The P-supply intensity and root-growth-space availability often affect the root morphology and arbuscular mycorrhizal (AM) colonization (Zhang et al., 2017; Shao et al., 2018; Wang et al., 2020), and in turn, impact PUE under maize production. Lyu et al. (2016) showed that at the root soil interface, available P could be enhanced by altering the root morphology. Moreover, P has been shown to stimulate root development and subsequent P uptake (Ma et al., 2020). In addition, P availability can profoundly influence the plant responses to AM colonization (Campos et al., 2018). The high level of P can inhibit AM colonization, reducing P uptake, and the benefits of AM colonization (Breuillin et al., 2010). Furthermore, increasing evidence demonstrates that high plant density can affect the plant root morphology and AM colonization (Schroeder and Janos, 2004; Niu et al., 2020). Space availability decreases with the increasing plant density, and the root growth is subsequently inhibited. In maize, the high plant density reduces the root to shoot ratio, root biomass, and root length (Shao et al., 2018); however, root length density increases with high-density planting, which increases the chances of roots crossing and overlapping, and could easily lead to P deficiency in the rhizosphere (Postma et al., 2014; Li et al., 2019). In contrast, AM colonization increases with an increase in the planting density, as AM fungi can partially alleviate P deficiency stress (Abdel-Fattah and Asrar, 2012). Hence, a trade-off exists between the root morphological traits and AM colonization to enhance P acquisition under intensive P supply and space availability; however, the mechanism of interactive effects of root morphological traits and AM colonization on maize P uptake is not fully understood. A deeper understanding of the mechanisms of root and AM interactive effects on the root growth space exploitation and maize P uptake is key to fostering high PUE.

The high plasticity of root system architecture and AM fungi responses to P supply intensity and space availability have indicated a high potential to improve PUE in maize production (Postma et al., 2014; Li et al., 2019; Shao et al., 2019). For example, PUE in maize production can be improved by manipulating the root morphology and AM colonization to maintain an appropriate P supply intensity in the root zone (Deng et al., 2017; Kobae, 2019; Chu et al., 2020). Similarly, maintaining space for proper root growth in intensive high-plant-density maize production systems could modify the root morphology and AM colonization to enhance maize yield (Yu et al., 2019;

Hou et al., 2021). However, most of the previous studies in high-density planting systems have focused on the regulation of root morphology. Our understanding of how AM colonization in high-density planting systems responds to P supply is poor (Ma et al., 2013; Teng et al., 2013; Testa et al., 2016), in addition to how altered P supply affects the root growth and AM colonization to compensate for limited root growth space. To simultaneously achieve high maize yield and PUE in high-density planting systems, it is necessary to comprehensively consider P supply in the root zone and root-growth space by modifying root morphology and AM colonization. An improved understanding of the compensatory effects of maize root expansion on the root growth space, under P supply intensity regulation, would further enhance our understanding of the biological potential for efficient P use in maize.

Here, a pot experiment was carried out with maize to determine the compensation mechanisms of soil P supply intensity on the maize root morphology, AM colonization, and P uptake under different space availability scenarios. The present study specifically aimed: (1) to investigate maize growth and P uptake under different P intensities and root-growth space treatments; and (2) to examine the compensatory effects of soil P supply on root-growth space to determine environments that enhance PUE in maize.

MATERIALS AND METHODS

Experimental Site

A greenhouse pot experiment was conducted from June to August 2020 at the Quzhou Experimental Station of China Agricultural University (36° 51' 57" N, 150° 0' 37" E), Quzhou County, Hebei province, China. Calcareous loamy soil was collected from the Quzhou Long-Term Fertilizer Station (36° 52' 0" N, 115° 02' 0" E) of China Agricultural University, Hebei province, China. The basic soil properties were as followed: pH, 8.13; soil organic carbon (SOC), 7.3 g kg⁻¹; Olsen-P, 2.40 mg kg⁻¹; soil total nitrogen (TN), 0.91 g kg⁻¹; and available potassium (AK), 183 mg kg⁻¹. The soil was air-dried and passed through a 2-mm sieve prior to experimentation. The soil pH was measured in a 1:2.5 (w/v) soil/water slurry. SOC was determined with 0.25-mm sieved soil as explained by Cambardella et al. (2001). Soil TN was determined using the Kjeldahl method (Carter and Gregorich, 2007). Soil Olsen-P was determined in 0.5 M NaHCO₃ extracts using Mo-Sb colorimetry (Olsen et al., 1954).

Experimental Design and Management

The experiment consisted of a 3 × 3 complete factorial design. There were three P levels (0, 200, and 400 mg P kg⁻¹ soil as CaH₂PO₄, hereafter referred to as P₀, P₂₀₀, and P₄₀₀, respectively) and three pot sizes (20 cm diameter × 50 cm height, 30 cm diameter × 50 cm height, and 40 cm diameter × 50 cm height, hereafter referred to as D = 20, D = 30, and D = 40, respectively). Each of the nine treatment combinations was replicated four times to yield a total of 36 pots.

Urea and muriate of potash were applied to all the treatments at a rate of 150 kg ha⁻¹ to supply nitrogen (N) and potassium (K),

TABLE 1 | Two-way ANOVA of the effects of phosphorous (P) supply, space availability, and their interaction on P supply and space availability.

Parameters	P supply		Space availability		P supply × Space availability

which are often limiting factors in the calcareous loamy soils. All fertilizers were incorporated and thoroughly mixed with the soil at the time of planting.

Maize seeds (*Zea mays* L. cv. Zhengdan958) were surface sterilized in 10% v/v H₂O₂ for 30 min, washed with deionized water, and placed in a dish containing aerated saturated CaSO₄ solution at 25°C in the dark until a radicle emerged. Then, four germinated seeds of uniform size were sown in each pot. Each pot was watered daily to 80% field capacity as measured by weight. The temperature ranged from a minimum of 22°C at night to a maximum of 30°C during the day.

Plant Harvest and Measurements

The plants were harvested 55 days after sowing. The shoots were cut at the soil surface, oven-dried at 105°C for 30 min and then, at 75°C for 3 days until they reached constant weight and weighed to record the biomass. Afterward, the shoots were crushed and homogenized. Shoot P concentration was determined using the vanadomolybdate method (Johnson and Ulrich, 1959) after wet digestion with a mixture of 5 ml of 98% H₂SO₄ and 8 ml of 30% H₂O₂.

Soil Sampling and Measurements

Bulk soil sample was obtained 20 cm from the soil surface using a soil auger. Rhizosphere soil was obtained by brushing off the soil adhering to the whole roots with a sterile brush. Visible roots were removed manually before the samples were ground to pass through a 2-mm sieve and dried naturally. Soil Olsen-P was determined in 0.5 M NaHCO₃ extracts using Mo-Sb colorimetry (Olsen et al., 1954).

Root Sampling and Root Parameter Measurements

After cutting off the shoots, the excavated roots were shaken briefly to remove a large fraction of the soil adhering to the root crown. The root angle was assessed using the method outlined by Hecht et al. (2019). Afterward, all the visible roots in each pot were collected from the soil on a 2 mm-diameter mesh and washed clean with running water in the lab. Total

root length was analyzed using Win-RHIZO software (Pro2004b, version 5.0, Regent Instruments Inc., QC, Canada). Lateral root density was the number of lateral roots per unit length of primary root, which was calculated by dividing the number of lateral roots per 5 cm of primary root by the 5 cm length of the root.

The fine roots were cut to 1 cm segments and thoroughly mixed. The root samples were cleaned with 10% (w:v) potassium hydroxide and placed in a water bath (90°C) for 2 h. The cooled root samples were cleaned in 2% HCl for 5 min and then stained with Trypan blue solution. For each sample, 15 root segments were used to evaluate AM colonization by scoring based on the findings of Trouvelot et al. (1986) and calculated using MYCOCALC program (<http://www.dijon.inra.fr/mychintec/Mycocalc-prg/download.html>). AM colonization (%) = number of intersections colonized (hyphae, arbuscules, vesicles, and hyphal coils)/total number of intersections examined × 100% (Zhang et al., 2014).

All roots were collected and dried at 75°C for 72 h and weighed to determine the biomass.

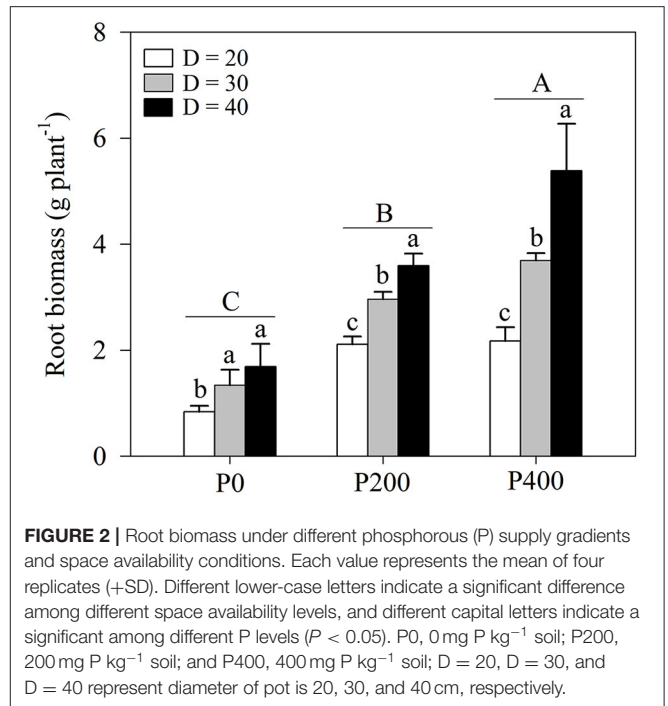

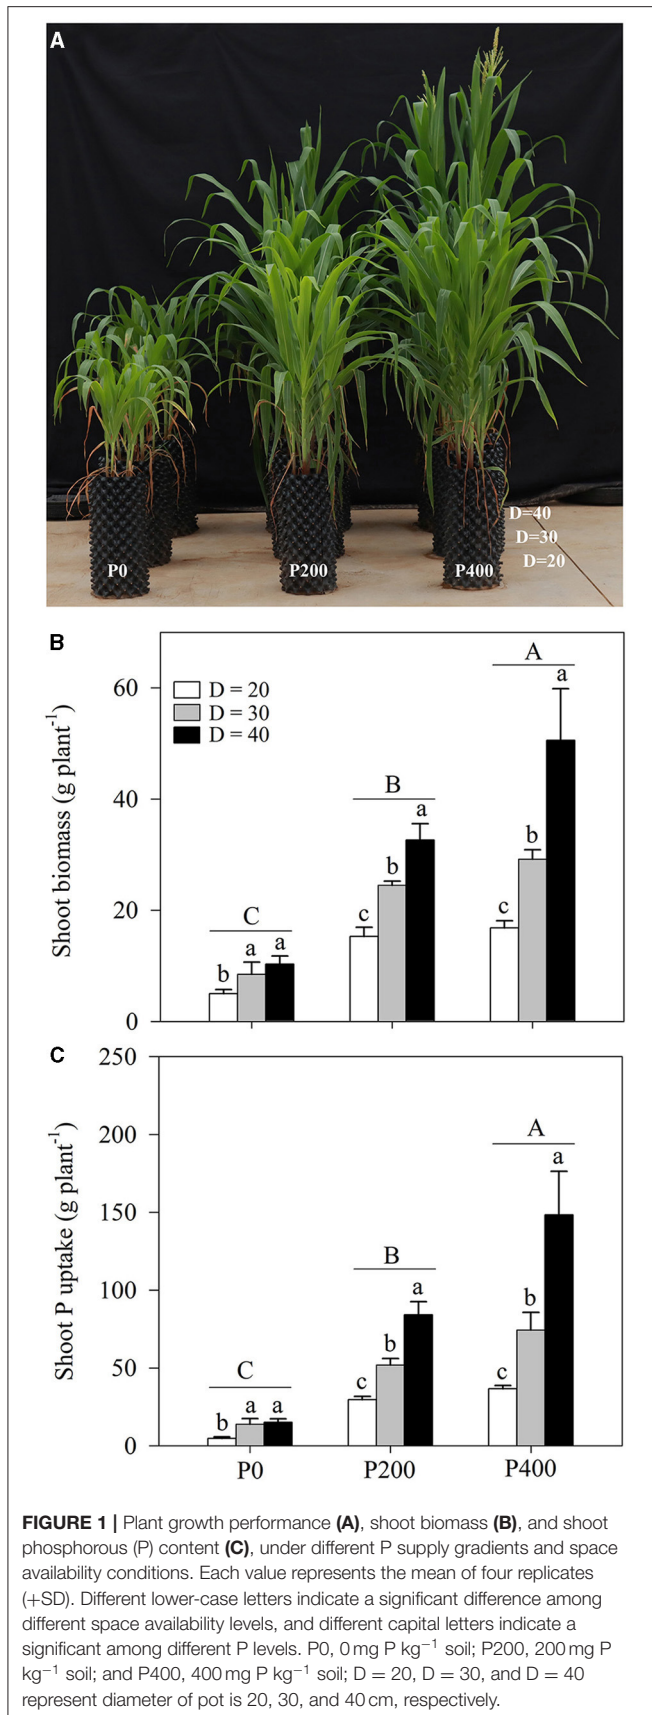

Statistical Analysis

IBM SPSS Statistics 20.0 (IBM Corp., Armonk, NY, USA) was used to compute one-way or two-way ANOVA. The mean differences among the means were determined by the least significant difference (LSD) at $P \leq 0.05$ probability level. The data were presented as graphs prepared by Sigmaplot version 10.0 (Systat Software Inc., San Jose, CA, USA).

RESULTS

Shoot Biomass and P Content

Shoot biomass was significantly affected by soil P supply and space availability ($P < 0.01$, **Table 1**; **Figures 1A,B**; **Supplementary Figures 1A,B**). Shoot biomass increased as the soil P supply increased, and the highest shoot biomass was obtained in the P400 treatment groups, followed by in the P200 and P0 treatments. The effect of space availability on shoot biomass was more prominent when more P was added

to the soil (P200 and P400 treatments); however, the limited space availability could restrict the growth of shoot biomass. Lower shoot biomass was obtained with the D = 20 treatment among all the P supply treatments (Figures 1A,B). However, the reduction in shoot biomass due to space limitation was compensated by soil P supply with certain space availability treatments. Higher shoot biomass was obtained in P400 under D = 30, which was equivalent to the shoot biomass observed in P200 under D = 40; the shoot biomass in P200 under D = 30 was significantly higher than that in P0 under D = 40. Furthermore, the shoot biomass in P400 under D = 20 was significantly lower than in P200 under D = 30. In addition, the shoot biomass did not tend to increase under the improving P supply conditions at lower space availability treatments. Under D = 30 and D = 40, the shoot biomass significantly increased as soil P supply increased, while there was no significant difference in the shoot biomass between P200 and P400 under D = 20, indicating that the shoot biomass was restricted by the amount of space and could not be compensated by soil P supply.

The shoot P content in maize among the treatments was also significantly affected by soil P supply and space availability ($P < 0.01$, Table 1; Figure 1C; Supplementary Figure 1C). The shoot P content increased as soil P supply increased, and the lower rates of shoot P uptake were obtained with the D = 20 treatment across different P supply rates, when compared with D = 30 and D = 40. Similar complementary effects of soil P supply and space availability on the shoot P content were obtained under some circumstances. When compared with that in P200 under D = 20 and D = 30, higher P content was obtained under D = 40. Further, the shoot P content in P200

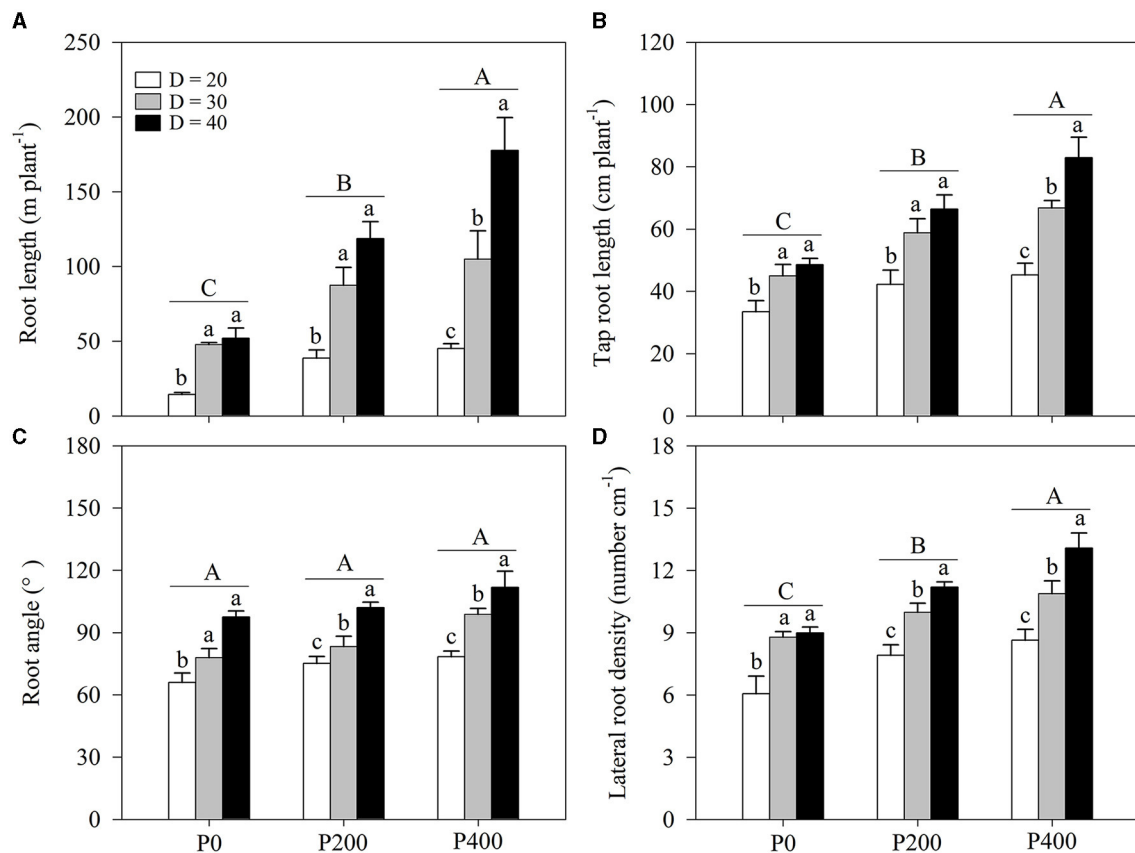

FIGURE 3 | (A) Root length, **(B)** tap root length, **(C)** root angle, and **(D)** lateral root density under different phosphorous (P) supply gradients and space availability conditions. Each value represents the mean of four replicates (+SD). Different lower-case letters indicate a significant difference among different space availability levels, and different capital letters indicate a significant among different P levels ($P < 0.05$). P0, 0 mg P kg⁻¹ soil; P200, 200 mg P kg⁻¹ soil; and P400, 400 mg P kg⁻¹ soil; D = 20, D = 30, and D = 40 represent diameter of pot is 20, 30, and 40 cm, respectively.

under D = 30 was significantly higher than in P0 under D = 40. In contrast, the shoot P content obtained in P200 under D = 30 was significantly higher than in P400 under D = 20. There was no significant difference in the shoot P content as P supply increased from P200 to P400 under D = 20 due to the space limitation.

Root Biomass

Root biomass was significantly influenced by soil P supply and space availability ($P < 0.01$, **Table 1**; **Figure 2**; **Supplementary Figure 2**). Root biomass increased as soil P supply increased, and the effect of space availability on root biomass was stronger under higher P supply (P200 and P400), while no significant difference was observed in P0 between D = 30 and D = 40. There was a strong complementary effect of soil P supply and space availability on root growth. Similar root biomass levels were observed in P200 under D = 40 and P400 under D = 30; root biomass in P200 under D = 30 was significantly higher than in P0 under D = 40. However, a higher root biomass was observed in P200 under D = 30 than in P400 under D = 20. In addition, root biomass increased as soil P

supply increased under higher space availability (D = 30 and D = 40).

Root Morphological Traits

The root length was strongly influenced by soil P supply ($P < 0.01$) and space availability ($P < 0.01$) (**Table 1**; **Figure 3A**; **Supplementary Figure 3A**). The effect of root length increased as soil P supply increased. The effect of space availability on the root length was stronger at higher P supply levels (P400). The complementary effects of soil P supply and space availability on root length were obtained; root length obtained in P200 under D = 40 was equivalent to the root length obtained in P400 under D = 30. Furthermore, the root length obtained in P200 under D = 30 was significantly higher than in P0 under D = 40; however, the root length did not increase as space availability decreased: there was no significant difference in the root length between P200 and P400 under D = 20. Finally, the root length in P400 under D = 20 was lower than that in P200 under D = 30.

Tap root length was also affected by soil P supply and space availability (**Table 1**; **Figure 3B**; **Supplementary Figure 3B**). Tap root length increased as space availability increased. Similar tap

root length was obtained in P400 under D = 30 and P200 under D = 40 and tap root length in P200 under D = 30 was significantly higher than that in P0 under D = 40. However, there was no significant difference in tap root length between P200 and P400 under D = 20. Furthermore, tap root length in P400 under D = 20 was lower than that in P200 under D = 30.

The root angle was strongly affected by space availability, with little relationship to soil P supply (Table 1; Figure 3C; Supplementary Figure 3C). Significantly higher root angles were observed in D = 40 compared with that in D = 20 and D = 30 among all P supply treatments; however, there was no significant difference in the root angle between P400 under D = 30 and P200 under D = 40. The effect of soil P supply on the root angle was negligible under low space availability (D = 20).

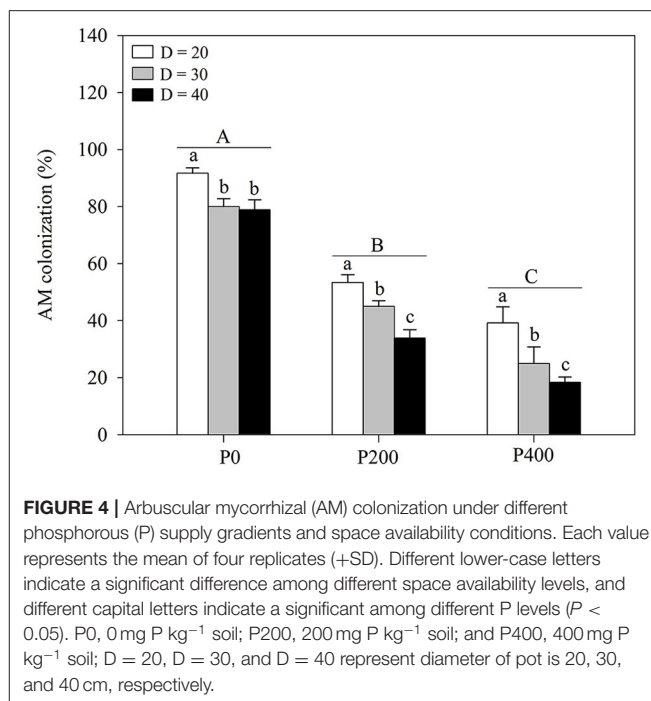

Soil P supply and space availability significantly influenced the lateral root density. The lateral root density significantly increased as P supply increased, while the effect of space availability on the lateral root density was considerable when more P was added to the soil (P200 and P400). Notably, the lateral root density obtained in P400 under D = 30 was equivalent to the lateral root density in P200 under D = 40. Significantly higher lateral root density was obtained in P200 under D = 30 than in P0 under D = 40. Similar to root angle, the effect of soil P supply on lateral root density was negligible under lower space availability (D = 20). The lateral root density in P400 under D = 20 was lower than that in P200 under D = 30.

AM Colonization

Arbuscular mycorrhizal colonization was significantly affected by soil P supply and space availability (Table 1; Figure 4; Supplementary Figure 4); AM colonization decreased with increasing P supply from P0 to P400, regardless of space availability. Furthermore, the effect of AM colonization decreased as the space availability increased in all P treatments; P supply in the root zone and intraspecific density altered plant responses to AM colonization. Higher levels of AM colonization were observed under D = 20 compared with under D = 30 and D = 40. No significant differences were found between AM colonization in P200 under D = 40 and P400 under D = 30, while AM colonization in P0 under D = 40 was significantly higher than that in P200 under D = 30. AM colonization decreased significantly as P supply increased under D = 30 and D = 40, whereas there was no significant difference between AM colonization under conditions of higher P supply (P200 and P400) under D = 20. In addition, AM colonization decreased as space availability increased. The findings imply that the absorption of P by maize is most dependent on AM fungi at the limit of space availability, especially under P0.

Soil Olsen-P Concentration

Bulk soil Olsen-P concentration was strongly affected by soil P supply, with little correlation with space availability (Table 1; Figure 5A; Supplementary Figure 5A). In contrast, the rhizosphere soil Olsen-P concentration was greatly influenced by both soil P supply and space availability (Table 1; Figure 5B; Supplementary Figure 5B). Soil Olsen-P concentration in the bulk and rhizosphere soils increased as soil P supply increased.

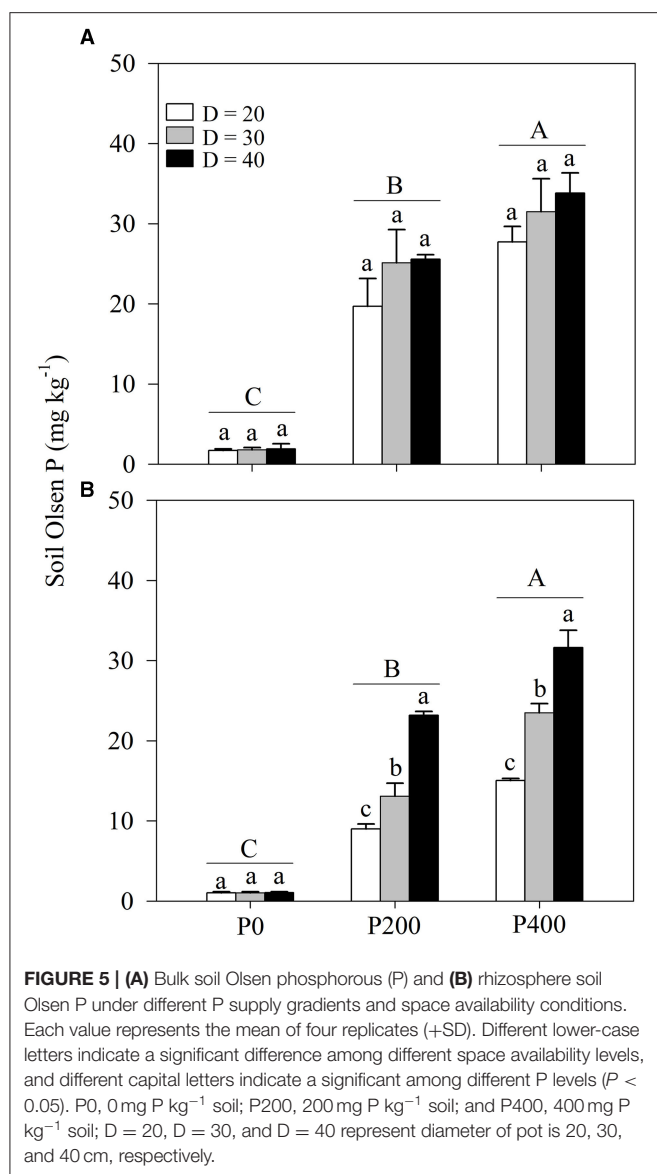

The highest soil Olsen-P concentration was observed in P400 followed by in P200 and then P0. Higher rhizosphere soil-Olsen P concentrations were obtained in P200 under D = 40 and P400 under D = 30.

DISCUSSION

Plants have evolved a series of mechanisms to acquire P from the soil (Lynch, 2011). In maize, the root morphology is a major pathway for obtaining P from soils (Liu et al., 2016; Lugli et al., 2020). Therefore, in addition to P supply in the root zone, space availability for root growth is critical for optimal maize production (Lynch, 2013; Poorter et al., 2016); however, in the maize plants grown at high density, root growth space can be limited, and whether additional soil P supply can compensate for such limitation and the underlying mechanisms are not fully understood. Understanding such interactions is crucial for improving the PUE of under high maize planting density production. In the present study, similar shoot biomass and P uptake were observed in P200 under D = 40 and P400 under D = 30 (Figure 1). Furthermore, the shoot biomass and P uptake in P400 under D = 30 were significantly higher than those in P200 under D = 40. Under insufficient space for root growth, the increasing P supply in the root zone could satisfy crop P demands to a certain extent (Poorter et al., 2012). The findings suggest that the negative effects of low space availability on shoot biomass and shoot P uptake could be counteracted by the improved soil P supply for enhanced maize growth.

With reduced space availability, the photoassimilates are less frequently allocated to the roots (Poorter et al., 2012; Shah et al., 2017). The findings of the previous studies have suggested

that root growth is more inhibited under high plant density than shoot growth, which may be a factor limiting nutrient uptake, especially immobilized soil P (Shao et al., 2018). In addition, under P deficiency, the plants may allocate more carbon to the belowground parts; in maize, the root to shoot ratio can increase along with the enhanced root length and lateral root density to increase the exploration of more areas (Postma and Lynch, 2011; Niu et al., 2020). Over the long-term, low P input is usually accompanied by low productivity. As P is immobilized, increasing mineral P input into the soil is a common agronomy practice used to improve productivity (Zhang et al., 2019). In the present study, both bulk and rhizosphere soil Olsen-P concentrations increased as P supply increased (Figure 5; Supplementary Figure 5), which is similar to the findings observed when alfalfa was grown in a loessial soil (Peng et al., 2020). P is a nutrient that stimulates shoot biomass production and more importantly, acts as a regulatory signal

mediating changes in root architecture (López-Bucio et al., 2003; Pongrac et al., 2020). Therefore, under lower space availability, a plant requires greater P supply to build a more efficient root system with a sufficient capacity to absorb P. In the present study, root dry weight in P400 under D = 30 was similar to that in P200 under D = 40, and root dry weight in P400 under D = 30 was significantly higher than that in P200 under D = 40 (Figure 2; Supplementary Figure 2). Root growth regulation by soil P supply and space availability could explain the complementary effects of the two factors on shoot biomass and P uptake.

Changes in space availability led to the plant responses that alter the root architecture (Ramireddy et al., 2018). The reduced space availability inhibits root length, tap root elongation, and the development of lateral roots (Figures 3A,B,D; Supplementary Figures 3A,B,D). In maize, the root architecture, such as root length, root surface area, root volume, and root diameter, can decrease under high plant density (Mi et al., 2016; Shao et al., 2018). In addition, the steeper root angles were obtained in treatments with lower space availability (Figure 3C; Supplementary Figure 3C), increasing the risks of rhizosphere P deficiency (Figure 5B). However, improved AM colonization was observed with lower space availability, suggesting that the soil P acquisition predominantly relies on root-associated AM fungi under high-planting density, where the formation of a sizeable hyphal network structure in the soil benefits P uptake (Deng et al., 2017). However, the regulation of root growth through P supply intensity is closely related to crop productivity through the exploitation of the biological potential for nutrient-use efficiency enhancement (Shen et al., 2013; McNickle, 2020). Root morphology exhibits high plasticity under varying P supply levels (Wang et al., 2020); increasing P supply induces root length growth, tap root elongation, and development of lateral roots and facilitates the acquisition of P through expansion into a greater soil volume, thereby increasing the absorptive surfaces of the roots (Williamson et al., 2001). In contrast, according to the results of the present study, AM colonization decreases as P supply increased. As expected, the root length, tap root length, and lateral root density increased as soil P supply increased through increased root-soil contact, subsequently enhancing P uptake (Figures 3A,B,D; Supplementary Figures 3A,B,D), while AM colonization decreased. Notably, this study results indicated similar root length, root angle, and lateral root density values in P200 under D = 40 and in P400 under D = 30. This finding suggests that P supply intensity may compensate for the limitation of growth space through the exploitation of the biological potential of maize to enhance P uptake through the root morphological changes.

At higher planting densities, plant growth and development can be limited by soil nutrients in the root zone (Dong et al., 2015). When the nutrient content is adequate for plant growth, increases in growth space may improve productivity (Fageria and Moreira, 2011). In the present study, shoot biomass and P uptake significantly increased with an increase in space availability under P200 and P400 (Figure 1; Supplementary Figure 1). In contrast, higher P supply (P200 and P400) did not improve shoot biomass and P uptake under D = 20 (Figure 1; Supplementary Figure 1).

Due to the existence of a threshold value for the efficient uptake of P by maize roots, maize cannot absorb more P than the threshold value, even if the amount of P supply is increased in a P-limited area (Santner et al., 2012). There are two plant P uptake pathways in the soil that include P uptake from soil: P uptake by roots and the AM fungal pathway (Watts-Williams et al., 2015). Root development and AM colonization are hindered under lower space availability considering that the plant density can lead to growth factor competition (Schroeder and Janos, 2004). The potential of root biology may not be fully exploited by P supply through the regulation of root morphology and AM colonization; therefore, only by matching P supply and space availability can root growth be regulated and the plant PUE can then be improved.

Collectively, the findings of the present study provide an important scientific basis for an enhanced understanding of the mechanisms *via* which soil P supply intensity could be used to counteract the adverse effects of high maize planting density on root morphology, P uptake, and PUE improvement, for sustainable crop production with high yields and high nutrient-use efficiency. Whether the advantages of soil P supply can compensate for the limited root growth spaces induced by high planting density under field conditions still requires further comprehensive studies.

CONCLUSIONS

Both P supply in the root zone and space availability influence the PUE in maize by influencing the root morphology and AM colonization dynamics. Similar shoot biomass and P uptake were observed in the conditions with high P supply and low space availability, and in the conditions with low P supply and high space availability. The lower maize biomass observed in conditions with relatively low space availability was fully counteracted by the relatively high P supply through the modification of root morphology and AM colonization activities. Furthermore, shoot biomass and P uptake did not increase with increased P supply in the root zone after

root-growth space was reduced; here, the lower maize biomass obtained under low space availability was not fully counteracted by the relatively high P supply. The findings highlight the need to optimally coordinate the root growth space and P supply in the root zone, specifically to achieve optimal PUE under the intensive high-density maize production. The results of the present study highlight that understanding the optimal P supply in the root zone and space availability are essential for high PUE under the intensive high-density maize production system.

Plants respond to environmental cues *via* adaptive cell reprogramming that can affect whole plant and ecosystem functionality. Microbiota constitutes part of the inner and outer environment of the plant. This *Umwelt* underlies steady dynamics, due to complex local and global biotic and abiotic changes. Hence, adaptive plant holobiont responses are crucial for continuous metabolic adjustment at the systems level. Plants require oxygen-dependent respiration for energy-dependent adaptive morphology, such as germination, root and shoot growth, and formation of adventitious, clonal, and reproductive organs, fruits, and seeds. Fermentative paths can help in acclimation and, to our view, the role of alternative oxidase (AOX) in coordinating complex metabolic and physiological adjustments is underestimated. Cellular levels of sucrose are an important sensor of environmental stress. We explored the role of exogenous sucrose and its interplay with AOX during early seed germination. We found that sucrose-dependent initiation of fermentation during the first 12 h after imbibition (HAI) was beneficial to germination. However, parallel upregulated AOX expression was essential to control negative effects by prolonged sucrose treatment. Early downregulated AOX activity until 12 HAI improved germination efficiency in the absence of sucrose but suppressed early germination in its presence. The results also suggest that seeds

inoculated with arbuscular mycorrhizal fungi (AMF) can buffer sucrose stress during germination to restore normal respiration more efficiently. Following this approach, we propose a simple method to identify organic seeds and low-cost *on-farm* perspectives for early identifying disease tolerance, predicting plant holobiont behavior, and improving germination. Furthermore, the research strengthens the view that AOX can serve as a powerful functional marker source for seed hologenomes.

Keywords: seed quality, ROS, Warburg effect, bacterial endophytes and mycorrhizal fungi, organic seeds, biotic stress, *on-farm* seed selection

INTRODUCTION

Understanding the role of microbiota in adaptive plant robustness is important for crop improvement and developing innovative tools that could allow more efficient plant selection (Arnholdt-Schmitt et al., 2014; Arnholdt-Schmitt et al., 2015, 2018; Nogales et al., 2015). Research on the relevance of endophytic and associated microbiota and usage of microbes as bioinoculants are often hampered by low reproducibility, due to a lack of better understanding of fundamental principles of the plant-microbe interactions (Arnholdt-Schmitt, 2008; Vicente and Arnholdt-Schmitt, 2008; Campos et al., 2015; Mercy et al., 2015, 2017; Bedini et al., 2018; Alborno et al., 2020) emphasized the need to study mycorrhizal benefits on a case-by-case basis which should consider more holistic and context-dependent views on mycorrhiza functioning at plant family and biome-wide levels. Also, it is widely confirmed that endophyte effects are genotype-specific (Abdelrazek et al., 2020a,b). Furthermore, Durán et al. (2018) identified bacterial endophytes as drivers for soil suppressive take-all disease. Nevertheless, they highlighted that they did not find a relevant correlation between disease suppression and reduced pathogen biomass. In our opinion, these are key observations. They encouraged us to initiate the work on the hypothesis that the competence of individual plant hosts for resilience plays the most critical role for beneficial or non-beneficial plant-microbe interactions, which can be superior to plant families and biome origins.

However, there is a lack of knowledge on traits that aid in (a) early prediction of the plant strength, (b) demonstration of its relevance for plant-microbe interactions, and (c) transformation of such knowledge toward user- and environment-friendly applications for sustainable agriculture. We earnestly aim with the perspective to understand these phenomena and to contribute to the knowledge base toward closing these three gaps.

Seed Germination/Reprogramming as a Model to Study Plant Adaptive Robustness

The capacity for efficient reprogramming as a trait *per se* is recognized as a marker for adaptive plant robustness (Cardoso and Arnholdt-Schmitt, 2013). Seed germination can serve as an experimental *in vitro* tool to study environmental stress-induced reprogramming and to identify early functional markers and tools for predicting plant performance under field conditions (Mohanapriya et al., 2019). Dry seeds are known to respond upon

water imbibition and subsequent penetration of oxygen. Thus, radicle emergence can be seen as an indicator of environmental stress recovery from the dry-to-water imbibed conditions and low-to-high oxygen status.

Efficient seed germination under field conditions is especially required in organic agriculture, where the application of chemical herbicides and pesticides to suppress competitors shall be avoided to support healthy food and feed production and to improve the sustainability of bio-based socioeconomic systems. At the same time, organic agriculture impacts seed quality and the amount of microbiota in seeds (Cope-Selby et al., 2017; Wassermann et al., 2019). Recently, the use of the so-called “organic seeds” vs. conventionally produced seeds is raised as an ethical issue (European Parliament and of the Council, 2018). However, the better quality of organic seeds in terms of their contribution to agriculture sustainability, nutritional quality, and yield performance is under intensive debate (e.g., Bhaskar et al., 2019; Voss-Fels et al., 2019) and requires scientific validation (Simon et al., 2017; Abdelrazek et al., 2020a,b). Appropriate methods and tools are in absolute need to discriminate organic vs. conventional seeds by traits that should allow predicting the superior quality of organic seeds.

The Complex Role of Sucrose in Adaptive Reprogramming

Cellular reprogramming is an energy intensive phenomenon. Reactive oxygen species (ROS) are known to interact with redox-sensitive protein cysteine thiol groups relevant for energy metabolism and metabolic channeling linked to cell differentiation and cell cycle regulation (Bigarella et al., 2014; Dumont and Rivoal, 2019; Gupta et al., 2020a,b; Pengpeng et al., 2020; Qi et al., 2020). Sugars and sugar phosphates interact with hormone-mediated signal networks to modulate energy metabolism. Auxin-stimulated sugar metabolism is frequently reported (e.g., Zhao et al., 2021); however, only few examples revealed that sucrose can induce new cell programs (Grieb et al., 1994; see in Zavattieri et al., 2010) and also, vice versa, can change auxin metabolism (Lin et al., 2016; Meitzel et al., 2021). In maize, sucrose induced several cell cycle markers during germination than glucose (Lara-Núñez et al., 2017). Downstream of sugars, two important antagonistic protein kinases are involved in energy sensing and physiological adaptation (reviews in Bailey-Serres et al., 2018; Sakr et al., 2018; Schmidt et al., 2018). While sucrose non-fermenting-1-related protein kinase 1 is activated when energy is depleted (Schmidt et al., 2018; Wurzing et al.,

2018; Wang et al., 2020), the target of rapamycin (TOR) is induced under conditions of energy excess to stimulate the cell cycle progression and the cell proliferation (Sangüesa et al., 2019). Sucrose can have various functions: besides its metabolic role, it acts as a signaling component (Baena-González and Hanson, 2017; Sakr et al., 2018), as an osmotic stressor that can disrupt communication within and between cells (Moon et al., 2015), shown to trigger aerobic alcohol fermentation in support of respiration, and biosynthesis of higher molecular weight compounds, such as lipids (Mellema et al., 2002).

Multifunctional Role of AOX as Switch Between Respiration and Fermentation During the Germination Process

Alcohol fermentation has been found to play a critical role in controlling tissue level pyruvate in plants, thereby, adjusting respiration rates to prevailing cellular energy status (Zabalza et al., 2009). Fan et al. (2020) identified hormone and alcohol degradation pathways that were mostly activated during the early stages of somatic embryogenesis (SE), which is a prominent example of *de novo* programming. Ethanol has been shown to reduce ROS levels and led to high induction of *alternative oxidase* (AOX) and *glutathione-S-transferase* transcripts (Nguyen et al., 2017). Transcriptome analyses at 2,4-dichlorophenoxyacetic acid (2,4-D) induced reprogramming indicated that the extent of aerobic fermentation is connected to cell proliferation and is regulated by interacting levels of sucrose and AOX (Costa et al., 2021). Transient upregulation of genes related to alcoholic and lactic acid fermentation is shown to be associated with glycolysis and modified complex stress signaling patterns with enhanced superoxide dismutase (SOD) and decreased transcript levels of nitric oxide (NO) producing *nitrate reductase* (NR). Furthermore, the data signaled activation of cell death-regulating system and arrested cell cycle by reducing α -tubulin gene transcription in the earliest step of reprogramming. Considering the generality of these observations, we proposed a reference transcriptome profile to identify virus traits that link to harmful reprogramming (Arnholdt-Schmitt et al., 2021). This approach helped to identify an early trait for combating SARS-CoV-2 that covers ROS/reactive nitrogen species (RNS) balancing, aerobic fermentation regulation, and cell cycle control (Costa et al., 2021).

In seeds, fermentation and alternative respiration (AR) are dominating metabolic reactions (Arnholdt-Schmitt et al., 2018; Mohanapriya et al., 2019). During seed germination, structural and functional acclimation of aerobic respiration is central and determines the temperature-dependent efficiency of germination (Bello and Bradford, 2016; Paszkiewicz et al., 2017). Nevertheless, markers for respiration and oxygen consumption were not superior to simple germination tests for predicting the vigor of single seeds (Powell, 2017). However, it is suggested that AR plays the most critical role during germination (Arnholdt-Schmitt et al., 2018; Mohanapriya et al., 2019). This role requires managing ROS/RNS increase and channeling energy and substance flow from fermentation, when carbohydrate storages are released and enzymes get into action (Saleh and Kalodimos, 2017), but the respiration chain is still structurally restricted

and overloaded by massively incoming oxygen. AOX is mainly regulated by pyruvate (Millar et al., 1996; Hoefnagel et al., 1997; Hakkaart et al., 2006; Albury et al., 2009; Carré et al., 2011; Selinski et al., 2018) and strikingly, Ito et al. (2020) showed in *Arum* that energy-related metabolic regulation can be determined by temperature-dependent switching between AOX polymorphisms in the binding site for AOX-pyruvate. In this scenario, it might be of interest that AOX is essential in ethylene-induced drought tolerance and mediating autophagy *via* balancing ROS levels (Zhu et al., 2018). Also, thermoinhibition of carrot seed germination could be circumvented by seed priming, which was found to be linked to increased ethylene production at higher temperatures (Nascimento et al., 2013). Ethylene biosynthesis is found to be induced by hydrogen peroxide (H_2O_2) and acted positively on germination, independent of auxin-coordinated hormonal crosstalk linked to abscisic acid suppression and gibberellin activation (Wojtyla et al., 2016). During ethylene biosynthesis, cyanide is generated as a by-product of the pathway and probably shifts cytochrome oxidase (COX)-mediated respiration to AR (Siegien and Bogatek, 2006; Machingura et al., 2016). Eckert et al. (2014) stressed that microbiota has developed ethylene-producing pathways to profit during the invasion and to evade defense responses of the host plants. Additionally, Mercy et al. (2017) observed that treating mycorrhiza-infected seedlings with potassium cyanide promoted local arbuscular formation.

AOX Is a Key Molecule for Cellular Reprogramming: Toward a Perspective

Recently, we identified AOX as the stress level sensing coordinator for auxin inducible metabolic reprogramming by comparing induction of SE and seed germination (Arnholdt-Schmitt et al., 2018; Mohanapriya et al., 2019). Association of AOX to target cell reprogramming is also observed in other systems such as adventitious root development in olive (Santos Macedo et al., 2009; Porfirio et al., 2016) and elicitor-induced hairy roots (Sircar et al., 2012). Furthermore, our group had contributed to novel functional marker strategies by highlighting AOX as a marker across taxonomic borders that includes “shared” AOX genes in plant holobionts (Arnholdt-Schmitt, 2005a,b, 2008; Arnholdt-Schmitt et al., 2006; Campos et al., 2015; Mercy et al., 2017; Bedini et al., 2018). Based on the role of AOX in carbohydrate metabolism (Vanlerberghe et al., 1994), our approach has been stimulated to understand the role of fermentation and sugars during plant-mycorrhiza interactions (Mercy et al., 2017; Bedini et al., 2018) and had led to a privately explored patent (Lucic and Mercy, 2014). However, the early phase of reprogramming was not sufficiently considered in that research (Mercy et al., 2017) to drive our core functional marker approach (Arnholdt-Schmitt, 2008; Mercy et al., 2015). Recently, Mohanapriya et al. (2019) observed that arbuscular mycorrhizal fungi (AMF) inoculation in carrot seeds interacted with the AOX-inhibitor salicyl hydroxamic acid (SHAM) and palliated negative SHAM effects on early germination. Also, AMF effects in seeds seemed to be modified by non-culturable microbiota. Integrated *in silico* studies on experimental data revealed that endophytes interact with AOX expression in

species-, stress-, and developmental-dependent manner. Also, Costa et al. (2021) highlighted the importance of microbiota-plant genotype interaction and its impact on early carrot seed germination which can be modified by SHAM.

In our earlier work in Mohanapriya et al. (2019), we demonstrated successful prediction of oxycaloric equivalents from germinating seeds at 10 HAI. The present perspective questions the metabolic nature of AOX coordination and provides deeper phenotyping during germination of endophyte-free and microbiota-inoculated seeds focused at early times around 12 HAI. **Figure 1** demonstrates the step-by-step rationale of fundamental insights and deduced practical strategies (methodology of experiments is provided in **Supplementary File 1**).

In our findings, we observed that (a) during *Arabidopsis thaliana* seed germination alcohol dehydrogenase (ADH) transcript levels were increased at 12 h after seed stratification (SL) in water followed by a decline, and the increase in ADH transcript levels is in general accompanied by increased AOX1a transcript accumulation (**Figure 1B2**). (b) In agreement with (a), germinating carrot seeds displayed a higher level of ADH activity at 12 HAI than 24 HAI. In the presence of 3% sucrose, this level was further enhanced (**Figures 1A3,B3**). (c) Two hours short pulses of sucrose before water imbibition enhanced early germination in seeds of two different species, viz., carrot and wheat (**Figures 1A2,E3** and **Supplementary Figure 2**). Additionally, in carrots, we showed that the effectiveness of such early sugar pulse was dependent on sucrose concentration. A short pulse could be substituted by a longer pulse at a lower concentration of sucrose (**Figure 1A2**). (d) On the contrary, SHAM treatment until 6 and 12 HAI suppressed germination in the presence of 3% sucrose. However, it favored early germination in the absence of sucrose (**Figure 1C1**).

