview of mean and 95% credible intervals for the effect sizes of the parameters of interest for Experiment 1.

Table 2 and **Figure 3** summarize the main results of the model for the effects of reading fluency, WMC, locality (embedded subject length × dependency), and its interaction with reading fluency and WMC, including the data from all the regions of interest.

In contrast to Null Hypothesis Significance Testing (NHST), where a sharp binary decision is made between "significant" and "non significant" effects, a Bayesian analysis allows us to compute the probability that the coefficient is positive or negative given the data. The 95% Bayesian credible interval has the interpretation that researchers often ascribe mistakenly to frequentist confidence intervals (Morey et al., 2016): it gives the range over which we can be 95% certain, given the data, that the true value of the parameter lies. This statement cannot even be made in NHST, since the true parameter is a point value with no probability distribution. A common way (Kruschke et al., 2012) to interpret the 95% credible interval is to consider an effect to be strong if 0 lies outside the interval. If 0 is included within the interval, there might still be weak evidence for an effect if the probability of the parameter being less than (or greater than) 0 may still be quite large. An example may clarify this: if the probability of the parameter being less than 0 is

0.04, i.e., $P(\hat{\delta} < 0) = 0.04$, this means that there is a 0.96 probability, given the data, that the parameter is negative. Here, it would be odd to say that "there is no effect" given that the posterior probability of the parameter being negative is 0.96. Accordingly, we will interpret the results as follows: if 0 lies outside the 95% credible interval, we assume that the evidence is strong that there is an effect; if 0 is included within the interval but the probability of the parameter being less than or greater than 0 ($P(\hat{\delta} < 0)$ or $P(\hat{\delta} > 0)$, depending on the expected sign of the effect) is high, we will say that there is weak evidence of an effect; and if the probability $P(\hat{\delta} < 0)$ or $P(\hat{\delta} > 0)$ is low, we will conclude that there is no evidence of an effect. For a detailed tutorial on fitting and interpreting Bayesian linear mixed models, see Sorensen et al. (2015).

The model reveals three main findings: (i) As expected, subjects with higher reading fluency scores tended to have shorter RTs (notice that even though zero is included in the credible interval, the effect size is between four and ten times larger than the rest of the effects, and 96% of its posterior probability is below zero); (ii) we did not find the hypothesized locality effects, that is, an interaction between embedded subject length and dependency type regardless of WMC; and (iii) the model shows evidence for an interaction between locality effects and WMC (embedded subject length × dependency type × WMC): For the conditions with unbounded dependencies only, the low-WMC readers showed a slight advantage for the long condition, which was reduced as WMC increased until it became an advantage for the short condition. Even though the interaction between locality effects (embedded subject length × dependency type) and reading fluency showed the predicted direction (smaller locality effects as reading fluency increases), the model shows very weak to no evidence for the effect. We do not report the interactions with the different regions in **Table 1** since they show no evidence that the pattern of the effects varies across regions (including the precritical region as it can be seen in **Figures 1**, **2**). However, nested comparisons where the models were evaluated at the different regions show that the locality × WMC interaction was mainly driven by the precritical, first critical, and spillover regions; see **Table 3**.

It is also worth noting that the length of the embedded subject had an effect on the RTs at the regions of interest, irrespective of the dependency manipulation. This effect would have been confounded with locality in the absence of appropriate baselines. This raises the concern that some of the previous studies that reported a main effect of locality could in principle have been reporting the effect of increasing the complexity of the subject that appeared prior to the verb.

WMC stands for working memory capacity and RF for reading fluency. The first column $\hat{\delta}$ shows the estimated effect size of the coefficients; the next two columns show the 2.5th and 97.5th percentiles of their posterior distribution, that is, where the effect size lies with 95% probability; and $P(\hat{\delta} > 0)$ indicates the posterior probability that each coefficient is positive.

2.3. Discussion

For this experiment, even though we found an effect of embedded subject length, we did not find evidence of locality effects (an embedded subject length × dependency type interaction) across the board. Furthermore, even though an interaction between WMC and locality effects was expected, the interaction was predicted in the opposite direction. We predicted that low-capacity participants would show the strongest locality effects, while counter-intuitively, in our experiment it was the high-WMC participants that showed the strongest locality effects (the largest difference between *(long unbounded − long baseline)* and

(short unbounded − short baseline)), while low-WMC showed antilocality effects; as shown in **Figures 1**, **2**.

This interaction seems counterintuitive because theories that predict locality effects would not predict that high-WMC participants would show stronger locality effects. Locality effects are hypothesized to be a behavioral response to either the use of more computational resources (Gibson, 2000), or higher retrieval costs due to more interference and decay (Lewis and Vasishth, 2005) when the distance between head and argument is increased. However, the speedup of low-WMC readers can be accounted for by adding two intuitively plausible assumptions to memory-based explanations, namely, that low-capacity readers experience retrieval failures more frequently than high-capacity readers, thus leading to unresolved dependencies and an incomplete sentence representation compatible with good enough processing (Ferreira and Patson, 2007); and that retrieval failures are faster on average than complete retrievals. We provide further evidence supporting this claim in the next experiment and the modeling section.

Furthermore, reading fluency correlated with comprehension accuracy (as strongly as WMC) for this experiment, and participants with higher scores in reading fluency tended to read faster the regions of interest. However, we found very weak to no evidence favoring the hypothesis that fluent readers would overcome more easily locality effects than less fluent readers.

While the pattern showing stronger locality effects for high-WMC participants begins at the precritical region (a proper noun that is either the subject or the last part of it) before the verb, memory driven locality effects are predicted to appear no sooner than the verb. However, pre-verbal locality effects have been detected also in Vasishth and Drenhaus's (2011) study, and they also appeared in some degree in the next experiment. This phenomenon will be addressed in the general discussion.

3. EXPERIMENT 2

The second experiment attempts to replicate Experiment 1 using SOV structures in German, in contrast to the SVO structures in Spanish of the previous experiment. The main objective of the second experiment was to verify whether the same account for the findings of Experiment 1 is valid for an SOV language. This is important because SVO structures seem to trigger mostly locality effects at the head verb (among others Grodner and Gibson, 2005; Lewis and Vasishth, 2005; Vasishth and Lewis, 2006; Demberg and Keller, 2008; Bartek et al., 2011), while SOV structures seem to trigger either antilocality effects (Konieczny, 2000; Konieczny and Döring, 2003; Vasishth, 2003; Vasishth and Lewis, 2006; but see Safavi et al., Submitted) or both locality and antilocality (Vasishth and Drenhaus, 2011; Levy and Keller, 2013; Husain et al., 2014). It was therefore important to verify whether the same results can be obtained with the same manipulation irrespective of the OV/VO order.

3.1. Methods

3.1.1. Participants

Seventy-two subjects aged between 17 and 43 years old (mean 24.6 years) were recruited using ORSEE (Greiner, 2004) at the University of Potsdam, Germany. All participants reported to be native speakers of German and were naïve to the purpose of the study. Three other participants had to be removed from the data: one subject answered randomly at the operation span task, another subject answered the comprehension questions at chance level, and the data of a third participant was lost due to technical reasons.

3.1.2. Stimuli

Similarly to Experiment 1, the stimuli for this experiment consisted of 48 items in German with four conditions in a two-by-two design: embedded subject length × dependency (see Example 8).

For this experiment, the embedded subject length manipulation was created by changing the determiner (*die*) of the noun phrase of the short condition with a longer genitive phrase such as *Marias äußerst kaltschnäuzige*, "Mary's extremely uncaring": (8a vs. 8b, and 8c vs. 8d). The dependency manipulation was created as in Experiment 1 by comparing conditions with an unbounded dependency vs. local dependency (baseline) conditions. Thus, conditions (8a–8b) were compared with two baseline conditions (8c–8d) with similar structure, but that lacked the unbounded dependency: The dependent of the verb *jemanden* (someone.ACC) appeared at the same distance of the verb in both short and long baseline conditions.

(8) a. SHORT - UNBOUNDED DEPENDENCY

Marias äußerst kaltschnäuzige Lehrerin fragte,
Mary's extremely uncaring teacher asked
wen die Mutter gestern beim Treffen
who.ACC the mother yesterday at.the meeting
angeschrien hat mit schriller Stimme.
yelled had with shrill voice

b. LONG - UNBOUNDED DEPENDENCY

Die Lehrerin fragte, **wen**
The teacher asked **who.ACC**
Marias äußerst kaltschnäuzige Mutter gestern
Mary's extremely uncaring mother yesterday
beim Treffen **angeschrien hat** mit schriller
at.the meeting **yelled had** with shrill
Stimme.
voice

c. SHORT - BASELINE

Marias äußerst kaltschnäuzige Lehrerin fragte,
Mary's extremely uncaring asked teacher
ob die Mutter jemanden beim Treffen
if the mother someone.ACC at.the meeting
angeschrien hat mit schriller Stimme.
yelled had with shrill voice

d. LONG - BASELINE

Die Lehrerin fragte, ob
The teacher asked if
Marias äußerst kaltschnäuzige Mutter jemanden
Mary's extremely uncaring mother someone

beim Treffen **angeschrien hat** mit schriller
at.the meeting **yelled had** with shrill
Stimme.
voice

The 48 experimental items of the current experiment were presented together with 98 experimental items belonging to experiments from unpublished studies. The sentences presented included (i) 32 items with subject and object relative clauses attached to the subject or the object of sentences; (ii) 42 items with attachment ambiguity involving dative and genitive noun phrases; and (iii) 24 items that contrasted personal and demonstrative pronouns.

3.1.3. Procedure

The procedure was the same as the one used in Experiment 1, with the exception that comprehension questions appeared after every trial in the self-paced reading experiment.

3.2. Results

3.2.1. Results of the Individual Differences Measures

3.2.1.1. Operation span

Partial-credit unit scores for the operation span test measuring WMC of the 72 participants had an average of 0.63 ($SE = 0.02$; range 0.28–0.92).

3.2.1.2. Rapid automatized naming

Average character speed for the rapid automatized naming task for measuring reading fluency ranged between 1.43 and 3.61 characters/second with an average of 2.64 ($SE= 0.06$) characters/second. As in Experiment 1, the reciprocal of the averaged reading time was used as the reading fluency measure.

As in Experiment 1, these two measures were not correlated for the participants of the experiment; $r = 0.02$, $CrI = [-0.23, 0.27]$. In contrast with the previous experiment, only WMC was correlated with the general accuracy for all the items; WMC: $r = 0.42$, $CrI = [0.23, 0.60]$; reading fluency: $r = 0.01$, $CrI = [-0.24, 0.27]$.

3.2.2. Results of the Self-Paced Reading Experiment

3.2.2.1. Comprehension accuracy

Participants answered correctly on average 80% (SE=1) comprehension probes of the trials belonging to the experiment.

3.2.2.2. Reading times

As for Experiment 1, we fitted a single model for our four regions of interest (9) using Helmert contrasts. **Figure 4** shows mean RTs for high- and low-WMC readers at each comparable region, while **Figure 5** shows only the locality effects × WMC interaction.

(9) ... fragte {wen; ob} {die; Marias äußerst
... asked {who.ACC; if} {the; Maria's extremely

kaltschnäuzige} Mutter	gestern	beim	Treffen	
uncaring} mother	yesterday	at.the	meeting	
			precritical	
angeschrien	hat	mit	schriller	...
shouted	have	with	shrill	...
critical 1	critical 2	spillover 1	spillover 2	

As in Experiment 1, RTs under 150 ms and above 5000 ms were removed from the data (2.83% of the observations).

Table 4 and **Figure 6** summarize the main results of the model for the effect of reading fluency, WMC, locality effect (embedded subject length × dependency), and its interaction with reading fluency and WMC, including the data from all the regions of interest. We omitted the interactions with the different regions since the effects of interest had the same pattern in all the regions. **Table 5** summarizes the results from nested comparisons where the models were evaluated at the different regions.

The models reveal the following: As in Experiment 1, even though it is with less certainty, subjects with higher reading fluency scores tended to have shorter RTs.

In addition, and as in the previous experiment, we did not find the hypothesized locality effects in this experiment. The models, however, show evidence for an interaction between locality effects and WMC. This interaction has the same pattern in all regions of interest. The resulting effect is similar to the one of Experiment 1, even though the underlying pattern is different (see **Figure 4**): the effect was mainly driven by a speedup in long baseline conditions in comparison with short baseline conditions. This speedup was reduced as WMC decreased until it became an advantage for the short condition for low-WMC readers; compare the figures depicting the effects for high- and low-WMC in Experiment 2 (**Figure 5**) with Experiment 1 (**Figure 2**).

We also found some evidence for a three-way interaction between embedded subject length, dependency type, and reading fluency, with the same direction as in Experiment 1, that is, decreasing locality effects as the score of reading fluency increases. The interaction had the following pattern: For the unbounded dependency conditions, as reading fluency increased, RTs at the long condition decreased in comparison with the RTs at the short condition; while for the baseline conditions this pattern was reversed.

3.3. Discussion

We found a dependency type × embedded subject length × WMC interaction, which had the same sign as in the previous experiment. However, while in Experiment 1 the effect seemed to be caused by the difference between the unbounded dependency conditions, in Experiment 2, the effect was mainly caused by a difference between the baseline conditions. In contrast to the Spanish stimuli, the subject did not immediately precede the verb in the German stimuli and therefore had to be retrieved from memory. Since the long conditions appear together with a more informative and salient subject, and the encoding of the longer subjects seems to have not spilled over the head verb; it may be the case that the subject retrieval is faster (Hofmeister, 2007; Hofmeister and Vasishth, 2014), thus leading to a speedup in both long conditions (both unbounded dependency and baseline conditions).

But crucially, the dependency type × embedded subject length × WMC interaction had the same direction and similar magnitude as in Experiment 1, that is, high-WMC participants showed the largest difference between *long unbounded − long baseline* and *short unbounded − short baseline*, while this difference is inverted for low-WMC readers. This outcome allows

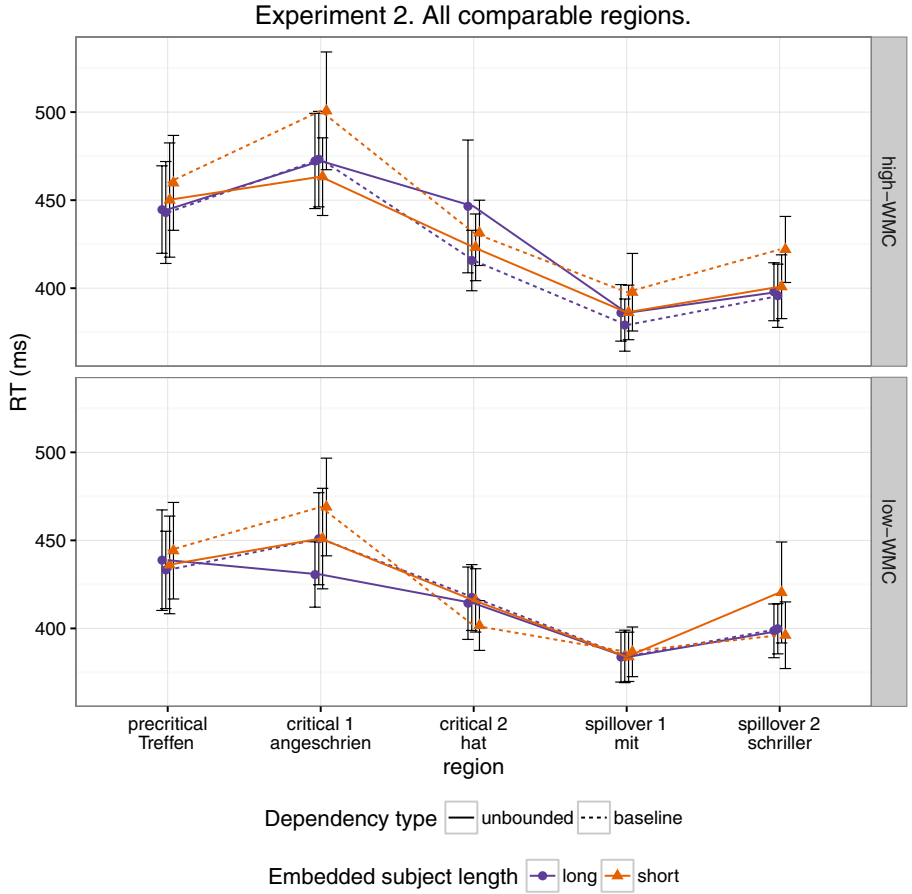

FIGURE 4 | Comparison of mean RTs for high- and low-WMC readers at each comparable region for every condition.

us to give the same interpretation to the results of the current experiment: high-WMC readers showed locality effects and low-WMC readers showed a speedup, which we argue that it is associated with a higher proportion of failure in retrieval in the long unbounded dependency condition.

In contrast with Experiment 1, reading fluency did not show a correlation with comprehension accuracy (while only WMC did). Similarly to the first experiment, however, participants with higher scores in reading fluency tended to read the critical region faster. In addition, we found somewhat stronger evidence favoring the hypothesis that fluent readers would overcome locality effects more easily than less fluent readers.

4. GENERAL DISCUSSION

We found no evidence for locality effects across the board in either experiment, that is, no evidence for an interaction between dependency type and embedded subject length independent of individual differences in WMC. However, we did find evidence for an interaction between locality effects and WMC (dependency × embedded subject length × WMC) for both Spanish and German experiments. Even though there were differences in how the three-way interaction was produced between the two experiments, this may be due to the differences in the overall structure of the sentences, namely, SVO and SOV structures (and see the previous discussion). More importantly, when the differences are controlled via baselines, we see an interaction with the same (counterintuitive) pattern in both experiments: high-WMC readers showed the strongest locality effects that were reduced with decreasing WMC and eventually changed direction, such that low-capacity readers showed a speedup effect.

The speedup of low-capacity readers is in line with independent evidence showing that in some cases high working memory load may lead to faster RTs: Van Dyke and McElree (2006) found that readers showed shorter RTs (together with lower comprehension accuracy) when a memory load was present in comparison with the conditions without the memory load. Furthermore, our findings are also compatible with studies showing that low-WMC subjects may take less time when ambiguities are present (at the expense of their accuracy) than high-WMCs (MacDonald et al., 1992; Pearlmutter and MacDonald, 1995).

It should be underscored that, unlike Just and Carpenter (1992), we do not argue that the effect of WMC is directly on mechanisms specific to language, such as parsing rules.

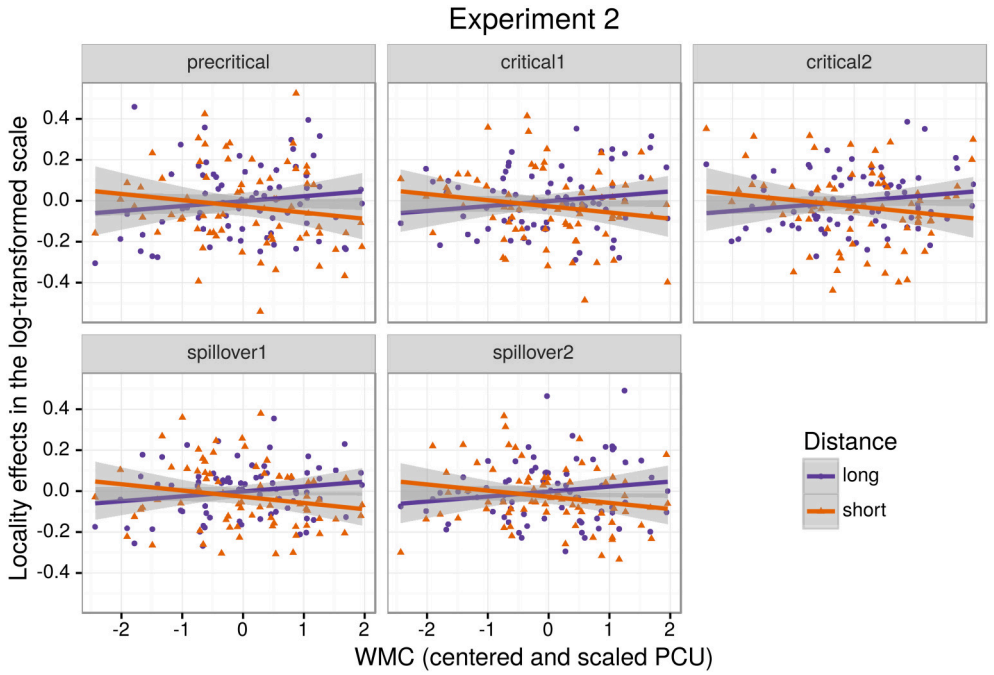

FIGURE 5 | The figure depicts the partial effect for the difference between unbounded conditions and baseline conditions, that is the (anti)locality effects, on the transformed scale of the analysis; random factors variance and effects due to reading skills were removed from the dependent variable (Hohenstein and Kliegl, 2013).

TABLE 4 | Main results for Experiment 2 (German).

Predictor	$\hat{\delta}$	95% CrI		$P(\hat{\delta} > 0)$
Length	−0.01	−0.04	0.02	0.2
Dependency	−0.02	−0.05	0.01	0.11
WMC	0.09	−0.1	0.28	0.83
RF	−0.14	−0.33	0.04	0.06
Length:dependency	0.02	−0.02	0.05	0.85
Length:dependency:WMC	0.03	0.01	0.06	0.99
Length:dependency:RF	−0.03	−0.05	0	0.04

The first column $\hat{\delta}$ shows the estimated effect size of the coefficients; the next two columns show the 2.5th and 97.5th percentiles of their posterior distribution, that is, where the effect size lies with 95% probability; and $P(\hat{\delta} > 0)$ indicates the posterior probability that each coefficient is positive.

We argue instead that the effect of WMC is on the retrieval of the dependents, which we assume is driven by the same cognitive mechanisms as retrieval outside sentence processing. There is a great deal of evidence suggesting that high-WMC participants tend to do better on tasks that involve retrieval in comparison with low-WMC ones, particularly under conditions of interference: for example, Conway and Engle (1994) found that high- and low-WMC individuals differed in retrieval efficiency only when items were associated with multiple cues (which caused more interference). In a study by Kane and Engle (2000), participants were shown a list of category exemplars followed by a distractor activity. After the distractor task, the participants were instructed to recall the category exemplars. Kane and Engle found that all participants recalled a similar number of words on the first trial but that low-WMC individuals recalled fewer items than high-WMC individuals as the task progressed. Kane and Engle concluded that low-capacity individuals were more susceptible to the buildup of proactive interference than were high-capacity ones. Conway et al. (2001) extended the investigation of the cocktail party phenomenon, the situation in which one can attend to only part of a noisy environment, but stimuli such as one's own name can suddenly capture attention. While previous investigations have shown that approximately 33% of the participants hear their name in an unattended, irrelevant message channel, Conway et al. found that 65% of low-WMC participants did detect their name in contrast with 20% of high-WMC ones. This result also suggests that low-WMC are also more susceptible to interference. Kane et al. (2001) reported similar differences in an antisaccade paradigm, which presents a conflict between task goals and visual cues. High-WMC participants made fewer errors, they recovered from these errors more rapidly, they initiated antisacades more quickly, and they identified targets more quickly than did low-WMC participants.

Besides ACT-R, two recent theories of WMC posit a role of individual differences in differential effects at retrieval: Unsworth et al. (Unsworth and Engle, 2007; Unsworth et al., 2009) have recently suggested a dual-component framework for interpreting individual differences in WMC. In this framework, WMC partially reflects differences in attention control abilities together with retrieval abilities in which information that could not be maintained in the focus of attention (due to

distraction and/or capacity constraints) is retrieved via a cue-dependent search process. In addition, Oberauer et al. (2012) have postulated a computational model, "serial order in a box - complex span" or SOB-CS (an extension of C-SOB; Farrell, 2006; Lewandowsky and Farrell, 2008, which originated as SOB; Farrell and Lewandowsky, 2002), where capacity is limited only by interference between representations. One of the individual differences that the model assumes is a parameter that determines the degree of discriminability between retrieval candidates.

In our view, non-local dependency resolution is a case where the individual differences in WMC may play a role: an argument that is no longer in the focus of attention has to be retrieved from memory, using information from the verb that is retrieved online, and after the parser has encoded a variable amount of lexical material that can produce interference together with either pure time-based decay or interference-based decay.

However, we must acknowledge that recent findings raise the concern that WMC may have limited value for explaining individual differences in linguistic contexts. A recent study by Van Dyke et al. (2014) replicated Van Dyke and McElree (2006) while including a battery of tests for measuring individual differences as well. This recent study showed that while high-span participants read more slowly in the conditions with high cognitive load and showed higher accuracy in comparison with low-span participants, the effect of WMC may be spurious. When receptive vocabulary was included in the analysis, it showed the same effects previously attributed to WMC, revealing that the participants with better scores in the vocabulary task were more affected by the interference during online reading. Similarly, a study of Traxler and Tooley (2007) investigating syntactic ambiguity showed that vocabulary size predicted the degree to which readers were disrupted by the syntactic misanalysis for several eye-tracking measures; while WMC was only a marginal predictor for total reading times. In addition, Long et al. (2008) study of recollection and familiarity of previously read sentences showed that only individual differences of readers' background knowledge was predictive of better performance but not WMC (but neither neither print exposure or vocabulary size). Long et al. (2008) argued that because retrieval cues were minimal, access to the text representation depended more on the reader's background knowledge than on the reading skills or WMC of the participants.

Our results do not rule out the possibility that retrieval processes in sentence processing are based on different mechanisms which are independent of WMC, and that the effect that we found is due to WMC being a proxy for other individual differences such as robustness of lexical representations (Traxler and Tooley, 2007; Van Dyke et al., 2014). This is a valid criticism, but it affects any experiment that includes individual differences. No matter how extensive the battery of tasks, there is always the possibility that a predictor is in fact a proxy for another unmeasured predictor.

In addition, the locality effects × WMC interaction in the two experiments should not be dismissed as a simple speed-accuracy trade-off. It is a well known phenomenon that accuracy deteriorates with increasing speed (see for example, Pachella, 1974, and more recently, Heitz, 2014). This general phenomenon, however, does not explain why low-WMC participants would decide to sacrifice accuracy for speed even to a rate that is higher than when there is a lower cognitive load (i.e., a shorter dependency). Furthermore, it also does not explain what mechanisms low-WMC participants may have used to identify the high-cognitive load conditions in order to speed up.

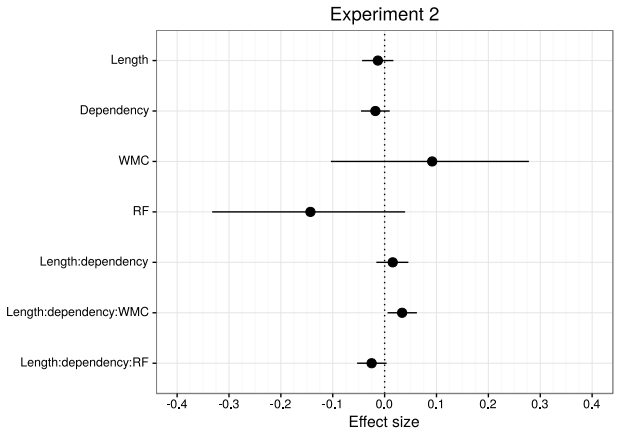

FIGURE 6 | Overview of mean and 95% credible intervals for the effect sizes of the parameters of interest for Experiment 2.

We suggest that the locality effects of the high-WMC readers and the speedup of the low-WMC readers can be explained by adding two assumptions to memory-based explanations, namely, (i) that failures of the retrieval of the dependent (the *wh*-element in this case) are more frequent in low-WMC participants than in high-WMC ones; and (ii) that retrieval failures are faster on average than complete retrievals.

The locality effects × WMC interaction in the two experiments may be related to some type of good-enough parsing strategy (Ferreira et al., 2002; Ferreira and Patson, 2007), where low-WMC readers failed to achieve a complete and fully specified representation of the sentence more often when faced with the long unbounded dependency condition. Without the possibility of re-reading, and since the comprehension questions were not targeting exclusively whether the dependency was understood, low-WMC readers may have failed in many cases to retrieve the dependent and continued reading.

In other words, we speculate that the average time T for the completion of a dependency is determined by:

$$T = T_{baseline} + P_{retrieval} \cdot T_{retrieval} + (1 - P_{retrieval}) \cdot T_{failure}$$

while the proportion of completed retrievals $P_{retrieval}$ is higher for high-WMC readers in comparison with low-WMC readers when the dependent-head distance is increased; and $T_{retrieval}$ at a long dependency is larger than $T_{retrieval}$ at a short dependency.

Notice, however, that without the proportion of completed retrievals ($P_{retrieval}$) for each case, the model previously presented is unidentifiable. The proportion of completed retrievals should be linked to the accuracy of the comprehension of the dependencies.

Length:dependency:RF	−0.02	−0.05	0.02	0.15

WMC stands for working memory capacity and RF for reading fluency. The first column $\hat{\delta}$ shows the estimated effect size of the coefficients; the next two columns show the 2.5th and 97.5th percentiles of their posterior distribution, that is, where the effect size lies with 95% probability; and $P(\hat{\delta} > 0)$ indicates the posterior probability that each coefficient is positive.

There is some evidence that high-WMC outperformed low-WMC in general comprehension in this experiment; but we could not target the comprehension of the dependencies in the experimental stimuli. The true-or-false statements used in both Experiment 1 and 2 (as in Nicenboim et al., 2015b) included many aspects of the stimuli to verify that participants paid attention to the sentences, but they did not target exclusively whether the dependency was understood. Since the dependencies included a wh-argument, comprehension questions would ideally need to verify unnatural constructions, namely, whether it is true that, for example, "Maria greeted whom." However, preliminary data from our lab (Nicenboim et al., 2015a), where the stimuli allowed for more informative question-response accuracy, suggest that at least for interference effects in relative clauses, both low-WMC and high-interference conditions seem to provoke more retrieval failures.

In the following section we present simulations based on the ACT-R framework to illustrate in which situations and under which assumptions our hypothesis holds.

Regarding the effect of reading fluency on locality effects, the experiments presented some weak evidence favoring the hypothesis that fluent readers may overcome locality effects more easily than less fluent ones. The evidence is rather weak for the following reasons: Reading fluency predicted comprehension accuracy in Experiment 1, where it interacted very weakly with locality effects and with much uncertainty. In contrast, reading fluency did not predict comprehension accuracy in Experiment 2, while it interacted more strongly with locality effects and with less uncertainty. Given the similarity between the experiments, it is hard to explain the discrepancies.

To some degree in Experiment 1 and with more uncertainty in Experiment 2, the pattern showing stronger locality effects for high-WMC participants begins at the precritical region before the verb. Memory driven locality effects, however, are predicted to be triggered by a retrieval process that would start presumably no sooner than the verb. One possible explanation proposed by Vasishth and Drenhaus (2011) is that the verb phrase may have already been built when the proper noun preceding the verb is processed. This assumption is consistent with Levy's (2008) expectation-based account, because the parser can deduce that the verb will appear immediately afterwards and thus anticipate the retrieval process.

It should be noted that expectations were controlled only under the simplifying assumption that given that a clause has a finite length, the probability that the next word will be the subcategorizing verb rises as the number of words after finding the wh-element increases. In a way, this is similar to the increasing hazard function proposed for visual search by Peterson et al. (2001). A more formal verification could not be conducted, since the sentences used for our two experiments were too complex for a correct parsing of a probabilistic top-down parsing (Roark, 2001; Roark et al., 2009) trained with Spanish (Moreno et al., 2003) and German treebanks (Brants et al., 2004). Even after unlexicalizing the treebanks, the parser failed to identify the structure of the sentences used in our stimuli. However, given that the speedup occurred for low-span readers in sentences with long dependencies, assuming that increasing the length of the dependencies still caused an increase in expectations beyond the control of the baseline would require the implausible assumption that low-span readers are better at making predictions than high-span readers.

5. MODELING

Even though both the activation-based account and DLT would intuitively predict that increasing the distance between dependent and head should have produced a slowdown (once expectations are controlled), our results do not show a main effect of locality and only an interaction with WMC. Thus, we first verified that the activation-based account in fact predicts locality effects and stronger effects for low-span readers using the ACT-R framework (see for example Anderson et al., 2004). ACT-R is a general cognitive architecture used to model a vast variety of cognitive phenomena; for our purposes, however, the relevant aspect of the architecture is that it can model the retrieval of items stored in memory. In order to simplify our models, we used only the equations that determine the probability and latency of a retrieval and not the full framework. In this section, we tested different implementations of WMC with the "default" ACT-R equations and we show that, no matter what the parameter settings are, they fail to account qualitatively for the results. Therefore, we tentatively suggest that a basic assumption about the relationship between latencies and activation needs some reconsideration; we propose that items in memory with an activation below a certain threshold may show shorter latencies because of an early aborting of the retrieval process.

The exact predictions of the ACT-R implementation of the activation-based account will depend on the exact syntactic structure and the type of parser that is assumed together with the values of the ACT-R parameters. In addition, it cannot at present accommodate certain aspects that seem to have an uncontroversial effect in language, such as expectations (Hale, 2001; Levy, 2008). Thus, we focused on the explanation of (anti-)locality effects, (i.e., the interaction distance × dependency), which was the theoretical comparison of interest; and we did not investigate the underlying processes that generated the reading times for each condition (see Introduction).

In this framework, the latency of the retrieval of an item from memory is assumed to be a function of the item's activation value A:

$$Latency = F \cdot e^{-A} \tag{1}$$

where F (the latency factor) is a scaling constant.

After verifying that ACT-R did not predict that other noun phrases would be mistakenly retrieved, we focused only on the retrieval of the wh-element. At the moment of retrieval, the activation A is calculated as the sum of (i) a *base level activation* BA that depends on the previous use of the item (i.e., the number of previous retrievals and the time passed since those retrievals); (ii) *spreading activation* S that depends on a limited amount of source activation W that is shared between all other items with features that match the retrieval cues; (iii) a penalty component for mismatching features (that we omit from the following equation); and (iv) a random noise component ϵ (that follows a logistic distribution with a mean of zero and scale σ):

$$A = BA + S + \epsilon \tag{2}$$

Locality effects affect only the base level activation due to decay; in our specific case, the base level activation of the wh-element can be described as:

$$BA = log(t^{-d}) + \beta \tag{3}$$

where d is the decay rate, t is the time since the encoding of the wh-element, and β is the base-level constant.

The equation for the spreading activation S ensures that the wh-element would be retrieved due to the boost of activation produced by the unique matching features. For simplicity, we can assume that the wh-element has a unique feature that distinguishes it from the other four competitor NPs (in example 6: Sofía, the younger sister, the younger sister of Sofía, and María), namely being $+wh$, and two non-unique features ($+animate$ and $+NP$) that it does share with the other NPs. The spreading activation of the wh-element is a function of the source activation W, and the weighted sum of the strength of association of the cues. The source activation is usually set to one, but it can also vary by participants (Daily et al., 2001), and it is divided between the cues. In the present case, this can be simplified as:

$$\begin{aligned} S = \; & W \cdot \big[w_{wh} \cdot (MAS - \log(1)) + w_{anim} \cdot (MAS - \log(5)) \\ & + w_{NP} \cdot (MAS - \log(5)) \big] \end{aligned} \tag{4}$$

where MAS is the maximum associative strength; and w_{wh}, w_{anim}, and w_{NP} are the weights given to the cues $+wh$, $+animate$, and $+NP$, and must sum to one. The maximum associative strength is subtracted by the natural logarithm of the number of competing items in memory that match a given cue plus one. MAS is an arbitrary value, which is usually fixed since it trades off with F (Schneider and Anderson, 2012). We fixed this parameter to two since the difference between MAS and $log(matchingcues + 1)$ must be always positive in ACT-R. The three summands of the previous equation represent three features that match with three retrieval cues: The first summand represents the unique feature $+wh$, which ensures the highest value of S for the wh-element, and the next two summands represent the features $+animate$ and $+NP$, which are shared with four competitors (hence log(5), as there are five noun phrases in total). (The spreading activation equations of the competitor noun phrases would have only the last two summands; and their activation would be reduced further by a penalty component that is also subtracted from their total activation).

WMC has been assumed to either affect the decay rate or affect in some way the spreading activation, that is, the activation shared between the retrieval cues (see the Introduction section). We simulated these possibilities by using standard ACT-R parameters from sentence processing (Lewis and Vasishth, 2005; Vasishth and Lewis, 2006), except for MAS, the latency factor, and the base levels constant that were adjusted to achieve realistic latencies based on previous studies.

The first possibility is the *capacity-as-decay-rate* model, which assumes that higher-WMC should predict a lower decay rate d (e.g., Byrne and Bovair, 1997; Cunnings and Felser, 2013). Then high-WMC participants will be less affected by longer dependency distance (which entails longer time since encoding); see **Figure 7A**.

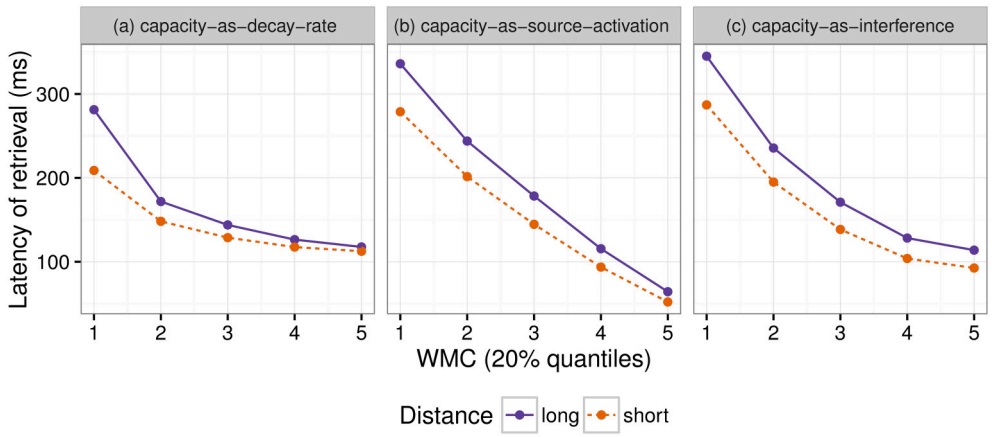

FIGURE 7 | The figures show simulated retrieval latencies at the critical region. The simulation is based on the default but simplified version of ACT-R. See **Table 6** for the parameters used.

TABLE 6 | Parameter values for the models with the default (simplified) ACT-R.

	cap-as-decay-rate	cap-as-source activation	cap-as interference
d	[0.06, 1.5]	0.5	0.5
W	1	[0.5, 3.5]	1
w_{wh}	1/3	1/3	[0.1, 1]
MAS	2	2	2
F	1.6	1.6	1.6
σ	0.25	0.25	0.25
β	−0.65	−1	−1
(Without threshold) τ	$-Inf$	$-Inf$	$-Inf$
(With threshold) τ	0	0	0

The decay time was calculated from the data of the German experiment; we used the mean reading time elapsed from the wh-element until the verb, which was 2614 ms for the short condition and 3922 ms for the long one.

If higher-WMC correlates with more spreading activation, there are two approaches: (i) The *capacity-as-source-activation* model assumes that the total amount of activation that is shared between matching cues (the source activation W) is a function of WMC (as in Cantor and Engle, 1993; Daily et al., 2001; van Rij et al., 2013); see **Figure 7B**. (ii) The *capacity-as-interference* model assumes that WMC represents susceptibility to interference (Bunting et al., 2004). Non-unique retrieval cues such as looking for a noun phrase or for the feature *+animate* cause the limited amount of source activation to be shared between competitor noun phrases, decreasing the total level of activation of the target (and also increasing the activation level of competitors). A way to model this susceptibility to interference is to change the weight given to unique cues and non-unique cues, so that as WMC increases, the weight given to a unique retrieval cue (such as being a wh-element) increases too; see **Figure 7C**.

These models predict mainly that an increase in WMC would increase the speed of the retrievals, as well as an interaction between WMC and dependency-head distance in raw RTs. The strength of the effect of WMC as well as the interaction will depend on the values of the parameters, and given that there is noise in the system (recall that the activation includes also a component ϵ), not every possible model will show these effects.

Given the relation between activation and latency, the models that assume that WMC affects the activation linearly (such as capacity-as-source-activation and capacity-as-interference) have two important implications: The first one is that if WMC affects the spreading activation S, locality effects *in raw latencies* should be modulated by WMC. The second implication is that for *log-transformed latencies*, the interaction should be exactly zero. The reason is the following: Locality effects are produced by the difference in the retrieval latencies, such that due to decay, the base level activation BA decreases as the distance between wh-element and head increases:

$$\begin{aligned} Locality &= Latency_{LongDep} - Latency_{ShortDep} \\ &= F \cdot (e^{-(BA_{low}+S)} - e^{-(BA_{high}+S)}) \\ &= F \cdot e^{-S} \cdot (e^{-BA_{low}} - e^{-BA_{high}}) \end{aligned} \quad (5)$$

If, as hypothesized, WMC only affects the spreading activation S, such that the S is higher for high-WMC than for low-WMC, then the interaction between locality effects and WMC would be defined as follows:

$$\begin{aligned} Locality \times WMC &= Locality_{LowWMC} - Locality_{HighWMC} \\ &= F \cdot (e^{-S_{low}} - e^{-S_{high}}) \cdot (e^{-BA_{low}} - e^{-BA_{high}}) \end{aligned} \quad (6)$$

However, log-transformed locality effects are independent of S:

$$\begin{aligned} log(Locality) &= log(F) - (BA_{low} + S) - [log(F) - (BA_{high} + S)] \\ &= -BA_{low} + BA_{high} \end{aligned} \quad (7)$$

and thus the difference between locality effects for high and low-WMC for log-transformed latencies would be simply zero.

But critically, no matter the values of the parameters, these two models cannot predict our findings, namely, a speedup for

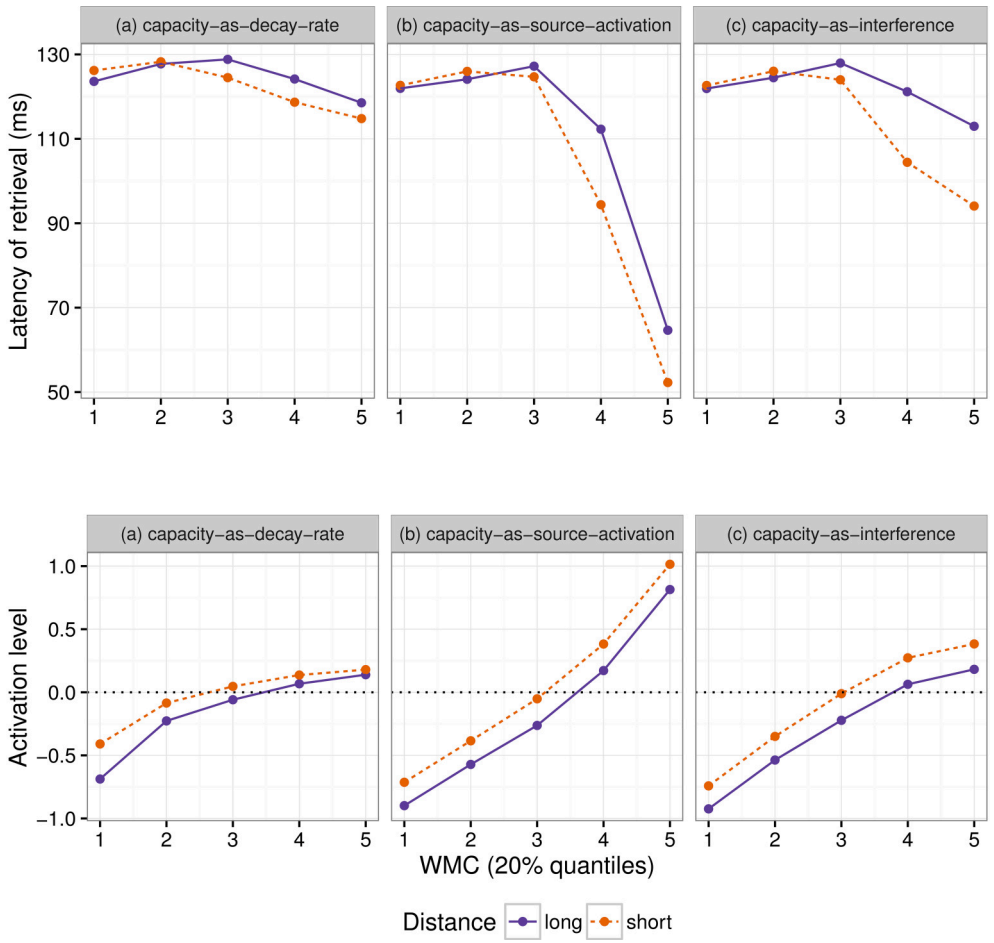

FIGURE 8 | The upper figures show simulated retrieval latencies and the lower figures the activation values that produced the latencies. The simulation is based on the default but simplified version of ACT-R, where the threshold τ is zero. See **Table 6** for the parameters used.

low-span participants. This is so because the baseline activation of the wh-element when it is retrieved after a longer time (due to more intervening material between itself and the head verb) can never be higher than the level of activation when the element is retrieved after shorter time; furthermore, the spreading activation can at most attenuate this effect and only as WMC increases.

It is further assumed in ACT-R models that there is a minimum level of activation τ that an item needs in order to be retrieved. This acts as a time-out: when an item has so low activation that it would take an unrealistic amount of time to be retrieved, the retrieval fails. The maximum amount of time is a function of this activation threshold τ such that:

$$max(Latency) = F \cdot e^{-\tau} \tag{8}$$

If τ plays a role in retrieval, because the activation level of the dependent does not always exceed this value, it will produce a ceiling effect. Under this view, if the activation level of the dependent for low-WMC failed more often than for high-WMC to surpass τ, it would entail a maximum possible time for both short and long conditions. This would produce a difference in retrieval probabilities between short and long conditions, since it is more likely that long conditions fail more often to surpass the value τ. However, this would also mean that with low-WMC, the difference between long and short conditions may disappear; see **Figure 8**. Our data cannot be accommodated in these models either, since the difference between long and short conditions was reversed for low-WMC.

The pattern that we found in our data, however, can only be accommodated in the models presented before by changing one assumption, namely, by assuming that in the cases where the activation does not reach the threshold τ, the retrieval would be aborted at any moment before the maximum amount of time. In this view, failed retrievals would take less time on average than the time needed to retrieve the item, with the activation influencing the retrieval probability and WMC in turn influencing the level of activation; see **Figure 9**. This would mean that τ would act as a critierion for aborting instead of a time-out. We simulated this by assuming that WMC affects the activation of the wh-element very weakly and, critically, that retrievals can fail at any time before the maximum retrieval latency (i.e., following a uniform distribution limited between zero and $max(Latency)$).

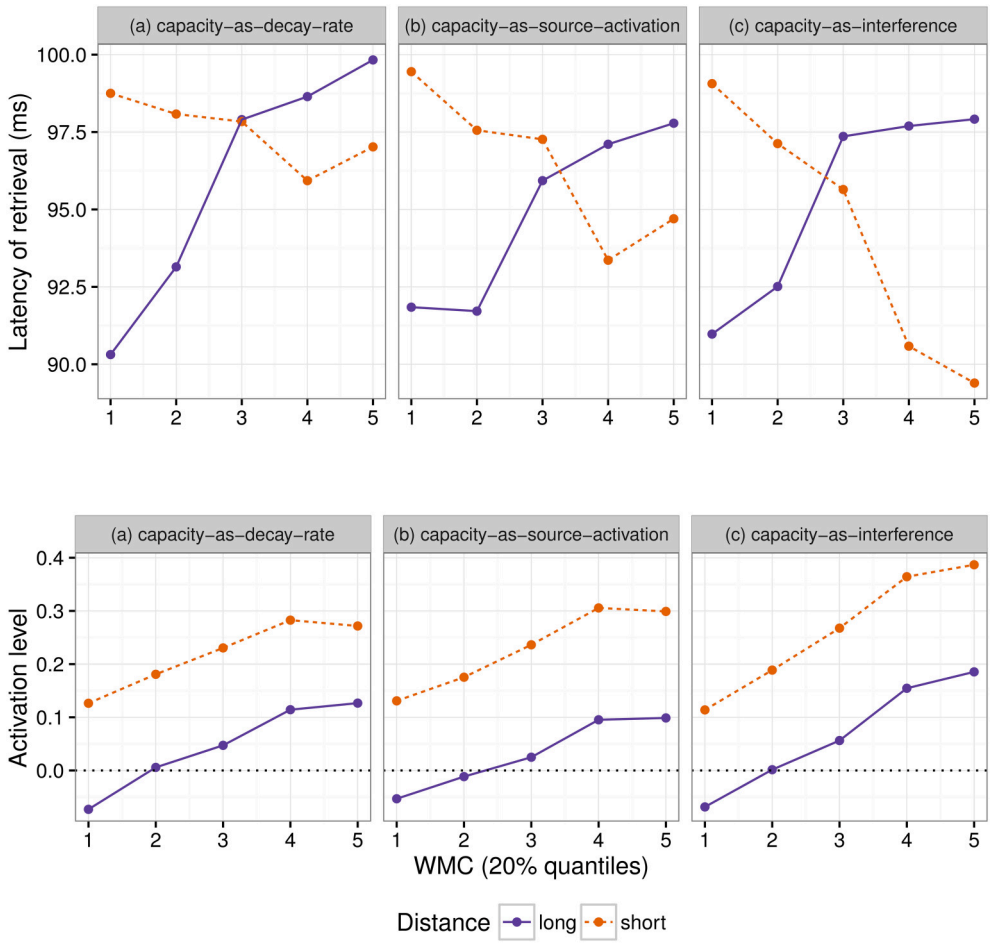

FIGURE 9 | The upper figures show simulated retrieval latencies and the lower figures the activation values that produced the latencies. The simulation is based on the modified version of ACT-R, where the threshold τ is zero. See **Table 7** for the parameters used.

There are, of course, other possibilities that will fit with the general pattern as well: Any distribution of latencies with a mean that is smaller than the average latency for a retrieval will show this pattern. Importantly, by relaxing the ACT-R assumption that too low activation must produce the longest possible latency, we are able to account qualitatively for the pattern in our data. This is so, because participants with lower-WMC would fail more often than high-WMC, and since they would complete retrievals relatively slowly, their failures would be on average faster. An interesting prediction from this modification is that in the small number of cases where a retrieval would fail for high-WMC participants, because high-WMC subjects should produce faster than average retrievals, they would still show slower failures in comparison to their retrievals.

There is some parallelism between fast failures in our experiment and fast errors in two-alternative forced choice tasks. Recent research in two-alternative forced choice tasks has shown that time-varying collapsing thresholds (e.g., Frazier and Yu, 2008; Drugowitsch et al., 2012; Thura et al., 2012) can explain wrong answers that are given too early, even though there is no apparent imposed deadline. Self-paced reading presents a paradigm, however, where the only possible choice at every point is to press the space bar to continue reading. In order to build a complete representation of the sentences,

TABLE 7 | Parameter values for the models with the modified (simplified) ACT-R.

	cap-as-decay-rate	cap-as-source-activation	cap-as-interference
d	[0.33, 0.62]	0.5	0.5
W	1	[0.9, 1.2]	1
w_{wh}	1/3	1/3	[0.2, 0.5]
MAS	2	2	2
F	1.6	1.6	1.6
σ	0.25	0.25	0.25
β	−0.3	−0.3	−0.3
(With threshold) τ	0	0	0

The decay time was calculated from the data of the German experiment; we used the mean reading time elapsed from the wh-element until the verb, which was 2614 ms for the short condition and 3922 ms for the long one.

participants reading the verb region should delay pressing the space bar, until they retrieve from memory the dependent and they complete the dependency. However, we have argued that, when the dependent does not have enough activation, retrieval processes are aborted early. Assuming time has a cost, Frazier and Yu (2008) argue that an optimal stopping rule for a process is to stop the first time that the expected cost of continuing exceeds that of stopping, and to continue only if it is going to improve the chances of success enough to offset the extra time. A stopping rule in self-paced reading would mean pressing the space bar and continue reading. When an item to be retrieved has enough activation, an optimal stopping rule could be to wait and continue reading only when the retrieval is finished. Alternatively, when an item has insufficient activation, the parser could evaluate that the activation would not be enough to finish the retrieval before a time out ($F \cdot e^{-\tau}$), abort the process, and continue reading, explaining the fast failures.

Further research with data that include RTs as well as some index of retrieval accuracy, which is as little contaminated as possible with general comprehension accuracy, other retrievals, and offline processes, could shed light on how and when exactly retrieval fails.

6. CONCLUSION

We presented two experiments showing that working memory affects locality effects. The results show that working memory affects retrieval times at unbounded dependency resolution, but in an unexpected manner: high-capacity readers showed the strongest locality effects that decreased with decreasing capacity and eventually changed direction, such that low-capacity readers showed antilocality effects.

We suggest that the results may not be simply due to a speed-accuracy trade-off and that they can be explained by adding two assumptions to memory-based explanations: (i) compared to high-capacity readers, low-capacity readers experience retrieval failures more frequently; and (ii) retrieval failures are on average faster than complete retrievals. We suggest that the retrieval failures end quickly because of insufficient activation, and this activation depends not only on dependent-head distance but also on the capacity of the readers.

All in all, both experiments show that translating longer RTs into processing difficulty and shorter RTs into facilitation may be too simplistic, especially when readers face long and complex sentences (which are not uncommon in psycholinguistic studies). Our results suggest that the same increase in processing difficulty may lead to slowdowns in high-capacity readers and speedups in low-capacity ones.

FUNDING

The work was supported by Minerva Foundation, Potsdam Graduate School, and the University of Potsdam. We acknowledge the support of the Deutsche Forschungsgemeinschaft and Open Access Publishing Fund of University of Potsdam.

ACKNOWLEDGMENTS

A preliminary version of this paper appeared in the Proceedings of TL/MAPLL 2014, Tokyo, Japan. Thanks to Richard McElreath for sharing his unpublished book, Statistical Rethinking, which influenced the statistical analysis. Thanks to Bob Carpenter and Stan's forum for help fitting the statistical models. Thanks to Lena Jäger for helpful comments on a draft and Felix Engelmann for help with ACT-R modeling.

Hyper-active gap filling

Much work has demonstrated that speakers of verb-final languages are able to construct rich syntactic representations in advance of verb information. This may reflect general architectural properties of the language processor, or it may only reflect a language-specific adaptation to the demands of verb-finality. The present study addresses this issue by examining whether speakers of a verb-medial language (English) wait to consult verb transitivity information before constructing filler-gap dependencies, where internal arguments are fronted and hence precede the verb. This configuration makes it possible to investigate whether the parser actively makes representational commitments on the gap position before verb transitivity information becomes available. A key prediction of the view that rich pre-verbal structure building is a general architectural property is that speakers of verb-medial languages should predictively construct dependencies in advance of verb transitivity information, and therefore that disruption should be observed when the verb has intransitive subcategorization frames that are incompatible with the predicted structure. In three reading experiments (self-paced and eye-tracking) that manipulated verb transitivity, we found evidence for reading disruption when the verb was intransitive, although no such reading difficulty was observed when the critical verb was embedded inside a syntactic island structure, which blocks filler-gap dependency completion. These results are consistent with the hypothesis that in English, as in verb-final languages, information from preverbal noun phrases is sufficient to trigger active dependency completion without having access to verb transitivity information.

Keywords: filler-gap dependency, active gap filling, prediction, verb transitivity, island, plausibility mismatch effects, eye-tracking

Introduction

A leading goal of sentence processing research is to understand how the parser adapts to a multitude of linguistic differences across languages to enable successful comprehension. In this regard, comparisons of verb-medial and verb-final languages have provided a valuable source of evidence (Mazuka and Lust, 1990; Inoue and Fodor, 1995). The main verb contains rich information such as subcategorization and thematic role information that is critical for constructing structural analyses and interpretations (e.g., Chomsky, 1965; Grimshaw, 1990; Pollard and Sag, 1994; Levin and Rappaport Hovav, 1995). Much experimental evidence shows that the verb is a valuable source of information for parsing (e.g., Ford et al., 1982; Tanenhaus and Carlson, 1989; Boland et al., 1990; MacDonald et al., 1994; Spivey-Knowlton and Sedivy, 1995; Garnsey et al., 1997; Mauner and Koenig, 2000; Traxler et al., 2002; Blodgett and Boland, 2004; Snedeker and Trueswell, 2004).

The importance of the information from the verb head has engendered theoretical claims that structure building processes do not even start until the parser encounters the head of a phrase (e.g., verbal head) to be constructed, even in verb-final languages where this would be significantly delayed (Abney, 1989; Pritchett, 1992).

However, subsequent empirical research on verb-final languages like Japanese or German has generated evidence against such head-driven parsing theories in their strongest form, demonstrating that the parser uses various morphological and syntactic cues to incrementally build structures and interpretations in verb-final languages (Bader and Lasser, 1994; Koh, 1997; Clahsen and Featherston, 1999; Kamide and Mitchell, 1999; Konieczny, 2000; Bornkessel et al., 2002; Felser et al., 2003; Kamide et al., 2003; Aoshima et al., 2009; Yoshida, unpublished doctoral dissertation). Thus, although verb information strongly influences parsing decisions when available, speakers of verb-final languages often begin building syntactic and semantic structure in advance of the verb.

These findings raise the question of whether pre-verbal structure building reflects a language-specific adaptation to the processing demands of verb-finality, or rather a property of a general parsing architecture that speakers of all languages use. For example, consider less frequent cases in verb-medial languages where multiple arguments precede the verb. A classic example of this comes from processing of 'filler-gap' dependencies as illustrated by the relative clause construction shown in (1), where the object noun phrase (NP) *the city* (called the *filler*) is dislocated from the post-verbal thematic position (called the *gap*[1]), and the parser needs to associate the filler and the gap in order to assign a thematic interpretation.

(1) The city that the author visited _____ was named for an explorer.

It has been reported that speakers of verb-final languages complete filler-gap dependencies in advance of verb information, associating the filler with the earliest structural position where a thematic role could be assigned (pre-verbal object gap creation: Nakano et al., 2002; Aoshima et al., 2004). The current study examines whether this may also be the case in a verb-medial language like English, and whether pre-verbal gap creation is a language-general parsing procedure rather than an adaptation specific to verb-final languages. Under this hypothesis, we predict that English speakers should posit a gap irrespective of whether the verb ultimately licenses a direct object gap position, and that signs of reading disruption should be observed in cases where the verb does not accommodate a direct object.

We report the results of three on-line reading experiments in English that tested this prediction by examining the effect of verb transitivity on reading times in filler-gap configurations. The results are consistent with the hypothesis that the parser actively associates the filler with the verb in advance of the verb across languages, regardless of differences in verb positions. These results suggest that the procedure for filler-gap dependency completion may be uniform across languages, and are consistent with the view that the parser predictively constructs rich representations at the earliest possible moment in advance of critical bottom–up evidence.

[1]In this paper we use the 'gap-filling' or 'gap-creation' terminology in a theory-neutral way, as is typical in the psycholinguistic literature. This terminology should not be taken as indicating a commitment to representations that include gaps or traces; all of the processing theories we discuss here could be specified in terms of representations that do not include empty categories.

Background on Active Filler-Gap Dependency Processing

Past research on filler-gap dependency processing has established that the parser postulates a gap before there is sufficient bottom–up evidence to confirm that analysis (*Active gap filling:* Fodor, 1978; Crain and Fodor, 1985; Stowe, 1986; Frazier and Flores d'Arcais, 1989). For example, Stowe (1986) observed the so-called *Filled gap effect* in (2), i.e., slower reading times at the direct object position *us* in the wh-fronting condition (2a) than in a control condition that did not involve wh-fronting (2b). This pattern of reading times suggests that the parser had already posited a gap following the transitive verb, before checking whether the direct object position was occupied.

(2) a. My brother wanted to know who Ruth will bring us home to _____ at Christmas.
b. My brother wanted to know if Ruth will bring us home to Mom at Christmas.

Converging evidence comes from an eye-tracking experiment by Traxler and Pickering (1996), who manipulated the thematic fit between the filler and the potential verb host, as in (3).

(3) We like the city/book that the author *wrote* unceasingly and with great dedication about _____ while waiting for a contract.

Traxler and Pickering found a plausibility mismatch effect at the critical verb in (3), i.e., the first fixation time at the optionally transitive verb *wrote* increased when the filler was an implausible object of the verb (i.e., *the city*), compared to when the filler was a plausible object of the verb (i.e., *the book*). This suggests that at least as early as the verb position, the parser postulates a gap and analyzes the filler as the object of the verb, even when the filler is a poor semantic fit to that role. In fact, there is ample time course evidence for active object gap creation, using a variety of dependent measures such as reading time and gaze duration measures (Crain and Fodor, 1985; Frazier, 1987; Frazier and Clifton, 1989; de Vincenzi, 1991; Pickering and Traxler, 2001, 2003; Aoshima et al., 2004; Phillips, 2006; Wagers and Phillips, 2009), cross-modal priming (Nicol and Swinney, 1989; Nicol, 1993; Nakano et al., 2002), visual world eye-tracking (Sussman and Sedivy, 2003) as well as event-related potentials (Garnsey et al., 1989; Featherston et al., 2000; Kaan et al., 2000; Felser et al., 2003; Phillips et al., 2005; Gouvea et al., 2010).

The work summarized above may suggest that filler-gap dependency completion is triggered only after the parser gains access to the verb and confirms that the verb is transitive and is able to syntactically accommodate an object. However, evidence

that active dependency completion does not depend on verb information has been presented by studies that investigated (i) subject gap creation in English, as well as (ii) object gap creation in verb-final languages. For example, Lee (2004) used sentences like (4) to reveal a filled gap effect in the subject NP position.

(4) a. That is the laboratory which, on two different occasions, Irene used a courier to deliver the samples to ___.
b. That is the laboratory to which, on two different occasions, Irene used a courier to deliver the samples ___.

Here, the content of the wh-filler is manipulated in such a way that the wh-filler can plausibly be a subject (4a) or not (4b). The results showed a longer reading time at the subject NP *Irene* in (4a) than in (4b), suggesting that the parser had postulated a subject gap before encountering the actual subject NP. Although this interpretation has been challenged (Staub, 2010), it would in any case not be surprising that the parser actively creates a subject gap without having access to verb information, given that a subject is present in any sentence, regardless of verb properties. In this sense, if verb information were to play a role in the parser's attempt to posit a gap, the critical empirical evidence should come from dependency completion at the object position, where the presence or absence of an object gap relies on properties of the verb.

Evidence for pre-verbal object gap creation has been reported for verb-final languages like Japanese in which the object gap position linearly precedes the verb. For example, Aoshima et al. (2004) examined processing of scrambling sentences in which a dative object NP was dislocated to the sentence initial position, and found a filled gap effect at a pre-verbal dative object position for the first verb phrase (VP) in the sentence (see also Omaki et al., 2014). Using similar sentences, Nakano et al. (2002) reported evidence for an antecedent priming effect for the scrambled NP at a pre-verbal gap position, although the priming effect was only found in the high working memory span group. These data indicate that the parser can in principle complete filler-gap dependencies before accessing verb information.

In verb-medial languages, no such evidence for pre-verbal object gap creation has been reported to date. This may reflect a real difference between languages in processing strategy, and pre-verbal object gap creation in verb-final languages may reflect the parser's adaptation to the demands of processing these languages. Maintaining a structurally unintegrated filler in memory has been argued to impose a burden on working memory (King and Just, 1991; Gibson, 1998; Gordon et al., 2002; Haarmann and Cameron, 2005). Alternatively, the parser may be architecturally constrained to assign a thematic interpretation to the filler as soon as possible (Pickering and Barry, 1991; Aoshima et al., 2004). On this view, the parser should prioritize integrating the filler into the first grammatically permissible structural position that can potentially receive a thematic role. Given that filler-gap dependencies are potentially unbounded, waiting for the verb before constructing the ultimate object gap position could impose a large processing burden on speakers of verb-final languages.

In verb-medial languages like English, verbs become available relatively earlier in the sentence, such that the average working memory cost of waiting for the verb would be less than in verb-final languages. The advantage of waiting for the verb information is that the parser can reduce the likelihood of making risky commitments, because the verb may turn out to be intransitive and disallow an object NP analysis for the filler. In English, therefore, the parser may create an object gap position only after the verb is confirmed to be transitive. This still constitutes active gap filling, in the respect that the ultimate gap position may turn out to be somewhere later than the object position [e.g., after a late-arriving preposition gap, as in (2) and (3)]. Let us call this a *conservative active gap filling* mechanism, since the bottom–up subcategorization information from the verb still plays a critical role in the parser's decision on whether to postulate an object gap or not. This view of active gap filling is rather standard for explaining filler-gap dependency completion in verb medial languages like English. For example, McElree and Griffith (1998) and McElree et al. (2003) have argued that the dependency completion process is triggered when the parser accesses information from the verb and initiates the retrieval process for the filler that is stored in working memory (see also Pickering and Barry, 1991; Lewis and Vasishth, 2005).

On the other hand, pre-verbal object gap creation in verb-final languages may reflect a language-general property of the processing architecture, although evidence for such mechanisms may be simply more difficult to obtain in verb-medial languages. In the English filler-gap case, for example, in any parser that adopts some form of left-corner strategy (Kimball, 1975; Abney and Johnson, 1991; Resnik, 1992; Shieber and Johnson, 1993; Stabler, 1994; Crocker, 1996; Lewis and Vasishth, 2005; Gibson, unpublished doctoral dissertation), the presence of the subject NP allows the parser to predict the presence of a VP. Given that a VP can contain an object NP position, the parser could project a VP with an object NP slot and assign the filler to this object position before confirming whether the upcoming verb is a transitive verb or not. Let us call this a *hyper-active gap filling* mechanism, because this involves a more risky predictive structure building process than is standardly assumed for active object gap creation in English. Filler retrieval and structural integration is still integral to the hyper-active gap filling mechanism, but the crucial difference is in what information triggers retrieval and integration, and consequently, at what point in the sentence this process is executed.

It is important to note that either of these two active gap filling mechanisms is compatible with the existing data on active object gap creation reviewed above. A filled gap effect only indicates that the gap had been created before the actual object NP is processed, and this result is compatible with both accounts, given that both hyper-active gap filling and conservative active gap filling mechanisms assume that object NP gap creation happens before or on the verb. A plausibility mismatch effect indicates that when the verb is potentially transitive, then the semantic fit between the filler and the verb is immediately assessed. This is also predicted by both accounts. The assessment of the semantic relation between the filler and the verb requires the parser to access the content of the verb, by which point the object gap

position should have been created on either account. Thus, neither paradigm allows us to tease apart the two hypotheses on what kind of information is sufficient for triggering object gap creation.

In the current study we aim to tease apart the predictions of two hypothesized mechanisms for active object gap creation processes. If English speakers construct the gap site before encountering the verb, just like speakers of verb-final languages, then disruption should be observed in filler-gap configurations when the verb turns out to be intransitive, relative to transitive verbs (e.g., *The party that the student arrived/planned. . .*). According to the conservative active gap filling mechanism outlined above, the parser waits for a transitive verb before postulating the corresponding gap structure. Here, no disruption is expected at an intransitive verb, since the parser has not postulated a gap that would require a transitive verb.

Two previous studies are relevant to the two hypotheses about active object gap creation in English. Previous work by Pickering and Traxler (2003) examined the effect of subcategorization frequency in optionally transitive verbs (e.g., *Those are the lines/props that the author spoke [about]. . .*). It was found that readers did not take subcategorization frequency into account in deciding where to posit a gap, as there was a strong preference to posit a gap in the verb object position (NP complement) even with verbs that more frequently take a PP complement. The absence of subcategorization frequency effect in active object gap creation could be taken to indicate that verb information is not relevant for object gap creation processes. However, all of the verbs in Pickering and Traxler's study could grammatically accommodate an NP complement, and the parser may therefore have relied on the transitivity information of the verb to create an object gap. Therefore, this finding does not distinguish the predictions of the two proposed mechanisms for active object gap creation.

To our knowledge, the only previous test of these two active object gap creation hypotheses is in Experiment 3 of Staub (2007). The test sentences in this experiment (5a–d) manipulated the transitivity of the verb (*called* vs. *arrived*) and sentence structure (relative clause with a gap vs. simple declarative with no gap). The filler was manipulated to be an implausible object of the transitive verb (*gadget-called*). Under the hyper-active gap filling hypothesis, the parser in effect predicts the presence of a transitive verb, and therefore the reading processes in the gap conditions should be disrupted in either intransitive or transitive condition, but for different reasons: when the verb turns out to be intransitive, and processing should also be disrupted when the verb is transitive because of the plausibility mismatch effect. On the other hand, the conservative active gap filling mechanism postulates a gap only after checking whether the verb is capable of hosting an object NP, and therefore reading disruption is predicted only in the transitive gap condition due to the plausibility mismatch effect.

(5) a. The gadget that the manager *called* occasionally about. . .
b. The manager *called* occasionally about the gadget . . .
c. The party that the student *arrived* promptly for . . .
d. The student *arrived* promptly for the party . . .

Staub (2007) found longer first-fixation durations in the transitive gap condition (5a) than in the transitive no-gap condition (5b), but no such difference was observed between the intransitive gap and no-gap conditions (5c) and (5d). This pattern of data supports the prediction of the conservative active gap filling hypothesis, suggesting that the parser does not create an object gap until it checks the transitivity information of the verb. One concern about this design, however, is whether the no-gap condition was truly a neutral baseline against which a transitivity mismatch could be measured, as the gap and no-gap conditions differed substantially in both the linear and structural position of the verb. As Staub (2007) points out, one piece of data suggesting that the control may not have been completely neutral is the fact that reading times on the intransitives were numerically (but non-significantly) shorter in the gap condition than in the no-gap condition. It is important to note here that the gap conditions (5a) and (5c) contain an extra NP (i.e., the head of the relative clause) prior to the critical verb region in comparison to the no-gap conditions (5b) and (5d). This may have led to a difference in the amount of contextual information available prior to the verb. Increased contextual information can facilitate processing for subsequent lexical items (Stanovich and West, 1983; Van Petten and Kutas, 1990; Kutas and Federmeier, 2000), and for this reason, lexical access for the intransitive verb in the gap condition may have become faster and masked the potential reading time slowdown associated with the structural manipulation. In an attempt to provide a better test of the predictions of the hyper-active and conservative active gap filling accounts, the current study used relative clause islands as a control condition, which allowed the target sentences to more closely match in informational content and word position.

Experiment 1

Experiment 1 was a self-paced reading study that was designed to test the predictions of the hyper-active and conservative active gap filling hypotheses, while addressing methodological concerns about previous work. We employed the transitivity mismatch paradigm used in Staub (2007) in order to test whether a verb transitivity manipulation affects reading time at the verb. Critically, in the baseline conditions the critical verb was embedded inside a relative clause structure, a syntactic 'island' domain that prohibits filler-gap dependency formation (Ross, unpublished doctoral dissertation; for a review, see Szabolcsi and den Dikken, 2003). A sample set of stimuli is shown in **Table 1**.

A number of previous studies have shown that the parser respects island constraints in real-time syntactic processing, such that it avoids actively constructing filler-gap dependencies that span syntactic island boundaries (Stowe, 1986; Kluender and Kutas, 1993; McKinnon and Osterhout, 1996; Traxler and Pickering, 1996; McElree and Griffith, 1998; Wagers and Phillips, 2009; Omaki and Schulz, 2011; Yoshida, unpublished doctoral dissertation). The relative clause island condition thus provided a baseline measure of reading times for the critical transitive and intransitive verbs, independent of processes of filler-gap

TABLE 1 | Sample materials and conditions for Experiment 1.

	Analysis regions										
	1	2	3	4	5	6	7	8	9	10	11
Transitive, non-island	The	city	that	the	author		wrote	regularly	about	was	named for an explorer

dependency completion. The use of island configurations allowed us to address the methodological concerns with previous work.

First, this design allowed the baseline condition to present a filler NP prior to the critical region, such that the same amount of contextual information from the lexical items was present in advance of the critical verb region across the four conditions. Second, the word position for the critical regions (Regions 7 and 8 in **Table 1**) was closely matched across conditions (word positions 6 and 7 in the non-island conditions, word positions 7 and 8 in the island conditions), and it was also placed away from the early portion of the sentence.

Furthermore, following Staub's design, we selected transitive verbs that are implausible hosts for the filler. Under this design, the hyper-active gap filling hypothesis predicted a reading time slowdown in both the non-island transitive and the non-island intransitive conditions relative to their island counterparts, but for a different reason in the two cases. In the transitive condition, the slowdown would reflect a plausibility mismatch effect triggered by the poor semantic fit between the filler and the verb. In the intransitive condition, the slowdown would result from a transitivity mismatch effect due to the mismatch between the expected subcategorization property of the verb (i.e., transitive) and the actual subcategorization property of the verb. On the other hand, the conservative active gap filling hypothesis predicted an interaction. A reading time contrast should be observed between the non-island transitive condition and the island transitive condition due to the plausibility mismatch effect, but no corresponding contrast should be observed between the two intransitive conditions, given that the parser should not actively create an object gap in either condition. Note that the lexical difference in the critical verb region across conditions was not problematic, since the critical contrast was between non-island and island conditions within each verb type.

Method

Participants

We recruited 32 native speakers of American English from the University of Maryland community. They received a course credit or were paid $10 for their participation and were naïve to the purpose of the experiment.

Materials

We used 28 sets of four sentences like those shown in **Table 1**. All of the stimuli from experiments reported in this paper are made available in Supplementary Materials. The transitive non-island and island conditions were taken from the implausible semantic fit conditions in Omaki and Schulz (2011), who used a modified version of the plausibility manipulation materials from Traxler and Pickering (1996). Omaki and Schulz replicated Traxler and Pickering's plausibility mismatch effect with native and non-native speakers alike, confirming that the semantic fit between the filler and the verb affects the reading time for the verb when the verb is in a gap filling (i.e., non-island) environment, but not when the verb is inside a relative clause island. Critically, it was also found that the implausible verb-filler combination in a non-island environment (e.g., *city-wrote*) led to a significant slow down at the verb compared to its island counterpart with the same implausible verb-filler combination. Thus, even though the current experiment did not include a plausible counterpart of the implausible transitive verb condition, we could be confident that a reading time contrast between the transitive non-island and island conditions results from the semantic misfit between the filler and the verb. In other words, the finding in Omaki and Schulz's study supports the notion that island conditions in general can be used as baseline conditions for a reading disruption associated with active object gap creation. The intransitive conditions were modeled after the transitive conditions by replacing the optionally transitive verb with unergative or unaccusative intransitive verbs (Levin and Rappaport Hovav, 1995).

The non-island and island conditions differed in the number of relative clauses. The non-island condition had only one relative clause (*the city that the author wrote/chatted regularly about*), such that the object position of the verb *wrote/chatted* was the first potential gap position after the embedded subject was encountered. In the island conditions, the critical verb was embedded inside another relative clause *the author who wrote/chatted regularly*, such that linearly this was still the first verb but grammatically the filler should not be accessible to the verb due to the relative clause island constraint. Thus, the first verb served as the critical region for testing the plausibility and transitivity mismatch effects. All the transitive verbs were optionally transitive, such that the sentences in the island conditions were all ultimately grammatical. The subcategorization frequency of the optionally transitive verbs was not controlled, since Pickering and Traxler (2003) have demonstrated that plausibility mismatch effects are attested for optionally transitive verbs regardless of subcategorization frequency. In all four conditions the same adverb immediately followed the verb, making

it possible to observe potential spill-over effects. The 28 sentence sets were counter-balanced across four lists so that each participant saw only one version of the target items and consequently read seven tokens of each condition. In addition, 72 fillers of similar length and complexity were constructed and added to each list.

Procedure

The self-paced reading task was implemented on the Linger software developed by Doug Rohde (http://tedlab.mit.edu/~dr/Linger/). We used a word-by-word, non-cumulative moving window presentation (Just et al., 1982). In this design, each sentence initially appears as a series of dashes, and these dashes are replaced by a word from left to right every time the participant presses the space bar. In order to ensure that the participants were paying attention while reading the sentences, all sentences were followed by yes-no comprehension questions, and feedback was provided if the questions were answered incorrectly. Comprehension questions never addressed the critical filler-gap portion of the sentence. At the beginning of the experiment, participants were instructed to read at a natural pace and to answer the questions as accurately as possible. Seven practice items preceded the self-paced reading experiment, and the order of presentation was randomized for each participant. The experiment took ~30 min. The experiment protocol for this study was approved by the Institutional Review Board at the University of Maryland.

Data Analysis

The data from two items were excluded from analyses due to coding errors. Only trials in which the comprehension question was answered accurately were included in the analysis, which affected 5.7% of the trials. We also analyzed the data without excluding the trials based on comprehension accuracy, but the overall pattern of results did not change.

Self-paced reading times for the target sentences were examined for each successive region, although the words after the auxiliary *was* were combined into a single region because these lay beyond the critical regions and were unlikely to show effects relevant for the critical manipulation. The critical regions where a potential plausibility or transitivity mismatch effect was expected consist of Region 7 (i.e., the verb *wrote/chatted*) and the following Region 8 (i.e., the adverb *regularly*), in which spill-over effects could be observed. Regions 1 through 6 were predicted to show no difference across conditions, since they were lexically matched. Regions 9 through 11 could reveal reading time differences after the filler-gap dependency is completed (Region 9 hosts the true gap site), and with a possible additional difference in the island conditions due to the structural complexity associated with the extra relative clause in these conditions.

Reading time data that exceeded three standard deviations from the group mean at each region and in each condition were excluded, affecting 1.7% of the data. The remaining reading time data were analyzed using linear mixed effects models (Baayen et al., 2008). These analyses were conducted in the R environment (R Development Core Team, 2011), using the lme4 package for R (Bates et al., 2014). The fixed effects of island structure type (non-island vs. island) and verb transitivity (transitive vs. intransitive) were coded using sum contrasts, with one level of the factor coded as −0.5, and the other as 0.5. This sum contrast coding makes the mixed effect model estimates roughly comparable to the actual average reading time contrasts. The model included random intercepts for participants and items. For random slopes, we used the following procedure to determine the optimal random effect structure (for discussions: Jaeger, 2011; Barr et al., 2013). First, we constructed a fully crossed model that included the fixed effects and an interaction term as random slopes for both participants and items. This fully specified model failed to converge, plausibly due to the complexity of the model and missing data points in some of the trials (Barr et al., 2013). Next, we simplified the random effect structure by only keeping the verb transitivity factor as a random slope for participants and items. In our experimental design, the island structure is invariant across all items, and it is also known to be robust across individuals, regardless of working memory capacity (see Sprouse et al., 2012). On the other hand, the verbs differed across items, and it is possible that the subcategorization bias differs across participants. This mixed effects model converged for all regions. We computed p values for linear mixed effects models using the lmerTest R package (Kuznetsova et al., 2014).

Results

Comprehension accuracy

The mean comprehension question accuracy for experimental items across participants and items was 93.0%. For the non-island conditions, the transitive items were answered with an accuracy of 93.7% (SE = 1.9), and the intransitive items with an accuracy of 94.6% (SE = 1.4). For the island conditions, the transitive items were answered with an accuracy of 91.5% (SE = 1.7), and the intransitive items with an accuracy of 92.0% (SE = 2.2). The mean accuracy did not differ reliably across conditions, although the fact that the mean accuracy for island conditions was numerically lower may reflect the complexity difference between non-island and island conditions.

Reading time data

The region-by-region mean reading time for the transitive conditions is presented in **Figure 1**, and the mean region-by-region reading time for the intransitive conditions is presented in **Figure 2**.

In the non-critical Regions 1–6, there were no significant differences in Regions 1, 2, 4–6 (ps > 0.06). In Region 3 there was a main effect of verb type (Estimate = −17.3, SE = 7.6, $t = -2.27$, $p < 0.05$), due to slower reading times in the transitive conditions than in the intransitive conditions (381 vs. 358 ms). Since this region was lexically matched across conditions, we conclude that this is a spurious effect. But given that the effect was small and occurred well ahead of the critical regions, this unexpected effect was unlikely to have impacted the observations in the critical regions.

At the critical verb in Region 7 there were no significant differences (ps > 0.1). The following spill-over region

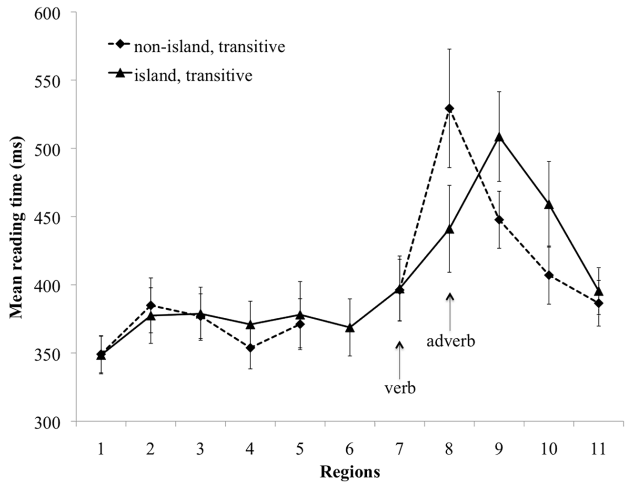

FIGURE 1 | Mean reading time (ms) for the transitive non-island and island conditions. Error bars indicate standard error of the mean.

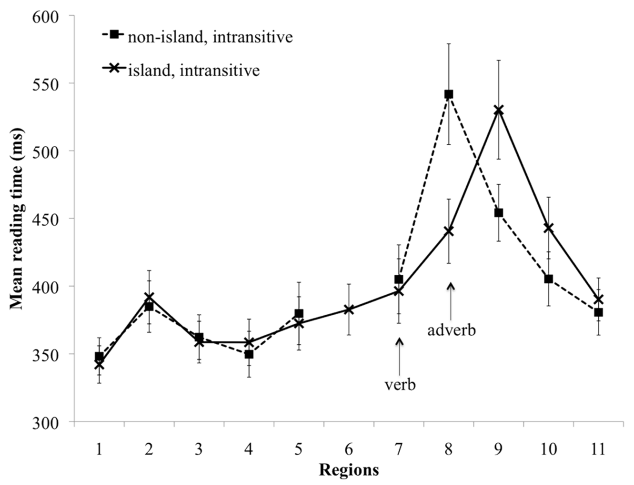

FIGURE 2 | Mean reading time (ms) for the intransitive non-island and island conditions. Error bars indicate standard error of the mean.

(Region 8) revealed no main effect of verb type, but there was a main effect of structure type (Estimate = −92.0, SE = 16.4, $t = -5.61$, $p < 0.001$), reflecting the fact that the non-island conditions produced significantly slower reading times than the island conditions (529 vs. 435 ms). There was no significant interaction of verb type and structure type ($p > 0.1$).

Region 9 consisted of a second verb in the island conditions and a preposition in the non-island conditions. We observed a main effect of structure type in Region 9 (Estimate = 63.7, SE = 15.9, $t = 4.01$, $p < 0.001$), as well as in Region 10 (Estimate = 46.1, SE = 11.5, $t = 4.0$, $p < 0.001$), in these cases due to slower reading times in the island conditions (Region 9: 519 vs. 451 ms, Region 10: 451 vs. 406 ms). Region 11 revealed no significant differences (ps > 0.09).

Discussion

In Experiment 1, we tested the predictions of two hypotheses about active object gap creation. The hyper-active gap filling hypothesis predicted the presence of reading disruption at intransitive verbs, because encountering an intransitive verb in a filler-gap context would be incompatible with the object gap structure constructed earlier. On the other hand, the conservative active gap filling hypothesis predicted no such reading disruption, because the parser should first consult the transitivity information of the verb to decide whether to posit an object gap or not. As a baseline for estimating the degree of disruption at the verb, we used relative clause island constructions, which block the association of the filler with the critical verb. The results were consistent with the predictions of the hyper-active account: in the region following the verb, we observed slower reading times for intransitive verbs in non-island conditions than in corresponding island conditions.

Previous work has shown a filler-gap plausibility mismatch effect at the verb such that mismatched transitive verbs in a non-island environment elicit longer reading times than their plausible non-island or plausible/implausible island counterparts (Traxler and Pickering, 1996; Omaki and Schulz, 2011), and here we replicated this finding. This effect can be interpreted as the result of active association of the filler with the transitive verb, which in these stimuli resulted in a verb–object plausibility mismatch. On the other hand, the slowdown observed in the intransitive non-island condition relative to the intransitive island condition can be interpreted as a *transitivity* mismatch. This suggests that the parser does not wait for bottom–up evidence from the verb that the verb can syntactically license a gap, but rather attempts to construct the dependency before this information is available. This slowdown cannot reflect the cost of maintaining the filler in working memory, because a filler is also being maintained at this position in the baseline island condition.

It is also important to note that the shorter reading times in the critical regions of the island conditions are theoretically informative. These findings suggest that the reading time increase in the non-island conditions is specifically due to an expectation violation following premature gap creation. A plausible alternative explanation of the reading disruption in the non-island conditions is that it reflects a more general cost associated with delaying gap creation decisions. Under this alternative account, we should expect to observe reading disruption in the island conditions as well, because gap creation must wait until the verb that follows the relative clause island region (e.g., *saw* in Region 9). However, this prediction is not supported by the data, as the reading time in the adverb region (Region 8) of the island conditions was reliably shorter than in non-island conditions.

In Regions 9 and 10, the island conditions were read more slowly for both levels of verb type. Region 9 corresponds to the word that licensed the true gap site across all conditions, and hence this slowdown could reflect a difference in the so-called integration cost (Gibson, 1998, 2000) between non-island and island conditions. Previous work on filler-gap dependency processing has demonstrated that increased complexity and length differences result in increased processing difficulties at the gap

site, as measured by reading time (Gibson and Warren, 2004; Wagers and Phillips, 2014) and reduced accuracy in speeded acceptability judgment tasks (McElree et al., 2003). However, the reading time difference in Region 9 may simply be due to lexical differences (prepositions in the non-island conditions vs. verbs in the island conditions), so the reading time contrast between the island and non-island conditions may not reflect an integration cost difference.

Note that it is unlikely that the reading time contrast between non-island and island conditions in Region 8 is related to the overall complexity of the constructions used in our stimuli, given that on all accounts that we are aware of, island domains have been argued to be syntactically more complex and more taxing for working memory resources (Deane, 1991; Kluender and Kutas, 1993; Kluender, 1998, 2004; Hofmeister and Sag, 2010). The fact that the putatively less complex non-island conditions were read more slowly allows us to attribute the slowdown to processes that uniquely occur in the non-island conditions, namely filler-verb association.

In summary, the presence of both a plausibility mismatch effect and a transitivity mismatch effect lends support to the hyper-active gap filling hypothesis, and argues against a conservative active gap filling hypothesis under which transitivity information is consulted before attempting to create an object gap. This finding directly contrasts with that of Staub (2007), who did not find evidence for a transitivity mismatch effect.

However, this conclusion is not warranted until two methodological concerns are addressed. First, the design in Experiment 1 was modeled after Staub (2007), who used a plausibility mismatch design for transitive verb conditions, and transitivity mismatch design for intransitive verb conditions. Our findings differed from Staub's as we found mismatch effects for both transitive and intransitive non-island conditions, but it is possible that some nuisance factor common to both non-island conditions led to a slow-down across the board. Stronger evidence for the hyper-active gap filling hypothesis can be obtained if we replicate the transitivity mismatch slowdown in the intransitive non-island condition, while at the same time observing no reading disruption in the transitive non-island condition. Experiment 2 accomplished this by making the filler and the verb semantically fit in the transitive conditions. The absence of reading disruption in the transitive conditions would suggest that the disruption in the non-island, intransitive condition is due to the intransitivity of the verb.

Second, it is important to note that our evidence for reading disruption for transitive and intransitive verbs (i.e., the slowdown in non-island conditions compared to island conditions) was not observed until the spill-over adverb region. Spill-over effects are widely observed in self-paced reading experiments, and it is thus common to attribute spill-over effects to processes triggered in a preceding region. However, in our experiment there is an alternative explanation for the effect in the adverb region that would not require hyper-active gap filling. For the intransitive condition, the slowdown in the adverb region could indicate that the parser had expected the presence of a preposition, which would allow structural integration of the filler. Under this alternative account, the slowdown is not due to a transitivity mismatch on the verb, but rather to a word category expectation mismatch in the adverb region that was triggered by the verb itself. This account is consistent with the conservative active gap filling hypothesis, since the parser's expectation regarding filler-gap dependency completion is based on the information from the verb. Incidentally, the reading disruption observed in the transitive conditions of Staub (2007) was at the verb region. One possible reason for this discrepancy is the difference in the dependent measure: Staub (2007) used an eye-tracking during reading method while we used self-paced reading in Experiment 1. An eye-tracking during reading method generally provides better temporal precision than the self-paced reading method (Rayner, 1998; Rayner and Pollatsek, 2006). Thus, an eye-tracking replication of Experiment 1 may yield a transitivity mismatch effect on the verb region, and provide stronger evidence for the hyper-active gap filling hypothesis. This is addressed in Experiment 2.

Experiment 2

Experiment 2 addressed two methodological concerns raised in Experiment 1 by removing sources of slowdown in the transitive conditions, and also by using the eye-tracking during reading method.

Method

Participants

We recruited 33 native speakers of American English from the Johns Hopkins University community, but data from one participant were removed due to calibration errors. Participants received course credit or $10 for their participation. They were all naïve to the purpose of the experiment.

Materials

We used 28 sets of four sentences as shown in **Table 2**. This experiment used the same transitivity mismatch logic as Experiment 1 and manipulated the verb transitivity type (intransitive vs. transitive). However, in this experiment the semantic fit between the filler and the transitive verb was always plausible, such that no reading disruption was expected at the transitive verb in the non-island condition. As in Experiment 1 we manipulated structure type (non-island vs. island), using conditions with relative clause island structures as baseline conditions. Relative clause islands provide an effective baseline, since they include the same filler NP and other lexical material as the non-island condition, while preventing dependency completion at the critical verb. As in Experiment 1, the transitive verbs were optionally transitive and the true gap position occurred outside the island domain, allowing the sentence to continue grammatically.

The 28 sentence sets were counter-balanced across four lists so that each participant saw only one version of the target items and consequently read seven tokens of each condition. In addition, 76 fillers of similar length and complexity were constructed and added to each list.

Procedure

An Eyelink 1000 eye-tracker (SR Research: Mississauga, ON, Canada) was used to record eye movements. The participant's

TABLE 2 | Sample materials and conditions for Experiment 2.

	Analysis regions				
	Sentence initial	**Pre-verb**	**Verb**	**Post-verb**	**Sentence final**
Transitive, non-island	The book that	the author	wrote	regularly	about was named for an explorer
Transitive, island	The book that	the author who	wrote	regularly	saw was named for an explorer
Intransitive, non-island	The book that	the author	chatted	regularly	about was named for an explorer
Intransitive, island	The book that	the author who	chatted	regularly	saw was named for an explorer
Example question	Was the book named for an explorer?				

head was stabilized by a chin rest and a forehead rest. The position of the right eye only was monitored at a sampling rate of 1000 Hz. The eye-tracker display allowed a maximum of 120 characters per line, in 10 pt Monaco font. Some filler sentences were displayed on two lines, but all target sentences were displayed on one line. Stimuli were displayed on a 21.5-inch Samsung SyncMaster monitor, and participants were seated 65 cm from the computer screen. Before the experiment started, participants were seated in front of the eye-tracker and received instructions for the experiment. A calibration routine was performed at the beginning of the experiment, and the experimenter monitored the calibration accuracy throughout the session, recalibrating when necessary. The experiment started with written instruction on the display and seven practice trials. At the beginning of each trial, a black circle was displayed on the left side of the monitor, which corresponded to the location of the beginning of the sentence. The text was displayed after the participant successfully fixated on the circle. After reading each sentence, the participant pressed a button to remove the sentence display. Each sentence was followed by a yes-no comprehension question, and the participant answered the comprehension question by pressing a left or right button. Comprehension questions never addressed the critical filler-gap portion of the sentence. The entire experiment lasted ∼35 min. The experiment protocol for this study was approved by the Homewood Institutional Review Board at the Johns Hopkins University.

Data Analysis

Comprehension accuracy for the target trials was 90.7%, and trials in which participants answered the comprehension question incorrectly were removed from the eye movement analyses, as data from these trials may reflect inattentive reading. For the remaining data, an automatic procedure pooled short contiguous fixations. The procedure incorporated fixations of less than 80 ms into larger fixations when they occurred within one character of each other and deleted any remaining fixations of less than 80 ms, because little information can be extracted during such short fixations (Rayner and Pollatsek, 1989). Unusually long fixations greater than 800 ms were also removed, because they usually reflect tracker losses or other anomalous events. This procedure resulted in the exclusion of 4.86% of all fixations.

For the purpose of analysis of the eye movement data, the sentences were divided into five analysis regions, as shown in **Table 2**. We report eye movement data in the following three regions: (a) the pre-verb region (*the author* in non-island conditions, *the author who* in island conditions), in order to ensure that there were no unexpected reading behavior differences that might compromise the interpretation of the data from the critical region, (b) the verb region, which is the critical region where potential transitivity mismatch effects might be observed, and (c) the post-verb region, which corresponds to the post-verbal adverb and could be used to probe for potential spill-over effects. The data in the remaining regions are not reported, because reading times at these regions are not critical for distinguishing the competing hypotheses. Moreover, after the post-verb region, the lexical items were not held constant across conditions and therefore any observed differences would be difficult to interpret. The island conditions contained one extra word, i.e., the relative pronoun (e.g., *who*), which could have affected reading times in the pre-verb region as well as regression measures for subsequent regions.

Following the data analysis procedures used in Staub (2007), four reading time measures were computed for the three regions of interests: *first fixation duration, first pass time, regression path time,* and *percent regressions* (Rayner, 1998; Rayner and Pollatsek, 2006; Staub and Rayner, 2007). First fixation duration is the duration of the very first fixation in a region, regardless of whether there is a single word or multiple words in that region. This measure is often used as an index of lexical difficulty (e.g., Reichle et al., 2003) but is also informative about the earliest syntactic processes that immediately follow lexical access (e.g., Frazier and Rayner, 1982; Sturt, 2003).

The *first-pass reading time* is calculated by summing the fixations in a region between the time when the eye-gaze first enters the region from the left and the time when the eye-gaze exits the region either to the left or the right. First-pass reading times also index early lexical and syntactic processes associated with a region, but given that they consist of multiple fixations on the same region, they may also reflect slightly later processes than the first fixation measure.

Regression path times are the sum of fixations from the time when the eye-gaze first enters a region from the left to the time when the eye-gaze exits the region to the right. Regression path time is identical to first-pass reading time if the eye-gaze first exits the region to the right, but if the eye-gaze exits the region to the left, then regression path times are longer than the first-pass time as they include all fixations in previous regions as well as re-fixations on the region before exiting the region to the right. Thus, regression path times are likely to reflect slightly later processes, such as integration of the critical region with the preceding

context. The *percent regressions* indicate the probability that a reader made a regressive eye movement to preceding regions after fixating a given region. This measure includes only regressions made during the reader's first pass through the region, and does not include regression made after re-fixating the region.

Reading time data (i.e., first fixation, first pass, and regression path durations) were analyzed using linear mixed effects models (Baayen et al., 2008), and percent regressions were analyzed by mixed effects logistic regression, as the dependent measure was categorical (see Jaeger, 2008). The mixed effects models included random intercepts for participants and items. We used the same procedure as Experiment 1 to simplify the random slope structure until the models converged in all regions and eye movement measures. This procedure led us to adopt verb transitivity as a random slope for participants and items for all fixation measures and regions, except for percent regression measures in the post-verb region. Here, we removed the verb transitivity random slope for participants, as the transitivity bias variance across different verbs (if any) is more likely to influence the data than variance in participants' experience with the verbs.

When the critical region demonstrated a significant interaction of verb and structure type, a planned comparison was conducted with separate mixed effects models to test for systematic differences between the island and non-island conditions within each verb type. These models included participants and items as random intercepts.

Results

Table 3 presents the participant means on each measure for each region as well as the standard errors of the participant means, and **Table 4** presents a summary of the statistical analyses.

TABLE 3 | Experiment 2 participant mean reading times in milliseconds (standard error) and percent regressions.

Measure	Pre-verb region	Verb region	Post-verb region
First fixation			
Transitive, non-island	212 (8)	249 (12)	242 (9)
Transitive, island	217 (7)	240 (7)	243 (9)
Intransitive, non-island	207 (8)	256 (10)	246 (10)
Intransitive, island	208 (5)	231 (8)	237 (7)
First-pass time			
Transitive, non-island	287 (14)	277 (13)	283 (13)
Transitive, island	386 (20)	275 (10)	287 (12)
Intransitive, non-island	299 (15)	303 (13)	296 (14)
Intransitive, island	396 (19)	266 (11)	284 (10)
Regression path time			
Transitive, non-island	463 (28)	373 (24)	402 (30)
Transitive, island	636 (43)	406 (31)	447 (35)
Intransitive, non-island	472 (38)	397 (23)	492 (35)
Intransitive, island	619 (41)	425 (38)	469 (26)
Percent regressions			
Transitive, non-island	33.1 (5.0)	17.1 (3.5)	17.9 (3.4)
Transitive, island	33.2 (4.0)	23.0 (4.4)	24.4 (3.4)
Intransitive, non-island	27.1 (4.8)	16.2 (2.8)	27.5 (3.7)
Intransitive, island	32.7 (4.7)	24.4 (3.7)	22.4 (3.1)

In the pre-verb region, the first pass time and regression path measures showed a main effect of structure ($p < 0.001$), with longer reading times in the island conditions than in the non-island conditions. This effect was expected because the pre-verb region in the island conditions contained the extra word *who*, which made it more likely to attract multiple fixations in that region. No other significant effects were observed in this region.

In the verb region, evidence for the hyper-active gap filling hypothesis was found in first fixation durations as well as in first pass measures. Both measures showed a main effect of structure with longer reading times for non-island conditions ($ps < 0.05$). First fixation durations showed a marginal interaction of structure and verb transitivity ($p = 0.06$), and first pass times showed a significant interaction ($p < 0.05$). Planned pairwise comparisons on first fixation durations and first pass times revealed that reading times in the non-island, intransitive condition were significantly longer than in the island, intransitive condition ($ps < 0.01$), but no significant difference was observed between the transitive conditions. No significant effect was observed for the regression path durations. There was a main effect of structure in percent regressions ($p < 0.05$), with a higher percentage of regression in the island conditions, which likely reflected the greater structural complexity in the island conditions.

In the post-verb region, there was a marginally significant interaction of verb and structure type ($p = 0.066$), but no significant effect was observed in other eye-movement measures.

Discussion

Experiment 2 used an eye-tracking during reading method to investigate whether the parser uses verb transitivity information in deciding whether to postulate a gap at the verb object position. First fixation durations and first pass times for intransitive verbs were significantly longer in a structure that allows a gap (non-island condition) than when the same verb appeared in an island configuration. This effect was not observed when the critical verb was transitive. The fact that there was a reading disruption for intransitive verbs but not for transitive verbs is consistent with the prediction of the hyper-active gap filling hypothesis. If the parser creates an object gap and integrates the filler into the object position before having access to verb transitivity information, reading disruption in the non-island intransitive condition should result from the mismatch between the predicted transitivity and actual transitivity of the verb.

It is also important to note that in this experiment the critical mismatch effects were observed in the verb region, unlike in Experiment 1 where the mismatch effects were observed only in the spill-over adverb region. This constitutes stronger evidence for hyper-active gap filling, because the mismatch effect must have resulted from properties of the verb itself. The question of why the critical effects were observed in the verb region in Experiment 2 (unlike in Experiment 1, where the effect was found in the spill-over region) likely reflects task-based differences whose effects are seen well beyond the current studies. Inhibition of the button pressing action in self-paced reading tasks is likely more difficult than inhibition of saccades in an eye-tracking task.

Verb = verb transitivity (transitive vs. intransitive); Structure = island type (non-island vs. island).
†$p < 0.10$; *$p < 0.05$; **$p < 0.001$.

We note that one other methodological difference between our experiments and Staub (2007) regards the types of intransitive verbs used. Our intransitive materials consisted of two types of intransitive verbs: we mainly used unergative verbs which only take a semantic agent as an argument, but we also used unaccusative intransitive verbs that only take a theme/experiencer as an argument (Perlmutter, 1978; Levin and Rappaport Hovav, 1995). On the other hand, Staub's intransitive condition used only unaccusative intransitive verbs. Both types of intransitive verbs are generally incompatible with an overt direct object NP, but in some restricted contexts unergative intransitive verbs are capable of hosting an NP object (e.g., "laugh a big laugh"; see Keyser and Roeper, 1984). It is possible that this special property of unergative verbs may have led the parser to treat it in the same way as transitive verbs in our experiments, whereas unaccusative intransitive verbs admit no such exceptions.

It is important to note that this difference in materials design does not challenge our interpretation of the data. First, our stimuli did not meet the lexical or structural condition for allowing unergative verbs to behave as transitive verbs. Second, if our participants treated the unergative verbs as transitive verbs, then there should have been no reason to observe a slow-down in the intransitive, non-island condition, contrary to the findings in Experiments 1 and 2. However, in order to ascertain that our findings are not restricted to unergative intransitive verbs, we conducted Experiment 3 in which we used only the unaccusative intransitive verbs that were used in Staub (2007).

Experiment 3

The goal of Experiment 3 was to replicate the findings from Experiments 1 and 2 with a different set of intransitive verbs. We constructed new sets of stimuli that used only the unaccusative intransitive verbs used in Staub (2007). Given that unaccusative intransitive verbs are syntactically incapable of hosting an overt direct object NP, this class of intransitive verbs provides a stronger test of the transitivity mismatch effect.

Method

Participants

We recruited 44 native speakers of American English from the University of Maryland community. All had normal or corrected-to-normal vision, and were naïve to the purpose of the experiment. They received course credit or were paid $10 for their participation, which lasted around 40 min.

Materials

We created 24 sets of four sentences. The experimental design in this study is identical to that of Experiment 2 (see **Table 2**), except that the sentences were modified such that the critical verbs in all items were unaccusative intransitive verbs used in Staub (2007). These verbs included *remain, depart, prevail, emerge, arise, die, persist, disappear, erupt, appear, vanish, arrive*. According to Staub (2007), these verbs are considered to disallow transitive frames. Although it may be possible to find some rare counter-examples, we note that this should only

work against the hyper-active gap filling hypothesis, because the possibility of transitive frame would eliminate reasons to observe a reading time slow-down. Thus, finding a robust mismatch effect on the intransitive verb region should eliminate any concerns about the potential transitivity of the intransitive verbs.

The 24 sentence sets were counter-balanced across four lists, such that each participant saw only one version of each of the target sentences. We used 12 intransitive verbs from Staub (2007), such that 2 of the 24 items used the same verb with a different context. Participants saw each intransitive verb twice across the course of the experiment, once in an island context and once in a non-island context. The target sentences were combined with 108 fillers of similar length and complexity.

Procedure

An SR Research (Mississauga, ON, Canada) Eyelink 1000 eye-tracker at the University of Maryland was used to record eye movements. The basic configuration of this eye-tracker as well as the instruction for participants was the same as for Experiment 2, except that the stimuli were displayed on a 17-inch monitor, which allowed a maximum of 100 characters per line. The entire experiment lasted ∼40 min. The experiment protocol for this study was approved by the Institutional Review Board at the University of Maryland.

Data Analysis

The data analysis procedure was the same as that of Experiment 2. The mixed effects models included random intercepts for participants and items. We used the same procedure as Experiment 2 to simplify the random slope structure until the models converged in all regions and eye movement measures. This procedure led us to adopt verb transitivity as a random slope for participants only.

Results

Mean comprehension accuracy for the experimental items was 91.9% across the four conditions, and did not differ across the four conditions. **Table 5** presents the participant means on each measure for each region as well as the standard errors of the participant means, and **Table 6** presents a summary of the statistical analyses.

TABLE 5 | Experiment 3 participant mean reading times in milliseconds (standard error) and percent regressions.

Measure	Pre-verb region	Verb region	Post-verb region
First fixation			
Transitive, non-island	229 (8)	277 (8)	268 (11)
Transitive, island	237 (8)	266 (8)	258 (9)
Intransitive, non-island	226 (7)	299 (10)	271 (9)
Intransitive, island	222 (6)	270 (9)	260 (9)
First-pass time

Transitive, island	706 (47)	520 (44)	529 (45)
Intransitive, non-island	538 (43)	528 (38)	545 (40)
Intransitive, island	762 (48)	527 (54)	497 (43)
Percent regressions			
Transitive, non-island	31.0 (3.7)	11.7 (2.7)	26.4 (3.8)
Transitive, island	26.3 (4.1)	28.4 (3.6)	25.9 (2.9)
Intransitive, non-island	26.7 (3.9)	14.4 (2.3)	24.0 (3.5)
Intransitive, island	32.1 (3.6)	24.0 (3.3)	21.2 (3.1)

Overall, the statistical analysis revealed a similar pattern to the results of Experiment 2. In the pre-verb region, first pass and regression path times showed a main effect of structure type (ps < 0.001), with longer reading times in the island conditions than in the non-island conditions. As explained above, this effect was expected since the pre-verb region in the island conditions contained the extra word *who*. Percent regressions showed a main effect of verb type ($p < 0.05$), with more frequent regressions in the intransitive conditions. Although this was unexpected, the regression frequency in the pre-verb region is unlikely to have affected reading times in subsequent regions.

In the verb region, first fixation durations revealed a main effect of structure type ($p < 0.05$), with longer reading times in the intransitive conditions, but the interaction was not significant. In first pass times, however, a significant interaction of verb and structure type effect was observed ($p < 0.05$). A pairwise comparison revealed that reading times in the non-island, intransitive condition were longer than in the island, intransitive condition ($p < 0.001$), but no significant difference was observed between the transitive conditions.

Because the regression path duration measure reflects differences in the probability of regressing from this region, we discuss the percent regressions results at the verb region first. There was a main effect of structure in percent regressions ($p < 0.05$). The greater percent regression in the island conditions most likely reflects the structural complexity of the island conditions. Next, regression path durations also revealed a main effect of structure ($p < 0.05$), as well as a significant interaction of verb and structure ($p < 0.05$). Pairwise comparisons revealed that the direction of this effect was the opposite of the expected pattern: a significant difference between the transitive conditions ($p < 0.01$), but no difference between the intransitive conditions.

This interaction was unexpected, but it receives a straightforward explanation once we consider the fact that regression path times reflects two different underlying measures: the first pass time and time spent regressing to earlier regions (for discussion see Staub and Clifton, 2006). As described above, transitivity mismatch was associated with longer first pass times and increased regressions in the intransitive non-island condition. However, the presence of an island appeared to have an independent cost as evidenced by the fact that the two island conditions had high percentages of regressions (24.0 and 28.4%), and this is reflected in the large regression path time in these conditions. In other words, the interaction in regression path may have resulted from the combination of complexity slowdowns in the two island

TABLE 6 | Summary of model estimates, standard errors, and *t*-values (for linear mixed effects models) and z-values (for logit mixed effects models) for four eye movement measures in Experiment 3.

conditions and transitivity mismatch slowdown in the intransitive non-island condition, such that all three were slower than the transitive non-island condition.

In the post-verb region, no significant effect was observed in any of the eye-movement measures.

Discussion

Experiment 3 was designed to replicate the results of Experiment 2 with the same intransitive verbs used by Staub (2007). We again observed that first pass times for intransitive verbs in a structure that would allow a gap (non-island condition) were significantly longer than when the same verb appeared within an island configuration. This contrast was not observed when the critical verb was transitive with a plausible direct object. This contrast is consistent with the hyper-active gap filling hypothesis, which states that the parser creates an object gap and integrates the filler into the object position before having access to verb transitivity information. This hypothesis predicts that reading disruption in the non-island intransitive condition should result from the mismatch between the predicted transitivity and actual transitivity of the verb.

We also found that regression path times at the verb region were much shorter for the transitive non-island condition than the other three conditions, a pattern that was also present but unreliable in Experiment 2. As discussed in the results section, this was due to a combination of the higher percentage of regressions in the island conditions and the longer first pass time in the intransitive non-island condition. Although speculative, one possible interpretation of the larger percentage of regressions in the island conditions is that island conditions contain an extra word (i.e., the relative pronoun *who*) and incur greater complexity.

General Discussion

Experiments 1, 2, and 3 all demonstrated evidence for reading disruption at an intransitive verb when the verb was in a potential gap-filling environment. The reading disruption that can be attributed to a transitivity mismatch effect was observed in the same region as the plausibility mismatch effect (Experiment 1), and this reading disruption for an intransitive verb was observed as early as the first fixation on the intransitive verb (Experiments 2 and 3). These results lend support to the hyper-active gap filling hypothesis, which claims that in English filler-gap dependency processing, object gap creation can be initiated based on pre-verbal information and can thereby lead the parser to expect a transitive verb. This is indeed what has been proposed for filler-gap dependency processing mechanism in head-final languages (Aoshima et al., 2004), but the current work suggests that the same mechanism extends to the processing of filler-gap dependency in verb-medial languages like English as well.

The view that object gap creation is triggered by pre-verbal information contrasts with a standard view in English filler-gap dependency processing that object gap creation is driven by properties of the verb (e.g., Pickering and Barry, 1991; McElree et al., 2003). In fact, the hyper-active gap filling mechanism suggests an alternative interpretation of existing evidence for active object gap creation. For example, the plausibility mismatch effect found in Traxler and Pickering (1996) has been taken to suggest that filler-retrieval occurs after accessing the transitivity information on the verb, and that subsequent structural integration of the filler leads to the implausible verb–object composition, which in turn results in reading time slowdown. However, under the hyper-active gap filling account, prior to the verb the reader analyzes

the filler as a direct object of the upcoming verb, and given the combination of the subject NP and the hypothesized object NP, the reader may already expect a certain class of transitive verbs that would be semantically compatible with the filler NP. In other words, plausibility mismatch effects could be reconsidered as a reflection of a violation of lexical expectations, which result from predictive structural analysis. Future studies are needed to examine to what extent this reinterpretation of plausibility mismatch effects is feasible.

The present study has focused on filler-gap dependency processing, but the current conclusion is consistent with a broader class of models of sentence processing that propose that the parser utilizes a variety of sources of linguistic and contextual information to predictively build structural representations (Kimball, 1975; Gibson, 1998; Hale, 2003; Kamide et al., 2003; Staub and Clifton, 2006; Levy, 2008). On the other hand, the present study does not reveal what kind of pre-verbal information is critical for triggering object gap creation in advance of the verb. One possible source that was already discussed in the Introduction is the grammatical knowledge of phrase structure rules, which suggest that the upcoming VP representation can contain an object NP slot. However, it is equally feasible that the parser could use non-grammatical information in predictively positing the object gap, such as differences in the relative conditional probabilities derived from the lexical and contextual information from the combination of the filler NP and the subject. For example, even when a clause appears to resemble a gap structure like a relative clause, with a certain combination an adjunct gap may seem much more plausible than an object gap analysis (e.g., *the day that*. . . can continue as involving an adjunct gap as in *the day that I was born,* or an object gap as in *the day that I have been looking forward to*). Further studies are needed to investigate what kind of information contributes to such predictive object gap creation processes (Chow et al., 2013).

We acknowledge that the data reported in this paper are compatible with an alternative explanation that assumes that verb information plays a critical enabling role in English filler-gap dependency formation. For example, it is possible that filler retrieval processes are automatically activated as soon as the parser accesses the category information of the verb without accessing the transitivity information of the verb. Such a procedure could be motivated by an incremental interpretation strategy that attempts to combine any N-N-V sequence into a proposition (for discussion, see e.g., Goodluck et al., 1991, 1995). Under this alternative account, the transitivity mismatch effect arises because the filler that was 'blindly' retrieved based on the verb category information mismatches the subcategorization property of the verb that is accessed later (see van Gompel and Liversedge, 2003, for a similar proposal for a gender mismatch effect in pronoun processing, and see Kazanina et al., 2007 for an alternative account based on predictive mechanisms).

Although our study does not completely rule out a non-predictive account, these data place important constraints on the form that such an account must take. Critically, a non-predictive account must assume that access to the contents of lexical information is ordered, such that category information is accessed earlier than the subcategorization property of the verb. However, as yet there is little evidence to support such ordered access to category vs. other contents of a verb (Farmer et al., 2006 is one rare case, but see Staub et al., 2009 for a counterargument), whereas there is an abundance of psycholinguistic and neurolinguistic research demonstrating extremely fast access to all aspects of lexical content (e.g., Federmeier et al., 2000; Dambacher et al., 2006; Hauk et al., 2006; Staub and Rayner, 2007; Tanenhaus, 2007; Almeida and Poeppel, 2013; Chow et al., 2014). Moreover, there has been a recent surge of empirical work demonstrating that structure building processes can proceed predictively based on various types of top–down linguistic and contextual information, as discussed above (e.g., Konieczny, 2000; Kamide et al., 2003; DeLong et al., 2005; Van Berkum et al., 2005; Lau et al., 2006; Staub and Clifton, 2006; Levy and Keller, 2013; Yoshida et al., 2013; Yoshida, unpublished doctoral dissertation), including access to transitivity information (Arai and Keller, 2013). The current work demonstrating extremely early object gap creation processes can be seen as another instance of such predictive structure building processes. While these other findings lead us to favor a predictive explanation, further work is needed to more firmly establish that the hyper-active gap filling hypothesis is a better account for the pattern of results observed across a variety of paradigms than this alternative category-driven approach.

The current finding may also seem to contradict findings by Boland et al. (1995) and Pickering and Traxler (2001). These authors tested the processing of filler-gap dependencies in sentences that contain verbs like *persuade* or *remind* that can have both an NP direct object slot and a clausal complement slot in their argument structure, and found no evidence for reading disruption when the filler was semantically incompatible with the direct object NP slot, but compatible with the complement slot. According to the hyper-active gap filling account, encountering a *persuade*-type verb should not result in a transitivity mismatch effect since *persuade* makes available an object position, but one may wonder whether it should result in a plausibility mismatch effect when the filler is a semantically incompatible object, since an object-gap structure is hypothesized to be predictively constructed before the verb.

We can see two ways of reconciling these findings with the results presented here. First, the plausibility mismatch slowdown observed for simple transitive verbs may largely reflect the cost of reanalyzing the predicted structure to one that is compatible with the new input, which may vary depending on the argument structure of the verb. Revision may be costly in the cases where the verb is intransitive or mono-transitive, where the argument structure does not provide sufficient information for the parser to anticipate an alternative structural position for the filler. In the *persuade/remind* cases, on the other hand, the revision may be less costly because the argument structure of the verb clearly indicates the presence of an upcoming clause in which the filler can be integrated. Second, the predicted filler-gap structure may be more abstract than we have indicated so far. Rather than specifically predicting an object gap when the filler and relative clause subject are encountered, the parser may simply predict an argument gap position somewhere inside the complement domain of an upcoming VP representation, such that a gap in either the NP slot

or in the clausal complement slot of *persuade*-class ditransitive verbs would be consistent with the prediction. The current results are compatible with either account. In sum, under either account, reading disruption at the verb can be mitigated when the verb makes more than one argument position available. This might explain why having an adjunct PP continuation (e.g., about) for mono-transitive verbs (e.g., wrote) still causes reading disruption at the verb while ditransitive verbs like *persuade/remind* do not lead to such reading disruption.

In the sentences used here, the intransitive structures are eventually resolved by the appearance of a preposition, which provides another structural position for the filler. Although this could be recognized as a possible reanalysis even at the verb position, this adjunct position is not specifically licensed by the input until the preposition is actually encountered (in contrast with the *persuade/remind* cases, in which the object position is available at the verb due to its argument structure information). One interesting question for further research is whether the difficulty of recovering from the simple transitive analysis is modulated by the frequency with which a particular intransitive verb co-occurs with a prepositional phrase that could host the filler. For example, many intransitive verbs can be combined with a prepositional complement to form a phrasal verb that takes the object of the preposition as an argument, e.g., *listen to the music*. If a particular intransitive verb occurs very frequently in a phrasal verb configuration, reanalysis to this structure in a filler-gap configuration might be less costly, even prior to the presentation of the preposition.

Finally, the conclusion that the same filler-gap dependency completion procedure is used across head-initial and head-final languages suggests that the parser's structure building procedures, at least for filler-gap dependency completion, may not be qualitatively different across languages. However, future studies extending beyond Japanese and English are needed to test the robustness of this generalization. Moreover, predictive dependency formation processes are observed in domains other than filler-gap dependency processing (e.g., resolution of backward anaphora; Kazanina et al., 2007; Aoshima et al., 2009; Yoshida et al., 2013), but it is not yet known whether these other predictive structure building processes are also relatively constant across languages. Overall, we believe this line of cross-linguistic investigation has the potential to shed further light on fundamental questions about the relationship between linguistic representations and real-time processes for constructing those representations.

Conclusion

The present study tested the hypothesis that predictive structure building processes underlie filler-gap dependency completion in English. In the presence of a filler-gap dependency, intransitive verbs consistently led to reading disruption, and this pattern was replicated in self-paced reading measures as well as in eye movement measures. These findings show that English speakers do not wait to check that the verb makes an object position available, and are consistent with the hypothesis that the parser postulates an object gap at least as soon as it encounters a filler phrase and a subject NP. We suggest that the parser uses pre-verbal information to predictively create rich syntactic representations regardless of word order differences across languages.

Thematic orders and the comprehension of subject-extracted relative clauses in Mandarin Chinese

Chien-Jer Charles Lin *

Department of East Asian Languages and Cultures, Indiana University, Bloomington, IN, USA

This study investigates the comprehension of three kinds of subject-extracted relative clauses (SRs) in Mandarin Chinese: standard SRs, relative clauses involving the disposal *ba* construction ("disposal SRs"), and relative clauses involving the long passive *bei* constructions ("passive SRs"). In a self-paced reading experiment, the regions before the relativizer (where the sentential fragments are temporarily ambiguous) showed reading patterns consistent with expectation-based incremental processing: standard SRs, with the highest constructional frequency and the least complex syntactic structure, were processed faster than the other two variants. However, in the regions after the relativizer and the head noun where the existence of a relative clause is unambiguously indicated, a top-down global effect of thematic ordering was observed: passive SRs, whose thematic role order conforms to the canonical thematic order of Chinese, were read faster than both the standard SRs and the disposal SRs. Taken together, these results suggest that two expectation-based processing factors are involved in the comprehension of Chinese relative clauses, including both the structural probabilities of pre-relativizer constituents and the overall surface thematic orders in the relative clauses.

Introduction

Relative clauses have been of great theoretical interest to sentence processing researchers, with decades of research comparing the processing of subject-extracted relative clauses (henceforth "SRs") to that of object-extracted relative clauses (henceforth "ORs"). A robust asymmetry has been repeatedly reported in languages where the relative clauses follow the nouns they modify (i.e., languages with head-initial relative clauses). In English, for example, relative clauses involving subject extractions like (1) have been found to be easier to comprehend than those involving object extractions like (2) (Ford, 1983; King and Just, 1991; King and Kutas, 1995; Gibson et al., 2005; Traxler et al., 2005). The head noun phrases in these constructions [indicated with boldface in (1, 2)] are conventionally referred to as the *fillers* in the sense that they fill the *gaps* located at the extracted positions in the subordinate clauses [indicated with underscores in (1, 2)].

(1) Subject-extracted relative clause:
{**The composer**$_i$ who $___i$ adored the musician} drank a glass of wine.
(2) Object-extracted relative clause:
{**The musician**$_i$ who the composer adored $___i$} drank a glass of wine.

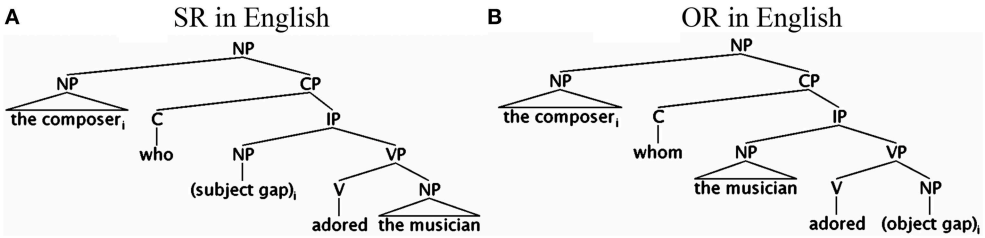

FIGURE 1 | Syntactic structure of relative clauses in English.

Two main groups of theories have been adopted to account for this processing asymmetry, here referred to as "integration-based theories" and "experience-based theories." The first group of theories focuses on the consumption of working memory in constructing filler-gap dependencies, suggesting that SRs in English are easier to comprehend (with shorter reading times and greater comprehension accuracies) because, relative to ORs, less working memory is required to process them. Within these integration-based theories, a number of proposals have been made as to precisely how the relevant processing costs are computed. A linearity account (e.g., Gibson, 1998) focuses on the number of referents intervening between the filler and the gap, attributing the easier comprehension of SRs to fewer new referents intervening between the filler and the gap. As a filler is assumed to remain active until a gap is reached in constructing filler-gap dependencies, the longer filler-gap distance in an OR consumes greater processing costs. A relevant variant of the linearity account focuses on the types of noun phrases intervening the filler and the gap, according to which similar types of noun phrases (NPs) create greater interference and therefore induce higher processing costs (Gordon et al., 2001). The activation and cue-based retrieval theory (Van Dyke and Lewis, 2003; Lewis and Vasishth, 2005) on the other hand takes into consideration the lexical items intervening a filler and a gap as contributors to activation and retrieval.

Within the integration-based theories, a structural account (e.g., O'Grady, 1997; Miyamoto and Nakamura, 2003; Hawkins, 2004; Lin, 2006) relies on the structural distance between the filler and the gap (e.g., computed by counting the number of intervening XPs) to compute processing costs. On this account, processing costs are determined by the number of intervening structural nodes inside a filler-gap dependency. Thus, an SR is easier to comprehend than an OR in English because a subject gap is structurally higher and closer to the relative clause operator (i.e., the complementizer *who/whom*) than an object gap (see **Figure 1**). Since fewer structural nodes intervene between the operator and the subject gap, less working memory is consumed in connecting the filler with the subject gap[1].

The second group of theories is experience-based, formalized either as constraints (e.g., MacDonald and Christiansen, 2002; Raeli and Christiansen, 2007; Gennari and MacDonald, 2008) or through a construct of "expectation" (Surprisal: Hale, 2001; Levy, 2008; Entropy Reduction: Hale, 2006). These theories account for the processing differences by resorting to probabilistic information associated with one's linguistic experiences, attributing the easier processing of SRs to the greater structural predictability associated with SRs than ORs. Since SRs have a higher frequency of occurrence than ORs in English (Roland et al., 2007), the parser is more likely to parse the head noun and relativizer in English as starting an SR than an OR. Thus, the increased predictability associated with SRs is claimed to be what induces the shorter reading times.

A related experience-based theory posits that the dominant (i.e., most frequent) thematic order in a language can be used as a perceptual strategy to facilitate sentence comprehension (Bever, 1970; Townsend and Bever, 2001; Lin, 2013). According to the thematic-order account, experience with thematic orders form *canonical thematic templates*, which may facilitate efficient thematic interpretations. Since the canonical word order in English is SVO and the canonical thematic order is agent-verb-patient, SRs, which present orders consistent with the dominant order, are predicted to be less costly to process[2]. The thematic order account predicts increases in reading time where word order mismatches take place.

This brief summary highlights the fact that the overall advantageous reading of SRs in English is consistent with multiple theories of sentence comprehension though specific predictions about where the processing differences should be observed may differ. Gibson and Wu (2013), for example, point out that an integration account predicts the increase in processing load where the filler-gap integration takes place (i.e., around the embedded verb region in head-initial relative clauses). An experience-based account, on the other hand, predicts the increase in processing load should occur where processing uncertainty increases (i.e., around the embedded subject but not on the embedded verb in an OR).

[1]The classification of these structure-based accounts as working memory accounts is my own. These original structure-based accounts did not necessarily specify the working memory component.

[2]The thematic template theory is of a similar flavor to the NVN strategy of Bever (1970). Whereas, Bever's NVN strategy focuses on the order of syntactic categories in a sentence, the thematic template account focuses on the linear orders of the semantic roles associated with noun phrases in relation to the verb position. What distinguishes the thematic order account from the word order account, therefore, is that the former does not link the semantic arguments to grammatical functions and therefore does not depend on the "structural" positions of the arguments.

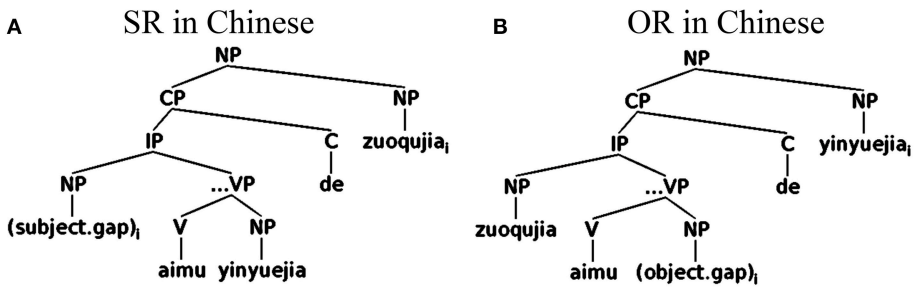

FIGURE 2 | Syntactic structure of relative clauses in Chinese.

An accumulating body of research over the past decade has painted a somewhat different picture of the processing of head-final relative clauses (Basque: Carreiras et al., 2010; Japanese: Miyamoto and Nakamura, 2003; Ueno and Garnsey, 2008; Korean: Kwon et al., 2010; Mandarin Chinese: Hsiao and Gibson, 2003; Lin and Bever, 2006; Lin and Garnsey, 2011; Packard et al., 2011; Qiao et al., 2012; Gibson and Wu, 2013; Jäger et al., 2015; Turkish: Kahraman et al., 2010). By definition, in a head-final relative clause construction, the relative clause appears before the head noun it modifies, meaning that the gap is encountered before the filler (rather than after it, as in English). Such structures are of crucial theoretical interest since they make it possible to reexamine the predictive power of the different competing sentence comprehension theories in a new context.

To illustrate the theoretical relevance of head-final relative clause processing, consider the Mandarin Chinese (henceforth "Chinese") sentences with relative clauses in (3) and (4)[3].

(3) Sentence with subject-extracted relative clause in Chinese:
_$_i$ aimu yinyuejia de zuoqujia$_i$ he-le yi bei jiu
_$_i$ adore musician REL composer$_i$ drink-ASP one glass wine
"The composer who adored the musician drank a glass of wine."

(4) Sentence with object-extracted relative clause in Chinese:
zuoqujia aimu _$_i$ de yinyuejia$_i$ he-le yi bei jiu
composer adore _$_i$ REL musician$_i$ drink-ASP one glass wine
"The musician whom the composer adored drank a glass of wine."

Chinese displays a head-initial structure in verb phrases: like English, Chinese is a Subject-Verb-Object (SVO) language, with verbs preceding their NP object complements. At the same time, however, Chinese displays a head-final structure in NP: modifiers of nouns exclusively appear before the head noun. Because of this combination, while subject gaps in Chinese are higher and structurally closer to the complementizer/relativizer than object gaps (as in English), subject gaps are linearly *farther* from the head noun (i.e., the filler) than object gaps, unlike English. These facts are illustrated in **Figure 2**, which diagrams the relative clauses from (3, 4)[4].

Regarding gap-filler integration, therefore, the linearity account predicts that the gap-filler relation in a Chinese OR should be less taxing to construct than that in an SR. The structure-based account predicts the opposite: since fewer structural nodes intervene between the head noun and a subject gap, the dependency between these two should be easier to construct compared to one involving an object gap. Both accounts would predict the locus of processing differences on the head noun where gap-filler integrations take place.

Regarding the effect of structural probabilities, given that SRs have higher frequencies than ORs in Chinese (Wu et al., 2011), greater surprisal values are associated with ORs and thus longer reading times in ORs are predicted. In terms of the effect of dominant thematic orders, since the canonical thematic order in Chinese is agent-verb-patient, ORs, which follow the dominant order, are predicted to be less costly to process (Lin, 2013, 2014). The experience-based effects make processing predictions for the whole sentences based on structural and word-order probabilities, not just for particular regions where integration costs incur.

Chinese has thus been taken as a valuable test case for validating the integration-based accounts and experience-based accounts depicted above (see also Jäger et al., 2015 for a review of the theoretical controversy). So far, research has provided a somewhat mixed picture. In the head-noun region, some studies have found that ORs took longer to read than SRs (Lin and Bever, 2006; Chen et al., 2012; Jäger et al., 2015) while others found the opposite (Gibson and Wu, 2013). One potential difficulty in acquiring consistent results is that studies differed regarding whether and how relative clauses are motivated. When relative clauses are not motivated (for example, when they appear in isolated sentences without referential contexts or structural cues preceding them), surprisal effects related to reanalyses may induce longer reading times in the disambiguating regions. Gibson and Wu (2013), for instance, pointed out that Chinese ORs may be more difficult to comprehend than SRs in neutral

[3]In these examples and throughout the paper, REL and ASP will be used as abbreviations for "relativizer" and "(perfective) aspect," respectively.

[4]We adopt a movement/raising analysis for the tree diagrams of subject-extracted and object-extracted relative clauses in Chinese (see Aoun and Li, 2003; Huang et al., 2009).

contexts because ORs are more likely to induce a garden path effect in the prenominal regions. Longer reading times for ORs are thus predicted in the head noun region, where disambiguation takes place.

On the other hand, when relative clauses are pragmatically motivated or structurally disambiguated, one needs to consider the potential effects of the different contextual cues. Chinese relative clauses have previously been pragmatically motivated by using discourse contexts (Gibson and Wu, 2013; Lin, 2014), and structurally disambiguated by using classifier-noun mismatching cues (Hsu et al., 2006) and classifier-adverbial sequences (Jäger et al., 2015). In studies that motivated relative clauses by using referential contexts (Lin, 2014; cf. Gibson and Wu, 2013), relative clause processing was shown to be sensitive to the order of thematic roles in the context: relative clauses whose thematic orders match those in the referential contexts showed shorter reading times in the regions after the head noun. In studies where relative clauses were structurally disambiguated, reading patterns have been found to be consistent with the conditional structural probabilities of SRs and ORs. Jäger et al. (2015), for instance, reported reading patterns consistent with surprisal predictions based on a corpus study and a sentence completion task. In Chinese relative clauses that follow disambiguating syntactic contexts like classifier-adverbial sequences, the conditional probability of an SR is higher than that of an OR in the embedded clause regions (i.e., IPs in **Figure 2**) but not on the head noun. Reading patterns confirmed that an SR advantage existed in the embedded clause regions but not on the head noun.

Methodologically, processing studies comparing Chinese SRs and ORs have reached a bottleneck. In most previous studies, SRs have been directly compared to ORs, meaning that SRs and ORs serve as each other's baseline conditions. Accordingly, any processing difference between the two has typically been associated with one single factor of theoretical interest. For instance, Gibson (1998) focuses on differences in linear distance between the gap and the filler, whereas theories of structural complexity (O'Grady, 1997; Hawkins, 2004) focus on differences in the number of structural layers/nodes intervening between the two. In fact, however, SRs and ORs are different from each other in multiple ways beyond these differences. In terms of constructional frequencies, SRs are more common than ORs (Lin, 2009; Wu et al., 2011). In terms of structural predictability, an SR is better expected than an OR (Jäger et al., 2015). In terms of nominal animacy preferences, the heads of SRs are preferably animate while those of ORs are preferably inanimate (Wu et al., 2012). Because SRs and ORs are simultaneously different from each other in so many ways, results from previous studies comparing the two are difficult to interpret.

The present study addresses this methodological issue by holding the extraction site constant (only SRs) and investigating the processing of three different *sub-types* of SRs: standard SRs, SRs with the disposal *ba* construction (henceforth "disposal SRs"), and SRs with the long passive *bei* construction (henceforth "passive SRs"). Both the disposal *ba* construction and the passive *bei* construction involve functional morphemes that have been analyzed as light verbs or grammaticalized verbs in Mandarin Chinese. An example for each construction is given in (5–7). Sentences with relative clauses appear after referential contexts, which are intended to pragmatically motivate relative clauses so that the prenominal relative clauses are parsed as relative clauses when they appear in sentences.

(5) Standard SR:
__$_i$ jiaoxing furen de zuoqujia$_i$ he yi bei jiu
__$_i$ wake.up lady REL composer$_i$ drink one glass wine
action *PATIENT* *AGENT*
"The composer that woke up the lady drank a glass of wine."

(6) Long passive (*bei*) SR:
__$_i$ bei furen jiaoxing de zuoqujia$_i$ he yi bei jiu
__$_i$ BEI lady wake.up REL composer$_i$ drink one glass wine
AGENT *action* *PATIENT*
"The composer that was woken up by the lady drank a glass of wine."

(7) Disposal (*ba*) SR:
__$_i$ ba furen jiaoxing de zuoqujia$_i$ he yi bei
__$_i$ BA lady wake.up REL composer$_i$ drink one glass
PATIENT *action* *AGENT*
jiu
wine
"The composer that woke up the lady drank a glass of wine."

Being SRs, all three structures involve the extraction and relativization of the subject NP, which, in Chinese, involves a movement type of dependency between the subject gap and the head NP (Aoun and Li, 2003). Where these three structures differ from one another is the internal structure of the pre-relativizer inflectional phrase (IP)—in particular, the structure of the verb phrase (VP) and the small verb phrase (vP) following the subject gap. Each of these three constructions will now be discussed in turn.

The syntactic structure of a standard SR is illustrated in **Figure 3**, representing the relative clause portion of (5). Standard SRs contain an SVO sequence with an empty subject NP inside the IP.

The syntactic structure of a passive SR is illustrated in **Figure 4**, representing the relative clause portion of (6) above. Under the main-verb analysis for Chinese long passives (Huang et al., 2009), this structure contains an empty subject and

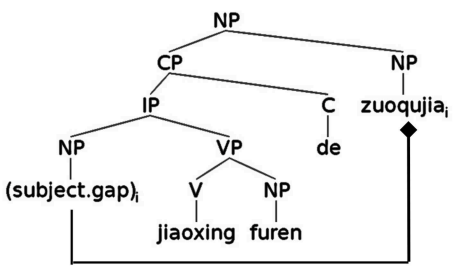

FIGURE 3 | Syntactic structure of a standard SR in Chinese.

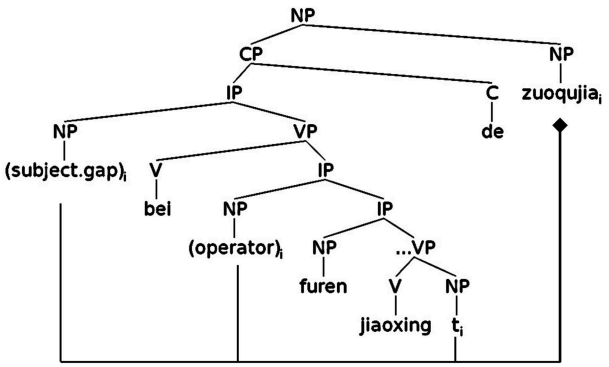

FIGURE 4 | Syntactic structure of a passive SR in Chinese.

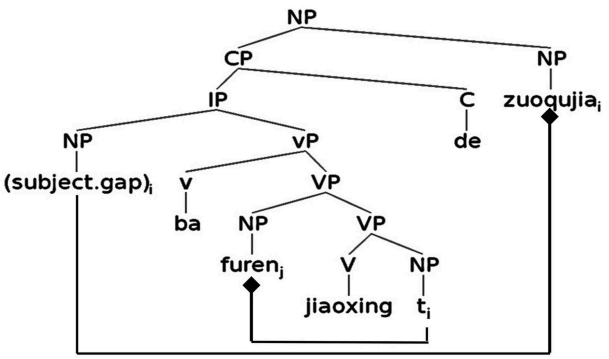

FIGURE 5 | Syntactic structure of a disposal SR in Chinese.

a VP headed by *bei*, followed by a secondary predicate IP[5]. Three dependencies are involved in this construction. First, as in all the SRs, a dependency exists between the subject gap and the head NP. Second, an additional dependency exists between the base generated object NP position in the lower VP and the NP operator at the periphery of the intermediate IP. Third, this NP operator holds the same identity as the subject gap. The three empty positions (the subject gap, the operator, and the trace) all bear the same identity as the head NP.

The structure of a disposal SR is illustrated in **Figure 5**, representing the relative clause portion of (7) above. Like passive SRs, disposal SRs also involve multiple dependencies. Under the light verb analysis of *ba* (e.g., Huang, 1997; Lin, 2001), the object NP of the lower VP is displaced to the specifier position. Two separate dependencies involving empty categories need to be constructed in the processing of a disposal SR: one between the subject gap and the head NP (outer connection in **Figure 5**), and the other between the moved object NP immediately following *ba* and the position of its trace (inner connection in **Figure 5**). Unlike passive SRs, the VP-internal dependency in a disposal SR is nested inside the dependency between the subject gap and the head NP[6].

The processing factors discussed above cast different effects on these three types of Chinese SRs. Let's first focus on the integration effects regarding the dependency between the subject gap and the head noun in each of the three structures, which are usually taken to be observable around the head noun region, where filler-gap integrations take place. In terms of linear locality (Gibson, 1998; Hsiao and Gibson, 2003), the same numbers of *new referents* intervene between the gap and the filler, thus predicting no processing differences. If linear distance is computed using the number of intervening *words*, then the passive SRs and the disposal SRs may both require greater processing load than the standard SRs because they involve an additional function word (*bei* and *ba*, respectively) between the gap and the filler. In terms of structural locality, since all three SRs involve extraction from subject position, the structural distance between the head noun and the gap are identical across all three structures (passing through two XP nodes—one CP and one IP), thus predicting no processing differences.

In addition to the gap-filler dependencies, the passive SRs and the disposal SRs involve additional displacement dependencies as depicted in **Figures 4**, **5**. For a passive SR, the sentence-initial passive marker *bei* indicates a missing subject NP that is to be connected with the object NP in the lower VP. Assuming that a relative clause parse has been adopted, the missing subject NP is taken to be connected both with the object NP and the head noun[7]. For a disposal SR, the sentence-initial light verb *ba* also indicates a missing subject NP. Assuming again the processing of a relative clause, this missing subject NP would be taken as a subject gap connected with the head noun. An additional dependency in a disposal SR involving the displaced object NP after *ba* would add to the processing cost already incurred by the SR. The integration-based accounts, taking into consideration these additional dependencies, would then predict that both a passive SR and a disposal SR should be harder than a standard SR because (a) the former SRs involve additional dependencies, and (b) the dependencies in the former SRs are longer and more complex than that of a standard SR.

[5]Alternatively, *bei* has also been analyzed as a preposition taking the NP following it as its oblique object in the long passives and the subject NP as an NP displaced from the object NP in the lower VP (Li, 1990). In this analysis, instead of three dependencies, two dependencies—one between the subject and the lower object and one between the subject gap and the head noun—are involved. While the main verb analysis, which Huang et al. (2009) persuasively argued for, is adopted in the present study, similar predictions about how passive SRs are processed in comparison with standard SRs and disposal SRs can be made when the alternative analysis is adopted.

[6]Like *bei*, the categorical status of *ba* is controversial. In addition to the light verb analysis adopted in the present article, it has also been analyzed as a lexical verb (Hashimoto, 1971), a preposition (Chao, 1968; Li, 1990), and a function word that assigns case (Huang, 1982; Goodall, 1987). In these analyses, the object NP forms a local syntactic constituent with *ba*, through which it is connected with the verb. The dependency between the object NP and the verb is still nested inside the dependency between the subject gap and the head noun.

[7]The integration cost associated with passive SRs may also need to consider the base-generated lowermost trace position, which is linearly closest to the head NP. Even though this short linear dependency may exist between the passivized NP trace and the head noun, it does not preclude the processor from establishing a dependency between the trace NP and the subject gap, which involves a longer linear distance than the dependency in a standard SR.

Processing differences are expected to appear on and before the head noun.

Next, we consider the overall structural complexity and structural frequencies involved in the three types of SRs. The standard SR is the simplest of the three constructions, as it contains the fewest number of structural layers and only has a single dependency relation (between the subject gap and the head). Passive SRs and disposal SRs are both more complicated in terms of the intricate dependency relations inside the VP/vP[8]. This hierarchy of complexity is consistent with the constructional frequencies of the 3075 relative clauses extracted from the Sinica Treebank (Version 3.0; Chen et al., 2003) by Lin (2009), among which standard SRs accounted for 53%, passive SRs accounted for 2%, and no instances of disposal SRs were found[9]. Thus, based on both structural complexity and constructional frequency, a standard SR should be the easiest to process among the three.

On the other hand, the thematic order effect predicts different processing preferences. Since the surface thematic order of a passive SR matches the canonical thematic order in Chinese (i.e., AGENT-*action*-PATIENT), a passive SR should be the easiest to process among the three. Conversely, the thematic orders of standard SRs and disposal SRs are inconsistent with this dominant thematic order and should be more difficult to process than the passive relatives.

One relevant hypothesis about effect locus proposed by Lin (2014) is that the pre-relativizer and post-relativizer regions of a head-final relative clause may reveal different processing effects. This hypothesis is directly related to the existence of uncertainty in processing head-final relative clauses: while the pre-relativizer regions are structurally ambiguous, the post-relativizer regions are structurally unambiguous. The pre-relativizer regions of an OR, for example, with the word order *Noun-Verb*, are more likely to be read as matrix clauses than subordinate relative clauses. The corresponding pre-relativizer *Verb-Noun* sequence of an SR would be parsed as a matrix clause with a missing subject argument before the verb (see Lin and Bever, 2011; Jäger et al., 2015 for more elaborated discussion on the issue of garden path in Chinese relative clauses). With the post-relativizer regions, however, no similar ambiguity exists since comprehenders tend to parse the functional morpheme *de* after the embedded clause as a relativizer. A corpus study and a sentence completion task by Jäger et al. (2015) have confirmed that a relative clause parse is already unambiguously established when the relativizer is reached. Lin (2014), in particular, proposes the effect of thematic templates, being a pattern matching effect, may be more observable in the post-relativizer regions where structural uncertainty has decreased.

In addition to the overall predictions of the effects, we thus further distinguish the processing effects in the pre-relativizer regions and the post-relativizer regions. In the pre-relativizer regions, disposal SRs and passive SRs are both expected to take longer to process than standard SRs given greater structural complexity and lower structural frequencies[10]. Integration effects based on linear locality and structural locality would make similar predictions given that simpler dependent relations exist in the standard SRs than in the disposal and passive SRs. The effect of thematic template mapping, on the other hand, predicts shorter reading time for passive SRs because they display thematic orders consistent with the canonical order in Chinese though this effect may emerge later in a prenominal relative clause construction.

In the post-relativizer regions, where the existence of relative clauses are clearly indicated by the relativizers and the head nouns, an integration account based on linear locality would predict that standard SRs be easier than both disposal and passive SRs, especially around the head noun region. An integration account based on structural locality would predict no processing differences, or easier processing for standard SRs due to the complexity effect possibly spilled over from the prenominal regions. The effect of thematic template mapping is the only theory that predicts an overturned reading pattern for passive SRs, with passive SRs being the least costly to read. The effect of thematic template mapping is expected to span across multiple post-relativizer regions.

The goal of the present study, in summary, is to examine the effect of thematic orders on Chinese relative clause processing. While Lin (2014) reported that the processing of SRs and ORs in Chinese is sensitive to the thematic orders presented in the context, it directly compared the processing of SRs and ORs, which as discussed, involve an array of differences that may obscure the effects. The present study contrasted the processing of three sub-types of SRs, thus keeping constant the extraction site regarding its grammatical function in the embedded clause. Furthermore, Lin (2014) studied the effect of thematic orders by varying the orders in the referential context while keeping the thematic orders in the relative clauses constant. The present study examined this effect by varying the thematic orders in the relative clauses while keeping the thematic orders in the context

[8]It is not a simple matter to determine whether a passive SR or a disposal SR is more complex. In terms of the number of dependencies and structural layers, a passive SR is more complex. In terms of the number of different NP identities involved in the dependencies, a disposal SR is more complex. Moreover, while both kinds of SRs exhibit nested dependencies, these dependencies are all associated with the same NP for passive SRs. This factor may make the construction of such dependencies easier to process than the multiple distinct dependencies of a disposal SR. In this sense, then, disposal SRs may be the more complex of the two.

[9]The Sinica Treebank can be found at the following URL: http://turing.iis.sinica.edu.tw/treesearch/. Passive constructions (using *bei*) and disposal constructions (using *ba*) are also less common in Chinese *overall* compared to canonical VO orders. In the Sinica Corpus, *ba* accounted for 14.4% of the words in the corpus and *bei* 14.8% (CKIP online word frequency list http://elearning.ling.sinica.edu.tw/eng_teaching.html, retrieved on September 17, 2012). These overall frequency differences are mirrored in processing differences: Lin (2006, 2008) found that, compared to canonical SVO sentences, disposal sentences and passive sentences showed lower acceptability ratings in naturalness-judgment questionnaires as well as longer reading times in online self-paced reading tasks.

[10]Constructional frequency is but one way to make expectation-based predictions. Alternatively, it is also possible to conduct a sentence completion task to generate word-by-word structural expectations (as has been done in Jäger et al., 2015). The sentence completion task will be particularly useful for distinguishing the processing of passive SRs and disposal SRs. Since the main contrast of interest in the present study is between standard SRs and passive SRs, using corpus counts and constructional frequencies should be sufficient for making the expectation-based predictions. Nonetheless, we leave an actual sentence completion task as an open possibility for generating more fine-grained word-by-word expectation-based predictions.

constant. It is hoped that this new manipulation can test the effect of thematic order on relative clause processing from a new angle.

Materials and Methods

Participants

Forty-eight Taiwanese college students at National Taiwan Normal University, all native speakers of Mandarin Chinese, participated in the experiment. The participants were screened for brain damage. All had normal (or corrected to normal) vision, and were naïve to the purpose of the experiment. Participants gave informed consent to take part in the study. The study protocol was approved by Indiana University's Institutional Review Board.

Materials

Twenty sets of sentences were included as the experimental trial, 16 of which were modified based on Gibson and Wu's (2013) stimuli. The experimental materials were created in such a way that they read naturally in Mandarin disposal and passive constructions. To motivate the relative clauses, each set consisted of a referential context introducing transitive relations in which three referents are involved, as in (8). The sentences in the context where these thematic relations were introduced present the thematic order of AGENT-*action*-PATIENT. Following each context was a dialogue between two interlocutors, Xiaoming and Xiaomei, in which Xiaoming asks Xiaomei to identify one referent out of the two active referents, as in (9). Xiaomei's response starts with the target relative clause presented in a word-by-word moving window format. A sample of the experimental materials is given below:

(8) Context:
Yidong gongyuli zhule fangdong yiji liangge fangke
one apartment lived landlord and two tenants
"A landlord and two tenants lived in an apartment."

Yiwei zhuhu chaoxingle fangdong
one tenant woke up landlord
"One of the tenants woke up the landlord."

Fangdong ze chaoxingle lingyiwei zhuhu
landlord then woke up the other tenant
"The landlord woke up the other tenant."

Xiaoming: Wo tingshuo qizhong yiming zhuhu hen gao
I heard among them one tenant very tall
"I heard one of the tenants was very tall."

Nayiwei zhuhu hen gao?
which.one tenant very tall
"Which tenant was very tall?"

(9) Target sentence with a relative clause:
(i) Standard SR
Xiaomei: Chaoxing fangdong de zhuhu hen gao
woke up landlord REL tenant very tall
V N REL Head Noun HN+1 HN+2
"The tenant that woke up the landlord was very tall."

(ii) Passive SR
Xiaomei: Bei fangdong chaoxing de zhuhu hen gao
BEI landlord woke up REL tenant very tall
BEI N V REL Head Noun HN+1 HN+2
"The tenant that was woken up by the landlord was very tall."

(iii) Disposal SR
Xiaomei: Ba fangdong chaoxing de zhuhu hen gao
BA landlord woke up rel tenant very tall
BA N V REL Head Noun HN+1 HN+2
"The tenant that woke the landlord up was very tall."

Forty-eight additional sets of sentences following a similar format served as fillers. Sixteen of these fillers had relative clauses of various types in them; the remaining 32 fillers did not contain relative clauses. Altogether, 68 sets of contexts and sentences were pseudorandomly presented so that no two experimental trials appeared consecutively. Comprehension questions followed each trial to ensure that participants paid attention in reading the experimental materials. The words used in the relative clauses are provided in the Supplementary Materials.

Procedure

The experiment followed the standard moving-window self-paced reading design and was conducted using Linger 2.94 (developed by Doug Rohde)[11]. In each trial, participants took their own pace hitting the spacebar to proceed to the next sentence or region. The contexts were presented sentence by sentence, and the target sentences (i.e., Xiaomei's response to Xiaoming's query) were presented word by word. For disposal and passive SRs, *ba,* and *bei* were presented in the same region as the following noun. After the last word, participants were given a true/false comprehension question focusing on the overall content of the context or the target sentence. Feedback was given if the participant's response was incorrect. Participants were instructed to read the sentences at a natural pace in order to answer the comprehension questions correctly. The reading time for each region, the time taken to answer the comprehension questions, and the responses to the comprehension questions were recorded. The whole experiment took an average of 40 min to complete.

Results

Linear mixed-effects models treating both subjects and items as random effects were fit to both the comprehension accuracy data and the region-by-region reading time data using the lme4 package version 1.1-7 in R (version 3.2.0; Bates et al., 2015). Two contrasts were defined comparing the passive SRs with the standard SRs (passive SR coded as +1, standard SR coded as −1) and comparing the passive SRs with the disposal SRs (passive SR coded as +1, disposal SR coded as −1). The analyses were carried out on log-transformed values of the reading times and residuals were checked to ensure that the normality requirement is met.

[11]See http://tedlab.mit.edu/~dr/Linger/ (retrieved on December 9, 2012) for documentation of Linger 2.94.

The package lmerTest (version 2.0-25) in R is used to verify the levels of statistical significance. The *t*-value of 2 is taken to be the threshold for statistical significance at $\alpha = 0.05$. Question-accuracies were analyzed using generalized linear mixed models with a binomial link function. The dependent measures included comprehension accuracies (binary results), latencies in answering comprehension questions, and region-by-region reading times.

Comprehension Accuracy

The mean comprehension accuracy for all items was 85% and the mean accuracy for the experimental trials was 90%. The accuracies of each of the three experimental conditions were 93.05% (passive SRs), 91.83% (standard SRs), and 86.28% (disposal SRs). These results are summarized in **Figure 6**. Statistical results are given in **Table 1**.

In terms of overall comprehension accuracy, passive SRs were comprehended more accurately than both standard SRs and disposal SRs. These results are consistent with the predictions of thematic order effect. Namely, passive SRs, whose thematic order followed the canonical thematic order, were comprehended with greater accuracies than both standard SRs and disposal SRs. No difference was found on the time taken to respond to the comprehension questions.

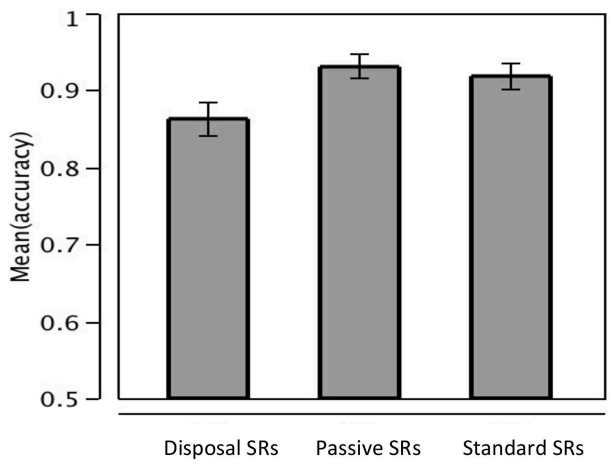

FIGURE 6 | Comprehension accuracies of disposal SRs, passive SRs, and standard SRs (error bars indicating one standard error).

Reading Times

Since the regions before and after the relativizers are hypothesized to be reflective of different processing effects, average reading times in the two pre-relativizer regions were compared to those in the post-relativizer regions (from the head noun to two regions after the head noun) across the three conditions. **Figure 7** illustrates the results of this analysis. Statistical results are given in **Table 2**.

In the pre-relativizer regions, passive SRs were read longer than standard SRs. In the post-relativizer regions, passive SRs were read faster than both the standard SRs and the disposal SRs. The reading time of each target region, including the two pre-relativizer regions, the relativizer, the head noun, and the two regions after the head noun, is further summarized in **Figure 8**. Statistical results of the by-region reading time analyses are given in **Table 3**.

Passive SRs were read longer than standard SRs in both regions inside the relative clause (i.e., the pre-relativizer regions), and faster than disposal SRs from the second region in the prenominal clause to the head noun region[12]. In the second region after the head noun, passive SRs were read faster than standard SRs.

To sum up, standard SRs were read with greatest ease in the earlier regions of the relative clauses. In contrast, in the regions following the relativizer, passive SRs were read more quickly than standard SRs and disposal SRs. The easier comprehension of standard SRs in the pre-relativizer regions is consistent both with integration effects (i.e., standard SRs having less complicated dependencies) and with expectation-based constructional frequency effects (i.e., standard SRs being more frequently experienced than passive SRs). The easier comprehension of passive SRs in the post-relativizer regions, on the other hand, is only consistent with the prediction of thematic template mapping.