(e) Three carrot native bacterial endophytes (EN1, EN2, and EN3) were used for carrot seed inoculations with two cultivars (cv. Kuroda, cv. Early Nantes) and showed a tendency to improve germination (**Figure 1D1**). However, a positive effect is dependent on cultivar-endophyte interaction. SHAM treatment reduced the early germination percentage of endophyte-treated seeds against the respective endophyte-treated controls. This was observed in all cases though to a different degree of inhibition (**Figure 1D2** and **Supplementary Table 2**). (f) Sucrose has displayed different impacts on endophyte-mediated effects on germination and is dependent on cultivar and endophytes. However, in no case did endophytes improved germination of sucrose-treated seeds when compared with endophyte-treated controls without sucrose (**Figure 1D2** and **Supplementary Table 2**). (g) In a good germinating carrot cultivar (cv. Kuroda), the two selected *Rhizophagus* species (*Rhizophagus irregularis* and *Rhizophagus proliferus*) acted negatively on early germination, while in a delayed germinating carrot cultivar (cv. Early Nantes), both *Rhizophagus* species acted positively (**Figure 1D1** and **Supplementary Table 2**). In both cultivars, sucrose could improve *Rhizophagus* effects on early germination to higher levels than the AMF-treated controls. However, this is dependent on cultivar-species interaction. In the presence of sucrose, *R. irregularis* (M1) improved germination of both cultivars compared to M1-treated control seeds in the absence of

sucrose (**Figure 1D2**). (h) In addition, at lower concentrations of SHAM (5 mM), early germination could be improved to higher levels as compared to the AMF-treated controls (**Figure 1D2**), but this is observed only in the cv. Kuroda variety, which did not show positive AMF effects against non-AMF-treated controls (**Figure 1D1** and **Supplementary Table 2**).

In **Figure 2**, we present a simplified scheme that summarizes our conclusion based on wet-lab experiments, state-of-the-art knowledge, and our hypothetical inferences related to the dynamic metabolic interplay between sucrose, aerobic fermentation, COX-mediated respiration, AOX regulation/AR, and microbiota on cell reprogram functioning. In this scheme, we separated AOX as a macromolecule (gene/protein) from its functional pathway, AR, to highlight the outstanding position of AOX as the key and only enzyme of the pathway that, if present in an organism, is recognized to provide a central metabolism-coordinating function for efficient survival (Mohanapriya et al., 2019; Arnholdt-Schmitt et al., 2021; Costa et al., 2021). We consider that under development- and/or environment-induced conditions of rapid sucrose increase, the COX pathway is stimulated *via* enhanced glycolysis, pyruvate production, and increased tricarboxylic acid (TCA) cycle, in a way that the respiratory chain can get overloaded by electrons followed by enhanced ROS/RNS levels and, on the other hand, restricted due to rapidly consumed oxygen and/or yet low numbers of functional mitochondria concerning the presence of oxygen during germination. In response, aerobic alcoholic and lactic fermentation are stimulated (refer points a, b, and c; Costa et al., 2021). At the same time, AOX is activated [refer point d and in Mohanapriya et al. (2019), Costa et al. (2021)] mainly through AOX gene sequence-dependent pyruvate regulation and ROS/RNS.

Depending on stress level and the amount of sucrose and duration of the situation of high sugar-level, anaerobic glycolysis can reach high turnover during cell reprogramming and high levels of adenosine triphosphate production even corresponding to the Warburg effect. This latter hypothesis is supported by parallel research on auxin-induced callus growth (Costa et al., 2021), where we observed a rapid increase in *ADH1* transcripts of 1,777% and a parallel increase in *LDH* (*Lactate dehydrogenase*) transcripts of 346%. Warburg effects are increasingly recognized also in human systems (Kutschera et al., 2020; Melkonian and Schury, 2020) as being part of normal physiology. However, in plants, they are studied still more concerning photosynthesis (Kutschera et al., 2020) and anaerobic conditions are best explored under flooding conditions and are related to anaerobic tolerance in rice (Narsai et al., 2017). It is shown that AOX plays a beneficial role under low oxygen and especially during reoxygenation (Jayawardhane et al., 2020).

Under increased sucrose, fermentation can escape feedback downregulation with the help of enhanced AR, since AOX-transferred electrons enable the continuation of the TCA cycle for metabolic reorganization though with relatively less energy efficiency. Thus, fermentation and AOX are complementing each other to maintain metabolic and energetic homeostasis thereby avoiding inefficient situations when the respiration chain is overloaded with oxygen availability. As soon as oxidative stress gets sufficiently diminished at equilibrated oxygen availability in the COX pathway, AOX will be downregulated and normal

FIGURE 1 | (Continued)

Step-by-step rationale of the perspective. **(A1)** Exogenous sucrose postponed germination of endophyte-free and superficially sterilized carrot seeds: Sucrose inhibited early germination [at 48 h after imbibition (HAI)] depending on increasing sugar concentrations. This trend is the same for endophyte-free seeds that were superficially sterilized. At 120 HAI, the effect of 0.5–3% sucrose could not be noticed anymore, while 7% sucrose inhibited germination for a prolonged time. This observation indicates a critical role of sucrose during the induction of adaptive performance. To confirm, the role of sucrose, in **Supplementary Figure 1**, the effect of sucrose is shown for auxin-dependent early induction of somatic embryogenesis (SE) as the most studied example of *de novo* programming. It demonstrates that (a) sugar is essential for cell reprogramming since SE induction was not observed at around 45 DAI (days after inoculation) in controls, but only at 2 and 3% sucrose supply and (b) that SE can be optimized with the help of increasing amounts of exogenous sucrose since SE induction efficiency is highest at 3% sucrose (**Supplementary Table 1**). Cell reprogramming competes with cell division. This is a common insight, which got here validated again through the observed delay in embryonic vs. non-embryonic callus emergence at lower sucrose concentrations. As a general tendency, at higher sucrose levels, less number of seeds showed callus growth, which was later demonstrated to be embryogenic, in comparison to the higher number of seeds with (non-embryogenic) callus growth at lower sucrose levels (**Supplementary Figure 1**). **(A2)** Short early pulses of sucrose enhanced early germination in carrot seeds: A total of 3% sucrose applied for 2 or 10 h imbibition enhanced early germination for about the same degree compared to the control and longer pulse of 30 h. A lower sucrose concentration of 0.5% had the highest effect only by a longer pulse of 10 h and, at 7% sucrose, a higher effect against the control was only indicated when given as a short pulse of 2 h. This observation was confirmed with a second carrot cultivar in a rapid *on-farm* check by using a ca. 5% solution of commercial sugar (significant) (**Supplementary Figure 2**). **(A3)** Exogenous sucrose enhanced the level of alcohol-dehydrogenase (ADH) at 12 HAI during carrot germination: At 12 HAI, treatment with 0.5 and 3% sucrose resulted in an increase in ADH activity as compared to the control, while for 7% sucrose no effect is observed. At 24 HAI, the control indicated a decline of ADH values. In the presence of 0.5 and 3% sucrose, this decline is not avoided or might even have been strengthened. However, at 30 HAI, a second phase started, where sucrose enhanced the levels of ADH in a concentration-dependent manner including a positive effect of 7% sucrose. **(B1)** Salicyl hydroxamic acid (SHAM) affects early germination and this links to expression of *AtAOX1a*: In wild-type *Arabidopsis thaliana* seeds, while monitoring germination at 72 HAI, showed that SHAM treatment led to reduced germination rates. This inhibition is dependent on its concentration of 0.5 or 1.5 mM. However, when alternative oxidase (AOX) had been silenced (antisense), SHAM did not affect germination. On the contrary, when AOX was constitutively overexpressed (OE), SHAM indicated stronger inhibition of germination than in the wild type. Nevertheless, the three genotypes germinated with similar efficiency about their respective controls. This latter observation points to the fact that AOX is critically important for germination, if present. However, in case it is not present or activated (antisense) alternative pathways can substitute the functional role of AOX during germination. **(B2)** *AtAOX1a* and *AtADH1 + 2* transcripts accumulated simultaneously: A study on ADH transcript accumulation in wild-type *A. thaliana* confirmed a biphasic activation of *ADH* during germination. A first increase was observed 12 h after stratification (significant), which includes the imbibition of water. The second enhancement occurred from 12 h SL shortly before root emergence was monitored at 24 h SL. In parallel to increased *ADH* transcript accumulation, *AOX1a* transcripts accumulated during both phases, i.e., induction and early initiation of germination. After early induction, *ADH* transcripts showed a high decline (significant) until the end of the dark stratification phase, while *AOX1a* transcript levels remained more stable. During the second phase at the initiation of exponential root length growth in light observed at 48 h SL, *AOX1a* transcript accumulation keeps on enhancing, while the increase of *ADH* transcripts stopped at that time point. This is also indicated in the first phase. *AOX2* transcript accumulation is differentially regulated in comparison to *AOX1a* and showed continuous downregulation during the whole period, which appeared to be stronger in the SL phase. **(B3)** Seeds germinating at 3% sucrose showed higher ADH levels at 12 and 30 HAI: During early germination of carrot seeds, ADH levels follow a parable, when monitored between 12 and 30 HAI. This is observed in control seeds and seeds germinating at 3% sucrose. Nevertheless, suppressed germination at 3% sucrose is linked to higher levels of ADH at 12 and 30 HAI. This means the more efficient germination in control seeds is linked at these two-time points to lower levels of ADH. Under both conditions, in the absence of exogenous sucrose and at 3% sucrose, 24 HAI displayed a turning point with the lowest ADH activity levels. However, ADH activity at 24 HAI is higher in controls (significant) than under conditions of sucrose-supplementation. **(B4)** Early chickpea plant vigor is critical for plant productivity under terminal drought conditions (Sivasakthi et al., 2017). From the two principle chickpea types, Desi and Kabuli, vast field experience has shown that Desi is superior in terms of multistress tolerance and yield performance (Purushothaman et al., 2014). In former research, we could discriminate both types at 10 HAI by a lower oxycaloric equivalent (R_q/RCO_2 ; calorespirometric ratio) value due to differential carbon use and, thus, predict *a posteriori* better yield stability of Desi (Mohanapriya et al., 2019). In this study, we show that Desi increased the level of ADH at 10 HAI during germination (significant at 23 and 28°C), while this is not seen in Kabuli. The reached level of ADH is higher at 23°C than at 28°C. **(B5)** Pronounced SHAM effects on ADH levels at 24 HAI that show interaction with sucrose: During the germination of carrot seeds, the most pronounced effect of SHAM treatment on ADH levels is observed at 24 HAI. At that time point, SHAM stimulated ADH levels compared to levels observed at 12 and 30 HAI. This happened independently of the presence of sucrose (3%). However, under both conditions, 5 mM SHAM showed a stronger stimulating effect on ADH levels (significant) at 24 HAI than 10 mM SHAM. But the level of SHAM-enhanced ADH is higher at both tested concentrations of SHAM when sucrose is not present. On the contrary, at time points 12 and 30 HAI, a higher ADH level in the 0% sucrose controls is associated with the higher concentration of 10 mM SHAM versus 5 mM SHAM. In the presence of 3% sucrose, ADH activity is at any time point higher at 5 mM SHAM than at 10 mM SHAM. Together, these observations point to the importance of differential AOX activity regulation for optimized germination during all three time points independently of the presence or absence of exogenous sucrose. **(C1)** SHAM pulses ≤ 12 HAI impact germination efficiency and interact with sucrose effects: In control seeds, short pulses of SHAM (10 mM) until 12 HAI enhanced germination efficiency and were more effective than pulses until 6 HAI. However, prolonged SHAM treatment of 72 HAI suppressed early germination. In contrast, at 3% exogenous sucrose, early germination efficiency is reduced against 0% sucrose controls (confirming panel **A1**) and SHAM pulses until 6 and 12 HAI led to complete suppression of early germination. However, from 48 HAI onward to 72 HAI, continuous SHAM treatment in the presence of 3% sucrose increased germination, but along with 0% sugar continuous SHAM suppressed germination also at 72 HAI. Collectively, these results show that plastic AOX regulation is critical for the timing of germination in controls and under conditions of sucrose supplementation. **(C2)** 10 and 30–40 HAI are critical times for sucrose–SHAM interaction during carrot germination: A total of 10 h of previous water imbibition reduced the strong negative effects of the combination of exogenous sucrose (3%) and SHAM (5 mM) on germination efficiency that was observed at only 2 h of previous water imbibition (significant). Also, during the phase of initiated root emergence at 30 Hours of imbibition (HOI), a transfer from water to media supplemented with sucrose and SHAM suppressed germination (significant). Water imbibition until 40 h before transfer to sucrose- and SHAM-containing media relieved and even supported germination when monitored at 30 and 48 HAI (significant). However, this increase in germination efficiency seemed to be restricted from 72 HAI onward (significant). **(D)** Sucrose and SHAM can improve the effect of arbuscular mycorrhizal fungi (AMF) on early germination: In panel **D1**, it is shown that carrot seeds treated with native endophytes (EN1—endophyte 1; EN2—endophyte 2; EN3—endophyte 3; isolated from cv. Kuroda) tend to improve early germination at 48 HAI in both the cultivars (not seen for EN3 in cv. Early Nantes). Exogenous sucrose had differential effects depending on endophyte and cultivar (Panel **D2**), but in no case does sucrose enhance early germination rates compared to the respective endophyte-treated controls (as shown also in **Supplementary Table 2**). However, SHAM treatment (Panel **D2**) reduced early germination against endophyte-treated controls in all cases (as shown also in **Supplementary Table 2**). In a separate trial, two AMF species (*R. irregularis*—M1 and *R. proliferus*—M2) were tested and acted negatively on germination in cv. Kuroda, but positively in slowly germinating seeds of cv. Early Nantes (Panel **D1**). Nevertheless, the effect of M1 on early germination could be improved in cv. Kuroda by 0.5 and 3% sucrose (Panel **D2**). However, this was not seen for M2. In the better germinating cv. Kuroda, the lower concentration of 5 mM SHAM (Panel **D2**) improved the effect of both mycorrhiza species on early germination. In later germinating seeds of cv. Early Nantes, 0.5% sucrose improved the already positive effect on germination (Panel **D1**) of *Rhizophagus* species M1 (Panel **D2**). In this cultivar, SHAM decreased

(Continued)

FIGURE 1 | (Continued)

the germination rate to the level of the untreated controls (**Supplementary Table 2**). **(E1)** On-farm organic vs. conventional seed discrimination and organic breeding with the help of quick germination tests, commercial sugar, and SHAM treatment: Seeds from six of seven winter wheat cultivars originated from organic agricultural management could be discriminated at 15 HAI through better germination against conventionally produced seeds when germinated in 5% sugar solution. In water, seeds of only four cultivars showed better germination than organic seeds. When conventionally produced material is compared, seeds of the first cultivar showed poor germination. This was much more pronounced when tested in a 5% sugar solution instead of water. Seeds of the second cultivar demonstrated the highest germination rates among all tested cultivars (as shown in **Supplementary Figure 4**). This was observed for seeds originating from both agricultural conditions, although higher germination in 5% sugar solution indicated the presence of microbiota (Panel **E1**). In contrast to all other cultivars, seeds of the second cultivar did not differ in germination rates for organic vs. conventional production under SHAM treatment when compared to the water control (as shown in also **Supplementary Figure 4**). This signals already low levels of AOX at 15 HAI for this cultivar no matter from which agricultural management system seeds originated. Overall, these observations indicate the interplay between plant genotype, sugar, and AOX activity that impacts differential germination capacities between organic and conventional seeds. **(E2)** Identification of disease tolerant pea seeds by germination tests under SHAM discrimination (T-tolerant reference; S-susceptible reference): Pea lines with differential degrees of root rot disease susceptibility could be ranked by employing SHAM inhibition. The most tolerant line (T) showed the lowest degree of SHAM-related inhibition of germination monitored at 27 HAI. This indicates the reasonability of germination tests under SHAM discrimination for the selection of seed vigor and plant robustness. **(E3)** On-farm simple seed germination improvement of stored conventional and organic wheat seeds by a 2 h initial pulse with commercial sugar (first cultivar in 1E1): This figure demonstrates the general potential of improving early germination through a short pulse of sugar its validity across species (in this study winter wheat, but also refer for carrot in Panel **A2** and **Supplementary Figure 2**), agricultural management practices and also related to the aging of seeds.

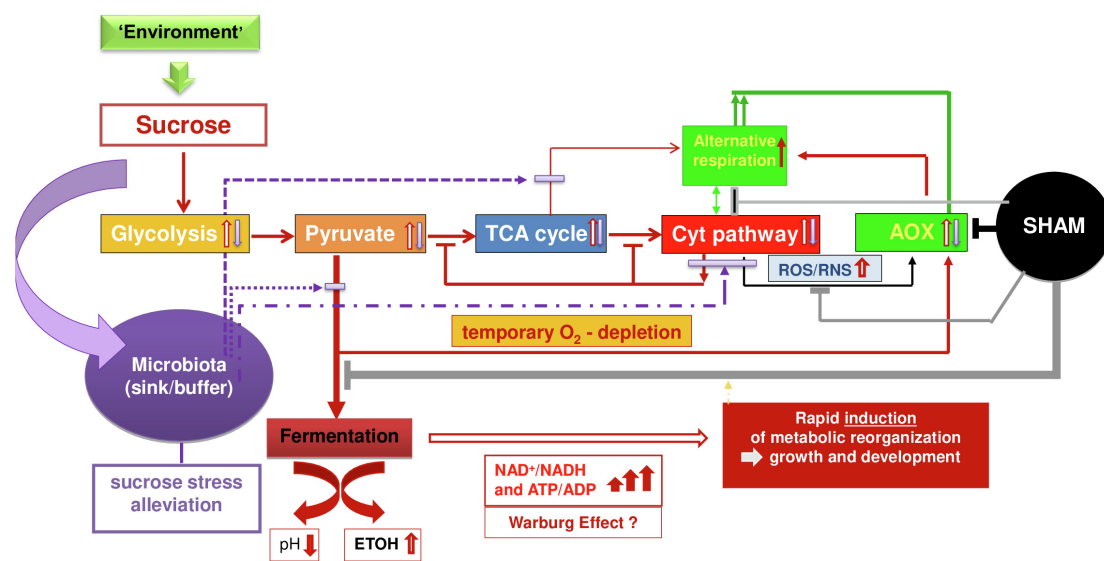

FIGURE 2 | A simplified scheme on hypothesis and conceptualization for working out metabolic principles on dynamic cell reprogram functioning (details explained in the text).

respiration will reach priority again for driving growth and development. Fermentation and AOX downregulation will again be regulated in adaptation to sucrose- and COX-mediated respiration-transmitted conditions embedded in adaptive hormonal crosstalk and overall complex cellular and apoplastic network signaling. Thus, rapid downregulation indicates efficient adaptation of COX-mediated respiration, a dynamic trait appropriate to mark seed vigor (Mohanapriya et al., 2019).

Sucrose can improve early germination of *Rhizophagus*-treated seeds (as shown in point g) while non-AMF-treated seeds respond upon sucrose typically with a delay in germination (as shown in **Figure 1A1**). This suggests that AMF and its associated bacteria (Pandit et al., under review) can alleviate or buffer the negative effects of sucrose on germination to relevant degrees by providing an additional sink. This is not indicated with the three tested endophytes (f). Also, early germination of endophyte-treated seeds is reduced at 48 HAI through the continuous presence of SHAM when compared to

endophyte-treated controls (e). On the contrary, when seeds from the cv. Kuroda were inoculated with *Rhizophagus*, SHAM treatment (5 mM) could improve early germination to higher levels than observed in AMF-treated controls. This observation is in agreement with the palliating effects observed by *Scutellopora calospora* on negative SHAM effects on carrot germination by using the same cultivar (Mohanapriya et al., 2019). In an overall assessment, it is inferred that AMF treatment might improve early germination by alleviating stress-induced by rapid sucrose excess through two mechanisms: providing an additional sink for sucrose and supplying an enhanced capacity and/or engagement of AR. *Rhizophagus* spores were shown to be a rich source for polymorphic AOX gene sequences (Campos et al., 2015). We believe that there could be an operation of two separate mechanisms since we observed differential effects on early germination of M1-treated seeds upon SHAM treatment in the two selected cultivars (**Figure 1D**). However, M1-treated seeds of both cultivars showed improvement in

early germination when sucrose was provided (**Figure 1D**). We tend to interpret that the isolated native carrot endophytes were already well integrated into the internal host cell habitat. Thus, their reinoculation tended to influence early germination positively, but could not provide a striking new advantage or disadvantage when sucrose is enhanced or SHAM treatment reduced the level of AR. However, we reported that endophytes modulate AOX transcripts in species-, stress-, and development-dependent manner, and endophytes could have modified the effect of AMF inoculation on seed germination efficiency (Mohanapriya et al., 2019).

OUTLOOK

The observations offer new perspectives for low-cost prediction of plant holobiont behavior of seeds and for providing simple and rapid *on-farm* support toward sustainable agriculture. We propose three tools for validation:

(A) Seed selection with the help of short germination tests under SHAM discrimination. This tool provides modalities to identify seeds with higher seed vigor, general adaptive plant robustness, and superior internal seed quality related to the content of secondary metabolites (**Figures 1E1,E2** and **Supplementary Figures 3, 4**).

(B) Discrimination of organic vs. conventionally produced seeds with the help of short duration germination tests in water solutions with 5% commercial sugar (**Figure 1E1**).

(C) Germination improvement by 2-h pulses of commercial sugar (**Figures 1A1,E3** and **Supplementary Figure 1**).

Furthermore, we encourage developing novel tests for AMF functionality in germinating seeds in the presence of sucrose. This approach targets compatibility between selected plants and AMF strains to support plant holobiont plasticity.

Our results suggest that polymorphic AOX gene sequences of symbiotic partners can impact plant-AMF compatibility. Therefore, we want to accomplish wider screening of major AOX polymorphisms in species-specific target cells for evaluating plant performance (Abe et al. 2002; Arnholdt-Schmitt, 2015; Nogales et al., 2016) and in AMF sources (Arnholdt-Schmitt, 2008; Vicente and Arnholdt-Schmitt, 2008; Campos et al., 2015). Such a strategy needs to also include near neighboring polymorphisms in conserved functional sites that can discriminate differentially regulated AOX1 and AOX2 (Costa et al., 2009). This approach would include a screening of compatible AOX polymorphisms from both partners in the proposed functional tests to identify the best plant-AMF combinations.

We hypothesize that the observed integration of bacterial endophytes into host plants with similar sensitivity against SHAM effects might point to synchronized AOX regulation in plant holobionts. Into this derivation would fit that we observed the same tendency of inhibiting sucrose effects on endophyte-free and superficially sterilized seeds (**Figure 1A1**), which we noticed also for SE induction (unpublished). Vicente et al. (2015) highlighted a “provocative” lack of interest in bacterial AOX. They anticipated that bacteria-harboring AOX could facilitate

adaptation to extreme conditions, which could also be of interest when thinking about plant endophytes and AMF-associated bacteria (Pandit et al., under review).

This present perspective is complementing Mohanapriya et al. (2019) and Costa et al. (2021). Joining the central figures of these publications is thought of as one teaching tool that can help to explain a straightforward way from fundamental interdisciplinary research to the application that might support sustainable socioeconomies because of the diversity of emergent environmental changes.

DEDICATION

The authors want to dedicate their work to FREEDOM and ETHICS.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/**Supplementary Material**, further inquiries can be directed to the corresponding authors.

AUTHOR CONTRIBUTIONS

RB performed lab analyses on carrot germination, endophyte isolation, and inoculation trials related to **Figures 1A1–3,B3,4,5, C1,2,D**. JHC coordinated transcriptome analyses supported by KT. JHC, RS, and CN discussed initially the approach of this manuscript with BA-S. GM carried out work on **Supplementary Figure 1** and **Supplementary Table 1**. SS was responsible for AMF inoculation trials under the head of AA and EM performed pea studies for **Figure 1E2** under the responsibility of BA-S. Under the supervision of KG and EM together with AK performed germination analyses of transgenic *Arabidopsis*, and AK carried out the ADH analyses on chickpea. BA-S performed *on-farm* analyses (**Figures 1E1,E3**). CN was responsible for statistics and was in part supported by MO. RB and IV helped BA-S in the literature search. DS contributed with **Supplementary Figure 3**. BA-S initiated the scientific approach, coordinated overall research, and discussion, and wrote the manuscript. All the co-authors commented on research and manuscript during its development and agreed to manuscript submission. RB organized manuscript submission.

FUNDING

RS, GM, and BA-S acknowledge support for academic cooperation and mobility of researchers by the India-Portugal Bilateral Cooperation Program (2013–2015), funded by “Fundação para a Ciência e Tecnologia” (FCT), Portugal, and the Department of Science and Technology (DST), India. RS lab is financially supported by UGC-SAP and DST-FIST. GM was grateful to UGC, India, for a doctoral grant

from the BSR fellowship. KG, MO, and BA-S acknowledge support by the India-Portugal Bilateral Cooperation Program “DST/INT/Portugal/P-03/2017.” MO research was partially supported by National Funds through FCT, Fundação para a Ciência e a Tecnologia projects UIDB/04674/2020 (CIMA). BA-S wants to thank RS for enabling intensive external online supervision of RB on the presented research and excellent collaboration and communication of RB. RB and SS acknowledge the infrastructure and stay support provided by DBT-TDNBC-DEAKIN-Research Network Across continents for learning and innovation (DTD-RNA) for AMF-related work at The Energy and Resources Institute, TERI, India. JHC was grateful to CNPq for the researcher fellowship (CNPq grant 309795/2017-6). KT was grateful to CNPq for the doctoral fellowship. BA-S was grateful to SK for his support in facilitating the coordination of the Indian FunCROP team. CN acknowledges the international scientific network BIOALI-CYTED, which contributed to establish FunCROP contacts. BA-S wants to acknowledge especially the extraordinary engagement of CN for online collaboration with RB on data evaluation and presentation and overall manuscript discussion. BA-S appreciates the collaboration of LIVESEED partners with seed material and information on this material and thanks for supporting EM (European Horizon 2020 project LIVESEED Grant No. 727230).

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fpls.2021.686274/full#supplementary-material>

Supplementary Figure 1 | Exogenous sucrose delayed callus emergence and was necessary for SE.

Supplementary Figure 2 | A total of 2-h pulse with commercial sugar improved carrot germination efficiency monitored at 40 and 50 HAI.

Supplementary Figure 3 | Effect of SHAM treatment on accumulation of soluble and wall-bound phenolics (A) and flavonoids and lignin (B) in elicitor-treated hairy roots of *Daucus carota*. Values obtained in only elicitor-treated root were considered as 100% and results were expressed in terms of percentage of maximum. The terms E and NE in the x-axis legend denote -with and -without elicitor, respectively. * Soluble phenolics. Values are mean of three independent experiments ± SD.

Supplementary Figure 4 | Rapid germination check of organic and conventional seeds from seven cultivars in water (control) or under SHAM (5 mM) treatment.

Supplementary Table 1 | Effect of exogenous sucrose concentration on carrot SE callus induction.

Supplementary Table 2 | Microbiota effect on the carrot seed germination at different sucrose and SHAM concentrations.

Supplementary File 1 | Materials and methods.

Fulvic acids are organic compounds widely distributed in soils, and the application of fulvic acids is thought to increase crop yield and quality. However, the effects vary among various sources and doses of fulvic acids and environmental and growth conditions of crops. Here, we investigated the effects of bioresource-derived (corn straw) fulvic acids on plant production and quality of tomato plants and soil chemical properties in soil cultures while experiments on seed germination and hydroponics were conducted to explore the underlying mechanism. Base dressing with 2.7 g kg⁻¹ increased the yield of tomato by 35.0% at most as increased fruit number. Fulvic acids increased the concentrations of minerals, such as Ca, Fe, and Zn and the concentrations of citric, malic, and some amino acids in berries of tomato but did not affect the concentrations of soluble sugars and aromatic substances in tomato fruits. Similarly, fulvic acids at 80–160 mg L⁻¹ increased germination rate, growth vigor, and radicle elongation of tomato seeds while it increased plant biomass, concentrations of nutrients, and root length of tomato plants in hydroponics to the greatest extent in general. The increases in yield and quality can be attributed to the improvement in root growth and, thus, increased nutrient uptake. In addition, the base application of fulvic acids improved soil cation exchange capacity and soil organic matter to an extent. In conclusion, base dressing and the addition into solution of fulvic acids at moderate doses facilitate root growth and nutrient uptake and, thus, vegetable production and quality; therefore, fulvic acids can be an effective component for designing new biofertilizers for sustainable agricultural production.

Keywords: humic substances, nutritional quality, plant biomass, seed germination, soil organic matter

INTRODUCTION

Fulvic acids are one portion of soil humic substances based on the solubility in strong acid and base solutions; the other two main portions are humic acids and humins (Hayes, 2006; Ahmad et al., 2018). Fulvic acids consist of a group of soluble organic compounds widely distributed in nature and are one of the critical components of soil organic substances (Piccolo, 2002;

Qin et al., 2016; Shah et al., 2018). These organic compounds contain many active functional groups, such as carbonyl, carboxyl, hydroxyl, phenolic hydroxyl, and quinone, and these are capable of chelating and exchanging anions or ions (Calvo et al., 2014; de Melo et al., 2016; Zhang et al., 2020). The mechanisms by which humic-like substances improve plant growth can be attributed to the increased ability of regulating membrane permeability and intracellular signaling, thus increasing root growth (Blomster et al., 2011), increasing concentrations of chlorophyll and photosynthetic activity (Haghighi et al., 2012), and activating carbon and nitrogen metabolism (Jannin et al., 2012). In addition, the biochemical fulvic acids encompass amino acids, vitamins, trace elements, and hormones, and all those compounds can stimulate cell division, root growth, and nutrient uptake and improve the antistress ability of plants and, thus, promote the growth and, thus, yield of crops (De Pascale et al., 2018; Shah et al., 2018; Qin and Leskovaar, 2020). For example, fulvic acids are demonstrated to relieve Pb toxicity to plants by reducing its uptake, thus alleviating various morphological, physiological, and biochemical functions of plants (Shahid et al., 2012).

In recent decades, numerous studies confirm the effectiveness of fulvic acids in agriculture. Fulvic acids are demonstrated to increase the yield and quality of cotton plants, soil fertility, fertilizer-use efficiency, and net profit (Geng et al., 2020). The application of fulvic acids alleviates the damage on wheat plants under salinity stress by improving antioxidant-defense systems, thus increasing growth and production (Elrys et al., 2020). With respect to vegetable production, fulvic acids increase the size and number of tomatoes while decreasing the incidence of cracking and blossom-end rotting (Suh et al., 2014). As a result of increased plant growth, fulvic acids are recommended as an essential constituent to achieve the goal of high yield and quality and sustainable agriculture in horticulture particularly (Olk et al., 2018).

However, due to the complex composition of fulvic acids, in-depth trials have not been not comprehensively investigated, especially the effects of bioresource fulvic acids on the yield and quality of vegetables and the underlying mechanisms. Bioresource fulvic acids are renewable and recyclable, and thus, the popular agricultural fulvic acids in recent decades are considerable for sustainable agriculture (Quilty and Cattle, 2011; Rose et al., 2014).

This study investigates the effects of straw-derived fulvic acids on vegetable plants. We carried out soil experiments, seed germination, and hydroponic cultures to explore the effects of various doses and application patterns on the production, yield, and quality of tomato plants and the underlying mechanisms that potentially facilitate the design of new biofertilizers by using fulvic acids.

MATERIALS AND METHODS

Bioresource-derived fulvic acids, abbreviated as Zhongliang or ZL in the study, were produced by the national company COFCO Nutrition and Health Research Institute, Beijing, China (Table 1).

ZL fulvic acids are derived from corn straw. The lignocellulosic corn straws were pretreated by continuous steam explosion and then hydrolyzed by a series of enzymes (cellulase, hemicellulase, and β -glucosidase) to get a sugar solution. The sugar solution was fermented by using a pentose/hexose co-fermentation strain (C5 strains, Green Tech America, United States) to get the mature fermented mash. Then, the mash was rectified to obtain biofuel ethanol from the top of the rectification tower while the residual mash was obtained from the bottom of the rectification tower. The residual mash was separated from the supernatant and then evaporated, concentrated, and tube-bundle-dried to get the final fulvic acids.

Experiment 1: Soil Culture of Tomato Plants

Experiment 1 was a soil culture to explore the effects of fulvic acids on the yield and quality of a fruit vegetable and soil fertility (Supplementary Figure 1). A randomized complete block design with 11 treatments consisted of various methods of fulvic acid application, i.e., top dressing, foliar, and base dressing (Table 2). Another commercial fulvic acid produced by Quanlinjiayou Co., Ltd. (Jiayou or JY) that was the most effective and popular product in China was used to compare with our product and to demonstrate the effectiveness of our Zhongliang (ZL) fulvic acids. Five replicates were set for each treatment.

The soil was collected from the top 0–20 cm in a high tunnel vegetable farm managed for 18 years in Shanghai, China (Table 3). In this area of the Yangtze River Delta, rice was

produced for several hundred years before, and then the fields were used for vegetable production in the recent two decades. The base dressing followed the local practice, 5 kg mixed soils were loaded into a pot, watered to 100% field capacity, and stabilized for 1 week before being transplanted. The seeds of the tomato cultivar *Hezuo906* is an anti-mosaic-virus cultivar, which was sterilized, germinated, and nurtured. Tomato seeds were soaked in 0.5% NaClO solution for 20 min, then washed by deionized water twice, and placed in Petri dishes to be germinated in a dark incubation chamber (CWI800, Sheyan, Shanghai, China) at 25°C. The 3-day-germinated seeds were sown into a peat-pearlite mixture (2:1, v/v) in a naturally lit greenhouse and watered with a mixture of 1% urea and 1% potassium phosphate. Twenty-day-old seedlings with four true leaves were transplanted into pots. Soils in pots were watered to 80% field capacity at a frequency of 1 or 2 days. Foliar spray and top dressing were conducted every 10 days six times commencing from the initial fruiting stage. The soils were covered by plastic films when the foliar application was conducted to avoid fulvic acids dropping into the soils. The temperature and light intensity were recorded every 10 min by loggers L95-82 and L99-LX (Hangzhou Loggertech Co., China), respectively. The entire growth period was 126 days from August 31 to January 03 in the same naturally lit greenhouse with an average temperature of 18.7°C ± 3.6°C, a light intensity of 253 ± 212 μmol m⁻² s⁻¹, and daily light integral of 12.6 ± 4.3 μmol m⁻² day⁻¹.

Experiment 2: Germination of Tomato Seeds

Experiments 2 and 3 were conducted to explore the mechanisms of fulvic acids increasing the production and quality of vegetables. We conducted Experiment 2 to explore the stimulation of fulvic acids on seed germination rate and radicle elongation (Supplementary Figure 2). It was a randomized complete block design with eight concentrations of fulvic acids in solution: 0, 10, 20, 40, 80, 160, 320, and 640 mg L⁻¹ with three replicates for each treatment. Two Chinese cultivars, i.e., *Huangmenren* (Jinfa Seed Company, Cangzhou, China) and *Zizhenzhu* (Huashu Seed Company, Qingxian, China) were used, and seeds were sterilized and germinated as in Experiment 1. The temperature and humidity in the incubation chamber were 28°C and 70%, respectively. The seed germination experiment lasted for 7 days. The fulvic acid solution was supplied daily to avoid water deficiency.

Experiment 3: Hydroponic Experiment With Tomato Plants

We conducted a hydroponic experiment with tomato plants to explore the effects of fulvic acids on root elongation and plant production (Supplementary Figure 3). The experiment was a

randomized complete block design with eight concentrations of fulvic acids and four replicates for each treatment. Eight concentrations of fulvic acids in hydroponic nutrient solution were 0, 10, 20, 40, 80, 160, 320, and 640 mg L⁻¹.

Tomato seeds of cultivar cv. *Zizhenzhu* were sterilized, germinated, and grown till transplanting as in Experiment 1. Seedlings with four true leaves in similar sizes were selected and then transplanted into containers with 5 L 1/2 Hoagland nutrient solution, and the solutions were shifted to a full-strength nutrient solution at the second week. The macronutrients of Hoagland solution consisted of 4 mM Ca(NO₃)₂·4H₂O, 6 mM KNO₃, 1 mM NH₄H₂PO₄, and 2 mM MgSO₄·7 H₂O, and the micronutrients were the universal formula (mg L⁻¹): 2.86, H₃BO₃; 13.9, FeSO₄·7H₂O; 1.81, MnCl₂·4H₂O; 0.22, ZnSO₄·7H₂O; 0.08, CuSO₄·5H₂O; and 0.02, (NH₄)₆Mo₇O₄·4H₂O. The nutrient solution's pH was maintained at about 6.5 by daily adjusting using 0.25 M H₂SO₄ or 0.5 M NaOH. All the plants were harvested after growth for 21 days from June 24 to July 15.

Sampling Methods

The tomato fruits were harvested twice a week once matured and stored in a -20°C fridge. All the fruits were cut finely and homogenized thoroughly after final harvest, using a fruit blender. The homogenates were centrifuged at 3,000 g for 10 min and filtered by a syringe filter (0.45 μM) for biological analysis. At the final harvest, the leaves, stems, and roots of tomatoes were separated and collected. Separated tissues were cleaned and green-killed, then dried at 65°C to a constant weight to record the dry mass. Fresh portions were stored in a -20°C fridge till analysis. After plant sampling, the soils in pots were sieved at 1 mm after mixing and air-drying to determine soil chemical properties.

Measurements of Seed Germination and Radicle Length

We took daily photos of each Petri dish in Experiment 2 with a digital camera (5D Mark IV, Cannon, Germany). The germination rates were achieved by counting the number of germinated seeds in the photos. The radicle length of each seed was measured by ImageJ (Version 1.51a, National Institute of Health, United States). The germination rate and vigor index are calculated using Equations (1) and (2), respectively.

$$\text{Germination rate} = \frac{\text{Number of germinated seeds}}{\text{Total number of seeds sown}} \times 100\% \quad (1)$$

$$\text{Vigor index} = (\text{mean radicle length}) \times \sum \frac{G_n}{D_n} \quad (2)$$

where G_n is the number of germinated seeds at the n th day and D_n is the number of the n th day.

Determinations of Root Morphology

The fresh roots in Experiment 3 were washed by deionized water three times and scanned (V700, Epson, Japan) to obtain root images. The images were then analyzed by WinRhizo Pro (Version 2013, Regent, Canada) to determine root length and the number of root tips.

Determinations of Soil Property

Soil organic matter (SOM) was determined by dichromate titration. Soil pH was extracted by deionized water at a soil-water ratio of 1:2.5 and determined by a pH meter. Soil available N was determined by the alkali-hydrolyzed reduction diffusing method using 1 M NaOH. Available P was extracted by 0.5 M NaHCO₃ and determined by the molybdenum-antimony anti-spectrophotometric method. Available K was extracted by 1 M CH₃COONH₄ and determined by ammonium acetate extraction-flame photometry (Bao, 2000).

Determination of Tomato Quality

The total soluble solids in the juice of tomato fruits were analyzed by a portable digital sugar meter (PAL-1, Atago, Japan). The fruit juice was used for the determination of various compounds. The concentrations of C and N in the ground plant tissues were measured by a CNS analyzer (Vario MAX CNS, Elementar, Germany). The concentrations of P, K, Ca, Mg, S, Fe, Mn, Cu, and Zn were determined by an ICP-OES (Optima 8000, PerkinElmer, Germany), using the HNO₃-H₂O₂-digested solutions or the fruit juice of the tomato. The concentrations of heavy metals Cd, Cr, and Pb were measured by an ICP-MS (X Series II, Thermo Fisher, United States). The concentrations of metalloids As and Hg were measured by an X-ray Fluorescence Spectrometer (Axios-Advanced, PANalytical, Netherlands). The quantity and composition of metabolites in tomato fruits were determined by LC-MS (Thermo Vanquish UHPLC, Company Thermo Fisher, United States), coupled with an Orbitrap Q Exactive series mass spectrometer (Orbitrap Q Exactive, Company Thermo Fisher, United States). The fresh tomato fruits (100 mg) were individually ground using a blender and centrifuged and then the homogenate was passed through a 0.45- μ m membrane. The supernatant was injected onto an Hyperil Gold column (100 mm \times 2.1 mm, 1.9 μ m), using a 16-min linear gradient at a flow rate of 0.2 mL min⁻¹ for analysis. The Orbitrap Q Exactive series mass spectrometer was operated in positive/negative polarity mode with spray voltage of 3.2 kV, capillary temperature of 320°C, sheath gas flow rate of 35 arb, and aux gas flow rate of 10 arb.

Statistical Analysis

All the data were analyzed according to the experimental design, using SPSS 22 software (SPSS Statistics 22.0, IBM, United States). Pictures were drawn by Origin 2016 (Origin 2016, OriginLab, United States) and ImageJ (ImageJ 1.8.0, National Institutes of Health, United States). The means of these parameters were compared using Duncan's multiple range test at $P < 0.05$.

RESULTS

Effects of Fulvic Acids on Soil-Culture Tomatoes

Moderate doses of fulvic acids applied by base and top dressing improved the yield and nutrient quality of tomato fruits in general. More specifically, base dressing of ZL fulvic acids of 2.7 g kg⁻¹ increased the yield and fruit number of tomatoes in soil cultures by 35.0 and 44.4% greater than other doses (Figure 1). The other commercial JY fulvic acids with top dressing increased the total biomass of tomato plants by 22.4% (Table 4).

The base dressing of 0.9 and 2.7 g kg⁻¹ tended to increase fold changes of essential and non-essential amino acids (Figure 2).

Total biomass is the biomass of entire plants but without fruits. Root/shoot is the ratio of root dry biomass to shoot dry biomass. Data are means (N = 5). The same letters denote insignificant differences ($P < 0.05$) among treatments according to Duncan's new multiple range test.

Base dressing of 2.7 g kg⁻¹ fulvic acids increased fold changes of phenylalanine, valine, and methionine by 55, 56, and 61%, respectively. Compared with the control, ZL fulvic acids by top and foliar application increased the fold changes of linolenic and linoleic acid by 209 and 275%, respectively. Fulvic acids increased fold changes of citric and malic acid with the greatest increased by 291 and 67% in JY top dressing treatment, 211 and 42% in Base 2.7 (Figure 2). However, fulvic acids in all treatments did not affect fold changes of soluble sugar (glucose, fructose, maltose, and sucrose) and some aromatic substances (β -ionone, citral, and eugenol) (Figure 2).

The base dressing of 2.7 g kg⁻¹ also increased the concentrations of mineral elements in tomato juice, especially Mg by 55.9%, Ca by 31.4%, and Zn by 43.1% (Table 5). The concentrations of Mg, S, Ca, and Fe increased in all modes of application.

Fulvic acids by top and base dressing tended to decrease soil pH and increase the soil CEC and SOM across all treatments while foliar application did not affect these soil properties (Table 6). More specifically, Base 2.7 treatment decreased soil pH from 8.06 to 7.81 while it increased EC by 102.9%.

Effects of Fulvic Acids on Germination of Tomato Seeds

The seed germination rates of both tomato cultivars increased and then decreased when the concentration of fulvic acids increased after 7 days (Figures 3A,B). Specifically, the most effective seed germination rate was 12.9% greater than the control when fulvic acids were at a concentration of 80 mg L⁻¹ on average. Fulvic acids of 80 mg L⁻¹ also increased the radicle length and vigor index by 32.2 and 49.7% compared with the control, respectively (Figure 3). The promotion of seed germination by fulvic acids on tomato seed cv. *Huangmeiren* was

greater than that of cv. *Zizhenzhu*. The average seed germination rates of *Huangmeiren* and *Zizhenzhu* across the various concentrations of fulvic acids were 62.6 and 89.9%, respectively.

Effects of Fulvic Acids on Hydroponic Tomatoes

Similar to seed germination, the effects on total biomass, foliar C/N ratio, and root growth of tomato plants in hydroponics increased at first and then decreased when the fulvic acid concentrations increased (Table 7 and Figure 4). Fulvic acids increased the total biomass and foliar C/N ratio by 40.8 and 14.5% at concentrations of 160 mg L⁻¹, respectively, compared with the control. Fulvic acids increased the root length and number of lateral root tips of hydroponic tomato plants (Figure 4). The optimal concentration of fulvic acids on root growth was 80 mg L⁻¹, which increased root length and root tips by 44.4 and 13.8% when compared with the control, respectively (Figure 4 and Supplementary Figure 4). Fulvic acids of 80 mg L⁻¹ also increased the concentrations of mineral elements in the leaf, especially Fe, by 109% compared with the control (Table 7).

Another soil-culture experiment with pak choi was conducted to expand the application of fulvic acids on leafy vegetables with shallow roots using the soils in Experiment 1 and a series of concentrations of fulvic acids the same as Experiments 2 and 3 (Supplementary Figure 5). The aboveground portions of pak choi were harvested on the 21st and 30th day from seeding, respectively. The yield and mineral concentrations in the edible portion were measured (Supplementary Table 1 and Supplementary Figure 6). The analysis of the cost and benefit of fulvic acid application is calculated in Supplementary Table 2. Results are shown in the Supplementary Material.

DISCUSSION

Humic substances are the end products of microbial decomposition derived from plant residuals, which play key roles in various soils and influence plant functions. Fulvic acids are components of humic substances according to their solubility and molecular weight. There are similarities between humic substances and fulvic acids, but the effects on plants depend on the source organic matter, the plant species, and the growth medium (Calvo et al., 2014). Although the effects of humic-like fertilizers differ, studies confirm their effectiveness and economic value in agricultural production. However, it lacks studies focusing on the effects of renewable sources of fulvic acids on vegetable production and yield under various growth mediums and the underlying mechanisms. Our study investigates the effects of straw-derived fulvic acids on the entire growth period of tomato from seed to fruit under either hydroponic or soil culture and give certain explanations on how fulvic acids work.

Fulvic Acids Increased the Yield and Production of Vegetables

Fulvic acids at moderate concentrations and applications of base and top dressing increased the production and yield of tomato

(Supplementary Table 2). Similarly, humic-like substances were reported to increase the production of various vegetable plants. Atiyeh et al. (2002) report that humic substances extracted from vermicompost of pig manures and food waste increased the shoot and root dry masses of tomato seedlings with the optimal concentration of the humic substance being 0.2–0.5 g kg⁻¹. Karakurt et al. (2009) treated 20 ml L⁻¹ humic-like substances with soil and increased the early and final yield of peppers by 38.3 and 11.8% compared with the control. The optimal doses in Karakurt et al. (2009) were lower than our current study; however, the fulvic acids in our study increased the plant yield to a greater extent. Our study demonstrates that fulvic acids have little effect on fruit size (Figure 1C), different from previous studies (Ferrara and Brunetti, 2010; Naidu et al., 2013; Suh et al., 2014). These differences in our study could be attributed to the variety of crops and the methods of cultivation, and the extent of increments and the specific performances also differed from the species of the plants and the sources of the humic-like substances (Morard et al., 2010). Haghighi et al. (2012) conclude that the mechanism of the increase in yield was the stimulation on N metabolism and photosynthesis activity, and Anjum et al. (2011) record that the application of fulvic acids increased the net photosynthesis, transpiration rate, and intercellular concentration of CO₂—effects that were related to plant growth promotion.

Fulvic Acids Increased the Quality of Vegetables

In our study, fulvic acids increased the concentrations of minerals and carbon-containing substances related to product quality in the edible portion of vegetables (Table 7, Supplementary Table 1, Figure 2, and Supplementary Figure 6). Several studies confirm an improvement of vegetable quality by humic-like substance application (Haghighi and Teixeira Da Silva, 2013).

Fulvic acids are demonstrated to improve the produce quality, e.g., by inducing the accumulation of secondary metabolites, vitamins, antioxidants, and minerals (Calvo et al., 2014; Gruda et al., 2018), confirming our results.