General Discussion

The present study contrasted the reading patterns of three types of SRs in Chinese: standard SRs, passive SRs, and disposal SRs. Distinctive reading patterns were observed in the

[12] As a caveat to the advantage of standard SRs observed in the pre-relativizer regions, the disposal SRs and the passive SRs involve an additional function word (i.e., *ba* and *bei*) in the first region, which could induce longer reading times in these regions. The different words in these two pre-relativizer regions also make region-by-region comparisons less straightforward.

regions before and after the relativizer, suggesting the effects of different processing factors being operative. While the current experimental design intends to motivate relative clauses by using referential contexts, it is still unclear whether a relativized gap has indeed been postulated in the pre-relativizer regions given that a relative-clause parse is but one of several possible parses for the pre-relativizer regions. The structurally-ambiguous pre-relativizer regions showed reading patterns consistent with expectation-based theories of sentence comprehension (e.g., the uncertainty-reduction accounts of Hale, 2006 and Chen et al., 2012; see also Jäger et al., 2015), which rely on the probabilities of particular syntactic categories and constituents appearing at particular positions of a sentence. Standard SRs, being the most common prenominal structure of the three, are found to be easier to understand. Besides expectation-based effects, the reading patterns in the pre-relativizer regions are also compatible with integration-based effects, which, as discussed, predict easier processing on structures that involve simpler dependencies. In comparing the three types of SRs, a standard SR involves fewer dependencies and presents a simpler dependency structure.

When the relativizer region is reached, the existence of a relative clause is unambiguously indicated. Consistent with the prediction of the thematic order effect, a passive SR was read faster than the corresponding standard SR and disposal SR given that the thematic order in a passive SR is more frequently experienced than that in a standard SR and that in a disposal SR. All other theoretical factors, by contrast, favor the processing of a standard SR given its structural simplicity and greater constructional frequency. Moreover, this effect of thematic ordering was observed to span across several post-relativizer regions, being attested from the relativizer to the second region after the head noun individually as well as in the sum total. The thematic order effect therefore seems qualitatively different from the gap-filler integration effects, which are usually *localized* to the head noun region.

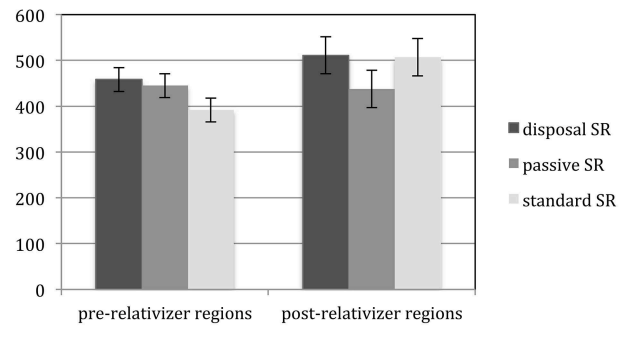

FIGURE 7 | Average reading times of disposal SRs, passive SRs, and standard SRs in the regions before and after the relativizer (error bars indicating one standard error).

In previous research on Chinese SR/OR processing, similar asymmetries have been found before and after the relativizer. Recall that, the thematic order of agent-verb-patient found in an OR, which is similar to that in a passive SR, may give a Chinese OR a processing edge over its SR counterpart owing to the thematic order effect. In contrast to an SR, the pre-relativizer regions of a Chinese OR present a word order (i.e., noun-verb) that matches the canonical order in a Chinese sentence and may be read with greater ease than those of a Chinese SR, whose pre-relativizer verb-noun sequence is non-canonical. In previous studies where relative clauses were not structurally disambiguated, greater processing costs were indeed associated with the pre-relativizer regions of an SR—an effect consistent with the prediction of structural probabilities as well as thematic orders (Hsiao and Gibson, 2003; Chen et al., 2008; Qiao et al., 2012). When the relative clauses were structurally disambiguated, however, SRs were processed with greater ease than ORs owing to SRs' greater structural predictability after disambiguating contexts (Jäger et al., 2015)—an effect that is consistent with the prediction of structural probabilities only.

In the post-relativizer regions, an OR disadvantage has been reported for relative clauses modifying the object of an SVO sequence (Lin and Bever, 2006). This effect has been attributed to the reanalysis of a garden-path parse in such structures given that no contextual cues indicated a relative clause parse on the left edge (Lin and Bever, 2011). Most relevant to the current findings, however, in studies that used referential contexts to motivate Chinese relative clauses, an OR advantage consistent with the thematic order effect reported in the current study was obtained (Gibson and Wu, 2013; Lin, 2014).

The thematic order effect on processing Chinese relative clauses is also supported by two offline studies on aphasic patients' processing of Chinese relative clauses: Law and Leung (2000) and Su et al. (2007). Using picture-matching tasks, both studies found better performance on ORs compared to SRs, which was attributed to the fact that Chinese ORs (but not Chinese SRs) match the canonical thematic order. These results are also compatible with the SR advantage of English-speaking aphasic patients (Caplan and Futter, 1986; Grodzinsky, 1986; Hagiwara and Caplan, 1990). An implication of the thematic

order effect is that the advantage previously reported for an OR advantage in Mandarin and an SR advantage in English should be re-considered since Mandarin ORs and English SRs, like the passive SRs in the current study, present a canonical thematic order. When comparing SRs and ORs, the advantage for processing Chinese ORs may be due to the ORs presenting canonical thematic orders, but not the SRs.

In the current study, the reading patterns of disposal SRs are contrasted with those of standard SRs and passive SRs. Given their lower constructional frequency and greater number of dependencies involving empty categories, disposal SRs were expected to be the most difficult to process. Indeed, the reading patterns in the present study showed that disposal SRs were the most difficult among the three SRs examined in both the pre- and post-relativizer regions. Given the additional dependencies and lower structural probability associated with passive SRs, it may be expected that they should be equally difficult to process. This result was only obtained for the pre-relativizer regions, where passive SRs were read longer than the standard SRs. In the post-relativizer regions, the reading times of passive SRs were shorter than those of standard SRs and disposal SRs. This can be taken as evidence that the canonical thematic order found in a passive SR induced shorter reading times in its post-relativizer regions. The fact that structural probability effects and thematic template

effects have been observed in different regions of a relative clause does not imply that these processes are only operative in different regions of a sentence. Taken together, the results from these different studies suggest that the surprisal-related effect and the thematic template effect are both active and can be independently observed in different regions of a Chinese sentence.

The effect of thematic ordering on sentence comprehension can be understood as a processing heuristic used for efficiently coming up with thematic interpretations for sentences. The sentence processor keeps track of the linear positions of the content words in a sentence in forming thematic interpretations. The dominant thematic order of a language may serve as an "interpretation template," to which the content words of a sentence are matched. The comprehension of sentences with more complex structures such as relative clauses can be facilitated by matching thematic orders against the dominant thematic templates. Since the dominant thematic template in Chinese is AGENT-*action*-PATIENT, constructions matching this thematic order (such as ORs and passive SRs) may be comprehended with greater ease. This thematic template effect may also be effective in the comprehension of SRs in English, whose surface thematic order matches the dominant thematic order in the language.

These effects of thematic order are in line with several existing theories of sentence processing. The idea of thematic templates has a similar flavor to Bever's (1970) NVN heuristics—later referred to as "pseudosyntax" in Townsend and Bever (2001). In addition, mapping with thematic templates is also consistent with the "good enough" or "shallow processing" heuristics advanced by Ferreira (2003)[13]. We suggest that in order to arrive at a "good enough" impression of thematic relations, nouns and verbs are matched with the preexisting thematic templates. When the argument order in a sentence follows the dominant thematic template, the thematic roles of the nouns and verbs are easy to identify. Conversely, when the argument order is atypical, it is more difficult to identify thematic relations.

[13]In experiments requesting participants to identify the thematic roles of subjects and objects, Ferreira (2003) found that participants made more errors in sentences with atypical thematic orders (e.g., English passive sentences) than sentences with typical thematic orders (e.g., English active sentences). Moreover, this effect was found to be independent of the frequency of the relevant syntactic structures.

Conclusion

In conclusion, the reading time data for three sub-types of Chinese SRs reported in the present study supported two processes that are involved in the comprehension of Chinese relative clauses. Before reaching the relativizer, where the structure of the sentence is temporarily ambiguous, expectation-based incremental processing theories such as those of Hale (2001, 2006) and Levy (2008) can account for the processing differences across the three kinds of SRs though the results are also compatible with the integration-based predictions. Starting from the relativizer and the head noun, where the existence of a relative clause is unambiguously indicated, a global effect of thematic ordering was observed.

The critical evidence for the effect of thematic ordering comes from the easier processing of passive SRs, whose thematic role order conforms to the canonical thematic order of Chinese. Despite their more complex structural dependencies and lower constructional frequency compared with standard SRs, passive SRs were nevertheless comprehended with the greatest accuracy and processed with the shortest reading times in the post-relativizer regions. The current study therefore suggests that the comprehension of relative clauses in Chinese is sensitive to both the structural probabilities of constituents as well as the thematic orders involved in the relative clauses. In our effort to understand relative clause comprehension, it is important to take both of these factors into account.

Acknowledgments

This research was partially funded by Indiana University's Office of the Vice Provost for Research through the Faculty Research Support Program. I thank Aaron Albin, Yu-Jung Lin, and Chung-Lin Yang for their research assistance.

Leiken K, McElree B and Pylkkänen L (2015) Filling Predictable and Unpredictable Gaps, with and without Similarity-Based Interference: Evidence for LIFG Effects of Dependency Processing. Front. Psychol. 6:1739. doi: 10.3389/fpsyg.2015.01739

One of the most replicated findings in neurolinguistic literature on syntax is the increase of hemodynamic activity in the left inferior frontal gyrus (LIFG) in response to object relative (OR) clauses compared to subject relative clauses. However, behavioral studies have shown that ORs are primarily only costly when similarity-based interference is involved and recently, Leiken and Pylkkänen (2014) showed with magnetoencephalography (MEG) that an LIFG increase at an OR gap is also dependent on such interference. However, since ORs always involve a cue indicating an upcoming dependency formation, OR dependencies could be processed already prior to the gap-site and thus show no sheer dependency effects at the gap itself. To investigate the role of gap predictability in LIFG dependency effects, this MEG study compared ORs to verb phrase ellipsis (VPE), which was used as an example of a non-predictable dependency. Additionally, we explored LIFG sensitivity to filler-gap order by including right node raising structures, in which the order of filler and gap is reverse to that of ORs and VPE. Half of the stimuli invoked similarity-based interference and half did not. Our results demonstrate that LIFG effects of dependency can be elicited regardless of whether the dependency is predictable, the stimulus materials evoke similarity-based interference, or the filler precedes the gap. Thus, contrary to our own prior data, the current findings suggest a highly general role for the LIFG in dependency interpretation that is not limited to environments involving similarity-based interference. Additionally, the millisecond time-resolution of MEG allowed for a detailed characterization of the temporal profiles of LIFG dependency effects across our three constructions, revealing that the timing of these effects is somewhat construction-specific.

Keywords: neurolinguistics, left inferior frontal gyrus, magnetoencephalography, Filler-gap dependency, object relative clause, verb phrase ellipsis, right node raising, similarity-based interference

INTRODUCTION

A classic finding within the cognitive neuroscience of language processing is that the comprehension of object relative (OR) clauses, such as (1), have been found to engender more hemodynamic activity in the left inferior frontal gyrus (LIFG, aka "Broca's Area") than subject relative (SR) clauses, such as (2) (e.g., Just et al., 1996; Stromswold et al., 1996; Caplan et al., 2000, 2008; Keller et al., 2001; Constable et al., 2004). This observed difference in hemodynamic activity mirrors the behavioral findings that ORs are more costly to process than SRs by various measures (Holmes, 1973; Hakes et al., 1976; Wanner and Maratsos, 1978; Holmes and O'Regan, 1981; Ford, 1983; Waters et al., 1987; King and Just, 1991).

(1) the fireman [(who$_i$) the deputy called $\underline{t_i}$] saved the sailor
(2) the fireman [who$_i$ $\underline{t_i}$ called the deputy] saved the sailor

In tandem with hypotheses developed from an older body of aphasia studies, this effect has given rise to the popular conception that Broca's area is somehow linked to syntactic processing (Berndt and Caramazza, 1980; Damasio and Damasio, 1989; Zurif, 1995; Grodzinsky, 2000). Of specific proposals, the narrowest in terms of LIFG function hypothesizes that this region is specifically responsible for the processing of displacement or movement (Grodzinsky, 2000; Ben-Shachar et al., 2003; Grodzinsky and Santi, 2008). It is important to note that these theories have primarily been tested using relative clause structures, such as those described above, which contain movement operations (or "transformations") that result in a long-distance dependency between two elements. Therefore, it is unclear whether it is the movement process itself or the consequential relation between non-adjacent components that induces the increase in activation. A more general set of hypotheses, but still specific to linguistic processing, includes the "linearization" computation (Bornkessel et al., 2005; Grewe et al., 2005), and the process of "unification" (Hagoort, 2003, 2005). Linearization involves maintaining hierarchical orderings of the members of a linguistic dependency. If this process takes place in the LIFG, then a violation of linguistic hierarchy should yield increased LIFG activity. Therefore, as English-type languages show a preference for subjects to precede objects, the LIFG effect for ORs could be taken to reflect the reversal of the subject–object order. Unification, on the other hand, is the process of integrating lexical information from a single word into a larger syntactic frame that has been retrieved from memory. Therefore, if this computation takes place in the LIFG, then integration of individual lexical items into the OR syntactic frame retrieved from memory might generate increased LIFG activity.

The above proposals contrast with hypotheses linking the LIFG primarily to non-language-specific processes, such as working memory (Caplan et al., 2000, 2008; Fiebach et al., 2001, 2005; Kaan and Swaab, 2002; Rogalsky et al., 2008; Makuuchi et al., 2009) or cognitive control (Botvinick et al., 2001; Miller and Cohen, 2001; Novick et al., 2005; Braver et al., 2007). Under both of these types of accounts, the LIFG increase relates not to any language-specific structural operation, but rather to the fact that, in ORs (but not in SRs), two noun phrases (NPs) are encountered prior to the verb, taxing working memory and/or inducing conflict.

The goal of the present work was to contribute to our understanding of LIFG function in language processing by examining LIFG dependency effects with a different methodology and a broader range of dependencies than previously studied, as well as by manipulating variables that affect memory retrieval operations in resolving a dependency. We employed magnetoencephalography (MEG), which, contrary to the traditional hemodynamic methods, allowed for a detailed temporal characterization of LIFG activity. Our design systematically varied not only the presence of dependency structures, but also the extent to which dependent structures elicited retrieval interference. In addition to commonly studied object extractions, we also explored dependencies resulting from verb-phrase ellipsis and right-node raising. Contrasting these constructions with ORs allowed us to narrow down the hypothesis space regarding the source of LIFG dependency effects. In sum, the central aim of this work was to assess whether dependency effects in the LIFG are only elicited for memory-intensive structures involving similarity-based interference or also for "easy" dependencies without much interference. The latter finding would conform to accounts implicating the LIFG for dependency resulting from movement operations (or long-distance dependency itself) whereas the emergence of LIFG effects only in the presence of interference would suggest a more memory-driven role. Note though that the interpretation of "movement" always involves retrieval whether or not the movement configuration places any extra burden on working memory. Thus a uniform effect of "movement" on the LIFG could reflect a generic role in retrieval, as opposed to a (language-) specific one in movement.

Retrieval Interference in Behavior and the LIFG

Enhanced LIFG activity for ORs as compared with SRs aligns with behavioral effects of increased processing time for ORs over SRs. However, recent behavioral studies have suggested that the retrieval process in ORs may only be more costly than that of SRs under conditions that engender retrieval interference (Gordon et al., 2001, 2002; Fedorenko et al., 2006; Van Dyke and McElree, 2006, 2011; Lee et al., 2007; Hofmeister, 2011). Evidence suggests that sentence comprehension relies upon a cue-driven, direct-access operation (e.g., McElree, 2000; McElree et al., 2003; Martin and McElree, 2008, 2009, 2011), in which cues formed at the retrieval site make contact with representations in memory that have matching content, without the need for a search process. Direct access is performed quickly, but can be highly susceptible to interference (Foraker and McElree, 2011). Basic memory research, as well as research on the role of memory in comprehension, indicates that the primary locus of interference occurs during retrieval (Van Dyke and McElree, 2006). Retrieval interference can result from "cue-overload," a

condition where retrieval cues are not distinctive enough to reliably elicit a desired target because they were associated with multiple items in memory (Watkins and Watkins, 1975; Nairne, 2002; Öztekin and McElree, 2007). In these circumstances, a sought-after element in memory may fail to be recovered, another element matching the retrieval cues may be recovered in its place, or "blend errors" may occur where two or more representations are "synthesized at retrieval" (Nystrom and McClelland, 1992).

It is natural to expect retrieval interference to be a key determinant of whether comprehension is successful. One type of retrieval interference that may impede the processing of OR dependencies is similarity-based interference: i.e., when two adjacent or nearby determiner-noun sequences are parallel in their surface syntax (Lewis, 1996). In fact, it has been shown that if the two NPs prior to the verb contrast in their surface structure, then the behavioral OR over SR effect diminishes (Gordon et al., 2001). This suggests that the processing delay is unrelated to the syntactic configuration of ORs. While a full spectrum of features that engender interference remains to be determined, interference has been recurrently observed when memory representations (i) overlap in their semantic category membership (Gardiner et al., 1972; Wickens, 1973; Dillon and Bittner, 1975; Watkins and Watkins, 1975; Crowder, 1976); (ii) have similar phonological forms (Haber and Haber, 1982; McCutchen et al., 1991; Acheson and Macdonald, 2011) or (iii) encode similar syntactic structures (Lewis, 1996; Gordon et al., 2001, 2002; Fedorenko et al., 2006; Van Dyke and McElree, 2006; Lee et al., 2007; Hofmeister, 2011).

Similarity-based interference effects have also been reported in neuroimaging studies. Increased activation in the LIFG has been associated with competition resolution in non-language-specific tasks (Thompson-Schill et al., 1997; Brandon et al., 2003, 2004; Derrfuss et al., 2004; Postle et al., 2004; Feredoes et al., 2006), and patients with lesions in this region have shown deficits when performing non-syntactic interference tasks (Costello and Warrington, 1989; Robinson et al., 1998; Thothathiri et al., 2010). This suggests that Broca's area should not merely be linked with syntactic processing, but instead plays a key role in resolving more domain-general interference.

In a previous study, we employed the time course sensitive technique of MEG to link the behavioral finding that OR effects depend on structural parallelism to the LIFG literature. Specifically, we investigated whether the LIFG effect would also be reduced when structural similarity between pre-verbal NPs is removed (Leiken and Pylkkänen, 2014). Our findings indicated that this was indeed the case; LIFG effects of similarity-based interference—but not the pure presence of a dependency—were found at the gap site in ORs. Thus, it was shown that MEG could indeed be employed for the study of object extraction, revealing effects at the gap site around 600 ms after verb onset; a time window consistent with the time course of EEG findings for dependency formation (King and Kutas, 1995; Kaan et al., 2000; Gouvea et al., 2010). Moreover, these results were consistent with working memory and/or conflict resolution-based hypotheses of the role of the LIFG, as opposed to purely syntactic accounts.

Three Constructions: Object Relatives, Verb Phrase Ellipsis, and Right Node Raising

Object Relative Clauses

In the current work, we engaged in a more large-scale investigation of the relationship between dependency formation and similarity-based interference. While the findings from our previous study—an LIFG increase only for ORs containing competing determiner-NPs—are consistent with a similarity-based retrieval interference account of LIFG activity (Öztekin et al., 2008, 2009), they do not yet conclusively rule out movement theories that LIFG activity increases for materials that contain a dependency resulting from a movement operation (Grodzinsky, 1986, 2000; Ben-Shachar et al., 2003, 2004; Grodzinsky and Friederici, 2006; Santi and Grodzinsky, 2007; Grodzinsky and Santi, 2008). Because of the predictable nature of an OR dependency, the lack of a gap-site effect in the LIFG for ORs without determiner-noun competitors may be due to the fact that dependency processing could primarily take place before the verb, prior to the gap. In fact, prior ERP studies have not only revealed P600 effects following the verb, but also a sustained anterior negativity at the point of the filler item in ORs prior to the verb (Phillips et al., 2005). This result could suggest that the bulk of dependency processing may occur in an anticipatory time window, preceding the completion of the gap-filling computation. Thus, one goal of the present study was to investigate whether the predictability of OR dependencies yields early effects in the LIFG, consistent with the dependency effects found in studies of movement theories, or whether ORs truly only elicit LIFG increases as a result of similarity-based interference. To address this question, the present MEG study (i) analyzed LIFG activity in earlier time windows prior to the gap site and (ii) compared LIFG activity elicited by ORs to LIFG activity elicited by non-predictable dependencies. With regards to the analysis of pre-gap LIFG activity, we employed OR clauses inside of sentence structures such as (3) to allow for more natural stimuli than in Leiken and Pylkkänen (2014).

(3) The husband hogged *the blankets that Jane grabbed* afterward.

The relative pronoun *that* may act as a signal that the object *the blankets* will be employed later on in a gap-filling dependency. It is possible that there are initial steps involved in computing a dependency, which may be able to be completed as soon as the filler item is recognized, even prior to the detection of a gap. Thus, once the gap is encountered, a sufficient portion of the processing sequence has been completed such that significant LIFG increases at the gap site would not be found. As this may have been the case in our previous study, in addition to measuring LIFG activity following the target verb *grabbed* prior to the gap site, the present study also analyzed activity in the earlier time window, following *that*, where predictive processing of the upcoming gap may take place.

Notice that the item of retrieval is a determiner-noun *the blankets*, which is different in its surface structure from the nearby proper name *Jane*. In order to investigate whether LIFG

activity results from similarity-based interference, we included OR conditions which, as in the previous study, allow for potential similarity-based inference between these two phrases by replacing *Jane* with a second determiner-NP (e.g., *the wife*).

To investigate whether LIFG activity, specifically at the gap site, results from a gap-filling process, non-gap-filling dependency constructions, such as (4), were employed as controls.

(4) The husband hogged the blankets and Jane grabbed *them* afterward.

Here, as there is no movement, there is no gap-filling dependency. However, it is important to note that the pronoun *them*, which replaces the gap in the OR construction, also forms a dependency with *the blankets*. Therefore, we might expect that a similar retrieval process occurs between retrieval at a pronoun and retrieval at an OR gap, and thus a comparison between condition (3) and condition (4) would yield little difference in LIFG activity. However, as we are using MEG, we will have the time course sensitivity to target activity immediately following the word *grabbed* in both conditions. We expect retrieval to be taking place in ORs during this time window, but later at *them* in controls. Furthermore, the results from Santi and Grodzinsky (2007) suggest that gap-filling shows a cost in the LIFG that retrieval at a pronoun does not. Therefore, we might expect increases for ORs in the LIFG over controls.

Verb Phrase Ellipsis

For the comparison of LIFG activity at the gap site in predictable ORs to the gap site of a non-predictable dependency, we employed a gap-filling dependency that does not contain a relative pronoun-like cue to the upcoming dependency; namely, verb phrase ellipsis (VPE). VPE is a two-clause construction that contains an overt verb phrase in the first clause, which, in the second clause, is interpreted, but replaced by an auxiliary verb. For example in (5), the dependency is between the overt verb phrase *called a cab* in the first clause and the gap resulting from ellipsis of the VP in the second clause.

(5) The pedestrian [called a cab]$_i$, and the bellhop did $\underline{t}_i$ too (Martin and McElree, 2008).

Like the retrieval of the filler at the gap site in ORs, the first-clause VP is retrieved later in the sentence. However, unlike ORs, VPE has no grammatical marking, like a relative pronoun, signaling that the verb phrase in the antecedent has a further role downstream (Martin and McElree, 2008).Without an early indication of a dependency, we expect the bulk of dependency-related neural activity to obligatorily take place after the ellipsis cue has been encountered. The present study, therefore, employs VPE constructions like (6), which will be analyzed following the ellipsis site, at *too*, in comparison with the OR gap site.

(6) The husband *hogged the blankets* and Jane did too.

If LIFG activity in response to gap-filling is reflective of a predictive process, then we expect ORs to show LIFG increases prior to the gap site, whereas we expect VPE to show LIFG increases following the ellipsis site.

On the other hand, LIFG activity for gap-filling constructions has previously been attributed to similarity-based interference. Therefore, to test this hypothesis this study included VPE conditions which contain a competitor for the VP item of retrieval. While a large literature exists for similarity-based interference in ORs, there is little precedent for what might induce this type of interference in VPE. Therefore, in order to introduce a rival VP, the present study interpolated an inner relative clause within VPE constructions, as in (7):

(7) The husband *hogged the blankets* and the wife who sometimes *nagged him* did too.

In this construction, the inner relative clause, *the wife who sometimes nagged him*, involves a VP *nagged him*, which may compete with *hogged the blankets* during retrieval at *too*. For consistency, similarity-based interference conditions of ORs also included these inner relative clauses. It is important to note that this yields parallel OR materials where one of the parallel NPs will contain an inner relative clause, while the other does not. This could potentially lower the similarity between these phrases, thus biasing against possible similarity-based interference effects in these conditions over non-parallel conditions.

According to Martin and McElree (2008), the information inside of the ellipsis site is not necessarily a structurally identical copy of the antecedent VP, as previously suggested (Frazier and Clifton, 2001). Instead, there was evidence that ellipsis may be interpreted using direct-access content cues. In this case, working memory will use a "pointer" mechanism to access the information in the antecedent. Therefore, measurements at *too* should essentially indicate the cost in the LIFG of this "pointing" mechanism. For comparison with a non-ellipsis construction, the present study will include controls, such as (8):

(8) The husband hogged the blankets and Jane did *that* too.

Note that this condition involves the pronoun *that* prior to the retrieval site. This pronoun forms a dependency with the VP from the first clause *hogged the blankets*. This pointing back to the antecedent VP is very similar to that in ellipsis. However, in VPE conditions the pointing is taking place at *too*, whereas in the controls this retrieval has already been completed at *that*. Therefore, a comparison at *too* might show increases for the ellipsis pointer mechanism over the control condition.

Right Node Raising

Object relatives and VPE not only differ in terms of their predictability, but also in terms of the syntactic category of their item of retrieval. That is, whereas ORs involve retrieval of an object or individual, VPE involves retrieval of a verb phrase. Therefore, any differences found in LIFG activity between these two constructions may not necessarily be attributable to predictability differences, but may be reflective of the difference in item retrieval. To control for this potential confound, we included a third predictable gap-filling construction, which also involved a dependency between a gap and verbal element; right node raising (RNR). There are several competing accounts of RNR,

including those that liken it to ORs[1] and others that associate it with VPE.[2] At present, however, it is a rather understudied construction, particularly in terms of how it is processed. Thus, we made a number of assumptions regarding the processing of RNR constructions.

(9) The husband *hogged* and Jane grabbed the pillows.

In (9), the verb in the first clause, *hogged*, requires an object, and the conjunction *and* indicates that what will follow will either be a VP-conjunct for *hogged*, or a larger DP-VP clause parallel to the one already presented. Therefore, when the DP, *Jane*, is encountered, it may lead to the expectation for the upcoming VP-conjunct, *grabbed the pillows*, which is parallel to the verb-gap phrase in the first clause. As a result, the object of the VP-conjunct in the second clause, *the pillows*, may be shared by the VP in the first clause. Under this set of assumptions, the item retrieved at the filler item, *the pillows*, is the verb-gap phrase *hogged*. This type of retrieval links RNR with VPE, which both have verbal items of retrieval, in contrast with ORs. It's important to note, however, that RNR is like ORs in terms of another property: predictability. If, as described above, the conjunction *and* followed by a DP acts as a cue to the upcoming VP, this would suggest that it is possible to begin processing the upcoming gap-filling computation prior to encountering the filler. Therefore, RNR will be included in the present study as a control for potential confounds, as it equates to VPE in terms of item of retrieval. Because of this shared property, in addition to the lack of existing literature on RNR processing, introducing the potential for similarity-based interference will be done in the same manner as VPE. That is, an inner relative clause will be interpolated, including a VP competitor for the item of retrieval, as in (10):

(10) The husband *hogged* and the wife who sometimes *nagged him* grabbed the pillows.

RNR will be analyzed at the retrieval site, *the pillows*, to examine similarity to VPE. Additionally, LIFG activity in the predictive region, *the wife*, will be analyzed. If RNR constructions are similarly predictable to ORs, then we might expect the bulk of LIFG activity to take place prior the filler item. RNR is also unique in that the gap precedes the filler, a configuration that is novel to the neurolinguistic literature. This reverse ordering of dependent elements might indicate a potential difference in the neural response between gap-filler RNR and filler-gap constructions.

In sum, using the temporal resolution of MEG, our aim was to assess to what extent the LIFG effect of dependency formation is modulated by predictability and/or syntactic similarity, in order to adjudicate between the multiple competing accounts of LIFG involvement in long-distance dependencies. Specifically, if the LIFG does not participate in dependency formation operations *per se*, but rather domain-general operations involved in retrieval and/or competition resolution, then LIFG effects should be modulated by similarity-based interference; specifically, conditions with the potential for high similarity-based interference should show strong LIFG effects. Additionally, if the absence of dependency effects in ORs without high similarity in Leiken and Pylkkänen (2014) was due to pre-gap predictive processing, then we would expect LIFG effects following the relative pronoun cue *that* in ORs. An unpredictable filler-gap construction, like VPE, which does not contain a cue to the upcoming dependency, would not allow for such predictive processing as in ORs. Therefore, we would expect LIFG effects to be delayed in VPEs until the late indication that ellipsis has taken place. Finally, RNRs, which enable prediction—albeit of a filler, rather than a gap—should pattern with ORs in allowing for pre-dependency LIFG effects. On the other hand, any similarity between RNR and VPE constructions (in contrast with ORs) would likely reflect retrieval of a verbal element as opposed to retrieval of an object. Unlike hemodynamic techniques, MEG provides the millisecond-by-millisecond temporal accuracy to attribute effects to specific portions of a trial. Thus, we can with confidence assess whether these effects are predictive of the upcoming gap, or result from encountering the gap.

Finally, it should be noted that although our region of interest (ROI) will simply be referred to as the LIFG, it is nowadays well-known that the LIFG (or "Broca's Area") is in fact a grouping of sub-regions with heterogeneous functionality, consisting of at least three Brodmann's areas (44, 45, and 47) and potentially further subdividing into multiple smaller regions according to evidence from multiple receptor mapping (Amunts et al., 2010). While both areas 44 and 45 have been implicated in sentence processing involving syntactic interference (e.g., Stowe et al., 1999; Cooke et al., 2002; Fiebach et al., 2004; Makuuchi et al., 2009), some linguistic competition tasks have distinguished between the two subparts, affecting only the pars triangularis/BA 45 (Gough et al., 2005; Guo et al., 2010) or only the pars opercularis/BA 44 (Mead et al., 2002; Gough et al., 2005). Crucially, MEG is unlikely to be able to distinguish between areas 44 and 45, and thus these two areas have been collapsed into a single region in our analysis. Therefore, our results will not inform any possible functional subdivision among these regions.

MATERIALS AND METHODS

Participants

Twenty-two right-handed native English speakers participated in the study (13 female; average age: 24.95 years). All had normal or corrected-to-normal vision. The study was formally approved by the New York University Institutional Review Board and all participants gave written informed consent.

[1]The gap-filling dependency of RNR is considered similar to ORs, in that it may involve the extraction of an element, resulting in a link between its overt position and its interpretation in the original location. While both ORs and RNR might involve extraction to a higher location, the extracted item in an OR undergoes leftward movement, whereas the extracted element in RNR would be moving rightward (Ross, 1968; Bresnan, 1974; Postal, 1974, 1998; Sabbagh, 2007). Therefore, the gap left behind in ORs follows the extracted item, whereas the gap left behind in RNR *precedes* the extracted item, as in the below example:

> Some people love $[t]_i$, but other people hate $[t]_i$, [the role that government plays in this country]$_i$. (Postal, 1974).

[2]On the other hand, non-movement analyses of RNR suggest that the shared object is simply an overt argument of the second clause, but deleted due to identity in the first clause. This representation of RNR would be more analogous to ellipsis accounts, which, as explained above, delete the VP in the second clause due to redundancy.

TABLE 1 | Experimental design with the critical items of MEG analysis bolded.

OR	Non-parallel	DEP	The husband hogged the blankets that Jane **grabbed** afterward
		Control	The husband hogged the blankets and Jane **grabbed** them afterward
	Parallel	DEP	The husband hogged the blankets that the wife who sometimes nagged him **grabbed** afterward
		Control	The husband hogged the blankets and the wife who sometimes nagged him **grabbed** them afterward
VPE	Non- parallel	DEP	The husband hogged the blankets and Jane did **too**
		Control	The husband hogged the blankets and Jane did that **too**
	Parallel	DEP	The husband hogged the blankets and the wife who sometimes nagged him did **too**
		Control	The husband hogged the blankets and the wife who sometimes nagged him did that **too**
RNR	Non- parallel	DEP	The husband hogged and Jane grabbed **the pillows**
		Control	The husband hogged the sheets and Jane grabbed **the pillows**
	Parallel	DEP	The husband hogged and the wife who sometimes nagged him grabbed **the pillows**
		Control	The husband hogged the sheets and the wife who sometimes nagged him grabbed **the pillows**

Stimuli and Task

As shown in **Table 1**, three different construction types were investigated: ORs (e.g., *The husband hogged the blankets that Jane grabbed afterward*); VPE (e.g., *The husband hogged the blankets and Jane did too*); and RNR (e.g., *The husband hogged and Jane grabbed the pillows*). Each type has two forms; one involving nearby elements that are parallel in their surface syntax to induce similarity-based interference ("par"), and one that contains elements which differ in their surface syntax ("nonpar"). Parallel types contain an interfering element designed to compete with the element being retrieved at a "gap" site. That is, a parallel NP in ORs, a parallel verb in RNR, and a parallel verb phrase in VPE. Sixty proper names (e.g., *Jane*), one for each set of non-parallel conditions, were employed. These names were replaced by a determiner-NP in parallel conditions (e.g., *the wife*). A non-dependency counterpart of each type was also included. This yielded a 2 × 2 design with similarity and dependency as factors within each construction type.

The specific conditions included: (i) sentences containing VPE (ellipsis-par; ellipsis-nonpar), (ii) VPE-controls containing *that* instead of ellipsis to point to the antecedent (ellipsis-control-par, ellipsis-control-nonpar), (iii) sentences containing ORs (OR-par, OR-nonpar), (iv) OR-controls containing a conjunction instead of a complementizer (OR-control-par; OR-control-nonpar), (v) sentences containing RNR (RNR-par; RNR-nonpar), (vi) RNR-controls in which an NP was inserted in the gap site resulting in a basic conjunction (RNR-par; RNR-nonpar), and (vii) filler sentences without syntactic dependencies for variability (filler-par; filler-nonpar). Each condition consisted of 60 trials, so altogether, each participant viewed 840 trials. The targets of MEG analysis were the dependency formation sites themselves (gap site in ORs, ellipsis-site in VPE, and filler-site in RNR) and anticipatory regions.

Obligatorily transitive verbs were used in the first clause of all conditions to prevent interpretation of RNRs as a basic conjunction. "*Did*" (which has an auxiliary verb use) was not used in the second conjunct of ORs/RNR to prevent a VPE reading. The item of retrieval in all conditions (the "filler" in the filler-gap construction), was designed to always been an inanimate object. For example, *the blankets, the bikes,* etc. (A full list of materials containing animate objects can be found in the Appendix.) Some psycholinguistic work has suggested that inanimacy of an object of retrieval may reduce the object-over-SR clause effect (Traxler et al., 2005), as well as neuroimaging work (Chen et al., 2006). Therefore, because the filler item was inanimate across all our sentence types, any effect of this type should be equivalent across conditions. Further, it should be more difficult to find an effect of similarity-based interference for ORs in the event that inanimacy diminishes processing load of OR clauses.

To ensure that the complexity of our materials did not sacrifice plausibility, we collected plausibility judgments on our stimuli using the Amazon Mechanical Turk (AMT) interface prior to the MEG recording (see Appendix 1). The test stimuli described above were complemented with syntactically grammatical, but highly implausible stimuli for comparison, following designs which similarly compare grammatical, but complex, stimuli with implausible items, such as Pylkkänen et al. (2004). The implausible stimuli were constructed by switching the verb in the first clause in the test items with the verb in the inner relative clause on one-third of the sentences in each condition, resulting in expressions such as *the husband nagged the blankets and the wife who seldom hogged him did too.* We gathered demographic information from 150 participants. Participants were obligated to indicate whether or not they were a native speaker of English and were informed that they were only permitted to participate in the experiment one time. Any participants who violated either of these criteria were rejected from analysis as were any participants who did not fill in the demographic survey. Also, those who far exceeded or fell below the average amount of time taken to complete their list were rejected if extreme durations were accompanied by unreasonable data (e.g., the same response for every trial). Items were distributed among 10 randomized different lists, so each list was completed by 15 subjects. Turk users saw each item and selected a plausibility rating on a 0–7 Likert scale (0 = completely implausible). Participants' raw ratings were averaged over each condition.

A *t*-test comparing the stimuli to be included in the MEG recording with implausible fillers showed that experimental stimuli ($M = 5.1408$) were rated significantly higher ($p < 0.001$) than their implausible counterparts ($M = 1.9199$) on a 0–7 scale, suggesting that the sentences intended for the MEG study were considered generally plausible.

Unsurprisingly, our stimulus manipulation affected the plausibility ratings, with a 2 × 2 × 3 ANOVA on the critical

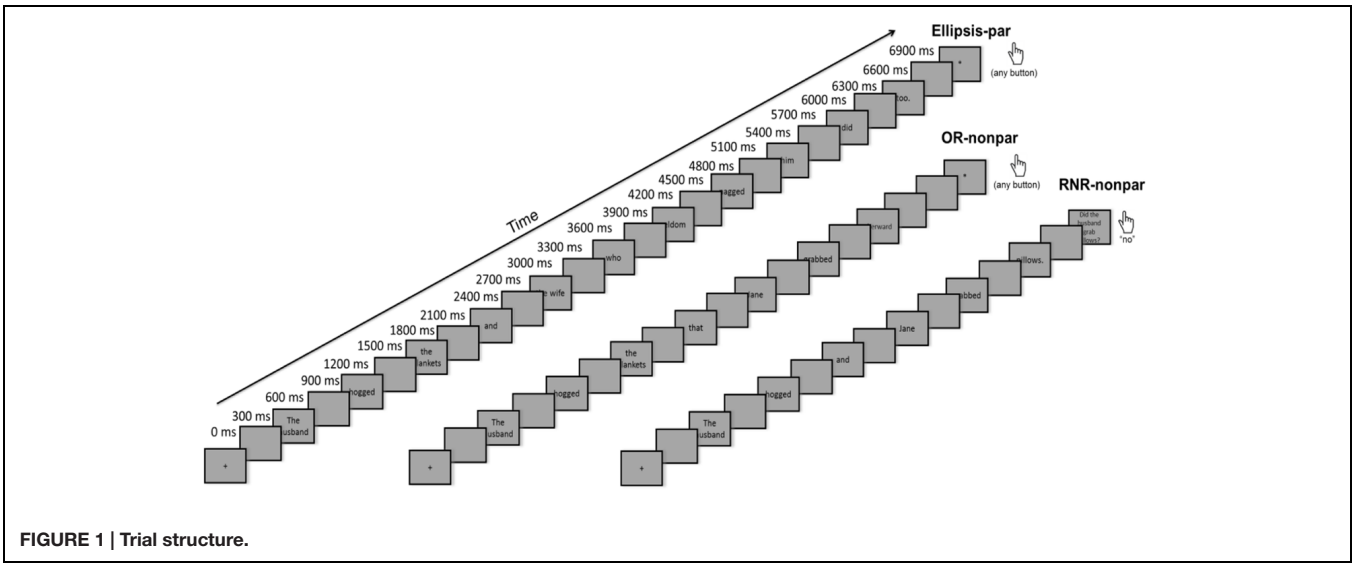

FIGURE 1 | Trial structure.

stimuli showing reliable main effects of all three factors. These effects were driven by lower ratings for parallel than non-parallel stimuli [Parallelism: $F(1,708) = 176.26$, $p < 0.001$; non-parallel $M = 5.51$, parallel $M = 4.81$], for dependency than control stimuli [Dependency $F(1,708) = 179.59$, $p < 0.001$, dependency $M = 4.80$, control $M = 5.51$], and by higher ratings for VPE than the other two constructions [Construction type: $F(2,708) = 41.858$, $p < 0.001$, VPE $M = 5.39$, OR $M = 5.25$, RNR $M = 4.83$].

The main effect of Parallelism was significant within each construction (all Fs > 25) though it was most robust within the OR-dependencies, as reflected by a reliable 2×2 interaction between Parallelism and Dependency within the ORs [$F(1,236) = 18.413$, $p < 0.001$, non-parallel control $M = 5.95$, parallel control $M = 5.29$, non-parallel dependency $M = 5.57$, parallel dependency $M = 4.21$], while no such interaction was observed within VPE [$F(1,236) = 1.998$, $p = 0.159$, non-parallel control $M = 5.45$, parallel control $M = 5.03$, non-parallel dependency $M = 5.87$, parallel dependency $M = 5.23$] or RNR [$F(1,236) = 0.072$, $p < 0.788$, non-parallel control $M = 5.97$, parallel control $M = 5.38$, non-parallel dependency $M = 4.25$, parallel dependency $M = 3.72$]. The three way interaction between Parallelism, Dependency and Construction was also significant [$F(2,708) = 4.43$, $p = 0.01$].

The main effect of Dependency was qualified by an interaction with Construction [$F(2,708) = 120.19$, $p < 0.001$], with reliably decreased ratings for dependency than control sentences for OR [$F(1,236) = 79.86$, $p < 0.001$; control $M = 5.62$, dependency $M = 4.89$] and RNR [$F(1,236) = 238.74$; $p < 0.001$, control $M = 5.67$, dependency $M = 3.98$], while the reverse held for VPE [$F(1,236) = 14.902$, $p < 0.001$; control $M = 5.24$, dependency $M = 5.55$].

In sum, parallelism uniformly decreased plausibility ratings, while the presence of a dependency decreased judgments for ORs and RNR but not for VPE. Thus any LIFG patterns tracking these effects could reflect plausibility instead of the independent variables of interest; we return to this in our report of the results.

During the MEG recordings, participants read all critical stimuli that were included in the MTurk study (with the exception of the implausible stimuli). Presentation was word-by-word (except in the case of determiner-NPs which were presented as a unit for time restriction purposes, e.g., *the wife*). After one-third of the linguistic stimuli, participants were presented with a comprehension question relating to the content of the previous text (e.g., *Did the husband grab the pillows?*) to which the answer was either "yes" or "no." For the purposes of this task, the participants were given practice outside the MEG machine and again inside the MEG machine prior to recording. Half of the questions had the answer "yes" and half had the answer "no." For a "yes," both the character and the action mentioned in the question needed to match those in the previous text.

Procedure

Before the MEG recordings, participants were instructed about the experimental task and their head shapes were digitized using a Polhemus (Colchester, VT, USA) FastSCAN COBRA 3D laser system. During the experiment, participants lay in a dimly lit, magnetically shielded room (Vacuumschmelze, Hanau, Germany). Using PsychToolbox, the experiment was presented on a 7x7-inch screen with a resolution of 1024×768 pixels placed approximately 9.5 inches above the subjects' eyes. Stimuli were presented word by word, 300 ms for each word, with a 300 ms blank screen between each word. To allow for longer processing time of complex stimuli, a blank screen was then presented for 700 ms prior to the question screen. Using a button press, the subject expressed whether the answer to the comprehension question was "yes" or "no" (**Figure 1**). Trial order was random. Subjects were in the machine for an hour, with five breaks (between each of the six blocks), and were then given an extended break outside of the MEG room, due to the length of the study. Subjects then returned to the machine for the next six blocks. The entire recording took about 2.5 h. MEG data were collected using a using a whole-head 157-channel axial gradiometer system (Kanazawa Institute of Technology, Nonoichi, Japan). For this

study, data were recorded at a sampling rate of 1000 Hz with a low-pass filter at 200 Hz using a DC recording and a notch filter at 60 Hz. Eye-blinks were recorded using an SR Research Eyelink 1000 Arm-Mounted Eyetracker sampling at 1000 Hz.

Data Analysis

Pre-processing of MEG Data

Raw data were noise-reduced (CALM; Adachi et al., 2001) and cleaned of artifacts (at a threshold of 4000fT). On average, no more than 25% of trials were lost during this procedure. Artifacts also included eye-blinks, which were removed by aligning the eye-tracking recording (described above) with the MEG recording. Data were high-pass filtered at 1 Hz. Data were then averaged by condition using a 200 ms pre-stimulus interval and a 1000 ms post-stimulus interval and baseline corrected using the 200 ms pre-stimulus interval. Data were low-pass filtered at 40 Hz after averaging, using the program BESA® 5.1 (MEGIS Software GmbH). Additionally, one subject was excluded as an outlier due to excessive blinking.

ROI Analysis of Minimum Norm Estimates

Magnetoencephalography data were analyzed as distributed sources using L2 minimum norm estimates calculated in BESA. The minimum norm images were depth weighted as well as spatiotemporally weighted, using a signal subspace correlation measure (Mosher and Leahy, 1998). LIFG activity at the site of dependency formation (OR: *grabbed*; VPE: *too*; RNR: *grabbed*) was examined via an ROI analysis. For the ROI analysis, sources were assigned to the anatomical LIFG region consisting of Brodmann's areas left 44 and 45, based on coordinates in Talairach space (Lancaster et al., 2000). Non-parametric, cluster-based permutation tests (Maris and Oostenveld, 2007) were performed in the same time windows as in Leiken and Pylkkänen (2014); an early "N400"-like time window (200–500 ms), associated with lexical access (Embick et al., 2001; Pylkkänen et al., 2002; Pylkkänen and Marantz, 2003), and basic combinatory effects (Bemis and Pylkkänen, 2011), and a late "P600" time window (500–800 ms) associated with OR versus SR P600 effects (Kaan et al., 2000). Additionally, due to the length and complexity of the current study's stimuli, a third, even later, analysis window was added (800–1000 ms). Permutation tests were employed to identify temporal clusters significantly affected by stimulus manipulation, corrected for multiple comparisons. Thresholds for initial cluster selection followed Leiken and Pylkkänen (2014), i.e., of waveform separations that lasted for 10 or more time points at $p < 0.3$, the one with the largest summed F or t statistic within each time-window was entered into 10,0000 permutations. The final corrected p-value for each cluster was calculated as the ratio of permutations yielding a test statistic greater than the actual observed test statistic ($\alpha = 0.05$). The tests were a 2 × 2 repeated measures ANOVA (Similarity × Dependency) over each time window ("N400," "P600," and late response) within each construction type at the site of dependency formation: at the onset of the verb preceding the gap in ORs, at the onset of the verb preceding the filler in RNR, and at the onset of the word following the ellipsis in VPE. The epochs were set to begin from the onset of each of these words through the following word. This extension allowed us to detect potential residual dependency effects which may have occurred early in the processing of the subsequent word. The ANOVA was then followed up with planned pairwise comparisons between parallel versus non-parallel subtypes, and dependency versus control subtypes. Effects at $p < 0.05$ will be discussed as significant and effects between this corrected level and $p < 0.10$ as marginal. Any p-values higher than this will be considered numerical trends. Our conclusions will, however, only rest on results reaching corrected significance at $p < 0.05$.

The above tests were followed by analyses at the pre-dependency time intervals (i.e., at the filler in ORs following the relative pronoun cue *that*, after the gap in RNR, and at a comparable lexical item in VPE). That is, analyses were performed in windows where the potential effects of dependency prediction may have taken place (i.e., prior to the gap in ORs, prior to the filler in RNR, and prior to the auxiliary verb in VPE). Unlike at the OR gap site, the lexical material in the predictive region was not matched in all four OR conditions (*that* in parallel and *and* non-parallel) Therefore, parallel and non-parallel ORs, along with their control counterparts could not be included in a single 2 × 2 ANOVA as above. Preverbal material was instead submitted to t-tests in order to examine potential anticipatory dependency processing in the same LIFG region. t-tests were performed after the presentation of the filler item: e.g., *the wife* in parallel conditions and *Jane* in non-parallels in the examples in **Table 1**. If effects of dependency prediction only occur in conjunction with similarity-based interference, then a difference would only be found between the two instances of *the wife* and not between the two instances of *Jane*. However, if anticipatory LIFG effects are independent of parallel syntactic structure, then both t-tests should show a difference. In RNR, the immediate post-gap lexical item *and* is the same in all four conditions, allowing for a 2 × 2 (similarity × dependency) ANOVA. This was then followed up by t-tests on the next word comparable to those performed on ORs; at *the wife* in parallel conditions, and *Jane* in non-parallel conditions. In VPE, no dependency distinction exists between the four conditions until after auxiliary verb. To confirm that no LIFG effect of dependency anticipation occurs in a time window prior to *did*, a 2 × 2 ANOVA at the conjunction *and* was performed. As in the ORs and RNR, t-tests were also performed within parallel conditions at *the wife* and within non-parallel conditions at *Jane*, to confirm the assumption that having no cue to an upcoming dependency prohibits dependency prediction. The t-tests employed the same settings as the above 2 × 2 ANOVAs; 10,000 permutations with the same cluster thresholds within the same three time intervals.

Full Brain Analyses

The ROI analyses were each supplemented by liberally thresholded uncorrected full brain contrasts. The goal of these analyses was to confirm that the effects found in the ROI analyses in fact reflected activity localized with the LIFG (as opposed to spillover from neighboring regions) and to reveal any other major cotemporaneous effects. We compared the minimum norm estimates of the activity elicited by the

experimental conditions sample-by-sample in the same pairwise comparisons described for the ROI analyses. Effects were visualized on the smooth BESA cortex when they remained reliable ($p < 0.05$, uncorrected) for at least three temporal samples and were observed in at least three spatially contiguous cortical sources.

RESULTS

Behavioral Data

After one-third of the sentences, participants were asked a comprehension question relating to the content of the stimulus sentence (e.g., Did the husband grab the pillows?) to which the answer was either "yes" or "no." Subjects performed fairly well on this complex task overall (M = 77.37%), and generally better (average accuracy ± SD) on the non-parallel (M = 82.75 ± 9.78%) than the parallel (M = 72.00 ± 8.12%) trials. In general, performance was slightly higher on control conditions (M = 77.60± 8.94%) compared with dependency conditions (M = 75.60± 9.28%). Performance was quite similar for the dependency version of each construction type: ORs (M = 76.89± 9.04%), VPE (M = 76.99± 9.20%), and RNR (M = 72.92± 9.61%).

MEG Data

Object Relative Clauses

As described above, only one of the two parallel NPs in parallel OR conditions contained an inner relative clause, potentially lessening similarity-based interference in these conditions. Nevertheless, our OR results showed a straightforward though late effect of parallelism after the gap-site, as well as a more complicated effect of dependency, as detailed below. No interactions between our two factors were observed. Test results are considered significant at $p < 0.05$, but for completeness in addressing our hypotheses we will report marginal results and numerical trends resulting from planned comparisons as well. Only significant findings will, however, contribute to our interpretation of results.

The early time window (200–500 ms) showed weak trends both toward a main effect of parallelism and for a main effect of dependency, but neither cluster survived the permutation correction for multiple comparisons (parallelism: $p = 0.1624$ at 397–500 ms; dependency: $p = 0.7253$ at 329–351 ms). The wave form separation during these non-significant main effects did, however, conform to the results of Leiken and Pylkkänen (2014), with only parallel dependencies eliciting increased amplitudes as compared to all other conditions.

No reliable effects were found in the 500–800 ms time window but the latest time-window, 800–1000 ms, showed both a reliable main effect of parallelism, with the cluster extending throughout this interval ($p = 0.0041$), as well as a reliable main effect of dependency, similarly covering the entire 800–1000 ms interval ($p = 0.0261$; **Figure 2**). These results reflected a pattern of parallel conditions eliciting increased LIFG amplitudes as compared to non-parallel conditions and dependency conditions eliciting increased amplitudes as compared to non-dependency controls. Planned pair-wise comparisons showed that within the dependency conditions, parallel ORs ($M = 6.16$) elicited significantly higher LIFG activity than non-parallel ORs ($M = 4.373$; 800–1000 ms, $p = 0.0087$) whereas within the control conditions, the increase for parallelism ($M = 4.504$) was only marginal (896–970 ms, $p = 0.0638$) versus non-parallel ORs ($M = 3.643$). The effect of dependency trended in the right direction for the parallel conditions (800–863 ms, $p = 0.1102$) but was significant for the non-parallel conditions (895–966 ms, $p = 0.0366$). Parallel ORs also elicited significantly higher LIFG activity than the non-parallel controls (800–1000 ms, $p = 0.001$). In sum, the pairwise comparisons showed increased activity for both dependency conditions over their controls and for both parallel conditions over their non-parallel versions.

However, before we can conclude that the LIFG ROI activity is modulated by the presence of a dependency, a complication arising from the lateness of this effect must be addressed. Namely, the effect occurred during the processing of the word immediately following the target verb; this word being *afterward* in the dependency conditions and *them* in the controls. Thus the LIFG increase could simply have reflected the increased activity for the longer and morphologically more complex *afterward* than *them*. However, since the word after *them* in the control conditions was *afterward* [the full contrast being *grabbed afterward* (OR) versus *grabbed them afterward* (control)], this lexically based explanation would predict that a comparison at *afterward* in the OR versus control conditions should not show the LIFG effect. In contrast, if the LIFG increase at *afterward* in the OR condition reflects dependency processing, it should replicate in a comparison of the two instances of *afterward*. To test this, the baseline was moved to 200 ms before the onset of *afterward* for all four conditions and 2 × 2 permutation ANOVAs were run in the 200–500 ms interval (covering the timing of the effect in the prior analysis) as well as in the 0–200 ms interval, covering any effects occurring at the very onset of this spill-over word. Though the ANOVA for 200–500 ms revealed a cluster replicating the pattern in the prior analysis (i.e., higher amplitudes for dependency than for control conditions), it did not survive correction for multiple comparison. However, in the earlier interval, 0–200 ms, a reliable main effect of dependency was observed (19–172 ms, $p = 0.0268$), with pairwise comparisons showing a significant increase for dependency ($M = 5.81$) over control ($M = 4.567$) within the non-parallel conditions (19–108 ms, $p = 0.0305$) and a similar trend for dependency ($M = 4.5.692$) over control ($M = 4.4.974$) within the parallel conditions (132–164 ms, $p = 0.1638$). These results converge on the finding that the presence of an OR dependency elicited a late LIFG increase occurring after 600 ms post-target verb onset. Interestingly, this effect was stronger for the non-parallel conditions, suggesting that it is not dependent on the presence of parallelism. This is in contrast to the findings of Leiken and Pylkkänen (2014), who for sentence fragments only found an LIFG increase for OR dependencies involving parallel NPs. Thus it is possible that the current full sentential stimuli may have been better test items for detecting a dependency effect in the absence of parallelism.

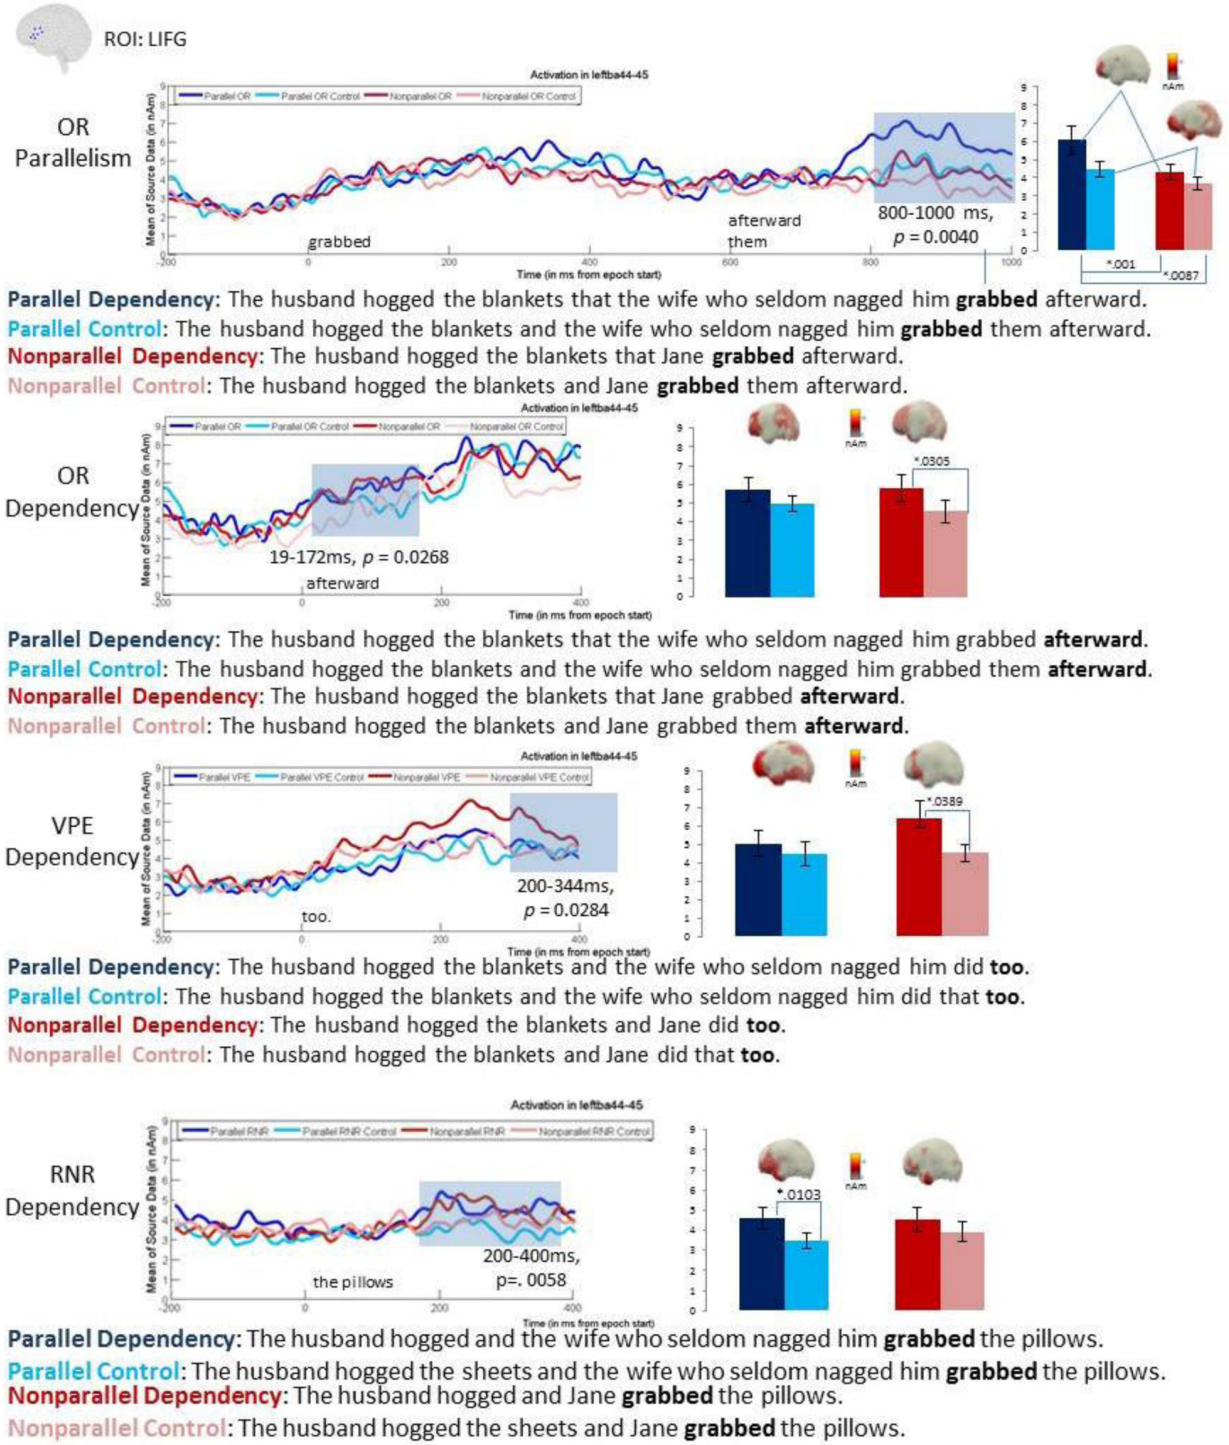

FIGURE 2 | Left inferior frontal gyrus (LIFG) ROI and Whole Brain results. The clusters of time points that were reliable in a cluster-based permutation *t*-test are shaded gray showing the LIFG increase for the dependency conditions as compared with control conditions. Red colors indicate non-parallel conditions, and blue colors indicate parallel conditions. Darker shades of each indicate dependency conditions, whereas the lighter shades stand for controls. Within 19–172 ms in the OR condition, there was a significant increase in the LIFG for OR dependencies versus control conditions ($p = 0.0268$). For the VPE condition, within 200–344 ms, there was a significant LIFG increase for VPE dependencies versus control conditions ($p = 0.0284$). The time window of 200–400 ms shows a significant LIFG increase for RNR ($p = 0.0058$). For each of the three constructions, an accompanying bar graph indicates the means for each condition (parallel dependency, non-parallel dependency, parallel control, non-parallel control) within the time window showing significant dependency increases in the LIFG. ROI findings were well-supported by full brain analyses, confirming LIFG increases within the time window showing significant clusters for each pairwise comparison.

Given that we did observe an effect of dependency after the gap-site, the prediction for such an effect in the predictive pre-gap region is weakened. In fact no such effects were observed when activity elicited by the filler items (*the wife* in parallels, and *Jane* in non-parallels) was compared in permutation *t*-tests. Thus our findings revealed no evidence for predictive gap-processing in the LIFG.

The whole brain graphs plot the same pair-wise comparisons as reported above on liberally thresholded whole brain minimum norms (time and space thresholds at 3 and *p*-value threshold at 0.05) at the time windows of the significant effects in the ROI analysis. The aim of this analysis was to ascertain that the ROI results in fact correspond to activity localized in the LIFG. These contrasts revealed activity overlapping with the BA 44–45 region during the time window of the parallelism main effect in ORs. Specifically, both parallel ORs and parallel control conditions showed an increase in this region compared with their non-parallel counterparts in the 800–1000 ms time window. The dependency effect early on after the presentation of *afterward* (19–172 ms after the onset) was also observable in the whole brain analyses for parallel ORs over parallel control conditions as well as for non-parallel ORs over non-parallel controls. In addition to left inferior frontal activity, posterior parieto-occipital activation was observed for the parallel control condition over non-parallel controls, as well as in both dependency contrasts.

Verb Phrase Ellipsis

For VPE, the cluster-based 2 × 2 ANOVA in the early time-window (200–500 ms) revealed a significant main effect of dependency at 200–344 ms ($p = 0.0284$). As with ORs, this effect was more strongly driven by a pair-wise effect in the non-parallel conditions (280–344 ms, $p = 0.0389$), with dependency ($M = 5.893$) over controls ($M = 4.330$). Parallel conditions showed a weaker trend ($p = 0.2123$ at 259–284 ms) of dependency ($M = 4.719$) over controls ($M = 4.178$). No reliable effect of parallelism was observed in this time-window nor any effects of either factor in the later time-windows. Finally, no effects were found in the pre-gap "predictive" time-windows (at *the wife* within parallels and at *Jane* within non-parallels), consistent with the fact that VPE dependencies are unpredictable.

Full brain analyses were also performed for the pairwise comparisons within the VPE conditions, specifically, contrasts between parallel VPE over parallel controls, and non-parallel VPE over non-parallel controls. These results confirmed to the ROI analyses in revealing LIFG effects within the time window of significant ROI findings. Namely, an effect was obtained at 200–344 ms for parallel VPEs over parallel controls, as well as for non-parallel VPEs over non-parallel controls. Again, the frontal effects were accompanied by more posterior activation in the parallel VPE condition over the parallel control condition, but not in the non-parallel contrast.

Right Node Raising

In the RNR analysis, the onset of the second verb (*grabbed* in **Table 1**) was treated as 0 ms, for consistency with the OR analyses. A reliable main effect of dependency was observed in the 800–1000 ms time window (or 200–400 ms following the RNR filler item, *the pillows*; $p = 0.0058$), with the cluster covering the entire analysis interval. In the pairwise comparison this effect was reliable within the parallels (267–400 ms, $p = 0.0103$), with dependency ($M = 4.600$) over controls ($M = 3.466$), and within the non-parallels, only trending in the same direction (299–332 ms, $p = 0.2251$) for dependency ($M = 4.528$) over controls ($M = 3.920$). No other effects were observed, including in the pre-gap "predictive" regions. Thus, like in VPE, parallelism did not appear to affect RNR processing in the LIFG. Timing wise, the RNR dependency effect occurred within 300 ms of encountering the site at which the dependency needs to be formed (which in RNR is the filler). This is similar to the dependency effect in VPE, suggesting that filler-gap order is not a strong modulator of LIFG dependency effects. This timing of course contrasts to the dependency effects observed for ORs, which were much later.

Whole brain pairwise comparisons were performed for the contrasts between parallel RNR and parallel controls, as well as between non-parallel RNR and non-parallel controls, with results conforming to the RNR ROI findings described above. That is, the time window of 200–400 ms after *the pillows*, which showed significant clusters of LIFG activity for parallel RNRs over parallel controls, also reveals significant effects in the full brain contrasts. Similarly, the increase of LIFG activity in non-parallel RNRs over non-parallel controls within 200–400 ms was evident from the full brain plots. For these contrasts, the effects were mostly anterior, though for both contrasts, the LIFG effect appears to be accompanied by an increase in activation in left anterior temporal cortex.

Results Summary

In sum, our results indicated an LIFG effect of Dependency for each construction type without interaction with Parallelism, suggesting that this effect is not dependent on similarity-based interference. In ORs, Parallelism had its own main effect, indicating that this factor can drive the LIFG even in the absence of a filler and gap. Importantly, neither effect tracked plausibility as rated in our MTurk norming study: parallelism lowered plausibility judgments across all constructions, but an MEG effect of Parallelism was only obtained for ORs; for Dependency, judgments were lower for dependency conditions in ORs and RNR but higher in VPE while in contrast, LIFG amplitudes increased for dependency conditions regardless of construction.

DISCUSSION

This study investigated LIFG activity during dependency processing using both a technique and constructions novel to the literature in order to shed light on the role of the LIFG in dependency formation. Our key question was whether dependency effects in the LIFG, whether the result of movement or not, require explicit taxing of working memory via similarity-based interference, or whether the sheer presence of a dependency is sufficient to drive this activity, as predicted by movement-based accounts of activity in this region. Our results show that similarity-based interference is a not a prerequisite for

LIFG effects: LIFG amplitudes showed a statistically significant increase when a dependency was present across our three constructions whether or not interference-inducing syntactic parallelism was built into the stimuli. Although sub-types of each construction contributed to the main dependency effect differently, we take the significant main effect within each construction type to show that for these materials, an activity increase was observed in the LIFG for any instance of retrieving the first member of a dependency chain. Thus, contrary to our own previous work, where we used sentence fragments as opposed to full sentences (Leiken and Pylkkänen, 2014), the current results support a role for the LIFG in dependency formation that generalizes across a variety of memory demands. The findings are compatible with the hypothesis that the LIFG computes syntactic movement, but also with the hypothesis that this region has a basic role in retrieval in a variety of non-movement contexts.

Given that Leiken and Pylkkänen (2014) found no purely dependency driven LIFG effects at an OR gap, an important goal for the current study was to investigate whether such effects could be observed in pre-gap LIFG activity, as potential reflections of gap anticipation. However, since here we did find an effect of dependency after OR gaps, the prediction for pre-gap dependency effects was somewhat weakened, and in fact, no anticipatory LIFG effects were observed for ORs or for either of the other construction types. Further, since significant LIFG increases for dependency were observed for ORs, specifically for the non-parallels, even though non-parallel control conditions also contained a type of retrieval at the pronoun *them*, these results conform to prior findings indicating that gap-filling may produce a greater LIFG cost than retrieval at a pronoun (Santi and Grodzinsky, 2007).

Left inferior frontal gyrus effects in OR dependencies were compared with VPE, which contains a non-predictable dependency and was thus anticipated to require the presentation of both filler and gap before the dependency could be processed. The VPE control condition, like that of ORs, also contained a type of non-gap-filling dependency between the pronoun *that* and the VP item of retrieval. Again, MEG time course sensitivity allows for fine-grained measurements at the post-gap word *too* in both conditions, where it was expected that retrieval takes place in VPE, but has already been completed in the control condition at *that*. Both of these expectations were supported, as VPE showed no anticipatory LIFG effects, but did show significant LIFG increases at the ellipsis-site.

While both OR and VPE constructions showed retrieval effects at the gap site in the LIFG, the timing of the effect was much earlier for VPE than that for ORs. While the OR results are compatible with the full time-course of gap-filling processes in previous SAT studies (McElree, 2001; McElree et al., 2003, 2006), their lateness with respect to VPE deserves some attention. Whereas the OR constructions involve retrieval of an object/individual, VPE involves retrieval of a verbal element. Thus, one possibility may be that the category of the retrieved item matters for retrieval time. Another possibility is that operations performed at the retrieval site differ for ORs and VPEs. Our RNR constructions bear on this issue, as they are predictable like ORs, but involve retrieval of a verbal element like VPE. A unique property of RNR constructions, however, is that they contain a gap-filling dependency where the gap precedes the filler, unlike in ORs or VPE. Despite this special property, RNR findings were closely linked with our VPE results. Specifically, RNR showed a significant increase for dependency in the LIFG. Therefore, we cannot attribute VPE-OR differences to predictability, as RNR is matched with ORs for this feature. Interestingly, we note that the similar processing profiles for VPEs and RNRs aligns with the theoretical proposal that RNRs are in fact a type of ellipsis (Wexler, 1980; Swingle, 1993; Kayne, 1994; Wilder, 1997; Hartmann, 2001, 2003; Abels, 2003; Ha, 2008). The slower timing effect for ORs could indicate that the word category of the item of retrieval affects retrieval speed, with access to verbal elements being faster than objects/individuals. Alternatively, and perhaps more plausibly, VPEs and RNRs could be processed more quickly than ORs because, as Martin and McElree (2008, 2009) argued, VPE can be resolved through a pointer mechanism, wherein retrieval consists of pointing to a structure in memory. On the other hand, processing ORs requires building the argument structure of the verb phrase after argument has been retrieved.

Taken together, the present set of findings can, in fact, be accounted for by hypotheses associating the LIFG with dependencies resulting from syntactic movement (Grodzinsky, 2000; Ben-Shachar et al., 2003; Grodzinsky and Santi, 2008), though the main effect of parallelism obtained for the ORs also provides evidence for the role of working memory independent of structure (Caplan et al., 2000, 2008; Fiebach et al., 2001, 2005; Kaan and Swaab, 2002; Rogalsky et al., 2008; Makuuchi et al., 2009) or cognitive control (Botvinick et al., 2001; Miller and Cohen, 2001; Novick et al., 2005; Braver et al., 2007). These results for parallelism are more convincing given that the item of retrieval in all conditions was an inanimate object. In other words, despite the fact that inanimacy has been associated with a reduction in OR processing load (Traxler et al., 2005), similarity-based interference effects were still found for parallel ORs versus non-parallels. Importantly, however, not only did these similarity-based interference effects appear rather late in the present study, at 800–1000 ms as opposed to at 300–400 ms in Leiken and Pylkkänen (2014), but they also only held for ORs, and not VPE or RNR. Regarding latency, it has been shown that the timing of P600 effects can be delayed when dependency length is increased (Phillips et al., 2005). Due to the full sentential stimuli of the present study, the distance between the gap and filler items was much greater than that in our previous study, where we employed minimal OR phrases. Therefore, it is possible that the later timing of similarity-based interference effects was due to the large amount of mediating material between filler and gap. The high complexity of the present study's materials may also be relevant for the fact that the parallelism effects were only found for ORs. That is, the ORs were contained inside of a complex sentential structure, as in (3), where the first constituent of the sentence, the matrix subject, (e.g., *the husband*)

was of the same determiner-noun structure as the item of retrieval (e.g., *the blankets*) and its competitor (e.g., *the wife*).

(1) *The husband* hogged *the blankets* that *the wife who sometimes nagged him* grabbed afterward.

This property may have induced *proactive* interference with the item of retrieval, where material prior to the initial encoding of the target item creates competition with it (Öztekin and McElree, 2007). The VPE and RNR stimuli did not have elements inducing possible proactive interference. This factor may also have contributed to the latency of the OR retrieval effect as compared with the other two conditions which showed similar effects in a much earlier time window.

In sum, our two main results are LIFG increases in response to similarity-based interference in ORs, and LIFG increases in response to the presence of the three different dependency types regardless of similarity-based interference. While both of these findings are attributed to "LIFG" activity, it is important to note that this region contains heterogeneous subparts. Therefore, it is possible that the interference effect is in one subdivision, whereas the effects for retrieval are in the other. The spatial resolution of MEG is, however, unlikely to be able to disambiguate the detailed localization of these effects within the LIFG and thus we must leave this question for future work.

CONCLUSION

This study took advantage of the detailed time-resolution of MEG and the stimulus properties of three different dependency constructions–ORs, VPE, and right-node-raising—to target several of the major competing accounts of the role of the LIFG in dependency processing. Our findings revealed that at the retrieval sites of each of these three dependencies, LIFG increases are observed, conforming to "movement" accounts. Additionally, in ORs only, effects of similarity-based interference were observed in the LIFG, consistent with working memory or cognitive control theories. Thus, our results add to the growing body of evidence that a complete understanding of "Broca's Area" must take into consideration both structure and memory related processes. Overall, our results are consistent with a hypothesis that the LIFG region subserves the recovery of an element from memory. The exact generality of this process across contexts remains a question for future work, but the current results enable a new level of temporal and computational precision in subsequent hypotheses about the type of retrieval that the LIFG contributes to.

Task-dependency and structure-dependency in number interference effects in sentence comprehension

We report three experiments on French that explore number mismatch effects in intervention configurations in the comprehension of object A'-dependencies, relative clauses and questions. The study capitalizes on the finding of object attraction in sentence production, in which speakers sometimes erroneously produce a verb that agrees in number with a plural object in object relative clauses. Evidence points to the role of three critical constructs from formal syntax: intervention, intermediate traces and c-command (Franck et al., 2010). Experiment 1, using a self-paced reading procedure on these grammatical structures with an agreement error on the verb, shows an enhancing effect of number mismatch in intervention configurations, with faster reading times with plural (mismatching) objects. Experiment 2, using an on-line grammaticality judgment task on the ungrammatical versions of these structures, shows an interference effect in the form of attraction, with slower response times with plural objects. Experiment 3 with a similar grammaticality judgment task shows stronger attraction from c-commanding than from preceding interveners. Overall, the data suggest that syntactic computations in performance refer to the same syntactic representations in production and comprehension, but that different tasks tap into different processes involved in parsing: whereas performance in self-paced reading reflects the intervention of the subject in the process of building an object A'-dependency, performance in grammaticality judgment reflects intervention of the object on the computation of the subject-verb agreement dependency. The latter shows the hallmarks of structure-dependent attraction effects in sentence production, in particular, a sensitivity to specific characteristics of hierarchical representations.

Introduction

The wide literature on agreement in sentence production has given rise to a large body of research on the phenomenon of interference called 'attraction.' In the standard and most explored case, the speaker incorrectly produces a verb that agrees with a plural noun situated in a modifying

prepositional phrase (PP) linearly intervening between the subject and the verb (e.g., **The time for fun and games are over*, from Bock and Miller, 1991; Bock and Cutting, 1992). As experimental evidence accumulated, it has become evident that various types of syntactic elements have the potential to trigger interference, including adjuncts (Franck et al., 2004) and immediately preverbal objects (Fayol et al., 1994; Hartsuiker et al., 2001; Hemforth and Konieczny, 2003; Konieczny et al., 2004; Franck et al., 2006, 2010; Häussler, unpublished), but also and more intriguingly elements that are not situated between the subject and the inflected verb in the linear word string. Such cases of interference have been reported in object relative clauses as illustrated in (1a) (Bock and Miller, 1991; Franck et al., 2006, 2010), questions (Vigliocco and Nicol, 1998), as well as cleft sentences (Franck et al., 2006). The present study addresses the question of whether similar interference effects are detectable in sentence comprehension. In particular, the work aims to address three questions. First, do the critical constructs from formal syntax, i.e., intervention, intermediate traces, and c-command, which capture attraction patterns in agreement production (Franck et al., 2006, 2010), also play a role in the computation of agreement in sentence comprehension? Second, are the processes involved in the computation of agreement features the same in production and comprehension? Third do different experimental techniques in comprehension tap on distinct aspects of agreement computation in performance?

(1) a. Jean parle aux **patientes** [$_{RC}$ que le médicament *guérissent.]
*Jean speaks to-the-PL patients-PL that the medicine-SG *cure-PL.*
*'John speaks to the patients whom the medicine *cure.'*
b. Jean dit aux **patientes** [$_{CC}$ que le médicament guérit.]
Jean tells to-the-PL patients-PL that the medicine-SG cures-SG.
'John tells the patients that the medicine cures.'

The paper is structured as follows. We first present the syntactic configurations underlying object interference. We then turn to the role of the experimental task in agreement computation. Subsequently, we report three experiments exploring the role of syntactic configurations in object interference in sentence comprehension. The first two experiments use different methodologies to test the role of movement and intermediate traces: they contrast attraction in the minimal structural pair consisting of object relative clauses, involving movement (as in 1a), and the superficially similar complement clauses without movement (as in 1b). The third experiment tests the role of c-command by manipulating attraction from moved complex objects. These objects involve both a c-commanding DP and a purely preceding DP within a PP modifier whose respective effects on attraction are systematically assessed (e.g., Quelles **patientes** du médecin dis-tu que le juriste défend? *Which-PL patients-PL of the doctor do you say that the-SG lawyer-SG defends-SG?* vs. Le chirurgien de quelles **patientes** dis-tu que le juriste défend? *The surgeon of which-PL patients-PL do you say that the-SG lawyer-SG defends-SG?*).

The Role of Syntactic Structure in Object Interference

In a detailed exploration of object attraction in sentence production, Franck et al. (2010) tested various hypotheses with respect to the structural conditions underlying agreement errors. The starting point of their work was the finding that despite its close superficial resemblance to the object relative (1a), the sentence complement clause (1b) fails to trigger attraction. Whereas in (1a) *patients* is the moved object of the target verb *cure* used transitively, in (1b) it is the unmoved object of the main verb *tells* while the target verb is used intransitively.

In four additional experiments, the authors explored the role of properties that distinguish relative clauses from complement clauses. Argumenthood was found to play no role in attraction since objects that are not part of the argument structure of the target verb, as in extraction from clausal complements, trigger similar attraction as thematic objects (e.g., Voici **les otages** que le journaliste *apprennent qu'on a blessés; *Here are the hostages-PL that the journalist-SG *learn-PL that someone injured*), while objects in their canonical post-verbal position did not generate attraction either. Participle agreement triggered by the object in French was also found to play no role in attraction, since attraction effects were found with elements that fail to trigger participle agreement like accusative clitics in the causative construction (e.g., Le directeur **les** *font acheter; *The director-SG them-PL make-PL *buy*). Moreover, the strength of object attraction in structures in which the object has moved to the front of the sentence and fails to intervene linearly between the subject and the verb (relatives and clefts) was shown to be of a similar strength to that of a linearly intervening object, as is the case of the clitic object pronoun (e.g., L'avocat **les** *défendent; *The-SG lawyer them-PL *defend*, Franck et al., 2006). All these cases involve an object (or its trace) intervening in a c-commanding position between the terms of the agreement relation, the subject and the agreeing verb (see Franck et al., 2006, 2010 for a graphical illustration of the hierarchical structure and c-command relations). Evidence suggests that attraction is significantly weaker if the attractor intervenes purely in terms of precedence, i.e., in a position situated lower down in the tree and that fails to c-command the agreement node, as is the case of the modifying PP (e.g., L'avocat des **patientes** *mentent; *The-SG lawyer of the patients-PL *lie-PL*) or the dative clitic (e.g., L'avocat **leur** *mentent; *The-SG lawyer to them-PL *lie, The lawyer lie to them*, Franck et al., 2006). In sum, the empirical evidence suggests that object movement is a necessary and sufficient condition for object attraction to arise in an SVO language like French (conditions may differ for SOV languages if the object originates in preverbal position), and that c-commanding attractors generate more interference than preceding ones.

But why does the object interfere with agreement even in cases like (1a), in which it is pronounced in a position from which it does not intervene, either linearly or hierarchically, between the subject and the verb? Franck et al. (2006, 2010) noted that interference with the object seems to occur at a position that is neither the final nor the initial position since these two positions failed to generate attraction. The authors proposed that the intermediate position of the object in the hierarchical structure, mediating

its initial position in the thematic structure and its final surface position, plays a crucial role. In a (much simplified) representation of example (1a) like, *Jean parle aux* ***patientes*** *[*$_{RC}$ *que le médicament* t_2 **guérissent* t_1*]*, the object *patientes* is initially generated in $\mathbf{t_1}$ and then moves in $\mathbf{t_2}$, a position which intervenes on the subject-verb agreement (AGREE) relation between the position hosting agreement morphology (ultimately attached to the verb) and the subject in its initial thematic position. Finally, the object moves higher to reach its final position. The intermediate position $\mathbf{t_2}$, unpronounced but with morphological reflexes in some cases such as participial agreement in French (Kayne, 1989) or wh-agreement in Austronesian languages (Chung, 1998), is postulated in formal syntactic analyses for locality reasons (e.g., to respect Phase Impenetrability in a system like Chomsky, 2001; see Gibson and Warren, 2004 for experimental evidence for the role of intermediate traces in the processing of long-distance dependencies). So, we argued that formal characteristics of abstract representations assumed in the "principles and parameters"/minimalist analysis of agreement form the representational basis over which agreement processes operate in performance. The intermediate trace of the object in the vP periphery may be thought of, in a phase-based architecture, as corresponding to a temporary memory buffer from which the object remains active and available for further processes (Chesi, 2005). The activation of the object in memory in this precise position intervening on agreement would be the locus of the interference effects observed in agreement production.

Task-Effects in Object Interference

Production and comprehension critically differ in that whereas in production the speaker has access to the conceptual structure of the sentence, this structure is incrementally built in sentence comprehension, under the strong guidance of predictive mechanisms (see e.g., Hale, 2001; Levy, 2008). Nevertheless, under the view that the effects reported in agreement production reflect properties of the hierarchical structure over which agreement is calculated, one expects the same effects to show up in sentence comprehension (e.g., see Kempen et al., 2012, for a model with shared representations and shared processes of syntactic encoding and decoding). Various studies have shown that plural attractors situated in the subject phrase interfere with verb agreement processing in sentence comprehension (e.g., Nicol et al., 1997; Pearlmutter et al., 1999; Pearlmutter, 2000; Kaan, 2002; Thornton and MacDonald, 2003; Häussler, unpublished). The typical finding is that participants spend more time reading or judging the acceptability of a sentence in the presence of a plural mismatching subject modifier as compared to when it is singular.

However, only a few studies have explored object attraction in comprehension. Clifton and colleagues conducted two grammaticality judgment studies exploring attraction in structures like (2) (Clifton et al., 1999). They found that although participants correctly reject ungrammatical sentences like (2a), they tend to accept ungrammatical sentences like (2b) in which a plural element (people) is situated higher than the subject and the verb. Clifton et al. argued that the relative acceptability of (2b) lies in the fact that the chain between the moved element and its trace is still active, and the agreement dependency is on its path. The effect was attributed to the passing of the plural feature on the agreement dependency and not to a late gap complexity effect affecting the general difficulty in processing (2b), since the same sentences with a singular attractor (*people* was replaced by *person*) were systematically rejected, attesting that the difficulty selectively arises in the presence of the plural feature (see also Kayne, 2000 for the hypothesis that the agreement pattern in (2b) is fully grammatical in some dialects). The authors concluded that interference arises because of the link of the projection path that is shared by two distinct syntactic dependencies (agreement and the NP-trace chain). These findings and the overall interpretation are consistent with the analysis (just summarized) in Franck et al. (2006, 2010), which would further specify that interference would be triggered in (2b) by the transit of the plural relative head *people* in the periphery of the vP headed by *think*, a position from which *people* hierarchically intervenes between *manager* and the agreeing head, thus giving rise to the plural form *think*.

(2) a. Lucine dislikes **the people** who think the manager *know the answers.
b. Lucine dislikes **the people** who the manager (*)think **t** know the answers.

Using a methodology based on a two-choice response time paradigm, Staub (2009, 2010) also found evidence for interference from moved objects when participants were asked to select between the two verb forms (singular vs. plural) presented simultaneously on the screen after being exposed to the subject phrase one word at a time in a Rapid Serial Visual Presentation (RSVP) procedure. Verb selection was found to be sensitive to attraction similarly to sentence production, with slower response times to select the correct verb form in the presence of a mismatching plural feature on the object of the sentence. Note, however, that it is unclear whether the task taps into comprehension or production, since both components are involved.

Wagers et al. (2009) investigated object interference in two experiments on object relative clauses (Experiments 2 and 3) involving a self-paced reading procedure. The results showed a significant effect of the object number in the region following the critical verb. However, the effect was restricted to ungrammatical sentences and showed up in the form of faster reading times in the presence of a mismatching plural attractor, suggesting that it reflects a grammatical illusion lying in the incorrect computation of agreement. More generally, across the five self-paced reading experiments on both object and subject modifier attraction, the authors consistently found no attraction in grammatical sentences. This finding appears prima facie to be in contradiction with the other reports of significant interference in grammatical sentences involving subject modifiers, but the careful testing of these structures by Wagers et al. (2009) suggests that the attraction effect observed at the verb in these studies was actually a spillover effect from the plural feature preceding the verb. In line with that interpretation, they found that the introduction of an adverb between the modifier and the verb dissolved the effect (e.g., The slogan on the posters unsurprisingly was designed to get attention). Recent evidence from on-line experimental techniques further supports the view that attraction is restricted to

ungrammatical sentences (eye-tracking: Dillon et al., 2013; ERP: Tanner et al., 2014). The possibility that attraction only arises in ungrammatical sentences in comprehension has important consequences for models of agreement computation. Wagers et al. (2009) suggest that attraction in sentence comprehension is driven by the properties of a cue-based retrieval process triggered when the parser encounters an agreement error: the system involves a predictive component by which the parser expects a particular number feature on the verb, and only if the bottom-up features of the verb mismatch the top–down predicted features is the cue-based-retrieval deployed to check whether the correct feature was missed during the first pass. On this view, number interference in comprehension arises from a fundamentally different cause from attraction errors in sentence production.

Nevertheless, as Wagers et al. (2009) point out, other studies reported reliable interference effects in grammatical sentences that cannot easily be explained by an extended effect of the plural attractor. In a series of five experiments using a Maze task (requiring for each upcoming word in the sentence to select amongst two words, and in the critical region, between a correctly agreeing verb and a word from a different grammatical category, e.g., *was* vs. *ink*) or a sentence classification task (requiring to determine whether the sentence is a legitimately ordered string of words), Nicol et al. (1997) found significant interference in grammatical sentences. Since in these tasks response times reflect either the selection of the correct grammatical category or the global assessment of the sentence word order, the interference found does not seem to be attributable to the spillover of the plural feature processing on the verb. In a speeded grammaticality judgment task on sentences containing an embedded clause with complex subjects modified by a genitive phrase, Häussler et al. (2003) reported interference from the plural attractor in grammatical sentences only; no interference was found in ungrammatical sentences. Using a similar procedure of grammaticality judgment, Häussler and Bader (2009) also found interference from a mismatching feature within a relative clause introduced by a possessive pronoun in both grammatical and ungrammatical sentences. Here again, the slow down observed in mismatch condition cannot be attributed to a spillover effect of processing the plural feature on the attractor linearly preceding the verb.

Summing up, while some studies of attraction in sentence comprehension point to similarities with sentence production, others suggest differences. Moreover, discrepancies are also found between studies of attraction in sentence comprehension, some reporting attraction in ungrammatical sentences only, others in both grammatical and ungrammatical sentences, and yet others finding attraction in grammatical sentences only. However, a direct comparison across these studies is difficult due to the fact that they involve different tasks and different syntactic structures. The role of the task in language performance gained increased interest in the recent years (e.g., Caplan et al., 2008; Caplan, 2010; see also Salverda et al., 2010 for an overview of task effects in the visual world paradigm), and it therefore seems crucial to collect finely controlled comparisons on agreement performance before conclusions be drawn with respect to the mechanism of attraction.

In order to test the potential influence of the task on attraction, Experiments 1 and 2 use the same materials tested in agreement production by Franck et al. (2010), but with two different experimental methods. Experiment 1 uses a similar self-paced reading procedure to that used by Wagers et al. (2009) but differs from it in that only grammatical sentences were introduced, to maximize the naturalness of the comprehension process and avoid any potential contamination from the presence of ungrammatical sentences. Experiment 2 uses a procedure of speeded grammaticality judgment on the ungrammatical versions of these sentences, with the aim of maximally promoting agreement computation in comprehension. Finally, since Experiment 2 only involved ungrammatical sentences, Experiment 3 manipulated grammaticality in order to assess its role in the same procedure of speeded grammaticality judgment used in Experiment 2.

Experiment 1: Object Interference in Self-Paced Reading

Experiment 1 explores the role of object movement, modulated by its number specification, in a maximally natural sentence comprehension task involving the self-paced reading of grammatical sentences. The same materials as in Experiment 1 from Franck et al. (2010) were used, involving a minimal contrast between a structure with object movement in an object relative clause (1a), and a structure without object movement in a complement clause (1b). The two structures are identical in surface order; the main difference lies in the selection of the main verb, which takes a single complement in (1a) (thus enforcing the analysis of the *que* clause as a relative modifying the object DP) and two complements in (1b) (thus giving rise to a sentential complement interpretation for the *que* clause). Interference is examined on the agreement of the verb in the subordinate clause (to cure). In the relative clause (1a), 'patient(s)' is the object of the target verb 'cures,' and is therefore assumed to transit via the intermediate position at the embedded vP periphery intervening on the subject-verb agreement relation (Franck et al., 2010). In the complement clause (1b), 'patient(s)' is the unmoved indirect object of the main verb while the embedded verb 'cures' is used intransitively. If the intervention of the intermediate trace of the moved object on agreement creates interference in sentence comprehension similarly to sentence production, a slow down is expected at the verb in the presence of a mismatching plural object as compared to a singular object in object relatives (1a), but not in sentence complements (1b). However, if attraction in sentence comprehension reflects a process of 'rechecking' triggered by an erroneous agreement, no interference is expected from the plural feature in either of the two structures.

Method

Participants

Seventy-two students from the University of Geneva, aged between 18 and 40, took part in the experiment. They

received course credit for their participation. The experiment was approved by the ethics committee of the Department of Psychology of the University of Geneva and informed consent was obtained from all participants.

Materials

The experimental materials consisted of the 24 sentences used in Franck et al. (2010) incorporated in a 2 × 2 design crossing structure (relative vs. complement) and the number of the object (singular vs. plural). All subject head nouns were singular. Subjects and objects were all animate. Since the initial sentences ended with the target verb, two windows were added after the verb in order to measure potential spillover effects. These windows contained an adverb followed by a locative phrase. Each sentence was decomposed into 8 windows corresponding to phrases (content word + grammatical word if present). All test sentences were grammatical with respect to subject-verb agreement. Each sentence was followed by a yes/no comprehension question that probed participants' interpretation of the thematic relations in the sentence. Examples of test items are presented in **Table 1** (the full list of items is available in the Supplementary Materials).

An additional set of 48 grammatical filler items were built. Half of them had the same structure as the experimental materials (12 Object relative clauses and 12 Complement clauses) but with plural subjects (half with singular objects). The other half involved a variety of syntactic structures (eight declaratives, eight relatives, four temporal modifiers, four PP modifiers) with a varying number of reading windows.

Procedure

Sentences were presented on a computer screen using the e-prime software in a self-paced moving window paradigm (Just et al., 1982). Each sentence was first presented with dashes replacing words. Participants were instructed to read sentences by pressing the space bar in order to have the segments appear. Once read, windows disappeared from the screen such that only one window was readable at a time. Participants were told that they would also have to answer yes/no comprehension questions about the content of these sentences. Instructions encouraged both rapid reading and correctness in answering the questions. Order of presentation of the sentences was randomized. The experiment started with four practice trials.

Data analyses

Analyses of reading times were run after excluding incorrect responses to comprehension questions (181 data points rejected representing 10.2% of the data). Remaining response times were then trimmed for outliers, defined as data points with a value above 3 s for all participants and all regions (representing 3.1% over all responses). They were treated as missing values. Log-transformed response times and accuracy proportions were analyzed with (generalized) linear mixed-effects regression models with random intercepts for participants and items (Baayen et al., 2008), using the statistical software R (R Development Core Team, 2013). Estimates, *t*-values (for LME), *z*-values (for GLME) and *p*-values for the fixed factors and interactions were obtained via the lmerTest package, which provides *p*-values calculated based on Satterthwaite's approximation. Significant interactions were further explored with (generalized) linear mixed-effects regression models separately on each of the two modalities of one of the variables involved in the interaction.

Results

Reading Times

The distribution of reading times across the different experimental conditions in the different regions is reported in **Figure 1**.

Region 2 (main verb). A marginal effect of structure was found with slower response times on the main verb of the relative clause condition (581 ms) than on the main verb of the complement clause (561 ms; $\beta = -0.033$, $t = -1.76$, $p = 0.081$). There was no effect of number and no interaction ($ts < 1$).

Region 3 (object NP). No main effect or interaction was significant (all $ts < 1$).

TABLE 1 | Example of item in the four experimental conditions of Experiment 1.

Relative clause	Match	Jérôme/parle/à la prisonnière/que/le gardien/sort/parfois/dans la cour. *Jérôme/speaks/to the prisoner-SG/that/the guard-SG/takes-SG out/sometimes/in the yard.*
	Mismatch	Jérôme/parle/aux prisonnières/que/le gardien/sort/parfois/dans la cour. *Jérôme/speaks/to the prisoners-PL/that/the guard-SG/takes-SG out/sometimes/in the yard.*
Sentence complement	Match	Jérôme/dit/à la prisonnière/que/le gardien/sort/parfois / dans la cour. *Jérôme/tells/the prisoner-SG/that/the guard-SG/goes-SG out/sometimes/in the yard.*
	Mismatch	Jérôme/dit/aux prisonnières/que/le gardien/sort/parfois/dans la cour. *Jérôme/tells/the prisoners-PL/that/the guard-SG/goes-SG out/sometimes/in the yard.*

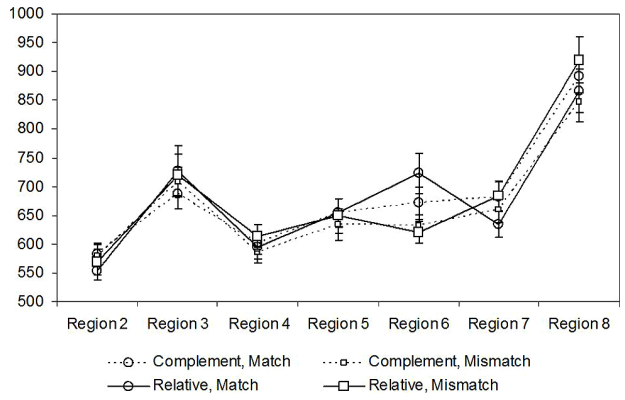

FIGURE 1 | Distribution of reading times (in ms) in the four experimental conditions of the different regions of Experiment 1. The critical region containing the test verb is Region 6.

Region 4 (complementizer). No main effect or interaction was significant (all $ts < 1$).

Region 5 (subject NP). No main effect or interaction was significant (all $ts < 1$).

Region 6 (target verb). A significant effect of number was found, with slower response times for singular objects (695 ms) than for plural objects (623 ms; $\beta = -0.078$, $t = -2.73$, $p = 0.006$). The main effect of structure was not significant ($t < 1$), but it entered into an interaction with number ($\beta = -0.013$, $t = -1.94$, $p = 0.053$). Subsequent models exploring the interaction showed that whereas number significantly affected reading times in the relative clause condition ($\beta = -0.115$, $t = -2.23$, $p = 0.027$), it failed to affect them in the complement clause condition ($t < 1$).

Region 7 (adverb). A trend toward slower response times in the complement clause condition (671 ms) than in the relative clause condition (657 ms) was found ($\beta = -0.029$, $t = -1.34$, $p = 0.180$). There was no effect of number and no interaction ($ts < 1$).

Region 8 (locative). A trend toward an interaction between number and structure was found ($\beta = 0.055$, $t = 1.17$, $p = 0.24$). There was no effect of number or structure ($ts < 1$).

Accuracy

The distribution of mean accuracy scores in the four experimental conditions is illustrated in **Figure 2**. Generalized linear mixed effect analysis showed that accuracy was significantly higher in the complement clause condition (0.97) than in the relative clause condition (0.89; $p < 0.001$; $\beta = -1.467$, $z = -3.89$, $p < 0.001$). The interaction and the number effect were not significant ($ts < 1$).

Discussion

Experiment 1 shows that the object's number feature influences processing speed at the verb in the object relative clause condition, but not in the corresponding complement clause condition, despite the surface similarity between the two structures. The observed effect shows that a feature mismatch between the extracted object and the subject of the relative clause speeds up reading of the verb segment. As mentioned in the Introduction, the experimentally elicited production of agreement is made more error-prone by the presence of a feature mismatch. Under the hypothesis that number mismatch influences the computation of agreement similarly in production and comprehension, one would have expected to find that it slows down sentence comprehension processes. Rather, it appears that a feature mismatch makes production of the relative clause verb error-prone, but reading of the relative clause verb faster. Why does a featural mismatch trigger opposite results in production and comprehension? Three observations suggest an answer, which is that the comprehension task did not tap into the mechanism of agreement computation, but rather in a mechanism of chain resolution responsible for linking a moved element to its trace.

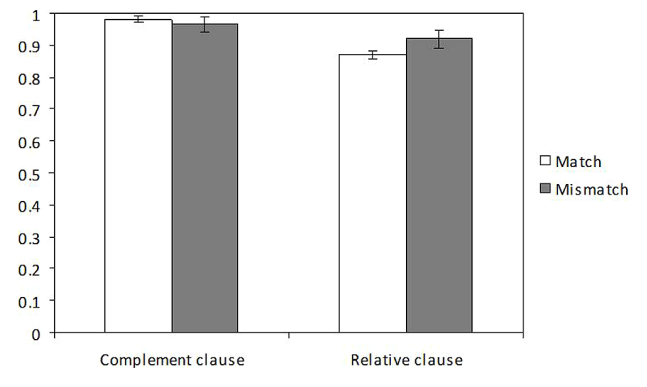

FIGURE 2 | Accuracy proportions in the comprehension questions of Experiment 1.

First, the present experiment shows an influence of the object's number in grammatical object relative clauses, which contrasts with the study by Wagers et al. (2009) who only found an effect in object relatives that contained an agreement error. Wagers et al. (2009) suggested that the interference effect they reported reflects reanalysis: only if the verb feature conflicts with the predicted feature would a cue-based retrieval process be deployed to actively retrieve the matching feature in the parsed tree. Our finding of object interference in the context of naturally reading a grammatical sentence cannot be accounted for by this view that the mismatch effect only arises as part of a second-pass process of agreement 'rechecking.'

Second, our finding that participants were faster in the presence of a plural feature mismatching the singular subject than in the presence of a singular feature matching the singular subject also contrasts with various comprehension studies showing a detrimental effect associated with a plural mismatching feature, whether it is on a subject modifier or a moved object, and whether comprehension is tested by way of self-paced reading or more indirect experimental procedures like maze tasks, classification tasks, grammaticality judgment or two-choice verb selection (Nicol et al., 1997; Clifton et al., 1999; Pearlmutter et al., 1999; Pearlmutter, 2000; Staub, 2009, 2010; Häussler, unpublished).

Third, although the direction of the interference effect in Experiment 1 may, at first glance, appear to be in line with that reported by Wagers et al. (2009) who also found faster reading times with plural mismatching objects, the two effects fundamentally differ since we found the effect in grammatical sentences whereas Wagers and colleagues found it in ungrammatical sentences. In the latter case, the parser is lured by the presence of a plural feature on the object creating an illusion of grammaticality. Hence, the finding that participants were faster in the plural mismatch condition also argues against a structure-based feature spreading mechanism like the one assumed to take place in production (Nicol et al., 1997; Vigliocco and Nicol, 1998; Franck et al., 2002; Eberhard et al., 2005). This raises the intriguing possibility that a different mechanism underlies the mismatch effect found here.

How do these different aspects of the data inform us about the mechanism underlying the number effect found in the present experiment? Directly relevant to the present study are the recent reports in the acquisition literature of intervention effects in the comprehension of object relatives. Adani et al. (2010) and Adani

(unpublished) found that both English and Italian speaking children showed better performance in a sentence-picture matching task when the object and the subject of the object relative clause mismatched in number (e.g., *Show me the elephant that the lions are washing* is better understood than *Show me the lion that the elephant is washing*). Using a similar task Belletti et al. (2012) reported better performance in Hebrew-speaking children for sentences involving a gender mismatch between the subject and the object relative. Empirical evidence suggests that only features that play an active role as triggers of syntactic movement have the potential to influence comprehension. This conclusion was reached on the basis of cross-linguistic evidence showing that in contrast to Hebrew children, Italian children failed to show a comparable sensitivity to gender mismatch in their comprehension of object relative clauses: this property was related to the different syntactic status of gender agreement in Italian.

According to the version of Relativized Minimality (Rizzi, 1990, 2004) assumed in the references quoted (along the lines developed in Friedmann et al., 2009), what makes the relevant kind of object relatives problematic for children is the intervention of the subject DP in the path connecting the relative head and its trace in object position. In particular, the difficulty is attributed to the set-theoretic relation of inclusion that characterizes the feature make-up of the object and that of the subject. When both the object and the subject are singular, the object is endowed with features [+R, +N, +Sg] (where +R is the feature designating the relative head) whereas the subject is endowed with features [+N, +Sg]: hence, the featural make-up of the intervener is included in the one of the antecedent. Friedmann et al. (2009) proposed that inclusion is problematic for children to explain their difficulty with making the required connection between the object and its trace. However, if the subject is plural, the number mismatch creates an intersection set, the object carrying [+R, +N, +Sg] and the subject [+N, +Pl]. Intersection is higher than inclusion in a natural scale of distinctness, a relation that is assumed to be accessible to the child's system in Belletti et al. (2012). Transposing this approach to the adult data collected in Experiment 1, the slowing down of reading time at the verb in the match condition as compared to the mismatch condition may be interpreted as an indication of the same gradation observed in children, inclusion being more difficult than intersection.

In this view, there is no contradiction between the number effect found in the production and comprehension studies of object relatives: whereas the production experiments directly tap into the agreement process, requiring the choice of a properly agreeing form, an operation which is penalized by the presence of a mismatching intervener in the immediate vicinity, the reading of the sentences primarily reflects the process of structure building, and in particular of the building of an appropriate A'-chain across an intervener, an operation which is enhanced by number mismatch. Hence the seemingly opposite consequences of mismatch in production and comprehension may be seen as a byproduct of the specific demands of the experimental tasks. If self-paced reading, as it is used in Experiment 1, mostly reflects the time taken by the parser to build the sentence structure and resolve the A'-dependency, it does not directly bear on agreement computation; one direct prediction of that account would be that the same effect of feature mismatch should be observed in sentences that do not involve an agreement configuration in their structure. We are currently exploring that possibility.

If self-paced reading does not tap into agreement processes, at least when complex sentences involving movement are involved, it may be relevant to identify a task that taps into the component of agreement processing in sentence comprehension. Experiment 2 uses a speeded grammaticality judgment task with sentences involving ungrammatical agreement, such that participants were forced to process agreement. If the same computational principles of agreement are at play in this task as in production, Experiment 2 should uncover the same structure-dependent attraction effects as found in sentence production.

Experiment 2: Object Attraction in Speeded Grammaticality Judgment

Experiment 2 tests the same experimental conditions as Experiment 1, contrasting object relatives and sentence complements, but this time with a speeded grammaticality judgment task in which agreement computation is explicitly assessed. Hence, in this task, agreement markers cannot be used for the structure building process; rather, agreement can only be computed once the hierarchical structure has been built. If the grammaticality judgment task allows tapping specifically into agreement processing in sentence comprehension, and if this process shows the signature of intervention effects as reported in sentence production, interference is expected to show up selectively in the condition where the object intervenes on the agreement dependency, i.e., in object relatives. In contrast, no interference is expected from the object of the main verb in sentence complements. Moreover, interference should take the shape of an attraction effect, with slower judgment times in the presence of plural mismatching objects.

Method

Participants

Thirty students of the University of Geneva, different from Experiment 1 and aged between 18 and 40, took part in the Experiment. They received credits for their participation. The experiment was approved by the ethics committee of the Department of Psychology of the University of Geneva, and informed consent was obtained from all participants.

Materials

Materials consisted of the same 24 test items as Experiment 1 without the last two windows, such that all sentences ended with the target verb. All sentences were ungrammatical with respect to subject-verb agreement: the verb in the subordinate clause was plural with a singular subject head noun. In addition to the test items, 120 filler items were built. Forty-eight of them were of the same structure as the experimental items; 16 correct with a singular subject (half with a singular object), 16 correct with a plural subject (half with a singular object) and 16 incorrect with a plural subject (half with a singular object). The 72 remaining

items had a different structure, with a subject modifier intervening linearly between the subject and the verb. Half of the modifiers consisted of subject relative clauses (e.g., Jean parle au gardien des bâtiments qui dort), the other half consisted of complement clauses (e.g., Jean dit que le programme des expériences fonctionne). Thirty-six (half) of these sentences were correct, the other half were incorrect. Half had a singular subject, the other half had a plural subject. Examples of test items are presented in **Table 2**.

Procedure

Materials were presented on a computer screen using the e-prime software. Sentences were split in windows corresponding to phrases (content word + grammatical word if present). Windows were presented for a fixed period of 500 ms, except at the verb, i.e., the final word of the sentence. These rather long presentation times were selected in order to minimize judgment errors, and avoid a possible trade-off between speed and accuracy. Grammaticality judgment times were measured at the verb onset. Participants were asked to judge the grammaticality of the sentences as quickly as possible and press on the corresponding response button. Pressing the button made the next window appear, such that a sustained rhythm was imposed.

Data Analyses

Incorrect grammaticality judgments representing 7.8% of the data were removed from the response times analyses. Analyses of response times were run both on the full dataset as well as on the data trimmed for outliers, defined as responses slower than 3 s (representing 7.9% of the data). Since both models provided similar outputs, the model of the complete data set is reported. Log-transformed response times and accuracy proportions were analyzed by way of (generalized) linear mixed-effects regression models with random intercepts for participants and items (Baayen et al., 2008), following the same procedure as for Experiment 1.

Relative clause	Match	* Jérôme parle à la prisonnière que le gardien sortent. * *Jérôme speaks to the prisoner-SG that the guard-SG take out-PL.*
	Mismatch	* Jérôme parle aux prisonnières que le gardien sortent. * *Jérôme speaks to the prisoners-PL that the guard-SG take out-PL.*
Sentence complement	Match	* Jérôme dit à la prisonnière que le gardien sortent. * *Jérôme tells the prisoner-SG that the guard-SG go out-PL.*
	Mismatch	* Jérôme dit aux prisonnières que le gardien sortent. * *Jérôme tells the prisoners-PL that the guard-SG go out-PL.*

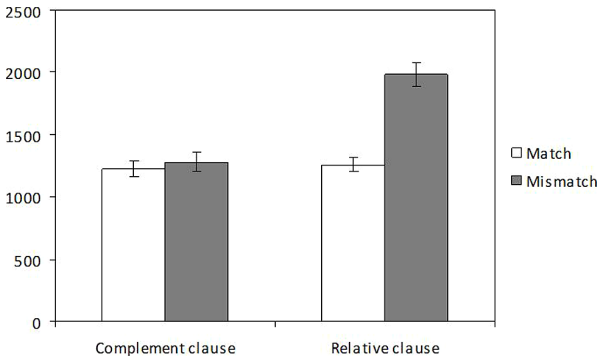

FIGURE 3 | Distribution of RTs (ms) for correct judgments at the target verb in the speeded grammaticality judgment task of Experiment 2.

Results

Response Times

The distribution of response times is illustrated in **Figure 3**. Mixed models revealed a main effect of number, with slower RTs with plural objects (1619 ms) than with singular ones (1242 ms; $\beta = 0.186$, $t = 4.449$, $p < 0.001$) as well as a main effect of structure with slower times for judging the grammaticality of object relatives (1609 ms) than for judging complement clauses (1253 ms; $\beta = 0.179$, $t = 4.277$, $p < 0.001$). The model showed a significant interaction between structure and number ($\beta = 0.273$, $t = 3.185$, $p = 0.002$): whereas number significantly affected response times in the relative clause condition ($\beta = 0.302$, $t = 4.463$, $p < 0.001$), no effect of number was found in the complement clause condition ($t < 1$).

Accuracy

Mean accuracy scores are reported in **Figure 4**. Accuracy was significantly affected by structure with better scores in the complement clause condition (0.97) than in the relative clause condition (0.90; $\beta = -1.379$, $z = -2.18$, $p = 0.03$). Number was marginally significant with higher scores for singular objects (0.97) than for plural ones (0.91; $\beta = -1.180$, $z = -1.863$, $p = 0.06$). The interaction was not significant ($t < 1$).

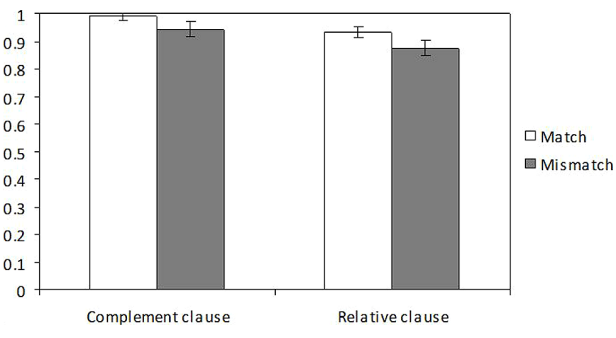

FIGURE 4 | Accuracy proportions in the speeded grammaticality judgment task of Experiment 2.

Discussion

In line with the production data reported on the same materials (Franck et al., 2010), participants were disturbed by the presence of a plural object in object relative clauses when performing a grammaticality judgment task bearing on the verbal agreement morphology: they were significantly slower to judge that the sentence was ungrammatical when the object was plural than when it was singular. By contrast, the plural feature in the sentence complement structure generated no or at least significantly reduced interference. The parallelism with production reports finds a natural explanation under the hypothesis that the same mechanism of agreement computation is at play in both tasks. This mechanism is sensitive to the hierarchical intervention of the intermediate trace of the object on the subject-verb dependency, which may have as processing consequence the local reactivation of the object, leading to interference in the processing of agreement, as argued in Franck et al. (2010). Under this hypothesis, the data provide evidence that agreement computation in sentence comprehension operates on the same syntactic representations as in sentence production (e.g., Nicol et al., 1997; Pearlmutter et al., 1999; Thornton and MacDonald, 2003; Hartsuiker, 2006; Badecker and Kuminiak, 2007).

Experiment 2 differs from Experiment 1 in the direction of the number effect: whereas faster response times were observed in the number mismatch condition in the self-paced reading Experiment 1, number mismatch slowed down grammaticality judgments in Experiment 2, in line with attraction effects found in sentence production. One could argue that the opposite direction of the effect found in Experiment 2 as compared to Experiment 1 is due to the fact that whereas Experiment 1 involved grammatical sentences, Experiment 2 involved ungrammatical sentences. Experiment 3 tests whether grammaticality affects the direction of the number interference effect in a grammaticality judgment task. If the effect reported in Experiment 2 merely reflects properties of syntactic representations, grammaticality should not affect performance since the same hierarchical structure underlies grammatical and ungrammatical sentences.

Experiment 3: The Role of C-Command

Findings in sentence production suggested that c-commanding interveners have a greater potential to trigger interference effects than preceding interveners (Franck et al., 2006, 2010).

Experiment 3 contrasts two conditions involving wh-movement of a complex objects, which potentially interferes with subject-verb agreement while transiting in a vP peripheral position, along the lines illustrated in the Introduction. The property that varies is where, in the complex object, the plural feature is expressed. In (3a) the DP head (hence, the whole object DP) is plural (*quelles patientes du médecin*), while in (3b) (*le chirurgien de quelles patientes*) only the embedded DP within a PP modifier is plural (here the embedded DP pied-pipes the whole object DP triggering its movement to the left periphery).

(3) a. Quelles **patientes** du médecin dis-tu que le juriste défend/*défendent?
*Which-PL patients-PL of the doctor do you say that the lawyer-SG defends-SG/*defend-PL?*

b. Le chirurgien de quelles **patientes** dis-tu que le juriste défend/*défendent?
*The surgeon of which-PL patients-PL do you say that the lawyer-SG defends-SG/*defend-PL?*
Which patients' surgeon do you say that the lawyer defends?

The crucial point here is that when the complex object DP transits through the vP peripheral position, intervening in the agreement process between the verbal inflection and the subject, the DP with plural marking intervenes in terms of c-command in (3a) (a hierarchical property), while it only intervenes in terms of precedence in (3b), where it is buried within the PP modifier. Under the hypothesis that the same guiding principles operate in sentence production and in the agreement checking process assumed to take place in grammaticality judgment, the plural feature on the c-commanding element 'patientes' in (3a) is expected to generate stronger attraction than the plural feature on the preceding element 'patientes' in (3b). While Experiment 1 tested grammatical sentences and Experiment 2 tested ungrammatical ones, Experiment 3 manipulates grammaticality in order to provide a systematic assessment of its role on agreement processing in grammaticality judgment.

Method

Participants

Twenty-six students of the University of Geneva different from Experiments 1 and 2 and aged between 18 and 40, took part in the Experiment. They received credits for their participation. The experiment was approved by the ethics committee of the Department of Psychology of the University of Geneva, and informed consent was obtained from all participants.

Materials

Materials consisted of 24 sets of 8 items. The variables manipulated include the number of the attractor (singular vs. plural), the position of the attractor with respect to the subject in its base position (c-command vs. precedence), and the grammaticality of subject-verb agreement (grammatical vs. ungrammatical). Questions, rather than declarative object relative clauses, were used to avoid attachment ambiguity (a relative clause could either be attached to the higher DP or to the DP embedded in the modifying PP). The position of the wh-marked element *quelles* was always on the target DP such that it was on the head in the c-commanding condition and on the PP modifier in the precedence condition. In this design, the plural DP was the wh-DP in both the c-command and precedence condition, so that the crucially varying DP would have the same role of wh-operator at Logical Form. As a result, the finding of an effect of structure would attest to a syntactic position effect, not of a semantic/logical form effect. All DPs were animate. An example of item across the eight experimental conditions is presented in **Table 3** (the full list of items is available in the Supplementary Materials).

Thirty-two filler grammatical items with the same structure as the test items but with plural subjects were created. An additional

TABLE 3 | Example of an item in the eight experimental conditions of Experiment 3.

C-command	Match	Quelle patiente du médecin dis-tu que le juriste défend/*défendent? *Which patient of the doctor do you say that the lawyer defends/*defend?*
	Mismatch	Quelles patientes du médecin dis-tu que le juriste défend/*défendent? *Which patients of the doctor do you say that the lawyer defends/*defend?*
Precedence	Match	Le chirurgien de quelle patiente dis-tu que le juriste défend/*défendent? The surgeon of which patient do you say that the lawyer defends/**defend*?
	Mismatch	Le chirurgien de quelles patientes dis-tu que le juriste défend/*défendent? The surgeon of which patients do you say that the lawyer defends/**defend*?

set of 40 fillers (half with singular subjects, half grammatical) was added. These consisted of object relatives (16), subject relatives (16) and PP modifiers in simple structures (8). Items were spread across four experimental lists that each contained 48 test items and the 72 fillers. Each list contained both the grammatical and the ungrammatical version of a test item, presented in two separate blocks with a short pause in between. Each block contained the same number of items in the eight conditions, presented in random order.

Procedure and Data Analyses

The same procedure and data analyses as Experiment 2 were adopted. Incorrect grammaticality judgments representing 17.3% of the data were removed from the response times analyses. Again, since the models with and without data trimming were identical, the models reported are those without data trimming. The number of incorrect judgments (216 data points) is small and their distribution is too complex to allow conclusions, nevertheless, the analysis is available in the Supplementary Materials.

Results

Response Times

The distribution of response times is illustrated in **Figure 5**. The model showed a main effect of number ($\beta = -100.73$, $t = -2.213$, $p = 0.027$), with slower response times in the condition with plural objects (766 ms) as compared to the condition with singular objects (658 ms). There was no effect of structure, and no effect of grammaticality ($ts < 1$). The predicted interaction between number and structure was significant ($\beta = 212.50$, $t = 2.341$, $p = 0.019$), and failed to interact with grammaticality, as attested by the non-significant three-way interaction ($t < 1$). Models run separately on each structure showed a significant effect of number of the c-commanding element ($\beta = -213.31$, $t = -3.173$, $p = 0.002$), with slower RTs for plural c-commanding elements (790 ms) than for singular ones (619 ms), but no significant effect of number of the preceding element (742 vs. 696 ms, $t < 1$). Grammaticality played no role in these models ($ts < 1$).

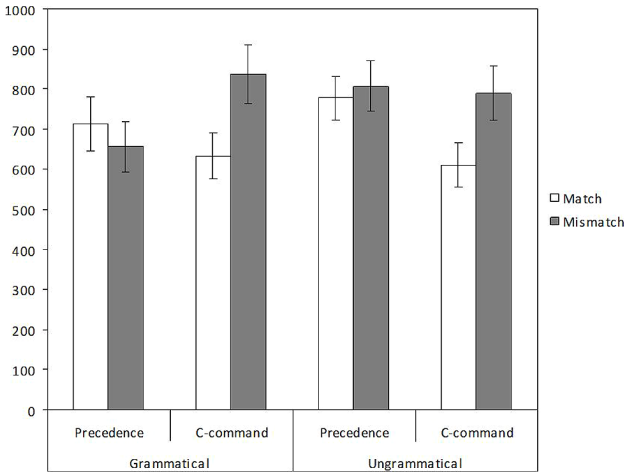

FIGURE 5 | Distribution of RTs (ms) for correct judgments in the speeded grammaticality judgment of Experiment 3.

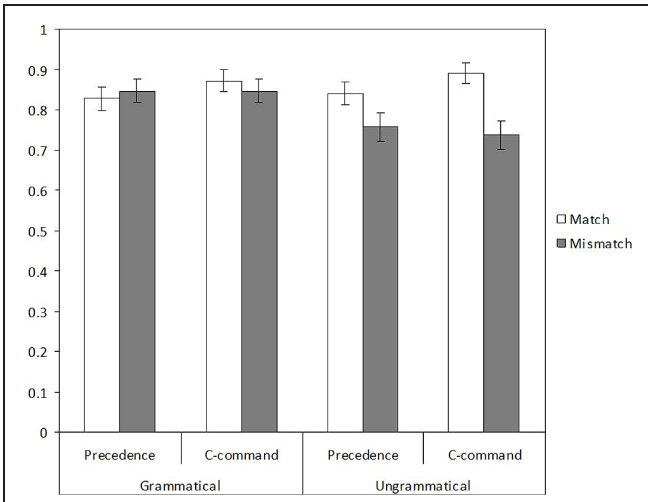

FIGURE 6 | Accuracy proportions in the speeded grammaticality judgment of Experiment 3.

Accuracy

Mean accuracy scores are reported in **Figure 6**. The model showed a main effect of number ($\beta = 0.442$, $z = 2.77$, $p = 0.006$), with lower accuracy rates with plural attractors (0.80) than with singular ones (0.86), as well as an interaction between number and grammaticality ($\beta = 0.817$, $z = 2.567$, $p = 0.010$). The interaction between number and structure failed to reach significance level ($\beta = -0.471$, $z = -1.48$, $p = 0.138$). Splitting the interaction into two separate models showed that whereas number significantly affected accuracy in ungrammatical sentences ($\beta = 0.817$, $z = 3.926$, $p < 0.001$), with better scores in the number match condition (0.87) than in the mismatch condition (0.75), it did not affect it in grammatical sentences ($z < 1$). Number and structure failed to interact significantly in the two models ($z < 1$).

Discussion

Experiment 3 brings two new findings. First, we found an effect of the structural variable manipulated: whereas the plural mismatching feature on the DP intervening in terms of c-command on agreement significantly contributed to slowing grammaticality judgments as compared to the singular matching feature, the plural feature on the DP intervening in terms of precedence failed to significantly affect response times. The finding that c-command intervention creates stronger interference than precedence intervention replicates previous reports in sentence production, with yet different constructions. Data from sentence production showed that the accusative clitic object pronoun situated pre-verbally creates more interference than a PP modifier situated in the same linear position (Franck et al., 2006) and more interference than the preverbal dative clitic (Franck et al., 2010). Both the PP modifier and the dative can be argued to intervene on the agreement dependency in terms of precedence, being embedded in a prepositional layer, whereas the accusative clitic intervenes in terms of c-command.

Second, grammaticality does not impact on performance in a speeded grammaticality judgment task: the same interference effect is found independently of whether the sentence is grammatical or not (see Häussler, unpublished, for a similar finding in German). This finding suggests that the differences in the direction of the number interference effect between Experiment 1 (self-paced reading), showing similarity-based interference, and Experiment 2 (speeded grammaticality judgment), showing attraction, is not due to the fact that that the former tested grammatical sentences whereas the latter tested ungrammatical sentences. Indeed, Experiment 3 shows that interference always shows up as an attraction effect in speeded grammaticality judgment. Hence, what seems critical is the process that the task taps into: whereas self-paced reading taps into the process of structure building and resolution of an A'-dependency, facilitated by the presence of a number mismatching feature on the subject intervening on the object-gap dependency, grammaticality judgment taps into the process of agreement checking, penalized by the presence of a number mismatching feature on the object intervening on the subject-verb dependency.

Finally, response times in Experiment 3 are faster than in Experiment 2, which showed particularly slow responses. The two experiments also differ in their overall error rates: in Experiment 2 where response times were between 1 and 2 s, the error rate was smaller than 10% overall; in contrast, the error rate in Experiment 3 where response times were between 600 and 850 ms was between 15 and 25%. It may therefore be the case that participants granted a privileged status to accuracy in Experiment 2. Nevertheless, it is important to note that there was no trade-off between response times and error rates across conditions in Experiment 3: conditions that were slower were also those that generated more errors.

General Discussion

We reported three studies exploring the consequences of a number featural mismatch in the comprehension of structures involving intervention configurations. The structures manipulated shared similar superficial characteristics, but critically differed in their hierarchical configurations. Experiments 1 and 2 contrasted object relatives clauses, involving an intermediate position created by movement of the object and intervening on the subject-verb agreement relation, and sentence complement clauses in which the object fails to intervene on the agreement relation at any point in the derivation of the hierarchical structure. Experiment 3 contrasted two structures involving complex objects also intervening on agreement in the object's intermediate position, but differing in the hierarchical position of the number mismatching feature situated either in a position of intervention in terms of c-command on agreement, or in terms of linear precedence.

The comparison between the first two experiments conducted on the same materials shows that self-paced reading (Experiment 1) and grammaticality judgment (Experiment 2) tap into distinct processes differently sensitive to intervention. The combination of the last two grammaticality judgment experiments illustrates the role of fine aspects of the hierarchical structure in agreement processing in sentence comprehension. Task-dependency and structure-dependency of number interference effects are discussed in turn.

Task-Dependent Interference in the Process of Structure Building

Experiment 1 using a self-paced reading procedure with grammatical sentences showed that participants read the verb significantly faster in the presence of a mismatching plural object in the relative clause, while no effect of number was found in the complement clause. Experiment 2 using a grammaticality judgment task specifically focusing on subject-verb agreement with the use of ungrammatical sentences also found an effect of the object's number restricted to relatives. However, this effect was reversed, with slower grammaticality judgments in the presence of a plural object, in line with attraction effects found in sentence production (Bock and Miller, 1991; Franck et al., 2006, 2010).

What is the mechanism underlying interference in the two experiments? We have suggested that both experiments reflect intervention effects on the hierarchical structure; however, the two experiments, because of the different techniques used, tap into two distinct processes, highlighting two different kinds of intervention effects. Experiment 1 reflects subject intervention on the object A'-dependency, Experiment 2 reflects object intervention on the subject-verb agreement dependency. More particularly, we have argued that self-paced reading taps into the process of structure building, in which the parser needs to resolve the required antecedent-gap dependency and assign the appropriate theta-roles to the arguments of the verb. The data of Experiment 1 are in line with recent developmental research attesting to children's better understanding of object relatives when the subject and object mismatch in number (Adani et al., 2010; Adani, unpublished). Similarly, mismatches in other features have also been found to facilitate object relative clause comprehension: gender mismatch (Belletti et al., 2012), animacy mismatch (e.g., Mak et al., 2002, 2006; Traxler et al., 2002) or mismatch in the

NP-type (DP, pronoun, proper name; e.g., Gordon et al., 2001, 2004; Warren and Gibson, 2002, 2005; Grillo, 2009; Belletti and Rizzi, 2013). Capitalizing on the theory of Relativized Minimality (Rizzi, 1990, 2004), Friedmann et al. (2009) suggested that the difficulty in building A'-dependencies in object relatives stems from the intervention of the subject DP in the path connecting the relative head and its trace in object position. Critically, the difficulty is hypothesized to be a function of the degree of overlap in syntactic features between the relative head and the intervener. According to this set-theoretic approach, the minimal degree of distinctness, identity, excludes the configuration from the grammar, while the maximal degree of distinctness, disjunction, makes the configuration fully accessible to both children and adults. The intermediate cases of inclusion and intersection would respectively engender stronger and weaker difficulty, the former manifesting itself in terms of the failure to build the A'-dependency in children and of a significant slowing down of processing in adults. In this framework, the facilitating role of number mismatch is captured in terms of the set theoretic relation in featural specification of the intervener with respect to the target.

The approach we have assumed expresses the intervention effect and the amelioration observed with feature mismatch directly in terms of a grammatical constraint, Relativized Minimality. Alternative approaches rooted in the psycholinguistic tradition do not appeal to a particular grammatical constraint and directly focus on the process of retrieving the object from memory when the verb is reached in parsing. Memory retrieval models assume that retrieval in long-distance dependencies involves a cue-based mechanism operating on content-addressable memory representations (e.g., McElree et al., 2003; Van Dyke and Lewis, 2003; Lewis and Vasishth, 2005; Van Dyke and McElree, 2006). These models grant a key role to similarity-based interference, which arises when memory units other than the retrieval target partially overlap with it in terms of their syntactic or semantic make-up. Although these models capture various interference effects reported in the literature (e.g., Lewis et al., 2006) only few attempts have tried to understand how the memory mechanisms posited can capture complex relational syntactic constraints (e.g., Vasishth et al., 2008; Dillon et al., 2013; Alcocer and Phillips, unpublished). One possible way in which our interpretation based on Relativized Minimality and more standard psycholinguistic approaches in terms of cue-based object retrieval may differ concerns the locus of the interference effect. If our interpretation is on the right track, the observed faster reading in the mismatch condition in sentences like (1a) has no direct relation with subject-verb agreement on the verb: it simply has to do with the resolution of an (object) A'-dependency across a partially matching intervener (the subject). If this is correct, we would expect the mismatch effect to enhance reading times at the verb (when the object trace is postulated and the A'-dependency resolved) even if the verb is uninflected, as for example in a sentence with a modal in English *(*e.g., *John talked to the patient(s) that the medicine can cure*), or in a sentence with an infinitival verb. If, as assumed in cue-based retrieval models, number on the verb serves as a linking address to memory units, the number effect should disappear with uninflected verbs. We intend to test this prediction in future work.

If a cue-based retrieval mechanism is at play in Experiment 1, it is, in any case, of a different type from the one assumed by Wagers et al. (2009) who tied it to a process of agreement 'rechecking,' triggered by the unpredicted number feature on the erroneously agreed verb. The number effect in Experiment 1 was found on grammatical sentences and in the verb region, while Wagers et al. (2009) found it in ungrammatical sentences and in the post-verbal region. These differences in the data suggest that if memory retrieval is responsible for the effect here, it must be tied to an early process of structure building and not to a late process of rechecking after the structure has been built, as proposed by Wagers et al. (2009). One could then wonder why Wagers et al. (2009) failed to find number interference in grammatical sentences in their work. The two studies differ in at least two respects. First, whereas Wagers et al. (2009) tested both grammatical and ungrammatical sentences, our materials only involved grammatical sentences. The presence of agreement errors in the English materials may have contributed to artificially disqualify number as a relevant cue to parsing, therefore explaining the lack of an effect in grammatical sentences. Second, our materials involved a mix of superficially similar object relatives and complement clauses; one cannot exclude the possibility that having to switch from one structure to the other increased the processing burden on structure building. The two factors may have played a cumulative role in the differences observed between the two studies.

The finding that the number effect in object relatives was reversed when measured in the grammaticality judgment task of Experiment 2, and turned into an attraction effect similar to the one found in sentence production, was taken as evidence that the task tapped into a different process. The grammaticality judgment task indeed forces the parser to first build the hierarchical structure over which agreement can be calculated, and can therefore be reasonably thought of as tapping into agreement computation proper. The finding that number interference arises as an attraction effect, and that the effect is restricted to object relatives and fails to manifest in complement clauses, suggests that the same mechanism underlies agreement computation in comprehension and production. In the next section, we describe our view of that mechanism.

Structure-Dependent Attraction in Agreement in Sentence Comprehension

In contrast to Experiment 1, Experiments 2 and 3 both showed that the presence of a number mismatching feature in the sentence significantly penalizes grammaticality judgments. Although Experiment 2 only tested ungrammatical sentences, Experiment 3 showed that the number effect arose independently of whether the sentence is grammatical or ungrammatical.

Results of Experiment 2 showed that attraction arises only in object relatives, when the attractor is the moved object of the target verb in the relative, but not when it is the object of the main verb in sentence complements, despite the superficial similarity of the two structures. Experiment 3 showed that a mismatching feature in a moved complex object intervening by c-command on an agreement configuration generates more attraction than one intervening by precedence. These two findings replicate our

previous reports in sentence production (Franck et al., 2006, 2010), arguing in favor of identical syntactic representations over which agreement takes place in production and comprehension (e.g., Nicol et al., 1997; Pearlmutter et al., 1999; Thornton and MacDonald, 2003; Hartsuiker, 2006; Badecker and Kuminiak, 2007).

What are the operating principles of agreement computation? In our production research, we suggested that attraction arises because of the intervention, on the subject-verb (AGREE) dependency, of the object transiting in its intermediate position at the periphery of the vP (Franck et al., 2006, 2010). Intervention by the intermediate object trace created by object movement, was argued to set the necessary condition for interference to arise. On that view, attraction results from the incorrect feature passing from the object to the verb via AGREE. One could nevertheless entertain a different scenario to account for the report of attraction in object relatives but not in sentence complements. A vast literature suggests that the parser reactivates the moved object when reaching the verb that it is an argument of (e.g., Stowe, 1986; McElree et al., 2003; Fedorenko et al., 2013). Hence, one cannot exclude the possibility that interference arises because the object is active during the same time window as the subject. Against this hypothesis, experimental evidence from sentence production shows that attraction arises even for moved objects that are not arguments of the target verb, as in (4).

(4) Voici les otages que le journaliste *apprennent qu'on a blessés. *Here are the hostages-PL that the journalist-SG *learn-PL that someone injured.*

Moreover, the strength of the attraction effect in this context is identical to attraction from the verbal argument tested in the context of object relatives (*John speaks to the patients that the medicine *cure*; Franck et al., 2010, Experiment 4). Hence, in order for a blind memory reactivation account to capture this report, one would need to assume that the parser reactivates all noun phrases from the parsed tree at the target verb to the same extent: *hostages* in (4) should be reactivated at the verb *learn*, of which it is not an argument, to a similar extent as the argument *patients* is reactivated at *cure* in the object relative clause. Even though retrieval is indeed known to be sensitive to interference from non-target elements sharing cues with the target (e.g., Van Dyke and McElree, 2006), it is marginal since, in the vast majority of the cases, the correct target is retrieved. Thus, a simple memory activation model fails to capture our finding that a moved object that is not part of the argument structure of the target verb triggers similar attraction to a moved verbal argument. The critical explanatory factor in interference rather appears to be the intervention of a moved DP in the hierarchical subject-verb dependency, a configuration which is identical whether the moved DP is an argument of the critical verb or not.

Results of Experiment 3 bring further support to our previous finding in agreement production that c-commanding interveners are more prone to trigger attraction than preceding ones. C-command has played a key role in syntactic theory, ever since work by Reinhart (unpublished), and has pervasive consequences on various morphosyntactic and interpretive processes like the binding of anaphors and the proper scope interpretation of quantifiers. The AGREE operation by which the subject's features are copied onto the agreement node in the functional layer of the clause also takes place under the constraint of c-command. Experiment 3 shows that an intervening object trace disrupts the processing of subject-verb agreement when a mismatching number feature intervenes between the subject and the verbal inflection in the hierarchical terms of c-command, and does so significantly more than when it intervenes in terms of mere precedence. This result parallels previous results on the stronger interference triggered by a c-commanding intervener in sentence production (Franck et al., 2010). In conclusion, both production and comprehension systems show a parallel sensitivity to the hierarchical relation of c-command, which thus has a central role both in grammar and performance.

Tanner et al. (2014) proposed that maintaining a unified account of agreement in production and comprehension minimally requires (1) that the same factors that modulate attraction in production also modulate attraction in comprehension, and (2) that interference in comprehension is symmetrical, as in production, meaning that attraction is expected to manifest independently of whether the sentence is grammatical or not in comprehension, or whether the correct verb form is ultimately chosen or not in production (a slowing down has been observed in the presence of a plural attractor in production even if correct agreement was used on the verb, Staub, 2009, 2010; Brehm and Bock, 2013). Results from the speeded grammaticality judgment Experiments 2 and 3 meet these requirements, suggesting that even though number interference effects may arise from different causes depending on the task used to measure sentence comprehension, the mechanism of agreement computation itself is the same in production and comprehension. This mechanism appears to operate under fine constraints as defined in formal syntax, including movement, intermediate traces and c-command.

Conclusion

The finding that the same structural effects as those found in sentence production are found in sentence comprehension is relevant both at the theoretical level and at the methodological levels. At the theoretical level, it argues in favor of a common syntactic component shared by production and comprehension, in spite of the obvious differences due to the intrinsically anticipatory nature of the parser. We suggested that the common component of agreement shows up when the comprehension task allows it to, as is the case when participants are required to judge the grammaticality of the sentence under time constraints. At the methodological level, grammaticality judgment is much easier to use than elicitation tasks, which often produce a very small range of errors that are problematic to analyze statistically. Speeded grammaticality judgment allows measuring not only errors but also response times, hence providing a finer measure necessary for subtle syntactic variables to show up in

an otherwise noisy performance. It therefore offers an ideal tool for the future exploration of the core syntactic components of agreement computation.

A corrigendum on

Task-dependency and structure-dependency in number interference effects in sentence comprehension

by Franck, J., Colonna, S., and Rizzi, L. (2015). Front. Psychol. 6:349. doi: 10.3389/fpsyg.2015.00349

The reference of the following sentence should be Adani et al. (2014) rather than Adani (unpublished).

"Adani et al. (2010) and Adani (unpublished) found that both English and Italian speaking children showed better performance in a sentence-picture matching task when the object and the subject of the object relative clause mismatched in number (e.g., Show me the elephant that the lions are washing is better understood than Show me the lion that the elephant is washing)."

Adani et al. (2014) should thus be added to the References.

Syntactic Constraints and Individual Differences in Native and Non-Native Processing of Wh-Movement

Adrienne Johnson[1, 2, 3]*, *Robert Fiorentino*[2] *and Alison Gabriele*[3]

[1] Department of Education, Missouri Western State University, St. Joseph, MO, USA, [2] Neurolinguistics and Language Processing Laboratory, Department of Linguistics, University of Kansas, Lawrence, KS, USA, [3] Second Language Acquisition and Processing Laboratory, Department of Linguistics, University of Kansas, Lawrence, KS, USA

There is a debate as to whether second language (L2) learners show qualitatively similar processing profiles as native speakers or whether L2 learners are restricted in their ability to use syntactic information during online processing. In the realm of wh-dependency resolution, research has examined whether learners, similar to native speakers, attempt to resolve wh-dependencies in grammatically licensed contexts but avoid positing gaps in illicit contexts such as islands. Also at issue is whether the avoidance of gap filling in islands is due to adherence to syntactic constraints or whether islands simply present processing bottlenecks. One approach has been to examine the relationship between processing abilities and the establishment of wh-dependencies in islands. Grammatical accounts of islands do not predict such a relationship as the parser should simply not predict gaps in illicit contexts. In contrast, a pattern of results showing that individuals with more processing resources are better able to establish wh-dependencies in islands could conceivably be compatible with certain processing accounts. In a self-paced reading experiment which examines the processing of wh-dependencies, we address both questions, examining whether native English speakers and Korean learners of English show qualitatively similar patterns and whether there is a relationship between working memory, as measured by counting span and reading span, and processing in both island and non-island contexts. The results of the self-paced reading experiment suggest that learners can use syntactic information on the same timecourse as native speakers, showing qualitative similarity between the two groups. Results of regression analyses did not reveal a significant relationship between working memory and the establishment of wh-dependencies in islands but we did observe significant relationships between working memory and the processing of licit wh-dependencies. As the contexts in which these relationships emerged differed for learners and native speakers, our results call for further research examining individual differences in dependency resolution in both populations.

Johnson A, Fiorentino R and Gabriele A (2016) Syntactic Constraints and Individual Differences in Native and Non-Native Processing of Wh-Movement. Front. Psychol. 7:549. doi: 10.3389/fpsyg.2016.00549

INTRODUCTION

Research on the processing of wh-dependencies has found evidence that both native speakers and second language (L2) learners are able to utilize abstract syntactic information in the course of online processing (e.g., Aldwayan et al., 2010; Omaki and Schulz, 2011; Kim et al., 2015). The focus of these studies has been whether island constraints, which constrain the type of structures from which wh-extraction is possible (Ross, 1967; Chomsky, 1973, 1986), are respected in real time. For example, building on the seminal work of Stowe (1986), Aldwayan et al. (2010) examined whether L2 learners, similar to native speakers, would attempt to resolve wh-dependencies only in grammatically licensed positions: evidence of a reading time slowdown in (1b) at either the filled subject position (*Barbara*) or the filled object position (*us*) as compared to the same positions in the declarative sentence in (1a) would suggest that the L2 parser actively posits gaps in licit positions, while a lack of slowdown in the prepositional object position in (2b) as compared to (2a) would suggest avoidance of positing gaps within grammatically unlicensed positions, such as within the Complex Noun Phrase (NP) island (*the boring comments about John's used car*).

(1a) My brother asked if **Barbara** will photograph **us** beside Mom at the graduation.
(1b) My brother asked who **Barbara** will photograph **us** beside ___ at the graduation.
(2a) My sister wondered if the boring comments about **John's** used car were intended to entertain the group.
(2b) My sister wondered who the boring comments about **John's** used car were intended to entertain ___.

The results of a self-paced reading experiment with native speakers of English and Najdi Arabic learners of English indeed showed this pattern: there was a clear reading time slowdown or "filled-gap effect" for both learners and natives at the licit verbal object position (1a, 1b) but not at the prepositional object position within the complex NP island (2a, 2b). In a follow-up study, Canales (2012) revised the stimuli in (2), embedding the critical object within a relative clause island as in (3) so that the critical position in both the licit (1) and illicit (3) contexts followed a verb.

(3a) My brother questioned if the journalist that followed **Henry** last Saturday provoked the guard at the store.
(3b) My brother questioned who the journalist that followed **Henry** last Saturday provoked _____at the store.

Canales (2012) found converging evidence in a study testing Spanish-speaking learners of English, showing evidence of a filled-gap effect at the direct object position (*us*) in (1) but no difference in reading times at the direct object position within the relative clause island (*Henry*) in (3a,b). The presence of the object filled-gap effects across studies suggests that the lack of a reading time slowdown within the island conditions in (2) and (3) is not due to, for example, a lack of statistical power. Both Aldwayan et al. (2010) and Canales (2012) also found limited evidence of subject filled-gap effects (e.g., a reading time slowdown at *Barbara* in 1b as compared to 1a) in both experiments, suggesting that the parser can actively generate a prediction for a gap immediately following the wh-element. While these results were not consistent across experiments or participant groups, both native and learner groups showed evidence of subject filled-gap effects in at least one experiment in each study. The inconsistent emergence of subject filled-gap effects in these studies is not surprising as subject filled-gap effects did not emerge in Stowe's original study, testing English native speakers (see Stowe, 1986; Gibson et al., 1994; Lee, 2004; Johnson, 2015 for further discussion). Overall, the results of the studies discussed above suggest that the L2 parser is guided by syntactic constraints, attempting to resolve wh-dependencies only in licit positions. Using a different paradigm, Omaki and Schulz (2011) and Kim et al. (2015) also provide evidence that Spanish-speaking learners of English actively posit gaps in licit positions but avoid positing gaps in islands. These recent results are in line with several earlier, behavioral studies that showed that L2 learners at very high levels of proficiency are able to show native-like levels of performance on a grammaticality judgment task with respect to the rejection of ungrammatical island violations (e.g., Martohardjono, 1993; White and Juffs, 1998; see review in Belikova and White, 2009).

However, there is a debate as to whether islands are indeed grammatically unlicensed structures and are thus a relevant test case for investigating the recruitment of syntactic knowledge during processing or whether islands are simply processing bottlenecks (e.g., Kluender and Kutas, 1993; Hofmeister and Sag, 2010; Sprouse et al., 2012). It has been proposed that the parser may avoid positing gaps within islands, not due to adherence to syntactic constraints as was suggested above, but because the complex structure inherent to islands simply overwhelms an individual's processing capacities (Kluender and Kutas, 1993; Kluender, 2004; Hofmeister and Sag, 2010).

GRAMMATICAL VS. PROCESSING ACCOUNTS OF ISLANDS

Under grammatical accounts, gap-filling inside islands is avoided due to constraints on wh-extraction; under these views, both the avoidance of gap-filling in islands during sentence processing and the low acceptability ratings that island-violating sentences incur in acceptability judgment tasks are due to the utilization of syntactic knowledge (e.g., Sprouse et al., 2012). On the other hand, according to recent processing accounts, at least some islands are not the result of grammatical constraints (e.g., Hofmeister and Sag, 2010). Instead, the appearance of island sensitivity during processing and the elicitation of low ratings for island-violating sentences in judgment tasks are a consequence of processing pressures which are argued to increase difficulty in resolving wh-dependencies. On these accounts, island effects emerge when various processing burdens combine to render processing particularly difficult, leaving few resources to resolve dependencies. These processing burdens arise from a range of factors that are not unique to islands. They include the presence of the filler-gap dependency itself, which is argued to incur a processing cost that may increase as distance increases, the

processing of additional referents along the path between the filler and gap, processing clause boundaries, and how complex or semantically rich the filler phrase is, among other factors (e.g., Kluender, 1992, 1998, 2004; Hofmeister and Sag, 2010; Hofmeister et al., 2013; see also Cinque, 1990). Since these factors are hypothesized to lead to island effects, manipulating them in order to ease processing difficulty is expected to ameliorate or remove island effects. This expectation is arguably not shared by grammatical accounts, which hold that the parser should not predict a gap within an island context, regardless of such factors. In support of the processing accounts, several studies have put forth evidence that manipulating one or more non-structural factors leads to both improved judgments and reduced processing difficulty as indexed by self-paced reading times. For example, Hofmeister and Sag (2010, Experiment 2) used self-paced reading to investigate whether the processing difficulty and low acceptability ratings of wh-islands such as (4b) below would be ameliorated by simply replacing a bare wh-element (*Who*) with a more complex, semantically rich wh-phrase (*Which employee*). Participants first read a lead-in sentence like (4a) below, and then a second sentence with either a bare wh-phrase in a wh-island construction (4b), a which phrase in a wh-island construction (4c), or a baseline condition involving no island violation (4d).

(4a) Albert learned that the managers dismissed the employee with poor sales after the annual performance review.
(4b) Bare Wh-phrase: Who did Albert learn whether they dismissed after the annual performance review?
(4c) Which phrase: Which employee did Albert learn whether they dismissed after the annual performance review?
(4d) Grammatical Baseline: Who did Albert learn that they dismissed after the annual performance review?

Reading times at the three regions following the embedded verb (*dismissed* in 4 above) were significantly faster for the Which phrase condition (4c) than the Bare Wh-phrase condition (4b); indeed, reading times for the Which phrase condition did not differ from the grammatical baseline condition (4d). These results suggest that manipulation of the semantic complexity of the filler phrase may reduce the difficulty of processing the wh-island. In a follow-up where bare wh- and which phrase sentences (presented in embedded questions) were rated for acceptability, the which-phrase sentences received higher acceptability ratings. That the manipulation of this factor both eased processing difficulty following the gap site and improved acceptability ratings was taken to suggest that processing pressures contribute to island effects.

Individual differences in processing resources (in particular, working memory) constitute another factor that may affect whether island effects emerge (e.g., Kluender, 1992; Hofmeister et al., 2012a,b). As Hofmeister and Sag (2010) point out, "Notably, some individuals seem fairly accepting of island violations, while others reject the same tokens. This type of variation in acceptability judgments, both within and across subjects emerges naturally on the processing account of islands. Individuals are known to differ significantly from one another in terms of working memory capacity (Daneman and Carpenter, 1980; King and Just, 1991; Just and Carpenter, 1992), and the same individual may have more or fewer resources available, depending upon factors such as fatigue, distractions, or other concurrent tasks" (p. 403). However, in cases of extreme processing difficulty, such individual differences may not emerge (e.g., Hofmeister et al., 2014).

In a series of large-scales studies, Sprouse et al. (2012) examined whether individual differences in processing resources modulate the acceptability of islands using off-line acceptability rating tasks and two measures of working memory capacity. The acceptability judgment tasks, testing four types of islands, used a factorial design manipulating the presence or absence of an island structure, as well as the position of the gap (in the matrix clause or in the embedded clause) as in (5). Sprouse et al. examined whether the combined effect of the presence of an island structure and extraction as in (5d) was "superadditive," yielding lower acceptability ratings than would be expected by the addition of the two individual factors.

(5a) Who ____ claimed that John bought the car?
NON-ISLAND/MATRIX
(5b) What did you claim that John bought ____?
NON-ISLAND/EMBEDDED
(5c) Who ___ made the claim that John bought a car?
ISLAND/MATRIX
(5d) *What did you make the claim that John bought ____?
ISLAND/EMBEDDED

According to Sprouse et al. (2012), processing accounts should further predict that effects of superadditivity or sensitivity to island violations would be reduced in those with superior processing resources. Grammatical accounts predict no such relationship. Sprouse et al. (2012) argue that their results showed no meaningful relationship between working memory and the "superadditive" effect on acceptability judgments that they observed, taking these findings to support the grammatical accounts of islands.

However, in response, Hofmeister et al. (2012a,b) point out that the lack of a relationship between acceptability ratings and processing resources in Sprouse et al. (2012) could be due to the nature of the tasks used. Hofmeister et al. argue that the stimuli tested, which included decontextualized questions with bare wh-fillers may have been particularly difficult to process, not allowing the variability in acceptability judgments that would allow a correlation to emerge. They also claim that the working memory tasks (n-back and serial recall) used in Sprouse et al. (2012) may assess short term memory, as opposed to working memory (see also Conway et al., 2005), and have not been shown to capture variability in sentence processing in other contexts.

Aldosari (2015) modified Sprouse et al.'s stimuli in order to address some of the concerns raised by Hofmeister et al. (2012a,b). In the acceptability judgment task, Aldosari included a context sentence which preceded the wh-question so as to not present decontextualized questions. The wh-questions themselves were revised to include lexical wh-fillers as opposed to bare wh-words (Hofmeister and Sag, 2010; see also Goodall,

2015). The goal of these revisions was to potentially decrease the processing difficulty in order to allow more room for variability to emerge in the judgments. Finally, a complex span task (operation span) was used. The results for both native speakers and Najdi Arabic learners of English showed, in line with Sprouse et al., clear effects of superadditivity, with low acceptance of the island sentences. In addition, the results revealed no significant relationship between working memory and sensitivity to island violations for either native speakers or L2 learners.

In addition to these recent studies examining the relationship between processing abilities and acceptability judgments, previous studies have also utilized reading-time measures in order to test whether islands can be indeed be explained via processing limitations, without recourse to grammatical constraints. The approach in these studies (e.g., Phillips, 2006; Wagers and Phillips, 2009) has been to examine whether gaps are posited in linguistic contexts that typically constitute islands, but can under some circumstances be rescued by later material in the sentence. For example, extraction from complex subjects (e.g., 6a below) is typically prohibited; however, extraction from subject islands is acceptable in "parasitic gap" constructions in which the wh-element is associated with two different gaps, one within the subject island and a second, object gap, which can "rescue" the violation (as is shown in 6b). Note, however, that a second gap cannot rescue the first if the verb is finite, as in (6c).

(6a) *What did [the plan to build *t*] ultimately destroy the house?
(6b) What did [the plan to build *t*] ultimately destroy *t* ?
(6c) *What did [the group that built *t*] ultimately destroy *t* ?

Phillips (2006) reasoned that, if the subject island in (6) results from processing pressures which simply make it too difficult to resolve the dependency there, then the possibility that extraction from that position may be rescued by the presence of a subsequent gap (as is true in non-finite structures like 6b) should not matter; a gap should never be posited in that position.

Phillips (2006) provided reading-time evidence that a gap was indeed posited within a subject island when the structure was non-finite, and thus potentially rescuable by a subsequent gap, but not when the structure was finite (see Ross, 1967). These results were taken to be consistent with grammatical accounts of islands. However, Hofmeister and colleagues challenge this interpretation, pointing out that, under their view, islands are positions that are difficult rather than impossible to extract from, and that factors like verb finiteness may indeed modulate how difficult it is to process the clause, thus rendering gap filling within the subject island more vs. less likely (Kluender, 2004; Hofmeister et al., 2013).

Using eye-tracking, Boxell and Felser (2013) replicated the results of Phillips (2006) with a group of native speakers but showed a somewhat different pattern for native German learners of English. According to first-pass reading measures, while native speakers posited gaps in islands only when such gaps might ultimately be rescued, L2 learners initially posited gaps in islands across the board (see also Kim et al., 2015). The L2 learners did however show a native-like pattern at the critical region in rereading time, a measure that includes all fixations in a region after it has been exited.

The distinct pattern that emerges in the early reading measures for the native speakers and L2 learners leads Boxell and Felser (2013) to propose that L2 processing differs significantly from native processing: while native speakers are immediately constrained by island restrictions, L2 learners' sensitivity to island constraints is delayed. A recent study by Felser et al. (2012) also argues that native and non-native processing differ in terms of the type of information that is prioritized at different stages of processing. Felser et al. (2012) conducted two experiments, one with a filled-gap paradigm and the other with a plausibility mismatch paradigm, both examining whether learners and natives would attempt to resolve wh-dependencies in non-island contexts but avoid positing gaps in relative clause islands. In the filled-gap experiment, a filled-gap effect emerged for natives at the critical region and for learners at the spillover region. Neither group attempted to resolve wh-dependencies in islands. In the plausibility mismatch experiment, it was the L2 learners who showed an immediate plausibility mismatch effect only for the non-island structures; the same effect for natives emerged in re-reading measures, also at the critical region. The results of the Boxell and Felser (2013) and Felser et al. (2012) study differ critically in that the learners in the Felser et al. study do not attempt to resolve wh-dependencies in islands at any point while the results of Boxell and Felser (2013) suggest an initial insensitivity to islands. Boxell and Felser speculate that differences in the processing complexity of the two different types of islands (subject islands vs. relative clause islands) may account for the differences in the two studies. The present study will further address whether L2 learners demonstrate island sensitivity similarly to native speakers; in addition, we bring together two strands of research discussed above by examining whether there is a relationship between individual differences and the online processing of wh-dependencies in both island and non-island contexts.

PRESENT STUDY

In the current study, we examine the relationship between working memory and filled-gap effects in both native speakers and L2 learners[1]. To our knowledge, no previous study has directly examined the relationship between processing abilities and filled-gap effects in islands, which provide an online measure of the processing of wh-dependencies. However, this approach may be advantageous as it is possible that offline measures of acceptability do not capture variability that may emerge in the course of processing the island itself. Grammatical accounts do not predict a relationship between working memory and the establishment of wh-dependencies in island contexts as the parser should simply not attempt to resolve dependencies in

[1]A reviewer suggests that it would have been beneficial to include an offline measure of acceptability. Note that this would primarily be a concern if learners do show filled-gap effects inside islands. However, even if an offline grammaticality judgment task had been included, native-like performance on this type of task would not necessarily indicate a native-like grammar of wh-dependencies (see Aldwayan et al., 2010).

grammatically unlicensed positions. In contrast, a processing account such as that proposed by Hofmeister and colleagues predicts that working memory and island sensitivity may be related (e.g., Hofmeister and Sag, 2010). Thus, as suggested by Sprouse et al. (2012), results showing that individuals with better processing abilities are better able to establish wh-dependencies in complex structures such as islands would be consistent with this kind of account, a claim that Hofmeister et al. (2012b) acknowledge to be broadly in line with their proposal.