More specifically, fulvic acids increase the concentrations of minerals at moderate doses, especially Mg, Fe, and Zn in either tomato or pak choi (Table 5 and Supplementary Table 1). It is demonstrated that the application of humic acids enhances the accumulation of minerals such as Ca, Fe, Mg, and Zn in soil-cultured garlic (Denre et al., 2014). Similarly, humic substances increased the concentrations of P and Fe in grapes (Sánchez-Sánchez et al., 2006). With respect to carbon-containing substances, base dressing of 2.7 g kg⁻¹ fulvic acids increased fold changes of phenylalanine, valine, and methionine, which possibly improved the fragrance of tomato berries (Ou et al., 2007), and the increased arginine contributed to an improvement in the quality of fruit berries (Micallef and Shelp, 1989; Nasibi et al., 2011). Consistent with our study, humic acids increased the concentrations of linolenic and linoleic acid in rapeseed (Amiri et al., 2020), the titratable acids in citrus (Hameed et al., 2018), and the amino acids in tomatoes (Yildirim, 2007). However, fulvic acids did not affect fold changes of soluble sugar and some aromatic substances (Figure 2), similar to a previous study (Canellas et al., 2013). That could be attributed to the application of fulvic acids that decreased the activity of enzymes involved in glucose metabolism (Canellas et al., 2015). The metabolites alternatively could be used to increase the growth of plants (Canellas et al., 2013), which confirms our results of tomato production and yield (Table 4 and Figures 1, 2). According to Trevisan et al. (2011), Jannin et al. (2012), and Canellas et al. (2015), the effects of fulvic acids on nutrients may be attributed to the regulation of enzymes and genes that are involved in the primary metabolism, and thus affect the transformation and accumulation of metabolic substances.

The increased quality indicators in tomato fruits by fulvic acids indicates an improved fruit quality and, thus, human nutrition in general. However, the quality of vegetables was not always improved by fulvic acids, such as some reduced sugars in tomato fruits (Figure 2) and mineral concentration in the edible portion of pak choi (Supplementary Table 1), so one need to be cautious when applying. These findings suggest that plant biostimulants, i.e., fulvic acids, may be used to improve product quality of vegetables in a sustainable way (Gruda et al., 2018). This will be imperative in the near future due to projected climate changes with high temperatures, water scarcity (Gruda et al., 2019a,b), and high CO₂ concentrations (Dong et al., 2018, 2020).

The Reasons for Increased Yield and Quality

The increases in production and quality might be attributed to the stimulants on plant growth, especially the promotion of root growth and, thus, the uptake of minerals. In our study, fulvic acids increased root growth of germinated seeds (Figure 3) and increased the root length and number of lateral root tips of hydroponic tomato plants (Figures 4A,B) while the uptake of mineral nutrients and the plant biomass

FIGURE 3 | The effect of fulvic acids on the germination rate, root length, and vigor index in of tomato seeds cv. *Huangmeiren* (A,C,E) and cv. *Zizhenzhu* (B,D,F) germinated for 7 days. Data are means \pm s.e (N = 3). The same letters denote insignificant differences ($P < 0.05$) among treatments according to Duncan's new multiple range test (Experiment 2).

increased (Table 7 and Figure 4). Fulvic acids are demonstrated to increase the root length of wheat seeds (Qin et al., 2016) and tomato plants (Dobbss et al., 2007, 2010) although humic extracts from hydrochar and Amazonian Dark Earth increased radicles and seminal lateral roots of maize seeds (Bento et al., 2020). The effects on root growth could be attributed to the hormone-like molecules and their auxin- and gibberellin-like effects that can promote the elongation of root cells, coleoptiles, and hypocotyls (Zhao and Zhong, 2013; Canellas et al., 2015), confirming the characteristics of our microbially fermented fulvic

acids. According to Blomster et al. (2011), fulvic acids enhance the activity of auxin signaling and the involved enzymes to increase the growth of roots. However, the current study lacks specific explanation; the roles and mechanisms by which humic substances affect plant growth need further investigation.

The increased root growth was observed to increase the nutrient uptake of vegetable plants. Fulvic acids increased the concentrations of Ca, Fe, and Zn in leaves in hydroponic tomato plants, especially Fe by 109% at most (Table 7). Similar to the effects on Fe in our study, humic acid improved the utilization

TABLE 7 | The effect of fulvic acids (FA) on nutrient concentration in leaves of tomato plants cv. *Zizhenzhu* in hydroponics for 21 days from transplanting (Experiment 3).

efficiency of Fe in both the whole plant and roots of tomato seedlings in hydroponics by 46 and 161%, respectively (Adani et al., 1998) while several studies report that fulvic acids can promote the absorption of Fe (Pinton et al., 1997, 1999; Halim et al., 2003; Cerozi, 2020). The effects on the concentrations of Fe could be attributed to the regulation of gene expression, which is related to reduction and transport of Fe, thus improving the iron chelation and availability and, thus, the root uptake (Bocanegra et al., 2006; Elena et al., 2009). In addition, similarly to natural chelators, fulvic acids chelate Fe and other micronutrients and move them through membranes, thus enhancing the mineral accumulation in plants (Calvo et al., 2014).

According to Calvo et al. (2014), humic substances stimulate the growth of root and chelate ions and, thus, increase plant uptake of nutrients. Humic substances upregulate the activities of genes and enzymes involved in the root-to-shoot translocation of nutrients (Mora et al., 2010). Better root growth facilitates the uptake of more nutrients due to the greater surface area. On the other hand, the effect can be attributed to the acidity of fulvic acids (Table 1), which decreases the pH of growth medium and, thus, improves the bioavailability of nutrients (Muscolo et al., 2007). Humic substances are reported to increase the root length and diameter of tomato seedlings and the yield of greenhouse-cultured tomato (Qin and Leskovar, 2020), and they also conclude that the increments were attributed to improvement on the structure of roots. The increase in nutrient uptake further contributed to the promotion on biomass, thus increasing the yield and quality. The C/N ratio of hydroponic plants shared the similar trends with root growth (Figure 4), which indicated the accumulation of carbohydrate contributing to plant yield and similar to a previous study (Aminifard et al., 2012).

Fulvic Acids Increased the Germination of Seeds

Similar to the root growth of plants, fulvic acids at moderate concentrations increased the germination rate and vigor index of tomato seeds (Figure 3). Several other studies confirm our results that fulvic acids increase the germination of seeds.

FIGURE 4 | The effect of fulvic acids on root length (A), root tips (B), total biomass (C), and ratio of carbon to nitrogen (D) in leaves of tomato plants cv. *Zizhenzhu* grown in hydroponics for 21 days. Data are means \pm s.e (N = 4). The same letters denote insignificant differences ($P < 0.05$) among treatments according to Duncan's new multiple range test (Experiment 3).

Soluble humates extracted from vermicomposted cattle manure in the soil substrate increased the germination rate of tomato seeds by 31.6% (Olivares et al., 2015). Humic substances

increased the germination rate and vigor index of cucumber seeds (Ahmed and Awad, 2020). Compared with our study, the humates in Olivares et al. (2015) increased the germination rate of tomato seeds to a greater extent, which might be attributed to their combined application of plant growth-promoting bacterium. The promotion on seed germination might be attributed to the auxin-like substances in humic products that can increase the activity of amylase and promote seed respiration (Zandonadi et al., 2007; Canellas et al., 2010; Canellas and Olivares, 2014). The different performances of seed germination between *Huangmeiren* and *Zizhenzhu* also indicate that fulvic acids facilitate the germination of cultivar with greater germination rates.

Fulvic Acids Affected the Chemical Properties of Soil

Fulvic acids by top and base dressing tended to decrease soil pH and increase the soil CEC and SOM across all treatments while foliar application did not affect these soil properties (Table 6). Base dressing of 8.1 g kg⁻¹ decreased soil pH while increasing soil EC, SOM, concentrations of available N, available K, and CEC to the greatest extent. The decrease in soil pH by fulvic acid application could be attributed to the acidity from fulvic acids (Sharif et al., 2002; Tahir et al., 2011). According to Suntari et al. (2015), fulvic acids increase soil fertility indicated by the increased concentration of available N. However, fulvic acids did not affect soil available P in our study, inconsistent with other reports finding that humic substances could enhance this parameter (Cimrin and Yilmaz, 2005; Jones et al., 2007). We believe that the result of our study can be attributed to the high level of P in the experimental soils (Table 2).

CONCLUSION

Our study demonstrates that the moderate application of bioresource compounds, i.e., straw-extracted and microbially fermented fulvic acids, enhanced seed germination, production and yield of vegetables, and vegetable quality to an extent in both hydroponics and soil cultures. The improvement in the growth and quality of vegetables can be attributed to the promotion of root elongation and, thus, increased nutrient uptake by more likely the auxin-like substances. Also, fulvic acids can improve

soil fertility indicated by the increased SOM and soil CEC. Our study confirms that optimal concentrations of fulvic acids were 2.7 g kg⁻¹ as base dressing and 80–160 mg L⁻¹ in solutions as seed soaking, top dressing, and hydroponic application. Future studies should aim to specify the effective components of fulvic acids and to explore the underlying mechanisms of how fulvic acids work from molecular perspectives.

Fusarium wilt of banana caused by *Fusarium oxysporum* f. sp. *cubense* tropical race 4 (TR4) is globally one of the most destructive soil-borne fungal diseases. Biological control using environmental microorganisms is considered as an alternative and sustainable strategy. Actinomycetes have the potential to explore biocontrol agents due to their production of diverse metabolites. The isolation and identification of high-efficiency and broad-spectrum antagonistic actinomycetes are the key for the application of biocontrol agents. In the present study, 60 actinomycetes were obtained from the rhizosphere soil of *Machilus pingii* in the primitive ecological natural reserve of Hainan province, China. Seventeen isolates and their extracts exhibited significant antifungal activity against *F. oxysporum* TR4. Particularly, strain BITDG-11 with the strongest inhibition ability had a broad-spectrum antifungal activity. The assay of its physiological and biochemical profiles showed that strain BITDG-11 had the ability to produce IAA and siderophores and had a positive response to gelatin liquefaction and nitrate reduction. Enzyme activities of chitinase, β -1,3-glucanase, lipase, and urease were also detected. Average nucleotide identity calculated by comparison with the standard strain genome of *Streptomyces albospinus* JCM3399 was 86.55% below the novel species threshold, suggesting that the strain could be a novel species. In addition, *Streptomyces* BITDG-11 obviously reduced the disease index of banana plantlets and promoted plant growth at 45 days post inoculation. The higher and lasting expression levels of defense genes and activities of antioxidant enzymes were induced in the roots of banana. Genome sequencing revealed that the *Streptomyces* BITDG-11 chromosome contained large numbers of conserved biosynthesis gene clusters encoding terpenes, non-ribosomal peptides, polyketides, siderophores, and ectoines.

Fifteen bioactive secondary metabolites were further identified from *Streptomyces* BITDG-11 extract by gas chromatography–mass spectrometry. Dibutyl phthalate demonstrating a strong antifungal activity was the major compound with the highest peak area. Hence, *Streptomyces* sp. BITDG-11 has a great potential to become an essential constituent of modern agricultural practice as biofertilizers and biocontrol agents.

Keywords: *Streptomyces* isolation, banana *Fusarium* wilt, antifungal activity, plant-growth promotion, biosynthetic gene clusters, GC-MS

INTRODUCTION

Banana (*Musa* spp.) is one of the world's most important staple and cash crops and widely cultivated in 135 countries in tropical and subtropical regions. Annual banana production in the world is estimated at over 145 million tons (Ploetz, 2015a). Due to the lack of effective cross-breeding techniques, commercial banana cultivars are usually multiplied by using vegetative propagation, resulting in a narrow genetic diversity and a susceptible defect to pests and diseases (Wang et al., 2012). *Fusarium* wilt of banana caused by *Fusarium oxysporum* f. sp. *cubense* is one of the most destructive soil-borne fungal diseases and seriously threatens the global banana industry. The causal agents are subdivided into four races based on the banana cultivars infected (Dita et al., 2018). *F. oxysporum* tropical race 4 (TR4) distributed in the main producing areas globally can infect almost all banana cultivars (Pegg et al., 2019). It can be spread by banana material, soil and machinery, irrigation water, etc. (Ploetz, 2015b).

Until now, there is a lack of a commercially effective method of controlling *Foc* TR4 due to the limited knowledge about its disease epidemiology (Bubici et al., 2019; Pegg et al., 2019). Selection of *F. oxysporum* TR4-resistant cultivars seems to be an optimal control strategy, but a productive alternative to the main cultivar Cavendish has not yet been found (Ploetz, 2015b). The poor fertility of Cavendish limits the improvement program through conventional breeding (Zorrilla-Fontanesi et al., 2020). Fungicides lead to chlorotic symptoms and unsatisfactory control efficiency for soil-borne pathogen due to a vascular pathogen penetrating into the plant roots or stems (Nel et al., 2010). Moreover, long-term use of fungicides causes safety concerns and enhances pathogenic resistance (Bubici et al., 2019). Crop rotation is also ineffective as *F. oxysporum* TR4 has a long survival in the soil beyond 20 years, even in the absence of host plants (Ploetz, 2015b). Therefore, before resistant cultivars are obtained, agronomic management approaches will be considered as the main strategy for controlling *Foc* TR4 with *F. oxysporum* TR4.

Recently, biological control using beneficial microorganisms has drawn the attention of scientists because of their economic and environmental advantages (Qi et al., 2019; Jing et al., 2020; Wei et al., 2020). Numerous microbial species have been identified as having the ability for biocontrol, such as *Bacillus* spp., *Burkholderia* spp., *Pseudomonas* spp., *Rhizobium* spp., and *Stenotrophomonas* spp., as well as other genera reported (Bubici et al., 2019). Particularly, *Streptomyces* can develop a symbiotic interaction with plants to promote growth of the host and produce diverse metabolites to inhibit the infection of pathogens

(Chen et al., 2018; van der Heul et al., 2018; Bergeijk et al., 2020). *Streptomyces* belonging to the actinomycetes family make up 1–20% of the culturable soil microbes (Olanrewaju and Babalola, 2019). A variety of bioactive compounds are produced with different bioactivities such as antimicrobial, antiviral, and anticancer properties (Bergeijk et al., 2020). Approximately two-thirds of natural antibiotics have been isolated from actinomycetes, and 75% of them are from the *Streptomyces* genus (Franco-Correa et al., 2010). They are the primary antibiotic-producing organisms exploited by the pharmaceutical industry (Olanrewaju and Babalola, 2019). Our previous studies also evidenced that the application of *Streptomyces* sp. could increase the diversity of antagonistic microbes and reduce the disease incidence of *Fusarium* wilt of banana (Jing et al., 2020; Li et al., 2021a; Yun et al., 2021). However, environmental factors limited their stability and biocontrol efficiency against phytopathogens (Saravanan et al., 2003). Thus, the isolation and screening of high efficiency and broad-spectrum antagonistic microorganisms are still key for the application of biocontrol agents.

The extreme niches contribute to the rapid expansion of *Streptomyces* into various species clusters (Bull and Stach, 2007). This ecological diversity drives the evolution of secondary metabolic repertoires and the production of some novel metabolites (Bergeijk et al., 2020). Specialized metabolites were isolated from marine organisms such as arctic *Streptomyces nitrosporeus* (Yang et al., 2013) and desert-dwelling *Streptomyces* sp. (Sayed et al., 2019). In the present study, our aim is to screen and identify actinomycetes with excellently antagonistic *F. oxysporum* TR4 from the primitive ecological environment. We further assessed its efficacy in the management of the pathogen and antifungal mechanisms. Hence, *Streptomyces* have a great potential to become an essential constituent of modern agricultural practice as biofertilizers and biocontrol agents.

MATERIALS AND METHODS

Soil Sampling

The rhizosphere soil of *Machilus pingii* was collected from the primitive ecological nature reserve of 'Yingge' mountain (1109°43'05"E, 19°02'03"N) in Hainan province, China. The subtropical region has a hot climate in summer (23–36°C) and cold in winter (16–24°C) with an average humidity of 60–80% and annual rainfall of 1,500–2,600 mm. The samples were

transported to the laboratory in sterile polythene bags and stored in an insulated container at 4°C.

Isolation of Actinomycetes

Actinomycetes were isolated by a gradient dilution separation method (Sadeghian et al., 2016). The air-dried soil was ground to powder and passed through a 60-mesh sieve. Five grams of soil samples were dissolved in 45 ml of sterile water. After being incubated at 55°C for 20 min in a water bath, the mixture was cultured at 28°C, 180 rpm, for 1 h. The homogenate was diluted with sterile water into 10^{-1} , 10^{-2} , and 10^{-3} using a serial dilution method (Li et al., 2021a). One hundred fifty microliters of each dilution were spread on the four-separation agar media, namely, humic acid–vitamin (HV), glucose–aspartic acid (GA), starch casein agar (SCA), and Gause's No. 1. These media were supplemented with potassium dichromate (50 mg/L) and nystatin (50 mg/L) to inhibit fungal and bacterial contamination. The plates were cultured at 28°C for 5–7 days. The colonies were streaked repeatedly on the ISP2 agar medium for purification until a single colony was obtained. The purified isolates were kept on the Gause's No. 1 agar medium at 4°C and 20% (v/v) of glycerol at –80°C.

Preliminary Screening for Antagonistic Actinomycetes Against *F. oxysporum* TR4

The antagonistic activity of actinomycetes against *F. oxysporum* TR4 was initially assayed using an agar diffusion method (Wei et al., 2020). A 5-mm hyphal disk of *F. oxysporum* TR4 was manufactured using a hole puncher and placed in the middle of a potato dextrose agar (PDA, 200 g/L of potato, 20 g/L of dextrose, and 16 g/L of agar) plate. The selected isolate was inoculated in four symmetrical points of about 2.5-cm distance from the pathogen. The *F. oxysporum* TR4 plate without the inoculation of the isolate was used as a control. All plates were cultured at 28°C for 5–7 days under dark conditions. The inhibition activity was measured until the mycelia of *F. oxysporum* TR4 covered the entire surface of the plate. The inhibition percentage was calculated using the following formula:

$$\text{the inhibitory percentage of growth} = [(C - T)/C] \times 100\%$$

where C and T were growth diameters of tested pathogens in the control and treated plates, respectively.

Secondary Screening of Antagonistic Actinomycetes Against *F. oxysporum* TR4

Selected actinomycetes with antifungal activity in a preliminary screening were subjected to small-scale fermentation. Briefly, the actinomycete was cultured in a broth medium (15 g of corn flour, 3 g of beef extract, 10 g of yeast extract, 10 g of soluble starch, 10 g of glucose, 0.5 g of K_2HPO_4 , 0.5 g of NaCl, 2 g of $CaCO_3$, 0.5 g of $MgSO_4$, pH 7.2–7.4) at 28°C, 180 rpm, for 7 days. The fermentation broth was centrifuged at 13,000 rpm, and the supernatant was mixed with an equal volume of ethanol (95%, v/v). The extract was concentrated using a separating funnel and

evaporated with a rotary evaporator (EYELA, N-1300, Japan). The dried extract was diluted with ethanol (50%, v/v) to a final concentration of 10 mg/ml. Antifungal activity was determined by the agar diffusion method as mentioned above after the plates were cultured at 28°C for 7 days.

Growth Characteristics of the Selected Actinomycetes

To detect the growth characteristics of actinomycetes, the isolate was first cultured in six standard ISP media (yeast extract–malt agar, ISP2; oatmeal agar, ISP3; inorganic salts–starch agar, ISP4; glycerol–asparagine agar, ISP5; peptone yeast–iron agar, ISP6; tyrosine agar, ISP7), PDA, and Gause's No. 1 (Shirling and Gottlieb, 1968). These plates were incubated at 28°C for 7 days under dark conditions. Colors of substrate and aerial mycelia as well as diffusible pigments were judged by comparing them with the ISCC-NBS color charts (Qi et al., 2019). Some biochemical profiles including nitrate reduction, gelation liquefaction, hydrolysis of cellulose, starch, Tween 20, Tween 40, Tween 80, and urease activities were also measured according to the previous description of Li et al. (2016). IAA production was qualitatively assayed as the development of pink color in the plate. Liquid chrome azurol S (CAS) assay was used to assess siderophore production on ISP2 (Milagres et al., 1999). Chitinase activity was quantitated by measuring the reducing end group of *N*-acetyl glucosamine (Lee et al., 2012). The β -1,3-glucanase activity was measured using laminarin (Sigma, MA, United States) as a substrate (Lee et al., 2012). Resistance evaluation to 20 standard antibiotics was tested by a disk diffusion method (Jing et al., 2020).

Assay of Broad-Spectrum Antifungal Activity of the Selected Actinomycetes

To detect the broad-spectrum antifungal activity of actinomycete, 18 phytopathogenic fungi were selected, namely, *Fusarium graminearum* Schwabe (ATCC MYA-4620), *Botrytis cinerea* (ATCC 11542), *Cryphonectria parasitica* (ATCC 9414), *Colletotrichum acutatum* (ATCC 56815), *Curvularia fallax* (ATCC 34598), *Colletotrichum fragariae* (ATCC 58689), *Colletotrichum gloeosporioides* (ATCC MYA-456), *Colletotrichum gloeosporioides* (Penz) Saec (ATCC 36351), *Curvularia lunata* (ATCC 42011), *Colletotrichum musae* (ATCC 44422), *Fusarium oxysporum* f. sp. *cubense* race 1 (ATCC 31271), *Fusarium oxysporum* f. sp. *cubense* tropical race 4 (ATCC 76255), *Fusarium oxysporum* (Schl.) f. sp. *cucumerinum* (ATCC 204378), *Fusarium oxysporum* f. sp. *lycopersici* (ATCC MYA-1199), *Colletotrichum gloeosporioides* Penz. (ATCC MYA-4130), *Alternaria tenuissima* (ATCC 96828), *Pyricularia oryzae* (ATCC 52083), and *Colletotrichum fructicola* (ATCC 16103). These phytopathogenic fungi were kept in the National Banana Industry Research and Development Center, China Academy of Tropical Agricultural Sciences, Haikou, China. Antifungal activities of the selected actinomycetes were evaluated based on the radial growth inhibition of phytopathogenic fungi *in vitro* (Wei et al., 2020). The control plates were poured with only phytopathogenic fungi. All experiments were performed in triplicate.

Stable Characteristics and Safe Evaluation of the Isolate Extract

The extract stock was diluted to 80 µg/ml using sterile water. Seven temperature gradients, namely, 50, 60, 70, 80, 90, 100, and 121°C, were selected to treat the isolate extract for 1 h. Different pH values were prepared from 3 to 10 at an interval of one unit using 1 mol/L HCl or 1 mol/L NaOH. The extract was irradiated by an ultraviolet lamp with an illumination intensity of 100 µW cm⁻² for 1, 3, 5, 7, 9, 11, and 13 h. Antifungal activity against *F. oxysporum* TR4 was used to evaluate extract stability after treatment of different physical factors. Hemolytic assay of human red blood cells treated with the extract was carried out to test its safety as in our previous description (Li et al., 2021b).

Genome Sequencing and Molecular Identification of the Selected Actinomycetes

The actinomycete strain with the highest antifungal activity was identified by using a molecular procedure. The isolate was cultured in the ISP2 liquid medium at 28°C for 4 days. Total genomic DNA was extracted using a Rapid Bacterial Genomic DNA Isolation Kit (Biotech Corporation, Beijing, China) according to the standard manufacturer protocol. The complete genome was sequenced using a paired-end sequencing method in the Illumina HiSeq × Ten platform (Illumina, San Diego, CA, United States) by the Shanghai Majorbio Bio-pharm Technology Co., Ltd. A multilocus sequence analysis (MLSA) was performed using 31 housekeeping genes, namely, *dnaG*, *frr*, *infC*, *nusA*, *pgk*, *pyrG*, *rplA*, *rplB*, *rplC*, *rplD*, *rplE*, *rplF*, *rplK*, *rplL*, *rplM*, *rplN*, *rplP*, *rplS*, *rplT*, *rpmA*, *rpoB*, *rpsB*, *rpsC*, *rpsE*, *rpsI*, *rpsJ*, *rpsK*, *rpsM*, *rpsS*, *smgB*, and *tsf*, from the selected actinomycete genome (Brady et al., 2008). The MLSA phylogenetic tree was constructed using the neighbor-joining method in MEGA 7.0 (Kumar et al., 2016). The confidence level was investigated using bootstrap analysis on 1,000 replicates. Average nucleotide identity (ANI) between genomes was calculated using the online OrthoANI (Yoon et al., 2017). The genome sequence of the standard strain (*Streptomyces albospinus* JCM3399) was downloaded from the public genome database of EzBioCloud¹.

Genomic Annotation of the Selected Actinomycetes

Sequencing data of the genome were analyzed on an online platform of Majorbio Cloud². Clean sequences were assembled using SOAPdenovo v2.04. The open reading frames (ORFs) and genome annotation were predicted by the Rapid Annotation using Subsystem Technology (Brettin et al., 2015). These genes were annotated using the Clusters of Orthologous Groups (COGs) and Kyoto Encyclopedia of Genes and Genomes (KEGG) (Ogata et al., 1999; Tatusov et al., 2000). Identification of potential biosynthetic gene clusters (BGCs) was proposed by the bioinformatics tool website antiSMASH v4.0.2 software (Weber et al., 2015)³. Gene function analysis was performed through

manual BLAST on NCBI⁴. The genome sequence data (accession number: SRR15506182) was deposited in the GenBank database.

Evaluation of Biocontrol and Plant Growth Promotion Under Greenhouse Conditions

The biocontrol and growth-promoting effects of the selected actinomycete were evaluated in greenhouse experiments. The genotype (cv. Brazilian, AAA group) of banana susceptible to *F. oxysporum* TR4 was multiplied by micropropagation. Plantlets with four to five leaves were transferred to soil and grew at 28°C with 70–80% of relative humidity. The selected actinomycete was cultured in a sterilized soybean liquid medium at 180 rpm for 7 days at 28°C. *F. oxysporum* TR4 was inoculated into a PDA broth at 200 rpm for 10 days at 28°C. The conidial suspension was filtered through eight layers of sterile gauze. The spore suspension of *F. oxysporum* TR4 was adjusted to 10⁶ CFU ml⁻¹ with sterile distilled water. Roots of banana plantlets were wounded with a scalpel and then dipped into 30 ml of fungal inoculum suspension for 30 min. The fermentation broth of the selected actinomycete (10⁶ CFU g⁻¹ soil) was also added to the roots of each plant. Three experimental groups were set, namely, medium treatment (T1), selected actinomycete + *F. oxysporum* TR4 treatment (T2), and *F. oxysporum* TR4 treatment (T3). The banana plantlets were kept in a greenhouse and maintained at approximately 70% of relative humidity at 28°C. The expression levels of defense genes and antioxidant enzyme activity were determined at 1, 2, 3, 4, 5, and 6 days post inoculation (dpi). Plant growth indicators including chlorophyll content, leaf area, leaf thickness, stem diameter, plant height, dry weight, and fresh weight were also measured at 45 dpi (Wei et al., 2020). The disease index was evaluated according to the description of Jing et al. (2020). Data were acquired from three independent experiments, and 36 plantlets were selected for each experiment. All experiments were carried out in triplicates.

Measurement of Antioxidant Enzyme Activity in Roots of Banana Plantlets

Five grams of frozen root samples were ground in 10 ml of precooled phosphate buffer (50 mM, pH 7.8) containing 2% of polyvinylpyrrolidone. The homogenate was transferred to a 15-ml tube and centrifuged at 15,000 rpm for 15 min at 4°C. The supernatant was used to determine the activity of superoxide dismutase (SOD), catalase (CAT), peroxidase (POD), and polyphenol oxidase (PPO) activities as described by Sun et al. (2013). H₂O₂ levels were measured according to the method of Ferguson et al. (1983). The content of malondialdehyde (MDA) was assayed using the thiobarbituric acid reaction method (Zhang et al., 2009).

Expression Analysis of Defense Genes

Total RNA of banana roots was extracted by the routine TRIzol method. The quality and quantity of RNA were measured by NanoDrop (Thermo Scientific, United States). cDNA was synthesized using the M-MLV reverse transcriptase (Takara,

¹<https://www.ezbiocloud.net/search?tn=Nocardioides>

²www.majorbio.com

³<http://antismash.secondarymetabolites.org/#/start>

⁴<https://www.ncbi.nlm.nih.gov/>

Kyoto, Japan) after treatment with the RNase-free DNase (Takara, Kyoto, Japan). Quantitative real-time polymerase chain reaction (qRT-PCR) was performed in a LightCycler® 480 System (Roche Diagnostics, Mannheim, Germany). A 10- μ l reaction system contained 50 ng of first-strand cDNA, 10 μ M of forward and reverse primers, and 5 μ l of TB Green Advantage qPCR Premix (2 \times) (Takara, Kyoto, Japan). The reaction program was set as follows: 95°C for 1 min, followed by 40 cycles of denaturation at 92°C for 5 s, annealing at 60°C for 30 s, and extension at 72°C for 30 s. The representative defense marker genes such as *Ma β -1,3-Glu* (accession number: AF001523) and mitogen-activated protein kinase 1 (*MaMAPK1*, accession number: XM018826311) were selected. Results were normalized using the expression levels of 18S rRNA gene (accession number: U42083). The prime sequences were shown in our previous study (Zhang et al., 2019). The data obtained from different PCR runs were analyzed using the mean of CT values from three biological replicates. The expression ratios were calculated using the $2^{-\Delta\Delta C_t}$ method (Zhang et al., 2019).

Component Identification of Actinomycete Extract by Gas Chromatography–Mass Spectrometry

The chemical compounds in the extract were identified using gas chromatography–mass spectrometry (GC-MS) as in our previous description (Li et al., 2021b). The strain extract was first dissolved in the chromatographic-grade methanol and filtered through a 0.2- μ m filter. The solution was injected into a gas capillary column (DB-FFAP, 30 m \times 0.25 mm \times 0.25 μ m) of a gas chromatography (5973 Inert XL MSD, Agilent, United States). Helium was used as a carrier gas with a flow rate of 1 ml min⁻¹. The mass spectrometer (EI with replaceable horn) was operated in the electron ionization (EI) mode at 70 eV with a continuous scan from 50 to 800 *m/z*. The peaks were identified by matching the mass spectra with the National Institute of Standards and Technology (NIST, United States) library.

Statistical Analysis

All experiments were performed in three biological triplicates. Data were expressed as the mean \pm standard deviation. The greenhouse experiments were carried out in a randomized design. All data were analyzed using analysis of variance (ANOVA) by the SPSS statistical package (version 22, SPSS Inc., Chicago, IL, United States). The *t*-test compared the mean of an outcome variable for different subjects. The LSD's multiple range test was applied to determine the significant difference at the level of *p* < 0.05.

RESULTS

Actinomycete Isolation

The primitive nature reserve of 'Yingge' mountain possessing great biodiversity was selected for the isolation of antifungal actinomycetes. A total of 60 actinomycetes were isolated from the rhizosphere soil of *M. pingii* using four culture media of HV (18),

GA (12), SCA (10), and Gause's No. 1 (20). Isolated actinomycetes showed well-developed aerial and substrate mycelia in **Figure 1**. Most aerial mycelia appeared hairy, granular, or powdery. Some isolates produced colored pigments in the substrate and were hard to pick from the media. It was a representative trait of the genus *Streptomyces*. All the isolates were deposited at the National Banana Industry Research and Development Center, the Institute of Tropical Bioscience and Biotechnology, China Academy of Tropical Agricultural Sciences, Haikou, China.

Antifungal Activity Assay of the Isolated Actinomycetes

Initially, all the isolates were subjected to a primary screening test against *F. oxysporum* TR4. We assessed the inhibition ability of the mycelial growth of *F. oxysporum* TR4. By antagonistic experiments in plates, 17 out of 60 isolates showed significant antifungal activities (**Supplementary Figure 1**), accounting for 28.3% of the total actinomycetes screened. The inhibitory activity of each isolate was further determined. Eleven actinomycetes owned more than 60% of antifungal activity against *F. oxysporum* TR4. Particularly, the strain numbered BITDG-11 had the best antifungal activity. The inhibition rate reached $80.48 \pm 1.49\%$.

A small-scale fermentation of the 17 isolates with prominent zones of inhibition from the primary screening was carried out. The antagonistic ability of their extracts was further investigated. The results demonstrated that extracts of all the selected isolates showed antifungal activity against *F. oxysporum* TR4, ranging from 27 to 60% (**Supplementary Figure 1**). The strong inhibition zone sizes were observed in extracts of four isolates (BITDG-11, BITDH-4, BITDG-7, BITDG-19, and BITDA-7). The inhibition rates were 58.44, 45.10, 43.92, 42.89, and 42.62%, respectively. Combined with primary and rescreening results, strain BITDG-11 was selected as an excellent isolate for the subsequent study.

Growth Characteristics of Strain BITDG-11

The cultural traits of strain BITDG-11 were recorded on eight media selected (**Table 1**). It had a good growth on ISP2 and a moderate growth on the rest of the media except for ISP4. The color of aerial mycelia varied from white to dark gray. Aerial hypha exhibited dark gray on ISP3, pale yellow on ISP5, and white on ISP2, ISP6, ISP7, PDA, and Gause's No. 1 media. Light yellow colors of the hyphal substrate were observed on all the media except for light gray on ISP5. Soluble pigment was produced on ISP5, ISP7, and Gause's No. 1. Production of melanin pigment on ISP7 could be taken as an identification criterion for the genus *Streptomyces* (Atta et al., 2011). Therefore, strain BITDG-11 exhibited typical morphological characteristics of *Streptomyces*.

The analysis of physiological and biochemical characteristics showed that strain BITDG-11 had the ability to hydrolyze starch and produce IAA. A positive response was observed to gelatin liquefaction and nitrate reduction. Enzyme activities of lipase and urease were also detected (**Figure 2A**). The level of chitinase was sharply increased during the exponential phase and reached the peak (3.50 U/mg protein) at 72 h (**Figure 2B**). The highest level of β -1,3-glucanase (0.49 U/mg protein) was found at 72 h

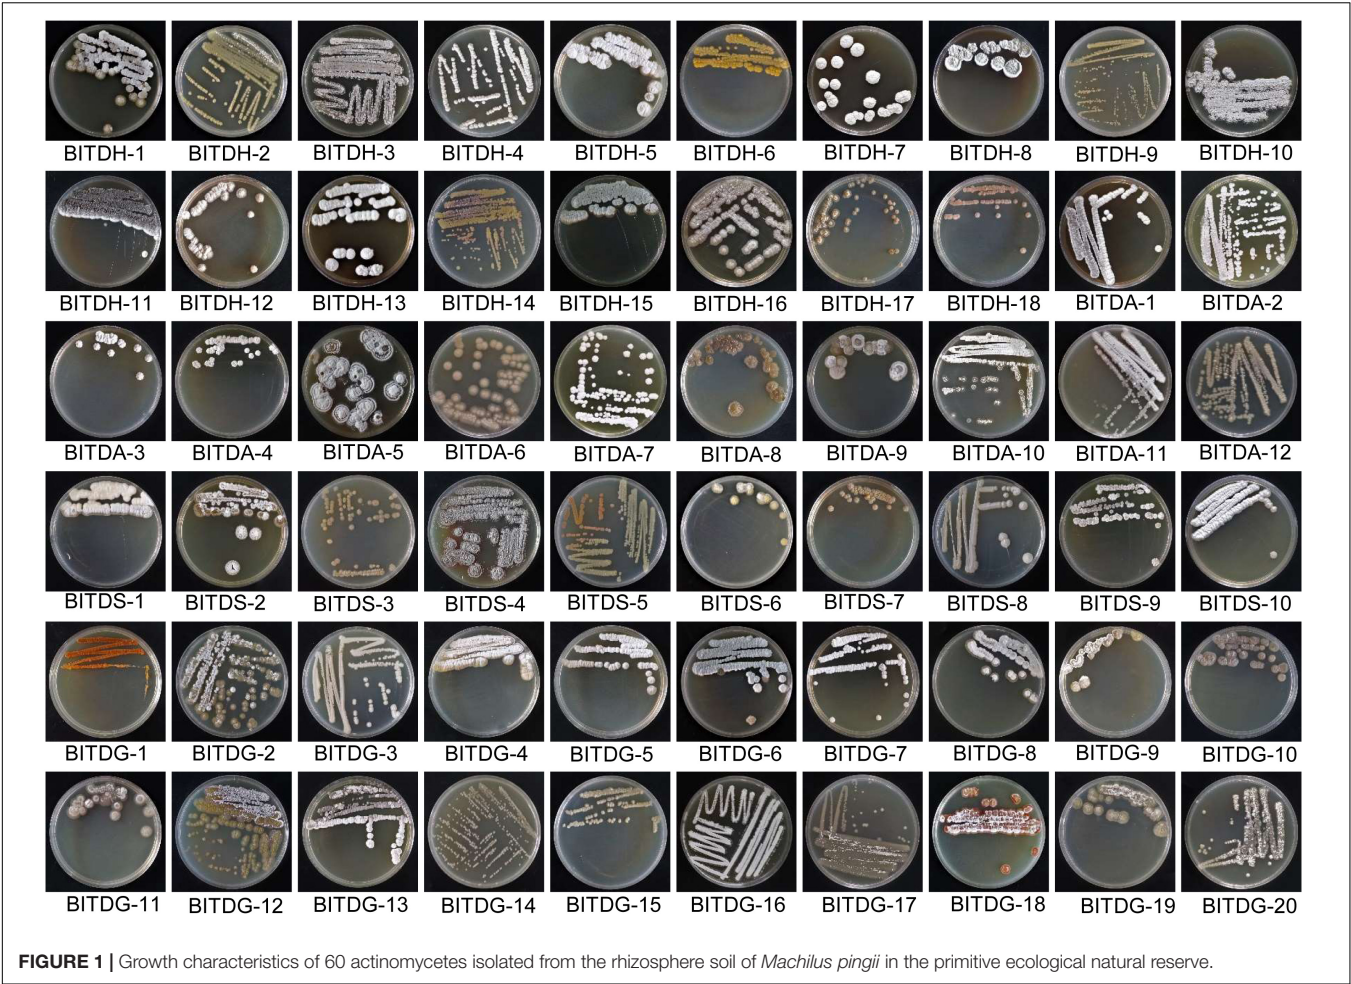

TABLE 1 | Growth characteristics of *Streptomyces* BITDG-11 on different media.

Medium	Growth	Aerial mycelium	Substrate mycelium	Soluble pigment	Colony characteristics
Yeast extract malt extract dextrose agar (ISP2)	Good	White	Lemon yellow	No	Hard and wrinkle
Oatmeal agar (ISP3)	Moderate	Dark gray	Rice yellow	No	Powder and dry
Inorganic salts starch agar (ISP4)	Normal	Creamy white	Light yellow	No	Powder and dry
Glycerol asparagine agar (ISP5)	Moderate	Pale yellow	Light gray	Light yellow	Compact and hard
Peptone yeast extract iron agar (ISP6)	Moderate	White	Pale yellow	No	Compact and wrinkle
Tyrosine agar (ISP7)	Moderate	White	Light yellow	Light purple	Powder and loose
Potato dextrose agar (PDA)	Moderate	White	Light yellow	No	Powder and dry
Gause's No. 1	Moderate	White	Light yellow	Light yellow	Powder and dry

of the incubation period (Figure 2C). Antibiotic susceptibility testing revealed that strain BITDG-11 manifested tolerance to 15 out of 22 kinds of antibiotics and sensitivity to erythromycin, kanamycin, gentamicin, amikacin, neomycin, midenomycin, and ofloxacin (Supplementary Table S1).

Identification of Strain BITDG-11

Based on the alignment of 16S *rRNA* sequence (1,523 bp, accession number: MW110901), the sequence shared 98.80% of similarity with that of *S. albospinus* NBRC 13846. It confirmed that the strain belonged to a member of the

genus *Streptomyces*. However, 58% of the bootstrap value in the neighbor-joining tree indicated that strain BITDG-11 was not distinguished from closely related species using 16S *rRNA* genes.

In order to further identify the species of strain BITDG-11, its whole genome was sequenced. Sequences of 31 housekeeping genes were selected to perform the MLSA. The method was considered as an alternative strategy for defining the *Streptomyces* systematics due to the high efficiency of species resolution and reproducibility (Rong and Huang, 2010). The neighbor-joining tree based on MLSA showed that strain BITDG-11

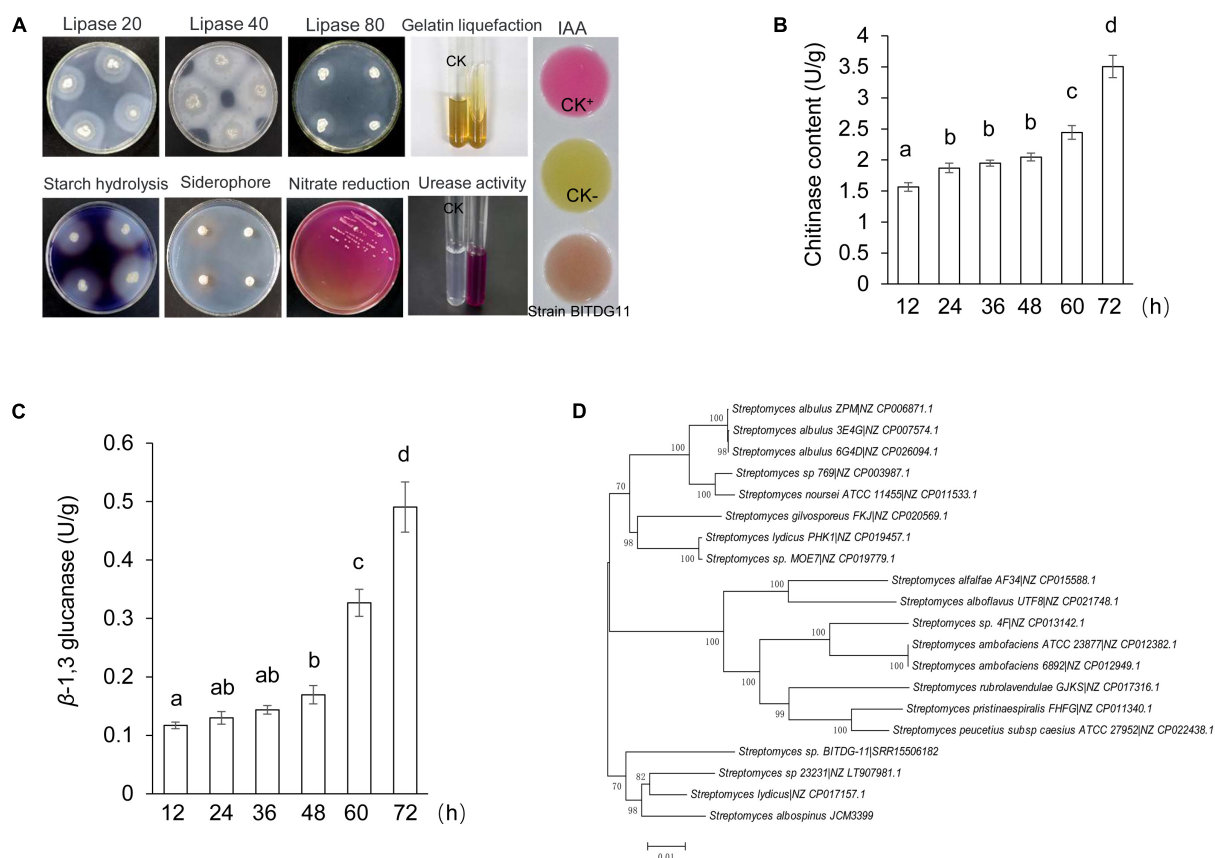

FIGURE 2 | Physicochemical property and identification of *Streptomyces* BITDG-11. **(A)** Physicochemical properties of *Streptomyces* BITDG-11. **(B)** Measurement of chitinase production during the culture process of *Streptomyces* BITDG-11. **(C)** Measurement of β-1,3-glucanase production. Data are the mean values from three biological repeats. Different lowercase letters indicate a significant difference in comparison with the initial time point of the strain growth (LSD's multiple range test, $p < 0.05$). **(D)** Construction of phylogenetic tree based on MLSA using the neighbor-joining method. The confidence level at all nodes was investigated using bootstrap analysis on 1,000 replicates.

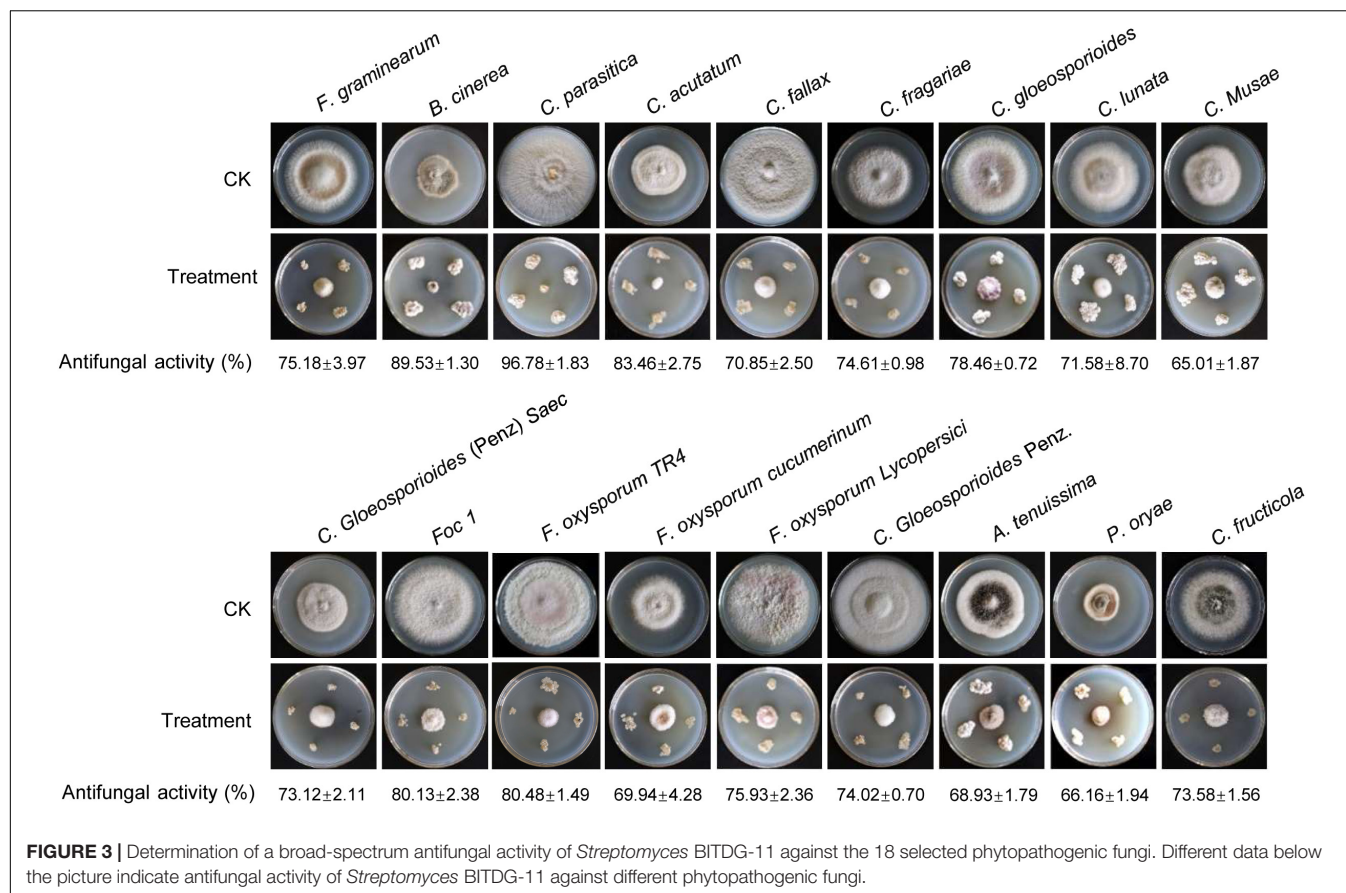

formed a distinct clade with *S. albospinus* JCM3399 with 70% of bootstrap value (Figure 2D). We further compared the strain BITDG-11 genome (accession number: SRR15506182) with the standard strain genome (*S. albospinus* JCM3399) (Supplementary Table S2). The ANI of 86.55% was below the threshold value of 95–96% for distinguishing a novel species (Richter and Rosselló-Móra, 2009). Thus, strain BITDG-11 might be a novel species of the genus *Streptomyces* and named after *Streptomyces* sp. BITDG-11.

Assay of a Broad-Spectrum Antifungal Activity

To assess whether *Streptomyces* BITDG-11 had a broad-spectrum antifungal activity, 18 fungal pathogens were selected in our study. Compared with the growth diameters of different phytopathogenic fungi in the control plate, the strain had strong antifungal activities against all pathogens selected (Figure 3). The inhibition rates ranged from 65 to 90%. The maximal and minimal inhibition rates were observed against *C. parasitica* ($96.78\% \pm 1.83$) and *C. musae* ($65.01\% \pm 1.87$), respectively.

Stability Evaluation of *Streptomyces* BITDG-11 Extract

To explore and apply *Streptomyces* BITDG-11 as biopesticides in the future, the stability of the extract expressed as antifungal activity was evaluated after treatment in different temperatures, pH values, and UV doses, respectively. The results showed that different temperatures reduced antifungal activity of the extract against *F. oxysporum* TR4, but 57.05% was kept after treatments at 121°C for 1 h (Figure 4A). For different pH treatments, the strongest antifungal activity was detected at pH 7.0–8.0 and decreased to 52% at pH 3.0 (Figure 4B). Additionally, the extract stability was negatively correlated with the increase of UV dose. A slight decrease was observed in the activity change of the extract treated with UV radiation after 7 h (Figure 4C). Although an obvious decrease (LSD's multiple range test, $p < 0.05$) of antifungal activity was detected in *Streptomyces* BITDG-11 extract after treatment with different physical factors, more than 50% of residual antifungal activity was retained in all the groups. It suggested that the *Streptomyces* BITDG-11 extract was relatively stable to some extent. To investigate the extract toxicity on eukaryotic cells, hemolytic activity was

analyzed. Human red blood cells were measured as the release of hemoglobin after treatment at 37°C for 1 h. Compared with the 100% hemolytic activity of Triton X-100 (0.1%, v/v), no obvious hemolytic activity was observed in the extract treatment group (Supplementary Figure 2).

***Streptomyces* BITDG-11 Improving Resistance to *F. oxysporum* TR4 and Promoting Growth of Banana Plantlets**

Streptomyces BITDG-11 perfectly inhibited the growth of different phytopathogenic fungi *in vitro*, indicating that it was a promising biocontrol agent. With an objective to evaluate *in vivo* biocontrol efficiency, we analyzed the effects of *Streptomyces* BITDG-11 fermentation broth on the infection inhibition of *F. oxysporum* TR4. By contrast, the bottom leaves of banana plantlets exhibited a significant chlorotic symptom at 45 dpi in the T3 group (Figure 5A). No obvious disease symptom was detected in the group of *Streptomyces* BITDG-11 + *F. oxysporum* TR4. Therefore, the protective treatment with *Streptomyces* BITDG-11 effectively prevented the infection of *F. oxysporum* TR4 and reduced disease index of plants (Figure 5B). We also evaluated actinomycetes and fungal numbers in the rhizosphere of banana seedlings (Supplementary Figure 3). The colony-forming units of *F. oxysporum* TR4 were very low when compared to other treated soils. The results showed that *Streptomyces*

BITDG-11 significantly increased competing bacterial and fungal counts along with the pathogen in the soil.

Moreover, various agronomic traits of plant health and condition were measured in Figures 5C–H. *Streptomyces* BITDG-11 significantly (LSD's multiple range test, $p < 0.05$) increased the fresh and dry weight of banana plantlets at 45 dpi (Figure 5C). Compared to those of control (T1, 45.5 ± 2.2 cm) or *F. oxysporum* TR4 treatment (T3, 34.0 ± 1.8 cm), the height of banana plantlets treated with *Streptomyces* BITDG-11 + *F. oxysporum* TR4 reached 50.9 ± 2.0 cm (Figure 5D). *F. oxysporum* TR4 significantly inhibited the increase of plant agronomic indicators (Figures 5E–H). Similar plant-growth-promoting effects were observed in stem diameters. Although no obvious difference of leaf thickness was detected between dual disposal and controls, a significant increase was found in leaf area and chlorophyll content of plants treated with *Streptomyces* BITDG-11.

***Streptomyces* BITDG-11 Enhancing the Antioxidant Abilities of Banana Plantlets**

As is well-known, the stress condition could induce the production of reactive oxygen species, thereby resulting in oxidative damage of plant cells. This effect can be assayed by quantifying H_2O_2 content and CAT activity. In our study, H_2O_2 content in banana roots was increased after *F. oxysporum* TR4

FIGURE 4 | Stability evaluation of the *Streptomyces* BITDG-11 extract after treatment at different temperatures (A), pH values (B), and UV doses (C). Data are the mean values from three biological repeats. Different lowercase letters indicated a significant difference of antifungal activity in comparison with the control (LSD's multiple range test, $p < 0.05$).

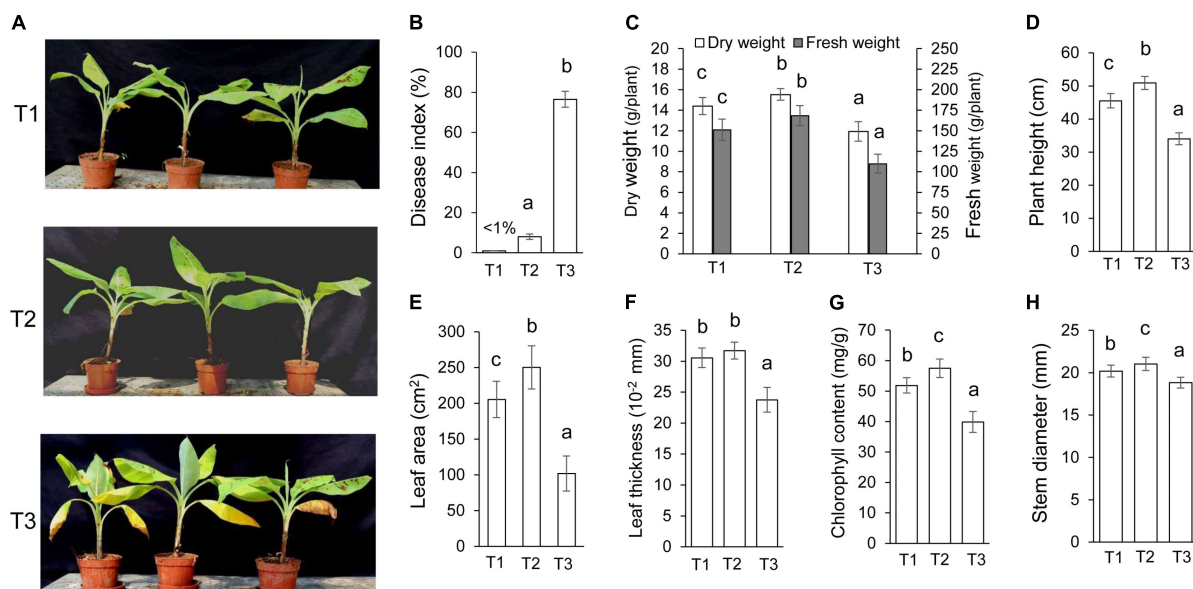

FIGURE 5 | Assay of chlorotic symptoms and plant growth promotion after treatment with *Streptomyces* BITDG-11 at 45 dpi. T1: medium treatment, T2: *Streptomyces* BITDG-11 + *F. oxysporum* TR4 treatment; T3: *F. oxysporum* TR4 treatment. (A) Chlorotic symptoms of banana plantlets in different treatment groups. (B) Quantitative analysis of disease indexes in different treatment groups. Measurement of physiological indicators including plant dry and fresh weight (C), plant height (D), leaf area (E), leaf thickness (F), chlorophyll content (G), and stem diameter (H) in different treatment groups. Error bars indicated standard errors of the means of three repeated experiments. Different letters indicated a significant difference in comparison with the treatment group of *F. oxysporum* TR4 (LSD's multiple range test, $p < 0.05$).

treatment (Figure 6A). Although a similar increase was detected in banana roots treated with *F. oxysporum* TR4 + *Streptomyces* BITDG-11, H_2O_2 content was reduced significantly (LSD's multiple range test, $p < 0.05$) by inducing high CAT activity (Figure 6B). Hence, *Streptomyces* BITDG-11 effectively alleviated the cell membrane damage. It was supported by the fact that MDA content was lower in roots treated with *Streptomyces* BITDG-11 (Figure 6C). Moreover, the strain also increased the higher activities of defense-related enzymes (PPO, POD, and SOD) in comparison with *F. oxysporum* TR4 or control treatment alone (Figures 6D–F). The maximal values of POD, PPO, and SOD were 83.20, 70.67, and 351.31 U/g in the banana roots after

inoculation with *Streptomyces* BITDG-11 combined with the challenge with *F. oxysporum* TR4 at 3, 6, and 2 dpi, respectively.

***Streptomyces* BITDG-11 Increasing the Expression of Defense Genes**

To further determine the defense mechanism of *Streptomyces* BITDG-11-induced resistance to *Fusarium* wilt of banana, the transcription levels of *MaMAPK1* (early defense response marker gene) and *Maβ-1,3-Glu* (downstream defense marker gene) were analyzed by qRT-PCR (Figure 7). In comparison with control and *F. oxysporum* TR4-only treatment, the transcripts

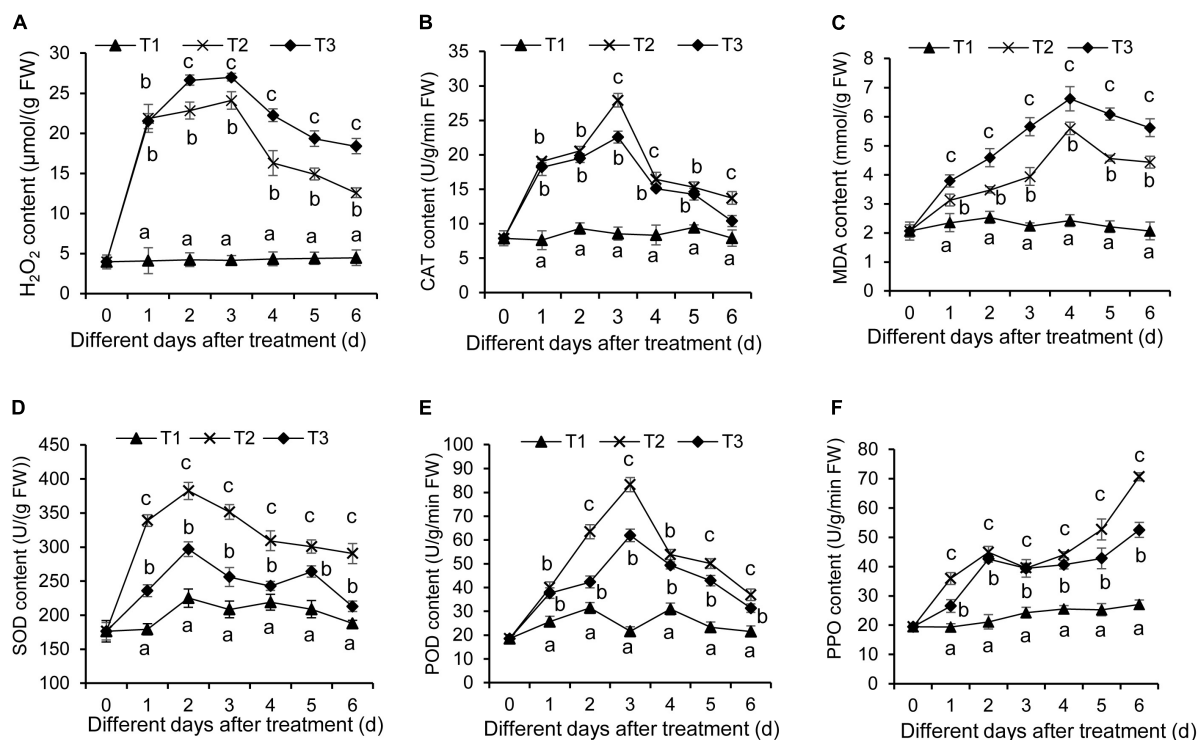

FIGURE 6 | Determination of hydrogen peroxide (A), CAT (B), MDA (C), SOD (D), POD (E), and PPO (F) in banana roots after treatment with *Streptomyces* BITDG-11 at different time points. T1–T3 represent different treatment groups as in the description in Figure 5. Error bars indicate standard errors of the means of three repeated experiments. Different letters indicate a significant difference in comparison with the medium treatment group at the same time points (LSD's multiple range test, $p < 0.05$).

of two tested genes were much stronger in the banana roots treated with *Streptomyces* BITDG-11 + *F. oxysporum* TR4 and reached their maximum values at 4 and 3 dpi, respectively. In addition, high transcription levels of defense genes were kept by *Streptomyces* BITDG-11 treatment until 6 dpi. These results indicated that *Streptomyces* BITDG-11 could prime the banana plants to enhance resistance to *F. oxysporum* TR4 by simultaneously activating the MAPK-mediated signaling pathway of defense response.

Bioinformatics Analysis of the Genome

The *Streptomyces* BITDG-11 genome was sequenced and contained 10,590,458 bp. The genome with 71.78% of GC content included seven *rRNA* genes, 78 *tRNA* genes, and 10,366 coding sequences (CDSs) (Figure 8A). By annotation, 68.45, 28.51, and 57.77% of CDSs were assigned to COG, KEGG, and GO, respectively. For 7,096 genes in COG, the top five categories contained transcription (749), amino acid transport and metabolism (502), energy production and conversion (398), and carbohydrate transport and metabolism (393). Notably, 2,402 of COG genes were clustered into an unknown function category (Figure 8B). The GO annotation showed that these genes were classified mainly into the biological process (2063), cellular component (2113), and molecular function (5023) (Supplementary Figure 4). Interestingly, 78% of genes participated in the regulation of metabolism in KEGG

(Supplementary Figure 5). By analysis of the antiSMASH software, 43 BGCs related to biosynthesis of the secondary metabolites were found in genome sequences of *Streptomyces* BITDG-11 (Supplementary Table S3). BGCs included one terpene-type I PKS-nucleoside-NRPS, one type III PKS, one thiopeptide-transatpks-type I PKS-NRPS, five terpene, three NRPS, four type I PKS, one type II PKS, one type I PKS-NRPS, one NRPS-lantipeptide, one lantipeptide-terpene, two lantipeptide, three bacteriocin, one ectoine, two butyrolactone, one terpene-NRPS, one type II PKS-oligosaccharide-type I PKS, one transatpks-NRPS, two siderophore, one indole, etc. Genome analysis further revealed that seven BGCs showed more than 70% of similarity with toyocamycin (100%), naringenin (100%), lantipeptide B (100%), ectoine (100%), mannopeptimycin (81%), desferrioxamine (80%), and rimocidin (72%) (Figure 8C).

Identification of the Chemical Composition of the *Streptomyces* BITDG-11 Extract

Gas chromatography–mass spectrometry was performed to identify the chemical composition in the *Streptomyces* BITDG-11 extract. In a comparison of their mass spectra with the NIST library, 15 compounds were identified based on their retention time and molecular weight (Table 2). The peak area represented the proportion of the given

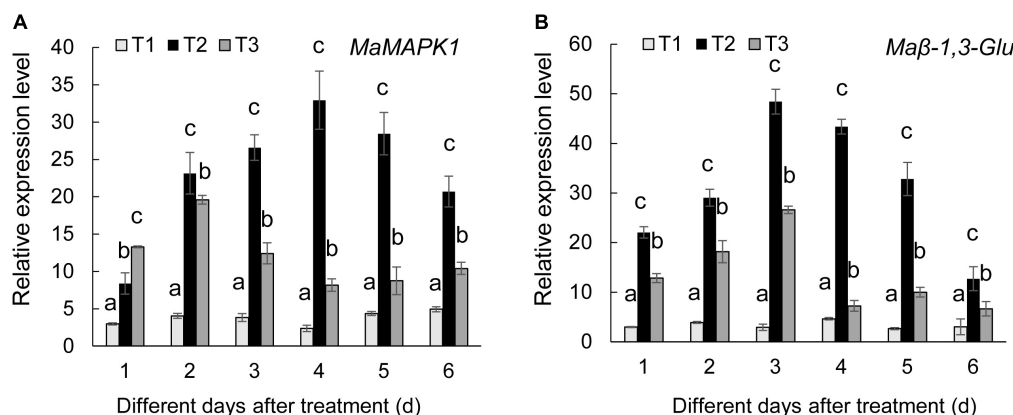

FIGURE 7 | Expression levels of the selected *MaMAPK1* (A) and *Maβ-1,3-Glu* (B) in banana roots after treatment with *Streptomyces* BITDG-11 at different time points. T1–T3 represent different treatment groups as in the description in **Figure 5**. Error bars indicate standard errors of the means of three repeated experiments. Different letters indicate significant differences in comparison with the medium treatment group at the same time points (LSD's multiple range test, $p < 0.05$).

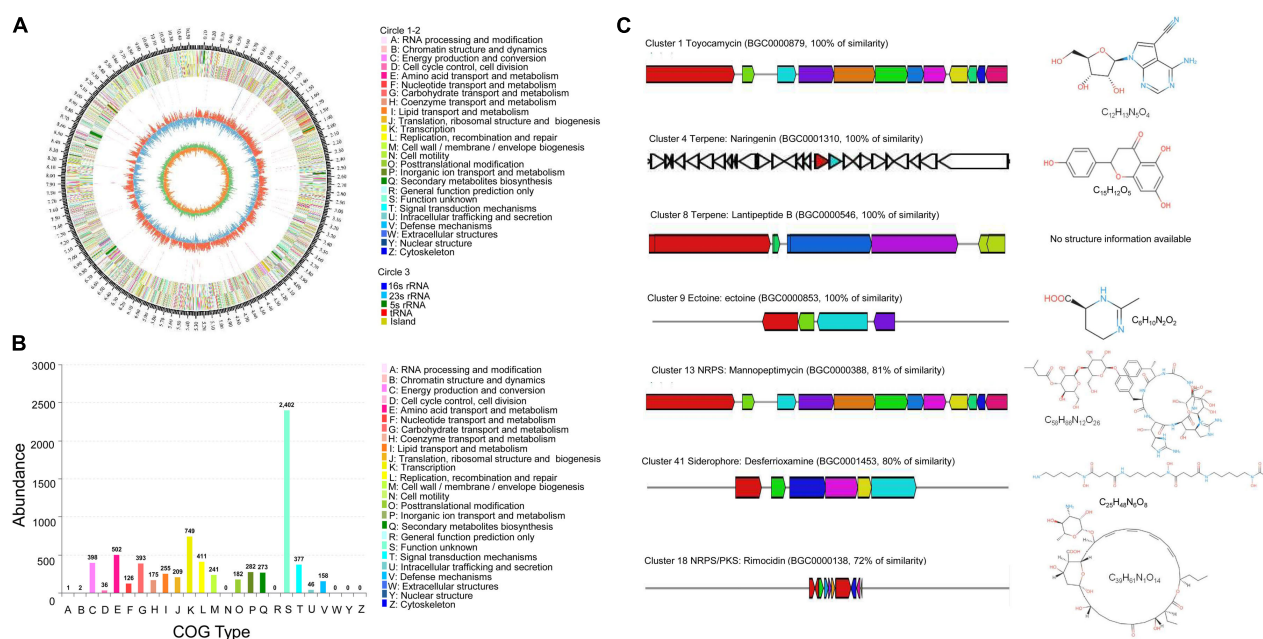

FIGURE 8 | Genome information and function annotation of *Streptomyces* BITDG-11. (A) Circular map of *Streptomyces* BITDG-11 genome. From outside to center, ring 1 is the mark of genome size. Rings 2 and 3 represent CDS on the forward/reverse strand. Different colors indicate the functional category of different COGs of CDS. Ring 4 is tRNA and rRNA. Ring 5 shows the G + C content. The outward red part indicates that the GC content of this region is higher than the average GC content of the whole genome. The inward blue part indicates that the GC content of this region is lower than the average GC content of the whole genome, followed by a G + C skew in ring 6. (B) COG annotation of *Streptomyces* BITDG-11 genome. (C) Biosynthesis gene clusters demonstrating more than 70% similarity with the known sequences.

compound in the total extract. According to the available library data, chemical compounds were identified as tetradecanoic acid, tricosene, *cis*-1-chloro-9-octadecene, pentadecanoic acid, *n*-hexadecanoic acid, linoleic acid ethyl ester, dibutyl phthalate, 1,2-bis(*p*-(trans-styryl)phenyl)-*cis*-ethylene, 3,3'-dihydroxy-4,4'-dinitrohexafluorobiphenyl, 1,2-bis(*p*-(*cis*-styryl)phenyl)-*trans*-ethylene, 4'-(3-(6-methyl-3-pyridyl)-1-(*p*-tolyl)-2-pyrazolin-5-yl)acetanilide, colchicineamide, 3,3'-dihydroxy-4,4'-dinitrohexafluorobiphenyl, 2-imidazoline,

3,5-di(4-chlorophenyl)-1-(4-fluorophenyl), naphtho[2,3-*c*]furan-1(3H)-one, 4-(3,4-dimethoxyphenyl)-3a,4,9,9a-tetrahydro-6,7-dimethoxy, and bis(2-ethylhexyl) phthalate.

DISCUSSION

Fusarium wilt of banana is globally one of the most destructive soil-borne fungal diseases. Fungicides cause serious problems for

TABLE 2 | Identification of chemical composition of the *Streptomyces* BITDG-11 extract by GC-MS.

Compounds name	Retention time (min)	Peak area (Ab*s)	Baseline height (Ab)	Absolute height (Ab)	Peak width 50% (min)	Molecular weight (amu)
Tetradecanoic acid	31.323	4,364,641	287,197	437,164	0.369	228.209
Tricosene	33.202	1,720,859	386,105	770,438	0.168	322.36
cis-1-Chloro-9-octadecene	33.521	10,411,455	1,506,075	1,927,431	0.235	286.243
Pentadecanoic acid	33.622	12,986,919	1,792,774	2,386,203	0.411	242.225
n-Hexadecanoic acid	35.434	54,441,054	8,332,937	9,724,659	0.512	256.24
Linoleic acid ethyl ester	35.97	4,713,086	1,093,523	2,704,558	0.193	308.272
Dibutyl phthalate	37.9	176,228,995	28,511,169	29,838,598	0.277	278.152
1,2-Bis(p-(trans-styryl)phenyl)-cis-ethylene	40.836	556,397	218,880	1,503,957	0.218	384.188
3,3'-Dihydroxy-4,4'-dinitrohexafluorobiphenyl	42.237	242,647	76,237	1,438,498	0.117	383.982
1,2-Bis(p-(cis-styryl)phenyl)-trans-ethylene	42.824	549,444	96,391	1,506,214	0.193	384.188
4'-(3-(6-Methyl-3-pyridyl)-1-(p-tolyl)-2-pyrazolin-5-yl)acetanilide	43.067	1,251,949	273,496	1,728,673	0.168	384.195
Colchicineamide	43.914	365,851	103,654	1,704,206	0.092	384.169

*represents the multiplication sign.

human health and environment pollution (Bubici et al., 2019). Biological control is considered as an alternative and sustainable strategy. In recent decades, the potential of plant-growth-promoting *Streptomyces* has been revealed for inhibiting pathogen infection and improving crop yield (Dias et al., 2017; Vurukonda et al., 2018). Although several antagonistic *Streptomyces* were investigated as biological control agents (Vurukonda et al., 2018; Jing et al., 2020; Wei et al., 2020; Li et al., 2021a), field application was limited due to the unstable and deficient antimicrobial activity. Therefore, screening highly efficient and broad-spectrum antagonistic *Streptomyces* is still the key for development of biocontrol agents. In the present study, 17 out of 60 actinomycetes obtained from the rhizosphere soil of *M. pingii* had antifungal activity against *F. oxysporum* TR4. Particularly, *Streptomyces* BITDG-11 showed the strongest growth inhibition for *F. oxysporum* TR4 and broad-spectrum antifungal activities against the 18 selected phytopathogenic fungi. In greenhouse experiments, the application of *Streptomyces* BITDG-11 could significantly alleviate the development of leaf chlorotic symptom and decrease the disease incidence of *F. oxysporum* TR4. Similar antagonistic effects of *Streptomyces* were found in controlling other phytopathogenic diseases (Chen et al., 2019; Xu et al., 2019; Sharma and Manhas, 2020; Zhang K. et al., 2020).

The antifungal mechanism of *Streptomyces* BITDG-11 might be related with its ability to produce hydrolytic enzymes including β -1,3-glucanase and chitinase (Figures 2B,C). These enzymes lead to the destruction of the fungal cell wall and leakage of cell contents, inhibiting the growth of phytopathogenic fungi (Hong et al., 2017). Similar reports showed that *Streptomyces cavourensis* SY224 prevented the infection of *Colletotrichum gloeosporioides* by producing hydrolytic enzymes (Lee et al., 2012). Antifungal activity of *Trichoderma harzianum* QTYC77 against *F. oxysporum* f. sp. *cucumerinum* was related to the secretion of chitinase and β -1,3-glucanase (Zhang S. et al., 2020). The cell-free culture filtrate of *Streptomyces violaceusniger*

MTCC 3959 exhibited a broad range of antifungal activity against both white rot and brown rot fungi through the production of chitinase and β -1,3-glucanase (Nagpure et al., 2014). Heterologous expression of chitinase from *T. harzianum* increased inhibition activity of *B. cinerea* (Deng et al., 2019). Mycotoxin production enhanced the fungal infection on plants by repressing chitinase gene expression of the biocontrol agent *Trichoderma atroviride* (Lutz et al., 2004). Indeed, *Streptomyces* BITDG-11 had the potential to degrade starch and cellulose on plate experiments. It was supported by the identification of glucanase and amylase genes in the genome of *Streptomyces* BITDG-11. Together, these findings indicated that the hydrolytic enzymes of *Streptomyces* may be linked to their antagonistic activity against phytopathogenic fungi.

Apart from the generated hydrolytic enzymes, *Streptomyces* species were prolific producers of bioactive metabolites (van der Heul et al., 2018; Bergeijk et al., 2020). Several commercial biofungicides were developed such as rhizovit, mycostop, thatch control, and Actinovate® from different *Streptomyces* species (Sharma and Manhas, 2020). Therefore, the antifungal activity of the *Streptomyces* BITDG-11 extract was evaluated against *F. oxysporum* TR4 in the present study. The results showed that the methanol extract could effectively inhibit the mycelial growth of *F. oxysporum* TR4. Although different physical factors were selected to treat the *Streptomyces* BITDG-11 extract, more than 50% of antifungal activity was retained in all the treatment groups, suggesting that the steadily secondary metabolites with antifungal efficiency were produced in the culture filtrate. Similarly, various metabolites were identified from *Streptomyces* as biocontrol agents, and none of them had any negative effect on plants (van der Heul et al., 2018; Olanrewaju and Babalola, 2019; Bergeijk et al., 2020). It was supported by our results that no hemolytic activity was detected in human red cells treated with the *Streptomyces* BITDG-11 extract (Supplementary Figure 2), suggesting that the extract had non-specific cell lytic activity and toxicity to eukaryotic

cells. Furthermore, 15 bioactive secondary metabolites were further identified from the *Streptomyces* BITDG-11 extract by GC-MS. Among these compounds, alkanolic acids including tetradecanoic acid, pentadecanoic acid, and linoleic acid were a main type of antifungal production. The previous study reported that tetradecanoic acid had the potential for controlling *Culex quinquefasciatus* and *Aedes aegypti* mosquitoes (Sivakumar et al., 2011). Its isomers can be successfully applied to agriculture and pharmacy industries due to their excellent anti-elastase, anti-urease, and antioxidant activities (Sokmen et al., 2014). The addition of exogenous pentadecanoic acid promoted lipopeptide production and enhanced the antifungal activities of *Bacillus amyloliquefaciens* (Ding et al., 2019). Linoleic acid ethyl ester was critical for fungal response to salicylic acid, mycelial growth, and virulence (Zhang et al., 2017). Particularly, dibutyl phthalate was the major compound with the highest peak number and area in the *Streptomyces* BITDG-11 extract. The compounds produced by *Streptomyces* strain KX852460 had a high antifungal activity against *Rhizoctonia solani* (Ahsan et al., 2017). Other antibacterial and antifungal agents including 9-octadecene, colchicineamide, and bis-(2-ethylhexyl) phthalate were also detected in microbial culture by the high-performance liquid chromatographic method (Hughes and Davis, 1981; Al-Bari et al., 2005; Thekkangil and Suchithra, 2019). A 9-octadecene compound identified from *Streptomyces albidoflavus* STV1572a contributed to the infection inhibition of *Trichophyton mentagrophytes* (Thekkangil and Suchithra, 2019).

In greenhouse experiments, *Streptomyces* BITDG-11 inhibited the infection of *F. oxysporum* TR4 and promoted the growth of banana seedlings. The possible mechanism might be related to the ability of *Streptomyces* BITDG-11 to produce IAA, siderophore, and antifungal compounds. Siderophore- and IAA-producing actinomycetes in rhizosphere were known to promote plant growth and stress tolerance in main crops (Dias et al., 2017; Vurukonda et al., 2018). Siderophores not only inhibited the growth of phytopathogens but also increased the iron supply to plants and microorganisms (El-Tarabily et al., 2009). This might explain our observation that *Streptomyces* BITDG-11 significantly increased plant height, fresh and dry weight, and chlorophyll content.

Additionally, the interaction of plant and antagonistic agents induces the production of specific root exudates and alters the microbial community diversity (Khamna et al., 2009). We also found that *Streptomyces* BITDG-11 improved the fungal and bacterial abundance to inhibit the growth of *F. oxysporum* TR4 in the rhizosphere soil of banana plantlets. These microbes play an important role in maintaining the stability of the soil ecosystem and reducing plant susceptibility to pathogens (Palaniyandi et al., 2011; Zhou et al., 2019; Trivedi et al., 2020). Accumulated evidences indicated that the plant immune system could be triggered after inoculation with pathogens or beneficial microbes (de Lamo and Takken, 2020). *Streptomyces* BITDG-11 induced higher and lasting expression levels of defense genes in roots of banana seedlings. Moreover, higher activities of antioxidant enzymes such as SOD, CAT, POD, and PPO were detected in the treatment group of *Streptomyces* BITDG-11 + *F. oxysporum* TR4 over pathogen only or control. POD could directly inhibit the spore germination and mycelia growth of some pathogenic

fungi like *Pseudocercospora abelmoschi* (Joseph et al., 1998). Enhanced activities of antioxidant enzymes were also reported in bacterium-treated banana plantlets demonstrating tolerance to banana bunchy top disease (Kavino et al., 2007). A recent report showed that combining different *Streptomyces* strains reduced the disease incidence of *Botrytis gray* mold by improving the activity of antioxidant enzymes in chickpea (Vijayabharathi et al., 2018). The higher activity of antioxidant enzymes in banana roots could be another additional mechanism attributing to the increase of the host immune response to pathogens. These findings opened up the possibility of priming defense reactions by *Streptomyces* BITDG-11 inoculation and thus enhanced disease resistance against pathogens.

Genome sequencing further revealed that the *Streptomyces* BITDG-11 chromosome contained a large number of conserved BGC encoding terpenes, non-ribosomal peptides, polyketides, siderophores, and ectoines. These BGCs had been proven to participate in the regulation of antimicrobial activities of *Streptomyces* strains (Bergeijk et al., 2020). Some compounds such as toyocamycin, naringenin, and ectoine analogs showed a 100% similarity with known structures. Toyocamycin produced by *Streptomyces* belonged to a member of the nucleoside antibiotic family. The compound had been recognized as a promising fungicide for the control of plant diseases (Shentu et al., 2018; Ma et al., 2020). Naringenin exhibited both antimicrobial and antioxidant activities (Ng et al., 2019). As a compatible solute and chemical chaperone, ectoine widely synthesized by bacteria enhanced a cellular defense against detrimental effects (Czech et al., 2019).

A detailed survey and analysis revealed that low similarity was found in other BGCs, suggesting *Streptomyces* BITDG-11 had a great potential for producing novel secondary metabolites. It was supported that 33.9% of genes clustered into the unknown function category in COG. The predicted cluster 12 containing 43 necessary genes showed 81% similarity with the biosynthetic gene cluster of mannopeptimycin. The compound was a novel class of lipoglycopeptide antibiotics active against multidrug-resistant pathogens (Magarvey et al., 2006). Cluster 17 exhibited 72% similarity with the biosynthetic gene cluster of rimocidin, a structurally unique type polyketide belonging to a polyene macrolide (Jeon et al., 2016). Rimocidin produced by *Streptomyces rimosus* M527 demonstrated a strong broad-spectrum antifungal activity (Zhao et al., 2019). Cluster 41 had 80% similarity with the known sequence responsible for the biosynthesis of siderophore. The production of siderophores was further confirmed by the appearance of a yellow halo around the colony on CAS agar (**Figure 2A**). Catechol-siderophore such as coelichelin (cluster 26) identified from the *Streptomyces* species was previously characterized with 2,3-dihydroxybenzoate (2,3-DHB) as a key functional group (Reitz and Butler, 2019). A recent study demonstrated that 2,3-DHB was a common precursor during the biosynthesis of the catecholate siderophores in *Streptomyces* sp. MBT76 (Gubbens et al., 2017). A similar functional crosstalk was also found during the biosynthesis of enterobactin and other secondary metabolites such as benzoxazoles and caboxamycin in other *Streptomyces* species (Cano-Prieto et al., 2015; Losada et al., 2017). The antiSMASH analysis showed a large number of PKS and NRPS gene cluster

distributed in the genome of *Streptomyces* BITDG-11, whether a similar crosstalk exists in *Streptomyces* BITDG-11 merits further investigation.

CONCLUSION

In our study, 60 actinomycetes were isolated from the rhizosphere soil of *M. pingii*. Among 17 isolates with antagonistic ability against *F. oxysporum* TR4, strain BITDG-11 had high and broad-spectrum antifungal activity. The strain can produce IAA, siderophores, chitinase, β -1,3-glucanase, lipase, and urease. The molecular identification suggested that strain BITDG-11 might belong to a novel species of the genus *Streptomyces*. It obviously promoted the plant growth of banana plantlets and reduced the disease incidence by inducing the expression levels of defense genes and the activities of antioxidant enzymes. Genomic sequencing and analysis revealed that the *Streptomyces* BITDG-11 chromosome contained 43 conserved biosynthesis gene clusters encoding terpenes, non-ribosomal peptides, polyketides, siderophores, ectoines, etc. Among 15 bioactive secondary metabolites identified by GC-MS in the *Streptomyces* BITDG-11 extract, dibutyl phthalate was the major compound with the highest peak area. These results implied that *Streptomyces* BITDG-11 might be developed as a multifunctional biopesticide against a wide range of phytopathogens and as a bioinoculant to enhance plant growth.

Reis MNO, Bessa LA, de Jesus AP, Guimarães Silva F, Moreira MA and Vitorino LC (2021) Efficiency of the Hydroponic System as an Approach to Confirm the Solubilization of CaHPO_4 by Microbial Strains Using *Glycine max* as a Model. *Front. Plant Sci.* 12:759463. doi: 10.3389/fpls.2021.759463

The sustainable development of agriculture can be stimulated by the great market availability of bio-inputs, including phosphate-solubilizing microbial strains. However, these strains are currently selected using imprecise and questionable solubilization methodologies in solid or liquid media. We hypothesized that the hydroponic system could be a more efficient methodology for selecting phosphate-solubilizing strains as plant growth promoters. This methodology was tested using the plant *Glycine max* as a model. The growth-promoting potential of the strains was compared with that of the Biomaphos® commercial microbial mixture. The obtained calcium phosphate (CaHPO_4) solubilization results using the hydroponic system were inconsistent with those observed in solid and liquid media. However, the tests in liquid medium demonstrated poor performances of *Codinaeopsis* sp. (328EF) and *Hamigera insecticola* (33EF) in reducing pH and solubilizing CaHPO_4 , which corroborates with the effects of biotic stress observed in *G. max* plants inoculated with these strains. Nevertheless, the hydroponic system allowed the characterization of *Paenibacillus alvei* (PA12), which is also efficient in solubilization in a liquid medium. The bacterium *Lysinibacillus fusiformis* (PA26) was the most effective in CaHPO_4 solubilization owing to the higher phosphorus (P) absorption, growth promotion, and physiological performance observed in plants inoculated with this bacterium. The hydroponic method proved to be superior in selecting solubilizing strains, allowing the assessment of multiple patterns, such as nutritional level, growth, photosynthetic performance, and anatomical variation in plants, and even the detection of biotic stress responses to inoculation, obtaining strains with higher growth promotion potential than Biomaphos®. This study proposed a new approach to confirm the solubilizing activity of microorganisms previously selected *in vitro* and potentially intended for the bio-input market that are useful in P availability for important crops, such as soybeans.

Keywords: phosphate solubilizing microorganisms, PSM, bio-inputs, plant nutrition, plant growth promotion

INTRODUCTION

The world population is estimated to reach ~9.735 billion people by 2050 (United Nations, 2019). Associated with the pressure for agriculture to meet the needs of human development, it is necessary to implement sustainable agricultural practices that increase productivity integrated with conservation measures (Taveira et al., 2019). The current productivity of important crops such as soybean is affected by phosphorus (P) deficiency in acidic soils since P plays a key role in the symbiotic capacity of nitrogen (N_2) fixation (Suliman and Tran, 2017; Wang et al., 2020; Jaiswal et al., 2021). Current agricultural practices use fertilizers to add P to the soil, however, the use of phosphate fertilizers is expensive and unsustainable (Situmorang et al., 2015). Nonetheless, these fertilizers are easily precipitated with aluminum (Al), iron (Fe), and calcium (Ca), forming low-solubility complexes that are not used by plants (Penn and Camberato, 2019). In this context, the dissemination of more economical and ecologically appropriate technologies to improve P availability in soil has become urgent.

Currently, the use of phosphate-solubilizing microbes (PSMs) has been shown as a promising method since they play a key role in P dynamics in soil and the subsequent availability of this element to plants (Islam and Hossain, 2012; Kafle et al., 2019). PSMs fractionate insoluble P forms into soluble forms through various biological mechanisms, including the production of organic acids and extracellular enzymes, which convert insoluble forms of P into forms available for plant absorption (Hanif et al., 2015; Li et al., 2015; Baliah et al., 2016; Gurikar et al., 2016; Doilom et al., 2020; Sarr et al., 2020; Zúñiga-Silgado et al., 2020). The organic acids produced include glycolic, 2-ketogluconic, acetic, citric, propionic, succinic, tartaric, formic, fumaric, lactic, malic, butyric, gluconic, valeric, oxalic, and citric acids (Hwangbo et al., 2003; Chen et al., 2006; Patel et al., 2008; Scervino et al., 2010; Zhu et al., 2012; Jog et al., 2014; Mehta et al., 2015; Yadav et al., 2015). However, despite their importance, few PSM strains are currently available in the global market for inoculants. This is partly due to faulty strain selection mechanisms, which often present a high potential for *in vitro* systems but a reduced potential for field systems.

Phosphate-solubilizing microbes strains are usually selected through screening in solid media containing phosphate sources, such as calcium phosphate ($CaHPO_4$), $Ca_3(PO_4)_2$, aluminum phosphate ($AlPO_4$), or iron phosphate ($FePO_4$). In these media, halo measurements determine the efficiency of the isolate in solubilizing the insoluble phosphate source. However, this qualitative method is considered inefficient for selection, as many isolates that do not produce any visible halo on solid media can solubilize various types of insoluble inorganic phosphates in liquid media (e.g., Nautiyal, 1999; Bashan et al., 2013; Salcedo et al., 2014; Sousa et al., 2016). Therefore, potential strains are commonly excluded by this screening. Another selection methodology is screening in a liquid culture medium. This methodology is currently accepted as the most reliable method, but it also presents inconsistencies as a colorimetric method. The most widespread protocol for solubilizing strains in a liquid medium for determining free P is described by Murphy and Riley

(1962). This protocol is based on the reaction of an ascorbic acid (vitamin C) stock solution with added molybdate, forming a blue phosphomolybdenum complex proportional to the amount of free P in the sample. Nonetheless, this method is highly susceptible to chemical interference from reducing agents present in the culture medium, such as ascorbate, which affects the formation of the blue complex and leads to under- or over-estimated free P concentrations (Jarvie et al., 2002; Kowalenko and Babuin, 2007; Kowalenko, 2008; Nagul et al., 2015; Anschutz and Deborde, 2016).

In this study, tests were performed using $CaHPO_4$ as a phosphate source, and the hydroponic method was compared with classic methodologies in solid and liquid media, for the selection of phosphate-solubilizing strains. The effects of the strains on plant growth promotion were evaluated. The methodology was tested using *Glycine max* plants as a model because their seedlings are easy to obtain and because of the current need for developing biotechnologies for the cultivation of this oilseed. In addition, the growth-promoting potential of the tested strains was compared with that of the commercial product Biomaphos[®], which consisted of a mixture of *Bacillus megaterium* and *B. subtilis* bacteria. We hypothesized that the hydroponic system could be more efficient in selecting phosphate-solubilizing strains, which are plant growth promoters, independent of other nutrients. The hydroponic system requires the presence of a root system, which provides data related to the effect of the isolates on growth promotion and photochemical and photosynthetic performance. Furthermore, the effectiveness of this system was proposed based on the greater induction of plant-microorganism interactions, since in the water-plant condition, root exudates are easily adsorbed in the solution (Hoffland et al., 2006) and are freer to stimulate the tested microorganisms. This study proposed a more efficient approach for selecting strains with the potential to satisfy the current demand for bio-inputs applied to P availability in important crops, such as soybeans.

MATERIALS AND METHODS

Microbial Strains

The potential of eight rhizospheric or endophytic microbial strains was evaluated, with six previously isolated from *Hymenaea courbaril* (for further information see Rocha et al., 2020) and two from Arecaceae *Butia purpurascens* (for further information see da Silva et al., 2018) (Table 1). These strains currently belong to the microorganism collection of the Agricultural Microbiology Laboratory of the IFGoiano Rio Verde campus, Brazil. The potential of these strains was compared with that of the commercial product Biomaphos[®] (BIOMA, Brazil), which consisted of a mixture of BRM034840 and BRM033112-B strains from *B. megaterium* and *B. subtilis*. The bacterial strains were reactivated in nutrient agar medium (3 g of meat extract, 5 g of peptone, 25 g of agar, and H_2O qs 1 L) for 48 h at 35°C in an incubation chamber, and then reactivated in potato dextrose agar (PDA; infusion of 200 g of potato, 20 g of dextrose, and 15 g of agar) for 7 days at 35°C in an incubator.

TABLE 1 | Microbial strains were used to compare experimental methodologies for the evaluation of the solubilization capacity of calcium phosphate (CaHPO₄).

Qualitative Assessment of the Solubilization Capacity of CaHPO₄ in Solid Medium

Bacterial and fungal strains were inoculated in Petri dishes containing GELP culture medium (10 g glucose, 5 g peptone, 0.05 g yeast extract, and 15 g agar). We added 25 ml of calcium dichloride (CaCl₂) (10%) and 12.5 ml of dipotassium hydrogen phosphate (K₂HPO₄) (10%) to form an inorganic phosphate precipitate from CaHPO₄ (10%), as described by Sylvester-Bradley et al. (1982). The ability of the microorganism to solubilize CaHPO₄ was confirmed by observing a clear halo around the colony of the bacteria or fungus, in contrast to the opaque medium (Souchie et al., 2007). Plates containing GELP culture medium with CaHPO₄ added without inoculum were used as negative controls for solubilization.

The capacity of the strains to solubilize CaHPO₄ was compared by measuring the diameters of the solubilization zones (halos) around the colonies after 7 days of incubation. The solubilization index (SI) was calculated using the method proposed by Berraquero et al. (1976):

$$SI = \frac{(\text{total diameter including colony and halo})}{(\text{colony diameter})}$$

The SI of the strains was classified according to the methods of Silva Filho and Vidor (2000) as low (SI < 2), medium (2 < SI < 3), or high (SI > 3). The test was conducted in triplicate for each strain tested.

Quantitative Assessment of CaHPO₄ Solubilization in Liquid Medium

For this test, bacterial samples were grown under constant agitation using an orbital shaker (NT 712, NOVA TÉCNICA, Brazil) rotating at 90 rpm for 24 h at 30°C in 7 ml of liquid GL culture medium (10 g glucose, 2 g yeast extract). Then, 3 ml of the samples were aseptically removed from each culture to determine the optical density (OD) at 600 nm. All bacterial

samples had their OD adjusted to 0.1 by dilution with saline solution (0.85%). Fungal samples were grown in a PDA medium for 4 days at 30°C. CaHPO₄ solubilization in liquid medium was quantified by inoculating 1 ml of the previously standardized bacterial culture in 10 ml of liquid GL medium, with 1.26 g L⁻¹ of the CaHPO₄ phosphate source. For the evaluation of fungi, 5 mm diameter disks with mycelial growth were removed, which were inoculated in 10 ml of medium (one disk per glass). The cultures were agitated at 90 rpm and 30°C for 72 h. The test was performed in triplicate for each strain tested, using GL medium without inoculum as a negative control. After growth, the pH was measured, and the amount of inorganic P was determined using the vitamin C colorimetric method at 725 nm, according to the methods of Gadagi and Sa (2002).

The *in vitro* solubilization experiments were conducted in a completely randomized design, considering nine treatments with microorganisms (eight strains + Biomaphos®) and a control treatment (without inoculation). CaHPO₄ solubilization means and pH were subjected to a one-way ANOVA to evaluate only the treatment effect. When significant, the effects were evaluated using the Scott-Knott test at 5% significance probability.

In vivo Assessment of the Solubilizing Potential of CaHPO₄ Using a Hydroponic System

Inoculum Preparation

Bacterial inoculates were prepared in nutrient broth for 24 h at 30°C under constant agitation at 90 rpm. The cell concentration in each culture was estimated by CFU counting in nutrient agar and was standardized to 10⁴ ml⁻¹ using 0.85% saline solution. The fungal mycelia were cultivated in a PDA medium for 14 days at 30°C. Subsequently, the plates were superficially washed using 10 ml of 0.85% saline solution per plate, and the spore concentration was determined by counting them in a Neubauer chamber (hemocytometer) using an optical microscope (BA210, MOTIC, Canada) (40–100 × magnification). The spore concentration of the cultures was adjusted to 10⁵ ml⁻¹.

Root Colonization and Microscopic Examination

This test was conducted to verify the colonizing potential of the strains to be tested in a hydroponic system. The test was conducted using *G. max* seeds of the Bonus 8579 RSF IPRO cultivar (BRASMAX, Brazil). The seeds were disinfected to remove epiphytes, successively washed in running water, and agitated in water and neutral detergent (Tween) for 5 min. Then, the seeds were immersed in 70% ethanol for 1 min, followed by immersion in sodium hypochlorite (2.5% active chlorine) for 1 min and 30 s, and then again in 70% ethanol for 30 s. Finally, the seeds were washed three times in autoclaved distilled water and planted in plastic trays containing autoclaved sand as substrate, where the seedlings remained for 7 days in a BOD Camera (SSBODU320, PROLAB, Brazil) at 25°C (77F) and 12/12 h photoperiod. During this period, the seedlings were aseptically watered once a day with sterilized water. The plants were then carefully removed from the sand, and the roots

were detached and washed four times with sterilized distilled water under vigorous agitation. The roots were then submerged in the previously prepared inoculum solutions and deposited in Petri dishes containing GELP medium. Plates containing roots immersed in autoclaved distilled water were used as a negative control and incubated at 28°C for 48 h. Subsequently, the roots were prefixed with glutaraldehyde, post-fixed with osmium tetroxide, dehydrated in an ethanol series, transferred to amyl acetate, and critically dried in a dryer with carbon dioxide (CO₂), following the methodology described by Ghosh et al. (2016). Then, they were coated with gold using an ion jet to evaluate microbial colonization under a scanning electron microscope (Jeol JSM-IT300LV, JEOL USA, Inc., Peabody, MA, US).