On the other hand, finding a relationship between working memory and the processing of grammatically licensed wh-dependencies would be consistent with both proposals. One possibility is that lower working memory may lead to greater filled-gap effects in licit positions. A number of models highlight effects of distance on dependency resolution, pointing out that the resolution of wh-dependencies becomes more difficult at a greater distance (e.g., Gibson, 1998) although the reasons for these effects and the specific circumstances under which increased distance indeed engenders processing burden remain a matter of investigation (e.g., Wagers and Phillips, 2014; Nicenboim et al., 2015). Considering that wh-dependency resolution may generally become more burdensome as distance increases (thus leading the parser to resolve the dependency as soon as possible; e.g., Frazier, 1987), perhaps those participants with low working memory will show greater eagerness to quickly resolve the dependency, and thus yield greater evidence of active gap-filling than those with high working memory.

However, there is also reason to speculate that higher working memory would lead to greater filled gap-effects in licit positions. Resolving wh-dependencies involves a range of processes, from initially encoding the wh-dependency, which is argued to involve generating predictions for upcoming gap sites in advance of unambiguous bottom-up evidence (e.g., Nakano et al., 2002; Lee, 2004; Omaki et al., 2015), to maintaining and/or retrieving dependency-related information while also processing bottom-up information, monitoring for conflicts among expected and encountered material, and ultimately resolving the dependency. All of these processes have been argued to make recourse to working memory or other resources related to attentional control (e.g., Daneman and Carpenter, 1983; Engle, 2002; Hutchison, 2007; Slevc and Novick, 2013). It may thus be those with greater resources who are more likely to successfully engage these processes.

Some evidence suggesting that higher working memory may lead to greater gap-filling effects comes from Nakano et al. (2002), who examined pre-verbal gap filling in Japanese using the cross-modal lexical priming paradigm. Nakano et al. examined whether evidence for pre-verbal gap filling depended on working memory, finding that only those participants with high working memory showed evidence of pre-verbal trace reactivation (see also Roberts et al., 2007). While there remains a paucity of studies directly examining individual differences in working memory/attentional control in wh-dependency resolution (Nicenboim et al., 2015), the above evidence is consistent with the prediction that those with higher working memory may show greater filled-gap effects in licit positions.

Examples of the target stimuli in our experiment, which were adapted from Canales (2012), are given below in (7) and (8). Our first comparison involves sentences that do not contain an island structure, the *Non-Island* sentences in (7a-b). The comparison of reading times for *Non-Island* sentences that do (7a) and do not (7b) involve wh-extraction allows us to probe for filled-gap effects in licit, filled subject (*Chris*) and filled object (*Tom*) positions. Our second comparison involves sentences that contain a relative clause island, the *Island* sentences in (8a,b). The comparison of *Island* sentences that do (8a) and do not (8b) involve wh-extraction allows us to probe for filled-gap effects both in the licit filled subject position (*the actress*) and a filled object position within the relative clause island (*Tyler*).

Non-Island, No extraction

(7a) The instructor wondered if **Chris** will film **Tom** with Susan at the reception.

Non-Island, Wh-extraction

(7b) The instructor wondered who **Chris** will film **Tom** with ____ at the reception.

Island, No extraction

(8a) My father asked if **the** actress that married **Tyler** last summer kissed the director during$_{15}$ the$_{16}$ rehearsal$_{17}$.

Island, Wh-extraction

(8b) My father asked who **the** actress that married **Tyler** last summer kissed ____ during the rehearsal.

The present study examines both native speakers and native Korean learners of English in order to better understand the nature of the processing of wh-dependencies in both native and learner populations. Previous studies have shown that Korean learners may not abide by island constraints during online processing (Kim et al., 2015), which they suggest may be due to the fact that Korean is a wh-*in situ* language which does not exhibit overt wh-movement (Sohn, 1980, 1999). However, as Kim et al. (2015) acknowledge, some recent papers have suggested that wh-*in situ* languages, such as Korean, do block extraction from relative clauses, just as in English (Han and Kim, 2004; Phillips, 2013). Our previous work with Najdi Arabic learners of English has also shown that is possible for native speakers of a wh-*in situ* language to abide by island constraints during processing. Thus, we include both native speakers and Korean learners of English to compare native and non-native processing broadly, but not necessarily to examine potential effects of L1 transfer.

The present study examines whether native speakers and learners show qualitatively similar patterns, as has been shown in some studies (e.g., Aldwayan et al., 2010; Omaki and Schulz, 2011), or whether learners are unable to use syntactic information on the same timecourse as native speakers (Felser et al., 2012; Boxell and Felser, 2013). If the two groups show qualitatively similar patterns, a filled-gap effect should emerge at the grammatically licensed direct object position in the *Non-Island* sentences (*Tom* in 7b) but not within the relative clause island in the *Island* sentences (*Tyler* in 8b) for both groups. In contrast, if learners are unable to prioritize syntactic information and use it in the earliest stages of processing (Felser et al., 2012), then learners should either show filled-gap effects at the direct

object positions in both the *Non-Island* and *Island* sentences, suggesting an attempt to resolve wh-dependencies within islands (Boxell and Felser, 2013; Kim et al., 2015) or they should show sensitivity to island contexts only at a delay. With respect to the second possibility, learners may, for example, pattern similarly to native speakers, positing a gap in (7b) and avoiding positing a gap within the island (no difference between 8b) but this pattern should emerge on a different timecourse from native speakers, perhaps emerging at a region later in the sentence as has been observed in previous studies (e.g., Felser et al., 2012). We will also examine effects at the licit filled subject positions in both Non-Island and Island sentences (*Chris* in 7b; *the actress* in 8b). However, as discussed above, the inconsistency of subject filled-gap effects in both native speakers and L2 learners in previous experiments using this same design (Stowe, 1986; Lee, 2004; Aldwayan et al., 2010; Canales, 2012) does not allow us to make strong predictions regarding similarities and differences between learners and native speakers. We will return to this issue in the discussion.

The study also examines the nature of islands, investigating whether there is a relationship between working memory and the processing of wh-dependencies in islands. No such relationship is predicted by the grammatical accounts. A positive relationship between working memory and the size of the filled-gap effect in the object position within the relative clause island (*Tyler* in 8a,b) would be consistent with Hofmeister and colleagues' versions of the processing account (e.g., Hofmeister et al. 2012a,b, 2014). Any significant relationships that emerge between working memory and the grammatically licensed potential gap sites (subject positions in 7b and 8b, object position in 7b) would be consistent with both proposals[2].

MATERIALS AND METHODS

Participants

Forty-nine advanced Korean learners of English and 54 native English speakers participated in the study. The Korean learners (mean age = 28.41; 28 females) were recruited from the University of Kansas and its surrounding community; their mean age of arrival was 22.89 years old. All learners reported no significant exposure to English before age of 12, and no learner reported significant exposure to any wh-movement language other than English. The learners' English proficiency was assessed using the University of Michigan Listening Comprehension Test, a 45 question test which covers various aspects of English grammar (mean proficiency score = 39.39). Eight additional Korean learners and eight additional native English speakers also participated in the study, but were identified as outliers with respect to magnitude of their filled-gap effects and excluded from the final analysis of the data, and one additional English speaker also participated but was excluded from the final analysis for showing exceptionally fast reading times (faster than 250 ms) across regions, as described in the *Data Analysis* section below. The Korean learners of English were provided with payment for their participation, and the native English speakers (mean age = 21.15; 41 females), who were all students at the University of Kansas, completed the study for extra credit. This study was approved by the Institutional Review Board of the University of Kansas and all participants provided their written informed consent before participating.

Stimuli

Non-Island stimuli

The *Non-Island* stimuli included 20 pairs of sentences, with each pair consisting of a control sentence with no extraction (9a) and a matched wh-extraction sentence (9b); the region number for each word is indicated by the subscripts in (9). A full list of stimuli is provided as Supplementary Material.

Non-Island, No extraction

(9a) The$_1$ instructor$_2$ wondered$_3$ if$_4$ **Chris**$_5$ will$_6$ film$_7$ **Tom**$_8$ with$_9$ Susan$_{10}$ at$_{11}$ the$_{12}$ reception$_{13}$.

Non-Island, Wh-extraction

(9b) The$_1$ instructor$_2$ wondered$_3$ who$_4$ **Chris**$_5$ will$_6$ film$_7$ **Tom**$_8$ with$_9$ _____$_{10}$ at$_{11}$ the$_{12}$ reception$_{13}$.

The wh-structure in (9b) involves extraction from the grammatically licit prepositional object position (region 10). Preceding this position are two grammatically licit potential gap positions that are filled with lexical material: the embedded subject position (region 5) which is filled with the subject *Chris*, and the post-verbal direct object position (region 8) which is filled with the object *Tom*; these positions are bolded in example (9) above. These two regions and their spillover regions (region 6 and 9, respectively) serve as critical regions to test for filled-gap effects in positions from which wh-extraction is grammatically licit.

The embedded verbs used in region 7 were all transitive verbs. The prepositional objects (region 8) were all proper names that were three letters long, and the embedded subjects (region 5) were all proper names as well (mean length = 5.4 letters, range 4–11 letters).

Island stimuli

The *Island* stimuli included 20 additional pairs of sentences, with each pair consisting of a control sentence with no extraction (10a) and a matched wh-extraction sentence (10b).

Island, No extraction

(10a) My$_1$ father$_2$ asked$_3$ if$_4$ **the**$_5$ actress$_6$ that$_7$ married$_8$ **Tyler**$_9$ last$_{10}$ summer$_{11}$ kissed$_{12}$ the$_{13}$ director$_{14}$ during$_{15}$ the$_{16}$ rehearsal$_{17}$.

Island, Wh-extraction

[2]A reviewer asked us to specify the predictions for the relationship between working memory and the size of the filled-gap effect if the Korean learners of English do not in fact show knowledge of syntactic constraints. If the Korean learners of English do not pattern similarly to the native speakers, then the specific nature of the relationship between working memory and the size of the filled-gap effect would need to be examined. For example, if Korean learners of English are found to establish wh-dependencies in islands, and further, if those learners with higher working memory resources showed larger filled-gap effects within islands, then the results would support a processing account. Note, however that, in our results, the Korean learners of English do show similar island sensitivity to the native speakers.

(10b) My$_1$ father$_2$ asked$_3$ who$_4$ **the**$_5$ actress$_6$ that$_7$ married$_8$ **Tyler**$_9$ last$_{10}$ summer$_{11}$ kissed$_{12}$ ____$_{13-14}$ during$_{15}$ the$_{16}$ rehearsal$_{17}$.

The wh-structure in (10b) involves extraction from the grammatically licit object position (regions 13–14). Crucially, preceding this position is a relative clause island, from which wh-extraction is illicit. While the relative island contains a post-verbal object position (region 9) filled with a proper name (*Tyler*, in 10b above), extraction from this position is not grammatically licensed. Thus, region 9 and its spillover region (region 10) serve as critical regions to probe for filled-gap effects in a grammatically illicit position (within a relative clause island). Region 5 and its spillover region (region 6) constitute the filled embedded subject position, a grammatically licit site for extraction. Like the embedded subject position in the *Non-Island* sentences, the embedded subject region 5 and its spillover region (region 6) serve as critical regions to test for filled-gap effects in the grammatically licit, subject position.

The verbs inside the relative clause island (region 8) were all transitive verbs. The post-verbal object position within the island (region 9) was always filled with a proper name that was five letters long. An adverbial phrase (e.g., *last summer*) always followed region 9 (e.g., *Tyler*) in order to provide a spillover region following the post-verbal object position that would precede the verb that licenses the actual gap position in the wh-extraction sentence (e.g., *kissed*). The embedded subject position from which extraction is grammatically licensed (region 5 and its spillover region, region 6) were comprised of a determiner-noun combination; the determiner in region 5 was always the three-letter-long determiner "the."

The 20 the *Non-Island* sentences, the 20 *Island* sentences, and 80 filler sentences were presented together, yielding a 1:2 target-to-filler ratio. Two Latin-square lists were created, such that every participant was presented with either the extraction or no-extraction version of every sentence, but no participant read more than one version of a given sentence. The sentences were presented in different randomized order for each participant.

Procedure

All participants completed a background questionnaire, the self-paced reading task, and then two working memory tasks (the reading span task and the counting span task) which are described below; the order of the two working memory tasks was counterbalanced across participants. Korean learners of English also completed the University of Michigan Listening Comprehension Test (1972), after completing all other tasks. The self-paced reading task, working memory tasks and proficiency test were all administered using *Paradigm* presentation software (Tagliaferri, 2005).

Self-Paced Reading Task

Each sentence was presented word-by-word in a non-cumulative moving window self-paced reading paradigm (Just et al., 1982). At the beginning of each trial, each word of the sentence was masked by a series of dashes; this masking included words and punctuation, but did not include the spaces between words. Each time the participant clicked a mouse button to advance through the sentence, the next word was unmasked, and the previous word was masked again. After the last word of each sentence, the sentence was then presented again in full, but with one word missing (e.g., "My _____ asked if the actress that married Tyler last summer kissed the director during the rehearsal."). Participants selected the missing word from among two options (e.g., "father" and "sister") which were presented on the screen, by pressing the appropriate key on the computer keyboard (either the key labeled "L" for the word on the left of the screen, or that labeled "R" for the word on the right of the screen). Prior to the experiment, participants completed a practice session consisting of five practice sentences. Participants were instructed to read the sentences naturally for comprehension, and to answer the end-of-sentence question as accurately as possible. Breaks were provided after 40 and 80 trials.

Working Memory Tasks

Participants completed a verbal measure of working memory, the reading span task (Daneman and Carpenter, 1980), and a non-verbal measure of working memory, the counting span task (Case et al., 1982). These tasks are argued to reflect working memory rather than short-term memory, as they involve both a memory component and a processing component, which interferes with rehearsal. Both tasks were presented to the native English speakers and the Korean learners of English in their native language, as it has been argued that measures of working memory capacity which are given in the second language are affected by the second language learners' English proficiency (e.g., Harrington and Sawyer, 1992; Juffs and Harrington, 2011).

In the reading span task, following the protocol in Conway et al. (2005), participants were asked to read sentences out loud and make sensicality judgments, while remembering random letters of the alphabet which followed each sentence (Kim, 2008). On each trial, the participant read the sentence out loud into a microphone, provided the sensicality judgment, and then said the letter that followed the sentence out loud, which triggered the next sentence in the series to immediately appear. After a series of 2–5 sentences, the participant was shown a screen prompting them to enter the letters that followed the previous set of sentences. Participants entered the recalled letters into boxes on this screen and were instructed to use a period (.) as a placeholder for letters that they could not recall.

The counting span task required participants to count target visual stimuli mixed in with distractor stimuli in a series of successive displays, while remembering the total number of target stimuli for each individual display (Conway et al., 2005). In each trial, the participant was presented with an array of target objects (dark blue circles) and distractor objects (light green circles); upon presentation of this array, the participant counted the number of target stimuli out loud, repeating the total, at which point the experimenter immediately entered the total using a computer keyboard, which triggered the next trial to begin. After a series of 2–6 trials, the participant was shown a screen prompting them to enter the total number of target objects from each of the previous arrays they had been presented. Participants entered the totals that they recalled into boxes on this screen, and

entered a period (.) as a placeholder for any totals that they could not recall.

For both the reading span task and the counting span task, participants were instructed to respond as quickly and accurately as possible. Stimuli within each task were presented in a randomized order. The entire testing session, including all of the above-mentioned tasks, took ∼60 min for native English speakers and 75 min for the Korean learners of English.

Data Analysis

As mentioned in the *Participants* section above, in addition to the 49 advanced Korean learners of English (mean age = 28.41; range 18–48 years old) and 54 native English speakers (mean age = 21.09; range 17–65 years old) reported in the current study, eight additional Korean learners of English and eight native English speakers were initially tested but identified as outliers and excluded from the final analysis, since their filled-gap effects were >3 standard deviations from the mean effect size of the dataset as a whole. Using filled-gap effect size as a value for identifying outliers is motivated by the fact that filled-gap effect size is a primary variable of interest in the regression analyses reported below. While these outliers are of most concern for the regression analyses, in order to keep the participant groups identical in the ANOVA analyses reported below (which probe for the presence of filled-gap effects in grammatically licit positions and for the avoidance of gap-filling inside islands) and in the regression analyses (which examine the relationships between individuals' filled-gap effect size and working memory), these participants were removed from both types of analysis. One additional native English speaker was also removed prior to analysis as this participant read at an extremely fast rate (faster than 250 ms) across regions and conditions.

For the dataset reported here, overall mean accuracy rate for the end-of-sentence question was 96.3% for native speakers and 93.4% for Korean learners of English; no participant in either group performed at <80% accuracy. Only those trials for which the end-of-sentence question was answered correctly were carried forward for statistical analysis. For *Non-Island* sentences, this resulted in exclusion of 3.43% of the data for native English speakers and 6.43% of the data for the Korean learners of English. For *Island* sentences, this resulted in exclusion of 3.8% of the data for the native English speakers and 6.73% of the data for the Korean learners of English.

Residual reading times were calculated by subtracting the raw reading time from the reading time predicted given a word's length by a regression equation that was constructed separately for each participant. Residual reading times beyond 2 standard deviations from the participant's mean for a given condition in a given region were excluded from the analysis (Ratcliff, 1993). For *Non-Island* sentences, this resulted in exclusion of 3.88% of the data for the native English speakers and 3.85% of the data for the Korean learners of English. For *Island* sentences, this resulted in exclusion of 4.1% of the data for the native English speakers and 4.03% of the data for the Korean learners of English.

2 × 2 mixed repeated-measures ANOVAs were performed on the remaining data, both by participants (F_1) and by items (F_2). For both the *Non-island* and the *Island* comparisons, the between-subjects factor was Group (native vs. learner) and the within-subjects factor was Condition (wh-extraction vs. no extraction). The critical regions for *Non-Island* sentences were region 8 (object filled-gap) and its spillover region (region 9), as well as region 5 (subject filled-gap) and its spillover region (region 6). The critical regions for *Island* sentences were region 9 (illicit object filled-gap within the relative clause island) and its spillover region (region 10), as well as region 5 (subject filled-gap) and its spillover region (region 6).

We also conducted a regression analysis to examine the relationship between filled-gap effect size and working memory both in grammatically licit positions and inside islands. For this analysis, we calculated for each individual the difference in mean reading times between the no extraction and wh-extraction conditions (subtracting the no extraction from the wh-extraction condition) in a given critical region; this measure, which we refer to throughout as Filled-gap Effect Size, serves as the dependent variable for the regression analyses. In order to obtain an independent variable reflecting working memory, we averaged for each individual their scores on the reading span task and the counting span task to create a Combined Working Memory Score. We use this score rather than the separate scores for each of the two working memory measures because the scores on these two measures are highly correlated ($r = 0.528$, $p < 0.001$). Because cognitive functioning, which includes working memory, declines with age (e.g., Hess, 2005; Oberauer, 2005; McArdle et al., 2007; Nettelbeck and Burns, 2010; Wass et al., 2012), we also control for age in our regression models. For both the ANOVA analyses and the regression analyses, we interpret $p < 0.05$ as significant and p-values between 0.05 and 0.10 as marginal.

Working memory score was calculated as a score from 1 to 100 based on percent of letters (for the reading span task) or numbers (for the counting span task) that were accurately recalled. Korean learners of English scored an average of 61.95% (range of 33.46–93.75%) on this composite measure of working memory, as compared to 59.73% (range of 29.25–88.93%) for native speakers of English. We used partial-unit scoring such that participants were given credit for each letter or number recalled in the correct position within a given trial. Performance on the processing tasks was not included in the working memory score, following the protocol outlined in Conway et al. (2005), who discuss the fact that accuracy on the processing tasks often correlates with the recall accuracy of the target items[3].

To address whether higher working memory capacity facilitates gap filling within or outside islands, we completed a sequential regression analysis for each critical and spillover region, while controlling for the effects of age. Filled-gap Effect

[3]Following a reviewer's suggestion, we examined the relationship between the recall and processing components of the working memory tasks. Recall and accuracy scores for the counting span task were significantly correlated ($r = 0.300$, $p = 0.002$) and those for the reading span task were moderately correlated ($r = 0.181$, $p = 0.067$). While there was a small but positive correlation between these components, we ran new regression models using a new composite working memory score which incorporated participants' performance on both the recall and processing components for each task (using an average of the processing and recall scores), in line with Waters and Caplan (1996). The pattern of results remains unchanged in these new analyses.

Size at each region was regressed on age, centered scores of Combined Working Memory, and Group (native = 0, L2 learner = 1) in the first block of a sequential regression. The cross-product of the centered Combined Working Memory scores and Group was then added in the second block and ΔR^2 was examined to determine if an interaction between groups was present. Follow-up analyses were conducted for those regions showing an interaction.

RESULTS

Filled-Gap Effects

Object Filled-Gap Effects

In the *Non-Island* comparison, the results of the mixed repeated measures ANOVA for region 8, the critical post-verbal object position from which extraction is grammatically licit, did not reveal main effects of Group [$F_{1(1,\ 101)} = 0.18$, $p = 0.67$; $F_{2(1,\ 38)} = 0.004$, $p = 0.95$] or Condition [$F_{1(1,\ 101)} = 0.802$, $p = 0.372$; $F_{2(1,\ 38)} = 2.160$, $p = 0.15$]. Furthermore, there was no interaction between these factors [$F_{1(1,\ 101)} = 0.308$, $p = 0.58$; $F_{2(1,\ 38)} = 2.750$, $p = 0.11$]. However, a main effect of Condition emerged at region 9 [$F_{1(1,\ 101)} = 6.032$, $p < 0.05$; $F_{2(1,\ 38)} = 13.967$, $p < 0.01$], reflecting a reading time slowdown in the wh-extraction condition as compared to the no extraction condition. There was no main effect of Group [$F_{1(1,\ 101)} = 0.657$, $p = 0.419$; $F_{2(1,\ 38)} = 1.909$, $p = 0.18$] nor was there an interaction at region 9 between Group and Condition [$F_{1(1,\ 101)} = 1.609$, $p = 0.207$; $F_{2(1,\ 38)} = 0.160$, $p = 0.69$]. Mean reading times for native English speakers in the *Non-Island* sentences are shown in **Figure 1**, and those for Korean learners of English are shown in **Figure 2**.

For the *Island* comparison, no main effects of Group [$F_{1(1,\ 101)} = 0.208$, $p = 0.65$; $F_{2(1,\ 38)} = 1.479$, $p = 0.23$] or Condition [$F_{1(1,\ 101)} = 0.779$, $p = 0.38$; $F_{2(1,\ 38)} = 1.269$, $p = 0.27$] emerged at the critical region 9, the post-verbal object position within the relative clause island. There was a marginal Group by Condition interaction at region 9 in the by-participants analysis [$F_{1(1,\ 101)} = 3.008$, $p = 0.09$; $F_{2(1,\ 38)} = 2.177$, $p = 0.148$]. However, *post-hoc* *t*-tests revealed that the reading time difference between the wh-extraction condition and the no extraction condition was not significant for either native English speakers [$t_{(53)} = -0.729$, $p = 0.47$, two-tailed paired *t*-test] or Korean learners of English [$t_{(48)} = 1.578$, $p = 0.12$, two-tailed paired *t*-test]. At the spillover region, region 10, there was a main effect of Group in the by-items analysis only [$F_{1(1,\ 101)} = 0.365$, $p = 0.55$; $F_{2(1,\ 38)} = 4.173$, $p < 0.05$]. This effect reflected the fact that residual reading times were slower overall for Korean learners of English than for native English speakers. Additionally, there was an effect of Condition in region 10 which reached significance only in the by-items analysis [$F_{1(1,\ 101)} = 2.605$, $p = 0.11$; $F_{2(1,\ 38)} = 5.240$, $p < 0.05$]. However, this effect was in the opposite direction of what would be expected if a filled-gap effect were to emerge; participants read faster in the wh-extraction condition as compared to the no extraction condition. There was also no interaction between Group and Condition at region 10 [$F_{1(1,\ 101)} = 0.096$, $p = 0.76$; $F_{2(1,\ 38)} = 0.484$, $p = 0.49$]. Overall, the results from the *Non-Island* comparison indicate that, although numerically small, a significant filled-gap effect emerged for both groups at the spillover region of the filled direct object position. In contrast, as evidenced by the results from the *Island* comparison, neither native English speakers, nor Korean learners of English show a filled-gap effect within the relative clause island. Mean reading times for the *Island* sentences for native English speakers are illustrated in **Figure 3**, and those for Korean learners of English are shown in **Figure 4**.

Subject Filled-Gap Effects

In addition to examining whether native English speakers and Korean learners of English showed evidence of object filled-gap effects, we also examined the critical region 5 and spillover region 6 in both the *Non-Island* and the *Island* sentences for possible subject filled-gap effects. Recall that for both sentence types, the subject gap positions are licit positions for wh-extraction.

In the *Non-Island* comparison, there was no effect of Condition in either region 5 [$F_{1(1,\ 101)} = 1.612$, $p = 0.21$; $F_{2(1,\ 38)} = 2.523$, $p = 0.12$] or region 6 [$F_{1(1,\ 101)} = 0.926$, $p = 0.34$; $F_{2(1,\ 38)} = 2.082$, $p = 0.16$]. There was an effect of Group in region 5 [$F_{1(1,\ 101)} = 17.157$, $p < 0.001$; $F_{2(1,\ 38)} = 4.990$, $p < 0.05$], reflecting the fact that Korean learners of English yielded slower residual reading times overall compared to native English speakers. There was no effect of Group in region 6 [$F_{1(1,\ 101)} = 0.05$, $p = 0.82$; $F_{2(1,\ 38)} = 0.010$, $p = 0.92$]. There was no interaction between Group and Condition in either the critical region 5 [$F_{1(1,\ 101)} = 0.309$, $p = 0.579$; $F_{2(1,\ 38)} = 0.069$, $p = 0.79$] or the spillover region 6 [$F_{1(1,\ 101)} = 0.257$, $p = 0.61$; $F_{2(1,\ 38)} = 1.465$, $p = 0.23$].

In the *Island* comparison, there was a main effect of Condition at region 5 [$F_{1(1,\ 101)} = 7.308$, $p < 0.01$; $F_{2(1,\ 38)} = 6.769$, $p < 0.05$] reflecting that participants showed a reading time slowdown in the wh-extraction condition as compared to the no extraction condition. There was no effect of Group at region 5 [$F_{1(1,\ 101)} = 0.029$, $p = 0.87$; $F_{2(1,\ 38)} = 0.173$, $p = 0.68$]. There was a marginal interaction in the by-participants analysis, and a significant interaction in the by-items analysis between Group and Condition at region 5 [$F_{1(1,\ 101)} = 3.759$, $p = 0.055$; $F_{2(1,\ 38)} = 9.826$, $p < 0.01$]. *Post-hoc* *t*-tests revealed that native English speakers showed a significant slowdown in the wh-extraction condition as compared to the no extraction condition [$t_{1(53)} = -3.507$, $p < 0.01$, two-tailed paired *t*-test; $t_{2(19)} = -5.284$, $p < 0.01$, two-tailed paired *t*-test]. However, the effect of Condition for Korean learners of English at region 5 was not significant [$t_{1(48)} = -0.506$, $p = 0.62$, two-tailed paired *t*-test; $t_{2(19)} = 0.317$, $p = 0.75$, two-tailed paired *t*-test]. At the spillover region 6, there was no main effect of Condition [$F_{1(1,\ 101)} = 0.492$, $p = 0.49$; $F_{2(1,\ 38)} = 0.067$, $p = 0.80$]. There was an effect of Group [$F_{1(1,\ 101)} = 13.117$, $p < 0.001$; $F_{2(1,\ 38)} = 2.696$, $p = 0.11$] reflecting slower residual reading times overall for Korean learners of English than for native English speakers. There was no interaction between Group and Condition at region 6 [$F_{1(1,\ 101)} = 0.016$, $p = 0.90$; $F_{2(1,\ 38)} = 0.745$, $p = 0.39$]. Thus, subject filled-gap effects emerged only for native English speakers, and only at the critical region in the *Island* comparison.

Results: Effects of Working Memory on Filled-Gap Effect Size

Gap-Filling within Islands

Regression models for the critical and spillover filled-gap regions (regions 9 and 10) within the relative clause island in *Island* sentences were not significant. For region 9, the first block of the sequential regression was not significant [adjusted $R^2 = 0.002$, $F_{(3, 99)} = 1.055$, $p = 0.372$]. The addition of the cross-product of Combined Working Memory and Group in the second block did not significantly increase the variance explained by the model [$\Delta R^2 = 0.000$, adjusted $R^2 = -0.009$, $F_{(1, 98)} = 0.001$, $p = 0.982$]. Similarly, for region 10 the first block of the sequential regression was not significant [adjusted $R^2 = 0.008$, $F_{(3, 99)} = 1.267$, $p = 0.29$]. The addition of the cross-product of Combined Working Memory and Group in the second block did not significantly increase the variance explained by the model [$\Delta R^2 = 0.000$, adjusted $R^2 = -0.002$, $F_{(1, 98)} = 0.000$, $p = 1.00$]. Thus, working memory does not predict gap-filling in positions which are subject to island constraints.

Gap-Filling in Grammatically Licit Positions

As individual differences in working memory may affect the resolution of wh-dependencies in grammatically licensed positions, we also examined whether working memory modulated the magnitude of filled-gap effects in the following positions: the filled object position in *Non-Island* sentences, and the filled subject position in both *Non-Island* and *Island* sentences.

Object Filled-Gap: Non-Island Sentences

No significant effect of Working Memory on Filled-gap Effect Size was found at the critical region 8 for the object filled-gap. In region 8, the first block of the sequential regression was not significant [adjusted $R^2 = 0.016$, $F_{(3, 99)} = 1.539$, $p = 0.209$]. The addition of the cross-product of Combined Working Memory and Group in the second block did not significantly increase the variance explained by the model [$\Delta R^2 = 0.003$, adjusted $R^2 = 0.008$, $F_{(1, 98)} = 0.285$, $p = 0.595$]. A significant effect of Working Memory on Filled-gap Effect Size was found at the spillover region for the object filled-gap. For region 9 the first block of the sequential regression was not significant [adjusted $R^2 = -0.001$, $F_{(3, 99)} = 0.949$, $p = 0.42$]. However, the addition of the cross-product of Combined Working Memory and Group in the second block significantly increased the variance explained by the model [$\Delta R^2 = 0.043$, adjusted $R^2 = 0.034$, $F_{(1, 98)} = 4.584$, $p < 0.05$]. Thus, the effect of working memory on object filled-gap effects in the spillover region depends on group membership. In follow-up analyses, the regression slopes were plotted separately by Group (**Figure 5**). To examine the differences in slope for the two groups, follow-up regression analyses were performed separately for native speakers and learners. The results show that the regression of Working Memory on Filled-gap Effect Size for native speakers, when controlling for age, was not significant [adjusted $R^2 = 0.002$, $F_{(2, 51)} = 1.049$, $p = 0.358$]. The regression of Working Memory and Age on Filled-gap Effect Size for Koreans was significant [adjusted $R^2 = 0.131$, $F_{(2, 46)} = 4.626$, $p < 0.02$]. When controlling for age, working memory had a moderately significant effect on Filled-gap Effect Size. For every one standard deviation increase in working memory score, Filled-gap Effect Size decreased by 0.268 standard deviations [$b = -1.40$, $t_{(46)} = -1.96$, $p = 0.056$, $\beta = -0.268$, 95% CI (-2.84 -0.036)]. Thus, the data shows a trend suggesting that working memory predicts the degree of Filled-gap Effect Size at the spillover object filled-gap region for Korean learners of English, but not native English speakers. Specifically, an increase in working memory predicts a reduced Filled-gap Effect Size, and thus decreased filled-gap effects, at the spillover region 9 in Korean learners of English.

Subject Filled-Gap: Non-Island Sentences

For the critical subject filled-gap region in the *Non-Island* sentences (region 5), the first block of the sequential regression

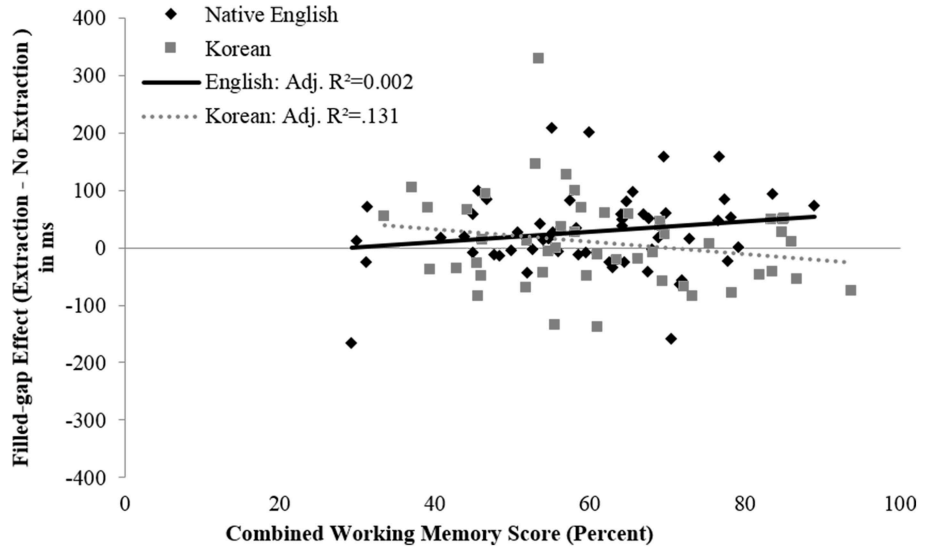

FIGURE 5 | Filled-gap effect size as a function of combined working memory score for the spillover region (region 9) of the licit object filled-gap position in Experiment 1. Linear trend lines (least-squares method) are illustrated in the figure; adjusted R^2-values are provided in the legend.

was not significant [adjusted $R^2 = 0.016$, $F_{(3, 99)} = 1.55$, $p = 0.206$]. However, the addition of the cross-product of Combined Working Memory and Group in the second block significantly increased the variance explained by the model [$\Delta R^2 = 0.084$, adjusted $R^2 = 0.093$, $F_{(1, 98)} = 9.392$, $p < 0.01$]. Thus, the effect of working memory on gap-filling, when controlling for age, depends on Group.

To better understand the nature of the moderation, the regression slopes were plotted separately by Group (**Figure 6**). To examine the differences in slope for the two groups at region 5, follow-up regression analyses were performed separately for the two groups. The results show that the regression of Working Memory on Filled-gap Effect Size for native speakers was significant [adjusted $R^2 = 0.2$, $F_{(2, 51)} = 7.621$, $p < 0.01$]. For every one standard deviation increase in working memory score, Filled-gap Effect Size increased by 0.433 standard deviations, when controlling for age [$b = 3.029$, $t_{(51)} = 3.506$, $p < 0.01$, $\beta = 0.433$, 95% CI (1.30–4.76)]. However, the effect of Working Memory on Filled-gap Effect Size for Korean learners of English was not significant [adjusted $R^2 = -0.017$, $F_{(2, 46)} = 0.602$, $p = 0.552$]. Thus, the data suggests that working memory does predict reading times at the subject filled-gap region for native English speakers, but not for Korean learners of English. Specifically, an increase in working memory predicts an increased slowdown, or filled-gap effect, at the filled subject gap region 5 in native speakers of English.

In the spillover region 6 for the subject filled-gap in the Non-Island sentences, the first block of the sequential regression was not significant [adjusted $R^2 = -0.022$, $F_{(3, 99)} = 0.253$, $p = 0.859$]. The addition of the cross-product of Combined Working Memory and Group in the second block did not significantly increase the variance explained by the model [$\Delta R^2 = 0.015$, adjusted $R^2 = -0.017$, $F_{(1, 98)} = 1.493$, $p = 0.225$].

Subject Filled-Gap: Island Sentences

For region 5 in the *Island* sentences, the first block of the sequential regression was not significant [adjusted $R^2 = 0.012$, $F_{(3, 99)} = 1.425$, $p = 0.24$]. The addition of the cross-product of Combined Working Memory and Group in the second block increased the variance explained by the model by a significant amount [$\Delta R^2 = 0.048$, adjusted $R^2 = 0.052$, $F_{(1, 98)} = 5.186$, $p < 0.05$]. However, follow-up regression analyses performed separately for the two groups found that the regression of Working Memory on Filled-gap Effect Size for Native Speakers, when controlling for age, was not significant [adjusted $R^2 = 0.016$, $F_{(2, 51)} = 1.418$, $p = 0.252$]. The regression of Working Memory on Filled-gap Effect Size for Korean learners of English, when controlling for age, was also not significant [adjusted $R^2 = 0.018$, $F_{(2, 46)} = 1.434$, $p = 0.249$]. There were no significant effects in the spillover region 6 in the *Island* sentences. The first block of the sequential regression was not significant [adjusted $R^2 = -0.021$, $F_{(3, 99)} = 0.302$, $p = 0.824$]. The addition of the cross-product of Combined Working Memory and Group in the second block did not significantly increase the variance explained by the model [$\Delta R^2 = 0.002$, adjusted $R^2 = -0.030$, $F_{(1, 98)} = 0.160$, $p = 0.690$].

DISCUSSION

The present study examined whether native speakers and L2 learners show qualitatively similar patterns in the processing of wh-dependencies in both licit and illicit contexts. Previous studies have shown that native speakers attempt to resolve wh-dependencies in grammatically licensed positions but avoid positing gaps in islands (Stowe, 1986; Traxler and Pickering, 1996). In the present study, we replicated this pattern for native English speakers and showed the same pattern of results for advanced Korean learners of English as well. In the non-island

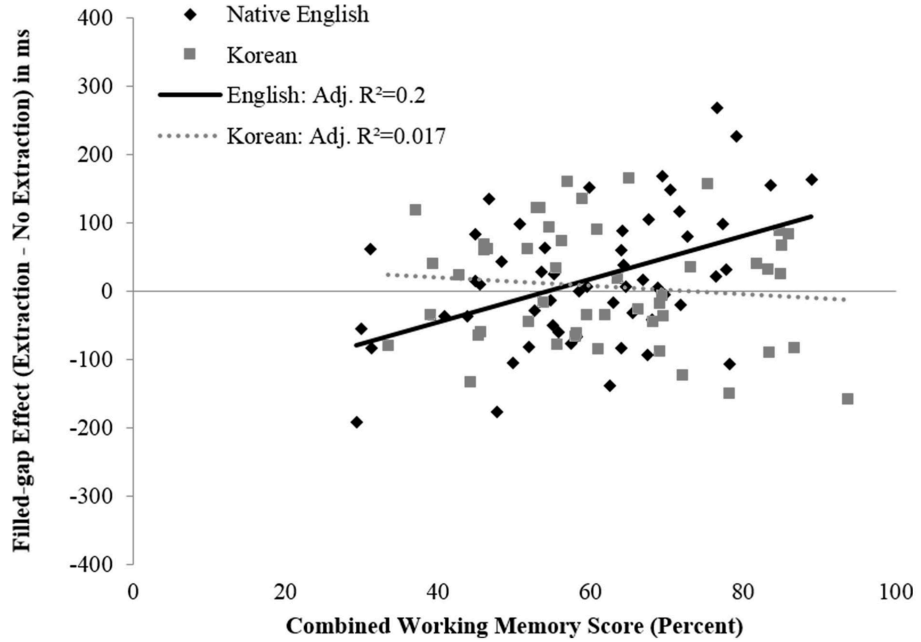

FIGURE 6 | Filled-gap effect size as a function of combined working memory score for the licit subject filled-gap position (region 5) in Experiment 1. Linear trend lines (least-squares method) are illustrated in the figure; adjusted R^2-values are provided in the legend.

sentences, a significant filled-gap effect emerged in the spillover region following the direct object of the verb. A significant interaction with group did not emerge, demonstrating qualitative similarity between the two groups. In Felser et al. (2012), evidence of a filled-gap effect emerged for L2 learners in a later region than the region in which the effect emerged for native speakers, a result which supported their proposal that learners cannot use syntactic information on the same timecourse as native speakers[4]. In contrast, the results of the present study are in line with our previous work, which also showed the same pattern for L2 learners and natives (Aldwayan et al., 2010). While it is true that self-paced reading does not allow the same range of dependent measures as eye-tracking in terms of characterizing the timecourse of processing, it is important to point out that in the Felser et al. (2012) study, the filled-gap effects for natives and learners emerged in distinct regions, not in different dependent measures within the same region.

In contrast to the non-island sentences, where significant object filled-gap effects emerged for both groups, there were no object filled-gap effects in island sentences, in which the critical region was embedded within a relative clause island. Our results are in line with several previous studies which have examined relative clause islands and have shown that learners avoid attempting to resolve wh-dependencies in grammatically unlicensed contexts (Aldwayan et al., 2010; Omaki and Schulz, 2011; Felser et al., 2012; Kim et al., 2015 for Spanish natives)[5]. In the current literature, both studies which showed evidence of gap-filling in islands by L2 learners used a plausibility mismatch paradigm (Boxell and Felser, 2013 in first pass reading measures; Kim et al., 2015 for Korean natives). However, it is important to point out that in the Felser et al. (2012) study, which also used a plausibility mismatch paradigm, learners showed effects of plausibility even earlier than natives but at no point did they show evidence of attempting to resolve wh-dependencies in islands.

Our examination of the subject position yielded a significant subject filled-gap effect for native speakers, but only in island sentences[6]. As we discussed above, this inconsistency across experiments and groups is in line with previous studies. There

[4]A reviewer suggests that the results of the present study may differ from the results of previous studies which showed differences between learners and native speakers because of differences in proficiency levels. The learners in the present study scored between intermediate and advanced levels on the proficiency test and were immersed in the L2 environment. However, the Felser et al. (2012) study also included intermediate-advanced learners who were immersed in an English-speaking environment. As different proficiency measures were used across studies, it is hard to directly compare proficiency levels.

[5]As a reviewer pointed out, the lexical items in the *Non-Island* and the *Island* sentences are not the same, questioning whether this may complicate interpretation of the findings. Our overall finding of a filled-gap effect in the licit object position, and avoidance of a filled-gap effect in object position within an island converges with a range of previous studies using either filled-gap or plausibility manipulations and more closely matched lexical material (e.g., Stowe, 1986; Traxler and Pickering, 1996; Omaki and Schulz, 2011; Felser et al., 2012). However, we agree that a future extension of the current study, with closely matched lexical items across the *Non-Island* and *Island* conditions would be ideal for addressing this open question.

[6]A reviewer pointed out that lexical differences may have played in a role in the distribution of the subject filled-gap effect, which emerged only in the Non-Island comparison. Indeed, as the lexical subject was a proper name in the first comparison but a determiner-noun sequence in the second comparison, this is a possibility. Although very few studies report significant subject filled-gap effects, across studies, significant effects have been reported for both determiner-noun sequences (e.g., Aldwayan et al., 2010) and proper names (e.g., Lee, 2004; Johnson, 2015). Moreover, not all studies which include a proper name in subject position

is an extensive literature discussing why evidence for filled-gap effects in subject position is mixed (Stowe, 1986; Clifton and Frazier, 1989; Clifton and De Vincenzi, 1990; De Vincenzi, 1991; Gibson et al., 1994; Lee, 2004; Johnson, 2015): several researchers have proposed that the adjacency of the wh-filler and the subject position may not provide sufficient time to either generate or commit to a prediction for a subject gap. This proposal would suggest that allowing more time, in terms of the distance between the wh-filler and subject position, may yield different results (see Lee, 2004). Also related to this proposal, one might also expect that individuals with greater processing resources would be more likely to be able to immediately generate a prediction for a subject gap; we will return to this point below in our discussion of individual differences.

The present study also examined the nature of islands by investigating the relationship between working memory and filled-gap effects in both native speakers and L2 learners. A pattern of results showing that individuals with more processing resources are better able to establish wh-dependencies in islands would be compatible with the processing account proposed by Hofmeister and colleagues (e.g., Hofmeister and Sag, 2010). In contrast, grammatical accounts do not predict such a relationship within islands as the parser should simply not predict a gap within island contexts. Note however that a pattern of results that shows no relationship between working memory and filled-gap effects within islands is also potentially compatible with the processing accounts as null results may be explained by a range of factors including, as discussed by Hofmeister et al. (2012a,b, 2013, 2014) inappropriate choice of working memory measures and selection of stimuli that are simply too complex for individual differences to emerge. As our results showed that there was indeed no significant relationship between working memory and filled-gap effects in island contexts for either native speakers or learners, we will consider this range of possibilities as related to our study. In the present study, the lack of a relationship between working memory and filled-gap effects in islands is unlikely to be due to the selection of an inappropriate measure of working memory or lack of statistical power as significant relationships between working memory and filled-gap effects emerged within licit contexts for both learners and natives (although the patterns for the two groups differed). Although the interpretation of these findings is complex, they do suggest, in line with previous studies, that our working memory measure is one that can indeed capture variability in linguistic processing (Daneman and Carpenter, 1980; King and Just, 1991; Just and Carpenter, 1992; Hofmeister et al., 2014; see Hofmeister et al., 2012a for discussion).

Next, we consider whether the difference between the licit and illicit island contexts is simply the result of differences in processing load: if the island sentences simply overwhelmed the parser, perhaps a significant relationship with working memory did not emerge because of a lack of variability. For example, Hofmeister et al. (2014) fail to show a relationship between reading span scores and acceptability judgments for sentences of extreme processing difficulty although significant relationships did emerge for less complex structures. We think that this explanation is unlikely due to the comparability of the stimuli which targeted licit and illicit gap sites (see 9, 10). In both the non-island and island conditions, the target sentences were all grammatical, indirect questions which allowed us to avoid presenting direct wh-questions in isolation, which Hofmeister et al. (2012a) have argued is unnatural. In terms of the comparison between the licit and illicit object positions, it is important to note that these potential gap sites occur at similar points in the sentence (region 8, region 9) and at similar distances from the wh-filler (three and four words after the filler). In addition, in both sentence types, the wh-filler is followed by a single animate noun phrase and a tensed verb. These similarities serve to minimize the differences in processing difficulty of the licit and illicit object gap sites. Thus, while it is difficult to argue categorically in support of or against either account on the basis of a lack of a relationship between working memory and filled-gap effects in islands, we believe the design of the present study can potentially be defended against some of the criticisms raised in the literature by Hofmeister et al. (2012a,b, 2014). In addition, we believe there is merit to the approach we have taken in examining the relationship between individual differences and processing-based dependent measures across both island and non-island contexts. Indeed, it would be interesting to examine whether the results of the current study would be replicated in an experiment testing sentences that include linguistic properties that have been shown to ease the processing of wh-dependencies, such as complex wh-fillers (e.g., Hofmeister and Sag, 2010; Goodall, 2015). Such an experiment would provide an ideal way to address the potential concern that the lack of variability in gap-filling inside islands in the current study could be because the processing of those island structures is simply beyond the reach of all participants, even those with high working memory.

As we discussed earlier, any significant relationships that emerge at the licit gap sites are consistent with both the processing and grammatical accounts of islands but we believe that our findings raise very interesting questions as to the nature of the relationship between working memory and the processing of wh-dependencies in both learners and native speakers. In the non-island sentences, a positive correlation emerged between working memory and the filled-gap effect size at the subject position; this effect was significant only for native speakers. As we discussed above, one possible explanation is that participants with greater processing resources are better able to immediately generate a prediction for a potential gap (e.g., Hutchison, 2007; Slevc and Novick, 2013; Johnson, 2015) and thus show a greater filled-gap effect. The question remains why this relationship did not emerge at the licit subject position in both non-island and island contexts or in the L2 learner group. In a recent study in our lab, Johnson (2015) conducted a large scale study of native speakers ($n = 110$) and intermediate and advanced Korean learners of English ($n = 100$). The self-paced reading experiment included sentences similar to the ones tested in the present study. The results showed that significant subject filled-gap effects emerged for both groups. All participants also completed

show significant subject filled-gap effects (e.g., Stowe, 1986). Thus, the effect of the structure of the noun phrase remains an interesting open question.

measures of cognitive abilities including working memory (counting span) and attentional control (number Stroop). The size of the subject filled-gap effect in both natives and L2 learners was significantly related to attentional control, which Hutchison (2007) has argued to be a key component in the ability to generate and maintain predictions. Taken together, these results show that there is even variability in the processing of wh-dependencies that are relatively simple in terms of structure but demanding in terms of the need to automatically generate a prediction for an upcoming gap. This variability may lead to a need for large sample sizes, such as those in Johnson (2015), in order for robust effects to emerge. In addition, in an effort to better understand the cognitive abilities that underlie this variability in both natives and learners, future studies should include a wider range of measures, allowing for a more precise examination of whether the cognitive abilities that underlie variability in native speakers are similar or different to the abilities that underlie the variability in learners.

Our results for the non-island sentences also showed a relationship between working memory and the size of the licit object filled-gap effect in the spillover region but this effect emerged only for the L2 learners. Unexpectedly, the results showed that an increase in working memory predicted a reduced reading time slowdown or a smaller object filled-gap effect. One possible explanation is that the learners with greater processing resources may have recovered more easily from encountering the filled-gap, resulting in a reduced filled-gap effect at the spillover region. To explore this possibility, we separated the Korean learners of English into high ($n = 22$) and low ($n = 27$) working memory groups, based on whether they scored above or below the mean for the group (62) and then compared the size of the filled-gap effects at both the critical region (region 8) and the spillover region (region 9), where the relationship with working memory emerged (see **Figure 7**).

This comparison demonstrates that the high working memory group showed a numerical slowdown in the predicted direction only at the critical region. Thus, it is at least possible that learners with higher working memory showed a reduced filled-gap effect at the spillover region because they had already recovered from encountering the lexical material in the preceding region. As this comparison is exploratory, we present this numerical pattern in the learner data in order to suggest a direction for future research, one that may also benefit from an increased sample size, as in Johnson (2015), which may allow a wider range of variability to emerge in both learners and native speakers. An alternative method such as eye-tracking may also allow a more precise characterization of the dynamics of attempting to resolve wh-dependencies, including the initial detection of a filled potential gap site and recovery from this mis-analysis.

Although the results of our individual differences analyses raise many open questions, they suggest that processing resources do modulate the processing of wh-dependencies in certain grammatically licensed contexts. Why different relationships with working memory arise for the learners and native speakers is a very interesting question for future research. Further study is needed to examine whether similar or different cognitive abilities facilitate processing at different points for the two populations.

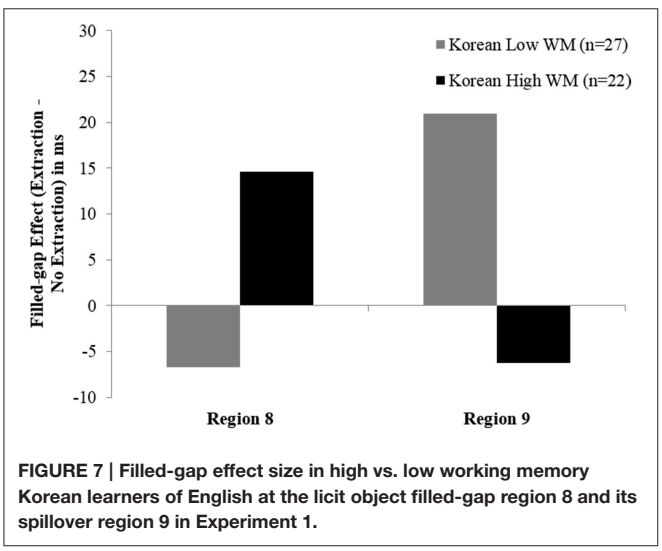

FIGURE 7 | Filled-gap effect size in high vs. low working memory Korean learners of English at the licit object filled-gap region 8 and its spillover region 9 in Experiment 1.

CONCLUSION

In the current study, we investigated the processing of wh-dependencies in both native speakers and L2 learners, examining whether the two groups show qualitatively similar patterns in processing and whether there is a relationship between working memory and filled-gap effects in both island and non-island contexts. The results showed that both native and non-native speakers posit gaps in grammatically licensed contexts but avoid positing gaps in islands. The processing profile of natives and L2 learners was qualitatively similar, showing no evidence of a delay in the use of syntactic knowledge as has been argued in recent proposals (Felser et al., 2012; Boxell and Felser, 2013). Our individual differences analyses showed no relationship between working memory and filled-gap effects within islands but we did observe significant relationships between working memory and the processing of licit wh-dependencies. As the contexts in which these relationships emerged differed for learners and native speakers, our results call for further research examining individual differences in dependency resolution in the two populations.

AUTHOR CONTRIBUTIONS

All authors listed, have made substantial, direct and intellectual contribution to the work, and approved it for publication.

ACKNOWLEDGMENTS

We are thankful to Goun Lee and Ji Yeon Lee for their help in preparing our experimental materials in Korean and in recruiting. We would also like to thank JoAnn Doll for assistance with testing participants, Alonso Canales for assistance with the stimuli construction, and Bruno Tagliaferri for his help with Python scripting. We thank the members of the Research in

Acquisition and Processing Seminar at the University of Kansas and the audience at the 38th *Boston University Conference on Language Development* for their feedback. We would also like to thank the reviewers for their feedback which helped to improve the paper.

Similarity of *wh*-Phrases and Acceptability Variation in *wh*-Islands

Emily Atkinson, Aaron Apple, Kyle Rawlins and Akira Omaki*

Department of Cognitive Science, The Johns Hopkins University, Baltimore, MD, USA

In *wh*-questions that form a syntactic dependency between the fronted *wh*-phrase and its thematic position, acceptability is severely degraded when the dependency crosses another *wh*-phrase. It is well known that the acceptability degradation in *wh*-island violation ameliorates in certain contexts, but the source of this variation remains poorly understood. In the syntax literature, an influential theory – Featural Relativized Minimality – has argued that the *wh*-island effect is modulated exclusively by the distinctness of morpho-syntactic features in the two *wh*-phrases, but psycholinguistic theories of memory encoding and retrieval mechanisms predict that semantic properties of *wh*-phrases should also contribute to *wh*-island amelioration. We report four acceptability judgment experiments that systematically investigate the role of morpho-syntactic and semantic features in *wh*-island violations. The results indicate that the distribution of *wh*-island amelioration is best explained by an account that incorporates the distinctness of morpho-syntactic features as well as the semantic denotation of the *wh*-phrases. We argue that an integration of syntactic theories and perspectives from psycholinguistics can enrich our understanding of acceptability variation in *wh*-dependencies.

INTRODUCTION

Much work in syntax has investigated the acceptability of English sentences that involve multiple *wh*-phrases, as in (1):

(1) a. **Who** __ wondered **who** bought the car?
b. ***What** did you wonder **who** bought __ ?

Despite the superficial resemblance of sentences in (1), native speakers of English perceive (1a) as a more acceptable sentence of English than (1b). This example illustrates the so-called *wh*-island constraint (Chomsky, 1964, 1977; cf. Ross, 1967): the grammar disallows dependency formation between the fronted *wh*-phrase (e.g., *what*) and its thematic position when there is another intervening *wh*-phrase (*who*). The discovery of this constraint raised a number of empirical and theoretical questions that remain unresolved: what types of representational or derivational constraints underlie the *wh*-island phenomenon? Are all *wh*-islands created equal, such that they all produce a similar degree of degradation? If not, what types of linguistic or cognitive factors affect the acceptability variation in *wh*-island violation?

The present paper aims to shed light on these questions through experimental tests of a recent, influential theory of *wh*-islands, called Featural Relativized Minimality (henceforth Featural RM;

Friedmann et al., 2009; Belletti et al., 2012; Rizzi, 2013; for related proposals, see also Starke, 2001; Boeckx and Jeong, 2003). As the review below illustrates, there are two reasons why this theory deserves ample attention from syntacticians and psycholinguists. First, unlike many syntactic theories that only distinguish grammatical from ungrammatical sentences, Featural RM predicts fine variations in acceptability across different types of *wh*-islands, in particular, how the acceptability of *wh*-island violations can *ameliorate* depending on the similarity of *wh*-phrases. Second, as noted by Rizzi (2013), Featural RM resembles memory constraints on sentence processing, where the similarity of competing words in the sentence often predicts comprehension difficulties. As such, empirical investigations of *wh*-island amelioration effects provide a unique opportunity to explore the link between Featural RM and memory constraints in parsing. We report 4 experiments that explore the empirical predictions of Featural RM, and demonstrate that the theory needs refinement by incorporating aspects of memory encoding and retrieval constraints that guide the real-time computation of syntactic representations.

Featural Relativized Minimality and Similarity Interference in Parsing

The definition of the Featural RM constraint can be summarized as in (2), which is slightly modified from Rizzi (2013) for expository purposes:

(2) In the configuration [. . . X . . . Z . . . Y . . .], X and Y cannot form a dependency if Z c-commands Y, and Z is the same structural type as X.

The syntactic condition as stated in (2) ensures that a *wh*-dependency cannot be established when there is a competing intervener [Z in (2)] that is structurally closer to the thematic position (Y) than the fronted *wh*-phrase (X). In Featural RM, the definition of the *structural type* that constitutes a violation of RM is stated in terms of morpho-syntactic features of those constituents.

A critical empirical observation that led to the use of morpho-syntactic features in Featural RM is the amelioration of *wh*-island violations with a D(iscourse)-linked *wh*-phrase (Pesetsky, 1987). While D-linked *wh*-phrases have been intuitively characterized as linked to previous discourse in some way, we will primarily use it here as a cover-term for *which*-phrases that denote a set of individuals. In the syntax literature, it has been reported that extracting the bare *wh*-phrase *what* from the *wh*-island, as in (3a), results in an ungrammatical sentence, but the extraction of the D-linked *wh*-phrase *which problem* in (3b) is considered marginally grammatical. This suggests that the *wh*-island violation in (3b) is somewhat ameliorated, though its acceptability is still degraded compared to the grammatical *wh*-extraction in (3c).

(3) a. *__What__ do you wonder __who__ solved __?
b. ?__Which problem__ do you wonder __who__ solved __?
c. __Which problem__ do you think that John solved __?

Assuming the acceptability pattern indicated in (3), Rizzi and colleagues proposed that the degree of overlap in morpho-syntactic features of *wh*-phrases accounts for the acceptability variation (Friedmann et al., 2009; Belletti et al., 2012; Rizzi, 2013). For example, the feature relation between the two *wh*-phrases can be characterized as identity (3a), inclusion (3b), and disjunction (3c). In (3a), the extracted constituent and the intervener both contain only a [+Q(uestion)] feature, and hence the feature sets are identical. This *identity* relation results in a severe degradation in acceptability. In (3b), the intervener only contains [+Q], whereas the feature set for the D-linked *wh*-phrase contains [+Q] as well as [+N(oun)], the latter of which represents the "referential status" of the D-linked *wh*-phrase (see Cinque, 1990). This configuration is called an *inclusion* configuration, as the extracted constituent is more richly specified, and its feature set is a superset of that of the intervener. This inclusion relation leads to a less severe degradation in acceptability, and the *wh*-island effect is ameliorated relative to (3a), but the sentence is not necessarily judged as fully acceptable. Finally, in (3c) the embedded clause contains no [+Q] feature, and hence the feature specifications for the extracted constituent and the (potential) intervener are distinct. This is termed a *disjunction* configuration, which leads to no violation of Featural RM. These three feature set relations and their well-formedness statuses are summarized in **Table 1**.

In summary, a key property of Featural RM is that it is concerned with the similarity of the fronted constituent and intervener in terms of morpho-syntactic features: the overlap of features causes degradation, and amelioration is observed when the extracted constituent has a richer or distinct set of morpho-syntactic features than the intervener.

The data discussed above concern the acceptability of sentences, but related observations have been made in adult and child sentence processing research on comprehension of filler-gap dependencies. For example, children experience greater comprehension difficulties with object *wh*-questions like *Which dog did the cat bite __ ?* than *Who did the cat bite __ ?*, possibly due to the overlap of [+N] feature in the fronted *wh*-phrase *which dog* and the intervening NP *the cat* (Friedmann et al., 2009; Belletti et al., 2012; for counter-arguments, see Goodluck, 2010; Bentea and Durrleman, 2014). In adult sentence processing, object relative clauses with two definite Noun Phrases (NPs) like *The banker that the barber praised __* pose greater comprehension difficulties than sentences in which the intervening NP is replaced by a pronoun or a name, as in *The banker that you/John praised__* (Gordon et al., 2001, 2002, 2004, 2006; Warren and Gibson, 2002, 2005). This adult finding may be compatible with Featural RM if we expand the relevant morpho-syntactic features to

TABLE 1 | Taxonomy of feature set and well-formedness in Featural RM.

X *Fronted phrase*	Z *Intervener*	Y *Thematic position*	Well-formedness	Type
+A	+A	<+A>	Ungrammatical (*)	Identity
+A, +B	+A	<+A, +B>	Marginal (?)	Inclusion
+A	+B	<+A>	Grammatical (√)	Disjunction

include features that distinguish definite NPs from pronouns or names.

An alternative explanation, which has received much support from sentence processing as well as domain-general working memory research, is that these observations reflect constraints on memory encoding and retrieval mechanisms, which are subject to so called *similarity-based interference* (Lewis and Vasishth, 2005; for a review, see Van Dyke and Johns, 2012). There are two ways in which similarity-based interference could occur. The first and more well-known type of similarity-based interference is *retrieval interference*. Comprehension of relative clauses or *wh*-questions requires the parser to retrieve the fronted *wh*-phrase and relate it to its thematic position. According to these memory accounts, this retrieval mechanism uses a cue-based search process, and activates all NPs that meet (some of) the search cues. The retrieval competition among candidates with similar features results in comprehension difficulties. The second type is called *encoding interference*. This type of interference is observed when the parser encounters words or phrases that are similar to one another, and the process of encoding and storing them as distinct items in memory is disrupted. The resulting representations that are stored in memory may be less precise or robust, and may require more cognitive resources to retrieve later in the sentence (see Gordon et al., 2002).

This raises questions about whether the variation of acceptability judgments in (3) may also be an instance of similarity-based interference: the identity relation in (3a) causes greater similarity-based interference than the inclusion configuration in (3b), which in turn causes more interference than (3c). In fact, it may even be possible to reduce Featural RM (**Table 1**) to constraints on working memory. However, as noted by Rizzi (2013), one key difference between Featural RM and memory retrieval accounts is that Featural RM is strictly concerned with the overlap of morpho-syntactic features, whereas similarity-based interference is typically sensitive to a variety of similarities, including semantic features (Van Dyke and McElree, 2006; Hofmeister, 2011; Hofmeister and Vasishth, 2014; Kush et al., 2015). Thus, further investigations of the role of semantic overlap in *wh*-island amelioration could shed light on the link between Featural RM and similarity-based interference.

The Present Study

The present study uses acceptability judgment experiments to explore the role of morpho-syntactic and semantic features in amelioration of *wh*-island violations. Specifically, we will explore the acceptability of the inclusion configuration (4a), and how it compares to the acceptability of the D-linked identity configuration (4b).[1]

(4) a. **Which athlete** did she wonder **who** would recruit __? (Inclusion)
b. **Which athlete** did she wonder **which coach** would recruit __? (D-linked identity)

In (4a) the extracted *wh*-phrase is D-linked and the intervener is a bare *wh*-phrase, whereas in (4b), both the extracted *wh*-phrase and the intervener *wh*-phrase are D-linked. Under Featural RM, the dependency in (4b) should be classified as an identity configuration, since both *wh*-phrases have features [+Q, +N]. We will refer to this configuration as *D-linked identity,* to distinguish it from the typical identity configuration [e.g., (3a)] that only includes bare *wh*-phrases. The dependency in (4a) is an inclusion configuration, since the intervening *wh*-phrase only has the feature [+Q]. Given these assumptions about the morpho-syntactic features, Featural RM predicts that (4b) should be less acceptable than (4a). On the other hand, both *wh*-phrases in the D-linked identity configuration (4b) are semantically more specific, as they characterize distinct sets of individuals: a set of athletes and a set of coaches. The *wh*-phrases in (4a) are less distinct because they do not denote distinct sets: the set of athletes is a proper subset of the set of people denoted by *who*. Thus, if semantic distinctness plays a role in dependency formation, the D-linked identity configuration (4b) may cause less similarity-based interference and lead to *wh*-island amelioration, possibly more so than in the inclusion condition (4a).

Informal judgment data reported in the syntax literature (Pesetsky, 1987, 2000; Comorovski, 1996; Shields, 2008) suggest that the D-linked configuration in (4b) should be more acceptable than the inclusion configuration in (4a); in fact, Pesetsky originally annotated them as fully grammatical, in contrast to non-D-linked identity examples. This may challenge the predictions of Featural RM, but it may reflect the fact that differences such as (4a) vs. (4b) are extremely subtle, and the reliability of the data in (4) may be in question. Although D-linked *wh*-phrases are reported to ameliorate *wh*-island violations, those sentences are still often described as unacceptable or ungrammatical to some degree. In other words, sentences like (4a) differ from non-D-linked identity sentences only in the severity of degradation, which is not guaranteed to be readily distinguishable in informal judgments. While D-linked identity examples are often (but not uniformly) annotated as fully grammatical in the linguistics literature, there is evidence that they have a different status than non-D-linked identity examples (Pesetsky, 2000; Shields, 2008). For example, Pesetsky (2000) demonstrates that they, unlike regular grammatical multiple-*wh* examples, e.g., (1a), show intervention effects, e.g., **Which book didn't which person read?* Because the contrasts are empirically subtle and complex, we will use acceptability judgment experiments with a 7-point scale that provide a quantitative measure of acceptability variation. Such experiments have proven useful for a variety of syntactic phenomena that involve subtle contrasts in acceptability intuitions (e.g., McDaniel and Cowart, 1999; Featherston, 2005; Alexopoulou and Keller, 2007; Hofmeister and Sag, 2010; Sprouse et al., 2012; Sprouse and Hornstein, 2013).

In fact, several experimental studies have provided preliminary evidence that semantic information may indeed play a role in island amelioration (Alexopoulou and Keller, 2013; Goodall, 2015; see also Fanselow et al., 2011). Alexopoulou and Keller (2013) investigated the acceptability of extraction out of *whether*-islands (e.g., *What does Claire wonder whether we will watch __ at the cinema?*) while manipulating the animacy

[1]For a related study in French, see Villata et al. (in press).

and D-linking status of the *wh*-phrase (e.g., *what, who, which movie, which colleague*). Here, it was found that bare inanimate *wh*-phrase *what* was less acceptable than the other three *wh*-phrase types, which did not differ from each other. This may suggest that inanimate nouns may be easier to extract out of an island, but this result is difficult to relate to the present study for two reasons. First, the animacy effect did not hold for the D-linked *wh*-phrases, suggesting that this may not be a robust effect. Second, *whether*-islands are different from *wh*-islands in (4) since the intervener (i.e., *whether*) itself does not relate to another (distant) thematic position. Goodall (2015) found clear evidence that D-linked *wh*-phrases ameliorate *wh*-islands that are more similar to those used in the present study. However, his D-linking manipulation compared bare *wh*-phrase against partitive *wh*-phrase (*What / Which of the cars do you wonder who might buy __ ?*). We note that, potentially, this partitive *wh*-phrase may have inflated the amelioration effect for a variety of reasons; for example, it contains a richer semantic content, which is known to facilitate retrieval processes in general (Hofmeister, 2011; Hofmeister and Vasishth, 2014). For this reason, our experiments will focus on D-linking manipulation that does not involve the partitive, in line with the D-linking manipulation that has been used more widely in the syntax literature.

Before presenting the experiments, it is important to clarify the scope of the present paper. The similarity-based interference accounts provide the motivation for the present study, as well as the critical predictions that semantic similarity should also play a role in acceptability variation in *wh*-islands. However, offline acceptability judgment data that we report here does not necessarily shed light on whether the observed acceptability variation in *wh*-islands actually reflects working memory constraints on encoding and retrieval processes during real-time sentence processing. As such, our aim is not to investigate how acceptability variation unfolds during real-time sentence processing, but rather to test whether the ultimate acceptability judgment data is compatible with the predictions of the similarity-based interference accounts.[2]

EXPERIMENT 1

This experiment investigates the acceptability of *wh*-island violations with D-linked identity and *wh*-island violations with an inclusion configuration, where only the extracted phrase is D-linked. We test this using a 2 × 2 design with movement from within a *wh*-island (non-island vs. island) and feature relation (non-identity vs. identity) as factors, as in **Table 2**. The extraction conditions contain extractions out of *wh*-islands. The non-extraction counterparts in do not contain *wh*-island violations and, hence, serve as baseline conditions.

Featural RM predicts that the D-linked identity condition should be severely degraded because the set of features on both D-linked *wh*-phrases (*which NP*, [+Q, +N]) are identical. On the other hand, the inclusion configuration should be less degraded than D-linked identity, because the features on the fronted phrase (*which NP*, [+Q, +N]) are a superset of the features on the intervener (*who*, [+Q]).

TABLE 2 | Sample item set from Experiment 1.

Non-identity	Non-island	Which student __ wondered who would invite the visitor?
	Island	Which visitor did you wonder who would invite __? *(Inclusion)*
Identity	Non-island	Which student __ wondered which teacher would invite the visitor?
	Island	Which visitor did you wonder which teacher would invite __? *(D-linked Identity)*

Method

Participants

Twenty-five self-reported native English speakers were recruited on the internet via Amazon Mechanical Turk, which has proven to be a useful venue in which participants provide reliable acceptability judgment data (Gibson et al., 2011; Sprouse, 2011). They were paid $0.30 for their participation. The data from 3 additional participants was excluded from the analysis, as they only used the extreme ends of the scale in the pre-test phase (see below). This and the following experiments were approved by the Johns Hopkins University Institutional Review Board, and all participants provided informed consent.

Materials

The stimuli for this experiment consisted of 16 sets of bi-clausal *wh*-questions (**Table 2**). These 16 items were counter-balanced across four lists, so that each participant saw only one version of each target item. Forty-eight filler items of comparable length and varying acceptability were randomly interspersed with these target items for a total of 64 items. Based on our informal judgments and acceptability judgment data in the literature, we manipulated the acceptability of filler items to create three groups of fillers: those that are expected to receive high acceptability rating (good fillers), those that are expected to receive low rating (bad fillers), and sentences whose acceptability was expected to fall in between (middle fillers). Fillers consisted of both declaratives and questions, which were included to ensure that the target items were not the only questions in the experiments. Having filler items with varying acceptability serves two purposes. First, this encourages the participants to use a large portion of the scale, which is critical for revealing subtle contrasts. Second, the data from fillers can serve as a baseline measure that can be used to estimate the magnitude of amelioration effects in target sentences. Stimuli from all four experiments, including the fillers, are provided in Supplementary Materials.

[2]While the present study does not directly tap the real-time generation of acceptability intuition, many studies have shown a correspondence between real-time comprehension difficulties and offline judgment data in processing of filler-gap dependencies (see, for example, Gibson and Thomas, 1999; Hofmeister and Sag, 2010; Vasishth et al., 2010; Hofmeister et al., 2013).

Procedure

All of the acceptability judgment experiments in this paper have the same basic procedure. Participants were instructed to rate sentences on a scale from 1 (bad) to 7 (good). Before beginning the experiment, participants were provided with detailed instructions and examples to illustrate that the task is not about stylistic considerations, prescriptive norms, or the plausibility of the event described. This was followed by additional examples with varying degrees of acceptability to illustrate what type of sentence corresponded to different parts of the scale. None of these example sentences used the same structure as the target sentences shown in (5).

Additionally, the first six experimental trials were identical for all participants and served as a pre-test phase. These six trials consisted of two highly acceptable sentences, two highly unacceptable sentences, and two marginal ones. These sentences were included to encourage participants to use the entire scale. The use of a large range of points on the scale was critical for the present study, because the target comparison involves two unacceptable sentence conditions. The acceptability contrast between such sentences may not be revealed if participants used, for example, only the two extreme ends of the scale and treated the task as a binary judgment task. If participants restricted their judgments to the extreme ends of the scale (i.e., 1 and 7) on these initial items, the data from these participants were excluded from further analyses, as it suggests that the participants are treating the scale as if it is a binary choice, which may skew the acceptability ratings in unexpected ways.[3]

Data Analysis

All experiments in this paper use the same data analysis procedure. First, the raw judgment ratings, including both targets and fillers, were converted to *z*-scores within participants (Schütze and Sprouse, 2013). The *z*-score transformation converts a participant's scores to units that represent the number of standard deviations a particular rating is from that participant's mean rating. This procedure corrects for the potential that individual participants treat the scale differently, e.g., using only a subset of the available ratings, because it standardizes all participants' results to the same scale. We also ran the reported analyses with the raw ratings and the results were unchanged in all experiments, although we will only report data and analyses based on *z*-scores.

Linear mixed-effect models were used to analyze the data; these models allow the simultaneous inclusion of random participant and random item variables (Baayen et al., 2008). Each model was fit using the maximal random effects structure that converged (Barr et al., 2013). These models were run in the R environment (R Core Development Team, 2015) using the lme4 package (Bates et al., 2015). *P*-value estimates for the fixed and random effects were calculated using the Sattherwaite approximation in the lmerTest package (Kuznetsova et al., 2015). When the results showed a significant interaction, planned pairwise comparisons were also performed to determine significance between individual conditions. These pairwise comparisons used separate linear mixed-effects models with maximal random effects structure; unlike other statistical analysis methods, mixed-effects models are robust to multiple comparisons.

[3]The overall pattern in our results did not change when the analysis included participants that would be removed according to this criterion. In this paper, we only present data that excluded those participants, as we think that this exclusion increases the chance of veridically representing the acceptability contrasts between conditions.

Results

Figure 1 presents the *z*-score transformed average ratings for each condition and for each filler type. Good filler sentences were rated as most acceptable (mean *z*-score = 0.80), while bad fillers were rated as least acceptable (mean *z*-score = −0.75). Middle fillers received ratings near participants' mean rating (i.e., near a *z*-score of 0, mean = −0.21). This pattern of acceptability for the fillers is common across all four experiments.

For the target items, we found that the island conditions were rated as less acceptable than the non-island conditions (island mean *z*-score = −0.71, non-island mean *z*-score = −0.05). Within the island conditions, the D-linked identity condition is rated as more acceptable than the inclusion condition (−0.58 vs. −0.84). In the non-island conditions, average *z*-scored ratings are around zero (means −0.04 and −0.07), suggesting that they were rated close to individual participants' mean ratings. This likely reflects the fact that sentences with two *wh*-phrases are generally uncommon and difficult to process out of context.

Table 3 presents the estimated coefficients and the standard error for the Linear Mixed Effect model with islandhood and feature relation as fixed effects and random intercepts and slopes for participants and items. Significant effects are marked by their beta estimates.

There is a main effect of islandhood such that *wh*-island violations are significantly less acceptable than non-island violating questions. There is no main effect of feature relation, but there is a significant interaction of islandhood and feature relation. The estimated coefficient of this interaction indicates that the feature combination had a significant effect in the island conditions, but not in the non-island conditions. This is supported by planned pairwise comparisons: the two non-island conditions are not significantly different from one another ($\beta = -0.02$, $SE = 0.12$, $p > 0.1$), while the D-linked identity condition is rated as significantly more acceptable than the inclusion condition ($\beta = 0.26$, $SE = 0.09$, $p < 0.01$).

Discussion

The results indicate that movement out of a *wh*-island generally results in severe degradation of acceptability. More importantly, this degradation is modulated by the feature relation between the two *wh*-phrases: the D-linked identity condition shows greater acceptability than the D-linked inclusion condition. These results replicate informal acceptability judgments in the literature that D-linking ameliorates *wh*-island effects, as well as judgment contrasts that D-linked identity leads to greater acceptability than inclusion (Comorovski, 1996; Shields, 2008). However, these results are not easily explained by the current formulation of

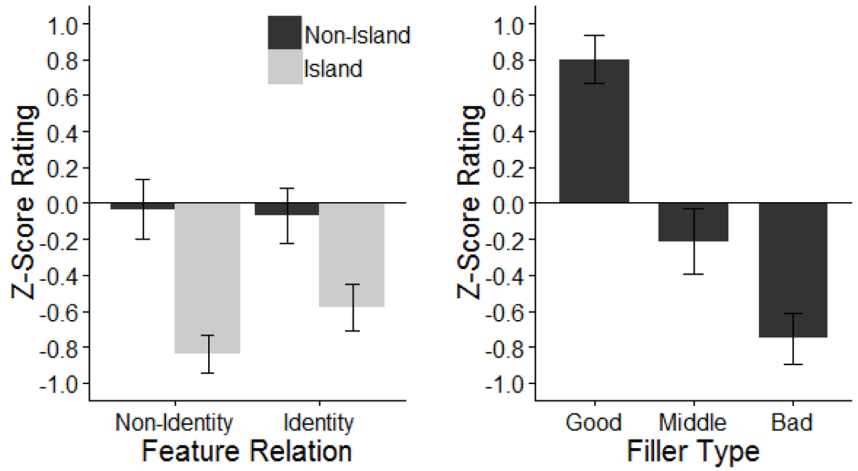

FIGURE 1 | Mean *z*-score acceptability rating of target questions by *wh*-phrase combination and islandhood, and mean *z*-score acceptability rating of filler sentences by filler type. Error bars indicate ± 1 SE.

Featural RM, which predicted that an identity configuration should be more degraded than an inclusion configuration. In fact, our results indicate that the D-linked identity configuration leads to a greater amelioration of the *wh*-island violation than an inclusion configuration.

We have so far focused only on the D-linked identity configuration. No items in this first experiment involve an identity configuration with bare *wh*-phrases, even though Rizzi's (2013) proposal critically relies on an acceptability difference between an identity configuration with bare *wh*-phrases and an inclusion configuration with a fronted, D-linked *wh*-phrase. In order to confirm the presence of *wh*-island amelioration in the inclusion configuration, as predicted by Featural RM, Experiment 2 compares the inclusion condition against a D-linked identity condition as well as a bare identity condition, where both the fronted *wh*-phrase and the intervener are bare *wh*-phrases.

EXPERIMENT 2

Method

Participants

Thirty-two self-reported native English speakers participated via Amazon Mechanical Turk. They were paid $0.50 for participating.

*$p \leq 0.05$, **$p \leq 0.01$, ***$p \leq 0.001$.

Materials

The stimuli for this experiment consisted of 24 sets of biclausal sentences, which were constructed by using a 2 × 2 × 2 design with three factors: matrix *wh*-phrase (bare vs. D-linked), feature relation (non-identity vs. identity), and islandhood (non-island vs. island). The experimental conditions shown in **Table 4** include the same four conditions as Experiment 1 (those with a D-linked matrix *wh*-phrase) as well as four new conditions (those with a bare matrix *wh*-phrase) to test Featural RM's broader predictions for *wh*-island amelioration effects. First, the acceptability of the island conditions is predicted to be significantly lower than that of non-island conditions. Second, Featural RM predicts that the identity island conditions should be the most severely degraded compared to all other conditions, including their non-island counterparts. It also predicts that the magnitude of degradation should not differ between the two identity island conditions. Third, the inclusion configuration should yield an amelioration of *wh*-island violations. Thus, the inclusion condition should yield a degradation compared to its non-island counterpart due to a *wh*-island violation, but the resulting acceptability should still be higher than the island identity conditions. Finally, the reverse inclusion configuration and its non-island counterpart are included in the design to test all combinations of the three factors we used in this experiment. The feature set taxonomy of Featural RM (see **Table 1**) does not make explicit predictions for these conditions; however, given that Rizzi and colleagues generally attribute the amelioration effects to the superset-subset relation of feature set between the fronted *wh*-phrase and intervener, we can infer the predictions of Featural RM to be that the acceptability of the reverse inclusion configuration should be similar to that of the two island identity conditions, and lower than the acceptability of the inclusion condition.

These 24 items were counter-balanced across eight lists, so that each participant saw only one version of a target item. Forty-eight filler items of comparable length and varying acceptability were randomly interspersed with these target items.

Bare matrix *wh*-phrase	Non-identity	Non-island	Who __ wondered which teacher would invite the visitor?
		Island	Who did you wonder which teacher would invite __?
			(Reverse Inclusion)
	Identity	Non-island	Who __ wondered who would invite the visitor?
		Island	Who did you wonder who would invite __?
			(Bare Identity)
D-linked matrix *wh*-phrase	Non-identity	Non-island	Which student __ wondered who would invite the visitor?
		Island	Which visitor did you wonder who would invite __?
			(Inclusion)
	Identity	Non-island	Which student __ wondered which teacher would invite the visitor?
		Island	Which visitor did you wonder which teacher would invite __?
			(D-linked Identity)

Procedure and Data Analysis

This experiment used the same procedure and data analysis steps as Experiment 1. In the statistical analysis, we added planned pairwise comparisons for the island version of the bare identity, inclusion, and D-linked identity conditions, as the comparison of these three conditions is critical for establishing the amelioration of *wh*-island violations that are predicted by Featural RM.

Results

Similar to Experiment 1, all four island conditions were judged as less acceptable than their non-island counterparts (island mean z-score $= -0.54$, non-island mean z-score $= 0.10$), see **Figure 2**. Among the non-island conditions, the non-identity bare matrix *wh*-phrase condition received the highest rating (mean $= 0.25$), but we will leave this aside as it bears no relevance to our goal of testing the predictions of Featural RM. The other non-island conditions were judged similarly with mean z-score ratings around zero (means -0.03, 0.10, and 0.09). Among the island conditions, the D-linked identity condition was rated as the most acceptable (mean $= -0.38$). The remaining three extraction conditions received similar ratings (means -0.57, -0.58, and -0.62).

The Linear Mixed Effect model analysis confirmed that the overall pattern is consistent with Experiment 1. **Table 5** presents the estimated coefficients, the standard error, and the estimated p-value for the Linear Mixed Effect model with islandhood, feature relation, and matrix *wh*-phrase as fixed effects and random intercepts for participants and items.

Intercept	−0.22***	0.05
Islandhood	−0.64***	0.12
Feature relation	−0.02	0.06
Matrix *wh*-phrase	−0.02	0.05
Islandhood × Feature relation	0.26**	0.10
Islandhood × Matrix *wh*-phrase	−0.09	0.10
Feature relation × Matrix *wh*-phrase	−0.26**	0.10
Islandhood × Feature relation × Matrix *wh*-phrase	0.01	0.19

The maximal random effects model did not converge; this model has random slopes for islandhood, feature relation, and their interaction.
*$p \leq 0.05$, **$p \leq 0.01$, ***$p \leq 0.001$.*

As in Experiment 1, there was a main effect of islandhood, but there was no main effect of either feature relation or matrix *wh*-phrase. Importantly, there was an interaction of islandhood and feature relation as well as feature relation and matrix *wh*-phrase, which suggests that the feature relation factor modulates the effects of islandhood or matrix *wh*-phrase type on the acceptability. Planned pairwise comparisons among island conditions revealed no significant difference between the bare identity condition and the inclusion condition ($\beta = 0.04$, $SE = 0.10$, $p > 0.1$). This suggests that the D-linking amelioration effect was not observed for the inclusion configuration. Additionally, there was no significant difference between the inclusion and reverse inclusion conditions ($\beta = 0.06$, $SE = 0.09$, $p > 0.1$). On the other hand, the D-linked identity condition is significantly more acceptable than the inclusion condition ($\beta = 0.23$, $SE = 0.11$, $p = 0.05$), and marginally more acceptable than the bare identity condition ($\beta = -0.19$, $SE = 0.11$, $p < 0.1$). This pattern suggests that the D-linked identity condition showed a reliable amelioration of *wh*-island violations. As reverse inclusion patterns with inclusion, there is no significant difference between reverse inclusion and bare identity ($\beta = -0.01$, $SE = 0.1$, $p > 0.1$), but D-linked identity is marginally more acceptable than reverse inclusion ($\beta = 0.18$, $SE = 0.1$, $p = 0.07$).

Discussion

Replicating the findings from Experiment 1, *wh*-island violations with D-linked identity received a reliably higher acceptability rating than bare identity or inclusion configurations. Furthermore, there was no clear evidence for amelioration of the *wh*-island violation in the inclusion condition. This selective *wh*-island amelioration effect is, again, not easily explained by Featural RM, which predicts that the inclusion configuration should be rated as more acceptable than bare or D-linked identity conditions. Finally, the finding that inclusion and reverse inclusion do not differ in acceptability also conflicts with the predictions of Featural RM.

The absence of an amelioration effect in the inclusion condition was surprising, given that amelioration effects in the inclusion configuration have been widely reported in the literature (Pesetsky, 1987; Cinque, 1990; Alexopoulou and Keller, 2013; Goodall, 2015). Experiment 3 explores whether the animacy of *wh*-phrases may play a role in amelioration of *wh*-island violations.

EXPERIMENT 3

Experiment 2 provided no evidence for *wh*-island amelioration in the inclusion configuration. One plausible source of this unexpected finding is the number of animate nouns in the stimuli. Examples for *wh*-island amelioration in the literature typically included a single animate *wh*-phrase (5a), whereas the stimuli used in Experiment 2 (5b) included two animate *wh*-phrases.

(5) a. Which book did you persuade which person to read __? (Pesetsky, 1987)
b. Which athlete did you wonder who would recruit __? (from **Table 3**)

It is plausible that having two animate *wh*-phrases makes them less distinct from one another, which may have increased confusability or processing demands in our stimuli. As discussed above, this is predicted by the similarity-based interference approach. In order to address this question, Experiment 3 replaces the animate *wh*-phrase [e.g., *which athlete* in (5b)] with an inanimate *wh*-phrase to more closely resemble the examples from the literature.

Method

Participants

Thirty-one self-reported native English speakers participated via Amazon Mechanical Turk. They were paid $0.50 for completing the task.

Materials

The stimuli for this experiment consisted of 24 sets of biclausal sentences, following the same 2 × 2 × 2 design used in Experiment 2, with three factors: islandhood, feature relation, and matrix *wh*-phrase (see **Table 6**). The non-island conditions were identical to those in Experiment 2, where the matrix *wh*-phrase was animate. In the new island conditions, on the other hand, the fronted *wh*-phrase was changed from an animate to an inanimate noun (e.g., *which event*). Because the animacy of the fronted NP has changed, *what* replaces *who* as the bare matrix *wh*-word in the bare identity and reverse inclusion conditions (i.e., *What did you wonder. . .?*).

The 24 items were counter-balanced across eight lists, such that each participant saw only one version of each. Forty-eight filler items of comparable length and varying acceptability were randomly interspersed with these target items for a total of 72 items.

Procedure and Data Analysis

The procedure and data analysis method were identical to those of Experiment 2.

Results

The acceptability judgment pattern in this experiment (**Figure 3**) resembles that of Experiment 2, as the D-linked identity condition received the highest rating among the extraction conditions (−0.06 vs. −0.62, −0.83, and −0.60).

These data were submitted to Linear Mixed Effect model analyses, which used islandhood, feature relation, and matrix *wh*-phrase as fixed effects and random intercepts for participants and items. The coefficient estimates, standard error, and estimated *p*-values are presented in **Table 7**.

The results revealed the same main effect of islandhood as in the previous experiments due to the decreased acceptability of the island violating conditions (island mean = −0.52, non-island mean = 0.11). Also, all three of the pairwise interactions are significant: islandhood and feature relation, islandhood and matrix *wh*-phrase, and feature relation and matrix *wh*-phrase. This suggests that all of these factors influence acceptability, even though the three-way interaction is not significant.

Next, following the data analysis procedure in Experiment 2, planned pairwise comparisons of the island conditions were conducted in order to examine the precise distribution of the amelioration effect. Replicating the results

of our previous experiments, the D-linked identity condition is significantly more acceptable than the inclusion condition ($\beta = 0.54$, $SE = 0.09$, $p < 0.001$) as well the bare identity condition ($\beta = 0.78$, $SE = 0.12$, $p < 0.001$). Also replicating Experiment 2, no difference was found between the inclusion and reverse inclusion conditions ($\beta = 0.02$, $SE = 0.09$, $p > 0.1$). Importantly, unlike Experiment 2, we found that the inclusion condition is significantly more acceptable than the bare identity condition ($\beta = -0.23$, $SE = 0.09$, $p < 0.05$). Again, reverse inclusion patterns with inclusion, so it is significantly more acceptable than bare identity ($\beta = -0.21$, $SE = 0.09$, $p < 0.05$) and marginally less acceptable than D-linked identity ($\beta = 0.13$, $SE = 0.07$, $p = 0.07$).

Discussion

Once again, this experiment found that the D-linked identity condition was more acceptable than the other island conditions. Also, the reverse inclusion conditions patterned with the inclusion conditions. Unlike Experiment 2, however, we found evidence for *wh*-island amelioration in the inclusion configuration, as the inclusion island condition was judged as more acceptable than the bare identity island condition. The fact that this effect was only found in Experiment 3 could be taken to suggest that the animacy manipulation plays a critical role in its emergence.

However, there are reasons to be cautious of this interpretation. In Experiment 3, island and animacy factors were confounded as the fronted *wh*-phrases were always inanimate in the island conditions. This design does not allow a direct comparison of *wh*-island violations with fronted animate *wh*-phrases to those with inanimate ones. Experiment 4 explores this issue by manipulating animacy within the island conditions.

EXPERIMENT 4

This experiment manipulates animacy and feature relation as in **Table 8**, in order to investigate whether *wh*-island amelioration in inclusion configurations is directly conditioned by the animacy of the fronted *wh*-phrase.

This allowed us to investigate the extent to which animacy contributed to wh-island amelioration effects. Given the results of Experiment 3, we predicted that the contrast between the

inclusion and bare identity conditions should only appear in conditions with an inanimate *wh*-phrase.

Method

Participants

Twenty-nine self-reported native English speakers participated via Amazon Mechanical Turk. They were paid $0.50 for completing the experiment. Three additional participants were excluded for using a single value ($n = 1$) or only the extremes of the scale ($n = 2$) during the calibration items.

Materials

The stimuli for this experiment consisted of 24 sets of biclausal sentences with a 2 × 2 design (**Table 8**), using animacy of the matrix *wh*-phrase (animate vs. inanimate) and feature relation (bare identity vs. inclusion) as factors. These items were largely based on stimuli from the previous experiments. The 24 test items were counter-balanced across four lists, such that each participant only rated a single item from each set. The addition of 48 length-matched filler sentences resulted in a total of 72 items.

Procedure and Data Analysis

The procedure and data analysis method were identical to those of previous experiments. Regardless of the presence of a significant interaction, planned pairwise comparisons of feature relation within animacy were conducted to directly test whether the amelioration effect of inclusion was modulated by animacy of the fronted *wh*-phrase.

Results

Figure 4 presents the mean *z*-score ratings in each condition. Overall, inanimate *wh*-phrase conditions are rated as more acceptable than those with animate *wh*-phrases (inanimates = −0.55, animates = −0.61), but the bare identity and inclusion conditions show little difference in their acceptability ratings (bare identity = −0.59, inclusion = −0.57). Within the animate conditions, bare identity and inclusion show little difference in their acceptability ratings (−0.59 vs. −0.63). Within the inanimate conditions, however, inclusion was rated as more acceptable than bare identity (−0.51 vs. −0.60).

These data were analyzed using a Linear Mixed Effect model analysis with feature relation and animacy as fixed effects. The coefficient estimates, standard error and estimated *p*-values are given in **Table 9**.

The model revealed no main effect of animacy or feature relation, but there was a marginal interaction between the two factors. Planned pairwise comparisons revealed that inclusion was marginally more acceptable than bare identity when the extracted *wh*-phrase was inanimate (inanimate: $\beta = 0.13$, $SE = 0.07$, $p < 0.1$), but not when the extracted phrase was animate ($\beta = -0.04$, $SE = 0.07$, $p > 0.1$).

Discussion

This experiment investigated whether the animacy distinctness between two *wh*-phrases is a pre-requisite for *wh*-island amelioration in inclusion configurations. The results provide weak support for this hypothesis: when the fronted *wh*-phrase was animate, there was little difference between bare identity and inclusion conditions, but there was a marginal difference between these configurations when the fronted *wh*-phrase was inanimate. This finding has two implications. First, the results of Experiments 3 and 4 taken together suggest that the animacy of the extracted *wh*-phrases can modulate *wh*-island amelioration effects, but that the effect can be weak. Second, *wh*-island amelioration in inclusion configurations is generally not as robust

as it has been reported in the literature; a weak amelioration may emerge when the fronted *wh*-phrase and intervener are distinct in animacy, but its effect is clearly not as consistently present as the amelioration effect observed in D-linked identity configuration in Experiments 1 through 3.

GENERAL DISCUSSION

The main goal of this study was to investigate the distribution of *wh*-island amelioration effects, and the extent to which they are modulated by morpho-syntactic and semantic features of *wh*-phrases. Specifically, we tested the acceptability of a *wh*-island violation involving two D-linked *wh*-phrases (i.e., D-linked identity) against violations with an intervening bare *wh*-phrase (i.e., inclusion) or with no D-linked *wh*-phrases (i.e., bare identity).

There are two main findings from the experiments reported above. First, we found consistent evidence against the predictions of Featural RM about D-linked identity configurations: such configurations reliably led to a higher acceptability than inclusion configurations. Featural RM predicts the opposite. Moreover, a study that was conducted in parallel in French used a similar design to our Experiment 3 and found the same pattern (Villata et al., in press). Thus, the increased acceptability of the D-linked identity configuration is robust across experiments and across English and French.

Second, we found that the D-linking amelioration effect for *wh*-island violations can be modulated by animacy, although the animacy effects were not always robust. Experiment 2 used only animate *wh*-phrases and found no evidence for *wh*-island amelioration in the inclusion configuration. Experiment 3 used inanimate nouns for extracted *wh*-phrases, and revealed evidence for amelioration in the inclusion configuration. This contrast between the experiments suggests that animacy might play a role. However, this effect did not hold robustly in Experiment 4, which showed that the amelioration effect was somewhat stronger for inclusion configuration than bare identity condition, which in turn showed no sign of amelioration regardless of the animacy manipulation. While a complete understanding of the role of animacy or the status of the inclusion configuration awaits further research, it is safe to conclude at this point that the *wh*-island amelioration effects for the inclusion configuration are not as robust as it has been reported in the literature.

TABLE 9 | Fixed effects summary for Experiment 4 with by-participant and by-item random intercepts for feature relation and animacy of the matrix *wh*-phrase.

	Estimate	*SE*
Intercept	−0.59***	0.05
Feature relation	−0.05	0.06
Animacy	0.05	0.05
Feature relation × Animacy	−0.18†	0.11

†$p \leq 0.1$, *$p \leq 0.05$, *$p \leq 0.01$, ***$p \leq 0.001$.

These findings are summarized in (6), which depicts the ranking of acceptability variation among the *wh*-island violations that were examined in this paper. We will now discuss the theoretical implications of these findings.

(6) Bare identity ≤ (Reverse) inclusion with an animate *wh*-phrase extraction ≤ (Reverse) inclusion with an inanimate *wh*-phrase extraction < D-linked identity ≤ no extraction

Implications for Featural RM

Our data suggests that Featural RM does not fully account for the distribution of *wh*-island amelioration effects, especially the fact that the D-linked identity configuration led to a robust amelioration effect. We do not present this as an argument against Featural RM *per se*, but minimally something else must be said to account for the behavior of D-linked *wh*-items beyond the inclusion/identity featural distinction. One potential implication is that the set of morpho-syntactic features assumed in papers by Rizzi and colleagues may need to be enriched. We will explore below the addition of Topic or Animacy features, but demonstrate that neither of these features provides a satisfactory explanation.

Rizzi (personal communication) suggests that the extracted D-linked *wh*-phrase has a [+Topic] feature that the intervening D-linked *wh*-phrase does not, as this feature is only licensed by the left periphery of the matrix clause (for a similar suggestion that the extracted *wh*-phrase may have a presupposition feature, see Grohmann, 2000; Boeckx and Jeong, 2003). If this is the case, then the sentences with two D-linked phrases are cases of inclusion rather than identity (7).

(7) **Which athlete** did you wonder **which coach** would recruit __?
[+Q, +N, +Topic] [+Q, +N] [+Q, +N, +Topic]

This amendment allows Featural RM to account for the increased acceptability of the D-linked identity configuration. However, this featural augmentation does not explain why this configuration should be reliably more acceptable than the inclusion condition with a bare *wh*-phrase in the intervener position. Given the feature sets assumed in (7), both of these configurations are inclusion configurations, which are not predicted to show a contrast in acceptability. If we were to grade acceptability based on the degree of featural overlap, the prediction would again go the wrong direction: the bare inclusion condition should have less featural overlap, and therefore be more acceptable than the D-linked identity condition under the analysis in (7).

Another morpho-syntactic feature that may deserve to be added to the Featural RM framework is an animacy feature. It is typically assumed that animacy features do not actively participate in syntactic operations in English. However, animacy is known to play important roles in syntax of other languages (e.g., Slavic languages, see Rappaport, 2003). Our observations of superior *wh*-island amelioration effects for inanimate *wh*-phrases may be the first evidence that animacy plays an important role in English syntax as well. However, the addition of an animacy feature with the same status as e.g., [+Q] above is not fully

motivated by our data either. First, it offers no explanation for the observed acceptability contrast between the D-linked identity and inclusion configuration in Experiments 1 and 2. Second, using animacy features in Experiment 3 would change the D-linked identity feature relation to that of a reverse inclusion, as shown in (8). Under this configuration, Featural RM predicts the sentence to be equally as degraded as identity configurations, which is the opposite of what was found in Experiment 3. Rather, if Experiment 3 is taken at face value, (8) should be ameliorated simply because the two D-linked *wh*-phrases have a different value for animacy.

(8) **Which award** did you wonder **which actress** should receive __?
[+Q, +N] [+Q, +N, +animate] [+Q, +N]

Finally, incorporating an animacy feature would predict that animacy based amelioration effects hold robustly across all *wh*-island violations, but this prediction is inconsistent with the observation in Experiment 4 that the animacy manipulation showed a selective, weak modulation of the acceptability of the inclusion conditions but not the bare identity configuration. While an animacy distinction is clearly relevant, it cannot easily be captured in featural terms.

In summary, it is not obvious what featural adjustments could account for the amelioration patterns we have shown in this paper in a way that is entirely internal to the principles of Featural RM.[4] If this effect cannot be accounted for with featural manipulations, then (minimally) something external to the featural system must lead to the amelioration pattern.

Memory Constraints and Semantic Distinctness in Acceptability Variation

More generally, these results present a challenge to any account of *wh*-island effects that assumes that D-linked identity examples are acceptable or fully amelioriated: the variable amelioration effect for even this case suggests that some constraint like Relativized Minimality may well be active (in contrast to accounts of D-linking that simply assign it a different LF where the constraint leading to the violation is not at play; Pesetsky, 1987, 2000 on superiority). An explanation for the distribution of *wh*-island amelioration effects in our experiments must take into account the superior amelioration effects in D-linked identity configurations, as well as the fact that extraction of an inanimate *wh*-phrase sometimes leads to a further increase in acceptability. Before we present such explanations, we first argue for a new descriptive generalization: the degree of semantic distinctness of the extracted *wh*-phrase and the intervener (rather than the distinctness of morpho-syntactic features) predicts the distribution of *wh*-island amelioration effects.

We suggest that participants in these experiments were able, to varying degrees, to use *semantic distinctness*, rather than morphosyntactic distinctness, as a strategy for interpreting ill-formed *wh*-island examples. First, we will adopt a broadly Hamblin semantics of *wh*-questions, and assume that (i) questions denote a set of possible answers (Hamblin, 1973; see also Karttunen, 1977, and many others), and (ii) *wh*-phrases denote a set of potential referents (Hamblin, 1973; Kratzer and Shimoyama, 2002). Intuitively, the set of referents for the *wh*-item in a single-*wh* question corresponds to possible fragment NP answers to that question. Under this family of assumptions, bare *wh*-phrases like *who* denote the set of all human individuals, whereas a D-linked *wh*-phrase like *which award* would denote a presupposed set of entities satisfying the NP restrictor, in this case award, and require the answer to the *wh*-question to be constructed from some referent in this set only. With these assumptions, let us examine the distinctness of sets of individuals or objects denoted by *wh*-phrases in **Table 10**, which illustrates the main feature configurations that were investigated in our acceptability judgment experiments.

In the bare identity condition with *who* as an extracted *wh*-phrase, both the extracted *wh*-phrase and the intervener denote the set of all humans, and therefore their domains are identical and non-distinct. If the extracted *wh*-phrase is *what,* we assume that *what* denotes a set of everything in the world, which includes human individuals.[5] Here, the set denoted by *what* is a superset of the set denoted by *who*, and these sets are thus overlapping. As for the inclusion configuration with animate *wh*-phrases, *which visitor* denotes a presupposed set of visitors, while *who* denotes a set of all human individuals. Thus, the sets of individuals denoted by these two *wh*-phrases are also overlapping. On the other hand, for the inclusion configuration with inanimate and animate *wh*-phrases, the set denoted by *which event* and the set denoted by *who* are distinct. This explains the amelioration effect that was observed in the comparison of Experiments 2 and 3. Finally, in the D-linked identity conditions, the sets of individuals or objects denoted by the two *wh*-phrases (*which visitor* and *which family,* or *which event* and *which family*) are clearly distinct. Thus, these observations lead to the generalization that the *wh*-island violations that were amenable to amelioration effects were those in which the sets denoted by the extracted *wh*-phrase and the intervener are distinct. We take this as a necessary condition for *wh*-island amelioration.

[4]One reviewer suggested the inclusion of both a topic and an animacy feature. In example (8), this would result in a configuration known as *intersection*, where the fronted *wh*-phrase and the *wh*-intervenor have distinct sets of features that share a subset (in the terms of **Table 1**, the fronted phrase is [+A,+B] and the intervener is [+A,+C]) (Belletti et al., 2012). However, it is unclear whether this configuration should pattern with disjunction or with intersection in acceptability judgments. Additionally, this does not address the concern that example (7) becomes a case of intersection with the addition of these features. It is still unclear why sentences like (7) are consistenly more acceptable than the other cases of inclusion included in our experiments.

[5]There are three empirical reasons for assuming that *what* is underspecified for human or animacy features, and therefore is able to denote humans (see Grosu, 2003). First, *what* can be combined with either animate or inanimate nouns to form complex *wh*-phrases (e.g., *What doctor did you see? What textbook did you buy?*), whereas this type of composition is not possible for *wh*-phrases like *who* with clear human and animacy feature specification (**who doctor*). Second, the answer to *what* can be human or non-human, especially when there are multiple answers (e.g., *What can you see? John, Mary, and a tree.*). This is not possible for *wh*-phrases that are specified for human features (e.g., *Who did you see? *John, Mary, and a tree.*). Third, free relative clauses with *what* can take a human or a non-human referent (Grosu, 2003). In a sentence like *What I thought was a policeman was just a log*, the *wh*-phrase *what* is treated as human (a policeman) internally to the free relative clause, whereas it is treated as inanimate (a log) externally.

TABLE 10 | Distribution of amelioration effects and semantic distinctness.

Conditions	Sentence	Amelioration?	Semantic distinctness
Bare identity	Who/what did you wonder who would host__?	No	Non-distinct
Inclusion (animate)	Which visitor did you wonder who would host __?	No	Non-distinct
Inclusion (inanimate)	Which event did you wonder who would host __?	Maybe?	Distinct
D-linked identity	Which visitor did you wonder which family would host __?	Yes	Distinct
D-linked identity	Which event did you wonder which family would host __?	Yes	Distinct

The semantic distinctness of the *wh*-phrases provides the beginnings of an explanation of many of the patterns in our data, but clearly we do not have evidence for any sort of categorical amelioration; in fact, our results could be taken as evidence against it. One possible explanation for this state of affairs is that similarity-based interference during memory retrieval operations is sensitive to the semantic distinctness of two *wh*-phrases. As noted in the Introduction, it has been widely observed that the processing of filler-gap dependencies can be impeded when the dependencies contain two similar NPs. This similarity interference effect is considered to follow from limitations of the memory system in either encoding two similar NPs as distinct items, or in retrieving the target NPs with accurate syntactic and semantic features. It is plausible that the semantic distinctness of *wh*-phrases modulates the ease of encoding or retrieval processes, and when these processes are readily performed, participants may perceive the *wh*-island violations to be less severely degraded. In this sense, the semantic distinctness of *wh*-phrases may serve as a formal characterization of NPs that are particularly confusable for memory operations.

This psycholinguistic explanation for the role of semantic distinctness and memory constraints has implications for theories of islands and syntactic amelioration effects in general. We suggest two potential approaches for integrating syntactic and psycholinguistic constraints, both of which are equally compatible with our findings. The first approach is to reduce island constraints to cognitive constraints on memory operations, such that "island violations" merely reflect difficulties in establishing *wh*-dependencies during real-time parsing (Kluender and Kutas, 1993; Hofmeister and Sag, 2010; for related explanations for Superiority effects, see Hofmeister et al., 2013). With respect to *wh*-islands, according to this reductionist approach, what used to be considered violations of Featural RM constraints would be reanalyzed as severe instances of similarity-based interference effects, which are sensitive to both syntactic and semantic features of retrieval candidates. Simplifying the theory of grammar and postulating fewer constraints that are specific to linguistic representations is a welcome result (Chomsky, 1995; Phillips, 2013), and it highlights how syntactic theories can be refined by a further collaboration between linguistics and broader cognitive science research. The future agenda for this approach includes extension of experimental investigations to other syntactic phenomena that Featural RM provided explanations for (e.g., intervention effects in *combien* extraction in French; Obenauer, 1983, 1994), as well as addressing counter-arguments for cognitive explanations of island constraints (Sprouse et al., 2012; see also Phillips, 2006). We leave these questions for future research.

The second approach for integrating syntactic constraints on *wh*-dependency formation and memory constraints is to situate similarity interference effects in *repair processes* that the parser initiates in order to cope with a violation of formal, syntactic constraints; we term this approach the Amelioration-as-Repair hypothesis. This explanation of amelioration effects relies on the following three assumptions. First, we assume that acceptability judgment intuitions minimally reflect the well-formedness of syntactic derivations and semantic representations that the parser assigns to a given sentence. When this process fails due to linguistic or other cognitive constraints, we perceive degradation in sentence acceptability (Schütze, 1996), and the severity of degradation reflects the number of constraint violations at all levels of representations (Legendre et al., 1991; Keller, 2000; Smolensky and Legendre, 2006; Haegeman et al., 2014). Second, we also assume that syntactic constraints on *wh*-islands do play an important role in accounting for the general acceptability degradation due to extraction out of *wh*-islands, and this constraint could be the original Relativized Minimality constraint in Rizzi (1990, 2004) which did not distinguish bare identity *wh*-island from inclusion *wh*-island. Finally, we also assume that in the face of sentences that violate syntactic constraints, the parser attempts to repair the structure in order to assign an interpretation to the structurally unintegrated *wh*-phrase. Such interpretive repair processes are well documented in the psycholinguistics literature on severe garden-path sentences (e.g., Christianson et al., 2001; Ferreira and Patson, 2007). While this style of repair may not "cancel" the initial violation of syntactic constraints, it would at least provide a strategy for obtaining a legitimate semantic representation for the sentence that can be passed onto the interpretive process.

Given these assumptions, acceptability judgment data should reflect the degree to which this repair process is able to (a) identify a gap position inside an island, and (b) retrieve the relevant *wh*-phrase in order to complete the *wh*-dependency for the semantic representation. Under the Amelioration-as-Repair approach, it is during this repair/retrieval process that the similarity interference effects arise. It is well known that the parser typically respects island constraints during real-time sentence processing (e.g., Stowe, 1986; Traxler and Pickering, 1996); thus, initially the parser should generate an ungrammatical structure with no gap for the *wh*-phrase. This syntactic violation initiates the repair process, and the search for a gap inside an island. This search process identifies a verb with a missing complement, which indicates that the verb could be a host for the gap. This gap identification subsequently triggers a retrieval of a *wh*-phrase,

using the thematic role and morphological features as retrieval cues.[6] This retrieval process should be sensitive to the semantic distinctness of *wh*-phrases. If the repair process fails due to similarity interference effects (e.g., in the bare identity condition), the semantic representation would veridically reflect the syntactic violation of the *wh*-island constraint (i.e., no gap for the *wh*-phrase), and the sum of these two violations results in more severe degradation. On the other hand, if the parser identifies a gap inside an island due to the lack of similarity interference effects (e.g., in D-linked identity conditions with semantically distinct *wh*-phrases), the resulting semantic representation no longer contains any violation, even though it is derived from a structure that does, and therefore the only source of acceptability degradation is the initial violation of the *wh*-island constraint (see Huang, 1982 for arguments that the semantic representation of islands with argument gaps does not incur any violation).

One consequence of the Amelioration-as-Repair hypothesis is that it provides a new direction toward a mechanistic understanding of acceptability judgment in general. To this day, even though acceptability judgment data has served as the primary source of data for linguists, there is very little theory of how such intuitions arise (cf. Schütze, 1996), or how the process of judging sentence acceptability reflects psycholinguistic constraints. As such, regardless of whether island constraints or Featural RM should remain as a formal constraint on linguistic representations, integration of perspectives and insights from psycholinguistics could help advance the field of syntax.

Finally, we note that either approach raises new research questions that need to be addressed in future research. First, the current study does not provide time course measures that shed light on the memory encoding and retrieval mechanisms that are assumed under either explanation. Second, it remains to be answered why the animacy-based modulation of *wh*-island amelioration effects was not reliably observed across experiments. Following the psycholinguistic explanations above, we tentatively suggest that the real-time encoding and comparison of semantic distinctness information could be subject to a variety of conceptual or cognitive factors that will then impact the behavior of amelioration. For example, accessing the set of all individuals denoted by *who* may be inherently complex when it is presented out of context, as in the current experiments. This difficulty may sometimes mask the potential advantage of semantic distinctness in the inclusion configuration with an inanimate *wh*-phrase, suggesting also that it may not be generally safe to test amelioration effects out of context.

[6] It is also plausible that the animacy effect observed in our experiments reflects the fit of the verb semantic retrieval cues and the *wh*-phrases (e.g., *event* may be a better object for *host* than *visitor*). Testing this hypothesis requires a careful control of verb-noun co-occurrence frequency and plausibility. We leave this question open for future research.

CONCLUSION

The present study investigated the distribution of *wh*-island amelioration effects, with a special focus on how it is modulated by morpho-syntactic features and semantic features of *wh*-phrases. We found that morpho-syntactic features alone, such as those to which Featural RM in its current form appeals, failed to account for the distribution of *wh*-island amelioration effects. We suggested that a full explanation of our results requires the consideration of semantic representations, which may, in turn, be related to constraints on the sentence processing mechanisms that give rise to similarity interference effects. This observation calls for future work that re-examines amelioration effects in other syntactic environments in light of constraints on sentence processing mechanisms.

ACKNOWLEDGMENTS

This work was supported in part by NSF BCS-1423117 to AO, and NSF BCS-1344269 to KR and AO. Our thanks to Eleanor Chodroff and Bob Wiley for their contributions to Experiment 1.

"D-linked" *wh*-phrases such as *which car* are known to increase the acceptability of sentences with island violations. One influential account of this attributes the effect to working memory: the D-linked filler is easier to retrieve at the site of the gap and this leads to the amelioration in acceptability. Such an account predicts that this effect should occur in general with non-trivial *wh*-dependencies, not just in island environments. An experiment is presented here to test this prediction. *Wh*-questions with both D-linked and bare *wh*-phrases and with both island and non-island embedded clauses are presented to participants, who rate their acceptability on a 7-point scale. Results show that D-linking significantly increases acceptability in both island and non-island environments, in accord with analyses that attribute the effect to working memory. In addition, the increase in acceptability is uniform in both types of environments, suggesting that the island effect itself may not be attributable to working memory.

Keywords: filler-gap dependencies, D-linking, island constraints, working memory, sentence acceptability

INTRODUCTION

The contrast between *wh*-phrases such as *which car* in (1a) and *what* in (1b) has been a major topic of research over the last few decades (e.g., Pesetsky, 1987; Cinque, 1990; Szabolcsi and Zwarts, 1993).

(1) a. **Which car** did you buy?
b. **What** did you buy?

Following terminology introduced in Pesetsky (1987), *wh*-phrases like *which car* are "discourse-linked or "D-linked," in that they naturally prompt an answer chosen from referents already existing in the discourse, whereas *wh*-phrases like *what* do not. (1a), for instance, is typically taken to be asking about a set of cars already known to the speaker and hearer, while (1b), under its most natural reading, is not (see also Katz and Postal, 1964 and Kuroda, 1968).

This distinction has been claimed to have two major consequences for the syntax of *wh*-dependencies. The first has to do with clauses containing two or more *wh*-phrases. English requires that one of these appear at the left edge of the clause, and generally, the syntactically more prominent *wh*-phrase (e.g., the subject vis-à-vis an object) is strongly preferred to play this role, as in (2a) and (2b), even though the less prominent *wh*-phrase is able to when there is no other, as in (2c).

(2) a. I wonder **who** bought **what**.
b. *I wonder **what who** bought.
c. I wonder **what** the man bought.

This is known as the Superiority effect (Chomsky, 1973). D-linking of the *wh*-phrases is claimed to weaken or erase this effect, such that any *wh*-phrase may appear at the left edge of the clause, as in (3) (Karttunen, 1977; Pesetsky, 1987; Comorovski, 1989).

(3) a. I wonder **which man** bought **which car**.
b. I wonder **which car which man** bought.

The second major consequence has to do with the gaps that are obligatorily associated with *wh*-phrase fillers. These gaps are not permitted in certain environments within the clause, a phenomenon known as an island effect (Ross, 1967). (4a) and (4b) show two such island environments, while (4c) shows a non-island environment, in which a gap is permitted.

(4) a. ***What** do you wonder [who bought __] ?
b. ***What** do you believe [the claim that the man bought __] ?
c. **What** do you think [that the man bought __] ?

As with Superiority, island effects are claimed to be weakened or erased when the *wh*-phrase is D-linked (Maling and Zaenen, 1982; Cinque, 1990; Rizzi, 1990; de Swart, 1992; Kiss, 1993; Chung, 1994):

(5) a. **Which car** do you wonder [who bought __] ?
b. **Which car** do you believe [the claim that the man bought __] ?

The above two consequences are surprising, at least initially, in that one might not expect *wh*-dependencies, which are often taken to be a quintessentially syntactic phenomenon, to be so sensitive to discourse-related factors. The effects of D-linking thus present an interesting puzzle, and a number of analyses have been proposed to explain them.

This paper explores this second consequence, the effect of D-linking on islands. We present evidence from a formal acceptability experiment showing that D-linking does indeed improve acceptability of sentences containing island violations, but that they are still significantly degraded compared to sentences without such violations. Moreover, D-linking results in a similar improvement in acceptability even in non-island environments, a finding that has important consequences for determining the sources of the D-linking and island effects.

We review the main classes of proposed explanations for the D-linking effect in islands in Section Three Accounts of D-linking and consider earlier acceptability experiments in this domain in Section Earlier Acceptability Studies. Section Experiment presents and discusses the experiment itself. Section Implications for Formal Acceptability Experiments discusses implications of the experiment for acceptability experiments in general, and general conclusions are presented in Section Conclusion.

THREE ACCOUNTS OF D-LINKING

One influential analysis (Szabolcsi and Zwarts, 1993, 1997; see also Honcoop, 1998) claims that the D-linking effect in islands is primarily due to semantic factors. Certain island domains, under this analysis, contain operators that require a Boolean operation (e.g., intersection), which in turn requires sets made up of discrete individuals. A D-linked *wh*-phrase facilitates an interpretation in which the set questioned consists of individuals, thus allowing for a coherent semantic interpretation of the sentence. With bare *wh*-words like *what*, on the other hand, an interpretation involving a set of individuals is unlikely (though possible under certain circumstances, as Szabolcsi and Zwarts discuss), so the sentence is perceived as ill-formed.

In another set of analyses, the source of the unacceptability of island violations such as (4a) is syntactic. In Rizzi (2001, 2004), for instance, the *wh*-dependency between *what* and its gap site in (4a) violates a putative fundamental property of syntax known as Relativized Minimality, which roughly speaking, disallows dependencies between a filler and a gap when there is an intervening filler [*who*, in the case of (4a)] that could also potentially enter into a dependency of the same type with this gap. Fronted topics are known to be immune to Relativized Minimality effects, so it is important to note in this analysis that D-linked *wh*-phrases bear certain crucial similarities to fronted topics: they contain lexical material beyond the *wh*-word itself, and they are dependent on previously mentioned elements in the discourse. To the extent that D-linked *wh*-phrases may be interpreted as topics, then, they should be able to circumvent the Relativized Minimality requirement and acceptability should increase.

In a third family of analyses, island violations such as (4a) result from limitations in working memory (Kluender and Kutas, 1993; Kluender, 1998; Hofmeister and Sag, 2010; Hofmeister, 2011). The filler *what* must be held in working memory until it can be reintegrated into the structure at the gap site in the embedded clause. Maintaining this filler in working memory while also processing a clause boundary and an intervening filler (*who*) overwhelms the limited capacity of the processor, so filler reintegration is less likely to succeed and the sentence is perceived as unacceptable. The situation changes when the filler is D-linked, because such a filler requires more initial processing, given its more referential nature and the presence of lexical material. The D-linked filler thus has a higher level of initial activation in working memory, and this enables it to survive more successfully until the point where it can be reintegrated at the gap site. There is considerable evidence that such a processing advantage for D-linked fillers exists (e.g., Kluender, 1998; Frazier and Clifton, 2002; Diaconescu and Goodluck, 2004; Hofmeister, 2007a,b, 2011; Hofmeister and Sag, 2010; Hofmeister et al., 2013), and it is reasonable to assume that it could result in higher acceptability [see Hofmeister et al., 2007, for an application of this type of analysis to the D-linking effect on Superiority, as in (2)-(3) above].

This working memory account of islands and D-linking differs from the other two in two important ways. First, it claims that the island and D-linking effects are essentially extragrammatical. That is, the grammar itself has nothing to say about island structures and D-linked fillers, other than that they are allowed, and the effects observed result from capacity constraints on working memory. In the other accounts, on the other hand, these same effects arise because the sentences in question would require an ill-formed semantic or syntactic structure, independently of how such a structure would be processed. Second, all three accounts attribute special properties to D-linked fillers, but only in the working memory account would these special properties be expected to increase acceptability even without an island structure. More concretely, D-linked fillers more readily allow for individuation in the semantic account and for a topic-like interpretation in the syntactic account. These properties permit the filler to avoid island effects, but there is no reason to expect them to affect acceptability in non-island environments. In the working memory account, however, the special property of D-linked fillers is that they have a higher level of activation, and this should facilitate retention in working memory and reintegration at the gap site regardless of the particular structure. Since easier reintegration is assumed to result in higher acceptability, this then predicts that making a filler D-linked will increase acceptability in both island and non-island environments.

We thus arrive at a clear distinction between the working memory analysis and the other two: The working memory account predicts that D-linking will increase acceptability in both islands and non-islands, while the grammatical (semantic and syntactic) accounts do not make this prediction. On the other hand, the three analyses are in agreement that without any auxiliary assumptions, whatever D-linking effect occurs in non-islands should be smaller than that in islands. In the grammatical accounts, this is straightforward: no prediction is made for non-islands, but a very clear effect is predicted for islands. In the working memory account, the predictions result from the way in which island phenomena themselves are accounted for. In these analyses, islands occur because of two main factors: the processing difficulty associated with a filler-gap dependency and that associated with a particularly complex embedded clause [such as the *wh*-clause in (4a) or the complex noun phrase in (4b)]. Crucially, there is an interaction between these two factors, in that the decline in acceptability when both occur together is greater than what would be expected given the decline associated with each

one on its own. Assuming that this interaction is straightforward (e.g., multiplicative), a weakening of one of the factors by amount *x* should result in an overall effect greater than *x*. More specifically, if D-linking lessens the processing difficulty found with filler-gap dependencies, the effect should be amplified when this difficulty is in interaction with the difficulty stemming from a complex embedded clause, and we thus expect D-linking to have a greater effect on acceptability in islands than it does in non-islands.

Two questions may now be posed: (i) Does D-linking increase acceptability in both islands and non-islands, and (ii) is the effect larger in islands than in non-islands? If the answer to the first question is positive, this would lend support to the working memory account of D-linking, and if it is negative, this would argue against it. As we have seen, the grammatical accounts do not make a specific prediction with regard to this question. As for the second question, a positive answer would confirm the predictions made by both the working memory and grammatical accounts. A negative answer would be consistent with the working memory account of D-linking, though inconsistent with the working memory account of islands, given straightforward assumptions about the nature of the interaction taken to underlie island effects. With regard to grammatical accounts, on the other hand, a negative answer would be inconsistent with the accounts of D-linking, though consistent with accounts of islands.

EARLIER ACCEPTABILITY STUDIES

The questions that we are now facing, whether D-linking of fillers increases acceptability even in non-island environments and whether the effect is greater in islands than in non-islands, are in principle able to be addressed experimentally, and some earlier studies have attempted to do so. Hofmeister (2007a) reports the results of a pilot study exploring the effect in non-islands, in which 16 subjects rate 9 sentences using a 7-point scale. The fillers are bare *wh*-words or phrases consisting of either *which* + noun or *which* + *of* + *the* + noun, as in the sample stimuli in (6).

(6) a. Justin proved **what** the engineers lied that they had invented __ without any help or instruction.
b. Justin proved **which devices** the engineers lied that they had invented __ without any help or instruction.
c. Justin proved **which of the devices** the engineers lied that they had invented __ without any help or instruction.

The differences in acceptability among the sentences are marginally significant, with type (6b) more acceptable than (6c), and (6c) more than (6a), but given the small-scale nature of the experiment and the lack of clear results, it is difficult to draw firm conclusions from this. Nonetheless, the study shows that designing an experiment that begins to address these questions is possible in principle.

Alexopoulou and Keller (2013) report on a study consisting of two sub-experiments. In one, the stimuli consist of *wh*-questions with gaps inside embedded *whether*-clauses, a known island environment. In the other, the gap is either in the main clause or in an embedded *that*-clause. In both sub-experiments, there are two factors: gap type (true gap vs. resumptive pronoun) and filler type (*what* vs. *what* + noun vs. *which* + noun vs. *which* + *of* + *the* + noun). Samples of the stimuli with a gap in a *whether*-clause are given in (7a), in the main clause in (7b), and in a *that*-clause in (7c).

(7) a. **What/What movie/Which movie/Which of the movies** does Jean wonder [whether they will watch __ at the cinema]?
b. **What/What movie/Which movie/Which of the movies** will they watch __ at the cinema?
c. **What/What movie/Which movie/Which of the movies** does Mary think [they will watch __ at the cinema]?

The stimuli are arranged in 8 lists using a Latin square design, and subjects respond to the stimuli using magnitude estimation (Bard et al., 1996).

Alexopoulou and Keller find some evidence of a D-linking effect in the *whether*-island case, with *which* + noun (though not *what* + noun or *which* + *of* + *the* + noun) resulting in significantly higher acceptability than bare *what* in cases like (7a). Crucially, however, this effect is not found in either of the non-island environments (see Sprouse et al., for a similar finding, though with D-linked vs. bare as a between-subjects factor). That is, when the gap is in the matrix clause, as in (7b), or in an embedded *that*-clause, as in (7c), there is no significant difference among the four filler types. As discussed above, a result such as this presents straightforward evidence against the working memory account of the D-linking effect, since this account predicts that D-linked fillers will be easier to reintegrate into the structure and that this will lead to increased acceptability, both in island and non-island contexts. The lack of an observed effect in the non-island contexts is entirely consistent with the grammatical accounts and thus provides an argument in their favor.

(7b-c) are standardly considered fully acceptable with any of the fillers, however, so in order to detect a D-linking effect in these cases, the experiment will need to be able to distinguish among sentences at the very high end of the acceptability scale. There is some indication in Alexopoulou and Keller's results that their experiment is not able to do this reliably. Sentences with short dependencies as in (7b), where the filler and the gap are within the same clause, have always been found in previous experimental work to be much more acceptable than those with long dependencies, such as in (7c), where the filler and the gap are in separate clauses, despite the fact that both are standardly treated as grammatical (e.g., Cowart, 1997; Alexopoulou and Keller, 2007). In Alexopoulou and Keller's results, though, the two sentence types are virtually identical, strongly suggesting the presence of a ceiling effect. If this is true for short vs. long filler-gap dependencies, for which the literature reports a very robust difference, then the fact that they find no difference among the four filler types is perhaps not as telling as it appears at first.

A similar lack of expected distinctions in the mid-range of the acceptability scale suggests that the experiment may not have attained a level of sensitivity sufficient to detect all potential contrasts of interest. The *whether*-islands tested are a canonical example of the type of island that is thought to exhibit D-linking effects (see, e.g., Szabolcsi, 2006), yet recall that this was only found with *which* + noun, not *what* + noun or *which* + *of* + *the* + noun, contrary to expectations. The absence of a D-linking effect with *that*-clauses in this experiment is thus perhaps not

surprising, given that this effect was also not detected in some of the cases where it would be most expected.

The possibility that the experiment was not sensitive enough to detect all potential D-linking effects gains further plausibility when one looks at the details of the experimental design, which show several features that could have contributed to a lowered level of sensitivity. In terms of the materials, each participant saw just one token of each condition, and there was a 1:1 filler/experimental ratio. In addition, there was only partial counterbalancing of the stimuli: There were 24 conditions overall, yet only 8 lexicalizations of each condition, and 8 lists of stimuli were created. These lists were distributed among 22 participants, so some lists (and stimuli) were seen by more participants than others. As for the participants themselves, they were self-reported native speakers of English recruited over the Internet. Given the nature of the English-speaking community, where bilingualism in many forms is very common and it is not always clear who counts as a "native speaker," it is possible that the participants' language histories were very heterogeneous, which in turn could have led to increased variability in their responses. In addition, participants took part in the experiment over the Internet. Although indications are that performing sentence acceptability experiments in this way gives adequate results (Gibson et al., 2011; Sprouse, 2011b), there is still the realistic possibility that it will result in increased noise, especially when the number of participants is small. Finally, the response method used with participants (magnitude estimation) may have also contributed to a decrease in sensitivity. This is still a matter of some controversy, but there are suggestions in the literature that magnitude estimation may not be as sensitive as initially thought and that it may even obscure fine-grained distinctions (Sprouse, 2011a; Weskott and Fanselow, 2011; Fukuda et al., 2012).

We of course cannot be sure that any of the above factors resulted in a decrease in the experiment's sensitivity, but given that the D-linking effect is likely very subtle, it would be prudent to avoid design features that might make detecting such an effect more difficult.

Given the existing literature, then, it is still an open question whether D-linking increases the acceptability of *wh*-dependencies in non-island environments and if it does, whether this effect is smaller in non-islands than in islands. In the Hofmeister (2007a) study, the results are not clear enough to draw firm conclusions, and in the Alexopoulou and Keller (2013) study, there are reasons to suspect that the results are compromised by a ceiling effect and a general lack of sensitivity. In the following section, we describe an experiment that is designed to address directly the questions of a possible D-linking effect in non-island environments and how this might compare to that in island environments.

EXPERIMENT

PARTICIPANTS

Fifty six people participated in this experiment. All were undergraduate students at the University of California, San Diego who were participating for course credit. The experiment was performed in a laboratory setting, with prior authorization from the university's Institutional Review Board. All participants gave their informed consent.

The results of two groups of participants were excluded. The first included those who on a language background questionnaire, gave a language other than English as their native language or their dominant language, or who indicated that they had been born outside of the U.S. This eliminated 6 participants. The second group included those who did not appear to be attending to the task, as evidenced by their responses on 9 key filler items that were unquestionably grammatical or unquestionably ungrammatical. Participants who made 2 or more "errors" on these fillers were excluded, where "errors" are defined as a response of 3 or below (on a 1–7 scale) to a grammatical filler or a response of 5 or above to an ungrammatical filler. 2 participants were eliminated in this way, leaving 48 in total (2 per experimental list).

MATERIALS AND METHOD

Experimental items were all *wh*-questions and were prepared using a 2 × 3 design, crossing filler type (bare vs. D-linked) and type of structure in which the gap is located (embedded complex noun phrase vs. *wh*-clause vs. *that*-clause). With regard to filler type, the bare filler was always *what* and the D-linked fillers all had the form *which of the* + plural noun. With regard to structure type, the complex noun phrases all contained a singular head noun (e.g., *claim*, *plan*, *idea*), followed by a clausal complement, and the *wh*-clauses all contained *who* as subject of that clause. The 6 conditions are exemplified in (8).

(8) a. **What / Which of the cars** do you believe the claim that he might buy?
b. **What / Which of the cars** do you wonder who might buy?
c. **What / Which of the cars** do you believe that he might buy?

(8a) and (8b) are classic violations of island constraints: the Complex Noun Phrase Constraint (CNPC) and the *Wh*-island Constraint, respectively (Ross, 1967). The gap in (8c) is within a *that*-clause, a classic non-island environment.

Twenty four sets of lexically matched stimuli were created and distributed into 6 counterbalanced lists using a Latin square design, such that each list contained 4 tokens of each condition. 81 filler items were added to each list, and the lists were then pseudo-randomized twice, resulting in 12 lists. An additional 12 lists were created by reversing the order of items, resulting in a total of 24 lists. 2 participants were randomly assigned to each list; each experimental item was thus seen by 8 participants. The full set of stimuli is presented in the Supplementary Material.

Participants saw the stimuli on a computer screen and were instructed to rate each sentence on a scale from 1 ("very bad") to 7 ("very good") based on how it sounded to them as a native speaker of the language. The scale was presented horizontally in evenly spaced increments with only the two extremes labeled and participants indicated their response by clicking on the appropriate number. They were told to rely on their first reaction, without trying to analyze the sentence, and that there were no "correct" answers. They were also told to rate each sentence on its own, regardless of how simple or complicated the sentence might seem.

RESULTS

The results were transformed to z-scores prior to analysis. The z-score mean and standard error for each of the six conditions is presented in **Figure 1**.

A linear mixed effects model was run with filler type and structure type as fixed factors, participant and item as random intercepts, and by-participant and by-item random slopes for filler type and a by-participant random slope for structure type, using the *lmer* function in the *lme4* package for R (Bates et al., 2014a,b; R Core Team, 2014). All *p*-values were calculated by Satterthwaite approximation, using the *lmerTest* package (Kuznetsova et al., 2014). This revealed a significant main effect for filler type (D-linked: −0.168 vs. bare: −0.444; $t = 3.446$; $p < 0.001$), and this effect remained significant when the model was restricted to each of the three structures individually: CNPC (D-linked: −0.441 vs. bare: −0.705; $t = 3.476$; $p < 0.01$), *wh*-island (D-linked: −0.545 vs. bare: −0.923; $t = 3.982$; $p < 0.001$), and *that*-clause (D-linked: 0.483 vs. bare: 0.295; $t = 2.416$; $p < 0.02$). To test for an interaction between filler type and structure type, a second model was constructed without an interaction between these two fixed factors and the results compared to the first by means of the *anova* function. This revealed no significant difference between the two models ($p = 0.155$) and thus no significant interaction between these two factors. The interaction between filler type and structure type was also not significant when the CNPC data were excluded and the model run as a 2 × 2 design, with *wh*-island and *that*-clause as the levels for structure type ($t = 1.866$; $p = 0.062$) and when the *wh*-island data were excluded and CNPC and *that*-clause used as the levels for structure type ($t = 0.771$; $p = 0.440$).

To a large extent, earlier observations in this domain are confirmed (e.g., general island effects and D-linking effects are readily apparent), but there are two novel findings here. First, the increase in acceptability associated with D-linked fillers occurs in all three structure types, not just in the islands. Second, this increase is uniform across all three types. That is, the amount of increase associated with D-linking does not appear to vary significantly between islands and non-islands.

As noted earlier, achieving sufficient sensitivity is a concern in this type of study, but the fact that all of the island effects and D-linking effects that the existing literature predicts did emerge suggests that the experiment was successful in this regard. It also appears that the experiment avoided a ceiling effect in the case of *wh*-questions with a gap in the *that*-clause. Although significantly more acceptable than the island violations, these sentences are still within the mid-range of the acceptability of the fillers. As seen in **Figure 2**, the acceptability of the fillers went as high as 1.61, much higher than the mean acceptability of the *that*-clause sentences with either a bare or D-linked filler (0.295 and 0.483, respectively).

DISCUSSION

The main purpose of this study is to determine whether D-linking of the filler improves the acceptability of *wh*-questions where the gap is in a non-island, and if so, whether this improvement is of the same size as that which occurs when the gap is within an island. We have now seen that the effect does occur in non-islands and that it is not different in size from that observed in islands. More specifically, D-linking leads to a significant increase in acceptability when the gap is in a non-island *that*-clause, and in addition, significant increases are also found in the two island cases examined. There is no significant interaction between filler type and structure type, suggesting that the amelioration due to D-linking is essentially uniform regardless of whether the gap is within an island or non-island.

These results confirm one crucial prediction of the working memory analysis of D-linking effects. If, as this analysis claims, D-linking effects arise because the nature of D-linking allows for easier reintegration of the filler at the gap site, and if this in turn results in higher acceptability, then we would expect to be able to

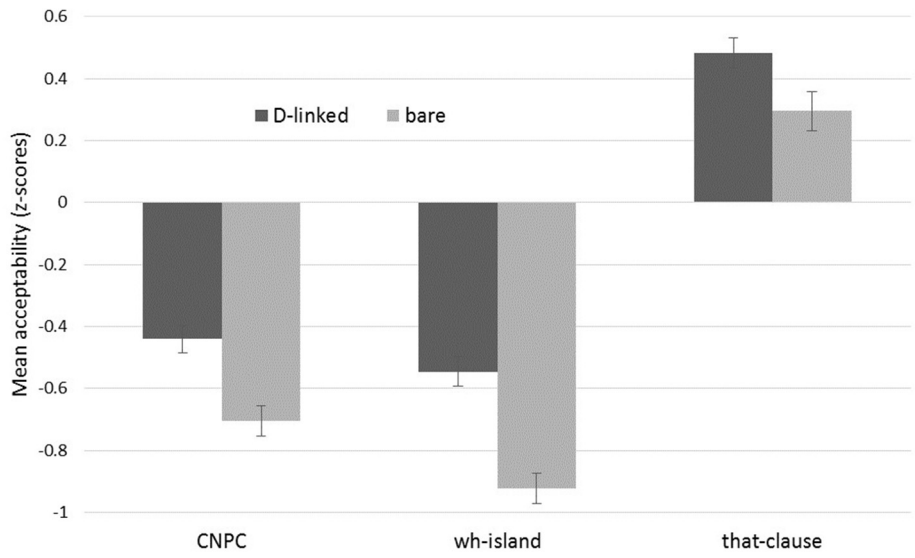

FIGURE 1 | Mean acceptability of experimental conditions (z-scores; error bars indicate SE).

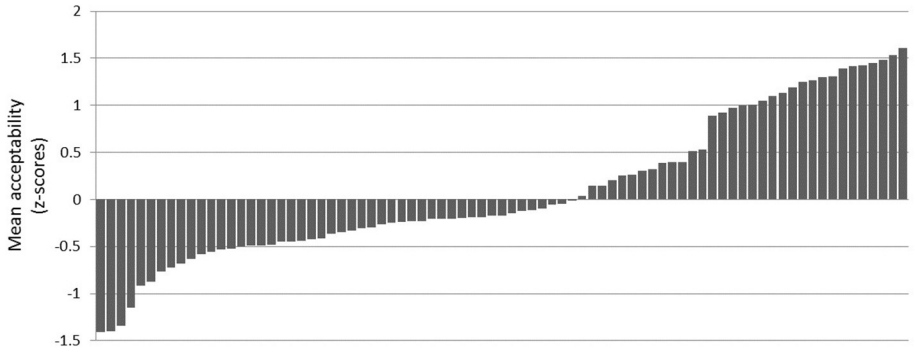

FIGURE 2 | Mean acceptability of fillers (z-scores).

detect this increase in acceptability no matter whether the gap is located in an island or a non-island. The results seen here suggest that this prediction is correct and thus provide new evidence in favor of the working memory analysis. This new evidence from acceptability complements and is in accord with the considerable evidence already existing that D-linking facilitates the processing of filler-gap dependencies.

The results of the experiment are at odds, however, with another prediction that is shared by both the working memory analysis and the grammatical analyses. Namely, the experiment finds an essentially uniform D-linking effect in both islands and non-islands, whereas both types of analyses, in their most straightforward forms, predict a larger effect in the case of islands. For the working memory analysis, this is because island phenomena are the result of an interaction between the difficulty of the dependency and the difficulty of the structure, so if we assume that this interaction is simple (e.g., multiplicative), facilitating the dependency in this case should lead to an increase in the acceptability of the island that is larger than what would be expected by facilitating the dependency alone, as in a non-island structure. For the grammatical analyses, it is because island phenomena are the result of limitations on the operation of the syntax and/or semantics, and D-linking has the effect of removing these limitations. In non-islands, these limitations do not exist, so no effect of D-linking is expected. Both the working memory and the grammatical analyses, then, predict a difference in behavior between islands and non-islands with regard to D-linking, but this difference is not found here.

On the one hand, then, the results of the experiment here provide important support for the idea that the D-linking effect is ultimately due to an effect of working memory. We have found that D-linking increases acceptability in both island and non-island environments, just as would be expected if D-linking facilitates reintegration of the filler at the gap site in filler-gap dependencies. On the other hand, though, the results suggest caution with the idea that the island phenomenon itself is ultimately due to working memory. As we have seen, we would expect a larger D-linking effect in islands than in non-islands if this were true, and this is not what we observe. The results here are most compatible, then, with the view that the D-linking effect is due to working memory and that the island effect is due to some independent mechanism. Crucially, this mechanism and the working memory effect should be such that they do not interact, as would be expected, for example, if the island effect (but not the D-linking effect) were the result of a grammatical constraint. Given the types of grammatical constraints that have been proposed for islands (e.g., Rizzi, 2004; Boeckx, 2008; Truswell, 2011), one would expect them to combine additively with working memory effects, without any interaction, and the results here thus provide some support for such an account of islands and D-linking. Clearly, though, any conclusion that islands themselves are independent of working memory effects must be approached with caution, given the evidence that has been put forward suggesting that the two are closely related (for recent discussion of the evidence for and against this idea, see Hofmeister et al., 2012a,b; Sprouse et al., 2012a,b; and Michel, 2014).

Further support for the idea that the D-linking effect itself is due to the effects of working memory comes from an experimental result not yet highlighted: both CNPC and *wh*-islands show a significant amelioration with D-linking. This finding is of interest because much of the literature on D-linking assumes that it affects only *weak* islands (i.e., those in which acceptability of an argument gap is much higher than that of an adjunct gap) and not *strong* islands (i.e., those in which argument gaps and adjunct gaps are equally unacceptable) (e.g., Cinque, 1990). *Wh*-islands are a standard example of a weak island and CNPC is typically taken to be a strong island (e.g., Szabolcsi, 2006), so the fact that both show a clear D-linking effect in the results here runs counter to common assumptions. It is exactly what the working memory analysis of D-linking predicts, however, so this finding represents additional support for it.

Another area where the experimental results here run counter to common assumptions in the literature concerns the relation between D-linking and islands. It is often stated that D-linking makes gaps within islands licit (e.g., Szabolcsi, 2006). The results here point to a more nuanced view, however. Although a D-linked filler does significantly increase the acceptability of a gap within an island, this increased acceptability is still relatively low: the mean z-scores are well below 0 (-0.441 for CNPC and -0.545 for *wh*-islands) and below most of the filler items (see also Goodall, 2004, 2010; and Sprouse et al., in press). The contribution of D-linking to acceptability seen here may thus be more modest

than what is sometimes suggested, but this fact is compatible with both processing and grammatical analyses of D-linking. In the processing analyses, the idea that D-linking leads to easier reintegration of the filler at the gap site does not mean that no difficulty remains, and this residual difficulty would reasonably be expected to lead to low acceptability. In the grammatical analyses, similarly, D-linking may make it easier to construe the filler as being individuated or as referring to material in the previous discourse, but it is very conceivable that such accommodation would come with a processing cost that would suppress acceptability. The fact that the increase in acceptability due to D-linking is relatively small is thus important to note, but it does not in itself necessarily differentiate among various analyses of the D-linking effect.

The experiment here was designed to test for D-linking effects across a range of syntactic environments. As is always the case, one must be cautious about generalizing the results beyond those structures tested. The experimental design included reasonable representative samples of a non-island structure (*that*-clause), for instance, and of island structures (CNPC and *wh*-islands), but these of course do not exhaust the possibilities (see Sprouse et al., in press, for an investigation of subject and adjunct islands, in addition to those explored here). Similarly, the type of D-linked filler used (*which of the* N) is a prototypical one, but there are other possibilities (*which* N or *what* N) that could also be tested. In addition, the stimuli in this experiment were presented without context (although by their very nature, D-linked fillers provide a kind of context that bare fillers do not), but D-linking is known to be sensitive to context, to such an extent that even bare *wh*-words can behave as D-linked *wh*-phrases if the context is strong enough (e.g., Cinque, 1990; Szabolcsi and Zwarts, 1993; Rizzi, 2004). There is no particular reason to expect that manipulating either the island/non-island structure or the properties of the filler would alter the results presented here, but prudence dictates caution in extending too far beyond what this study provides evidence for.

IMPLICATIONS FOR FORMAL ACCEPTABILITY EXPERIMENTS

The use of formal experiments to measure acceptability is relatively recent, primarily coming after the publication of Schutze (1996) and Cowart (1997), and has only become common in the last few years (see, e.g., Myers, 2009 and Sprouse and Hornstein, 2013 for overviews). As a consequence, there are still certain methodological concerns and questions for which there does not yet exist a full consensus, and some of these relate to aspects of the present study.

One of these concerns the proper way to interpret participant responses to stimuli on the numerical scale. In this study, as in many others, participants were asked to indicate their responses using a 7-point scale, where 1 was labeled "very bad" and 7 "very good." This method is known to yield results that are reasonably valid, reliable and sensitive (Myers, 2009; Weskott and Fanselow, 2011; Fukuda et al., 2012), but there remain concerns that participants may use different areas of the scale in different manners. In particular, Poulton (1979, 1989) demonstrates equalizing biases in rating tasks in which participants spread out responses over the full range of the scale and tend to use each response category equally often. In acceptability studies, this means that if there were a large number of low-acceptability stimuli and many fewer high-acceptability stimuli, for example, the differences among the lower ones could be exaggerated (i.e., participants would spread their responses out over a larger portion of the scale) while differences among the higher ones could be suppressed (i.e., participants would compress their responses into whatever portion of the scale was not being used for the lower stimuli). A possibility like this is a special concern in the present study for two reasons. First, the essential question being asked is whether a small difference in the lower end of the scale (i.e., the D-linking effect in island environments) is also found in the higher end of the scale (i.e., in non-island environments). Since this latter difference was indeed found, one could legitimately worry that this finding results simply from a tiny difference being exaggerated because of an equalizing bias. Second, there is some initial indication that the results are consistent with an equalizing bias, in that many of the response categories were used at similar rates, as seen in **Figure 3** (especially categories 2, 3, 5, and 7), and furthermore, the number of responses at the lower end (categories 1–3) and at the higher end (categories 5–7) of the scale were almost identical: 2183 and 2151, respectively.

There is thus a real concern that the results are influenced by an equalizing bias on the part of participants. However, closer inspection of participant responses reveals that despite the overall distribution in **Figure 3**, most individual participants used the seven response categories at very uneven rates, as seen in **Figure 4**, suggesting that there was no clear equalizing bias for most participants.

Moreover, Cowart (1997), notes that rating experiments can be designed so as to discourage the possibility of equalizing bias. For example, the stimuli (including filler items) can be created so that no particular area of the scale is likely to predominate, thus decreasing the possibility of distortion in one area of the scale. In addition, the response scale can be presented to subjects in such a way that clearly invites an interpretation of the numbers as representing equal intervals. Both of these measures were taken in the present study. The stimuli included many filler items that were unquestionably of very high acceptability, as in (9), and of very low acceptability, as in (10), as well as many of intermediate status, as in (11).

(9) What do you think was on the table yesterday? (raw mean = 6.67).

Are all of the children in the room? (raw mean = 6.88).

(10) What would the girl could the tiger suddenly do? (raw mean = 1.54).

Would the this store is successful? (raw mean = 1.54).

(11) What does everybody say that Marge saw the books? (raw mean = 2.69).

Who were sculptures of on exhibit in the gallery? (raw mean = 3.58).

About which bike will several ads be shown to the athletes? (raw mean = 4.61).

Second, the response categories were presented after each stimulus in left-to-right increasing order in evenly spaced increments, in the manner of a ruler, with each numeral underneath its

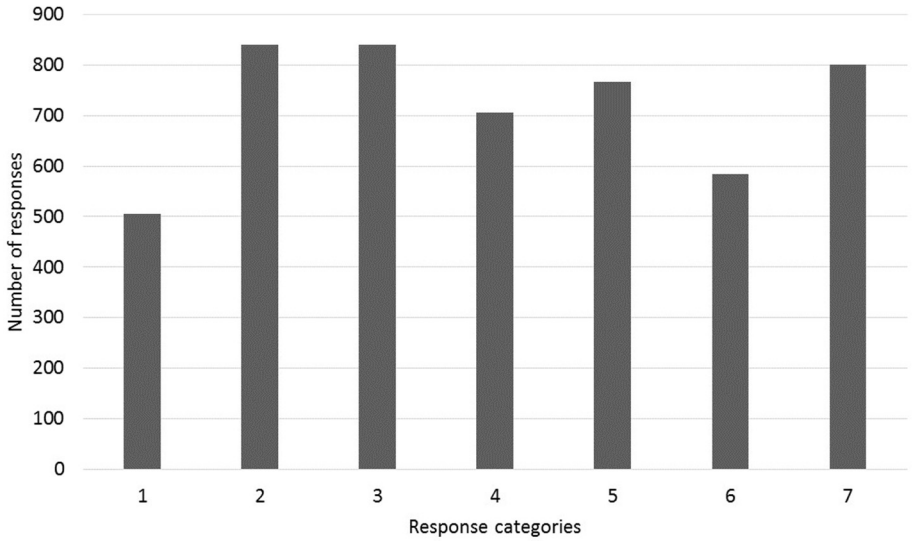

FIGURE 3 | Distribution of the 5040 participant responses per response category.

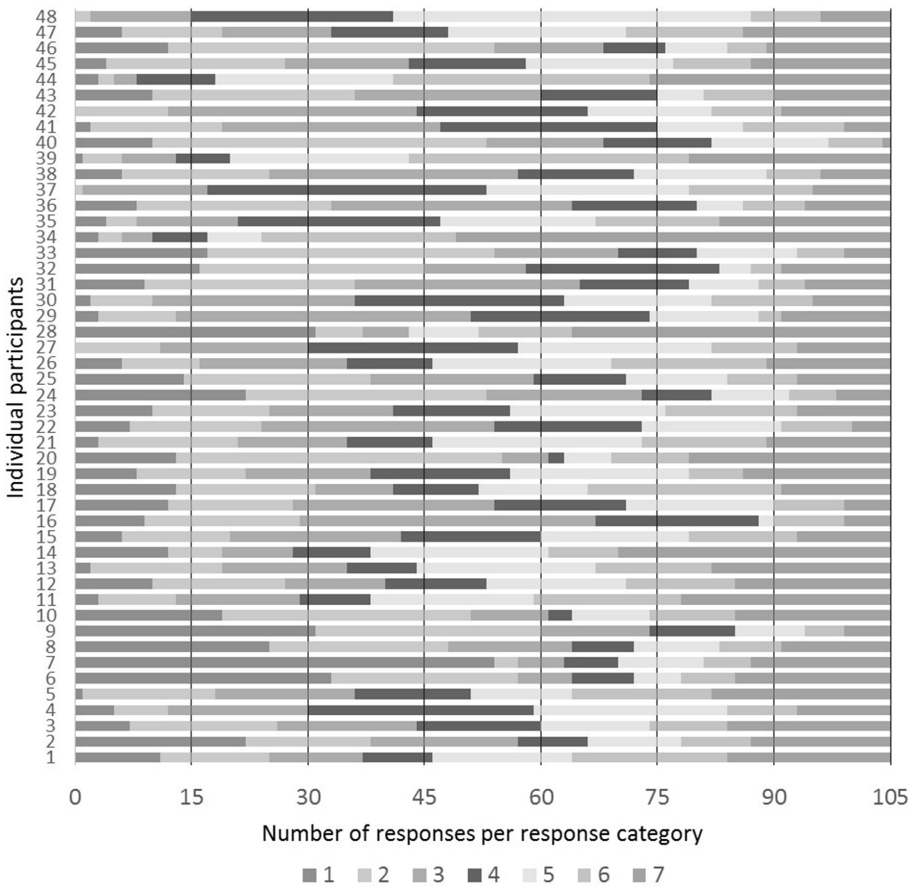

FIGURE 4 | Distribution of responses by individual participant. An equal distribution of responses would consist of 15 responses per category per participant.

corresponding response button. Neither of these steps can eliminate the possibility of response biases, but together, they make it more likely that the D-linking amelioration that we observed with non-islands at the higher end of the scale is in fact similar and comparable to the amelioration seen with islands at the lower end of the scale.

Another area of concern in the recent literature on formal acceptability experiments has been cases where the experimental results and those obtained through more traditional means (i.e., by asking a small number of speakers (perhaps including the investigator) for judgments on a representative set of sentences) seem to diverge (Sprouse and Almeida, 2012, 2013; Gibson and Fedorenko, 2013; Gibson et al., 2013; Sprouse et al., 2013). The present experiment is of interest in this regard, because some of the results align with the traditional literature and others do not. For instance, the D-linking effect that was observed here with *wh*-islands lines up well with what has been reported in more traditional studies, but the similar effect seen with *that*-clauses does not. This then leads to a clear question: If there really is a D-linking effect with gaps in *that*-clauses, why has this never been observed in studies using more traditional methodology? Two possible answers arise. First, it may be simply that no one found this effect because no one was looking for it. From the standpoint of a researcher exploring properties of the grammar, gaps within *that*-clauses are highly acceptable and thus presumably grammatical (i.e., allowed by the grammar). Finding that these gaps become even more acceptable when the filler is D-linked would not be informative, because in standard models, there is no way for the sentence to become even more grammatical. Put simply, standard grammatical models can capture gradations of ungrammaticality (e.g., by counting the number of violations or their severity), but not gradations of grammaticality. From this standpoint, then, there would be no particular reason to look for D-linking effects in otherwise grammatical sentences.

A second answer might be that formal acceptability experiments appear to be very sensitive to strains on working memory in a way that more traditional methods are not, especially for sentences in the higher range of acceptability. For example, filler-gap dependencies within a single clause and those spanning two clauses are, other things being equal, taken to be equally acceptable in traditional studies, but formal acceptability experiments typically find a sharp decline in acceptability for the latter (Kluender and Kutas, 1993; Cowart, 1997; Alexopoulou and Keller, 2007). It is not clear why this divergence between the two methods occurs, but given that it does, the fact that the present study found a distinction that traditional studies have not begins to make sense. If the D-linking effect truly is a working memory effect, then we might not expect traditional methods to be sensitive to it in the case of *that*-clauses, which are of relatively high acceptability.

There thus appear to be reasonable ways in which one might explain the discrepancy between traditional methods and the experiment presented here with regard to the effect of D-linking in non-island environments. In this case or more generally, it is not a question of which of these methods is right or wrong, but of which is appropriate given the resources available and the nature of the phenomenon being investigated. Since the focus of investigation here concerns the possibility of small differences in acceptability among sentences that are taken to be grammatical, where working memory effects might crucially be involved, a formal experiment seems appropriate.

Finally, the present experiment highlights the fact that there is as much need for careful design and attention to detail in sentence acceptability experiments as in any other experimental methodology. Many of the acceptability contrasts that interest researchers are very robust and are easily detectable across a wide range of methodologies: traditional fieldwork, traditional introspection, very simple experiments, etc. For more subtle contrasts, however, the method may need to be chosen more carefully. In this study, several steps were taken in order to ensure adequate sensitivity and to avoid a ceiling effect, a particular danger in this case since the crucial sentences of interest were of relatively high acceptability. For example, participants were screened for language background and attention to task, and they performed the experiment in a laboratory setting. The materials were also fully counterbalanced: experimental stimuli were distributed across lists following a standard Latin square design, and each experimental item was seen by exactly the same number of participants. Filler items represented a wide range of acceptability, including many of very high acceptability. In addition, there was a relatively large number (192) of observations per condition (4 tokens of each condition per participant; 48 participants), and the response method used by participants (7-point scale) is one that has been shown capable of capturing small differences in acceptability (Weskott and Fanselow, 2011; Fukuda et al., 2012). These various aspects of the experimental design were chosen deliberately in response to the particular needs presented by this study.