Experiment in the Hydroponic System

The experiment was conducted in a greenhouse at the Plant Tissue Culture Laboratory of the IFGoiano Rio Verde campus (17° 48' 15.9" S – 50° 54' 19.5" W), from July to August 2020, under an average temperature of 26.85°C and relative humidity of 23.7%. Soybean seeds of the same cultivar were subjected to the same disinfection and germination treatment in autoclaved sand, where the seedlings remained until they reached a mean size of 15 cm, and then transferred to 4 L pots containing the hydroponic nutrient solution proposed by Hoagland and Arnon (1950) with half ionic strength for 15 days of adaptation. After this period, the plants were subjected to a nutrient solution with full ionic strength.

The inoculation of microorganisms occurred during phase R5 of soybean development. For this, 10 ml of the previously prepared inoculate solutions were added to the nutrient solution along with 10 g L⁻¹ of aseptic glucose to stimulate microbial growth in the nutrient solution. Biometric, physiological, and anatomical evaluations were conducted after 10 days of exposure to the tested strains. Plants grown in a nutrient solution without adding microorganisms and grown in a nutrient P-free solution (without the addition of CaHPO₄) were used as control treatments.

The *in vivo* experiment was conducted in randomized blocks, with nine treatments with microorganisms (eight strains + Biomaphos®) and two control treatments (plants grown in a nutrient solution without microorganisms and plants grown in P-free nutrient solution). All treatments were evaluated in five repetitions, with each repetition consisting of two plants per pot. The results obtained for biometric analyses, tissue P content, and physiological and anatomical analyses were subjected to ANOVA to evaluate the treatment effect. When significant, the effects were evaluated using the Scott-Knott test at 5% probability.

Subsequently, all variables were evaluated using a correlation matrix and combined in a principal component analysis (PCA). Since these variables had different measurement units, a correlation PCA was performed which was constructed using standardized data with a mean of 0 and a standard deviation of 1. The number of components was chosen as a function of the eigenvalues (>1) and explained variance (above 80%). The variables were also evaluated using Pearson's correlation coefficient, and the strength of the relationship was analyzed

through R-values and the significance of the interaction at 5% probability. All statistical tests were performed in the R software version 4.0.4 (R Core Team, 2021), using the "ExpDes.pt" (Ferreira et al., 2014) and "FactoMineR" (Husson et al., 2010) packages.

Biometric and Tissue P Content Evaluations

The biometric variables plant height, stem diameter (SD), root length (RL), number of leaves (LN), and biomass were evaluated. For biomass evaluation, the plants were segmented into leaves, stems, and roots, and the material was dried in a forced-air oven at 65°C to a constant mass. Subsequently, the dry mass (DM) of each plant part was determined. The sum of the values corresponding to the biomass of each structural component of the plants (LDM + SDM + RDM) enabled the determination of the total DM (TDM).

Leaves, stems, and roots were oven-dried at 65°C until they reached a constant weight (Oven; SL-102/1152, SOLAB, Brazil) and crushed in a Willey mill with a 20 mm-mesh sieve (R-TE-680, TECNAL, Brazil). Finally, the P content was estimated according to the procedure described by Malavolta et al. (1997).

Anatomical Evaluation of the Root

The diameter of the root pot elements was evaluated as an indication of root development because it is commonly associated with P availability to plants (Rosolem and Marcello, 1998). Thus, root samples were fixed in glutaraldehyde solution (2.5%) and paraformaldehyde (4%) in sodium cacodylate buffer (pH 7.2) and added to 5 mM calcium chloride (Karnovsky, 1965). The roots were cross-sectioned into 5-μm-thick slices and stained with toluidine blue at pH 6.8 (O'Brien et al., 1964). In these sections, the diameter of the vessel elements was measured using the Anati Quanti 2 software (Aguiar et al., 2007). Each repetition was measured 15 times, and the treatments were evaluated in quintuplicate.

Gas Exchange

Gas exchange was evaluated from 7:00 AM to 10:00 AM on the third leaf counted from the apex of the plant using an infrared gas analyzer with a fluorometer (LI-6800xt, LI-COR Inc., Lincoln, USA) and photosynthetically active radiation (1,000 μmol photons m⁻² s⁻¹) at a block temperature of 27°C and relative humidity of ~70%. The net photosynthesis rate (A) (μmol CO₂ m⁻² s⁻¹), stomatal conductance (g_{sw}) (mol of H₂O m⁻² s⁻¹), transpiration (E) (H₂O m⁻² s⁻¹), and internal carbon concentration (Ci) (mmol m⁻² s⁻¹) were measured (see Hunt, 2003).

Photosynthetic Pigments

The concentration of photosynthetic pigments was evaluated using leaf disks (three fresh matter mass disks of 5 mm diameter each). These disks were covered with a DMSO solution and saturated with calcium carbonate (CaCO₃) (Santos et al., 2007). Subsequently, they were stored in tubes wrapped in Al foil for 24 h at 65°C. The absorbance of the obtained extract was determined by spectrophotometry at 664, 649, and 480 nm. Chlorophyll *a*, *b*, and total and carotenoid concentrations were

determined according to the methods described by Wellburn (1994).

Chlorophyll *a* Fluorescence

Chlorophyll *a* fluorescence OJIP transient was determined using a portable FluorPen FP 100 fluorometer (Photon Systems Instruments, Drasov, Czech Republic). The third leaf of all sample units was previously dark-adapted for 30 min for complete oxidation of the photosynthetic electron transport system. They were later subjected to a 3,000 $\mu\text{mol m}^{-2} \text{s}^{-1}$ blue light pulse, with minimum fluorescence (F_0) and maximum fluorescence (F_M). These values were used to estimate several PSII bioenergetic indices, according to the methods described by Strasser et al. (2000). The values of the specific light absorption flow per reaction center (ABS/RC), energy flow captured per reaction center at $t = 0$ (TRo/RC), electron transport flow per reaction center (ETo/RC), specific energy dissipation flow at the level of the antenna complex chlorophylls (DIO/RC), photosynthetic performance index (Pi_Abs) that incorporates energy cascade processes from the first absorption events to PQ reduction, the maximum quantum yield of primary photochemistry (PHI_Po), the probability of an exciton moving an electron through the electron transport chain after quinone (PSI_O), and the quantum yield of electron transport (PHI_Eo) after dark adaptation of the leaves (30 min) were determined in this study.

Chlorophyll *a* fluorescence in *G. max* leaves was also evaluated using the modulated Imaging-PAM fluorometer to obtain fluorescence images. Initially, the initial fluorescence (F_0) and maximum fluorescence (F_m) were determined in leaves pre-adapted to the dark for 30 min. Then, it was possible to calculate the potential quantum yield of photosystem II (PSII) (Genty et al., 1989). Sequentially, the fluorescence in the light-adapted sample before the saturation pulse (F) and F_m in a light-adapted sample (F_m') were used to obtain the effective quantum yield of photochemical energy conversion in PSII, $\Phi_{II} = (F_m' - F)/F_m'$.

RESULTS

In vitro Experiment: Solid Culture Medium

In a solid medium, only the *B. thuringiensis* (SC10), *B. megaterium*, *B. subtilis* (Biomaphos®), and *B. cereus* (SC5) strains demonstrated potential for CaHPO_4 solubilization through the production of solubilization halos. The solubilizing capacity of these strains was classified as low ($\text{SI} < 2$) (Table 2).

In vitro Experiment: Liquid Culture Medium

B. thuringiensis (SC10), *Paenibacillus alvei* (PA12), and *B. cereus* (SC5) strains showed the highest solubilization efficiency in a liquid medium containing CaHPO_4 as a phosphate source. All microbial strains reduced the pH of the medium compared with the control without inoculation, except for fungal *Hamigera insecticola* (33EF) and *Codinaeopsis* sp. (328EF) strains, which presented the lowest solubilization means (Table 3).

TABLE 2 | Evaluation of calcium phosphate (CaHPO_4) solubilization in solid medium (GELP) by rhizospheric or endophytic bacterial and fungal strains from *Hymenaea courbaril* or endophytic bacterial and fungal strains from *Butia purpurascens*.

Microorganisms	Solubility index	Solubilization capacity
SC10	1.25 a	Low
PA12	NS	NS
Biomaphos®	1.27 a	Low
SC5	1.14 a	Low
SC15	NS	NS
PA26	NS	NS
SC4	NS	NS
33EF	NS	NS
328EF	NS	NS
Control	NS	NS

Means followed by the same lowercase letter in the column do not significantly differ according to the Scott-Knott test at 5% probability. NS, did not form a solubilization halo.

TABLE 3 | Evaluation of calcium phosphate (CaHPO_4) solubilization in liquid medium (GL) by rhizospheric or endophytic bacterial and fungal strains from *Hymenaea courbaril* or endophytic bacterial and fungal strains from *Butia purpurascens*.

Treatments	pH	Soluble P (mg L ⁻¹)
SC10	4.79 c	5.53 a
PA12	4.80 c	5.62 a
Biomaphos®	4.89 c	4.61 b
SC5	4.96 b	5.13 a
SC15	5.28 b	3.15 c
PA26	5.48 b	3.69 b
SC4	5.53 b	3.18 c
33EF	6.37 a	1.82 d
328EF	6.49 a	1.48 d
Control	6.73 a	0.33 e

Means followed by the same lowercase letter in the column did not differ significantly according to the Scott-Knott test at 5% probability.

Root Colonization

All bacteria and fungi evaluated demonstrated the ability to effectively colonize the root system, forming large superficial aggregates (Supplementary Figures 1, 2). Electron microscopy analyses showed the formation of protein crystals in *B. thuringiensis* (SC10) colonies and bacterial spores in *Lysinibacillus fusiformis* (PA26) root colonies (Figures 1A–D). They also found a large concentration of fungal spores in *Codinaeopsis* sp. (328E) colonies (Figures 1E,F).

In vivo Experiment: Hydroponic Cultivation Evaluation of Growth Promotion

The exposition of *G. max* seedlings to the microorganisms tested did not affect the height of the plants; the means ranged between a minimum of 84.8 cm in plants inoculated with *Epicoccum keratinophilum* (SC4) and a maximum of 93.8 cm in plants treated with *P. alvei* (PA12). However, the development of plants

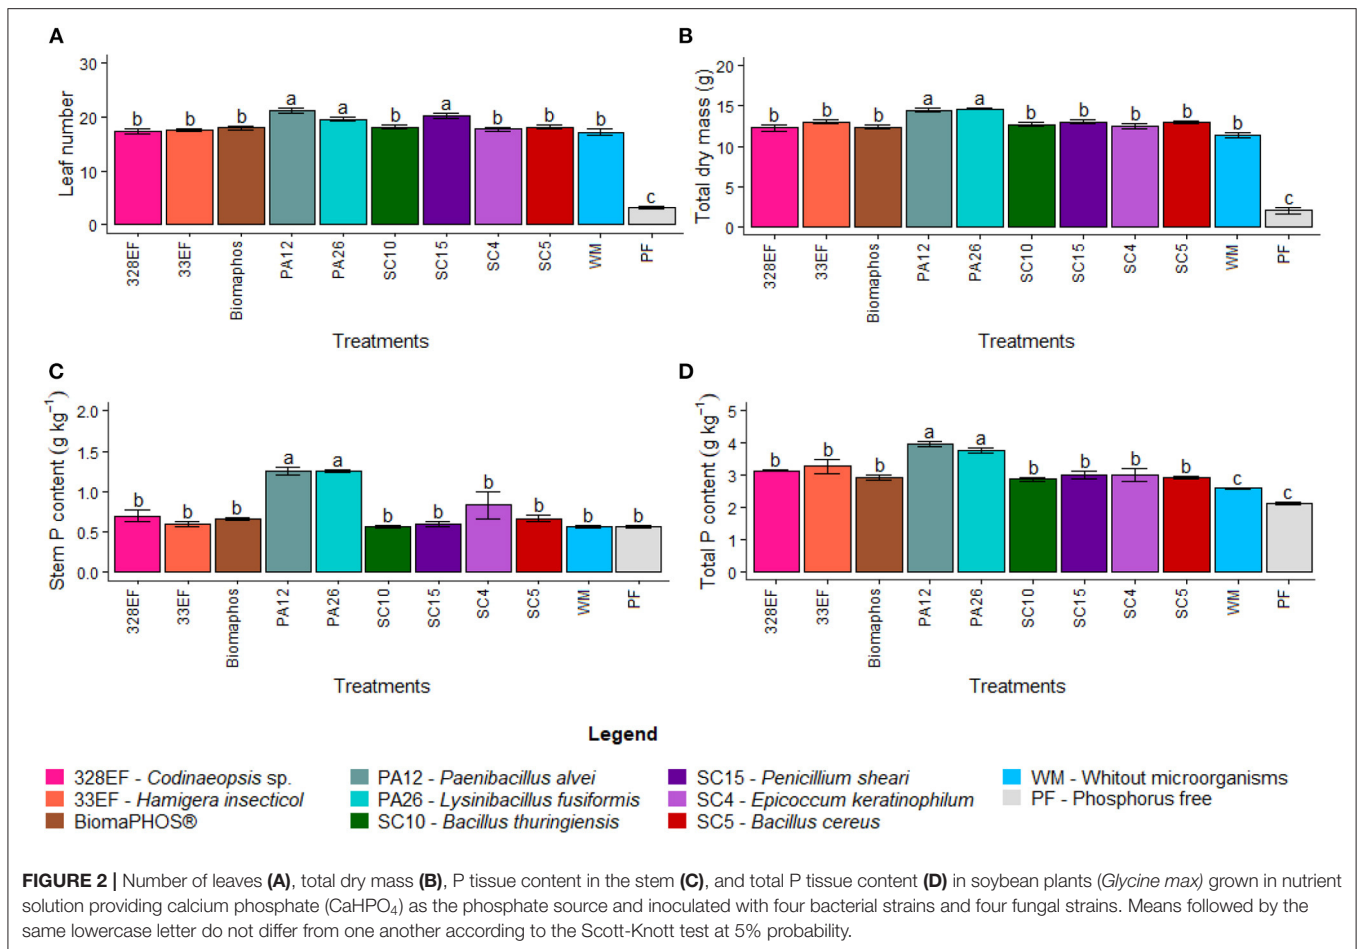

FIGURE 1 | Microscopic aspects of root colonization in soybean plants (*Glycine max*) treated with the bacterial strains SC10 = *Bacillus thuringiensis* (A,B) and PA26 = *Lysinibacillus fusiformis* (C,D), and the fungal strain 328E = *Codinaeopsis* sp. (E,F). Red arrows indicate the presence of protein crystals (B) and spores (D–F).

in a control solution without P was significantly affected by the unavailability of this element, with a mean height for these plants of only 64.25 cm (**Supplementary Figure 3A**). Similar results were obtained for RL, which remained statistically equal in plants inoculated with different microorganisms and in a solution without microorganisms, with the means ranging between a minimum of 46.5 cm in plants inoculated with *E. keratinophilum* (SC4) and without microorganisms and a maximum of 93.8 cm in plants treated with *P. alvei* (PA12). Plants kept in a nutrient solution without P also had their RL affected, with a mean of 34 cm (**Supplementary Figure 3B**).

Standard deviation means also followed the same pattern: not differing between plants grown in a solution without microorganisms and inoculated plants, ranging from a minimum

of 0.38 mm in non-inoculated plants to a maximum of 0.46 mm in plants treated with *P. alvei* (PA12). As described for the previous variables, plants subjected to a nutrient solution without P also presented low SD development (0.16 mm) (**Supplementary Figure 3C**). However, the LN was significantly affected by the inoculation treatments, with the highest values for plants inoculated with *P. alvei* (PA12), *L. fusiformis* (PA26), and *Penicillium sheari* (SC15) (21.2, 20.2, and 19.6 leaves, respectively). The absence of P in the solution also affected the LN in the plants, with a mean of only 3.25 leaves in plants developed with this treatment (**Figure 2A**).

The dry matter mass of leaves, stems, and roots did not differ between plants inoculated with microorganisms and plants grown in a solution without microorganisms. Leaf dry matter

means varied between a minimum of 4.39 g in non-inoculated plants and a maximum of 5.2 g in plants treated with *L. fusiformis* (PA26) (Supplementary Figure 4A). Shoot dry matter mass followed a similar trend, ranging from a minimum of 4.05 g in non-inoculated plants and a maximum of 5.31 g in plants treated with *L. fusiformis* (PA26) (Supplementary Figure 4B). Root dry matter also followed the pattern described above, ranging from a minimum of 2.91 g in non-inoculated plants to a maximum of 4.12 g in plants treated with *L. fusiformis* (PA26) (Supplementary Figure 4C). However, plants grown in a solution without P presented the lowest values for LDM, SDM, and RDM (0.196, 1.036, and 0.847 g, respectively).

For TDM, the highest values were observed for plants inoculated with *P. alvei* (PA12) and *L. fusiformis* (PA26) (14.63 and 14.43 g, respectively). Plants grown in solution without microorganisms had a mean of 11.35 g TDM, but plants kept in solution without P had the lowest values (2.08 g) (Figure 2B).

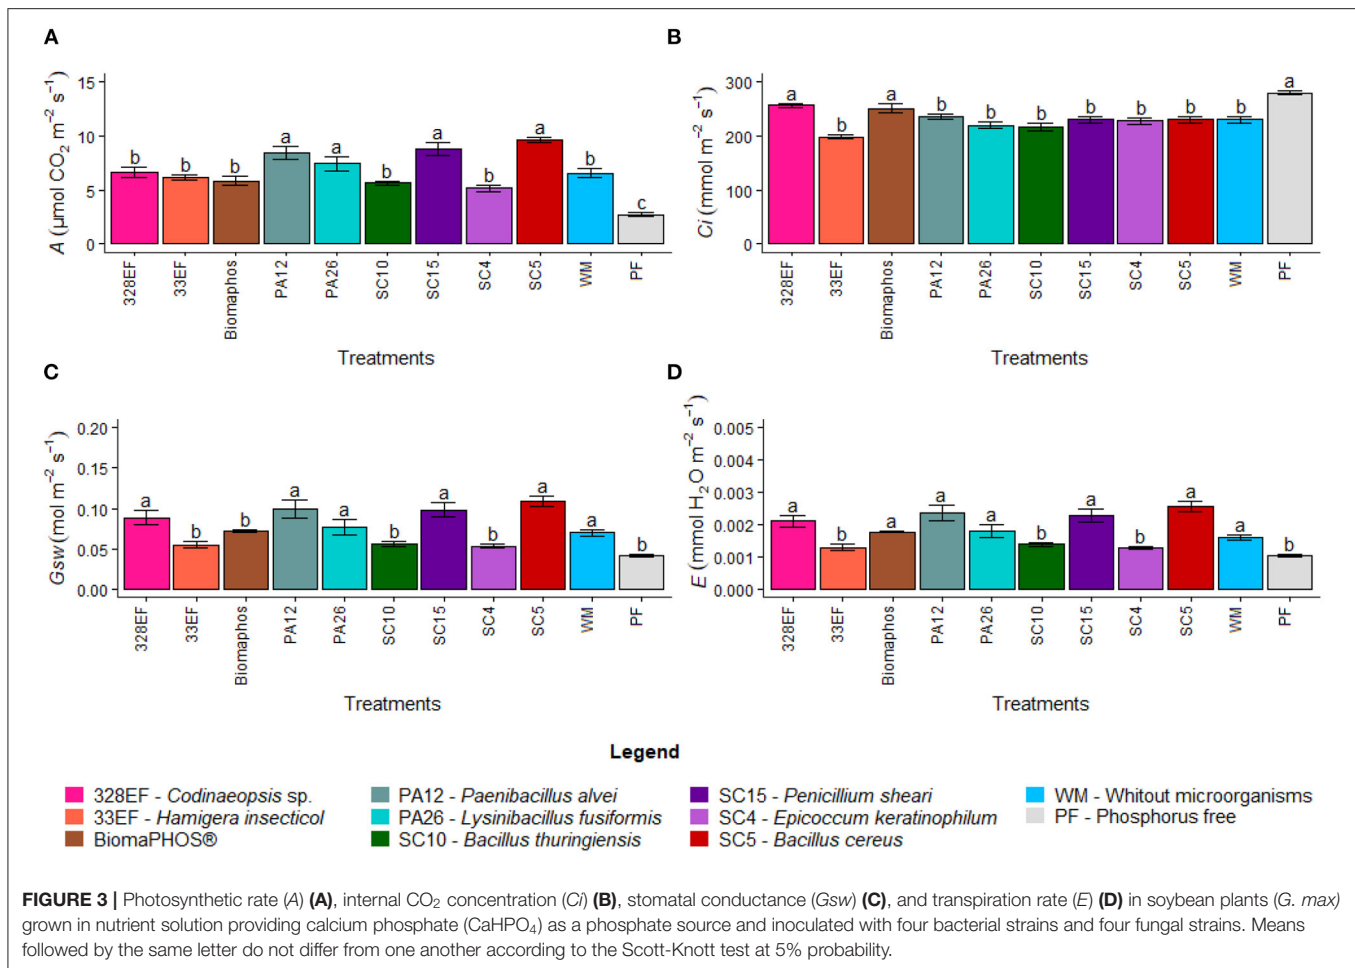

P Absorption Performance Evaluation in P Tissue Content

Phosphorus content did not differ in leaves of plants subjected to the different treatments evaluated, and the means ranged between a minimum of 0.67 g in plants grown without P and a maximum of 1.30 g kg⁻¹ in plants treated with *P. alvei* (PA12)

(Supplementary Figure 5A). Stem P content was affected by the inoculation treatments, being higher in plants inoculated with *P. alvei* (PA12) and *L. fusiformis* (PA26) (1.25 and 1.25 g kg⁻¹, respectively) (Figure 2C). The P content in roots was higher for plants inoculated with *Codinaeopsis* sp. (328EF), *H. insecticola* (33EF), *P. alvei* (PA12), *L. fusiformis* (PA26), *B. thuringiensis* (SC10), and *P. sheari* (SC15) (1.50, 1.57, 1.40, 1.45, 1.35, and 1.35 g kg⁻¹, respectively) (Supplementary Figure 5B). The evaluation of total P content showed the highest means in plants inoculated with the bacteria *P. alvei* (PA12) and *L. fusiformis* (PA26) (3.95 and 3.77 g kg⁻¹), while the lowest means were verified in plants growing in a solution without microorganisms (2.58 g kg⁻¹) and P-free (2.13 g kg⁻¹) (Figure 2D).

Photosynthetic Performance Assessment: Gas Exchange

Microbial inoculation significantly affected gas exchange rates in *G. max*. The net CO₂ assimilation rate (A) was higher in plants inoculated with the strains *P. alvei* (PA12), *L. fusiformis* (PA26), *B. cereus* (SC5), and *P. sheari* (SC15) at 8.41, 7.43, 9.65, and 8.78 μmol CO₂ m⁻² s⁻¹, respectively (Figure 3A). However, these plants presented low rates of internal CO₂ (Ci) concentration, respectively 235.56, 219.9, 230.85, and 230.24 mmol m⁻² s⁻¹, while the highest means were verified in plants grown in a

solution without P ($280.32 \text{ mmol m}^{-2} \text{ s}^{-1}$) and inoculated with *Necropsied* sp. (328EF) and Biomaphos® (256.96 and $251.16 \text{ mmol m}^{-2} \text{ s}^{-1}$) (Figure 3B). A behavior similar to that observed for A was observed for stomatal conductance (Gsw), with the highest means obtained for inoculation treatments with *Necropsied* sp. (328EF), *P. alvei* (PA12), *L. fusiformis* (PA26), *P. sheari* (SC15), and *B. cereus* (SC5) strains (0.072 , 0.099 , 0.077 , 0.098 , and $0.109 \text{ mol m}^{-2} \text{ s}^{-1}$, respectively), and for plants grown in solution without microorganisms ($0.07 \text{ mol m}^{-2} \text{ s}^{-1}$) (Figure 3C). The transpiration rate (E) was higher in plants grown in a solution without microorganisms (0.0016) and inoculated with *Necropsied* sp. (328EF), Biomaphos®, *P. alvei* (PA12), *L. fusiformis* (PA26), *P. sheari* (SC15), and *B. cereus* (SC5) at 0.0021 , 0.0018 , 0.0024 , 0.0018 , 0.0023 , and 0.0026 E, respectively (Figure 3D).

Photosynthetic Performance Assessment: Photosynthetic Pigments

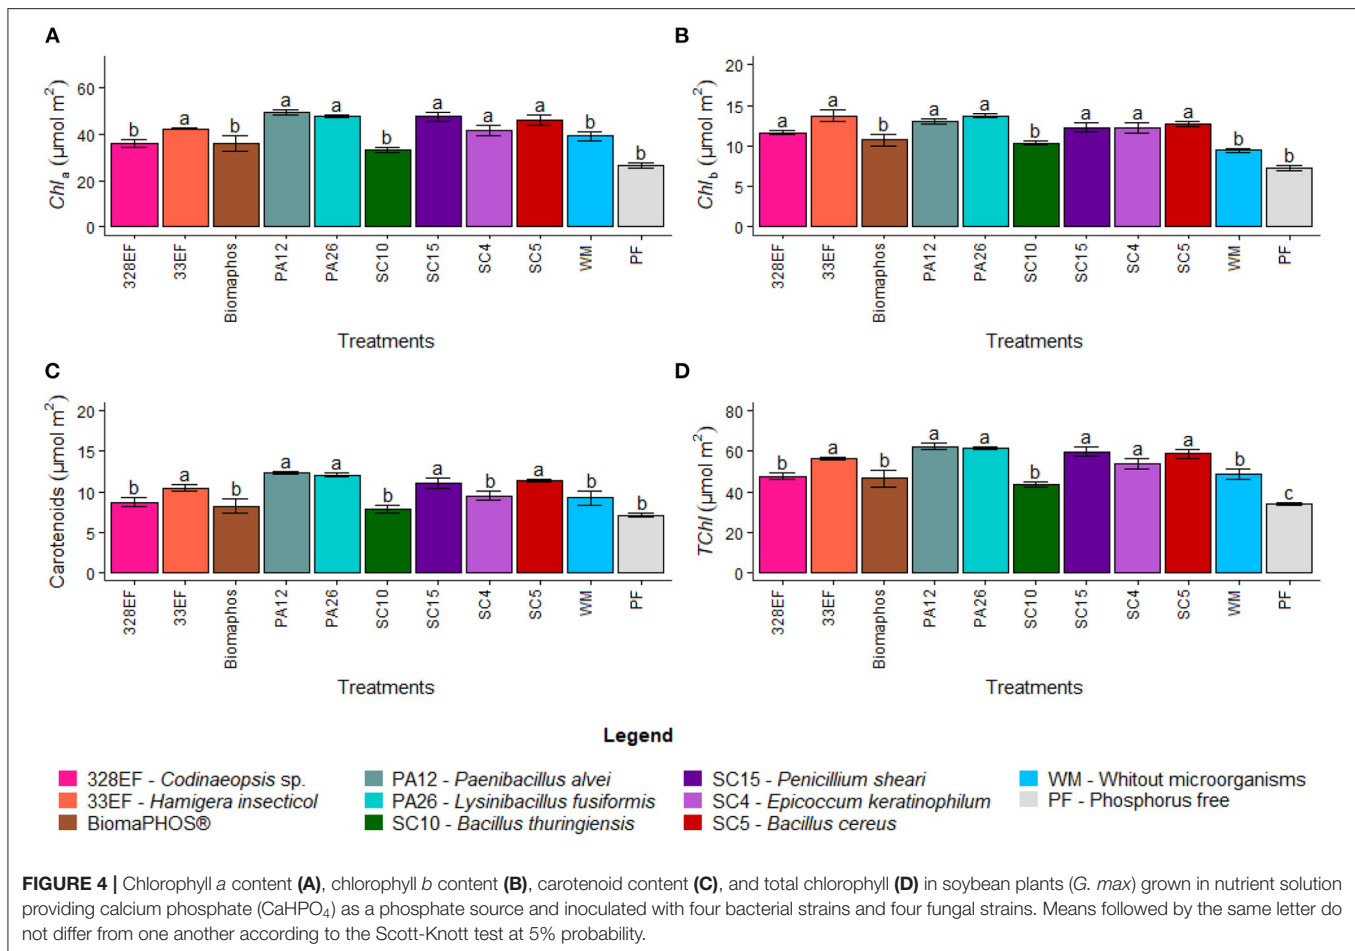

Chlorophyll *a* content increased in plants inoculated with *H. insecticola* (33EF), *P. alvei* (PA12), *L. fusiformis* (PA26), *P. sheari* (SC15), *E. keratinophilum* (SC4), and *B. cereus* (SC5) at 42.437 , 49.240 , 47.717 , 47.571 , 41.469 , and $46.052 \mu\text{mol m}^{-2}$, respectively (Figure 4A). Chlorophyll *b* content also increased

following a pattern similar to that observed for chlorophyll *a*, but it was higher in plants subjected to inoculation with *Necropsied* sp. (328EF), *H. insecticola* (33EF), *P. alvei* (PA12), *L. fusiformis* (PA26), *P. sheari* (SC15), *E. keratinophilum* (SC4), and *B. cereus* (SC5) strains (11.644 , 13.723 , 13.069 , 13.726 , 12.231 , 12.269 , and $12.704 \mu\text{mol m}^{-2}$) (Figure 4B).

Microbial inoculation also affected the carotenoid content, which was higher in plants inoculated with *H. insecticola* (33EF), *P. alvei* (PA12), *L. fusiformis* (PA26), *P. sheari* (SC15), and *B. cereus* (SC5), with mean values of 10.458 , 12.275 , 12.084 , 11.034 , and $11.382 \mu\text{mol m}^{-2}$ (Figure 4C). Similar to other chlorophylls, the total chlorophyll content varied, with the highest means obtained in plants treated with *H. insecticola* (33EF), *P. alvei* (PA12), *L. fusiformis* (PA26), *P. sheari* (SC15), *E. keratinophilum* (SC4), and *B. cereus* (SC5) (56.161 , 62.309 , 61.444 , 59.802 , 53.738 , and $58.756 \mu\text{mol m}^{-2}$). However, much lower mean values were observed in plants grown in a solution without P ($33.832 \mu\text{mol m}^{-2}$) (Figure 4D).

Photosynthetic Performance Assessment: Chlorophyll *a* Fluorescence

As expected, the specific energy flows of the active reaction centers ABS/RC and DIO/RC were similarly affected by microbial

inoculation; therefore, the lowest mean ABS/RC values were observed in plants grown with the microorganisms *P. alvei* (PA12), *L. fusiformis* (PA26), *B. thuringiensis* (SC10), *P. sheari* (SC15), and *B. cereus* (SC5) (2.986, 2.962, 3.127, 2.989, and 2.859, respectively), as well as in plants grown in a solution without microorganisms (2.935) (Figure 5A). The lowest mean DIO/RC values were obtained in plants subjected to the same treatment sequence as above (0.714, 0.686, 0.842, 0.796, 0.660, and 0.667, respectively) (Figure 5B). The means observed for TRo/RC and ETo/RC were not affected by any of the evaluated treatments. TRo/RC values ranged from a minimum of 2.193 in plants inoculated with *P. sheari* (SC15) and a maximum of 2.546 in plants treated with *H. insecticola* (33EF), whereas ETo/RC means varied between a minimum of 0.985 in plants grown in nutrient P-free solution and a maximum of 1.384 in plants treated with the fungus *H. insecticola* (33EF) (Supplementary Figures 6A,B).

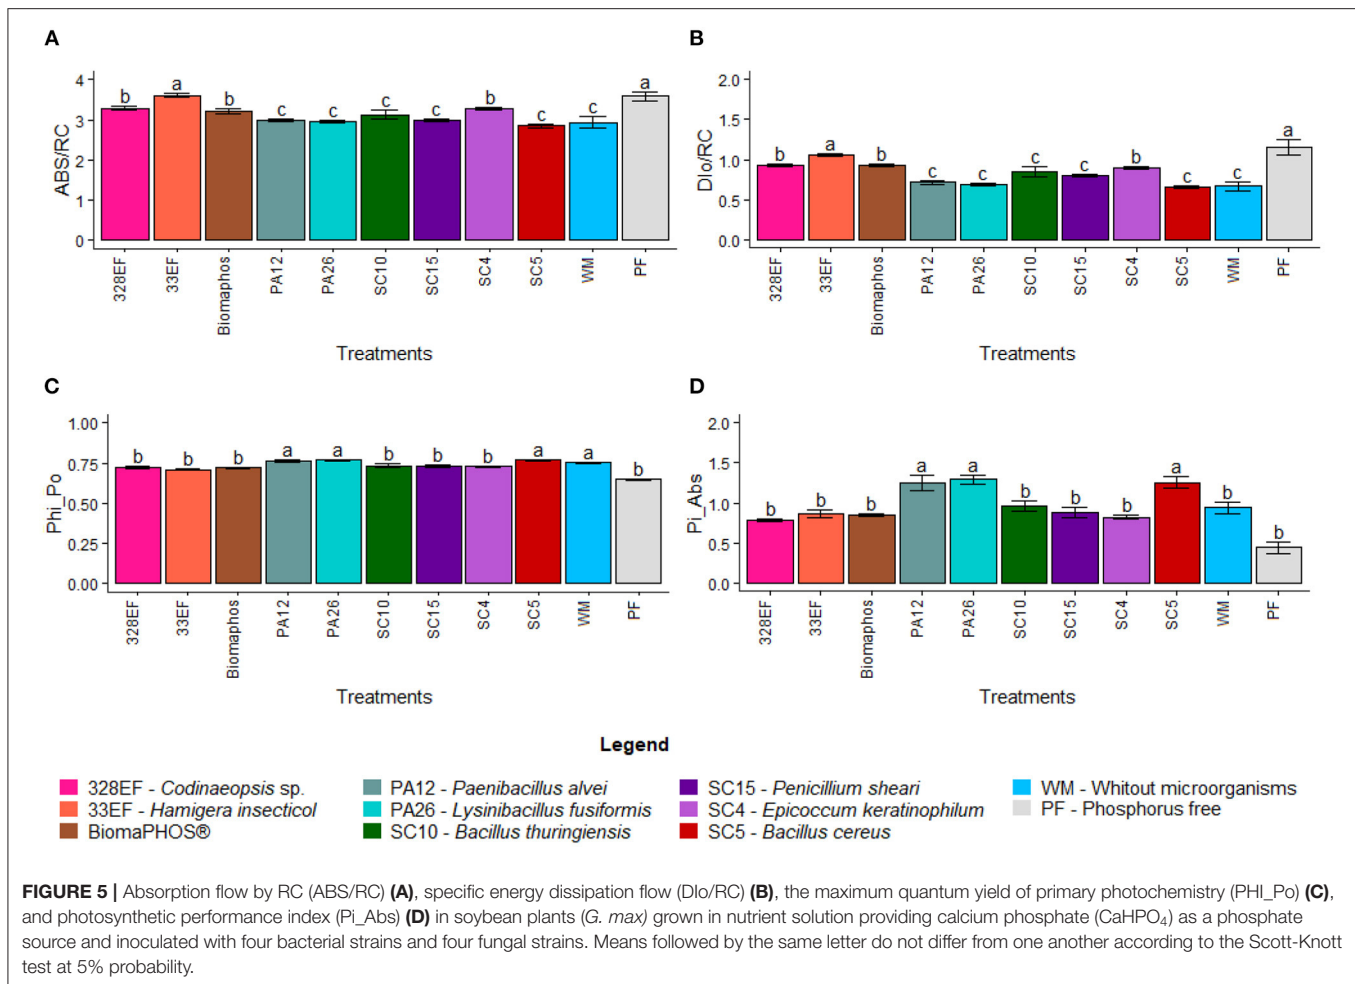

The kinetic parameters of Chl *a* fluorescence were also significantly affected by inoculation with microorganisms. The maximum quantum yield of primary photochemistry (Φ_{Po}) was higher for plants inoculated with *P. alvei* (PA12), *L. fusiformis* (PA26), and *B. cereus* (SC5) (0.763, 0.769, and 0.769, respectively), as well as in plants grown in a solution without microorganisms (0.752) (Figure 5C). The probability of an exciton moving an electron through the electron transport chain

after quinone (Qa) (Ψ_{o}) was reduced in plants inoculated with *Codinaeopsis* sp. (328EF) (0.443) and under P-free solution (0.406) (Supplementary Figure 6C). The means observed for the quantum yield of electron transport (Φ_{Eo}) followed the same pattern reported previously for Ψ_{o} , with reduced values under *Codinaeopsis* sp. (328EF) (0.323) and P-free solution (0.277) (Supplementary Figure 6D). The photosynthetic performance index (Pi_{ABS}) was higher in plants inoculated with *P. alvei* (PA12), *L. fusiformis* (PA26), and *B. cereus* (SC5) (1.244, 1.289, and 1.255), suggesting that these plants have better performance in converting light energy into chemical energy (Figure 5D).

Fluorescence imaging analyses confirmed the superiority of the behavioral pattern of chlorophyll *a* fluorescence in plants inoculated with *P. alvei* (PA12), *L. fusiformis* (PA26), and *B. cereus* (SC5) and the inferiority of the pattern observed in plants grown in a P-free solution, as well as in plants inoculated with *E. keratinophilum* (SC4), *Codinaeopsis* sp. (328EF), and *H. insecticola* (33EF) (Figure 6).

Assessment of Anatomical Performance: Root Anatomy

The inoculation treatments affected the diameter of the root vessel elements. Therefore, the highest means were observed in plants inoculated with *P. alvei* (PA12), *L. fusiformis* (PA26),

P. sheari (SC15), *E. keratinophilum* (SC4), and *B. cereus* (SC5) (55.383, 52.223, 49.943, 49.867, and 49.32 μm , respectively). In contrast, the lowest means were observed in plants grown in a P-free solution (28.787 μm), followed by a solution without microorganisms (39.91 μm) (Figure 7).

Anatomical analyses showed superior development of vessel elements and root caliber of plants treated with *P. alvei* (PA12) and *L. fusiformis* (PA26) strains. Root development was compromised in plants grown in a P-free solution, as well as in plants not subjected to microbial action (Figure 8).

PCA and Correlation Between Variables

The two-dimensional graph of principal components showed a negative correlation between the parameters Dio/RC, ABS/RC, TRo/RC, and *Ci* and the other biometric parameters: fluorescence, photosynthetic pigment content, and gas exchange, signaling the means for plants subjected to *E. keratinophilum* (SC4), *Codinaeopsis* sp. (328EF), Biomaphos®, and *H. insecticola* (33EF); plants grown in P-free solution accounted for most of the variation found in these variables. Thus, these plants were mainly associated with negative photosynthetic performance indices. On the other hand, the means verified in plants inoculated

with *P. alvei* (PA12), *L. fusiformis* (PA26), and *B. cereus* (SC5) defined most of the variation in growth parameters, P content, photosynthetic performance, and photosynthetic pigments. These symbiotic microorganisms seem to improve the overall performance of the inoculated *G. max* plants (Figure 9A). The negative correlation between Dio/RC, ABS/RC, TRo/RC, and *Ci* means and the other biometric parameters (fluorescence, photosynthetic pigment content, and gas exchange) was more evident when the graphic pattern of the correlations between all variables was analyzed (Figure 9B).

DISCUSSION

Solubilization Results Obtained Using *in vitro* Methodologies Are Not Consistent With the Hydroponic System

Tests conducted in solid medium attested to the solubilizing potential of *B. thuringiensis* (SC10), *B. cereus* (SC5), and Biomaphos®, while in a liquid medium, the capacity was observed for *B. thuringiensis* (SC10), *P. alvei* (PA12), and *B. cereus* (SC5). The superposition of the two strains in these results

FIGURE 6 | Fluorescence images of chlorophyll-a obtained for the effective quantum yield of photochemical energy conversion in PSII (Φ_{II}) in leaves of *Glycine max* grown in nutrient solution providing calcium phosphate (CaHPO_4) as a phosphate source and inoculated with four bacterial strains and four fungal strains. SC5, *Bacillus cereus*; SC10, *B. thuringiensis*; PA12, *Paenibacillus alvei*; PA26, *Lysinibacillus fusiformis*; SC15, *Penicillium sheari*; SC4, *Epicoccum keratinophilum*; 33EF, *Hamigera insecticola*; 328E, *Codinaeopsis* sp.; Biomaphos®, *B. megaterium* and *B. subtilis*; WM, without microorganisms; PF, phosphorus-free.

showed a low coherence between these two methodologies. However, *in vivo* analysis using the hydroponic system showed that *P. alvei* (PA12) and *L. fusiformis* (PA26), strains not shown to solubilize CaHPO_4 in any of the *in vitro* tests were more efficient at promoting growth and providing free P to the plant, which was demonstrated by the higher total P content in *G. max* tissues. In fact, *in vitro* solubilizing potential assessments were susceptible to the influence of many factors, as they significantly modify the living conditions of microorganisms. The growth temperature, pH, and nutritional composition of the culture medium could affect growth and metabolism (e.g., Gibson and Mitchell, 2004; Walpole et al., 2012; Tan and Ramamurthi, 2014; Yang et al., 2018), including the ability of isolates to produce organic acids or phosphatase enzymes directly associated with the potential of the microorganism to release P from forms where it is immobilized as CaHPO_4 , $\text{Ca}_3(\text{PO}_4)_2$, AlPO_4 , and FePO_4 .

In general, solubilization in a liquid culture medium is considered more reliable, as it is a quantitative methodology (Sousa et al., 2016). In this methodology, free P could be quantified, and the access of organic acids and phosphatase enzymes to the phosphate source was more direct. However, the absence of a host and the impossibility of quantifying the actual P absorbed by the plant made this methodology questionable. Therefore, the use of *G. max* as a model for growth, tissue content, and photosynthetic and anatomical performance evaluations characterized *P. alvei* (PA12) and *L. fusiformis* (PA26) strains was more effective in the solubilization of CaHPO_4 because of its general effects on general growth promotion.

Paenibacillus is one of the Firmicutes genera predominantly found in association with plants (Yadav et al., 2017), and the potential of *P. alvei* has already been described in the literature as a disease suppressor and an inducer of crop growth and yield (Schoina et al., 2011; Kumar et al., 2012; Kalaiselvi et al., 2019). *Lysinibacillus* species have also drawn attention as effective bioremediation, biostimulant, and biocontrol agents (Ahsan and Shimizu, 2021). In the studies

by Vendan et al. (2010) and He et al. (2014), *L. fusiformis* was described as an effective phosphate solubilizer, although other functional traits have already been associated with this species, such as auxin synthesis and fungal biocontrol (Hanh and Mongkolthanaruk, 2017; Passera et al., 2021). Our work corroborated the direct association between these species and plant growth promotion.

The Hydroponic System Allows the Association of Phosphate Solubilization With Growth Promotion and Improved Photosynthetic and Anatomical Performance

The inoculation of *P. alvei* (PA12) and *L. fusiformis* (PA26) strains in the nutrient solution resulted in higher P absorption

by *G. max* plants, and this better nutritional aspect improved growth, such as increased LN and TDM. Some studies have confirmed that solubilizing strains improve the nutritional status of plants, which results in increased chlorophyll concentrations and improved gas exchange parameters (Singh et al., 2018; Linu et al., 2019; Liu et al., 2020; Borowiak et al., 2021).

Plants inoculated with *P. alvei* (PA12) and *L. fusiformis* (PA26) strains also showed improved photosynthetic rates compared with plants grown in a solution without microorganisms. High A values are closely related to high RuBisCO activity (Bowes, 1991). Studies have suggested that an optimal P supply increases RuBisCO concentration and activity in leaves (Warren and Adams, 2002; Lin et al., 2009; e.g., Alori et al., 2017; Wang et al., 2018). Chu et al. (2018) demonstrated that decreased photosynthetic rates in *G. max* could be due

to the stress caused by low P availability, as it participates in the structural regulation of the leaf, ATP synthesis, CO_2 absorption and transport, photosynthetic electron transport, and determination of the levels of enzymes related to the Calvin cycle. Thus, phosphate-solubilizing microorganisms can play an important role in photosynthetic performance by increasing P availability for plants (e.g., Wu et al., 2019; Anbi et al., 2020).

The inoculation of *G. max* with *P. alvei* (PA12) and *L. fusiformis* (PA26) bacteria also resulted in increased concentrations of photosynthetic pigments compared with plants that grew without microbial inoculation or P administration. These solubilizing strains ensured the necessary supply for pigment synthesis by increasing P release and absorption by plants. Some studies have reported that P deficiency decreases chlorophyll synthesis (Choi and Lee, 2012; Viégas et al., 2018), and that root colonization by growth-promoting microorganisms, such as phosphate solubilizers, can increase the synthesis of carotenoids (Vafadar et al., 2014; Chen et al., 2017), and plant resistance to biotic and abiotic stress factors (Vafadar et al., 2014) by protecting the photosynthetic apparatus, reducing photodamage, and photoinhibition effects (Sharma et al., 2015; Uarrota et al., 2018). Furthermore, microorganisms can affect the N_2 fixation process and the synthesis of growth-promoting substances and other compounds, such as auxins, which also have a positive effect on photosynthetic pigment production (Bashan and De-Bashan, 2010; Ahemad and Kibret, 2014; Santos et al., 2019). Phosphate-solubilizing microorganisms influence some

growth-associated compounds, such as cytokinins (Abbamondi et al., 2016; Kudoyarova et al., 2017), which have a positive effect on chlorophyll biosynthesis, delaying senescence, and programmed death processes (Kunikowska et al., 2013; Zwack and Rashotte, 2013; Danilova et al., 2020; Zhang et al., 2021). Jinal et al. (2021) demonstrated that inoculation of maize seeds with *Lysinibacillus* can improve the growth and synthesis of chlorophylls-a and -b. The effects observed on the concentration of photosynthetic pigments in *G. max*, induced by *P. alvei* (PA12) and *L. fusiformis* (PA26) may be associated with the phosphate solubilizer and phytohormone producer potential (Vendan et al., 2010; Hanh and Mongkolthanaruk, 2017) of these species.

In general, plants treated with *P. alvei* (PA12) and *L. fusiformis* (PA26) absorbed more P, which is an adaptive reflection of the increased diameter of RVE. The roots were efficiently colonized by these bacteria. Microbial colonization is commonly related to increased size and density of the primary root and root hairs (Verbon and Liberman, 2016), which are important for increasing P absorption (Gahoonia et al., 2001). However, *in vitro* culture conditions seem to stress *L. fusiformis* (PA26), with evidence of spore formation in the root colonies of this strain. This occurs because when many species of the order Bacillales are subjected to abiotic stress, they tend to sporulate as a resistance mechanism (Paredes-Sabja et al., 2011; Tan and Ramamurthi, 2014). Spore inactivity may explain the inefficiency of this strain in solubilizing CaHPO_4 in a liquid medium.