CONCLUSION

It has been known for many years that D-linking, where the filler in a *wh*-question prompts an answer chosen from referents already existing in the discourse, increases the acceptability of sentences where the gap is inside an island configuration. It has been claimed in a number of analyses that this phenomenon reflects the way that working memory operates in sentence processing, in that at the point of the gap site, D-linked fillers are easier to access and then integrate into the existing structure, and that this ease of processing results in higher acceptability. These analyses clearly predict that this D-linking effect should be found not just with islands, but with filler-gap dependencies in non-islands as well. The experiment presented here tested this prediction directly by probing for D-linking effects on acceptability in two island and one non-island environments. It was seen that the effect occurs in all three cases, confirming the prediction made by the analyses that attribute the effect to the operation of working memory.

In addition, the effect is essentially uniform across all three cases, contrary to what many analyses of the islands themselves would predict. The combined results are most compatible with a view in which the D-linking effect is due to working memory and the island effects are due to something independent of this, such as grammar. The results here suggest that these two effects may combine additively, but do not interact.

ACKNOWLEDGMENTS

Aspects of this work have been presented at the CUNY Conference 2013, the Linguistic Society of America Annual Meeting 2014, the Workshop on Understanding Acceptability Judgments at the University of Potsdam, and the University of Chicago. I am grateful to the audiences there for their valuable feedback and to Adrienne LeFevre and Michelle McCadden for their assistance in carrying out this research.

Distinctiveness and encoding effects in online sentence comprehension

In explicit memory recall and recognition tasks, elaboration and contextual isolation both facilitate memory performance. Here, we investigate these effects in the context of sentence processing: targets for retrieval during online sentence processing of English object relative clause constructions differ in the amount of elaboration associated with the target noun phrase, or the homogeneity of superficial features (text color). Experiment 1 shows that greater elaboration for targets during the encoding phase reduces reading times at retrieval sites, but elaboration of non-targets has considerably weaker effects. Experiment 2 illustrates that processing isolated superficial features of target noun phrases—here, a green word in a sentence with words colored white—does not lead to enhanced memory performance, despite triggering longer encoding times. These results are interpreted in the light of the memory models of Nairne, 1990, 2001, 2006, which state that encoding remnants contribute to the set of retrieval cues that provide the basis for similarity-based interference effects.

Keywords: encoding, retrieval, similarity, distinctiveness, sentence processing

1. INTRODUCTION

In everyday life and in laboratory experiments, people remember the unusual better than the usual. Von Restorff's classic findings illustrate this in terms of superior memory for isolated items, such as a bright green word in the context of a list of words colored black (von Restorff, 1933). More generally, a background of homogeneous stimuli favors the recall and recognition of contextually isolated stimuli. These so-called isolation effects share certain key characteristics with another set of memory effects tied to meaning-related processing. The latter include findings that people recall random trivia facts better if they subsequently hear causally-related information (Bradshaw and Anderson, 1982). Word recall and recognition benefits, too, from meaning-related processing (e.g., assessing the pleasantness of word meanings) compared with the processing of superficial features (e.g., identifying whether the word contains the letter "e"), at least under conditions where the memory retrieval phase taps word meaning (Craik and Lockhart, 1972; Hyde and Jenkins, 1973; Craik and Tulving, 1975; Stein et al., 1978).

Although clearly different in some respects (meaning-related processing is not typically taken to be 'unusual' or 'bizarre'), these two sets of effects can be thought of as being parallel in light of their relationship to both encoding and retrieval. In particular, elaboration and isolation each tend to give rise to longer encoding or study times. Elaboration, like isolation, also raises the probability of contextually unique features that serve to differentiate study items at retrieval, because elaboration typically yields highly diagnostic, meaning-related units of information. Thus, these two memory phenomena both potentially reflect a common set of core principles on the encoding-retrieval relationship and the dynamics of retrieval interference.

Correspondingly, mechanistic explanations for both kinds of effects have hinged on processes operative at either the encoding or the retrieval stage. From one view, the mnemonic benefits may arise from increased processing or attention during the encoding phase (Hirshman et al., 1989; Watkins et al., 2000; Shiffrin, 2003), leading to higher fidelity representations, more highly activated representations, or simply a richer set of self-generated features that form a partly redundant network with the core memory representation. This implies a type of investment-reward strategy; by paying for the cognitive costs of "enhanced" representational encoding, the costs of memory retrieval are lessened.

From a different but not mutually exclusive perspective, semantic processing increases the *distinctiveness* of the stimuli at the time of retrieval: "additional conceptual or semantic features help to differentiate the studied words from each other, making these memories less susceptible to interference and/or providing more features that can be cued on a typical recall or recognition memory test" (Gallo et al., 2008, p. 1096; see also Moscovitch and Craik, 1976; Fisher and Craik, 1977; Jacoby and Craik, 1979; Hunt and Worthen, 2006). In other words, semantic processing of words trumps superficial processing because processing a word's meaning generates more contextually unique features than focusing on its sound or orthographic features. For instance, many words in memory may have the sound [aʊ] or the letter sequence "ch." But relatively few items in memory may be associated with features like "sandy" and "next to the ocean." Consequently, such accounts predict more than a simple contrast

between meaning-related and non-meaning related processing. If semantic processing increases the chances of conceptual distinctiveness, then as semantic processing increases, the chances for successful retrieval from memory should improve up to some arbitrary limit. One implication for at least some such distinctiveness accounts is that a memory target will contrast more with other stimuli, and hence be remembered better, if those *competing* representations elicit more semantic processing. That is, differentiation of two study items may in principle be modulated by the presence/absence of unique semantic features of *either* item, as adding contextually unique features to a competitor cuts down on potential overlap between a competitor and memory target.

Much of this prior research deals with explicit memory for language stimuli, particularly word lists. How linguistic representations are recovered in their most natural setting—online sentence processing—as a function of either elaboration or isolation has not played a significant part in this line of research. This is no doubt due to the implicit nature of memory retrieval during comprehension. Yet comprehending sentences perpetually requires reaccessing some previously perceived information, such as when a pronoun must be interpreted or when the subject of a verb needs to be remembered, and this prior content may vary considerably in the requisite amount of syntactic and semantic processing. Another context in which retrieval from memory happens is in so-called long-distance dependencies (a.k.a. filler-gap dependencies), as in 1:

(1) I finally gave up reading the novel that James Joyce wrote ___ in the 1930s.

To understand this sentence, "the novel" must be retrieved at the embedded verb "wrote" to be properly interpreted as the thematic patient. Evidence that memory retrieval of the argument takes place at the verb comes from reading time data, cross-modal priming tasks, neurophysiological studies, and speed-accuracy tradeoff data (Tanenhaus et al., 1985; Nicol and Swinney, 1989; Kluender and Kutas, 1993; Osterhout and Swinney, 1993; McElree, 2000).

The purpose of the present investigation is to identify whether elaboration and isolation effects occur in online sentence processing and the extent to which such effects might be explained by relating encoding times to retrieval times. The working hypothesis, therefore, is that factors that predict the *success of explict recall* also contribute to the *efficiency of implicit retrieval*. While extant sentence processing models generally ignore variation in the encoding stage as a potential source of processing variation at retrieval sites, cue-based models of retrieval do predict that unique features in a memory target can facilitate retrieval (McElree, 2000; Van Dyke and Lewis, 2003; Lewis and Vasishth, 2005; Lewis et al., 2006; Van Dyke and McElree, 2006, 2011). However, such theories do not make across-the-board predictions that targets with more semantic features, or contextually unique features, ought to be easier to retrieve. This is due to the fact that only those features cued by the retrieval trigger bear on assessments of similarity. For instance, in 2 below, "was complaining" initiates a retrieval probe targeting the animate subject NP "the resident":

(2) a. The worker was surprised that the resident who was living near the dangerous warehouse *was complaining* about the investigation. [= LOW INTERFERENCE]
b. The worker was surprised that the resident who said that the neighbor was dangerous *was complaining* about the investigation. [= HIGH INTERFERENCE]

In the high interference condition, the head and dependent are separated by an NP ("the neighbor") which is a type of semantic object that "can complain" and is also subject marked, similar to the retrieval target. The intervening NP in the low interference condition, in contrast, is inanimate and the object of a preposition, thus mismatching the target semantically and syntactically. Using such materials, Van Dyke (2007) observed evidence of a processing disruption in the high interference condition beginning at the key verbal cluster, which she interpreted in terms of the mechanics of cue-based retrieval. On such an account, features not in the retrieval probe triggered by the verb should have little bearing on memory interference. Whether a target is the only word to begin with an "r" or appears in an unusual font should be immaterial to retrieval efficacy, for example, if verbs do not trigger retrieval probes containing such cues.

In the present experiments, key targets for implicit retrieval in long-distance dependencies differ in the amount of elaboration or "complexity" associated with them (Experiment 1), or with respect to the homogeneity of their text color with the surrounding text (Experiment 2). In both cases, the key features—prenominal modifiers and text color—are unlikely to be directly cued by the retrieval triggering verbs, i.e., verbs don't normally select arguments on the basis of color or the number of modifiers. If elaboration and isolation effects pattern in implicit memory retrieval tasks as they do in explicit memory tasks, then we should expect to see retrieval-related benefits in sentence processing given elaboration or isolation.

Recent reading time data provide some initial evidence that memory retrieval in sentence processing is sensitive to a memory target's representational complexity (Hofmeister, 2011). The term "complexity" is shorthand for the idea that discourse references can differ in semantic complexity via category hierarchy differences, e.g., "a thing" vs. "a stethoscope," as well as syntactic complexity. For instance, "the landmark on the bluff" encodes both syntactic and semantic features absent in "the landmark." In clefted constructions like those in 3, participants spent longer reading the head noun of the clefted element as the number of modifiers increased. At the words immediately following the subcategorizing verb (underlined below), however, reading times were faster given more features associated with the target. It is at this subcategorizing verb and the immediately following regions that we expect to observe signs of reactivation and retrieval of the representation in the cleft. Notably, the faster reading times for elaborated conditions do not appear until the subcategorizing verb or shortly thereafter:

(3) a. It was a communist that the members of the club banned from ever entering the premises.
b. It was an alleged communist that the members of the club banned from ever entering the premises.

c. It was an alleged Venezuelan communist that the members of the club banned from ever entering the premises.

Further experiments showed this same pattern even when holding the number of words and syntactic complexity constant, e.g., "which person" vs. "which soldier." At least in some contexts, therefore, syntactic and semantic processing of linguistic representations facilitates their retrieval from memory. It further suggests that recoverability increases gradiently with semantic processing—something that the list memory literature has so far not shown.

The present self-paced reading studies expand upon these findings in several ways. In Experiment 1, not only the target noun phrase, but also a preceding non-target noun phrase varies in syntactic and semantic complexity. In 4, for example, the matrix object noun phrase is the target for retrieval at "encouraged" and appears in either elaborated or non-elaborated form:

(4) The (senior foreign) diplomat contacted the (ruthless military) dictator who the activist from the United Kingdom encouraged to preserve natural habitats and resources

In addition, the preceding matrix subject noun phrase also varies between an elaborated and non-elaborated form. This manipulation of a competitor's complexity serves two purposes (note: "the activist" serves as a second potential competitor). First, it addresses the previously discussed question of whether elaborative processing linked to non-targets/competitors may facilitate differentiation at retrieval points. Such an idea is plausible from the perspective that providing more detail about any discourse referent or event lowers the chances that it will be confused with some other candidate for memory retrieval. Second, in 4 above, the key retrieval region ("banned") appears later in the complex sentences than in the simpler ones, opening the door to an explanation based on word position effects. Due to the manipulation of the complexity of multiple phrases in Experiment 1, it will be possible to directly assess whether the effects observable at retrieval sites are reducible to word position effects.

In Experiment 2, the essential components of von Restorff's design are carried over to the domain of sentence processing. Key words in the test sentences are systematically manipulated to make them superficially homogeneous or isolated with the expectation that this will give rise to longer encoding times. The question is whether superficial isolation or differentiation of words in sentences produces retrieval effects that are qualitatively similar to the effects of elaboration in online sentence processing. If they do, then we have evidence of a tight correspondence between implicit and explicit retrieval processes targeting linguistic stimuli.

As we shall see, both elaboration and isolation give rise to longer encoding times, but only the former yields strong evidence for faster reading times at sentence-internal retrieval sites. Moreover, while the elaboration associated with a non-target has striking downstream effects on encoding processes for other discourse referents, the evidence for an effect of non-target complexity on the retrieval of target representations is considerably weaker.

2. EXPERIMENT 1: TARGET AND NON-TARGET COMPLEXITY

2.1. PARTICIPANTS

Fifty-two University of Essex undergraduates participated in this study for course credit or payment. All participants identified themselves as native English speakers without significant exposure to a second language before the age of five. No participant data was removed on the basis of accuracy, as all participants scored above 67% correct.

2.2. METHODOLOGY AND MATERIALS

In this 2 × 2 self-paced, moving window experiment, 28 items varied in terms of the complexity of a target noun phrase and a non-target noun phrase in the same sentence. Specifically, all sentences contained a transitive matrix clause of the form [NP V NP], where the object noun phrase was modified by an object relative clause. The matrix subject (NP1) appeared with either 0 or 2 modifying words, as did the matrix object NP (NP2), as illustrated below:

(5) a. The congressman interrogated the general who a lawyer for the White House advised to not comment on the prisoners. (= SIMPLE SIMPLE)
b. The conservative U.S. congressman interrogated the general who a lawyer for the White House advised to not comment on the prisoners. (= COMPLEX SIMPLE)
c. The congressman interrogated the victorious four-star general who a lawyer for the White House advised to not comment on the prisoners. (= SIMPLE COMPLEX)
d. The conservative U.S. congressman interrogated the victorious four-star general who a lawyer for the White House advised to not comment on the prisoners. (= COMPLEX COMPLEX)

The subject of the object relative clause (NP3) was always of the form [DET NOUN]. At the critical embedded verb ("advised" in the example above), proper interpretation of the sentence requires retrieval of the representation referred to by NP2. It is also at such sentence internal retrieval sites that prior psycholinguistic evidence has repeatedly identified signs of similarity-based memory retrieval interference from competing representations (Gordon et al., 2001, 2002, 2006; Van Dyke and McElree, 2006).

Each participant saw only one condition of each item. All sentences were followed by a yes/no comprehension question, and participants received feedback if they answered incorrectly. The comprehension questions targeted information about one of the three referents introduced in the sentence, e.g., "Was the general advised not to comment on the prisoners?" with numerous questions asking about the relationship between two referents, e.g., "Did a photographer embarrass a celebrity?" In Experiment 1, mean comprehension accuracy across all trials, including fillers, was 84% (min = 70%, max = 97%). 70 fillers accompanied the

main experimental items for this experiment. Twenty eight of these were from an unrelated experiment.

Materials were presented and randomized with the reading time software LINGER v. 2.94, developed by Doug Rohde (available at http://tedlab.mit.edu/~dr/Linger/). The experimental items were randomized by the experimental software, and at least one filler separated each critical item. At the beginning of each trial, a fixation cross at the left of the screen appeared on the same line where the target sentence subsequently appeared. On pressing a key, the cross disappeared and the first word of the sentence was shown. Words not currently being read were not presented on screen and were not masked with dashes, i.e., the screen was blank except for the word currently being read. We opted for this method to prevent participants from using end-of-sentence information to modulate their reading rate, since the target sentences differed in overall length.

Prior to statistical analysis, raw reading times greater than 5000 ms or less than 100 ms were removed, affecting a total of 0.001% of the data. No additional outlier removal processes were performed. All data were analyzed regardless of comprehension accuracy in order to capture any reading time differences that may reflect memory retrieval failures. In other words, as we are investigating not only retrieval efficiency but also success, excluding trials that were incorrectly responded to would eliminate an important and relevant subset of the data on which retrieval of the target NP potentially failed. However, in the Supplementary Materials, we also present secondary analyses using only data from correctly answered trials.

Reading times were log-transformed to normalize the residuals and reduce the effect of extreme data points. Then, the log reading times for all stimuli (fillers included) were regressed against several predictors known to affect reading times in self-paced reading tasks: word length and log list position (Ferreira and Clifton, 1986; Hofmeister, 2011). Specifically, longer words predict longer reading times and later list positions predict faster reading times as participants progress through the experiment. The model estimating these effects included a random effects term for participants, i.e., by-participant random intercept adjustments. We used data from fillers in this process to produce maximally general estimates of word length and list position. The residuals of this model—RESIDUAL LOG READING TIMES—are the dependent variable analyzed here (**Figure 1** shows raw reading times to provide a more interpretable scale for the effects). All categorical predictors variables were sum coded to reduce effects of collinearity.

All analyses were conducted with Bayesian hierarchical models, fit with Stan and the `R` package `rstan`. We employed these models because they allow us to fit complex hierarchical models with maximal random effect structures that often do not converge using other popular linear regression packages such as `lme4`. Moreover, as noted in Husain et al. (2014), using Bayesian models allows us to assess and compare the weights of evidence for particular hypotheses. This means that we avoid categorizing effects as significant or non-significant, eschewing traditional statistical inference based on p-values. Instead, we make statistical inferences for particular hypotheses by computing the posterior probabilities for relevant parameters θ_i by sampling from their posterior distribution.

Each word region model used 4 chains, 5000 samples per chain, a warm-up of 2500 samples, and no thinning, resulting in 10,000 samples for each parameter estimate. All models contained fixed effect parameters for NP1 complexity, NP2 complexity, and their interaction. They also included by-participant random intercept adjustments and random slopes for all fixed effect terms (3 parameters), and by-item random intercept adjustments and random slopes for NP1 complexity, NP2 complexity, and their interaction (3 parameters). We utilized weak, uninformative priors for all key parameters, including participant and item adjustments. For each model, $P(\theta|data)$ indicates the probability that the parameter estimate is negative, i.e., speeding up occurs. For instance, an estimate that $P(\theta_{complex} < 0) = 0.99$ signifies that we can be 99% certain that complexity speeds up reading; in contrast, if $P(\theta_{complex} < 0) = 0.01$, we can infer with 99% certainty that complexity slows down reading. These probabilities

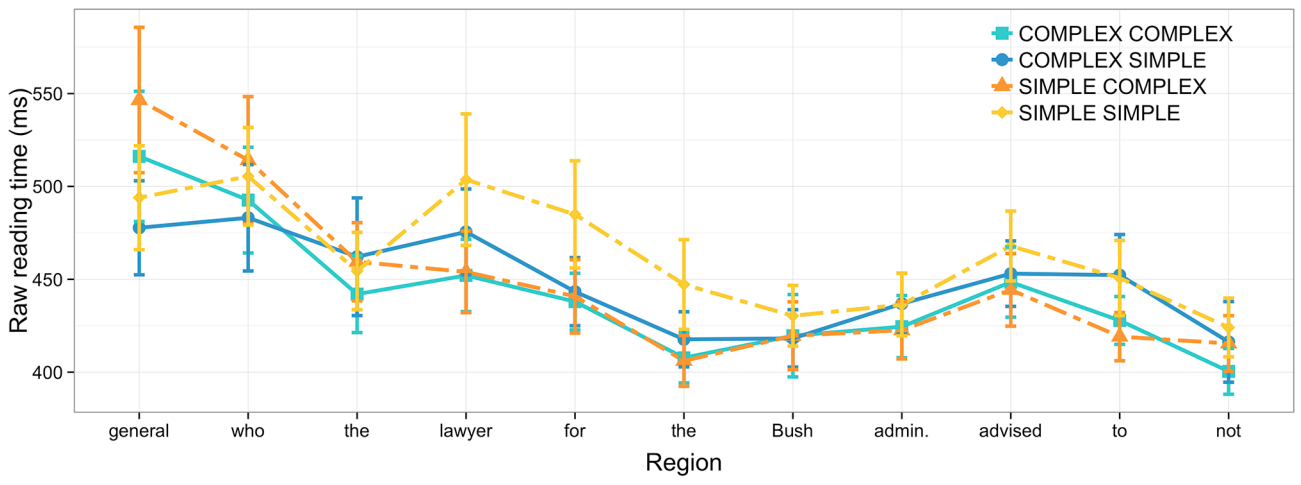

FIGURE 1 | Raw reading times in Experiment 1 by region; error bars show 95% confidence intervals.

were obtained by calculating the percentage of posterior samples above or below zero. To improve readability we will write $P(\theta < 0)$ for $P(\theta < 0|data)$.

Three regions are analyzed in Experiment 1: the head noun of NP2, the head noun of NP3, and the verb that subcategorizes for NP2. As reading time effects in self-paced reading experiments often spill over onto subsequent words, results for the word regions immediately after the relevant sites are also reported. No significant effects of the experimental manipulations on comprehension accuracy were found so they are not discussed here (see data in Supplementary Materials).

2.3. RESULTS

2.3.1. NP2 head noun

As shown in **Table 1**, greater syntactic and semantic complexity of NP2 leads to longer reading times at this region. Greater complexity of NP1, however, has a weaker effect in the opposite direction. That is, reading times at the NP2 head noun were somewhat faster when NP1 was complex, compared to when it was syntactically and semantically simple. There is no compelling evidence for an interaction at this word region.

2.3.2. NP3 head noun + spillover

Complexity of NP2 also has an effect on reading times at the head noun of NP3 (e.g., "lawyer"): reading times are faster when NP2 is relatively complex. At the word immediately following the head noun ("for" in 2.2), an interaction of NP1 & NP2 complexity arises, along with main effects of NP1 & NP2 complexity. This interaction stems from the fact that NP1 complexity leads to faster reading times only when NP2 is simple.

2.3.3. Relative clause verb + spillover

A main effect of NP2 complexity is evident at the critical relative clause verb: when NP2 is complex, reading times are faster than when NP2 is simple. Alongside this main effect, the results provide weak support of an interaction due to the fact that the complexity of NP1 affects reading times more when NP2 is simple. Put differently, there is no added processing facilitation due to the complexity of NP1 when NP2 is itself complex. The NP2 complexity effect also carries over onto the word immediately after the verb. In fact, the effect is even more pronounced at this region. Here, signs of an interaction are considerably weaker, as illustrated in **Figure 1**.

2.3.4. Correctly answered trials only

We conducted secondary, *post-hoc* analyses using only data from correctly answered trials to determine whether the observed complexity effects were tied to trials where participants answered incorrectly. As depicted in **Figure 2**, all main findings persist in this data subset with NP2 complexity effects at the NP3 and the relative clause verb slightly increasing in magnitude.

2.4. DISCUSSION

When readers encode additional syntactic and semantic features, they read faster at sentence-internal retrieval sites. This pattern holds, however, primarily for NP2—the downstream retrieval target. At the relative clause subject, reading times are faster when NP2 is syntactically and semantically complex, and this effect re-emerges at the retrieval triggering verb, continuing on into the spillover region.

Table 1 | Model summary for Experiment 1 for each region and fixed effect factor.

Region	Factor	Mean	CrI lower	CrI upper	$P(\beta < 0)$
Head noun	NP1 complexity	−0.012	−0.033	0.009	0.866
	NP2 complexity	0.038	0.011	0.065	0.002
	NP1 × NP2 complexity	−0.003	−0.024	0.017	0.621
RC subject head noun	NP1 complexity	−0.005	−0.025	0.014	0.702
	NP2 complexity	−0.022	−0.039	−0.005	0.996
	NP1 × NP2 complexity	0.002	−0.016	0.020	0.397
RC subject head noun + 1	NP1 complexity	−0.014	−0.032	0.002	0.955
	NP2 complexity	−0.012	−0.027	0.002	0.951
	NP1 × NP2 complexity	0.013	−0.002	0.027	0.043
RC verb	NP1 complexity	−0.005	−0.019	0.010	0.757
	NP2 complexity	−0.014	−0.027	−0.001	0.979
	NP1 × NP2 complexity	0.011	−0.005	0.025	0.079
RC verb + 1	NP1 complexity	−0.004	−0.009	0.017	0.281
	NP2 complexity	−0.019	−0.035	−0.004	0.991
	NP1 × NP2 complexity	0.006	−0.007	0.019	0.200

Summary includes the posterior 95% Credible Interval (CrI), i.e., the lower CrI refers to the 2.5% bound and the upper CrI refers to the 97.5% bound. $P(\beta < 0)$ indicates the probability that complexity slows reading times effects, i.e., values closer to 0 indicate slowing down and values closer to 1 indicate speeding up due to complexity.

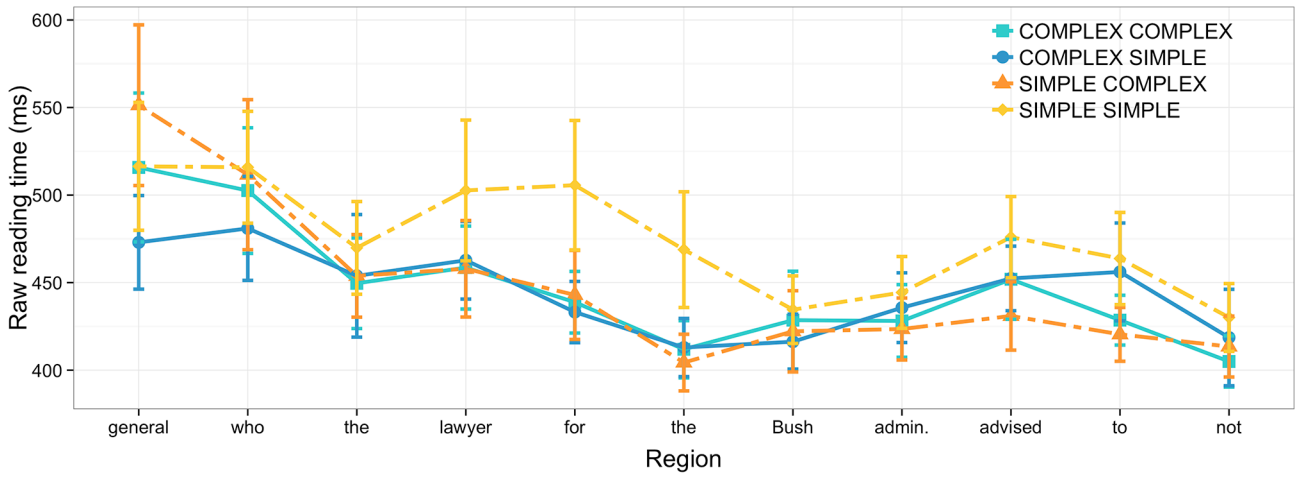

FIGURE 2 | Raw reading times in Experiment 1 for correctly answered trials; error bars show 95% confidence intervals.

Effects tied to NP1—the preceding non-target—are comparatively weaker and tied to the status of NP2. Whereas the effects of the complexity of NP2 show up at the head noun of NP3, the impact of NP1 complexity does not emerge until the head noun's spillover region. More tellingly, NP1 complexity affects reading rates selectively: only when NP2 is simple, and hence syntactically similar to NP3, does greater NP1 complexity reduce reading times. At the retrieval region, too, effects of the complexity of NP1 are weak compared to those of NP2. While there are hints at the relative clause verb that NP1 complexity has some facilitatory effects, such effects (1) do not have the duration of those tied to NP2, (2) are statistically weaker, and (3) only appear when NP2 is simple. In essence, differences in the feature-based complexity of a competitor do not weigh as significantly on retrieval in sentence comprehension as differences in target complexity. This suggests rather specific constraints on the dynamics of encoding and retrieval with respect to the computation of similarity-based interference in sentence processing that are dealt with in the General Discussion.

Two notable conclusions can be drawn from these results. First, word position alone cannot account for the reading time differences at the retrieval sites. Inside the relative clause, the COMPLEX-SIMPLE and SIMPLE-COMPLEX conditions match each other with respect to word position, yet display different profiles at the word following the subcategorizing verb. Moreover, if elaboration effects at the retrieval region owe their existence to a basic linkage between word position and reading rate, then we would expect the reading times for the conditions to be ordered according to word position. However, the COMPLEX-COMPLEX condition proved to be no faster than the SIMPLE-COMPLEX, despite the retrieval region appearing two words later in the sentence. Second, the lack of a main effect of NP1 complexity at the retrieval region argues against a general preference for maximal descriptiveness. Indeed, nowhere in the sentence does there seem to be a notable advantage for modifying both NPs in the matrix clause. As noted above, however, NP1 complexity does impact the processing of NP3 when NP2 is simple. We take this to mean that encoding interference arises at NP3 when all the NPs match in form, but altering the form of either of the preceding NPs mitigates these interference effects.

A valid concern with respect to these data concerns the relationship between the effects at NP3 and the verb. Are these separate effects, or do the effects at the verb simply reflect extended spillover effects that originate with processing NP3 in the above stimuli? This concern is amplified by signs of NP2 complexity effects at the region before the retrieval-triggering verb. Several arguments, however, speak against the interpretation that the differences at the verb and its spillover region reflect a continuation of previously initiated processes. First, a separate analysis revealed that the NP2 complexity effect at the verb remains intact even after including reading times from the word before the verb as a covariate ($\hat{\mu} = -0.022$; CrI Lower $= -0.038$; CrI Upper $= -0.006$: $P(\beta < 0) = 0.997$). Second, consideration of only correctly answered trials shows that the effects at the verb are magnified, while differences at the preceding region are minimized (see Supplementary Materials for model summaries). Some of the variation across conditions immediately prior to the verb thus comes from trials where encoding or retrieval processes may have been compromised. Further supporting this interpretation, it was found that several poorly-performing participants (who averaged 56% correct on the critical trials) were the primary source of reading times differences at the word region preceding the verb. In the case of these participants, it is indeed possible that encoding difficulties continued on into the retrieval region[1]. Taken together, these observations support the interpretation that the effects at the verb and subsequent word reflect cognitive processes that begin at the verb.

[1]This might be taken as justification to exclude these participants altogether; however, we see no reason to exclude participants because they encounter more encoding problems or read less accurately than their peers.

3. EXPERIMENT 2

If complexity effects arise during sentence processing because additional semantic or conceptual features distinguish representations from one another, this raises the question of whether all types of unique features distinguish comprehension-based representations. There may be nothing special, mnemonically speaking, about syntactic and semantic features in comprehension. Experiment 2 consequently looks at whether unique features in general stimulate faster processing at retrieval sites in comprehension. But this experiment also has a secondary purpose. In Experiment 1, longer encoding times match up with shorter reading times at or directly after the retrieval site. Thus, one take on the previous results is that additional semantic features stimulate more processing, which facilitates downstream retrieval. By manipulating the homogeneity of superficial features in Experiment 2, we address both issues due to the expectation that isolated word stimuli will not only generate contextually unique features (by definition), but will also lead to extended processing times during the encoding phase. The question is how this will bear, if at all, on the processing of words that trigger the retrieval of these encodings.

3.1. PARTICIPANTS

Forty-four UC-San Diego students participated in this study, in exchange for course credit. All subjects identified themselves as monolingual American English speakers without any known history of color blindness. The results from two participants were removed due to comprehension question accuracies below 67%.

3.2. METHODOLOGY AND MATERIALS

Thirty-two items were constructed with an object noun phrase in a transitive main clause modified by an object relative clause, as in 6 below. Textually, the conditions were identical to each other.

(6) The congressman interrogated the **general** who the lawyer for the Bush administration advised ___ to not comment on the detainees.

To manipulate processing during the encoding phase, the head noun of the object NP ("general" above) appeared either in the same color as the surrounding sentence text (white), or else in an incongruent color (bright green). Additionally, the color of the word that triggered retrieval ("advised") also varied between congruent and incongruent. This second manipulation provides a needed check to ensure that participants do not read later word regions faster because of anticipation for an incongruently colored word. Moreover, in the condition with the green head noun and green verb, we can assess whether reinstating features of the encoding phase aids in retrieval. Hence, each item had four conditions (WHITE-WHITE, WHITE-GREEN, GREEN-WHITE, GREEN-GREEN), but each subject saw only one condition of each item.

Participants received instructions that the color of the words in the sentences was immaterial to the task and that they did not need to respond to color changes. Yes/no comprehension questions followed each item, and participants received negative feedback if they answered a question incorrectly. Sixty fillers accompanied these critical items: 20 with 0 green words, 20 with 1 green word, and 20 with 2 green words. For filler items with 1 green word, the word was randomly selected from all words in the sentence. For fillers with 2 green words, one appeared randomly in the the first half of the sentence and the other in the second half. All fillers had a syntactic structure different from that used in the critical items.

The materials were presented in a self-paced, center presentation paradigm via a propriety software package. Only one version of each item appeared on each of four experimental lists, whose contents were pseudo-randomized such that at least one filler intervened between each critical item. A fixation cross in the center of the screen appeared before each trial, and a comprehension question followed every experimental trial, including fillers. Participants received feedback only on incorrectly answered trials.

The outlier removal process, computation of residual log reading times, and Bayesian analysis procedure all followed those used in Experiment 1. As in that experiment, there were no differences in comprehension accuracy (GREEN-GREEN = 76%, GREEN-WHITE = 77%, WHITE-WHITE = 76%, WHITE-GREEN = 76%). Here, we analyze residual log reading times at the head noun of the matrix object phrase and the relative clause verb that triggers its retrieval.

3.3. RESULTS

At the object head noun, incongruent, green words slow reading times, compared to the congruent, white words (see **Figure 3**). Similarly, looking at reading times at the retrieval region ["advised" in (3.2)], a perceptually incongruent, green verb slows reading speed compared to a congruent, white one.

In contrast to the pattern observed in Experiment 1, the increased encoding time at the object head noun due to superficial incongruence leads to relatively weak facilitation effects at the retrieval site, as shown in **Table 2**. In fact, the mean parameter value resides less than one standard deviation (=0.011) from zero, according to the model results. The mean value for the condition where both the noun and the verb are incongruently colored reflects slightly faster reading than for the condition where only the verb is incongruent (GREEN-GREEN: -0.015, $SE = 0.021$; WHITE-GREEN: 0.011, $SE = 0.024$). This difference of roughly one standard error is why the model acknowledges a relatively weak effect of noun color (and an interaction with verb color) on reading times at the verb. At regions after the verb, there is no evidence that processing an incongruently colored target noun facilitates processing.

3.4. DISCUSSION

Increased processing times triggered by incongruent stimuli at the encoding site had weak effects on processing at the retrieval site when compared to the complexity effects observed in Experiment 1. Only when the relevant perceptual features were reinstated at the retrieval site was there any numerical retrieval advantage for perceptually incongruous stimuli. Even in this case, the facilitating effects were quite mild and would be deemed insignificant on classical frequentist methods of analysis. These findings imply that contextually unique features do not necessarily lead to

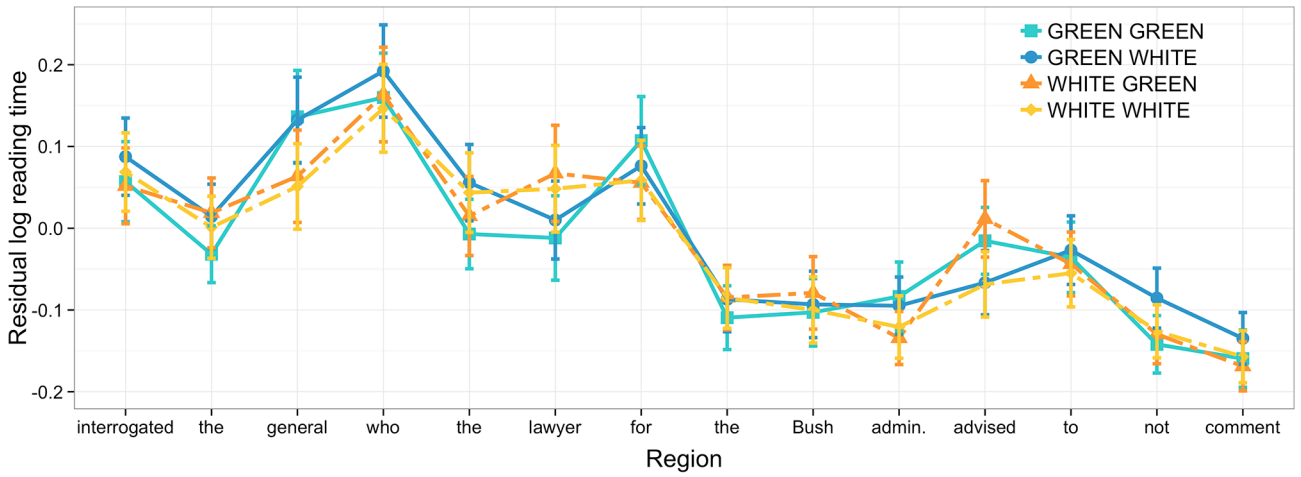

FIGURE 3 | Residual log reading times at verb in Experiment 2; error bars show 95% confidence intervals.

Table 2 | Model summary for Experiment 2.

Region	Factor	Mean	CrI lower	CrI upper	P($\beta < 0$)
Head noun	Noun color	0.039	0.007	0.071	0.008
	Verb color	0.005	−0.025	0.034	0.362
	Noun color × Verb color	−0.001	−0.031	0.028	0.532
RC verb	Noun color	−0.007	−0.029	0.016	0.731
	Verb color	0.032	0.008	0.056	0.001
	Noun color × Verb color	−0.008	−0.034	0.017	0.734

Summary includes the posterior 95% Credible Interval (CrI), i.e., the lower CrI refers to the 2.5% bound and the upper CrI refers to the 97.5% bound. P($\beta < 0$) indicates the probability that incongruence slows reading times effects, i.e., values closer to 0 indicate slowing down and values closer to 1 indicate speeding up due to incongruence.

improved memory performance, nor does increased processing time.

These findings may initially seem to contrast with memory results for recognition/recall of items presented in lists. For instance, von Restorff (1933) observed better recognition for words that appeared in superficially incongruent states. Similar findings of improved memory performance for superficially incongruent linguistic items (within mixed lists, but not unmixed lists) appear in Bruce et al., 1976, Hunt and Elliot, 1980, Hunt, 1995, Dunlosky et al., 2000, *inter alia*.

However, the current evidence reinforces the idea that the memory retrieval context is of utmost importance—a point frequently reiterated by memory researchers such as Tulving, Nairne, and others. In the present case, color or other superficial orthographical features rarely matter in written, sentence comprehension. Particularly if subjects are requested to ignore such information, there is little reason for subjects to recruit such potentially distinctive features in memory retrieval, whether or not they elicit more processing. In contrast, standard list recall or recognition tasks are novel encoding and retrieval contexts for participants—we are not standardly shown a list of words and then asked to retrieve them later, so we have few if any entrained habits. Consequently, in such novel circumstances, participants reasonably utilize all manner of perceptual features in recovering representations from memory.

In short, this experiment establishes that the uniqueness effects in language comprehension depend heavily on the retrieval context. What counts as unique critically depends on the nature and demands imposed at the retrieval site. Ultimately, if some set of representational features are unimportant for memory retrieval, then their congruence with other local feature appears to also have little import for memory retrieval.

4. GENERAL DISCUSSION

Increased processing during the encoding phase leads to more efficient retrieval processing in sentence comprehension, but only under certain conditions. Experiment 1 illustrated that increased processing associated with the downstream target benefits retrieval-related processing, whereas processing related to non-targets had relatively weak, short-lived effects that only arose when the target itself was not elaborated. Experiment 2 expanded on this by showing that not just any sort of extra processing facilitates memory (even for targets)—indeed, the results suggest that it is not about processing *per se* so much as the role of

the features themselves in the retrieval process. In many respects, these results parallel the findings of studies assessing the effects of elaboration on long-term memory performance for linguistic stimuli (Stein et al., 1978; Eysenck, 1979; Jacoby and Craik, 1979; Reder, 1980; Bradshaw and Anderson, 1982; Reder et al., 1986; McDaniel et al., 1988). At the same time, they add to these studies by showing that memory performance improves as meaning-related processing increases for linguistic stimuli in the context of sentence comprehension. Secondly, they demonstrate that these effects occur even in covert retrieval settings, where the time constraints of real-time comprehension limit the options for retrieval strategies. Third, the results from the final experiment demonstrate that unique representational target features and increased processing do not always lead to improved memory retrieval.

Both sets of findings—the advantage of additional processing for targets compared to non-targets, and the fact that increased processing time does not necessarily benefit memory retrieval—can be understood through the lens of the short-term, feature-based retrieval model of Nairne (1990, 2001, 2006), with some minor new assumptions (several other memory models make similar predictions, e.g., Oberauer and Kliegl, 2006 and Shiffrin, 2003, although the details differ). In Nairne's model, memory items are represented as a vector of features, e.g., [C X 1 2 3]. Retrieval cues consist of lingering, typically blurry, records of the immediate past, e.g., [C X ? 2 3], as well as cues from the local retrieval context. In turn, these two sets of cues form a memory probe that is compared against a set of candidate memory items. The ultimate objective is to "redintegrate" the retrieval cues with a memory item, as the cues by themselves cannot be directly interpreted (Ericsson and Kintsch, 1995). The probability of retrieving an event E_1, given a retrieval probe X_1 depends upon the similarity or feature-overlap of X_1 and E_1, as well as the similarity of X_1 to other memory candidates:

$$P_r(E_1|X_1) = \frac{s(X_1, E_1)}{\sum s(X_1, E_n)} \quad (1)$$

The similarity between a memory item and a retrieval probe is determined by the number of mismatching features divided by the total number of compared features (d):

$$s(X_1, E_1) = e^{-d(X_1, E_1)} \quad (2)$$

Because retrieval probes consist of remnants of the original encoding process that need to be interpreted by comparing them against candidate memory items, any contextually unique features in a target will improve the chances for successful retrieval. In short, a target's recoverability increases if it possesses a feature that no other competitor shares.

Nairne (2006) employs this model to explain isolation or distinctiveness effects, since odd/bizarre items possess features that mismatch with the features of some homogeneous background set. For instance, imagine a context where the original encoding is perfectly intact and acts as the sole source of retrieval cues, e.g., $X_1 = E_1$. Any contextually unique features will increase the dissimilarity or mismatch between the retrieval cues and competitors, even though contextual uniqueness does not directly affect the similarity value between the target and retrieval probe.

An implied consequence of such a theory is that simply adding features to a target is predicted to increase the odds of sampling from memory, so long as these features are unique. **Table 3** shows how the probability of sampling a target increases as the number of mismatching features between the target and non-targets increases, even though the number of shared features remains constant (see Hofmeister et al., 2013 for an application of this model to the processing and acceptability of multiple wh-questions in English). The added features Q, R, & N in the undegraded probe lack any correlates in the competitors, meaning that the mismatch between them and the probe increases, effectively upping the chances for sampling the target.

As **Figure 4** illustrates (left panel), the effect of adding mismatching or contextually unique features faces some restrictions: increasing the number of mismatches yields diminishing returns, ultimately asymptoting at a level that depends upon the number of features involved and the number of feature matches. In less formal terms, adding a little unique, diagnostic information can be quite helpful for memory retrieval, but adding lots of unique information is not likely to contribute much more. This model also predicts that the number of competitors affects retrieval probability much more dramatically than the number of overlapping features. On the right side, **Figure 4** shows that going from one competitor to three competitors which each share two features with the probe nearly halves the chances of retrieval. In contrast, the difference between two competitors with 2 vs. 10 matching features never exceeds 10% (see left side of **Figure 4**).

A key component of this type of model is that a fragile copy of the original encoding process stored in primary memory provides a source of retrieval cues. This makes explicit the idea that syntactic and semantic features not directly invoked by the local sentence context can influence retrieval processes, in contrast to assumptions that only the similarity of features "grammatically derived from the current word and context" enter into considerations of similarity-based interference (Lewis et al., 2006, p. 448)[2]. Sentence processing models built upon the latter kind of assumption face difficulty explaining some classic retrieval interference effects in the sentence processing literature (Logačev and Vasishth, 2012). For instance, Gordon et al. (2001) show that processing in object-cleft sentences like 7 is easier at the subcategorizing verb ("saw") when the two NPs are of different types

[2]Current sentence processing models are not without means to explain effects of complexity on memory retrieval. For instance, on the ACT-R-based theory of Lewis and Vasishth (2005), processing syntactic material that modifies some previously constructed representation requires the restoration of the stored memory item. This retrieval process, in turn, raises the overall activation level of the item, making it easier to retrieve subsequently. Thus, complexity-based effects on retrieval emerge most straightforwardly as the byproduct of encoding processes. Moreover, additional study time potentially allows for more accurate encoding, providing greater chances that target features will be cued at the retrieval site (see also Shiffrin, 2003). However, as retrieval cues are limited to those provided by local grammatical context, there is no guarantee that unique semantic or syntactic features will factor into estimates of similarity and thus retrieval difficulty.

(proper name vs. definite description), but that such effects are absent in subject relativization constructions:

(7) It was John/the barber that the lawyer/Bill saw in the parking lot.

These effects are commonly understood in terms of similarity-based interference: if the target noun phrase overlaps in form with another local noun phrase that appears before the verb, memory retrieval difficulty ensues, ostensibly because the retrieval cues match multiple memory representations. As the second NP occurs after the verb in subject relatives, no possibility for interference exists. Notably, the verb triggering retrieval ("saw") does not itself supply cues as to the nominal type of the clefted element; indeed, no language appears to explicitly code whether a verb requires a lexical, pronominal, or some other type of nominal argument. So, if the similarity effects arise because retrieval cues match multiple representations, then those cues must come from a source besides the verb. The original encoding of the target provides the most obvious source of such cues. Not only does this open up a way to explain similarity-based effects due to overlapping referential form, it can also accommodate phonological similarity effects such as the observed reading time contrast at the embedded verb in sentences like "The baker that the banker sought found the house" vs. "The runner that the banker sought found the house" (Acheson and MacDonald, 2011)[3].

Table 3 | Similarity values and predicted sampling probabilities for two retrieval contexts.

Cue	Traces	Similarity	Samp. prob.
[C C 2 3 1]	[C C 1 2 3]	0.55	0.26
	[C C 2 3 1]	1.0	0.48
	[C C 3 1 2]	0.55	0.26
[C C 2 3 1 Q R N]	[C C 1 2 3]	0.47	0.24
	[C C 2 3 1 Q R N]	1.0	0.52
	[C C 3 1 2]	0.47	0.24

The current findings add a further data point to our developing picture of similarity-based interference in sentence processing: non-target distinctiveness has a weaker role to play in retrieval interference than target distinctiveness. These effects can be straightforwardly accommodated with some specifications about how similarity is calculated. Following Nairne (2006), let's assume that similarity at retrieval sites is calculated by establishing mismatches with the lingering features of a target's encoding remnant and any other features in the retrieval probe. A memory probe such as [C X 1 2 3] will mismatch equally with a competitor representation like [C X 4 5 6] as [C X 4 5 6 L M], e.g., 3 out of 5 probe features will mismatch with competitor features. In other words, it is the number of features in the probe that determine how many mismatches there can be, and not the number of features in a memory retrieval candidate. Adding unique features to some non-target, therefore, will not directly affect the probability of sampling the target because it does not contribute to the set of retrieval cues.

The data hint nonetheless at some retrieval effects linked to the elaboration of non-targets, specifically when the retrieval target itself was syntactically and semantically simple. This would seem to initially contradict the above view that the uniqueness of non-targets does not directly bear on retrieval efficiency. There is no contradiction, however, if these non-targets effects are byproducts of encoding interference. That is, we presume that the uniqueness of features in non-target nominals affects how other

[3]Acheson and MacDonald (2011) illustrate similar effects in subject relatives, as well, suggesting that phonological similarity gives rise to encoding interference and not simply retrieval interference.

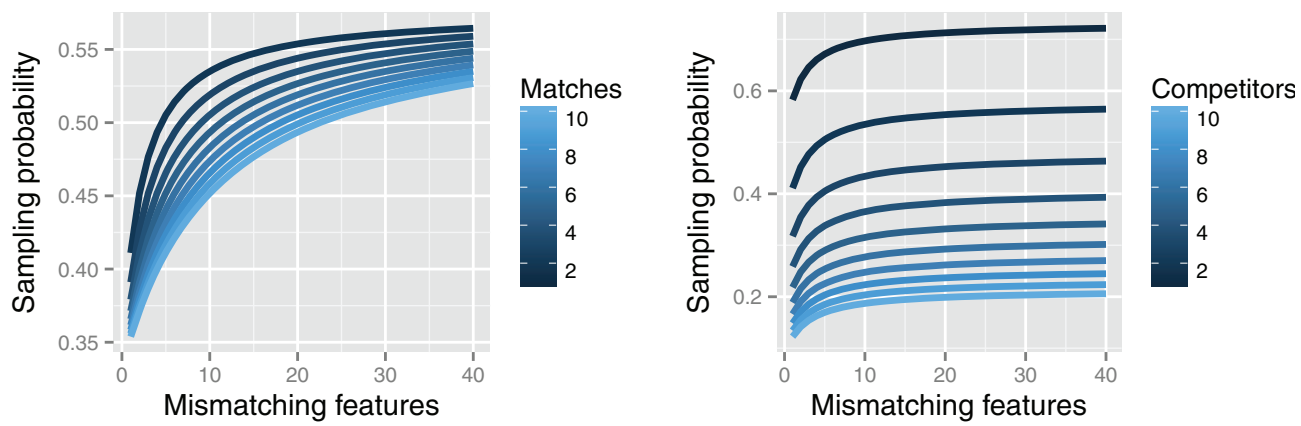

FIGURE 4 | Left: Relationship between number of unique target features (mismatching with non-targets) and average sampling probability of target with two competitors. In descending order, the lines show the varying sampling probability curves for 2 to 10 probe features matching with each competitor. **Right:** Relationship between number of unique target features and average sampling probability of target as a function of the number of competitors (from 1 to 10 in descending order), assuming two matching features between the probe and each competitor. The retrieval sampling curves illustrate the diminishing effects of mismatching features and the relatively greater effect of the number of competitors compared to the number of matching features.

local nominals, including downstream targets, are encoded, and indirectly influence retrieval operations *via such encoding effects*. Even more generally, encoding interference feeds into retrieval interference.

Already, evidence exists that similarity between linguistic representations in memory and those being encoded can lead to processing disruptions, during both encoding and retrieval stages (Gordon et al., 2002; Acheson and MacDonald, 2011). For example, Gordon et al. (2002) provide evidence of reading slowdowns when words on a sentence-external memory list are similar to key words inside the sentence, e.g., proper names vs. definite descriptions, both at the encoding site for the sentence-internal words and later at retrieval sites for those same words. We would add to this by hypothesizing that encoding interference may contribute to the degradation of memory representations, following research that suggests that forgetting in short-term memory for linguistic representations can stem from feature overwriting (Oberauer and Lange, 2008; Oberauer, 2009). Because these features that are susceptible to overwriting also contribute to retrieval cues on the account sketched above, feature loss could compromise any cue-based retrieval process.

Applying these hypotheses to the results of Experiment 1, encoding interference emerges as an indirect (and accordingly, weaker) contributor to retrieval differences, beyond what is predicted by the model of memory retrieval inspired by Nairne. Specifically, similarity between the referring expressions determines encoding interference, which can affect the integrity of the trace for the target nominal. So, when NP1 is complex and NP3 is simple or vice versa, this translates to a reduced danger of feature overwriting, compared to when they are both simple. In turn, the potential for retrieval interference is mitigated when the two initial NPs mismatch in complexity, because the trace for NP2 is more likely to be intact. Things are somewhat more complicated when NP1 and NP2 are both complex: while overlapping in structural form, the NPs carry more unique semantic features than their simpler counterparts. In this case, we tentatively take the results to mean that encoding interference is relatively low, compared to the case where both NPs are simple, but not any lower than when just one such NP is complex. These ideas require further tests to be substantiated, as the current experiments were not designed to test them. Nonetheless, we maintain that the relatively weak effects of non-targets can best be explained by appealing to the effect of encoding interference on memory retrieval.

Notably, redintegration-based models of memory do not require that every perceivable feature matters for memory retrieval. Listeners or readers may preferentially not encode some features in typical language settings, such as modality-specific features or exclude such features from the retrieval probe based on prior experience of the efficacy of such features. The advantage of increased processing thus depends upon the discourse context and the extent to which processing engenders unique features that come into play during the retrieval stage. From this perspective, encoding manipulations cannot have a predictable effect on memory in the absence of information about the encoding and retrieval contexts—what other memory candidates are available and what the retrieval cues are.

The results of Experiment 2 align with this perspective, in light of the absence of isolation or superficial processing effects. Modality-dependent features, such as orthography, font style, text color, etc., often play a large role in various laboratory tests of memory and in effects such as the auditory recency effect, but they appear to have a lesser role in guiding retrieval in sentence processing contexts. Such contrasts, though, are explicable in terms of task demands and prior experience. Word recall and recognition tasks lie outside the typical range of personal pastimes, whereas sentence comprehension is an everyday occurrence. This arguably leads participants to utilize a wider range of possible retrieval cues in word recall tasks, whereas prior experience with sentence processing would bias against the use of modality-specific features to distinguish memory representations. Instead, modality-independent features—properties that largely remain constant across presentations or modalities such as syntactic category and meaning—provide the basis for restoring linguistic representations during sentence processing because of their diagnostic potential. Thus, it is due to the fact that discrimination between language representations in sentence comprehension depends on syntactic and semantic features that the uniqueness of these features bears on determinations of retrieval ease and success. Correspondingly, the primary source of retrieval difficulty in language comprehension—overlapping semantic and syntactic representations and the resulting interference—is what gives additional linguistic processing mnemonic value, and why other types of processing such as superficial processing have little mnemonic value.

5. CONCLUSION

These tests of implicit memory establish that elaboration effects occur in online sentence processing tasks, as they do in explicit tests of memory. In Experiment 1, we found that increased processing of syntactic and semantic features connected to the target benefits memory retrieval in sentence processing; however, additional processing directed toward non-targets had substantially weaker effects on processing at retrieval sites. In Experiment 2, it was established that the processing of superficial features or features connected to non-targets yielded insubstantial processing advantages at retrieval sites, despite leading to longer encoding times. As sentence processing demands differ from those of explicit memory tasks, it is unsurprising that the effects of encoding manipulations can differ drastically across tasks with inherently different retrieval contexts. This apparent dynamic interaction between encoding and retrieval led Tulving (1983, p. 239) to argue against any statements of the form that "encoding operations of class X are more effective than encoding operations of class Y" (see also Neath and Surprenant, 2005 for a recent review). In short, encoding manipulations are unpredictable without additional information about the nature of the retrieval task and the background of competing representations.

The comparison of memory findings in the broader psychology and psycholinguistics literature also led to a unified theoretical account of distinctiveness effects, applicable across tasks. Capturing the interplay between representational uniqueness and retrieval probability, Nairne's feature-based model provides a means for introducing retrieval cues that are unlikely

to be cued by local grammatical memory triggers via the use of a fragile copy of the original encoding. This fills a critical gap in cue-based models of retrieval in sentence processing by pointing to alternative sources of retrieval cues beyond the local context, thus accounting for a variety of otherwise unexplained similarity-based effects in sentence processing.

Elaboration over a Discourse Facilitates Retrieval in Sentence Processing

Melissa Troyer[1], Philip Hofmeister[2] and Marta Kutas[1,3]*

[1] Department of Cognitive Science, University of California at San Diego, La Jolla, CA, USA, [2] Department of Cognitive, Linguistic, and Psychological Sciences, Brown University, Providence, RI, USA, [3] Department of Neurosciences, University of California at San Diego, La Jolla, CA, USA

Language comprehension requires access to stored knowledge and the ability to combine knowledge in new, meaningful ways. Previous work has shown that processing linguistically more complex expressions ('*Texas cattle rancher*' vs. '*rancher*') leads to slow-downs in reading during initial processing, possibly reflecting effort in combining information. Conversely, when this information must subsequently be retrieved (as in filler-gap constructions), processing is *facilitated* for more complex expressions, possibly because more semantic cues are available during retrieval. To follow up on this hypothesis, we tested whether information distributed across a short discourse can similarly provide effective cues for retrieval. Participants read texts introducing two referents (e.g., two senators), one of whom was described in greater detail than the other (e.g., '*The Democrat had voted for one of the senators, and the Republican had voted for the other, a man from Ohio who was running for president*'). The final sentence (e.g., '*The senator who the* {*Republican*/*Democrat*} *had voted for*…') contained a relative clause picking out either the Many-Cue referent (with '*Republican*') or the One-Cue referent (with '*Democrat*'). We predicted facilitated retrieval (faster reading times) for the Many-Cue condition at the verb region ('*had voted for*'), where readers could understand that '*The senator*' is the object of the verb. As predicted, this pattern was observed at the retrieval region and continued throughout the rest of the sentence. Participants also completed the Author/Magazine Recognition Tests (ART/MRT; Stanovich and West, 1989), providing a proxy for world knowledge. Since higher ART/MRT scores may index (a) greater experience accessing relevant knowledge and/or (b) richer/more highly structured representations in semantic memory, we predicted it would be positively associated with effects of elaboration on retrieval. We did not observe the predicted interaction between ART/MRT scores and Cue condition at the retrieval region, though ART/MRT interacted with Cue condition in other locations in the sentence. In sum, we found that providing more elaborative information over the course of a text can facilitate retrieval for referents, consistent with a framework in which referential elaboration over a discourse and not just local linguistic information directly impacts information retrieval during sentence processing.

Keywords: sentence processing, retrieval, elaboration, representational complexity, semantic memory, self-paced reading

INTRODUCTION

Real-world knowledge is activated rapidly and richly in language comprehension (e.g., Kutas and Federmeier, 2000; DeLong et al., 2005; Metusalem et al., 2012). Knowledge about events, actions, and entities in the world can rapidly affect people's expectations about upcoming linguistic information (e.g., Kamide et al., 2003; DeLong et al., 2005; Borovsky et al., 2012). What's more, real-world knowledge use during language comprehension is dynamic, and new information can update, amend, or contradict prior information.

The ability to access this continually updated information depends on a number of factors, including the linguistic context. For instance, Bransford and Johnson (1972) provided participants with labeled and unlabeled versions of prose passages. One passage described an activity in which people typically arrange things into groups, go to the appropriate facilities, and perform a routine where a mistake may be rather expensive. Participants who initially received a label (e.g., *washing clothes*) had better memory for the passages. Similar effects have been observed when people are asked to remember information that has been causally linked [e.g., (1) someone needing change because (2) they need to do their laundry] compared to unrelated information (Smith et al., 1978; see also Bradshaw and Anderson, 1982). These findings, among others, demonstrate how language comprehension is fundamentally linked to the supporting knowledge structures, or schema, that are available to the comprehender (Radvansky and Zacks, 1991).

In addition to affecting offline processes like explicit memory, the availability of related linguistic information in a sentence (e.g., the number of adjectives modifying a noun) appears to affect online sentence processing (Hofmeister, 2011; Hofmeister and Vasishth, 2014). Modifying a referent's description with a likely attribute description (e.g., *a ruthless dictator*) leads to faster reading times at words that trigger retrieval of this discourse referent, compared to a referring expression with no modifiers. However, modification with attributes that are unlikely based on real-world knowledge (e.g., *a lovable dictator*) does not lead to the same facilitation, compared to the baseline condition (Hofmeister, 2011). In short, re-accessing previously encoded content appears to be influenced by the ability to access and use prior world knowledge in both online and offline language tasks.

Here, we test whether providing more (vs. less) information about referents across a discourse similarly can increase the ease of language comprehension when these referents are subsequently referred to. In previous work on the role of elaboration in sentence processing (Hofmeister, 2011; Hofmeister and Vasishth, 2014), the syntactic constructions used to investigate elaboration and retrieval were limited to pre-nominal modification and filler-gap dependencies that linked elements within a sentence. A natural question is whether the effects observed in such environments are specific to that particular combination of encoding and retrieval conditions, or whether elaboration can facilitate online language comprehension more generally. This work therefore examines the generality of conceptual elaboration effects in language processing.

Given variability in knowledge due to individual experience, it is likely that individuals also differ from one another in their ability to access and use any particular knowledge structure. If the performance profiles described above depend significantly on the availability of existing knowledge structures, then individual profiles ought to vary as a function of their experience accessing relevant knowledge or the availability of richer or highly structured representations in memory. Before outlining the current experiment, we briefly describe work underscoring the importance of world knowledge for guiding online language comprehension.

When understanding sentences, people seem to anticipate upcoming information based on the relationship between current linguistic information and prior world knowledge (e.g., Tanenhaus et al., 1995; Kamide et al., 2003; Borovsky et al., 2012). For instance, if a listener hears '*The pirate chases the. . .*,' it is reasonable for her to expect that the sentence will continue with something that a pirate (the agent) might chase (the action verb), such as a ship. Visual world eye-tracking paradigms, in which participants listen to spoken language while looking at images of items on a computer screen, have shown that both children and adults are sensitive to this type of information and use it to anticipate upcoming linguistic content (e.g., Kamide et al., 2003; Borovsky et al., 2012, 2013; Troyer and Borovsky, 2015).

In addition to eye-tracking paradigms, event-related brain potential (ERP) experiments support the role of real-world knowledge in guiding language comprehension. For instance, the N400 ERP component, whose amplitude is modulated by the semantic fit of meaningful input with prior context (Kutas and Hillyard, 1980, 1984; Kutas and Federmeier, 2000; see Kutas and Federmeier, 2011, for a recent review), is sensitive not only to fit of (or expectations about) semantic information but also to incoming information as it relates to individuals' real-world knowledge (Hagoort et al., 2004; Nieuwland and Van Berkum, 2006; Hald et al., 2007; Filik and Leuthold, 2013). For instance, Hagoort et al. (2004) presented participants with sentences drawing upon world knowledge, such as the fact that the color of Dutch trains is yellow. They found reduced N400 amplitude to words like '*yellow*' in the sentence '*Dutch trains are yellow and very crowded*' compared to sentences like '*Dutch trains are sour and very crowded*' (where '*sour*' is semantically inconsistent) and '*Dutch trains are white and very crowded*' (where '*white*' is semantically consistent but inconsistent with world knowledge about Dutch trains). These findings support the notion that experienced-based world knowledge (Dutch trains are yellow) affects language comprehension with the same time course as (and possibly via similar mechanisms to) semantic information (trains cannot be sour).

Furthermore, Metusalem et al. (2012) showed that rich information about events in the world is available during language comprehension. In their study, people read short scenarios about events—for example, a football game: '*Jeremy is a great athlete despite being prone to injury. During his last high school football game, he was knocked unconscious twice. That still didn't keep him from scoring the winning {TOUCHDOWN/HELMET/LICENSE} with only seconds remaining.*' Unsurprisingly, N400 amplitude was reduced to

predictable words fitting both with event-related information and with the semantics of the sentence (like '*touchdown*') compared to anomalous words (like '*license*'). Critically, N400 amplitude was intermediate to words which were not plausible continuations of the sentence but which were event-related (e.g., '*helmet*,' which is situationally related to football). These findings suggest that a rich landscape of knowledge can be rapidly activated during language comprehension, likely contributing to the flexibility of language comprehension.

Participants in the Metusalem et al. (2012) study also completed two tasks called the Author and Magazine Recognition Tests (ART and MRT, respectively), which require participants to select the authors and magazines that they recognize from lists containing both real and false examples (Stanovich and West, 1989). These tests provide an estimate of print experience, and the authors suggested that, by proxy, higher performance on the ART/MRT could reflect richer world knowledge. Indeed, performance on the ART/MRT predicts measures of declarative knowledge, including tests of cultural literacy recognition ($rs = 0.53 - 0.72$; West et al., 1993; Stanovich et al., 1995); tests about history and literature knowledge ($rs = 0.59 - 0.62$; Stanovich and Cunningham, 1992); a range of tests about cultural and practical knowledge ($rs = 0.53 - 0.85$, Stanovich and Cunningham, 1993); and, in children, the General Information subtest of the Peabody Individual Achievement Test (using a modified Title Recognition Test for Children; $r = 0.43$; Cunningham and Stanovich, 1991). If prior world knowledge influences access to event-related information, then N400 amplitude might vary with performance on the ART/MRT. The authors found that scoring higher on the ART and MRT was associated with a greater numerical reduction in N400 amplitude for implausible, yet event-related, continuations (e.g., '*helmet*,' in the example above), compared to participants who scored lower on the ART/MRT. However, the authors were unable to draw strong conclusions about the relationship between the N400 and scores on the ART/MRT, partly due to the number of participants ($N = 30$), which is relatively low for examining individual differences.

In combination with prior world knowledge, new information—for example, information encountered in the current discourse—can be exploited rapidly to aid future language processing. For example, Nieuwland and Van Berkum (2006) presented participants with short texts in which they ascribed human-like properties (e.g., the ability to fall in love) to typically inanimate objects (e.g., peanuts). In their experiments, the N400 was sensitive to these newly learned features, suggesting that people easily updated their mental models of the discourse to include these properties.

The current work investigates how variability in the amount of recently encountered information, providing elaboration of a referent, affects subsequent access. This work extends recent findings from self-paced reading studies that suggest that longer or more semantically complex linguistic representations of referents can facilitate subsequent access to those referents (Hofmeister, 2011; Hofmeister and Vasishth, 2014). For instance, Hofmeister (2011) asked participants to read (word-by-word) sentences in which a critical noun was described by zero, one, or two adjectives (low, mid, and high complexity conditions, respectively). Participants might read, '*It was a [famous (deaf)]* ***sculptor*** *that the aristocrats at the gallery ridiculed during the exclusive art show*.' At a subsequent critical verb (e.g., '*ridiculed*'), the critical noun had to be understood as the grammatical object of the verb. In order to access this information, participants must somehow retrieve information about the initial noun (e.g., '*sculptor*'). Hofmeister (2011) reported decreased reading times during (or in some cases, immediately following) the critical verb for items in the highest-complexity condition (i.e., where critical nouns were preceded by two adjectives) compared to the other conditions. In similar experiments, such findings also were observed for nouns which were semantically richer/more specific (e.g., '*soldier*') compared to less rich/less specific (e.g., '*person*'). Hofmeister (2011) interpreted these results as showing that additional semantic (and possibly syntactic) features of a linguistic representation led to facilitated retrieval of the information later in the sentence.

Studies like those of Hofmeister (2011) and Hofmeister and Vasishth (2014) have primarily focused on pre-nominal descriptors ('*Texas cattle rancher*') or differences in the semantic specificity/richness of a single word ('*soldier*' vs. '*person*') but have not explored the roles of other types of descriptions across a discourse. Pre-nominal adjectives are likely to change the processing of an upcoming noun for multiple reasons. First, in an information-theoretic sense, pre-nominal modification can lower the entropy of (or uncertainty about) the upcoming noun. Second, modifiers might be predictive of the noun for other reasons such as semantic relatedness (consider the relationship between the three words '*Texas*,' '*cattle*,' and '*rancher*,' for example). And finally, pre-nominal modification entails a specific type of syntactic relationship between modifiers and the noun, with the entire bundle of linguistic information [modifier(s) + noun] constituting a phrasal unit.

In the current study, we investigate how complex descriptions impact the subsequent retrieval of information about referents in language comprehension across sentence boundaries. We vary the additional linguistic information not in adjectival modifiers directly preceding the noun, but using post-nominal modification across multiple sentences in a short discourse. We predicted that providing higher-complexity descriptions about referents would make it easier for participants to process subsequent language referring to those referents compared to referents with linguistically simpler descriptions. Such a finding would indicate that conceptual complexity, above and beyond the phrasal unit, can influence retrieval in real-time language comprehension.

We also asked participants to complete a simple test designed to assess print exposure, which has been used as a proxy for real-world knowledge (e.g., Metusalem et al., 2012). We predicted that participants with greater world knowledge would be able to more effectively make use of additional information—possibly due to richer networks of conceptual representations and/or more effective access to relevant conceptual information. We therefore predicted these participants would be more likely to show effects of linguistic complexity at subsequent retrieval sites.

MATERIALS AND METHODS

Participants

A total of 101 participants, ages 18–29 ($M = 20.7$, 77 women) took part in the experiment. Participants were excluded from analysis if their overall accuracy on comprehension questions was less than 70%. This resulted in the exclusion of nine participants, for a total of 92 participants in the final dataset. Participants were students at UCSD who reported that they were native English speakers. They received partial class credit for participation. All participants provided informed consent for the study, which was approved by the University of California, San Diego Institutional Review Board.

Design and Materials

The materials for the study were 24 experimental items and 36 filler items of similar length and syntactic complexity. The majority of our materials were created by modifying materials from Fedorenko et al. (2012). A full listing of the experimental and filler items can be found in the Appendix in the Supplementary Data Sheet. Each item consisted of a short text of three sentences. All items began with two sentences, which were presented and read (self-paced) as whole sentences. The third sentence was presented word-by-word, using a moving-window self-paced reading paradigm (Just et al., 1982). Filler items were constructed to be similar to experimental items in length and content.

For experimental items, the first sentence always introduced four individuals, two of whom were referred to using the same noun (e.g., '*senator*,' in the example below). The second sentence always described relationships between the first two individuals (e.g., the two senators) and the second two (e.g., the Democrat and the Republican), with one of the first two individuals being described in more detail more than the other. In the third and final sentence, the second noun was varied to unambiguously pick out a referent for its object. In the example below, for instance, '*The senator who the Republican had voted for*' would refer to the senator from Ohio who was running for president (the Many-Cue condition), while '*The senator who the Democrat had voted for*' would refer to the other senator (the One-Cue condition).

(1) Sentence 1: Two senators were arguing with a Democrat and a Republican after a big debate.
Sentence 2: The Democrat had voted for one of the senators, and the Republican had voted for the other, a man from Ohio who was running for president.
Sentence 3: The senator who the {Republican/Democrat} had voted for was picking a fight about health care reform.

As described above, Cue condition refers to the presence or absence of additional descriptive information in the second sentence. To mitigate any effect of recency of information on reading times, we also created a second version of the materials in which the Many-Cue item came earlier than the One-Cue item. For example, in the second version of the example shown in (1), the second sentence would read, '*The Democrat had voted for one of the senators, a man from Ohio who was running for president, and the Republican had voted for the other*.' The factor Mention Order refers to whether the critical item (i.e., the object of the relative clause in Sentence 3) was mentioned relatively early or relatively late in the second sentence. In the example above (1), the information is Early for the One-Cue condition (i.e., '*The Democrat had voted for one of the senators*') but Late for the Many-Cue condition (i.e., '*The Republican had voted for one of the senators*'). The design was therefore a 2 × 2: Cue condition (Many-Cue, One-Cue) and Mention Order (Early, Late). This resulted in four lists, randomized across participants according to a Latin-square design such that no participant saw the same exact order of experimental and filler items.

Finally, each text was followed by a comprehension question, which participants answered with *yes* or *no* by key press. Across the experiment, comprehension questions queried each of the three sentences in a text so that a third focused on Sentence 1, a third on Sentence 2, and a third on Sentence 3. Half of the sentences were answered correctly with *no* and half with *yes*. For the example above in (1), the comprehension question asked about the first sentence and was correctly answered with *yes*: *Were the senators arguing before a big debate?* Similarly, filler questions asked about either the first, second, or third sentence, in equal proportions. Half of each set were correctly answered with yes, and half with no.

Author and Magazine Recognition Tests

Prior to testing, participants also completed an updated version of the ART and the MRT (Stanovich and West, 1989). These tasks were designed to provide a simple yet powerful way to estimate print experience and, by proxy, world knowledge. Previous work has found correlations in the range of r = 0.5 – 0.8 between ART/MRT and many measures of declarative/cultural knowledge (Cunningham and Stanovich, 1991; Stanovich and Cunningham, 1992, 1993; West et al., 1993; Stanovich et al., 1995); in addition, both tests correlate (rs = 0.3 – 0.4) with measures of reading comprehension, and the ART also correlates with measures of orthographic and phonological processing (Stanovich and West, 1989). Participants were given a printed list of 80 potential author names (ART) and 80 potential magazine titles (MRT; presented separately) and were asked to put a check mark next to the ones they knew to be true authors/magazines. In actuality, only half were real authors/magazines. Participants were asked to avoid guessing because some of the names on the lists were not actual authors/magazines. Scores for these tasks were calculated by summing the number of hits (correct items checked) minus the number of false alarms (checked items which were incorrect). The scores for both tasks were computed separately but combined (summed) for analyses.

Procedure

We used Linger (version 2.88) by Doug Rohde to collect self-paced reading data. For this part of the experiment, participants were instructed that they would be reading short texts made up of three sentences and that they should read the sentences for content, as there would be comprehension questions following each text. They were provided with examples and familiarized

with the task before they began, including practice on two items very similar to those used in the study, preceded by a few simpler examples of word-by-word self-paced reading.

Accuracy was computed on the fly and in aggregate in subsequent analyses. If participants responded incorrectly, a warning flashed on the screen to encourage them to try harder to answer correctly on subsequent questions. Participants were given a break halfway through the experiment and instructed to take short breaks as needed in between items.

Following testing, participants completed an exit questionnaire including questions about the ease of the experiment. The experiment was typically completed in under an hour.

Analysis

Although the final sentence of each text was presented word by word, five regions were created, the last four of which were analyzed (an example is demarcated below). Region 1 always consisted of a noun phrase (two words); Region 2 was the start of the relative clause (three words); Region 3 was the verb phrase of the relative clause (1–3 words); Region 4 was the matrix verb phrase region (2–5 words); and Region 5 was a final region including direct objects, adverbials, or prepositional phrases (2–7 words).

(2) The senator/who the Republican/had voted for/was picking a fight/about health care reform.

For the primary analyses, we first identified any trial containing single-word responses that were less than 100 ms or greater than 5000 ms and removed these trials from subsequent analysis, affecting less than 1% of the data. Next, for each trial, RTs for words within a region were averaged. These averaged RTs were then log-transformed, and data points falling more or less than 2.5 SDs from the mean (by region and condition) were eliminated, affecting ∼2.5% of the data.

Statistical analyses used linear mixed-effects models (Baayen, 2008) incorporating random effects for both items and subjects as well as fixed effects of Cue condition, Mention Order, and Spillover (log RT of the preceding region) as fixed effects, unless otherwise indicated. In addition, we included by-subjects and by-items random slopes for Cue condition, as this was our primary independent variable of interest. All analyses were performed in the statistical programming environment R.

RESULTS

Self-Paced Reading

Mean log reading times by region are shown in **Figure 1**, and full model estimates and statistics are provided in **Table 1**.

At the second region (which is the point at which the noun phrase '*The senator*' begins to be disambiguated), we observed no main effect of Cue condition or Mention Order, but there was a significant interaction of the two ($\beta = -0.011$, $SE = 0.005$, $t = -2.055$, $p < 0.05$). Visual inspection revealed this interaction appeared to be driven by slower reading times for conditions from Version 1 (Many-Late, One-Early) compared to Version 2 (Many-Early, One-Late; see above for an example of Version 1 vs. Version 2 of the materials). A follow-up analysis with Version (V1, V2) as fixed effects and Subject and Item as random effects indicated this was the case, with a significant difference between the two ($\beta = -0.011$, $SE = 0.005$, $t = -2.04$, $p < 0.05$).

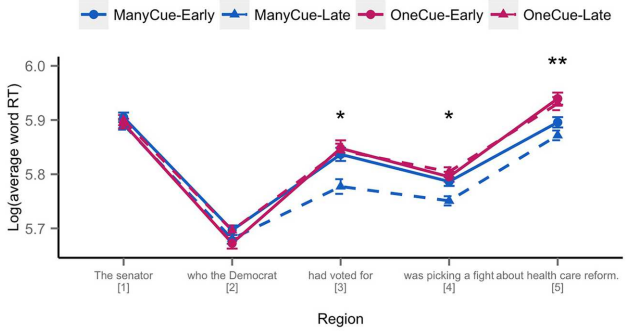

FIGURE 1 | Log average word reading times by region for sentence 3. Errors bars represent by-subject standard errors of the mean. There was a main effect of Cue condition at Regions 3–5 (Many-Cue > One-Cue; $^*p < 0.05$; $^{**}p < 0.001$). See **Table 1** for full model statistics.

Region 3 was the retrieval region where we predicted a main effect of Cue condition. Here, we observed the predicted main effect of Cue condition, with faster reading times in the Many-Cue compared to the One-Cue condition ($\beta = 0.019$, $SE = 0.008$, $t = 2.394$, $p < 0.05$). In addition, we also observed a marginal effect of Mention Order, with relatively Late information leading to faster reading times compared to Early information ($p = 0.07$) as well as a marginal interaction of Cue and Mention Order ($p = 0.09$).

The effect of Cue condition persisted into both Regions 4 ($\beta = 0.016$, $SE = 0.006$, $t = 2.632$, $p < 0.05$) and 5 ($\beta = 0.026$, $SE = 0.006$, $t = 4.074$, $p < 0.001$). No significant main effects or interactions with Mention Order were observed in either region, though there was a marginal interaction between Cue and Order in Region 4 ($p = 0.05$).

ART/MRT Scores

Scores on the ART and MRT were calculated separately and then summed to create a single composite score. For the ART, scores ranged from −5 (one participant checked more incorrect items than correct items, leading to the negative score) to 25, with a mean of 7.28 ($SD = 3.87$). Scores for the MRT ranged from 1 to 20, with a mean of 7.97 ($SD = 3.83$). The two tasks were positively correlated ($r = 0.415$, $p < 0.0001$). When combined by summation, the mean composite score was 15.25 ($SD = 6.47$).

Comprehension Question Accuracies

Comprehension questions were included primarily to encourage participants to read the texts carefully. Comprehension question accuracy was 88.32% ($SD = 6.14\%$) for filler materials. Analyses using mixed-effects logistic regression (with Cue condition and Mention Order as fixed effects and Subject and Item as random

Region	Effect	Estimate	Standard Error	*t*-value	*p*-value
Region 2	**(Intercept)**	**5.693**	**0.023**	**247.15**	**0.000**
	Cue condition	0.000	0.007	−0.059	0.953
	Mention Order	−0.003	0.005	−0.656	0.512
	Cue × Order	**−0.011**	**0.005**	**−2.055**	**0.040**
Region 3	**(Intercept)**	**5.834**	**0.026**	**222.01**	**0.000**
	Cue condition	**0.019**	**0.008**	**2.394**	**0.025**
	Mention Order	0.014	0.008	1.794	0.073
	Cue × Order	−0.013	0.008	−1.680	0.093
Region 4	**(Intercept)**	**5.786**	**0.022**	**264.604**	**0.000**
	Cue condition	**0.016**	**0.006**	**2.632**	**0.015**
	Mention Order	0.005	0.005	0.899	0.369
	Cue × Order	−0.011	0.005	−1.953	0.051
Region 5	**(Intercept)**	**5.916**	**0.025**	**238.968**	**0.000**
	Cue condition	**0.026**	**0.006**	**4.074**	**0.000**
	Mention Order	0.008	0.005	1.639	0.101
	Cue × Order	−0.003	0.005	−0.544	0.586

Statistically significant predictors ($p < 0.05$) are in bold.

effects) revealed that accuracy did not differ as a function of Cue condition or Mention Order, with a mean of 79.35% ($SD = 14.80\%$) for the Many-Cue condition and a mean of 77.26% ($SD = 13.82\%$) for the One-Cue condition. We therefore observed that our manipulation of interest, Cue condition, had no measurable effect on offline comprehension accuracies.

Accuracies were also analyzed by the type of question, that is, whether the question asked about the first, second, or third sentence. Mixed-effects logistic regression with question type (first, second, third sentence) as a fixed effect and Subjects and Items as random effects revealed that questions about the second sentence ($M = 70.92\%$, $SD = 20.89\%$) were answered less accurately than questions about the final sentence ($M = 84.51\%$, $SD = 13.54\%$; $\beta = -0.46$, $SE = 0.17$, $z = -2.75$, $p < 0.01$), though the difference between questions about the first sentence ($M = 79.48\%$, $SD = 14.30\%$) and second sentence did not reach significance ($p = 0.14$). This pattern likely reflects the fact that the second sentence was the most complex/longest of the three sentences.

Relationship between Reading Times and ART/MRT

We predicted that individuals scoring higher on the ART/MRT, and who are therefore likely to have greater world knowledge, would show the greatest effects of Cue condition during the retrieval region. However, adding the continuous ART/MRT composite scores as a predictor did not indicate any effect of ART/MRT on reading times during Region 3 nor was there any interaction with Cue or Mention Order (all $ps > 0.16$).

However, ART/MRT scores interacted with Cue condition at an un-predicted location, in Region 2 ($\beta = -0.002$, $SE = 0.001$, $t = -2.247$, $p < 0.05$). To follow up on this interaction, we used both group comparisons based on a median split as well as a correlational analyses. Numerically, individuals scoring higher on the ART/MRT had faster reading times for the One- ($M = 5.66$ log ms, $SD = 0.31$) compared to the Many-Cue condition ($M = 5.69$ log ms, $SD = 0.33$), but individuals scoring lower on the ART/MRT had the opposite numeric pattern (One-Cue, $M = 5.72$ log ms, $SD = 0.31$; Many-Cue, $M = 5.70$, $SD = 0.31$). Mixed-effects models performed separately over each group with Cue as a fixed effect and subject and item as random effects indicated that these were only trends ($ps = 0.09$, 0.11, respectively). However, a correlational analysis of ART/MRT scores and differences between One-Cue minus Many-Cue RTs was significant, $r = -0.216$, $p < 0.05$. We had no specific predictions for any effect of Cue at this region nor any interactions with ART/MRT (but see Discussion).

In addition, ART/MRT scores interacted with Cue condition in Region 4 ($\beta = -0.002$, $SE = 0.001$, $t = -2.172$, $p < 0.05$). We again inspected both group differences and correlations between ART/MRT and reading time differences. For the higher-scoring group, there was little difference based on Cue condition (One-Cue, $M = 5.80$ log ms, $SD = 0.33$; Many-Cue, $M = 5.79$ log ms, $SD = 0.34$; difference n.s.). However, a mixed-effects model (see above) revealed a difference between the One-Cue ($M = 5.81$ log ms, $SD = 0.32$) and Many-Cue ($M = 5.76$, log ms, $SD = 0.29$) conditions for the group scoring lower on the ART/MRT ($\beta = 0.027$, $SE = 0.008$, $t = 3.537$, $p < 0.001$). The correlation between ART/MRT scores and differences between One-Cue minus Many-Cue RTs was significant ($r = -0.283$, $p < 0.01$), indicating that lower scores were associated with larger differences between conditions. Although this pattern occurred at Region 4, a region subsequent to the critical retrieval region in our experiment (Region 3), it is possible the interaction between ART/MRT and Cue condition at this region relates to continued retrieval processes. We further discuss this possibility in the discussion.

There were no other interactions with ART/MRT at any other region in this analysis.

DISCUSSION

Summary of Findings

This study had two primary aims. The first was to test whether a greater amount of linguistic elaboration about a referent over a short discourse could facilitate subsequent access to that information during online language processing. If so, the second was to test whether this facilitation was greater for those with more world knowledge (determined using scores from the ART and MRT as a proxy) would lead to increased facilitation based on elaboration.

Supporting our hypothesis that elaborative information would provide more cues to retrieval, we found reduced reading times at a critical retrieval site when the referent had previously been described in more detail, albeit not more so for those with greater world knowledge. This work provides a novel contribution by suggesting that elaboration can affect retrieval-related processes in cross-sentential dependencies. These findings demonstrate the generality of elaboration effects in sentence processing (Hofmeister, 2011; Hofmeister and Vasishth, 2014).

It is particularly noteworthy that various formal syntactic theories treat anaphoric dependencies as fundamentally different than filler-gap dependencies. For instance, in transformational theories of syntax, filler-gap dependencies are licensed via cyclic movement of the filler, leaving behind a trace, whereas no such process applies to anaphoric dependencies (co-indexing provides the necessary connection; e.g., Chomsky, 1995, among many others). More importantly, the retrieval conditions in filler-gap dependencies are quite different from those in the current study. In filler-gap dependencies, the retrieval target is necessarily within the same sentence, which may limit the retrieval search space, relative to that for anaphoric dependencies. Further, the onset of a filler-gap dependency signals that the target information must be restored in the near future. That is, once a filler is encountered, a process is initiated that necessarily ends with retrieval; hence, it is predictable that the filler information will be needed again. Up to that point, the parser is actively engaged in searching for the first available integration point (Clifton and Frazier, 1989; Frazier and Clifton, 1989; Frazier and d'Arcais, 1989). This contrasts with anaphoric dependencies where there is no guarantee that a referent will ever be mentioned again—as was the case for the elaborative information presented in our short texts. In sum, anaphoric dependencies do not come with the same set of expectations or retrieval cues that accompany filler-gap dependencies. Thus, demonstrating that elaboration effects nevertheless arise in cross-sentential dependencies suggests that they are not contingent upon any of the idiosyncrasies of filler-gap dependencies.

We did not observe the predicted interaction between ART/MRT and Cue condition at Region 3. However, two unpredicted related results were the interactions between ART/MRT scores and Cue condition on reading times at Regions 2 and 4. In Region 2 ('The senator/who the Democrat/. . .'), participants may begin to anticipate the upcoming object of the relative clause, though there is still ambiguity with respect to which referent will be mentioned. We tentatively speculate that differences in language experience/world knowledge (as indexed by ART/MRT scores) may affect the individual's sensitivity to this ambiguity (or ability to predict an upcoming referent), possibly resulting in the observed interaction.

We initially hypothesized that having greater world knowledge (and higher scores on the ART/MRT, by proxy), would associate with greater ease of access for meaningful cues to retrieval. We therefore predicted greater facilitation in retrieval (at Region 3) for the Many-Cue condition, or possibly in a subsequent region, for those with greater world knowledge. However, the interaction between Cue and ART/MRT scores which we observed at Region 4 did not support our hypothesis; rather, individuals with lower ART/MRT scores drove effects of Cue condition in this region, with lower reading times associated with the Many-Cue compared to the One-Cue condition. One possibility is that for our materials, having more information benefited those with less language experience/less knowledge more, meaning that the group scoring lower on ART/MRT was able to benefit from the additional information in the Many-Cue condition while the higher-scoring group showed less of a difference between conditions. Future work using more tightly controlled stimuli (e.g., with identical numbers of words in each region, with identical syntax, etc.) might shed more light on the nature of these individual differences.

Overall, we interpret our findings as evidence that having more information about a referent is beneficial during retrieval and perhaps during subsequent comprehension, as the sentence progresses and information accumulates.

The Role of Elaboration in Online Sentence Processing

Work by Hofmeister (2011) and Hofmeister and Vasishth (2014) has shown that under many circumstances, elaborative information, typically in the form of adjectives preceding a noun, increases processing times at the point of encoding (at the noun) but facilitates processing times at a subsequent dependency. This finding holds for words which are more elaborated in the sense that they are semantically richer (e.g., '*soldier*' is richer than '*person*'), but it does not hold when adjectives preceding a noun are atypical descriptors (e.g., '*ruthless military dictator*' is typical but '*lovable military dictator*' is not). Here, we add to this literature by showing that elaborative information presented across multiple sentences, and not just locally (at the point of modifying a noun, for example), can facilitate subsequent access to or retrieval of that information.

What may account for the benefit of retrieving representations that have relatively many features associated with them, even across discourse boundaries? On one hand, such effects are surprising since it would seem to imply that more content must be retrieved. On the other, these effects align naturally with several non-mutually exclusive hypotheses about the nature of memory retrieval in language processing. For instance, in the cue-based retrieval model of Lewis and Vasishth (2005), the efficacy of retrieval for some item in memory is driven partly by its retrieval history, i.e., how many times an item has been restored and how recently. Modifying a word or phrase that has been encoded in the past reactivates that item, leading to an increase in its

activation. This reactivation process can even arguably offset any effects of time-based decay, giving rise to so-called anti-locality effects (Vasishth and Lewis, 2006). From this point of view, the increased ease of retrieval observed in Regions 3–5 is ascribable to a boosted level of activation of the target either prior to retrieval, or possibly during retrieval, as relevant cues spread activation to other cues (see Hofmeister, 2011). A separate, though not mutually exclusive, view suggests that adding semantic features to a discourse referent typically gives rise to a conceptually unique representation in the current discourse context. The advantage of this elaboration is manifested at the retrieval region, as the broader memory literature demonstrates a robust memory advantage for targets with contextually unique features (Moscovitch and Craik, 1976; Fisher and Craik, 1977; Jacoby and Craik, 1979; Hunt and Worthen, 2006; Gallo et al., 2008). In essence, adding details about a person or event increases the likelihood that this entity bears conceptual features that no other memory item (or very few others) shares, reducing the chance for similarity-based interference at retrieval. Both of these views capture the observed effects in our experiment without adjudicating between them.

CONCLUSION

The present findings are novel in showing that when (potentially) relevant semantic information is associated with a concept, it may directly impact its retrieval, even when the elaborative information is distributed across a discourse, and not just or at all in the local (within-sentence) linguistic context (as in Hofmeister, 2011; Hofmeister and Vasishth, 2014). Relatedly, one recent study found that when participants read longer descriptions (e.g., '*The actor who was frustrated and visibly upset*' vs. '*The actress*'), they were more likely to refer back to them with a pronoun, a finding the authors attributed to enhanced prominence of the referent due to the elaboration (Karimi et al., 2014). When concepts are more elaborated, subsequent processing advantages may occur because (a) there are more semantic features available and/or (b) those features lead to increased activation levels of the concept. Our findings suggest that variability in the elaboration of referents may have relatively long-term consequences for their processing across the subsequent discourse.

Representing number in the real-time processing of agreement: self-paced reading evidence from Arabic

Matthew A. Tucker[1]*, *Ali Idrissi*[2] *and Diogo Almeida*[1]

In the processing of subject-verb agreement, non-subject plural nouns following a singular subject sometimes "attract" the agreement with the verb, despite not being grammatically licensed to do so. This phenomenon generates agreement errors in production and an increased tendency to fail to notice such errors in comprehension, thereby providing a window into the representation of grammatical number in working memory during sentence processing. Research in this topic, however, is primarily done in related languages with similar agreement systems. In order to increase the cross-linguistic coverage of the processing of agreement, we conducted a self-paced reading study in Modern Standard Arabic. We report robust agreement attraction errors in relative clauses, a configuration not particularly conducive to the generation of such errors for all possible lexicalizations. In particular, we examined the speed with which readers retrieve a subject controller for both grammatical and ungrammatical agreeing verbs in sentences where verbs are preceded by two NPs, one of which is a local non-subject NP that can act as a distractor for the successful resolution of subject-verb agreement. Our results suggest that the frequency of errors is modulated by the kind of plural formation strategy used on the attractor noun: nouns which form plurals by suffixation condition high rates of attraction, whereas nouns which form their plurals by internal vowel change (ablaut) generate lower rates of errors and reading-time attraction effects of smaller magnitudes. Furthermore, we show some evidence that these agreement attraction effects are mostly contained in the right tail of reaction time distributions. We also present modeling data in the ACT-R framework which supports a view of these ablauting patterns wherein they are differentially specified for number and evaluate the consequences of possible representations for theories of grammar and parsing.

1. Introduction

A fundamental feature of language comprehension in real time is the online integration of grammatical information in the form of structural cues expressed morphologically on individual lexical items. For instance, many languages display grammatical agreement—a process whereby verbs co-vary in form with features of their arguments. Integrating agreement cues to resolve verb-argument agreement dependencies provides the parser with valuable information concerning

structural relations in the input and therefore provides important clues to the correct parse. Moreover, humans are quite good at completing this resolution: it is conducted relatively quickly, and failures to resolve agreement dependencies result in failures of parsing in many instances.

Despite this relative aptitude in comprehending agreement, speakers do make mistakes in both the comprehension and production of agreement dependencies. Since the initial study of Bock and Miller (1991), a large amount of theorizing concerning the nature of this integration has been based upon failures of agreement called *agreement attraction* errors. In an agreement attraction error, an agreeing element does not correctly match its controller in all features but instead matches a local *distractor* or *attractor* in a subset of the mismatching features. A key property of these errors is that this distractor NP is typically thought to be grammatically inaccessible insofar as it is not normally capable of controlling agreement because of its structural position. For instance, in English subject-verb agreement dependencies, attraction errors have been noted for several configurations, including prepositional phrase modifiers/complements, relative clauses, and the like (1)[1]:

(1) a. *The sheer weight* of **all these figures *make*** them hard to understand.
(based upon Ronald Reagan 13 October 1982; quoted in Francis, 1986 and Wagers et al., 2009)

b. *The boy* that liked **the snakes *sleep*** throughout the afternoon.
(based upon Bock and Miller, 1991)

c. *The request* to begin **the projects *were*** overwhelming because of the cost.
Tucker and Wagers (2010)

d. *Studying* **micro-climates** like this ***have*** helped me to understand if it's gonna be a minor event, or a catastrophic one.
(Jim Wood, professional blog post 13 August 2012[2])

Errors such as these are often discussed by both grammarians and syntactic theorists alike (see Jespersen, 1924; Zandvoort, 1961; Kimball and Aissen, 1971; Quirk et al., 1985; Francis, 1986; Kayne, 2000; Den Dikken, 2001; *inter alia*) and—despite their *prima facie* ungrammaticality—are common in both everyday speech and formal writing. Both production and comprehension studies have shown that the probability of agreement attraction errors is influenced by a large number of factors, including linear order, relative structural embedding, and the amount of featural overlap between distractor and verb (Bock and Cutting, 1992; Bock and Eberhard, 1993; Vigliocco and Nicol, 1998; Pearlmutter et al., 1999; Hartsuiker et al., 2001; Franck et al., 2002; Thornton and MacDonald, 2003; Haskell and MacDonald, 2005; Wagers et al., 2009; *inter alia*).

The factors which have been shown to influence the possibility of these errors include both processing and grammatical constraints. For instance, several researchers beginning with Bock and Miller (1991) have noted that agreement attraction errors are asymmetric in both their occurrence and salience in English. Specifically, whereas errors leading to erroneously plural verbs (2a) are commonly produced and more difficult to notice, erroneously singular verbs (2b) are rarely produced and seem much more salient to speakers:

(2) a. *The key* to **the cabinets *have*** become rusty from years of disuse. (**SG → PL**)

b. *The keys* to **the cabinet *has*** become rusty from years of disuse. (**PL → SG**)

One plausible explanation for this asymmetry is the grammatical notion of MARKEDNESS, wherein one marked value of a feature (in this case, plural) is defined by its opposition to another unmarked value (in this case, singular). By tapping into this grammatical notion, the reason for the particular direction of this asymmetry becomes explainable as attraction to the marked plural case in (2a). In (2b), on the other hand, the presence of an unmarked attractor means the verb is less easily misconstrued.

Similarly, the grammatical notion of a syntactic hierarchy has also been shown to be relevant by both Bock and Cutting (1992) and Franck et al. (2002), among others. In the Franck et al. (2002) study, the authors contrasted preambles such as (3) in a sentence production study to determine whether linear distance or syntactic prominence (defined in terms of structural height in a parse tree) contributes more to attraction. In these preambles, the linearly closest NP is not the structurally most prominent NP computed in terms of structural height:

(3) a. *L'-ordinateur* avec **le programme des expériences** . . .
the-computer with the program of.the experiments . . .
"*The computer* with **the program** of **the experiments** . . ."

b. *L'-ordinateur* avec **les programmes** de **l'expérience** . . .
the-computer with the programs of.the experiment . . .
"*The computer* with **the programs** of **the experiment**. . ."

In (3), the PP containing *expérience(s)* is a complement, and therefore structurally contained within the NP headed by *programme(s)*. The authors observed that the syntactically higher noun [*le(s) programme(s)*] has a larger impact on attraction error rates than the linearly closest noun (*des expériences*) leading the authors to conclude that syntactic hierarchical prominence plays a larger role than linear adjacency in modulating attraction rates.

On the other hand, processing constraints clearly matter, as well. Most concretely, attractions are errors, and only appear in

[1]In these examples and throughout the paper, the grammatical controller is in *italics*, the distractor in **bold**, and the erroneous verb in both *italic* and **bold** typeface. We do not mark ungrammatical sentences with a diacritic in this paper, as the nature of the acceptability of *prima facie* ungrammatical sentences is the object of study here.

[2]http://jimwood8.wordpress.com/2012/08/13/non-adjacent-agreement-attraction/.

a subset of observations for any given language community[3]. Moreover, emerging comprehension literature has shown that attraction errors in comprehension only occur in *ungrammatical* utterances, not grammatical ones (see, e.g., Wagers et al., 2009; Tucker and Wagers, 2010; Tanner et al., 2014). Thus, one does not find the comprehension correlates of attraction in examples such as (4):

(4) *The key* to **the cabinets *has*** become rusty from years of disuse.

Despite the fact that the attractor noun phrase mismatches the subject and is plural, reading times at *has* and error rates in speeded grammaticality studies do not reflect difficulty for the parser. Thus, error rates on examples such as (4) are low, and reading times at *has* do not differ from normal reading times for grammatical verbs. The explanation given for this asymmetry by Wagers et al. (2009) is that the attraction in ungrammatical sentences is the result of the parser's attempt to interpret an obviously erroneous verb by searching working memory for a matching noun phrase. Crucially, Wagers and colleagues contrast this with a view wherein grammatical representations are themselves fallible by observing such a view should apply equally in grammatical and ungrammatical utterances. This parsing strategy therefore provides a superior explanation for the grammaticality asymmetry in attraction than a view more wedded to grammatical representation.

1.1. Representations and Processes

A recently emerging hypothesis concerning the proper interpretation of dependency errors takes them to be a failure of the working memory implementation of agreement dependencies (Badecker and Kuminiak, 2007; Badecker and Lewis, 2007; Wagers et al., 2009; Dillon et al., 2013) following a general hypothesis that at least some of the processes involved in language comprehension are underwritten by a kind of skilled memory retrieval (Lewis and Vasishth, 2005; Lewis et al., 2006). Architecturally and programmatically, viewing dependency resolution as skilled memory retrieval allows the development of explicit hypotheses about the relationship between behavioral results and architectural claims about language comprehension insofar as researchers are forced to be explicit about both representational and procedural commitments.

In comprehension-as-retrieval models, some or all agreement morphology on a lexical item triggers a working memory retrieval event wherein the system attempts to find an available controller in a content-addressable memory. In order to do so, a procedural component searches all available chunks (constituents) in memory in parallel and attempts to locate a match along several cue dimensions, with the winner being decided by which element matches along the most dimensions. When the controller matches the agreeing element in all grammatical features, the number of matching retrieval cues will result in a proper retrieval of the true grammatical controller. However, when the controller and agreeing element do not match in all cues, those mismatched cues which the distractor bears can, in some instances, be sufficient to trigger an erroneous retrieval of the distractor, resulting in an attraction error.

The retrieval hypothesis is well-suited to explain the sensitivity of attraction to mismatches in controller and distractor cues (Bock and Miller, 1991; *et seq.*), the absence of attraction-like illusions of ungrammaticality in grammatical utterances (Wagers et al., 2009), and the relative error proportions in various constructions (Dillon et al., 2013). Finally, recently emerging work suggests that memory models are also, when combined with proper representational specifications, well-suited to explaining differing behavioral profiles for at least some different kinds of grammatical dependencies (Dillon et al., 2013; though see Parker, 2014 for some critical discussion).

Linking agreement attraction errors to more general comprehension models provides for some important possibilities for research into both the grammar and parsing. Specifically, as Dillon et al. (2013) demonstrate, in places where experimental data are suggestive of a particular representational commitment in the parser, modeling can provide additional evidence for this commitment when it dovetails with experimental results. Moreover, the success of memory models in accounting for particular experimental results across a range of languages adds to the validity of the models themselves. In order to do this modeling of experimental results, however, researchers must stake particular claims about the relationship between parsing and grammar in order to decide on representations and processes in the models. Any such claims, therefore, help elucidate the connection between parsing *per se*, grammar, and working memory.

By contrast to the memory models, several alternatives have been proposed which view agreement attraction as either grammaticalized alternatives (Kimball and Aissen, 1971; Kayne, 2000; Den Dikken, 2001) or an improper representation driven by feature movement or percolation of number features to incorrect nodes in syntactic trees (Nicol et al., 1997; Vigliocco and Nicol, 1998; Franck et al., 2002; Eberhard et al., 2005). However, as was first pointed out by Wagers et al. (2009), models which eschew the role of memory are only successful insofar as one can identify correlates of their representational claims in all aspects of processing behavior. Grammaticalization models assume that, at the very least, attraction should be possible outside of error contexts, a finding which has yet to be conclusively demonstrated. As for representational models, memory models have been argued to be superior to purely representational approaches in understanding the comprehension of grammatical sentences which contain the structural configurations supporting the creation of erroneous representations. As Wagers et al. (2009) have argued, erroneous representations should be possible in ultimately grammatical utterances, yet experiments designed to test for the presence of "agreement attraction" in grammatical utterances consistently yield null results (see Wagers et al., 2009; Tanner et al., 2014; and our results below). We therefore conclude, with these authors, that memory models provide a better

[3]See any of the previously cited studies for examples of this. Note that this runs counter to the claims of some formal linguists who have occasionally treated these errors as dialectal or idiolectal variation in need of explanation (i.e., Kimball and Aissen, 1971; Kayne, 2000; Den Dikken, 2001). At the very least, one would have to maintain that the data underwriting these studies are dialectically distinct from standard English, as Kimball and Aissen (1971) do.

avenue for exploration in the service of explaining possibly erroneous dependency processing in natural language and couch the study reported here in memory retrieval terms.

1.2. Crosslinguistic Considerations

What working-memory models require, however, is a well-understood theory of the relationship between formal linguistic features usually referenced in linguistic theories of agreement (such as those proposed by Chomsky, 1995, 2000, 2001; and related work) and the cues used in models of working memory tasks. It is therefore conspicuous that the prevailing views on feature-cue mapping have been developed with a comparatively small sample of languages in mind: the majority of studies have examined either Germanic languages such as Dutch, English, and German or Romance languages such as French, Spanish, and Italian (For English, see any of the previously cited works except Franck et al., 2002, among many others. For Dutch, see Hartsuiker et al., 1999; Meyer and Bock, 1999; Bock et al., 2001; Kaan, 2002; Hartsuiker et al., 2003; for German, see Hartsuiker et al., 2003; Häussler, 2009; for Spanish, see Vigliocco et al., 1996; Antón-Méndez et al., 2002; Franck et al., 2008; Lago et al., 2014; for French, see Fayol et al., 1994; Vigliocco et al., 1995; Vigliocco and Franck, 2001; Franck et al., 2002, 2008, 2010 and for Italian, see Vigliocco et al., 1995; Vigliocco and Franck, 1999, 2001; Franck et al., 2006, 2008). The only exceptions to this tendency involve two studies on the Slavic languages Russian (Lorimor et al., 2008) and Slovak (Badecker and Kuminiak, 2007), however even this sample of languages is wholly contained within the larger Indo-European family. To our knowledge, no studies of agreement attraction exist in languages outside Indo-European. A theory of the relationships connecting grammar, parsing, and working memory is ultimately a theory about the implementation of language in the mind, and therefore would benefit from the largest possible cross-linguistic coverage since it is conceivable that there is crosslinguistic variation here.

This lacuna is additionally striking when one considers the possible range of variation in the expression of verbal agreement. Germanic and Romance languages display subject-verb agreement for grammatical number, and while nominals in these languages have formal gender, this gender does not impact the subject-verb agreement system. This is not true of the Slavic languages studied by Badecker and Kuminiak (2007) and Lorimor et al. (2008), where converging evidence seems to suggest that gender does play a role in attraction. However, in these languages, nominal morphology also includes grammatical case-marking, which is shown to play a confounding role insofar as the case a nominal bears helps to disambiguate its grammatical function (for similar evidence in German, see Häussler, 2009). In these languages, it may be possible to set up an attraction configuration involving gender, but grammatical case on the attractor serves to disambiguate its grammatical role in a way which drives down attraction rates. It is thus important to broaden the empirical base of agreement attraction errors by considering their properties in languages outside the handful of well-studied languages in this domain of research, as the restriction to these languages could in principle unduly influence representational commitments made on the basis of particular kinds of verbal agreement paradigms.

A crosslinguistic perspective is an important one for addressing a pressing question in memory models concerning the distinction between a grammatical feature and a processing/memory retrieval cue. While it is clear that theoretical work can identify features utilized by the grammatical system, it is an open question how these features map onto cues which are used in the memory retrieval system. Just because grammar provides a feature as part of a contrast does not mean that the parser must utilize this feature in dependency resolution. Here, again, the memory retrieval models force an explicit commitment insofar as predictions about which constituents in memory are retrieved (as well as the latency of that retrieval) can only be made when one is explicit about the inventory of cues available to the system. Investigating these questions in languages which utilize different grammatical features in distinct ways is therefore a necessary part of understanding the feature-to-cue mapping.

Finally, an additional reason that crosslinguistic consideration is important relates to the way that memory models relate available cues to available activation in the system. Since the eventual retrieval target is the chunk in memory which has the highest activation at the retrieval event, and this activation is itself a function of two things: (1) the number of cues which a chunk shares with the goal and (2) the total number of chunks associated with each individual cue. A corollary of this architecture is that the number of available cues in a language directly modulates the amount of activation in the system. Adding more morphological features to discriminate NPs in memory should, in principle, drive down error rates. It is therefore an open question whether one expects agreement attraction in a language which is sufficiently morphologically rich in its verbal agreement[4]. Understanding the predictions such a system makes as available cues vary crosslinguistically is therefore an important way of validating such architectures more generally. Here, again, we believe testing memory models across the widest variety of languages should be an important research objective.

1.3. The Relevance of Arabic

It is here where Modern Standard Arabic (MSA; also equivalently just "Arabic" in what follows) is particularly well-suited as a language of interest. Arabic is spoken by over 200 million people worldwide and MSA is a *lingua franca* used in writing and formal speech across different regional varieties of spoken Arabic (as well as within-dialect groups). MSA is relevant for agreement attraction studies because it has verbal agreement for grammatical gender for both masculine and feminine subjects, a dual number (Ryding, 2005, pp. 438–444), and case marking which is optional on NPs under particular circumstances (Ryding, 2005, pp. 165–205). These kinds of agreement are in addition to the more standard singular/plural distinction seen in languages such as English and demonstrated for Arabic in (5)[5]:

[4]This is actually true of a broader array of models than just the ones considered here, such as the Competition Model (e.g., MacWhinney, 1987; MacWhinney and Bates, 1989; MacWhinney, 2001).

[5]In this and all subsequent glosses, we use the following abbreviations for grammatical features: MASC = masculine gender, FEM = feminine gender, 3 = third person, PERF = perfect aspect, NOM = nominative case, ACC = accusative case, and COMP = complementizer. Finally, because Arabic orthography is ordered

(5) a. الطالب درس اللغة العربية.

the-student(.MASC.PL) study-3.MASC.PL.PERF
al-luɣa al-ʕarabiyya.
the-language the-arabic

"The students studied Arabic."

Additionally, MSA has two distinct strategies for forming plurals on nouns: (1) a plural formed by suffixation, called the "sound" plural (طالبة – طالبات/t$^{\varsigma}$*aaliba*—t$^{\varsigma}$*aalib-aat*, "student ∼ students (fem.)") and (2) a plural formed by ablaut, called the "broken" plural in traditional Arabic grammar (شيخ – شيوخ ʃajx ∼ ʃujuux, "sheikh ∼ sheikhs"). While the latter strategies for pluralization would normally be referred to as "irregular" in the English literature, the broken/ablauting plural strategy is very common in Arabic—if not more common than the sound/suffixing plural strategy (see, e.g., Ryding, 2005, pp. 132–204). For nouns which take suffixes in the plural, these suffixes are absolutely regular: in the feminine there is only /-aat/ (Ryding, 2005, pp. 132–133). For masculine nouns which take suffixing plurals, there are up to two suffixes, /-uun/ for nominative case and /-iin/ for genitive and accusative case (Ryding, 2005, p. 140)[6]. By contrast, the number of broken plural patterns is considerably higher: (Ryding, 2005) lists 26 distinct patterns and (McCarthy and Prince, 1990b), following (Wright, 1889a,b), give 31 patterns. This sound/broken contrast is an important one because it cross-cuts other grammatical concerns in Arabic: what type of case morphology is available for a noun depends on what kind of plural it takes (Ryding, 2005, pp. 165–204); affects theoretical conceptions of morphological process (McCarthy and Prince, 1990b); and may affect lexical access at the word level (Mimouni et al., 1998).

These two types of plurals are of particular interest because they allow investigation of the representation of plurality in both linguistic representation and the working memory system. A recurring question in experimental work on Semitic is to what extent grammatical theories concerning word representation postulate representational constructs which are useful for psycholinguistic theorizing. Specifically, traditional Arabic grammars characterize most words as consisting of a consonantal ROOT (made up of two to five consonants) interleaved among vowels in a so-called prosodic TEMPLATE (see, e.g., Ryding, 2005, pp. 45–50), a characterization which has heavily influenced linguistic theories of the language, as well (see, for example, McCarthy, 1979, 1981; McCarthy and Prince, 1990a,b; Ussishkin, 2000, 2005; Tucker, 2010, 2011; Ussishkin et al., 2015). For instance, (6) gives examples of several distinct words all sharing the root $\sqrt{\text{ktb}}$:

(6) a. كتب/kataba, "he wrote"
b. كاتب/kaataba, "he corresponded"
c. كتاب/kitaab, "a book"
d. اكتب/uktub, "write!"
e. مكتب/maktab, "an office/desk"
f. مكتبة/maktaba, "a library"

Formal Arabic grammar is mostly uniform in its description of Arabic morphology in these root and template terms. However, depending on the part of grammar being considered, psycholinguistic work has found variable evidence for the template, mainly from priming (for Hebrew, see Frost et al., 1997; Deutsch et al., 1998; Frost et al., 2000; for Maltese, see Ussishkin and Twist, 2007; Ussishkin et al., 2011; and for Arabic, see Boudelaa and Marslen-Wilson, 2001, 2004b,a, 2005; Boudelaa et al., 2010; Boudelaa and Marslen-Wilson, 2011). Notably, this reliance on priming has led to most conclusions about the psycholinguistic validity of these representations being confined to lexical decision independent of sentential context. However, one thing which is not addressed in most of the recent work on Semitic morphosyntax is how this root-and-pattern system interacts with the representation of plurality in both grammar and parsing (a notable exception being the early work of McCarthy, 1981, where it is explicitly claimed that templates are morphemes which bear grammatical content). For instance, one can easily wonder, for broken plurals, where the grammatical plural feature is located in the representation and how such a representation translates into use for parsing. Given that there is enough linguistic and psycholinguistic evidence that suggests one should take the broken/ablauting vs. sound/suffixing contrast seriously on Arabic-internal terms, here we attempt to see whether this contrast is informative for diagnosing how the processing system encodes nouns in general and plurality more specifically. While this question is particularly salient for Semitic-internal debates, it is germane to research on morphological representations outside of this language family, as well insofar as other languages have similar representations for morphological features.

1.4. The Present Study

As promising as the grammatical situation is in MSA for probing the mapping between features and cues in agreement dependency resolution, it remains to be seen whether or not agreement attraction exists for the standard number features seen in previous studies. The study reported here took up this question by considering the resolution of agreement dependencies involving plural attractors. In better-studied languages such as English, one finds that plural attractors occasionally condition erroneous plural verbal morphology, as in (7):

(7) *The key* to **the cabinets *are*** rusty from years of disuse.

In production, agreement attraction errors manifest as production of the erroneous verb (Bock and Miller, 1991; *et seq.*),

right-to-left, we do not gloss the Arabic itself; it is included for reference, and a gloss is included for the phonetic transcription.

[6]For both masculine and feminine nouns, the situation is modulated by definiteness, where definiteness is defined as marking with the definite article /al-/. Since all the nouns used in our study were definite, we focus on definite NPs only in this description. See (Ryding, 2005) for ample discussion.

whereas in comprehension attraction errors manifest as facilitation on ungrammatical verbs when attraction configurations are present (Pearlmutter et al., 1999; Wagers et al., 2009; Dillon et al., 2013; Tanner et al., 2014) or as a reduced-amplitude P600 in attraction configurations in ERP research (Tanner et al., 2014).

The study reported below therefore also investigated the representation of number cues across different kinds of plurals in Arabic using self-paced reading while counterbalancing attractor plural type. We predicted the existence of such errors in comprehension in MSA as a facilitation to erroneously plural verbs in the presence of a plural attractor relative to singular attractors in the same context. As for plural type, we were more reserved in our prediction, being unsure as to the theoretical status of plural types in the language. It has previously been observed for English (Bock and Eberhard, 1993) that irregular plural formation (*ox∼oxen*, *mouse∼mice*) on an attractor NP does not condition differential error rates. However, in that production study, the focus was on a language for which ablauting plurals are exceptionally rare and form a small corner of the nominal inventory of the language. In MSA, the relative abundance of ablauting plurals may very well mean differential behavior between suffixing sound plurals and ablauting broken plurals. Any such difference, in turn, would have implications for the mapping between grammatical plural features and plural retrieval cues on NP constituents in working memory.

2. Self-Paced Reading

As a prerequisite for any systematic investigation of the unique properties of Arabic morphology and their effect on agreement attraction, it is first necessary to be sure that attraction errors of the kind documented for other languages occurs in MSA. We think this an especially important contribution given the relative inhospitability of the Arabic agreement system to agreement attraction errors: the system involves a large number of cues (person, number, and gender) which assist the parser in retrieving the correct subject. In order to determine whether attraction errors are possible in MSA, an experiment was designed based upon the relative clause stimuli in the initial (Bock and Miller, 1991) study. The purpose of this experiment was to ensure that subject-verb agreement errors for singular and plural number do occur in a relatively frequently-occurring grammatical configuration that allows for subsequent manipulation of less well-studied number and gender alternations.

We therefore test the Arabic equivalents of a subset of preambles from the Bock and Miller (1991) study on English. Specifically, Bock and Miller (1991) tested production agreement errors elicited after giving participants preambles such as *The boy(s) that liked the snake(s)* … which varied based on the number for the subject [*the boy(s)*] and the local distractor noun [*the snake(s)*]. However, we were also interested in the real-time processing properties of attraction errors, so we investigate comprehension by measuring the reading times for complete versions of these sentences. This allowed us to simultaneously remain close to the original phenomenon in English while simultaneously exploring the comprehension of agreement in Arabic.

2.1. Method

2.1.1. Participants

Participants were 114 native speakers of Arabic from the University of the United Arab Emirates and NYU Abu Dhabi student bodies (113 female; mean age 21.1 years)[7]. All participants had no history of language disorders and read MSA regularly. Each participant provided written informed consent and was compensated for their participation. This experiment was approved by the NYU Abu Dhabi Institutional Review Board and the UAEU Ethics Committee.

2.1.2. Materials

A set of 48 sentences was constructed, each containing a subject relative clause with an animate object modifying the animate subject of a transitive verb. Subject relative clauses were chosen because they are a long-standing example of a configuration which creates agreement attraction errors (e.g., Bock and Miller, 1991) and are relatively common in MSA. In this sense they are a better choice than the canonical *NP—PP* configuration in more memorable examples such as *The key to the cabinets*.... The issue these constructions pose for the present study is that Arabic does not easily allow adverbs to be placed between subject and verb (Tucker, 2011) the inclusion of which was a *desideratum* of our stimuli. This is because, following (Wagers et al., 2009), we wished to insert an adverb or adverbial prepositional phrase between the end of the relative clause and the target main clause verb in order to mitigate plural NP spillover effects into the target region. All the stimuli therefore had the structure *NP1—Complementizer—RC Verb—NP2—Adv/PP—Verb—Continuation*. An example of such a sentence appears in (8):

(8) المترجم الذي ساعد الرئيس أحيانًا يتكلم خمس لغات بفصاحة

ʔal-mutarʒim-u ʔalla ii
the-translator-NOM COMP.MASC.SG
saaʕad-a ʔal-raʔiis-a ʔaħjaanan
helped-3.MASG.SG the-president-ACC often
ja-takallamu xamsata luʁaat-in
3.SG.MASC-speaks five languages-ACC
bi-fasˁaaħatin.
with-fluency

"The translator who helped the president often speaks five languages fluently."

Several constraints guided the construction of these experimental sentences: Firstly, Arabic has a series of prepositions which are only a single syllable/orthographic character and which are written with no space separating them from the complement NP. Only these prepositions were used in constructing adverbial PPs, meaning that the buffer region between distractor NP and target verb was no more than one orthographic word for any sentence.

[7]The discrepancy in gender in this sample is a product of the student body makeup at the UAEU, where the majority of testing was conducted. This university has a 3:1 female-to-male student ratio and has gender-segregated campuses. Testing was conducted on the female side because of the larger number of students, meaning that male students were not able to participate at the UAEU.

Secondly, for any given sentence both the subject and distractor NP were the same grammatical gender (masculine or feminine), and the total number of masculine and feminine gender nouns was balanced across sentences (24 masculine, 24 feminine). We decided not to allow different genders in the same sentence because of the confound introduced by the complementizer in MSA, as it must agree with definite head nouns (Ryding, 2005, pp. 322–324). Because of this, the true subject would receive an additional disambiguating cue from the complementizer's gender. However, the complementizer does inflect for grammatical number, meaning that in our stimuli the true subject receives reinforcement from the singular complementizer in conditions with plural attractors.

Additionally, we sought to vary the kind of plural which the attractor NP takes in the plural conditions. However, grammatical case in Arabic is normally optionally expressed in diacritics which are not written in everyday MSA, with the exception of suffixing masculine plurals, which do show an orthographic distinction between accusative and nominative case (represented by a change in an orthographically obligatory long vowel). In order to avoid adding a potentially disambiguating cue, case-marking, all masculine distractor NPs took broken plurals and all feminine distractor NPs took suffixing plurals. We also opted to conflate gender and plural type because MSA does not furnish a sufficiently large number of broken feminine plurals which refer to animates. This strategy allowed balancing of gender and suffixation in the plural in a grammatically natural way without introducing confounds from orthographically-represented grammatical case. This design allows us to check whether different pluralization processes (ablaut vs. suffixation) influence agreement attraction effects differently, although in our design this is necessarily confounded with grammatical gender.

In addition to gender and plural type, the sentences were also counterbalanced for whether the target verb appeared in the present or past tense. This was done because MSA has two distinct series of affixes for verbal agreement: (1) the present tense, with both a prefix and suffix and (2) the past tense, with suffixes only (see, e.g., Ryding, 2005, pp. 438–444). Counterbalancing in this way allowed conclusions to be drawn about agreement independent of the specific affix series employed. We did assess the effect of tense/aspect in the reading time results presented below and found no effect of the affix series employed.

Finally, stimuli in Arabic must stake a position on the orthographic representation of short vowels. Arabic is written in an alphabet which only represents long vowels, where short vowels are only written in religious texts, poetry, and texts for language-learners. In everyday formal written Arabic, short vowels are sometimes employed when an orthographic string is lexically ambiguous without some short vowel specification or in a way which is not resolvable from sentential context. The effects of adding superfluous or normally unwritten short vowels to Arabic language stimuli is understudied, and therefore a point of particular concern. In our stimuli, we therefore employed minimal diacritics only where lexical ambiguity would result if the diacritics were not used. This is a common scheme for representing diacritic marks in MSA and matches what is seen in everyday formal writing in the Arab world.

For each experimental sentence, four variants were constructed by systematically varying the morphological number of the object of the relative clause (*NP2*, the *attractor* or *distractor*) and the main clause verb (the *Verb*). This resulted in four conditions per sentence which are labeled according to the number of *NP2* and *Verb*: (S)ingular or (P)lural. We call the conditions in which the verb is plural *ungrammatical* conditions, since all subjects were singular in the experimental items. A complete item set appears in **Table 1** and the complete list of sentences appears in the Supplementary Materials.

The 48 sets of four sentences were distributed across four lists in a Latin Square design and combined with 144 grammatical filler items of a similar length in order to distract from the target items. None of the fillers contained the subject relative clause construction contained in the stimuli. This resulted in a filler-to-item ratio of 3:1 with 25% of the sentences being ungrammatical.

In this study we expect several things based upon the previously published studies for Germanic, Romance, and Slavic languages. Specifically, we expect to find a main effect of grammaticality in the critical verb region (RCV) and subsequent regions owing to possible spillover. Moreover, we expect to find a interaction between this factor and the attractor number factor in the critical verb region (possibly including spillovers) driven by slower reading times for the Sg/Ungram condition relative to the Pl/Ungram condition—this is the attraction configuration. Moreover, we expect to find no difference between the two grammatical conditions, Sg/Gram and Pl/Gram, given that no comprehension attraction effects have been observed in the previous literature. Additionally, following the discussion in Wagers et al. (2009), we expect to find a main effect of attractor number alone in the attractor region (NP2), a plural reading time effect noted in that work but not presently well-understood. Finally, we have no *a priori* expectations about the nature of the effect of plural type, but suspect that it is relevant for on-line processing given its centrality in the grammatical and lexical access literature.

2.1.3. Procedure

Subjects were seated comfortably up to eight at a time at a table in a quiet room in front of computers on which the experimental software had been pre-loaded. Sentences were presented using the Linger software (Rhode, 2003) in a self-paced word-by-word moving window paradigm (Just et al., 1982). Each trial begin with the display of a screen containing the sentence masked by dashes (including spaces and punctuation). Each time the participant pressed the space bar, a single word was revealed and the previous word re-masked. All items were presented in the Courier New Arabic font in 28pt bold type. A yes/no comprehension question (not an acceptability judgment) followed each sentence, appearing on the screen all at once. Comprehension questions were designed in such a way that the answer could be provided independent of experimental manipulations—no questions asked about the attractor NP or the main clause verb. None of our comprehension questions required lexical elaboration of the item or difficult semantic processing. A majority of the comprehension questions asked about the relative clause verb or the post-critical region continuation. As an example, the item *The*

TABLE 1 | A complete item set for one sentence for the experiment.

student who saw the professor(s) yesterday studied electrical engineering at the university. was followed by the question *Did the student see someone?*. The 'f/ب' key was used for "yes (نعم)" and the 'j/ت' key used for "no (لا)." Onscreen feedback was provided for both correct and incorrect answers. Participants were instructed to read at a natural pace ensuring comprehension and were not alerted to the presence of grammatical errors in the stimuli. The order of sentence presentation within each list was randomized by the experimental software for each participant. Four practice items were presented before the start of the experiment.

2.1.4. Data Analysis

Subjects which were less than 70% accurate on comprehension questions were excluded from further analysis on the grounds that they were not sufficiently attentive to the task; this criterion resulted in the exclusion of 10 subjects. Outliers were handled by Winsorizing the extreme 5% of the data (Ratcliff, 1993). No other exclusion criteria were used.

Data from both the comprehension question responses and remaining region-by-region reaction times were analyzed using mixed effects regression (Baayen et al., 2008). The answers to the comprehension questions were entered into several logistic mixed effects models including experiment, condition, and experimental independent variables (attractor number and grammaticality) as fixed effects and subjects and items as random effects with intercepts only. Self-paced reading data for each region of interest (R4, the attractor region, through R8, the second post-critical verb region) were entered into a linear mixed effects model fit using restricted maximum likelihood estimation with both subjects and items as random effects and several predictors as fixed effects: (1) attractor number, (2) grammaticality, (3) attractor plural type (ablauting/suffixing), (4) item order in the experimental presentation, (5) log frequency of the plural of the attractor according to the arabiCorpus (Parkinson, 2012), (6) word length in characters, (7) the previous region's reading time, and (8) interactions of terms (1–3). Categorical predictors were dummy-coded using the following default values: (1) grammaticality = grammatical, (2) attractor number = singular, and (3) gender/plural type = feminine (sound/suffixing) and neither categorical nor continuous predictors were centered. Our random effects structure was comprised of intercepts for subjects and items. For both the comprehension and reading-time results we used a minimal random effects structure in order to ensure convergence of the models (but see Barr et al., 2013). Degrees of freedom were estimated using the Welch-Satterthwaite approximation in order to calculate a p-value; we therefore report t-values directly instead of $z-$scores or 95% confidence intervals generated by bootstrapping or MCMC sampling. More details on the modeling for the reading time results can be found in the Supplementary Materials.

2.2. Results

2.2.1. Comprehension Question Accuracy

The mean comprehension question accuracy pooled across subjects and items to both experimental items and fillers was 88.2% and was significantly lower for experimental items (80.0%) than for fillers (91.1%) (logistic mixed-effects model $\hat{\beta}_1 = 1.44$; $z = 19.80$; $p < 0.0001$). We believe this lower accuracy to the experimental item comprehension questions is due to errors in the construction of some of the questions themselves. Participants reported confusion over the intent of seven of the questions; with these questions excluded, experimental item accuracy increased to 86.1%. Nevertheless, we exclude data from these items when the comprehension question was answered incorrectly in the reading-time analysis which follows, as this is the most conservative approach.

Accuracy rates for singular attractors were 81.0 $\pm$ 1.2% (with standard errors computed over participant means) for grammatical sentences and 78.8 $\pm$ 1.3% for ungrammatical sentences. For plural attractors, accuracy rates were 82.7 $\pm$ 1.3% for grammatical sentences and 76.0 $\pm$ 1.4% for ungrammatical sentences. The configuration of plural attractor and grammatical verb had a significant impact on question accuracy ($\hat{\beta} = 0.36$; $z = 2.11$; $p = 0.03$) such that participants were more likely to be correct in this condition relative to the attraction configuration of plural attractor and ungrammatical verb.

2.2.2. Self-Paced Reading

The self-paced reading results for all items are presented immediately below. Because of our *a priori* interest in the impact of grammatical and lexical access-related differences in plural

formation type on agreement attraction, we provide some additional results by gender/plural type, as well. In what follows, we focus our reporting on the results of the experimental manipulations of Attractor Number, Grammaticality, and Gender/Plural Type. We do not comment on the presence of effects due to the frequency of the attractor, word length, or previous region's reading time, as these predictors are commonly found to be explanatory in reading time studies and we have nothing to add here to their interpretation as determinants of reading time.

2.2.2.1. All items

The results from the experiment are presented in **Figure 1** and the mixed-effects model results for the attractor region (R4) and critical verb region (R6) appear in **Tables 2**, **3**. Linear mixed-effects model results for all other regions of interest are included in the Supplementary Materials.

The relative clause attractor region (R4) contained a main effect gender/plural type such that masculine attractor NPs were read more slowly than feminine attractor NPs [$\hat{\beta} = 72.00$; $t_{(143.00)} = 2.53$; $p = 0.01$]. Additionally, there was an interaction between gender/plural Type and attractor number [$\hat{\beta} = -62.24$; $t_{(3833.00)} = -2.37$; 0.02] which was driven by significantly longer reading times to plural attractors for feminine attractors [$t_{(207)} = 2.99$; $p = 0.003$; plural mean = 674.80 ms; singular mean = 629.10 ms]. The same was not true of masculine attractors [$t_{(207)} = -1.11$; $p = 0.27$; plural mean = 600.42 ms; singular mean = 615.34 ms]. However, there was no main effect of attractor number alone [$\hat{\beta} = 14.47$; $t_{(757.00)} = 0.65$; $p = 0.51$, *n.s.*; singular mean = 624.87 ms; plural mean = 637.37 ms]. In the adverb region (R5), there were no effects of any of the experimental manipulations (all t's < 1.3).

The main clause verb region (the critical region, R6) showed a main effect of grammaticality such that ungrammatical utterances were read much more slowly than grammatical utterances [$\hat{\beta} = 102.56$; $t_{(3657.00)} = 6.70$; $p < 0.0001$ ungrammatical mean = 651.15 ms; grammatical mean = 575.91 ms]. The main verb region also displayed an interaction of grammaticality and gender/plural type [$\hat{\beta} = -59.85$; $t_{(1157.00)} = -2.50$; $p = 0.01$]. This appeared to be due to a larger grammaticality effect for masculine items (ungrammatical mean = 653.00 ms; grammatical mean = 567.54 ms) than for feminine items (ungrammatical mean = 653.11 ms; grammatical

mean = 582.06 ms). Crucially, the main clause verb region also yielded an interaction between attractor number and grammaticality [$\hat{\beta} = -72.40$; $t_{(3925.00)} = -3.44$; $p = 0.0006$]. Planned comparisons revealed that this was driven by an effect of attractor number in the ungrammatical conditions such that plural attractors were read more quickly than singular attractors [$t_{(103)} = 4.48$; $p < 0.0001$; plural mean = 622.48 ms; singular mean = 679.83 ms] but no difference in the grammatical conditions [$t_{(103)} = -0.04$; $p = 0.97$; plural mean = 576.09 ms; singular mean = 575.74 ms]. This agreement attraction interaction did not appear to be modulated by gender/plural type in the main clause region [$\hat{\beta} = 39.08$; $t_{(3928.00)} = 1.31$; $p = 0.19$], though see the following section for some consideration on this finding.

Following the critical main verb, the first spillover region (R7) showed a main effect of attractor number such that plural attractor sentences were read more slowly in R7 than singular attractor sentences [$\hat{\beta} = 27.53$; $t_{(1598.00)} = 2.51$; $p = 0.01$; plural mean = 520.22 ms; singular mean = 520.18 ms], though as the means suggest this effect is not significant in a follow-up comparison [$t_{(207)} = 0.005$; $p > 0.99$]. We believe this effect attributable to our use of dummy coding, as a sum-coded model does not reveal this effect [$\hat{\beta} = 0.87$; $t_{(757.00)} = 0.34$; $p = 0.74$] despite qualitatively different results for all other effects. The effect of grammaticality which began at the main clause verb persisted into the first spillover region, with ungrammatical sentences read more slowly than grammatical sentences [$\hat{\beta} = 70.58$; $t_{(3925.00)} = 7.37$; $p < 0.0001$; ungrammatical mean = 541.16 ms; grammatical mean = 499.24 ms]. Additionally, the attraction interaction of attractor number and grammaticality which began in the previous region persisted into R7 [$\hat{\beta} = -37.92$; $t_{(3924.00)} = -2.81$; $p = 0.005$]. However, in this region this interaction was driven by significantly longer reading times to plural attractors in grammatical conditions [$t_{(103)} = -2.37$; $p = 0.02$; plural mean = 506.48 ms; singular mean = 492.01 ms]. In ungrammatical conditions, plural attractors conditioned faster reading times than singulars, though this effect did not reach significance [$t_{(103)} = 1.58$; $p = 0.11$; plural mean = 533.95 ms; singular mean = 548.36 ms]. Additionally, R7, the first spillover region, also showed a significant interaction of grammaticality and gender [$\hat{\beta} = -30.40$; $t_{(3925.00)} = -2.26$; $p = 0.02$]. This interaction was due to significantly longer reading times to grammatical sentences with masculine attractors than those with feminine attractors [$t_{(207)} = 4.12$; $p < 0.0001$; masculine mean = 515.22; feminine mean = 486.90]. A similar trend was only marginal in the ungrammatical sentences [$t_{(207)} = 1.77$; $p = 0.07$ feminine mean = 536.89 ms; masculine mean = 553.46 ms].

Finally, in the second spillover region, there were no significant effects of any of the experimental manipulations (all *t*'s < 1.85), however the main effect of grammaticality was marginally present [$\hat{\beta} = 14.04$; $t_{(3926.00)} = 1.83$; $p = 0.07$]. This was again because ungrammatical sentences were read longer two words downstream from the main clause verb than grammatical sentences (ungrammatical mean = 491.79 ms; grammatical mean = 477.76 ms).

2.2.2.2. By gender/plural type

Results for the experiment segregated by plural type/gender of the attractor NP are presented in **Figure 2**. While our mixed-effects model presented above did not show a significant interaction of gender/plural type and the attraction effect (the three way interaction of Attractor Number × Grammaticality × Gender/Plural Type was not significant), we had two reasons for investigating the interaction further: (i) *a priori* considerations concerning the grammatical status of plural formation type in MSA (see §1.3, above) and (ii) visual inspection of the difference between the two genders in **Figure 2**. Specifically, we were suspicious of the possibility that feminine items were showing more attraction relative to masculine items, if the latter were indeed displaying attraction at all.

We also suspected that the lack of a significant interaction in our mixed-effects model was partially due to our choice of outlier exclusion method: Winsorizing five percent of the data could have erroneously removed long reading times to critical verbs in the Sg/Ungram and Pl/Ungram conditions—these conditions are fully ungrammatical, and since this is the first reading-time study on MSA, there was no *a priori* way to know the expected size of reading time increases to fully ungrammatical verbs. Such an interpretation is also consistent with an emerging view that agreement attraction effects are driven by reading times in the right tail of the distribution (Staub, 2009, 2010; Lago et al., 2014) It is therefore possible that a 5% cutoff by-region is too conservative and results in the exclusion of data mistaken for outliers. To this end, we ran an identical analysis with no Winsorization. The results of this analysis are qualitatively identical to the analysis presented above, save for the three-way interaction of Attractor Number × Grammaticality × Gender/Plural Type in the main clause verb region (R6); in unwinsorized model, this term emerges as marginal [$\hat{\beta} = 99.13$; $t_{(3926.00)} = 0.05$]. This marginal effect is driven by longer reading times to Sg/Ungrammatical conditions relative to Pl/Ungrammatical conditions in the feminine items [$t_{(103)} = 3.38$; $p = 0.001$; Sg/Ungram mean = 732.05 ms; Pl/Ungram mean = 640.11 ms], a contrast which is not present for masculine items [$t_{(103)} = 0.24$;

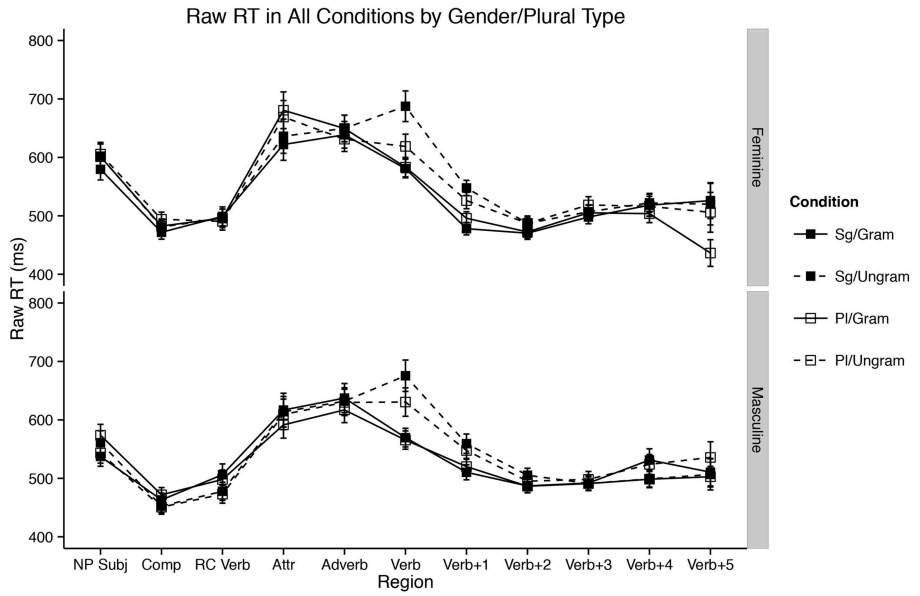

FIGURE 2 | Self-paced reading results. Region by region means segregated by attractor number and verb number for both genders/plural types. Error bars represent the standard error of the mean computed across subject averages.

$p = 0.81$; Sg/Ungram mean = 701.74 ms; Pl/Ungram mean = 694.74].

3. Discussion

The results of our study clearly show that agreement attraction errors can be elicited in the comprehension of written MSA. The results from the critical verb region in this study show that reading times are universally increased in the presence of a grammatically incorrect verb, but that the magnitude of this increase in reading time is modulated by the kinds of non-subject (and therefore, structurally inaccessible for subject–verb agreement) NPs appearing in the preceding context. Specifically, when one of these preceding nouns has features which match the erroneous verb along the dimension the subject does *not* match, then a smaller increase in reading time is observed relative to cases in which no nouns in the preceding context overlap in features with the verb. Alternatively, one can view this effect as a facilitation relative to ungrammatical sentences where the attractor does *not* match the erroneously plural verb. However, it is viewed, this effect is one of the hallmarks of agreement attraction errors.

Another distinguishing feature of agreement attraction phenomena which our data reveal in MSA is the general *absence* of an analogous effect in grammatical utterances. That is, when the verb and subject agree completely in grammatical features, there is no corresponding marginal increase in reading times when a distractor NP bears distinct grammatical features—a plural NP distractor has no effect in the context of a singular subject and verb. We do observe what could be effects of this kind at the first spillover region to a small degree. However, it is worth stepping back to consider the fact that in our study, in general, effects spill over less than they do in languages such as English. We do not have an explanation for this, but note that the agreement attraction effect does not spill over in either the full items analysis or the feminine items analysis for *ungrammatical* utterances. Moreover, the magnitude is suspect: one can assess the magnitude of an attraction effect by subtracting the reading time for plural conditions from the reading time to singular conditions (see §4, below)—what Dillon et al. (2013) call the *Intrusion Effect Size*. For ungrammatical utterances, this will be a positive number (erroneous facilitation to ungrammatical verbs), whereas for grammatical utterances, this would be a negative number (erroneous inhibition to grammatical verbs). At the critical verb region, our observed intrusion effect size is 57.35 ms, whereas in the first spillover region, the observed grammatical intrusion effect is −14.47 ms. We therefore think it safe to conclude that the transient effect in the first spillover region for feminines is not a *bona fide* attraction effect in grammatical utterances. If this logic is correct, Arabic self-paced reading responses to agreement attraction configurations mirror those observed for English in Tanner et al. (2014) and Wagers et al. (2009), but not (Pearlmutter et al., 1999).

Furthermore, our results add another piece to the growing body of evidence that there is something special about the processing of plural NPs in context (Wagers et al., 2009; Tanner et al., 2014). In our data, feminine plural NPs display longer reading times than their singular counterparts in the attractor region, a finding not shared by masculine NPs (see the attractor region in **Figure 2**). Two explanations have been advanced for this finding in the literature: (1) that it is the result of a "plural complexity effect" insofar as it is simply more difficult to process plurals than it is to process singulars, *ceteris paribus* (Wagers et al., 2009) and (2) that it is due to a "plural integration effect" insofar as it is difficult to integrate a semantically plural NP into a context which

features other singular nouns (Tanner et al., 2014, with support from findings in Nicol et al., 1997). Our findings from MSA help to shed some light on this debate. While it is possible to imagine a more nuanced version of the integration story, it is not obvious how to square the simple version of that account with the observation that semantically plural masculine/broken plural NPs do not display the reading time increase shown for feminines—both masculine and feminine plural attractors are semantically plural. If the integration explanation were correct, we might expect integration costs in both cases. While we will not attempt to resolve this fully here, we note that either one must elaborate the complexity story to include consideration of morphological plural formation strategies or return to the complexity suggestions of Wagers et al. (2009). Specifically, if one were to assume that complexity effects were correlated with the salience of plural marking on a noun (see §4, below, for some development of this idea), then we could take complexity to be about integrating plural marking with nominals stems. Alternatively, one could eschew this assumption about the salience of marking and take our data to support neither hypothesis, though we will not develop this idea here[8].

More broadly speaking, the differences between attractor genders/plural types in both the attractor and main clause verb regions are a significant diversion from both our prediction for Arabic and the established facts for English—masculine/broken/ablauting plurals behave distinctly from feminine/sound/suffixing plurals in our data. However, one must be careful in stating *how* this difference manifests. It would be tempting to conclude that attraction occurs with feminine/sound attractors but does not occur with masculine/broken items. This conclusion, while certainly possible, must be made cautiously, as we do not have sufficient evidence in this paper to reject the idea that attraction occurs in both genders/plural types (to wit, the lack of a three-way interaction in the main clause verb region). However, at the very least one could conclude that if attraction is present in the masculine/broken/ablauting items, the effect is much smaller than it is with feminines/sound/suffixing items (**Figure 5**). Again here, the intrusion effect size is instructive: with feminines, the mean agreement intrusion effect is 68.72 ms, whereas for masculines it is 45.00, computed across subject means. While we must be agnostic as to which, one of two things is true in our data: (i) masculine/broken/ablauting items do not display attraction or (ii) they do, but to a smaller degree than feminine/sound/suffixing items.

Even more broadly, we believe our results confirm a growing body of evidence in the literature about the location of agreement attraction effects in the distribution of reaction times to ungrammatical verbs (Staub, 2009, 2010; Lago et al., 2014). That is, previous work by Staub as well as Lago and colleagues has shown that the canonical pattern of agreement attraction in comprehension—facilitation to ungrammatical verbs in the presence of a matching distractor relative to ungrammatical verbs without a matching distractor—is present most strongly in the right tail of reaction time distributions to ungrammatical verbs. This appeared confirmed in our data by the change in the strength of the three-way interaction between Attractor Number, Grammaticality, and Gender as a function of our Winsorization cutoff. This can be seen for three values of Winsorization cutoffs in **Figures 3**, **4**. In both plots, decreasing the amount of data replaced by Winsorization does not change the qualitative pattern of results anywhere except in the shaded region, the critical verb. For the feminine items (**Figure 3**), decreasing the amount of removed data increases the separation between the Sg/Ungram condition and the remaining three conditions. For the masculine items (**Figure 4**), changing the cutoff affects both the Sg/Ungram and Pl/Ungram conditions, moving the two closer together. With no cutoff, the two conditions are identical, i.e., there is no attraction present. We take this to be further evidence that the right tail of reaction time distributions is vitally important for the study of violation responses, such as those seen with agreement attraction[9].

While we believe there is clearly a difference between feminine/suffixing and masculine/ablauting attractor items in our data, in this study this pluralization strategy-based difference is necessarily conflated with gender, both on the attractor NP and the verb itself. This is because of the way our stimuli were designed: all the suffixing plurals in our study were feminine nouns and all the ablauting plurals were masculine nouns. This is because of the grammar of MSA, which affords very few broken/ablauting feminine plurals which refer to animates. Moreover, grammatical case is necessarily orthographically present on masculine sound/suffixing plurals but not feminine sound plurals, making direct comparison somewhat confounded if those NPs were included.

Nevertheless, we find it plausible to tentatively assume that the differential agreement attraction effect across gender/plural type items is brought about by the different pluralization strategies and not by grammatical gender marking on the verb because of the absence of plural-based reading time trend on the attractor NPs for ablauting plurals. While it is conceivable that this lack of an effect is driven by their masculine gender, such an explanation cannot relate the *presence* of the slowdown in feminine/suffixing plurals to similar effects noted for English by Wagers et al. (2009). On the other hand, assuming the strength of the agreement attraction effect is driven by plural type allows for this cross-linguistically and theoretically coherent link as well as a unified explanation of the absence of the NP plural complexity and attraction effects.

[8]An intriguing possibility, raised by a reviewer, is that the lower accuracy rates to comprehension questions in the Pl/Gram condition could be a grammatical agreement attraction effect. We cannot rule this explanation out, but note two things: first, our comprehension questions were constructed to avoid use of lexical items which underwent an experimental manipulation (such as the attractor NP and main clause verb). Therefore, such an effect would have to be driven by the main clause subject, which was invariantly singular. Second, however, not *all* of our comprehension questions asked about this subject, making it difficult to assess this hypothesis in our current data, but the idea is viable for future research.

[9]Another possibility, raised by a reviewer, is that item order matters. Concretely, the idea would be that subjects are susceptible to grammatical effects early in the experiment, with these effects diminishing over time (as the participant begins to realize what is happening in the manipulations). We agree this is a possibility in our data, but have included item order as a predictor precisely so that our experimental effects can be trusted with item order held in abeyance. We hope to return to the issue of item order more concretely in future work.

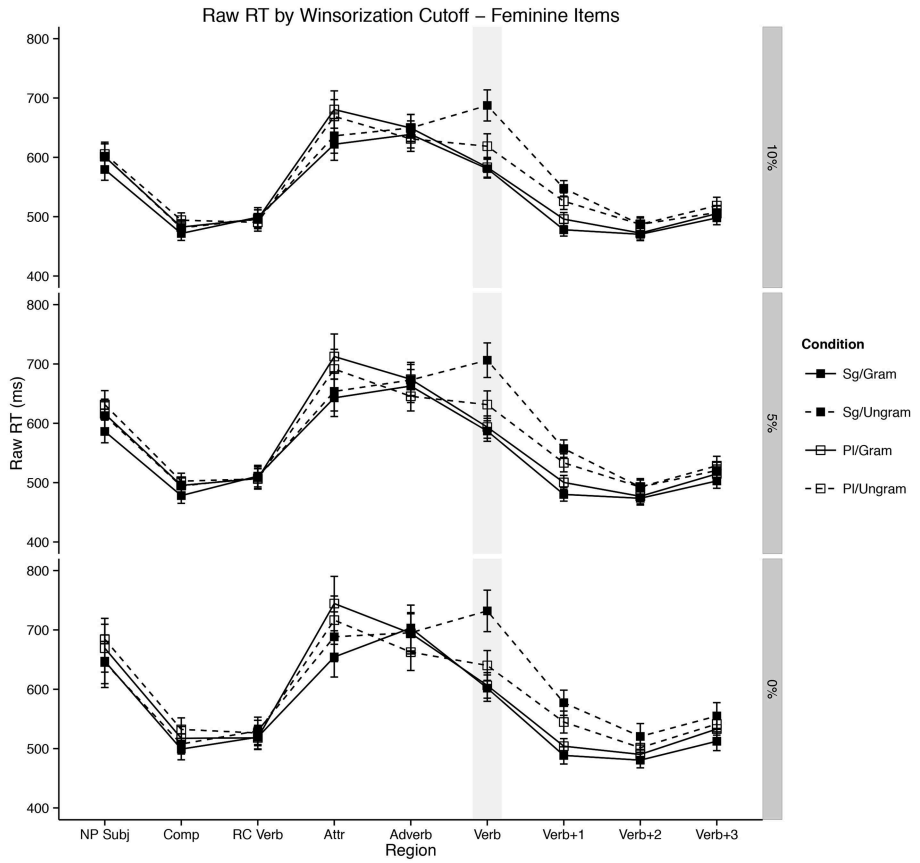

FIGURE 3 | Self-paced reading results. Region by region means of feminine items segregated by attractor number and verb number for three Winsorization cutoff thresholds. Error bars represent the standard error of the mean computed across subject averages.

One might reasonably wonder, at this point, what role, if any, frequency plays in explaining the observed patterns in MSA. In order to address this question, we calculated the token frequency of each attractor NP in the singular and plural form in the *Al-Hayat 1996* sub-corpus of the BYU arabiCorpus (Parkinson, 2012) and entered the plural log frequency values into our mixed effects models. In neither the attractor (R4) nor critical verb (R6) region were these terms significant in the model. However, it is worth noting that both singular [masculine mean $= 1.11$; feminine mean $= -0.18$; $t_{(39.97)} = 6.38$; $p < 0.0001$] and plural [masculine mean $= 0.70$; feminine mean $= -1.14$; $t_{(39.58)} = 9.27$; $p < 0.0001$] nouns did have significantly different log-frequencies for masculine and feminine nouns. A complete table of the frequencies for the attractor nouns in our experimental items appears in the Supplementary Materials.

The question still remains, however, as to what the explanation of this difference between the suffixing and ablauting plurals might be. Here we entertain two possibilities: (1) that the processing system does not have sufficient time for attraction effects to emerge because the system is at floor in the ungrammatical conditions and (2) there is something morphologically distinct about broken/ablauting plurals such that attraction cannot occur because the representation of number with these plurals is fundamentally different.

The first solution is plausible because broken/ablauting plurals in MSA are, on the whole, orthographically shorter than sound/suffixing plurals—usually between one and two characters shorter. Moreover, there is a clear, reliable difference between broken/ablauting and sound/suffixing plurals evident in our data set such that the latter are read around 70 ms slower than the former (see R4 **Figure 2**). The explanation in this approach would be that this shorter reading time is small enough that appreciable agreement attraction effects are not observable in such a short time frame—the system is simply under too much time pressure to reveal these effects and is at the *a priori* floor.

However, we do not believe this to be the correct approach for several reasons. Firstly, the directionality of this change in broken/ablauting plural reading times is in the wrong direction. Attraction in our data is revealed by the difference between plural-attractor plural-verb (Pl/Ungram) and singular-attractor plural-verb (Sg/Ungram) conditions—in both cases the plural verb is ungrammatical but only in the former case does a partially matching attractor lead to decreased reading times. However, broken/ablauting plurals clearly involve *faster* reading times across the board, meaning that the Pl/Ungram condition is

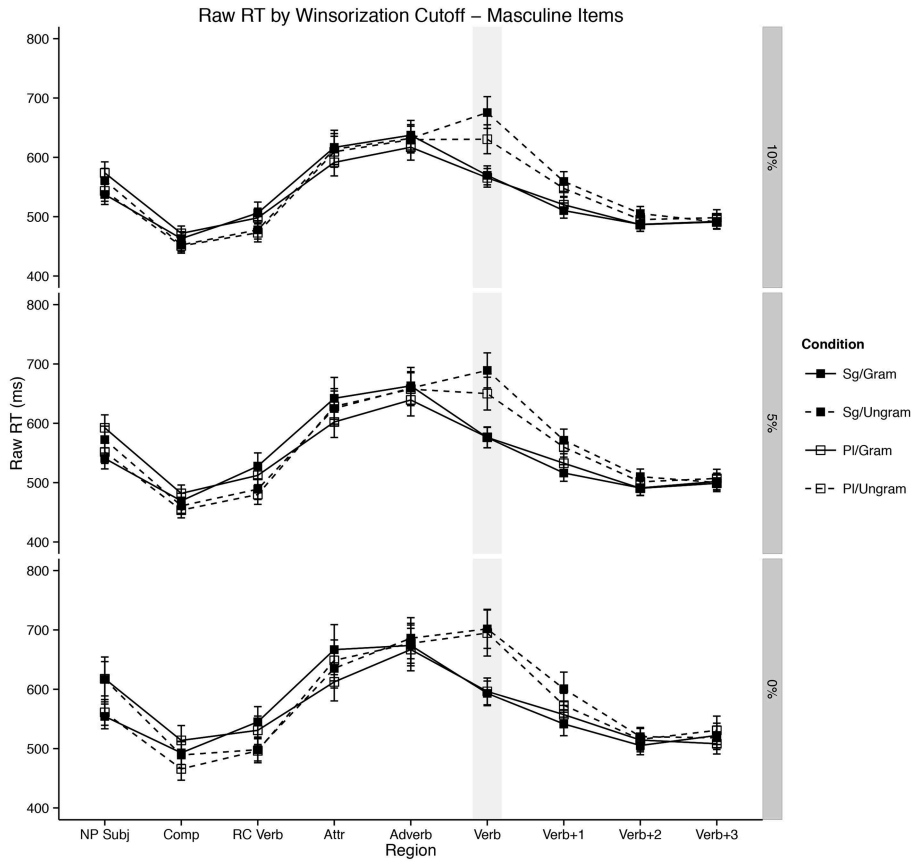

FIGURE 4 | Self-paced reading results. Region by region means of masculine items segregated by attractor number and verb number for three Winsorization cutoff thresholds. Error bars represent the standard error of the mean computed across subject averages.

undergoing an additional reading time decrease when the plural involved is broken/ablauting as opposed to when it is singular—this should increase the magnitude of the attraction effect, not decrease it. Furthermore, in our item set, the difference between mean length of plural and singular items was 1.06 characters for the feminine attractors and 0.72 characters for the masculine attractors, making it hard to specify what role a difference in mean length of 0.3 characters could be playing in a way which accounts for such a large difference between conditions.

Thus, it is reasonable to conclude that nouns with plurals formed by morphologically discontinuous CV-templates *may* drive less agreement attraction, a novel finding in sentence-level reading studies, as far as we know. The split between ablauting and suffixing lends support to the notion that *morphological marking of number* is necessary for agreement attraction to occur in Arabic. The reason for this is that—despite their decreased attraction—broken/ablauting plurals *are* still plurals semantically. Nevertheless, this semantic plurality does not contribute as much as morphological form in driving attraction rates at the critical verb region.

Two things are clear from this limited data set: (1) agreement attraction does occur with attractors in Arabic relative clauses despite the relatively inhospitable grammatical environment relative to non-clausal modifiers such as PPs (Bock and Miller, 1991) and (2) that this effect is modulated by the plural type of the attractor[10]. An immediate follow-up experiment present itself for which preparations are underway: a direct manipulate the gender of the attractor independent of number in order to confirm the argumentation that gender is not the relevant effect in this data.

4. Computational Modeling

Since we take the procedural implementation of agreement dependency resolution to be universal, the important question thus becomes what drives language-specific differences in error profiles and what impact, if any, our findings have on theoretical explanations of agreement attraction. Here we discuss whether or not working-memory models of attraction provide a mechanism for explaining the contrast between broken/ablauting and sound/suffixing plurals seen in our data. The question is one of representation: do explicit models of agreement attraction as

[10]One issue which we have not addressed here is the possibility raised by Gillespie and Pearlmutter (2013) that the inhospitability of relative clauses for attraction is due to lack of consideration for the semantic weight of the relative clause verb and not, say, structural or length differences between relative clauses and PPs. This interpretation is possible for our results and we hope to return to it in future work.

working memory retrieval errors provide a representational way to model the distinction between ablauting and suffixing plurals?

We answer this question by way of computational modeling in the ACT-R system of language comprehension presented by Lewis and Vasishth (2005). Given that well-specified computational models of the sentence processor exist, computational modeling can allow us to evaluate different representational commitments against the results of a system known to accurately model many aspects of working memory and sentence processing. We use ACT-R in particular because of its recent popularity in the sentence processing literature (see Lewis and Vasishth, 2005; Lewis et al., 2006; Dillon et al., 2013) and its requirement that modelers be explicit about representational commitments made for constituents in memory.

One key feature of these models that we believe is implicated by our data is the notion of activation as a zero-sum game across specified retrieval cues. In the ACT-R system, the strength of a particular retrieval cue is proportional to the logarithm of the number of items associated with that cue (Lewis and Vasishth, 2005, p. 381). Given this relationship, one can reduce the strength of, e.g., the number cue for a particular chunk, by removing that chunk's specification for the number cue. This in turn increases the strength of that cue for other chunks in memory which remain specified for number. The result is a reduction in the error rates and retrieval latency intrusion effect size.

In our data, one might therefore consider modeling the ablauting plural attractors with *underspecification*. Underspecification is an approach to the organization of the lexicon wherein certain grammatical features are not present at the lexical level of representation[11]. This approach would therefore remove number from the ablauting attractors and therefore increase the strength of this cue for the true subject. This is a common strategy in the ACT-R language literature for modeling disappearing and reappearing intrusion effects—see (Dillon et al., 2013) for discussion and references in the context of the difference between agreement and reflexive anaphora.

In order to test this idea with Arabic nouns, we need to make some preliminary assumptions. The first of these is that the traditional approach to Arabic grammar which organizes the lexicon in terms of consonantal roots which associate with prosodic templates (see McCarthy, 1981 for the generative approach)[12]. Furthermore, we assume that the prosodic template, despite being morphophonologically abstract, can bear grammatical information for the system—in the case of Arabic nouns, the key feature will be that the template can bear the functional load of number. Finally, we assume that the parser gives access to some form of root/template decomposition during reading, though we will remain agnostic as to the exact mechanism by which this happens.

With this background in mind, we can now ask whether underspecification of grammatical number on the template is an appropriate way to model our data from our ablauting items. Here we consider three distinct models which differ only on their representation of grammatical number as a cue to retrieval:

(9) a. A **fully-specified** model wherein number is a bivalent cue which can take two values: singular and plural

b. A **underspecified NP** model in which nouns appearing in broken plural templates have no specification for number.

c. A **fully-underspecified** model in which number is a fully privative cue that has only one value: plural

The fully-specified model (9a) is meant as a control, a model which accounts for the suffixing data in Arabic and against which we can compare two possible models of ablauting templates. The two models in (9b–c) are two different ways of modeling underspecification in ACT-R, and the viability of either model is the modeling result of interest.

In both the underspecified models (9b–c), underspecification is represented by the absence of a number cue on one or more constituents in memory. In the Underspecified NP model (9b), only NPs which are part of the broken/ablauting plural system lack a number cue; in the Fully Underspecified model (9c), singular verbs *also* lack a number cue. The model in (9c) therefore corresponds to a fully privative number cue system. In either of the underspecified models, representation of a sound/suffixing plural noun simply requires specifying that NP as plural.

To evaluate these models, we ran 10,000 Monte Carlo simulations in ACT-R of each of the four conditions in our experiment with each of the three models (using code first written for Badecker and Kuminiak, 2007; Badecker and Lewis, 2007). ACT-R has several free parameters which must be specified, such as the amount of activation noise present in the system. Instead of computing results across different parameter sets, these parameters were set to the most common values found in the Wong et al. (2010) Online Database of ACT-R Estimated Parameters. While this approach does not provide an argument for the robustness of our results across different parameter values, it does provide for model results using the most neutral parameter specifications.

Our interest in the ACT-R model is in the predictions it makes with respect to a retrieval event triggered at the critical verb which searches for the correct controller of agreement. The model itself provides two dependent measures of interest: (1) the rate of retrieval of each constituent chunk in memory and (2) the latency of retrieval predicted by the model. Both of these dependent measures depend on the schedule of retrievals inputted to the model, which for us included: (1) a retrieval which searches for a NP host for the relative clause at the complementizer, (2) a retrieval which searches for the subject of the embedded clause verb, and (3) a retrieval which searches for a subject of the main clause target verb. (3) is the critical retrieval for us, and all quantitative results we report concern this retrieval.

Figures 6, **7** show activation time-course plots for two of the conditions in our experiment, Pl/Gram and Pl/Ungram, in the Fully Specified model. Pl/Ungram is the attraction condition and Pl/Gram is a control insofar as it involves the same attractor/subject configuration but should yield no attraction. As can be seen in **Figure 6**, the retrieval triggered at the singular

[11]This idea dates back to Trubetskoy's (1958) conception of the lexicon, and the modern instantiation of this notion first appears in Halle (1959).

[12]However, since our data requires no commitment to the position of vowels in this model, we will assume they are part of the prosodic template itself, *contra* (McCarthy, 1981).

main clause verb involves no increased activation of the attractor, whereas when the verb is plural (**Figure 7**), the attractor receives a boost in activation which corresponds to the attraction effect. This is a correct result for agreement attraction insofar as the increased activation translates to a proportional increase in incorrect retrievals of the attractor.

Turning now to error rates, **Table 4** shows the percentage of retrievals in which the true subject or attractor is retrieved at the main clause verb across the three model types[13]. Crucially, **Table 4** shows a marked increase in error rates in the Pl/Ungram condition in the Fully Specified model; this is a predicted attraction effect. Notably, however, either of the underspecification models cause this attraction rate to fall off considerably, decreasing from 24.15 to 6.30% in the Underspecified NP model and from 24.15 to 5.88% for the fully underspecified model. Moreover, in both the underspecified models the error rate is flat across all four experimental conditions. This is a prediction of no or very little attraction effect in for broken/ablauting plurals in these models.

Moving to predictions more analogous to our results, the ACT-R model also furnishes latencies to retrieval of any chunk, and these latencies can be used to predict the size of the agreement attraction or intrusion effect, exactly as is shown in **Figure 5** for our data. **Figure 8** shows the predictions of the ACT-R model across the three model types in (9). Starting with the Fully Specified Model, **Figure 8** shows that the system predicts a large intrusion effect for ungrammatical utterances, exactly as we observe in our data. Turning to the two underspecification models, we observe a flattening of this effect across grammaticality. Both the Underspecified NP and Fully Underspecified models predict no obvious difference between grammatical and ungrammatical conditions.

How one views the success of these modeling results depends on one's interpretation of the empirical results in our study. If one assumes that the masculine/broken/ablauting plural attractors cause a *smaller* attraction effect than the feminine/sound/suffixing attractors, then these modeling results point to a weakness in the representational commitments or architecture of the computational model. Specifically, the dependency between number of items associated with a cue and cue strength means that the reduction in cue strength given by underspecification is all-or-nothing. What is required here is another mechanism for allowing cue strength to modulate in a continuous way—one possibility couched entirely in the memory architecture is to assume that the number cues present on broken/ablauting plurals are somehow different from the number cues present on sound/suffixing plurals in a way which leads the number cues on masculine items to be confusable (Jäger et al.,

[13]Note that these rates do not sum to 100 because the two NPs are not the only constituents in memory, and some small percentage of the time the system retrieves a nonsensical constituent such as a VP or CP. We ignore those results here.

TABLE 4 | ACT-R Retrieval rates for the target/attractor NPs in 10,000 model runs.

	Condition			
Model Type	**Sg/Gram**	**Sg/Ungram**	**Pl/Gram**	**Pl/Ungram**
Fully Specified	90.82/6.15%	90.90/6.29%	94.95/1.63%	74.07/24.15%
Underspecified NP	95.09/1.64%	91.07/6.53%	94.65/2.00%	90.85/6.30%
Fully Underspecified	93.90/4.63%	91.99/5.60%	93.50/4.98%	91.89/5.88%

A fully specified model takes plurality to be a bivalent cue with possible values [SG] and [PL]; a NP underspecified model considers only ablauting plurals as underspecified for number; a fully underspecified model considers all non-plural constituents underspecified for number.

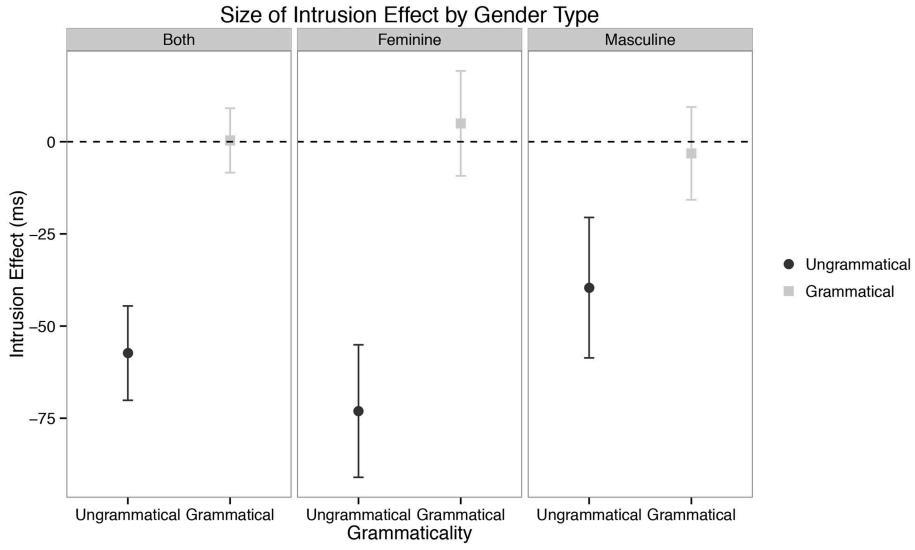

FIGURE 5 | Actual sizes of intrusion effects across different grammaticalities and gender/plural types in the self-paced reading data. Intrusion effects are computed by subtracting retrieval times in plural attractor conditions from times in singular attractor conditions. Error bars represent the standard error of the mean computed across subject averages.

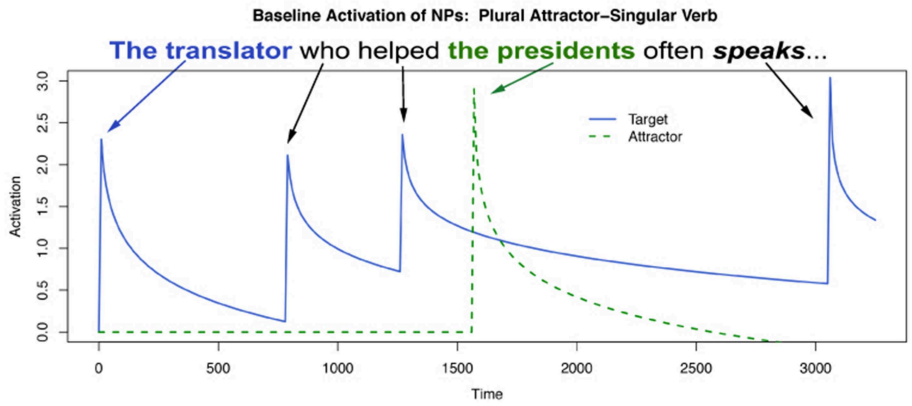

FIGURE 6 | Model activation values over time for an ACT-R model of grammatical attraction conditions.

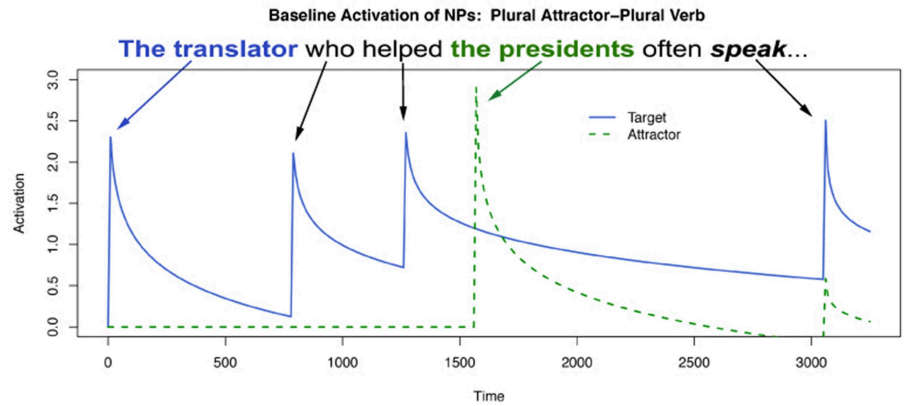

FIGURE 7 | Model activation values over time for an ACT-R model of ungrammatical attraction conditions.

2014) with the number cue present on the main clause verb. In a system where matching is not all-or-nothing, a confusable number cue on the masculine items would lead to lower, but not completely absent, rates of attraction. We do not implement this here because of the relative novelty of the confusability proposal as well as the focus of this paper, but note that it is an intriguing possibility.

On the other hand, if one views our results as showing that masculine/broken/ablauting attractors lead to a complete *absence* of attraction effects, then our modeling exercise here can be taken to show the limited utility of underspecification in the retrieval system (but not the grammar, or the mapping between features and cues; see below) Specifically, our results would show that the model matches the data reasonably well if one assumes that underspecification is the operative difference between ablauting and suffixing plurals insofar as the former are underspecified for number. However, it is important to step back and ask why this is: it is not surprising that a model taught to ignore number (via the absence of number cues on masculines) would yield results that are invariant for plurality. The question should be whether such a state of affairs is congruent with theories of grammar or the mapping between representations used in grammar and representations used in processing[14]. This, however, is a significant shift in perspective: it requires examining the consequences of assuming that number features are not fully specified on ablauting plurals. However, this is not a innocuous assumption as it requires complicating the relationship between grammatical features and retrieval cues; we return to it in the general discussion.

5. General Discussion

5.1. Universal Procedural Components

The results of our study suggest that agreement comprehension errors occur in Arabic similar in broad strokes to the way they occur in Slavic, Romance, and Germanic languages. Specifically, our results show that plural attractors in subject relative clauses can spuriously attract agreement in such a way that an erroneously plural verb can be read as grammatical some percentage of the time. This is an especially striking result given

[14]We thank an anonymous reviewer for forcing us to be clearer about this point.

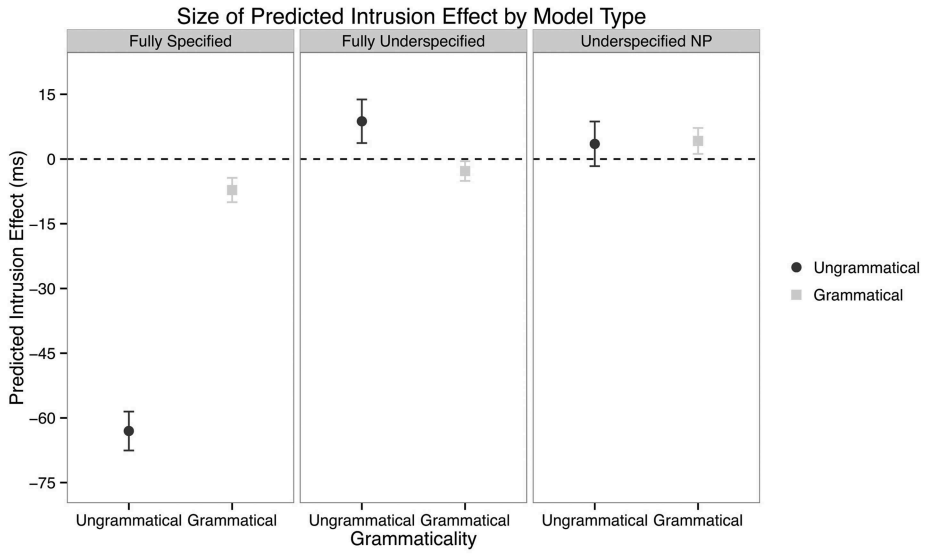

FIGURE 8 | Predicted sizes of intrusion effects for three different ACT-R models. Intrusion effects are computed by subtracting retrieval times in plural attractor conditions from times in singular attractor conditions. Error bars represent the standard error of the mean of 10,000 Monte Carlo trials. A normal model takes number cues to be bivalent, an underspecified NP model takes number to be privative on the broken plural template NPs only, and a fully underspecified model takes number to be privative on all constituents.

two properties of our stimuli which mitigate against high attraction rates: 1) the use of a distractor in a relative clause and 2) the agreeing status of the complementizer in MSA. While other studies such as Dillon et al. (2013) have demonstrated that relative clauses can still contribute to attraction at a possibly lower rate, combining the presence of these relative clauses with the disambiguating cues provided by the complementizer yields an environment where one could imagine that error rates are driven to floor or precluded altogether; nevertheless, this is not what happens in MSA.

The first property has historically been shown to drive down error rates, starting with the original study by Bock and Miller (1991) (see also Bock and Cutting, 1992). In their Experiment 2 using single-clause stimuli where the attractor was contained inside a modifying prepositional phrase, the error rate was 2.39% vs. an error rate of 1.80% for Experiment 3 using bi-clausal stimuli with the attractor inside the embedded relative clause. Note, additionally, that error rates are low across the board due to the sentence-completion task employed in that study, a task which usually results in very low error rates. There are numerous ways to model such a near-halving of the error rates, but a common approach is to assume that subject-hood or clause-mate status is relevant for cue-based retrieval—when this feature is shared by the true subject and critical verb, activation of the correct NP is boosted at the cost of the activation of the attractor NP.

This activation benefit of the true subject conferred by the clause-mate is augmented by the fact that complementizers in MSA necessarily agree in grammatical number and gender with definite NPs to which they are attached or with which the gap in the relative clause is co-construed (Ryding, 2005, pp. 322–323). If one assumes that constituent activation levels are augmented when a relative clause is attached to a head noun, then this must occur at the complementizer position in MSA. Moreover, this retrieval event necessarily includes a number (and gender) cue, unlike the equivalent retrieval event in languages without an inflecting complementizer, such as English. Thus, by the time the critical verb is encountered, more temporal decay of activation of the true subject should have occurred in English than in Arabic. This, in turn, should imply smaller error rates in Arabic than in English, since the number and gender cues on the complementizer reinforce the activation of the proper subject NP. Even in model-neutral terms, something like this is expected, since the bare fact is that the complementizer provides the speaker with additional cues to the proper subject in Arabic, but not in English.

Nevertheless, these potentially mitigating factors did not result in a complete absence of agreement attraction errors in Arabic. In both perfect and imperfect aspect, each with distinct verbal agreement affixes, attraction by the plural attractors is clearly evident in the decreased reaction time in the ungrammatical sentences with plural attractors which match the verb relative to cases where the attractor does not match the verb. Such a result is consistent with the working-memory model of agreement attraction which views the procedural underpinning of these errors as a universal part of the language comprehension system. In this model, decreased reaction times in ungrammatical sentences with matching attractors are driven by partial cue overlap between the attractor and the erroneous verb—a result which is driven by the fundamental architecture of the memory system.

5.2. Representing Plurality

However, one marked difference between our data and those reported for other languages is the role of the morpheme which carries plural marking. Our results indicate a difference between plurals formed by suffixation and those formed by ablaut in

the size or presence of the attraction effect. This is a novel observation in the agreement attraction literature for any language, as far as we are aware. In §4 we noted that the representational implications of this result for the retrieval system depend in part on the assessment of its nature: if the difference is just one of quantity, then complications could be made to the way that plurality is represented solely in the memory system (*cf.* the discussion of cue confusability). If, on the other hand, one takes the difference to be qualitative, then complications need to be in the feature-cue mapping algorithm. It is that complication which we explore in this section.

In the case where the difference between feminine/sound/suffixing and masculine/broken/ablauting plural attractors is taken to be large, then one needs to articulate the way in which grammatical features map onto retrieval cues. Recall that underspecifying a broken plural for a plural feature results in a model which matches data in which no attraction occurs in broken plural items reasonably well. However, the question would then be how to articulate the relationship between grammatical plurality and the absence of an effect of plurality in the retrieval system. One simplistic option would be to claim that semantic plurality does not not contribute to retrieval interference for plural cues expressed morphologically on the target verb. However, this simple idea is unlikely to be the entire story given the finding in the literature that semantic overlap contributes to retrieval interference elsewhere (for a close parallel to our data in English, see Bock and Eberhard, 1993; for an overview of semantic contributions to interference, see the overview and references in Van Dyke and Johns, 2012). A more nuanced view would take features from various components of formal grammar to contribute additively to cues in the retrieval system[15].

In an additive approach, one could imagine that semantic and morphological features combined underwrite what is ultimately expressed as a plural cue in on NP chunks in memory. One could then specify that the morphology of these broken plurals contributes less to the sum that ultimately makes up plural cue values for constituents in memory such that broken plurals appear to the memory system as less plural than the sound plurals. Our results would then speak to the nature of the weights of various featural components that underwrite such an additively composite cue such that semantic plurality alone is not sufficient to yield a plural cue that causes measurable agreement attraction. Underspecification can then be seen as coherent insofar as only the morphological component of an additive cue is underspecified. This allows for a way to understand our data in a theoretically meaningful way.

More generally and independently of any one interpretation of the models of feature-cue mapping involved, the results here suggest some important conclusions about morphological representation in general and Arabic templates in particular. Regardless of the model-theoretic interpretation of these results, one fact is clear: a discontinuous and/or abstract morphological constituent modulates error rates related to plural nouns in Arabic. This is important because it underscores the morphological contribution of discontinuous alterations in form in the language. Not only is this a point which is important for language-independent theorizing, but it is a point currently under contention in the Semitic-specific priming literature. The results of this study suggest that whatever the correct representational view of the CV-template is, it must minimally be allowed to augment plurality-driven effects in reading comprehension.

[15]We thank an anonymous reviewer for this intriguing suggestion.

6. Conclusion

We have demonstrated that agreement attraction errors exist in MSA in a configuration which is relatively inhospitable to the presence of such mistakes: subject relative clauses with an agreeing complementizer in a morphologically rich language. Furthermore, we showed that MSA, like English, has a plural complexity cost associated with reading suffixed plural NPs. However, we also showed that MSA differs from English in important ways concerning the nature of plural formation. Specifically, we showed that plurals formed by suffixation strongly attract agreement, whereas plurals formed by ablaut/internal vowel change do so at greatly reduced rates, if at all. Moreover, we have suggested that Arabic also provides evidence that agreement attraction effects are driven mostly by observations in the right tail of the reaction time distribution. Finally, we have provided model evidence which suggests that morphologically discontinuous plural forms in MSA require some elaboration of the way grammatical features are translated into processing cues for the memory retrieval system. Finally, we discussed how these results suggest a somewhat form-driven comprehension mechanism for agreement resolution, provided that such a model allows discontinuous form-based differences to modulate comprehension of agreement dependencies.

Acknowledgments

The authors wish to thank Eias Al-Daman, Souad Al-Helou, Meera Saeed Al-Kaabi, Esma Mansouri, and Samer Nehme for assistance with stimuli creation and Tommi Leung for help with participant recruitment. Thanks to Joseph King, Stephen Politzer-Ahles, Kevin Schluter, Shravan Vasishth, Matt Wagers, audiences at the 20th Architectures and Mechanisms for Language Processing (AMLaP) in Edinburgh, Scotland and the 2015 Annual Meeting of the Linguistic Society of America for comments on previous versions of this work. Additionally, thanks to two anonymous reviewers for comments which led to a considerable improvement in this paper. Finally, thanks to Rick Lewis for the creation of the code used for ACT-R modeling, Brian Dillon for sharing his modifications thereto, and Dave Kush for substantial help with debugging. None of these people are responsible for errors in this manuscript, the fault of which lies solely with the authors.

Agreement attraction errors (such as the number error in the example "The key to the cabinets are rusty") have been the object of many studies in the last 20 years. So far, almost all production experiments and all comprehension experiments looked at binary features (primarily at number in Germanic, Romance, and some other languages, in several cases at gender in Romance languages). Among other things, it was noted that both in production and in comprehension, attraction effects are much stronger for some feature combinations than for the others: they can be observed in the sentences with singular heads and plural dependent nouns (e.g.,"The key to the cabinets..."), but not in the sentences with plural heads and singular dependent nouns (e.g., "The keys to the cabinet..."). Almost all proposed explanations of this asymmetry appeal to feature markedness, but existing findings do not allow teasing different approaches to markedness apart. We report the results of four experiments (one on production and three on comprehension) studying subject-verb gender agreement in Russian, a language with three genders. Firstly, we found attraction effects both in production and in comprehension, but, unlike in the case of number agreement, they were not parallel (in production, feminine gender triggered strongest effects, while neuter triggered weakest effects, while in comprehension, masculine triggered weakest effects). Secondly, in the comprehension experiments attraction was observed for all dependent noun genders, but only for a subset of head noun genders. This goes against the traditional assumption that the features of the dependent noun are crucial for attraction, showing the features of the head are more important. We demonstrate that this approach can be extended to previous findings on attraction and that there exists other evidence for it. In total, these findings let us reconsider the question which properties of features are crucial for agreement attraction in production and in comprehension.

Keywords: agreement, gender, attraction, production, comprehension, Russian

1. INTRODUCTION

1.1. The Phenomenon of Agreement Attraction

Grammatical agreement is one of the most basic linguistic operations. It is well-known, however, that it is not always accurate. In the last 20 years many studies have looked at so-called agreement attraction errors, exemplified in (1). In (1a) the verb agrees not with the head of the subject NP *key*[1], but with another, embedded NP *cabinets* (we will further call such NPs "attractors"). In (1b) the verb in a relative clause agrees with the subject of the matrix clause.

(1) a. The key to the cabinets **were** rusty (Bock and Miller, 1991).

b. The musicians who the reviewer **praise** so highly will probably win a Grammy (Wagers et al., 2009).

Agreement attraction errors are observed in spontaneous speech and in well-edited texts. They have also been studied experimentally, mostly in English, but also in French, Spanish, Italian, Dutch, German, and some other languages (Bock and Miller, 1991; Vigliocco et al., 1995, 1996; Pearlmutter et al., 1999; Anton-Mendez et al., 2002; Hartsuiker et al., 2003, to name just a few). The first accounts suggested that the verb simply agrees with the linearly closest noun (Jespersen, 1924; Quirk et al., 1972; Francis, 1986, a.o.). However, later studies demonstrated that agreement attraction is a structural phenomenon. For example, Vigliocco and Nicol (1998) showed that people make attraction errors producing questions, e.g., "Are the helicopter for the flights safe?." Various factors that influence attraction have also been identified. However, the overwhelming majority of studies focused on number agreement in the languages where number has only two values: singular and plural. It is not clear to what extent these results can be generalized to other cases.

In this paper, we analyze subject-predicate gender agreement. Gender attraction has been investigated only in a few studies, and mostly in Romance languages, which have two genders. We report one production and three comprehension experiments on Russian, a language with three genders. To the best of our knowledge, this is the first comprehension study looking at agreement attraction in a non-binary category. Below we present several findings from the research on number agreement, which will be most important for our study, and different accounts of attraction. Next, we review the few existing studies on gender attraction, providing rationale for the present work.

1.1.1. Plural Markedness Effect

In all studied languages, attraction effects were found to be asymmetric. They can be observed when the head is singular, and the attractor is plural [as in (1) above], but are much weaker or virtually non-existent in the opposite configuration. In the majority of agreement attraction studies, this asymmetry is explained in terms of feature markedness. Plural is assumed to be the marked value of number feature[2], and the asymmetry is attributed to the fact that attractors with a marked feature are more disruptive. Hence it is known under the name of "plural markedness effect."

However, the concept of markedness is not widely agreed upon. Different authors adopt different theoretical approaches and different tests to determine marked and unmarked feature values [including frequency, presence of a non-zero affix, default use of a form (e.g., in impersonal sentences), various semantic tests etc.; see Haspelmath, 2006]. It is impossible to evaluate them looking only at singular and plural. To figure out which of these properties may be relevant for the asymmetry between feature values (and whether it makes sense to attribute it to markedness in a particular theoretical framework), it is crucial to look at other features systems. As we will show below, Russian gender is interesting in this respect because the results of different markedness tests do not converge, letting us tease several approaches apart.

1.1.2. Parallel Results in Production and Comprehension

Experimental studies demonstrated that attraction exists not only in production, but also in comprehension. In production it manifests itself as agreement errors. In comprehension attraction errors have been observed to trigger more grammaticality judgment mistakes and to provoke less pronounced effects in reading time and EEG studies than other agreement errors. In other words, people perceive ungrammatical sentences as if they were grammatical or had a minor violation. This is often called a "grammaticality illusion."

The results from production and comprehension are largely parallel (in particular, significant attraction effects are observed only with plural attractors). This is often used to conclude that the mechanism of attraction is the same in both modalities. We will come back to this problem discussing our findings because we did not observe parallelism that we expected based on the previous studies.

1.1.3. Debate on Ungrammaticality Illusions

We just mentioned that in comprehension, attraction causes grammaticality illusions, making ungrammatical sentences more acceptable. Can it also lead to ungrammaticality illusions, and make grammatical sentences less acceptable? For example, if people tend to miss agreement errors in sentences like (2a), do they sometimes see non-existent errors in sentences like (2b)? As we show below, different approaches to attraction make opposing predictions about ungrammaticality illusions, so this is an important question.

(2) a. The key to the cabinets were rusty.

b. The key to the cabinets was rusty.

Several studies (e.g., Nicol et al., 1997; Pearlmutter et al., 1999) suggested that ungrammaticality illusions do arise. However, Wagers et al. (2009) demonstrated that at least on-line findings may be artifactual (they might be due to the fact that processing

[1]Here and further, the following standard symbols are used: N, noun; NP, noun phrase; P, preposition; PP, prepositional phrase; V, verb; M, masculine gender; F, feminine; N, neuter.

[2]Notably, in semantics there is an ongoing debate whether singular or plural is the default (e.g., Sauerland et al., 2005; Farkas and de Swart, 2010).

plural nouns carries an additional cost compared to singular ones, not to any aspects of subject-verb agreement processing). This hypothesis can be tested by analyzing some cases where this problem does not apply, and we do so in the present study looking at gender agreement [3].

1.1.4. The Role of Morphophonology

Hartsuiker et al. (2003) showed that when the form of the attractor is morphologically ambiguous and coincides with nominative, the rate of attraction errors increases. They compared German sentences like (3a,3b). People made more errors in (3a), where the attractor (*die Demonstrationen*) is ambiguous between accusative and nominative, compared to (3b), where the attractor (*den Demonstrationen*) is unambiguously dative. We do not explore the role of morphophonology in the present study, but take this factor into account. Several studies also demonstrated that heads with regular inflections are more resistant to attraction, but no similar effects were observed for attractors (e.g., Bock and Eberhard, 1993; Vigliocco et al., 1995).

1.2. Models of Agreement Attraction

There exist two major approaches to agreement attraction. Here they will be referred to as the "representational account" and the "retrieval account." Models that belong to the **representational account** share one crucial assumption: agreement attraction takes place because the mental representation of the number feature on the subject NP is faulty or ambiguous (Nicol et al., 1997; Vigliocco and Nicol, 1998; Franck et al., 2002; Eberhard et al., 2005; Staub, 2009, 2010; Brehm and Bock, 2013). In some models, it is assumed that syntactic features can "percolate" or otherwise move to neighboring nodes: for example, sometimes number features from the embedded NP percolate to the subject NP (which normally has the same number marking as its head).

Another model known as Marking and Morphing (Eberhard et al., 2005) postulates that the number value of the subject NP is a continuum, i.e., it can be more or less plural. For example, if a subject NP contains a singular head and a plural dependent NP it is more plural than a subject NP with a singular modifier. A subject NP that is formally singular, but refers to a collective entity is more plural than the ones referring to singular entities. The more plural the subject NP, the higher the possibility of choosing a plural verb. In such accounts there is no way to avoid ungrammaticality illusions: if the agreement controller can be mis-construed or ambiguous, there is no way to restrict such mis-construals to only ungrammatical sentences. They happen even before we encounter the verb, i.e., even before it is clear whether the sentence is or is not grammatical.

Now let us turn to the **retrieval account** (Solomon and Pearlmutter, 2004; Lewis and Vasishth, 2005; Badecker and Kuminiak, 2007; Badecker and Lewis, 2007; Wagers et al., 2009; Dillon et al., 2013). Research on memory suggests that the amount of material a person can hold in a ready-to-process state is extremely limited (McElree, 2006; Cowan, 2001). Thus, it can be hypothesized that when we reach an agreeing predicate, the subject needs to be reactivated. This reactivation can be done via so-called cue-based retrieval (Lewis and Vasishth, 2005; McElree, 2006): we query the memory with a set of cues (e.g.,"number: plural," "case: nominative" etc.) and select an element that matches the maximum number of cues.

This process is not error-free, and the retrieval account argues that attraction arises at this stage. For example, in a sentence like "The key to the cabinets are rusty" the form of the verb suggests that we need to look for an NP with the features "subject" and "plural." However, no NP perfectly satisfies these conditions: *key* is the subject, but is not plural, and *cabinets* is plural, but is not the subject. It is hypothesized that in such conditions we may mistakenly select the wrong NP . The retrieval approach predicts the absence of ungrammaticality illusions: if a sentence is grammatical, the true subject is a *perfect* match and will always be selected. Thus, unlike in the representational account, there is nothing wrong or ambiguous in the syntactic structure, errors are access failures. Such cases with several elements competing for retrieval are an instance of "retrieval interference." Other examples are discussed in Van Dyke and Johns (2012).

1.3. Studies of Gender Agreement Attraction

Relatively few studies of gender agreement attraction have been conducted so far. Their results do not always converge, but one thing seems to be certain: attraction effects are present. They have been observed in several experiments on different languages.

1.3.1. Previous Studies on Languages with Two Genders

As far as we know, the first attempt to induce gender agreement attraction was made in the production study on Italian by Vigliocco et al. (1995). Virtually no evidence of attraction was found: out of 1920 responses only four (0.2%) contained a gender error. However, in a later study Vigliocco and Franck (1999) observed gender agreement attraction in Italian.

Vigliocco and Franck carried out four production experiments: two on Italian and two on French. Both languages have two genders: masculine and feminine. In all experiments, participants saw a masculine and a feminine adjective at the same time (one above the other) and then a noun phrase, and had to combine them saying the resulting sentence aloud. The gender of the head and the attractor were manipulated. When the genders

[3]In production, looking for symmetric effects in ungrammatical and grammatical sentences is less straightforward. However, several authors suggested not only counting errors, but also measuring RTs during elicitation tasks (e.g., Staub, 2009, 2010; Brehm and Bock, 2013). They demonstrated that participants slow down when the subject contains a singular head and a plural attractor both when they eventually answer correctly and when they do not [to be precise, Staub observed this for the subjects containing a PP attractor, but not for the subjects contained within relative clauses, as in (1b)].

mismatched, people were found to make more agreement errors. In Italian, there was no significant difference between FM and MF conditions[4]. In French, more errors were made in FM conditions (the difference was significant in Experiment 2 and marginally significant in Experiment 4). Whether the head gender was purely grammatical (on inanimate nouns) or conceptual (on animate nouns) also played a role. Participants made fewer errors in the latter case. Thus, semantic factors do enter the picture in case of gender agreement attraction, but, as far as we can judge, only to suppress it (on the contrary, conceptual numerosity can increase the number agreement attraction rate).

The observed pattern of attraction errors was different from number agreement studies. Firstly, a significant number of errors was made in all mismatch conditions, while in case of number agreement, the error rate in the conditions with plural heads and singular attractors was very low, often the same as the error rate without attraction. Secondly, both in French and in Italian, masculine is used as the grammatical default (for example, it appears in impersonal constructions and in the cases where the predicate must agree with several masculine and feminine nouns) and is more frequent. So the pattern observed in French (more errors in FM conditions) is the reverse of the number agreement attraction pattern found across languages.

The authors concluded that feature markedness does not matter for gender agreement and outlined an explanation based on inflectional differences between Italian and French. However, this explanation was undermined by Anton-Mendez et al. (2002) who conducted a production study on Spanish. Spanish is similar to Italian in terms of adjectival inflections, but the results were the same as in French. In addition to that, Vigliocco and Zilli (1999) and Franck et al. (2008) demonstrated in a number of experiments on Italian, Spanish, and French that the morphophonological properties of the head influence the error rate in gender agreement attraction. As in the studies of number agreement attraction, there were fewer errors when heads had regular inflections, but no similar effects were found for attractors.

We could find only two studies examining gender agreement attraction in comprehension: Acuña-Fariña et al. (2014) and Martin et al. (2014). Both looked at Spanish, eye-tracking was used in the first and ERPs in the second. Attraction effects were detected, but no differences between M and F genders were reported.

1.3.2. Previous Studies on Languages with Three Genders

Badecker and Kuminiak (2007) (henceforth, B&K) report results of three production experiments on Slovak. Slovak has three genders: masculine, feminine, and neuter. M is the most frequent, N is the least frequent, but is used in impersonal constructions. In all experiments, participants were given subject NPs (often called "preambles') and asked to generate complete sentences. In Experiment 1, B&K compared the number of errors in two groups of conditions: MM, MF, FF, FM and MM, MN, NN, NM. As in the previous studies, there were significantly more errors in mismatch conditions than in match conditions. But the pattern was different: there were more errors in the MF condition compared to the FM and in the NM compared to the MN.

Experiment 2 confirmed the results of Experiment 1 (it contained MM, MF, FF, and FM conditions and was designed to test the role of morphophonological factors). In Experiment 3, NN, NM, and NF conditions were compared. NM and NF preambles provoked more errors than NN preambles; but the number of errors in NM and NF conditions was comparable. Explaining this pattern, B&K adopt an optimality-theoretic approach and argue that there is no single markedness hierarchy in the Slovak gender system (such as N < M < F), but markedness is defined in pairs (N < M, N < F, M < F). Among other things, the results of this study show that frequency does not play a role for feature asymmetries.

Another production experiment was conducted on Russian (Lorimor et al., 2008). The authors manipulated both the number and the gender of heads and attractors (only M and F genders were used). In all trials, participants saw *and* heard the predicate and then saw the preamble. Their task was to construct a sentence using these two parts and to say it aloud. Out of 1155 answers where gender agreement was necessary (in Russian, as well as in Slovak, verbs agree in gender only in past tense singular forms), only seven (0.6%) contained an agreement error. Based on this, the authors concluded that gender agreement attraction does not exist in Russian.

To summarize, in all gender agreement attraction studies, if any effects are observed, error rates in all mismatch conditions are higher than in match conditions (unlike in number attraction studies, where significant effects are found only in one mismatch condition: with singular heads and plural attractors). Otherwise, the results of gender agreement studies are different: larger effects are found in the FM condition (compared to the MF condition) in Spanish and French, and in the MF and NM conditions (compared to the FM and MN conditions) in Slovak. The results from Slovak are closer to the pattern observed for number, if we assume that feminine and masculine genders and plural number are marked.

Out of several approaches to attraction outlined above, the existence of gender agreement attraction is hardly compatible with the Marking and Morphing model, primarily because in the absolute majority of cases, gender features are semantically empty. Moreover, even if we take nouns with conceptual gender, as *mal'čik* "boy$_M$" or *sestra* "sister$_F$" in Russian, it makes little sense to assume that, for example, having an M dependent NP could make an F noun "more masculine." Notably, we do not want to say that the existence of attraction with semantically empty features implies that conceptual numerosity cannot play any role for number agreement attraction - various experimental findings clearly indicate that it does (e.g., Bock and Cutting, 1992; Eberhard, 1999; Haskell and MacDonald, 2005; Mirkovic and MacDonald, 2013). We would only like to stress that attraction is possible without any semantic effects of this sort and therefore should result from some process that does not depend on them

[4]In combinations like MFM the first letter shows the gender of the head, the second letter - the gender of the attractor, the third letter (if present) the gender of the predicate.

(e.g., from the formal properties of features). Semantic effects can be added to the picture, but this is optional.

1.4. The Present Study

Apparently, gender agreement attraction errors are more difficult to induce than number errors. For example, Vigliocco et al. (1995) did not observe them in Italian, although they were found in subsequent experiments. So we decided to run another production experiment on Russian replicating B&K's first experiment on Slovak (which, in terms of its gender system, is very close to Russian). Our goal was to see whether any attraction errors would be induced, and, if yes, whether the pattern would be similar to B&K's study or to what has been observed for French, Spanish, or Italian. We also planned comprehension experiments because no existing studies had looked at comprehension in a language with three genders. We were particularly interested to find out whether production and comprehension results would be parallel and whether ungrammaticality illusions would be found. Before we move on to the experiments, let us present a brief overview of the Russian gender system.

1.4.1. Russian Gender System

Russian nouns are inflected for number and case, and the ones that have the same endings in the majority of forms are grouped into declension classes. Russian has three declension classes for nouns (and a separate class for substantivized adjectives). The first class includes almost all M nouns (they have zero endings in nominative singular, like *mal'čik* "boy") and all N nouns (they have *-o* or *-e* endings, like *okno* "window"). These M and N nouns use the same set of endings in all cases except for genitive plural and nominative and accusative in singular and plural (in plural, all declension classes have the same endings in dative, instrumental and locative). The second class includes the majority of F nouns (they end in *-a* or *-ja*, like *devočka* "girl") and a small group of animate M nouns with the same endings, like *mužčina* "man." The third class includes F nouns with zero endings in nominative singular, like *doč'* "daughter." In addition to that, there are some irregular and uninflected nouns.

Thus, in most cases, it is impossible to determine the gender of the noun unambiguously looking at the noun itself, and, at least prima facie, we cannot speak of something like morphological markedness in the noun system. Let us add that M nouns are the most frequent and N nouns are the least frequent. M nouns constitute about a half of the lexicon, F nouns - about 30–35%, N nouns are the rest (Yanovich and Fedorova, 2006; Slioussar and Samoilova, 2014).

Gender agreement can be observed only in singular, on adjectives, participles and past tense verb forms. Russian adjectives and participles have so-called full forms (used attributively and predicatively) and short forms (used only in predicates and inflected for number and gender, but not for case). M form is the citation form (i.e., the form would appear in dictionaries, grammatical descriptions etc.).

Verb forms and short forms of adjectives and participles have zero endings in M gender (e.g., *byl* "was$_M$" - *byla* "was$_F$" - *bylo* "was$_N$"), otherwise all forms have non-zero endings (e.g., *krasivyj* "beautiful$_{M.NOM.SG}$" - *krasivaja* "beautiful$_{F.NOM.SG}$" - *krasivoe* "beautiful$_{N.NOM.SG}$"). Thus, we cannot say that M forms are morphologically unmarked, even if we limit ourselves to predicates. In impersonal sentences, where unmarked forms are expected, N predicates are used, as (4) shows.

(4) Svetalo.
dawn$_{PST.N.SG}$
It dawned.

As for gender conflict resolution, another classical test for markedness, it is of limited use in Russian because there is no gender agreement in plural. Gender conflict resolution can be observed only in constructions like "X and Y each did something." We conducted an informal questionnaire, asking about 30 native speakers.

As we discuss below, acceptability of such sentences differs depending on animacy of the nouns and the genders that are combined, and there is substantial individual variation among speakers. However, one crucial generalization can be made: examples with the feminine or neuter forms of *každyj* "each' are never found even marginally acceptable, only some examples with the masculine forms are.

Firstly, let us consider sentences with M and F nouns, like in (5). Not all speakers of Russian find these examples acceptable, but for those who do, this construction sounds better with human animates (5a) than with non-human animates (5b). Nobody accepts this construction with inanimate nouns, as in 6a), although they can be used in such sentences if both nouns are of the same gender, as in (6b)[5].

(5) a. Mužčina i ženščina každyj
man$_{M.NOM.SG}$ and woman$_{F.NOM.SG}$ each$_{M.NOM.SG}$
sjeli po jabloku
ate$_{PST.PL}$ PREP$_{DISTR}$ apple$_{DAT.SG}$

b. Jož i svin'ja
hedgehog$_{M.NOM.SG}$ and swine$_{F.NOM.SG}$
každyj sjeli po jabloku.
each$_{M.NOM.SG}$ ate$_{PST.PL}$ PREP$_{DISTR}$ apple$_{DAT.SG}$

(6) a. Divan i krovat' každyj
sofa$_{M.NOM.SG}$ and bed$_{F.NOM.SG}$ each$_{M.NOM.SG}$
stoili celoe sostojanie.
cost$_{PST.PL}$ whole$_{ACC.SG}$ fortune$_{ACC.SG}$

b. Kušetka i krovat' každaja
couch$_{F.NOM.SG}$ and bed$_{F.NOM.SG}$ each$_{F.NOM.SG}$
stoili celoe sostojanie.
cost$_{PST.PL}$ whole$_{ACC.SG}$ fortune$_{ACC.SG}$

Now let us look at M and N nouns. More than half of the speakers we asked rejected this construction even with animate human nouns (7a) as ungrammatical, but those who accepted it used masculine form. All our informants rejected examples with non-human animates like (7b) or

[5]Since acceptability ratings for some sentences vary from speaker to speaker, we do not mark any of the examples below with asterisks or question marks used to indicate ungrammaticality or marginal acceptability.

found them only marginally acceptable. This might be at least partly due to independent factors (the relevant neuter words, like *mlekopitajuščee* "mammal," *životnoe* "animal," *nasekomoe* "insect," tend to be abstract), but is still telling.

(7) a. Voin i dit'a každyj
warrior$_{M.NOM.SG}$ and child$_{N.NOM.SG}$ each$_{M.NOM.SG}$
sjeli po jabloku.
ate$_{PST.PL}$ PREP$_{DISTR}$ apple$_{DAT.SG}$

b. Gryzun i nasekomoe každyj
rodent$_{M.NOM.SG}$ and insect$_{N.NOM.SG}$ each$_{M.NOM.SG}$
vypili po kaple.
drank$_{PST.PL}$ PREP$_{DISTR}$ drop$_{DAT.SG}$

Finally, such constructions with F and N nouns, as in (8), were rejected by most of our informants. The few people who accepted them again preferred the masculine form.

(8) Ženščina i dit'a každyj
woman$_{F.NOM.SG}$ and child$_{N.NOM.SG}$ each$_{M.NOM.SG}$
sjeli po jabloku.
ate$_{PST.PL}$ PREP$_{DISTR}$ apple$_{DAT.SG}$

Let us add that M nouns are used to refer to groups of people of mixed or uncertain gender, or to an arbitrary member of such groups. This generalization is discussed by Yanovich (2012) who shows that it does not hold for animals. For example, the word *sobaka* "dog" is feminine. There are specific words to denote male and female dogs, but they are much more often used as swearwords, like the English *bitch*. To sum up, N appears to be the grammatical default as the gender used in impersonal constructions, while all cases where M is used as the standard option are limited to the nouns denoting humans and sometimes other animates. In all our experiments, we used only inanimate nouns as heads and attractors (we wanted to avoid additional factors before the general picture becomes clear)[6].

2. EXPERIMENT 1

Experiment 1 was designed to check whether the findings of Badecker and Kuminiak (2007) would be replicated in Russian, which is very close to Slovak in the relevant part of the grammar. In particular, both languages have three genders, M is the most frequent, N is the least frequent, but is used in impersonal sentences. There are no articles. Gender agreement can be observed on adjectives and participles (in singular) and on verbs (in past tense singular). The system of declensions is very similar as well.

2.1. Participants

Thirty native speakers of Russian (8 male, 22 female) participated in Experiment 1. Ages ranged from 18 to 50 (mean age 28.7, *SD* 9.4). No participant took part in more than one experiment. All experiments reported in this paper were carried out in accordance with the Declaration of Helsinki and the existing Russian and international regulations concerning ethics in research. All participants provided informed consent. They were tested at the Laboratory for Cognitive Studies of Saint-Petersburg State University.

2.2. Materials

In this experiment, participants first saw a predicate, then on the next slide a subject at which point they were asked to produce a complete sentence. In half of the cases, predicates did not agree with the subject in gender, and participants were asked to modify them. Like in B&K's study, subject noun phrases were always built according to the following schema: NP_1–preposition–NP_2, e.g., *okno vo dvor* "window$_{N.SG}$ to yard$_{M.SG}$." NP_1 was always in nominative singular, NP_2 was in accusative singular. We selected inanimate nouns that have the same form in accusative and nominative, since this was shown to inflate the error rate (Badecker and Kuminiak, 2007). As in many other agreement attraction studies, we had both adjunct and argument PPs.

The predicates always consisted of two words: the copula *byt'* "to be" in the past tense (where gender agreement can be observed) and an adjective or participle. We opted for such predicates because they are short and do not contain any objects or other nouns that could cause additional disturbance of subject-predicate agreement (initially, we wanted to use single verbs, but could not come up with such predicates for all experimental stimuli). Adjectives and participles were always in instrumental singular form[7].

The genders of NP_1 and NP_2 were manipulated. As **Table 1** shows, these two factors were not fully crossed. Like in B&K's Experiment 1, we used only seven out of nine possible combinations of genders. Additionally, we manipulated the agreement marking on the predicate[8]. Sample stimuli in conditions 1-4 in **Table 1** represent one set: two variants of the subject NP (one head and two different dependent nouns, or attractors) and two variants of the predicate (matched or mismatched in gender with the subject). We constructed 48 sets, 12 for each of the four combinations of conditions. This approach to the construction of materials (one head noun and several attractors of different genders, plus a grammatical and an ungrammatical version of the predicate) holds for all experiments in this article. All materials are listed in Appendices in Supplementary Material.

In addition to that, we constructed 100 fillers, also consisting of a predicate and a subject. Subject NPs had singular or plural

[6] Vigliocco and Franck (1999) demonstrated that the gender agreement error rate was lower when the gender of the head noun was conceptual, rather than purely grammatical, but we would not expect markedness patterns to be reversed in such cases.

[7] As we explained in the introduction, participles, adjectives, and nouns in predicates can appear either in nominative or in instrumental, and adjectives and participles also have short forms used only in predicates and inflected for gender and number, but not for case. Often only one variant is grammatical, but sometimes two or even three are, or one is fine, while the others are marginally acceptable. Meaning nuances associated with them can be very subtle. It will suffice to say that we chose instrumental forms because, unlike nominative and short forms, they suited all our stimuli. But, if the participants occasionally responded with nominative or short forms, we did not count this as a mistake.

[8] We opted for this design primarily to facilitate the comparison with B&K's study. In addition to that, when we were pretesting the experiment, we found that the experimental session was relatively short, but very intense because we prompted the participants to respond very fast. We concluded that making it 1.5 times longer to fully cross the two factors could make it too taxing.

TABLE 1 | Gender combinations used in Experiment 1.

Condition	NP_1 gender	NP_2 gender	Predicate gender	Example
1 / 2	M	M	M / F	*byl prosročennym / byla prosročennoj + recept na porošok* ($was_{M.SG}$ $expired_{M.SG}$ / $was_{F.SG}$ $expired_{F.SG}$ + $prescription_{M.NOM.SG}$ for $powder_{M.ACC.SG}$)
3 / 4	M	F	M / F	*byl prosročennym / byla prosročennoj + recept na maz'* ($was_{M.SG}$ $expired_{M.SG}$ / $was_{F.SG}$ $expired_{F.SG}$ + $prescription_{M.NOM.SG}$ for $ointment_{F.ACC.SG}$)
5 / 6	F	F	F / M	
7 / 8	F	M	F / M	
9 / 10	M	M	M / N	
11 / 12	M	N	M / N	
13 / 14	N	N	N / M	*byl otkrytym / bylo otkrytym + okno v pole* ($was_{M.SG}$ $opened_{M.SG}$ / $was_{N.SG}$ $opened_{N.SG}$ + $window_{N.NOM.SG}$ to $field_{N.ACC.SG}$)
15 / 16	N	M	N / M	*byl otkrytym / bylo otkrytym + okno vo dvor* ($was_{M.SG}$ $opened_{M.SG}$ / $was_{N.SG}$ $opened_{N.SG}$ + $window_{N.NOM.SG}$ to $yard_{M.ACC.SG}$)

heads and adjectival or prepositional modifiers (the NPs inside these PPs were not in accusative). Predicates were similar to the ones in target stimuli and did not agree with subjects in gender in one third of the cases.

Each participant saw only one target stimulus from each set. Consequently, we had four experimental lists with 148 items (48 stimuli and 100 fillers). The number of conditions was balanced for every list. Thus, every participant saw three target items per condition: for example, three FF stimuli (having an F head and an F attractor) with a matched F predicate, three FF stimuli with a mismatched M predicate etc. All lists began with ten fillers, and then fillers and experimental items were presented in a pseudo-random order, with the constraint that no more than two experimental items occur consecutively.

2.3. Procedure

In a pilot experiment, we used the same procedure as in B&K 's study: participants listened to preambles and were asked to generate complete sentences. But after running six subjects, we did not get any attraction errors. This can be explained by the fact that such errors are in general relatively infrequent. In B&K 's study, they occurred in 3% cases on average. Since the number of errors varies from subject to subject, the probability to elicit no errors from several people in a row is considerably high. However, we decided to switch to a different method in the main experiment in hope to elicit more errors.

The experiment was run on a Macintosh computer using PsyScope software (Cohen et al., 1993). In every trial, participants saw on the computer screen a fixation point (for 300 ms), then a predicate (for 800 ms), and then a subject NP (for 800 ms). Their task was to combine the predicate and the subject in a grammatical sentence and to say it aloud. If the predicate did not agree with the subject, participants were instructed to modify the predicate. Before the main session started, the experimenter explained the task on two sample items (saying that participants would see two phrases and would be asked to combine them into a correct sentence as fast as possible, i.e., without explicitly mentioning gender agreement). Then there were four practice items.

To encourage participants to respond faster, a time counter appeared on the screen after both the predicate and the subject were presented. As soon as the participant responded, the experimenter pressed a key, and the next trial started. All participants' responses were tape-recorded. An experimental session lasted around 7.5 min.

2.4. Results

The participants' responses were transcribed, and each of them was assigned into one of the following categories:

i. Correct response: the sentence is grammatical, the subject and the predicate provided as stimuli are repeated faithfully.
ii. Agreement error: the sentence is correct except for a gender agreement error.
iii. Repetition error: the sentence is grammatical, but the subject or the predicate is repeated incorrectly (for example, the word *krem* "cream" was used instead of the word *maz'* "ointment").
iv. A combination of a repetition error and an agreement error.
v. Incomplete response: the participant utters only a part of the sentence or says nothing at all.
vi. A combination of an incomplete response and an agreement error: the sentence is incomplete, but a verb, a participle or an adjective was uttered and did not agree with the subject (cf. 9a – 9b).

(9) a. Recept na maz' byla …
recipe$_{M.NOM.SG}$ for ointment$_{F.ACC.SG}$ was$_{F.SG}$ …

b. Recept na maz'
recipe$_{M.NOM.SG}$ for ointment$_{F.ACC.SG}$
prosročennaja…
expired$_{F.SG}$ …

Errors in subject-verb gender agreement were the only grammar errors participants made, all other errors involved incorrectly repeating or omitting lexical material (we did not expect any

TABLE 2 | The distribution of responses in Experiment 1.

Correct responses	1018 (71.2%)
Agreement errors	61 (4.3%), 8 of them partial[a]
Repetition errors	111 (7.8%)
Repetition and agreement errors	9 (0.6%), 3 of them partial
Incomplete responses	224 (15.7%)
Incomplete responses with agreement errors	7 (0.5%)

[a]*In most sentences with agreement errors, both the verb and the adjective or participle were in a wrong form. They are components of a complex predicate, so we counted this as one error (note that counting them as two errors instead would not affect the outcome, because the differences between the relevant conditions would only be inflated). However, in several cases only one of the two components did not agree with the subject.*

other grammar errors, for example, in number or case, but they could have occurred accidentally). To exclude mishearings during transcription, both authors of this paper and two other native speakers of Russian listened to all responses to target stimuli. The number of errors in each category is given in **Table 2**. In case of self-corrections, only the first variant was counted, both when participants changed an answer with an error to a correct one and when they did the opposite (this happened in three cases).

At the following stage of analysis, we collapsed all agreement errors together. The distribution of errors by experimental conditions is given in **Table 3**. In total, there were 77 agreement errors (5.4% from all responses). Only 13 out of them were not due to attraction (they are discussed in more detail below). The difference between the number of agreement errors with and without attraction is statistically significant according to the chi-square test[9] [$\chi^2_{(1,\,N=77)} = 18.97$, $p < 0.01$], so our results show that gender agreement in Russian is subject to attraction.

As **Table 3** shows, agreement errors were more frequent in predicate mismatch conditions, but were not limited to them. Out of 13 errors without attraction, in eight cases, a mismatched predicate was not changed, but there were also five cases where participants produced a neuter predicate with an MF subject, a masculine predicate with an NN subject etc., although they were provided with other forms, matched or mismatched with the subject. Out of 64 attraction errors, 11 errors occurred in predicate match conditions, i.e., participants changed the correct gender of the predicate they were provided with to an incorrect one due to attraction.

Conditions with matched and mismatched predicates are collapsed in **Table 4** showing that the number of agreement attraction errors differs depending on the combination of genders of the head and attractor nouns. To test whether these differences are statistically significant, we modeled the data with a mixed-effects logistic regression in the statistical software program R (R Core Team, 2014) using the *glmer* function from the *lme4* package (Bates et al., 2015).

Firstly, we compared MF and FM conditions. The logistic regression evaluated the likelihood of an agreement attraction error (coded as 1) vs. a correct response (coded as 0). The combination of genders was treated as a fixed effect. For the predictors we used contrast coding: MF was coded as 0.5, FM was coded as −0.5. Random intercepts by participant and by item were also included in the model. The results of the analysis are reported in **Table 5**. The coefficient for the intercept was significant, reflecting that most responses were correct. There was also a significant main effect of Gender Combination indicating that F attractors trigger significantly more errors than M attractors.

Secondly, we compared MN and NM conditions in the same way. MN was coded as 0.5, NM was coded as −0.5. The coefficient for the intercept was again significant because most responses were correct. But the main effect of gender combination did not reach significance. We also compared MF and MN conditions and FM and NM conditions, as well as the number of non-agreement ("other") errors in different conditions, but did not find any significant differences.

TABLE 3 | The distribution of responses by condition in Experiment 1.

	Correct response	Agr. error (attraction)	Agr. error (no attraction)	Other errors
Condition 1 (MM + M)[a]	69	0	0	16
Condition 2 (MM + F)	69	0	0	16
Condition 3 (MF + M)	66	3	1	20
Condition 4 (MF + F)	53	19	1	17
Condition 5 (FF + F)	65	0	0	25
Condition 6 (FF + M)	57	0	3	30
Condition 7 (FM + F)	66	1	0	23
Condition 8 (FM + M)	50	10	1	29
Condition 9 (MM + M)	74	0	0	16
Condition 10 (MM + N)	64	0	3	23
Condition 11 (MN + M)	69	1	0	20
Condition 12 (MN + N)	59	11	0	20
Condition 13 (NN + N)	64	0	1	25
Condition 14 (NN + M)	68	0	2	20
Condition 15 (NM + N)	62	6	1	21
Condition 16 (NM + M)	63	13	0	14

[a]*Due to our mistake, there are 85 responses in conditions 1 and 2 rather than 90.*

TABLE 4 | The Number of gender agreement attraction errors by condition in Experiment 1.

Head/attractor gender	Correct responses	Attraction errors	Other errors
MF	119	22	39
FM	116	11	53
MN	136	12	42
NM	125	19	36

[9]In half of the conditions, where the genders of the head and the attractor coincided, no agreement errors with attraction were possible, while in the other half of the conditions, these errors prevailed, but there were also agreement errors without attraction, as **Table 3** shows. This is why we chose the chi-square test.

TABLE 5 | Results of the analysis for Experiment 1.

Conditions	Predictor	Coefficient	Std. error	Wald Z	*p*
MF vs. FM	(Intercept)	−3.04	0.43	−7.01	<0.01
	GenComb	−0.95	0.48	−1.96	0.05
MN vs. NM	(Intercept)	−2.68	0.30	−8.82	<0.01
	GenComb	0.62	0.39	1.59	0.11

2.5. Discussion

The results of Experiment 1 are similar to the results of B&K's first experiment, which can be explained by the fact that the two languages have similar gender systems, as we demonstrated in the introduction. In both studies, F attractors triggered more errors than M attractors. N attractors triggered fewer errors than M attractors, but this difference was statistically significant only in B&K's study. As we mentioned in the introduction, other authors studying gender attraction in French and Spanish (which have two genders and where M is grammatical default), observed a different pattern: there were more errors with M attractors than with F attractors. We postpone further discussion until the general discussion section.

3. EXPERIMENT 2A

Experiment 2a was designed to find out whether gender agreement attraction can also be detected in comprehension. For the sake of comparison with Experiment 1, we used the same combinations of head and attractor noun genders.

3.1. Participants

Forty-eight native Russian speakers (19 female and 29 male) took part in the experiment. Ages ranged from 19 to 26 (mean age 20.9, *SD* 1.9).

3.2. Materials

The materials consisted of target and filler sentences. All target sentences were 9–10 words long and followed the schema: NP_1–preposition–NP_2–copula (*byt'*) - adjective/participle - four-five words modifying the predicate. We had the same 16 conditions as in Experiment 1 (see **Table 1** above). Almost all subject NPs and predicates were based on the materials from Experiment 1 and followed the same constraints. In half of the conditions, the predicate did not agree with the subject. Given existing findings on number agreement attraction, we expected parallel results in production and comprehension. In particular, we expected to find grammaticality illusions in conditions MFF, FMM, MNN, and NMM (this would mean that they would be read significantly faster than the other four ungrammatical conditions: MMF, FFM, MMN, NNM).

As in Experiment 1, conditions were grouped in sets, each set containing four conditions with the same head nouns. An example of a stimuli set is given in (10)[10]. For each condition set we constructed 12 sentences, 48 target sentences in total.

[10]The translation for all sentences is identical, so we only give it for the first one.

(10) a. Recept$_{M.NOM.SG}$ na porošok$_{M.ACC.SG}$ byl$_{M.SG}$ pom'atym$_{M.SG}$ iz-za sil'nogo volnenija$_{GEN.SG}$ pacienta.$_{GEN.SG}$
"The recipe for the powder was crumpled due to the patient's extreme nervousness."

b. Recept$_{M.NOM.SG}$ na maz'$_{F.ACC.SG}$ byl$_{M.SG}$ pom'atym$_{M.SG}$ iz-za sil'nogo volnenija$_{GEN.SG}$ pacienta.$_{GEN.SG}$

c. Recept$_{M.NOM.SG}$ na porošok$_{M.ACC.SG}$ byla$_{F.SG}$ pom'atoj$_{F.SG}$ iz-za sil'nogo volnenija$_{GEN.SG}$ pacienta.$_{GEN.SG}$

d. Recept$_{M.NOM.SG}$ na maz'$_{F.ACC.SG}$ byla$_{F.SG}$ pom'atoj$_{F.SG}$ iz-za sil'nogo volnenija$_{GEN.SG}$ pacienta.$_{GEN.SG}$

Additionally, we constructed 120 fillers, which had roughly the same structure as experimental sentences. Subject NPs in fillers consisted of a single noun modified by an adjective, or of a complex NP, where the embedded noun was not in accusative. All fillers were grammatical. Thus, we had 24 ungrammatical and 144 grammatical sentences, making the grammatical-to-ungrammatical ratio 6:1. Experimental sentences and fillers were distributed in four counterbalanced experimental lists. Every list started with ten fillers; then stimuli and fillers were presented in pseudo-random order with the constraint that a maximum of two stimuli could occur consecutively.

3.3. Procedure

The sentences were presented on a PC using Presentation software (http://www.neurobs.com). We used the word-by-word self-paced reading methodology (Just et al., 1982). Each trial began with a sentence in which all words were masked with dashes while spaces and punctuation marks remained intact. Participants were pressing the space bar to reveal a word and re-mask the previous one. One third of the sentences was followed by forced choice comprehension questions to ensure that the participants were reading properly. Two answer variants were presented on the left and on the right of the screen. Participants pressed "f" to choose the answer on the left, and "j" to choose the answer on the right. Participants were instructed to read at a natural pace and answer questions as accurately as possible. They were not informed in advance that sentences would contain errors. An experimental session lasted around 14 min.

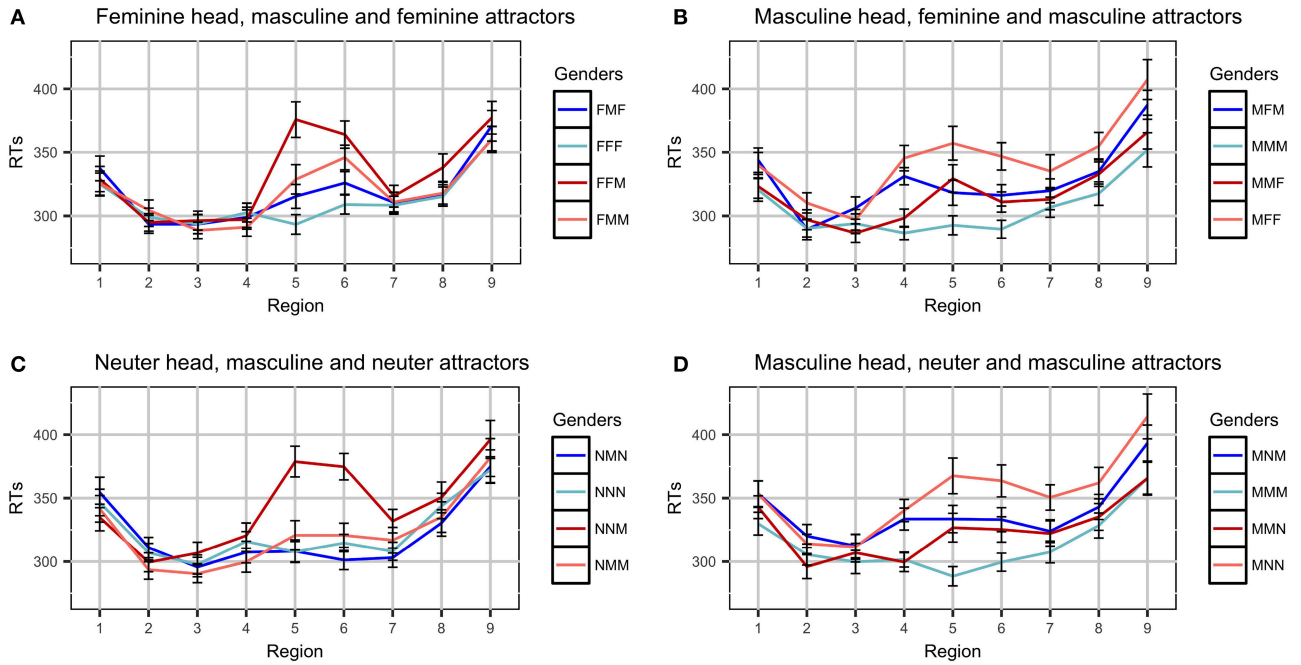

FIGURE 1 | Plots of mean RTs (in ms) by conditions in Experiment 2a. Error bars represent standard errors of the means. Regions: NP_1 (1) - preposition (2) - NP_2 (3) - copula *byt'* (4) - Adj/Part (5) - spillover (6–9). Ungrammatical conditions are red, grammatical ones are blue. Conditions where the gender of the attractor and the predicate coincide (for example, FFF and FMM) have dark colors, conditions where they do not (for example, FMF and FFM) have light colors. **(A)** Feminine head, masculine and feminine attractors, **(B)** Masculine head, feminine and masculine attractors, **(C)** Neuter head, masculine and neuter attractors, and **(D)** Masculine head, neuter and masculine attractors.

3.4. Results

We analyzed participants' question-answering accuracy and reading times. Two participants answered more than 20% questions incorrectly, so their data were discarded. Otherwise no participant made more than two mistakes when answering questions to target sentences (i.e., 10% at most). Reading times that exceeded a threshold of 2.5 standard deviations, by region and condition, were excluded (Ratcliff, 1993). For two participants, this led to the exclusion of more than 15% responses, so we did not include their data in further analysis.

After four participants were excluded, we had 44 participants (11 in each experimental list). In total, 2.3% of the data were excluded as outliers (never more than 3.6% per region and condition). Average RTs per region in different conditions are presented in **Figure 1**.

The data for each set of conditions (e.g., MMM - MFM - MMF - MFF) were entered in a 2 × 2 Repeated Measures ANOVA with grammaticality and gender match between the attractor and the head nouns as factors. We used IBM SPSS software (www.ibm.com/software/analytics/spss/). Analyses by items and by participants were performed. Data from all regions were tested, but there were significant results only in regions 4–6 in the conditions with M heads and in regions 5–6 in the conditions with F and N heads. Region 4 is the copula, region 5 is an adjective or participle, regions 6–10 contain several words modifying the predicate. The results of the tests for the relevant regions are given in **Table 6**.

3.4.1. Feminine Head, Masculine Attractor

The main effect of Grammaticality is significant in analysis by subjects and by items in regions 5–6, reflecting the fact that ungrammatical sentences were read slower than grammatical ones. The main effect of Gender Match is not significant in any region. The interaction of Grammaticality and Gender Match is significant in analysis by subjects and by items in region 5 and only in analysis by subjects in region 6. Ungrammatical sentences were read faster if the head and the attractor were mismatched in gender (i.e., in the FMM condition compared to the FFM condition). This is the classical attraction pattern.

3.4.2. Neuter Head, Masculine Attractor

The main effect of Grammaticality is significant in regions 5–6, reflecting longer RTs in ungrammatical conditions. The main effect of Gender Match is significant only in analysis by subjects in regions 5–6. The interaction of Grammaticality and Gender Match is significant in regions 5–6, which is again a reflection of the classical attraction pattern: NMM condition was read faster than NNM and, in fact, almost as fast as grammatical conditions.

Analyses with $p \leq 0.05$ are shown in bold.

3.4.3. Masculine Head, Feminine Attractor

The main effect of Grammaticality is significant in analysis by subjects in region 4 and in analysis by subjects and by items in regions 5–6. This reflects the fact that RTs were longer in ungrammatical conditions. The main effect of Gender Match is significant in analysis by subjects and by items in region 4, and only in analysis by subjects in regions 5–6. This corresponds to longer RTs in conditions where the genders on the nouns were mismatched. The interaction of Grammaticality and Gender Match did not reach significance in any regions, which points to the absence of agreement attraction.

3.4.4. Masculine Head, Neuter Attractor

The main effect of Grammaticality is significant in analysis by subject and by items in regions 5–6: the ungrammatical conditions are read slower than grammatical. The main effect of Gender Match is significant only in analysis by subjects in regions 4–6. The interaction of Grammaticality and Gender Match is not significant in any region, so these conditions also show no agreement attraction.

3.5. Discussion

As can be seen from the analyses, the results fall into two groups. In the conditions with F or N heads and M attractors there is clear evidence for gender agreement attraction. RTs exhibit the classical attraction profile with grammaticality illusions: ungrammatical sentences where the attractor and the predicate have the same gender (FMM and NMM) are read faster than other ungrammatical sentences (FFM and NNM). Discussing comprehension studies of number agreement attraction in the introduction, we outlined different approaches to this phenomenon, but will opt for one of them ourselves only in

TABLE 7 | Frequencies of the attractors used in Experiments 2a and 2b (in ipm, or instances per million).

Experiment	Head gender	Attractor gender	Mean attractor freq (ipm)
Experiment 2a	F	F	138.1
		M	120.0
	N	N	105.9
		M	81.7
	M	M	91.8
		F	41.1
	M	M	134.9[a]
		N	78.9
Experiment 2b	M	M	61.4
		F	61.9
	M	M	69.2
		N	68.1

[a]*It should be noted that one really frequent M noun influences this number a lot. If we get rid of it and of the corresponding N attractor, the frequencies become very close: 73.9 for M attractors and 84.6 for N attractors.*

the general discussion section once all experimental findings are presented. Let us also note that ungrammaticality illusions are absent: in the sentences with N heads there are virtually no differences between grammatical conditions; in the sentences with F heads, they are insignificantly small.

On the other hand, the conditions with M heads and F or N attractors do not show any evidence of attraction. Both grammatical and ungrammatical sentences where the head and the attractor match in features (MMM, MMF, and MMN) are read faster than the sentences where they are mismatched (MFM, MNM, MFF, and MNN). In case of ungrammatical sentences, this pattern is *the reverse* of what we usually see in attraction cases.

Looking for an explanation of such pattern, we discovered that we need to rule out an important confound first. Unfortunately, we made a mistake during the preparation of experimental materials, and the frequencies of attractors in conditions with M heads were not well balanced. Since this could influence the results in some unexpected way, we conducted an additional experiment where the frequencies were carefully controlled. Conditions with F and N heads did not have this problem, and the results reported for them hold.

4. EXPERIMENT 2B

In this experiment we follow up on potential frequency effects in the conditions with M heads from Experiment 2a.

4.1. Participants

Thirty-five native Russian speakers (17 female, 18 male) took part in the experiment. Ages ranged from 21 to 47 (mean age 31.3, *SD* 6.2).

4.2. Materials

We constructed 32 sets of stimuli according to the same schema as in Experiment 2a and observing the same constraints. Head nouns were always masculine. In 16 sets, the attractors were masculine and neuter; in the other 16 sets, the attractors were masculine and feminine. Most of the head nouns were re-used from the Experiment 2a, but we replaced attractors so that their frequencies were closely matched inside the two groups of conditions. We used *The Frequency Dictionary of Modern Russian Language* (Lyashevskaya and Sharoff, 2009). Average frequencies of head and attractor nouns in Experiments 2a and 2b are shown in **Table 7**. As in Experiment 2a, half of the predicates did not agree with the subject in gender. Additionally, we used 80 fillers from Experiment 2a. Experimental sentences were distributed into four experimental lists, with factors counterbalanced. As a result, we had 112 sentences per list (16 ungrammatical and 96 grammatical), making the grammatical-to-ungrammatical ratio 6:1.

4.3. Procedure

The procedure was the same as in Experiment 2a. An experimental session lasted around 9 min.

4.4. Results

Like in Experiment 2a, we analyzed participants' question-answering accuracy and reading times. At the first stages of analysis, the data from three participants were discarded: one of them had <75% accuracy in comprehension questions; the other two read too slowly compared with the others, so more than 15% of their RTs would have to be excluded as outliers (exceeding the threshold of 2.5 standard deviations). As a result, we had 32 participants, eight for each experimental list.

After three participants were excluded, on average, 1.5% RTs were excluded as outliers (never more than 3.1% per region and condition). Average RTs per region in different conditions are presented in **Figure 2**.

2 x 2 Repeated Measures ANOVAs with grammaticality and gender match as factors were used to analyze RTs, as in Experiment 2a. Significant results were found only in regions 5 (adjective/participle) and 6–7 (spillover regions). They are presented in **Table 8**.

4.4.1. Masculine Head, Feminine Attractor

The main effect of Grammaticality was significant in analysis by subjects and by items in regions 5–6, and only in analysis by subjects in region 7. This reflects the fact that ungrammatical sentences were read slower than grammatical ones. The main effect of Gender Match was significant only in analysis by subjects in regions 5–7. The interaction between Grammaticality and Gender Match was not significant in any region.

4.4.2. Masculine Head, Neuter Attractor

The results were almost the same as in the other set of conditions. The main effect of Grammaticality was significant in regions 5–7. The main effect of Gender Match was significant only in analysis by subjects in regions 5–7. The interaction between the factors never reached significance.

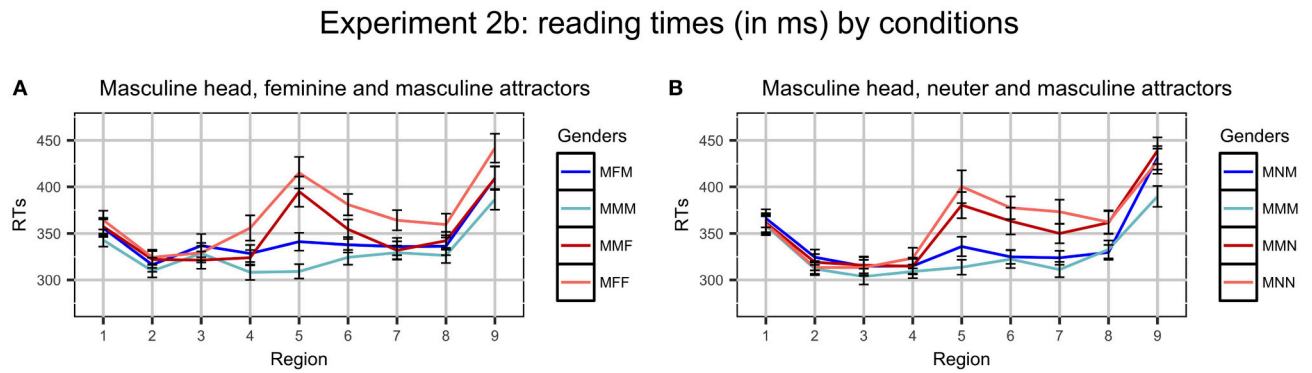

FIGURE 2 | Plots of mean RTs (in ms) by conditions in Experiment 2b. Error bars represent standard errors of the means. Regions: NP_1 (1) - preposition (2) - NP_2 (3) - copula *byt'* (4) - Adj/Part (5) - spillover (6–9). Ungrammatical conditions are red, grammatical ones are blue. Conditions where the gender of the attractor and the predicate coincide (for example, MMM and MFF) have dark colors, conditions where they do not (for example, MFM and MMF) have light colors. **(A)** Masculine head, feminine and masculine attractors, **(B)** Masculine head, neuter and masculine attractors.

Analyses with $p \leq 0.05$ are shown in bold.

4.5. Discussion

The results of this experiment show that the basic finding from Experiment 2a holds: there is no evidence for agreement attraction in the sentences with M heads. The plots of the data also suggest that the unbalanced frequencies in Experiment 2a had some influence on reading times. In Experiment 2b, where this confounding factor was excluded, two ungrammatical and two grammatical conditions pattern more closely together within each condition set. Still, the conditions where the genders of heads and attractors are mismatched have longer RTs.

Notably, this difference in RTs is not an instance of ungrammaticality illusion, since it is observed in both grammatical and ungrammatical conditions. In case of illusions, a different pattern would be expected: gender mismatch between the head and the attractor should increase RTs in grammatical conditions and decrease RTs in ungrammatical ones. Rather, it can be suggested that gender mismatch carries some processing cost in the sentences with M heads. In any case, our data do not allow for strong claims: the main effect Gender Match is significant in by subjects analysis in regions 5–7, but never reaches significance in by items analysis.

Since the outcome of comprehension experiments was not parallel to the results of Experiment 1 and earlier experiments on Slovak (Badecker and Kuminiak, 2007), we decided to look

at the remaining combinations of head and attractor genders in Experiment 3 before suggesting an explanation.

5. EXPERIMENT 3

In this experiment, we studied sentences with N heads and N, F, and M attractors and sentences with F heads and F, N, and M attractors in comprehension. NF and FN combinations have not been examined before, and we added M attractors to be able to compare sentences with all possible attractors.

5.1. Participants

Thirty-nine native Russian speakers (22 female, 17 male) took part in the experiment. Ages ranged from 19 to 40 (mean age 25.4, *SD* 6.4).

5.2. Materials

We constructed 36 sets of stimuli according to the same schema as in Experiments 2a and 2b and observing the same constraints. Half of the sets had F head nouns and the other half had N head nouns. In all sets, we used M, N, and F attractors. Their frequency was closely matched inside the three groups of conditions, as **Table 9** shows. Half of the predicates were grammatical, and half were not. As a result, every target sentence appeared in six conditions: NNN, NNF, NMN, NMM, NFN, NFF for the sentences with N heads and FFF, FFN, FMF, FMM, FNF, FNN for the sentences with F heads. Thus, out of all possible combinations of head, attractor and predicate genders, we did not use NNM and FFM. We decided to do so to keep the number of grammatical and ungrammatical conditions equal and sacrificed two conditions without any potential for agreement attraction that we have already looked at in Experiment 2a. Additionally, we used 100 fillers from Experiment 2a. Experimental sentences were distributed into six experimental lists, with factors counterbalanced. As a result, we had 136 sentences per list (18 ungrammatical and 118 grammatical), making the grammatical-to-ungrammatical ratio 6.6:1.

5.3. Procedure

The procedure was the same as in Experiments 2a and 2b. An experimental session lasted around 11 min.

5.4. Results

We analyzed participants' question-answering accuracy and reading times. The data from three participants were discarded because they had <75% accuracy in comprehension questions. As a result, we had 36 participants, six for each experimental list. None of them made more than two mistakes when answering questions to target sentences (i.e., 12.5% at most).

As in the previous experiments, reading times that exceeded a threshold of 2.5 standard deviations, by region and condition, were excluded. In total, 1.8% of the data were excluded (never more than 3.7% per region and condition). Average RTs per region in different conditions are presented in **Figure 3** (notice that coloring conventions are different from the previous plots).

TABLE 9 | Frequencies of the attractors used in Experiment 3 (in ipm, or instances per million).

Head gender	Attractor gender	Mean attractor freq (ipm)
F	F	83.2
	M	76.6
	N	79.8
N	F	92.1
	M	92.8
	N	95.7

In Experiments 2a and 2b, we observed agreement attraction for some combinations of head and attractor genders (FM and NM), but not for the others (MF and MN). So the first question we asked in this experiment was whether there would be agreement attraction in NF and FN combinations. If the answer was yes, we were going to compare N and F attractors to M attractors. To answer the first question, we took two groups of conditions: FFF, FFN, FNF, FNN and NNN, NNF, NFN, NFF, and analyzed RTs using 2 x 2 Repeated Measures ANOVAs with grammaticality and gender match as factors, as in the previous experiments. Significant results were found only in regions 5 (adjective or participle) and 6–7 (a spillover region). They are presented in **Table 10**.

5.4.1. Feminine Head, Neuter Attractor

The main effect of Grammaticality was significant in analysis by subjects and by items in regions 5–6. This reflects the fact that ungrammatical sentences were read slower than grammatical ones. The main effect of Gender Match was significant only in analysis by subjects in regions 5–6. The interaction of Grammaticality and Gender Match was significant in analysis by subjects and by items in region 6 and only in analysis by subjects in region 5. Ungrammatical sentences were read faster if the head and the attractor were mismatched in gender (i.e., in the FNN condition compared to the FFN condition). This is the classical attraction pattern, also known as a grammaticality illusion. At the same time, there are no differences between grammatical conditions, i.e., no evidence of ungrammaticality illusions was found.

5.4.2. Neuter Head, Feminine Attractor

The results were the same as in the other set of conditions. Thus, the answer to our first experimental question was positive, so we proceeded to compare the size of the attraction effect for attractors of different genders. We compared two groups of conditions: FNF, FNN, FMF, FMM and NFN, NFF, NMN, NMM. We used 2 x 2 Repeated Measures ANOVAs with grammaticality and attractor gender as factors. Only the main effect of Grammaticality in region 6 was statistically significant [for conditions with *F* heads, $F_1(1, 35) = 19.31$, $p < 0.01$, $MS_{effect} = 86064.00$; $F_2(1, 17) = 10.17$, $p = 0.01$, $MS_{effect} = 24457.35$; for conditions with N heads, $F_1(1, 35) = 55.80$, $p < 0.01$, $MS_{effect} = 126973.44$; $F_2(1, 17) = 7.32$, $p = 0.02$, $MS_{effect} = 52915.47$]. The main effect of Attractor Gender or the interaction between the factors were not significant in any region.

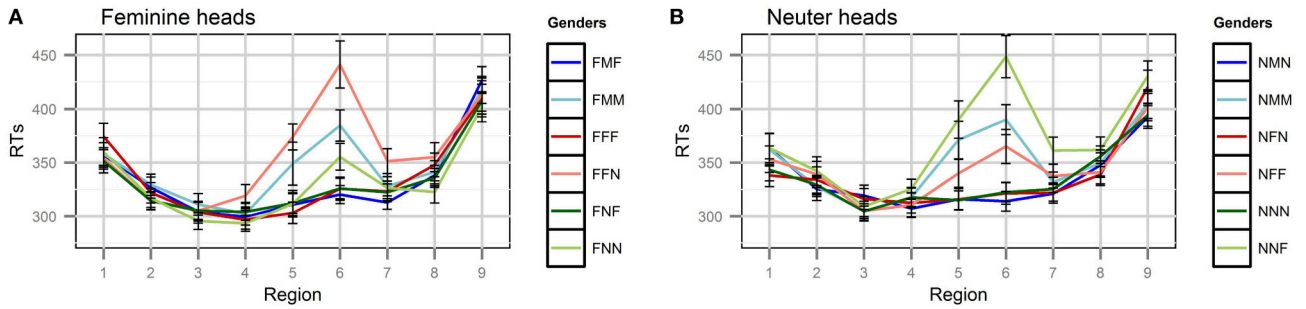

FIGURE 3 | Plots of mean RTs (in ms) by conditions in Experiment 3. Error bars represent standard errors of the means. Regions: NP_1 (1) - preposition (2) - NP_2 (3) - copula *byt'* (4) - Adj/Part (5) - spillover (6–9). The conditions with M attractors are blue, with F attractors - red, with N attractors - green. Analyses with $p \leq 0.05$ are shown in bold.

5.5. Discussion

Let us summarize the results of Experiments 2a, 2b, and 3. Gender agreement attraction was observed with F heads and M or N attractors and with N heads and M or F attractors, but not with M heads and F or N attractors. This leads us to the conclusion that attraction depends primarily on the features of the head rather than on the features of the attractor. If the features of the attractor played an additional role, ungrammatical sentences with M attractors would be read *faster* than ungrammatical sentences with other attractors. However, when we compared sentences with F heads and N or M attractors and sentences with N heads and F or M attractors, the Attractor Gender or the interaction between this factor and Grammaticality never reached significance, and average RTs even showed the opposite pattern: they were *longer* in the ungrammatical sentences with M attractors. This goes against the assumptions entertained in the absolute majority of previous agreement attraction studies, so a detailed analysis of this result will be presented in the General Discussion Section.

6. GENERAL DISCUSSION

In this paper we reported four experiments on gender agreement attraction in Russian. We observed attraction effects both in production and in comprehension. Badecker and Kuminiak (2007) is the only previous production study where gender agreement attraction was examined in a language with three genders (Lorimor et al., 2008 elicited very few gender errors in their experiments on Russian). In this paper, we replicated one of Badecker and Kuminiak's experiments and conducted the first comprehension experiments analyzing attraction with non-binary features.

Two outcomes of our experiments can be identified as the most important. Firstly, our results suggest that gender attraction works differently in production and comprehension. This does not agree with previous studies of number agreement attraction, in which production and comprehension results were largely parallel: only the combination of a singular head and a plural attractor triggered attraction. Secondly, our reading experiments

suggest that the features of the head, rather than the features of the attractor are crucial to determine the pattern of agreement attraction, while the absolute majority of previous agreement attraction studies rely on the opposite assumption.

6.1. Overview of Experimental Findings

In our comprehension experiments, attraction was observed in some combinations of head and attractor genders, but not in the others, while in the production experiment, all combinations exhibited attraction, only to a different extent. We will first consider production results, and then comprehension findings. The outcome of the production study was similar to the results of the first experiment conducted by Badecker and Kuminiak (2007): there were more errors with MF subjects than with FM subjects and with NM subjects than with MN subjects. Both differences were statistically significant in the Slovak study, while in our experiment, only the first one was.

Badecker and Kuminiak ran an additional experiment comparing NF and NM preambles and found that the error rates in these conditions were roughly the same. They claim that this pattern can be explained only in an optimality-theoretic framework where markedness effects are by definition relational. We believe that this is not the case. Given the impressive body of literature on number and gender features, we do not think that we can select a particular approach based on experimental data without a detailed consideration of other arguments. So we chose two models that have been applied to Russian to demonstrate that they are also compatible with the pattern described by Badecker and Kuminiak and may be better suited to explain other findings we reported.

In Kramer (2015), F is encoded as [+FEM], M is [−FEM] and N corresponds to no gender features. When zero and non-zero feature values are compared, the latter are marked, and it can be argued that for this comparison, it is not important whether non-zero values are plus or minus. Therefore, the same error rates are observed with NF and NM preambles. When non-zero values are compared, plus values are more marked. In Nevins (2011), F is [+FEM], [−MASC], M is [−FEM], [+MASC] and N is [−FEM], [−MASC]. N is less marked than M and F because it contains only minus values, while M and F both contain one plus value. But when we compare F and M directly, it can be argued that feature hierarchy becomes important. [FEM] is standardly assumed to be lower than [MASC], so F is more marked than M.

Now let us focus on another property of production findings from Slovak and Russian that is not discussed by Badecker and Kuminiak (2007), but seems crucial to us. In case of gender agreement, attraction errors are produced with all preambles in which the genders of the head and the attractor are mismatched, while in case of number agreement, errors are virtually absent with plural heads and singular attractors. One way to capture this would be to assume that all genders are marked by some feature combinations, as Nevins (2011) suggests, while singular corresponds to no number features.

Another important problem is the difference between experimental findings from Slovak and Russian on the one hand and Romance languages on the other. In Russian and Slovak, more errors are produced with MF preambles than with FM preambles, while in Spanish and French the situation is the opposite. Badecker and Kuminiak (2007) do not comment on this discrepancy, and we cannot offer any explanation for it so far. We can only note that the pattern observed in Slovak and Russian is similar to what we see with number: more errors when the head is less marked than the attractor.

Now let us turn to comprehension experiments. Attraction was observed in NMM, NFF, FMM, and FNN conditions, but not in MFF and MNN conditions. As we already noted, this indicates that features of the heads rather than features of the attractors play a crucial role for attraction. Before discussing this finding in the next section, we want to make two important observations. Firstly, the M gender exhibits a different pattern from the F and N genders. This can hardly be attributed to feature markedness: N is the grammatical default in Russian, and the psycholinguistic relevance of this fact is confirmed by the production data discussed above. We will explore alternative explanations below. Secondly, no ungrammaticality illusions (differences between grammatical conditions depending on whether the head and the attractor have matched or mismatched gender features) were detected in our experiments, which lends further support to the retrieval approach to agreement attraction.

6.2. The Role of Head and Attractor Features in Attraction

In the literature on agreement attraction, the presence or absence of the effect is traditionally associated with the features of the attractor. There are at least two reasons for this. Firstly, experimental findings suggest that *some* properties of attractors do influence attraction effects [e.g., as we discussed in the introduction, Hartsuiker et al. (2003) showed that the incidence of agreement errors was much higher when attractors were formally similar to nominative plural forms]. The second reason is tradition: the first proposed account of agreement attraction relied on feature percolation, which means focusing exclusively on the attractor whose features can erroneously spread upwards.

The assumption that the features of the attractor are crucial has been maintained in the more recent retrieval account. However, it is important to realize that in this account the properties of the head can influence the agreement process as well. For example, to explain the plural markedness effect, it is traditionally assumed that singular nouns are not marked for number, and "the system is biased to return explicitly number marked constituents" (Wagers et al., 2009, p. 233), therefore plural attractors can easily be retrieved, while singular ones almost never are. But another interpretation is possible: the plural feature makes the heads easier to retrieve and thus more stable, less prone to attraction errors. This is why attraction in the plural-singular configurations is virtually non-existent. On the other hand, the retrieval of singular heads is prone to error, hence the abundance of errors in singular-plural configurations[11].

While we look at binary features or at the cases where attraction is observed in all feature combinations (as in production experiments on Slovak and Russian), we can only

[11]Let us note that under this scenario an attractor can also be retrieved in a singular-singular configuration, but this will not provoke any agreement errors.

use indirect evidence to estimate the contribution of head and attractor features to the agreement process. Our reading experiments allow for the first direct comparison and show that at least in comprehension, the features of heads, not attractors play the crucial role. We observed attraction with attractors of all three genders, but only with N and F heads. The gender of the attractor did not even influence the size of the effect. These results suggest that the gender of the attractor has very little or no influence on its chances to be retrieved (it should only match the gender of the incorrect verb form).

Notably, Julie Franck expressed similar ideas in a recent talk (Franck, 2015). The first part of the talk was dedicated to summarizing existing data on agreement attraction. Franck adopted the retrieval approach for production and comprehension and identified the following groups of factors that can lead to attraction: semantic factors (primarily related to the conceptual numerosity of the subject NP), stability of the head's features, accessibility of the attractor (defined by its structural position) and similarity between the head and the attractor. Discussing stability of the head's features Franck examined asymmetries between feature values, morphophonological and semantic influences.

Franck's reexamination of attraction phenomena was driven by the findings on morphophonology (other data she considered could be accounted for in the old models). As we noted in the introduction, studies on several languages demonstrated that number and gender agreement attraction errors are less frequent when heads have regular inflections, but this plays no role for attractors (e.g., Bock and Eberhard, 1993; Vigliocco et al., 1995; Vigliocco and Zilli, 1999; Franck et al., 2008). For attractors, only morphological ambiguity making them more similar to a subject is important (e.g., Hartsuiker et al., 2003; Badecker and Kuminiak, 2007)[12]. This led Franck to conclude that the features of the head are crucial, and she reanalyzed existing data according to this idea. She argued that features that have a semantic correlate are more resistant to attraction (for example, Vigliocco and Franck, 1999 observed lower error rates when heads had conceptual rather than purely grammatical gender) and that the same is true for marked feature values. The latter conclusion was based on number agreement attraction findings and on the results of Badecker and Kuminiak's and our production experiments.

Thus, the findings summarized by Franck and the outcome of our reading experiments point into the same direction, but we still have to explain the difference between our comprehension and production results. Of course, to make definitive conclusions, it would be great to have data from several languages (for example, comprehension data from Slovak), but let us suggest several hypotheses based on existing findings. Our reading experiments strongly indicate that M heads are resistant to attraction, while N and F heads are not. The data from production experiments on Russian and Slovak are open to several interpretations because attraction was observed in all head-attractor combinations with mismatched genders. Therefore, we assume that M heads in general are the most stable ones and the least prone to attraction, and production data need an independent explanation. This assumption is supported by independent evidence: several production experiments on number agreement attraction in Russian reported by Nicol and Wilson (1999) and Yanovich and Fedorova (2006) demonstrated that the incidence of number errors depends on the gender of the head noun. Errors arise most often with N heads and least often with M ones.

If our assumption is on the right track, M heads and plural heads exhibit similar properties in comprehension. But why should they do so, given that M features are neither the most marked nor the least marked in Russian? Let us come back to the idea expressed in the previous subsection: number is privatively marked (i.e., singular nouns have no number features), while gender is not (all nouns have some gender features with plus and minus values). We hypothesize that with privative features, the non-zero value is the most stable, while with non-privative features, where all values are non-zero, other considerations come into the picture. We are reluctant to appeal to frequency, but maybe it plays a role that M gender vastly outnumbers F and N in Russian. In any case, our data indicate that that there is no straightforward relation between feature markedness and stability. The next subsection considers some differences between comprehension and production and how these differences could explain our results.

6.3. Differences between Production and Comprehension

Based on parallel results from number agreement attraction experiments most authors assume that the same mechanisms underlie attraction in production and comprehension. The opposite view has been recently advocated by Tanner et al. (2014). They claim that the mechanisms responsible for attraction in comprehension are a subset of those involved in production. In particular, they argue that attraction in comprehension is due to retrieval interference, while attraction in production is best described by the representational account, namely, by the Marking and Morphing model (Eberhard et al., 2005), although retrieval interference is also present.

As we noted above, the Marking and Morphing model is incompatible with gender agreement attraction. We believe that the core mechanism underlying number and gender agreement attraction in production is the same, so we opt for the retrieval approach. Evidently, in case of number, semantic factors influence agreement, and it is expected that their influence is much more readily detected in production than in comprehension: in production, we start with the conceptual structure, while in comprehension, it is our goal. Vigliocco and Franck (1999) demonstrated that gender agreement attraction errors are less frequent when head nouns have conceptual, rather than purely grammatical gender. So semantic factors also play a role here, but, given the relevant distinctions[13] between number

[12]Let us add that Badecker and Kuminiak (2007) demonstrated that ambiguity is important not only for attractors, but also for heads: if the form is ambiguous between nominative and accusative, the chances of the head to be retrieved are lower.

[13]In case of number, we can find many words that are formally singular, but denote plural entities, for example, nouns like *crowd* or heads of the phrases like *the label on the bottles* that have a distributive interpretation. Gender is usually semantically

and gender, this role is different: they mainly reduce the size of the effect. It would be very interesting to assess their influence on gender agreement attraction in comprehension: we expect that it should be much smaller, as in case of number agreement. Thus, the differences between production and comprehension noted by Tanner et al. (2014) may also be relevant for gender agreement, but the picture revealed by our experiments cannot be explained by them.

In the previous subsection we argued that agreement attraction patterns in comprehension are due to the fact that heads with plural features and M features are resistant to attraction, i.e., that during the retrieval process, they tend to be identified correctly, while the retrieval of heads with other features can be disturbed by attractors. Findings summarized by Franck (2015) show that the stability of head's features should also be relevant for agreement attraction in production. This is further confirmed by the results from Nicol and Wilson (1999) to Yanovich and Fedorova (2006) indicating that heads with M features are indeed more stable when we look at number agreement production in Russian. Based on these data, we would expect to see no errors in MF and MN conditions in production experiments on gender agreement, but this is not what we found.

To address this problem, we should specify in more detail how retrieval may work in comprehension and production. Wagers et al. (2009) who analyze comprehension show that the retrieval account has two versions that may be difficult to tease apart based on the current experimental data. On the one hand, cue-based retrieval may be initiated every time we deal with an agreeing verb. On the other hand, we may predict the features of the upcoming verb relying on the subject NP and initiate retrieval only when our predictions are not met. Both versions give roughly the same results if we assume that when the true subject matches all the cues, it is successfully retrieved in the absolute majority of cases. Then in both scenarios, problems are expected only when we encounter an incorrect verb form and the sentence contains an attractor a non-subject NP that matches the incorrectly specified feature of the verb.

We believe that two similar scenarios can also be distinguished for production: we can decide which features we need on an agreeing predicate while processing the subject or once we get to the predicate. Accordingly, retrieval might be initiated every time we deal with an agreeing predicate or only when a wrong verb form that does not match our predictions is spuriously generated. The models proposed by Solomon and Pearlmutter (2004) or by Badecker and Kuminiak (2007) instantiate the first scenario. For example, Solomon and Pearlmutter argue that attraction in production arises because two nouns, the head of the subject NP and the attractor, are simultaneously active in the syntactic structure, and a wrong agreement controller may be selected. However, we argue for the second scenario below.

To summarize, in comprehension, we construct the set of retrieval cues based on the verb form that is provided to us. As we demonstrated above, different versions of the account share this basic observation. If the first scenario is adopted for production (the features of the upcoming verb are predicted, and retrieval is initiated only when we spuriously generate a wrong verb form), the picture should be quite similar: the set of cues will be based on this form.

However, we do not believe that this scenario is the most plausible. In particular, it implies that we generate the subject NP with all its feature specifications before we turn to the verb. In reality, the process should be much more complicated. On the one hand, we cannot determine the case of an NP before we select the predicate (for example, experiencers may receive nominative, accusative, or dative case in Russian, depending on the verb, so it is impossible to plan a nominative NP having only some abstract V in mind). On the other hand, we cannot select some features of the verb form without looking at the subject.

This leads us to adopt the second scenario, in which the relevant features are retrieved at some point during the derivation, rather than predicted and then rechecked. Then we do expect certain differences between production and comprehension. Namely, under the second production scenario it is not the case that we look for an NP with a particular number or gender feature. Rather, we look for the values of number and gender features inside the subject NP. These features should belong to the head of this NP, but sometimes we spuriously pay attention to the features of other nouns. We hypothesize that feature markedness plays a role in this process, and this is what causes different outcomes in our production and comprehension experiments.

To explain how markedness effects may arise, let us summarize different factors that have been shown to play a role for retrieval. More stable head nouns have more chances to be retrieved than less stable ones. Structurally accessible attractors looking like subjects have more chances to be retrieved than the attractors without these characteristics. This is true both for production and for comprehension. And, independently of these factors, marked features have more chances to be retrieved. In comprehension, when we encounter a particular verb form and construct a set of retrieval cues based on it, different number or gender features do not compete with each other: we always look for a particular value. In production, we need to find the value of the gender feature of the subject NP, there is no value that is provided in advance, thus different values may enter the competition[14]. Thus, production involves competition and comprehension does not, therefore we can observe feature markedness effects in production, but not in comprehension. This is why production and comprehension results for gender agreement are different. We do not observe any differences in case of number agreement because plural is at the same time a more stable feature and a marked one. This is a very tentative hypothesis, so further experiments are necessary to test it or to suggest an alternative explanation for the observed asymmetry between production and comprehension findings.

empty, and when it is not, the conceptual and formal gender typically coincide (and thus the former reinforces the latter). If they do not coincide, it never depends on the properties of modifiers, only on the noun itself (for example, *vrač* "doctor$_M$" can refer both to a man and to a woman in Russian).

[14]In our production experiment, participants were provided with predicates in a particular form. Still, we also expect competition here because participants had to produce a correct form if the provided form was wrong, and to do so, they had to retrieve the subject NP and determine its gender.

Minimal Interference from Possessor Phrases in the Production of Subject-Verb Agreement

Janet L. Nicol[1,2]*, *Andrew Barss*[2] *and Jason E. Barker*[3]

[1] *Department of Linguistics, Program in Cognitive Science, University of Arizona, Tucson, AZ, USA,* [2] *Department of Psychology, Program in Cognitive Science, University of Arizona, Tucson, AZ, USA,* [3] *Formerly Affiliated with Department of Psychology, Program in Cognitive Science, University of Arizona, Tucson, AZ, USA*

We explore the language production process by eliciting subject-verb agreement errors. Participants were asked to create complete sentences from sentence beginnings such as *The elf's/elves' house with the tiny window/windows* and *The statue in the elf's/elves' gardens.* These are subject noun phrases containing a head noun and controller of agreement (*statue*), and two nonheads, a "local noun" (*window(s)/garden(s)*), and a possessor noun (*elf's/elves'*). Past research has shown that a plural nonhead noun (an "attractor") within a subject noun phrase triggers the production of verb agreement errors, and further, that the nearer the attractor to the head noun, the greater the interference. This effect can be interpreted in terms of relative hierarchical distance from the head noun, or via a processing window account, which claims that during production, there is a window in which the head and modifying material may be co-active, and an attractor must be active at the same time as the head to give rise to errors. Using possessors attached at different heights within the same window, we are able to empirically distinguish these accounts. Possessors also allow us to explore two additional issues. First, case marking of local nouns has been shown to reduce agreement errors in languages with "rich" inflectional systems, and we explore whether English speakers attend to case. Secondly, formal syntactic analyses differ regarding the structural position of the possessive marker, and we distinguish them empirically with the relative magnitude of errors produced by possessors and local nouns. Our results show that, across the board, plural possessors are significantly less disruptive to the agreement process than plural local nouns. Proximity to the head noun matters: a possessor directly modifying the head noun induce a significant number of errors, but a possessor within a modifying prepositional phrase did not, though the local noun did. These findings suggest that proximity to a head noun is independent of a "processing window" effect. They also support a noun phrase-internal, case-like analysis of the structural position of the possessive ending and show that even speakers of inflectionally impoverished languages like English are sensitive to morphophonological case-like marking.

Keywords: subject-verb agreement, possessive, possessor, genitive, production error, attraction error, case marking, semantic integration

Nicol JL, Barss A and Barker JE (2016) Minimal Interference from Possessor Phrases in the Production of Subject-Verb Agreement. Front. Psychol. 7:548. doi: 10.3389/fpsyg.2016.00548

INTRODUCTION

When speakers produce language, they need to map the elements of a to-be-conveyed proposition onto an appropriate sentence structure, and keep track of these assignments as the utterance is produced. This process is relatively straight-forward for simple sentences like *The key is shiny*, but becomes more challenging when additional information needs to be encoded. For example, in *The key to the cabinets is shiny*, the subject of the verb is the phrase *the key to the cabinets*; however within this phrase, *key* is the head, and *cabinets* is part of a modifying phrase, and the head noun must be selected as the controller of verb agreement. Speakers need to keep this distinction in mind if they are to produce sensible sentences: for the most part, the head noun is the thing the sentence is about, the main element of the predicate's argument (the key, not the cabinets, is what is shiny), and the element a verb may need to agree with. Occasionally, the process goes awry, and a subject-verb agreement error is the result. Studying the variables that affect the incidence of such errors illuminates the language production process.

Subject-verb agreement errors occur with some regularity in both spoken and written language (Jespersen, 1913/1961; Visser, 1963; Quirk et al., 1985; Bock and Miller, 1991). In a seminal paper, Bock and Miller (1991) elicited errors in the laboratory by presenting participants with sentence beginnings, or *preambles*, and asking them to repeat these and create a sentence ending that included a verb. The results showed that agreement errors arise when a singular head is modified by a prepositional phrase containing a plural noun (typically called the *local noun*, or when it is plural, the *attractor*); e.g., *The key to the cabinets were shiny*. The error is not simply due to participants' forgetting the head and implementing agreement "locally" between the attractor and the verb because *The keys to the cabinet* does not elicit errors at the same rate. One explanation for the difference is that the singular is seen as the default: a plural is derived from the singular by the addition of a marked feature, and this plural feature has an autonomy that allows it to intrude on the number specification of a verb. Since that initial study, a great deal of research has explored the kinds of variables that influence the production of agreement errors, and these have led to a refinement and elaboration of syntactic encoding operations in language production.

The focus of this paper is the production of subject-verb agreement errors in English sentences containing a complex subject noun-phrase that includes a singular head noun and a local noun[1], but also a possessor phrase bearing the possessive marker ["s/"], as in (1) and (2). Our experiments examine possessors in two positions: modifying the head noun, as in (1), and modifying a local noun, as in (2).

(1) The women's subscription to the newsletter...
(2) The subscription to the women's newsletter...

The effects of possessors have, until now, been unexplored. In addition to expanding the range of constructions examined in this experimental paradigm, they permit us to explore two issues: (a) the nature of the structural effects that have been argued to influence the presence and magnitude of errors; and (b) the role of the possessive ending as a potential cue to non-subjecthood in potentially reducing errors, akin to the role that overt case marking has been found to play in several languages.

These two issues, and predictions for our experiments, are detailed below.

Proximity Effects

Previous research has shown that an attractor that appears within a modifier that is adjacent to the head noun triggers more errors than one that is located more distantly from the head noun. Several accounts have been offered for this difference, which make contrasting predictions with respect to the behavior of the two types of possessors in (1)–(2).

First, consider some of the empirical findings. Bock and Cutting (1992) found that an attractor within a prepositional phrase (PP) modifier (e.g., 3 and 5 below) elicits significantly more agreement errors than a plural attractor within a clausal modifier (e.g., 4 and 6), and further, that a plural attractor within a relative clause modifier (e.g., 4) elicits more errors than one in a complement clause (e.g., 6).

(3) The editor of the history books
(4) The editor who rejected the books
(5) The dream about the castles
(6) The dream that Anne inherited the castles

Further proximity effects are presented by Franck et al. (2002), who examined contrasts like the following, in which a plural attractor appears inside one of two PP modifiers with different syntactic attachment heights (see **Figure 1**):

(7) The helicopter for the flights over the canyon
(8) The helicopter for the flight over the canyons

A comparison of error rates associated with these sentence types revealed a substantial difference, with the latter eliciting very few errors.

Bock and Cutting (1992) argued that the difference in error rates between (6) and (3–5) was due to the extent to which the head noun and attractor are co-active, and that because a complement clause contains its own subject and predicate, its contents are insulated, in a sense, from the head, making an attractor less likely to be co-active with the head noun. An attractor within a PP or relative clause modifier is not insulated in this way. A variant of the co-activation view is that of Nicol (1995), who proposes that the verb-valuing operation must occur

[1] All noun phrases have head nouns, but we use the term "head noun" in this article, following common practice in the literature, to refer to the noun that is the structural head of the subject noun phrase, and "local noun" to refer to the head noun of a modifier of the subject head noun. Thus in *the treasure in the cave*, *treasure* is the head noun and *cave* is the local noun.

Throughout the paper, we use the term "noun phrase" to refer to phrases like *the key to the cabinets*, although they are analyzed in some current work as maximal projections of a determiner, i.e., a DP (see **Figures 1–4**). The DP may be thought of as the "extended projection" of the noun (Grimshaw, 1990). For most of the discussion the distinction between an NP and a DP is not important, and we use "noun phrase" due to its familiarity.

We refer to examples like *the elf's house* as a possessive construction, and to *the elf* as the possessor.

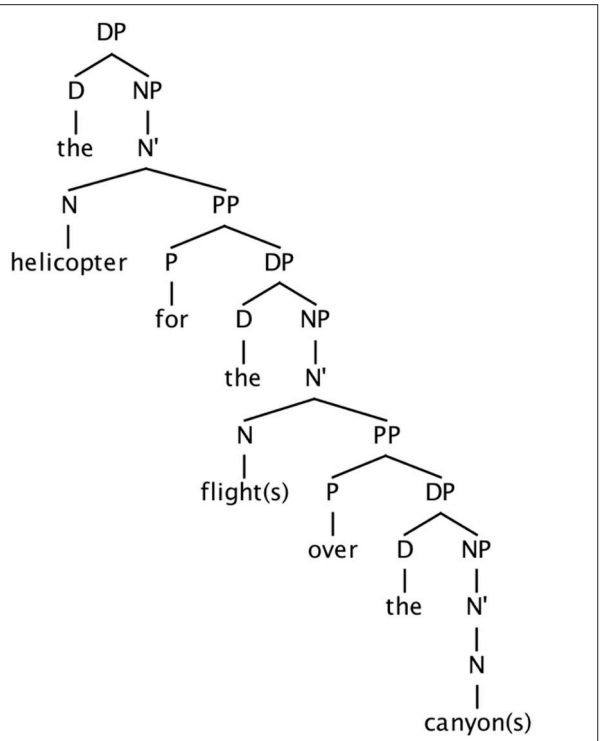

FIGURE 1 | Approximate structure for examples (7) and (8), showing relative embedding of two PP modifiers.

within the limited timeframe in which the subject noun phrase is active. A limited processing window exists, and only noun phrases that are co-active with the head noun (i.e., within the same processing window) will produce errors. This account extends to the complement-clause modifier vs. relative-clause/PP modifier contrast in (3–6), as well as the stacked PP modifiers in (7) and (8). The first modifier noun phrase down [e.g., *flights* in (7)] will be more likely than the deepest modifier (e.g., *canyons*) to be within this processing window, and therefore will be more likely to cause an agreement error. (A similar argument was reiterated by Gillespie and Pearlmutter, 2011).

Note that the processing window hypothesis treats the much lower rate of errors in (6) and (8) as a type of threshold effect: the attractors in those cases lie outside a processing window which includes the head noun and the more local plural attractor in (5) and (7). An attractor is either within the window, in which case it will potentially cause errors, or outside it, in which case error rates will be low. And the experimental results suggest that the processing window including the head noun extends rightward to encompass the first noun phrase, and not the second.

An alternative view is presented by Vigliocco and Nicol (1998). They attributed the difference to *relative* structural proximity of the head noun and attractor: the closer the attractor is to the head noun, the more likely it is to produce an error. In (5) and (7), the plural attractor is closer to the head noun (in terms of hierarchical distance, i.e., nodes separating the two) than the plural attractor is in (6) and (8), and thus more likely to cause errors.

Returning to our possessor phrases in (1) and (2), the two accounts make differing predictions with respect to expected error rates. Note that the possessors are embedded to different extents within the structure of the subject noun phrase. The head-noun-modifying possessor in (1) is more shallowly embedded than the local-noun-modifying possessor in (2), and closer to the head noun. On the relative structural proximity account, head-noun-modifying possessors should produce more errors than the local-noun-modifying possessors. The processing window analysis makes a different prediction: both possessors should lie within the processing window that includes the first PP modifier, and so both types of possessor should produce an equal number of errors. Our experiments compare error rates for the two possessor positions, allowing us to empirically distinguish the two accounts.

The Possessor Ending and Case Marking

A number of studies have examined the effect of case marking of a local noun on attraction errors, and reported that overt case—case marking that is phonologically realized—acts to dampen errors. Case is variation in the form of a noun or determiner that depends on its grammatical function, e.g., subject, object, indirect object, oblique, etc., and is largely redundant with structural information. Yet the additional phonological marking appears to help speakers keep straight which noun is the agreement controller.

Local nouns inflected for case are less likely to produce errors when that case is unambiguously non-nominative (i.e., incompatible with the local noun being the head of a subject noun phrase) relative to local nouns that are either unmarked for case or bear case that could be nominative (i.e., a case marker that is ambiguous between nominative and non-nominative). The logic of this is clear: subject head nouns are typically nominative (either explicitly or covertly marked as such), and a local noun is less likely to become confused with this controller when its morpho-phonology is incompatible with subjecthood. Studies showing this effect include Nicol and Wilson (1999) and Lorimor et al. (2008) for Russian, Hartsuiker et al. (2001) for Dutch, Badecker and Kuminiak (2007) for Slovak, and Nicol and Antón-Méndez (2009) for English.

In the one study conducted on English, Nicol and Antón-Méndez (2009) created English preambles containing as the local noun either a non-casemarked full noun phrase or a case-inflected pronoun. Comparing e.g., *The bill from the accountants...* and *The bill from them...*, they found a significant reduction in the number of agreement errors associated with the case-marked condition. (The rate of agreement errors following the plural pronouns was about 6%, compared with 15% following full noun phrases which were not explicitly case-marked; this reduction in error rate by more than half mirrors that in several of the aforementioned studies).

We note that although case can be manifest somewhat differently in different languages, it always appears internal to the noun phrase[2], a point relevant to our next prediction.

[2]It is encoded synthetically on the English pronouns (Nicol and Antón-Méndez, 2009), as a noun affix in Russian (Nicol and Wilson, 1999; Lorimor et al., 2008), and in Slovak (Badecker and Kuminiak, 2007), and on noun-adjacent determiners

There is a puzzle presented by the prepositional phrase modifier cases that have been extensively studied in English, e.g., *the key to the cabinet(s),* and which robustly produce attraction errors. Although neither the noun nor the determiner in *the cabinets* is casemarked, the presence of the preposition to the left of the determiner has a similar non-subjecthood signaling function: a noun phrase immediately preceded by a preposition is never the subject. Cross-linguistically, there is a close affiliation of case and preposition use. It is something of a puzzle, then, that the presence of case marking dampens agreement errors in a way that the occurrence of a preposition does not. A formal way to resolve this puzzle is to distinguish case marking from prepositions by observing that only the prepositions lie outside the noun phrase, and to conjecture that *only information internal to the noun phrase itself* is capable of acting as a non-subject cue strong enough to significantly reduce agreement errors.

This conjecture is relevant to formal syntactic treatments of the possessive. In the next section we review syntactic analyses of the possessive ending, and note that there is controversy as to whether the ending is part of the possessor phrase structurally (which would put it on a par with case inflection), or a structurally separate phrase-structure head, which would make it more like the noun-phrase-external prepositions which do not dampen agreement errors to the extent that casemarkers do. Exploring errors triggered by possessors offers a way to experimentally distinguish these formal analyses: an overall lower rate of errors with possessors would provide support for the noun phrase-internal view, and an error rate comparable to that with prepositional phrase modifiers would provide support for the noun phrase-external analysis of the possessor ending.

The Phrase Structure of English Possessives

The possessive ending ["s/"] and the possessor phrase that it attaches to have received two distinct types of analysis in formal syntax. The possessor phrase itself occurs as the Specifier of a determiner phrase (DP). On the first type of analysis (Abney, 1987; Zwicky, 1987; Barker, 1991) the possessive ending is analyzed as a phrase-final affix, attached at the right edge of the possessor, as in **Figure 2**. We refer to this analysis as the *noun phrase-internal view* of the possessive ending, since it is both syntactically and morpho-phonologically part of the possessor noun phrase. On this account, the determiner of the overall possessive construction is null. On the second account, the possessive ending is analyzed as a syntactically autonomous determiner, as in **Figure 3**, which then phonologically encliticizes onto the possessor phrase (Abney, 1987; Delsing, 1998; Carnie, 2013). We refer to this as the *noun phrase-external view* of the possessor ending.

What is important for our discussion below about the latter analysis is that the ending is external to the noun phrase syntactically, occurring in a different region of the phrase structure. In this regard it is much like a preposition—occurring adjacent to, but not as a part of, the noun phrase itself. Since

in German (Hartsuiker et al., 2003). In all these cases the morphological expression of case is structurally within the noun phrase.

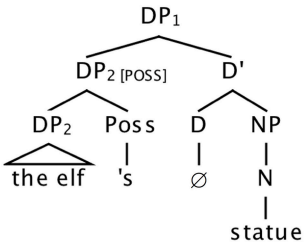

FIGURE 2 | Structure for *the elf's statue*, with possessive ending analyzed as noun phrase-final syntactic clitic.

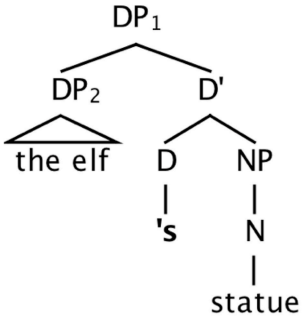

FIGURE 3 | Structure for *the elf's statue*, with possessive ending as a syntactic determiner head, external to the noun phrase/DP.

attractors in prepositional-phrase modifiers robustly elicit errors, the preposition—perhaps due to this structural separation from the noun phrase—apparently does not act as a strong cue for non-subjecthood in the way that noun phrase-internal case marking does in the studies discussed in the previous section showing a dampening effect of case marking.

This pair of contrasting syntactic analyses of the possessor ending leads to differing predictions about the effect that ending will have on agreement errors. If possessors are robust attractors, this will be consistent with the *noun phrase-external* syntactic analysis (**Figure 3**) of the possessor ending, which treats the ending as a syntactically autonomous head, much like a preposition (see **Figure 4**). On the other hand, if possessors are weak attractors, this would be consistent with the analysis of the possessor ending that assimilates it to the class of *noun phrase-internal* case morphology (**Figure 2**).

In our materials, possessors either occur to the left of the head noun, as (9a) (Experiments 1 and 2), or to the right of the head noun (and to the left of the local nouns) when modifying the local noun, as in (9b) (Experiment 3).

(9) a. The elves' statue in the garden
b. The statue in the elves' garden

Before turning to the experiments, we summarize the two sets of predictions we have presented. As noted above, the two possessor positions contrast in proximity to the head noun. Possessors of type (9a) are expected to have a higher error rate due to their greater proximity to the head noun, all other factors being

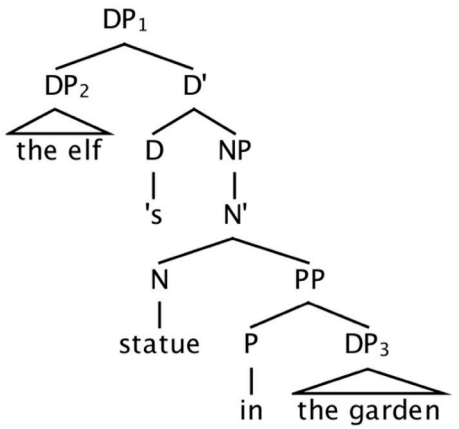

FIGURE 4 | Structure for *the elf's statue in the garden,* showing possessive ending and preposition as DP-adjacent and DP-external heads.

equal, if the relative hierarchical proximity hypothesis (Vigliocco and Nicol, 1998) is the correct account of the locality effects seen in attraction errors. By contrast, the two possessor types should induce equal numbers of errors if the processing window hypothesis (Bock and Cutting, 1992; Nicol, 1995) is correct. And overall error rate for both types of possessors (compared to PP-contained local nouns) will reveal whether the possessor ending functions like noun phrase-internal case information in dampening errors, or a noun phrase-external preposition in not having such an effect.

EXPERIMENT 1—AUDITORILY-PRESENTED PREAMBLES, POSSESSOR MODIFIES HEAD

The purpose of the first experiment was to examine whether a plural possessor phrase modifying the head noun (type 9a) causes interference in the agreement process. For this first experiment, auditory presentation of preambles was chosen, in line with the majority of experiments using the usual paradigm of providing subjects with preambles to turn into complete sentences.

Method

Participants

Forty-four native English-speakers participated in this experiment. Here, and in the studies described below: All were undergraduates at the University of Arizona who received course credit for their participation. They were native English speakers 18 years of age or older. All provided written consent to participate in these experiments, which had received prior approval by the University of Arizona Human Subjects Protection Program.

Materials

Because the stimuli were to be presented auditorily, we needed to ensure that the possessor was unambiguously singular or plural. This meant that we could not use possessors such as *girl's* and *girls'*, because these are homophonous. Therefore, the possessor in our experimental preambles was always a noun with an irregular plural form. The set of possessors included items such as *woman, child, person, housewife, midwife, wolf, thief, elf.*

Twenty quadruplets were such as those in (10) were created. (Here and throughout, preamble types are coded as follows: "s" = singular, "p" = plural, uppercase = head noun. Within the preamble examples, the head noun is underlined and plural nouns are boldfaced).

(10) a. sSs The elf's house with the tiny window...
b. sSp The elf's house with the tiny **windows**...
c. pSs The **elves'** house with the tiny window...
d. pSp The **elves'** house with the tiny **windows**...

Each member of the quadruplet contained a singular head that was preceded by a possessor noun that was singular or plural, and followed by a prepositional phrase modifier containing a singular or plural noun. These were counterbalanced across four presentation lists such that a given participant was presented with only one member of a quadruplet (the full set of experimental items for this and subsequent experiments appear in the Supplementary Material). Each list also included 16 plural-head filler preambles which contained a singular possessor that modified either the head or the (singular or plural) noun within a PP modifier. In addition, there were 64 preambles that were the focus of a separate experiment. These contained a head noun followed by a PP and relative clause modifier; each of the three nouns was singular in half the items and plural in the other half. Finally, there were eight fillers that contained a head noun followed by a PP modifier; each of the two nouns was singular in half of the items and plural in the other half. The preambles were arranged in a fixed pseudorandom order (the same order for each list), and preceded by four practice items. The preambles were recorded by a female speaker.

Procedure

Participants were tested individually in a small test room. Preambles were presented auditorily over headphones. Participants were instructed to repeat each preamble and form a sensible completion. All utterances were recorded for transcription purposes.

Scoring

Transcribed sentences were scored using the following response categories: (a) Correct Inflected (the preamble was repeated correctly and the correct form of an inflected verb was used); (b) Correct Uninflected (the preamble was repeated correctly and an uninflected verb was used); Agreement Error (the preamble was repeated correctly and an incorrectly inflected verb was used); Other Error (the preamble was incorrectly repeated, and/or the verb was missing, or there was no response).

Analyses

Here, and in the following experiments, analyses of variance were performed on the error data, one with subjects (F1) and one with items (F2) as the random variable.

TABLE 1 | Results of Experiment 1 (Auditory Preambles).

Type	Examples	Agreement error (%)	Correct inflect-ED (%)	Correct uninflected (%)	Other errors (%)
sSs	The elf's house with the tiny window	1	67	22	10
sSp	The elf's house with the tiny **windows**	8	49	19	24
pSs	The **elves**' house with the tiny window	2	57	20	21
pSp	The **elves**' house with the tiny **windows**	12	43	17	28

Percentage of responses in each response category for each preamble type. Preamble examples are coded by type (s = singular, p = plural, uppercase = head). Within preamble examples, the head is underlined, and plurals are boldfaced. (Note: due to rounding error, rows sum to 100% only approximately).

In addition, statistical analyses were performed by fitting a linear mixed-effects model to error scores using logit mixed-effects models (Jaeger, 2008). We used the lme4 and lmerTest packages in R (version 3.2.3; CRAN project; R Development Core Team, 2008). Included in each analysis were by-subject and by-item random intercepts, and, if warranted (i.e., if the random intercepts analysis showed a significant effect), also random slopes. The models contained as fixed and random effects the same factors as in the analyses of variance.

We provide the results of the ANOVAs for each experiment, with a brief reference to the results of the mixed-effects modeling with further details of these results offered in the endnotes.

Results and Discussion

The results are shown in **Table 1**.

More errors were associated with plural local nouns than singular ones. Analyses of variance revealed this to be significant. $F1_{(1,\ 43)} = 29.900$, $p < 0.001$; $F2_{(1,\ 19)} = 19.106$, $p < 0.001$. The effect of possessor number was not significant [$F1_{(1,\ 43)} = 2.342$, $p = 0.113$; $F2_{(1,\ 19)} = 2.021$, $p = 0.171$, and the interaction of the two variables was not significant (p's > 0.33]. Mixed effects modeling showed the same pattern: only the main effect of local noun number was significant[3].

A pairwise test of the two conditions containing only one plural [plural possessor (pSs) and plural local noun (sSp)] revealed a significant difference [$F1_{(1,\ 43)} = 9.38$, $p = 0.002$; $F2_{(1,\ 19)} = 9.73$, $p = 0.002$]. The mixed effects analysis also showed a significant difference[4].

Data for the other response conditions were not analyzed statistically; they are displayed in order to show that for the two preamble types in which a single element is plural (pSs vs. sSp), the "opportunity" for an agreement error (derived by summing agreement errors and correctly inflected verbs) is similar, and that the Correct Uninflected and Other Errors are similar in magnitude.

[3]Linear mixed effects modeling showed a main effect of Local Noun Number (Estimate = −2.2065, $SE = 0.4521$, $z = -4.880$, $p = 1.06e\text{-}06$); the effect of Possessor Number was not significant ($p = 0.125$). The Local Noun Number effect was still significant when by-participant and by-item Local Noun Number random slopes were included (Estimate = 0.08809, $SE = 0.02499$, $t = -3.525$, $p = 0.001431$). A comparison of the models (using X2 tests) showed that inclusion of local noun number random slope provided a better fit to the data.

A model that included the interaction of Possessor Number and Local Noun Number showed the interaction to be nonsignificant ($p = 0.771$).

[4]Mixed effects modeling showed a significant effect of Attractor Type (Possessor vs. Local Noun): Estimate = 1.5956, $SE = 0.5652$. $z = 2.823$, $p = 0.00476$. However, with the inclusion of random slopes, the model failed to converge.

Although possessor number had no statistically significant effect on error production, we note that, numerically, more errors were associated with the plural possessor items than the singular possessor items. This difference could become statistically significant with greater power and a more challenging task. This is the motivation for Experiment 2.

EXPERIMENT 2—VISUALLY-PRESENTED PREAMBLES, POSSESSOR MODIFIES HEAD

In this experiment, we used a visual mode of presentation of stimuli in order to increase the overall error rate. Past experiments from our lab have indicated that visual presentation typically results in more errors than auditory presentation. Visual presentation also allowed us to use orthographically distinct cases such as *girl's* vs. *girls'* so that we could increase the number of preambles. Finally, in order to further increase the production of usable data, we included an adjectival ending to promote the use of the copula, which is inflected for number.

Method

Participants

There were 40 participants in this experiment, drawn from the same population as Experiment 1.

Materials and Procedure

Each preamble was paired with an adjective that participants would be asked to use in their sentence completions. We used the 20 quadruplets used in Experiment 1 and created 20 additional quadruplets, for a total of 32. These were counterbalanced across four presentation lists, as described above. Each list also contained 56 filler preambles. Twenty-four of these contained a plural head modified by a singular or plural possessor and by PP containing a singular or plural head. There were also 32 preambles containing a head and PP. Of these, 20 contained a plural head and singular or plural local noun and 12 contained a singular head and singular or plural local noun. Across the set of 88 items, half contained a singular head and half contained a plural head. The preambles were presented in a different random order to each subject, but always preceded by 8 practice trials.

During the experiment, the preamble appeared along with an adjective, as follows: *The elf's house with the tiny window... cute*. Each preamble appeared for approximately 2 s. Participants were asked to silently read each preamble and adjective and then say a

TABLE 2 | Results of Experiment 2 (Visual Preambles).

Type	Examples	Agreement error (%)	Correct inflect-ED (%)	Correct uninflected (%)	Other errors (%)
sSs	The elf's house with the tiny window...cute	4	95	0	2.0
sSp	The elf's house with the tiny **windows**...cute	28	69	0.6	1.0
pSs	The **elves**' house with the tiny window...cute	11	88	0	0.2
pSp	The **elves**' house with the tiny **windows**...cute	35	63	0.3	0.3

Percentages of responses in each category, for each preamble type.

complete sentence out loud. They pressed a foot-pedal to advance to the next item.

Scoring and Analyses

The same response categories and statistical analyses described previously were used here.

Results and Discussion

The results appear in **Table 2**. As the table shows, the error rates were indeed higher than in Experiment 1.

Analyses of variance revealed a significant effect of possessor number [$F1_{(1, 39)} = 10.75$; $p = 0.002$; $F2_{(1, 31)} = 28.63$, $p < 0.001$], and a robust effect of local noun number [$F1_{(1, 39)} = 66.62$, $p < 0.001$; $F2_{(1, 31)} = 88.07$, $p < 0.001$]. The two factors did not significantly interact (p's = 1.0). Mixed effects modeling showed significant main effects, but also a marginal interaction[5].

A comparison of the sSp condition (e.g., *The elf's house with the tiny windows...*) with the pSs condition (e.g., *The elves' house with the tiny window...*) reveals a significant difference between the two, shown by ANOVAs [$F1_{(1, 39)} = 32.94$; $p < 0.001$; $F2_{(1, 31)} = 41.59$; $p < 0.001$] and mixed effect modeling[6].

Data from the other categories were not analyzed statistically. The percentages of correctly inflected verbs complement the Agreement Error results. Very few uninflected verbs were used, and there were very few errors in the Other category.

These results show that, within this more challenging task, plural possessors can induce attraction errors, though significantly fewer than plural local nouns. Further, the presence of a plural possessor and plural local noun appear to have additive effects, resulting in a relatively high rate of errors in the pSp condition.

The next study investigates whether increasing the distance between a potential attractor and the head reduces the potency of the attractor.

EXPERIMENT 3—VISUALLY-PRESENTED PREAMBLES, POSSESSOR MODIFIES LOCAL NOUN

This experiment was conducted in order to explore the effect of a plural possessor when it appeared with the local noun. Just as in the previous experiments, local noun number was also manipulated. Here, it is especially important to show that local nouns induce attraction effects; if the local noun induces errors, it must be co-active with the head, and if it is, then the possessor must also be co-active with the head.

Method

Participants

There were 40 participants in this experiment; again drawn from the same pool as in the previous experiments.

Materials and Procedure

The materials from Experiment 2 were revised to create sensible preambles containing local nouns modified by possessor phrases. Within each quadruplet, the head noun was always singular, the possessor was either singular or plural, and the local noun was either singular or plural [see the examples in (11)]. The filler items were identical to those used in Experiment 2, except that in the 24 fillers containing possessors, the possessor now appeared with the local noun.

(11) a. Sss The statue in the elf's garden ... amusing.
b. Ssp The statue in the elf's **gardens** ... amusing.
c. Sps The statue in the **elves'** garden ... amusing.
d. Spp The statue in the **elves' gardens** ... amusing.

The procedure was identical to that of Experiment 2.

Scoring and Analyses

These were identical to those used in Experiments 1 and 2.

Results

The percentages of agreement errors across conditions appear in **Table 3**.

[5]The mixed effects analysis of the data from Experiment 2 showed a significant effect of Possessor Number (Estimate = 0.5577, $SE = 0.1593$, $z = -3.502$, $p = 0.000462$); with the inclusion of Possessor Number random slope, this was still significant (Estimate = −0.06875, $SE = 0.02200$, $z = -3.126$, $p = 0.0035$. (This model was no better than the original model).

Local Noun Number was also significant (Estimate = −1.9620, $SE = 0.1842$, $z = -10.652$, $p < 2e\text{-}16$); and still significant when the model included Local Noun Number random slope (Estimate = −0.24063, $SE = 0.03573$, $t = -6.734$, $p = 2.31e\text{-}08$). This model was significantly better than the original.

A model that included the interaction of the two variables showed a just significant effect Estimate = −0.7559, $SE = 0.3845$, $z = -1.966$, $p = 0.049328$). Analyses that also included Local Noun Number random slopes showed only a marginal interaction effect (Estimate = −0.7484, $SE = 0.3953$, $z = -1.893$, $p = 0.058295$). The model that included Possessor Number random slopes failed to converge. A comparison of the first two models showed the second to be a better fit.

[6]The pairwise comparison of the plural possessor vs. the plural local noun conditions showed a significant effect (Estimate = 1.2290, $SE = 0.2244$, $z = 5.478$, $p = 4.31e\text{-}08$) that held up when random slopes were included (Estimate = 0.17188, $SE = 0.04011$, $t = 4.285$, $p = 0.000103$). A comparison of the two models reveals the second to be better than the first.

TABLE 3 | Results of Experiment 3 (Visual Preambles).

Type	Examples	Agreement error (%)	Correct Inflect-ED (%)	Correct uninflected (%)	Other errors (%)
Sss	The statue in the elf's garden...amusing	4	92	2	3
Ssp	The statue in the elf's **gardens**...amusing	23	66	2	10
Sps	The statue in the **elves'** garden...amusing	6	89	1	4
Spp	The statue in the **elves' gardens**...amusing	24	64	1	10

Percentages of responses in each category, for each preamble type.

Statistical analyses of the agreement errors revealed a robust effect of local noun number [$F1_{(1, 39)} = 79.77$, $p < 0.001$; $F2_{(1, 31)} = 104.52$, $p < 0.001$], and a non-significant effect of possessor number [$F1_{(1, 39)} = .92$, $p = 0.343$; $F2_{(1, 31)} = 1.05$, $p = 0.307$]. The interaction of the two variables was not significant (p's = 1.0). A comparison of the conditions in which only one element was plural—Sps vs. Ssp—revealed a significant difference [$F1_{(1, 39)} = 43.45$, $p < 0.001$; $F2_{(1, 31)} = 40.76$, $p < 0.001$]. The effects appear not to be additive. Results of mixed effects modeling showed exactly the same effects[7].

In contrast to Experiment 2, the appearance of a plural possessor downstream from the head has virtually no effect on the rate of agreement errors. A comparison of error rates across Experiments 2 and 3 for the conditions in which a plural possessor appeared with a singular head and local noun (pSs vs. Sps) revealed a significant difference by both ANOVA [$F1_{(1, 78)} = 5.6$, $p = 0.02$; $F2_{(1, 62)} = 6.02$, 0.017], and mixed-effect analyses[8].

Discussion

Overall, our results have shown the following: (a) The closer the possessor attractor to the head noun, the greater the likelihood of verb agreement errors. This cannot be reducible to a processing window effect because the local noun attractor in downstream position does produce errors (showing that it is within the same processing window as the head), providing support for the relative proximity hypothesis. (b) Plural possessors in general induce few errors, suggesting that the cue to non-headedness provided by the possessive ending is robust in the same way overt case-marking is, and quite distinct from the cue that is specified by a preposition, lending support for the noun phrase-internal syntactic analysis of the possessive ending.

This latter result is consistent with findings for case-marking languages like Russian (Nicol and Wilson, 1999; Lorimor et al., 2008), which show low rates of error. But note that some of the research on case-marking languages has shown that phonological distinctiveness also plays a role. For example, Hartsuiker et al. (2003) found that an attractor with unambiguous non-nominative case marking induced fewer errors than a case-ambiguous attractor. We observe that the two variants of the possessive ending, ['s] and ['], differ in salience (both phonological and orthographic), and question whether salience plays a role in the effectiveness with which the possessor ending dampens errors.

In order to assess whether this kind of form-related distinctiveness played a role in our studies, we conducted a *post-hoc* analysis of the data from Experiment 2, the only experiment in which possessor number had a significant effect. We divided the items into two groups: plural possessors which marked the possessive with the morpheme –s (e.g., *policewomen's, children's, councilmen's*, etc...) vs. those which marked the possessive only with an apostrophe (e.g., *companies', families', elves'*). The former set of materials contained 15 items; the latter set 17 items. The mean percentages of agreement errors are displayed in **Table 4**.

As **Table 4** shows, there were more errors when case-marking was less salient (orthographically and phonologically).

ANOVAs showed a main effect of case-marking type [$F1_{(1, 39)} = 12.75$, $p = 0.001$; $F2_{(1, 30)} = 6.73$, $p = 0.015$]. Type of case-marking did not interact with possessor number. Linear mixed effects analyses showed the same effects[9].

Overall, then, we have seen that both structural and morphophonological variables affect the rate of agreement errors. But we can flesh out the picture even further by investigating semantic effects.

Research by Pearlmutter and his colleagues (e.g., Solomon and Pearlmutter, 2004; and by Brehm and Bock, 2013) has shown that the extent to which a head and local noun are integrated—in a semantic sense—affects whether the ensuing verb is singular or plural. For example, the component elements *drawing* and *flowers* are more tightly integrated in *the drawing of the flowers* than in *the drawing with the flowers*. Interestingly, although Solomon and Pearlmutter (2004) found more agreement errors associated with preambles of the former type (the "of" preambles) than the latter, Brehm and Bock (2013) found the opposite. Brehm and Bock posit that highly integrated

[7]Analysis of Experiment 3 data showed a significant effect of only Local Noun Number (Estimate = −1.9738, $SE = 0.2152$, $z = -9.172$, $p = <$ 2e-16). Inclusion of Local Noun Number random slopes: Estimate = −0.18750, $SE = 0.02765$, $t = -6.780$, $p =$ 5.43e-08). Chi-square analysis shows the latter to better fit the data than the former.

The effect of Possessor Number was not significant ($p = 0.261$).

Mixed effects modeling that included the interaction of the two variables was not significant ($p = 0.430$).

The comparison of the sPs and ssP conditions showed a significant effect (Estimate = 1.7694, $SE = 0.2994$, $z = 5.911$, $p =$ 3.41e-09) that was maintained with the addition of random slopes (Estimate = 0.17188, $SE = 0.04011$, $t = 4.285$, $p = 0.000103$). Comparison of the two models indicated the latter to be superior.

[8]The effect of the plural possessor in different positions within the complex noun phrase subject was analyzed. Linear mixed effect modeling revealed a significant effect (Estimate = −0.7751, $SE = 0.3630$, $z = -2.135$, $p = 0.0327$) that remained significant with the inclusion of random slopes (Estimate = −0.05304, $SE = 0.02526$, $t = -2.100$, $p = 0.0398$). A chi-square test showed the latter model to better fit the data.

[9]Mixed modeling analysis of Case-marking Type: Estimate = 0.6197, $SE = 0.2331$, $z = 2.659$, $p = 0.00784$. With Case-marking Type random slopes: Estimate = 0.07588, $SE = 0.03055$, $t = 2.484$, $p = 0.018964$).

phrases such as *the drawing of the flowers* are simply more likely to be treated as a unitary conceptual object (at what is called the "message level" representation, the conceptual representation that feeds the production system). If such phrases are construed as singular, they will be treated as the unmarked singular in the linguistic representation. In contrast, *the drawing with the flowers* is more likely to be treated at the message level as referring to several objects, and thus would be more likely to be marked linguistically with a plural feature.

In phrases containing PP modifiers, the relationship between the head and local noun is signaled by the preposition. But with possessors, the relationship must be computed based on real-world knowledge. Possessors can serve sometimes as arguments to the head (e.g., bearing the agent role in *the salesman's promise* to *the customers*) but need not. Possessors have a very broad and essentially unlimited range of possible connections to the head noun[10]: *the elf's house* can be the house owned by the elf, occupied by the elf, designed by the elf, in which the elf is kept as a prisoner, where the elf bakes cookies, defended by the elf as a matter of duty, etc...

Do speakers compute these various relationships? To address this question, we divided our materials based on which preposition would be used if the possessor-head relationship were recast as a head-PP relationship, choosing the most appropriate preposition in each case. For example, the *women's position* would be recast as *the position of the women* and the *spokeswomen's announcement* would be recast as *the announcement by the spokeswomen*. The semantic integration/referential subordination notion aligns with the preposition choice in our recasting of our materials. In the cases with high referential subordination, the preposition in the converted materials is *of*, unique among prepositions in having no lexical-semantic meaning (it is, for example, the default preposition used with objects of deverbal nouns: *announce the award, announcement of the award*, where the complement of the verb has no accompanying preposition, and the same thematic role between verb or noun and object is understood). The less integrated, less referentially subordinate possessors tend to be converted with prepositions with lexical meaning: *from, by*, and *to*.

We grouped the "of" versions together (seventeen items), and the other conditions together (fifteen items). Results appear in **Table 5**.

Analyses of variance show a main effect of Encoded-Preposition Type (*of* vs. other): $F1_{(1,\ 39)} = 12.71$, $p = 0.001$, $F2_{(1,\ 30)} = 5.84$, $p = 0.022$). This variable did not interact significantly with the other variables (which is similar to the Brehm and Bock, 2013, findings). Results of linear mixed effects modeling were similar[11].

We found significantly fewer errors associated with the "of" versions, in line with Brehm and Bock's findings (2013).

GENERAL DISCUSSION

Our findings can be summarized as follows.

First, a possessor attractor that is closer to the head induces more agreement errors than one that is more distant from the head, even when the more distant attractor is co-active with the head[12]. The difference between the two possessor positions shows that relative structural proximity to the head noun is a key factor in determining the magnitude of errors, supporting the view of Vigliocco and Nicol (1998), and arguing against a processing window analysis as an alternative to a proximity account (Nicol, 1995).

[10]Some nouns have an inherent argument structure, including relational nouns like *sister*, *friend*, and *mother*, and deverbal nouns like *teacher, author*. With such nouns the dominant reading of the Possessor is that of one of the arguments of the noun, though other readings are available—*the teacher's mother* could be a mother assigned as helper to the teacher, for example. For nouns with no argument structure, the possible semantic connections between the Possessor and noun is unlimited. Partee and Borschev (2003) present the example *John's team*, and observe that it may be the team John owns, founded, works for, is a teammate on, covers as a reporter, is a fan of, runs in a fantasy league, etc. See Partee and Borschev (2003) and Barker (1991) for much discussion.

[11]Possessor semantics (preposition type): Linear mixed effects modeling showed a significant effect of possessor semantics (*of* vs. other): Estimate = 0.6113, *SE* = 0.2338, $z = 2.615$, $p = 0.008925$.
A model that included the interaction of the variables showed a just-significant interaction of possessor number and possessor semantics: Estimate = 0.618546, *SE* =0.309129, $z = 2.001$, $p = 0.0454$. No other interactions were significant.

[12]As shown by the robustness of errors with the local nouns that occur downstream from the possessors, showing them both to be within the same activation window as the subject head noun.

Second, compared to a local noun attractor within a modifying PP, plural possessors are much less robust as attractors. Averaging across Experiments 2 and 3, and using the all-singular condition as a baseline, net rates of attraction (subtracting out errors associated with the all-singular condition) were roughly 21.5% for plural local nouns and 4.5% for plural possessors. We have suggested that one reason possessors induce fewer errors is that they carry *within their form* information that they are nonheads. In contrast, when a local noun is the object of a preposition, information about its nonhead status derives from information that is not inherent in its noun phrase: its position within the complex subject noun phrase structure, and the fact that it is the object of a preposition. We conclude that the possessor ending is an element of the noun phrase itself, on a par with case markers, thus supporting the syntactic analysis shown in **Figure 2**, and arguing against the noun phrase-external analysis of the ending as a separate determiner head (**Figure 3**).

The fact that form information matters is supported by our first *post-hoc* analysis that showed that the more salient the orthographic/phonological cues about the possessor's role, the fewer errors there were, with possessors with more salient marking such as *women's* causing fewer errors than those with less salient marking like *countries'*.

It is interesting to note that the attraction effect elicited by a possessor as a satellite of the local noun induces fewer errors than that caused by a pronoun in local noun position. Recall the study by Nicol and Antón-Méndez (2009). They showed that a case-marked pronoun in local noun position elicited 6.5% verb agreement errors (5.8% if singular-pronoun errors are subtracted, the *net effect*). This is still substantially larger than the 2% net effect observed in Experiment 3. Obviously, cross-experiment comparison must be interpreted with caution. However, possessors and pronouns are both case-marked, and in the relevant experiments, both intervened between and head and the verb and are roughly the same distance from the root node. In addition, the contrast between singular vs. plural and nominative vs. accusative forms (e.g., *he/him* vs. *they/them*) is more salient than the contrasts in the experiments here. If salience reduces errors, it is even more surprising that pronouns are relatively more powerful attractors. We conjectured that this may be tied to the message level representations of pronouns vs. possessives, specifically with respect to the degree of semantic integration involved.

Our results suggest that the semantic integration between the head and its possessor also matters: when the possessor merely possesses (as in *the elves' house*), fewer errors result than when the possessor is a creator or recipient (e.g., *the congressmen's telegram*). One way in which integration can be understood is that in cases of high integration one entity (the referent of the head noun) is referentially dominant and foregrounded, with the other(s) subordinate to it; this will encourage a singular construal of cases like *the drawing of the flowers*. This referential subordination is reflected in one's intuitions about whether both entities are called to mind with more equal foregrounding. In the case of our possessives, *the elves' house,* plausibly gives rise to a house-dominant conceptual representation, while *the congressmen's telegram* could elicit a representation in which congressmen and telegram are both highlighted (perhaps reflecting the fact that the specifics of a telegram are dependent upon the type of author).

This set of results is consistent with the dominant theory of how verb agreement is computed during language production: the Marking and Morphing model proposed by Bock and colleagues (e.g., Bock et al., 2001; Eberhard et al., 2005). This model assumes a multi-staged architecture in which processing proceeds from top to bottom. First, a non-linguistic proposition (the *message*) leads to the selection of abstract (non-phonological) lexical representations that correspond to concepts within the message, and simultaneously to the computation of a predicate-argument structure. Within the message representation, the roles of the participants are identified, and this information is transmitted to, and coded within, the predicate-argument structure. This includes information about whether, for example, the subject as a whole is singular or plural, and whether the elements that comprise the subject (like modifier-contained noun phrases) are singular or plural. In addition, components of the predicate-argument structure are linked to the abstract lexical representations such that a given lexical item may be assigned to a theme/object role, etc.... At a second stage, a phrasal structure is computed; this structure inherits grammatical number features from the predicate-argument structure. (Other grammatical features are inherited as well, including definiteness, verb tense, and so forth). Verb number is specified via a copying operation that copies number marking from the subject phrase to the verb. Ultimately, form information associated with the selected lexical items is retrieved and slotted into position within the phrasal structure, and inflectional and other grammatical elements are also phonologically realized.

There are two ways for an agreement error to arise. One is during the *marking* process, in which a subject phrase is marked as singular or plural based on its conceptual representation within the message (see also, Vigliocco and Franck's, 1999 *Maximal Input Hypothesis*). Semantic integration of a complex subject exerts its influence here. Following our discussion above, a conceptual level representation corresponding to *The elves' house* will likely be determined to be singular (referring to a singular entity), and marked as such. By comparison, *The congressmen's telegram* will slightly more often receive plural marking, if the message-level representation highlights both congressmen and a telegram.

The other way an error arises within this model is during the later *morphing* process. Morphing involves a set of operations that include connecting lexical information to positions within a syntactic frame that is annotated for number (and other grammatical features), and copying the number feature from the subject noun phrase to the verb (or inflectional node). Part of this process also includes the possibility of percolation of the number feature from the head noun to the root node of the subject phrase. Percolation is a way for the number specification of a head noun to modify the number specification of the subject phrase at the root node (this is described as a "reconciliation" process). (This mechanism is necessary to accommodate cases in which notional number and grammatical number diverge, such

as *scissors*, a singular entity with plural marking. If *scissors* is the head, the plural feature percolates to the highest node, effectively turning the subject phrase plural, and triggering plural agreement with the verb). Occasionally, a plural feature from the wrong noun can percolate to the subject's root node, leading to a verb agreement error. The more deeply embedded the attractor, the less likely it is that percolation of a feature would be able to overwrite the phrasal feature. Our results are consistent with this: the greater the distance between a plural possessor and head noun, the smaller its impact.

Morphophonological effects to do with case marking also come about during the morphing process. Bock and Middleton (2011) describe the effect of case ambiguity as follows: "A plausible consequence of this ambiguity is a sparse or unstable feature set when such nouns serve as agreement controllers...this would induce competition between the (intended) nominative and (uninvited but consorting) accusative. In turn, competition increases the likelihood of attraction, which arises when the morphological specifications of an attractor occupy the feature set of the controller." (p. 1052). In our preambles, the head noun was always case-ambiguous, and therefore subject to competition from the other two nouns, the local noun and the possessor. The local noun was also case-ambiguous, offering greater competition with the head than the case-marked possessor. But in order for case-marking to be useful, it needs to be noticed; our *post-hoc* analysis show that within the set of case-marked possessors, more salient phonological/orthographic case-marking was associated with fewer errors.

CONCLUSION

The present results extend the empirical domain of studies of the production of verb agreement by examining possessors, previously unstudied. We have experimentally investigated the magnitude of errors induced by possessors in two positions differing in structural proximity to the head noun, both in comparison to one another and to local nouns in the canonical position investigated in much previous research. We have shown that the higher possessor produces errors at a greater magnitude than the lower, and that both types induce fewer errors than a local noun. These results show that proximity to the head noun matters, and further that some property of possessors significantly dampens errors with this type of phrase, a property we have identified as case marking.

These results bear on three theoretical issues in the account of agreement production. The first is the nature of the proximity effect, where we have argued from the asymmetry between head-modifying and local-noun modifying possessors that relative structural proximity to the head noun plays a key role. The second issue is the role that the possessor ending has in modulating errors, where we have argued it plays a role akin to case marking in richly inflected languages, thus showing English speakers attend to case in spite of the relative lack of case in that language. We have also noted that the salience of the two variants of this ending affects the magnitude of errors, as does the semantic integration of the possessor with the noun it modifies. Finally, we have argued that the psycholinguistic results bear upon the formal syntactic analysis of the possessor ending.

AUTHOR CONTRIBUTIONS

JN conceived of study, created materials, oversaw lab in which experiments were run, conducted statistical analyses and *post-hoc* analyses, cowrote paper. AB provided linguistic expertise and cowrote paper. JB set up experiments to run, supervised testing of subjects and coding of data, did preliminary statistical analyses.

Language Processing as Cue Integration: Grounding the Psychology of Language in Perception and Neurophysiology

Andrea E. Martin *

Department of Psychology, School of Philosophy, Psychology and Language Sciences, University of Edinburgh, Edinburgh, UK

I argue that cue integration, a psychophysiological mechanism from vision and multisensory perception, offers a computational linking hypothesis between psycholinguistic theory and neurobiological models of language. I propose that this mechanism, which incorporates probabilistic estimates of a cue's reliability, might function in language processing from the perception of a phoneme to the comprehension of a phrase structure. I briefly consider the implications of the cue integration hypothesis for an integrated theory of language that includes acquisition, production, dialogue and bilingualism, while grounding the hypothesis in canonical neural computation.

Keywords: language comprehension, sentence processing, cue-based retrieval, cue integration, neurobiology of language

INTRODUCTION

Despite major advances in the last decades of language research, the linking hypothesis between ever-more plausible neurobiological models of language and ever-better empirically supported psycholinguistic models is weak, if not absent. Moreover, we are struggling to answer, and even to ask well, questions like *why is language behavior the way it is? How is language processed? What is "processing difficulty?" What is the source of difficulty in psychological and neurobiological terms? What can it tell us about the computational architecture of the language system?* These questions, however frustratingly difficult, speak to our persistent awe at the fact that we humans flap our articulators, we move the air, and in doing so, stimulate formally-describable complex meaning in the heads of other people. And then those people usually do it to us back. So how do we, or rather, our brains, do it?

There must be a good reason for the weak link between psycho- and neurobiological theories of language—namely that it is really hard to find a concept that would be explanatory on multiple levels of analysis in cognitive science (see Marr, 1982). Questions like *what makes language the way it is* probe the computational level of Marr's tri-level hypothesis, asking what the system's goal is, what computation is being performed and to what end. Questions like *how does the system do it* occur at the algorithmic level, asking what the nature of the mechanism that carries out the computation is. Recent debates in cognitive science have cast these two kinds of questions in opposition, or at least, in opposing theoretical camps. Bayesian modelers of perception and cognition form the statistical *what* camp, and non-Bayesians the mechanistic *how* camp (Jones and Love, 2011; Bowers and Davis, 2012). The *what* camp is purportedly less interested in how the mind "does it," but is focused on reverse engineering how

the natural world (or the statistics that describe it) makes cognition the way it is. The *how* camp purportedly wants to uncover the mechanism that the mind/brain uses, instead of a statistical approximation (Jones and Love, 2011; Bowers and Davis, 2012). I will argue that any model of language computation must answer both *how* and *what* questions, and the best model will most likely include both mechanistic and probabilistic elements. The model articulated here asserts a mechanistic psychological operation over representations derived via Bayesian inference (or an approximation there of), which are represented by neural population codes that are flexibly combined using two simple canonical neural computations: summation and normalization.

Rather than trying derive novel psychological mechanisms specific to language, I will ask whether insights from perception and psychophysiology can inform process models of psycholinguistic theory to try to explain why language behavior is the way it is *and* how formal linguistic representations might be extracted from sensory input and represented by the brain. First, I will briefly consider two recent advances in psycholinguistic theory, the Cue-based Retrieval framework (CBR) and Expectation-based parsing (EBP), which have shaped the field in the last decade. Then I will briefly explore the implications of sensory processing models in order to argue that the main insights of these frameworks can be transferred to psycholinguistics as a single mechanism derived from neurobiological principles. Then I will attempt to apply this principle to sentence comprehension, and briefly explore its implications for production, dialogue, language acquisition, and bilingualism. Finally, I will try to deliver predictions that could falsify this approach.