The Hydroponic System Allows Separating Growth-Promoting Action From Biotic Stress Induction Through Photosynthetic Performance

Microbial inoculation affected ABS/RC and DIO/RC parameters. An increased ABS/RC ratio indicates that plants grown in P-free solution and plants inoculated with *Codinaeopsis* sp. (328EF), *H. insecticola* (33EF), Biomaphos®, and *E. keratinophilum* (SC4) showed a higher density of absorbed photons per reaction center than PSII, possibly because of the inactivation of some reaction centers or increased antenna size to compensate for energy loss as heat (Schöttler and Tóth, 2014; Urban et al., 2017). This observation suggests competition between the plants and the tested strains, which negatively affects performance (Pi_Abs). Some studies have shown that symbiotic microorganisms can become opportunistic pathogens under excess water conditions, such as in hydroponic systems (Aung et al., 2018). Thus, plants reduce the number of active reaction centers, which is considered a mechanism used by leaves under stress against photo-oxidative damage and excess light energy absorption (Kalaji et al., 2014, 2018). Image fluorescence showed decreased photochemical performance in plants inoculated with *E. keratinophilum* (SC4), *Codinaeopsis* sp. (328EF), and *H. insecticola* (33EF), at physiological stress conditions. Previous studies have described species of these genera as producers of secondary metabolites and antagonists to phytopathogens (e.g., Breinholt et al., 1997; Giridharan et al., 2014; Braga et al., 2018; Puri et al., 2018; Zhu et al., 2021); however, when we forced the interaction of these species with *G. max* plants, biotic stress responses were observed in the plants.

The phytopathogenic opportunism of *Codinaeopsis* sp. (328EF), when interacting with *G. max* roots, was also confirmed by the high sporulation observed *via* electron microscopy during colonization by this strain. Phytopathogenic fungi often sporulate in the presence of host tissues (Su et al., 2012), which is a mechanism used to stimulate the *in vitro* sporulation of this class of fungi (e.g., Crous et al., 2006; Li et al., 2007; Liu et al., 2010). The biotin present in plant tissues may change the synthesis of wall polysaccharides and oleic acid, triggering the selective expression of genes involved in sporulation (Su et al., 2012).

Plants inoculated with *P. alvei* (PA12) and *L. fusiformis* (PA26) presented low ABS/RC and DIO/RC values, which is compatible with non-inoculated plants and indicates the absence of biotic stress promotion by these strains since the potential of these plants to capture photons was not reduced. Plants often try to improve their adaptability under stress by adjusting energy distribution. Therefore, higher DIO/RC values indicate a shift from photochemically active centers to photochemically inactive PSII centers (Malnoë, 2018; Guidi et al., 2019). Likewise, the high Pi_Abs values observed in plants treated with *P. alvei* (PA12) and *L. fusiformis* (PA26) indicate high vitality, which, in general, is due to the significantly increased density of chlorophyll reaction centers. The Pi_Abs value reflects the functionality of both photosystems I and II and represents quantitative information about the current state

of plant performance under stress conditions (Strasser et al., 2004). These high values reflected positive *P. alvei* (PA12) and *L. fusiformis* (PA26) inoculation effects on Phi_Po, indicating improved photosynthetic functionality (Ivanov et al., 2017; Dalal and Tripathy, 2018).

The Hydroponic System Proved the Positive Effect of Microbial Inoculation on P Absorption and Photosynthetic Performance in *G. max*

Plants grown without the inoculation of microorganisms presented tissue P contents compatible with those observed in plants grown in P-free solution, which negatively affected pigment synthesis, photosynthetic performance (Pi_Abs), and pigment development in RVE. Rhizobacteria or growth-promoting fungi can induce metabolic processes that improve photosynthetic and developmental yields (e.g., De Andrade et al., 2019; Bakhshandeh et al., 2020; Kartik et al., 2020; Moretti et al., 2020; Jabborova et al., 2021). Some studies have shown that inoculation can be important under stressful conditions to improve the resilience, development, and productivity of different plant species (Bruno et al., 2020; Forouzi et al., 2020; Pritesh et al., 2020; e.g., Batool et al., 2020).

Component analysis showed that non-inoculated plants were not related to negative fluorescence factors, nor positive developmental and physiological performance factors. Plants under P-free solution and inoculated with microorganisms *Codinaeopsis* sp. (328EF), *H. insecticola* (33EF), Biomaphos®, and *E. keratinophilum* (SC4) were strongly correlated with DIO/RC, ABS/RC, TRo/RC, and Ci parameters, which are negatively related to positive biometric and physiological patterns, reinforcing the hypothesis that these patterns constitute biotic stress responses in *G. max*.

CONCLUSION

Calcium phosphate solubilization results obtained using a hydroponic system were inconsistent with those observed in solid and liquid media; however, tests in liquid medium demonstrated the poor performance of *Codinaeopsis* sp. (328EF) and *H. insecticola* (33EF) in reducing the pH and levels of solubilizing phosphates, corroborating the effects of biotic stress observed in *G. max* plants inoculated with these strains. On the other hand, the hydroponic system allowed the characterization of *P. alvei* (PA12), which was also efficient in solubilizing CaHPO₄ in a liquid medium, and *L. fusiformis* (PA26) was the most effective in CaHPO₄ solubilization because of its better effects on P absorption, growth promotion, and physiological performance observed in plants inoculated with these bacteria. Therefore, the use of a hydroponic system indicated strains with higher potential than Biomaphos® for growth promotion. These results demonstrated the effectiveness of this approach in confirming the functional traits of strains previously selected as solubilizers, as it allowed the evaluation of tissue nutritional content patterns, growth patterns, photosynthetic performance, anatomical patterns, and even the detection of

biotic stress responses to inoculation, the latter making the use of strains unfeasible.

Salt stress has long been a prominent obstacle that restricts crop growth, and increasing the L-ascorbic acid (ASA) content of crops is an effective means of alleviating this stress. 2-Keto-L-gulonic acid (2KGA) is a precursor used in industrial ASA production as well as an ASA degradation product in plants. However, to date, no study has investigated the effects of 2KGA on ASA metabolism and salt stress. Here, we evaluated the potential of using 2KGA to improve crop resistance to salt stress (100 mM NaCl) through a cultivation experiment of non-heading Chinese cabbage (*Brassica campestris* ssp. *chinensis*). The results showed that the leaf and root biomass were significantly improved by 2KGA application. The levels of metabolites and enzymes related to stress resistance were increased, whereas the hydrogen peroxide (H₂O₂) and malondialdehyde (MDA) contents were decreased. Lipid peroxidation and cell membrane damage were alleviated following 2KGA treatment. Positive correlations were found between photosynthetic pigments and organic solutes, ASA and photosynthetic pigments, and ASA and antioxidant enzymes. In contrast, negative correlations were observed between antioxidant enzymes and H₂O₂/MDA. Moreover, the expression levels of *L-gulono-1,4-lactone oxidase*, *GDP-mannose pyrophosphorylase*, *dehydroascorbate reductase-3*, and *ascorbate peroxidase* were increased by 2KGA treatment. These results suggested that exogenous 2KGA application can relieve the inhibitory effect of salt stress on plant growth, and the promotion of ASA synthesis may represent a critical underlying mechanism. Our findings have significant implications for the future application of 2KGA or its fermentation residue in agriculture.

Keywords: 2-keto-L-gulonic acid, L-ascorbic acid, organic acid, salt stress, lipid peroxidation, non-heading Chinese cabbage

INTRODUCTION

Abiotic stress refers to specific environmental factors that are unfavorable for plant survival and development, such as high temperature, drought, and saline-alkali soils (Zandalinas et al., 2020). There are large areas of saline-alkali soils globally, and crops grown in these soils usually have a low yield and are of poor quality (Zhao et al., 2014). Moreover, hydroponic agriculture with desalinated seawater is also associated with the detrimental effects of salt stress (Santos et al., 2019). These observations highlight that saline-alkali soils or environments constitute key factors that restrict the sustainable development of agriculture.

L-ascorbic acid (ASA, vitamin C) is a non-enzymatic antioxidant commonly found in plants and plays a vital role in protecting plants from oxidative damage caused by abiotic stress. ASA is employed as an electron donor by ascorbate peroxidase (APX; EC 1.11.1.11), which catalyzes the conversion of hydrogen peroxide (H_2O_2) to water and O_2 (Tyagi et al., 2020). Simultaneously, humans must obtain ASA from the diet, especially vegetables and fruits, to maintain good health. Current evidence shows that the fluctuation of ASA metabolism in plants greatly influences the resistance of plants to salt stress. Several studies have emphasized that increasing ASA levels can strengthen the salt stress tolerance of plants. Liu et al. (2013) demonstrated that, in tobacco, the knock-in of cDNA encoding L-galactose-1,4-lactone dehydrogenase (GLDH; EC 1.3.2.3), which catalyzes the conversion of L-galactono-1,4-lactone to ASA, increased *GLDH* expression and ASA content, thereby enhancing salt stress tolerance in the plant. Similarly, the overexpression of *dehydroascorbate reductase* [encoding dehydroascorbate reductase (EC 1.8.5.1), the enzyme that catalyzes the regeneration of ASA from dehydroascorbic acid] in rice also increased ASA content, consequently enhancing the adaptability of rice to salt stress (Kim et al., 2014). Moreover, the application of exogenous ASA can also increase the ASA content and salt stress resistance of plants (Shalata and Neumann, 2001). Despite these benefits of ASA, concerns regarding the use of genetically modified crops and the inherent instability of ASA have complicated their application in agriculture. Additionally, low ASA synthesis in plants under abiotic stress can greatly inhibit their growth and development (Huang et al., 2005; Gao and Zhang, 2008). Combined, the above evidence suggests that increasing the level of ASA can enhance the ability of plants to resist salt stress.

2-Keto-L-gulonic acid (2KGA) is an intermediate metabolite of ASA metabolism in plants and is produced *via* the degradation of ASA (Jia et al., 2019). In grape tissues, 2KGA is used to synthesize tartaric acid (Jia et al., 2019). However, no study to date has investigated the effects of 2KGA on ASA metabolic activities or plant growth and development. Interestingly, 2KGA, mainly produced *via* two-step microbial fermentation using sorbitol as a substrate, is also a key precursor used in the chemical synthesis of ASA (Yang et al., 2017). Currently, the global production of 2KGA is approximately 160,000–180,000 tons per year (Xu et al., 2021), and the application of this organic acid is merely limited to the industrial production of

ASA. In addition, more than 50,000 tons of fermentation residue are discarded every year from the ASA industry in China (Kong et al., 2014), with 2KGA accounting for approximately 25–30% of this residue. Unlike many industrial waste products, this fermentation residue does not contain harmful chemicals or an excess of heavy metals; nonetheless, it is now treated as a wastewater (Xu et al., 2021). One study showed that treatment with the 2KGA-containing fermentation residue can increase the biomass and ASA content of plants in saline soil (Kong et al., 2014), suggesting that it has potential for agricultural application. However, this fermentation residue is a solution comprising a mixture of organic acids, such as 2KGA, oxalic acid, formic acid, and acetic acid, among others. To assess its suitability for use in agriculture, it is necessary to investigate the effects of 2KGA in isolation.

Non-heading Chinese cabbage (*Brassica campestris* ssp. *chinensis*) is widely cultivated in China, including in hydroponic agriculture. In this study, this crop plant was used as the research material to determine whether 2KGA can enhance the resistance of crops to salt stress. In addition to ASA, organic solute [e.g., soluble carbohydrates (SC), soluble proteins (SP), and proline] and photosynthetic pigment contents and the activities of antioxidant enzymes [e.g., superoxide dismutase (EC 1.15.1.1), peroxidase (EC 1.11.1.1), APX, and catalase (EC 1.11.1.6)] are also known to be important for plant resistance to salt stress (Nounjan et al., 2012; Ahanger et al., 2019); here, these parameters were also examined to evaluate the potential of 2KGA in relieving salt stress in plants. Furthermore, we measured the expression levels of genes involved in the ASA biosynthesis and recycling pathways to reveal the effect of 2KGA treatment on plant ASA metabolism under salt stress. The aim of this study was to provide a basis for the future application of 2KGA or its fermentation residue in agriculture.

MATERIALS AND METHODS

Plant Materials and Cultivation Conditions

The experiment was conducted in a laboratory of the Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang, China. 2KGA (>99.4%) was supplied by Northeast Pharmaceutical Group Co., Ltd., Shenyang, China. Non-heading Chinese cabbage seeds were soaked in 8% sodium hypochlorite solution for 10 min, washed with desalinated water at least three times, and then placed on moist germination paper. After 6 days, the cabbage seedlings at the first new leaf stage were transplanted into 1/2 Hoagland nutrient solution. When the third new leaf appeared, the seedlings were divided into the following three groups (90 seedlings per group): Group 1 (CK group), in which cabbage seedlings were transplanted into fresh 1/2 Hoagland nutrition solution as a control; group 2 (Na^+ group), in which the fresh 1/2 Hoagland nutrient solution was supplemented with NaCl (final concentration: 100 mM); and group 3 (Na^+ +2KGA group), in which the fresh 1/2 Hoagland nutrient solution was supplemented with NaCl (final concentration: 100 mM) and 2KGA (final concentration: 1 mM);

Figure 1). The cultivation conditions of the seedlings were as previously reported (Lacerda et al., 2003). During the experiment, the temperature was set at $26 \pm 2^\circ\text{C}$, the relative humidity at $60 \pm 10\%$, and the illumination at 8,000 lx. Plant samples were collected on days 3, 6, and 9 after the nutrient solution was replaced.

Analysis of Photosynthetic Pigments

The assay for photosynthetic pigment content was based on the method of Lichtenthaler (1987). Photosynthetic pigments were extracted from leaves with 95% ethanol. The absorbance of the extract was measured at the 470, 649, and 665 nm wavelengths. Full details are provided in **Supplementary Method 1**. Chlorophyll a (Chla), chlorophyll b (Chlb), total chlorophyll (Chlab), and carotenoid (Car) contents were calculated according to the following formulas:

$$\begin{aligned} C_{\text{Chla}} &= 13.36 \times A_{665} - 5.19 \times A_{649} \quad (\mu\text{g/ml}) \\ C_{\text{Chlb}} &= 27.43 \times A_{649} - 8.12 \times A_{665} \quad (\mu\text{g/ml}) \\ C_{\text{Chlab}} &= 5.24 \times A_{665} + 22.24 \times A_{649} \quad (\mu\text{g/ml}) \\ C_{\text{Car}} &= (1,000 \times A_{470} - 2.13 \times C_{\text{Chla}} - 97.64 \times C_{\text{Chlb}}) / 209 \quad (\mu\text{g/ml}) \end{aligned}$$

Leaf and Root Sampling

Leaves and roots were collected on day 9 for the determination of the relevant parameters. The length and width of the leaves were measured. Total root length (the sum of detectable primary and lateral root lengths), root tip number, root average diameter, and surface area were measured using a Microtek ScanMaker i800 plus scanner, and the related parameters were collected *via* the instrument's supporting software. Root morphology was observed under a microscope.

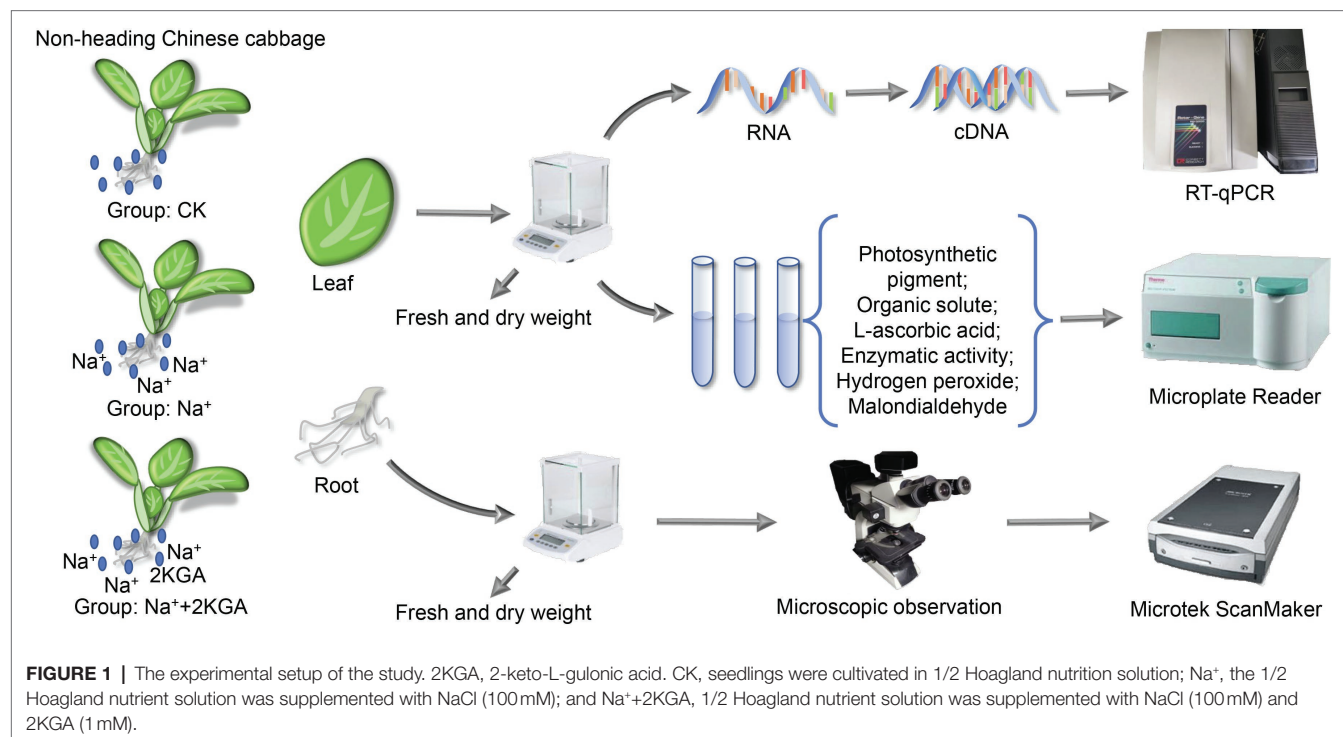

Fresh plant samples were directly weighed to record fresh weight and then dried to constant weight at 75°C to record dry weight. Fresh roots were soaked in desalinated water, placed at 4°C in the dark for 24 h, and then weighed to determine root turgor weight. Root relative water content was calculated according to the reported formula (Annunziata et al., 2017):

$$\text{Root relative water content} = (\text{root fresh weight} - \text{root dry weight}) / (\text{root turgor weight} - \text{root dry weight}) \times 100\%.$$

Determination of Soluble Carbohydrate, Soluble Protein, Proline, and ASA Content in the Leaves

Soluble carbohydrate content in the leaves was determined using the phenol-sulfuric acid method (Nielsen, 2010). Leaves (0.5 g) were chopped and placed in a centrifuge tube containing 5 ml of desalinated water. The tube was placed in a boiling water bath for 30 min and then cooled to room temperature. Next, the samples were centrifuged at $7,200 \times g$ for 10 min at room temperature. The supernatant was transferred to a graduated test tube, and desalinated water was added to a total volume of 10 ml, yielding the extract solution. A 1-ml aliquot of extract, 0.5 ml of phenol solution (9% w/v), and 2.5 ml of concentrated sulfuric acid (98%) were placed in a stoppered glass test tube, mixing, and placed in a boiling water bath for 15 min. After cooling to room temperature, the absorbance was measured at 490 nm. SC content was calculated using a glucose standard curve.

Soluble proteins concentration was assessed using the Bradford assay (Bradford, 1976). Proline was extracted from the leaves using sulfosalicylic acid (3% w/v) and quantified based on a

previous report (Ghoulam et al., 2002). Details of the method are provided in **Supplementary Methods 2, 3**.

Ascorbic acid content was measured using a HPLC as previously reported (Cronje et al., 2012), with some modifications. The leaves (0.3 g) were ground with liquid nitrogen and dissolved in 5 ml of 1% (w/v) metaphosphate in an ice bath. The homogenate was centrifuged at $7,200\times g$ for 10 min at 4°C , and the resulting supernatant was diluted with metaphosphate and filtered using a $0.22\text{-}\mu\text{m}$ injection filter. A $20\text{-}\mu\text{l}$ aliquot of the filtered solution was injected into an AQ-C18 column for analysis. The detection conditions were as follows: mobile phase, 95% 20 mM phosphate buffer, pH 2.8 ± 0.1 , and 5% acetonitrile; flow rate, 1 ml/min; temperature, 40°C ; detection wavelength, 243 nm. The ASA content of the samples was determined according to a standard curve.

Antioxidant Enzyme Activity

Leaf samples (0.2 g) in 2 ml of PBS (20 mM, pH 7.2 ± 0.1) supplemented with 0.1 mM EDTA-Na, 0.5 mM ASA, and polyvinylpyrrolidone (0.1% w/v) were evenly ground in an ice bath using a mortar and pestle. The homogenate was centrifuged at $7,200\times g$ for 10 min at 4°C , and the supernatant was collected as the crude enzyme solution. The activities of superoxide dismutase (SODa), ascorbate peroxidase (APXa), catalase (CATa), and peroxidase (PODa) were assayed as previously described (Azevedo Neto et al., 2006; Wang et al., 2014). More details of the experiment are provided in **Supplementary Method 4**.

Measurement of H_2O_2 and Malondialdehyde Levels

The H_2O_2 content was determined using potassium iodide (KI; Velikova et al., 2000). Leaf samples (0.5 g) were ground in an ice bath with 5 ml of trichloroacetic acid (TCA, 0.1% w/v). The homogenate was centrifuged at $7,200\times g$ for 10 min at 4°C , and 0.5 ml of the supernatant was mixed with 0.5 ml of 0.1 mol/l potassium phosphate buffer (pH 7.0 ± 0.1) and 1 ml of 1 mol/L KI solution and kept at room temperature in the dark for 1 h. Absorbance was then determined at 390 nm. The H_2O_2 concentration was calculated using a H_2O_2 standard curve.

Malondialdehyde (MDA) content was determined using the thiobarbituric acid (TBA) method (Li and Yi, 2012). One gram of sample was mixed with 2 ml of TCA (10% w/v) and a small amount of quartz sand and ground to obtain the homogenate. Subsequently, 8 ml of TCA (10% w/v) was added to allow the even mixing of the homogenate. The homogenate was then centrifuged at $7,200\times g$ for 10 min at 4°C , and the supernatant was used as the sample extract solution. Then, 2 ml of the extract solution was added to 2 ml of TBA (0.6% w/v) solution and the mixture were placed in a boiling water bath for 15 min to initiate the reaction. The mixture was subsequently rapidly cooled and centrifuged at $7,200\times g$ for 3 min at room temperature. The absorbance of the supernatant was measured at 450, 532, and 600 nm. The MDA concentration was calculated using the following formula:

$$C_{\text{MDA}} = 6.45 \times (A_{532} - A_{600}) - 0.56 \times A_{450} \quad (\mu\text{mol/L})$$

The Expression of Genes Related to ASA Accumulation

The expression levels of *L-gulonolactone oxidase* (GLO), *GDP-mannose pyrophosphorylase* (GMP), *Myo-inositol oxygenase* (MIOX), and *GLDH* in the ASA biosynthesis pathway and *monodehydroascorbate reductase* (MDHAR), *dehydroascorbate reductase-1* (DHAR1), *dehydroascorbate reductase-3* (DHAR3), and *APX* in the ASA recycling pathway were examined. Total RNA was extracted from leaves according to the instructions of the SteadyPure Universal RNA Extraction Kit (Code No. AG21017; Accurate Bio, Inc., Hunan, China). cDNA was prepared using Evo M-MLV RT Premix for qPCR (Code No. AG11706; Accurate Bio, Inc., Hunan, China). qPCR was performed using the SYBR Green Premix Pro Taq HS qPCR Kit (Code No. AG11701; Accurate Bio, Inc., Hunan, China). Details of the primers used are shown in **Supplementary Table S1**. Relative gene expression levels were calculated using the $2^{-\Delta\Delta\text{Ct}}$ method (Livak and Schmittgen, 2001).

Statistical Analysis

Two-tailed Student's *t* tests were used for statistical analysis. A value of $p < 0.05$ was considered statistically significant. Each parameter was evaluated in at least three biological replicates. Spearman's method was used to analyze putative correlations among the metabolites. Cytoscape 3.7.2 was used to plot the correlation networks.

RESULTS

Leaves and Photosynthetic Pigments

We found that salt stress significantly inhibited seedling growth. Compared with the CK (control) group, seedlings in the Na^+ group were stunted and the leaves were significantly smaller (**Figure 2A**). Additionally, the fresh and dry weights of the salt-stressed leaves were reduced by 48.21 and 51.37%, respectively, compared with those of the CK group (**Figure 2B**). However, the addition of 2KGA (Na^+ +2KGA group) significantly increased the fresh weight and dry weight of the seedlings under stress by 45.77 and 48.44%, respectively, thereby effectively counteracting the negative impact of stress on seedling growth.

To improve the resistance of plants to salt stress, their photosynthetic efficiency must be enhanced by increasing the photosynthetic pigment content. Compared with those of the Na^+ group, leaves in the Na^+ +2KGA group exhibited a greater accumulation of photosynthetic pigments. The Chlab content was also significantly greater in the leaves of the Na^+ +2KGA group on day 6; however, no difference in the Chla/Chlb ratio was observed between the two groups. Interestingly, 2KGA treatment led to a marked increase in carotenoid content, with the highest increase (12.5%) being recorded on day 3. Correspondingly, the Chlab/Car ratio of the Na^+ +2KGA group was lower (**Figure 2C**).

Root Growth and Development

Compared with the CK group, Na^+ -only treatment significantly reduced the root fresh weight and dry weight by 41.17 and 39.56%, respectively (**Figures 3A,B**), while the total root

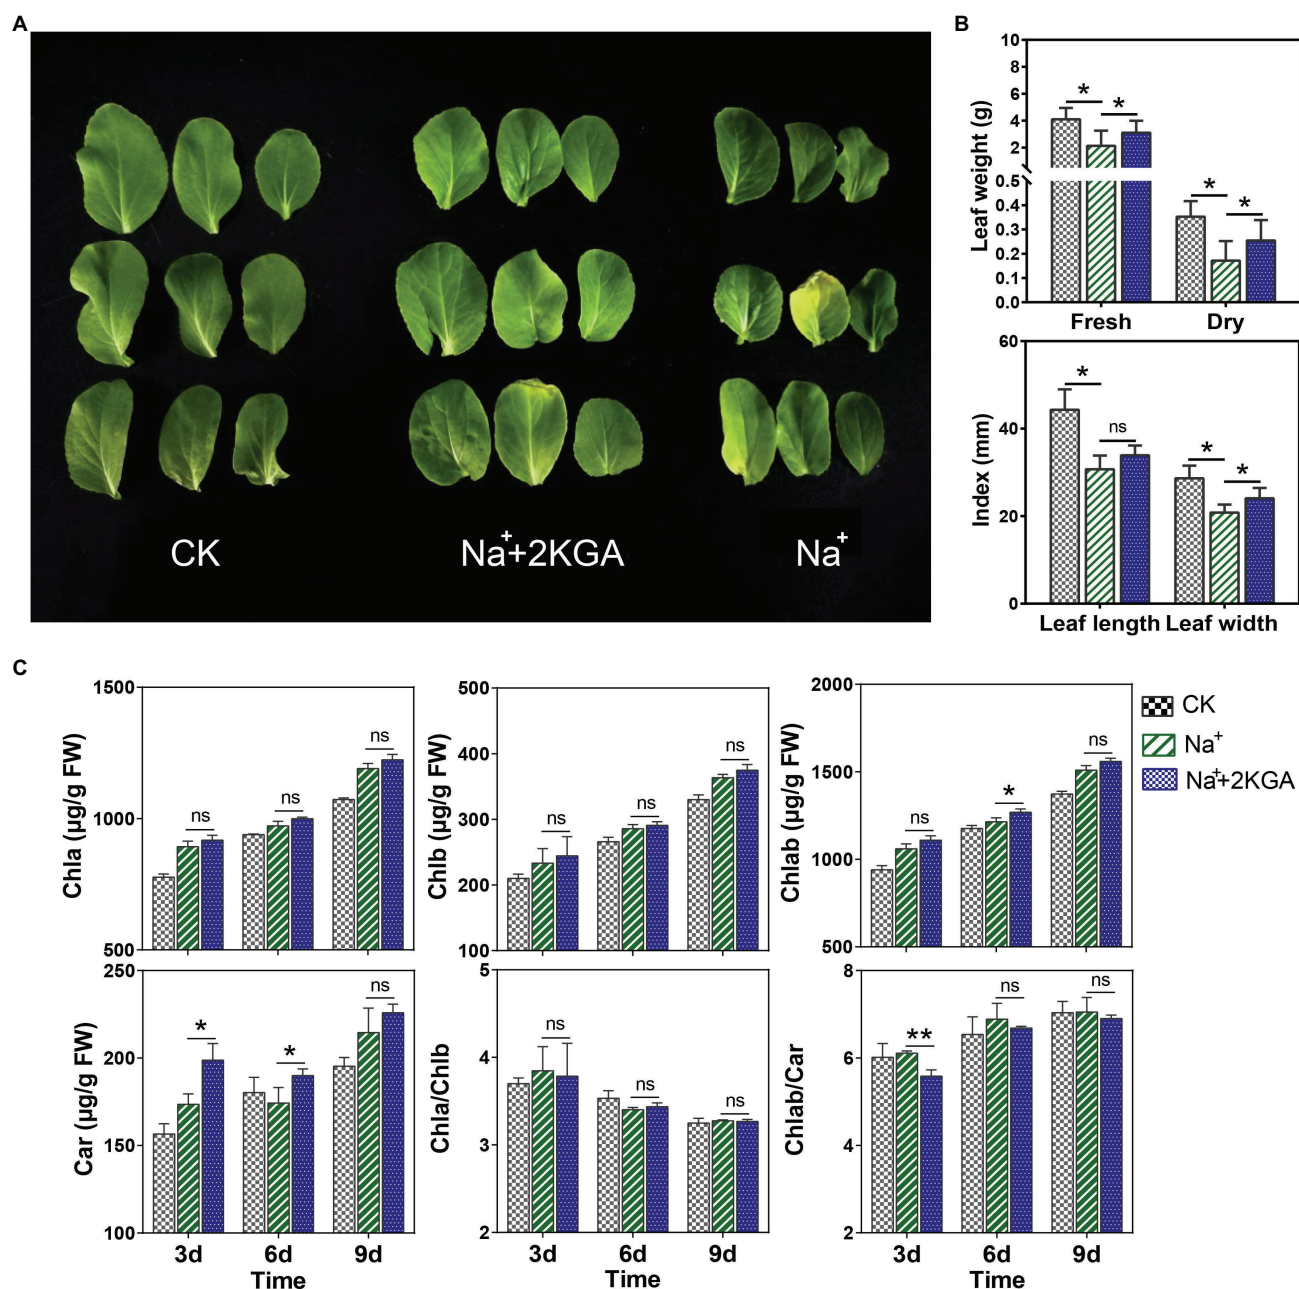

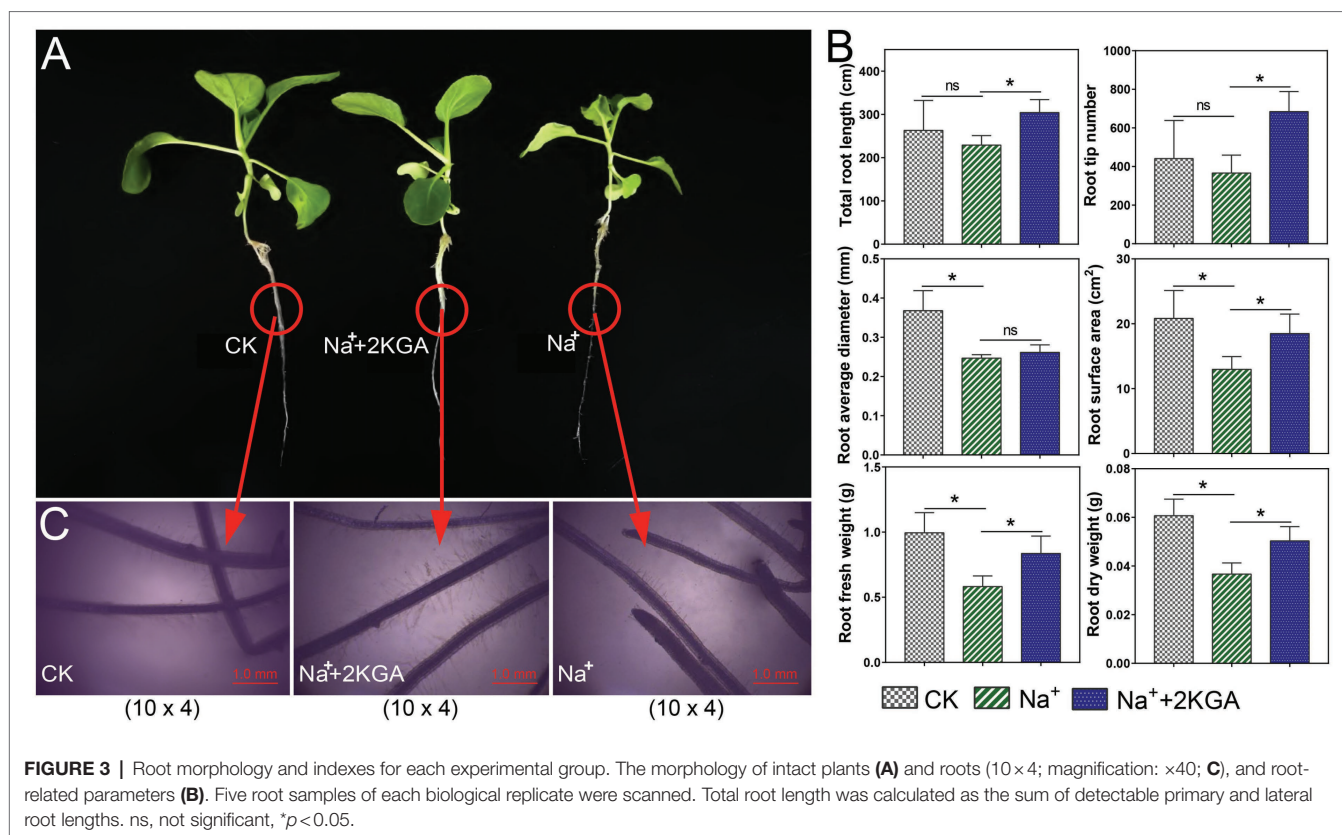

FIGURE 2 | Leaf morphology, biomass, and photosynthetic pigment content. The morphology (A), biomass, length, and width (B), and photosynthetic pigment content (C) of the leaves. Chla, chlorophyll a; Chlb, chlorophyll b; Car, carotenoids; Chlab, total chlorophyll; Chla/Chlb, the ratio of chlorophyll a content to chlorophyll b content; Chlab/Car, the ratio of total chlorophyll content to carotenoid content; FW, fresh weight; and ns, not significant; * $p < 0.05$, ** $p < 0.01$.

length, root surface area, average diameter, and root tip number were reduced by 12.89, 37.73, 32.90, and 16.94%, respectively. However, 2KGA supplementation relieved the inhibitory influence of salt stress on the roots. The corresponding root indices in the Na⁺+2KGA group showed increases of 43.73, 37.27, 32.72, 42.56, 5.92, and 86.86% compared to the Na⁺ group. Surprisingly, even under salt stress, the addition of 2KGA (Na⁺+2KGA group) increased

the total root length and root tip number by 15.62 and 55.21%, respectively, compared with that of the CK group. Moreover, microscopic analysis showed that the roots of the Na⁺+2KGA group contained more and longer fine roots (Figure 3C). Unlike with the plant biomass, no significant changes in water content or root relative water content were recorded between the Na⁺ and Na⁺+2KGA groups (Supplementary Figure S1).

Organic Solutes, ASA, Antioxidant Enzymes, H₂O₂, and MDA

Under salt stress, plants must increase their levels of anti-osmotic organic solutes (such as SC, SP, and proline) to maintain cell morphology and balance osmotic pressure. In the early stage of stress (day 3), the SC concentration of the Na⁺ group increased by 30.47% compared with that of the CK group. Subsequently, however, the SC levels in the Na⁺ group decreased rapidly and were lower than those of the CK group on days 6 and 9. There was no significant difference in SC content between the Na⁺+2KGA and Na⁺ groups on day 3; however, the SC content in the Na⁺+2KGA group remained at a high level on days 6 and 9, showing increases of 81.68 and 98.03%, respectively, relative to those of the Na⁺ group (Figure 4).

The SP concentration displayed a continuous increase over time. The Na⁺+2KGA group had a greater SP content than the Na⁺ group, showing increases of 7.37, 9.53, and 4.74% on days 3, 6, and 9, respectively. From day 6, proline accumulation was significantly improved in the Na⁺ group and was 6.15-fold higher compared with that of the CK group. The proline content in the Na⁺+2KGA group was similar, albeit slightly greater, to that of the Na⁺ group. The ASA content of all the groups peaked on day 3. Compared with the Na⁺ group, the ASA content in the Na⁺+2KGA group was significantly increased (16.24%). After day 3, the ASA content of each group began to decline and was lower in the Na⁺ and Na⁺+2KGA groups than in the CK group on days 6 and 9; however, the ASA level was always higher in the Na⁺+2KGA group than in the Na⁺ group (Figure 4).

Superoxide dismutase was 7.90% higher in the Na⁺+2KGA group compared with that of the Na⁺ group on day 9. Meanwhile, PODa in the Na⁺+2KGA group was 9.63, 10.17, and 18.15% higher on days 3, 6, and 9, respectively, compared with that of the Na⁺ group. Additionally, compared with the Na⁺ group, APXa in the Na⁺+2KGA group was increased by 27.80, 11.03, and 10.29% on days 3, 6, and 9, respectively. Similarly, 2KGA caused a continuous increase in CATa of 31.85, 21.97, and 23.19% on days 3, 6, and 9 compared to that of Na⁺ (Figure 4).

In plants, MDA is a product of cell membrane lipid oxidation and is a biochemical marker for assessing the degree of membrane lipid peroxidation (Silva et al., 2010). The results showed that H₂O₂ and MDA remained at a stable level in the seedlings under normal growth conditions but increased under salt stress. In the early stage (day 3), 2KGA did not affect H₂O₂ metabolism; from day 6, however, the H₂O₂ level in the Na⁺+2KGA group decreased rapidly compared with that of the Na⁺ group and was reduced by 16.16% on day 9. Simultaneously, the MDA content decreased by 8.97% on day 9. These results indicated that membrane lipid peroxidation was attenuated following 2KGA treatment. The level of H₂O₂ in the Na⁺+2KGA group was similar to that of the control group on day 9 (Figure 4).

Analysis of Correlations Among Leaf Metabolites

Under salt stress, variations in the levels of organic solutes and photosynthetic pigments and activities of antioxidant enzymes in leaves were correlated with H₂O₂ and MDA contents

FIGURE 4 | Variations in the contents of organic solutes, ASA, antioxidant enzymes, H₂O₂, and MDA in seedling leaves at different time points. Data were normalized relative to the control (CK) group. The absolute results are shown in **Supplementary Table S2**. SC, soluble carbohydrate; SP, soluble protein; ASA, L-ascorbic acid; SODA, superoxide dismutase activity; PODa, peroxidase activity; APXa, ascorbate peroxidase activity; CATa, catalase activity; H₂O₂, hydrogen peroxide; and MDA, malondialdehyde. * $p < 0.05$, ** $p < 0.01$.

(**Supplementary Figure S2**). Under 2KGA treatment, changes in photosynthetic pigment levels were correlated with the osmotic resistance of organic solute contents (**Figure 5A**). The Chla/Chlb ratio was negatively correlated with SP and proline levels and positively correlated with SC levels; however, Chlab/Car levels were positively correlated with SP and proline content and negatively correlated with SC content. Antioxidant enzyme activity was negatively correlated with H₂O₂ and MDA concentrations (**Figure 5B**). ASA content was positively correlated with antioxidant enzyme activity and photosynthetic pigment levels (**Figure 5C**).

ASA-Related Gene Expression

The expression levels of *GLO* and *GMP*, genes acting in the ASA biosynthesis pathway, were significantly increased in the Na⁺+2KGA group relative to those of the Na⁺ group; in particular, the *GLO* expression level was consistently higher in the Na⁺+2KGA group than in the Na⁺ group (**Figure 6**). *MIOX* and *GLDH* levels were not significantly different between the Na⁺ and Na⁺+2KGA groups.

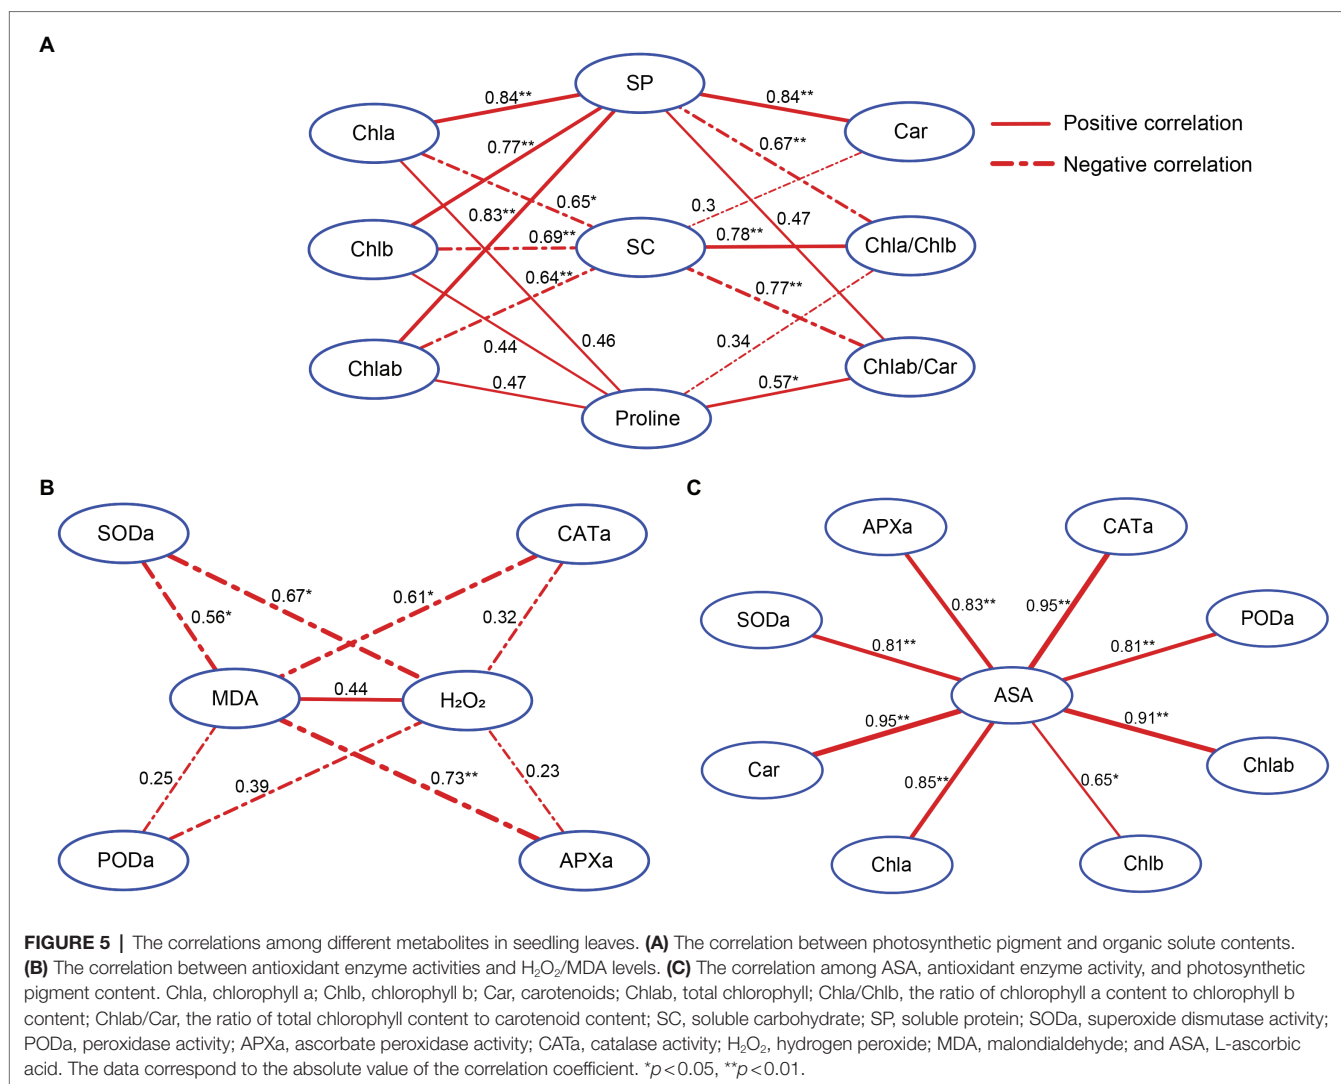

In the ASA recycling pathway, 2KGA treatment did not affect the expression of *MDHAR* or *DHAR1*. Compared to the Na⁺ group, the expression level of *DHAR3* was significantly increased on day 6 in the Na⁺+2KGA group, but no significant difference was observed between the two groups on day 9. Furthermore, the expression of *DHAR3* was lower in both the Na⁺ and Na⁺+2KGA groups than in the control group ($p < 0.05$; **Supplementary Figure S3**). The expression of *APX* in the Na⁺+2KGA group was higher than that in the Na⁺ group at each sampling time point (**Figure 6**). The results of nucleic

acid quality assessment are provided in **Supplementary Table S3** and **Supplementary Figure S4**.

DISCUSSION

We have previously shown that a 2KGA-rich fermentation residue from the vitamin C industry could increase soil organic matter content and endogenous ASA concentrations in crops, thereby leading to increased crop yields in saline soil (Kong et al., 2014). However, this fermentation residue was a mixture, and its main effectors had not been identified. The 2KGA content in the residue varies between 25 and 30%, that of oxalic acid is approximately 1–2%, while the levels of other organic acids comprise less than 1%; much of the rest is water. This suggested that the 2KGA component of the residue might be a key to enhancing ASA production in plants. In this study, we found that 2KGA treatment increased the biomass of non-heading Chinese cabbage subjected to salt stress.

In this study, under salt stress, the levels of H₂O₂ and MDA in non-heading Chinese cabbage seedlings were significantly increased, and peroxidative damage in the cell membrane was aggravated, resulting in the inhibition of seedling leaf and root development. However, the observed increase in leaf and root biomass, especially that of roots, in the Na⁺+2KGA group suggested that 2KGA could effectively relieve this inhibitory effect and promote seedling growth and development. Because it has been shown that enhancing endogenous ASA levels can promote root development (Aghaei et al., 2008), we speculated that these effects were most likely related to an increase in

ASA levels in the seedlings. In general, fluctuations in the concentrations of anti-osmotic organic solutes (including ASA), photosynthetic pigments, and antioxidant enzymes are essential for plants to resist salt stress.

Salt stress reduces the osmotic potential of plant cells by creating a high-salinity environment, which results in osmotic stress. The latter will lead to a reduction in the relative water content of plants and is not conducive to the maintenance of cell morphology (Annunziata et al., 2017). Osmotic adjustment represents an adaptive mechanism that helps cells maintain osmotic pressure and ensures normal metabolism and crop growth. In this study, we found that 2KGA treatment increased the SC, SP, and free proline contents in the leaves of non-heading Chinese cabbage under salt stress. The accumulation of SC is especially important for osmotic regulation, while SP and proline are believed to play a more important role in protecting cells from oxidative damage and enhancing defensive responses (Zhang et al., 2011; Li et al., 2019; Alfosea-Simón et al., 2020).