Two Influential Theories: Cue-Based Retrieval and Expectation-Based Parsing

The cue-based retrieval framework offers an account for processing difficulty in language comprehension that is based on architectures and mechanisms from human memory, specifically recognition memory (McElree, 2000; McElree et al., 2003; Lewis et al., 2006). It originates from the classic insight that retrieval from memory might be needed to form grammatical interpretations, especially for syntactic structures where words that form a linguistic dependency are separated from each other by other words (Miller and Chomsky, 1963). Quite naturally then, CBR has focused on non-adjacent dependencies of different kinds, mostly subject-verb dependencies (McElree, 2000; McElree et al., 2003; Lewis et al., 2006; Van Dyke, 2007; Wagers et al., 2009; Van Dyke and McElree, 2011; Tanner et al., 2014) but also pronouns, ellipsis and other situations with referential or anaphoric consequences (Foraker and McElree, 2007; Martin and McElree, 2008, 2009, 2011; Xiang et al., 2009; Martin et al., 2012, 2014; Dillon et al., 2013; Jäger et al., 2015).

The appeal of the cue-based framework is the parsimony of explanation—language behavior is the way it is because of the architecture of human memory. Memory is *content-addressable*[1], or organized by content, and therefore is highly susceptible to interference (see McElree, 2000; McElree et al., 2003; Lewis and Vasishth, 2005; Lewis et al., 2006; and see McElree, 2006; Van Dyke and Johns, 2012, for reviews). Interference occurs when the link between the cues used at retrieval and the intended target representation is not diagnostic (McElree, 2000, 2006; McElree et al., 2003; Martin et al., 2012). Therefore, according to CBR, processing difficulty in language comprehension is due to interference[2], or more specifically, *cue overload*, the term for the situation when the cues at retrieval are insufficient to elicit the needed representation (McElree, 2006; Van Dyke and McElree, 2011; Van Dyke and Johns, 2012). Whether cue overload arises purely due to similarity between representations and cues, or whether distinctive items in memory are somehow disruptive during retrieval, is an on-going challenging question (see Jäger et al., 2015, for an overview on effect reversals for pronouns). Another important architectural assumption of CBR is that retrieval speed is constant, so effects on performance (either accuracy or reaction time) arise from differences in representation, namely cue-target match vs. the match of the cue to other items in memory (McElree, 2006; see Nairne, 2002 for more on diagnostic cues). Additionally, representations appear to be retrieved without a serial or parallel search (see Townsend and Ashby, 1983; McElree and Dosher, 1989, 1993; Martin and McElree, 2009, for details on how parallel search is falsified). CBR has been well-implemented: Lewis and Vasishth (2005) and Lewis et al. (2006) describe compelling symbolic models of parsing implemented with only one additional parameter than the standard ACT-R model (Anderson, 1983).

Expectation-based parsing has focused on modeling classic sentence processing phenomena (syntactic ambiguity resolution and relative clause processing asymmetries) in a Bayesian framework (Hale, 2001; Levy, 2008, 2013; Smith and Levy, 2013). The approach aim to predict which parts of a sentence will be more difficult to process as reflected in behavioral measures. It marks a renaissance for the role of expectation and its formalization in psycholinguistic theory (cf. MacDonald et al., 1994; Altmann and Kamide, 1999; DeLong et al., 2005; Van Berkum et al., 2005). In EBP, parsing decisions are based on probabilities built up from prior experience, and difficulty stems from the violation of word-by-word expectations of syntactic structure. In other words, the main claim is that surprisal, or the degree to which expectations are not met, is the best predictor of reading time slow down and therefore, of processing difficulty (Hale, 2001; Levy, 2008). This striking insight has a lot in common with ideal observer models of perception, which I will review

[1] In contrast to location-addressable systems, where data is stored irrespective of its content and a search must be executed to retrieve a particular target item.

[2] Cue-based retrieval interference, although some psycholinguistic work invokes the notion of *encoding* interference, whereby representations fail to be stably encoded when there are multiple similar items in memory (Hofmeister and Vasishth, 2014). However, the spirit of that notion is usually cached out as *proactiveinterference* in the recognition memory literature, whereby forgetting occurs due to information learned or encoded prior to the onset of the study item, but is still due to cue-overload (Anderson and Neely, 1996; Öztekin and McElree, 2007; Martin and McElree, 2009; Van Dyke and McElree, 2011; Van Dyke and Johns, 2012). Retroactive interference refers to forgetting due to information acquired after the onset of the study item (Gillund and Shiffrin, 1984; Anderson and Neely, 1996; McElree, 2006).

shortly, by virtue of the fact that both are rational and formalized with Bayes' rule. EBP continues the tradition of frequentist accounts of parsing (e.g., MacDonald et al., 1994) and statistical learning in psycholinguistics (e.g., Charniak, 1996; Saffran et al., 1996; Tabor et al., 1997; MacDonald and Christiansen, 2002). EBP's advantage over previous statistical learning accounts might be that it is formalized with a probabilistic grammar and can be highly predictive of which parse or *where* in a structure difficulty will be encountered (Levy, 2008).

Challenges for CBR and EBP

Each of these approaches is motivated by the central challenge of parsing: incorporating incoming, new information (phonemes, syllables, morphemes, or lexical items) into a continuously unfolding complex representation. Each approach brings an important insight from a related areas of cognitive science to bear on language processing: (1) for CBR, the parsimony of ACT-R principles and the explanatory concepts of cues and interference, and (2) for EBP, the vital importance of prior experience and expectations, and of formalizing uncertainty. Despite these important insights, the architectural claims that each approach makes are not fully articulated. CBR and EBP might tell us about how an aspect of language processing is carried out, but many questions remain about the nature of the representations and mechanistic processes that are at stake.

The beauty of CBR is that its principles are independently motivated by the architecture of human memory. But despite this, many issues still need to be resolved. First, the psychological mechanism that the additional CBR parameter might correspond to would need to be hypothesized about and tested. Larger architectural questions persist, such as whether retrieval is identical during lexical access and dependency resolution, and whether additional mechanisms besides retrieval might be needed for a fully specified model of parsing. More fundamentally, if grounding language processing in memory processes is what gives explanatory power, then difficult issues about memory processes, such as whether encoding and retrieval ever really separate, need also be addressed. Similarly, complex questions about cues remain: why some representations function as cues and other not, how cues are learned and represented, and how their weights are determined, and whether those weights are determined dynamically all need to be established. The *how* questions might be clearer in CBR, but the answer to *what* questions is offloaded onto memory research.

Similarly, though Levy and colleagues have exacting predictions as to where in a sentence reading slow down will occur, EBP's explanation for "processing difficulty" is not psychological or mechanistic in nature. It is computationally descriptive: re-ranking of probability distributions regarding expected input. Re-ranking of probability distributions actually has a neurophysiological appeal, but is not yet a psychological concept. Since EBP focuses on capturing extant behavioral data patterns and predicting patterns of reading slow down, rather than deriving representational states and processing mechanisms that are both neurobiologically and psychologically plausible, it is not clear how EBP would answer *how* questions. Simply put, EBP is not a process model. Architectural questions about representation also persist, especially as to which representations are being counted and why, and how are probabilistic estimates of being in a parse given the input are formed. The origin of these representations is also unclear, as is the mechanism that is acquiring the statistics and the mechanism that is re-ranking the distributions. If the claim of EBP is that ranking of probabilistic representations what parsing difficulty is, it begs questions as to how the system parses sequences that it has never encountered before, or how it can parse something that is highly unexpected at all, and moreover, what parsing is qua mechanism. If experience is the basis of obtaining probabilistic estimates of a given structural configuration, then it is unclear how parsing might occur without lots of or sufficient experience. Furthermore, how the system acquires experience about parsing, if experience is what is used to generate representations of the parse and probabilistic estimate regarding it, might lead to a circular explanation.

For these reasons, I see the core principles of interference and representing uncertainty as being valuable terms in a larger mechanistic process model, which, hopefully, can also be grounded in neurophysiological computation. By synthesizing mechanistic and Bayesian approaches, we can pose questions both about how language processing functions and why it is that way. But that does not mean that mapping hypotheses about representations and processes onto hypotheses about their priors is will be straightforward.

Ideal Observer Models in Perception

Ideal observer models have dominated research on perception because they lay bare the computational and statistical structure of the complex problems that the brain solves. They force the researcher to define the information available to the brain, and to construct a quantitative, predictive account of performance (Gibson, 1966; Marr, 1982). The *ideal observer* formally describes human behavior in terms of optimal performance on a given problem or task given uncertainty stemming from the environment or sensory system (Trommershauser et al., 2011). The main source of uncertainty in ideal observer models of visual perception is the probabilistic relationship between a given cue (e.g., contrast, color, shading) and a stimulus (e.g., an edge or object) in the environment. In other words, uncertainty stems from the probability of detection of the stimulus in the face of sensory or neuronal noise (Fetsch et al., 2013). Past experience weights the likelihood function of a cue. Thus Bayesian models that incorporate the right combination of cues and priors have become the best predictors of performance on motor control and visual or multisensory perception tasks (Griffiths et al., 2012; Ma, 2012), although some argue that they need not be Bayesian nor rational to achieve this (Maloney and Zhang, 2010; Rehder, 2011). The psychological mechanism by which the statistical relationship between the state of the environment and internal representation is achieved is not the primary focus of these models, rather finding the formal expression of the statistical relationship between cues, uncertainty, and stimulus such that human behavior is accurately predicted. Once the "right" statistical relationship is uncovered, conclusions can be

drawn about the algorithm that best reflects that relationship, and inference can be made as to whether that is indeed what the brain is doing (Griffiths et al., 2012). This approach implicitly assumes that performance or information is optimized, which, of course, does not have to be the case—in fact, a case can be made that energy efficiency or processing time, not information, are what cognitive systems optimize (Friston, 2010; Markman and Otto, 2011).

In any case, ideal observer models have not been prominent in comprehension and production apart from models of reading, speech perception, and rule learning in language (cf. Legge et al., 1997; Norris, 2006, 2013; Goldwater et al., 2009; Frank et al., 2010; Toscano and McMurray, 2010; McMurray and Jongman, 2011; Norris and Kinoshita, 2012). The paucity of ideal observer models in sentence parsing is particularly striking given that we arguably might know more about the formal descriptions of the representations being processed during language use (i.e., formal linguistic representations, perhaps especially during speech perception) than we do about the formal descriptions of levels of representations for visual objects and scenes, or multi-modal sensory representations. One reason ideal observer models might not have taken theoretical hold in parsing, apart of EBP, might be the difficulty in constraining or separating the likelihoods of language processing outcomes that are embedded in the perceptual tasks (button pressing, reading, and making overt linguistic judgments) that most psycholinguistic studies employ. Differences in the task demands of these paradigms may mask, or at least mix in non-straightforward ways, with reliably estimating "pure" language processing likelihoods. Moreover, the source of priors and how they are acquired and updated remains unknown. However, core principles from ideal observer models of perception, namely that including estimates of uncertainty can expose the nature of the problem the brain solves, may be suitable for the addressing the computational challenges that language processing presents.

Cue Combination and Integration

In both psychophysical and neurobiological models of perception, *cues* are any signal or piece of information that reflect the state of the environment (Fetsch et al., 2013). For example, when perceiving and localizing an object to act on, such as trying to catch a toddler who is screaming while running away from you, one cue is likely the visual contrast information created by the toddler moving across the visual scene, and another is the screaming, or more accurately the change in interaural time of the screams as the toddler moves in relation to your ears. And lastly, cues can come from any proprioceptive or tactile stimulation that is generated as you prepare to grab your toddler before s/he runs into traffic. Our brains combine and integrate these cues, often from different modalities, to form a stable percept upon which to act (see **Figure 1**, Ernst and Bülthoff, 2004). The key to stable and robust perception given sampling uncertainty is the integration of multiple sources of sensory information via two important psychophysiological operations, cue combination and cue integration. *Cue combination* is the process of combining cues via summation, and describes interactions between cues that are not redundant in the information they carry. Cues may be in different units during combination, and may signal complementary aspects of the same environmental property. For example, when knocking on a door, one perceives the knock as emanating from the location where one knocked. This percept is the result of the combination of sensory signals from vision, audition, and proprioception (see **Figure 1**). After cue combination, comes integration, or the weighting of the cues by estimates of their reliability as cue to the true stimulus. *Cue integration* describes an interaction between cues of the same units that may carry redundant signals, and that regard the same aspect of the environment. Evidence across different domains and species implicate cue integration as the mechanism from which stable percepts emerge (Deneve et al., 2001; Ernst and Bülthoff, 2004; Fetsch et al., 2013). Summation is the canonical neural computation, and Carandini and Heeger (2012) argue that normalization, the principle operation underlying cue integration, is also a canonical population-level neural computation for brains of all levels of complexity.

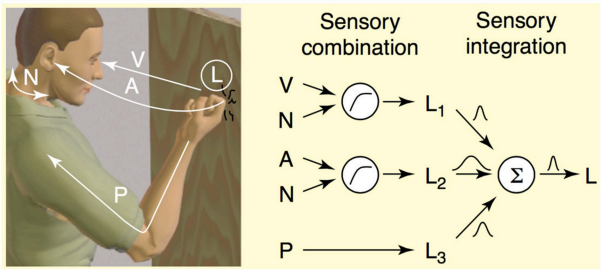

FIGURE 1 | Illustration of cue combination and integration of the perception during knocking on wood from Ernst and Bülthoff (2004). Sensory cue combination occurs between sensory signals that are not redundant, which can be represented in different units or coordinate systems, and which might reflect complementary aspects of the environment, for example visual or auditory information (Ernst and Bülthoff, 2004). This figure from Ernst and Bülthoff (2004) depicts how three sensory estimates about the location (L) of the knocking event are combined to form a stable percept. Information from visual (V), auditory (A), and proprioceptive (P) sensory percepts comprise three different signals about location. Before these signals can be integrated, V and A signals can be combined with the proprioceptive signals (N) to be transformed into body-centric coordinates with the same units. Following that, the three signals (L_1, L_2, L_3) are integrated with their reliabilities to form a coherent percept of the location of the knocking event. Sensory cue integration occurs between so-called redundant signals, or signals that are in the same units or coordinates and that reflect the status of the same aspect of the stimulus in the environment.

Cue integration is typically expressed in an estimate of the likelihood of the stimulus being present in the environment ($\hat{S}$) given the cues[3] ($c_1 ... c_n$) and scaled by the reliability of those cues ($\hat{r}_1 \ldots \hat{r}_n$):

$$\hat{S} = \sum_{i=1}^{n} c_i \hat{r}_i + \ldots c_n \hat{r}_n, \quad \hat{r} = \frac{1}{\sigma_c^2}$$

Equation (1) From Ernst and Bülthoff (2004) the equation above describes the processing moment at the onset of a stimulus. It

[3]Summation of the activation of the neural population tuned to a given stimulus or feature of the environment.

describes the activation state of a neural population that codes for a given sensory representation. This representation can be said to emerge from integrated sensory cues.

An estimate of *cue reliability* ($\hat{r}$) is the inverse variance of the distribution of inferences made based on a given cue (Bülthoff and Yuille, 1996; Jacobs, 2002). The smaller the variance in the relationship between cue and stimulus, the more reliable the cue is. Correlation between cues also affects their reliability: a cue is regarded as more reliable if the inferences based on it are consistent with the inferences based on other cues in the environment (Averbeck et al., 2006). If a cue is inconsistent with other cues, it is regarded unreliable. Studies on cue reliability have shown that cues that have not changed their value in the recent past are weighted more strongly (Jacobs, 2002). Thus, returning to our example of the screaming toddler, cue combination summates activation from the sensory populations associated with the visual, auditory, proprioceptive, and tactile stimuli that issue from chasing a screaming toddler. Upstream from these primary sensory cue population codes, other neural populations code for combined or composite representations of these cues. At each stage of representation, cue integration weights the representation by that cue's reliability. The reliability of combined cues is equal to the sum of the individual cue reliabilities, so the only neurophysiological operations required are summation and normalization (Fetsch et al., 2012). I will discuss the appeal of this point in Section A Neurophysiologically Inspired Mechanism for Neurobiological Models of Language. Whether cue reliability is best thought of as a prior in a Bayesian framework, or as a probabilistic variable in a Statistical Decision Theory framework is an open question (Maloney and Zhang, 2010; Rehder, 2011). In any case, even non-optimal weighting by cue reliability is probably a better estimate than an individual trial data or single sample measurements (Ernst and Bülthoff, 2004).

CAPTURING MULTIPLE DISTINCTIONS IN PARSING

A desideratum of psycholinguistic theory is a taxonomy of the mental representations and computational mechanisms that language use requires. A particularly satisfying theory would unify the mechanisms occurring during diverse computations such as speech perception, word recognition, parsing into phrase structures, establishing referential and agreement relations, forming long-distance dependencies, and forming discourse representations. Such a theory would have general principles derived from domain general canonical neural computations, and would hold for both for comprehension and production. Processing difficulty would be predictable from first principles, that is, from how the representations at stake are generated. Traditionally, mechanistic theories of language comprehension and production have proposed multiple language-specific mechanisms, often operating at distinct levels of linguistic representation. These have been as diverse as lexical access, reanalysis, binding, lemma selection, and unification (Frazier and Fodor, 1978; Marslen-Wilson and Welsh, 1978; Swinney, 1979; Clifton and Frazier, 1989; Ferreira and Henderson, 1991; Levelt, 1999; Hagoort, 2005), or have invoked heuristics like Minimal Attachment, Late Closure, the Active-filler Strategy, Attach Anyway (Frazier and Rayner, 1982; Frazier and Clifton, 1996; Fodor and Inoue, 1998). Other impactful approaches to parsing have focused on metrics to quantify the difficulty of certain structural configurations in terms of capacity limits on memory, or the number of dependencies to be resolved, or the number of parses to be considered, but not on mechanism *per se* (Just and Carpenter, 1992; Gibson, 2000; Vosse and Kempen, 2000). Yet other dynamical systems approaches to parsing derive empirical phenomena, such as *local coherence*, where local match between constituents' features can override the global parse from architectural aspects of the model (Tabor et al., 2004; Tabor and Hutchins, 2004). A notable antecedent psycholinguistic theory based on cues, albeit with a different goal and level of analysis, comes from Bates and MacWhinney (1987)'s Competition Model (CM), a lexicalist framework focused on the acquisition of grammar in the face of the challenge of cross-linguistic variation. As its name suggests, its main processing claim is that lexical representations compete with each another for case and thematic role assignment during comprehension, and that languages differ in how information is expressed via cues. The CM is an important antecedent for cue integration because it invokes both the notions of cues and cue reliability, but in different senses than in the perceptual literature and thus, than herein. It posits that languages vary in how their forms cue meaning, and in how linguistic form and function are related by cues, and is largely concerned with how different linguistic representation types cue argument relations in different languages and how cues and their reliability facilitate language acquisition. However, the framework I will outline draws strongly on the notion of cues and their reliabilities as internal representations, processed by a neurophysiologically plausible mechanism, rather than on cross-linguistic variation in how information is carved up to cue between form and meaning.

In some ways, mechanistic approaches are just as vulnerable to the criticism of falsifiability that Bayesian approaches are—just as you can change the priors to fit your data—you can, similarly, change the number of hypothesized mechanisms at stake, fail to generate falsifiable hypotheses or testable predictions, or arbitrarily change the architectural bottlenecks in your process model to account for your data (Bowers and Davis, 2012; Griffiths et al., 2012). How does one keep from "over fitting" a process model? Moreover, the frameworks that developed past hypothesized language-specific mechanisms were steeped in the modularity debate, which naturally focused on questions about what operations are language specific or not (Fodor, 1983), and whether processes operated in serial or in parallel (Frazier and Clifton, 1996). Though there is less worry now about sterility and modularity of linguistic representation, and more about incrementally in language processing, it remains a fact that the brain can be said to be modular in its organization (Carandini and Heeger, 2012; cf. Fedorenko et al., 2012) though likely with interesting and important overlap or redundancy in coding in diverse systems (e.g., Schneidman et al., 2003; Puchalla et al., 2005; Rothschild et al., 2010). This presents our desired linking hypothesis between psycholinguistic and neurobiological

theories with a conundrum wrapped in a mystery: capturing the incrementally of language processing within a modular system of neural populations, whose coding we do not yet know how to read. In other domains of cognition focused population codes, the relevant questions become: what factors determine the organization of neural populations, what are populations coding for, and how are those representations transformed from population to population (see Pouget et al., 2000; Averbeck et al., 2006)? Translating these questions to a psycholinguistic level of analysis, we then must ask whether signals in brain or behavior that reflect representation of linguistic units can be detected, whether such a modular neural architecture can indeed capture important distinctions for linguistic representation and processing, and whether cue combination and integration alone can account for language processing from speech and visual onset all the way to higher level meaning.

Language Comprehension as Cue Combination and Integration

Can a satisfying analogy can be made between language comprehension and perceiving a complex natural environment? Like object perception or localization, scene perception, or motor control, language processing is multimodal. In conversation, language comprehension minimally involves integration of auditory and visual information[4]. All this must occur while planning and producing language in return. Furthermore, language use is highly goal-directed and joint, an issue that is rapidly gaining theoretical importance (Pickering and Garrod, 2004; Gambi and Pickering, 2013; MacDonald, 2013). But aside from the issues of modality and joint-action, language may present a processing situation that fundamentally differs in the kind of representational relationships that the brain must form in order to explain linguistic taxonomy. Information from multiple, sometimes hierarchical, sources of formally discriminable representations must be perceived from the environment. Extracting linguistic representations from a speech or visual input may be, in some ways, analogous to the binding problem in vision and attention (cf. Treisman, 1999). In both situations, information that is distributed over time and space at different frequencies must be grouped or bound into higher-level representations for processing to occur. Cues, whatever they may be, from each sensory input level are combined and integrated with their reliability estimates, and emerge as a linguistic representation, e.g., a phoneme or phrase. Populations coding the reliability of a given representation as a cue to higher-level representations are activated and updated. Those reliabilities are integrated with the population code representation for a given representation, which in turn produces the next level of representation.

As in the psychophysical literature, most of the explanatory work would be carried out by cues, a notion that is difficult to define both in the positive (what cues are), and in the negative (what can't be a cue). In fact, often the term "cue" is treated as if should be implicitly understood, as in, as if it has no specialist or jargon meaning. In the perception literature, a cue is any sensory information that gives rise to an estimate of the state of the environment (Ernst and Bülthoff, 2004). Here I will augment that definition as follows: a psycholinguistic cue is any internal representation that signals, indicates, or is statistically related to the state of some property of the environment relevant for language processing. Thus, a cue to a given psycholinguistic representation is simply any representation that is reliably related to that given representation, in contrast with a representation that is not related to it. The only way for this simple definition of cue to become explanatory is if it can speak to how abstract linguistic representations might be formed from perceptual inputs, or more specifically, formed from an interaction or convolution of sensory percepts with extant knowledge (read: other representations) in the brain[5]. The problem of satisfactorily defining a cue for functional use in a process model bumps up against the even harder problem of defining mental representation, or defining what perceptual or cognitive features are. Both of these philosophical challenges are, luckily, beyond the scope of this model. However, the functional role of cues may be to simply to map out the structure, path, or links between representations as they are activated in moment-to-moment processing. In this sense, is it not so much what cues precisely are that matters (although that is no doubt an important, troubling question), but which representations cue which other representations to form a map of language processing, from percept to abstract representation that matters for a model. Thus, cues are representations of linguistic input *and* what links those representations in a "chain" for processing from sensory input to abstract representations. I will sketch how a cue integration model might handle processing from speech onset to phrase or sentence comprehension (see **Figure 2** for visual illustration). I simplify the representational levels at stake as: phonemes, syllables, morphemes, words, phrases, syntactic and event structures, and discourse context.

Sensory Resampling to Recover Hierarchical Representations

In the case of linguistic representations, aside from the first perceptual cues to enter the processing stream, further cues must come from the same sensory input: a sort of resampling of the sensory percept, or a form of perceptual inferencing (Ernst and Bülthoff, 2004). This resampling would recover hierarchical representations in memory that are activated by that percept, via the same cue integration mechanism that is hypothesized to work for exogenous cues. In other words, cue integration can take as its input an endogenously stimulated representation or set of sensory features (e.g., phonemes from acoustic features, or on a higher level, morphemes and lexical entries), and output another

[4]Though the highest levels of hierarchical representation are reached via an arguably single modality in phone conversations, sign language, and reading—it is an empirical question as to whether processing in these cases activates linked representations generated from other modalities.

[5]Such an assertion then attributes most of the burden (and magic) of online language processing onto language acquisition. In a system of representation where only cues and their reliabilities are computed to activate the next representation, it is this existing knowledge that parses input and links up the right representations properly. But how in the world are these all important, pre-existing, parse-making representations acquired? See Section Cue Integration in Language Acquisition and Bilingualism for more discussion but no definitive answers.

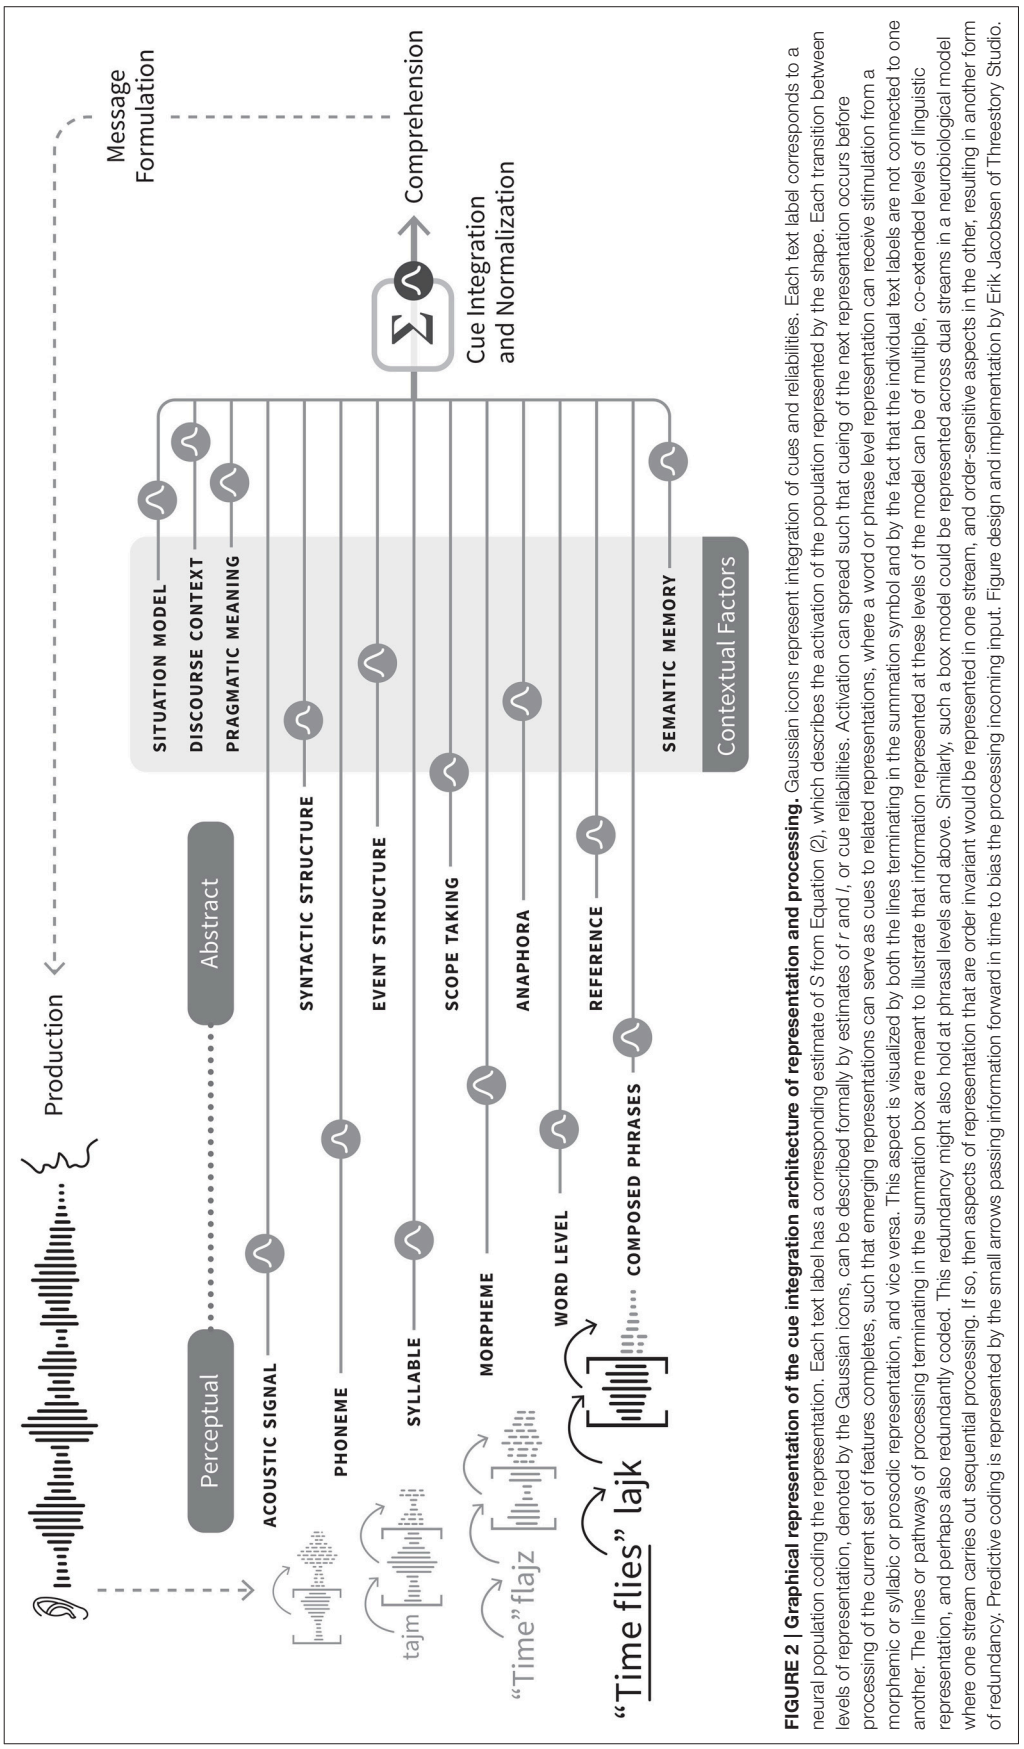

FIGURE 2 | Graphical representation of the cue integration architecture of representation and processing. Gaussian icons represent integration of cues and reliabilities. Each text label corresponds to a neural population coding the representation. Each text label has a corresponding estimate of S from Equation (2), which describes the activation of the population represented by the shape. Each transition between levels of representation, denoted by the Gaussian icons, can be described formally by estimates of *r* and *l*, or cue reliabilities. Activation can spread such that cueing of the next representation occurs before processing of the current set of features completes, such that emerging representations can serve as cues to related representations, where a word or phrase level representation can receive stimulation from a morphemic or syllabic or prosodic representation, and vice versa. This aspect is visualized by both the lines terminating in the summation symbol and by the fact that the individual text labels are not connected to one another. The lines or pathways of processing terminating in the summation box are meant to illustrate that information represented at these levels of the model can be of multiple, co-extended levels of linguistic representation, and perhaps also redundantly coded. This redundancy might also hold at phrasal levels and above. Similarly, such a box model could be represented across dual streams in a neurobiological model where one stream carries out sequential processing. If so, then aspects of representation that are order invariant would be represented in one stream, and order-sensitive aspects in the other, resulting in another form of redundancy. Predictive coding is represented by the small arrows passing information forward in time to bias the processing incoming input. Figure design and implementation by Erik Jacobsen of Threestory Studio.

pattern of activation or representational state (e.g., syllables from phonemes, or on a higher level, phrases). The representations from the last cycle of processing serve as cues to the next level of representation or cycle of processing.

The architectural hypothesis is that each level of representation is a cue to higher levels of representation, resulting in a cascaded architecture: phonetic features are cues to phonemes that are cues to syllabic and morphemic representations, which in turn are cues to lexical and phrasal representations, leading to phrase-based parsing and larger sentential or event structures. **Figure 2** illustrates how the phrase *Times flies like an arrow* would be processed using cue integration. Activation can spread such that cueing of the next representation occurs before processing of the current set of features completes, such that emerging representations can serve as cues to related representations, where a word or phrase level representation can receive stimulation from a morphemic or syllabic or prosodic representation, and vice versa[6] (see **Figure 2** for illustration). As the phonemes in *time* are parsed, they cue the morpheme and word representations of "time," which in turn activates syntactic or structural representations, and conceptual representations associated with *time* (e.g., phonotactically licensed syllables, verbs, phrases, related semantic knowledge).

Population coding parameters would constrain how information is represented in the model, but how can such a radically interactive and redundantly coded system be represented? An efficient way to represent a true multitude of representations without overcommitting neural "real estate" might be opponent channel processing. In color vision, a multitude of colors are perceived from photons interacting with photopsin proteins that are tuned to different frequency spectra in cone cells in the retina. The activation patterns of these cells together form opponent channels, where a given channel can be said to detect the difference in activation between cone cells (with different photopsin proteins) tuned to two opponent ends of a spectrum of light (e.g. red and green, blue and yellow), rather than representation via a series of cells or ensembles dedicated to each color or frequency band. Such an opponent system has also been implicated for spatial coding in auditory cortex, where, while most auditory neurons respond maximally to sounds located to the far left or right side, few appear to be tuned to the frontal midline (Stecker et al., 2005). Paradoxically, psychophysical performance reflected optimal acuity in the frontal midline, thus the existence of an opponent process system synthesized these apparently conflicting findings (Stecker et al., 2005). Opponent processing may be a possible architectural feature to represent a multitude, or even a discrete infinity, of linguistic representations via cue integration (e.g., of minimal pairs or other representations in complementary distribution), though it thus far observed has only been observed in much more primary or lower-level sensory processing stages. An opponent channel representational system, operated on by cue combination and integration, would likely be able to flexibly and efficiently code the number of representations needed for such a massively interactive architecture without taking up an implausible amount of neural real estate.

While cues determine which representation is activated, cue reliabilities determine the strength of the evidence for a particular representation and thus how good of a model of the world the system has. To create and maintain an accurate and robust set of representations reflecting the linguistic environment, reliabilities need to reflect local context as well as latent knowledge, or a global prior. Cue integration can account for processing variables in one of two ways: either by modulating the information expressed in the cue reliabilities, or by modulating the circuit of representations, the order or domain of cue computations. Information from memory might be expressed as both an immediate prior (*r)*, representing recent processing and the local environment, similar to the notion put forth by Jaeger and Snider (2013), and as a more stable, long-term set of global priors (*l*) that reflect information like discourse context and pragmatic meaning, and semantic and world knowledge. In the set of expressions below, I separate reliability into two terms (see Equation 2). Although both terms are subject to summation, I want to make it clear that they represent different sources of uncertainty, that are likely to be represented by different populations, or redundantly on different levels.

$$\hat{S} = \sum_{i=1}^{n} c_i \hat{r}_i \hat{l}_i + \ldots c_n \hat{r}_n \hat{l}_n, \qquad \hat{r} = \frac{1}{\sigma_{ci}^2}, \qquad \hat{l} = \sum_{i=1}^{n} \frac{1}{\sigma_{c}^2}_{i}$$

Equation (2) Ernst and Bülthoff (2004)'s expression of likelihood of activation adapted to parsing. It describes the activation state of a neural population that codes for a given representation. This estimate of activation is composed of cues (e.g., representational features or any representation), weighted by their reliability, or the likelihood that the stimulus is in the environment given the cue. Estimate of *S* is the likelihood a level of representation is activated by the cues or representational features denoted by *c,* weighted by their reliability *r*, the recent inverse variance of the link between that cue and its related or antecedent representation, and by its latent reliability *l*, the global reliability of that cue over a longer time scale. Estimates of *S* would describe the activation represented by any of the shapes denoted in **Figure 2**, while estimates of *r* and *l* would be denoted by the arrows feeding forward on back between each level of representation.

To unpack the cue integration process, we can take the example phrase "Times flies like an arrow…" from **Figure 2**, and examine how the first two words *time* and *flies* would be extracted from the phonemic stage to achieve the morphemic- lexical stage. I will outline how Equation (2) would describe this step in processing. The phonemic string /tajmflajz/ has been parsed from acoustic information[7], so the next step is for /tajmflajz/ to cue the morphemes/words [tajm|*time*] and [flajz|*flies*] into the phrase *time flies:*

Cartoon process: */tajmflajz/->[taj][m][flajz]-> time, flies -> Time flies*

[6]Also in feedback or top-down connections, which Singer (2013) claims are more numerous in neocortex than feed-forward connections.

[7]Out of fear, and for simplicity's sake, I am skipping how acoustic representations are transduced into phonetic and then phonemic representations.

$$S\widehat{[[tajm]]} = \sum_{i=1}^{n} c_{[taj]}\hat{r}_{[taj]}\hat{l}_{[taj]} + \ldots c_{[m]}\hat{r}_{[m]}\hat{l}_{[m]},$$

$$\hat{r} = \frac{1}{\sigma_{ci}^2}, \qquad \hat{l} = \sum_{i=1}^{n} \frac{1}{\sigma_{c\ i}^2}$$

$$S\widehat{[[time]]} = \sum_{i=1}^{n} c_{[tajm]}\hat{r}_{[tajm]}\hat{l}_{[tajm]},\ S\widehat{[[flies]]}$$

$$= \sum_{i=1}^{n} c_{[flajz]}\hat{r}_{[flajz]}\hat{l}_{[flajz]},$$

$$S\widehat{[[time\ flies]]} = \sum_{i=1}^{n} c_{[tajm]}\hat{r}_{[tajm]}\hat{l}_{[tajm]} + c_{[flajz]}\hat{r}_{[flajz]}\hat{l}_{[flajz]},$$

$$\hat{r} = \frac{1}{\sigma_{ci}^2}, \qquad \hat{l} = \sum_{i=1}^{n} \frac{1}{\sigma_{c\ i}^2}$$

Equation (3) Describing processing moments from the phonemic representation of /tajmflajz/ cueing the words *time* and *flies*, and finally the phrase *Time flies*

We can already see that the description of the activation of the model or system as described by Equation (3) is completely dependent upon the time step or processing moment that we choose to analyse or observe. The importance of time step may not be an issue for implementing a computational model based on cue integration that is dynamic in its activation, but it certainly is a theoretically troubling issue. Would processing moments or cycles be determined solely by the external stimulus, e.g., by speech envelope? Or would the current state of the system upon input instead structure processing time, for example, actually result convolving current activity with the incoming physical (and later, the abstract linguistic) properties of the input? I will explore this problem more in Section A Neurophysiologically Inspired Mechanism for Neurobiological Models of Language.

A second important consequence of cue integration is that it implies a hybridized notion of modularity: perceptual representations might still be encapsulated in the Fodorian sense, but once representations become either multi-modal, or are resampled as the cue other representations further up the processing stream, they are no longer so. In fact, as a reviewer pointed out, higher levels of representation in such a model would flatly deny Fodorian modularity (see Fodor, 1983). Another way of putting it is that, under cue integration, early representations, which tend to be perceptual, may be encapsulated until they are summated with other cues. This hybridized modularity would also play out in terms of deeming the pathways and networks that process the representations to be domain-specific or not.

Returning to the important psycholinguistic notions captured by EBP and CBR, how would a cue integration model cache out surprisal and interference? Surprisal might be cached out in terms of sub-optimal cue integration with reliability, poor trading off of global cue reliabilities for recent ones, such that global reliabilities are overweighting the current representation. Interference would amount to sub-optimal cue combination, where the cues for a competing parse or related representation activate an "attractor" representation, instead of the true stimulus. It would arise when sub-threshold activation is shared between representations that share features with the input, a form of cue overload, and may or may not fully activate the "attractor" representation. Cue overload in such a system would still depend upon how diagnostic a cue, or summated cue set, is to a unique representation in the system. Garden-path effects and other parsing ambiguities might be cached out in terms of poor estimates of recent reliabilities compared to global ones, such that summated cues point to ultimately ungrammatical representations. A cue integration process model would extend the notion of cue combinatorics during retrieval and formation of non-adjacent dependencies (Clark and Gronlund, 1996; Lewis and Vasishth, 2005; Van Dyke and McElree, 2011; Kush et al., 2015) to a general processing principle and makes a claim about how cues are combined with one another. The model would assert that processing difficulty is essentially always a form of cue overload, which stems from architectural first principles of how activation of representations occurs and how uncertainty flows through the system dynamically.

Even the first input step in sketching a processing stream is grossly oversimplifying and glossing over important and vibrant subareas, especially in the neurobiology of speech perception (Hickok and Poeppel, 2007; Poeppel, 2014). Recent compelling evidence suggests that neural populations entrain with an auditory stimulus using acoustic-phonetic "sharp edges" to latch onto the speech envelope (Luo and Poeppel, 2007; Doelling et al., 2014; see Poeppel, 2014 for discussion). Giraud and Poeppel (2012) show an emerging role for oscillatory activity as entrainment with speech envelope and syllable structure. This entrainment could be performing cue combination and integration of phonetic features into phonemes, but a clear experimental question is if cues and their reliabilities are coded in or recoverable from oscillatory activity. Such a simple process model must be able, at minimum, to capture the vagaries of speech perception, it being the stage of language processing most firmly grounded in perceptual processing (Samuel, 2001; Samuel and Kraljic, 2009).

Representations and Grammar

An issue that will clearly determine the success of a cue integration process model is the nature of the representations the model posits. The basic representational claim of a cue integration process model is that representational features make up a level of representation, and serve as cues to subsequent levels. They do so in a cascaded way and incorporate at least two error terms. This would mean that the system's organization comes from, or even just *is* the grammar of the language it was trained on. But probably any cue-based model also makes that claim that ungrammatical representations might be formed if the rest of the cues, i.e., non-structural ones, point toward a given representation. One way to avoid the "bag of words" problem (Harris, 1954), where semantic and other non-structural features dominate over structural relations would be to simply weight syntactic features more strongly in their reliability.

Without a traditional mechanistic structure that assumes multiple operations, one possible consequence is that

representations need to be similar to something like slash categories in a combinatorial constituent grammar, as in Combinatorial Categorical Grammar (CCG; Szabolcsi, 1989, 2003; Steedman, 1996, 2000; Jacobson, 1999). If they were, then the dependencies that are cached out as empty categories in other grammars, as well as other forms of dependency, could be carried forward during processing without the need for positing constructs like buffers or maintenance[8], because the dependency is represented as a grammatical feature that can "percolate[9]" to the highest tree, representation or population code. Separate operations for retrieval and interpretation may also become moot if grammatical features (of which dependency is now just one example of) can percolate up the path of population codes. By caching out problems like non-adjacent dependency as representational feature parsing, CCG, and perhaps cue integration, perform the classic programmer's trick of changing data structures to increase expressive power when of the processing architecture. However, this trick only means that the difficulty is merely transmogrified—now the cue integration process model is generating hypotheses about both psychological processing mechanisms *and* about the nature of representation. This is especially problematic because traditional dependent measures (e.g., performance on a task, brain responses, but especially reaction times) cannot discriminate between effects arising from differences in processing speed (a proxy for mechanism) and differences in representation strength or other aspect (Wickelgren, 1977; Davidson and Martin, 2013). This means that experimental designs will have to be careful not to conflate predictions about representation with predictions about mechanism itself. The speed-accuracy trade off procedure (SAT; Reed, 1973) offers a way to measure effects of processing speed orthogonally from representation-based differences, but it relies on an overt metalinguistic judgment. Given cue integration's grounding in perception, it is not unreasonable to think that SAT could be applied to study both the representations of cues and their reliabilities, especially because discriminability between signal and noise, or *d'*, is composed of hits (yes responses to trials from the signal distribution) and false alarms (yes responses to trials from the noise distribution). Nonetheless, deriving testable predictions about the natures of the representational architecture in a cue integration process model for behavioral data will be challenging.

A NEUROPHYSIOLOGICALLY INSPIRED MECHANISM FOR NEUROBIOLOGICAL MODELS OF LANGUAGE

How can we formulate a meaningful linking hypothesis between a psycholinguistic process model and current circuit-based neurobiological theories of language? First we must try to formulate it in term of mechanisms that are both grounded in canonical neurophysiological computation and psychologically meaningful. The class of neurobiological models exemplified by Hickok and Poeppel (2004, 2007) focus on sub-lexical processing and speech as the first information-processing hurdle. Such models tend to have more fine-grained, detailed claims about neurobiological architecture than models that focus on syntactic or semantic processing (Hagoort, 2005, 2013; Friederici, 2012), although some very recent phrase and sentence level models are becoming much more articulated in the complexity of the dual-stream circuitry and in claims about directionality and interaction of processing streams (Rauschecker, 2012; Hagoort and Indefrey, 2014; Bornkessel-schlesewsky et al., 2015; Friederici and Singer, 2015). In any case, trying to find a mechanistic foothold can be difficult. Cue combination and integration maps broadly onto the general concept of Unification from Hagoort (2005)'s Memory Unification and Control model, as a mechanism to combine processing units into larger, hierarchical structures. In MUC, unification is separated by modality or representational type, such that phonological, syntactic and semantic unification are separate, as are the processing streams that deal with them (Hagoort and Indefrey, 2014). A cue integration model would not stipulate encapsulation by formal representation class but, rather, by order of cue summation and thereby connectivity of the populations, which may or may not turn out not to be equivalent to representation class.

The cue integration model also differs from Unification in that it makes the claim that uncertainty, specifically cue reliability, is integrated with the population activation for a given cue or cue set. This would mean that cue reliabilities would need to be dynamically updated, and more broadly, that the representations carried by a given neural circuit would need some element of flexibility and would be robust due to redundant coding of features across certain populations. They would also need to be robust, and so redundantly represented in multiple populations. Friederici and Singer (2015) propose that the sparse, flexible, feature-based coding that is seen in other cognitive systems applies to linguistic representations in the brain. In such a system, there is both temporary coupling of populations coding cues or features of larger representations, as well as lasting couplings or "firmware" of anatomical assemblies, as outlined in Singer (2013). Careful experimental work would be needed to test this hypothesis and to determine if flexible sparse coding can handle formally complex linguistic representation, and furthermore, to determine which aspects of phonological, lexical, syntactic, semantic, discourse, or pragmatic representations are flexibly coded or "hard coded." Such an architecture would be highly suited to a cue integration process model but in combination with redundancy in coding to generate robust representations. Such an architecture may enable the system to represent discrete infinity.

To emphasize, the only computational mechanisms stipulated in a cue integration process model would be *summation*, the neurophysiological mechanism for cue combination, and *normalization*, the neurophysiological mechanism that integrates a cue with its reliability. If parsing and other language processing phenomena can be accounted for using only these two stalwart neurobiological mechanisms, it would be a step in the direction

[8]Along with the notion of search, both theories of grammar and processing often tacitly assume buffers and maintenance in the architectures they imply.

[9]By "percolate" I mean persist in being represented or coded in active neural populations as processing proceeds.

toward a unified theory of human information processing that includes language but is based on "brain-general" processes.

Cue Integration and Forward Models

Another powerful capacity that any process model would need to account for is the role of predictive processing in language behavior. Forward models from vision and motor control have already had some influence on theoretical work in cognition and language (Pickering and Garrod, 2007; Pickering and Clark, 2014), but have yet to be fully specified in models with clear predictions for language processing. In a classic computational model of vision, Rao and Ballard (1999) describe an architecture wherein top-down feedback connections carry predictions about bottom-up or lower-level population codes, and feed-forward connections carry residual error between those top-down predictions and the actual input. They illustrated that in this kind of forward model, architectural facts about the visual system, such as receptive field characteristics and surround suppression[10], emerge naturally. This seems to suggest that such architectural features occur as a result of cortico-cortical feedback, and that cortico-cortical feedback is a promising candidate mechanism for predictive coding (Rao and Ballard, 1999). Synthesizing predictive coding via cortico-cortical feedback with a cue integration process model, feed-forward connections would carry bottom-up activity corresponding to integrated cues and reliabilities. A subset of feed-forward cue reliability activity would be the error signal in response to predictive activation forecast via the top-down feedback circuit. Although predictive coding and forward models will no doubt play a larger role in psycholinguistic theory in the coming years, the fact that we can understand the unpredicted or unexpected utterances at all, or with reasonable ease, suggests that prediction is not the core language processing device (see also Jackendoff, 2002; Rabagliati and Bemis, 2013; Huettig, 2015; Huettig and Mani, 2016). But the fact remains that predictive coding plays a huge role in most sensory processing domains, so any model of language ought to have an architecture that can implement it using existing neural infrastructure.

Cue Integration in a Neurobiological Circuit

A cue integration process model could make contact with neurobiological models in two ways: (1) in terms of the claims being made about the cue-based computations being carried out in various neural circuits, and (2) in terms of the implied population codes or representations needed in a given circuit. The first issue returns to the question of how to falsify hypotheses about the number and kind of processing mechanisms. A way to circumvent the problem is to focus on the end-state computation or the transformation that a representation undergoes in a given processing stream.

In a similar spirit, Bornkessel-schlesewsky et al. (2015) derive a dual-route model for human language processing from speech to syntax that is rooted in primate audition (Rauschecker and Tian, 2000). The key differences between the antero-ventral and postero-dorsal pathways in Bornkessel-schlesewsky et al. (2015) is time invariance or order sensitivity: the antero-ventral stream processes or extracts increasingly complex hierarchical auditory representations with commutative properties whilst the postero-dorsal stream processes sequence information or is order sensitive. The postero-dorsal stream makes use of forward models via an efferent copy that carries predictions and detects error, enabling sequential order-sensitive processing (Bornkessel-schlesewsky et al., 2015). The cue integration process model does not make any claims about the location or make-up of language circuits, nor does it have fundamentally different assumptions about basic representation types (phonetic features, phonemes, lexical, phrasal, event, etc.) that many extant models posit. Rather, cue integration makes a specific claim about (1) the psychological and neurophysiological mechanism underlying formation of these representations (i.e., summation of population codes for cue combination and normalization of those codes for integration with reliability), and (2) the representational infrastructure (e.g., dynamic and redundant population-level encoding of feature-based representations and uncertainty about them).

The debate about the modularity of language from other cognitive systems has featured compelling arguments that theories of language evolution must shape or constrain theories of language and language processing (Hauser et al., 2002). The claim that language evolved too recently to derive a new domain-specific neural mechanism is linked to the notion that brain processes can be repurposed to suit timely organism-environment interaction needs (see Gervain and Mehler, 2010 for discussion; Knops et al., 2009). Cue integration is a good candidate for such a repurposed process. However, though the cue integration architecture can represent recursion in principle, that fact alone cannot explain why recursion is not more widely found in other representational systems in cognition (Jackendoff and Pinker, 2005). That is unsatisfying, especially if, in a hardline reductionist thought experiment, one really wants to claim that there is only one neurophysiological brain process relevant for cognition (or extraction of further representations from sensory input), and that process is cue integration. To entertain such a thought experiment further, or for such a reductionist position to be tenable, language also needs to be learnable using only cue integration over the cue-based architecture with reliabilities.

CUE INTEGRATION IN LANGUAGE ACQUISITION AND BILINGUALISM

A crucial aspect of any theory of language is that it must be learnable. How might representations be acquired under the assumptions of a cue integration process model?

The cue integration model does not radically differ from current thought on language development—it would hypothesize that linguistic representation develops in the infant as a function of perceptual cue decoding via statistical learning (Saffran et al., 1996), but that first hierarchical representations depend on

[10]Surround suppression is a characteristic of neurons in primary visual areas wherein a given neuron's activity is reduced in the presence of a stimulus outside its receptive field; lateral inhibition from neurons with different receptive fields is one possible mechanism through which surround suppression may arise (Xing and Heeger, 2000).

acquiring a cue-based architecture and cue reliabilities, which in turn shape the development of the assembly networks. Much of the same how-why camp tension exists in language acquisition between pure statistical learning-based accounts and nativist process models (Kuhl, 2004; Gervain and Mehler, 2010). Gervain and Mehler (2010) argue that the hard work for language acquisition theorists is discovering how the system combines statistical learning and rule acquisition or language-specific cues. Only from this combination can an account capture cross-linguistic variation and sensitivity to language-specific cues in infants and neonates (Kuhl, 2004; Gervain and Mehler, 2010). To this end, Gervain and Mehler (2010) synthesize nativist and statistical learning accounts of speech processing up to the acquisition of morphology, concluding that some types of linguistic representations may be more suited to statistical learning (e.g., consonants) than others (e.g., vowels). But the challenge lies in how acquisition occurs in learning situations where, for example, frequent monosyllabic speech that arises as in some infant directed speech and even in some languages, which renders statistics like transitional probability useless (Gervain and Mehler, 2010). Under their account, acquiring complex hierarchical representations must capitalize on both the statistical information from the linear of sequences, and on language-specific cues, or the formal representations of a particular language, but how that tradeoff or interaction occurs is of course unknown. The cue integration process model offers an architecture that may be able to capture both statistical learning aspects (via reliabilities) and rule-based aspects (through assemblies or cascaded cues networks). In order to avoid some of the same criticisms lodged earlier in this article, the cue integration model needs to be able to derive abstract hierarchical representations from noisy, sparse inputs with few priors. That seems dubious at the moment, mainly because the representations or the bias toward forming certain types of representations would have to be innate. This situation echoes the learning problem that statistical models usually face: how do you parse input without the representations to do so? In other words, how do you count anything if you don't know what it is you are trying to count? I turn to a model of concept learning for inspiration because learning by analogy seems to avoid many of the pitfalls of both nativist and statistical accounts (Doumas and Hummel, 2005), as well as having some striking computational overlap with current neurobiological models of language.

At least at the level of the sentence, the tension between statistical and nativist perspectives might be eased somewhat by well-articulated claims about acquisition of relational concepts like *above*, *bigger*, or *more*. The Discovery of Relations by Analogy (DORA) model of relational concept development by Doumas et al. (2008), uses associative learning to create symbolic, hierarchical relational concepts from linear input sequences. DORA learns multiple argument predicates using time or onset of activity in sub-nodes, or systematic synchrony or asynchrony of firing of the sub-nodes representing each argument[11]. In other words, DORA learns *bigger than* (X, Y) by predicating *larger* (X) and *smaller* (Y) and combining these single argument predicates by their occurrence in time, such that the model can discriminate between X is bigger than Y and Y is bigger than X (see Doumas et al., 2008 Figure 3 for illustration). Such a strategy would work well in a redundant, flexible architecture that is also self-organizing and associative in nature (cf., Singer, 2013; Friederici and Singer, 2015). Firing asymmetry offers an additional level of description or representational state for the model without positing another psychological mechanism or neurophysiological process. Modeling, in combination with empirical work, would of course be needed to substantiate any of these claims.

For the bilingual brain, the cue integration model has modest implications but casts several existing questions in relief. First, that reliabilities and cue architecture may or may not be shared between languages (Nieuwland et al., 2012). Second, that age of acquisition might determine how assemblies are formed (Nieuwland et al., 2012). Third, proficiency may be cached out as differences in network density, representational interconnectedness, or unstable reliabilities, all of which could underlie non-native performance for bilinguals. If assemblies are malleable until the critical period is over, at which point only reliabilities are in flux as a function of language experience, any subsequent language learning would require the system to use alternate circuits to form new language-related assemblies, resulting in differing neural infrastructure that can (but does not have to) affect the competence and performance of late bilinguals.

Cue Integration in Production and Dialogue

Regarding performance, the challenges facing an integrated theory of comprehension and production endure. Questions like whether the same representations are used in comprehension and production or whether analogs or "mirror image" representations are working in concert during production and comprehension are exciting but difficult to test. Brain imaging evidence suggests that similar areas are engaged during production and comprehension (Rauschecker and Scott, 2009; Menenti et al., 2011) but whether the representations at play are identical or analogous is not yet clear. Certainly an important interaction occurs that leads to suppression of activity in auditory cortex in response to one's own speech (Numminen et al., 1999). Cue integration would make a claim about the process through which representations are activated during production, and there is no principled reason why the cue integration process and cue-based architecture cannot be the same in both processes. However, reliabilities pertaining to the representations might need to be different for comprehension and production. Regarding the claim that prediction is based on production (Pickering and Garrod, 2007, 2013) and the claim that production difficulty is at the root of comprehension difficulty (MacDonald, 2013), cue integration forces an opposing view. Cue integration stipulates that the cue-based architecture for language arises from perceptual processing. There are several difficult challenges for the account to claim otherwise: first, if cue integration is a repurposed neurophysiological mechanism from perception, and it gives rise to linguistic representations from auditory percepts, then it is fundamentally based on comprehension, at least during

[11]Note the similarity in time-based mechanisms with Bornkessel-schlesewsky et al. (2015) and Giraud and Poeppel (2012), and similar to the notion of noise correlation in population coding put forth by Averbeck et al. (2006).

acquisition. Secondly, comprehension occurs before production during development, furthering support for basing at least the origins of linguistic representation in comprehension. Third, receptive vocabulary is larger and accrues faster in development, and is larger in bilinguals (Benedict, 1979; Laufer, 1998), so it is unclear how these facts fit into a model where comprehension and production draw on exactly the same representations. These arguments do not exclude the possibility that a significant portion of cue reliability during comprehension is uncertainty stemming from dynamic production-based experience in the adult, leading to a situation where comprehension difficulty is rooted in a production-based variable, as MacDonald (2013) argues.

Producing an utterance in the cue integration architecture would go as follows: activation for an event structure cascades down representational levels in a planning-cycle-sized chunk. The cue-architecture basically fires in reverse order, and reliabilities include uncertainty from articulatory planning and other production-based priors. Predictive coding would also have to operate in the opposite direction. The system would still be susceptible to cue overload whether or not production and comprehension representations are identical. Coupling between processing streams or analog representations during both production and comprehension could occur.

During dialogue, language production often based on comprehension of what was just by an interlocutor. If production reverses what is top-down and bottom-up and changes the predictive coding direction, then dialogue is a cascaded engagement of this stream coupled with the comprehension stream. In dialogue, these streams become coupled between two brains, forming a sort of ultimate cacophony of synchronous and asynchronous firing. The only new claim a cue integration model would make is that cue reliabilities would then have endogenous and exogenous sources, from the speaker and interlocutor, and would crucially have to contain predictions about the interlocutor's representational states. Alignment then might be cached out as how well-entrained dialogue partners' cue reliabilities for each other are. Cues in dialogue might also place more weight on non-linguistic percepts or cues, which may end up influencing the reliabilities of linguistic representations, for example, gaze, facial expression, gesture, and goal-directed or joint-action contexts and behavior. Turn-taking and other time-based behaviors between interlocutors would be entrained with or based on asynchronous firing across speakers (Stephens et al., 2010).

Predictions from Cue Integration and Persistent Challenges for any Cue-Based Model

The real work for this developing theory is generating testable predictions. What can a simple process model based on psychophysiological principles mean for brain data and for behavior?

Given the architectural nature of the claim, a starting point might be computational models of language that are based on primate and avian auditory processing (à la Doupe and Kuhl, 1999; Rauschecker and Tian, 2000; Bornkessel-schlesewsky et al., 2015) using associationist learning to acquired symbolic representations. If such a computational model can approximate human learning and processing of language, it would still be a form of confirmatory evidence rather than an attempt at falsification. But such an implemented computational model might be able to generate finer grained predictions for electrophysiology and behavior.

Another approach to falsification might be via the manipulation of the cue relationships between representations, and of cue reliabilities, in an artificial language. This approach would try to manipulate the reliability of a phoneme as a cue to a morpheme, or a morpheme as a cue to a phrase structure, to see if participants track reliabilities and if manipulating them affects reading time. Cue integration also predicts that a noise term for each level of representation should exist. An elegant point from Maloney and Zhang (2010) is that one way to falsify Bayesian accounts it to observe that estimates of priors transfer onto other trials or related tasks. Thus, estimates of priors might be expected to transfer onto other item sets, syntactic structures, lexical items, discourse or information structures. It is yet unknown how much of a role individual differences in language experience might contribute to both recent and global priors or cue reliabilities.

Another class of predictions the cue integration model might make regard neuroimaging data. Although the relationship between something like a population code and an electrophysiological frequency band or event-related component is highly speculative at best, I will try to generate predictions both on the population level (though they are not yet measureable in humans apart from intracranial electrocorticography), and try to predict an analog for a signal our existing psycholinguistic electrophysiological dependent measures can detect. First, formal linguistic distinctions in a particular language should determine population codes. Under an opponent processing system, the opponents in a channel would be determined by that language's minimal pairs at various levels of representation. Beyond the population level, such a language-specific population coding architecture's first fundamental prediction is, certainly for abstract constructs like event-related brain potentials (ERPs), for variety of indices (i.e., different ERP components elicited by strings with the same meaning across languages) showing sensitivity to different processing variables across languages (see Bornkessel-Schlesewsky et al., 2011).

Second, if firing asynchrony is important for perceptual grouping (both in processing and in learning), then a cue integration approach predicts a lack of phase in electrophysiological signal with stimulus onset. This "delay" should be true for population codes, oscillatory activity, and ERPs. But there should be some temporal relationship with onset as a function of the number or complexity of representations being extracted from the auditory percept (Luo and Poeppel, 2007; Giraud and Poeppel, 2012; Golumbic et al., 2013), though discovering what that relationship seems very challenging. Nonetheless, discovering the relationship may make contact with neurophysiological principles about oscillatory activity, namely regarding questions as to how oscillatory activity is driven both by the temporal properties of the incoming, exogenous stimulus *and* by the current endogenous processing moment,

and what the nature of the relationship between those two oscillation timescales is. Third, the cue integration model, which is built on cue reliabilities, or the representations of the probabilistic relationship between a given cue and an upcoming representation, predicts that there should be some neural signal that is related to the reliability of each level of representation as a cue to the next.

At least two fundamental problems seem to endure for a cue-based model. First, a persistent challenge is understanding why processing similar representations before or after the onset of a target representation is sometimes facilitatory (resulting in priming) and at other times inhibitory (resulting in interference). Is firing asynchrony somehow underlying the spectrum of priming and interference? Second, how might long-distance structural relationships, syntactic domains, and scope be encoded in a cue-based direct-access system (see Kush, 2013 for a discussion of c-command)? How does the parser "know where it is" to carry out these computations?

Summary

I have argued that any model of language computation must answer both *how* and *why* questions, and that the ideal model should be a fusion of mechanistic and probabilistic elements. I have sketched a framework for language processing based on the psychophysiological mechanism of cue integration. The cue integration framework asserts a mechanistic psychological operation over probabilistic representations, which are represented by neural population codes that are flexibly combined using two simple canonical neural computations: summation and normalization. Together these operations comprise the cue integration mechanism. By restricting computation to canonical neural mechanisms, cue integration may be able to form a linking hypothesis between psycholinguistic, computational, and neurobiological theories of language.

The heart of this mechanistic claim is that the relationship between a given level and the next level of representation (between cue and "target") is probabilistic, and that, in turn, this uncertainty forms a vital aspect of representation, incorporated via the cue integration mechanism of normalization. The main representational hypothesis of cue integration is that every level of representation is a cue to higher levels of representation, resulting in a cascaded architecture where activation can spread before processing of the current set of features completes. Crucially, cue integration can take as its input an endogenously stimulated representation and output another representational state, allowing all levels of linguistic input to be extracted from sensory input. While cues determine which representation is activated, cue reliabilities determine the strength of the evidence for a particular representation and thus how good of a model of the world the system has. Reliabilities reflect local processing context as well as global knowledge. Cue integration accounts for processing variables either by modulating the information expressed in the cue reliabilities, or by modulating the circuit of representations, in other words, changing the order of cue computations.

To close, the main criticism laid out in the first part of this article can of course be applied to the cue integration hypothesis: a central challenge for the cue integration model is to achieve a parsimony of cues, reliabilities, and population codes while preserving explanatory satisfaction.

Grammatical number processing and anticipatory eye movements are not tightly coordinated in English spoken language comprehension

*Brian Riordan[1], Melody Dye[2] and Michael N. Jones[2]**

[1] Aptima, Inc., Fairborn, OH, USA, [2] Department of Psychological and Brain Sciences, Indiana University, Bloomington, IN, USA

Recent studies of eye movements in world-situated language comprehension have demonstrated that rapid processing of morphosyntactic information – e.g., grammatical gender and number marking – can produce anticipatory eye movements to referents in the visual scene. We investigated how type of morphosyntactic information and the goals of language users in comprehension affected eye movements, focusing on the processing of grammatical number morphology in English-speaking adults. Participants' eye movements were recorded as they listened to simple English declarative *(There are the lions.)* and interrogative *(Where are the lions?)* sentences. In Experiment 1, no differences were observed in speed to fixate target referents when grammatical number information was informative relative to when it was not. The same result was obtained in a speeded task (Experiment 2) and in a task using mixed sentence types (Experiment 3). We conclude that grammatical number processing in English and eye movements to potential referents are not tightly coordinated. These results suggest limits on the role of predictive eye movements in concurrent linguistic and scene processing. We discuss how these results can inform and constrain predictive approaches to language processing.

Riordan B, Dye M and Jones MN (2015) Grammatical number processing and anticipatory eye movements are not tightly coordinated in English spoken language comprehension. Front. Psychol. 6:590. doi: 10.3389/fpsyg.2015.00590

Introduction

In the study of spoken language comprehension, the discovery that language processing is closely coordinated with patterns of eye movements represents a major advance for the discipline (Tanenhaus and Trueswell, 2006). Not only does the the visual context influence how the unfolding linguistic input is structured (Tanenhaus et al., 1995), but fixations to referents in the visual scene have been shown to reflect the fine-grained time course of spoken word recognition (e.g., Magnuson et al., 2007).

When processing linguistic and visual input simultaneously, listeners rapidly integrate across information streams, making anticipatory eye movements to likely referents. For example, Altmann and Kamide (1999) demonstrated that when listeners encounter verbs such as *eat*, they shift their visual attention to edible objects. Kamide et al. (2003) further demonstrated that listeners can integrate morphosyntactic and semantic information at the verb to drive eye movements to

likely referents. Other work has demonstrated anticipatory looking behavior during thematic role assignment (Dahan and Tanenhaus, 2004; Knoeferle and Crocker, 2006).

These findings are consistent with a host of related experimental results suggesting that, like other aspects of human cognition, language comprehension and production are incremental, predictive processes. In making predictive inferences about upcoming speech or text, communicators draw on multiple sources of linguistic information, ranging over lexical, semantic, and discourse levels (for reviews, see Pickering and Garrod, 2007; Ramscar et al., 2010). This has been demonstrated empirically in a number of ways. For instance, in reading, more predictable items are processed faster and more efficiently (McDonald and Shillcock, 2003; Hare et al., 2009), and in speech production tasks, such items are uttered more quickly, often in a reduced form (Gahl et al., 2012), with fewer disfluencies (Arnold et al., 2007). Eye movement studies complement these traditional experimental domains, furnishing a rich picture of how various linguistic factors conspire to affect processing in real time (Huettig et al., 2011).

Grammatical Gender

One important question that the visual world paradigm has begun to answer, is how syntactic agreement patterns assist comprehension processes. Agreement is thought to establish local and global coherence by linking temporally separated elements in discourse. However, precisely how it accomplishes this is an active area of research. A key line of enquiry concerns the influence of grammatical gender on lexical access. Gender systems are obligatory morphological systems found in many languages, which group nouns into a small number of mutually exclusive classes, and mark neighboring words – such as articles and adjectives – for agreement. In Romance languages, like French and Spanish, nouns are typically divided into two separate classes: masculine and feminine. Other major languages, such as Russian and German, add a third neuter category, and more are possible; Swahili has six (Corbett, 1991).

While historically gender has been viewed as an arbitrary or superfluous system (see Kilarski, 2007 for a review), there is an accumulating body of evidence to indicate otherwise. For one, while gender systems are not always semantically transparent, neither are they opaque to their speakers; there are typically multiple, converging linguistic cues to class membership (Frigo and McDonald, 1998). Further, gender systems may confer distinct advantages for native speakers. A leading hypothesis is that gender information reduces the lexical search space, delimiting the set of nouns to gender-consistent possibilities (but see Friederici and Jacobsen, 1999 for alternative proposals). On this view, speakers use gender to guide lexical access, helping them better predict upcoming nouns in discourse, as well as likely referents in the visual scene. This suggests that gender should both facilitate processing (when the marker is consistent with a following noun) and inhibit it (when the marker mismatches). Supporting evidence comes from a variety of sources, including lexical decision (Grosjean et al., 1994), naming times (Schriefers, 1993), word repetition (Bates et al., 1996), artificial grammar learning (Arnon and Ramscar, 2012), and ERP, where gender agreement violations have been found to produce neural error responses to the mismatch (Wicha et al., 2004; Van Berkum et al., 2005).

Yet perhaps the strongest support for the 'limited search' hypothesis comes from tasks that illuminate the time course of spoken language comprehension. In auditory gating paradigms, subjects hear short sequences in which a word fragment appears, and are asked to produce the target word. In a study of native French speakers, Grosjean et al. (1994) found that when gender information was provided, subjects correctly identified the target at shorter durations, and with greater confidence. More importantly, an inspection of subject errors revealed that gender information not only significantly reduced the number of misidentifications (both in terms of types and tokens), but also limited errors to gender-consistent candidates. Indeed, "in the presence of gender marking, no word candidate ever (had) the wrong gender" (Grosjean et al., 1994; p. 594). Similarly, in tip-of-the-tongue (TOT) states, Italian subjects can reliably guess the gender of the noun they are trying to retrieve, even when they cannot produce it (Vigliocco et al., 1997).

These findings are paralleled in studies of visual search. Dahan et al. (2000) investigated how gender-marked definite articles influenced the looking behavior of French-speaking participants. Subjects viewed a visual display with four possible referents, and heard instructions such as *Cliquez sur le bouton* (*Click on the$_{masc}$ button*). When gender information was provided at the determiner, listeners rapidly shifted their attention to gender-consistent referents, ignoring potential phonological competitors. Lew-Williams and Fernald (2007) reported a comparable result for Spanish-speakers, finding that both children and adults are faster to orient to the correct referent on trials when nouns of different genders are displayed than on trials showing nouns of the same gender (see also Weber and Paris, 2004; van Heugten and Shi, 2009).

Taken together, these results support the conclusion that grammatical gender does not merely prime lexical candidates, but rather restricts the space of subsequent possibility. However, the studies reviewed here focus exclusively on several closely related Romance languages. There is also evidence to suggest that the function and strength of gender, as a morphosyntactic cue, may vary significantly by language (see, e.g., Miozzo and Caramazza, 1999). This is quite clearly the case when it comes to grammatical number.

Grammatical Number

Grammatical number offers another promising domain of investigation for eye movement research. If gender is a widespread feature of the world's languages, number is nearly universal. In the simplest number systems, a noun's morphological form is modified to represent the numerosity of its referents, indicating whether the noun references a single entity or multiple entities, and neighboring words are marked for agreement (Corbett, 2000). In English, number is obligatory, and typically indicated by the presence or absence of a terminal sibilant *+s* (*cat*/*cats*), with several phonologically related families of irregulars (*mouse*/*mice*). A theoretical distinction is often drawn

between *count nouns*, which alternate freely between singular and plural forms, and *mass nouns*, which are treated as a single, indivisible set, regardless of numerosity. Compare, for instance, the usage of the semantically related pairs *noodles*$_{\text{count}}$/*pasta*$_{\text{mass}}$, *colds*$_{\text{count}}$/*flu*$_{\text{mass}}$, and *jobs*$_{\text{count}}$/*work*$_{\text{mass}}$.

As with grammatical gender, number information may be a potentially useful resource for predicting upcoming referents. Listeners appear to process grammatical number information quickly and automatically. Grammatical number violations are registered particularly rapidly, a conclusion that has been established through reading times (Wagers et al., 2009) and ERP (Pulvermüller and Shtyrov, 2003; Barber and Carreiras, 2005). Complementary results have been reported in TOT paradigms, where English-speakers have been found to reliably discriminate the appropriate sentential contexts for count nouns, even on failure to retrieve them (Vigliocco et al., 1999). Collectively, these findings imply that available agreement information scaffolds prediction of upcoming items in discourse.

If this is the case, simply hearing the string *Look, there are some*— might serve to restrict gaze to plural objects in a visual display. This is precisely what Kouider et al. (2006) found in a study of English-speaking children. On critical trials, toddlers saw pictures of novel objects on two screens; one picture depicted a single object and the other, multiple copies of the same object. Children heard sentences such as *Look, there are some blickets!* Beginning at 24 months, children were able to use the number marking on the copula and the indefinite article to launch anticipatory eye movements to the correct picture. Similar findings have been reported for French (Robertson et al., 2012). Complicating this picture, however, Johnson et al. (2005) report that in a picture selection task, English-speaking toddlers fail to use verb agreement marking as a cue to subject number (see Brandt-Kobele and Höhle, 2010 for a parallel finding in German).

Thus, despite some promising results, there is reason to suspect that grammatical number may not be as consistently informative about upcoming referents as grammatical gender. A variety of different theoretical accounts provide for different representations for gender and number (see discussion in Barber and Carreiras, 2005). One hypothesis is that whereas gender information is a property of the lexical item, stored in its lexical representation, number is is an independent morphological feature that combines with the stems of lexical items. These representational differences have processing consequences in models of lexical retrieval: gender information is retrieved with lexical access, while number information is involved only in a postlexical process of grammatical agreement as part of integration with the context. On this account, because grammatical number information does not directly activate lexical representations, processing of this information should only be weakly reflected in eye movements to referents in the visual scene.

Another source of difference may arise from number and gender's very different relations to semantics (Eberhard et al., 2005). Speaking broadly, a noun's number specification tends to be semantically motivated, reflecting the numerosity of the referent. By contrast, a noun's gender specification tends to be semantically arbitrary, with little obvious correspondence between the conceptual properties of the referent and its noun class, and substantial cross-linguistic variation. Thus, whereas number tends to be an extrinsic, inflectional feature that is highly responsive to semantics, gender tends to be intrinsic and non-inflectional, with comparatively limited interaction with semantics (see Vigliocco et al., 2005). This suggests that as a predictive cue, number may be less informative in languages in which semantic factors strongly bias agreement patterns.

For this reason, it is important consider the distributional facts of the language under study: namely, English. In number agreement in English, the mapping between inflection and semantics is highly context-dependent, and is difficult to capture with simple, easily generalizable rules (Huddleston and Pullum, 2002). To grasp this point, it is helpful to consider just how far the language departs from a highly simplified case, in which agreement is computed solely as a function of a referent's numerosity (singular/plural) and its semantic type (count/mass), and in which the semantic type distinction is clear-cut (e.g., mass nouns always refer to an undifferentiable whole).

The first complication is that, on inspection, there are certain systematic mismatches between syntax and semantics. For instance, mass nouns like *furniture* and *clothing* can be notionally plural while behaving like singulars (as when, e.g., there are multiple *pieces* of *furniture* or *articles* of *clothing* present), while pluralia tantum like *scissors* and *binoculars* can be notionally singular while behaving like plurals (as when there is a singular *pair* of *scissors* or *set* of *binoculars*). Nor is nominal inflection always a reliable guide to syntactic behavior, as evidenced by nouns whose meaning contravenes their marking, such as *news* (always singular), *police* (always plural), or *sheep* (which has the same singular and plural form).

Another wrinkle is that there is no straightforward way in which to tag nouns as countable, or not. While certain nouns fall on opposite ends of the *count*/*mass* spectrum, most nouns can behave in either way, depending on the semantic context (e.g., *I would like to buy a cake*/*I would like some more cake*). Further, countable nouns are not themselves a uniform class, and many show lexically specific preferences for (or restrictions on) the quantifiers they pair with. More broadly, item differences appear to be graded and distributional in kind, rather than rule-based and categorical (Baldwin and Bond, 2003). This suggests that agreement must be computed with reference to the entire noun phrase (NP), rather than simply the noun itself (Allan, 1980).

Finally, subject-verb agreement conventions are subject to variation both within and between speakers, and are closely influenced by semantics (Haskell and MacDonald, 2003; Eberhard et al., 2005). Singular collectives can take plural verbs (*the faculty are deliberating*/*neither of them are happy*) and plural quantities can take singular verbs (*ninety days is a long time*). In addition to these 'legal' alternations, agreement errors are common; speakers are especially prone to interference when the main verb is proximate to a noun with a different number than its head noun, as in *The key to the cabinets were missing* (Bock and Miller, 1991). In short, grammatical number in English is a highly complex system, in which agreement and marking conventions furnish, at best, an incomplete guide to the numerosity of the referent.

In the studies presented here, we sought to establish whether English-speaking adults make use of the partial information afforded by grammatical number to drive eye movements to likely referents, in contexts in which the predictive cue validity of number should be relatively weak. In online comprehension of both declarative and interrogative sentences, listeners first encountered grammatical number marking on the copula, in constructions such as *There are the cars* and *Where are the cars*? In addition, listeners heard sentences that incorporated multiple cues to number, such as *There are some cars*, in which the indefinite article was also marked.

Experiment 1

We recorded participants' eye movements as they listened to declarative and interrogative sentences. Following Lew-Williams and Fernald (2007), participants were exposed to two types of trials. On *same-number* trials, participants saw two pictures that each had the same number of object exemplars. On these trials, participants could not determine the target referent until the onset of the noun. On *different-number* trials, the two pictures differed in the number of exemplars depicted. On these trials, participants could use grammatical number information that preceded the noun to quickly orient toward the correct referent. If grammatical number information is rapidly exploited in sentence comprehension, participants should be faster to fixate the picture that matches the linguistic input on different-number trials than on same-number trials.

Method

Participants

Thirty native English speakers with normal or corrected-to normal vision participated for course credit.

Stimuli and Design

Noun targets were 16 object names with early age-of-acquisition. The words were divided into two sets of eight. Across participants, each set of eight words appeared in each condition. Within each set, no words shared the same initial phoneme. The noun targets were inserted in simple declarative and interrogative sentences. Sentences were of the form *There/Where [copula] [article] [noun]*.

Two conditions varied the number of grammatical number cues in the sentences. In the definite determiner condition, both declarative and interrogative sentences included the definite determiner *the*. In this condition, the grammatical number information was only available on the copula. In the indefinite determiner condition, all sentences included an indefinite determiner, *a* or *some*. Here, grammatical number information was available on both the copula and the indefinite determiner.

There were 64 total test trials in each condition (see **Table 1**). Half of the trials were *same-number* trials, and half were *different-number* trials. In addition, half of the trials were sentences with singular number, and half with plural number. Within each condition, the target referent appeared equally often in the left and right locations. Each participant was exposed to half of the total stimuli in each condition (32 trials per condition), and eight filler trials. Thus participants saw a total of 80 trials during the experiment.

Sentences were recorded by a female speaker using a natural speech rate. All sentences employed the uncontracted form of the copula. Across sentences, the mean duration of copulas was 152 ms (range = 100–225), the mean duration of determiners was 151 ms (range = 50–275), and the mean duration of nouns was 591 ms (range = 300–800 ms).

The visual stimuli were drawn from Rossion and Pourtois (2004). To form plural versions of each stimulus, four copies of each individual image were reduced in size and concatenated. The total surface area of the singular and plural images was identical. **Figure 1** depicts an example visual display for a different-number trial.

Procedure

Participants were instructed to click on the picture that was mentioned in the sentence (Weber and Paris, 2004). They were told to listen normally; no time constraints were imposed. As they listened, participants' eye movements were recorded using a desktop-mounted SR Research EyeLink eyetracker sampling at 1000 Hz. Each trial began with the presentation of a fixation dot for 750 ms. There was 2000 ms preview time before sentence onset. Using the fixation dot as a cursor, participants clicked on the picture that matched the sentence. The trial ended with

TABLE 1 | Composition of test trials in Experiment 1.

Condition		Trial type		Example
		Same-number	Different-number	
Definite	Singular	16	16	*There is the lion.*
	Plural	16	16	*There are the lions.*
Indefinite	Singular	16	16	*There is a lion.*
	Plural	16	16	*There are some lions.*

Across the definite and indefinite conditions, each participant was exposed to half of the test items.

FIGURE 1 | Example visual display from a different-number trial.

the mouse click. Each participant completed both the definite and indefinite conditions. Sentence order was randomized within condition, and the order of presentation of the conditions was counterbalanced across participants.

Analysis

The primary dependent variable was reaction time (RT) to initiate a saccade to the target referent (Lew-Williams and Fernald, 2007). We calculated RT as the latency of the first saccade or fixation that marked the start of an uninterrupted series of fixations on the target referent until the mouse click that ended the trial. RT was measured from copula onset.

Only trials that met the following conditions were included in the analysis. First, the participant must not have been fixating the target referent at the onset of the copula. Second, a saccade to or fixation on the target referent could not occur prior to 200 ms after the copula onset – approximately the earliest time a saccade could have been launched to the target referent after the copula onset (Altmann and Kamide, 2004). Third, RT must have occurred before 700 ms after the onset of the noun.

Results and Discussion

Figure 2 presents the time course of looking at each object in the display as the linguistic input unfolds in the definite condition. The curves represent the mean proportion of fixations to target objects on same-number trials versus different-number trials beginning with the start of the sentence. Participants shifted to the target object as the unfolding utterance allowed them to identify the correct picture. The trajectory of fixations is very similar across trial types, indicating that participants did not reliably use the grammatical number information encoded on the form of the copula to anticipate the target referent.

Figure 3 shows the time course of fixations for the two trial types in the indefinite condition. In this condition, too, the trajectory of fixations is similar across same-number and different-number trials. Participants did not make use of the two grammatical number cues preceding the noun – the copula and the indefinite article – to anticipate the correct referent.

These findings were confirmed with the RT analyses. Because sentence lengths varied with the type of copula (*is* vs. *are*) and the type of determiner (definite vs. indefinite, and within indefinite determiners, *a* vs. *some),* participants' processing of the grammatical number information is likely to have varied across sentence types. Therefore, we report separate RT analyses by sentence type. Mean RT was calculated both by-subjects (F_1) and by-items (F_2). **Table 2** presents the results of within-subjects ANOVAs for each comparison. Although there were trends toward faster RT on different-number vs. same-number trials, in no case were these differences reliable in the expected direction.

To explore the degree to which participants made anticipatory eye movements to the correct picture, we calculated the percentage of trials in which participants launched saccades to the target before they could process the noun (estimated as 200 ms after noun onset). Participants anticipated the target on only 35.1% of distracter-initial trials in the definite condition, and 39.6% of trials in the indefinite condition.

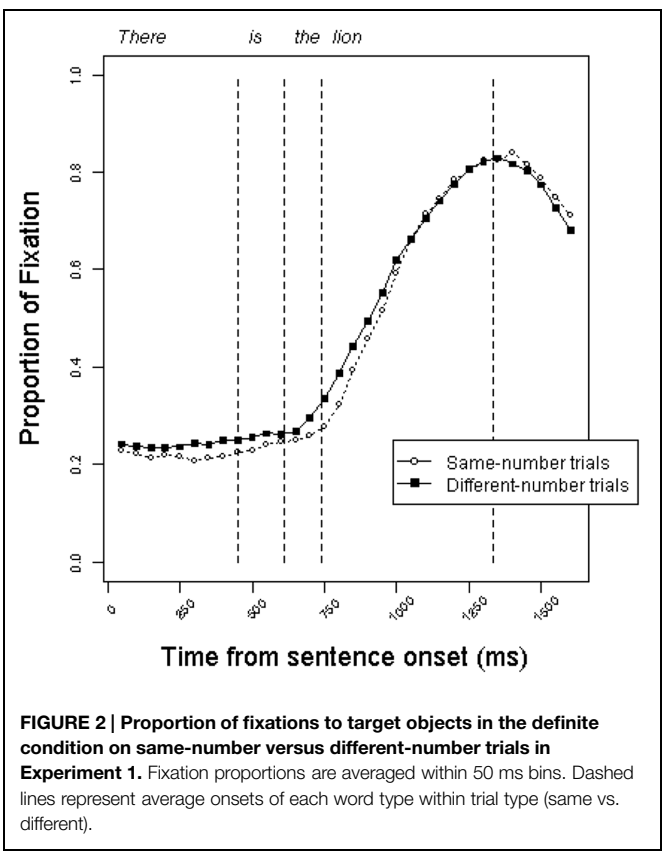

FIGURE 2 | Proportion of fixations to target objects in the definite condition on same-number versus different-number trials in Experiment 1. Fixation proportions are averaged within 50 ms bins. Dashed lines represent average onsets of each word type within trial type (same vs. different).

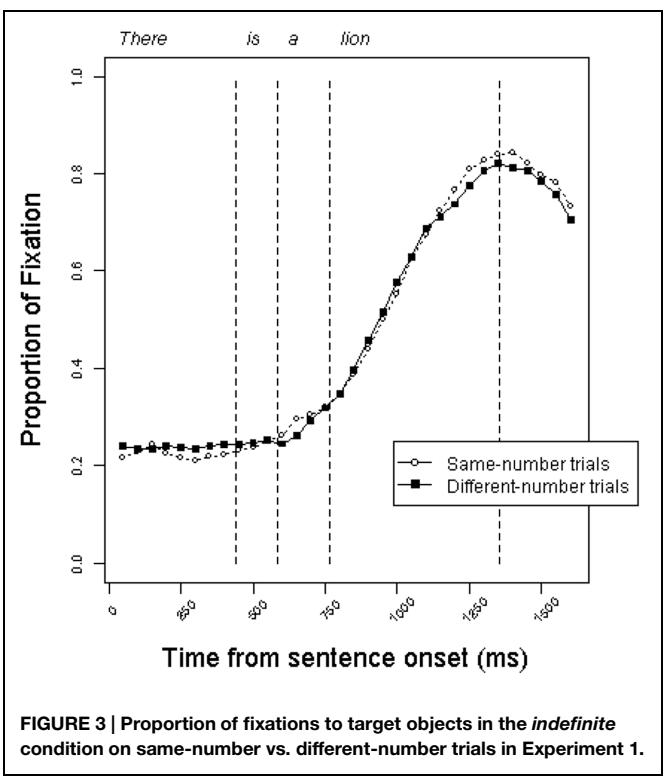

FIGURE 3 | Proportion of fixations to target objects in the *indefinite* condition on same-number vs. different-number trials in Experiment 1.

TABLE 2 | Experiment 1 reaction time (RT) analyses.

Condition		Same-number *M* (SD)	Different-number *M* (SD)	F_1	*p*	F_2	*p*
Definite	Singular	572 (109)	553 (142)	0.003	0.95	1.564	0.22
	Plural	574 (118)	555 (146)	0.132	0.72	0.003	0.96
Indefinite	Singular	524 (128)	572 (117)	0.778	0.38	8.836	0.006[1]
	Plural	613 (129)	560 (136)	0.017	0.90	0.400	0.53

[1] *In this case, RT on different-number trials was slower than on same-number trials.*

These results suggest that adults listening normally to simple declarative and interrogative sentences do not exploit grammatical number information to launch anticipatory eye movements to likely referents. We think it is unlikely that this null finding is due to a lack of power, given the consistent findings across both subjects and items, and the large number of exposures to each sentence type for each subject. Further, power analysis suggested sufficient observations for adequate sensitivity. However, it is possible that the surface structure led to strategic processing: anticipating that all sentences would have similar word order, participants may have adopted a strategy of simply waiting for the noun before shifting their gaze to the correct referent. Experiment 2 evaluated this possibility using the same stimuli and design as Experiment 1, but participants were instructed to select the correct referent as quickly as possible. Under these conditions, participants should use the grammatical number information on the copula and indefinite determiner to quickly orient to the correct picture.

Experiment 2

Method

Participants

Thirty native English speakers (not from Experiment 1) with normal or corrected-to-normal vision participated for course credit.

Stimuli and Design

Identical to Experiment 1.

Procedure

Participants were instructed to click on the picture that was mentioned in the sentence as quickly as possible without sacrificing accuracy. Otherwise, the procedure was identical to Experiment 1.

Results

An ANOVA with Experiment as a between-subjects factor revealed that the change in instructions had a dramatic effect on RTs: Experiment 2 RTs ($M = 496$, SD $= 121$) were faster than Experiment 1 RTs ($M = 566$, SD $= 129$) [$F_1(1,454) = 35.9$, $p < 0.001$; $F_2(1,252) = 40.8$, $p < 0.001$]. The percentage of trials on which participants launched saccades to the target before they could process the noun also increased: 51.9% of trials in the definite condition and 49.9% of trials in the indefinite condition.

Figures 4 and **5** present the time course of mean fixation proportions to the target pictures in the definite and indefinite conditions, respectively. Surprisingly, the trajectory of fixation proportions is similar to those in Experiment 1. The curves

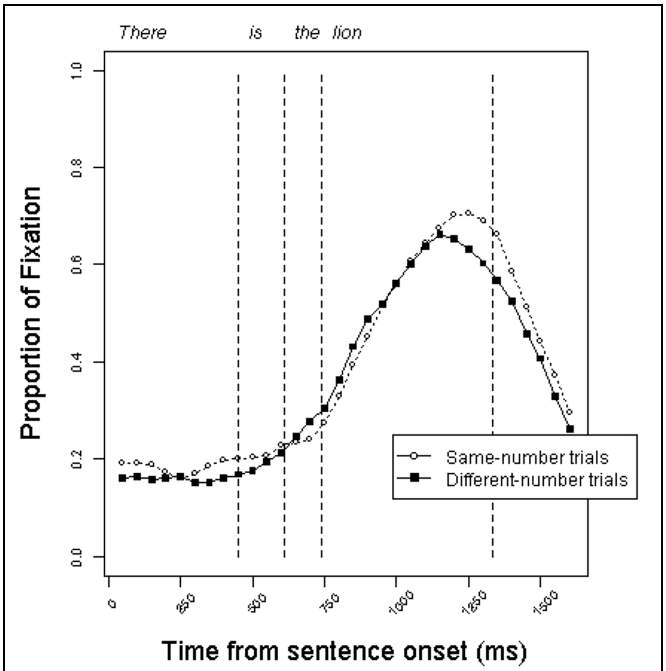

FIGURE 4 | Proportion of fixations to target objects in the definite condition on same-number vs. different-number trials in Experiment 2.

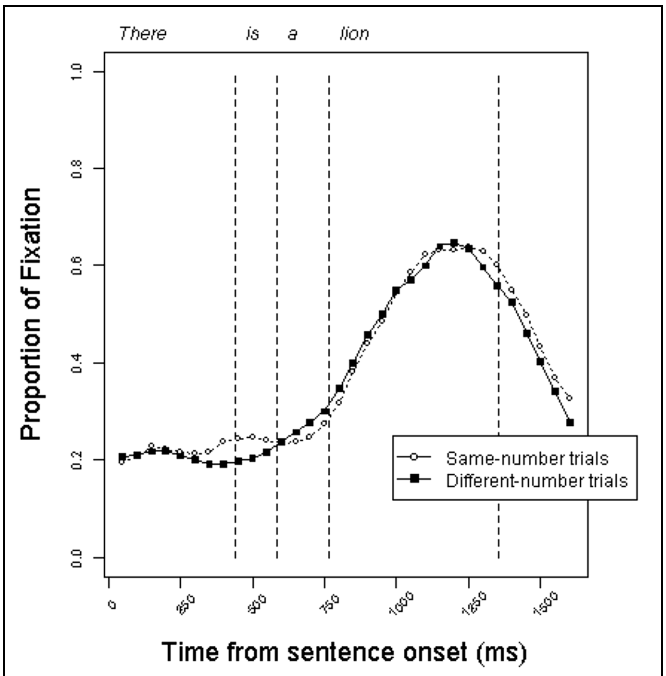

FIGURE 5 | Proportion of fixations to target objects in the *indefinite* condition on same-number vs. different-number trials in Experiment 2.

do not give an indication of anticipatory eye movements on different-number trials relative to same-number trials.

The RT analyses are presented in **Table 3**. As in Experiment 1, although there was a trend toward faster processing in the different-number trials, this impression was not statistically reliable in any of the analyses. This was true for both the definite and indefinite conditions, despite the difference in grammatical number information that was available to participants. The results of Experiment 2 corroborate the results of Experiment 1, suggesting that the result of Experiment 1 was not an artifact of strategic processing.

However, a potential concern still remains with Experiments 1 and 2. Since only declarative and interrogative sentences were used for the stimuli, it is possible that the results reflect strategies specific to the sentence types rather than a more general phenomenon of grammatical number processing in online language processing. Experiment 3 was designed to investigate this possibility using a similar design to Experiments 1 and 2 but with a wider range of sentence types.

Experiment 3

Method

Participants

Twenty native English speakers (not from Experiments 1 or 2) with normal or corrected-to-normal vision participated for course credit.

Stimuli and Design

Noun targets were 30 object names selected from McRae et al. (2005). These targets appeared in five conditions spanning auxiliary verbs in questions, declarative sentences, and demonstrative determiners. Each condition had singular and plural sentence versions, making 10 sentence sets. Three words were assigned to each sentence set and targets and distracter images were drawn from within the words in the sentence set. Distracters could not share the same initial phoneme as targets. Each target appeared in both same and different grammatical number conditions in separate trials of the experiment, yielding 60 unique grammatical number trials for each participant.

Because word types differ and length and word tokens differ in length with each utterance, across utterances, there is variation in the start and end of windows of interest. Therefore, it is common to align utterances based on the start of a window of interest for the purpose of analysis. An extension of this methodology to multiple windows of interest within an utterance involves resynchronizing at the start of each window (Altmann and Kamide, 1999). However, these techniques are only valid when the length of window, and word tokens within each window, are relatively homogeneous. Simply aligning utterances in this case runs the risk of glossing over utterance-specific eye movement behavior. Since our interest is in comparing the likelihood of launching a saccade based on information contained in function words, which are often phonetically reduced and of variable length, we chose to enforce an alignment of windows of interest across utterances by fixing the length of each window as shown in **Table 4**. Tokens shorter than the length of the window were followed by a short silence extending to the end of the window.

In addition to the grammatical number sentences, 60 new sentences were constructed using feature-target pairs selected from McRae et al. (2005) from 10 different feature types in order to compare anticipatory saccades as a function of feature type. However, these results will not be discussed in the current article. In order to ensure that participants did not develop an expectancy that target words would come later in the sentence, 60 filler sentences were created such that the first word was always the target referent. Target words for the filler sentences were the words from the feature experiment and filler sentences were generic sentences with plural subjects. The predicates of the filler sentences were features of the target word, but these features were different from the stimuli used in the feature experiment. Distracters could not share the same initial phoneme as targets. In 45 trials, both target and distracter images were plural. On the other 15 trials, the target image was singular while the distracter was plural. This was done to ensure that across the experiment participants did not develop expectations about the type of sentence they would hear based on the number-composition (i.e., target = singular, distracter = plural; etc.) of the image.

Procedure

Participants were required to make a saccade to an area of size 100 × 100 pixels surrounding a fixation dot in the center of the screen in order to initiate the sentence. This served to bring participants' fixations to a uniform location before the start of the sentence. Once a saccade was registered to the center interest

Window onset (ms)	0	300	600	900	1500	1900	2300
	is	there	a	dog			
	are	there	some	dogs			
		does	the	dog	have	brown	fur
		do	the	dogs	have	brown	fur
	there	is	the	dog			
	there	are	the	dogs			
	there	is	a	dog			
	there	are	some	dogs			
			that	dog	is	black	
			those	dogs	are	black	

area, there was a 300 ms pause, then the sentence was played. Otherwise, the procedure was identical to Experiment 2.

Results

The probability of initiating a saccade to the target object during a period starting 200 ms after the first word with grammatical number information and ending 150 ms after the onset of the target word was calculated for each participant by summing the number of trials in which a saccade to the target during this period occurred and dividing by the total number of trials. Since eye movements take approximately 180–200 ms to program, this is the critical period in which anticipatory eye movements could occur in response to the grammatical number information. Probabilities were calculated across all sentence types for each participant.

The anticipatory eye movement analyses are presented in **Table 5**. As in Experiments 1 and 2, no significant difference was observed between same-number and different- number trials, either for singular or plural sentences. The results of Experiment 3 further support the results of Experiments 1 and 2, suggesting that the results observed in these experiments were not due to the effect of strategic processing for different sentence types.

General Discussion

Many studies have demonstrated the important role that prediction plays in language processing. Prediction has been central to the study of world situated language comprehension, with demonstrations of anticipatory eye movements in response to a variety of different kinds of linguistic information. However, the three experiments presented here failed to find evidence that eye movements are tightly coordinated with the processing of morphosyntactic information. Listeners did not respond reliably faster on trials where grammatical number cues were informative about the identity of the upcoming referent relative to trials where grammatical number cues were uninformative. This was true both under natural listening conditions (Experiment 1) and when emphasizing a speeded response (Experiment 2). In addition, listeners were no more likely to look at the upcoming referent when grammatical number cues were informative as compared to trials where grammatical number was uninformative, using a mixed variety of sentence types (Experiment 3).

Our adults participants, all native English-speakers, presumably had considerable previous experience with the distributional structure of their mother tongue, and could use that knowledge to anticipate discourse as it unfolded (Haskell et al., 2010). That they did not capitalize on number as a predictive cue, even under speeded conditions, suggests that number has low cue validity; though verb number was a reliable guide to conceptual number in our experiments, this is not true of the language at large. This dovetails nicely with theoretical work indicating that in sentence processing, English speakers pay relatively little attention to subject–verb agreement marking in establishing numerosity, instead relying on word order to resolve key dependencies (MacWhinney et al., 1984), and with a raft of findings indicating that cue validity is key to attentional orienting.

TABLE 5 | Experiment 3 anticipatory eye movement analyses.

Condition	Same-number *M* (SD)	Different-number *M* (SD)	*F*	*p*
Singular	0.246 (0.217)	0.307 (0.218)	1.824	0.193
Plural	0.329 (0.229)	0.321 (0.248)	0.031	0.863

These results also complement that of Knoeferle and Crocker (2006), who found only a weak effect of tense and auxiliary words on eye movements. They found that auxiliary verbs such as *will* and *being* alone did not affect eye movements, but may have made the processing of the following verb and thematic role assignment faster. Knoeferle and Crocker (2006) concluded that there is generally a close coordination of scene processing and utterance comprehension, but this may be less so for words that only indirectly affect processing.

The finding that adult English-speakers do not reliably use grammatical number information to direct eye movements contrasts with the findings of Kouider et al. (2006) for young children (but see Johnson et al., 2005). As our experiments demonstrated, the nature of the task can have a large impact of the speed of eye movements in relation to linguistic input. Thus, the difference in findings could be attributed to differences in task, stimuli, or experimental procedure. A more interesting possibility is that novice and experienced English-language comprehenders differ qualitatively in their looking behavior during language comprehension.

Given the simplified nature of child-directed speech, adults may be more attuned to the range of possible continuations of the utterance following an opening such as *There is a. . .* For example, sentences with the singular copula *is* followed by the indefinite article *a* can be associated with plural referents, as when the referent is a collective noun, e.g., *There is a group of ducks in the water*. Thus, more experience with language in a variety of communicative contexts, and specifically with more complex NPs, may reduce adults' confidence in grammatical number morphology as a reliable cue to the identity of the upcoming referent. Indeed, because grammatical number information may not always be reliable, adults may make use of a form of "good-enough" processing (Ferreira et al., 2002) in these cases, computing an underspecified semantic expectation for possible referents (Sanford and Sturt, 2002).

This may be particularly true of certain constructions, such as the simple declaratives and interrogatives employed here, where grammatical number is only ever a partial guide to the numerosity of the referent. Naturally, there are many cases in which grammatical and conceptual number *do* align in such expressions, as was true of the sentences in our experiments. However, adults will also have been exposed to many instances in which grammatical number is highly unreliable as a predictive cue. For example, it will always be ambiguous for concrete mass nouns (*Where is the luggage she brought?*) and pluralia tantum (*There are some tongs on the counter*), where the number of the referent is left unspecified. Similarly, it will often be misleading when the verb is followed by a NP, and agreement is struck with the NP rather than the noun itself (*There is a herd of sheep*).

Varied conventions are not the only issue. A pair of large-scale corpus studies of British English confirms that agreement errors are quite common in declarative expressions, particularly in spoken language (Breivik and Martínez-Insua, 2008). Indeed, teenage speakers fail to achieve number agreement between the verb and post-verbal NP in more than a fifth of such utterances. The fact that number is not consistently informative in these contexts may help explain the growing tendency to omit number marking from them altogether (Meechan and Foley, 1994). In speech, English-speakers increasingly opt for the grammaticalized variants – *There's* and *Where's* – using these forms interchangeably with both singular and plural referents (*There's two ladies outside*).

It is not surprising then, that our participants did not rely on the number information encoded at the copula and determiner. Our null results argue against the notion that number in English is systematically informative about the numerosity of upcoming referents (see also Humphreys and Bock, 2005). More broadly, these results suggest that caution must be exercised in attempting to generalize the results of any one study – in any one language – to other studies in other languages, or to draw sweeping conclusions about the function of features like gender or number (MacWhinney et al., 1984). There is now an accumulating body of research attesting to cross-linguistic differences in morphosyntatic processing, showing systematic variation in number (Vigliocco et al., 1996; Berg, 1998) and gender processing (Miozzo and Caramazza, 1999; Schriefers and Teruel, 2000). Even within the same language, agreement processes may vary depending on the particulars of the construction (Kreiner et al., 2013), or the specific task demands (Brandt-Kobele and Höhle, 2010).

Cross-linguistic differences are to be expected. Languages vary widely in their "degree and specificity of morphological encoding" (Lupyan and Dale, 2010, p. 2), with some languages, like German, relying heavily on inflectional morphology to convey information, and others, like English, leaving more to the surrounding context—achieving lexically, what morphologically rich languages achieve through obligatory marking. In related work, Ramscar et al. (2015) have proposed that prenominal adjectives, in English, play a similar role to grammatical gender marking, in German. Both assist predictive processing; the difference is that one system is deterministic (only a certain set of nouns can legally follow the masculine article *der*), while the other is probabilistic (the distribution of nouns that follow *massive* and *moist* is markedly different, but not mutually exclusive). Thus, a possibility left open here is that rather than employing a rigid grammatical device, English simply relies on a more graded, semantically based means of specifying conceptual numerosity. This is consistent with the proposal that, in English, countability is a characteristic of NPs, rather than nouns (Allan, 1980), and that semantic principles selectively bias English agreement patterns (Berg, 1998).

In sum, English-speaking adults have difficulty consistently making use of grammatical number information to direct eye movements when processing simple declarative and interrogative sentences. This result indicates that the link between eye movements and linguistic processing is variable, depending especially on the linguistic information involved and the goals of language users.

An interference account of the missing-VP effect

Jana Häussler[1]* *and Markus Bader*[2]

[1] Department of Linguistics, University of Potsdam, Potsdam, Germany, [2] Department of Linguistics, Goethe University Frankfurt, Frankfurt, Germany

Sentences with doubly center-embedded relative clauses in which a verb phrase (VP) is missing are sometimes perceived as grammatical, thus giving rise to an illusion of grammaticality. In this paper, we provide a new account of why missing-VP sentences, which are both complex and ungrammatical, lead to an illusion of grammaticality, the so-called missing-VP effect. We propose that the missing-VP effect in particular, and processing difficulties with multiply center-embedded clauses more generally, are best understood as resulting from interference during cue-based retrieval. When processing a sentence with double center-embedding, a retrieval error due to interference can cause the verb of an embedded clause to be erroneously attached into a higher clause. This can lead to an illusion of grammaticality in the case of missing-VP sentences and to processing complexity in the case of complete sentences with double center-embedding. Evidence for an interference account of the missing-VP effect comes from experiments that have investigated the missing-VP effect in German using a speeded grammaticality judgments procedure. We review this evidence and then present two new experiments that show that the missing-VP effect can be found in German also with less restricting procedures. One experiment was a questionnaire study which required grammaticality judgments from participants without imposing any time constraints. The second experiment used a self-paced reading procedure and did not require any judgments. Both experiments confirm the prior findings of missing-VP effects in German and also show that the missing-VP effect is subject to a primacy effect as known from the memory literature. Based on this evidence, we argue that an account of missing-VP effects in terms of interference during cue-based retrieval is superior to accounts in terms of limited memory resources or in terms of experience with embedded structures.

1. Introduction

Some sentences are more difficult to process than other sentences, and some sentences are so complex that they exceed the processing capacity of the human parser and thereby lead to processing overload. A striking illustration of the parser's limited capacity is provided by sentences with multiple center-embedding as illustrated by the example in (1) from Frazier (1985).

(1) The patient the nurse the clinic had hired admitted met Jack.

Sentences with multiple center-embedding have long been known to be difficult to process (Chomsky and Miller, 1963; Miller and Chomsky, 1963; Miller and Isard, 1964; Bever, 1970; Kimball, 1973, e.g.,). Sentences with two degrees of center-embedding can still be comprehended under certain conditions, as demonstrated by the following sentence from Bever (1974), in which the subject of the most deeply embedded relative clause is a first-person pronoun and not a lexical NP.

(2) The reporter who everyone *that I met* trusts said the president won't resign yet.

Sentences with two degrees of center-embedding are also produced from time to time, at least in written language (cf. Karlsson, 2007). With two levels of center-embedding, the maximum degree of center-embedding is already reached, however, and sentences with three or more degrees of center-embedding seem to be beyond the capacity of human parsing and human sentence production.

In comparison to sentence (1), the closely related sentence in (3) seems much easier to understand.

(3) The patient the nurse the clinic had hired met Jack.

Sentence (3) is an example of the so-called *missing-VP effect*, a term coined by Gibson and Thomas (1999) for the observation that people often fail to notice the lack of a verb phrase in sentences involving multiple center-embedding. The effect was first discussed by Frazier (1985), who attributes the observation to Janet Fodor.

Missing-VP sentences contain two degrees of center-embedding and an uncontroversial ungrammaticality. Each of these properties alone should suffice to decrease the acceptability of such sentences, and when the two properties occur together, a highly degraded sentence should result. However, instead of being perceived as highly degraded, the acceptability of such sentences is as high or even higher as the acceptability of corresponding complete and thereby grammatical sentences. This was first demonstrated by Gibson and Thomas (1999) in a rating study examining sentences like (4)[1].

(4) The ancient manuscript that the graduate student who the new card catalog [$_{VP3}$ had confused a great deal] [$_{VP2}$ was studying in the library] [$_{VP1}$ was missing a page].

Sentences were either complete or were missing one of VP1, VP2, or VP3 and had to be rated for their intuitive complexity. While sentences with either missing VP1 or missing VP3 were rated as being significantly more complex than complete sentences, the ratings for sentences with missing VP2 did not differ significantly from the ratings for complete sentences. Later research by Christiansen and MacDonald (2009) and Vasishth et al. (2010) showed that sentences in which VP2 is missing are more often perceived as grammatical and are easier to process than corresponding complete sentences with two degrees of center-embedding. Gimenes et al. (2009) have found similar results for French, another SVO language. The only SOV language for which evidence on the missing-VP effect exists seems to be German, but this evidence is mixed. Since our experiments investigate German sentences, we postpone a discussion of the missing-VP effect in this language to Section 4.

The missing-VP effect belongs to a small class of grammatical illusions—sentences which tend to be perceived as grammatical despite containing an undisputed ungrammaticality. In their review of grammatical illusions, Phillips et al. (2011, p. 166) exclude the missing-VP effect from further consideration because examples as in (3) "differ from the others discussed here in the respect that they plausibly reflect complexity-induced overload, and it is not clear what parse is assigned to such dramatically ill-formed sentences". We take the view that the missing-VP effect reflects complexity-induced overload to be uncontroversial. However, there are competing conceptions as to the source of parsing overload. The major aim of this paper is to provide an account of the missing-VP effect that follows much recent work in cognitive psychology and psycholinguistics claiming that overload is mainly a matter of interference during memory retrieval. Based on this hypothesis, we will argue that the parse assigned to missing-VP sentences differs minimally from the parse assigned to corresponding complete sentences. The only difference is that for complete sentences, all VP slots of the syntactic representation are filled by lexical material whereas for missing-VP sentences one of the VP slots remains empty. These claims are based on a review of prior experimental investigations of the missing-VP effect in German and on two new experiments, which were run with the additional aim of resolving some contradictions that concern the status of the missing-VP effect in German.

The organization of this paper is as follows. In Sections 2 and 3, we discuss two approaches to capacity limitations of cognitive processes and how they might account for the missing-VP effect. Section 2 introduces the resource account of capacity limitations and Section 3 the interference account. Section 4 reviews evidence from German favoring the interference account over the resource account. Some concerns regarding this evidence is addressed by two experiments that are presented in Sections 5 and 6. Section 7 concludes with a general discussion of the experimental results.

2. Resource Accounts of the Missing-VP Effect

The parser is not alone in being capacity limited. Most if not all cognitive abilities share this property. For example, our ability for mental calculations is restricted to a small subset of numbers, our ability to recall lists of unrelated items is limited to lists of no more than seven or eight items, and so on. Limitations of this kind are often attributed to a working memory system of limited

[1]In Gibson and Thomas (1999), VPs are numbered according to their linear position in the sentence string. In later publications (Christiansen and MacDonald, 2009; Gimenes et al., 2009; Vasishth et al., 2010), VPs are numbered according to their hierarchical position in the phrase-structure tree. In this paper, we adopt the latter numbering. VP1 is the VP of the matrix clause (S1), VP2 is the VP of the upper relative clause (S2), and VP3 is the VP of the lower relative clause (S3). The VPs therefore appear in the linear order VP3 VP2 VP1.

capacity. The question then becomes why working memory has such a severely limited capacity. Over time, this question has received various answers (see overviews in Oberauer and Kliegl, 2001; van Dyke and Johns, 2012).

Before we take a closer look at these answers, let us first get clear about the tasks that have to be accomplished in order to parse sentences successfully. By definition, a parser takes the words of an input string and constructs a syntactic structure for them. In the following, we assume the syntactic structure to be a conventional phrase-structure tree. Given the strong evidence that human parsing proceeds in an incremental way, the parser's task can be divided into two major subtasks (see Just and Carpenter, 1992; Gibson, 1998). First, the parser must store the syntactic structure, which is incremented word-by-word, in some kind of temporary buffer. Secondly, the parser must integrate each word of the input string into the unfolding syntactic structure as soon as the word is encountered. This subtask can be decomposed further. First, the parser must find a place within the ongoing syntactic structure where the word can be attached. Second, the word must be connected to words that are already part of the ongoing syntactic structure. For example, a verb must be connected to its arguments for thematic role and case assignment and for checking agreement requirements.

With the distinction between storage and integration at hand, we now come back to the question of why human parsing is subject to severe capacity limitations. For a long time, the dominant approach to capacity limitations was based on the claim that cognitive processes draw on a limited pool of processing resources. Applied to the issue of sentence parsing, the Resource Hypothesis states that the parser can use only a fixed amount of resources for the storage and computation of syntactic structures. When the available resources do not suffice for processing sentences of high complexity, processing overload results. An influential theory of sentence comprehension building on the Resource Hypothesis is the Capacity Theory of Just and Carpenter (1992). According to the Capacity Theory, each individual has a fixed amount of processing resources available for processing language. These resources can be allocated flexibly to the storage of intermediate syntactic structures and the incremental integration of words into the intermediate structure built thus far. The assumption that the parser must use a fixed pool of resources for both storage and processing is shared by the Syntactic Prediction Locality Theory (SPLT) of Gibson (1998) and its successor, the Dependency Locality Theory (DLT) of Gibson (2000).

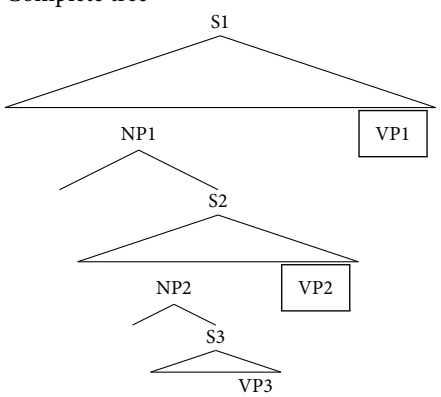
According to resource-based theories, sentences with a high degree of center-embedding cannot be successfully parsed because they require more resources than are available. This suggests an explanation of the missing-VP effect along the following lines. When the parser is processing a sentence of high syntactic complexity, it may be short of running out of resources. In such a case, the parser can try to proceed by forgetting some part of the structure built thus far, thereby freeing resources needed to continue the ongoing parsing process. Two implementations of this idea are the *Disappearing Syntactic Nodes Hypothesis* of Frazier (1985) and the *High Memory Cost Pruning Hypothesis* of Gibson and Thomas (1999). Both implementations share the idea that the phrase structure tree is cut down under conditions of high memory load. For reasons of space, we only give the High Memory Cost Pruning Hypothesis below.

(5) *The High Memory Cost Pruning Hypothesis* (Gibson and Thomas, 1999, p. 231)
At points of high memory complexity, forget the syntactic prediction(s) associated with the most memory load.

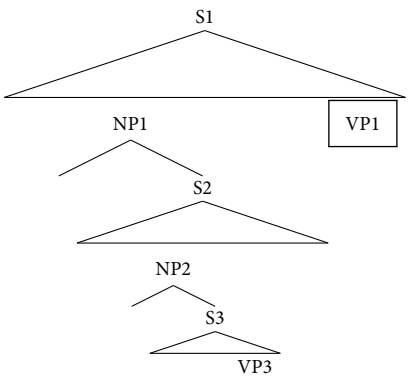
The High Memory Cost Pruning Hypothesis was formulated within the SPLT of Gibson (1998). According to the SPLT's definition of storage cost, the prediction of VP2 is associated with the most memory load in sentences with doubly center-embedded relative clauses (see Gibson and Thomas, 1999; Vasishth et al., 2010, for details). The prediction of VP2 is therefore forgotten. Instead of the complete tree shown on the left side in (6), the incomplete tree on the right side is available for the parser at the point where the two final VPs of a missing-VP sentence are about to be integrated.

The first VP that the parser encounters is put into the open slot for VP3 and the next VP into the slot for VP1. In a sentence with missing VP2, all VPs of the input string can thus be successfully integrated. Because the slot for VP2 is no longer present in the syntactic representation, the parser fails to notice the lack of a VP. In the case of complete sentences with a doubly center-embedded relative clause, the representation on the right side of (6) does not provide an attachment site for each VP. Such sentences should

(6) Complete tree



Tree with VP2 pruned



thus be more difficult to process than sentences with a missing VP. This was not the case in the off-line ratings reported in Gibson and Thomas (1999), but on-line evidence obtained by Christiansen and MacDonald (2009) and Vasishth et al. (2010) shows that sentences in which VP2 is missing are easier to process than corresponding sentences in which VP2 is present.

A conceptual drawback of the High Memory Cost Pruning Hypothesis is that it does not follow from independently motivated principles of storage or computation. Resource-based accounts of capacity limitations typically assume that trace decay is an important source of storage limitations. When applied to sentences with double center-embedding, the prediction of VP1 should be less available than the prediction of VP2 because it was introduced earlier and had therefore more time for decay. This is just the opposite of what the Pruning Hypothesis claims and is accordingly not compatible with the findings for missing-VP sentences. Additional machinery is therefore necessary in order to derive that the prediction of VP2 is pruned but not the prediction of VP1. For example, the parser must somehow be able to calculate the memory load of each prediction in order to prune the one with the most memory load. These calculations are heavily theory dependent. As discussed in more detail in Vasishth et al. (2010), the memory-load definitions of the DLT do no longer predict that VP2 is pruned, although—as also shown in Vasishth et al. (2010)—it is possible to adapt the Pruning Hypothesis to the particular properties of the DLT.

We will not dwell further on this issue because resource-based accounts of capacity limitations in general and the concept of trace decay have fallen into disreputation, both for theoretical reasons (e.g., Navon, 1984, MacDonald and Christiansen, 2002) and for lack of empirical support (e.g., Oberauer and Kliegl, 2001). Two influential alternatives to the resource-based view are the *interference account* and the *experience-based account* (further alternatives are discussed in Oberauer and Kliegl, 2001). In the next section, we propose an explanation of the missing-VP effect that is based on the interference account. The experience-based account is discussed in the final section[2].

3. An Interference Account of the Missing-VP Effect

The interference account is based on the observation that the retrieval of material from working memory becomes less reliable in the presence of similar material. In order to apply the interference account to the process of sentence parsing, we have to take a closer look at the steps that lead to the integration of new words into the unfolding syntactic representation. A crucial first step for successful integration is the retrieval of the correct attachment site for the word that is to be integrated. If the retrieval cues used for this purpose match more than a single attachment site, finding the proper place for attaching the next word can become more difficult.

While interference from similar items can make the integration of new items more difficult, whether interference does indeed occur depends on the particular syntactic configuration. Consider first the situation that obtains in sentences with double center-embedding at the point where the verb of the most deeply embedded relative clause has to be integrated, that is, *met* in sentence (7).

(7) [$_{S1}$ [*The reporter*] [$_{S2}$ who [**everyone**] [$_{S3}$ that I [$_{V3}$ met]] [$_{V2}$ **trusts**] …
[$_{S1}$ NP1 [$_{S2}$ NP2 [$_{S3}$ NP3]

The syntactic representation built up to this point contains three clauses which still need a VP, namely the matrix clause S1 and the two relative clauses S2 and S3. Despite the existence of three potential attachment sites, the integration of the verb *met* into the embedded relative clause will not be disturbed by the presence of other potential attachment sites. The reason for this is that the most recently read subject is in the focus of attention and therefore immediately available for integration (see McElree, 2006, for the notion of focal attention as used in the memory literature).

The situation changes when the parser encounters the verb of the higher relative clause, *trusts* in sentence (5). After the most deeply embedded relative clause has been processed, the ongoing phrase-structure representation still contains two possible attachment sites for a verb. In this case, choosing the correct attachment site is not so easy for the parser because due to the intervening relative clause S3, the parser faces the task of switching back to a clause that is no longer in the focus of attention. Because there are two such clauses and each contains a slot for a VP, retrieving the correct integration site is difficult due to interference from the competing integration site.

Experimental evidence that attaching a word into the current clause is qualitatively different from attaching it to a clause that has been interrupted by one or more embedded clauses has been provided by McElree et al. (2003). In an experiment using a response-signal speed-accuracy tradeoff procedure, the verb either occurred adjacent to the head noun of the subject NP or was separated from it by either one or two relative clauses plus an additional PP in some cases. The results show that sentences in which the verb was adjacent to the subject head noun were associated with a higher asymptotic accuracy and also with a faster retrieval speed. This suggests that integrating a word with the immediately preceding word has a special status, in accordance with findings from the memory literature that only the most recent item is in focal attention (see McElree, 2006). However, Foraker and McElree (2011) and McElree and Dyer (2013) cite unpublished data by McElree and Wagers that argue against a too narrow definition of focal attention for the purpose of sentence parsing. McElree and Wagers found that an intervening relative clause removes the subject head noun

[2]Resource-based and interference-based accounts are not necessarily incompatible with each other. For example, cognitive architectures such as ACT-R and its relatives SOAR and 3CAPS usually include both assumptions—a limited amount of resources as well as interference from similar items—but differ with regard to the component they emphasize.

from focal attention but an intervening PP (8a) or an intervening adverbial (8b) do not.

(8) a. The crowd gasped as the driver *of the ambulance* fainted.
b. The crowd gasped as the driver *abruptly* fainted.

At the current state of knowledge, it does not seem to be possible to come up with a precise definition of the scope of focal attention. What can be concluded from the literature is that an intervening relative clause removes material preceding it from focal attention whereas at least some non-clausal constituents do not. We therefore propose the *Discrimination Hypothesis* in (9) (for related ideas, see Bader et al., 2003; Lewis and Vasishth, 2005; and Bader, 2015).

(9) The *Discrimination Hypothesis*
The integration of new material becomes difficult when an intervening clause separates the word that is to be integrated next from the required integration site and an incorrect but similar integration site competes for attachment.

When processing a sentence with doubly center-embedded relative clauses, two potential integration sites are available at the point where the second verb has to be integrated into the ongoing syntactic representation. According to the *Discrimination Hypothesis*, these two integration sites are difficult to discriminate. When the second verb has to be integrated, the parser may therefore retrieve S1 as integration site for V2 instead of S2. This will result in a syntactic representation in which the verb slot of S1 is filled whereas the verb slot of S2 remains empty. Because complete sentences exhibiting double center-embedding and corresponding missing-VP sentences diverge only after the second verb, such an ill-formed representation can arise for both of them. A mis-attachment of V2 to the verb slot of S1 can therefore happen in both cases. In complete sentences, this can give rise to the well-known processing difficulties of sentences with double center-embedding. For missing-VP sentences, this can lead to an illusion of grammaticality.

Crucially, the Discrimination Hypothesis does not claim that anything is deleted from the ongoing syntactic representation of a sentence. The only claim is that the parser sometimes attaches a word to an incorrect attachment site. As a result, the syntactic structure for a sentence can contain a node that has not been filled with lexical material. In order for a grammatical illusion to occur, the parser must not detect that a VP slot is still empty after the last word of the sentence has been processed. We therefore have to complement the Discrimination Hypothesis with appropriate assumptions concerning the processes that check whether a sentence obeys all syntactic constraints or not[3].

What could be the reason that the parser at times fails to detect that a sentence is incomplete? To begin with, consider sentence (10), a variant of sentence (4) of Gibson and Thomas (1999).

(10) [$_{S1}$ A page was missing in the ancient manuscript
[$_{S2}$ that the graduate student [$_{S3}$ who the new card catalog had confused a great deal]]].

In contrast to the original example, the higher relative clause appears in a sentence final position in (10) and is thus no longer center-embedded. In sentence (10), VP2 (the VP of the higher relative clause) is missing, but in this case the resulting ungrammaticality seems easy to detect[4]. This shows that a missing VP goes unnoticed only under conditions of high processing load. The question then is what these conditions are. One major issue concerns the absence of a grammatical illusion when VP1 is missing, that is, in sentences as in (11) [partially repeated from (4)].

(11) The manuscript that the graduate student who the new card catalog had confused a great deal *was studying in the library*.

a. Integration of the final verb *was studying* as VP1 into S1:

[$_{S1}$ *The manuscript* [$_{S2}$ that the graduate student [...] Δ] *was studying in the library*.]

b. Integration of the final verb as VP2 into S2:

[$_{S1}$ The manuscript [$_{S2}$ *that the graduate student* [...] *was studying in the library*.] Δ]

Sentences of this type were rated as highly complex in the experiment of Gibson and Thomas (1999). There are at least two alternative reasons for this. First, the final VP in (11) is integrated into S1 as VP1, giving rise to the configuration in (11a), which is complex due to its semantic implausibility. Alternatively, the final VP could be integrated into S2 as VP2, resulting in the configuration in (11b). This configuration will be perceived as complex only when one detects that the initial NP remains without a VP.

According to the Discrimination Hypothesis, VP2 and VP1 are both available as attachment sites when the final VP in (11) is about to be integrated. The finding of Gibson and Thomas (1999) that a missing-VP effect occurs when VP2 is missing but not when VP1 is missing can be accounted for in an interference-based framework by recourse to the notion of primacy. The opposite notion, namely recency, has already been made responsible for the fact that integrating V3 into S3 is not subject to interference and therefore unproblematic. S1 in sentences like (11) is the first clause not only in a hierarchical sense but also in a temporal sense. It therefore enjoys the advantage of primacy that is well-known from studies of memory retrieval (e.g., Knoedler et al., 1999). This advantage can have two consequences. First, it can cause V2 to be integrated more readily into S1 than into S2, resulting in configuration (11a). Second, it can ease the detection of a missing VP1 in case V2 was correctly integrated into S2, as in (11b). If this reasoning is on the right

[3]Note that similar assumptions would also be necessary for accounts assuming the deletion of a VP from the phrase structure representation. Pruning of a predicted VP leaves a subject NP without corresponding predicate within the ongoing syntactic structure. Thus, for a missing-VP sentence to be judged as grammatical, a pruning account has to claim that the parser overlooks the dangling subject NP.

[4]For English, Gibson and Thomas (1999) cite an unpublished acceptability experiment by Gibson and Kaan as providing evidence for this claim. In an unpublished experiment using the procedure of speeded grammaticality judgments, we found that German sentences corresponding to (10) were rejected as ungrammatical in almost 90% of the trials.

track, it should be possible to find evidence for a missing-VP effect for VP1 when the primacy advantage is taken away from S1. Evidence of this kind is discussed in the next section.

4. Evidence for the Interference Account

Experimental evidence for the interference account presented in the preceding section comes from an investigation of the missing-VP effect in German by Bader et al. (2003). In contrast to Gibson and Thomas (1999), who had participants rate the complexity of sentences on a scale from 1 to 5, Bader et al. (2003) required participants to give a binary grammaticality judgment. The rationale behind this decision was as follows. The defining property of a grammatical illusion is that a sentence is perceived as grammatical despite containing an undisputed ungrammaticality. Thus, the most straightforward way to test whether an ungrammatical sentence causes a grammatical illusion or not is to have native speakers judge its grammaticality. If the sentence is judged as grammatical, we can conclude that it caused a grammatical illusion.

Things are more complicated because we cannot expect that the illusion of grammaticality will arise on each single occasion. For some of the grammatical illusions that are discussed in Phillips et al. (2011), judgment data are available, showing that the strength of such illusions can vary considerably. For example, sentences with a negative polarity item and a negation not c-commanding the polarity item give rise to a negative polarity illusion. In a judgment experiment by Drenhaus et al. (2005), such sentences were erroneously accepted as grammatical in 30% of the time, which is only 10% more than for sentences with a negative polarity item and no negation at all. For the case illusion reported in Bader et al. (2000) and Meng and Bader (2000), the false acceptance rate was about 40% for sentences in which the verb assigned dative case to an NP which was case-ambiguous but not compatible with dative case (Bader et al., 2000). When this NP was made more complex by adding a relative clause, the false acceptance rate increased to a value of about 60% (Meng and Bader, 2000). Grammatical illusions are thus not an all-or-nothing matter, but a probabilistic phenomenon instead. Grammatical illusions do not differ from semantic illusions in this respect. For example, when testing the Moses illusion by means of a truth judgment task, Erickson and Mattson (1981) found that the sentence *Moses took two animals of each kind on the Ark.* was judged as true by 41% of the participants who possessed the relevant knowledge. Thus, semantic illusions are probabilistic too.

The particular procedure for obtaining grammaticality judgments used by Bader et al. (2003) was the procedure of speeded grammaticality judgments. Sentences were presented visually one word at a time. Participants were asked to judge sentences as either grammatical or ungrammatical as quickly as possible. A time limit of 2000 ms starting at the offset of the last word was imposed in order to encourage fast decisions. On average, participants responded even faster. Using this method, Bader et al. (2003) investigated whether the evidence provided by Gibson and Thomas (1999) can be replicated for German. The experiments provided two major results. First, participants accepted sentences with a missing VP as grammatical in a substantial number of trials. This shows that the grammatical illusion caused by a missing VP also occurs in German—at least when participants have to judge sentences under time pressure. The second major finding concerns the difference between sentences in which VP1 is missing and sentences in which VP2 is missing. In accordance with the initial observation in Frazier (1985), Gibson and Thomas (1999) found that the missing VP effect occurs when VP2 is missing but not when VP1 is missing. The same was found for German sentences which were similar to the sentences investigated by Gibson and Thomas in that the head noun of the highest relative clause was part of a main clause. When this noun was part of an embedded that-clause, however, participants often accepted incomplete sentences whether VP1 or VP2 was missing.

Thus, missing-VP sentences in which the final VP was syntactically and semantically compatible with attachment to either S1 or S2 were accepted most of the time. A relevant example is provided in (12).

(12) *Missing VP, singular S2 subject*

	Klaus	hat	mir	erzählt,							
	K.	has	me	told							
S1	dass	**jemand**		die	Sängerin,						
	that	someone.SG		the	singer.SG						
S2	*die*	den	Moderator,								
	who.SG	the	moderator								
S3	der	das	Interview	trotz	einer	Grippe	führen	musste,			
	who	the	interview	despite	a	flu	conduct	must			
S1/S2	***beleidigt***	***hat***.									
	insult	has.SG									

final verb in S2: "Klaus told me that someone Δ the singer who insulted the moderator who had to conduct the interview despite a flu"

final verb in S1: "Klaus told me that someone insulted the singer who Δ the moderator who had to conduct the interview despite a flu"

In (12), a verb with an animate subject and an animate direct object is required for completion of both S1 and S2. Since the clause-final verb *beleidigt hat* ("insulted has") meets both requirements, it can be attached to either S1 or S2. For such sentences, the acceptance rate reached a high value of about 75%, which is even slightly higher than for complete sentences. When syntactic or semantic constraints only allowed attachment to either S1 or S2, missing-VP sentences were accepted significantly less often, although still about half of the time. In the context of other types of grammatical illusions, missing VPs thus give rise to a rather strong illusion.

There is a caveat, however. Grammaticality judgments provide the most direct way of testing whether participants experience a grammatical illusion, but they are not without problems. This holds in particular when judgments must be given under time pressure, as in the experiments of Bader et al. (2003). Without further evidence, it cannot be excluded that the grammatical illusion found by Bader et al. was caused by the strict timing conditions imposed by the procedure of speeded grammaticality judgments. In order to address this issue, Experiment 1 replicates one experiment of Bader et al. (2003) using a judgment procedure that neither limits the time to process a sentence nor the time for giving a judgment.

An even more serious issue was brought about by Vasishth et al. (2010) who investigated the missing-VP effect in both English and German by recording reading times. A German example from Vasishth et al. (2010) is shown in (13).

(13) [$_{S1}$ Der Anwalt, [$_{S2}$ den der Zeuge, [$_{S3}$ den der Spion [$_{VP3}$ betrachtete,]] [$_{VP2}$ schnitt,]] [$_{VP1}$ überzeugte den Richter.]]
the lawyer who the witness who the spy watched avoided convinced the judge
"The lawyer that the witness that the spy watched avoided convinced the judge."

The study included complete sentences as in (13) as well as incomplete sentences in which the intermediate verb [= *schnitt* in (13)] was missing. In a self-paced reading experiment and in an eye-tracking experiment, Vasishth and colleagues found longer reading times for the last verb (*überzeugte*) and the following NP in incomplete sentences compared to complete sentences. For English, in contrast, Vasishth and colleagues found the opposite pattern. Reading times for the last verb were longer in complete sentences than in incomplete sentences. The authors take the reading time increase in German as indicating that their participants noticed the ungrammaticality. Based on the crosslinguistic difference between German and English, Vasishth et al. conclude that the German reader's parser is more adapted to keeping track of upcoming verbs due to the verb-final nature of German.

Using again a speeded grammaticality judgment procedure, Bader (2015) found evidence for a missing-VP effect in sentences structurally similar to those investigated by Vasishth et al. (2010). When taking the whole literature into account, we arrive at the generalization that a missing-VP effect was found for German when using the method of speeded grammaticality judgments but not when using reading time measures. Experiment 2 therefore uses a self-paced reading procedure that does not require any grammaticality judgments at all in order to test whether the missing-VP effect also occurs under more natural reading conditions for the kind of sentences for which only judgment data are available so far.

5. Experiment 1

Experiment 1 has two aims. The first aim concerns the question of whether the illusion of grammaticality caused by missing-VP sentences also occurs when participants are not set under time pressure. To answer this question, Experiment 1 obtained grammaticality judgments without time limits on either reading a sentence or judging its grammaticality.

If the missing-VP effect is indeed independent of time constraints on reading and judging a sentence, the next question is whether we can replicate the finding of Bader et al. (2003) that a grammatical illusion can arise not only when VP2 is omitted but also when VP1 is omitted. In the prior literature, sentences with a missing VP1 were rarely investigated after Gibson and Thomas (1999) found that such sentences are rated as highly complex. In Bader et al. (2003), the missing-VP1 effect was restricted to sentences in which S1 is an embedded clause. The second aim of Experiment 1 is therefore to examine whether a missing-VP1 effect arises and whether it depends on the clause type of the corresponding S1.

To test this question, Experiment 1 adopts the design and materials of Experiment 2 in Bader et al. (2003). Experiment 1 varies the clause type of S1 such that S1 is either an embedded complement clause as in (14) or a main clause as in (15). In addition, the experiment varies whether VP1 or VP2 is omitted as indicated in (14) and (15) by crossing.

Two subprocesses within the human parser are crucially involved when sentences with a missing VP elicit a grammatical illusion. First, either S1 or S2 is retrieved as integration site for the final VP. Second, the resulting structure is accepted as grammatical despite the lack of a VP. When S1 is selected for integration, a missing-VP effect arises when the lack of VP2 goes unnoticed. When S2 is selected for integration, a missing-VP effect arises when the lack of VP1 goes unnoticed. The clause type of S1 could influence both the likelihood of retrieving the wrong attachment site and the likelihood of noticing the lack of a VP. It will thereby determine the probability that a missing-VP effect is observed.

Why should clause type of S1 matter? When S1 is a main clause, it is the first clause and might benefit from primacy effects as observed in the literature on memory retrieval (for a recent overview, see Knoedler et al., 1999). Adding a level

(14) *Relative clauses within a complement clause*

Ich habe gehört
I have heard
S1 dass seit heute Mittag die Praktikantin,
that since today noon the intern
S2 die den Systemabsturz,
who the system_crash
S3 der die Technikerin für etliche Stunden beschäftigt hatte,
which the engineer for several ours occupied had
S2 [$_{VP2}$ ~~*verursacht*~~ ~~*hat*~~],
caused has
S1 [$_{VP1}$ ~~*verschwunden*~~ ~~*ist*~~.]
disappeared.PTCP is

Complete: "I have heard that the intern who caused the system crash which occupied the engineer for several hours disappeared since noon."
Missing VP2: "I have heard that the intern who Δ the system crash which occupied the engineer for several hours disappeared since noon."
Missing VP1: "I have heard that the intern who caused the system crash which occupied the engineer for several hours Δ since noon."

(15) *Relative clauses within a main clause*

S1 Seit heute Mittag ist die Praktikantin,
Since today noon is the intern
S2 die den Systemabsturz,
who the system_crash
S3 der die Technikerin für etliche Stunden beschäftigt hatte,
who the engineer for several hours occupied had
S2 [$_{VP2}$ ~~*verursacht*~~ ~~*hat*~~],
caused has
S1 [$_{VP1}$ ~~*verschwunden*~~.]
disappeared.PTCP

Complete: "Since noon, the intern who caused the system crash which occupied the engineer for several hours is missing."
Missing VP2: "Since noon, the intern who Δ the system crash which occupied the engineer for several hours is missing."
Missing VP1: "Since noon, the intern who caused the system crash which occupied the engineer for several hours is Δ."

of embedding changes the accessibility of S1. As an embedded clause, S1 is no longer the first clause but occurs in an intermediate position in the sequence of clauses. S2, in contrast, occurs always in an intermediate position between at least two clauses, namely S1 and S3 regardless of the type of S1. A primacy advantage of S1 in sentences in which S1 is a main clause could affect the processing of missing-VP sentences in two ways: First, it might increase the probability of integrating the final VP into S1 and thus decrease the probability of integrating it into S2. Second, in case the final VP was integrated into S2, the primacy advantage might increase the probability of detecting that S1 is missing a verb. These two possible consequences of the increased salience of S1 do not exclude each other. Both could jointly prevent a missing-VP effect in sentences in which S1 is a main clause and VP1 is missing. In these sentences, integration of VP2 into S1 results in a syntactic and semantic conflict, which prevents the illusion of grammaticality. Attachment to S2 would leave S1 with a missing VP, which will be noted thanks to the salience of S1. Thus, primacy predicts that the likelihood of a grammatical illusion in missing-VP2 sentences depends on the level of embedding of S1.

In missing-VP2 sentences, a grammatical illusion arises when the remaining VP1 is correctly integrated into S1 and the lack of a VP in S2 goes unnoticed, or when VP1 is integrated into S2 and the lack of a VP in S1 goes unnoticed. Primacy effects might increase the chance of S1 integration and thereby increase the likelihood of a grammatical illusion (under the assumption that the likelihood of detecting a missing VP in S2 is independent of the status of S1). But at the same time, primacy would increase the chance of detecting a missing VP in S1 when VP2 is correctly integrated into S2. Taken together, primacy predicts a lower rate of grammatical illusions in sentences in which S1 is a main clause and VP1 is missing.

5.1. Method

5.1.1. Participants

Twenty-four students at the University of Konstanz participated in Experiment 1. In this and the following experiment, all participants were native speakers of German and were naive with respect to the purpose of the experiment. They were either paid or received course credit for participation in the experiment.

5.1.2. Materials

The materials for Experiment 1 consisted of 30 sentences that were taken from Bader et al. (2003). Each sentence appeared in six versions according to the two factors Clause Type and Structure. The factor Clause Type varied the type of the matrix clause of the higher relative clause. This was either an embedded complement clause as in (14) or a main clause as in (15). The factor Structure manipulated whether the sentence was complete or not. In case it was not complete, either VP2 or VP1 was missing as indicated in (14) and (15) by crossing.

Sentences in the condition "main clause" consisted of three clauses: a main clause (S1), a relative clause (S2) center-embedded into the main clause, and a second relative clause (S3) center-embedded into the first relative clause. All main clauses started with an adverbial followed by the finite auxiliary and the subject NP. This subject NP was modified by the first relative clause. This relative clause was a subject-initial relative clause whose object NP was modified by the second relative clause. Each relative clause ended in a lexical verb followed by an auxiliary whereas the main clause ended in a lexical verb only because the main-clause auxiliary occurred already in the second position of the sentence. Sentences in the condition "embedded clause" contained one more level of embedding and thus consisted of four clauses: a short main clause, a complement clause (S1) and two center-embedded relative clauses (S2 and S3). The short main clause always preceded the complement clause. In complete sentences, all three verbs were present. In missing-VP sentences, either VP2 (lexical verb and auxiliary) or VP1 [lexical verb and auxiliary in the condition "embedded clause" and just lexical verb in the condition "main cause," in which the auxiliary appeared in the main clause, cf. (15)] was missing. The lexical verbs in VP1 and VP2 were always compatible with an animate subject and insofar compatible with both S1 and S2. However, their syntactic properties prevent them from being interchangeable: V1 was an intransitive verb while V2 was transitive.

The sentences were distributed across six lists using a Latin square design. Each list contained only a single version of each sentence and an equal number of sentences in each condition. The experimental lists were interspersed in a list of about 260 filler sentences for Experiment 1. The majority of filler sentences was from unrelated experiments. Each participant saw only one list.

5.1.3. Procedure

Participants received a questionnaire on which the experimental sentences were printed. They were asked to judge the grammaticality of each sentence on the questionnaire by marking one of the two options "grammatical" or "ungrammatical" printed beneath each sentence. Participants could spend as much time as they wanted on reading the sentences and giving their judgments. On average, they needed about 45–50 min to complete the questionnaire.

5.2. Results

For each participant and item, we recorded the grammaticality judgment. **Table 1** shows the results in terms of acceptance rates. All statistical analyses reported in this paper were computed using the statistics software R, version 2.14.2 (R Development Core Team, 2012). Responses were analyzed by means of linear mixed-effects logistic regression using the R-package *lme4* (Bates and Maechler, 2010). Forward difference coding was used for the experimental factors. That is, they were coded in such a way that all contrasts tested whether the means of adjacent factor levels were significant. Contrasts were specified as follows. For the factor Clause Type, the mean results in the condition "main clause" are contrasted with the mean results in the condition "embedded clause." For the factor Structure, two contrasts were defined. The first one compares complete sentences to sentences with a missing VP2 and the second one compares sentences with a missing VP2 to sentences with a missing VP1. Since not all possible contrasts can be tested within one model, we chose the contrasts such that the condition with the highest acceptance rates (complete sentences) is compared to the condition with intermediate acceptance rates (missing VP2), which in turn is compared to the condition with the lowest acceptance rates (missing VP1). If both contrasts turn out to be significant, we can conclude that the remaining contrast (complete sentences vs. sentences missing VP1) is significant as well. We included participants and items as crossed random effects. Following the advice given in Barr et al. (2013), we first computed a model containing the full factorial design in the random slopes. Since this model did not converge, we dropped the interaction term from the random sentence factor, which resulted in a converging model. For each contrast, **Table 2** shows the estimate, the standard error, the resulting z-value and the corresponding p-value.

The factor Clause Type was significant, with sentences in the condition "embedded clause" being judged as grammatical more often than sentences in the condition "main clause" (52 vs. 41%). The two contrasts of the factor Structure were also significant. Complete sentences received higher acceptance rates than missing-VP2 sentences (81 vs. 37%) which in turn received higher acceptance rates than missing-VP1 sentences (37 vs. 22%). Of the two interactions, only the one involving the second contrast of the factor Structure was significant. This reflects the

TABLE 1 | Acceptance rates in Experiment 1.

	Complete	Missing V2	Missing V1
Main clause	81 (5.6)	33 (7.1)	10 (4.0)
Embedded clause	81 (5.4)	41 (8.5)	33 (7.5)

Standard error (by participants) is given in parentheses.

TABLE 2 | Mixed-effects model for the judgment results of Experiment 1.

Contrast	Estimate	Std. error	*z*-value	Pr(>|*z*|)
Clause Type	−3.585	0.834	−4.297	< 0.001
Structure 1	−1.311	0.524	−2.502	< 0.05
Structure 2	0.903	0.435	2.083	< 0.05
Structure 1 × Clause Type	0.419	0.721	0.581	0.562
Structure 2 × Clause Type	1.834	0.771	2.377	< 0.05

finding that for complete and missing-VP2 sentences, the factor Clause Type did not have much of an effect whereas for missing-VP1 sentences, sentences in the condition "embedded clause" were more often accepted as grammatical than sentences in the condition "main clause."

Pairwise comparison were computed in order to explore the interaction more closely. Sentences with a missing VP1 received significantly fewer grammatical judgments than sentences with a missing VP2 when S1 was a main clause (33 vs. 10%, $z = 4.71$, $p < 0.001$). In sentences with an embedded S1, in contrast, the difference between missing VP2 and missing VP1 was not significant (41 vs. 33%, $z = 1.49$, $p = 0.14$). Furthermore, sentences with a missing VP1 were judged as grammatical significantly less often when S1 was a main clause than when S1 was an embedded clause (10 vs. 33%, $z = 4.82$, $p < 0.001$). For sentences with a missing VP2, the contrast between main and embedded S1 clause was marginally significant (33 vs. 41%, $z = 1.65$, $p = 0.10$).

5.3. Discussion

Experiment 1 has yielded two major results. First of all, although participants had unlimited time for reading and judging a sentence, sentences in which a VP was missing were accepted as grammatical in a substantial number of cases. Though the observed missing-VP effects were somewhat weaker in the current experiment than in the corresponding speeded grammaticality judgment experiment from Bader et al. (2003), the questionnaire results closely replicate the pattern from the speeded grammaticality judgments study (correlation coefficient for grand means: $r = 0.94$, $p < 0.01$; for items means per condition: $r = 0.31$, $p < 0.001$). Moreover, the average acceptance rate for missing-VP sentences in the questionnaire study was still 29% despite the lack of time pressure. The mean acceptance rate was even higher when we excluded main clauses with a missing VP1. For these sentences, no missing-VP effect was expected, and in accordance with this expectation, they were rejected as ungrammatical in about 90% of the time. The finding that the other missing-VP sentences are accepted as grammatical to a substantial degree despite the lack of time constraints corroborates the existence of the missing-VP effect in German. Given the interaction of Clause Type and Structure, the missing-VP effect cannot be attributed to an undifferentiated tendency to accept sentences of this type as grammatical. In sum, participants experience a grammatical illusion with missing-VP sentences not only when put under time pressure, but also when they have as much time as they want. The possibility to reread sentences and to engage in deliberate reasoning reduces the missing-VP effect, but it does not eliminate it.

The second major finding of Experiment 1 is that a missing-VP effect for VP2 is independent of clause type whereas a missing-VP effect for VP1 is restricted to sentences in which S1 is an embedded clause. Sentences lacking a VP in their main clause were reliably rejected as ungrammatical with a 90% rejection rate. This finding is compatible with the proposal that primacy effects make it easier to spot the lack of a VP in the first clause, i.e., the main clause, of a complex sentence.

For sentences with a missing VP2, clause type had no effect. The lack of a difference between main and embedded clauses indicates that properties of S1 did not affect the probability of detecting that VP2 was missing. This is expected under the primacy perspective since S2 is always an embedded clause. Promoting S1 to a main clause brings S1 into first position but leaves S2 in an intermediate position.

The clause type of S1 had also no effect for complete sentences. The finding of identical acceptance rates for main and embedded matrix clauses confirms earlier claims that clausal embedding does not cause increased processing costs as long as clauses are embedded in sentence final position (see Gibson, 1998; Gibson and Thomas, 1999). Erroneous integration of VP2 or VP1 into the wrong clause might occur from time to time but is easily detected because of the other VP. If VP2 is erroneously attached to S1, the subsequent verb (VP1) signals the error. An attempt to attach VP1 to S2 will fail because the verb slot of S2 is already occupied by VP2.

In sum, Experiment 1 has shown that the grammatical illusion caused by a missing VP2 is a robust phenomenon which is not affected by whether S1 is a main clause or an embedded clause. A missing VP1, in contrast, causes a grammatical illusion only when S1 is an embedded clause. An interesting question raised by these findings is whether the same holds for English. Since our account did not appeal to any special properties of German, it predicts that a missing VP1 should also cause a grammatical illusion in an English sentence as in (16), which is identical to the original example of Gibson and Thomas (1999) with the exception that S1 is now an embedded clause.

(16) I believe that the ancient manuscript that the graduate student who the new card catalog [$_{VP3}$ had confused a great deal] [$_{VP2}$ was studying in the library].

6. Experiment 2

In contrast to the SVO languages English and French, all experiments demonstrating a missing-VP effect in German relied on some form of grammaticality judgments, either under time constrained conditions (Bader et al., 2003; Bader, 2015) or without time limitations (Experiment 1). The only study that investigated the missing-VP effect in German using on-line reading measures (selfpaced reading and eye tracking) is Vasishth et al. (2010), and this study failed to find evidence for a grammatical illusion in German whereas it found such evidence for English. Based on the current evidence, it can thus not be excluded that in an SOV language like German a missing-VP

effect only occurs when explicit grammaticality judgments are required but not when participants simply process sentences for the purpose of comprehension.

A different possibility is suggested by the results of Bader (2015). These results show that the likelihood of a missing-VP effect in German is modulated by the syntactic configuration in which the center-embedded relative clauses occur. The sentences from Vasishth et al. (2010) contain the relative clauses in the initial position of the main clause whereas the sentences in the current study contain the relative clauses in a sentence-medial position. Using the same speeded grammaticality judgment task as Bader et al. (2003), Bader (2015) found a higher acceptance rate for missing-VP sentences in the latter configuration. The lack of a reading time advantage for missing-VP sentences in the experiments of Vasishth et al. (2010) may thus be due to a weak missing-VP effect in sentences in which the relative clauses belong to a sentence initial NP. If so, we expect that reading time evidence for a missing-VP effect can be found for sentences for which the missing-VP effect is more likely to occur. Experiment 2 tests this prediction by collecting reading times for sentences that, like the sentences investigated in Experiment 1, contain the relative clauses in a sentence medial position.

In the sentences in Experiment 2, S1 is an embedded clause. The sentences are thus structurally similar to the sentences in the "embedded clause" condition of Experiment 1. An example is given in (17). Incomplete sentences were derived by dropping VP2, as indicated by crossing in (17). The subject of S2 is either a singular or a plural NP. The verb of S2, which is only present in complete sentences, is accordingly either a singular or a plural verb. The verb of S1 is always present and always marked for singular in agreement with the subject of S1.

(17) *Example sentences of Experiment 2*

	Ich	glaube					
	I	think					
S1	dass	man	(den	**Direktor**,	/ die	**Direktoren**,)	
	that	one	the	principal.SG	the	principals.PL	
S2	(**der**	/ **die**)	den	Schulrat,			
	who.SG	who.PL	the	schools.inspector			
S3	der	das	Projekt	absegnen	soll,		
	who.SG	the	project	approve	should		
S2	~~alarmiert~~	(~~hat,~~	/	~~haben,~~)			
	alarmed	has.SG		have.PL			
S1	belogen	**hat**,					
	lied.to	has					
	um	von	dem	eigentlichen	Problem	abzulenken	
	for	from	the	actual	problem	distract	

"I think that the principal who ~~alarmed~~ the schools inspector who was supposed to approve the project was lied to in order to distract him from the actual problem."

If German was immune to the missing-VP effect, as claimed by Vasishth et al. (2010), reading times should be longer in incomplete sentences compared to complete sentences. The increase should start after the final verb since only then does it become evident that no further verbs are coming and thus a verb is missing. If, on the other hand, the missing-VP effect is present in German too, longer reading times are predicted for the final verb in complete sentences. This prediction is made both by the Pruning Hypothesis and by the Discrimination Hypothesis. Hence, the purpose of Experiment 2 is not to decide between the two hypotheses. Instead, the aim is more modest. The main objective of Experiment 2 is to test whether the missing-VP effect in German can be observed in online measures like reading times at all.

In addition, Experiment 2 tests whether the effect of number reported by Bader et al. (2003) also occurs in on-line reading times. In complete sentences with a plural S2 subject and therefore a plural verb V2, the attempt to integrate V2 into S1 results in a fleeting agreement violation which should increase reading times. Moreover, the integration of the actual verb of S1 then becomes difficult because the verb slot of S1 is already filled by the preceding verb. In incomplete sentences with a plural S2 subject, integration of the final verb, which is always singular, into S2 results in an agreement violation.

6.1. Method

6.1.1. Participants

Twenty-four students at the University of Konstanz participated in Experiment 2. They were paid for participation or received course credit.

6.1.2. Materials

We constructed 20 sentences each in four versions. An example is given in (17). All sentences started with a short main clause followed by a complement clause introduced by the complementizer *dass* ("that"). This complement clause (S1) contained an indefinite pronoun as subject and a definite NP as the object followed by a relative clause (S2) modifying the object. The relative clause contained another relative clause (S3), again modifying the object. Due to the clause-final position of verbs in embedded clauses in German, the verbs for S3, S2, and S1 occur in a row after the object of S3. As before, the final

position of each clause was filled by a verb cluster consisting of a lexical verb and an auxiliary. The final verb was followed by an adjunct clause in order to minimize wrap-up effects and to provide space for potential spillover effects. Two factors were fully crossed resulting in four conditions. The factor Structure varied whether the sentences were complete or incomplete; in incomplete sentences the intermediate verb (VP2) was omitted. The factor S2-Subject varied the number specification of the head noun of the higher relative clause and thereby of the subject of this relative clause. If present, VP2 matched the S2 subject in number.

For each sentence, we designed a question that probed understanding of the sentence. The example in (18) gives the probe question for (17).

(18) Hat der Direktor falsche Informationen erhalten?
has the principal wrong information received
"Did the principal receive wrong information?"

As in the example, all probe questions asked for an event involving the subject of S2 which is at the same time the object of S1. Low attachment of VP1 and subsequent interpretation of V1 as the verb of S2 would result in a wrong answer to the probe question. Half of the questions required a positive answer, the other half required a negative answer.

The experimental stimuli were distributed over four lists using a Latin square design. Each participant saw only one list. The order of items in a list was pseudo-randomized for each participant individually. In addition to the experimental stimuli, an experimental session included 94 filler sentences. Most of them served as experimental stimuli in unrelated experiments. Filler sentences were always grammatical and covered a variety of syntactic constructions. The order of filler sentences and experimental items was arranged in such a way that no two experimental items followed each other.

6.1.3. Procedure

Experiment 2 used a word-by-word non-cumulative self-paced reading procedure. Participants read sentences on a computer screen using a moving window display in which all non-space characters of the sentence were initially replaced by underlines (Just et al., 1982). Participants pressed a key on the keyboard to see each new word of the sentence. On each key press, a new word was uncovered and the previous word was again replaced by underlines. The time between successive key presses was recorded automatically. Once the last word of the sentence had been reached, pressing the key again cleared the screen and revealed the word "Frage" ("question"). The next key press produced the question which had to be answered by pushing the "j"-key for "Ja" ("yes") or the "n"-key for "Nein" ("no"). Participants received no feedback for their answers. To become acquainted with the procedure, participants read four training sentences before the experiment started.

6.2. Results

Despite the complexity of the sentences, participants answered probe questions with an overall accuracy of 87%. There were only minimal differences between conditions (range 84–89%). A statistical analysis using a mixed effects model did not find significant effects.

Reading times >2000 ms were removed from the analysis. This affected <1% of the data. The remaining mean reading times are summarized in **Table 3**. In accordance with Vasishth et al. (2010), we log-transformed raw reading times before fitting linear mixed effects models to the data. Contrasts were coded as follows. The contrast for the factor S2-Subject compares sentences with a singular S2 subject to sentences with a plural S2 subject. The contrast for the factor Structure compares complete sentences to sentences missing the second verb cluster. Fixed effects results for the models are given in **Table 4**. All models reported in the table contain the full factorial design in the crossed random slopes for participants and items. Since degrees of freedom can only be estimated in linear mixed effects models (Baayen, 2008), we report estimates, standard errors and t-values but no p-values. An absolute t-value of 2 or greater indicates significance at the α-level 0.05. We also computed residual reading times (Ferreira and Clifton, 1986) and repeated all analyses; the results were similar as for the log-transformed raw reading times.

For VP3 and VP2, joint reading times for the lexical verb and the auxiliary are virtually identical across conditions (VP3 in sentences with a singular S2 subject: 946 ms, with plural S2 subject: 931 ms; VP2 in sentences with a singular S2 subject: 1029 ms, with plural S2 subject: 1038 ms). The statistical models indicate no significant effect. For VP1, however, reading times are longer in complete sentences (1066 ms in complete sentences, 953 in incomplete sentences). Reading times for individual words reveal that the effect occurs at the lexical verb (550 vs. 483 ms). Numerically, the effect is still visible at the auxiliary but no longer significant (513 vs. 477 ms). At the next word, the effect is gone. The factor S2-subject had no effect at all.

6.3. Discussion

The major finding of Experiment 2 is that reading times for the final verb were shorter in incomplete sentences compared to complete sentences. Thus, the missing-VP effect observed in prior judgment experiments occurs as well when participants only have to read for meaning. The difference between the current results and the results of Vasishth et al. (2010) can be attributed to structural differences between the respective sentence materials. As discussed above, the missing-VP effect is weaker when the relative clauses modify an NP in sentence initial position, as in the study of Vasishth et al. (2010). If readers experience a grammatical illusion in only a subset of trials, it may well be that any reading time advantage resulting from trials eliciting a grammatical illusion is offset by a reading time penalty for trials in which readers detect the ungrammaticality.

In contrast to the finding in Bader et al. (2003), the number manipulation had no effect in Experiment 2. We surmise that this difference reflects the fact that Experiment 3 of Bader et al. (2003), but not Experiment 2 of the current study, involved an explicit grammaticality judgment. Since no judgment was required in Experiment 2, the temporary ungrammaticality that might have arisen in conditions with a plural S2 subject

TABLE 3 | Mean reading times in experiment 2.

Subject S2	Structure	VP3	VP2	VP1			Post-VP1
				V1	Aux1	V1 + Aux1

could be internally repaired by the parser without any overtly observable effect.

7. General Discussion

This paper has presented an interference account of the missing-VP effect, that is, the observation that sentences in which a VP is missing can give rise to an illusion of grammaticality. This account is based on experimental investigations of the missing-VP effect in German. While prior reports of the missing-VP effect in German relied on speeded grammaticality judgments, the experiments reported in this paper show that the missing-VP effect is rather robust with regard to the experimental procedure. In particular, the missing-VP effect is so strong that it also occurs when participants have to judge sentences without time pressure, and it occurs as well when participants simply have to read sentences for meaning.

The finding of missing-VP effects in German points to the cross-linguistic generality of this kind of grammatical illusion. It is not confined to languages with SVO order but is found in languages with SOV order too. This suggests that the source of the effect is not language-specific but results from more general mechanisms that apply across languages. Interference during cue-based retrieval is a promising candidate for such a general mechanism. It provides a unified account of how sentences with double center-embedding—whether complete or incomplete—are processed. In sentences with double center-embedding, the parser faces two competing attachment sites for the second verb, as illustrated in (19).

(19) $[_{S1}$ NP1 … $[_{S2}$ NP2 … $[_{S3}$ NP3 … VP3] … **VP2** … (VP1)

Processing of NP1 causes the creation of a sentence node and thereby leads to the expectation of a verb. Similar expectations result from the processing of NP2 and NP3. Integration of VP3 fills the open verb slot of S3. After processing of S3, the next verb generates retrieval cues that call for a sentence with an open verb slot. Since both S1 and S2 fit this cue, interference arises and hampers the correct integration of the second verb into S2. As a result, the second verb is occasionally integrated into the wrong clause, namely S1, and thereby analyzed as VP1. Erroneous integration of VP2 into S1 entails difficulties for the subsequent integration of VP1 in complete sentences and it contributes to the illusion of grammaticality in missing-VP sentences. To make the illusion perfect, the lack of lexical material in the VP2 slot must go unnoticed. A failure to detect the missing VP is especially likely because the incomplete clause (S2) is no longer the current clause as soon as the parser returns to the higher clause, what it does when attaching the final verb to S1. This reasoning also explains why the status of S1 (main clause vs. embedded clause) had no effect for the likelihood of a missing-VP2 effect. Since the clause lacking VP2 is always an embedded clause, its processing must be completed when the last verb is integrated into the higher clause.

Since nothing is ever deleted according to our account, S1 and S2 are always available as attachment sites and therefore as targets for retrieval. The additional finding of a grammatical illusion when VP1 is missing indicates that the VP slot of S2 is retrieved for integration in some of the cases. In contrast to cases of a missing VP2, a grammatical illusion for a missing VP1 was observed only when S1 was an embedded clause but not when S1 was a main clause. We have argued that this finding is a primacy effect. When S1 is a main clause and thereby occurs in sentence initial position, the probability of erroneously attaching VP2 to it increases as does the probability of detecting that VP1 is missing in case VP2 has correctly been attached to S2. Taken together, this prevents the occurrence of a missing-VP effect for VP1 in main clauses.

Two alternatives to an interference-based account of the missing-VP effect are the resource-based account of Gibson and Thomas (1999) and the experience-based account of Christiansen and MacDonald (2009). The resource-based account of Gibson and Thomas (1999), which was already discussed above, is based on the idea that the parser has only a limited amount of resources available for storage and integration. Their Pruning Hypothesis proposes pruning as a last resort mechanism to free resources and thereby to avoid an overload of the parser. After deletion of VP2, the second verb can only be integrated into S1, creating the illusion of completeness in missing-VP sentences. The assumption of VP2-pruning is disconfirmed by the finding that omitting VP1 can lead to a missing-VP effect as well under certain circumstances. In addition, the Pruning Hypothesis is not attractive from a theoretical point of view. Pruning is a mechanism specific for situations with high memory load and has to be stipulated. Interference, on the other hand, is a general phenomenon that follows from cue-based retrieval. Similarity-based interference arises whenever two or more items in a memory representation are similar to each other. Interference can emanate from an item preceding the target item (proactive interference) or from an item following the target item (retroactive interference). Under the Discrimination Hypothesis, the missing-VP effect is an instance of proactive interference. Interference has been shown to be effective in explaining various phenomena in language comprehension (cf. van Dyke and Johns, 2012; Gordon and Lowder, 2012). We conclude that an interference-based explanation of the missing-VP effect is both empirically and conceptually more adequate than a resource-based explanation.

An experience-based account of the missing-VP effect was proposed by Christiansen and MacDonald (2009). This account draws on earlier work by Christiansen and Chater (1999) who proposed a connectionist model of recursion in natural language. This model is cast as a simple recurrent network (Elman, 1990) that learns from experience to predict the next word of a sentence from the words processed so far. Simulations by Christiansen and MacDonald (2009) show that when processing an English sentence with double center-embedding, the model expects only a single verb after it has encountered V3, as in a missing VP sentence, and not two verbs, as in a corresponding complete sentence. This approach was extended to German by Engelmann and Vasishth (2009). The model that they trained for German predicts that missing-VP sentences do not give rise to a grammatical illusion in German. Based on the experimental evidence from Vasishth et al. (2010), Engelmann and Vasishth (2009) conclude that an experience-based account of the missing-VP effect is superior to a memory-based account (e.g., the Pruning Hypothesis of Gibson and Thomas, 1999) because only the former account predicts that the missing-VP effect is present in English but absent in German.

With regard to the difference between SVO- and SOV-languages, the main thrust of the experience-based account has been succinctly summarized by Vasishth et al. (2010, p. 558): "One consequence of German head-finality is that—due to the relatively frequent occurrence of head-final structures—predictions of upcoming verbs may have more robust memory representations in German than in English. This could result in reduced susceptibility to forgetting the upcoming verb's prediction, even in the face of increased memory load." As the results of the present study show, this conclusion is premature. When presented with missing-VP sentences, native speakers of German experience a grammatical illusion as well. Furthermore, native speakers also produce such sentences from time to time. In an ongoing analysis of the deWaC corpus[5], we found a number of authentic missing-VP sentences. A small selection of such examples is provided in **Table 5**.

Such examples make two points. First, the missing-VP effect is not restricted to language comprehension but occurs in language production as well. Second, the missing-VP effect is not merely a laboratory phenomenon. Since this is evidence from German, we can conclude that the verb-final nature of German does not lead to memory structures that prevent the missing-VP effect from occurring. At face value, this contradicts experience-based accounts which have derived the absence of a missing-VP effect in German from corpus-based simulations. However, drawing strong conclusions at this point would be premature. For example, the training corpus used by Engelmann and Vasishth (2009) for their simulation is not described in detail, which leaves the possibility that their training input did not include all relevant syntactic configurations. Additional simulations are necessary in

[5]DeWac is the German part of Wacky, a family of large corpora built by web crawling (Baroni et al., 2009). DeWac contains 1.7 billion tokens of text which is POS tagged and lemmatized (using TreeTagger). Partial results from an ongoing corpus study of complete and incomplete doubly embedded relative clauses in the DeWac corpus can be found in Bader (2015).

TABLE 5 | Authentic examples of the missing-VP effect from the deWac corpus.

| | | |

order to address the issues raised above, but this is beyond the scope of the present paper.

The seeming contradiction between the evidence presented by Vasishth et al. (2010) on the one hand and the evidence provided by Bader et al. (2003) and the analysis of the deWac corpus on the other hand was addressed by Bader (2015). Based on corpus evidence and on evidence from yet another experiment using the method of speeded grammaticality judgments, Bader (2015) showed that the strength of the missing-VP effect varies with the syntactic position occupied by the doubly center-embedded relative clause. The probability that a missing-VP effect occurs is smaller when the relative clauses occupy the initial position of a main clause, as in the sentences investigated by Vasishth et al. (2010) [see (13)], than when they are contained within the lower part of the clause, whether this is an embedded clause as in (14) or a main clause as in (15).

In sum, the results of the present study confirm the existence of the missing-VP effect in German and thereby show that the occurrence of this grammatical illusion does not depend on whether a language is SVO or SOV. The results challenge resource-based and experience-based accounts of the effect, but they lend further evidence to interference-based accounts of human parsing. In particular, the missing-VP effect adds to the existing evidence for proactive interference during language comprehension and supports cue-based parsing architectures.

Many experiments have shown that listeners actively build expectations about up-coming words, rather than simply waiting for information to accumulate. The online construction of a syntactic structure is one of the cues that listeners may use to construct strong expectations about the possible words they will be exposed to. For example, speakers of verb-final languages use pre-verbal arguments to predict on-line the kind of arguments that are likely to occur next (e.g., Kamide, 2008, for a review). Although in SVO languages information about a verb's arguments typically follows the verb, some languages use pre-verbal object pronouns, potentially allowing listeners to build on-line expectations about the nature of the upcoming verb. For instance, if a pre-verbal direct object pronoun is heard, then the following verb has to be able to enter a transitive structure, thus excluding intransitive verbs. To test this, we used French, in which object pronouns have to appear pre-verbally, to investigate whether listeners use this cue to predict the occurrence of a transitive verb. In a word detection task, we measured the number of false alarms to sentences that contained a transitive verb whose first syllable was homophonous to the target monosyllabic verb (e.g., target "dort" /dɔʁ/ *to sleep* and false alarm verb "dorlote" /dɔʁlɔt/ *to cuddle*). The crucial comparison involved two sentence types, one without a pre-verbal object clitic, for which an intransitive verb was temporarily a plausible option (e.g., "Il dorlote" / He *cuddles*) and the other with a pre-verbal object clitic, that made the appearance of an intransitive verb impossible ("Il le dorlote" / *He cuddles it*). Results showed a lower rate of false alarms for sentences with a pre-verbal object pronoun (3%) compared to locally ambiguous sentences (about 20%). Participants rapidly incorporate information about a verb's argument structure to constrain lexical access to verbs that match the expected subcategorization frame.

Keywords: linguistic expectation, verb argument structure, lexical search, on-line syntactic structure construction

INTRODUCTION

To understand spoken sentences, listeners have to process speech sounds, recognize words and morphemes, and decode the syntactic structure of the sentence to recover its meaning. All of these complicated processes seem effortless and are performed in a very short amount of time (Pylkkänen and Marantz, 2003; Poeppel et al., 2008). One way to explain the speed with which spoken language

is processed is to suppose that the human language parser is able to exploit the context—both linguistic and non-linguistic—to compute expectations about upcoming material, thus reducing the number of possible options available at any given point in time and anticipating the processes it is likely to have to complete next (e.g., Levy, 2008; Gibson et al., 2013).

Many experiments have shown that listeners indeed use context to build linguistic expectations (see e.g., Kamide, 2008; Rayner, 2009, for reviews). The use of lexico-semantic knowledge to anticipate upcoming words was one of the first studied phenomenon: comprehenders were shown to use the beginning of a sentence to look faster to likely referents (e.g., Altmann and Kamide, 1999), to read predictable words faster (e.g., Frisson et al., 2005), and they also displayed smaller N400 responses to content words that were made more likely by their preceding contexts (e.g., Kutas and Hillyard, 1980; Federmeier, 2007; Xiang and Kuperberg, 2015). Once they've generated a prediction about a possible upcoming content word, listeners can also build specific expectations regarding the phonological shape of the article that precedes it (DeLong et al., 2005), or the gender of a preceding adjective or article (Wicha et al., 2004; Van Berkum et al., 2005; Foucart et al., 2015). In addition, they are able to integrate other kinds of information within their anticipatory processes, such as the prosodic/rhythmic pattern of a sentence (Brown et al., 2011) or the phonological patterns typical for specific syntactic categories (Farmer et al., 2006).

Syntactic structure *per se* should be another good candidate for activating anticipatory linguistic processes: Indeed many studies have observed that participants are able to extrapolate syntactic information on the fly to build expectations regarding an upcoming word or structure (e.g., Boland et al., 1990; Konieczny, 2000; Kamide et al., 2003; Boland, 2005; Hare et al., 2009; Levy and Keller, 2013), and modeling work shows that probabilistic parsers trained on linguistic corpora account for a whole range of human experimental data (e.g., Jurafsky, 1996; Hale, 2001; Levy, 2008). For instance, comprehenders exploit a verb's argument structure to expect specific kinds of arguments (e.g., Boland et al., 1990), and use the selectional constraints imposed by the verb to predict probable referents (i.e., listeners expect an eatable entity after hearing the verb "to eat," Altmann and Kamide, 1999). In a verb-final language such as Japanese, a verb's argument structure can be exploited even before the verb is heard, so that the presence of an indirect object, for instance a DP marked with a goal marker, leads the parser to search for a patient before hearing the corresponding DP (Kamide et al., 2003).

This ability to build an argument structure before hearing its head (the verb), might be a specific adaptation from head-final languages comprehenders, to cope with the fact that verbs systematically appear after their arguments, and avoid lengthy delays. It could also, however follow from a general property of the human parser, which would use all the information available to constrain its ongoing syntactic structure on-line. A very recent paper by Omaki and colleagues addressed this precise issue (Omaki et al., 2015). They exploited filler-gap dependency completion in object relative clauses, as in "the city that the author chatted regularly about was named after an explorer," and measured participants' surprise upon hearing the intransitive verb "chatted" which cannot take a direct object (the preposition "about" provides a slot as an indirect object for "the city" and makes the sentence grammatical in the end). If participants wait until they process the verb in order to posit an object position for that verb, then they should show no surprise upon hearing an intransitive verb (since they haven't attempted yet to assign "the city" to a direct object position), and should simply wait longer until they find a suitable slot for the DP "the city." Instead, in three experiments, Omaki et al. observed delayed reading (interpreted as delayed processing) upon encountering an intransitive verb in such a position. These results thus strongly suggest that in English too, a verb-medial language, comprehenders posit an argument structure even before they have processed the verb.

In this paper, we will address this same question through a different angle. Rather than looking for the effect of specific content words on the predictability of upcoming words (integrating them within the on-going syntactic structure), we focus on purely structural effects: namely, we wonder whether participants are able to exploit the syntactic structure they've heard so far—irrespective of the semantic content of the specific lexical items involved—in order to build expectations as to the type of word that is likely to occur next. Previous work on this topic has yielded somewhat mixed results: within the noun phrase, Dahan et al. (2000) have shown that after hearing a gender-marked article, listeners successfully reduce their lexical search to gender-matching referents. When ambiguous words of different syntactic categories are involved (e.g., noun/verb, or adjective/noun), some studies have found that both meanings of a homophone are initially activated (Tanenhaus et al., 1979) while others found that context allowed listeners to completely ignore the unintended meaning, when one member of the homophone pair was a function word (Shillcock and Bard, 1993, e.g., "would" vs. "wood"), when the preceding linguistic context marked syntactic constituent boundaries through phrasal prosody (Millotte et al., 2008; de Carvalho et al., 2015), and when the visual context led listeners to expect either an adjective or a noun, for pragmatic reasons (Magnuson et al., 2008). Here, we focus on the level of the verb phrase, and wonder whether listeners are able to use elements from the subcategorization frame of a verb in order to constrain lexical access to upcoming verbs.

To do so, we tested whether the presence of a preverbal direct object pronoun blocks the activation of intransitive verb candidates, or not. In French, as in other Romance languages, the direct object of a verb is pronominalized as a clitic accusative pronoun ("le," "la," or "les") that rises in the left periphery of the transitive verb (Kayne, 1991). For example the DP complement of the French verb "manger" *to eat*, "la souris" in "Le chat mange la souris" *The cat eats the mouse* moves to the left-periphery of the verb when pronominalized, as in "Le chat **la** mange" *the cat eats **it***. This situation resembles the one in head-final languages such as Japanese; however, whereas all direct objects are preverbal in Japanese, whether they are pronominalized or not, in French only pronoun direct objects are pre-verbal, while full DP objects

appear post-verbally. Thus, in French the presence of pre-verbal objects is not a standard configuration (although it is reasonably frequent). Consequently, if French listeners are able to integrate the object pronoun clitic into the syntactic structure, and deduce on-line that this utterance calls for a transitive verb, this will confirm Omaki et al.'s finding that the fast integration of pre-verbal arguments is a general ability of the human parser, rather than a specific adaptation from listeners of head-final languages where objects systematically appear pre-verbally. Additionally, such a result would enlarge the growing body of evidence that the human parser is processing a wide variety of available cues in order to anticipate the linguistic material that might follow. In contrast, if French listeners do not make use of pre-verbal object pronouns to anticipate transitive verbs, this will suggest that the ability to anticipate upcoming materials is fine-tuned to the specific properties of the language being processed, such that only features that are usually relevant will be put to use by the parser.

We investigated this question using a false alarm paradigm with adult French speakers. Subjects were instructed to respond as quickly and accurately as possible to an intransitive monosyllabic verb (e.g., "dormir" *to sleep*, that surfaces as "il dort" /**dɔʁ**/ *he sleeps* when conjugated in the 3rd person singular present tense). While half the sentences did contain the target verb, the other half did not contain it, but contained instead a multisyllabic transitive verb that started with the same first syllable (e.g., "dorloter" *to cuddle,* that surfaces as "il dorlote" /**dɔʁ**l**ɔt**/ when conjugated in the 3rd person singular present tense). The number of false alarms triggered by this multisyllabic verb was the measure of interest here. To test the impact of the under-construction syntactic structure upon lexical access, we inserted this multisyllabic catch verb in two kinds of sentences: In the first experimental condition, it appeared immediately after the pronoun subject, and was followed by an object DP (e.g., "elle dorlote son nounours" *she cuddles her teddybear*); thus, at the point when the verb was processed, the available information was still compatible with an intransitive verb (only the pronoun subject had been heard), and the intransitive target verb was thus a plausible option to continue this sentence (e.g., "elle dort toute la nuit" *she sleeps through the night*). We expected this condition to trigger a baseline amount of false alarms. In the second condition, the catch verb appeared after a pronoun subject and an object clitic (e.g., "elle le dorlote toute la nuit" *She cuddles it through the night*). In that case, when listeners heard the beginning of the verb, they had already heard the clitic object: if they spontaneously integrate this clitic object on-line to the syntactic structure they are building, they should be able to reject the intransitive target verb as a possible continuation for that sentence, and should therefore exhibit a very low proportion of false alarms, close to zero. If, in contrast, lexical access is primarily based on the available phonological information (here, the first syllable of the catch verb, which matches the target verb), together perhaps with a coarse syntactic information (e.g., that a verb is expected), then the proportion of false alarms triggered should be roughly equal in both conditions, irrespective of the fact that the second one contains a pre-verbal object clitic and the first one does not.

MATERIALS AND METHODS

Participants

Twenty-five native speakers of French took part in this experiment and were paid 5€ for their participation. Two additional participants were tested but their data were discarded from the final analysis because their hit rate was too low (<30%). This work was approved by the local ethics committee (Paris Ile de France III), and all participants signed an informed consent form.

Stimuli

Using the LEXIQUE 3.55 database (New et al., 2001), we selected 14 pairs of verbs consisting of an intransitive monosyllabic verb (or, more precisely, a verb that could not take a direct object), and a multisyllabic transitive verb whose first syllable was homophonous to the intransitive monosyllabic verb. For example, the verb "dormir" *to sleep* was paired with the verb "dorloter" *to cuddle.* While both "il dorlote…" *he cuddles…* and "il le dorlote" *he cuddles it* are grammatical structures, the sequence "*il le dort" *he sleeps it* is ungrammatical (see Supplementary Material for a complete list of the verbs). Only the intransitive verb of each pair was used as a target in the word detection task.

Each pair of verbs was used to build one or several quadruplets of sentences, for a total of 31 quadruplets. Each quadruplet contained two HIT sentences that actually contained the target monosyllabic intransitive verbs (e.g., "Quand il fait nuit, elle dort tranquillement," *During the night, she sleeps peacefully* and "Quand il fait nuit, elle dort dans son lit," *During the night, she sleeps in her bed*), as well as two False Alarm sentences that contained the multisyllabic transitive verb. One of these false alarm sentences contained a pre-verbal object pronoun ("le," "la," or "les" *it masc, fem, plural*): this created an ungrammatical context for an intransitive verb (as in "Quand il fait nuit, elle **la** dorlote plus," *During the night, she cuddles it more*). The other false alarm sentence was locally ambiguous, in that the verb immediately followed a subject DP (which could be a personal pronoun), such that both members of a verb pair, the transitive and the intransitive one, were compatible with the structure heard so far (e.g., "Quand il fait nuit, elle dorlote sa poupée," *During the night, she cuddles her doll*). Crucially, all sentences from a quadruplet contained the same sequence of words before the verb phrase ("Quand il fait nuit, elle…" in the examples): this ensures that the only pre-verbal cue that can be used to constrain lexical access to the verb is the object clitic (when it is present). In other words, if the false alarm rate is greater for locally ambiguous sentences than for non-ambiguous sentences (with an object clitic), this can only be due to the fast integration of the pronoun object clitic which makes subjects discard the possibility of encountering an intransitive verb.

To check whether or not there were acoustic/prosodic differences across conditions on the syllable homophonous with the target word, we measured the duration and F0 of the first syllable of the multisyllabic verbs of the false alarm sentences (e.g., "dor" from "dorlote"). We compared these values with a Wilcoxon rank test (since visual inspection showed that the

duration and F0 values were not normally distributed).The results of this analysis are presented in **Table 1**. We observed a marginally significant effect of duration, with FA_CLI sentences tending to have somewhat shorter first syllables than FA_AMB sentences (about 10 ms). It is unlikely that such a small difference would trigger a major difference in False Alarm rates between the two conditions.

The 31 quadruplets thus amounted to a total of 124 test sentences. Experimental sentences were recorded by an expert speaker (the last author) and marked at the onset of the critical verb using PRAAT (Boersma and Weenink, 2015). Each participant heard each of the 124 experimental sentences once within two blocks of 62 sentences: for each quadruplet, one block contained one HIT and one ambiguous False Alarm sentence (FA_AMB), while the other block contained the other HIT sentence and the non-ambiguous False Alarm sentence, which featured a pre-verbal clitic (FA_CLI). Each block contained roughly the same amount of FA_AMB and FA_CLI sentences. In total, a subject was exposed to 62 HIT sentences, 31 FA_CLI and 31 FA_AMB sentences. Within each block, the order of the sentences was pseudo-randomized so as to avoid sequences of five or more false alarm sentences.

Procedure

Each participant was tested individually. They were instructed to press the spacebar from a computer keyboard as soon as they could identify the target verb. A trial began with the visual presentation of the target word, always an intransitive verb written in the infinitive form (1.5 s), followed by a black screen with a white fixation cross (1 s), then a sentence was played (the auditory stimuli were stored at a sampling rate of 22,050 Hz and were presented through headphones). The trial ended 2.5 s after the subject's response or after the end of the auditory presentation (whichever came first), and a new trial began immediately. Response times were measured from the onset of the target word. Speed and accuracy were emphasized in the instructions. Before the experiment began, participants performed a short training. If they gave an incorrect or delayed response during training (more than 1 s response time), a warning message appeared on the screen asking them to correct or speed up their response (depending on the situation). The whole experiment was run using the Psychotoolbox of Matlab (Kleiner et al., 2007) and lasted about 15 min including a pause (of about 2 min) between blocks.

Analysis

Since the false alarm responses were categorical (0 for no response, 1 for a FA), we used a logit model to analyze whether false alarms were distributed differently between the FA_CLI and FA_AMB conditions. We ran a mixed model analysis using R 3.2 and the lme4 package (v 1.1-6, based on Bates and Sarkar, 2007). Each false alarm F_{isc}, for a given item i (where an item represents the pair of False Alarm sentences from the same quadruplet, i varied between 1 and 31) and a given subject s (between 1 and 25), in a given Condition c (FA_CLI vs. FA_AMB), was modeled via an intercept β_0 reflecting the baseline probability of making a false alarm, and a slope estimate β_1 of the predictor variable C (Condition), reflecting the impact of the context on the probability of making a false alarm (either a locally ambiguous context, FA_AMB condition, or non-ambiguous context with a pre-verbal clitic that makes an intransitive verb unlikely, FA_CLI condition). Since we used the maximal random effect structure (recommended by Barr et al., 2013), we also included by-subjects and by-items intercepts (S_{0s} and I_{0i} allowing the baseline to vary from β_0 by a fixed amount for each subject s and each item i) and slopes (S_{1s} and $I_{1i,}$ respectively, allowing each subject and item to deviate from the population slope $\beta_1$in their sensitivity to Condition). The categorical predictor Condition C was coded as 0 for the ambiguous context (FA_AMB) and 1 for the object pronoun context (FA_CLI). The resulting equation for the model, taking into account a normally distributed error for each observation, e_{is}, is the following:

$$\text{Logit}(\text{P}(F_{is} = 1)) = \beta_0 + S_{0s} + I_{0i} + (\beta_1 + S_{1s} + I_{1i}).\, C + e_{is} \quad (1)$$

β estimates are given in log-odds (the space in which the logit models are fitted). To compare the probabilities of making a false alarm across the two levels of C (Conditions: ambiguous context vs. non-ambiguous object clitic pronoun context), we computed the difference: $\text{P}(F_{is} = 1; C = 0$ i.e., FA_AMB) – $\text{P}(F_{is} = 1; C = 1$ i.e., FA_CLI) by taking the inverse logit of the right-hand side of Equation (1).

We computed Wald's Z statistic using the mixed model described above. This statistic tests whether the estimates are significantly different from 0. Hence the intercept corresponds to the probability of making a false alarm when participants are exposed to an ambiguous context, while the slope corresponds to the modification in the probability of making a false alarm when participants hear an object clitic before the verb.

TABLE 1 | Mean and standard error for the duration and F0 of the first syllable of the multisyllabic carrier verb from the false alarm sentences (e.g., "dor" in "dorlote").

	FA_CLI mean (std. error)	FA_AMB mean (std. error)	Wilcoxon rank test $Z(p)$
Duration (ms)	173 (9.63)	183.5 (9.79)	−1.86 ($p = 0.062$)
Mean F0 (vowel) (Hz)	245.4 (4.89)	255.8 (4.16)	−0.975 ($p > 0.3$)

RESULTS

The Hit rate was 90.8%, with an overall False Alarm rate of 11.6% (averaged across FA_CLI and FA_AMB conditions), showing that participants performed the task adequately. To assess whether or not French listeners quickly integrate the presence of a clitic object pronoun in order to compute the probability of occurrence of a transitive vs. intransitive target verb, we compared the false alarms produced by subjects when they were exposed to non-ambiguous FA_CLI sentences containing a clitic object (as in "Quand il fait nuit, elle la dorlote plus" *During the night, she cuddles it more*) to ambiguous FA_AMB sentences that did not contain a clitic object (as in "Quand il fait nuit, elle dorlote sa poupée," *During the night, she cuddles her doll*). The mean proportion of false alarm responses is plotted in **Figure 1**. As can

be seen, subjects made many more false alarms to ambiguous sentences, presenting a syntactic context that is appropriate for both the transitive and intransitive verbs (20% false alarms, range 3.23–41.94%, by participants), than to non-ambiguous sentences featuring a clitic object pronoun: sentences of this type only triggered 3% of false alarms (range: 0–9.68%). This result was confirmed by our mixed model analysis exhibiting a main effect of the predictor Condition ($\beta = -3.01$; $z = -4.35$; $p = 1.4\text{e-}05$) corresponding to a decrease of 0.16 in the probability to make a false alarm when the participant heard an object pronoun clitic (FA_CLI condition) relative to when there was no object pronoun (FA_AMB condition).

Thus, the probability that participants would be influenced by the sound similarity between the target verb (intransitive) and the verb that was actually present in the sentence (multisyllabic transitive), was largely reduced by the presence of the pre-verbal object clitic. As pointed out by a reviewer, every sentence which exhibited a pre-verbal clitic object did not contain the target. As a result, one may wonder whether the reduced rate of false alarms on FA_CLI sentences with a pre-verbal object did not result from participants learning, over the course of the experiments, that clitic objects signaled sentences without a target. If this were the case, the difference in False Alarm rates between conditions should start at zero and increase with time, as participants start using the strategy. To examine this possibility, we checked whether the difference in false alarm rates increased between the two experimental conditions, over the course of the experiment. **Table 2** shows the percentage of False Alarms, in both conditions, for each quarter of the experiment (first 31 trials, trials 32–62, trials 63–93, and 94–124).

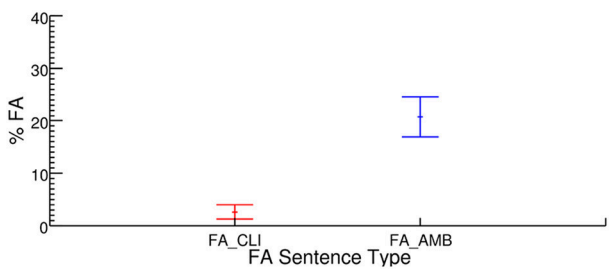

FIGURE 1 | Percentage of false alarms made by participants for each type of false alarm sentence presented, non-ambiguous FA sentences with a clitic (FA_CLI) in red (left-hand side) and ambiguous FA sentences (FA_AMB) in blue (right-hand side). Error bars represent the standard error of the mean (by participants).

TABLE 2 | Percentage of False Alarms, in both conditions (FA_AMB and FA_CLI), for the 4 quarters of the experiment.

	FA_AMB (%)	FA_CLI (%)
1st quarter	32	7.5
2nd quarter	23	2
3rd quarter	15	0.9
4th quarter	18	0.3

As can be seen, the difference in proportion of False Alarms between conditions does not increase with time. The only observable effect is a sharp decrease in overall False Alarm rate, as the experiment unfolds, suggesting that as participants became aware that they got caught on some of the false alarm sentences, they adopted a more conservative response bias. However, this pattern occurs for both types of False Alarms. In particular, there is already a massive difference between the FA_AMB and FA_CLI conditions in the first quarter of the experiment, suggesting that the lower rate of responses in the FA_CLI condition is present from the start, and therefore unlikely to be the result of a specific strategy developed as a function of the experiment (specifically, noticing that whenever a clitic is present the target is not there).

All in all, these results show that subjects dismiss the possibility that the target intransitive verb will occur, when they process the clitic object pronoun, an argument that is incompatible with the target intransitive verb.

DISCUSSION

We investigated the ability of French listeners to quickly compute the match or mismatch between the subcategory of an upcoming verb, and the presence or absence of a pre-verbal direct object pronoun. The logic here is that if French listeners are able to rapidly integrate the information conveyed by the object pronoun, they should be able to completely rule out an intransitive verb as a possible continuation of that sentence—since, by definition, an intransitive verb cannot take a direct object. We observed that participants' tendency to falsely detect a monosyllabic intransitive target verb was much higher when the multisyllabic carrier verb occurred in a syntactic context which was congruent with the target (e.g., "elle dorlote…" *she cuddles…*, FA_AMB condition), than when the carrier verb was preceded by an object pronoun (e.g., "elle le dorlote"/ *she cuddles it*, FA_CLI condition), making the syntactic context impossible for the target verb ("*elle le dort"/**she sleeps it*). This result shows that the participants integrated the clitic object pronoun on-line into the syntactic structure of the sentence, and inferred from this that the target intransitive verb would not follow.

This study confirms, with a different experimental technique, a different language, and in a different modality (listening vs. reading), the results obtained by Omaki et al. (2015) in English: They studied filler-gap dependency completion in object relative clauses and observed that processing of "chatted" was slowed down in a sentence such as "the city that the author chatted regularly about was named after an explorer," because there was a mismatch between the verb "chatted" which cannot take a direct object, and the implicit assumption that "the city" will be the direct object of the next encountered verb. Omaki et al. concluded from their series of three experiments that English-speaking comprehenders build argument structure before having heard the verb itself—just like Japanese-speaking comprehenders do, even though English is a verb-medial language. In their discussion, however they acknowledge the fact that their data are compatible with an alternative interpretation in which argument structure building does not occur ahead of the verb (p. 14). Under that alternative interpretation, participants would initially

access only very coarse category information about the verb, namely that it is a verb; at that first step, filler retrieval processes would be activated and an object filler would be posited for the verb; only later would finer-grained information about the verb subcategory be retrieved, transitivity information would then become available and reveal the mismatch between the filler and the verb. In our experimental design, this alternative processing strategy would have led to opposite effects: As we mentioned in our introduction, if participants initially generated expectations about lexical items on the basis of coarse category information (e.g., Verb, Noun), then the two contexts, with and without an object clitic, should have led to approximately the same number of false alarms. Indeed, both are equally good verb contexts, and should have led participants to occasionally respond too fast upon hearing a word starting with the target verb, in a verb position. The fact that participants made almost zero false alarms to the sentences with an object clitic shows that they were able to compute that this context was inappropriate for the target intransitive verb, even before they had started hearing the first phonemes of the verb itself. Taken together, the available experimental evidence thus suggests that comprehenders' ability to exploit pre-verbal arguments to constrain their interpretation of sentences, even before they have heard the verb itself, is not a specific adaptation to verb-final languages, but reflects instead a more general behavior of the human language parser.

Note that two mechanisms are compatible with the present set of results: either a predictive account, in which the preceding context is used to generate specific expectations about upcoming words, which are then matched with the input; or an integrative account, in which the preceding context is integrated very rapidly with the available phonological information. As we mentioned above, the fact that almost zero False Alarms were observed in the FA_CLI condition suggests that participants were able to compute that the target was unlikely to occur even before they heard its first syllable, which might be interpreted as evidence in favor of the predictive account over the integrative account. However, since the target verb was specified as a target before the sentence itself, it is likely that it was pre-activated before participants even started to process the sentence. As a result, the integration between context and target verb could start even before the first syllable of the carrier verb was heard, because the target verb was pre-activated. In other words, at every point in time, participants could try to work out whether their target word is likely or not in that context. When it is consistent with the context (as in FA_AMB sentences), it is likely to occur next, and hearing consistent phonological information probably results in the increased rate of False Alarms. When it is not consistent with the context (as in FA_CLI sentences), then it is unlikely to occur, and the processing of phonological information in the hope of finding the target verb may stop very early (and result in the almost-zero rate of false alarms we observed). In other words, the task we used makes it possible for participants to integrate the preceding context both with the phonological information as it becomes available, and the information about the target verb that was provided before the sentence began. All in all, both the predictive and the integrative interpretations account equally well for the present set of results[1].

An interesting particularity of the experimental paradigm we chose to use is that it allowed us to test participants' ability to use abstract syntactic information, in the absence of any semantic information conveyed by content words. Indeed, in the sentence quadruplets that were used, the first words of all four sentences, up to the critical word, were always identical, and the only difference was the presence or absence of the clitic object pronoun just before the critical verb. Because there was no difference whatsoever in the content words that were heard before the critical verb, participants' behavior was thus necessarily due to their processing of the syntactic role of the object pronoun. Thus, listeners can exploit the syntactic structure they are constructing on-line to restrict their lexical search to word candidates that fit this syntactic structure.

This conclusion might seem at odds with recent results from Chow et al. (2015), in which they conclude that comprehenders initially rely on the lexical meanings of arguments—but not their structural roles—to compute predictions about a likely upcoming verb (using sentences in which arguments were reversed, e.g., "which customer the waitress had served," vs. "which waitress the customer had served"). In the present experiment, we conclude that listeners exploit the structural role of an argument—e.g., direct object—to infer whether a target intransitive verb is plausible or not in that context. The apparent discrepancy here comes from the difference in experimental paradigms, which tested different kinds of inferences about the upcoming verb. In Chow et al. (2015) what was delayed was not really the computation of a structural role of an argument (e.g., subject, or direct object), but rather the computation of an argument's likely thematic role based on its structural role. For instance, if an argument occupies the subject position, is it the agent of the action or not? Often yes, but not necessarily (depending on the nature of the verb and the structure of the sentence). In the present experiment, simply knowing whether the verb takes a direct object or not (irrespective of the thematic role played by the referent occupying that position), was sufficient to constrain lexical access and eliminate the intransitive candidate. In Chow et al. (2015) participants had not only to find events involving waitresses (which might be fast), but also to find events in memory involving waitresses as agents (which might be slower). So overall, the available evidence suggests that structural roles are computed fast, and exploited on-line, so long as this does not involve an extra step (assigning thematic roles to arguments, and/or retrieving specific event types in memory).

If all the experiments presented above clearly point out the capacity of the linguistic parser to exploit various features of its input to anticipate different aspects of upcoming materials, it remains unclear to what extent these phenomena actually occur outside of the lab. Indeed, within experiments, participants are often placed in closed-choice situations, which restrict the number of possible anticipations that might be entertained. For the experiment reported here, participants are presented with the target verb before hearing a sentence, thus reducing considerably

[1]We thank a reviewer for helping us to clarify this important point.

the possible verbs that are expected. The same issue can be addressed to the "visual-word" paradigm, where participants are exposed to a finite number of images representing the sentence they are exposed to. As an aside, this is not such an artificial situation, as people in real-life situations will often have access to other elements of context, either visually (with a less impoverished visual context than in the visual-world paradigm), or through preceding linguistic materials (with a small set of words that can be made highly plausible by the preceding context). Even in reading experiments in which no visual or discourse context is available, participants are repeatedly exposed to sentences with similar syntactic structures, which may restrict the kind of materials they are led to expect—and participants do exploit this kind of experiment-specific information (see e.g., Gibson et al., 2013). However, all these results clearly show the capacity of the parser to rapidly integrate useful information to facilitate the process of on-line comprehension. Future research should investigate how this type of anticipation processes can be used in less constrained situations.

To conclude, the study reported here focused on the ability of French listeners to rapidly integrate syntactic cues to constrain lexical access and eliminate verb candidates on the basis of a mismatch between their sub-category and the syntactic context. Participants were shown to be able to take into account a very subtle cue, a clitic object pronoun, to infer that a target intransitive verb was unlikely to come next. This result proves that the human language parser can use subtle syntactic cues to constrain lexical access on-line, and restrict the lexical search to candidates that fit the ongoing syntactic structure. This study nicely aligns with previous data suggesting that each element from the input can be analyzed and exploited by listeners, on-line, to improve the precision of linguistic processing at all levels of linguistic analysis.

Dependency Resolution Difficulty Increases with Distance in Persian Separable Complex Predicates: Evidence for Expectation and Memory-Based Accounts

Delaying the appearance of a verb in a noun-verb dependency tends to increase processing difficulty at the verb; one explanation for this locality effect is decay and/or interference of the noun in working memory. Surprisal, an expectation-based account, predicts that delaying the appearance of a verb either renders it no more predictable or more predictable, leading respectively to a prediction of no effect of distance or a facilitation. Recently, Husain et al. (2014) suggested that when the exact identity of the upcoming verb is predictable (strong predictability), increasing argument-verb distance leads to facilitation effects, which is consistent with surprisal; but when the exact identity of the upcoming verb is not predictable (weak predictability), locality effects are seen. We investigated Husain et al.'s proposal using Persian complex predicates (CPs), which consist of a non-verbal element—a noun in the current study—and a verb. In CPs, once the noun has been read, the exact identity of the verb is highly predictable (strong predictability); this was confirmed using a sentence completion study. In two self-paced reading (SPR) and two eye-tracking (ET) experiments, we delayed the appearance of the verb by interposing a relative clause (Experiments 1 and 3) or a long PP (Experiments 2 and 4). We also included a simple Noun-Verb predicate configuration with the same distance manipulation; here, the exact identity of the verb was not predictable (weak predictability). Thus, the design crossed Predictability Strength and Distance. We found that, consistent with surprisal, the verb in the strong predictability conditions was read faster than in the weak predictability conditions. Furthermore, greater verb-argument distance led to slower reading times; strong predictability did not neutralize or attenuate the locality effects. As regards the effect of distance on dependency resolution difficulty, these four experiments present evidence in favor of working memory accounts of argument-verb dependency resolution, and against the surprisal-based expectation account of Levy (2008). However, another expectation-based measure, entropy, which was computed using the offline sentence completion data, predicts reading times in Experiment 1 but not in the other experiments. Because participants tend to produce more ungrammatical continuations in the long-distance condition in Experiment 1, we suggest that forgetting due to memory overload leads to greater entropy at the verb.

1. INTRODUCTION

A long-standing claim in sentence processing is that increasing distance in a linguistic dependency, such as a noun-verb dependency, leads to greater processing difficulty (Chomsky, 1965; Just and Carpenter, 1992; Gibson, 2000; Lewis and Vasishth, 2005); it is common to refer to this increase in processing difficulty as the locality effect. One explanation for the locality effect is in terms of constraints imposed by working memory. According to one account, the Dependency Locality Theory (DLT; Gibson, 1998), the processing difficulty experienced when resolving a long dependency depends on the decay experienced by the noun; a related account by Lewis and Vasishth (2005) attributes the locality effect to decay and/or interference. Constraints on working memory may be a plausible explanation given that individuals' working memory capacity seems to affect the processes involved in dependency resolution (Caplan and Waters, 2013; Nicenboim et al., 2015). Although there is evidence consistent with the memory-based explanation in English, German, Chinese, Russian, and Hindi, (Hsiao and Gibson, 2003; Grodner and Gibson, 2005; Bartek et al., 2011; Vasishth and Drenhaus, 2011; Levy et al., 2013; Husain et al., 2014, 2015), research on some of these languages has also uncovered evidence that increasing noun-verb distance facilitates processing at the verb (Konieczny, 2000; Vasishth, 2003; Vasishth and Lewis, 2006; Jaeger et al., 2008; Vasishth and Drenhaus, 2011; Levy and Keller, 2013; Husain et al., 2014; Jäger et al., 2015). One explanation for these anti-locality effects is in terms of surprisal (Hale, 2001; Levy, 2008). Surprisal extends and formalizes the old idea of predictive sentence processing—which has been extensively investigated in the EEG literature (e.g., Kutas and Hillyard, 1984)—in terms of probabilistic parse continuations (also see Jurafsky, 1996). The surprisal account assumes that the comprehender maintains and uses linguistic knowledge probabilistically to parse a sentence incrementally. Surprisal is the claim that rare transitions are difficult: increased processing difficulty is predicted when a parser is required to build a low-probability syntactic structure. Formally, surprisal is defined as the negative log probability of encountering a particular part of speech or word given previous context. We will refer to surprisal as the expectation-based account, following the terminology of Levy (2008)[1].

In many of these studies, evidence has been found for both the memory-based accounts and the expectation-based account. One conclusion that has emerged is that both memory and expectation play a role. For example, in his eye-tracking (ET) study investigating processing difference in English object vs. subject relative clauses, Staub (2010) finds evidence for both expectation-based processing and locality constraints, although these occur in different regions of the target sentence. An example of Staub's design is provided below. In this study, processing difficulty was found on the noun phrase *the fireman* in the ORC (object relative clause) 1b, compared to the SRC (subject relative clause) 1a; this is consistent with the expectation account because the reader would be forced to build a rare object relative in the ORC condition when he/she encounters the noun phrase. However, this study also found greater processing difficulty at the relative clause verb in ORCs than SRCs, which is predicted by memory accounts.

(1) a. The employees that noticed the fireman hurried across the open field.

b. The employees that the fireman noticed hurried across the open field.

As further examples, both Vasishth and Drenhaus (2011) and Levy and Keller (2013) have argued that locality effects may appear when high working memory load is experienced; anti-locality effects may be present when the load is low.

In a recent development, Husain et al. (2014) argue that the strong predictability for a head (predicting an exact lexical item) can neutralize the locality effect; locality may manifest itself only when predictability strength is weak, that is, when only a verb phrase is predicted, and not the exact identity of the verb. In their self-paced reading (SPR) study, Husain et al. (2014) used a 2×2 design, crossing Predictability and Dependency Distance to investigate locality and anti-locality effects. In the strong predictability conditions, Hindi complex predicates (CPs) were used. In these noun-verb sequences, the noun strongly predicted the upcoming light verb, e.g., the noun *khayaal*, "care," strongly predicts the verb *rakhnaa*, "put," in *khayaal rakhnaa*, literally, "care put" ("to take care of"). The weak predictability condition, on the other hand, used the same verb used in the complex predicate, but the noun did not predict the verb. An example is *gitaar rakhnaa*, "guitar put"; "to put (down) a guitar"; here, the verb retains its literal meaning. Thus, when the reader sees *gitaar*, they cannot predict the exact identity of the verb, because many other verbs are possible here (e.g., bought). To summarize, in the strong predictability condition, the noun predicted the exact identity of the verb, while in the weak predictability condition the exact identity of the verb was not predicted with high certainty—although *a* verb was predicted. The second factor, dependency distance, was manipulated by placing one to two adverbials between the nominal predicate/object and the verb in the short condition. The long condition had two to three intervening adverbials. Reading time was measured at the verb. The results showed that CP light verbs were read faster in long vs. short distance conditions, but for the non-CP verb there was a tendency toward a slowdown in long vs. short conditions. Finally, there was weak evidence for an interaction (estimate on the log ms scale: 0.03, Bayesian 95% credible interval $[-0.02, 0.07]$, posterior probability of the effect being greater than 0 was 0.77). That is, there was some indication that with increased distance there was a speedup at the light verb in the CP conditions and a slowdown in the non-CP conditions. Although these results can also be interpreted as showing no interaction, Husain and colleagues suggested that strong predictability of the head could be canceling the locality effect, with the locality effect manifesting itself only when predictability strength was weak.

[1]Another expectation-based account in the literature is the entropy reduction hypothesis or ERH (Hale, 2006); we do not investigate ERH in this paper, but we do discuss a related idea, entropy, in Section 8.

In the present study, we build on the work by Husain et al. (2014) described above. Husain and colleagues' work suggested that the strength of the predictability may modulate whether locality effects occur or not; we investigate the cross-linguistic generality of this claim using Persian, which, like Hindi, also has a complex predicate construction that allows us to manipulate strong and weak predictability. We turn next to a short discussion of the complex predicate construction in Persian as it relates to our experiments.

2. COMPLEX PREDICATES IN PERSIAN

CPs consist of a sequence containing a non-verbal element (e.g., a noun) and a verb, where the meaning of the sequence is non-compositional (Samvelian, 2001). An example is shown in (2).

(2) Maryam be man latme zad
Maryam to me damage hit
'Maryam caused damage to me (Maryam harmed me).'

The verb, often called a light verb, lacks sufficient semantic force to function as an independent predicate (Vahedi-Langrudi, 1996; Karimi-Doostan, 1997, 2005) and can be combined with different types of non-verbal items such as nominal, adjectivals or prepositional phrases (Dabir-Moghaddam, 1997).

In our study, we used separable CPs as defined by Karimi-Doostan (2011). According to Karimi-Doostan, a complex predicate can be separated if it satisfies both of the following two conditions: (1) if the nominal part is a noun to which adjectives, demonstratives, and wh-words, etc. can be attributed, and (2) if this noun has an internal argument structure (referring to an action or event). From this perspective, Persian CPs are categorized in three groups: (1) predicative verbal nouns (e.g., *anja:m da:dan*, perform+to give), (2) predicative nouns (e.g., *latme zadan*, damage+to hit), and (3) non-predicative nouns (e.g., *gush da:dan*, ear+to do). Among these three types, only the second one satisfies both of the conditions.

We began by independently validating our assumption that the CPs we used in our experiments are predictable and separable. We first conducted a norming study (a sentence completion task), to establish that the light verbs (of the separated CPs) are highly predictable when the nominal is provided, as compared to non-CP verbs in simple predicate conditions. We then conducted an acceptability rating study to determine how acceptable Persian CPs are when they get separated.

3. NORMING STUDIES

In order to prepare appropriate stimuli, two norming studies were run. The first study involved offline sentence completion and served to validate (i) whether the identity of the verb in the complex predicate is highly predictable, and (ii) whether the identity of the verb in the control conditions is not predictable.

The second study involved offline acceptability rating; the goal was to choose CPs for our experiments which are separable. That is, we wanted to identify CPs which native speakers would find acceptable even if an intervener occurs between the noun-verb sequence. Instructions for both studies are provided in the supplementary Datasheet 1.

The sentence completion study was carried out to derive the predictions of the expectation account. Previous work on expectation effects suggests that sentence completion data may be useful for this purpose. For example, Levy and Keller (2013) used sentence completion data to complement their corpus analyses for deriving their predictions. In their study, the key issue was whether the intervening material (e.g., a dative marked NP) leads to a prediction of a dative verb. Their Table 4 shows that the intervening material sharpened the expectation for the type of verb predicted. This shows that sentence completion data can be used to determine empirically whether the prediction for a specific verb or a verb type is sharpened by intervening material; in the Levy and Keller case, it makes sense that the intervener sharpens the expectation, but clearly the nature and content of the intervening phrases will be crucial in determining whether expectations are sharpened (Konieczny, 2000; Grodner and Gibson, 2005)[2]. Similarly, Husain et al. (2014) used sentence completion to establish that the identity of the verb in a complex predicate is highly predictable given the preceding context, but the identity of the verb in a simple predicate is not (see their Table 4). A third example is Jäger et al. (2015); they used both corpus data and sentence completion to establish that a sentence starting with a determiner, classifier, and an adverb leads to the prediction of a relative clause continuation in Chinese, and that the conditional probability of a subject relative continuation is higher than that of an object relative continuation (see their Table 2). Given these previous results, we assume that sentence completion data is informative about the predictions of the expectation-based account.

3.1. Sentence Completion Studies

Two groups (32 participants each) of Persian native speakers, who did not take part in any of the other experiments, participated in two sentence completion pre-tests in which they were asked to complete the sentences after they were presented the sentence fragment until the pre-critical word. For example, as shown in example 3, subjects were shown incomplete sentences which they had to complete; in this example, the missing verb is shown in parentheses. The participants were allowed to complete the sentence with as many words as they wanted, but our interest was only in the first word that they would write, which would most likely be a verb. This allowed us to calculate the proportion of continuations in which the exact verb was produced.

(3) a. Ali a:rezouyee bara:ye man (kard) …
Ali wish-INDEF for 1.S (do-PST …
'Ali (made) a wish for me …'

[2]We return to this point in the Section 8, where we discuss the effect of entropy on reading times.

b. Ali a:rezouyee ke besya:r doost-da:sht-am
Ali wish-INDEF that a lot like-1.S-PST
bara:ye man (kard) …
for 1.S (do-PST) …
'Ali (made) a wish that I liked a lot for me …'

The materials were exactly the same as the ones used in the experiments presented below. For the Experiment 1 items, the average prediction accuracy for the exact verb in the strong predictability conditions was 64.46% for the short condition and 59.44% for the long condition; for the Experiment 2 items, it was 65.28 and 62.85% for the short and long conditions respectively. By contrast, the average prediction accuracy for the exact verb in the weak predictability conditions in Experiment 1 was 35.42 and 34.03% for the short and long conditions; and in Experiment 2, it was 36.36 and 30.21% for the short and long conditions. As shown in **Tables 1**, **2**, an analysis using Bayesian generalized linear mixed models with a binomial link function shows a main effect of predictability in both the first experiment and the second experiment.

In the Bayesian models, we used weakly informative priors for the fixed effects (a Student t-distribution with 2 degrees of freedom), and for the random effects (a so-called LKJ prior on the correlation matrix of the random effects' variance-covariance matrix). For an introduction specifically for psycholinguistics, see Sorensen and Vasishth (2015); Nicenboim and Vasishth (2016). One way to interpret whether there is an effect of a particular factor in Bayesian (G)LMMs is to check that the 95% uncertainty interval does not contain zero.

As is clear from the mean percentages for each condition, the light verbs used in the complex predicate conditions were relatively predictable, and the heavy verbs used in the simple predicate conditions were relatively unpredictable. It is also clear from this study that, in our materials, increasing the amount of intervening material does not render the upcoming verb more predictable. The additional information provided by the intervening material for predicting the upcoming verb has been suggested by Konieczny (2000) as one possible explanation for shorter reading times at the verb in long- vs. short-distance conditions. Although this proposal is likely to be correct for some constructions (see discussion in Grodner and Gibson, 2005), in our materials, the sentence completion data do not provide any evidence that the intervening words we used in our design sharpen the expectation for the verb[3].

3.2. Acceptability Rating of Separable vs. Inseparable CPs

Because the noun-verb sequences must be separable for our design to work, we also carried out an acceptability rating pre-test to make sure that the separability of the CPs used in our study is acceptable to native speakers. We tested for the acceptability of different types of noun-verb dependencies by interposing a short prepositional phrase between them. Taking Karimi-Doostan's classification of CPs into account, 36 items from each of the three categories were selected and randomized to test 50 native speakers of Persian (these participants did not take part in any other experiments reported here). They were asked to rate the sentences from 1 (unacceptable) to 7 (completely acceptable). Every participant saw all items. The average acceptability ratings for predicative verbal nouns, predicative nouns and non-predicative nouns were 3.23 (first quartile 1, third quartile 5), 6.08 (first quartile 6, third quartile 7), and 3.12 (first quartile 1, third quartile 5) respectively. That is, items with predicative nouns were the most acceptable. We used all the 36 items of the predicative noun condition in our Experiments 1, 2, and 32 items in Experiments 3, 4 (see the Section 6.1 of Experiment 3 for an explanation).

4. EXPERIMENT 1

4.1. Method

4.1.1. Participants

Forty-two participants aged between 17 and 40 years old (mean 24 years) participated in this experiment in Tehran, Iran. All participants were native speakers of Persian and were unaware of the purpose of the study. This study was carried out in accordance with the Helsinki Declaration, and letters of consent were obtained from all the participants.

4.1.2. Materials

We created 36 experimental sentences with a 2 × 2 factorial design, manipulating predictability strength and distance between the object noun and verb. The short intervener was a prepositional phrase and the long intervener was a relative clause added before the prepositional phrase. In order to mask

[3]In fact, in our sentence completion data, as discussed in the Section 8, entropy increases with distance.

the experiment, we included 100 filler sentences with varying syntactic structures (see supplementary materials). Here is an example of the target sentences:

(4) a. Strong predictability, short distance (PP)
Ali a:rezouyee bara:ye man kard va…
Ali wish-INDEF for 1.S do-PST and…
'Ali made a wish for me and…'

b. Strong predictability, long distance (RC+PP)
Ali a:rezouyee ke besya:r doost-da:sht-am
Ali wish-INDEF that a lot like-1.S-PST
bara:ye man kard va…
for 1.S do-PST and…
'Ali made a wish that I liked a lot for me and…'

c. Weak predictability, short distance (PP)
Ali shokola:ti bara:ye man xarid va…
Ali chocolate-INDEF for 1.S buy-PST and…
'Ali bought a chocolate for me and …'

d. Weak predictability, long distance (RC+PP)
Ali shokola:ti ke besya:r doost-da:sht-am
Ali chocolate-INDEF that a lot like-1.S-PST
bara:ye man xarid va…
for 1.S buy-PST and…
'Ali bought a chocolate that I liked a lot for me and….'

The critical region is the verb (*kard* and *xarid*).

Each sentence (including fillers) was followed by a yes/no comprehension question which targeted different thematic roles in the sentence. Half the questions had a yes answer and half had a no answer. The questions used for the target sentences are provided in the supplementary material.

4.1.3. Procedure

Participants were tested individually using a PC. They were explained the task before they performed the SPR experiment. The participants were instructed to read for comprehension in a normal manner and had a practice session of five sentences. All the sentences were displayed on a single line and were presented in 22 pt Persian Arial font using Linger software (http://tedlab.mit.edu/~dr/Linger/). In order to read each word of a sentence successively in a moving window display, participants had to press the space bar; then the word seen previously was masked and the next word was shown. After each sentence, they were asked to answer a comprehension question to ensure that the participants paid attention to the complete sentence.

4.1.4. Data Analysis

The data analysis was conducted in the R programming environment (R Development Core Team, 2013), using Bayesian hierarchical (so-called linear mixed) models using Stan (Stan Development Team, 2014; Gabry and Goodrich, 2016). Sum contrasts were used to code main effects and interactions. In addition, a nested contrast was defined for a secondary analysis in order to look at the effect of distance in CPs vs. the control conditions separately; these were also coded as sum contrasts. We fit full variance-covariance matrices for participants and items (the so-called maximal model, Barr et al., 2013; Bates et al., 2015). All data and code are available from http://www.ling.uni-potsdam.de/~vasishth/code/SafaviEtAl2016DataCode.zip.

4.2. Predictions

Based on the Husain et al. (2014) results, in Experiment 1, we expected that increasing noun-verb distance would lead to faster reading time at the verb in the strong predictable conditions, but slower reading time in the weak predictable conditions. Thus, we expected to obtain a cross-over interaction.

The memory based accounts (Just and Carpenter, 1992; Gibson, 2000; Lewis and Vasishth, 2005) predict that increasing distance should lead to a slowdown at the verb; these accounts make no predictions about the strength of predictability.

There are two alternative predictions possible for the expectation account, depending on how one operationalizes expectation. First, if sentence completion probabilities are a reasonable proxy for conditional probabilities—and the previous research reported above (Levy and Keller, 2013; Husain et al., 2014; Jäger et al., 2015) suggests that they may be—then we predict (a) no difference in reading time at the verb as a function of distance, and (b) faster reading time at the verb in the strong predictable conditions than the weak predictable conditions. Prediction (a) arises because, in the sentence completion data, we see no effect of distance on the predictability of the upcoming verb, in either the strong or weak predictability conditions; prediction (b) arises due to the difference in predictability of the exact verb that we see in the strong vs. weak predictability conditions (see the results of the sentence completion studies).

An alternative possible prediction of the expectation account is that increasing distance should facilitate processing at the verb. Surprisal predicts facilitation with increasing distance whenever distance causes the number of possible parses to decrease; this decrease in the number of possible parses leads to the probability mass being reassigned among the remaining parses. In our materials, when a participant reads the noun in the noun-verb complex predicate, they are expecting the light verb with high probability (nearly 1). However, in the long distance condition, the next word begins a relative clause; this leads to an expectation that the light verb will appear *after* the relative clause verb. But what appears after the relative clause verb is a PP that modifies the upcoming light verb. For a facilitation to be predicted in this long-distance condition by the surprisal metric, it would have to be the case that the conditional probability of the light verb following the RC and PP would be higher than the conditional probability of the light verb in the short-distance (PP) condition. In order to get a sense of how the conditional probabilities change in the noun-light verb conditions as a function of distance, we extracted all light verb sentences from a Persian corpus (Seraji, 2015) and then counted, for different numbers of

TABLE 3 | The conditional probability of a light verb appearing given the complex predicate noun and *n* intervening phrases between the noun and the light verb.

n Intervening phrases	Probability of verb
0	3826/4003 = 0.95
1	131/133 = 0.98
2	28/31 = 0.90
3	5/5 = 1
4	2/2 = 1
6	1/1 = 1

TABLE 4 | The conditional probability of a light verb appearing given the complex predicate noun and *n* intervening words between the noun and the light verb.

n Intervening words	Probability of verb
0	3826/4003 = 0.96
1	104/104 = 1
2	36/39 = 0.92
3	4/5 = 0.8
4	9/10 = 0.9
5	3/3 = 1
6	3/3 = 1
7	1/1 = 1
8	2/2 = 1
10	2/2 = 1
12	1/1 = 1
13	1/1 = 1
14	1/1 = 1

modifying phrases, the proportion of cases that a verb followed the intervening phrase. For example, in a Persian sentence such as *John in the morning went*, there is one intervening phrase, the PP. As shown in **Table 3**, we find that the conditional probability of the verb appearing next is always high, but goes to 1 with increasing distance. This suggests that in general, increasing distance tends to sharpen the expectation for an upcoming verb. We also did this calculation using the number of intervening words as a metric, rather than the number of intervening phrases. The result, shown in **Table 4**, is substantially the same as in **Table 3**. Of course, these corpus counts don't give us any direct information about the predictions regarding our particular experiment design.

Regarding the strong vs. weak predictability conditions, note that the expectation account of Hale and Levy does not predict that processing should be facilitated when the exact identity of the upcoming verb is predicted (strong predictability condition), compared to the case when just some verb is predicted (weak predictability condition). This is because the surprisal metric is usually calculated using the conditional probability of the part-of-speech (verb) given preceding context, and this will be the same in both the strong and weak predictability conditions. However, it is possible to subsume the difference between strong and weak predictability under the surprisal account by reframing the conditional probabilities in terms of the exact identity of the verb. In this case, the expectation account would predict faster reading times in the strong predictability conditions compared to the weak predictability conditions, regardless of distance.

To summarize, regarding the distance manipulation, the expectation account predicts either no effect or a facilitation at the verb as a function of distance; and regarding the predictability manipulation, the expectation account (appropriately formulated to include the conditional probability of the exact lexical item predicted) would predict a main effect of predictability.

TABLE 5 | Means, 95% uncertainty intervals, and $P(b < 0)$, the probability of the estimate being less than 0, in the question-response accuracy analysis for Experiment 1.

Predictability	−0.0328	−0.0566	−0.0096	0.998
Distance × Predictability	−0.0179	−0.0405	0.0046	0.942

4.3. Results

4.3.1. Comprehension Accuracy

Participants answered correctly on average 93% of all comprehension questions (excluding fillers). Accuracy was 91, 94, 95, and 91% respectively for the four conditions in (1). As shown in **Table 5**, a Bayesian generalized linear mixed model of the binary responses showed no evidence for an effect of distance or predictability, or an interaction between predictability and distance.

4.3.2. Reading Time

Reading times (RTs) were analyzed at the verb. As shown in **Table 6** and **Figure 1**, there was a main effect of distance, such that increasing distance led to longer reading times. There was also a main effect of predictability: the complex predicate conditions were read faster overall. A weak interaction was also seen: stronger locality effects were seen in the control conditions than in the complex predicate conditions. A nested analysis shows that the distance effect was driven by the control (weak predictability) condition. The estimates for the strong predictability condition were coef. = 0.0218, [−0.0094, 0.0524], $P(b < 0) = 0.0875$); and the estimates for weak predictability were coef. = 0.0581, 95% uncertainty intervals [0.0261, 0.0912], $P(b < 0) = 2e\text{-}04$.

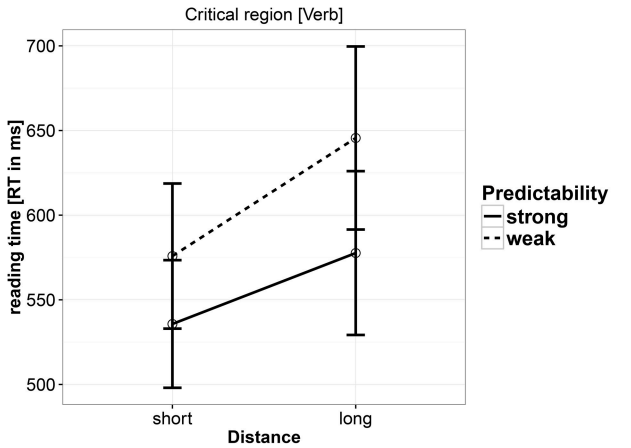

FIGURE 1 | Reading times at the critical verb in Experiment 1.

4.4. Discussion

Experiment 1 found a main effect of predictability such that the strong predictability conditions were read faster than the weak predictability conditions, and a main effect of distance, such that the short conditions were read faster than the long conditions. A nested contrast showed that this effect of distance was driven by the weak predictability conditions, i.e., reading time at the verb in condition c was faster than the reading time in condition d. A weak interaction suggests that the locality effect may be somewhat stronger in the weak predictability condition. The suggestion of an interaction seems to provide only weak support, if any, for the idea that strong predictability can at least attenuate locality effects (Husain et al., 2014). The overall effect of distance is consistent with memory-based accounts, which correctly predict a slowdown at the verb in the long conditions, i.e., a main effect of distance. However, as the nested comparison shows, the main effect of distance is driven only by the weak predictability (non-complex predicate) conditions. Memory-based theories would be unable to explain this because they predict a slowdown in long conditions irrespective of predictability strength. However, note that the absence of an interaction makes this absence of a distance effect in the strong predictability conditions difficult to interpret. The expectation account's prediction regarding distance, that increasing the argument-verb distance would either have no effect or result in a facilitation, was clearly not validated; however, the main effect of predictability is consistent with a version of the expectation account that uses the conditional probability of the exact lexical item (verb) appearing given the preceding context.

Our original motivation for this study was to attempt a replication of the Husain et al. (2014) findings. The results are not entirely inconsistent with those of Husain et al. (2014), but they are also not a strong validation of the expectation-memory cost tradeoff posited in that paper. As in the Husain et al. study, we see a main effect of predictability driven by the complex predicate condition. This effect could be explained in terms of reduced retrieval cost at the verb due to its high expectation. An obvious confounding factor here is that the verbs in the strong vs. weak predictability conditions are not identical; this prevents us from ruling out the possibility that low-level differences in the verbs might be responsible for the facilitation due to prediction strength.

We turn next to Experiment 2, in which we manipulate the type of intervener. Here, in the long distance condition, instead of a relative clause and prepositional phrase (PP) intervener, a long PP intervenes. The motivation was to increase distance without having different types of interveners in the short vs. long conditions, as this might be a fairer comparison.

5. EXPERIMENT 2

5.1. Method

5.1.1. Participants

Forty-three participants, with the same criteria as in Experiment 1, participated in this experiment in Tehran, Iran. This study was carried out in accordance with Helsinki Declaration, and consent forms were obtained from all the participants.

5.1.2. Materials

The stimuli and fillers were the same as in Experiment 1 except for the long conditions (b and d), where the intervener was a longer prepositional phrase (PP) instead of the combination of a relative clause and a PP as in the previous experiment. The PP was lengthened using several different structures, all of which had one or more instance of the ezafe possessive marker (Samvelian, 2007):

1. N-ez N-ez N/pronoun/proper name
2. N-ez adj-ez N/pronoun/proper name
3. N-ez adj-ez N
4. N-ez N-ez adj
5. N adj-ez adj
6. superlative adj N N/pronoun/proper name
7. N-ez pronoun

One set of examples using the first type of PP shown above is as follows:

(5) a. Strong predictability, short distance (PP)

Ali a:rezouyee bara:ye man kard va…
Ali wish-INDEF for 1.S do-PST and…

'Ali made a wish for me and…'

b. Strong predictability, long distance (longer PP)

Ali a:rezouyee bara:ye doost-e xa:har-e man kard va…
Ali wish-INDEF for friend-EZ sister-EZ 1.S do-PST and…

'Ali made a wish for my sister's friend…'

c. Weak predictability, short distance (PP)

Ali shokola:ti bara:ye man xarid va…
Ali chocolate-INDEF for 1.S buy-PST and…
'Ali bought a chocolate for me and…'

d. weak predictability, long distance (longer PP)
Ali shokola:ti bara:ye doost-e xa:har-e
Ali chocolate-INDEF for friend-EZ sister-EZ
man xarid va…
1.S buy-PST and…
'Ali bought a chocolate for my sister's friend and…'

More details about the PPs are provided in the supplementary materials.

5.1.3. Procedure and Data Analysis

The procedure and data analysis methodology was the same as Experiment 1.

5.2. Predictions

In Experiment 2, the distance manipulation involves lengthening the PP. There are two possible predictions of surprisal. One is that surprisal may predict no difference at the verb; this would be because the end of the PP raises a strong expectation for a verb, and this strong expectation for a verb would be the same in both the short and long PP conditions. Another alternative possible prediction of surprisal is that lengthening the PP could lead to a facilitation. This prediction could hold if increasing distance, counted in terms of the number of intervening words, generally increases the predictability of the upcoming verb; this is a possibility given the corpus counts in **Table 4**.

5.3. Results

5.3.1. Comprehension Accuracy

Participants answered 93% of all comprehension questions correctly on average (excluding fillers). The accuracies by condition were 96, 92, 94, and 89% respectively for the four conditions in (2). As shown in **Table 7**, the Bayesian generalized linear mixed models of the responses showed a main effect of distance, such that accuracies were lower in the long conditions. No effect of predictability strength, and no interaction between predictability strength and distance were found.

5.3.2. Reading Time

As shown in **Table 8** and **Figure 2**, the results showed a main effect of distance, with long distance conditions being read slower. There was only a weak effect of predictability, with the strong predictability condition being read faster than the weak predictability condition. No interaction was found between predictability and distance. A nested contrast showed that the distance effect is seen in both strong predictability (coef. = 0.0623, [0.0274, 0.0965], $P(b < 0) = 0$) and weak predictability (coef. = 0.0475, [0.0098, 0.085], $P(b < 0)$=0.0078) conditions.

5.4. Discussion

In this experiment, we replicated the locality effects found in Experiment 1, but we no longer see a weakening of the locality effect that was seen in Experiment 1 (a marginal interaction was found in Experiment 1). Nested contrasts showed that locality effects are equally strong in both the strong and weak predictability conditions. In Experiment 2, we also see an effect of predictability, with the strong predictable verb being read faster. Thus, regarding the distance manipulation, the working-memory account's prediction is validated, and the expectation-based account's prediction is not supported. The main effect of predictability does furnish evidence consistent with the expectation-based account.

A secondary analysis was conducted to compare the strength of the locality effect in the two experiments, and to determine whether an interaction between distance, predictability and experiment was present. The between-participant factor experiment was coded using sum coding: Experiment 1 was coded −1, and Experiment 2 was coded +1 (further details are available in the supplementary materials). The results are shown

TABLE 7 | Means, 95% uncertainty intervals, and $P(b < 0)$, the probability of the estimate being less than 0, in the question-response accuracy analysis for Experiment 2.

Comparison	Mean	Lower	Upper	$P(b < 0)$

in **Table 9**. There isn't any convincing evidence for an interaction between distance and experiment; there is only weak evidence for a larger effect of distance in Experiment 2. We cannot therefore argue for a qualitative difference in the distance effects found in Experiments 1 vs. 2.

In Experiment 2, the intervener was a long, uninterrupted prepositional phrase whereas in Experiment 1, the intervener consisted of a short RC followed by a PP. One can speculate as to why Experiment 2 shows equally strong distance effects in both predictability conditions: processing a single long intervening phrase may be harder than processing two different phrases because it may be harder to chunk a single long phrase compared to two shorter phrases; this is predicted by the Sausage Machine proposal of Frazier and Fodor (1978). If this is correct, then the complexity of the intervener may indeed be a relevant factor in determining whether strong expectation can weaken locality effects. It is possible to test this claim by using an intervener that is much easier to process; an example would be an adverb containing no noun phrases.

We were motivated by the recent replication crisis in psychology (Open Science Collaboration, 2015) to attempt to replicate our results using a different method. Furthermore, replications using ET would be very informative because it is possible that SPR overburdens the working-memory system in an unnatural manner. If this is the case, one prediction would be that the ET data would not necessarily show locality effects. We describe these experiments next.

6. EXPERIMENT 3

6.1. Method

6.1.1. Participants

Forty participants, with the same criteria for inclusion as in the previous experiments, participated in the ET study in University of Potsdam, Germany.

6.1.2. Materials

The experimental items were exactly the same as Experiment 1 (SPR), except that the following four items from Experiment 1 were removed: item id 5, *sheka:yat kardan* (complain + to do), item id 9, *sahm bordan* (share + to win), item id 26, *pishraft kardan* (progress + to do), and item id 32, *hes kardan* (feel + to do). The reason for removal was that the results of the sentence-completion studies suggested that these light verbs had lower predictability than the other light verbs in the stimuli. It could be that this lower predictability is due to the existence of some other alternative light verbs with which the nominal part can combine to make other possible CPs. The last two CPs also had a lower acceptability rating (item 26 had 4.7, and item 32 had 3.5). As a consequence, in our ET study, we had thirty-two experimental items and 64 fillers. All items, including fillers are available in the supplementary materials.

6.1.3. Procedure

An ET study was prepared using Experiment-Builder software, and participants' eye-movements were recorded using an EyeLink 1000 tracker, with a connection to a PC. Before the experiment started, the participants were instructed to read the sentences silently at a normal pace and had a practice block consisting of five sentences. After answering the comprehension questions of the practice block, they were provided with feedback indicating whether or not the answer was correct. A 21-inch monitor was placed 60 centimeters from the participants' eyes. In order to reduce head movements, the participants were asked to use the chin-rest. They viewed the sentences with both eyes, but only the right eye was recorded. The items were presented in one line and in 18 points Persian Arial font (from right to left). First, they had to fixate on a dot at the right edge of the screen so that the sentence appeared. After they finished reading, they had to fixate on the dot in the bottom left corner of the screen; once they fixated on the dot, the comprehension question was presented. Unlike the practice items, they were not provided with any feedback. Calibration was performed at the beginning of the experiment, after their 5-min break (which occurred after they had were halfway through the experiment), and whenever it was necessary.

6.1.4. Data Analysis

Raw gaze duration data was obtained using the Data Viewer software[4]. This data was then processed to get different ET measures using the `em2` package (Logačev and Vasishth, 2014). As discussed earlier, Bayesian linear mixed models were used for the analysis. All analyses were carried out using log-transformed data. Zero ms reading times were removed before carrying out the analysis.

6.2. Results

6.2.1. Comprehension Accuracy

On average, participants correctly answered 92% of the target comprehension questions. Mean accuracy by condition was 91 % for condition a, 91% for condition b, 95% for condition c, and 89% for condition d. We found no effects of distance and predictability, and no interaction.

6.2.2. Reading Time

The critical region was the verb, as in Experiments 1 and 2. The same sum contrast coding was used as in Experiments 1 and 2; in addition, nested contrast coding was used to investigate the effect of distance within the two predictability conditions. We present results for first-pass reading time and regression path duration.

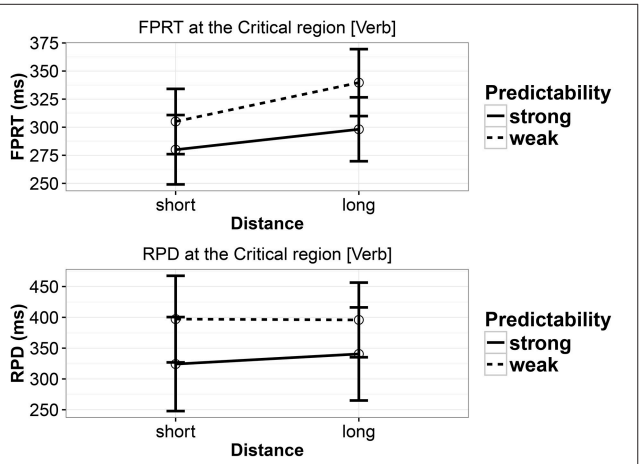

FIGURE 3 | First-pass reading time and regression path duration in Experiment 3 at the critical verb. Error bars show 95% confidence intervals.

The effect of predictability, seen in Experiments 1 and 2, is also present in first-pass reading time (FPRT) and regression path duration (RPD); the strong-predictability conditions had shorter reading times. There was also an effect of distance in FPRT but only a weak effect in RPD; the long-distance conditions had longer reading times. **Figure 3** and **Table 10** show the details of the analyses. A nested contrast showed that in FPRT the distance effect was present in the weak-predictability conditions (coef. = 0.0613, [0.0155,0.1081], and $P(b < 0) = 0.004$); in the strong-predictability conditions the effect was weak (coef. = 0.0423, [−0.0022,0.0865], and $P(b < 0) = 0.0318$). RPD showed only a weak effect of distance within the two predictability levels. For the weak-predictability level, coef. = 0.0359, [−0.0169,0.0884], $P(b < 0) = 0.0891$; and for the strong-predictability level, coef. = 0.0294, [−0.0305,0.0883], $P(b < 0) = 0.1596$.

6.3. Discussion

In the ET Experiment 3, we replicated the locality effects found in the Experiment 1 in first-pass reading time. Nested contrasts showed that the locality effect appeared in weak-predictability conditions, which is similar to the result in Experiment 1. A main effect of predictability was found in FPRT and RPD, replicating the effect in Experiment 1.

Since we failed to find any interaction between predictability and distance, we cannot conclude, as Husain et al. (2014) did, that expectation effects can cancel locality effects. The locality effects are consistent with working memory accounts (Gibson, 2000; Lewis and Vasishth, 2005) and inconsistent with the distance-based predictions of the expectation account (Levy, 2008). As in the SPR experiments, we have evidence consistent with a version of the expectation account that predicts that strong predictability conditions will be read faster than the weak predictability conditions.

In sum, the main result in Experiment 3 is that we have replicated the locality effect and the facilitation due to strong predictability.

7. EXPERIMENT 4

7.1. Method

7.1.1. Participants

Forty participants, with the same criteria as in the previous experiments, participated in the ET study in Golm campus, University of Potsdam, Germany.

7.1.2. Materials

The experimental items were exactly the same as Experiment 2 (SPR), but with 32 items (see the explanation for Experiment 3 regarding the four items that were removed). The experimental items were complemented with 64 filler sentences with varying syntactic structures (see supplementary materials).

7.1.3. Procedure and Data Analysis

The procedure and data analysis were exactly the same as Experiment 3 (ET).

7.2. Results

7.2.1. Comprehension Accuracy

On average, participants answered 90% of comprehension questions correctly. They had 94% response accuracy for condition a, 88% for condition b, 94% for condition c, and 86% for condition d. None of the factors had an effect on accuracy.

7.2.2. ET Measures

The reading times at the critical region are summarized in **Figure 4**. Unlike Experiment 3, in the current experiment, we found effects of distance and predictability in both the measures (see **Table 11**). In other words, in the two measures reported, the long conditions (b and d) were read slower than the short conditions (a and c), and the weak predictability conditions (c and d) were read slower than the strong predictability conditions (a and b). None of the measures showed any interaction between predictability and distance.

Nested comparisons showed that in first-pass reading time, the locality effect was seen in the strong-predictability condition (coef. = 0.0507, [0.0011, 0.1003], $P(b < 0) = 0.022$), but there

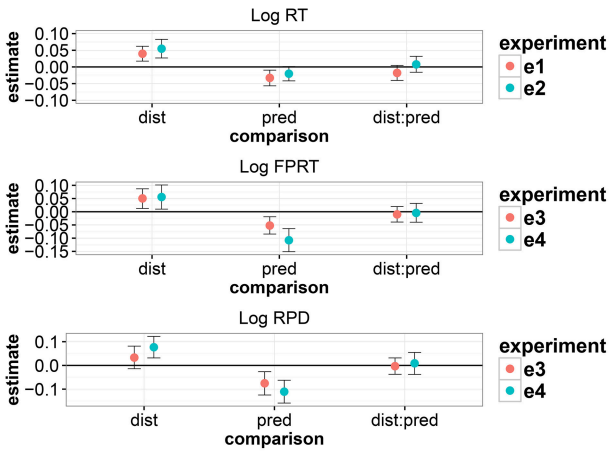

FIGURE 5 | Summary of the magnitudes of effects (derived from the linear mixed models) across the four experiments. The error bars show 95% uncertainty intervals and show the range within which we can be 95% certain that the true parameter lies given the data.

TABLE 11 | Means, 95% uncertainty intervals, and $P(b < 0)$, the probability of the estimate being less than 0, in the reading time analysis for Experiment 4.

ET measure	Comparison	Mean	Lower	Upper	$P(b < 0)$
FPRT	Intercept	5.6731	5.6015	5.7448	0
	Distance	0.0557	0.0099	0.1013	0.0082
	Predictability	−0.1079	−0.1512	−0.0638	1
	Distance × Predictability	−0.0046	−0.0397	0.0315	0.6088
RPD	Intercept	5.7958	5.7113	5.8799	0
	Distance	0.0767	0.0316	0.1225	5e-04
	Predictability	−0.1108	−0.1588	−0.0626	1
	Distance × Predictability	0.0089	−0.0381	0.0547	0.3452

was a weaker tendency toward a locality effect in the weak-predictability condition (coef. = 0.061, [−0.0046, 0.1261], $P(b < 0) = 0.0355$). In regression-path duration, both strong- and weak-predictability conditions showed a locality effect (strong-predictability: coef. = 0.0858, [0.0253, 0.1492], $P(b < 0) = 0.0031$; low-predictability: coef. = 0.0675, [0.0027, 0.1317], $P(b < 0) = 0.0211$.

7.3. Discussion

Experiment 4 replicated the results of Experiment 2: a main effect of distance and a main effect of predictability, with no evidence for an interaction. The effects in FPRT and RPD showed essentially the same patterns as in the first ET study. However, the locality effects were even stronger, in the same way that the second SPR study showed stronger locality effects. Also, these effects are equally strong in both strong and weak predictability conditions, mirroring our finding in the second SPR study.

Overall, regarding the distance manipulation, the results are consistent with memory-based accounts, and inconsistent with the expectation account. The main effect of predictability is consistent with the expectation account, as discussed earlier. In Experiment 4, we don't see any evidence consistent with the Husain et al. (2014) proposal; if anything, the locality effect is *stronger* in the strong-predictability conditions.

8. GENERAL DISCUSSION

As summarized graphically in **Figure 5**, our main finding from the four Persian studies is that the locality effect predicted by memory accounts is upheld, but there is no evidence for the expectation-based account's prediction of facilitation in longer distance conditions. We consistently see a main effect of predictability, which is consistent with expectation accounts. Finally, there is no compelling evidence in the Persian data that strong expectations cancel locality effects.

There is also suggestive evidence that the complexity of intervening material could strengthen the locality effect: when the intervener is an RC followed by a PP, we see a marginal interaction between distance and predictability, but when the intervener is a single long PP, we see no evidence for an interaction between distance and predictability strength, and we tend to see stronger effects.

We consistently found a main effect of predictability in all four experiments: the strong predictability conditions were read faster at the verb than the weak predictability conditions. This is consistent with the expectation-based account. Since the verbs in the strong and weak predictability conditions are not identical, we cannot rule out the possibility that word frequency or other such low-level factors are responsible for these effects. However, it is plausible that the highly predictable verb is processed faster than the less predictable verb. Thus, the main effect of predictability can be seen as evidence for expectation-based accounts, operationalized in terms of the conditional

probabilities of the appearance of the exact verb given the preceding context.

It is possible that we were unable to replicate Husain et al's findings because of the nature of the intervener used in the Persian studies. Unlike, Husain et al. (2014) where the long distance condition had extra adverbials compared to the short condition, in Experiment 1 we have a more complex intervener, a relative clause. Another reason for finding the effects which are different from the study by Husain et al. (2014) could be that in Persian, separating the nominal part of the CP from the light verb occurs relatively rarely, compared to Hindi. There is some support for this in corpus data. Based on the Hindi dependency treebank (Bhatt et al., 2009), the average distance, counted as the number of intervening phrases, between an object and its (heavy) verb is 0.82 (with minimum 0 and maximum 15, and first and third quantiles 0 and 1), and the average distance between a noun and light verb is 0.07 (minimum 0 and maximum 18, with first and third quantiles 0 and 0). In the Persian dependency treebank (Seraji, 2015), the average distance between an object and (heavy) verb is 2.48 (with minimum 0 and maximum 9, and first and third quantiles 1 and 3), while the average distance between a noun and light verb is 0.05 (with minimum 0, and maximum 6, and first and third quantiles 0 and 0). Thus, the adjacency of CPs in Persian is strongly preferred (maximum 6 vs. Hindi's maximum 18), although as validated in the acceptability rating norming study, this separability is apparently acceptable and not considered ungrammatical[5].

8.1. An Alternative Explanation of Locality Effects in Terms of Entropy

Could there be an alternative explanation for the locality effect seen in the four experiments, one that does not invoke greater memory cost in the long-distance conditions? One possibility is that entropy (uncertainty) increases with increasing distance. Entropy is an information-theoretic measure that essentially represents how uncertain we are of the outcome (Shannon, 2001). In the present case, this would translate to our uncertainty about the upcoming verb. If there are n possible ways to continue a sentence, and each of the possible ways has probability p_i, where $i = 1, \ldots, n$, then entropy is defined (Shannon, 2001) as $-\sum_i p_i \times \log_2(p_i)$. The entropy associated with the upcoming verb can be calculated using our offline sentence completion data[6].

8.1.1. Evaluating the Effect of Entropy

In order to evaluate whether entropy could explain the locality data, we computed entropy for each item in each condition for both experiments. The estimated entropies for each condition in the two experiment designs are shown in **Figure 6**. It is important to note here that entropy for each condition in **Figure 6** is based on only nine data points per condition (we only have $9 \times 4 = 36$ items); for different items, there is substantial variability in the entropy patterns by condition. Nevertheless, in the figure we can see that in the items used for Experiments 1 and 3, the entropy is higher in the long-distance conditions. The effect of entropy is less clear for the items used in Experiments 2 and 4, because of the relatively wider confidence intervals. Clearly uncertainty is higher in the RC+PP experiment than in the long PP experiment. A closer look at the high predictability conditions shows that the entropy difference between the long and short distance conditions is larger in the RC+PP intervener items than the entropy difference in the long PP intervener items (it is larger by 0.14, with 95% uncertainty intervals −0.01 and 0.28, probability of the difference in entropy being less than 0 is 0.03). This is suggestive—if weak—evidence that the intervening RC may be responsible for creating a greater degree of uncertainty regarding the upcoming verb. This is a bit surprising because stronger locality effects were seen in the long PP experiments.

In order to investigate whether entropy affects reading times at the verb, we fit a maximal Bayesian linear mixed model with predicate type and distance as sum-coded factors, and entropy (centered) as a continuous predictor; all higher order interactions were also included. The dependent variable was log reading time at the critical verb. As shown in **Table 12**, in Experiment 1, in addition to the effects of predictability and distance, we find an effect of entropy, and an interaction between distance and entropy, such that long distance conditions lead to a greater effect of entropy. None of the other experiments showed any effects of entropy. Thus, although the evidence in favor of entropy is far from overwhelming, a potentially important finding here is that entropy could explain locality effects at least in our Experiment 1. To our knowledge, this is the first demonstration

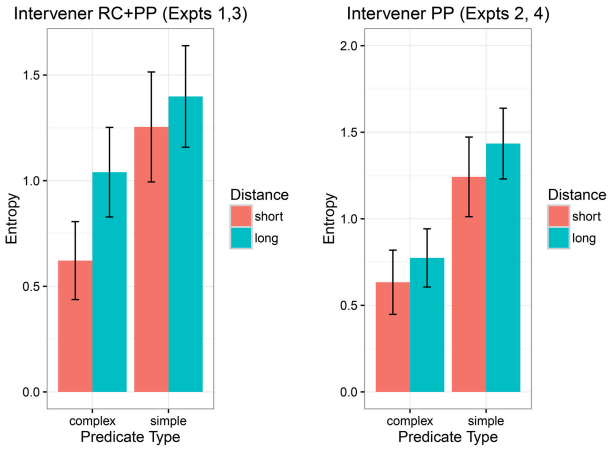

FIGURE 6 | The estimated entropy (with 95% confidence intervals), computed using the sentence completion data, for the two experiment designs.

[5]These intervening phrases have been computed using dependency treebanks. Consequently, phrasal boundaries are approximations. Also, because of annotation differences between the two treebanks, phrase boundary criteria sometimes differ for the two languages. The phrasal counts lead to the same conclusions regardless of whether one counts intervening phrases or words.

[6]See Linzen and Jaeger (2015) for a recent empirical investigation of entropy in sentence comprehension using corpus data instead of sentence completion data. Linzen and Jaeger calculated entropy in several ways, and also evaluated another metric called entropy reduction (ER), which was proposed by Hale, 2006; however, we cannot evaluate ER here because that would require knowing the entropy for the word preceding the verb.

TABLE 12 | Model results from the Bayesian linear mixed model for the effect of entropy (apart from other predictors) on log reading times in Experiment 1.

Comparison	Mean	Lower	Upper	$P(b < 0)$
Intercept	6.23	6.16	6.3	0
Predictability	−0.02	−0.04	0	0.95
Distance	0.03	0.01	0.06	0.01
Entropy	0.05	0.02	0.09	0
Pred:Dist	−0.01	−0.03	0.02	0.71
Pred:Entropy	−0.02	−0.06	0.01	0.88
Dist:Entropy	0.04	0.01	0.07	0.01
Pred:Dist:Ent	0	−0.03	0.04	0.45

Shown are the mean and 95% uncertainty intervals, and the probability of the parameter being less than 0.

that locality effects may arise due to factors other than memory costs.

But why does entropy increase in longer-distance dependencies? A possible explanation suggests itself in terms of memory overload causing forgetting. It is possible that the participants forgot that a noun-verb dependency exists in the long-distance complex predicate condition. One prediction of this forgetting-inducing-entropy account would be that in the sentence completion study, participants would tend to produce more ungrammatical continuations in the long-distance condition than the short-distance condition. This is borne out in Experiment 1: the accuracy in the short condition was 97%, and in the long condition it was 92%. A Bayesian generalized linear mixed model was fit with a full variance-covariance matrix for participants and items[7]. The results of the model fit showed a reduction in grammaticality of sentence completions in the long vs. short conditions; the log odds were −0.9436 [−2.042, −0.1284], with a probability of the log odds being negative being 0.99. The sentence completion study corresponding to Experiment 2 (which showed no effect of entropy on reading times) showed no difference in grammaticality of completions; the short and long conditions had grammatical continuations with the proportions 0.97 and 0.98.

Thus, it is possible that in Experiment 1, the increase in entropy is due to participants forgetting the left context partially. Clearly, a planned experiment is called for to investigate this further. An important point to note here is that the increased entropy in the long-distance condition may be a *consequence* of forgetting, not a cause in itself: entropy itself would not predict any increase in ungrammatical continuations, but the forgetting hypothesis does.

8.1.2. Does Predictability of an Upcoming Verb Increase with Distance?

We showed above that increasing uncertainty about the upcoming verb may explain locality, at least in Experiment 1. One important question that arises, especially in the strong predictability conditions, is the following: does increasing distance nevertheless sharpen the expectation for the verb, as suggested by Konieczny (2000)? In order to address this question, we fit a Bayesian generalized linear mixed model (GLMM) with a logistic link function that investigated the change in probability mass for the target verb as a function of distance in the strong predictability conditions.

For the first sentence completion study (which had the RC+PP intervener in the long condition), in the long-distance condition, the probability of producing the target verb fell: on the log-odds scale, the mean and 95% uncertainty interval were −0.305 [−0.8127, 0.1591] and the posterior probability of the reduction being less than 0 was 0.9. The odds ratio of producing a target verb in the long vs. short condition was 0.74, with 95% uncertainty interval [0.44,1.17]. This means that in the long condition, participants are less likely to produce the target verb, but since the uncertainty interval for the odds ratio includes 1, the reduction in probability of target verb production is possibly unchanged in the short vs. long distance conditions. If anything, there is a weakening of the expectation for the target verb, contrary to the sharpened expectation proposal of Konieczny (2000).

For the second sentence completion study (which had a PP in the long condition), in the long-distance condition, the probability of producing the target verb also fell: the logs odds were −0.17 [−0.5,0.12]; and the posterior probability of the reduction being less than 0 was 0.86. The odds ratio of producing a target verb in the long vs. short condition was 0.84, with 95% uncertainty intervals [0.61, 1.13]. Thus, in the second sentence completion study, there is only weak evidence of a reduction in probability of producing the target verb in the long-distance condition.

To summarize, our sentence completion data for Experiments 1 and 2's strong predictability condition show that increasing distance tends to reduce the proportion of target verbs produced, although the evidence for this reduction is rather weak overall. Our data from Persian therefore seem to go against the suggestion by Konieczny (2000) that increasing distance leads to narrowing down the prediction to the target verb.

Caution is needed in interpreting these results based on the sentence completion data. The biggest issue with the sentence completion data is that it was an offline task; it is difficult to argue that offline completion data can inform us about online processes. It would be much more informative to run an online sentence completion study, forcing participants to make quicker decisions about the sentence completions. Further, most of our

[7]The predictor (short vs. long condition) was coded using sum contrasts, with the long condition coded as 1 and the short condition as −1; the dependent variable was binary and represented whether a target verb was produced by the participant for a particular item-condition combination or not. Participants and items were specified as partially crossed random factors, and a full variance-covariance matrix was fit for both random effects. The priors for the intercept and slope were the Student's t-distribution with 2 degrees of freedom, allowing a range of approximately −10 to 10 on the log odds scale, with 0 the most likely value. The prior on the variance-covariance matrices was defined via the LKJ prior (Stan Development Team, 2013, 2014) on the correlation matrix; see Sorensen and Vasishth (2015) for a tutorial intended for psycholinguists and cognitive scientists. The model was fit using the `stan_lmer` function from the `rstanarm` package (Gabry and Goodrich, 2016).

findings relating to the sentence completion data are *post-hoc* and based on exploratory analyses. It would also be very informative to carry out sentence completion studies for experiments such as those of Konieczny (2000); Grodner and Gibson (2005); Vasishth and Lewis (2006); Bartek et al. (2011); Vasishth and Drenhaus (2011); Levy and Keller (2013) in order to establish whether increasing distance can weaken expectation cross-linguistically.

In future work it may be worth investigating existing locality effects in English, German, and Hindi from the perspective of forgetting inducing entropy. A further possibility worth investigating is whether entropy reduction (Hale, 2006) rather than entropy can explain the locality effects cross-linguistically. In our Persian experiments, it is possible that the entropy at the word preceding the verb is higher than the entropy at the verb, and it is possible that the reduction in entropy is larger in the long-distance condition. Unfortunately, we have no way to test this in the present design, but future studies could compute entropy reduction empirically in the same way that we computed entropy using sentence completion data. Thus, in principle it is possible that entropy reduction could explain locality effects as well. A related issue that would then arise is whether entropy or entropy reduction furnishes a better explanation for locality effects.

A broader issue that the above discussion raises is, can all intervention effects be explained via an appeal to information-theoretic metrics? Levy (2008) had pointed out that information-theoretic metrics cannot explain all the results relating to intervention effects; he was mainly referring to locality effects, which can only be explained through memory-based accounts. In later work, Vasishth and Drenhaus (2011); Levy and Keller (2013); Levy et al. (2013) also find that both memory and expectation-based accounts are needed to explain the range of observed effects. It is because of the inability of information-theoretic metrics to explain locality effects that Levy (2008) argued for "two-factor" accounts. If entropy or some other entropy-based measure turns out be an explanation for locality effects, can we argue for a simpler account that only appeals to information-theoretic metrics? A major empirical problem for such a reductionist account would be the large range and variety of intervention effects (see Engelmann et al., Manuscript submitted). for a review and computational modeling) that can only be explained through memory-based accounts. Other recent results that would be impossible to explain via a reductionist account are the work by Nicenboim et al. (2015) and Nicenboim et al. (2016). Thus, a reductionist account that assumes that *all* effects can be explained by what is predicted next would always falter when it comes to explaining effects that arise not from predictive processes but from retrieval-based processes.

9. CONCLUDING REMARKS

In conclusion, as regards the distance manipulation, the evidence from Persian is in favor of working-memory accounts, although forgetting-causing-entropy is also a candidate explanation. There is not much evidence from Persian that strong-predictability conditions cancel locality effects, as Husain and colleagues had suggested. Interestingly, there is no evidence in these experiments for the prediction of the expectation account regarding the distance manipulation, that increasing argument-verb distance facilitates processing due to increasing conditional probabilities of the upcoming verb. The suggestion in Levy et al. (2013) that "the verb-medial languages tend to exhibit the general patterns predicted by memory-based theories, whereas verb-final languages tend to exhibit the general patterns predicted by expectation-based theories" seems to be difficult to maintain (also see Husain et al., 2015, for locality effects in Hindi). One implication of our findings from Persian is that locality and expectation effects observed across studies seem to be highly conditional on the language and syntactic construction being considered—broad cross-linguistic generalizations may be difficult to make.

AUTHOR CONTRIBUTIONS

MS, SV, and SH designed the experiments; MS prepared the items, recruited participants, and conducted all the studies reported; SH conducted all the corpus analyses and extracted the statistics from the corpora; SV, MS, and SH analyzed the data and prepared the final document.

FUNDING

This work was supported by the IDEALAB program, and the University of Potsdam. We acknowledge the support of the Deutsche Forschungsgemeinschaft (German Research Foundation) and Open Access Publication Fund of Potsdam University.

ACKNOWLEDGMENTS

Thanks to Prof. Dr. Shahla Raghibdoust in Allameh Tabataba'i University who helped the first author to recruit the participants in Iran. We are grateful to Carla Kessler in University of Potsdam for her help in designing the eye-tracking study using Experiment-Builder software. Many thanks to Lena Jäger who carried out a careful sanity check for the eye-tracking results. We would like to thank the anonymous reviewers of this article, and the audience in the 28th CUNY conference of human sentence processing in University of Southern California for their insightful feedback.

Poor readers' retrieval mechanism: efficient access is not dependent on reading skill

Clinton L. Johns[1]*, *Kazunaga Matsuki*[1,2] and *Julie A. Van Dyke*[1]

[1] Haskins Laboratories, New Haven, CT, USA, [2] Department of Linguistics and Language, McMaster University, Hamilton, ON, Canada

A substantial body of evidence points to a cue-based direct-access retrieval mechanism as a crucial component of skilled adult reading. We report two experiments aimed at examining whether poor readers are able to make use of the same retrieval mechanism. This is significant in light of findings that poor readers have difficulty retrieving linguistic information (e.g., Perfetti, 1985). Our experiments are based on a previous demonstration of direct-access retrieval in language processing, presented in McElree et al. (2003). Experiment 1 replicates the original result using an auditory implementation of the Speed-Accuracy Tradeoff (SAT) method. This finding represents a significant methodological advance, as it opens up the possibility of exploring retrieval speeds in non-reading populations. Experiment 2 provides evidence that poor readers do use a direct-access retrieval mechanism during listening comprehension, despite overall poorer accuracy and slower retrieval speeds relative to skilled readers. The findings are discussed with respect to hypotheses about the source of poor reading comprehension.

INTRODUCTION

The ability to comprehend written language is an enormously important skill, as shown by robust correlations between poor reading comprehension and a variety of undesirable consequences, including constrained economic mobility, reduced economic success, and increased risk of poor health outcomes (Kutner et al., 2007; National Institute for Literacy, 2008). Many models of text processing (e.g., Kintsch, 1988, 1998; Myers and O'Brien, 1998; van den Broek et al., 1999; for reviews see Long et al., 2006; McNamara and Magliano, 2009), sentence processing (Gibson, 2000; Van Dyke and Lewis, 2003; for review see Van Gompel, 2013), and reading disability (e.g., Hogaboam and Perfetti, 1975; Shankweiler and Crain, 1986) incorporate the idea that comprehension is constrained by the architecture of the human memory system. Given this, it is important to understand the interaction between memory mechanisms—such as retrieval—and the sentence parsing processes on which successful comprehension depends. Previous research has shown that university students employ a content-addressable, direct-access mechanism to efficiently retrieve information from memory during reading (e.g., McElree and Dosher, 1989; McElree, 2001; McElree et al., 2003; for reviews see McElree and Dyer, 2013; McElree, 2015). In this article, we assess the potential relation between reading skill and memory retrieval. We report two speed-accuracy tradeoff (SAT) experiments that (1) validate an auditory implementation of the technique for the assessment of the dynamics of memory retrieval, and (2) investigate whether

poor readers, like skilled readers, are able to employ a content-addressable direct-access retrieval mechanism during online auditory sentence comprehension. Our goal is to determine whether poor comprehenders possess the architectural primitives that are known to support skilled reading comprehension.

Models of sentence parsing typically offer richly detailed accounts of the linguistic processes that drive parsing operations. Examples of such operations include heuristic routines (e.g., minimal attachment, late closure, main assertion preference, active filler strategy); serial (or parallel) control structures, which may or may not activate (or inhibit) competing interpretations; ranked vs. unranked consideration of extra-syntactic (e.g., semantic, referential, pragmatic, visual) information; and so on. When these processes go awry, errors are often either explicitly or implicitly associated with increased demands on the memory system, which are assumed to yield suboptimal application of these parameters. To illustrate, consider sentences (1) and (2), from a study by Frazier and Rayner (1982):

(1) While Susan was dressing the baby played on the floor.
(2) Since Jay always jogs a mile seems like a short distance to him.

Sentences such as (1) and (2) are thought to tax the memory system because an accurate parse, and consequent comprehension, is only possible by violating initial syntactic commitments (licensed by minimal attachment in (1) and late closure in (2); Frazier, 1979, 1987; for review, see Frazier, 2013). In such cases the parser must construct, assess, abandon, and reconstruct entire syntactic structures, and reassessment is assumed to involve costly search and diagnosis processes (e.g., Fodor and Inoue, 1994, 1998, 2000). Or, alternatively, it could be the case that the parser constructs and actively maintains multiple syntactic structures during online processing, the extra burden of which leads to processing difficulty (e.g., MacDonald et al., 1994). Furthermore, it is not just parsing errors that tax the memory system during language processing; complexity effects, in which more complex syntactic structures are claimed to be more memory-intensive, have been widely studied. A classic example is the difference in processing elicited by unambiguous sentences such as (3), which contains an object-extracted relative clause, and (4), in which the embedded subject-extracted relative clause results in a simpler syntactic structure (from King and Just, 1991):

(3) The banker that the barber praised climbed the mountain.
(4) The banker that praised the barber climbed the mountain.

In (3), it is thought that the initial filler noun phrase (*the banker*) must be actively maintained during the processing of the embedded clause, after which it may be integrated with the matrix verb *climbed* (e.g., via an active filler strategy; Clifton and Frazier, 1989); in contrast, (4) elicits no such active maintenance, and consequently is less demanding of the memory system.

These examples highlight the fact that the centrality of memory operations during parsing is both widely acknowledged and uncontroversial. In spite of this, theories of parsing (and text processing) are frequently vague regarding the memory mechanisms that support their finely-specified linguistic operations. Further, when a memory component has been elaborated, the focus has been almost entirely on the *storage* component, which is conceptualized as a limited-capacity working memory (WM) system (e.g., Just and Carpenter, 1992; Caplan and Waters, 1999; see also Daneman and Carpenter, 1980). In this system, the dynamic allocation of resources between language and memory operations must support incremental parsing operations, maintenance of critical sentential information, and retrieval of information from both WM and long-term memory (LTM). A fundamental tenet of this approach is that information required for interpretation must be maintained in an active, highly accessible state, and when this is difficult—perhaps owing to low capacity, or to increased computational costs, or both—processing suffers. There is no shortage of research whose findings have been interpreted as evidence for a capacity-based memory architecture (e.g., King and Just, 1991; Fedorenko et al., 2006; Nieuwland and Van Berkum, 2006, among many others). Implicit in these approaches is the idea that stored information is accessed via a serial search process (Just and Carpenter, 1992; Gibson, 1998, 2000): thus, the greater the amount of linguistic material intervening between dependent constituents (which must, therefore, be searched), the more difficult a given construction will be.

Despite the abundance of psycholinguistic studies that adopt this conception of memory, there is substantial disagreement about the nature of the unit of "active maintenance" that defines these search processes. Various proposals have characterized it as words (Warner and Glass, 1987), discourse referents (Gibson, 2000), incomplete grammatical dependencies (Abney and Johnson, 1991; Gibson, 1998), syntactic embeddings (Miller and Chomsky, 1963), or representations of entire alternative syntactic structures (Just and Carpenter, 1992; MacDonald et al., 1992). The fact that consensus has been elusive indicates the weakness of this approach. In addition, significant practical concerns exist, such as poor test-retest reliability of metrics designed to gauge WM capacity (Waters and Caplan, 2003), and collinearity with many other cognitive measures (e.g., Van Dyke et al., 2014). Further, the approach has also been questioned on theoretical grounds; for example, innate capacity differences that limit comprehension ability could emerge naturally from individual linguistic experience rather than from a separable memory system (e.g., MacDonald and Christiansen, 2002).

However, the most fundamental objection to assuming that a search-based limited-capacity memory mechanism supports language comprehension derives not from the need to reconcile these kinds of inconsistencies, but from the disparity between the proposed WM architecture and the empirical evidence regarding the memory structures and operations themselves. For example, there is substantial evidence that the amount of information that can be maintained in an active, accessible state is far more constrained than has been assumed by any parsing architecture supported by a fixed-capacity WM system. Memory studies using the SAT method report that only a

single item (i.e., the last item processed) is actively maintained, meaning that only this item would not require retrieval (McElree, 1998, 2001, 2006; McElree and Dosher, 2001)[1]. All other items—that is, items that should be both *within* as well as *outside of* a traditional WM span—are accessed 30–50% more slowly than the active item (Wickelgren et al., 1980; McElree, 1996, 1998). Results such as these clearly indicate that the capacity of active memory is limited to information that is currently in the focus of attention, while information that is outside focal attention is passively represented. Moreover, items that are outside of focal attention are accessed with constant speed, regardless of how recently they occurred in relation to the retrieval probe. This pattern is consistent with the operation of a cue-based, direct-access retrieval mechanism in which all available cues are matched simultaneously, with the degree of featural overlap between the target and the available retrieval cues determining retrieval success (for a review see Clark and Gronlund, 1996). While language processing with such a severely constrained active memory capacity may seem implausible, the feasibility of a processing architecture in which only the most recent item remains in focal attention has been demonstrated in an implemented computational model (Lewis and Vasishth, 2005; Lewis et al., 2006). Within this architecture, it is the direct-access mechanism that provides the computational power to compensate for the severely constrained memory capacity. Indeed, there are now a number of studies, across a broad range of sentence constructions, that provide evidence for direct access in language processing (e.g., McElree, 2000; McElree et al., 2003; Martin and McElree, 2008, 2009, 2011; Van Dyke and McElree, 2011; for reviews see McElree, 2006, 2015).

The paradigmatic evidence for direct-access retrieval in sentence processing was provided by McElree et al. (2003), who asked university students to read sentences containing grammatical dependencies in which the distance between the grammatical head (e.g., *book*) and its dependent (e.g., *ripped*) was manipulated:

(5) The *book ripped*.
(6) The *book* that the editor admired *ripped*.
(7) The *book* that the editor who quit the journal admired *ripped*.

McElree and colleagues found that as the amount of material interpolated between the matrix verb and the sentential subject increased, the probability of accurate retrieval decreased: participants responded very accurately in (5), less accurately in (6), and still less accurately in (7). If "book" were accessed via a serial search mechanism, similar systematic differences should also have been observed in indices of retrieval speed; that is, a serial search mechanism also predicts that participants should be fastest to access *book* in (5), slower to access *book* in (6), and slower still in (7). Instead, McElree and colleagues found that participants resolved the *book-ripped* dependency very quickly in sentences such as (5), and with a slower—but constant—speed in (6) and (7)[2]. Thus, although the memory representations did vary in their availability (perhaps because of decay, or reduced distinctiveness as the number of NPs increased, or both), participants used the cues provided by the verb (e.g., selectional information) to guide direct retrieval of the appropriate NP from memory. Crucially, these results are not compatible with a serial search-based retrieval mechanism, which predicts that items that vary in their availability should not be accessed with equal speed. Hence, this study clearly shows that the collegiate readers were not engaging in a serial, backwards search through information that is no longer active in memory.

In light of this evidence, it seems plausible to suggest that content-addressable, direct-access retrieval is a fundamental property of the human language faculty, and that a cue-based retrieval parser (e.g., Van Dyke and Lewis, 2003; see also Lewis and Vasishth, 2005; Lewis et al., 2006) is the "default" processor for linguistic input. However, there are two potential objections to this proposal. First, all of the studies attesting to this type of retrieval during language processing have employed visually presented stimuli. That is, these studies only provide evidence that a cue-based retrieval parser is active during *reading*; it remains possible that processing *spoken* language initiates qualitatively different memory operations than those observed in reading tasks. The presence of orthographic information could enhance encoding and access during reading in ways that would necessarily be absent during listening comprehension (e.g., Harm and Seidenberg, 2004)—a potential confound that is amplified by extensive evidence that deficient orthographic decoding plays a role in reading difficulty (Shankweiler and Crain, 1986; Bell and Perfetti, 1994; Long et al., 2006). Second, these studies have uniformly tapped university subject pools for their participants, with the result that evidence for the cue-based retrieval parser comes entirely from relatively skilled readers. This raises the possibility that cue-based, direct-access retrieval develops concomitantly with reading skill; that is, more reading or language experience may "tune" the parser to make it more efficient, while less skilled readers may employ less efficient (e.g., search-based) memory operations during language comprehension. Such an account is consistent with some models of WM that suggest that efficient retrieval is predicated on efficient access structures that are derived from acquisition of skill proficiency (e.g., Ericsson and Kintsch, 1995).

[1]There are two known circumstances, both task-specific, in which multiple items may be in focal attention: the task must either promote the "chunking" of information (McElree, 1998), or encourage participants to actively maintain distant information (McElree, 2001, 2006). The connection between these findings and language operations has not been systematically explored. The only attempt of which we are aware is unpublished data suggesting that some phrase types (PP, adverbial) do not displace information in focal attention (Wagers and McElree, 2009; discussed in McElree, 2015). However, as these structures are not examined in our experiments, we adopt the formulation that is most consistent with findings from published language research: that a single word—the most recently processed item—is maintained in focal attention.

[2]McElree et al. (2003) also included a condition containing two embedded object-relative clauses, of comparable length to items such as (7), which also contain two embedded clauses (a subject-relative and an object-relative). The double-object condition yielded both significantly lower response accuracy and a significantly slower rate of retrieval than all other conditions. McElree and colleagues discussed these findings at length, noting that the data pattern remains inconsistent with a search-based explanation; we refer interested readers to McElree et al. (pp. 81–82).

EXPERIMENT 1

Our first experiment examines memory retrieval during auditory language comprehension. This is crucial for assessing whether both auditory and written language processing use direct-access retrieval, as well as for studying retrieval mechanisms in poor readers, whose poor orthography-to-phonology decoding represents an important confound for any study implemented in the visual modality. We created an auditory implementation of the SAT procedure, in which participants listened to, and responded to, a series of sentences that either were or were not grammatically acceptable.

The SAT procedure provides an unambiguous estimate of access speed, which is required to differentiate direct-access retrieval from serial search processes. This contrasts with more commonly used timing measures, such as reaction and reading times, which are not "process pure": in these paradigms, slower RTs may occur as a result of either actual speed differences, differences in the relative likelihood that information will be successfully recovered from memory, or both. In addition, these measures are vulnerable to idiosyncratic response criteria—that is, participants can adopt liberal or conservative response patterns, emphasizing accuracy at the expense of speed, or speed at the expense of accuracy (see McKoon and Ratcliff, 1992; McElree, 1993; Ratcliff and McKoon, 2008). In contrast, the SAT procedure permits the assessment of both by computing response functions that model the entire time course of information accrual (Wickelgren, 1977). The SAT procedure's fine-grained assessment of retrieval dynamics forms the basis for all unambiguous evidence that a fast, content-addressable, direct-access retrieval mechanism with a single-item focal span supports typical online language comprehension processes (e.g., McElree and Griffith, 1995, 1998; McElree, 2000; McElree et al., 2003; Foraker and McElree, 2007; Martin and McElree, 2008, 2009, 2011; Van Dyke and McElree, 2011; for reviews see Foraker and McElree, 2011; McElree, 2015).

Our goal in Experiment 1 was to validate our auditory implementation of the SAT technique by replicating Experiment 2 of McElree et al. (2003) with a comparable population (university students) using auditory versions of the stimuli from that study. Consistent with that study, we predicted that access would be fastest when the critical item was still active in the focus of attention (i.e., the most recently processed word). If the speed of access in the longer conditions, in which retrieval is necessary, is invariant, this supports an account of listening comprehension in which direct-access retrieval is used. However, if retrieval speed in the longer conditions varies systematically according to the distance between the retrieval cue and its target, this would support a search-based retrieval mechanism.

Method

Participants

Informed consent was obtained from five undergraduates at Yale University. The participants were right-handed native English speakers, and were paid for their participation ($20/h). Each participated in one 1-h SAT training session, followed by two 3-h experimental sessions; these sessions were comprised of two 1-h SAT sessions (for a total of four), separated by a 1-h period in which they completed additional cognitive assessments (for a separate study) and rested. Details about the training and experimental sessions are described below.

Materials

Materials were adapted from those used in Experiment 2 of McElree et al. (2003). These constructions permit assessment of the speed and accuracy with which a matrix intransitive verb (e.g., *ripped, laughed*) retrieves its grammatical subject noun (e.g., *book*); examples appear in **Table 1**. Because we planned to test a population with a wide range of comprehension ability in our second experiment, our materials did not include all of the conditions presented in McElree et al. We selected a subset of conditions that linearly increased the surface distance, and the corresponding time, between each sentence's subject NP and matrix verb. For each item, participants were required to determine whether the subject-verb relation was either acceptable or unacceptable (see Procedure and Data Analysis, below). The conditions in both this and the next experiment are:

No Interpolation (T1 and T2): in the shortest conditions, the subject and verb are directly adjacent to each other (no retrieval needed).

Interpolated Object Relative Clause (T3 and T4): distance between subject NP and verb is increased by four words. T3 and T4 are identical to T1 and T2 with the exception of the additional embedded clause.

Interpolated Object and Subject Relative Clauses (T6 and T7): in the longest conditions, the subject and verb are separated by eight words. T6 and T7 are identical to T3 and T4 with the exception of the additional embedded subject relative clause.

Additional processing encouragement (T5 and T8): as in McElree et al. (2003), we included a second type of unacceptable item in each of the longer conditions. These items, exemplified by T5 and T8, are identical to the other items in their corresponding conditions with one exception. In these items, the grammatical inconsistency that determined acceptability was located in the interpolated information. For example, as shown in **Table 1**, although the embedded transitive verb requires a direct object,

TABLE 1 | Constructions used in Experiments 1 and 2 (adapted from McElree et al., 2003).

Construction	Acceptability	Example
No Interpolation	Acceptable	T1. The book ripped.
No Interpolation	Unacceptable	T2. The book laughed.
Object relative	Acceptable	T3. The book that the editor admired ripped.
Object relative	Unacceptable	T4. The book that the editor admired laughed.
Object relative	Unacceptable	T5. The book that the editor amused ripped.
Object relative + subject relative	Acceptable	T6. The book that the editor who quit the journal admired ripped.
Object relative + subject relative	Unacceptable	T7. The book that the editor who quit the journal admired laughed.
Object relative + subject relative	Unacceptable	T8. The book that the editor who quit the journal amused ripped.

book is not an acceptable argument for *amused*. These types of sentences were included to encourage our participants to attend to (and process) the interpolated material.

We selected 48 instances of each of the eight types of sentence (T1–T8, i.e., three acceptable and five unacceptable) from the original materials used in McElree et al. (2003). This yielded a total of 384 experimental items, which we edited slightly in order to make the vocabulary level more appropriate to the participants in our second experiment. From this set of items, we generated four experimental lists of 96 sentences. Each list was comprised of 12 instances of each sentence type. Participants listened to one list during each of the four SAT sessions.

Procedure

All stimuli were randomized within each testing session and presented using the E-Prime experimental package (Schneider et al., 2002). Unlike the original study in which a single-response Speed Accuracy Tradeoff (SR-SAT) paradigm was used, we adopted the multiple-response Speed-Accuracy Tradeoff (MR-SAT) method (Wickelgren et al., 1980; McElree, 1993; see also Bornkessel et al., 2004; Foraker and McElree, 2007; Van Dyke and McElree, 2011). Because more responses are collected per trial, MR-SAT paradigms require fewer items, and consequently fewer experimental sessions to complete an experiment. Each trial began with the words "Listen carefully," which appeared in the center of the screen throughout the trial. The initial appearance of these words was accompanied by an auditory fixation cue (a tone). This cue alerted participants to the imminent auditory presentation of a sentence, which began 500 ms after the offset of the cue. All sentences were prepared using version 2.0.3 of Audacity® recording and editing software (Audacity Team, 2015; http://audacity.sourceforge.net). The sentences were presented at a natural speaking rate (in contrast to previous visual SAT studies, in which sentences were segmented word-by-word or phrase-by-phrase). A sequence of 15 tones (100 ms, 1000 Hz, every 350 ms) was spliced into the sentence recording, beginning 200 ms prior to the onset of the sentence-final critical word. The tones were presented simultaneously with and following the critical word, forming a 5000 ms response period. Participants were instructed to judge whether each sentence was an acceptable English sentence. They were trained to press the response key(s) corresponding to their acceptability judgment in time with the tone sequence. At the onset of the tones, participants began responding by pressing both response buttons, indicating that they did not yet know whether or not the sentence was acceptable. After hearing the sentence-final word, participants indicated whether the sentence was acceptable or unacceptable by choosing either the YES or NO response key, and continuing to press only that button in time with the tones.

During the training session, participants first heard and responded to response tones in isolation, in order to become familiar with the auditory and motor aspects of the SAT procedure; they subsequently heard and responded to practice items similar to those in the experiment. In addition to the initial training, participants also completed a 15-min refresher session at the beginning of the second experimental session in order to refamiliarize themselves with the task. Participants received feedback about their responses in both training sessions, indicating whether their responses were faster or slower than, or out of sync with, the rhythm of the response tones. In addition, they were taught that they could change their response; for example, if at first they decided that a sentence was acceptable (and consequently stopped pressing the NO response key while continuing to press the YES response key), but subsequently changed their mind and deemed it unacceptable, they could switch their response (i.e., stop pressing YES, and resume pressing NO). Participants were taught that they could change their response at any time—and multiple times, if necessary—during the 5000 ms response period.

Data Analysis

SAT data provide indices of both accuracy and speed associated with responses. In studies using the SAT method, a stable SAT function can be calculated for each participant and, as a consequence, each participant is analyzed separately. This approach has two advantages: it reduces the variance associated with each participant's data, and it minimizes distortion associated with averaging across participants. Consistent patterns that emerge across participants are subsequently considered through analyzing both modeling consistency across individuals and modeling of the averaged data.

Accuracy was computed for each time point in the response period using a standard measure of sensitivity (d'). Potential response bias was controlled by calculating d' using z-scores for hits and false alarms [$d' = z(\text{hits}) - z(\text{false alarms})$]. In this experiment, a "hit" is a YES response to an acceptable sentence, and a "false alarm" is a YES response to an unacceptable sentence.

The asymptote, rate, and intercept for each response function were assessed by fitting the d' accuracy scores at each response point (t), with an exponential approach to a limit:

$$d'(t) = \lambda(1 - e^{-\beta(t-\delta)}) \text{ for } t > \delta, \text{ else } 0$$

Thus, d' is the result of the interaction of the two factors that define an SAT function: the asymptote of the function (λ), and the speed with which that asymptote is reached. Speed is jointly determined by two distinct parameters: the intercept of the function (δ), which is the point at which response accuracy rises above chance, and the rate at which response accuracy reaches asymptotic performance (β). Calculated d' scores are then fit to hierarchically nested models ranging from a null model, in which the experimental conditions are fit using a single asymptote, rate, and intercept, to a fully saturated model, in which the conditions are each fit with a unique set of parameters. For data modeling, we used functions from the package *mrsat* (Matsuki et al., in preparation)[3]. The fitting function applied four different optimization algorithms that are implemented in R functions: (1) an iterative hill-climbing algorithm (Reed, 1976) similar to STEPIT (Chandler, 1969), which has been used in the majority of previous SAT studies of language processing and is implemented

[3] Available from GitHub (https://github.com/). Contact matsukk@mcmaster.ca for details.

in the *acp* function; (2) a limited-memory Broyden–Fletcher–Goldfarb–Shanno algorithm with box constraints (Byrd et al., 1995) implemented as a part of the *optim* function; (3) a box-constrained optimization algorithm based on PORT routines developed by Bell Labs (Fox et al., 1978) as implemented in the *nlminb* function; (4) an unconstrained optimization algorithm based on a Newton-type method implemented in the *nlm* function (Dennis and Schnabel, 1983; Schnabel et al., 1985). Each of these algorithms were applied 10 times with randomly chosen starting parameter values on each run, and the resulting set of parameters that provided the best model fits were selected. Fit quality was assessed in two ways. First, we calculated a modified R^2 statistic, in which the number of parameters present in each model is used to adjust the proportion of variance accounted for by each model (Judd and McClelland, 1989). Second, we evaluated the consistency of the parameter estimates across participants.

All SAT response function and statistical analyses were carried out with the R statistical software, version 3.2.1 (R Core Team, 2015). For analyses, we used the package *lme4* (Bates et al., 2015). We used linear mixed-effect regression (*LMER*; Baayen, 2004, 2008; Baayen et al., 2008) to assess the observed empirical data and the fitted parameter estimates for each of the candidate models described in the Results Section. Mixed-effects models included fixed effects of Construction and random intercepts for participants. For evaluation of the main effect of Construction, we report the associated *F*-value, as well as the denominator degrees of freedom and *p*-values that were calculated based on Satterthwaite's approximation using the *lmerTest* package (Kuznetsova et al., 2015). We also report the *t*-values associated with our analyses, adopting the convention whereby any effect whose absolute *t*-value exceeds 2 is considered significant (Gelman and Hill, 2007).

Results

Figure 1 shows the averaged d' data at each response point, as well as smoothed curves depicting the best fitting model (3λ-1β-2δ; see below) as a function of processing time for the three Construction conditions (No Interpolated Material, Interpolated Object Relative, Interpolated Object + Subject Relative). As in McElree et al. (2003), visual inspection of the data suggests that asymptotic accuracy is negatively correlated with the amount of material interpolated between the matrix verb and its subject. This observation is supported by the LMER analysis of the mean of the last four d' values, which is the empirical estimate of asymptotic accuracy. This confirmed a main effect of Construction, $F_{(2,\ 8)} = 40.17$, $p < 0.001$. Pairwise comparisons showed that accuracy was higher when there was no material between subject and verb ($d' = 3.58$) than when there was an intervening object relative clause ($d' = 2.55$), $t = -4.33$, or when there were intervening subject and object relative clauses ($d' = 1.45$), $t = -8.96$. In addition, the asymptotic accuracy of the Interpolated Object Relative condition was significantly higher than that of the Interpolated Object + Subject Relative condition, $t = -4.63$. This pattern of results replicates the pattern reported in McElree et al. (2003) for these conditions.

Initial hierarchical modeling of the data assessed three models, differing only by the number of asymptote parameters assigned to the models. First, we assessed the null model, in which a common asymptote (λ), rate (β), and intercept (δ) was assigned to each condition. The 1λ-1β-1δ model fit produced an adjusted R^2 for the averaged data of 0.585, ranging from 0.292 to 0.782

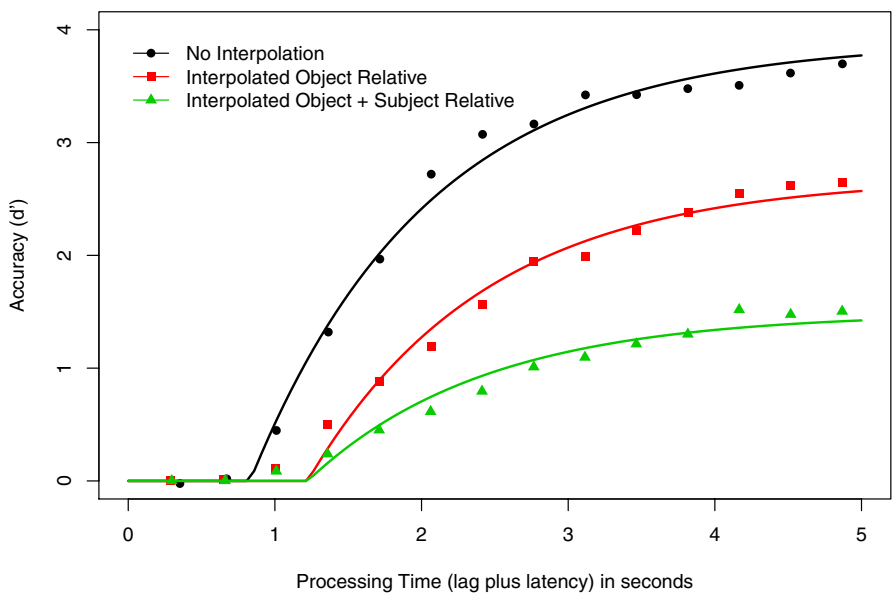

FIGURE 1 | Speed-accuracy tradeoff results for Experiment 1. Average d' accuracy as a function of processing time (in seconds) for the grammaticality judgments of sentences with the following constructions: no embedded material (circles), one object-relative clause (squares), and one object- and one subject-relative clause (triangles). Smooth curves show the 3λ-1β-2δ exponential model (see text of Experiment 1).

across all participants. We next fit a 2λ-1β-1δ model to the data, in which one asymptote was assigned to the No Interpolation condition, and a second was assigned to the conditions with material intervening between the subject and the verb. This model fitting produced an adjusted R^2 for the averaged data of 0.903, ranging from 0.823 to 0.945 across all participants. All participants showed an increase in adjusted R^2 compared with the null model (average adjusted R^2 increase = 0.337; minimum = 0.164; maximum = 0.641). The third fitting assigned a unique asymptote parameter to each Construction condition, a 3λ-1β-1δ model; this produced an adjusted R^2 for the averaged data of 0.980, ranging from 0.955 to 0.993. The addition of an asymptote parameter again showed an increase in adjusted R^2: compared to the 2λ-1β-1δ model, the average adjusted R^2 increase was 0.074 (minimum = 0.029; maximum = 0.153); further, the average adjusted R^2 increase was 0.411 (minimum = 0.192; maximum = 0.700) when this model was compared to the 1λ-1β-1δ model. The λ estimates (in d' units) for the averaged 3λ-1β-1δ model were 4.06 for the No Interpolation condition, 2.58 for the Interpolated Object Relative condition, and 1.43 for the Interpolated Object + Subject Relative condition. An LMER analysis of the λ estimates showed a significant effect of Construction, $F_{(2, 8)} = 104.74$, $p < 0.001$. Pairwise comparisons closely tracked the pattern of the analysis of the empirical d' data above. Specifically, the λ estimates for the No Interpolation condition were higher than both the Interpolated Object Relative ($t = -8.16$) and Interpolated Object + Subject Relative conditions ($t = -14.43$), and the Interpolated Object Relative condition λ estimate was greater than the Interpolated Object + Subject Relative estimate ($t = -6.27$). This finding—that a model with three asymptote parameters better fits the data than do models with two or one asymptote—is consistent with our analysis of the empirical d' data. Thus, subsequent analyses focus on models with three asymptotes.

We next evaluated the effect of Construction on processing speed. Unlike the original study (McElree et al., 2003), the data do not suggest that these analyses should exclude speed differences in either the intercept or the rate; hence, we tested for differences manifesting in the intercept (δ); rate (β); and in both parameters together. We began by fitting a 3λ-1β-2δ model to the data, with potential speed differences assigned to the intercept. As in the asymptote comparisons, one parameter was assigned to the No Interpolation condition, and the second was assigned to the conditions with intervening material. This model produced an adjusted R^2 for the average data of 0.992, ranging from 0.983 to 0.994 for individuals. All participants showed an increase in the adjusted R^2 for the 3λ-1β-2δ over the 3λ-1β-1δ model (average increase = 0.014; minimum = 0.001, maximum = 0.028). We subsequently fit a 3λ-1β-3δ model to the data, but the addition of a third intercept parameter was not warranted: no participants showed an improved adjusted R^2 for this model relative to the 3λ-1β-2δ model (adjusted $R^2 = 0.992$; average increase = −0.002, minimum = −0.003, maximum = −0.001). Parameter estimates for the 3λ-1β-2δ are shown in **Table 2**.

We next evaluated potential speed differences that could result from the rate parameter, and fit a 3λ-2β-1δ model to the data. This model produced an adjusted R^2 of 0.996 for the average data, ranging from 0.990 to 0.993 for individuals; however, data from two participants could not be fit to this model without overestimating the asymptote parameters. For those participants that were successfully fit with this model, the addition of a second rate parameter yielded an improved model fit over the 3λ-1β-1δ model (average adjusted R^2 increase = 0.018; minimum = 0.001; maximum = 0.038). In addition, the 3λ-2β-1δ model fit the data better than the 3λ-1β-2δ model for two of these participants (average adjusted R^2 increase = 0.008; minimum = 0.005; maximum = 0.010). A subsequent fit using a 3λ-3β-1δ model, excluding both participants without 3λ-2β-1δ model parameter estimates, showed that a third rate parameter was not warranted by the data (adjusted $R^2 = 0.996$; average adjusted R^2 increase = 0).

Finally, we considered a 3λ-2β-2δ model, in which speed differences could arise from both rate and intercept; one participant's data could not be modeled, again due to overestimated asymptotes, and was not included. Although this model (adjusted $R^2 = 0.997$) did result in improved adjusted R^2 for the average data relative to the model with two intercept parameters (3λ-1β-2δ; average adjusted R^2 increase = 0.003; minimum = −0.001; maximum = 0.010), there was no adjusted R^2 difference between this model and the 3λ-2β-1δ model (average adjusted R^2 increase = 0; minimum = 0; maximum = 0.002).

LMER analyses of the parameter estimates for the models with two (3λ-2β-1δ, 3λ-2β-2δ; all ts < 1.7) and three [3λ-3β-1δ; $F_{(2, 6)} = 2.41$, $p = 0.171$] rate parameters were non-significant, possibly due to the small number of participants. However, the

LMER analyses of the model with three intercept parameters (3λ-1β-3δ) revealed a significant main effect of Construction, $F_{(2,\ 8)} = 6.31$, $p = 0.023$). *T*-tests indicated that the No Interpolation condition was significantly different than both the Interpolated Object Relative condition ($t = 2.84$) and the Interpolated Object + Subject Relative condition ($t = 3.27$), but the two long conditions were not statistically different ($t < 1$). In addition, the LMER test of the 3λ-1β-2δ model confirmed that the two intercept parameters differed significantly ($t = 2.576$). These analyses are all consistent with the modeling conclusions that adding a third rate or intercept parameter is not warranted. Overall, these analyses indicate that the best model for both individual and average data is the 3λ-1β-2δ model: all participants were fit by this model, and alternative models did not yield consistent improvement. However, because our conclusions do not depend on whether the second speed parameter manifests on either the rate or the intercept, we present the parameter values for both models (see **Tables 2, 3**). The key conclusion is that there is no evidence to support the inclusion of a third speed parameter (either rate or intercept) for any participant or for the average data.

Discussion

Consistent with previous research (e.g., McElree, 2000; McElree et al., 2003), we observed a negative correlation between response accuracy and the amount of material interpolated between the sentences' matrix verbs and the subject nouns. The significant differences in the empirical d' data and in the model asymptotes confirm that as the distance between the subject and verb increases, the probability of accurately resolving the long-distance dependency decreases. Such asymptotic decreases are attributable to either an overall decrease in the quality of the memory representation over time, or to a decrease in the diagnostic distinctiveness of the retrieval cue (i.e., the featural characteristics of the verb) relative to the to-be-retrieved information (see Van Dyke and Johns, 2012). In addition, SAT response functions were best fit by a model in which there were two speed parameters, one reflecting fast access when no retrieval was necessary (i.e., the condition in which no material intervened between a verb and its grammatical head noun, leaving the most recently processed item active), and a second reflecting slower access when the critical item was not in focal attention and required retrieval. Critically, there was no benefit to including a third speed parameter (either on the rate or intercept), which would have supported a search-based retrieval mechanism: verbs retrieved their subjects with the same speed regardless of interpolated material. This pattern of asymptotic and dynamic differences is the characteristic signature of direct-access retrieval, and is apparent in the individual participants' data (see **Table 2**)[4].

In addition, our participants' performance on conditions with grammatical anomalies in an embedded clause (conditions T5 and T8) suggests that they were not simply focusing on the initial noun and final verb in order to make their grammaticality judgments. Averaged correct rejection rates for these conditions for each of the response lags were 49.8, 50.4, 51.3, 54.9, 61.7, 64.3, 70.8, 75.0, 76.3, 78.4, 80.3, 82.3, 83.2, and 84.3%. Correct rejection rates for the corresponding experimental conditions (T4 and T7), in which the ungrammaticality derived from the sentence-final verb, were 49.6, 49.9, 50.7, 54.7, 63.1, 69.2, 75.6, 80.3, 81.9, 83.6, 84.1, 85.6, 85.2, 84.7%. As in McElree and colleagues' original study (McElree et al., 2003), accuracy was higher in the experimental conditions than in the conditions designed to discourage strategic processing. However, unlike the original study, correct rejection rates were not asymptotic at early lags in conditions T5 and T8; rather, the pattern of correct rejections seems to reflect an exponential response function. This difference could arise from any of the ways our study differs from the original, including our use of the multiple-response variant of the SAT technique, our use of auditory presentation of the sentences, or some combination of the two. For example: perhaps the relatively faster presentation of the sentences in an auditory (relative to the previously used visual) modality prevented early decision making. Alternatively, perhaps the need to process (at each response tone) an acceptable verb in light of an earlier anomaly, reduced participants' confidence in rejecting the sentence and/or prolonged repair routines aimed at finding a correct interpretation. However, such explanations are speculative, and ultimately are unrelated to the main issues addressed here. The value of these correct rejection rates is their clear demonstration that our participants processed the interpolated material, rather than simply ignoring it.

[4]One participant, S2, shows speed dynamics contrary to the predicted direction. This is also true of one participant in Experiment 2 (S9). We believe this to be an artifact of the fitting function: modeling the dynamic portion of the SAT function can be difficult if d' scores are very low (McElree, personal communication). However, because these participants' asymptotic accuracy is consistent with both the other participants and the pattern observed in the original study (McElree et al., 2003), and out of consideration for the sample sizes in both experiments, we ultimately elected to include these data in our analyses. If these participants are excluded, our results do not change—and indeed become stronger in the predicted direction.

The results of this experiment replicate McElree and colleagues' demonstration of direct-access retrieval (McElree et al., 2003). These results are significant for three reasons. First, our MR-SAT replication of the original SR-SAT study continues a tradition of validating important findings about the operation of the human memory system across SAT techniques (e.g., McElree and Dosher's SR-SAT replication of Wickelgren and colleagues' MR-SAT findings regarding the focus of attention; Wickelgren et al., 1980; McElree and Dosher, 1989). Second, these results constitute the first evidence that, as in reading comprehension, collegiate comprehenders employ a content-addressable, direct-access retrieval mechanism during listening comprehension. Finally, unlike previous research, this interpretation is not susceptible to any confound related to orthographic processing. Thus, these results suggest that direct-access retrieval is a modality independent cognitive operation. Additionally, they validate the auditory MR-SAT procedure as an appropriate tool for investigating the retrieval mechanism in individual participants regardless of reading skill.

EXPERIMENT 2

The results of our first experiment, in tandem with previous studies, suggest that direct-access retrieval may be the "default" setting during language comprehension, as it has now been observed both during reading and listening comprehension. Experiment 2 assessed the potential for direct-access retrieval in poor readers. Motivation for this work comes from studies indicating that capacity-based explanations are unlikely to account for poor reading comprehension (e.g., Traxler et al., 2012; Van Dyke et al., 2014; for review see Van Dyke and Johns, 2012). Rather, they point to limited capacity parsing architectures that rely on a fast, direct-access retrieval mechanism to restore information into the focus of attention as needed (e.g., Lewis and Vasishth, 2005; Lewis et al., 2006). However, studies establishing the presence of direct-access retrieval during language comprehension have been conducted exclusively with university students, presumably possessing a relatively high degree of comprehension skill. As such, this evidence only suggests that memory capacity is not important for argument integration in adult *skilled readers*. This leaves open the question of whether less-skilled readers are able to employ the same direct-access retrieval mechanism as skilled readers; that is, poor comprehension in these readers may arise because they simply do not have access to a direct-access retrieval mechanism, and must instead rely upon a slower, less efficient mode of retrieval (i.e., search) during comprehension. Numerous findings showing that less-skilled readers are typically slower than skilled readers to retrieve phonologically encoded information during comprehension support this possibility (Perfetti, 1985; Swan and Goswami, 1997a,b; Wolf and Bowers, 1999; Goswami, 2011).

Thus, our goal in Experiment 2 was to use the auditory SAT technique to determine whether less-skilled readers have access to an efficient, direct-access retrieval mechanism *at all*. The question of whether less-skilled readers are able to use direct-access retrieval is particularly important given that the prevailing account of memory limitations during reading comprehension suggests that poor readers' comprehension is inherently compromised—that reading skill is essentially predetermined by fundamental, fixed differences in the memory system. The most obvious example of this approach is the notion of intrinsic, fixed WM capacities, which are thought to determine the facility with which a given comprehender may process linguistic information (e.g., Just and Carpenter, 1992; Caplan and Waters, 1999). According to this account, those with low WM capacities are predestined to be poor comprehenders, while those with higher WM capacities are not.

An alternative possibility is suggested by Ericsson and Kintsch (1995) in their Long-Term WM model. According to this model, skilled performance on any task (e.g., mental calculations, medical diagnosis, playing chess) is predicated on the development of highly efficient, skill-specific access structures, in which retrieval cues in active memory facilitate access to information in LTM. In each case, skilled practitioners enjoy rapid access to critical information, while those less-skilled will retrieve information more slowly and with difficulty. In the context of skilled reading comprehension, the development of proficient decoding, by which readers use orthographic representations to access lexical information, may provide the critical link between active and LTM. That is, because skilled readers have highly efficient mappings between the orthographic, phonological, and semantic characteristics of a word, they may enjoy direct-access retrieval of the lexical information upon which higher-level language processes (syntactic parsing, semantic, and discourse integration) depend. Less-skilled readers, in contrast, may instead be forced to rely on less efficient, search-based retrieval.

Critically, both of these accounts suggest that poor readers simply do not have access to an efficient retrieval mechanism to support reading—either because they do not (and cannot) have one, or because they do not have sufficient expertise to develop one. Thus, the importance of this experiment derives from its assessment of less-skilled readers' memory operations *when they are not reading*. If poor readers show the ability to employ content-addressable direct-access during auditory language processing, then they are not inherently saddled with a less efficient default retrieval mechanism. Furthermore, if less-skilled readers demonstrate the ability to use a direct-access retrieval mechanism, then it also cannot be the case that efficient retrieval is a byproduct of the development of reading expertise.

We used the same materials as in our first experiment. In addition, the participants in this study were not university students; we recruited a community-based sample of non-college bound young persons. Our previous experience with this population led us to expect large skill differences on a range of cognitive measures (e.g., Braze et al., 2007, in press; Shankweiler et al., 2008; Kuperman and Van Dyke, 2011; Magnuson et al., 2011; Johns et al., 2014; Van Dyke et al., 2014; Kukona et al., submitted). Our sample was age-matched to the standard college subject-pool population, which permits comparisons with previous studies of memory operations during language processing. As in those studies, we expected our participants' accuracy to vary according to the length of our experimental sentences (see Materials, Experiment 1), with the

lowest accuracy in the longest conditions. As in Experiment 1, the critical comparisons for assessing the retrieval mechanism derive from the processing speed dynamics (rate and intercept) of their response functions. If poor readers use a search-based mechanism, then retrieval speed should vary as a function of the length of the experimental sentences (i.e., as a function of the amount of material interpolated between the matrix verb and its head noun). However, if poor readers are able to use a direct-access retrieval mechanism, speed should be fast when no retrieval is required (i.e., when there is no intervening material) and invariant across all other conditions, which do require retrieval.

Method

Participants

Informed consent was obtained from 22 young people (ages 16–24) recruited from the local New Haven community. We recruited participants in a number of ways, including presentations at adult education centers, advertisements in local newspapers, flyers placed on adult school campuses, community centers, public transportation hubs, local retail and laundry facilities, and referrals from current and past study participants. All participants were right-handed native English speakers without a diagnosed reading or learning disability, and were paid for their participation ($20/h). Each participated in two 3-h experimental sessions identical to those described in Experiment 1, including initial training and an intersession period in which they completed additional cognitive assessments (for another study) and rested.

We assessed Reading Ability via the Peabody Picture Vocabulary Test (PPVT, 3E; Dunn and Dunn, 1997), which is a measure of receptive (i.e., interpretive, rather than productive) vocabulary. Vocabulary is known to be a limiting factor in the development of reading comprehension (Joshi, 2005; Perin, 2013). It frequently emerges as a unique predictor of reading ability, accounting for variance beyond that captured by other measures such as decoding, or by indices of reading comprehension (e.g., Braze et al., 2007, in press; Fraser and Conti-Ramsden, 2008; Ouellette and Beers, 2010; Tunmer and Chapman, 2012). There are now many psycholinguistic studies in which vocabulary was the critical measure for investigating individual differences in linguistic performance (e.g., Traxler and Tooley, 2007; Prat and Just, 2011; see also Long et al., 2008; Hamilton et al., 2013), including work from our lab using the PPVT (Braze et al., 2007, in press; Van Dyke et al., 2014). The distribution of scaled PPVT scores is shown in **Figure 2**; descriptive statistics and age equivalents are shown in **Table 4**. (Our participants completed the vocabulary assessment together with other skill assessments as part of a different study. We present a summary of these assessments in **Table 4** so as to further

characterize the cognitive abilities of this sample; however only the vocabulary assessment is used in the current analyses.)

Materials, Procedure, Data Analysis

The materials, procedure, and parameters of the data analysis were identical to Experiment 1, except that the analyses included fixed effects of Reading Ability and the interaction of Reading Ability × Construction.

Results

Figure 3 shows the averaged d' data (data points) and the best fitting 3λ-1β-2δ model (smoothed curves) as a function of processing time for the experimental conditions (No Interpolated Material, Interpolated Object Relative, Interpolated Object + Subject Relative). The LMER analysis of the mean of the last four d' values yielded significant main effects of Construction, $F_{(2, 40)} = 161.00$, $p < 0.001$, and Reading Ability, $F_{(1, 20)} = 56.11$, $p < 0.001$. This effect is depicted in **Figure 4**. However, the interaction of Construction × Reading Ability was not significant, $F_{(2, 40)} = 1.563$, $p = 0.222$. Pairwise comparisons to resolve the main effect of Construction showed that accuracy was higher when there was no material between subject and verb ($d' = 2.41$) than when there was an intervening object relative clause ($d' = 1.32$), $t = -11.57$, or when there were intervening subject and object relative clauses ($d' = 0.73$), $t = -17.66$. In addition, the asymptotic accuracy of the Interpolated Object Relative condition was significantly higher than that of the Interpolated Object + Subject Relative condition, $t = -6.09$. This pattern replicates the empirical d' findings from both our first experiment and McElree et al. (2003).

Hierarchical modeling of the data proceeded as in the previous experiment, first comparing the 1λ-1β-1δ (null), 2λ-1β-1δ, and 3λ-1β-1δ models. The 1λ-1β-1δ model fit produced an adjusted R^2 for the averaged data of 0.540, ranging from 0.299 to 0.895 across all participants. The 2λ-1β-1δ model (in which the additional asymptote parameter was again assigned to the conditions with interpolated material) produced an adjusted R^2 for the averaged data of 0.947, ranging from 0.863 to 0.984 across all participants. All participants showed an increase in adjusted R^2 compared with the null model (average adjusted R^2 increase = 0.409; minimum = 0.03; maximum = 0.665). Finally, the 3λ-1β-1δ model produced an adjusted R^2 for the averaged data of 0.990, ranging from 0.960 to 0.991 for individuals. Compared to the 1λ-1β-1δ model, the average adjusted R^2 increase was 0.455 (minimum = 0.08; maximum = 0.692); compared to the 2λ-1β-1δ model, the average adjusted R^2 increase was 0.046 (minimum = 0; maximum = 0.11). The λ estimates (in d' units) for the averaged 3λ-1β-1δ model were 2.80 for the No Interpolation condition, 1.43 for the Interpolated Object Relative condition, and 0.80 for the Interpolated Object + Subject Relative condition. The LMER analysis of the λ estimates revealed significant main effects of Construction, $F_{(2, 40)} = 196.66$, $p < 0.001$, and Reading Ability, $F_{(1, 40)} = 50.53$, $p < 0.001$, but the interaction was again non-significant, $F_{(2, 40)} = 2.24$, $p = 0.12$. Pairwise comparisons to resolve the significant Construction effect closely tracked the pattern of the analysis of the empirical d' data above. Specifically, the λ estimates for the No Interpolation condition were higher than both the Interpolated Object Relative ($t = -13.34$) and Interpolated Object + Subject Relative conditions ($t = -19.38$), and the Interpolated Object Relative condition λ estimate was greater than the Interpolated Object + Subject Relative condition ($t = -6.04$). This finding—that a model with three asymptote parameters better fits the data than do models with two or one asymptote, and that Reading Ability does not interact with this pattern—is consistent with our analysis of the empirical d' data. Thus, our subsequent analyses again focused on models with three asymptotes.

We next evaluated the potential effects of Construction and Reading Ability on processing speed. It was first necessary to determine the best-fitting model for the average and individual data, so that each participant's rate (β) and intercept (δ) parameters could be examined in light of their scores on our vocabulary assessment. As in our first experiment, the data do not suggest that either the intercept or rate parameters can be excluded from analysis (see **Figure 3**). We first assigned an additional parameter to the intercept, so that the 3λ-1β-2δ model assigned one δ for the No Interpolation condition, and another for the conditions with intervening material. The adjusted R^2 for this model's averaged data was 0.995, ranging from 0.969 to 0.994 for individuals. All participants but four showed an increase in the adjusted R^2 for the 3λ-1β-2δ over the 3λ-1β-1δ model (average increase = 0.006; minimum = −0.001, maximum = 0.02). A subsequent fitting of a 3λ-1β-3δ model to the data showed that the addition of a third intercept parameter was

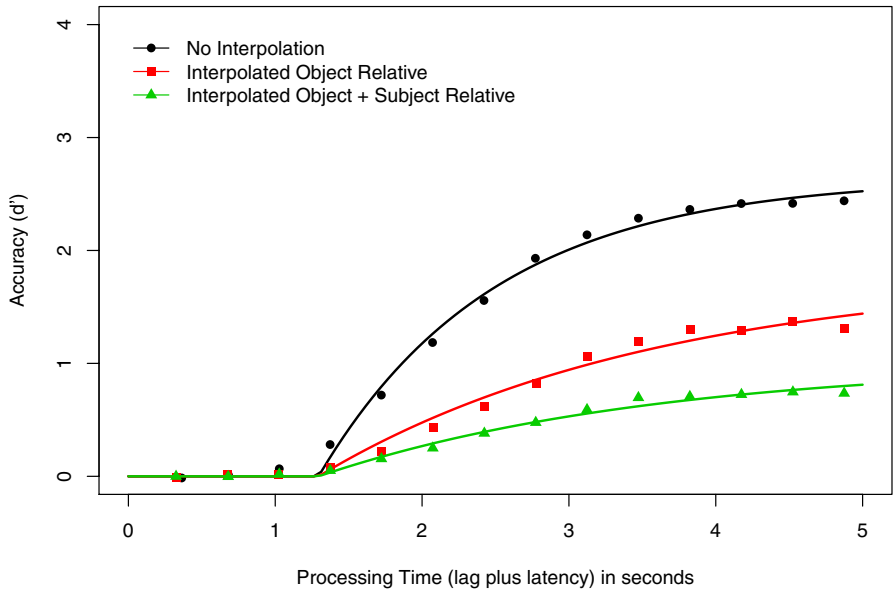

FIGURE 3 | Speed-accuracy tradeoff results for Experiment 2. Average *d′* accuracy as a function of processing time (in seconds) for the grammaticality judgments of sentences with the following constructions: no embedded material (circles), one object-relative clause (squares), and one object- and one subject-relative clause (triangles). Smooth curves show the best fitting 3λ-1β-2δ exponential model.

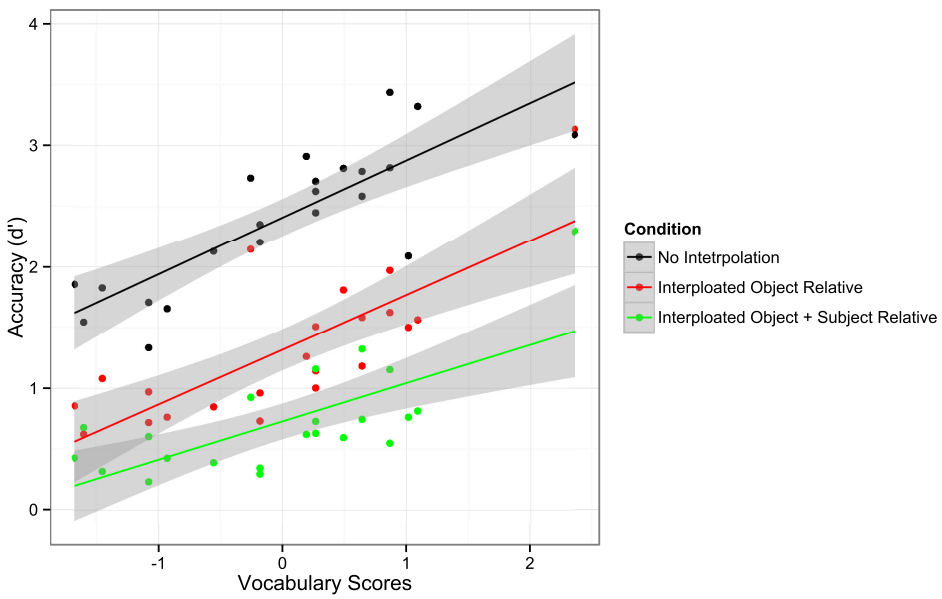

FIGURE 4 | The main effect of Reading Ability on *d′* accuracy in Experiment 2.

not warranted: although eight participants showed an improved adjusted R^2 for this model relative to the 3λ-1β-2δ model, on average the adjusted R^2s were identical (adjusted R^2=0.995; average increase = 0.001; minimum = −0.001, maximum = 0.007).

Next, we evaluated the rate parameter, adding a β so that one parameter was assigned to the No Interpolation condition, and the other to the conditions with interpolated material. This 3λ-2β-1δ model (average adjusted R^2 = 0.995, individual adjusted R^2 = 967 to 0.994) improved model fit over the 3λ-1β-1δ model: all but three participants showed an increase in adjusted R^2 (average adjusted R^2 increase = 0.006; minimum = 0; maximum = 0.034). However, this model was only a minimal improvement over the 3λ-1β-2δ model: although eight participants showed an increased adjusted R^2 (average increase = 0.001; minimum = −0.004; maximum = 0.017), the remaining 14 showed either no improvement or a decrement in fit (from −0.001 to −0.004). Moreover, the adjusted R^2 for the 3λ-2β-1δ

model's average data was identical to the 3λ-1β-2δ model. A subsequent 3λ-3β-1δ model fitting indicated that a third rate parameter was not warranted by the data (adjusted $R^2 = 0.994$; average adjusted R^2 increase = 0.001, minimum = −0.001; maximum = 0.005). In light of this, the absence of a clear difference between the 3λ-2β-1δ and 3λ-1β-2δ models suggests that differences in retrieval speed may derive from the addition of either a second δ or β parameter, determined individually for each participant.

Finally, we considered a 3λ-2β-2δ model, in which speed differences could arise from both rate and intercept. This model (adjusted $R^2 = 0.995$) was a slight improvement for nine participants (and a decrement for one participant) relative to the 3λ-1β-2δ model (average adjusted R^2 increase = 0.001; minimum = −0.001; maximum = 0.016); it was also a slight improvement over the 3λ-2β-1δ model for eight participants (average adjusted R^2 increase = 0.001; minimum = 0; maximum = 0.004). Of those participants showing an increased adjusted R^2 with a 3λ-2β-2δ model, only two showed an increase relative to both of the models with six parameters.

Overall, this pattern of model fits makes two critical points. First, models with three parameters for either the rate or intercept are not appropriate for this data. Second, although it is clear that a model with two speed parameters is appropriate for this data, the additional parameter may manifest on the rate, the intercept, or potentially both indices of retrieval dynamics.

We conducted a series of LMER analyses of the β and δ estimates for the five models considered above. In addition, in order to determine whether our participants' retrieval dynamics varied according to reading skill, Reading Ability was included as a factor (and interaction term) in all comparisons where appropriate. However, across all models, there were no main effects or interactions associated with Reading Ability (3λ-3β-1δ, 3λ-1β-3δ: both Fs < 1.5, lowest p-value = 0.158; 3λ-1β-2δ, 3λ-2β-1δ, 3λ-2β-2δ: all ts < 1.4). Therefore, all subsequent analyses focus only on the Construction factor.