In the present study, the photosynthetic pigment content was found to be correlated with the SC level. When 2KGA

was added under conditions of salt stress, the Chlab/Car ratio was negatively correlated with SC content. The results also showed that SC content was significantly increased on day 3 post stress induction and then rapidly decreased in the CK and Na⁺ groups, while the addition of 2KGA could effectively reverse the loss of SC content. Simultaneously, the Na⁺+2KGA group had a lower ratio of Chab/Car. Under all treatments, the photosynthetic pigment content continuously increased along with the growth of the seedlings. Under salt stress, photosynthetic pigments accumulated at a high level, and the variations in H₂O₂ and MDA contents were positively correlated with photosynthetic pigment levels. This indicated that enhanced photosynthesis was a defense mechanism employed by seedlings to resist salt stress, and the addition of 2KGA further promoted the accumulation of photosynthetic pigments. This was in agreement with the results of previous studies, in which an increase in photosynthetic pigment levels was shown to improve photosynthetic efficiency and promote plant growth (Garg et al., 2002; Li and Yi, 2020). In contrast, in a recent study, Gautam et al. (2020) found that the photosynthetic efficiency of tobacco

FIGURE 6 | Relative gene expression related to ASA accumulation. Data were normalized relative to that of the control (CK) group. *GLO*, L-gulonono-1,4-lactone oxidase; *GLDH*, L-galactose-1,4-lactone dehydrogenase; *GMP*, GDP-mannose pyrophosphorylase; *MIOX*, Myo-inositol oxygenase; *DHAR1*, dehydroascorbate reductase-1; *DHAR3*, dehydroascorbate reductase-3; *MDHAR*, monodehydroascorbate reductase; *APX*, ascorbate peroxidase. * $p < 0.05$, ** $p < 0.01$.

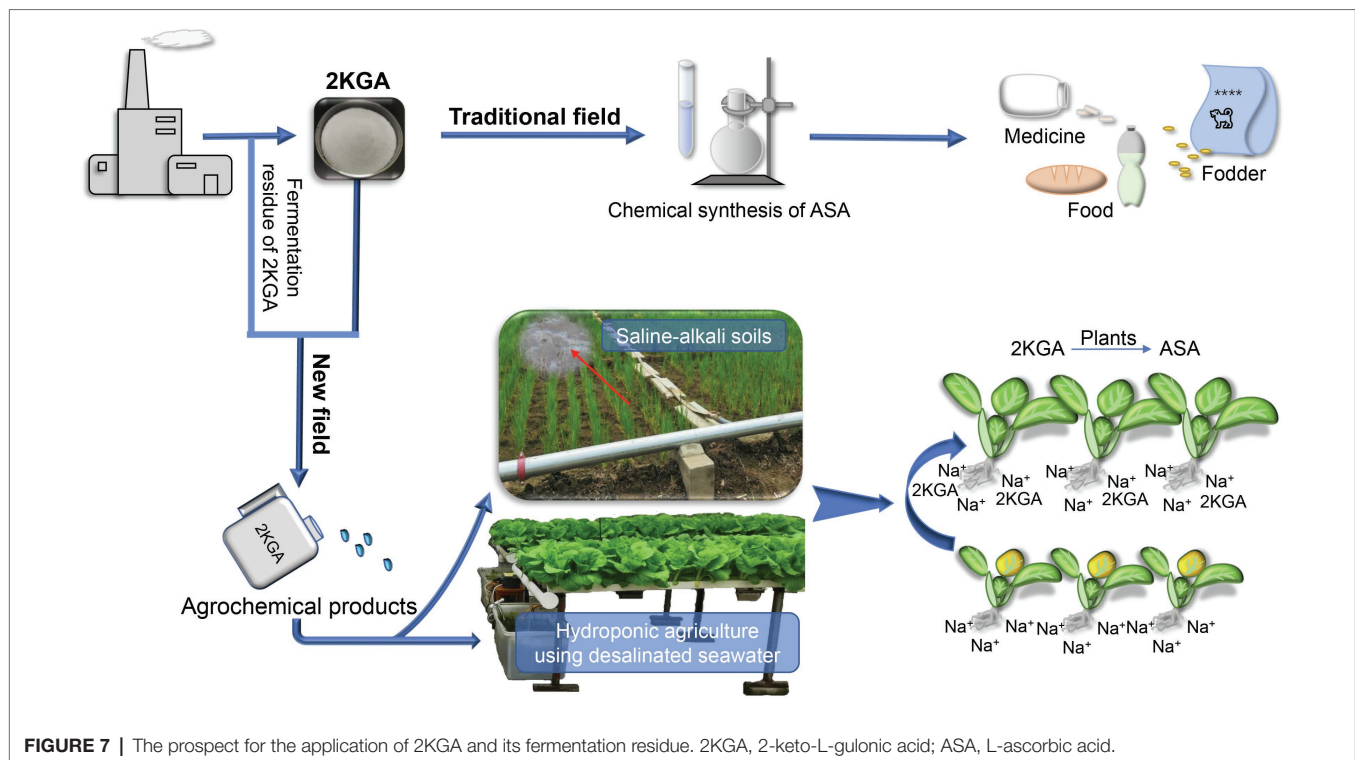

was reduced under salt stress. Differences in crop species investigated, time of action, or salt stress intensity might explain these discrepant results.

Photosynthesis is the primary means by which plants obtain carbon sources in the environment. However, in this study, the increase in photosynthetic pigment concentrations did not improve SC content in seedlings. Interestingly, photosynthetic pigment levels were positively correlated with variations in SP and proline content, indicating that seedlings could respond to salt stress by increasing photosynthetic pigment production and adjusting the Chla/Chlb and Chlab/Car ratios. Combined, these observations suggested that the addition of 2KGA enhanced the ability of the seedlings to regulate photosynthetic pigment levels, thereby resisting salt stress.

The photosynthesis system is also one of the main sites of reactive oxygen species (ROS) production in plant cells (Foyer and Noctor, 2011). Here, we found that salt stress increased the H_2O_2 content. The accumulation of ROS leads to an increase in antioxidant enzyme activity (Attia et al., 2020; Li and Yi, 2020). Accordingly, PODa, CATa, and APXa were higher in the Na⁺ group than in the CK group and were positively correlated with fluctuations in H_2O_2 and MDA levels (Supplementary Figure S2). However, with the application of 2KGA, the activities of all four enzymes increased relative to those in the Na⁺ group, and they were all negatively correlated with H_2O_2 and MDA contents. These results suggested that salt stress promoted the increase in H_2O_2 and MDA concentrations in seedlings, which subsequently led to a passive increase in antioxidant enzyme activities. Nevertheless, the addition of 2KGA enhanced antioxidant enzyme activity in the leaves, leading to faster H_2O_2 and MDA clearance.

Our findings demonstrated that the application of 2KGA could significantly increase ASA concentrations in non-heading Chinese cabbage seedlings exposed to salt stress. ASA content was positively correlated with antioxidant enzyme activities and photosynthetic pigment levels, indicating that the increase in ASA levels promoted the increase in antioxidant enzyme activities and photosynthetic pigment contents in the seedlings. Plants use ASA to remove large amounts of ROS produced by the photosynthesis system to avoid peroxidative damage (Talla et al., 2011), which is indicative of the importance of ASA in the protection of the photosynthesis system. Lim et al. (2012) reported that under salt stress, increasing endogenous ASA content in the tomato could enhance the photosynthetic pigment content. Meanwhile, exogenous ASA application can reportedly increase the levels of endogenous ASA and the activities of antioxidant enzymes in plants under heavy metal stress and salt stress (Athar et al., 2008; Chao and Kao, 2010). The above results suggested that ASA has a crucial function in plant defenses against salt stress.

To explore the mechanism underlying the 2KGA-mediated enhancement of ASA synthesis in non-heading Chinese cabbage under salt stress, we analyzed the expression levels of eight genes involved in the ASA accumulation. *DHAR3* was more highly expressed in the Na⁺+2KGA group relative to that in the Na⁺ group, but only in the early stage of the experiment; in later stages, *DHAR3* expression was downregulated in both groups. This observation may explain why the ASA content was lower in the salt-stressed groups than in the CK group. The increase in *GMP* expression in the Na⁺+2KGA group reached significance only on day 9, and its contribution to ASA accumulation in the early stage was thus likely to have been limited. At present, *GLO* is the only confirmed enzyme involved in the synthesis of ASA in the L-gulose pathway. The expression level of *GLO* in the Na⁺+2KGA group was maintained at a higher level throughout the whole test period compared with that in the Na⁺ group, while greater ASA accumulation was also observed in the former. An earlier study on the potato showed that an increase in *GLO* expression promoted the accumulation of ASA and enhanced abiotic stress tolerance (Lim et al., 2012). As a downstream product of ASA metabolism, the ketone group of 2KGA can be reduced to a hydroxyl group (Jia et al., 2019), which has the possibility of forming gulonic acid, a precursor in gulonolactone synthesis (catalyzed by *GLO* and converted to ASA) in plants (Cruz-Rus et al., 2012). This suggests strongly that exogenous 2KGA supplementation may increase the endogenous 2KGA content in non-heading Chinese cabbage. Meanwhile, the higher levels of gulonic acid and gulonolactone, both ASA precursors, finally leads to an increase in ASA content *via* *GLO* catalytic activity. The increase in *GMP* and *DHAR3* expression levels also exerted a positive effect on plant ASA accumulation (Lin et al., 2011; Wang et al., 2019). Moreover, in agreement with the observed increase in APX enzyme activity, APX gene expression was found to be upregulated with 2KGA administration, which further implied that 2KGA enhanced the resistance of non-heading Chinese cabbage seedlings to salt stress by increasing the endogenous ASA content. APX catalyzes the conversion of H_2O_2 to water and O_2 , with ASA serving as the reductant

(Tyagi et al., 2020). Thus, the higher ASA content and APXa in the Na^+ +2KGA group explains why the level of H_2O_2 was lower in this group than in the Na^+ group.

Although we demonstrated that 2KGA can relieve the inhibition of salt stress on the growth of non-heading Chinese cabbage seedlings, this is a preliminary study in this field. Many aspects remain to be explored, such as whether 2KGA has the same effect on different crops, whether 2KGA influences acetylsalicylic acid synthesis and carbon and nitrogen metabolism, and how 2KGA can efficiently be applied in agricultural practice. As a precursor of industrial ASA synthesis, 2KGA is produced on a large scale using a two-step microbial fermentation process; however, that 2KGA is only used in the chemical synthesis step of ASA production. In addition, a large amount of fermentation residue is discarded from the ASA industry. This provides a reliable industrial base for the application of 2KGA or its fermentation residue in a new field, that is, agriculture. Consequently, given the function of 2KGA against salt stress and its availability in the ASA industry, the prospect of applying 2KGA in agriculture, such as for crop cultivation in saline-alkali soils and hydroponic agriculture, merits further investigation (Figure 7).

CONCLUSION

In summary, to the best of our knowledge, this is the first study to report that 2KGA relieves the inhibitory effect of salt stress on non-heading Chinese cabbage, which has laid the foundation for the future application of 2KGA in agriculture. Meanwhile, a potential novel direction for the study of plant ASA metabolism was also identified. Our findings suggest that exogenous 2KGA

application strengthens non-heading Chinese cabbage defenses against salt stress, for which the promotion of ASA accumulation may represent a crucial underlying mechanism.

Among heavy metals, chromium (Cr) contamination is increasing gradually due to the use of untreated industrial effluents for irrigation purposes, thereby posing a severe threat to crop production. This study aimed to evaluate the potential of compost, biochar (BC), and co-composted BC on the growth, physiological, biochemical attributes, and health risks associated with the consumption of *Brassica* grown on Cr-contaminated soil. Results revealed that Cr stress (Cr-25) significantly reduced the growth and physiological attributes and increased antioxidant enzyme activities in *Brassica*, but the applied amendments considerably retrieved the negative effects of Cr toxicity through improving the growth and physiology of plants. The maximum increase in plant height (75.3%), root length (151.0%), shoot dry weight (139.4%), root dry weight (158.5%), and photosynthetic rate (151.0%) was noted with the application of co-composted BC under Cr stress (Cr-25) in comparison to the control. The application of co-composted BC significantly reduced antioxidant enzyme activities, such as APX (42.5%), GP (45.1%), CAT (45.4%), GST (47.8%), GR (47.1%), and RG (48.2%), as compared to the control under Cr stress. The same treatment reduced the accumulation of Cr in grain, shoot, and roots of *Brassica* by 4.12, 2.27, and 2.17 times and enhanced the accumulation in soil by 1.52 times as compared to the control. Moreover, the application of co-composted BC significantly enhanced phytostabilization efficiency and reduced associated health risks with the consumption of *Brassica*. It is concluded that

the application of co-composted BC in Cr-contaminated soil can significantly enhance the growth, physiological, and biochemical attributes of *Brassica* by reducing its uptake in plants and enhanced phytostabilization efficiency. The tested product may also help in restoring the soils contaminated with Cr.

Keywords: chromium, *Brassica*, health risks, phytostabilization, heavy metals

INTRODUCTION

The contamination of heavy metals (HMs) in soil is a serious threat to sustainable crop production and soil quality because these metals are non-degradable and persist in soil for longer durations (Kamran et al., 2019). HMs accumulation deteriorates the physicochemical and biological properties of soil, which results in poor nutrient availability and ultimately decreased crop yield (Mehmood et al., 2018b). Naturally, HMs are the constituent of sediments, adsorbed on soil organic matter, and their toxicity increased as free ions in soil solution (Abbas et al., 2020). Modern agricultural practices, especially excessive use of inorganic fertilizers and agrochemicals, have polluted soil and ultimately resulted in enhanced environmental degradation and threatened sustainability (Ditta et al., 2015; Murtaza et al., 2021b). Moreover, the application of organic waste manure, sewage sludge, and irrigation with industrial effluents contributes significant amounts of HMs into agricultural systems (Kamran et al., 2019; Bashir et al., 2020a,b).

Among HMs, chromium (Cr) is considered a major environmental pollutant due to its severe toxicity and recalcitrant nature (Ali et al., 2018). Industrial effluents from electroplating, catalytic manufacturing and wood preservation, leather tanning, and alloy preparation contain large amounts of Cr, which are the major sources of Cr contamination in the soil (Govil and Krishna, 2018). In the environment, Cr exists in various oxidation states, but Cr(III) and Cr(VI) are dominant in soil (Junaid et al., 2016; Bashir et al., 2020a). Cr(III) is an essential micronutrient for animals and involved in cell metabolism (de Oliveira et al., 2014), relatively stable, and 10–100 times less toxic as compared to Cr(VI) (Tepanosyan et al., 2020). Cr(VI) is a highly soluble, potentially mobile across membranes with strong oxidation potential, toxic, allergenic, carcinogenic, and irritant that damages the liver, kidney, and lungs (Bashir et al., 2020a,b; Tepanosyan et al., 2020).

The application of contaminated water with a higher concentration of Cr to the agricultural land not only results in detrimental effects on plant growth and loss of production, food security, and animal health but also affects the overall ecosystem (Mehmood et al., 2021). Cr phytotoxicity severely affects seed germination, decreases root growth and shoot growth, and ultimately reduces biomass production (Bashir et al., 2020a,b). Cr disrupts photosynthesis, nutrient utilization, water relation, and enzymatic activity which produces reactive oxygen species (ROS) that oxidize lipids, protein, and nucleic acid and ultimately result in plant death (de Oliveira et al., 2014; Bashir et al., 2020b; Murtaza et al., 2021b).

Various physical (e.g., soil incineration, landfill, excavation, and soil flushing), chemical (e.g., oxidation–reduction),

and biological techniques (e.g., phytoremediation and biodegradation) have been used for remediation of metal-contaminated soils or conversion into less toxic form and reduced bioavailability to plants (Mustafa et al., 2020; Sabir et al., 2020; Irshad et al., 2021). Physical and chemical remediation techniques are laborious, time-consuming, and energy-consuming, and considerable toxic waste products are the main cause of limited application despite high efficiency and utility (Mustafa et al., 2020; Sabir et al., 2020). Among organic amendments, farmyard manure, animal waste, and compost are used to reduce HMs uptake for a shorter duration because these amendments improve soil physicochemical properties, nutrient uptake, soil aggregation, and maintain soil quality (Mehmood et al., 2018a; Chukwuka et al., 2020; Hu et al., 2020; Murtaza et al., 2021a). It is, therefore, a need of the hour to develop efficient *in situ* immobilization techniques that should be cost-effective, less destructive, and environment friendly for soil restoration.

In recent years, biochar (BC) is gaining popularity for the restoration of metal-contaminated sites and carbon sequestration in the soil for longer periods due to its recalcitrant nature, cost-effective, and ecofriendly approach (Mehmood et al., 2018a; Kamran et al., 2019). BC is a fine-grained black color porous material with carbonaceous nature produced from organic wastes (e.g., crop residues, sewage slug, animal wastes, and farmyard manure) at high temperatures under limited or no oxygen supply (Abbas et al., 2020; Hu et al., 2020). BC has unique physicochemical properties such as porous structure, high surface area, variety of oxygen-containing functional groups that make it an excellent material for soil fertility improvement, carbon sequestration, wastewater treatment, metal stabilization, and organic pollutant degradation in soil (Mehmood et al., 2018a,b; Chukwuka et al., 2020; Hu et al., 2020; Murtaza et al., 2021a). BC has a stable carbon pool that influences soil physicochemical and biological properties and directly increases soil organic carbon contents (Sarfraz et al., 2019; Ijaz et al., 2020; Ullah et al., 2020). The application of BC in agricultural soil improves aeration, increases nutrient availability, and increases soil organic matter, a microbial activity that ultimately increases crop production, decreases fertilizer requirement and nutrient leaching, and reduces soil erosion by controlling soil pollution (Doumer et al., 2016; Rizwan et al., 2021). BC reduces metal mobility through physical adsorption, ion exchange, surface precipitation, and metal complexation (Sarfraz et al., 2019; Irshad et al., 2021); cation exchange; and electrostatic interaction in metal-contaminated soil (Brassard et al., 2016). The adsorption property and high carbon contents of BC make it an excellent material to minimize Cr toxicity in the terrestrial ecosystem (Jia et al., 2017).

Various studies reported that combined application of compost and BC could be a better approach as BC increases compost stability and improves the productiveness of the soil, HM adsorption, and production of crop and carbon sequestration (Agegnehu et al., 2015; Coelho et al., 2018). The mixing of BC and compost adds value in increasing soil fertility by different aspects such as reducing the volatility of ammonia from manure or minimizing methane emission (Coelho et al., 2018). Compost provides high nutrients to the soil compared to BC, whereas BC could be reducing the decomposition rate of compost (Ditta et al., 2015). Many studies showed the combined application of BC and compost had a synergistic impact in improving soil structure, water-holding capacity, and nutrient contents under field conditions with reduced fertilizer use and nutrient loss from soil (Agegnehu et al., 2015). BC co-composting can reduce compost decomposition, decrease nutrient loss in the environment, improve soil structure by direct organic matter addition, and increase microbial biodiversity and activity in the soil. We hypothesized that co-composted BC could act as a better ameliorant for improving growth, physiology, and antioxidant machinery by retrieving the harmful effects of Cr in Cr-contaminated soil. The objectives of this study were to investigate the impact of compost, BC, and co-composted BC on growth, physiological, antioxidant, and biochemical attributes of *Brassica* grown under Cr-contaminated soil and the phytostabilization efficiency of compost, BC, and co-composted BC in addition to the Cr-contaminated soil and associated health risk assessment of *Brassica* grown under Cr stress.

RESULTS

Growth Attributes

Results of this study showed that the application of compost, BC, and co-composted BC significantly ($p < 0.05$) improved the growth of *Brassica* under Cr contamination (Figure 1). It was observed that the application of co-composted BC (Com-BC-2) resulted in the maximum increase in plant height (49.8%), root length (85.6%), shoot fresh (72.9%) and dry weight (70.0%), and root fresh (89.6%) and dry weight (74.0%) as compared to the control under normal soil, i.e., 0 mg Cr kg⁻¹ (Figure 1). Soil spiked with Cr (25 mg Cr kg⁻¹) decreased the growth parameters of *Brassica*. However, the application of co-composted BC resulted in the maximum increase in shoot and root length, shoot fresh and dry weight, and root fresh and dry weight of *Brassica* by 75.3, 151.0, 140.0, 139.4, 193.9, and 158.5%, respectively, as compared to the control (Cr-25). It was followed by sole application of BC and compost in comparison to the controls under normal (Cr-0) and Cr stress (Cr-25).

Physiological Attributes

The application of BC and co-composted BC significantly ($p < 0.05$) enhanced the physiological attributes of *Brassica* under normal soil (Cr-0) or contaminated soil (Cr-25) when compared to the control (Figure 2). Under normal soil (Cr-0), the application of compost, BC, and co-composted BC significantly improved the physiological attributes of *Brassica* as

compared to the control under Cr stress (Cr-25). In the case of chlorophyll contents (SPAD index), the maximum increase (2.25 times) was noticed with co-composted BC as compared to the control under normal soil (Cr-0). In soil spiked with Cr-25 concentration, the application of co-composted BC increased 2.17 times more chlorophyll contents (SPAD index) than the control under Cr stress (Cr-25). The same treatment caused an increase in 151.0, 104.3, 127.0, and 101.6% in photosynthetic rate, transpiration rate, stomatal conductance, and relative water contents, respectively, with the application of co-composted BC under Cr contamination (Cr-25). It was followed by BC and compost application under Cr contamination.

Antioxidant Enzyme Activities

Under Cr stress (Cr-25), the maximum APX (56.78 mol min⁻¹ mg⁻¹ protein), GP (88.43 mol min⁻¹ mg⁻¹ protein), CAT (16.87 nmol min⁻¹ mg⁻¹ protein), GST (267.13 μmol min⁻¹ mg⁻¹ protein), GR (30.70 mol min⁻¹ mg⁻¹ protein), and RG (133.27 nmol min⁻¹ mg⁻¹ protein) values were recorded without any treatment (Figure 3). The application of organic amendments (compost, BC, and co-composted BC) significantly reduced antioxidant enzyme activities as compared to the control. The maximum decrease in APX (42.5%), GP (45.1%), CAT (45.4%), GST (47.8%), GR (47.1%), and RG (48.2%) was observed with the application of co-composted BC in comparison to the control treatment.

Bean Weight and Total Soluble Sugars

Bean weight was significantly reduced under Cr stress, while a significant increase was noted with the application of compost, BC, and co-composted BC under Cr stress, i.e., Cr-25 (Figure 4). Under Cr stress, the minimum bean weight (3.29 g) was noted in the control treatment without any amendment, while the maximum bean weight (15.13 g) was recorded with the application of co-composted BC under normal conditions (Cr-0). The maximum bean weight (10.76) recorded with the application of co-composted BC was 3.27 times more as compared to the control (Cr-25). In the case of total sugar content (TSC), an opposite trend was recorded with the application of compost, BC, and co-composted BC (Figure 4). The maximum TSC (16.5) was observed under the control treatment (Cr-25), while the minimum TSC (7.83) was observed with the application of co-composted BC under normal conditions (Cr-0). The application of co-composted BC significantly reduced TSC (36.8%) in *Brassica* as compared to the control under Cr stress (Cr-25).

Chromium Accumulation

With the application of compost, BC, and co-composted BC, Cr accumulation in grain, root, and shoot samples of *Brassica* was significantly reduced in comparison to the control under Cr stress (Figure 5). However, Cr accumulation in soil was significantly enhanced with the application of co-composted BC in comparison to the control under Cr stress (Cr-25). With the application of co-composted BC, the minimum accumulation in grain (1.06 μg kg⁻¹ DW), shoot (3.40 mg kg⁻¹ DW), and root (5.33 mg kg⁻¹ DW) portions of *Brassica* were 4.12, 2.27, and 2.17 times less as compared to that observed in the control

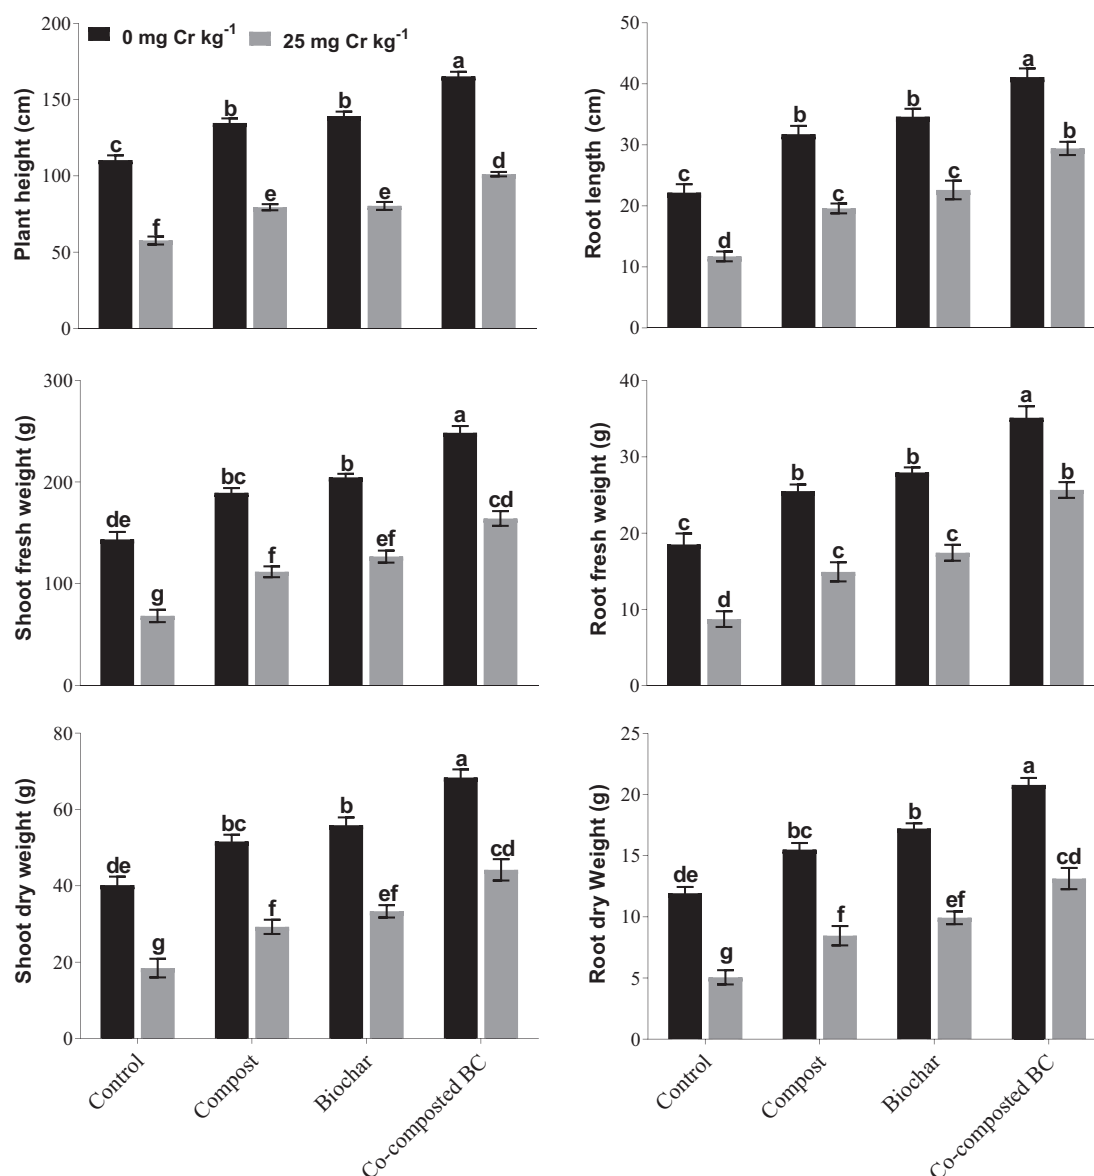

FIGURE 1 | Impact of compost, biochar, and co-composted biochar on growth and yield parameters of *Brassica*. The values are presented as mean \pm standard error ($n = 3$). The values sharing the same letter(s) in bars are statistically non-significant with each other at $p < 0.05$.

treatment under Cr stress (Cr-25). The Cr accumulation in soil was maximum (20.33 mg kg^{-1} soil) with the application of co-composted BC and it was 1.52 times more as compared to that observed in the control treatment without any amendment under Cr stress (Cr-25). Moreover, significant positive and negative correlations were observed among Cr concentration in plant parts and growth and physiological attributes of *Brassica* (Figure 6).

Phytostabilization Efficiency and Health Risk Assessment

To estimate the phytostabilization potential of different amendments, bioconcentration factor (BCF), bioaccumulation

factor (BAF), and bioaccumulation concentration (BAC) of *Brassica* were calculated (Figure 7). The application of compost, BC, and co-composted BC showed significant potential for the phytostabilization of Cr in the soil in comparison to the control treatment. The minimum values of BCF (0.43%), BAF (0.0000526%), and BAC (0.1667) were recorded with the application of co-composted BC as compared to the control under Cr stress (Cr-25). The health risk assessment was determined by calculating the daily intake of metal (DIM), hazard index (HI), cancer risk (CR), and total hazard quotient (THQ). The application of compost, BC, and co-composted BC significantly reduced the health risks associated with the accumulation of Cr in the edible portion of *Brassica* (Figure 8).

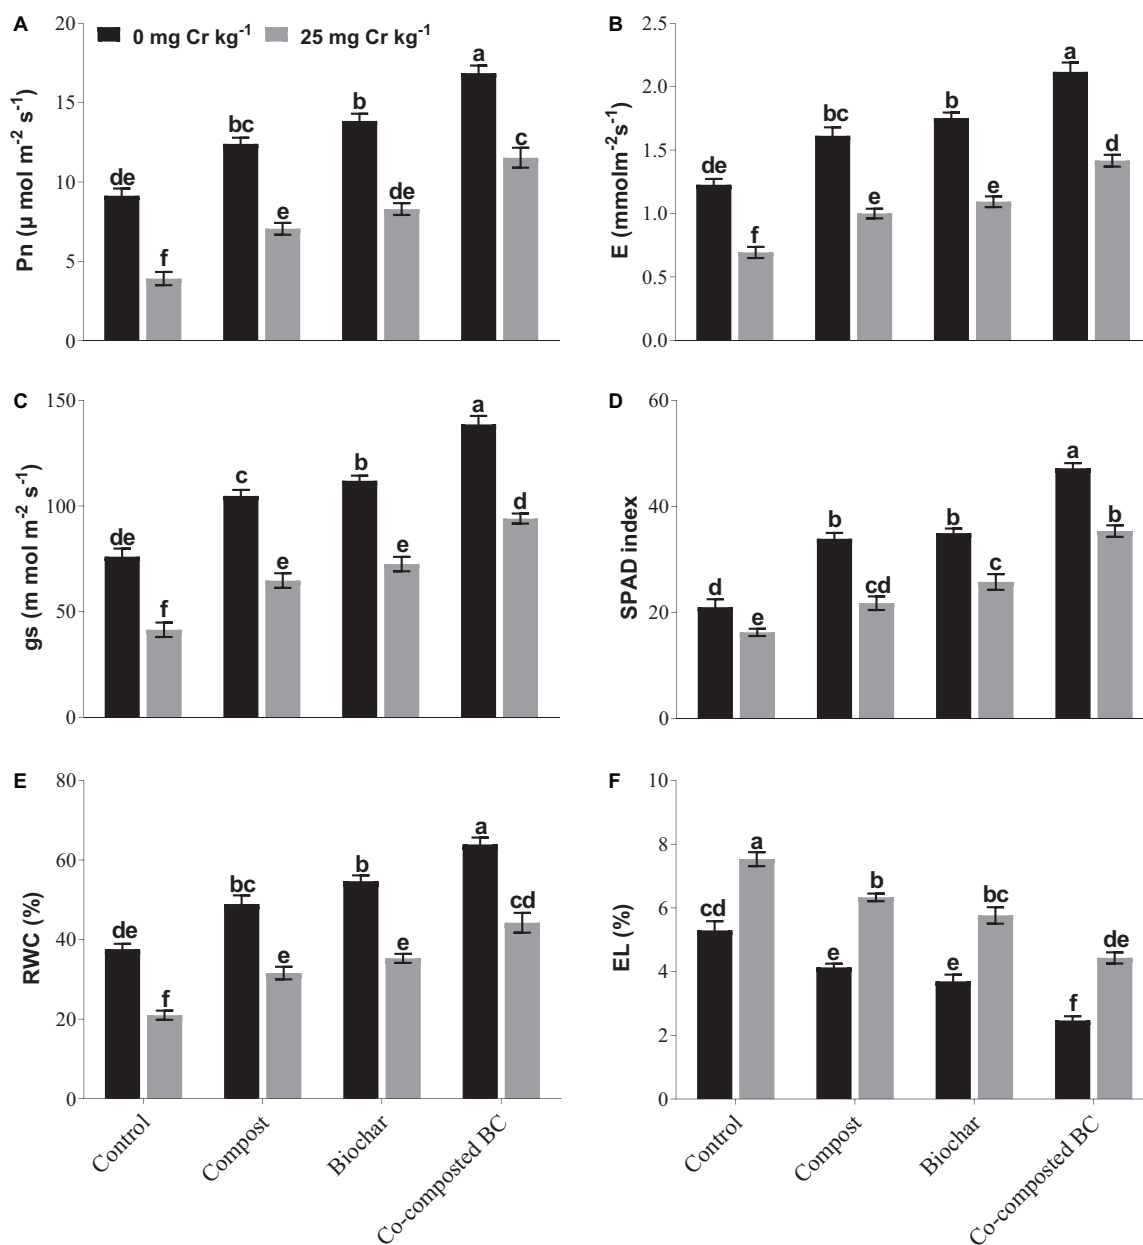

FIGURE 2 | Impact of compost, biochar, and co-composted biochar on physiological parameters of *Brassica*. **(A)** Photosynthetic rate, **(B)** transpiration rate, **(C)** stomatal conductance, **(D)** chlorophyll content, **(E)** relative water content, and **(F)** electrolyte leakage. The values are presented as mean \pm standard error ($n = 3$). The values sharing the same letter(s) in bars are statistically non-significant with each other at $p < 0.05$.

With the application of co-composted BC, the minimum values of DIM (8.667×10^{-6}), HI (5.667×10^{-6}), CR (0.431), and THQ (3.2×10^{-7}) were recorded, and these were 4.21, 4.24, 4.00, and 4.00 times less as compared to the control treatment without any amendment under Cr stress (Cr-25).

DISCUSSION

Results showed that the application of compost, BC, and co-composted BC significantly ($p < 0.05$) improved the growth

attributes of *Brassica* in uncontaminated and contaminated soil (Cr-25). The soil under Cr stress (Cr-25) showed reduced shoot and root length, shoot fresh and dry weight, and root fresh and dry weight of *Brassica* (Figure 1). Many researchers have reported reduced morphological parameters under Cr stress (Adrees et al., 2015; Maqbool et al., 2018). Cr toxicity inhibits cell division and elongation in plant root cells (Adrees et al., 2015), thus reducing root surface area for enhanced water and nutrient uptake from the soil (Medda and Mondal, 2017; Ahmad et al., 2020) and ultimately growth and biomass production. Our findings are in line with the study by Jun et al. (2009) that Cr-contaminated soil

reduced shoot length, root growth, and biomass production in cereals, vegetables, and forages.

Our results showed that plant growth significantly improved with the application of compost, BC, and co-composted BC. Novak et al. (2019) observed growth improvement when different combinations of BC and compost were used under Cd-contaminated soil. Abbas et al. (2020) observed that a combination of BC (3%) and AMS (5%) increased shoot length

(93%), root length (222%), shoot dry weight (60%), and root dry weight (164%) of maize grown in Cr-contaminated soil. Arshad et al. (2017) reported that the pine wood chip BC produced at 450°C significantly improved maize root and shoot fresh weight, root length, and root surface area. Similarly, various studies have reported that BC application improved plant growth under a Cr stress environment (Agegnehu et al., 2017; Arshad et al., 2017). BC addition improves nutrient retention

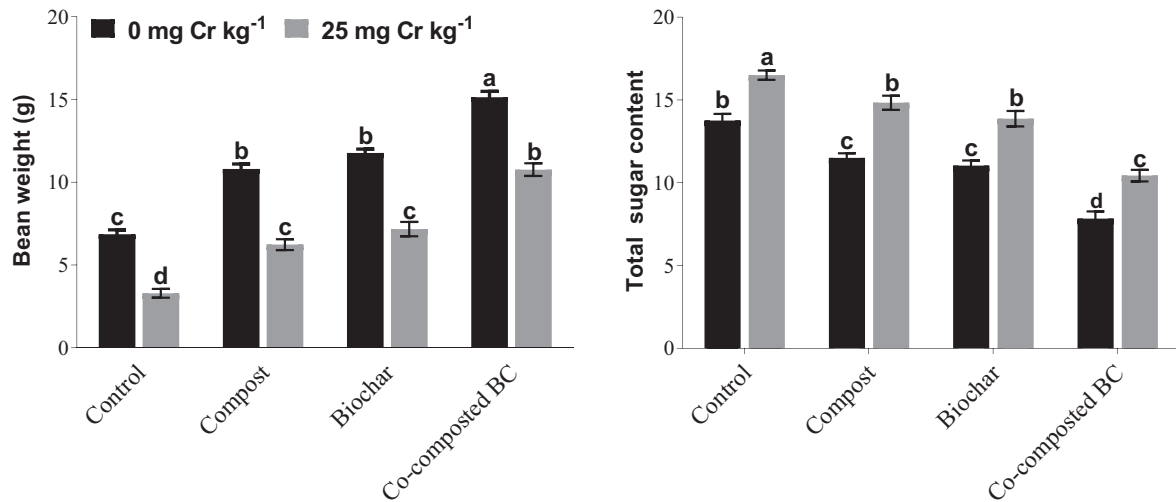

FIGURE 4 | Impact of compost, biochar, and co-composted biochar on bean weight and total sugar contents (TSCs) of *Brassica napus*. The values are presented as mean \pm standard error ($n = 3$). The values sharing the same letter(s) in bars are statistically non-significant with each other at $p < 0.05$.

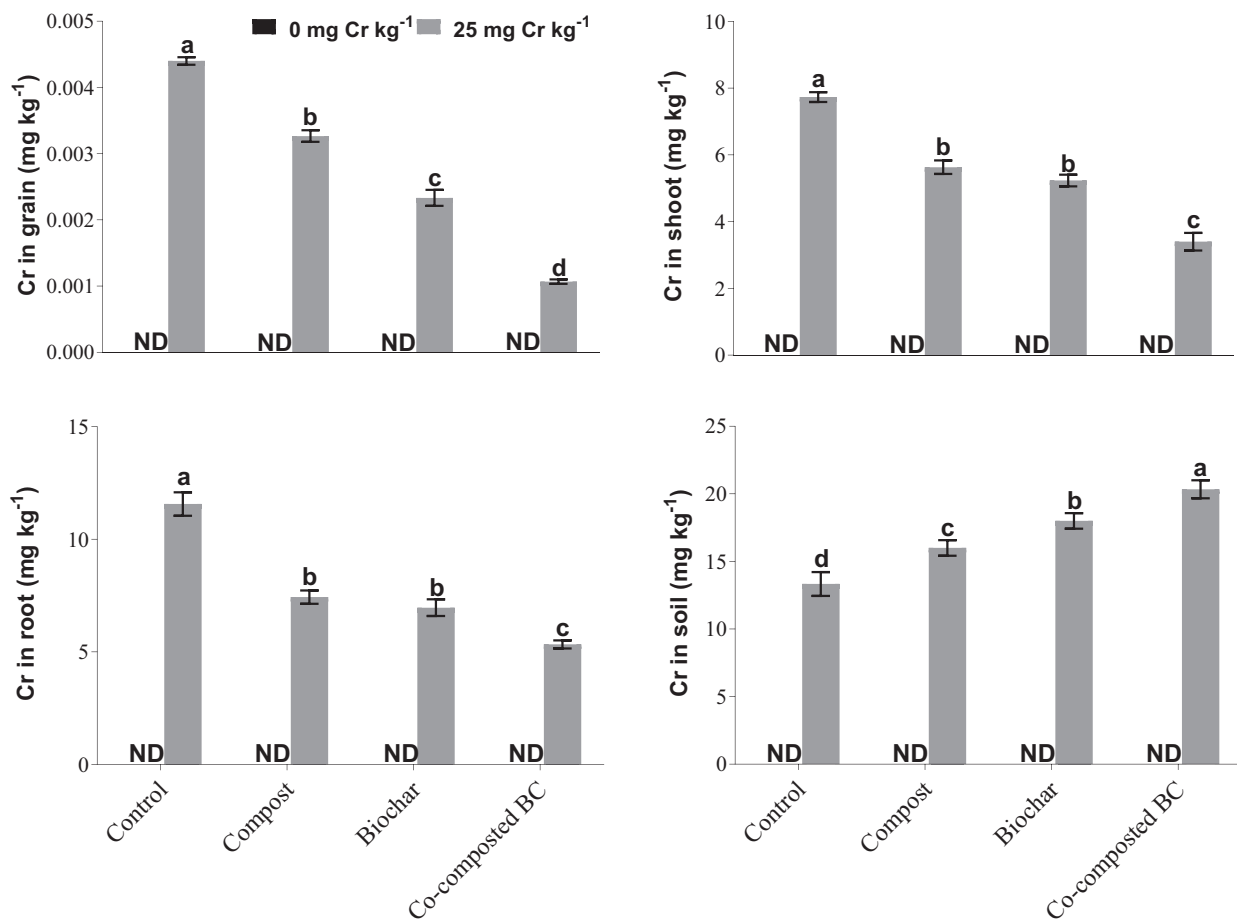

FIGURE 5 | Impact of compost, biochar, and co-composted biochar on Cr accumulation in different portions of *Brassica napus*. The values are presented as mean \pm standard error ($n = 3$). and water uptake and increases organic carbon (Rizwan et al., 2016; Cheng et al., 2020), thus enhancing soil fertility and boosting vegetative growth (Ali et al., 2018). In addition, the combined compost and BC influenced soil properties, such as pH, cation exchange capacity (CEC), soil organic matter, and nutrients availability, and ultimately increased soil fertility and plant growth (Agegnehu et al., 2017). In this study, an increase in plant growth parameters might be due to decreased Cr bioavailability with enhanced nutrient uptake under BC-amended Cr-contaminated soil. It may also be the BC-mediated conversion of Cr(VI) to Cr(III) in soil, which is relatively less mobile and less toxic (Rizwan et al., 2016).

Cr toxicity severely affects plant physiology and our results showed that the application of compost, BC, and co-composted BC significantly ($p < 0.05$) improved physiological attributes of *Brassica* in soil under Cr stress (Cr-25). Cr toxicity severely affects chlorophyll contents by disrupting chloroplast and discontinuing electron transport chain reaction, relative water contents, and electrolyte leakage in leaves. Many studies have shown that Cr toxicity damages photosynthetic machinery and produces a large amount of ROS in plants, which results in reduced growth (Ali et al., 2018; Bashir et al., 2020a).

Results of this study demonstrated that the application of compost, BC, and co-composted BC significantly reduced Cr uptake from soil under Cr contamination (Cr-25). Mustafa et al. (2020) observed that BC applied at the rate of 1 and 2% (w/w) reduced Cr uptake by 21 and 41%, respectively, under 500 μM of Cr stress. Similarly, Ali et al. (2018) observed that the application of BC efficiently removed Cr(VI) from wastewater. Cheng et al. (2020) noticed bamboo BC reduced Cu, Ni, Hg, and Cr uptake from water and soils. The reduction in Cr uptake might be due to the high surface area of BC that facilitates sorption, ion exchange, electrostatic interaction, complexation, precipitation, and co-precipitation (Rizwan et al., 2016). BC surface contains phenolic,

hydroxyl, and carboxylic functional groups that facilitate metal binding (Mehmood et al., 2021; Murtaza et al., 2021a).

Under normal conditions, plants produce ROS in a controlled amount but under stress conditions; their production increases many times, which leads to oxidative stress, membrane permeability, DNA damage, and even cell death (Ahmad et al., 2010, 2019; Kohli et al., 2019). Plants have developed certain antioxidant enzymes to scavenge ROS and produce resistance against stress (Ditta and Khalid, 2016; Niamat et al., 2019). It was observed in many studies that the application of organic amendments enhanced resistance of plants against abiotic stresses (Seneviratne et al., 2017; Ali et al., 2018; Niamat et al., 2019). Our results showed that the application of co-composted BC indirectly influenced the antioxidant activity by reducing Cr bioavailability. In our findings, CAT activity was increased under Cr stress (Cr-25) in the control treatment. BC addition increased CAT activity (38.79%) in *Zea mays* and *Brassica rapa* (Ali et al., 2018; Bashir et al., 2020b). Similarly, Arshad et al. (2017) observed significant reductions in antioxidant enzyme activities under increasing levels of Cr stress. BC addition markedly improved antioxidant enzyme activities under Cr stress, which might be due to reduced Cr uptake (Seneviratne et al., 2017). Our results showed CAT, GSH, GR, GP, GPX, and GST activities in *Brassica* leaves increased under Cr stress (Cr-25), and the application of compost, BC, and co-composted BC reduced antioxidant activities. As discussed earlier, it was observed increased antioxidants activity in *B. napus* under Cd-spiked soil (Sabir et al., 2020).

This study results showed the co-composted BC significantly reduced Cr uptake in the *Brassica* plants. Novak et al. (2019) observed that the combined BC and compost reduced Cd uptake in plants. Seneviratne et al. (2017) also noted a significant reduction in cadmium (19.4%) and lead (22.0%) uptake when BC at the rate of 40 t ha⁻¹ was applied in *Vigna radiata*.

It was observed by many researchers that BC reduced HMs bioavailability by manipulating soil pH, precipitation, sorption, and changing HMs redox state (Ditta and Khalid, 2016; Rizwan et al., 2016; Cheng et al., 2020). BC contains a variety of oxygen-containing functional groups (such as carbonyl, carboxylic, hydroxyl, and phenol) that might be involved in complexation with HMs and cation exchange process with metals cations present on BC surface (Seneviratne et al., 2017; Niamat et al., 2019). With time, BC undergoes an oxidation process and new reactive sites are formed on BC surface that facilitates HMs immobilization (Bian et al., 2014) and ultimately results in reduced HMs uptake in plants. Such mechanisms of applied amendments might have resulted in reduced values of metal uptake in *Brassica* plants grown in this study and hence improved phytostabilization efficiency (Figure 7) and reduced health-associated risks (Figure 8). This was further evidenced by the negative correlations observed among Cr concentration in roots and shoots and growth and physiological parameters recorded for *Brassica* (Figure 6). The BCF and BAC values have further shown that the *Brassica* has the potential to

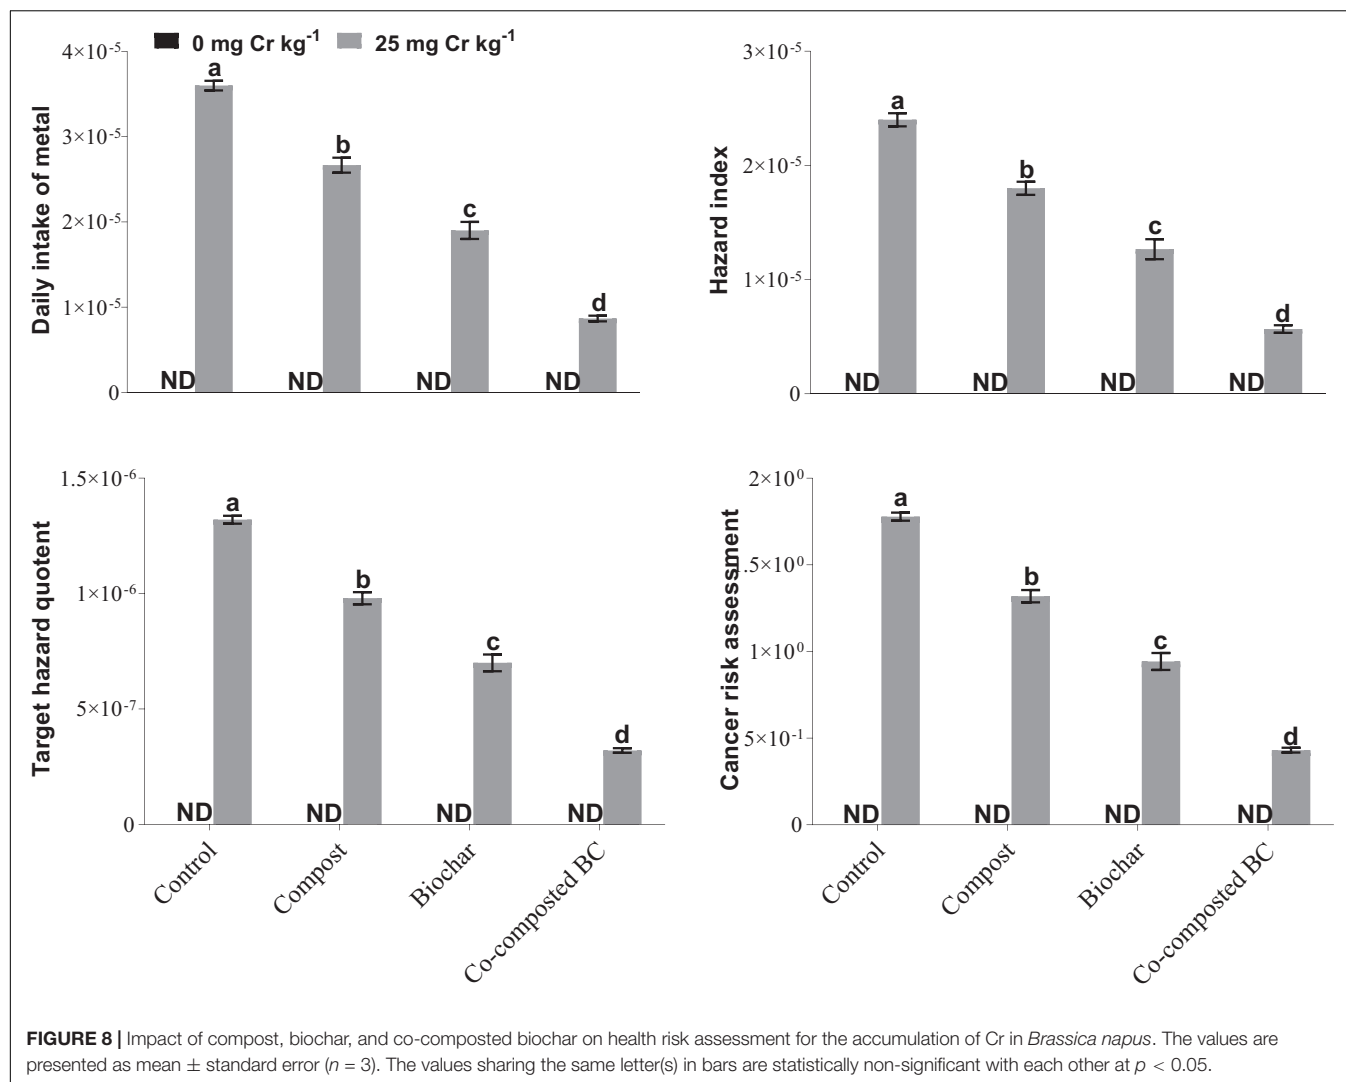

extract Cr at higher concentrations and hence can be grown in metal-contaminated soils. Moreover, the values for DIMs and health risk index (HRI) were <1 , which indicated that the consumption of *Brassica* was safe with no associated health risks.