The LMER analysis of the estimates for the model with three rate parameters (3λ-3β-1δ) was non-significant, $F_{(2, 40)} = 1.39$, $p = 0.259$. For the model with three intercept parameters (3λ-1β-3δ), the LMER test revealed a main effect of Construction, $F_{(2, 40)} = 14.21$, $p < 0.001$. Subsequent t-tests revealed that the intercept parameters for the No Interpolation condition were significantly different than both the Interpolated Object Relative ($t = 4.72$) and Interpolated Object + Subject Relative conditions ($t = 4.51$); but the intercepts in the two long conditions (Interpolated Object Relative and Interpolated Object + Subject Relative) were not significantly different ($t < 1$). Both LMER analyses indicate that the addition of a third dynamics parameter is not warranted, and that only models with two dynamics parameters are justified.

We now turn to the models with two dynamics parameter estimates. The more conservative of these models only have six parameters (i.e., 3λ parameters, and 3 parameters divided between the β and δ). T-tests confirm a significant difference between the intercepts in the 3λ-1β-2δ model ($t = 6.41$) and between the rates in the 3λ-2β-1δ model ($t = -2.76$). For the 3λ-2β-2δ model, t-test revealed that the difference between the rate parameter estimates was non-significant ($t = -1.14$); however, the intercept estimates differed significantly ($t = 3.62$). Thus, a conservative interpretation of the current pattern of results suggests that the 3λ-1β-2δ model should be preferred (see **Table 5** for both the average and the individual parameter estimates for this model).

Discussion

The results of this experiment replicate both Experiment 1 and the SR-SAT experiment in McElree et al. (2003). Analyses of both the d' and model asymptote estimates confirm that response accuracy decreased linearly in relation to the amount of material that intervened between sentential NPs and matrix verbs. Thus, as in previous studies, processing the additional interpolated material decreases the likelihood of retrieving the correct constituent and/or mis-parsing the syntactic relations among sentence constituents. These possibilities arise because the additional material either negatively affects the representation of the target constituent, or else the additional material (i.e., the introduction of additional NPs) decreases the diagnostic value of the matrix verbs' retrieval cues (McElree et al., 2003; see also Van Dyke and McElree, 2011; Van Dyke and Johns, 2012). In addition, we also observed individual differences in both d' and asymptotic accuracy based on Reading Ability, such that higher ability was associated with more accurate overall performance. However, there was no interaction of Reading Ability with the amount of interpolated material. Thus, the interpretation of the effect of Reading Ability is straightforward: more skilled readers were able to more accurately resolve the subject-verb dependency than less skilled readers, regardless of distance between subject and verb.

We also observed speed dynamics differences showing that access to the critical item was fastest when there was no interpolated material between noun and verb (i.e., when no retrieval was necessary); and, when intervening material necessitated retrieval, the speed of access did not vary according to how much material intervened between noun and verb. Both the modeling and the inferential statistics indicate that retrieval speed is invariant, regardless of the amount of embedded material. In addition, although we observed differences related to Reading Ability in accuracy measures, we observed no effect (or interaction) of Reading Ability with any index of retrieval dynamics. That is, readers retrieved information that was outside focal attention with equal speed, regardless of Reading Ability.

As in Experiment 1, there is important independent evidence that participants were processing the embedded material. Correct rejection rate at each response lag for the conditions with the anomaly within the interpolated region (T5 and T8) was 49.9, 49.7, 49.6, 51.0, 52.4, 53.5, 54.5, 56.4, 55.8, 56.4, 61.2, 61.2, 61.7, and 60.4%. Correct rejection rates for the corresponding conditions containing a sentence-final ungrammaticality were 49.9, 50.2, 50.3, 51.4, 53.3, 56.9, 60.3, 64.0, 66.5, 68.4, 69.6, 69.8, 71.5, and 71.7%. This pattern is identical to that observed in Experiment 1: overall accuracy is higher in the experimental conditions, and responses to the control conditions appearing to follow an exponential function. One distinction between the two experiments is that these rejection rates—although still clearly

above chance for all conditions—are lower than those in the first experiment. This is consistent with the overall performance of the participants in this experiment, who had considerably lower *d*'s in every condition than the university students in Experiment 1, and is undoubtedly a function of the broader range of reading ability.

This pattern of results—in which accuracy differs systematically according to the amount of material interpolated between the retrieval cue and the to-be-accessed item, but retrieval speed does not—is once again consistent only with content-addressable, direct-access retrieval. Thus, this experiment provides the first evidence that memory capacity is not important for argument integration in both skilled and less-skilled readers during listening comprehension. In addition, based on these results, the slowing associated with poor reading comprehension (e.g., Perfetti, 1985; Swan and Goswami, 1997a,b; Wolf and Bowers, 1999; Goswami, 2011) cannot be directly attributed to the absence of an efficient mechanism for retrieving critical information from memory. That is, the direct-access retrieval mechanism that is thought to subserve basic memory operations (see Clark and Gronlund, 1996), and which has been observed during language processing in collegiate readers (e.g., McElree et al., 2003; for review see McElree, 2015) was not innately compromised in our sample of less-skilled readers. These results also indicate that direct-access retrieval is not the result of increasingly proficient reading ability, as many of our participants had low word reading and comprehension ability (see **Table 4**). This suggests that a model of retrieval from LTM based on task-specific expertise (e.g., Ericsson and Kintsch, 1995) does not support argument integration during routine language processing. Rather, the pattern of results we observed suggests that individual variation in language processing is driven by the quality of the representation to be retrieved, and not the mechanism by which it is retrieved (Van Dyke and Shankweiler, 2013). This conclusion is bolstered by the use of the auditory SAT procedure: none of our effects can be attributed to either felicitous or impaired processing based on orthographic information (Harm and Seidenberg, 2004).

GENERAL DISCUSSION

These experiments contribute to the growing body of evidence in support of cue-based direct-access retrieval as the memory mechanism supporting argument integration during online sentence processing. Both of our experiments demonstrate the signature pattern of direct-access retrieval: variation in accuracy based on dependency distance, but constant retrieval speed when a distal constituent is required to complete a long-distance dependency. Our results replicate previous findings that suggest that a direct-access retrieval mechanism supports online parsing operations (McElree et al., 2003; see also McElree, 2000; Martin and McElree, 2008, 2009, 2011; Van Dyke and McElree, 2011).

Our results also extend previous findings, as we are the first to report that this type of mechanism supports comprehension of spoken language. As such, these studies suggest that direct-access retrieval is modality independent. Consequently, they further suggest that this retrieval mechanism, long known to subserve basic memory operations outside the domain of linguistic processing, may also be a core property of the human language faculty (see also McElree, 2015).

Our findings with respect to reading ability are consistent with this possibility. The results of Experiment 2 confirm that poor readers do not *de novo* employ a qualitatively different memory mechanism than that used by good comprehenders. Moreover, the use of the SAT methodology allows us to make several nuanced (and, perhaps, surprising) claims with respect to poor reading ability. For example, that we observed no main effects or interactions of Reading Ability on indices of retrieval speed may be unexpected in light of the many previous reports of lower fluency and slower reading rates in poor readers (for reviews see Torgesen et al., 2001; Chard et al., 2002); models of reading frequently attribute such behavior to impaired speed of retrieval (e.g., LaBerge and Samuels, 1974; Stanovich, 2000). However, because standard fluency measures capture both speed and the overall quality of readers' interaction with a text (Adams, 1990; Ashby et al., 2013), they do not take into consideration the speed-accuracy tradeoffs inherent in any timed assessment. Accordingly, it is not possible to clearly distinguish the contributions of representation quality and memory access speed to reading speed measures with traditional assessments.

In contrast, the implication of our results are clear: differences in representational quality, rather than in retrieval speed, contribute more to a comprehender's performance. Specifically, all our effects of Reading Ability were found only on the asymptote, which is understood within the SAT literature as an index of representation quality (e.g., memory strength; see Dosher, 1979; Wickelgren et al., 1980). Indeed, readers are known to differ in their ability to differentiate memory representations along various dimensions, with skilled readers able to make fine-grained distinctions that less skilled readers cannot (Perfetti and Hart, 2002; Perfetti et al., 2005; Landi and Perfetti, 2007; Perfetti, 2007; see also Long and Prat, 2008). Clinical reports showing that dyslexic readers are less able to make linguistically relevant phonetic distinctions compared to age-matched reading-level controls (e.g., Bogliotti et al., 2008; Goswami et al., 2011) are also consistent with this interpretation. Finally, there is also evidence that interventions that specifically attempt to increase reading speed are largely unsuccessful (Torgesen et al., 2001; Berends and Reitsma, 2005; Marinus et al., 2012), unless the intervention seeks to strengthen the representation of specific words or word parts (Mattingly, 1972; National Reading Panel, 2000; Thaler et al., 2004; Conrad and Levy, 2011). Findings such as these support the argument that representational quality is the crucial determinant of whether a given representation will be available for argument integration (e.g., Perfetti and Hart, 2002; Perfetti, 2007; Perfetti et al., 2008; Frishkoff et al., 2011).

Our observation of direct-access retrieval in our poor readers has important implications for the study of, and remediation of, reading difficulty and disability. Although the current study of auditory sentence processing does not demonstrate that poor readers employ direct access during reading, it does demonstrate that direct-access retrieval is not inherently "broken" or unavailable to these readers. This suggests that, like skilled readers, they are eligible to use a parsing architecture characterized by a severely limited active memory and an efficient direct access retrieval mechanism (Lewis et al., 2006). Because all readers, regardless of skill, have the minimal capacity required by such a system—the most recently processed item—inherent differences in WM capacity cannot be the source of comprehension difficulty, at least with respect to basic argument integration. Further support for this position comes from our recent study of a community-based sample of adult readers, in which comprehension of visual sentences was related not to WM capacity but, as in our second experiment, to receptive vocabulary (Van Dyke et al., 2014). Other recent work, in which first-grade children's development of reading comprehension skill was tracked before, during, and after intensive training on WM tasks, is similarly consistent: even when WM performance increased significantly, there was no measurable effect on the children's development of reading comprehension skill (Fuchs et al., 2014; see also Banales et al., 2015).

Poor quality lexical representations have a particularly serious impact on the efficiency of direct-access retrieval, wherein retrieval cues must be able to uniquely identify target representations. If representations do not instantiate important or relevant distinctions, then the mapping between cue and target will be indeterminate, leading to retrieval of incorrect representations. This situation has been studied extensively in the memory domain under the rubric of "cue-overload" (e.g., Watkins and Watkins, 1975) and has also been referred to as retrieval interference (see Van Dyke and Johns, 2012 for a review). Van Dyke and McElree (2006) demonstrated this effect in the language domain using a dual task paradigm (see also Gordon et al., 2002). Participants read sentences such as these:

(8a) It was the boat that the guy who lived by the sea *sailed* over two sunny days.
(8b) It was the boat that the guy who lived by the sea *fixed* over two sunny days.

For each sentence, a memory load was either present or absent; if present, participants received a short list of words to memorize prior to reading the sentence (e.g., TABLE-SINK-TRUCK). The presence of retrieval interference was determined by the main verb. In conditions such as (8a), the verb *sailed* is not overloaded: because the memory list words are not "sailable," the verb's semantic cues are able to uniquely identify the displaced subject NP *boat*. However, in conditions such as (8b), the verb *fixed* is an overloaded retrieval cue: that is, because the semantic cues provided by *fixed* are not uniquely diagnostic of its target in memory, the "fixable" items in the memory list compete with the "fixable" target in the sentence. Van Dyke and McElree found, in university students, that cue-overload increased reading difficulty at the verb—an effect which disappeared when the competing matches in the memory list were absent. (Similar effects in reading paradigms without a dual

task have also been reported; e.g., Gordon et al., 2001; Van Dyke and Lewis, 2003; Van Dyke, 2007.) A subsequent study, using the same paradigm and materials with a community-based sample of participants, found that readers' sensitivity to interference induced by overloaded retrieval cues varied negatively with receptive vocabulary (indexed, as in our SAT experiment, by PPVT; Van Dyke et al., 2014). In that study, low vocabulary scores were uniquely predictive of greater interference effects, including online reading difficulty and impaired performance on offline comprehension questions. Van Dyke and colleagues proposed that such readers—many of whom also had low scores on a range of other linguistic skill measures—were likely to have lexical representations in which important distinctions (on orthographic, phonologic, and/or semantic dimensions) were absent. It is precisely these distinctions that could be crucial for discriminating among similar, competing lexical representations when a retrieval cue is overloaded.

Van Dyke et al. (2014) were the first to report that poor readers were more vulnerable to retrieval interference than skilled readers. However, the association between low verbal ability and effects related to the strength or quality of representations, rather than retrieval speed, is also broadly consistent with a recent SAT study examining individual differences in interference resolution in recognition memory (Öztekin and McElree, 2010). Using an extreme groups design, Öztekin and McElree assessed recognition of words that were either present in a studied list; absent from, but consistent with the semantic categories of, studied list items ("distant negatives"); or absent from the studied list, but nonetheless present in the immediately preceding study list ("recent negatives"). As in the current study, there were no individual differences associated with retrieval speed, which was invariant for all items but the most recently processed list word. Also as reported here, individual differences emerged only on the SAT parameter associated with representation quality: low ability participants had lower asymptotic accuracy. This difference was driven by low ability participants' greater rate of false alarms to the recent negative lure trials. Öztekin and McElree suggested that this greater susceptibility to interference could result from lower-quality representations, or from the impaired ability to distinguish between information based on familiarity and episodic details (i.e., cue-overload). As this study also used the SAT method, we take these results as important corroborating evidence for our own position: namely, that individual differences have their effect on measures of representation quality (or strength), and not on retrieval speed[5]. Taken together, these studies converge on the notion that it is the probability of retrieving the necessary item, determined by qualitative properties of the item's representation, that is a crucial determinant of reading ability—rather than intrinsic capacity differences, or the absence of an efficient retrieval mechanism.

Finally, as this is the first time the SAT method has been used to examine individual differences in language processing, we acknowledge that the suggestion that poor reading ability may be unrelated to slowed retrieval should be treated cautiously. Moreover, although the size of the current sample is in line with other published SAT studies, it would be desirable to replicate our study with an even larger sample to verify our results with respect to speed parameters. However, it is important to note that the main conclusion from this study is actually entirely orthogonal to whether poor reading ability is associated with slower retrieval speed. The crucial finding here is that regardless of reading ability, retrieval speed was unaffected by the amount of interpolated material between the target subject and its verb. The fact that the speed to access the target subject in our longest condition (Interpolated Object + Subject Relative Clause condition) was the same as that for accessing the target in the shorter Interpolated Object Relative Clause condition means that these retrievals occurred without executing a backwards sequential search through the contents of memory. Rather, all participants employed a direct-access retrieval mechanism irrespective of Reading Ability. Thus, even if we had observed a main effect of ability on speed parameters, this would have only attested to the possibility that retrieval was slower overall. This would have said nothing about the presence or absence of a direct-access retrieval mechanism in poor comprehenders.

The experiments reported here validate the auditory SAT procedure as a useful, highly sensitive tool for investigating the architecture of language comprehension across individuals with widely varying linguistic abilities. Because it gauges performance in the auditory modality, the procedure is not susceptible to problems related to inefficient orthographic decoding skills that confound other online assessments. This opens up new possibilities for investigations of memory access during language processing to special populations, such as adolescents with poor reading comprehension, dyslexics, spoken language bilinguals (e.g., heritage language speakers), or functionally illiterate language users. In addition, because longer, multi-sentence and passage-length materials have been difficult to implement in the visual SAT paradigm, our findings suggest the possibility of investigating memory retrieval during the online processing of discourse-level dependencies. Especially considered alongside the potential to investigate the influence of a broader range cognitive abilities on the dynamics and accuracy of memory retrieval during online language comprehension, the results of this study raise many exciting possibilities for future research.

[5]Öztekin and McElree (2010) used a working memory assessment as their only skill measure. There is much evidence for high correlations between this assessment and other language and reading-related measures, including vocabulary, phonological processing, decoding ability, rapid naming, reading fluency, and spoken language ability. Hence, we prefer to interpret this result as referring to a more general verbal skill ability rather than about working memory capacity per se. See Van Dyke et al. (2014) for further discussion of this issue.

ACKNOWLEDGMENTS

This research was supported by the following NIH grants to Haskins Laboratories: R21 HD-058944 (JV, PI), R01 HD-073288 (JV, PI), R01 HD-071988 (David Braze, PI), and P01 HD-01994 (Jay G. Rueckl, PI). The authors are grateful to Brian McElree for access to materials from the McElree et al. (2003)

study; Erica Davis and Joshua Coppola for assistance with data collection; Emma Voytek (née Chepya) for assistance adapting and recording all stimuli; Victor Kuperman for consultations regarding skills testing and statistical analysis; and Morgan L. Bontrager, Andrew A. Jahn, Hannah R. Jones, and Dave Kush for their insightful comments and advice.

Processing implicit control: evidence from reading times

Michael McCourt[1]*, *Jeffrey J. Green*[2], *Ellen Lau*[2] and *Alexander Williams*[1, 2]

[1] Department of Philosophy, University of Maryland, College Park, MD, USA, [2] Department of Linguistics, University of Maryland, College Park, MD, USA

Sentences such as "The ship was sunk to collect the insurance" exhibit an unusual form of anaphora, implicit control, where neither anaphor nor antecedent is audible. The non-finite reason clause has an understood subject, PRO, that is anaphoric; here it may be understood as naming the agent of the event of the host clause. Yet since the host is a short passive, this agent is realized by no audible dependent. The putative antecedent to PRO is therefore implicit, which it normally cannot be. What sorts of representations subserve the comprehension of this dependency? Here we present four self-paced reading time studies directed at this question. Previous work showed no processing cost for implicit vs. explicit control, and took this to support the view that PRO is linked syntactically to a silent argument in the passive. We challenge this conclusion by reporting that we also find no processing cost for remote implicit control, as in: "The ship was sunk. The reason was to collect the insurance." Here the dependency crosses two independent sentences, and so cannot, we argue, be mediated by syntax. Our Experiments 1–4 examined the processing of both implicit (short passive) and explicit (active or long passive) control in both local and remote configurations. Experiments 3 and 4 added either "3 days ago" or "just in order" to the local conditions, to control for the distance between the passive and infinitival verbs, and for the predictability of the reason clause, respectively. We replicate the finding that implicit control does not impose an additional processing cost. But critically we show that remote control does not impose a processing cost either. Reading times at the reason clause were never slower when control was remote. In fact they were always faster. Thus, efficient processing of local implicit control cannot show that implicit control is mediated by syntax; nor, in turn, that there is a silent but grammatically active argument in passives.

Keywords: anaphora, implicit control, implicit argument, rationale clause, self-paced reading

BACKGROUND

Sometimes an aspect of speaker meaning has unclear provenance. Is it semantic or pragmatic? Is it or is it not determined, that is, by the structural identity of the sentence itself? In such cases online measures may help us find the source of the meaning, as the two routes to interpretation may take measurably different paths.

One familiar example comes from verb phrase ellipsis, as in (2). After (1), the speaker of (2) means that the Yankees traded an outfielder. But is this decided by the structural identity of his sentence token?

(1) The Red Sox traded an outfielder.
(2) The Yankees did too.

Many answer *yes* (Sag, 1976; Williams, 1977; Fiengo and May, 1994; Merchant, 2001). They say that this use of (2), unlike others, has the verb phrase *trade an outfielder*, with all the structure of the verb phrase in (1), just silent. Others answer *no* (Dalrymple et al., 1991; Hardt, 1993; Ginzburg and Sag, 2000; Culicover and Jackendoff, 2005). Every use of (2), they say, has an unstructured verb phrase that simply means *P*, where *P* is a free variable over properties. The value of that variable is then decided "by context," not by the sentence itself. On the first account, the string in (2) is ambiguous between infinitely many sentences, each with a different verb phrase and hence a different meaning. On the second, it has a single meaning that is sensitive to context. These two routes to interpretation—semantic vs. pragmatic, disambiguation vs. anaphora, recovery of structure vs. resolution of a variable—might involve different cognitive processes, and might also register differently in some online processing measure. If they do, that measure may provide some evidence for which account is correct, a question that remains contentious. Accordingly, a rich body of literature has pursued this idea (Tanenhaus and Carlson, 1990; Shapiro and Hestvik, 1995; Frazier and Clifton, 2001, 2005; Martin and McElree, 2008; Kertz, 2010; Yoshida et al., 2012; see Phillips and Parker, 2014 for an overview).

We explore another area in this same light, namely *implicit control of reason clauses,* on display when we use (3) to mean (5).

(3) The candidates were interviewed to find the best person for the job.
(4) Someone interviewed the candidates in order to find the best person for the job.
(5) Someone_k interviewed the candidates in order for them_k to find the best person for the job.

Both (3) and (4) have an infinitival *reason clause* with the verb *find*, adjoined to a *target clause* with the verb *interview*. A reason clause, or *rationale* clause (Faraci, 1974; Jones, 1985), offers a teleological explanation of the fact expressed by its target clause. Why were the candidates interviewed, according to this use of (3)? Because then the interviewers might find the best person for the job. The understood subject of a reason clause, called PRO, may be construed anaphorically, as denoting a thing previously mentioned or implied. Anaphora involving PRO is called *control*, though we commit to no analysis with this term. When (3) is used to mean (5), PRO names the interviewer entailed by the verb in the target clause, *interview*. But the interviewer is named by no audible dependent in that clause; (3) is a *short* passive, with no *by*-phrase. So here control is *implicit*. Control is *explicit* when we use (4) to mean (5). Now the interviewer is audibly realized, here as the subject of an active target clause.

On the *standard theory* of implicit control (Roeper, 1987), the relation is not pragmatic, but syntactic and therefore semantic. Specifically, it is encoded in the context-invariant meaning of the two-part sentence that combines the reason clause and its target clause host; and this encoding goes by way of a syntactic dependency, *binding*[1], which effects sameness of reference. Binding links PRO in the reason clause to a postulated silent argument in the passive target clause, providing PRO with an antecedent.

Semantically, the silent argument is linked to the *deep-S role* of the verb: the semantic relation assigned to the subject of an active clause with that verb. For *interview*, this is the role of interviewer. Syntactically, the silent argument has one of two representations, depending on the analysis of the passive. It may be a formal feature of the verb, part of a feature array that syntactically indexes certain semantic properties, perhaps a "Theta Grid" (Stowell, 1981), "Argument Structure" (Grimshaw, 1990; Manning and Sag, 1998), or "Logical Structure" (van Valin, 1990). Or it may be a separate expression that combines with the verb in syntax (Baker et al., 1989; Stanley, 2000). Either way, the silent argument serves here to provide PRO with a formal antecedent. This allows PRO to be bound, and hence for implicit control to be fixed syntactically, and thus in the compositional semantics. In this way implicit control is assimilated to the paradigm cases of control, where PRO must be coreferent with a particular argument in the next clause up. In (6) or (7), for example, it is must be coreferent with the subject of the *promise* or *rob* clauses, respectively.

(6) Lee heard Mo promise PRO to leave.
(7) Lee robbed Mo while PRO distracting her.

This theory has a good motive. Many restrictions on control of reason clauses, or *reason control*, can be described in syntactic terms (Keyser and Roeper, 1984; Roeper, 1987). When reason control is explicit, the antecedent can be the subject but not the object of its clause (Williams, 1974)[2]. Thus, we can use (8) but not (9) to talk about how the sharks have their gills kept clean, since *these sharks* is the subject in (8) but the object in (9). Conversely only (9) implies that the parasites have gills.

(8) These sharks cover themselves with parasites to have their gills kept clean.
(9) Parasites cover these sharks to have their gills kept clean.

The antecedent can also be a *by*-phrase, when the target clause is a long passive. Thus, we can use (10) to convey that the Red Sox hoped to acquire a better pitcher in trading two outfielders.

(10) Two outfielders were traded by the Red Sox to acquire a better pitcher.

But the right conclusion is not that the antecedent must be assigned the deep-S role of the verb in the target clause. This is not

[1]Binding of PRO is normally called *control*. But we use "control" more neutrally, just to denote the resolution of PRO's reference, whether or not this is decided by binding.

[2]Control by objects is possible, however, for infinitival "purpose clauses" (Faraci, 1974; Williams, 1974; Bach, 1982; Jones, 1985). An example is *Maria brought Mary along to translate*, where the translator is Mary, not Maria. Jones (1985) distinguishes these from reason (rationale) clauses in three further ways, following Williams (1974) and Faraci (1974). Only reason clauses have or permit *in order to*. Only reason clauses can be preposed to sentence-initial position. And only purpose clauses can have a gap in their VP, bound by an argument in the main clause, as in *Mary brought a pen to write with*, where *a pen* binds a gap after *with*. But see Whelpton (2002) for concerns about this taxonomy.

necessary (Williams, 1974; Zubizaretta, 1982; Roeper, 1987), as shown by (11), which can be used to mean that Lisa was arrested so that *she* might seem like a radical.

(11) Lisa was arrested just to seem like a radical.

The better conclusion is that explicit control must be by a *subject*, so long as we presume that a *by*-phrase counts as a subject for at least these purposes. Let us use the term *S* for an argument that "counts as a subject" in this sense, so that reason control must be by an S when explicit. Then we can describe implicit control in analogous terms, if we link the deep-S role in a short passive to a silent S argument, called "implicit" because it is grammatically active. This is the standard theory.

Standard theory in hand, we have a syntactic account of some cases where implicit control is impossible. Sentence (12) describes the theft of a ship, and therefore entails a victim from whom the ship was stolen. But we cannot use (12), it seems, to say that the entailed victim was the intended collector of the insurance, even if he hired the crook for this very purpose. On the standard theory, this is because the role of victim is not linked to an implicit S. And this conclusion is well-justified, since the victim role is assigned to the subject in neither actives nor passives with *steal*.

(12) A hired crook stole the ship to collect the insurance.

Middles, such as (13a), receive a more stipulative account. In a middle as in a short passive, the deep-S role of the verb is assigned to no audible dependent; no audible part of (13a) refers to killers, for example. But with middles this role can never antecede a reason clause PRO (Keyser and Roeper, 1984; Roeper, 1987; Mauner and Koenig, 2000). After (13a), for example, we cannot use (13b) to say that the winter survival of the *killers* explains why prey animals kill easily in the autumn.

(13a) In the autumn the prey animals kill easily.
(13b) #to survive the winter without hunger.

To capture this, the standard theory stipulates a difference in argument structure. In a middle, it says, the deep-S role is not linked to an S, unlike in a passive.

These conclusions have broader implications beyond the analysis of reason clauses, as they make it more plausible that an argument may be silent but grammatically active (Stanley, 2002)[3]. But the standard theory leaves several questions unanswered. It suggests no reason why the implicit S in a passive does not always function as a subject, in relation to all types of adjunct clauses (Vinet, 1988; Iwata, 1999; Landau, 2000), not just reason clauses. By hypothesis (14) has a silent S in the role of thief, and yet we cannot use (14) to mean that my wallet was stolen while the *thief* was distracting me, letting this implicit S control the non-finite temporal adjunct.

(14) My wallet was stolen while distracting me.

The standard theory is also silent on why implicit control is not available to the deep-S role of every passive clause. The meaning that is unavailable to (14) is also unavailable to (13) (Williams, 2015). Yet (15a) is a passive, not a middle, and so should have an implicit S in the role of killer.

(15a) In the autumn the prey animals are killed easily
(15b) #to survive the winter without hunger.

Nor can the standard theory accommodate data like (16) (Williams, 1985, 2015; Lasnik, 1988). Sentence (16) can be used to convey that a young girl cut the ribbon so that the organizers of the event might acquire the support of female voters (Williams, 2015). Yet in a clause with *cut*, there is no argument that stands for organizers of the cutting, as distinct from the cutters.

(16) A young girl cut the ribbon just to acquire the support of female voters.

Finally, the standard theory cannot account for what we call *remote control*, to which we turn in a moment.

Given these doubts, we should welcome additional evidence for the standard theory; and some has been offered in the previous psycholinguistic literature. In a series of stop-making-sense and self-paced reading time studies, Mauner et al. (1995) compared implicit with explicit control of reason clauses. They did so by comparing reason clauses following active, full passive, short passive and intransitive target clauses (15–18).

(17) Someone sank the ship to collect the insurance.
(18) The ship was sunk by someone to collect the insurance.
(19) The ship was sunk to collect the insurance.
(20) The ship sank to collect the insurance.

No differences in acceptability judgments or in reading times were observed in the reason clause in conditions (15–17), but significantly slower reading times and more "unacceptable" responses were observed following the intransitive (20). Mauner and colleagues took these results to support the standard theory of implicit control, on the basis of the following reasoning. First, something like the standard theory of explicit control was assumed: in active examples like (17), PRO is locally bound by the surface subject of the target clause. It was then assumed that finding similar processing profiles for two interpretive dependencies—such as implicit vs. explicit control—would provide evidence that the same mechanisms are at work in resolving them both. Since explicit control by the surface subject of an active target clause is supposed to be mediated syntactically, and since no behavioral differences were observed between explicit (15, 16) and implicit control conditions (19), these earlier results were taken to support the standard view that implicit control is syntactic binding of PRO by a silent argument in the short passive.

Although Mauner and colleagues' results have been taken to constitute important evidence in favor of the standard view of implicit control, this interpretation relies on the assumptions outlined above. In the current study, we test these assumptions further by examining the case of *remote* control. Prior studies

[3]There is a strong case for silent arguments with an anaphoric or "definite" (Fillmore, 1986) interpretation (Partee, 1989; Condoravdi and Gawron, 1996). But the silent argument in a short passive would not be anaphoric or definite. Its interpretation would be equivalent to a narrow-scope existential quantifier: "The candidates were interviewed carefully by *someone*." And the case for such arguments is much weaker (Williams, 2015).

considered only *local* control, where the target and reason clauses are syntactically dependent, forming a single sentence. In *remote* control (Higgins, 1973; Sag and Pollard, 1991; Williams, 2015), as in (21), the two clauses are independent, in two separate sentences. But we can still use (21) to mean (5).

(21) The candidates were interviewed. The goal was to find the best person for the job.
(5) Someone$_k$ interviewed the candidates in order for them$_k$ to find the best person for the job.

In remote control, the infinitival clause is the complement to an equative (or specificational) copula, in a sentence that is separate from the target clause. The subject of the target clause is something like *the goal*, *the reason*, or *the purpose*, a description with a relational noun. We understand that, here, this description is used to refer to a relation that is directed at the target fact, taking *the goal* in (21), for example, to refer to the goal of interviewing the candidates.

Crucially, remote control shows exactly the same restrictions as local control (Williams, 2015). Among others, the contrasts in (1–13) are all preserved when control is remote. (8′) and (9′) show that subjects, but not objects, can be implicit controllers in remote configurations; only (9′) implies that parasites have gills.

(8′) These sharks cover themselves in parasites. The goal is to have their gills kept clean.
(9′) Parasites cover these sharks. The goal is to have their gills kept clean.

And, as with (12) above, it is not possible to use (12′) to mean that the hired crook stole the ship so that his employers could collect the payout.

(12′) A hired crook stole the ship. The reason was to collect the insurance.

Yet here these patterns cannot be explained in terms of syntactic binding. Binding cannot cross independent sentences, and the reason clause, when remote, is syntactically separate from its target. Conceivably—though we do not think that this is correct, for reasons we discuss elsewhere (Green and Williams, in preparation)—the copular clause has hidden structure that conceals a local (same-sentence) binder for PRO, one that is itself anaphoric to an S in the target clause[4]. But even if it did, the anaphoric relation between this local binder and its antecedent in the target clause would still be intersentential. Hence, whatever it is that underlies the interpretive dependency between PRO and the implied interviewer in (21), it cannot be syntactic binding.

The anaphora in (21) must therefore be pragmatic. PRO in a remote reason clause—or, on the alternative that we reject, its hidden local binder—must function not like a bound pronoun, but like a free pronoun or definite description. In turn, the limits on its interpretation cannot be explained directly in terms of structure in the target clause. Rather, its domain of reference must be highly restricted, in terms that only correlate, partially and indirectly, with subjecthood in the target clause[5]. Examples such as (12) suggest that a notion of *responsibility* may be relevant: perhaps PRO in a reason clause, as a matter of the meaning of the construction, ranges only over parties viewed as explanatorily *responsible* for the fact it is meant to explain, a class that may but need not include the individual in the deep-S role to the event of the verb (often, its agent)[6]. However, the grammatical analysis of remote control is beyond the scope of the current work. Here, the key observation is just that the restrictions on local and remote control appear to be identical. Since remote control must be pragmatically mediated, this weakens the motive for a semantic, hence syntactic, account of local control, and at the same time provides a new means of examining the extent to which reading time measures provide support for the syntactic account. If the standard theory is correct, then different mechanisms must be at work in resolution of local (one-sentence) and remote (two-sentence) control: syntactic binding and something like free pronoun interpretation, respectively. On the other hand, if what we now call the *pragmatic theory* is correct, then something like free pronoun interpretation supports resolution not only of remote control, but also of local control.

In the current study, we investigate these alternative hypotheses by examining processing measures in a series of self-paced reading time studies comparing remote and local reason clauses, with and without explicit antecedents. The predictions are the following. Since the standard theory proposes different mechanisms for resolving local and remote control, and the pragmatic theory proposes the same mechanism, the standard theory predicts differences in the processing of local and remote control, while the pragmatic theory does not. These differences might be realized in several ways. First, following the logic in Mauner et al. (1995), implicitness may be costly in forming pragmatic dependencies (because a referent must be inferred), but not costly in forming syntactic dependencies (because binding to the syntactic argument position proceeds in exactly the same way whether it is audible or not). Given this assumption, the standard theory would predict in the current experiments an interaction between implicitness and distance: an effect of implicitness should be present in the pragmatically mediated remote conditions but not in the syntactically mediated local conditions. Second, pragmatically mediated or syntactically mediated dependencies are likely to differ in processing cost

[4]For example, the subject of the copular clause might contain a silenced genitive pronoun, [*his*] *reason*, or a silent relative clause elided under identity with the target clause, *the reason* [*that the candidates were interviewed*]. Then the clause would to be restructured at an unpronounced level of syntax, so that the silent binder is in a local relation to PRO. On the special grammar of copular clauses, see the review in Mikkelsen (2011).

[5]A referential dependency that is intersentential cannot be syntactic, but it may still be sensitive to structural properties of the antecedent. VP Ellipsis is sensitive to voice, for example, and pronominal reference may be sensitive to gender class. Neither of these cases is itself a good model for remote control. But it remains coherent to claim both that PRO in a reason clause is a free anaphor, and that its resolution is sensitive to something like subjecthood. We return to this in passing in the General Discussion.

[6]Constructional restrictions on the domain of a pronoun are not in the standard semantic toolkit, and therefore much more would need to be said. For thoughts see Landau (2000) and Williams (2015), which refine a suggestion in Farkas (1988), with roots in Williams (1974). Also see Whelpton (2002) in opposition, and the discussion in Sag and Pollard (1991).

independent of implicitness because they involve reference to different kinds of memory representations. Therefore, in the current experiments, the standard theory could also predict a main effect of distance, but the direction of this difference depends on the linking hypothesis assumed. If syntactic binding is more costly to resolve than free pronoun interpretation, then the effect of implicitness should be larger in remote control. If free pronoun interpretation is more costly, then the effect of implicitness should be larger in local control. As previous psycholinguistic work does not provide clear predictions about which should be more costly (see Frazier and Clifton, 2000, for discussion), either could be taken to be consistent with the standard theory, although it could also be the case that binding and free pronoun interpretation do not differ fundamentally in processing cost (Cunnings et al., 2014).

The pragmatic theory does not predict any difference in the costs of implicitness in remote vs. local control. If we observed no such differences, this could be due to the fact that local and remote control are both mediated by the same kind of pragmatic mechanism. However, such a conclusion would be too strong here. It might be that reading times in particular are not a sensitive enough measure to detect differences between local and remote control that other measures might detect. Or it could be that processing cost is more generally not a reliable diagnostic of whether a dependency is semantically or pragmatically mediated. However, it is important to remember that Mauner et al.'s (1995) finding of no processing cost for local implicit vs. explicit control is one of the key pieces of evidence currently taken to support the standard theory, and that reading time was one of the online measures used in that study. Skepticism about the ability of self-paced reading to detect differences in processing of local and remote control would thus undermine earlier arguments in favor of the standard theory. These relied on the premise that, in fact, behavioral measures could reflect differences in processing as a function of whether a dependency was semantically or pragmatically mediated. Thus, if we observe no differences in processing of local vs. remote reason clauses, we can at the very least conclude that these earlier results do not in fact provide evidence for the standard account.

EXPERIMENTS

Experiment 1

The goal of Experiment 1 was to test whether differences obtain in processing of local vs. remote control, or between implicit and explicit control within local vs. remote configurations. Experiment 1 manipulated explicitness with passive sentences that varied in the presence or absence of a *by*-phrase that explicitly named the agent of the event described by the passive. Observation of differences in processing of remote and local control, or between implicit and explicit control in local vs. remote configurations, would provide support for the standard theory. Should we observe no such differences, this would either raise a challenge for the standard theory, or undermine previous arguments in its favor, as discussed above.

Methods and Materials

Participants

Participants were 38 native speakers of English from the University of Maryland community. Participants gave informed consent, and received credit in an introductory linguistics course or were compensated $5 for their participation in the experiment. All participants were naïve to the purpose of the experiment. The self-paced reading task lasted for approximately 30 min.

Materials

Sentences were created by combining a finite passive clause with a non-finite reason clause. In a 2 × 2 design, stimuli varied in whether the target clause contained an overt antecedent for the understood subject of the reason clause (*explicitness*), and in whether the target and reason clauses were syntactically independent (*distance*). In conditions labeled *implicit*, the target clause was a short passive and therefore lacked an overt antecedent for PRO. In conditions labeled *explicit*, the target clause was a passive with a *by*-phrase describing the agent of the event, which served as the antecedent of PRO. The dependency was *local* when the reason clause was syntactically an adjunct of the target clause. The dependency was *remote* when the two clauses were syntactically independent, the reason clause being hosted by a copular clause in a separate sentence. An example set of materials is provided in **Table 1**.

In order to control the position of the reason clause across explicit and implicit conditions, we substituted a temporal adjunct, such as *for several hours*, in the implicit conditions in place of the *by*-phrase. Our materials were also crafted to strongly favor interpreting PRO as the satisfier(s) of the deep-S role in the target clause. To this end, we controlled several properties across item sets. First, the reason clause always expressed a property that can be satisfied by people, but not by facts or events. While people can find the best employees for a job, for example, facts or events cannot. This eliminated the possibility, otherwise readily available (Williams, 1985; Lasnik, 1988), of resolving PRO to the fact or event named by the target clause itself. This can happen in (22), which can be used to say that the candidates were interviewed because interviewing them might make a good impression.

(22) Candidates were interviewed to make a good impression.

Second, our passive target clauses mostly had subjects that were semantically implausible as subjects for the reason clause, lowering the chance that they would be taken to antecede PRO. Third, in general our passive target clauses also resisted being read as "adjectival passives," as in *the shoes are polished*. This matters, since adjectival passives do not readily support implicit control by the deep-S role of their verb root. And finally, our target clauses never contained first-person, second-person or impersonal pronouns. This lowered the likelihood, however small, that PRO was read as logophoric or impersonal, like English impersonal *one*, denoting a group that shares the interlocutors' perspective.

Twenty-four sets of four items in these conditions were distributed across four lists in a Latin square design. 96 filler sentences were also included, such that each participant read

TABLE 1 | Experiment 1 materials.

	Regions of analysis											
	Pre-target	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**Post-target**

im. loc:	The candidates were interviewed	three	weeks	ago				to	find	the	best	person for the job.
ex. rem:	The candidates were interviewed	by	the	committee.	The	reason	was	to	find	the	best	person for the job.
im. rem:	The candidates were interviewed	three	weeks	ago.	The	reason	was	to	find	the	best	person for the job.

a total of 120 sentences. Approximately half of the fillers were one-sentence fillers. The other half were two-sentence fillers, roughly matching the 1:1 ratio of one- to two-sentence items in the main experimental stimuli. Some of the fillers involved adjectival passives and prepositional *to* in order to reduce the likelihood of within-task effects. Such constructions are syntactically very similar to our experimental items, but are differentiated semantically. Their inclusion was intended as a distraction, to make it less likely that readers would gain familiarity during the task with handling reason clauses.

Each sentence was followed by a comprehension question. Comprehension questions varied in whether they targeted information in the target clause, in the reason clause, or concerning the relation between target and reason clause. This reduced the likelihood of participants developing superficial reading strategies during the task.

Procedure

Sentences were displayed on a desktop PC in a moving-window self-paced reading display using the Linger software package (Doug Rohde, MIT). Each sentence initially appeared on a black screen masked by white dashes, with spacing and punctuation intact. Participants revealed the first word by pressing the space-bar on a keyboard. Subsequent words appeared in place of their respective dashes non-cumulatively as participants pressed the space-bar. The order of presentation of target and filler items was randomized for each participant. Participants were instructed to read the sentences carefully and for understanding but at their normal pace. Before the beginning of the experiment, participants were able to gain familiarity with the task with four practice items. Each sentence was followed by a yes/no comprehension question. Incorrect answers to comprehension questions elicited onscreen feedback. The entire procedure took approximately 30 min.

Data analysis

The minimum comprehension question accuracy required for inclusion of a participant's data in the analysis was 80%. Data from two participants were excluded due to comprehension question inaccuracy, resulting in a final dataset of 36 participants.

Statistical analysis was performed in regions 1–10, where region 1 was the first region in which conditions differed (the region beginning the *by*-phrase or temporal adjunct prior to the reason clause), and region 7 was the *to* region that began the critical reason clause. We used mixed-effects linear regressions to assess the reliability of the effects associated with the experimental factors. The effects of *explicitness* and *distance* on reading times were tested using linear mixed effects models in R (Bates et al., 2014; R Core Team, 2014), and p-values were obtained using lmerTest (Kuznetsova et al., 2014), which uses Satterwaithe approximations to calculate degrees of freedom. Note that regions 4–6 (*The reason was*) were only included in the remote conditions, and therefore tests in these regions necessarily examined only the effect of explicitness.

Reading times above 2000 ms were excluded. This resulted in loss of 0.16% of the data. Reading times were then converted to a log scale for statistical analysis. The fixed effects in the model were the factors *explicitness* (explicit vs. implicit), *distance* (local vs. remote), and their interaction. In addition to these fixed-effects, participants, and items were crossed, starting with random intercepts and slopes, and removing one level of complexity until the model converged with correlations of less than 0.9 in random effects in all regions and experiments described here, following the recommendations of Baayen et al. (2008) and Barr et al. (2013). This resulted in a model including random intercepts for subjects and items, but no random slopes.

Results

Mean comprehension question accuracy for experimental stimuli across participants and items was 92% (range across conditions: 91–93%), suggesting that participants were successful in comprehending the main experimental stimuli.

Logged reading times are plotted in **Figure 1**, with significant effects summarized in **Table 2**. Unexpectedly, in self-paced reading times, the most prominent effect we observe was a slowdown for the explicit local condition relative to the other four conditions. Results of the linear mixed effects models are presented in **Table 2**. In regions 1–3, immediately following the short passive, we found no significant main effects of either distance (whether the reason clause is local or remote) or explicitness (whether the target clause is a short or long passive) and no interactions, although the explicit local condition was already numerically slowest by region 3. There was also no significant difference between the remote explicit and implicit conditions in regions 4–6 (*The reason was*), although reading times for the explicit condition were numerically longer. However, at the infinitival *to*, region (9), we observed significant main effects of explicitness ($\beta = -0.14$, $t = -6.0$, $p < 0.001$) and distance ($\beta = -0.09$, $t = -3.7$, $p < 0.001$) and a significant interaction between explicitness and distance ($\beta = 0.09$, $t = 2.8$, $p < 0.01$). Follow-up pairwise comparisons indicated that this

the	Explicitness × Distance	0.024	0.036	0.68	0.498

interaction was driven by a significant effect of explicitness in local conditions ($\beta = -0.09$, $t = -3.3$, $p < 0.001$) but not in remote conditions ($\beta = 0.004$, $t = 0.2$, $p > 0.2$). In short, there appears to be a strong slowing effect of the *by*-phrase on reading times at the infinitival in the reason clause, but only in one-sentence conditions. In region 8 we observed the same pattern numerically, but here the interaction did not reach significance (main effect of distance: $\beta = -0.09$, $t = -3.9$, $p < 0.001$; main effect of explicitness: $\beta = -0.08$, $t = -3.3$, $p < 0.001$; interaction between explicitness and distance: $\beta = 0.05$, $t = 1.6$, $p = 0.1$). These differences diminished following the main verb in regions 9 and 10, although we observed a main effect of distance in region 9 ($\beta = -0.06$, $t = -2.4$, $p < 0.05$) and a marginal main effect of explicitness in region 10 ($\beta = 0.02$, $t = 0.46$, $p > 0.2$).

Discussion

The goal of Experiment 1 was to investigate differences in the cost of resolving implicit vs. explicit control of reason clauses, in local and remote configurations. In this experiment we used a comparison between short and long passives to manipulate whether the antecedent to PRO was implicit or explicit, respectively. The main effect we observed is unexpected according to either the standard theory or the pragmatic theory: the local explicit condition was slower at the beginning of the reason clause than the other three conditions. The logic in Mauner et al. (1995) would predict the longest reading times for the remote implicit condition, which requires the costly operation of inferring an antecedent for PRO. A more generic version of the standard theory would predict only a main effect of distance. What, then, can explain our results? Why were the longest reading times observed when the antecedent was both explicit, and closer to the position at which the dependency is resolved?

Because this pattern contradicts the predictions of all theories about implicit arguments that we are aware of, we conclude that the slowdown for the explicit local condition is most likely due to an independent factor. In particular, we suggest that this slowdown is an index of continued processing difficulty elicited by the preceding *by*-phrase. Normally *by*-phrases carry narrow focus. That is, we would normally read our long passive example—*The candidates were interviewed by the committee*—with prosodic prominence on *committee*, contrasting the committee with other possible interviewers that might be presently relevant. It has been observed that linguistically focused items elicit slower reading times (Lowder and Gordon, 2015). Furthermore, this effect may be particularly pronounced in the

current experiment, because the interpretation of the reason-clause is sensitive to focus (Dretske, 1972): the reason why the candidates were *interviewed*, for example, may not be the reason why they were interviewed *by the committee*. As for why the effect of the *by*-phrase does not obtain in the remote conditions, this is plausibly explained by the availability of more time for processing the focused *by*-phrase prior to the focus-sensitive reason clause during the intervening *The reason was* segment in the remote conditions. Indeed, reading times for the explicit condition were numerically larger during this region.

If this is the correct explanation for the unexpected effects we observe in Experiment 1, then long passives are not ideal as a baseline condition of explicit control, if we want to isolate the specific costs of implicit control. Therefore, in our subsequent experiments, we instead use active transitive clauses for this purpose.

Experiment 2

Experiment 1 tested the effect of explicitness in local vs. remote control configurations by comparing short and long passives, but we found that the *by*-phrases in long passives introduce independent reading time costs. Experiment 2 therefore manipulated explicitness by comparing short passives with active transitive clauses instead.

Methods and Materials

Participants

Participants were 36 native speakers of English from the University of Maryland community. Participants gave informed consent, and received credit in an introductory linguistics course or were compensated $5 for their participation in the experiment. All participants were naïve to the purpose of the experiment. The self-paced reading task lasted for approximately 30 min.

Materials

Twenty-four sets of four target sentences again varied in a 2 × 2 design with the factors *explicitness* and *distance*. However, explicitness is now manipulated by comparing control by short passives with control by active transitive clauses, as shown in **Table 3**. The same fillers and comprehension questions were used as in the earlier experiments. An example set is provided in **Table 3**.

Procedure

The procedure for Experiment 2 was the same as the procedure for Experiment 1.

Data analysis

Comprehension question accuracy was above 80% for all participants. Statistical analysis was performed in regions 1–9, where region 1 was two regions prior to the critical word *to* in the local conditions and region 6 was the *to* region that began the critical reason clause. Analysis procedures were the same as described for Experiment 1. The exclusion of reading times above 2000 ms resulted in a loss of 0.2% of the total data. Note that regions 3–5 (*The reason was*) were only included in the remote conditions, and therefore tests in these regions necessarily examined only the effect of explicitness.

Results

The mean comprehension question accuracy for experimental items across participants and items was 96% (range across conditions: 95–97%), suggesting that participants were successful in comprehending the main experimental stimuli.

Logged reading times are plotted in **Figure 2**, with significant effects summarized in **Table 4**. In the regions preceding the reason clause (1–5), the only significant effect observed was slower reading times for the explicit remote condition than the implicit remote condition for the first word of the second sentence, *The* ($\beta = 0.08$, $t = 2.1$, $p < 0.05$). Although the reason for this difference is not clear, we note that the conditions come back together in the next region and are very tightly matched prior to the beginning of the critical reason clause.

At the infinitival to (region 6), a main effect of distance was observed, with slower reading times for local conditions ($\beta = 0.06$, $t = 2.2$, $p < 0.05$), and we also observed an interaction of explicitness and distance ($\beta = 0.09$, $t = 2.4$, $p < 0.05$). However, this interaction was not in the direction predicted by the standard theory; rather than implicitness requiring costly inference in the pragmatically-mediated remote condition, we observed a cost of implicitness in the local conditions. Pairwise comparisons show that the implicit local condition was significantly slower than the explicit local condition ($\beta = 0.08$, $t = 2.4$, $p < 0.05$), but no differences in reading times were observed for implicit and explicit remote conditions ($p > 0.2$). A similar pattern was observed at the subsequent verb (region 7), with a main effect of distance ($\beta = 0.06$, $t = 2.1$, $p < 0.05$) and a marginal interaction between explicitness and distance ($\beta = 0.06$, $t = 1.7$, $p = 0.09$). At the region following the verb (region 8), no main effects were observed, but we continued to observe an interaction between explicitness and distance, in the same direction ($\beta = 0.08$, $t = 2.1$, $p < 0.05$). No other significant main or interaction effects were observed in the regions of analysis.

Discussion

The standard theory requires different mechanisms for resolving local and remote control (binding vs. contextual interpretation) and the pragmatic theory proposes the same mechanism (contextual interpretation). Hence, the standard theory predicts differences in the processing of local and remote control, while the pragmatic theory does not. As noted above, these differences might take several forms.

First, Mauner et al. (1995) suggest that syntactic resolution of PRO should have the same processing cost whether the antecedent is explicit or implicit, but that pragmatic resolution of PRO should require costly inference when the antecedent is implicit. According to these assumptions, if local control reflects a syntactically-mediated dependency and remote control reflects a pragmatically-mediated dependency, an interaction between distance and explicitness should be observed such that explicitness has an effect on processing in remote control but not in local control. In Experiment 2 we observed a significant interaction between distance and explicitness at the reason clause, but in the opposite direction: the implicit condition appeared to be costly in the *local* cases and not the remote cases. This pattern is not predicted by either the standard theory or the pragmatic theory, and it also differs from Mauner et al.'s earlier results in which no cost of explicitness was observed for local control of reason clauses.

We hypothesize that the slowdown in the implicit local condition may not reflect the cost of implicitness *per se*, but may rather have been due to the time course of processes elicited by the current materials. We assume that constructing the syntactic and thematic representation associated with the passive may take time (Chow et al., 2015). If this process is not complete by the time the reason clause is encountered, which may have been the case in the local conditions, resolution of PRO will not be immediately possible, causing temporary processing difficulty. However, in the remote conditions, the extra intervening material (*The reason was*) may have acted as a "buffer," providing enough time for the passive sentence to be fully processed by the time the reason clause was encountered. Experiments 3 and 4 include such a buffer in both local and remote conditions and show that this eliminates the cost of implicit control in the local conditions.

Second, the standard theory assumes that local and remote control are mediated by different mechanisms (contextual interpretation and syntactic binding, respectively), and this difference in representational encoding could be reflected online in behavioral measures such as reading time as differences between local and remote configurations that are

independent of explicitness—in other words, a main effect of distance.

In Experiment 2, we observed a significant main effect of distance at the infinitival and the verb in the reason clause, with faster reading times in remote conditions. That is, readers appear to be faster to process a reason clause that is syntactically independent of its target clause as compared to a reason clause whose target clause is a syntactic co-dependent within the same sentence. We refer to this as *the remote speed-up effect* of Experiment 2. These results are thus consistent with the predictions of the standard theory: contextual interpretation of PRO in a reason clause is less costly than syntactic binding.

However, there are also several alternative explanations of the remote speed-up effect, which we explore in Experiments 3 and 4. First, in remote conditions the presence of *the reason was* provided readers with extra time to process the target clause. If target clause was not fully interpreted when the reason clause appeared, processing difficulty would naturally ensue. Second, this phrase also provided readers with a cue that an infinitival reason clause may be on its way. This might facilitate resolution of PRO, and lead to faster reading times in the remote conditions. Experiment 3 tested the first possibility by adding a temporal modifier to the target clause in local conditions to better match the time course with the remote conditions. Experiment 4 tested the second possibility by adding a cue to the reason clause in the local condition (*just in order*) to parallel *the reason was* in the remote conditions.

Experiment 3

Experiment 3 used the same design as Experiment 2 but added an intervening temporal modifier to the local conditions in order to match the distance between the target clause and the reason clause across local and remote conditions. If the overall slowdown for local conditions and the cost of implicitness for local conditions in Experiment 2 were because the target clause had not been fully processed by the time the reason clause was encountered, these differences should be eliminated in Experiment 3.

Methods and Materials

Participants

Participants were 39 native speakers of English from the University of Maryland community, none of whom had taken part in the previous experiments. They either received credit in an introductory linguistics course, or were compensated $10. All participants were naïve to the purpose of the experiment. The self-paced reading task lasted for approximately 30 min.

Materials

Twenty-four sets of four target sentences again varied in a 2 × 2 design with the factors *explicitness* and *distance*. However, to match the amount of time available for processing between the verbs in the local and remote conditions, buffer material was included in the local target clauses, usually a temporal modifier like 3 weeks ago, as shown in **Table 5**. The same fillers and comprehension questions were used as in the earlier experiments. An example set of materials is provided in **Table 5**.

Procedure

The procedure for Experiment 3 was the same as the procedure for Experiments 1 and 2.

Data analysis

The minimum comprehension question accuracy required for inclusion of a participant's data in the analysis was 80%. Data from three participants were excluded due to comprehension question inaccuracy, resulting in a final dataset of 36 participants.

Statistical analysis was the same as described above for Experiment 2, except that because of the additional material in the local conditions, all nine regions of interest could now be analyzed with the full model including both distance and explicitness. Reading times above 2000 ms were again excluded, resulting in a loss of 0.23% of the total data.

Results

Mean comprehension question accuracy for experimental stimuli across participants and items was 91% (range across conditions: 89–92%), suggesting that participants were successful in comprehending the main experimental stimuli.

Logged reading times are plotted in **Figure 3**, with significant effects summarized in **Table 6**. The reason clause began in region 6, and we observed no significant main or interaction effects in preceding regions 1–4. However, region 5, just prior to the infinitival (*was* in the remote conditions and the last word of the temporal modifier in the remote conditions) showed a strong main effect of distance ($\beta = 0.1$, $t = 3.7$, $p < 0.001$) due to faster reading times in remote conditions, and a marginal main effect of explicitness ($\beta = 0.05$, $t = 1.9$, $p = 0.06$) that appeared to be due to slower reading times in the explicit local condition.

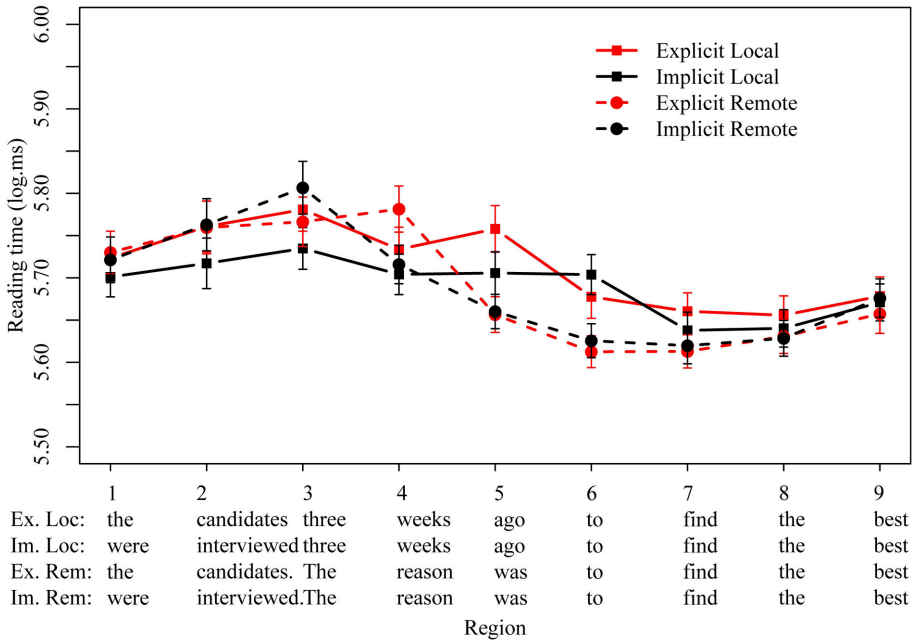

FIGURE 3 | Mean logged reading times (ms) for all four conditions in regions of interest in Experiment 3.

TABLE 6 | Experiment 3 results.

Region	Factors	Estimate	S.E.	*t*-value	*p*-value
	Explicitness	−0.054	0.028	−1.9	0.058
5	Distance	−0.104	0.028	−3.67	0.0003
ago/was	Explicitness × Distance	0.057	0.04	1.44	0.151
	Explicitness	0.026	0.026	1	0.318
6	Distance	0.065	0.026	−2.5	0.013
to	Explicitness × Distance	−0.013	0.037	−0.35	0.724
	Explicitness	−0.023	0.025	−0.95	0.344
7	Distance	−0.048	0.025	−1.95	0.051
find	Explicitness × Distance	0.03	0.035	0.86	0.388

At the infinitival *to* and the subsequent verb (region 6–7), we see no sign of any main effects or interactions involving explicitness, but we again observe faster reading times in the remote conditions (region 6: $\beta = 0.07$, $t = 2.5$, $p < 0.05$, region 7: $\beta = 0.05$, $t = 2.0$, $p = 0.05$). Importantly, we observe no effect of implicitness within the local conditions, in contrast with Experiment 2. That is, in both local and remote conditions, readers are just as fast to process reason clauses whether they follow a short passive or an active target clause.

Discussion

Experiment 3 was designed to better understand two differences between local and remote conditions that were observed in Experiment 2. First, Experiment 2 showed an interaction between distance and explicitness at the reason clause, such that the local conditions showed a cost of implicitness but the remote conditions did not. Because this pattern was predicted by neither the standard theory nor the pragmatic theory, we suspected that it reflected the fact that the passive had not been fully processed by the time the reason clause appeared in the local condition. The results of Experiment 3 are consistent with this hypothesis, as when a temporal modifier was added as a "buffer" between the target clause and the reason clause, no cost of implicitness was observed at the reason clause in the local conditions. This result is thus in keeping with earlier findings concerning local control (Mauner et al., 1995).

Importantly, neither Experiment 2 nor Experiment 3 showed any evidence of one possible pattern of processing differences between local and remote control that might have been predicted by the standard theory. If, as suggested by Mauner et al. (1995), resolving control when the antecedent is implicit requires costly inference when control is pragmatically mediated but not when it is syntactically mediated, then the standard theory would predict a cost of implicitness for remote control and not for local control. This prediction is not borne out by the current results, which show no sign of processing cost for implicitness in the remote control conditions.

In Experiment 2 we also observed overall faster reading times at the reason clause in remote control compared to local control. This pattern would also be consistent with the standard theory if the processes involved in resolving the pragmatic dependency are faster or less effortful than the processes involved in resolving the syntactic dependency. However, this pattern could also have simply been due to the fact that the extra intervening material between the target and reason clause in the remote conditions

(*the reason was*) might have provided more time to fully process the target clause.

The results of Experiment 3 appear to argue against this alternative explanation, because when we control for timing between the local and remote conditions, we continue to observe a strong effect of distance in the reason clause, once again with faster reading times in remote as compared to local reason clauses. However, we also noted another alternative explanation for the facilitated processing of remote control observed here, which is that the content of the intervening material in *the reason was* provided a predictive semantic cue for the upcoming infinitival reason clause. The temporal modifier included in the local conditions in Experiment 3 provided additional processing time, but did not include this kind of semantic cue. In support of this explanation, in Experiment 3 significantly longer reading times were also observed for local relative to remote conditions in the region immediately prior to the reason clause. This early effect cannot be driven by control *per se*, but could be explained if the predictability of *the reason was* sped up reaction times in the remote condition relative to the less predictable temporal modifier (e.g., 3 weeks ago) in the local condition. Experiment 4 was designed to address this remaining discrepancy by making the material immediately preceding the reason clause equally predictable across conditions.

Experiment 4

Experiment 4 used the same design as Experiments 2 and 3 but used the phrase *just in order to* in the local conditions such that both local and remote conditions contained a semantic cue that could be used to predict or prepare for the upcoming reason clause. If the faster reading times in the remote conditions observed in Experiments 2 and 3 were due to the presence of the semantic cue *The reason was*, this difference in processing time should be eliminated in Experiment 4.

Methods

Participants

Participants were 38 native speakers of English from the University of Maryland community, none of whom had taken part in the previous experiments. They received credit in an introductory linguistics course for participating. All participants were naïve to the purpose of the experiment until after participating, when an explanation was provided. The self-paced reading task lasted for approximately 30 min. The task was performed as part of a 1 h session involving an unrelated experiment.

Materials

Twenty-four sets of four target sentences again varied in a 2 × 2 design with the factors *explicitness* and *distance*. However, we included *just in order* in the local conditions in Experiment 4 to match not only the time course, but also the predictiveness of the upcoming reason clause in remote and local conditions. The same fillers and comprehension questions were used as in the earlier experiments. An example set of materials is provided in **Table 7**.

Procedure

The procedure for Experiment 4 was the same as that described above.

Data analysis

The minimum comprehension question accuracy required for inclusion of a participant's data in the analysis was 80%. Data from one participant were excluded due to comprehension question inaccuracy. Data from one participant who was not a native speaker of English were also excluded.

Statistical analysis was the same as described above for Experiment 3. Reading times above 2000 ms were excluded, resulting in a loss of 0.28% of the total data.

Results

Mean comprehension question accuracy for experimental stimuli across participants and items was 93% (range 92–95%), suggesting that participants were successful in comprehending the main experimental stimuli.

Logged reading times are plotted in **Figure 4**, with significant effects summarized in **Table 8**. In the regions preceding the reason clause (1–5) we observed no significant differences except for a main effect of distance due to slower reading times in the remote conditions in region 3 ($\beta = 0.1$, $t = 3.1$, $p < 0.01$), which corresponded to the sentence-initial determiner *the* in remote conditions and *just* in the same region in local conditions. This difference may be associated with the presence of the sentence boundary in the remote conditions.

No other regions showed a significant effect of distance. In particular, at the infinitival *to* and the verb in the reason clause (regions 6–7), we again observed no sign of any main effects or interactions between distance and implicitness. Reading times were numerically faster in remote vs. local conditions in regions

TABLE 7 | Experiment 4 materials.

6–9 (*to find the best*). However, in Experiment 4, these differences were small and unreliable, eliciting only a marginal effect of distance in region 7 ($\beta = 0.04$, $t = 1.8$, $p \leq 0.07$; all other regions $p = 0.2$)[7].

Discussion

Experiment 4 examined whether processing differences would be observed in the resolution of reason clauses in local and remote control configurations when both local and remote conditions included a semantic cue for the upcoming reason clause. As the remote conditions necessarily include such a cue in the phrase *the reason was*, in Experiment 4 we included the phrase *just in order* in the local conditions to balance both the distance between the target and the reason clause as well as the presence of a semantic cue for the upcoming reason clause across conditions. Controlling for both timing and predictiveness in this way, we observe no reliable differences in reading times in the reason clause as an effect of whether its target is local or remote, although we continue to observe a trend in this direction. This suggests that much of the "remote speed-up" effect that was observed in Experiments 2 and 3 was due to differences in the extent to which the upcoming reason clause was cued by the prior context, rather than differences between the local and remote configurations in the difficulty of resolving the reason clause.

Because the standard theory proposes different mechanisms for resolving local and remote control (binding vs. contextual interpretation), it predicts differences in the processing of these two configurations; but the pragmatic theory, which proposes the same mechanism (contextual interpretation), does not. In Experiment 4 we observe no such differences in the effect of explicitness on processing of remote vs. local control as reflected in reading times, and no effect of distance in the reason clause. Therefore, to the extent that differences in representation should be reflected as differences in constructing such a representation in online processing, the absence of such differences in Experiment 4 raise a potential challenge for the standard theorist. As we discuss in more detail below, several responses are possible on behalf of the standard theory; it could be that reading times in particular are not a sensitive enough measure to detect differences between local and remote control, or that processing cost more generally does not index whether a dependency is semantically or pragmatically mediated. To the extent that either of these responses are adopted, however, they undermine some earlier arguments in favor of the standard theory.

[7]In Experiment 3, we observed a slow-down in reading times at the first word in the second sentence ("The") in remote conditions, while the same effect did not obtain in Experiment 4. Hence, as a reviewer pointed out, it is precisely when we do not see sentence-boundary effects that we find no advantage for remote control, as in Experiment 4. Whether this is due to a relationship between sentence-boundary effects and implicit control, or some incidental difference between the two experiments, we leave for future investigation.

GENERAL DISCUSSION

In four self-paced reading time experiments, we examined the processing of infinitival reason clauses, in contexts that favor anaphoric construals of PRO, their understood subject. In our materials, the likely referent for PRO is always the individual who satisfies the deep-S role for the preceding target clause; for example the interviewer when the target clause has *interview* as its verb. We compared explicit control, where this role is linked to an audible noun phrase, to implicit control, where it is not. In implicit conditions, the target clause is a short passive. Already Mauner et al. (1995) made this comparison in the local configuration, where the reason and target clauses are syntactically dependent. Ours is the first study to do this for the remote configuration as well, where the two are in separate sentences. What we found, in summary, is this. First, reading times at the reason clause were not longer when the antecedent was implicit relative to when it was explicit, once we controlled the length and content of what intervenes between target and reason clauses across conditions, as in Experiment 4. For local configurations, this agrees with the findings of Mauner and colleagues. That study too found no significant differences in relevant regions between implicit and explicit control, on measures that did distinguish both from cases where, offline, control is judged unacceptable. Our new finding is that no such differences are observed in the inter-sentential remote configuration either, where one might have thought that a costly pragmatic inferencing operation would be required. Second, we also did not observe significant main effects of distance between local and remote control when both the length and the content of intervening material were matched.

Our results bear on a question of grammatical representation. When the understood referent of PRO in a reason clause is an individual mentioned or implied by the target clause, what sort of relation does PRO have to that clause? Is it syntactically linked to an argument there? Or is this a kind of discourse anaphora, with PRO here ranging over a specially restricted domain? On the standard theory (Roeper, 1987), the same relation underlies both explicit and implicit control. This much is consistent with our results, and with those in Mauner et al. (1995), none of which show any relevant effects of the difference. However, the standard theory also takes the common relation to be syntactic, a binding relation between PRO and an argument in the target clause. Such a syntactic link is possible in the local configuration, since the reason clause is adjoined to the target clause. But it is not possible in the remote configuration, since the two clauses are independent. Therefore, if reason control is syntactic when local, as the standard theory says, it must have a different analysis when remote; and if it has the same analysis either way, it cannot be syntactic, and must in both cases be mediated by discourse. Thus, given the standard theory of reason control, we expect a main effect of distance, local vs. remote, on some online measure, while on a uniformly pragmatic theory we do not. On our reading-time measure we found no such effect, not once we controlled for both timing and predictiveness across conditions, as in our Experiment 4. Thus, our results fail to confirm the standard theory.

More importantly, the current results subvert the earlier argument for the standard theory from processing measures. In past work, both the self-paced-reading-time and the stop-making-sense task showed no relevant difference between implicit and explicit control in local configurations (Mauner et al., 1995), while processing costs were observed in baseline conditions (intransitives and middles) in which control of reason clauses appears unacceptable. These data were taken as evidence that both implicit and explicit control were syntactic dependencies. We agree that a similar processing profile may suggest that these are dependencies of the same sort. But the current work illustrates that these prior data cannot be taken to argue that both are syntactic dependencies, since remote control cannot be syntactic, and there too our measures do not distinguish implicit from explicit control.

While these results thus remove a previous argument in favor of the standard theory, they challenge the standard theory directly only if we think that self-paced reading times are sensitive to the difference between syntactic vs. pragmatic anaphora. But as discussed in Section Background, they may not be. Indeed, perhaps these two routes to interpretation are not reliably distinguished by processing cost (see Cunnings et al., 2014, for discussion), or any existing measure of processing. In the latter case there could be no processing evidence for the analysis of control. However, either observation weakens not only our own conclusions, but also the earlier defense of the standard theory. That defense was primarily based on behavioral processing measures (stop-making-sense task and reading times) that were not independently demonstrated to distinguish binding from free anaphora. Hence, our results either provide direct evidence against the standard theory, or undermine earlier arguments in its favor, depending on the evidentiary status of reading times.

Our experiments also highlight the importance of several design factors. Experiment 1 suggested that narrow focus in target clause can increase reading times in the reason clause, a construction whose semantics is sensitive to focus (Dretske, 1972). We believe this makes the long-passive a poor baseline for comparison with implicit control, since normally the *by*-phrase carries narrow focus. Experiments 2 and 3 illustrated the importance of controlling both the length and content of what comes between the target and reason clauses. Reading times for the infinitival verb in the reason clause are slower when it immediately follows the target clause than when it is separated from the target clause by a buffer, either a temporal adjunct in local configurations, or *the reason was* in remote configurations. This may reflect the time it takes to process the passive target clause (Chow et al., 2015). Even with a temporal buffer, reading times were still faster at the infinitive when the buffer is predictive of a reason clause (*the reason was*) than when it is not (*3 days ago*). Yet reading times at the infinitive did not differ significantly between remote and local control in Experiment 4, where we matched the buffers for both length and content, pairing *the reason was* in remote conditions with *just in order* in local conditions.

To finish, let us turn briefly to the issue of implicit arguments. Our results undermine earlier arguments in favor of the standard theory. Although they do not prove an alternative pragmatic

theory correct, they suggest that further investigation of this kind of account would be worthwhile. As we note in the introduction, in a pragmatic theory many of the constraints on control of reason clauses could be captured by a domain condition that is not syntactic but conceptual. Anaphoric uses of PRO in a reason clause denote the individual(s) viewed as responsible for the fact that the reason clause is meant to explain (Farkas, 1988; Landau, 2000; Williams, 2015). This condition is manifest in cases like (10), where PRO finds its antecedent in the surface subject of a passive: the referent of PRO must be viewed as responsible for what happened (Williams, 1974; Zubizaretta, 1982; Roeper, 1987). To be adequate, such a theory would need to say, for example, that the referent of a direct object is never viewed as responsible for the fact expressed by its clause. If it does, a silent argument in passives would play no role in explaining implicit control. Having weakened some of the previous motivation for the standard theory, we suggest that future research ought to explore such pragmatic alternatives in greater detail.

AUTHOR CONTRIBUTIONS

AW and MM designed the experiments. MM and JG implemented the experiments. JG and EL analyzed the data. AW, EL, and MM wrote the paper. All four authors participated in editing and revising the manuscript.

ACKNOWLEDGMENTS

This project was supported in part by NSF IGERT grant #0801465. We wish to thank Aleksandra Fazlipour for her assistance with data collection and preliminary statistical analysis. We also wish to thank many people who have offered helpful comments on earlier versions of this paper. In particular, we thank members of the Cognitive and Neuroscience of Language (CNL) lab at the University of Maryland, participants at the 27th and 28th CUNY Human Sentence Processing conferences and at XPRAG 2015, and audiences at Rutgers University.

Previous psycholinguistics studies have shown that when forming a long distance dependency in online processing, the parser sometimes accepts a sentence even though the required grammatical constraints are only partially met. A mechanistic account of how such errors arise sheds light on both the underlying linguistic representations involved and the processing mechanisms that put such representations together. In the current study, we contrast the negative polarity items (NPI) interference effect, as shown by the acceptance of an ungrammatical sentence like "*The bills that democratic senators have voted for will* ***ever*** *become law*," with the well-known phenomenon of agreement attraction ("*The key to the cabinets are . . .* "). On the surface, these two types of errors look alike and thereby can be explained as being driven by the same source: similarity based memory interference. However, we argue that the linguistic representations involved in NPI licensing are substantially different from those of subject-verb agreement, and therefore the interference effects in each domain potentially arise from distinct sources. In particular, we show that NPI interference at least partially arises from pragmatic inferences. In a self-paced reading study with an acceptability judgment task, we showed NPI interference was modulated by participants' general pragmatic communicative skills, as quantified by the Autism-Spectrum Quotient (AQ, Baron-Cohen et al., 2001), especially in offline tasks. Participants with more autistic traits were actually less prone to the NPI interference effect than those with fewer autistic traits. This result contrasted with agreement attraction conditions, which were not influenced by individual pragmatic skill differences. We also show that different NPI licensors seem to have distinct interference profiles. We discuss two kinds of interference effects for NPI licensing: memory-retrieval based and pragmatically triggered.

Keywords: memory interference, pragmatic inference, individual differences, autistic traits, NPI licensing

INTRODUCTION

During the processing of long distance dependencies, sometimes an element in a sentence that should be irrelevant for constructing a dependency interferes—a phenomenon that has been dubbed the "interference effect." For instance, agreement attraction errors, such as **the key to the cabinets are . . .*, involve an agreement dependency between the singular subject *the key* and the plural copula verb *are* which is ungrammatical because of a number mismatch. However, the intervening noun "*cabinets*" interferes, facilitating the processing of the ungrammatical sentence[1]. Facilitation effects from an interfering element have been shown by various processing measures: such sentences are relatively common in spontaneous production; they can be elicited in controlled laboratory experiments; they are judged to be relatively acceptable; and online reading times on the otherwise problematic verb are generally reduced compared to number mismatched verbs without interference (Bock and Miller, 1991; Bock and Eberhard, 1993; Pearlmutter et al., 1999; Eberhard et al., 2005; Wagers et al., 2009; Dillon et al., 2013).

Such interference effects have been explained as instances of memory interference triggered during cue based memory retrieval. During incremental parsing of a long distance dependency, the tail of the dependency initiates the retrieval of the head in memory. This retrieval is prone to interference when the intermediately preceding material shares certain features with the set of retrieval cues that the parser employs (McElree et al., 2003; Lewis and Vasishth, 2005; Lewis et al., 2006; Wagers et al., 2009). Memory interference can be driven by partially matched morpho-syntactic features, as has been repeatedly shown by agreement attraction errors like the example above, and examples like "*The new executive who oversaw the middle managers were dishonest*" (example from Dillon et al., 2013). In such cases, memory retrieval is initiated in order to search for a plural subject at the plural verb, e.g., "were." Because the search mechanism is content addressable (McElree et al., 2003), it may target any item in memory during the search process, leading to erroneous acceptance of interfering material which bears feature similarity to the correct retrieval target.

[1]Cue similarity does not always lead to facilitation effect. For instance, Van Dyke and Lewis (2003) and Van Dyke and McElree (2006) have shown that cue overload leads to increased processing difficulty. In this paper, we only focus on the facilitatory interference effect.

A large body of the research on interference effects has focused on deriving a thorough mechanistic account of the errors people make in interference situations, as such an account helps in constructing a precise parsing algorithm for long distance dependencies. But the pursuit of a domain-general parsing mechanism has somewhat overshadowed the question of whether or not different kinds of linguistic dependencies should be handled by the same parsing algorithm, and hence whether or not interference arises in the same way across different dependency types. One reasonable hypothesis is that the precise nature of a particular type of linguistic dependency is relevant to explaining differences in how dependencies are processed. In the current study, we tackle the question of whether or not there are dependency-dependent interference effects by looking at a case of interference that seems very much like agreement attraction on the surface, but that may at least partially arise from a different underlying mechanism. The particular type of interference we will discuss appears in the licensing of negative polarity items (NPIs), as in the sentence "**The documentaries that no network TV stations have played during prime time have ever been very controversial*," where the presence of *ever* is illicit. We argue that although such interference may superficially look the same as the subject-verb agreement errors discussed above, there are actually multiple different sources that contribute to NPI interference. In particular, in addition to a memory-retrieval based interference that is similar to agreement interference, there is also a separate rout of pragmatic inferences made at the message level during semantic integration. A sufficient account of NPI interference needs to take into account the close interaction between grammar (e.g., syntax and semantics) and pragmatic inference in sentence processing.

NPI LICENSING AND INTERFERENCE

NPIs are lexical items that need to be licensed in an environment that possesses a particular logical-semantic property. Negation is a cross-linguistically attested licensor for NPIs (as noticed in Klima, 1964). Licensing typically requires the NPI to be in the semantic and syntactic scope (i.e., c-command domain) of negation (Ladusaw, 1979, 1980; Giannakidou, 1998, 2011 for an overview). As shown in (1), the NPIs *any* and *ever* are grammatically licensed when they appear within the scope of negation (1a, b), but they are ungrammatical when there is no negation present (1c, d), or when negation is present, but doesn't c-command the NPI (1e, f).

(1) a. John *didn't* talk *to anybody*.
b. John *hasn't ever* talked to Bill.
*c. John has *ever* talked to Bill.
*d. John talked to *anybody*.
*e. *Anybody didn't* talk to John.
*f. The debate that *nobody* cared about will *ever* end.

Because of their apparent sensitivity to the presence of negation, *any* and *ever* are labeled "negative" polarity items (NPIs)[2], but it must be noted that their distribution, and that of similar NPIs crosslinguistically, is quite broad and includes a vast range of negative and non-negative licensors, including conditionals, modal verbs, generic sentences, questions, the scope of universal quantifiers, comparatives, disjunctions (see Giannakidou, 2011 for detailed overview). Given this broad distribution and the potential differences among NPI classes in English and crosslinguistically, what semantic property unifies licensors as a natural class has been a matter of intense study—and researchers generally agree that NPIs appear in non-veridical environments. Non-veridical environments are (a) negative environments with negation and negative quantifiers (Baker, 1970a; Linebarger, 1980), (b) downward entailing environments (Ladusaw, 1980; Zwarts, 1986, 1996; Hoeksema, 1994; von Fintel, 1999, inter alia), and (c) other non-veridical environments that may not be negative or downward entailing (e.g., modal expressions, questions, imperatives, generic statements; Zwarts, 1995; Giannakidou, 1998, 2006, 2011; Bernardi, 2002). We cannot provide a detailed survey here; but as background for the specific data we address, we discuss licensing by negation and downward entailment (DE) in the next section[3].

In the domain of NPI licensing, an "interference effect" is said to result when an unlicensed NPI becomes more acceptable if a licensor is inserted into the preceding context—but crucially, is *not* in the right structural (c-commanding) position (Drenhaus et al., 2005; Vasishth et al., 2005, 2008). In the example below (examples taken from Drenhaus et al., 2005), the expected contrast obtains between (2a) and (2b); however, there is also a significant difference between the ungrammatical sentences (2b) and (2c). (2c) is judged as "more acceptable" than (2b), even though the licensor *no* doesn't c-command the NPI *ever*, so that it should be unlicensed.

(2) a. **No** man who had a beard was *ever* happy.
*b. A man who had a beard was *ever* happy.
*c. A man who had **no** beard was *ever* happy.

In the (c) example, negation is present but not in a position c-commanding *ever,* as is required for licensing. The NPI *ever* therefore remains unlicensed. In online measures, NPI interference effects have appeared as facilitatory effects (e.g., shorter RTs or smaller ERP amplitudes) on the problematic NPI in the interference condition, as compared to the NPI in the condition with no licensors anywhere in the sentence (Drenhaus et al., 2005; Vasishth et al., 2008; Xiang et al., 2009; Parker et al., 2013).

The interference effect above is on the surface very similar to the memory interference phenomenon introduced earlier

[2]Some NPIs, such as any, seem to obtain so-called *free choice* readings in modal environments and with imperatives, such as *You may talk to any student*, and *Pick any card*!. We won't discuss the free choice use in this paper. The particular NPI *ever* studied in our experiment, does not have a free choice use and it is typically blocked in modal contexts: * *You may ever go to Paris.*

[3]A scalar component has also been posited for some NPIs (Kadmon and Landman, 1993; Krifka, 1995; Lahiri, 1998; Chierchia, 2006), but scalarity doesn't characterize *all* NPIs as a class. There are many non-scalar NPIs (see Giannakidou, 1998, 2011, for a recent overview (Lin, 1996; Giannakidou and Yoon, 2012). And scalar NPIs such as *any* and *ever* do not have only scalar uses (Duffley and Larivée, 2010), and are not morphologically marked as scalar either, i.e., they do not contain scalar markers such as *even* and the like. Whether scalarity plays a role in the interference effect is an open question for future research.

for subject-verb agreement. One account of NPI interference is indeed couched upon retrieval interference due to feature similarity between the retrieval cues and the previously processed linguistic information. Vasishth et al. (2008) argued that the parser uses lexical semantic cues such as [+negative] and syntactic cues such as [+c-command] to retrieve a proper licensor for *ever* from previously processed material in memory. For (2b), no such match is found, and the sentence is determined to be unacceptable. For (2c), however, the quantifier *no* in the embedded subject position partially matches the search criteria: although it doesn't match the syntactic cue [+c-command], it does satisfy the cue [+negative]. During retrieval of a licensor, this partial feature match may boost the activation level of the memory representation of the embedded quantifier *no*, causing it to be more likely to be retrieved once its activation level goes beyond a certain threshold.

Although such an account is plausible, as well as parsimonious, we think it falls short of providing a complete account of NPI interference, because it misses some important distinctions between NPI licensing, on the one hand, and syntactic dependencies such as subject-verb agreement and those involved in relative clauses and cleft constructions, on the other hand. Specifically, while the latter dependencies types involve syntactic relations between lexical items (e.g., a subject and an agreeing verb, or a head noun and a verb in a relative clause), NPI licensing involves not only syntactic conditions (e.g., the c-command requirement on a proper licensor, but also see our remarks in the general discussion about this syntactic condition), but also logical-semantic (e.g., negation, DE, non-veridicality), and pragmatic conditions. Crucially different from subject-verb agreement, pragmatic inferences derived from global semantic interpretation (which traditionally have been considered outside of the grammar proper), can be used to license NPIs (Linebarger, 1980, 1987; Giannakidou, 1998, 2006). We will discuss the pragmatic licensing mechanism in more detail in the next section.

Closely related to the fact that NPI licensing involves multiple mechanisms, there are many different types of licensors other than just the negative determiner *no*, which has been the focus of most of the studies on NPI interference. Interference under the licensor *no* may look superficially similar to subject-verb agreement, because one can identify a [+negative] feature on the licensor, which, when served as a memory retrieval cue, may lead to interference. Whether or not this is indeed the underlying mechanism, or only one of the mechanisms involved, is an empirical question we will address in this paper, but a cue-driven process is at least a logical possibility here. Importantly, when we look at a larger set of licensors, postulating a lexical [+negative] feature becomes untenable for many of them: for instance, with a universal quantifier *every*, focus *only*, conditional *if*, emotive factives like *surprised*, *amazed*, etc. We focus on *only* here, since it can be used as a determiner and therefore constitutes a minimal pair with *no*. We assume that *only* licenses NPIs through a negative exceptive component, since a sentence of the form "[Only NP] VP" entails "[Nobody other than NP] VP" (see the discussion in the section below). But there is little reason to believe that *only* itself contains in its lexical entry a grammatical/syntactic [+negative] feature. Klima (1964) gave syntactic diagnostics for syntactically negative expressions, which include phonologically and morphologically negative expression such as *no*, *none*, *never*, but also negative expressions that are not overtly marked in morphology or phonology as negative, such as *few*, *scarcely*, *hardly*, *seldom*, *rarely*, etc. For example, all of these expressions can be followed by a conjunct with a *neither*-tag, but not by *so*-tag; they may also co-occur in a conjunct with *either*, but not with *too*; etc. We provide some examples below, showing that *only* is not a negative expression under these syntactic diagnostics. Nor are the other non-negative licensors we mentioned above, as the reader may verify.

(3) a. Publishers will usually reject suggestions, and ***no/few/*only/*a few*** writers will accept them, ***either***.
b. Publishers will ***not/hardly/seldom/rarely/*only/*usually*** accept suggestions, and ***neither*** will the writers.

In the absence of a lexically coded [+negative] feature that can trigger a similarity-based interference effect (as with *only*), the question arises whether or not we will still see interference, and, if we do see such an effect, what would account for it. We will address these questions in the current study by examining both the licensors *only* and *no*.

FLEXIBILITY OF LICENSING WITH ENGLISH NPIs: THE ROLE OF PRAGMATIC INFERENCING

It has long been observed that some NPIs become licensed even when no grammatical lexical licensors are present on the surface that contain the required logical-semantic property for licensing. The following examples are largely taken from Linebarger (1987):

(4) a. John kept writing novels *long after* he had *any* reason to believe they would sell.
b. *Exactly four* people in the world would have *ever* read that dissertation: Bill, Mary, Tom, and Ed.
c. Mary was *surprised* there was *any* food left.
d. I am *sorry* that I ever met him.
e. *Only* the students who have *ever* read anything about phrenology attended the lectures. [=117 in Ladusaw (1980)]

In all these examples, there aren't any explicit lexical items that can serve as grammatical licensors, in the sense that they possess the logical property necessary for licensing. Surely, the items *long after*, *exactly four*, *amazed*/*surprised*, and *only* are responsible for the appearance of *any* and *ever*, but they are not logically negative, nor DE, nor non-veridical. Consider the property of negation/DE. DE expressions, as is traditionally stated, allow logical inferences in their scope from a set to a subset. Consider the following entailment relations with negation [examples adapted from Linebarger (1987)].

(5) a. John didn't eat a green vegetable for dinner.
b. John didn't eat kale for dinner.

Kale is a subset of green vegetables. If John didn't eat a green vegetable for dinner (5a), it logically follows that John didn't eat

kale for dinner (5b). The superset-to-subset logical inference is the hallmark of negative and DE expressions. Ladusaw proposed that NPIs appear in the scope of negative and other DE expressions (such as negative quantifier *few*, or the restrictor of universal quantifier *every*). However, none of the examples in (4) contains a DE expression. We show below on this point for "*only*" and "*long after*" [see Linebarger (1987); Atlas (1993); Horn (1996); von Fintel (1999) and Giannakidou (2006) for more discussion that *only* and emotive factive verbs such as *sorry* and *surprise* are not DE in its strict sense].

(6) a. Only Bill went to Greece;
b. Only Bill went to Athens.
(7) a. Bill married Samantha long after he travelled to Europe.
b. Bill married Samantha long after he travelled to France.

We see here that the subset inference from (a) to (b) sentences in (6) and (7) is not licensed with the critical expressions "only" and "long after," and they are therefore *not* logically DE[4].

Faced with many examples of this kind, in which a grammatical licensing mechanism relying on the logical properties of a licensor does not seem to suffice, several researchers have advanced proposals to distinguish a pragmatic licensing mechanism from a grammatical (syntactic/semantic) one. Giannakidou (1998, 2006), for example, talks about two modes of licensing, one semantic, relying on a (c-commanding) grammatical licenser ("direct" licensing), and another, "global pragmatic" licensing ("indirect" licensing) that relies on the availability of a negative inference. In the regular case, NPIs are licensed directly by an expression that bears the required logical-semantic property. However, in the absence of such a grammatical licensor, either the use of an NPI leads to ungrammaticality, or the context enables comprehenders to derive a negative inference pragmatically, which in turn licenses NPIs (see also Baker, 1970a,b; Linebarger, 1987). Such pragmatic inferences have been called "implicatures," and we will refer to them as such from now on[5]. Linebarger (1987) and Giannakidou (2006) have considered *only* as a candidate for pragmatic licensing. The basic intuition there is that the exclusive component in the meaning of *only* is responsible for licensing NPIs (e.g., *Only John ate kale* entails that *Nobody other than John ate kale*). In our recent work (Xiang et al., 2012, 2013), based on ERP evidence, we argued that *only* is a semantic licensor that licenses NPIs through negation in the asserted content (see Atlas, 1993; Horn, 1996, for the semantics of *only*). Although they are different in their specific details, none of these proposals treat *only* as a negative expression that contains a lexically coded [+negative] feature, keeping in line with our discussion in the last section.

It is also crucial to note that, although licensing through global pragmatic reasoning is a possible mode of licensing for many NPIs, not all negative implicatures can be used to make NPIs acceptable (Linebarger, 1987; Horn, 1989, 2002; Giannakidou, 2006). For instance, "*almost*"—though clearly inviting a negative inference (*John almost finished the book* implies that *he did not finish it*)—does *not* license NPIs: **John almost finished anything*[6]. Although the boundary between inferences that can and cannot license NPIs is still an open question, we follow the suggestion in Linebarger (1987) and assume that in order for a derived negative inference to be able to license NPIs, it should be prominent in the sense that the derived proposition warrants the truth of the original proposition. Consider our earlier example with *long after*:

(8) a. John kept writing novels *long after* he had *any* reason to believe they would sell.
b. John kept writing novels even though he didn't have any reason to believe they would sell.

The NPI *any* in (8a) is licensed under the derived negative implicature (8b). There is a very strong inference to (8b) from (8a), and in fact the two are almost semantically equivalent. Most important, if (8b) is true, then it is also true that *John kept writing novels long after he had any reason to believe they would sell*. It seems, then that a "useful" negative inference is one that is semantically close enough to the original proposition. How to formally quantify the notion of "semantic closeness" is an open question and is beyond the scope of the current discussion. What is crucial for current purposes is, first that negative implicatures provide a possible licensing mechanism, at least in English; and second, not all negative implicatures can license NPIs. It is possible that the difference between the "useful" and "useless" inferences is a categorical one, but it is also possible that the two simply occupy different ends of a continuum of pragmatic inferences, on which one finds different degrees of "licensing strength." We will leave this question open. We turn below to the empirical focus of the current paper: the case of NPI interference. We will argue that the interference observed in NPI licensing is at least partially driven by the over-application of the pragmatic licensing mechanism. That is, in cases of NPI interference, comprehenders resort to the pragmatic strategy, i.e., they attempt to use a pragmatic inference, which, however, cannot properly license NPIs. The effect is that such an illicit interference will occasionally boost the acceptability of unlicensed NPIs. The availability of such pragmatic inferences, as we will show, is modulated by individual subjects' pragmatic skills.

INTERFERENCE DRIVEN BY PRAGMATIC INFERENCE

Xiang et al. (2009) argued that the NPI interference effect stems from over-application of a flexible, inference-based licensing

[4]There is ongoing discussion on these expressions. For *only* and *emotive factives*, von Fintel (1999) and Gajewski (2005) analyzed them as Strawson DE, rather than regular DE expressions. Limited by space, we won't discuss further about this possibility, but see theoretical and experimental evidence for problems of this approach in Linebarger (1987), Giannakidou (2006) and Xiang et al. (2012, 2013). We also won't go into further discussion about *long after*, since it is not the focus of this paper, but see Condoravdi (2010) that proposed a DE analysis, and also Krifka (2010) for a discussion.

[5]Although we adopt the term "implicature" here, it should be clear from our discussion that we are aware this concept is still very vague. Not all negative implicatures can license NPIs. The exact grammatical constraints and mechanisms that rule in some "implicatures" but rule out others remain as an open question.

[6]See Horn (2002) for the idea and the negative component in "almost" is "assertorically inert," in contrast to "barely," and hence does not license NPIs.

mechanism that is already in place in the grammar. One possibility, as suggested in Xiang et al. (2009), is that, while parsing a statement like "*the bills that no democratic senators have voted for will* P" ("P" stands for an upcoming predicate), people generate a negative inference about a contrasting set of referents "*the bills that democratic senators HAVE voted for will NOT have the same property P*" on some proportion of trials. Note that such an inference is not logically valid, nor can it be derived from any proper grammatical device. But the particular construction involved in NPI interference effect, i.e., relative clauses, may be responsible for triggering such negative inferences. It is known that restrictive modifiers generally invite inferences about a contrastive set of referents pragmatically (Altmann and Steedman, 1988; Tanenhaus et al., 1995; Sedivy et al., 1999). It has been shown that people are very sensitive to the pragmatic cues of restrictive modifiers: restrictive modifiers perform a discourse function to distinguish the set of referents that possess the property described by the modifier and the set that do not. Such discourse principles are active in parsing because interlocutors engaged in a discourse interaction adhere to the general communicative principle that the exchange of information should be as informative as it needs to be (Grice, maxim of quantity, 1975). To our knowledge, almost all studies on NPI interference so far in the literature have used restrictive relative clauses to host an "intruding" licensor. It is plausible then to argue that the choice of this particular structure facilitates the triggering of negative inferences about a contrasting set.

Although pragmatic inferences driven by communicative pressure are very common in natural language communication, they in general are not qualified to actually license NPIs. If we adopt our rudimentary notion of "semantic closeness" in the last section, the negative inferences made in the interference scenarios are not "close" enough to the original propositions. Consider again the interference example "*The bills that no democratic senators have voted for will become law*." The potential negative inference "*The bills that democratic senators have voted for will NOT become law*" does not have similar enough truth-conditions to the original proposition. Not being semantically close, the negative inference is too weak to render NPIs totally acceptable. But since pragmatic inferences may in principle license NPIs in English, comprehenders may overapply this mechanism and use it in some proportion of the ungrammatical trials, so that negative inferences that are normally not useful for NPI licensing have a facilitating effect on acceptability.

If the interference effect with NPIs is due to over-application of pragmatic inferences, in which subjects extract a negative implicature from the given context, we predict that NPI interference effects should be modulated by individual participants' ability to extract pragmatic inferences from context. Different individuals may possess varying abilities to carry out complex pragmatic reasoning, and we hypothesize that participants who are better at pragmatic reasoning will be more prone to an NPI interference effects, since it is more likely for these participants to successfully construct negative inferences from context, making them more vulnerable to over-applying the pragmatic licensing mechanism. On the other hand, participants who are less skilled in pragmatic inference will generate fewer inferences, and these participants will be more likely to avoid the interference effect.

Furthermore, in the current study, we compare NPI interference with a purely syntactic dependency: subject-verb agreement. We predict that, if the correlation between pragmatic skills and interference in NPI licensing is driven by over-application of a pragmatic-licensing mechanism that is specific to NPIs, no similar correlation should hold between the magnitude of the agreement interference (attraction) effect and individual pragmatic differences, despite the superficial similarity between NPI interference and agreement attraction errors. We test these predictions in the current study. Individual pragmatic skills of our participants were assessed and quantified by the autism-spectrum quotient (AQ, Baron-Cohen et al., 2001), which we turn to now.

THE AUTISM-SPECTRUM QUOTIENT

Pragmatic language problems are among some of the defining characteristics of children and adults with autism (Bishop, 1989; Tager-Flusberg et al., 2005). For example, their linguistic behavior may often consist in inappropriate comments; and they may have difficulty comprehending jokes, sarcasm, and indirect requests (Happé, 1993; Ozonoff and Miller, 1996; Wang et al., 2006). However, it is increasingly recognized that autistic traits are likely to be present on a continuum among the general population, and people who are diagnosed as autistic simply represent one end of this continuum. This raises the possibility that even among the neurotypical population, there exist individual pragmatic differences associated with individual autistic traits. The AQ (Baron-Cohen et al., 2001) assesses the extent of autistic traits that neurotypical individuals possess. There are a total of 50 questions, divided into 5 subscales, each with 10 statements, to which the subject must reply with one of the choices: "Definitely agree," "Slightly agree," "Slightly disagree," or "Definitely disagree." The 5 subsets of questions are designed to tap into five different cognitive functions that have been found to be important when characterizing autistic behavior. The five subscales and a corresponding example item are: social skills (e.g., "I prefer to do things with others rather than on my own."); communication (e.g., "Other people frequently tell me that what I've said is impolite, even though I think it is polite."); attention to detail (e.g., "I often notice small sounds when others do not."); imagination (e.g., "If I try to imagine something, I find it very easy to create a picture in my mind."); attention switching (e.g., "I prefer to do things the same way over and over again"). Half of the questions are designed to elicit an answer of "definitely agree" or "slightly agree"; and the other half, "definitely disagree" or "slightly disagree." Baron-Cohen et al. (2001) provide scoring guidelines. Higher scores indicate more association with autistic traits.

There is an increasing number of studies that document the correlation between AQ (or AQ subscale) scores and processing in certain specific linguistic domains among the neurotypical population (Stewart and Ota, 2008; Nieuwland et al., 2010; Yu, 2010). Particularly relevant for current purposes, the communication and social skills subscales have been linked to pragmatic language comprehension; in particular, the processing of scalar implicatures (Nieuwland et al., 2010; Sikos et al., 2013) and

perspective taking (Grodner et al., 2012). For example, Nieuwland et al. (2010) showed that when computing scalar implicatures (e.g., *some* implies *not all*), participants' ability to generate scalar implicatures online was significantly correlated with their communication subscale scores (CS scores). In particular, participants with better communication skills (i.e., lower CS scores) were more likely to access the scalar implicature interpretation of a sentence like "*some elephants have trunks*," and consequently detect the anomaly of under-informativity.

The growing body of work that shows a correlation between AQ scores and pragmatic language skills makes the AQ a suitable tool for the current study to probe the underlying differences between NPI and subject-verb agreement dependencies. Admittedly, such a correlation only provides a classificatory diagnostic, rather than an explanation of the mechanisms underlying pragmatic reasoning, since it is not yet clear how the communicative and social skills measured in the AQ are recruited in language comprehension. Although the exact nature of the link between extra-linguistic skills and linguistic pragmatic reasoning is not well-understood, the link itself is nevertheless supported by empirical evidence, suggesting that the same cognitive mechanisms may be shared between the two types of tasks. Thus, the AQ provides us with a way to operationalize individual differences in pragmatic reasoning.

CURRENT EXPERIMENT

METHOD

Materials

There are two types of target items in this study: NPI and subject-verb agreement. **Table 1** gives an example of each type. For the NPI materials, there are three basic types of conditions. In the ***Licensed*** conditions (9a and 9b), the NPI *ever* is licensed by a grammatical licensor. In the ***Interference*** conditions (9c and 9d), *ever* is not licensed properly: even though there are licensors (*no* and *only* again) in the same context, they are not in a syntactically c-commanding position. Finally, the ***Plain Unlicensed*** conditions contain unlicensed NPIs with no potential licensors in the preceding context.

Table 1 | Example stimuli.

(9) NPI	
a/c Licensed	***No***/*only* documentaries that the network TV stations have played during prime time have ***ever*** been very controversial.
b/d Interference	The documentaries that ***no***/***only*** network TV stations have played during prime time have ***ever*** been very controversial.
e Plain Unlicensed	The documentaries that the network TV stations have played during prime time have ***ever*** been very popular.
(10) AGREEMENT	
a Grammatical	The ***receptionist*** who the ***boss*** depends on never ***fails*** to do a stellar job.
b Interference	The ***receptionist*** who the ***bosses*** depend on never ***fail*** to do a stellar job.
c Plain Ungrammatical	The ***receptionist*** who the ***boss*** depends on never ***fail*** to do a stellar job.

For the Licensed and the Interference conditions, we looked at the two licensors *no* and *only* in this study to test the generality of previously observed interference effects. *Only* is different from *no* in at least two ways: first, as discussed earlier, *only* does not contain a [+negative] feature; second, *only* is much less frequent than *no* as a licensor (Xiang et al., 2009). This raises the question whether or not interference will arise for *only*, and, if so, whether or not the same account should apply to both licensors.

The set of agreement items (10a–c) was created using the same design. In the ***Grammatical*** condition, the main verb agrees with the matrix subject (*the receptionist*) in its singular number. In addition, the embedded subject (*the boss*) is also singular, creating no interference. In the ***Interference*** condition, the matrix verb fails to agree with the matrix subject, since the matrix subject is singular whereas the verb is plural. However, the intervening embedded subject also carries plural number, and hence may be incorrectly accepted as being in an agreement relation with the main verb. Finally in the ***Plain Ungrammatical*** condition, the main verb fails to agree correctly with the singular matrix subject, but the embedded subject is also singular, mismatching the main verb.

There were 60 sets of the NPI items, 40 sets of the agreement items, as well as 38 extra fillers. The items were distributed into multiple lists using a Latin square design, such that no participant was presented with more than one condition from the same item set.

Participants and procedure

Ninty-two native English speakers (mean age = 20, *sd* = 3.2, 52 female, 40 male) from the University of Chicago campus and surrounding area participated in the study for $10 payment or course credit. Each participant finished a self-paced reading task and also completed an AQ questionnaire (see below). The self-paced reading task was presented using the Linger software (Doug Rohde, MIT). Participants read through each sentence word by word at their own pace. After the last word of each sentence, a question appeared that said: "Is this acceptable?" After participants pressed one of the two answer keys (Y or N) on the keyboard, they went on to the next trial. Practice trials were provided before the experimental session to familiarize participants with the task. Each subject also completed an AQ questionnaire either before or after they completed the self-paced reading task (in a random order).

DATA ANALYSIS AND RESULTS

Among the 92 participants, one did not finish the AQ questionnaire, and his data was not included in any of the analyses below. Three additional participants were excluded from the analysis due to very low overall accuracy across the whole experimental session (<50% correct). For the rest of the 88 participants, we analyzed their acceptance rate results and their online reading times at the critical word *ever*. The grand average results are presented in **Table 2**.

For the data analysis, we will present results from mixed effects logistic regression models on the acceptance rate data and results

Table 2 | Average acceptance rate and RTs on the critical word, presented separately for the NPI and the agreement items (with *sd* in the parenthesis).

	NPI Licensing				
	***No*-Licensed**	***No*-interference**	***Only*-Licensed**	***Only*-interference**	**Plain unlicensed**
Acceptance rate	0.87 (0.16)	0.25 (0.30)	0.81 (0.17)	0.27 (0.32)	0.16 (0.27)
RT at the CW (ms)	421 (114)	439 (120)	420 (120)	453 (146)	473 (155)
	Agreement				
	Grammatical	**Interference**	**Plain ungrammatical**		
Acceptance rate	0.92 (0.18)	0.28 (0.23)	0.12 (0.17)		
RT at the CW (ms)	463 (125)	509 (169)	547 (202)		

from mixed effects linear regression models on the reading times (Baayen et al., 2008). The models were constructed using the *lmer* function in the lme4 package in R (Bates et al., 2012). Separate analyses were carried out for each subset of the target materials (i.e., NPIs and agreement materials). All models reported here are maximal models that have converged (Barr et al., 2013). For the mixed effects models, main interest of comparisons were set up as contrasts with Helmert coding (Venables and Ripley, 1999; Vasishth and Broe, 2011; Vasishth and Drenhaus, 2011), and they were included in the mixed effects models as fixed effect predictors (see below). Since the CS from the AQ questionnaire was the major subscale that has been shown to reflect speakers' pragmatic reasoning abilities in language processing (Nieuwland et al., 2010; Sikos et al., 2013), we will mainly focus on this subscale of the AQ[7]. Each participant's CS score was entered into the mixed effects models as an additional fixed effect predictor. Random effect structure included random intercepts for subjects and items, as well as random slopes of the fixed predictors. Before constructing the models, reading times longer than 2000 ms were removed, and all reading times were log-transformed.

NPI licensing

Acceptance rate. The averaged acceptance rate of each condition is presented in **Table 2**. As expected, the two licensed grammatical conditions (9a and 9c) have the highest acceptance rate (0.87 and 0.81), the unlicensed ungrammatical condition (9e) has the lowest acceptance rate (0.16). Critically, the interference conditions (9b and 9d) were accepted more often than the non-interference ungrammatical one (0.25 and 0.27), manifesting a standard interference effect.

We first analyzed all the data together, using a mixed effects logistic model. We defined three orthogonal contrasts: the first contrast examined the grammaticality effect (***Grammaticality***), in which the licensed grammatical conditions were contrasted with the ungrammatical conditions (i.e., *a, c* vs. *b, d, e*,); the second contrast examined the interference effect (***Interference***), in which the interference ungrammatical conditions *b* and *d* were contrasted with the unlicensed ungrammatical condition *e* (*b, d* vs. *e*); in the third contrast (***Licensor***) the two types of licensors were compared (*a, b* vs. *c, d*). These three contrasts were entered into the mixed effects model as fixed effect predictors. In addition, we included each participant's CS scores from the Autism Quotient as another fixed effect predictor in the model. Among the 88 participants included in this analysis, the minimum CS score was 0 and the maximum was 10, with a mean of 3.1 (median 3, and standard derivation 2.2). For the random effect structure, we included random intercepts for both subjects and items, as well as random slopes of the three user-defined contrasts above. The model output is presented in **Table 3** below:

Table 3 | NPI licensing acceptance rate: fixed effects from the mixed effect logistic model for the overall data.

	Estimate	**Std. Error**	***z* value**	***Pr*(>|*z*|)**
Grammaticality	5.08	0.66	7.74	9.63E-15***
CSscore	−0.11	0.08	−1.36	0.18
Interference	1.30	0.22	5.79	6.97E-09***

CSscore:Inter:Licensor	0.06	0.21	0.27	0.79

*lmer[acceptance ~ gram * CSscore + interfence * CSscore + licensor * CSscore + licensor:interference + licensor:interference:CSscore + (1 + gram + interference + licensor|subj) + (1 + gram + interference + licensor|item), data = dataframe, family = "binomial*[8]*"]. *p < 0.05; ***p < 0.001.*

[7]Among the other subscales, social skill showed a very similar effect as CS. Other subscales did not show any effect. We report the interactions between these sub-scales and other fixed effects in the appendix.

[8]The model in **Table 3** did not include all the interaction terms between the three user-defined contrasts. Note that the interaction between Grammaticality and Interference is irrelevant, since there is no interference to start with on the grammatical conditions (i.e., interference conditions are themselves all ungrammatical). For the interaction between Licensor and Grammaticality/Interference, since our experimental design is not a full 2 × 3 factorial design (i.e., there is only one plain unlicensed condition in **Table 1**), not all possible interaction combinations are possible. Therefore, we only included Licensor:Interference in the regression formula, which is essentially the same as the Licensor:Grammaticality interaction.

Not surprisingly, the model revealed a significant effect for both Grammaticality and Interference. What is crucial, is that there is a significant interaction between the effect of Interference and CS scores, indicating that the difference between the interference condition on the one hand, and the plain unlicensed condition on the other, is affected by participants' general pragmatic skills assessed via their CS scores. In addition, there is also an effect of Licensor, suggesting a difference between the *no* and *only* conditions.

The effect of licensor type

The data from licensor *no* and *only* are plotted separately in **Figure 1**. The unlicensed condition is shared by the two licensor groups (i.e., condition *e* in **Table 1**).

Paired comparisons between conditions showed that sentences licensed under *no* were accepted more often than those licensed under *only* (condition *a* vs. *c* in **Table 1**, $p < 0.001$); but the interference condition under *no* is not different from the interference condition under *only* (condition *b* vs. *d*, $p > 0.2$). Therefore, the effect of Licensor observed in **Table 3** was mainly driven by the grammatical conditions: subjects were slightly more resistant in accepting *only* as a grammatical licensor. We will come back to this observation in the general discussion.

The Interference-by-CS-scores interaction

Our model showed a robust interaction between the Interference effect and CS scores. We further discuss what this interaction entails in this section. Since our model revealed no interaction between CS scores and licensor type (i.e., neither three-way nor two-way interactions), we do not expect the effect of CS scores on interference to be conditioned by licensor type. For the completeness of our presentation, however, we present results from *no* and *only* separately.

In the analysis of licensor *no*, we only present the three relevant conditions in **Table 1**: conditions 9*a*, *b*, and *e*. The mixed effects model was constructed largely in the same way as before, except that only two contrasts were defined as fixed effect predictors: ***Grammaticality***, which contrasted the grammatical condition 9*a* with the other two ungrammatical conditions (i.e., *a* vs. *b* and *e*); and ***Interference***, which compared the interference ungrammatical condition 9*b* with the unlicensed ungrammatical condition *e* (*b* vs. *e*). For *only*, the three relevant conditions were 9*c*, *d*, and *e* in **Table 1**, and the two contrasts were defined as ***Grammaticality*** (*c* vs. *d*, *e*) and ***Interference*** (*d* vs. *e*). The model results for the fixed effects are presented in **Table 4**.

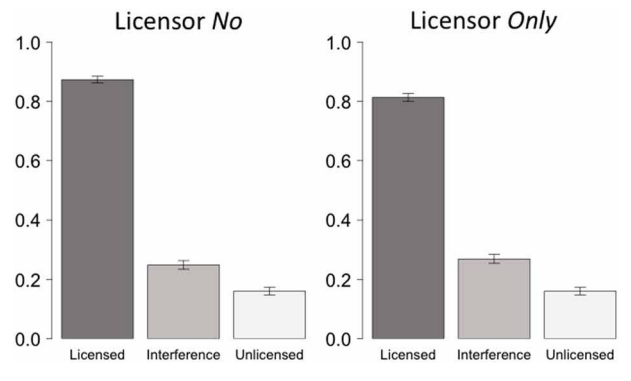

FIGURE 1 | Acceptance rate for the two different licensors.

As expected, both the Grammaticality effect and the Interference effect are highly significant, and the interaction between Interference and CS scores is also significant. To better understand the interaction between CS scores and the interference effect, we did the following two analyses for licensor *no* and *only* separately. For each subset of the data, we first carried out a correlation analysis between the size of the interference effect and individual participants' CS scores. For each participant, we calculated a difference score between their acceptance rates, averaged across items, in the interference condition and the plain unlicensed condition. This difference score represents the size of the interference effect for each subject. We then correlated these difference scores with their CS scores. There is a significant *negative* correlation between the difference scores and participants' CS scores for licensor *no* [Pearson's $r = -0.28$, $t_{(86)} = -2.7$, $p < 0.01$], as well as for licensor *only* (Pearson's $r = -0.21$, $p < 0.05$). The negative correlation suggests that the higher a participant's CS score, the smaller the difference between their

*model = lmer[logRT ∼ gram * CSscore + inter * CSscore + licensor * CSscore + licensor:inter + licensr:inter:CSscore + (1 + gram + licensor + inter |subj) + (1 + gram + licensor + inter |item), data = dataframe]. *p < 0.05; **p < 0.01; ***p < 0.001.*

interference condition and plain unlicensed condition. In other words, participants with higher CS scores treated the interference conditions like the plain unlicensed condition, and rejected them both; on the other hand, participants with lower CS scores were more likely to erroneously accept the interference conditions. We plot the correlation results in **Figures 2A**, **3A**.

Second, we carried out a split-group analysis. We separated our participants into two groups along the median split of their CS scores: participants in one group had CS scores above 3 (high CS group, $n = 36$), and participants in the other group had scores below 3 (low CS group, $n = 43$). Participants who had a CS of exactly 3 were not included in either group. In **Figures 2B**, **3B**, we present the mean acceptance rate results for these two participant groups, separated by licensor type.

We carried out mixed effects models for each CS group under each licensor. Licensor *no* and *only* showed very similar patterns. For licensor *no* (**Figure 2B**), both high and low-CS groups showed the expected Grammaticality effect ($ps < 0.0001$); but only the low CS group showed an Interference effect (high CS: $p > 0.3$; low CS: $p < 0.0001$). For licensor *only* (**Figure 3B**), both high and low CS groups showed a clear Grammaticality effect ($ps < 0.0001$). The low CS group also showed a strong Interference effect ($p < 0.0001$), whereas this effect was much weaker for the high CS group ($p < 0.06$).

To summarize the acceptance rating data on NPIs, the group averaged data showed an interference effect, but this effect is crucially modulated by individual subjects' pragmatic-communicative skills, across different licensors.

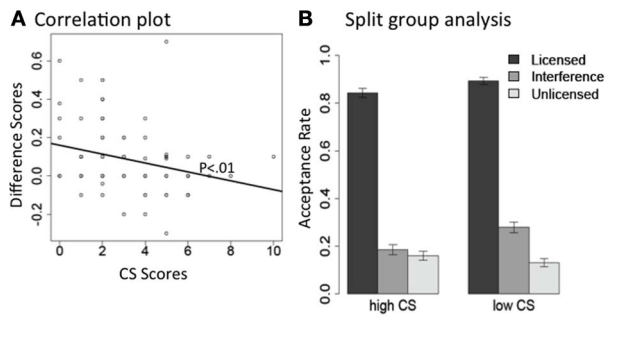

FIGURE 2 | The interaction between interference effect and CS scores in acceptance rate, for the NPI licensor *no*. (A) Correlation between each individual subject's difference scores between their interference condition and the plain unlicensed condition (*Y*-axis: acceptance rate of Interference—acceptance rate of Unlicensed) and their CS scores (*X*-axis: CS scores). **(B)** Acceptance rate for each condition plotted separately for the high and low CS groups.

Self-paced reading time

In **Figure 4**, we plot the reading time from four words prior to the NPI word *ever* and two words after it, with combined data from licensor *no* and licensor *only*. As shown in the plot, combined data from *no* and *only* showed differences among the licensed, interference, and unlicensed conditions only immediately at the critical NPI word (CW) *ever*. The grand average RTs on the CW are shown in **Table 2**.

We carried out mixed effects linear regression modeling on the RTs at the CW. The fixed and random effect structures are essentially the same as in our mixed effects logistic models discussed earlier. Prior to the analyses, we log-transformed all the RTs, and centered the CS scores. We first did analyses on the entire data set, and then did separate analyses for licensors *no* and *only*. The model output from the entire data set on the CW is presented below.

On the CW, the results revealed the expected effects for Grammaticality and Interference, but in contrast to the acceptance rate results, there was no interaction between CS scores and Interference. On the spill-over word CW + 1, there was a Grammaticality effect, but no Interference. There was also an unpredicted effect of Licensor. Further examination showed that this effect appeared because the grammatical and interference conditions under "only" were both read slower than the same two conditions under "no." Since this effect wasn't predicted under any of our hypotheses, we will not go into it further. We next analyzed data for *no* and *only* separately.

Licensor no

On the word CW. The word-by-word RTs (4 words prior and 2 words after the CW) are plotted in **Figure 5A**. On the CW *ever*,

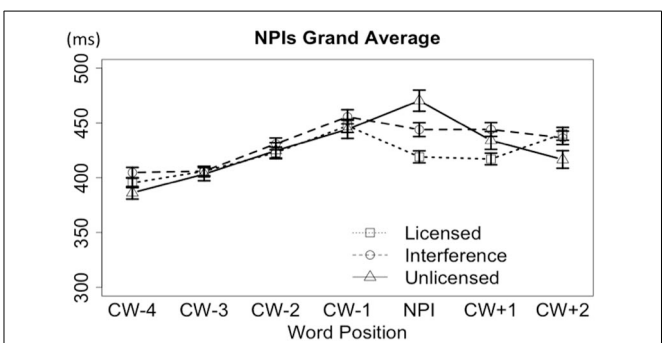

FIGURE 4 | Word-by-word reading times for the NPI stimuli set, collapsing the licensors "*no*" and "*only*."

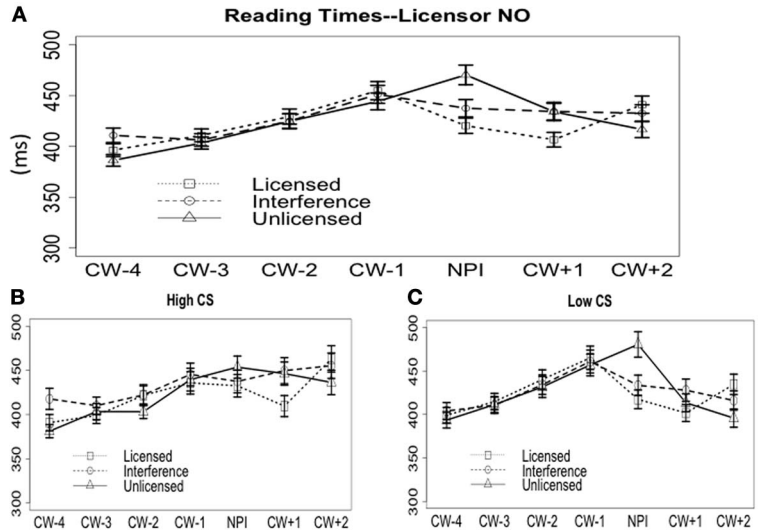

FIGURE 5 | Reading times when the NPI licensor was "*no.*" (A) Word-by-word reading time cross all subjects. **(B)** Word-by-word reading time for the high CS group. **(C)** Word-by-word reading time for the low CS group.

Table 6 | NPI licensing RTs: fixed effects from the linear mixed effect models, separated for two different licensors.

	Word CW		Word CW+1	
	Licensor *No* *p*-value	**Licensor *Only* *p*-value**	**Licensor *No* *p*-value**	**Licensor *Only* *p*-value**
Grammaticality	**0.0005*****	**<0.0001*****	**0.01***	0.2
Interference	**0.005****	0.15	0.5	0.1
CSscore	0.60	0.96	0.3	0.4
Gram:CSscore	0.35	0.53	0.4	0.1
Inter:CSscore	0.79	0.92	0.5	0.6

*model = lmer(logRT ~ gram * CSscore + inter * CSscore + (1+ gram + inter|subj) + (1+ gram + inter + CSscore|item),data = dataframe). *p < 0.05; **p < 0.01; ***p < 0.001.*

the grammatical condition was read faster (421 ms) than both the plain unlicensed condition (473 ms) and the interference condition (439 ms); but, the interference condition was also faster than the plain unlicensed condition, suggesting an interference effect.

The output of the mixed effects linear regression model for reading times on the CW is presented in **Table 6**. The model output shows a significant effect of Grammaticality and Interference, suggesting that the grammatical condition is read significantly faster than both ungrammatical conditions, while the interference condition is read faster than the plain unlicensed condition. But, the model did not show any effect of CS scores, nor any interaction between CS scores and any other effects.

Although the interaction between CS scores and Interference shown in **Table 6** isn't significant, to find out if there was any trend of an effect from CS scores, we carried out an exploratory correlation and split group analysis for the CW. The procedure was the same as with the analyses of acceptance rate data presented above. The first result is that there was no correlation between CS scores and interference [Pearson's $r = -0.05$, $t_{(86)} = -0.49$, $p > 0.6$]. For the split group analysis, we again separated participants into a high-CS ($n = 36$) and a low-CS group ($n = 43$) based on the median-split (CS = 3) of their CS scores. The mean RT for each group is plotted in **Figures 5B,C**. For the high-CS group, on the CW *ever*, neither the effect of Grammaticality nor Interference was significant (ps > 0.2)—there was no difference between any of the conditions (licensed, 433 ms; interference, 438 ms; unlicensed, 454 ms). For the low-CS group, however, both Grammaticality ($p < 0.01$) and Interference ($p < 0.05$) were significant. The licensed NPI (417 ms) was read faster than the unlicensed (480 ms) and the interference condition (433 ms); the interference condition was also faster than the unlicensed condition.

To summarize, on the CW, the averaged data showed the standard Grammaticality and Interference effect, but neither the mixed effects model nor the correlation analyses suggested any interaction between CS scores and the Interference effect. The split group analysis showed a small trend of modulation by CS scores: only the low-CS-scores group showed Interference, but it is difficult to draw any conclusions from this result since the high-CS-scores group did not show any difference between conditions, let alone an interference effect.

On the word CW + 1. On the spillover word (**Figure 5A**), the grand average over all the participants showed a faster reading time on the licensed condition (407 ms) than on the interference and unlicensed conditions (both were 434 ms). There is a significant Grammaticality effect, but no effect of Interference, CS scores, or any interactions (see **Table 6**). The exploratory correlation analysis found no correlation between the size of the interference effect and the CS scores [Pearson's $r = -0.07$, $t_{(86)} = -0.7$, $p > 0.4$]. The exploratory split-group analysis in

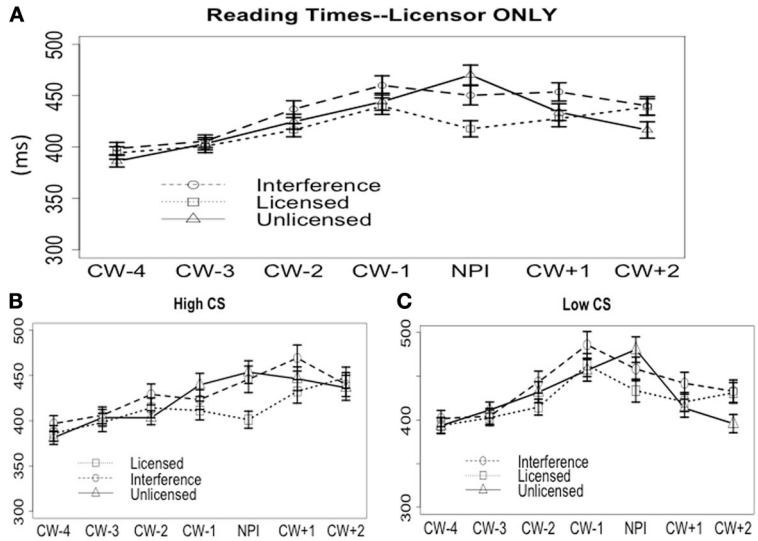

FIGURE 6 | Reading times when the NPI licensor was "*only.*" (A) Word-by-word reading time cross all subjects. **(B)** Word-by-word reading time for the high CS group. **(C)** Word-by-word reading time for the low CS group.

which we separated the high-CS and low-CS groups of participants, however, revealed different trends for the two groups (see **Figures 5B,C**). For the high-CS group, there was an effect of Grammaticality ($p < 0.01$), but no Interference ($p > 0.6$). The licensed condition (410 ms) was read faster than both the interference (450 ms) and the unlicensed conditions (446 ms), and there was no difference between the latter two. For the low-CS group, there was no effect of Grammaticality or Interference (Grammaticality, $p > 0.2$; Interference, $p > 0.5$; licensed, 402 ms; interference, 428 ms; unlicensed, 413 ms).

To summarize the results for the licensor *no*, grand average data showed a significant Grammaticality effect and an Interference effect on the CW. For the spillover word, there was only a Grammaticality effect. However, when we separated the high-CS group from the low-CS group, there was a trend of an effect of CS scores: for the high-CS group, there was no difference at the CW, but there was a grammaticality effect at the spill-over word, without an interference effect; for the low-CS group, there was both a grammaticality and an interference effect on the CW, yet no differences at the spill-over word. In other words, the low-CS group showed immediate sensitivity to ungrammaticality at the critical NPI word, but this sensitivity is also prone to an interference effect; the high-CS group, on the other hand, was slightly delayed in showing sensitivity to ungrammaticality, but, at the same time, was more resistant to the interference effect. Some caution is warranted, however, in interpreting the results from the split-group analysis, since based on the comprehensive model and the exploratory correlation analysis, the interaction between CS scores and Interference essentially presented a null result.

Licensor only

On the word CW. The grand average of the word-by-word RTs are shown in **Figure 6A**. On the CW *ever*, the licensed condition (420 ms) was read faster than the plain unlicensed condition (473 ms) and the interference condition (453 ms). The model output in **Table 6** shows only a significant Grammaticality effect, but no Interference effect. This is significantly different from licensor *no*, and we will discuss it further in the general discussion.

Table 7 | Number-agreement acceptance rate: fixed effects from the mixed effect logistic model.

	Estimate	Std. Error	*z* value	*Pr*(>|*z*|)
Grammaticality	1.99	0.2	9.4	<2e-16***
Interference	0.82	0.15	5.59	2.3e-08***
CSscore	0.09	0.07	1.25	0.2
Gram:CSscore	0.04	0.06	0.68	0.5
Inter:CSscore	−0.02	0.04	−0.61	0.5

*model = lmer(acceptance ~ gram * CSscore + inter * CSscore + (1+ gram + inter|subj) + (1+ gram + inter + CSscore|item),data = dataframe, family = "binomial"). ***p < 0.001.*

The results from the exploratory correlation analysis found no correlation [Pearson's $r = 0.03$, $t_{(86)} = 0.3$, $p > 0.7$]. Results from the split group analysis are shown in **Figures 6B,C**. For the high-CS group, there was an effect Grammaticality ($p < 0.001$), but no effect of Interference ($p > 0.4$): the licensed condition (401 ms) was read significantly faster than both the interference condition (446 ms) and the unlicensed condition (454 ms), and there was no difference between the latter two. For the low-CS group, there was also an effect of Grammaticality ($p < 0.01$). There seems to be a numerical trend of interference, but the effect of Interference wasn't significant ($p > 0.2$) (licensed 434 ms; unlicensed 480 ms; interference 458 ms).

On the word CW + 1. On the spillover word, the grand means (**Figure 6**) of the three conditions are: licensed 428 ms, interference 454 ms, and unlicensed 434 ms. The comprehensive mixed-effect model did not reveal any significant effects of Grammaticality or Interference (**Table 6**), and this was confirmed by the mixed effect models within each CS group (all *p*s > 0.1).

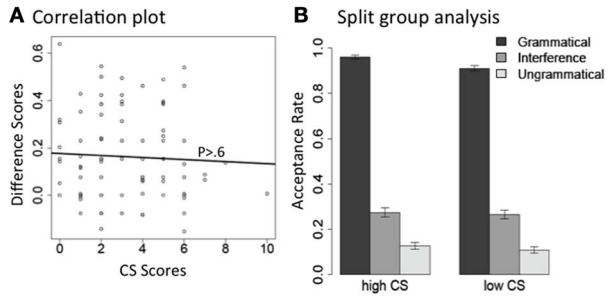

FIGURE 7 | The interaction between interference effect and CS scores in acceptance rate, for subject-verb agreement errors. (A) Correlation between each individual subject's difference scores between their interference condition and the plain unlicensed condition (*Y*-axis: acceptance rate of Interference—acceptance rate of Ungrammatical) and their CS scores (*X*-axis: CS scores). **(B)** Acceptance rate for each condition plotted separately for the high and low CS groups.

Table 8 | Number agreement RTs: fixed effects from the linear mixed effect model.

	Word CW ***p*-value**	**Word CW + 1** ***p*-value**
Grammaticality	**<0.0001*****	**<0.0001*****
Interference	**0.01***	0.5
CSscore	0.5	0.6
Gram:CSscore	0.6	0.5
Inter:CSscore	0.6	0.6

*model = lmer(logRT ~ gram * CSscore + inter * CSscore + (1+ gram + inter|subj) + (1+ gram + inter + CSscore|item), data = dataframe). *p < 0.05; ***p < 0.001.*

To summarize the self-paced reading time data from the licensor *only*, the grand average data showed a grammaticality effect without an interference effect. The same pattern largely holds for both high and low-CS groups, but the low-CS group showed a small trend of interference, as well.

Subject-verb number agreement

Within the subject-verb number agreement materials, two Helmert contrasts were defined in order to examine both the grammaticality effect: ***Grammaticality*** (10a vs. 10b and 10c in **Table 1**), and the interference effect: ***Interference*** (10b vs. 10c). Everything else about the mixed effects model structures was set up in the same way as for the analyses of NPI licensing.

Acceptability rating

The average acceptability rating (see **Table 2**) was 0.92 for the grammatical condition (10a), 0.12 on the plain ungrammatical condition (10c), and 0.28 on the interference ungrammatical condition (10b). The mixed effects logistic model showed a significant Grammaticality effect and a significant Interference effect. No other effects were significant. Crucially different from the NPI results (see **Tables 3**, **4**), CS scores did not affect participants' judgment of subject-verb agreement errors. The model output for the fixed effects is shown below in **Table 7**.

To make a parallel comparison with the NPI stimuli, **Figure 7A** presents the correlation between the interference effect and CS scores, and **Figure 7B** presents the median-split analysis. The lack of correlation in **Figure 7A** (Pearson's $r = 0.05, p > 0.6$) confirms that CS scores did not affect the interference effect in the agreement items. And the mixed effect models within each group also found the same Grammaticality and Interference effects for both high and low-CS groups (all *p*s < 0.0001).

Self-paced reading time

On the word CW. Word-by-word reading times are plotted in **Figure 8A**. The average RTs on the critical verb (e.g., *fail* in example 10b) are 463 ms for the grammatical condition (10a), 547 ms for the plain ungrammatical condition (10c), and 509 ms for the interference condition (10b). The mixed effects model showed a significant effect of Grammaticality and Interference (see **Table 8**) on the CW, such that the grammatical condition was read faster than the other two conditions (*a* vs. *b*, *c*, $p < 0.001$), and the interference condition was read faster than the plain ungrammatical condition (*b* vs. *c*, $p < 0.01$). There were no interactions between Interference and CS scores.

The split-group analysis, as shown in **Figures 8B,C**, revealed qualitatively similar patterns for high-CS and low-CS groups. For the high-CS group, there was an effect of Grammaticality ($p < 0.001$): the grammatical condition (439 ms) was read significantly faster than both the ungrammatical condition (511 ms) and the interference condition (481 ms); and an effect of Interference as well (although slightly weaker, $p < 0.07$). For the low CS group, the grammatical condition (480 ms) was read significantly faster than both the ungrammatical condition (576 ms) and the interference condition (521 ms); and the difference between the latter two was also significant (Grammaticality, $p < 0.01$; Interference, $p < 0.01$).

On the word CW + 1

At the spillover word, grand averages of the three conditions were: grammatical 428 ms, interference 480 ms, and ungrammatical 493 ms. The mixed effects model showed a significant effect of Grammaticality, but no effect of Interference (see **Table 8**). The split-group analysis (see **Figure 8**) revealed very similar results for both participant groups. For the high-CS group, the grammatical condition (429 ms) was read faster than the ungrammatical condition (502 ms) and the interference condition (500 ms), and there was no difference between the latter two (Grammaticality, $p < 0.0001$; Interference, $p > 0.8$). The low-CS group showed the same pattern: the grammatical condition (420 ms) was read faster than the ungrammatical (485 ms) and interference (477 ms) conditions (effect of Grammaticality, $p < 0.001$), with no significant difference between the latter two (effect of Interference, $p > 0.8$).

To summarize, for the agreement stimuli, we observed the grammaticality effect and the interference effect in both acceptability ratings and the self-paced reading time on the critical word. On the spillover word, self-paced RTs only showed a grammaticality effect, but no interference. In all these measures, the high and low-CS participants performed in very similar ways.

GENERAL DISCUSSION

The current study revealed three main findings. First, only NPI interference, but not agreement interference, is affected by

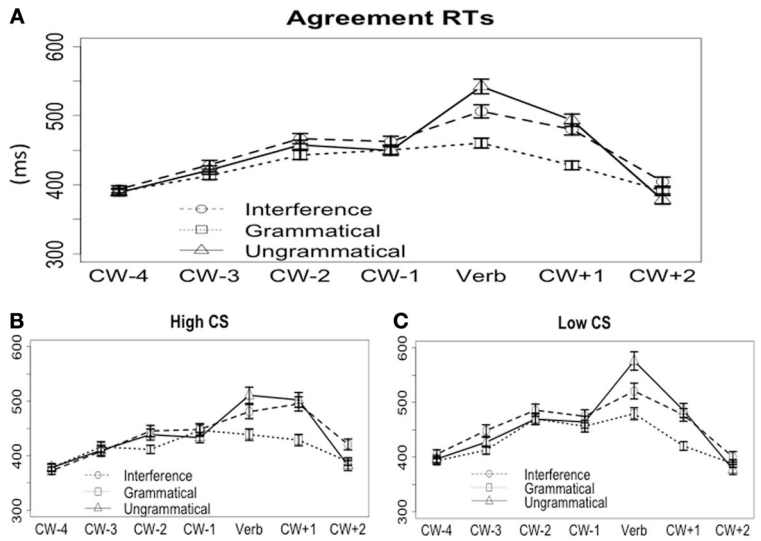

FIGURE 8 | Reading times for the agreement set of the stimuli. (A) Word-by-word reading times across all subjects. **(B)** Word-by-word reading times for the high CS group. **(C)** Word-by-word reading times for the low CS group.

individual subject's pragmatic-communicative skills. Second, the modulation of pragmatic-communicative skills mostly has its effect on offline acceptability rating, but not online reading time, although there seems to be a trend of effect in online RTs as well. And third, different NPI licensors, in particular, *no* and *only*, presented distinct interference profiles: while both showed offline interference in acceptability, NPIs under *only* did not show online interference. We turn below to the discussion of these observations.

INTERFERENCE IN ACCEPTANCE RATE AND THE EFFECT OF AUTISTIC TRAITS

A critical finding of the current study is that for the NPI materials, but not for the agreement interference stimuli, participants' acceptance rate was affected by their autistic-associated traits; in particular, their communication skills, as measured by the CS of the AQ questionnaire. Participants with higher CS scores, i.e., those that are relatively worse in their general pragmatic communicative skills, were less prone to NPI interference, as demonstrated by their more accurate acceptability judgments. On the other hand, participants with better communicative skills (lower CS scores) more often accepted the interference conditions. In contrast to the case with NPI licensing, participants' autistic traits did not seem to affect their acceptance of subject-verb agreement sentences, suggesting that subject-verb interference and NPI interference, although on the surface they look very similar, may arise from different sources.

We argue that the different interference profiles stem from the fact that NPI licensing and subject-verb agreement are different types of linguistic dependencies. It is uncontroversial that subject-verb number agreement involves a syntactic matching process that checks the number features on the subject and its corresponding verb. In incremental parsing, the subject of a sentence is likely to have been removed from focal attention when the verb is encountered (McElree, 2001); therefore, the real-time construction of a subject-verb agreement relationship depends on the successful retrieval of the subject's features. Memory-retrieval-based interference arises when the target of retrieval shares certain features with other items that have recently been processed (Lewis and Vasishth, 2005; Lewis et al., 2006). Under this account of subject-verb agreement and the corresponding interference effect, interference errors stem from misapplication of the mechanism by which number agreement is computed.

We likewise argue that NPI interference is closely tied to one of the mechanisms by which NPIs are regularly licensed. As discussed in the introduction, in addition to a logical-semantic mechanism, there is also a pragmatic component to NPI licensing in English. Particularly relevant to our purposes here, negative inferences are employed regularly as part of a pragmatic licensing mechanism for NPIs. During the comprehension process, the parser may over-apply the pragmatic licensing strategy, and use even unwarranted negative inferences to license NPIs, resulting in interference.

Under this account, interference in syntactic agreement and interference in NPI licensing are driven, at least partially, by different underlying sources. This shouldn't be totally unexpected, since these two linguistic phenomena involve different representations and computations in the first place: the agreement process is purely syntactic, whereas NPI licensing is at the interface of different systems, including syntax, semantics, and pragmatics. It is not surprising that the specific linguistic properties of each construction lead to substantial differences in how they are processed in comprehension.

The current results also add to the growing literature that autistic traits are present among the neurotypical population and they affect language processing in non-trivial ways. Our results, in line with previous findings, suggest that the two sub-scales from the AQ—Social Skill and Communication—may have particular

influence on pragmatic language processing. Since case studies in this regard are still relatively sparse, more future research is needed to further establish this association. There are many different kinds of pragmatic phenomena in language processing, and it is an open question whether they are in general affected by individual differences along the dimension of autistic traits. If it turns out that autistic traits only selectively target a subset of these phenomena, it would be very informative for the construction of a constrained pragmatic theory of language processing.

ONLINE INTERFERENCE AND THE (LACK OF) EFFECT OF AUTISTIC TRAITS

Although there is a strong effect of autistic traits on the offline acceptability rating, their effect on online reading time is much weaker. The split group analysis seems to show a trend where there is more interference for the low-CS group than the high-CS group, but the mixed effects models revealed no interaction between CS scores and interference effect. The lack of an interaction in the comprehensive model could be due to insufficient power in the data, in which case we may still consider the online interference effect as being qualitatively similar to the offline effect. This is a potential explanation, but also one that is difficult to validate given the null result. While keeping this possibility in mind, we will entertain the alternative possibility that there is genuinely no effect of CS scores on online interference and discuss the implications of that possibility. Another interesting observation about the online interference effect is that, for NPI licensing, we only observed interference for the licensor *no*, but not the licensor *only*. The difference between these two licensors is important for our explanation of the online interference effect, but we will focus only on *no* for the moment, and come back to *only* in the next section.

The lack of modulation by participants' communicative-pragmatic skills on the online interference effect suggests that NPI licensing may actually involve a syntactic matching process, like subject-verb agreement. This was the original hypothesis in Vasishth et al. (2008), which postulated a search process for a syntactic [+Neg] feature when an NPI word such as *ever* is encountered. We questioned this hypothesis earlier because it does not fully represent how NPIs are licensed—it overlooks the fact that NPI licensing is not *just* a syntactic process, but involves semantic and pragmatic mechanisms. However, the fact that NPI licensing is an interface phenomenon that involves multiple levels of representations and processes does not exclude the possibility that syntactic matching exists within one sub-component of the licensing process. The syntactic [+Neg] feature is a particularly suitable candidate to serve as the relevant matching feature, since, cross-linguistically, negation is the most robust NPI licensor. This line of reasoning would make NPI licensing similar to subject-verb agreement in some respects. If the regular memory retrieval mechanisms apply in both cases, one would expect similar online interference with no modulation from individual pragmatic skills.

We also want to point out that, by recognizing such a syntactic licensing process, at least for licensors such as *no* (see the contrast with *only* below), we acknowledge a syntactic process for NPI licensing that has not been fully recognized or emphasized in previous research for weak NPIs like *ever*, which can be licensed under a broad range of licensors. Polarity items that are only licensed by negation—called "strict" NPIs (Giannakidou, 1998, 2011; Zwarts, 1998)—are cross-linguistically common, for example, so-called "n-words" in Romance languages. Purely syntactic mechanisms like agreement have been proposed to account for the distribution of n-words (Haegeman and Zanuttini, 1991; Zanuttini, 1991; Zeijlstra, 2004, inter alia). But, traditionally, the general account of NPI licensing, especially for weak NPIs like *ever*, has been deliberately divorced from an agreement-based explanation. We agree with the traditional wisdom, but based on the current data, we also suggest that a syntactic feature matching process may exist in parallel with other licensing mechanisms, even for weak NPIs, at least for a subset of licensors—those that contain a syntactic [+Neg] feature.

Licensing as an integrated syntax-semantics process is to be expected if (a) we take seriously the idea that NPI licensing is a grammatical phenomenon driven by the logical properties of lexical expressions, and (b) there is a strict isomorphism between the syntax and the semantics. Under these two theses, the logical property of negation is mapped onto a morphosyntactic feature [+negative] (for an early discussion of such a model see Giannakidou, 1998). NPI licensing will then always involve at least this component of integrated syntax-semantics matching, and online processes access that. But importantly, even if we recognize a syntactic feature-matching component in NPI licensing, the overall process is still crucially different from subject-verb agreement in many ways. In particular, NPI licensing involves semantic *and* syntactic, as well as pragmatic mechanisms, as we discussed earlier. But for the agreement sentences, whether they are acceptable or not is determined only by whether or not the syntactic matching process on the relevant number feature is successful—there is no obvious connection between the processing of syntactic agreement and the final interpretation of a sentence. For instance, Lau et al. (2008) showed that when people were lured by interfering agreement number features, as in "*The phone by the toilets were . . .*," they nevertheless did not make mistakes in assigning the correct thematic role to the subject. NPI licensing, on the other hand, is a very different phenomenon. The presence of an NPI makes important contributions to the final propositional content. The acceptability of an NPI is not determined by the syntactic matching process alone, but is instead crucially regulated by semantic and pragmatic integration conditions. The effect of pragmatic inferences could be particularly strong in offline tasks, since participants are given enough time to reflect on what the target stimulus actually means, or could have meant.

The strong offline effect of individual subject's pragmatic skills leads to the question why such effects did not surface in online interference. One possibility is that the influence of pragmatic factors in online measures could have been masked by the strong presence of the memory-retrieval based effect, and hence was undetectable. This is not the most likely hypothesis, since for the licensor *only*, which we argue did not participate in a memory-retrieval based interference effect, we still did not observe a pragmatically driven interference in online measures. The other possibility is that since these interference sentences are ultimately

ungrammatical, the pragmatic inference may be a "last resort" strategy" in these situations, and hence have a delayed effect. We discuss these issues in more details in the next section, together with data from the licensor *only*.

Our current discussion about the source of online interference for *no* departs somewhat from our earlier work in Xiang et al. (2009), in which we conjectured that even the online interference effect for *no* (and *few*) was driven by pragmatic processes. In the current discussion we draw a distinction between online and offline interference effects, and argue that since a syntactic matching process is possible between *no* and an NPI, (some) online interference may thereby arise through a memory retrieval process, as argued in Vasishth et al. (2008) (modulo the possible additional contribution of a pragmatic process, as shown by the trend in the split group analysis). However, one important feature of the original analysis in Vasishth et al. (2008) is that memory search targets positions that are ruled out on syntactic grounds, and that NPI interference under *no* is a demonstration of syntactic interference, as accessing a licensor in a non-commanding position purportedly violates syntactic constraints. We do not think that the current results necessarily commit us to this position. We contend that questions about the search mechanism (i.e., whether or not the search process is blind/insensitive to syntactic constraints) and whether or not NPI licensing shows similarity-based feature interference may be two orthogonal issues. Although NPIs are generally c-commanded by their licensors, it is not obvious that a c-command requirement should be stated explicitly as part of the syntactic requirements on NPI licensing. It could simply be an epiphenomenon, within an isomorphic syntax-semantics level, of the semantic requirement that an NPI needs to stay in the semantic scope of its licensor. The computation of the semantic scope may track configurational relations like c-command, but this does not necessarily mean that the parser actually makes reference to the c-command condition in online processing. In other words, the memory retrieval process may target a [+negative] element, instead of a [+negative, +c-command] element, while there is simultaneously a semantic condition that checks whether or not the NPI falls within the semantic scope of the retrieved target. Of course this leaves open a number of non-trivial questions as to how semantic scope is tracked in online processing. One possibility is that we encode [+scope] in some way as a lexical feature on the retrieval target, and interference would arise largely in the same fashion as the proposal in Vasishth et al. (2008), but with the syntactic feature [+c-command] replaced by the semantic feature [+scope]. This approach calls for a detailed implementation as to how scope relations could be encoded as lexical features, when they obviously are not features stored in the lexicon. The other possibility is that scope relation can only fall out while propositional content is being incrementally composed, rather than being encoded on lexical items. If this is true, we need an explicit algorithm that can both derive correct scope relations at the proposition level, and also allow incorrect scope relations to be derived, in order to account for the interference effect. We do not have answers to these questions. But we think it would be too hasty to reach a conclusion about the exact search mechanism involved in NPI interference without fully exploring all of these logical possibilities.

DIFFERENT TYPES OF NPI LICENSORS

The perspective that multiple mechanisms are acting in parallel to license NPIs also helps explain the difference observed between the licensors *no* and *only*.

As discussed above, there is consensus that *only* does not license NPIs through a lexically encoded (syntactic) [+negative] feature, though the exact licensing mechanism for *only* as an NPI licensor is still under debate. The difference between *only* and other negative licensors such as *no* (or *few*) can be demonstrated by the syntactic diagnostics provided in Klima (1964), as was illustrated earlier.

In the current results, we saw that on grammatical conditions, NPIs licensed under *only* were accepted less often than those licensed under *no* (**Figure 1**). This could be due to a number of factors. For instance, *no* is a more frequent licensor than *only* in naturally occurring utterances (Xiang et al., 2009). This may have influenced the acceptability ratings of the two licensors. Alternatively, under the licensor *no*, an NPI can be licensed both syntactically and semantically. Syntactically, a feature-matching process may search and identify a target with a [+Neg] feature; semantically, a negative meaning may also be calculated. Syntactic and semantic processes converge on the final representation in which an NPI is licensed. With the licensor *only*, however, the syntactic feature-matching process fails, since *only* does not contain a morphosyntactic feature [+Neg]. Then, only the semantic route (via the exceptive entailment "nobody other than") would be available. The failure of isomorphism between syntax and semantics, in contrast with *no,* may have reduced the acceptability of NPIs under *only*. In a recent study (Xiang et al., 2013), acceptability ratings were collected for a larger set of licensors, including *no*, *few*, *only*, and emotive factives such as *amazed*, *surprised*, etc. It was found that the two syntactically negative licensors *no* and *few* are judged more acceptable than *only* and emotive factives, which are both non-negative. This is completely in line with the results reported here. Furthermore, since *few* is also much less frequent than *no* as an NPI licensor (Xiang et al., 2009), this result also suggests that lexical frequency *per se* does not completely determine the degree to which a licensor is accepted.

It is worth noting that the current study also revealed some difference between *no* and *only*: there was no obvious online interference effect for *only* (modulo the possibility that the low-CS group may have shown a trend of online interference). In a previous self-paced reading study, Xiang et al. (2006) also showed a lack of interference effect in online RTs for *only*. As mentioned earlier, the interference effect of *only*, or the lack of one, has not been widely tested. Although the current results showed a difference between *no* and *only* when we analyzed these two licensors separately (**Table 6**), there wasn't a Licensor by Interference interaction in the overall model in **Table 5**. This could be due to insufficient power in the data. We are fully aware that the lack of an interaction may undermine our proposed account of *only* here. More studies are needed to verify whether or not *only* is indeed resistant to online interference. But if it is, such a result is completely in line with the distinction we draw here between *no* and *only*: the former, but not the latter, is targeted by a syntactic feature-matching process. Therefore, similarity-based interference, which crucially relies on specific lexical features, will

not arise for *only* online. The immediate question for this explanation is why pragmatically-driven interference does not appear online.

One possibility is that the pragmatic inferences that drive the interference effect cannot be generated in time to trigger online interference. Instead, they are delayed until a later stage, and therefore only offline tasks can detect them. This is not the most likely hypothesis, however, given the large literature that has suggested that pragmatic inferences can be incrementally generated online (Altmann and Steedman, 1988; Sedivy et al., 1999; van Berkum, 2009; Nieuwland and Kuperberg, 2008). We propose that the reason pragmatically-driven interferences were predominately observed offline in the present study is not that such inferences failed to become available in time, but rather that the available inferences were not immediately adopted by the comprehension system to license NPIs.

First of all, the pragmatic licensing mechanism could in general be a more costly strategy than regular syntactic and semantic mechanisms. In a recent ERP study, Xiang et al. (2012, 2013) showed that, even for grammatically acceptable sentences, there is difference between NPIs that are licensed under pragmatically-derived negation (e.g., the negative implicature from emotive factive predicates) and those that are licensed under regular semantic negation (such as *no*)—only the semantic negation, but not the pragmatic negation, had a small P600 compared to the ungrammatical control condition. Second, as we mentioned above, while we recognize that pragmatically-derived negative implicatures can license NPIs, we also recognize that not all implicatures can do so. The specific conditions characterizing the "usable" implicatures are yet to be isolated, but we have conjectured that the kind of pragmatic implicatures that trigger interference effects are normally insufficient to actually license NPIs. It is likely that the comprehension system does not resort to such implicatures unless it is pushed into a corner, as in the presence of an ungrammatical sentence. If pragmatically-driven interference were the result of a last-resort strategy, it wouldn't necessarily surface in online processing.

A MULTI-DIMENSIONAL SYSTEM OF NPI LICENSING

NPI licensing reveals a case in which syntactic, semantic, and pragmatic processes act in parallel during parsing, which makes NPI licensing qualitatively different from purely syntactic dependencies, such as subject-verb agreement. The processing profile of NPI licensing is therefore much more complicated. Some licensors, such as *no*, which can participate in a syntactic licensing relation with an NPI, may be targeted by the same memory retrieval mechanisms that target other syntactic dependencies; but, for other licensors that do not bear the relevant syntactic features, memory retrieval of a lexical feature does not apply. In addition, since pragmatic licensing is a regular mechanism for NPI licensing, at least for English weak NPIs, the comprehension system may stretch it to cases in which pragmatic licensing normally does not apply, leading to pragmatically-driven interference.

To account for the full complexity of NPI licensing and the interference effect associated with it, a number of open issues need to be addressed in future work. First of all, if, as we argued above, interference associated with feature similarity only arises for licensors that contain a lexical [+negative] feature, we predict that online interference should be observed for some NPI licensors, but not others. Expressions that can license NPIs and, at the same time, are categorized as real negative expressions (i.e., under Klima, 1964) include *no*, *none*, *not*, *never*, *few*, *hardly*, *scarcely*, *seldom*, etc.; on the other hand, licensors that are not negative in the regular sense include the examples we mentioned earlier, such as *only*, *every*, comparatives, conditionals, emotive factives, questions, etc. Neither of these two groups has been tested exhaustively.

Second, we have argued that NPI interference is partially driven by pragmatic inferences, especially in the case of offline interference. We have made suggestions both about how such inferences arise and why they seem to be more prominent in offline measures. Our account of pragmatic interferences is closely associated with a particular construction that has been heavily tested by other researchers, as well as in our current work—that is, relative clauses. We made use of the well-known fact that modifiers, with relative clauses as a prime example, invite contrastive inferences. This gives rise to the following prediction: complement clauses (such as "*The fact that no student passed the exam …*"), which are minimally different from relative clauses but do not serve a modifier function, should not show interference effects, or at least not the kind of interference effect we have shown that can be modulated by individual subjects' pragmatic skills. Some results from Parker and Phillips (2011) provide preliminary support for this prediction. These authors showed a reduced interference effect for complement clauses, compared to relative clause structures, under the licensor *no*. Furthermore, with a licensor like *only* (as in "*The fact the only the best students passed the exam …*"), we predict that the interference effect on such clauses should be reduced to minimum, since the pragmatic source of interference has been entirely eliminated by the complement clause, and, in the meantime, "*only*" does not trigger syntactically associated interference either.

Finally, most of the current work on NPI interference has focused on languages that allow weak NPIs. These have a broad distribution and can be licensed under a variety of licensors. We conjectured that, for such NPIs, an independently available pragmatic licensing mechanism is over-applied in some situations, resulting in interference. Cross-linguistically, however, many languages have NPIs that are much more restricted in their distribution. It is possible that for some of these stricter NPIs, pragmatic-licensing mechanisms are never available in the grammar. This territory—interference with such NPIs—is still largely uncharted (for a recent examination of this sort, see Yanilmaz and Drury, 2013)[9]; and if they do show interference, we predict

[9]The recent ERP findings in Yanilmaz and Drury (2013) tested Turkish NPIs that have a very limited distribution. Interference was found on these NPIs. Since the constructions tested there were very different from the ones tested here (sentential complement of a matrix verb was tested), we won't go into further details. But the additional novel factor in Yanilmaz and Drury (2013) is that NPIs in Turkish come before their licensors in linear order, which may result in a forward expectation of a licensor (e.g., similar to a regular filler-gap dependency), rather than just backward search, as in the case of English NPIs.

it to be syntactically-driven interference, and not to be subject to individual differences in pragmatic skills.

CONCLUSION

In this study, we compared the interference effects in syntactic agreement and NPI licensing, especially with respect to their modulation by individual subjects' pragmatic skills. We showed that the interference profile for NPI licensing is more complicated than that for syntactic agreement, due to their representational differences. In particular, NPI interference is affected by (a) the type of NPI licensors involved, (b) the particular experimental tasks, and (c) individual subjects' pragmatic-communicative skills. All together, our results show that NPI licensing, different from the pure syntactic processes involved in agreement, evokes multiple different processes corresponding to different levels, or dimensions, of linguistic representations.

ACKNOWLEDGMENTS

The authors thank Lelia Glass, Steven SanPietro and Genna Vegh for their assistance in data collection, Matt Wagers for sharing his sentence material, and Brian Dillon and Ellen Lau for their constructive comments and suggestions.

APPENDIX

The interactions between the other four sub-scales from AQ and each of the fixed effect predictors, for NPI licensing and number agreement separately. The mixed effect models are constructed in similar ways as the models in **Tables 3**, **5**, **7**, **8**. As shown below, the only significant effect observed is the interaction between the Social Skill sub-scale and the offline NPI interference effect (i.e., acceptance rate). This is similar to the effect of the Communication sub-scale. No other interaction was observed.

Table 9 |

	NPI licensing			Number agreement	
Acceptance rate (*p*-value)	**Interaction with Interference**	**Interaction with Licensor**	**Interaction with Grammaticality**	**Interaction with Interference**	**Interaction with Grammaticality**
Social skill	0.006**	0.14	0.89	0.16	0.96
Attention to details	0.44	0.17	0.92	0.16	0.73
Attention switching	0.98	0.9	0.63	0.13	0.56
Imagination	0.15	0.44	0.94	0.61	0.096
RT at the critical word (*t*-value)	**Interaction with Intrusion**	**Interaction with Licensor**	**Interaction with Grammaticality**	**Interaction with Intrusion**	**Interaction with Grammaticality**
Social skill	−1.28	0.65	0.97	0.43	0.56
Attention to details	0.58	0.89	−0.74	0.65	−1.02
Attention switching	−1.46	0.98	0.54	0.86	0.54

Advantages of publishing in Frontiers

OPEN ACCESS
Articles are free to read, for greatest visibility

COLLABORATIVE PEER-REVIEW
Designed to be rigorous – yet also collaborative, fair and constructive

FAST PUBLICATION
Average 85 days from submission to publication (across all journals)

COPYRIGHT TO AUTHORS
No limit to article distribution and re-use

TRANSPARENT
Editors and reviewers acknowledged by name on published articles

SUPPORT
By our Swiss-based editorial team

IMPACT METRICS
Advanced metrics track your article's impact

GLOBAL SPREAD
5'100'000+ monthly article views and downloads

LOOP RESEARCH NETWORK
Our network increases readership for your article