MATERIALS AND METHODS

Soil Sampling and Analysis

The contamination-free surface soil (0–15 cm) was collected from the research area of the Institute of Soil and Environmental Sciences, University of Agriculture Faisalabad. The soil was air-dried, ground, and sieved (2 mm) to remove stones and other undesired plant materials. Composite sampling was followed for soil homogenization. For pre-sowing analysis, the soil sample was taken from the composite sample.

Standard procedures were followed for basic soil analysis regarding physicochemical properties. Soil pH was determined by making a saturated soil paste of 250 g soil and pH was measured

with a pH meter (Kent Eil 7015) (US Salinity Laboratory Staff, 1954). The electrical conductivity (EC) of soil was determined by taking soil extract from saturated soil paste, and extract EC was determined using EC meter (US Salinity Laboratory Staff, 1954). Soil texture was determined with the hydrometer method, and soil organic matter was determined by the potassium dichromate method (Moodie et al., 1959). Soil CEC was determined by the ammonium acetate method (Chapman, 1965), total soil nitrogen was determined through the Kjeldahl method (Jackson, 1962), soil available P by using NaHCO₃ (Watanabe and Olsen, 1965), and soil K was determined through ammonium acetate (1N, pH = 7.0) method (US Salinity Laboratory Staff, 1954). Different physicochemical properties of soil are provided in Table 1.

For bioavailable Cr concentration, the soil sample (10 g) was extracted with AB-DTPA solution (20 ml) and shaking at 180 rpm on a reciprocal shaker for 15 min (Soltanpour and Schwab, 1977). Concentrated HNO₃ (100 ml) was added to the extract and analyzed for bioavailable Cr using atomic absorption spectrophotometer (PerkinElmer Model 700, United States). For total Cr concentration in soil,

the method proposed by Soltanpour and Schwab (1977) was adopted. Briefly, soil samples (0.5 g) were digested with 15 ml of three acids mixture (HNO₃, H₂SO₄, and HClO₄ in a ratio of 5:1:1) and heated at 160°C in digestion chamber until a colorless solution appeared. After digestion, the samples were cooled, filtered, and diluted to a 50-ml solution using a volumetric flask with deionized water. An atomic absorption spectrophotometer (PerkinElmer Model 700) was used for the determination of total Cr concentration in the samples.

Compost, Biochar, and Co-composted Biochar Production and Characterization

For compost preparation, a locally fabricated composting unit was used involving animal manure as an easily available raw material (Ditta et al., 2015, 2018a,b). The animal manure was collected from Animal Husbandry Farm, the University of Agriculture, Faisalabad, and sun-dried to remove excess moisture and unwanted plant debris, stone, and plastic material. During

TABLE 1 | Physicochemical characteristics and nutritional composition of compost, biochar, co-composted biochar, and soil utilized in this study.

Physical/chemical properties	Soil	Compost	Biochar	Co-composted biochar
Textural class	Sandy clay loam	–	–	–
Sand (%)	56 ± 3.21	–	–	–
Silt (%)	24 ± 1.86	–	–	–
Clay (%)	20 ± 1.57	–	–	–
pH	7.88 ± 0.35	6.85 ± 0.03	7.964 ± 0.08	7.01 ± 0.09
Electrical conductivity (dS m ⁻¹)	1.06 ± 0.08	1.2 ± 0.01	2.75 ± 0.07	1.58 ± 0.08
Cation exchange capacity (cmol _c kg ⁻¹)	6.85 ± 1.62	73.01 ± 2.11	98.46 ± 2.86	92.35 ± 2.38
Moisture %	26 ± 1.26	10.57 ± 1.18	4.25 ± 0.19	7.32 ± 1.08
Organic matter (%)	0.72 ± 0.18	–	–	–
Carbon (g kg ⁻¹)	–	199.2 ± 3.68	633.51 ± 5.67	398.92 ± 4.33
Nitrogen (g kg ⁻¹)	–	21.8 ± 1.26	11.25 ± 0.86	16.42 ± 0.67
Total phosphorus (g kg ⁻¹)	–	0.42 ± 0.05	1.43 ± 0.54	1.18 ± 0.67
Total potassium (g kg ⁻¹)	–	1.67 ± 0.18	9.29 ± 0.22	7.32 ± 0.63
Zinc (mg kg ⁻¹)	–	47.0 ± 3.70	45.61 ± 2.91	46.27 ± 2.87
Iron (mg kg ⁻¹)	–	70.8 ± 4.09	85.31 ± 4.76	82.29 ± 3.67

The values are presented as mean ± SE (n = 3).

composting, 50% moisture at 65°C was maintained with 50-rpm speed and this process was completed after 40 days. Co-composted BC was prepared by mixing 30% (w/w) wheat straw BC with composted material during the last week of composting. For wheat straw BC preparation, straw feedstock was collected from the field area of the Department of Agronomy, University of Agriculture Faisalabad, washed with tap water to remove dust, sun-dried, and crushed. Sanchez et al. (2009) described a process that was followed for BC production in which feedstock was filled in a Pyrex flask having 2 L capacity. BC was prepared in a muffle furnace (Gallagher, England) at 400°C under an oxygen-limited environment, with 20 min of retention time at heating at the rate of 10°C min⁻¹ increase in temperature. Gases and water vapor produced during pyrolysis were removed by using a silicon-made bent glass rod attached to the flask outlet. After pyrolysis, the furnace remained closed until 20°C, and the prepared BC was stored in plastic bags for further analysis.

For pH and EC, each compost, BC, and co-composted BC was separately mixed with deionized water in 1:20 ratio (w/v), shaken for 1 h, and pH and EC were measured using pH meter (PHS-38W) and EC meter (4510 conductivity meter). Nutrient analysis was carried out through wet digestion of each sample using H₂SO₄ and H₂O₂ (Wolf, 1982). In 1 g of each sample, H₂SO₄ (15 ml) was added and placed in the sample overnight.

On the next day, the digestion mixture was heated on a hotplate until the boiling started. In the boiling digestion mixture, H₂O₂ (10 ml) was added repeatedly until a colorless solution appeared. The volume of the digested sample was made 50 ml in a volumetric flask using deionized water and preserved until the analysis was performed. Total nitrogen was determined through the Kjeldahl method (US Salinity Laboratory Staff, 1954), P was measured by NaHCO₃ method using a spectrophotometer (UV-1201, Shimadzu, Tokyo, Japan), and K was determined using a flame photometer (PFP7, Jenway, Essex, United Kingdom). Different physicochemical properties of compost, BC, and co-composted BC are given in Table 1.

Pot Experiment

After the preparation of different organic amendments, a pot experiment was conducted in rain-protected wirehouse of Institute of Soil and Environmental Sciences (31.439052° N, 73.069335° E), University of Agriculture Faisalabad, Pakistan. In each pot, 10 kg soil was used and recommended rate of NPK (90:60:75 kg ha⁻¹) using urea, di-ammonium phosphate, and sulfate of potash fertilizer was mixed. Compost, BC, and co-composted BC were applied at the rate of 2% (w/w). For Cr contamination, the soil was spiked with potassium dichromate (K₂Cr₂O₇) solution at two levels (0 and 25 ppm) and applied to plants at a three-leaf stage after complete germination. In each pot, six seeds of *B. napus* (cv. AARI canola) were sown, and each treatment was applied in triplicate. The pots were placed in the wirehouse under natural conditions as day/night temperature of 25°C/15°C and relative humidity of 50%/70%, respectively. Recommended agronomic practices were followed during the course of the study. The harvesting was done after 60 days of plant growth at maturity. Data regarding growth, physiological, and biochemical parameters were measured as follows.

Growth and Physiological Parameters

After harvesting the plants, data regarding various growth and yield parameters were taken following standard procedures. For shoot and root length, measuring tape was used. For fresh biomass, the root and shoot samples were weighed on a digital balance. For dry biomass, the samples were put in a drying oven at 65°C for 48 h or until a constant weight was obtained. The shoot samples with grain pods were dried in sun. The threshing of shoot samples was done to separate grains, and the grain yield was measured by weighing the grains on a digital balance. Plant physiological attributes such as photosynthetic rate, transpiration rate, and stomatal conductance were measured by using an infrared gas analyzer (IRGA; Analytical Development Company, Hoddesdon, England) at morning time (Ben-Asher et al., 2006). Chlorophyll contents were measured in the morning time with a portable chlorophyll meter (SPAD-502, Konica-Minolta, Japan) following the method suggested by Arnon (1949), while relative water contents were measured using the method suggested by Barrs and Weatherley (1962).

To assess membrane permeability against Cr stress, electrolyte leakage was determined following the method suggested by Lutts et al. (1996). Briefly, the youngest fully expanded leaf sample (1 cm) from each replicate was taken into a vial (10 ml) and

washed three times with distilled water to remove any dust material. Each vial with leaf sample was placed in the shaker (100 rpm) at room temperature (25°C) for 24 h. On the following day, the EC of the leaf sample in the vial was measured using an EC meter and denoted as EC₁. Then, each leaf sample in the vial was autoclaved at 121°C for 20 min. After cooling the samples, again EC was measured using an EC meter and denoted as EC₂. The electrolyte leakage was determined by using the following formula:

$$\text{Electrolyte leakage (\%)} = \frac{EC_1}{EC_2} \times 100$$

Antioxidant Enzyme Activity

For different antioxidant enzyme activities, fully expanded, uppermost fresh leaf samples after 40 days of germination were used. For this purpose, 0.5 g leaves were homogenized in 3 ml Tris buffer (50 mM) having pH 7.8, centrifuged at 12,000 rpm for 20 min, and the total soluble enzyme activities were calculated by using a spectrophotometer. Leaf CAT activity was measured following the method suggested by Aebi (1983), while ascorbate peroxidase activity was measured by using a spectrophotometer at 290 nm (Nakano and Asada, 1981). The method suggested by Fryer et al. (1998) was used for the determination of glutathione reductase and that by Rahman et al. (2006) for the measurement of reduced glutathione activity, in which DTNB (5,5'-dithiobis-2-nitrobenzoic acid) reduced to TNB (2-nitro-5-thiobenzoic acid) and changed the absorbance. For glutathione peroxidase activity, the method suggested by Rahman et al. (2006) was followed. Similarly, the methodology suggested by Habig et al. (1974) was followed for glutathione-S-transferase activity in leaf samples.

For the determination of TSC, the method suggested by Yem and Willis (1954) was used. Briefly, 0.5 g of ground leaf samples were extracted in ethanol solution (80%). Then, 10 ml of extract solution was taken in a 25-ml test tube along with 6 ml anthrone reagent and heated in the water bath for 10 min. Anthrone reagent was freshly prepared by taking 150 mg of anthrone in 72% pure H₂SO₄. Heated samples were cooled for 10 min, and the absorbance was measured at 625 nm using a spectrophotometer (UV-1201, Shimadzu, Tokyo, Japan).

Evaluation of Phytoimmobilization Efficiency

For BAC and BCF, the following equations were used to assess the phytoimmobilization/phytostabilization potential of *B. napus* as proposed by Amin et al. (1954) and Zhuang et al. (2007).

$$BAC = \frac{Ni [\text{shoot}]}{Ni [\text{soil}]}$$

where Ni [shoot] and Ni [soil] are the concentrations of Ni in the shoots and the soil, respectively.

$$BCF = \frac{M (\text{harvested tissue})}{M (\text{soil water})}$$

where *M* (harvested tissue) is the metal concentration in the harvested plant parts (root, shoot, and grains), and *M* (soil

water) is the total amount of applied metal for the corresponding treatment.

Intake of Heavy Metals From Vegetables and Health Risk Assessment

The DIM index was calculated by using the following equation (Latif et al., 2018):

$$DIM = \frac{M \times I \times K}{W}$$

where *M* is the concentration of HMs in plants (mg kg⁻¹), *K* is the conversion factor, *I* is the daily intake of vegetables, and *W* is the average body weight (BW). The average adult BW was considered 60 kg, while the average daily vegetable intake for adults was considered 0.345 kg⁻¹ person⁻¹ (Latif et al., 2018).

The HRI for Ni caused by the consumption of contaminated vegetables was calculated using the following equation (Jan et al., 2010):

$$HRI = \frac{DIM}{Rfd}$$

where *DIM* is the daily intake of metals and *Rfd* is the reference oral dose. According to US-EPA IRIS, the *Rfd* value for Ni is 0.02 mg kg⁻¹ BW day⁻¹.

Statistical Analysis

Data collected were evaluated using analysis of variance (ANOVA), and treatment means were compared by using Tukey's HSD test at 5% probability level using Statistix 8.1 (Analytical Software, Tallahassee, FL, United States) (Little and Hills, 1978). The figures were plotted using GraphPad Prism computer-based software (GraphPad Software, San Diego, CA, United States). The correlation matrix was computed using R software (<https://www.R-project.org/>).

CONCLUSION

The results showed that Cr stress (Cr-25) significantly reduced growth, physiological and biochemical parameters of *Brassica* under the control treatment without any amendment. The application of compost, BC, and co-composted BC significantly alleviated Cr stress and enhanced various growth, physiological, and biochemical parameters. With the application of co-composted BC, the maximum increase in growth, physiological, and biochemical parameters of *Brassica* was recorded in comparison to the control treatment without any amendment under Cr stress (Cr-25). Similarly, the application of co-composted BC maximized the phytostabilization efficiency as revealed through the minimum values of BCF, BAF, and BAC of *Brassica* as compared to the control treatment under Cr stress (Cr-25). Moreover, the same treatment significantly reduced the health risks associated with the consumption of *Brassica* under Cr stress (Cr-25) as clear from the lowest values of DIM, HI, CR, and THQ. In conclusion, the application of co-composted BC could serve as an effective amendment in the alleviation of Cr stress in *Brassica* via phytostabilization and reduction in associated health risks.

doi: 10.3389/fpls.2021.749422

Ozone is a destructive pollutant, damaging crops, and decreasing crop yield. Therefore, there is great interest in finding strategies to alleviate ozone-induced crop losses. In plants, ozone enters leaves through the stomata and is immediately degraded into reactive oxygen species (ROS), producing ROS stress in plants. ROS stress can be controlled by ROS-scavenging systems that include enzymatic or non-enzymatic mechanisms. Our research group has developed a product from rice bran, a by-product of rice milling which has bioactive molecules that act as an antioxidant compound. This product is a water-soluble rice bran enzymatic extract (RBEE) which preserves all the properties and improves the solubility of proteins and the antioxidant components of rice bran. In previous works, the beneficial properties of RBEE have been demonstrated in animals. However, to date, RBEE has not been used as a protective agent against oxidative damage in agricultural fields. The main goal of this study was to investigate the ability of RBEE to be used as a biostimulant by preventing oxidative damage in plants, after ozone exposure. To perform this investigation, pepper plants (*Capsicum annum*) exposed to ozone were treated with RBEE. RBEE protected the ozone-induced damage, as revealed by net photosynthetic rate and the content of photosynthetic pigments. RBEE also decreased the induction of antioxidant enzyme activities in leaves (catalase, superoxide dismutase, and ascorbate peroxidase) due to ozone exposure. ROS generation is a common consequence of diverse cellular traumas that also activate the mitogen-activated protein kinase (MAPK) cascade. Thus, it is known that the ozone damages are triggered by the MAPK cascade. To examine the involvement of the MAPK cascade in the ozone damage *CaMPK6-1*, *CaMPK6-2*, and *CaMKK5* genes were analyzed by qRT-PCR. The results showed the involvement of the MAPK pathway in both, not only in ozone damage but especially in its protection by RBEE. Taken together, these results support that RBEE protects plants against ozone exposure and its use as a new biostimulant could be proposed.

Keywords: ozone, ROS, rice bran, enzymatic extract, MAPK

INTRODUCTION

Ozone (O_3) is a destructive pollutant with negative effects on human and ecosystem health that induces abiotic stress in plants – affecting photosynthetic carbon assimilation, stomatal conductance, and plant growth – that damages crops and decreases crop yield (Ainsworth et al., 2012).

In plants, O_3 enters through the stomata and is degraded into secondary reactive oxygen species (ROS), including H_2O_2 , $O_2^{\cdot-}$, and HO^{\cdot} , in the apoplastic space (Vainonen and Kangasjärvi, 2015). High levels of ROS can lead to ROS stress that causes direct or indirect ROS-mediated damage on a variety of molecules including lipid peroxidation in cellular membranes, protein denaturation, carbohydrate oxidation, and pigment breakdown (Sharma et al., 2012). Even more, ROS stress can eventually lead to changes in gene expression and even cell death. However, ROS are generated in the metabolism of plant cells and therefore plants need systems that scavenge oxidizing species. Constitutive enzymatic and non-enzymatic systems in cells protect them from ROS-induced damage and are inducible under biotic and abiotic stress that triggers a rapid increase in ROS, including O_3 exposure (Sachdev et al., 2021). Enzymatic ROS-scavenging mechanisms include antioxidant enzymes such as superoxide dismutase (SOD), catalase (CAT), ascorbate peroxidase (APX), glutathione peroxidase (GP), guaiacol peroxidase (GPX) and dehydroascorbate reductase (DHAR) (Gill and Tuteja, 2010).

Specific ROS also act as “second messengers” in signal transduction pathways that lie downstream initial event in cells. The mitogen-activated protein kinase (MAPK) cascade is one of the signaling pathways sensitive to the cell’s redox status. Therefore ROS generation is a common consequence of diverse cellular traumas that activate the MAPK cascade and studies in different plants have demonstrated that O_3 exposure activates

some components of the MAPK cascade (Marcus et al., 2000; Liu et al., 2015; Liu and He, 2017).

Studies on the effect of O_3 on agricultural productivity showed an estimated 5–15% crop yield loss in the United States (Avnery et al., 2011) and a 5% in Europe (Mills et al., 2007). To alleviate the drop in crop productivity, the main defense strategy over the past four decades has been the application of chemicals, mainly synthetic antioxidants (fungicides, insecticides, herbicides, nematocides, growth regulators, antitranspirants, antioxidants from the rubber industry, etc.) (Didyk and Blum, 2010). These xenobiotic products have varied protection capacity with some producing ineffective or even detrimental side effects. The most effective product was found to be EDU (ethylene diurea- (*N*-[2-(2-oxo-1-imidazolidinyl) ethyl]-*N*O phenylurea), developed by the duPont Chemical company (Archambault et al., 2000) whose main mechanism of action is not yet clear. Currently, more effective alternatives are being sought, such as extracts of plant origin, which do not generate environmental toxicity.

Rice Bran is a by-product of rice (*Oryza sativa*) milling that retains most of the bioactive compounds present in rice grain. These bioactives include naturally occurring antioxidants, mainly γ -oryzanol, tocopherols, tocotrienols, and polyphenols. Besides that, rice bran is also a good source of protein and fat (Goufo and Trindade, 2014). However, the low bioavailability of its biopolymers and bioactive compounds due to its high insolubility is the main drawback when considering rice bran as a biostimulant. Using enzymatic technology, our group has developed a process that enables obtaining a stable, water-soluble rice bran enzymatic extract (RBEE) from rice bran. RBEE has shown a high content in bioactive compounds, particularly phytosterols, γ -oryzanol, and tocols, and an increased content in peptides and free amino acids (Santa-María et al., 2010).

According to its content in bioactive compounds, RBEE has shown both *in vivo* and *in vitro* functional properties such as antioxidant capacity (Santa-María et al., 2010), hypocholesterolemic activity (Revilla et al., 2009), and antiproliferative and immunoactivatory abilities (Revilla et al., 2013). Beneficial effects found in cells and animal models, especially those derived from its antioxidant capacity, lead us to consider the use of RBEE as a biostimulant in agriculture.

This work aims to evaluate the biostimulant capacity of RBEE. To this end, we propose studying the role of RBEE in plant protection against abiotic stress mediated by ROS, specifically in O_3 exposure. We chose pepper plants (*Capsicum annuum*) since pepper is a vegetable crop of great agricultural and economic importance being the second most traded spice in the world. Heavy losses in pepper production are frequently caused by abiotic stresses including O_3 exposition, in fact *Capsicum* pepper cultivation is almost entirely located in regions where O_3 concentration is increasing to phytotoxic levels (Bortolin et al., 2016). For these reasons pepper plants are an interesting research target to evaluate the negative effects of O_3 .

Pepper plants exposed to O_3 were treated with RBEE and antioxidant enzyme activities and specific functional parameters were analyzed. Treatment with RBEE improved

physiological parameters, such as net photosynthetic rate and photosynthetic pigments content in plants exposed to with O₃. RBEE treatment also decreased the induction of antioxidant enzyme activities in leaves (CAT, SOD, GPX, and APX) due to O₃ exposure.

Additionally, to search whether MAPK cascade is involved in the protective role of RBEE against O₃-induced damage we analyzed the transcriptional expression of *CaMPK6-1*, *CaMPK6-2*, and *CaMKK5* genes. The high expression of genes studied strongly support that RBEE protective capacity involved the MAPK signaling cascade.

MATERIALS AND METHODS

Rice Bran Enzymatic Extract Preparation

Rice bran (*O. sativa* var. *indica*) raw material was provided by Herba Ricemills, S.L.U (Sevilla, Spain). Rice bran is obtained during the polishing/milling of raw rice grains once their husks have been stripped. Rice bran was processed by enzymatic hydrolysis using the hydrolytic agent (Biocom, Spain) subtilisin (EC 3.4.21.62), a protease from *Bacillus licheniformis* as hydrolytic agent (Biocom, Spain) in a bioreactor with controlled temperature (60°C) and pH (pH 8), using the pH-stat method (Parrado et al., 2006). The processing of this product follows different steps, including solid separation and concentration. The final product RBEE is a brown syrup that is completely water-soluble.

Rice bran enzymatic extract bran macro and micronutrient composition was characterized as previously described (Parrado et al., 2006).

Plant Treatment

Capsicum annum L. var. *grossum* (pepper) plants were raised from seeds in plastic pots containing an organic commercial substrate (Gramoflor GmbH und Co., KG.) and Osmocote® (NPK 15-9-12), and grown inside the University of Seville Glasshouse General Services on a phytoclimatic chamber, with a controlled temperature of 18–22°C, 50% relative humidity, adequate irrigation with tap water and a photoperiod of 16 h light (1200 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$)/8 h darkness. After 8 days of transplantation, 20 pepper plants were selected and divided in 4 treatments (5 plants per treatment): control plants (C), plants treated with RBEE, control plants under O₃ exposition (C + O₃), and plants treated with RBEE under O₃ exposition (RBEE + O₃).

To evaluate the protection capacity of the treatment with RBEE, RBEE and RBEE + O₃ plants were foliar sprayed with an aqueous solution of RBEE at 0.1% a total of four times at 5-day intervals. At the same time, control plants (C and C + O₃) were sprayed with distilled water the same times. After 5 days of the last spray treatment, C + O₃ and RBEE + O₃ plants were transferred to another phytoclimatic chamber with an O₃ generator (ZONOSISTEM GM 5000 O3 Generator) attached and exposed to three consecutive fumigations with 100 ppB of O₃ for 6 h (from 10:00 a.m. to 4:00 p.m.). After O₃ fumigation, plants

of all treatments were sprayed again with the corresponding solution (RBEE 0.1% or distilled water).

Finally, 24 h after the last exposure to O₃, foliar samples were taken from each plant and the analyses described below were carried out.

Physiological Status in Plants

Determination of Net Photosynthetic Rate

Twenty-four hours after the last ozone treatment, the net photosynthetic rate (A_N) was measured in plants using an IRGA (LI-6400XT, LI-COR Inc., Nev., EEUU) with a light chamber for the leaf (LI-6400-02B, Li-Cor Inc.). Measurements ($n = 20$) were performed between 10 a.m. and 2 p.m. hours under a photosynthetic photon flux density of 1500 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$, a deficit of vapor pressure of 2–3 kPa, a temperature around 25°C, and a CO₂ concentration environment of 400 $\mu\text{mol}\cdot\text{mol}^{-1}$ air. Each measurement was recorded after the stabilization of the exchange of gases was equilibrated (120 s).

Chlorophyll Content in Leaves

Chlorophyll content was extracted from random leaves from plants of each treatment. Fifty milligrams of leaves were homogenized in acetone 100% (v/v) and saline solution 0.9% (w/v) using a homogenizer (Hiscox and Israelstam, 1979). The total chlorophyll content was determined at 652 nm by using the absorbance coefficient of extinction 34.5 $\text{cm}^{-1}\cdot\mu\text{g}^{-1}$ (Arnon, 1949):

$$\text{Abs}_{652\text{nm}} = [\text{chlorophyll}] \cdot 34.5 \text{ cm}^{-1} \cdot \mu\text{g}^{-1}.$$

Delayed Fluorescence Measurements

Delayed fluorescence (DF) was detected using a plant imaging system (NightShade LB 985, Berthold Technologies, Germany) equipped with a deeply cooled CCD camera according to López-Jurado et al. (2020). From plants of each treatment, 2–3 intact leaves of approximately the same size were separated and placed in the plant imaging system. The leaves were illuminated for 20 s with light supplied from far red (730 nm), red (660 nm), green (565 nm), and blue (470 nm) LED panels at 2, 105, 40, and 110 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$, respectively. Immediately after the LEDs were turned off, DF was measured, and the recorded intensities of light were converted to counts per second (cps). Data were then normalized to each leaf area to obtain comparable cps values across treatments.

Oxidative Stress Evaluation in Plants

Determination of Lipid Peroxidation

To quantify lipid peroxidation in leaf homogenates malondialdehyde (MDA) content was determined using the thiobarbituric acid reactive substances (TBARS) assay (Esterbauer and Cheeseman, 1990). Samples of 1 g of leaves were homogenized with 2 ml of 0.1% trichloroacetic acid (TCA). The homogenates were centrifuged at 8000 $\times g$ for 10 min at 4°C, and the supernatants were filtered through a 0.2 mm aseptic filter. Then, 0.3 ml of each sample was mixed with 0.9 ml of 20% TCA containing 0.5% TBA. The solutions were heated at 95°C for 1 h, immediately cooled, and centrifuged as above. Finally,

the absorbance at 532 and 600 nm of the supernatants was recorded, and MDA concentration was calculated by subtracting the non-specific absorption at 600 nm from the absorption at 532 nm by using the absorbance coefficient of extinction $156 \text{ mM}^{-1} \text{ cm}^{-1}$. The results obtained were expressed in nmol.g^{-1} fresh weight (FW).

Antioxidant Enzymes Analyses

To observe the stress of plants, enzymatic activities of APX, SOD, guaiacol peroxidase (GPX), and CAT were measured as described by Duarte et al. (2015). Briefly, vegetal extract was extracted in extraction buffer (50 mM sodium phosphate buffer; pH 7.6) from 500 mg of leaves. Catalase activity was determined at 240 nm in a reaction solution containing the assay buffer (50 mM sodium phosphate buffer, pH 7.0) and 100 mM H_2O_2 . APX activity was assayed in the assay buffer with 12 mM H_2O_2 and 0.25 mM L-ascorbate and measured at 290 nm. SOD activity was determined by monitorization of the pyrogallol oxidation at 325 nm by the addition of 3 mM pyrogallol. Guaiacol peroxidase activity was measured at 470 nm in a reaction mixture containing the assay buffer, 2 mM H_2O_2 , and 20 mM guaiacol. To determine the auto-oxidation of the substrates, control assays were performed in absence of enzymatic extract samples (Duarte et al., 2015). Finally, the total protein content in the enzymatic extracts was measured according to Bradford (1976).

Oxidative Stress Index

Oxidative stress index (OSI) is a parameter that expresses the global oxidative stress in plants (Pérez-Palacios et al., 2017). It was calculated with the formula described in Paredes-Páliz et al. (2018). Values greater than 1 indicated that the leaves were stressed, whereas values less than 1 indicated that the leaves were without oxidative stress.

Plant RNA Extraction and qRT-PCR Assay

RNA was extracted from 100 mg of leaves using RNeasy® Plant Mini Kit (Qiagen, Germany) following the manufacturer's instructions. Then, RNA samples were treated with DNA-free™ kit (ThermoFisher, United States) to remove the residual DNA. Immediately, RNA samples were retrotranscribed to cDNA using QuantiTect® Reverse Transcription kit (Qiagen, Germany) according to the manufacturer's instructions, and the expression of *CaMPK6-1*, *CaMPK6-2* (*Arabidopsis* orthologs *AtMPK6*, Liu et al., 2015), and *CaMKK5* (*Arabidopsis* orthologs *AtMKK5*, Liu et al., 2015) genes were analyzed by qPCR by triplicate. qPCR was performed using SensiFAST™ SYBR® No-ROX kit (Bioline, France) and primers described in Table 2 following the supplier's instructions, in a LightCycler® 480 II thermo-cycler (Roche, Switzerland) under the next conditions: 95°C for 2 min and 50 cycles at 95°C for 5 s, followed by 60°C for 10 s, and finally 72°C for 15 s. The beta-tubulin housekeeping gene was used to normalize results from different samples. Primers used in these assays are described in Table 1. Expression signals were quantified

and normalized using LightCycler® 480 Software version 1.5 (Roche). The expression fold was calculated according to Livak and Schmittgen (2001):

$$\Delta\text{Cq} = \text{AVECq}(\text{TargetAssay}) - \text{AVECq}(\text{ReferenceAssay})$$

$$\Delta\Delta\text{Cq} = \Delta\text{Cq}(\text{TestSample}) - \Delta\text{Cq}(\text{ReferenceSample})$$

$$\text{RQ} = 2^{-\Delta\Delta\text{Cq}}.$$

Statistical Analysis

Statistical analysis was performed using Statistica software version 6.0 (StatSoft Inc.). First, the normality was checked by the Kolmogorov–Smirnov test. The means of the different treatments were compared using two-way ANOVA and the statistic differences were carried out by Tukey test (*F*-test).

RESULTS

Rice Bran Enzymatic Extract Chemical Characterization

The enzymatic process of obtaining the new water-soluble biostimulant (RBEE) from rice bran has been previously shown (Parrado et al., 2006). The biological tool involved in the enzymatic process for obtaining the RBEE is subtilisine (EC 3.4.21.62). This protease extracts, solubilizes, and hydrolyzes the initial insoluble proteins in brans, reducing the size of original rice bran proteins to soluble peptides. This process also led to the solubilization of hydrophobic compounds as lipids and bioactive metabolites in an emulsion (w/o). The chemical composition is shown in Table 2.

The two major components in RBEE are the proteins and lipids in equal amounts. Protein fraction is mainly comprised of peptides <5 kDa (see Supplementary Figure SM1). These peptides interact with the lipid fraction that allows fatty acids and hydrophobic bioactive compounds such as polyphenols, phytosterols, tocopherols, and tocotrienols (Revilla et al., 2009) to be soluble in water, leading to a greater bioavailability.

Rice bran is rich in prominent bioactives such as phytosterols. Interestingly, our RBEE retains major phytosterols described in rice bran (Santa María et al., 2016), the most abundant phytochemical found being γ -oryzanol (Table 2).

Other bioactive molecules such as tocopherols and tocotrienols (vitamin E) are also present in rice bran. Seven homologs of tocopherols were identified in RBEE (α -, β -, γ -, and δ -tocopherols and α -, γ -, and δ -tocotrienols). Among these, γ -tocotrienols were the most abundant, followed by α -tocopherols and α -tocotrienols (Table 2).

Rice bran enzymatic extract components also include polyunsaturated fatty acids, so linoleic acid and linolenic acid constitute 35.76% of total fatty acid content (Table 2). Finally, RBEE also contains flavonoids (flavonols, 0.62 mg/g; flavanols, 2.90 mg/g) and phenolic acids (20.14 mg/g).

Accordingly, the enzymatic process increases the bioavailability of RB without losing bioactive components.

All data are presented as mean ± SD of three independent experiments.

Physiological Status in Plants

After the experiments, the physiological status in pepper plants was determined by assaying diverse parameters, such as net photosynthetic rate, chlorophyll content, and DF.

The net photosynthetic rate was significantly affected by O₃ exposure (**Figure 1A**). After the treatments with RBEE, plants showed similar values to the control plants indicating that the RBEE does not interfere with the photosynthesis. However, when the plants were exposed to O₃ this rate significantly decreased. This decrease was recovered by 88% in the plants exposed to O₃ and treated with RBEE.

The total chlorophyll content in plants was significantly affected by both O₃ exposure and RBEE treatment (**Figure 1B**). Leaves of control plants treated with ozone showed 4.6-folds less content of total chlorophyll than non O₃-exposed control plants. However, despite RBEE treatment did not recover the content of total chlorophyll under O₃ conditions, this treatment improved this content by 53%.

To monitor plant stress status, DF closely related to photosynthetic reactions and chlorophyll content was also measured (Zhang et al., 2019). Both RBEE treatment and O₃ exposure produced a significant decrease in DF emissions. The lowest measurements were detected in untreated, O₃-fumigated

FIGURE 1 | Physiological parameters. **(A)** Net photosynthetic rate (A_N) and **(B)** total chlorophyll content in pepper plants in response to two conditions of ozone (O_3) (0 and 100 ppm) under a treatment without and with rice bran enzymatic extract (RBEE). Values represent mean \pm SD, $n = 5$. Different letters indicate means that are significantly different from each other (two-way ANOVA, O_3 exposition \times RBEE treatment; HSD test, $P < 0.05$). O_3 exposition and RBEE treatment in the corner of the panel indicate main or interaction significant effects (* $P < 0.05$; ** $P < 0.01$; *** $P < 0.0001$).

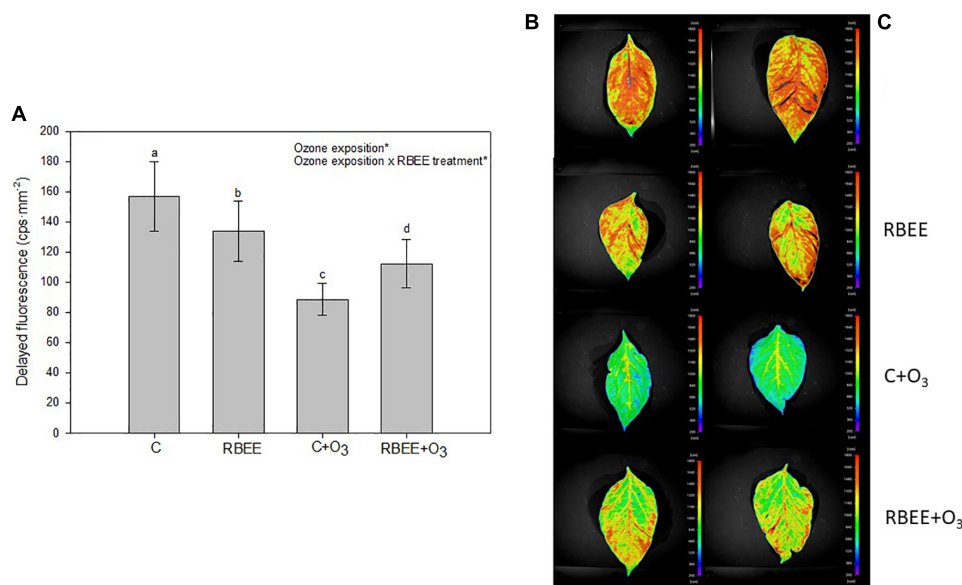

FIGURE 2 | Delayed fluorescence in leaves of pepper plants in response to two conditions of ozone (O_3) (0 and 100 ppm) under a treatment without and with rice bran enzymatic extract (RBEE). **(A)** Counts per second (cps) values for each treatment. Values represent mean \pm SD, $n = 5$. Different letters indicate means that are significantly different from each other (two-way ANOVA, O_3 exposition \times RBEE treatment; HSD test, $P < 0.05$). O_3 exposition and ozone exposition \times RBEE treatment in the corner of the panel indicate main or interaction significant effects (* $P < 0.0001$); **(B)** photographs taken by the plant imaging system NightShade LB 985. The color scale mirrors the detected counts per second (cps) of delayed fluorescence emission in leaves.

plants, and the RBEE and RBEE + O_3 plants showed a less substantial decrease in DF emissions than the C + O_3 plants (Figures 2A,B). Although O_3 also produced a loss of DF signals in the RBEE-treated plants, this decrease was much less marked compared to C + O_3 plants, highlighting a lower stress state of these plants.

These results suggest that RBEE protects plants against photosynthetic damages by O_3 exposure and maintain the physiological status of plants under these conditions. With the naked eye, although with less significant differences, we could also observe the attenuation of the visible foliar symptoms caused by ozone in the plants treated with RBEE before ozonization.

C + O_3 plants showed a more widespread chlorosis, as well as the appearance of small brown spots that were not present on RBEE + O_3 plants (Supplementary Figure SM2).

Oxidative Stress Level in Plants

To observe the oxidative stress after O_3 exposure and RBEE treatment, antioxidant enzyme activities were measured. Both variables had significant effects on these activities (Figure 3). As expected, O_3 -exposed plants showed a significant increase in their enzymatic activities in comparison with the control to alleviate the oxidative stress caused by ozone, underline that SOD and APX showed more activity than the other enzymes.

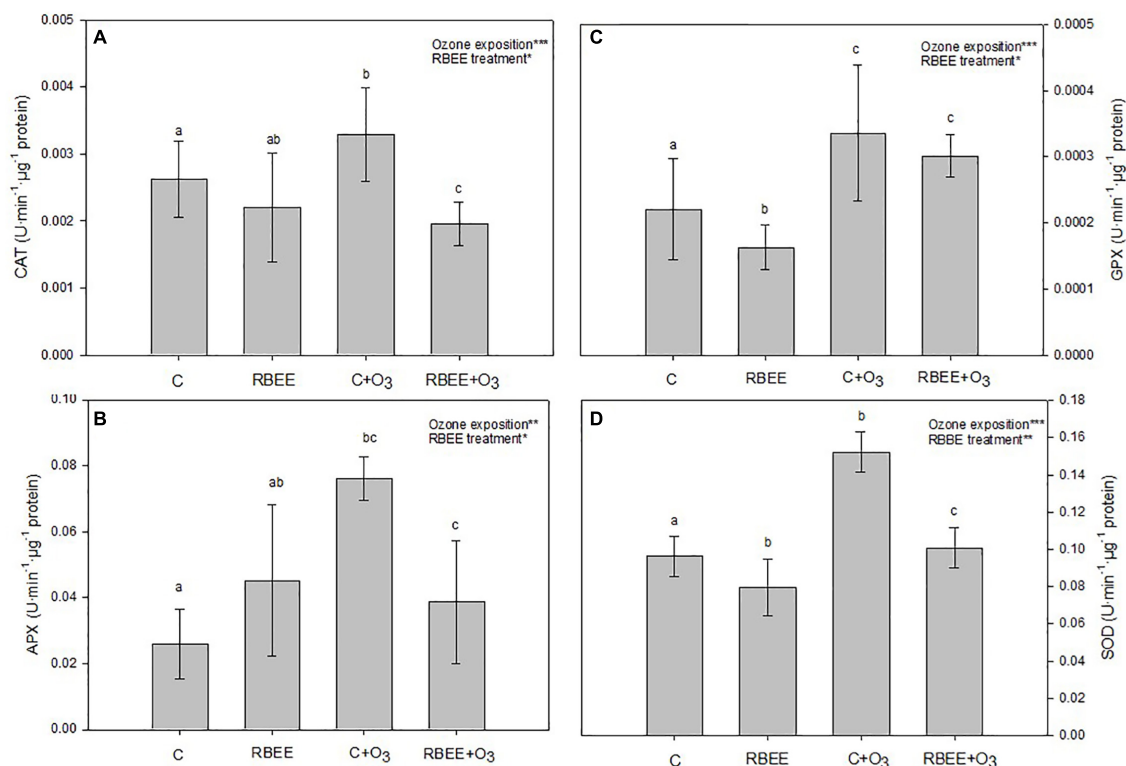

FIGURE 3 | Antioxidant enzyme activities. **(A)** Catalase (CAT), **(B)** ascorbate peroxidase (APX), **(C)** guaiacol peroxidase (GPX), and **(D)** superoxide dismutase (SOD) activities from leaves of pepper plants in response to two conditions of ozone (O₃) (0 and 100 ppm) under a treatment without and with rice bran enzymatic extract (RBEE). Values represent mean \pm SD, $n = 5$. Different letters indicate means that are significantly different from each other (two-way ANOVA, O₃ exposition \times RBEE treatment; HSD test, $P < 0.05$). O₃ exposition and RBEE treatment in the corner of the panels indicate main or interaction significant effects (* $P < 0.01$; ** $P < 0.001$; *** $P > 0.0001$).

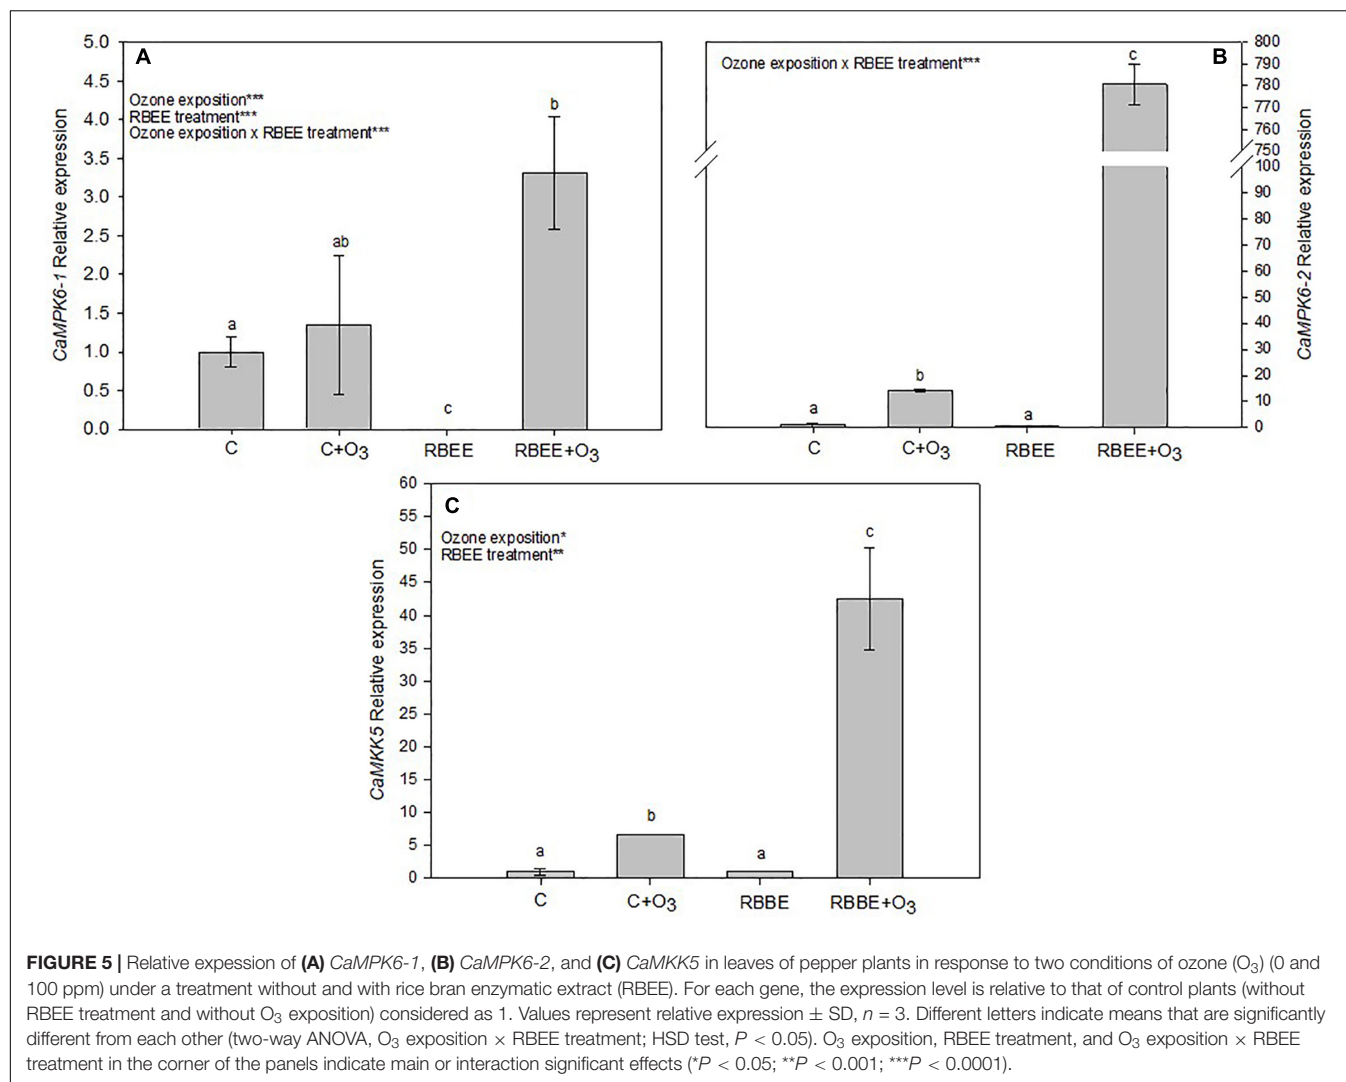

FIGURE 4 | Malondialdehyde concentration (MDA) **(A)** and oxidative stress index (OSI) **(B)** in leaves of pepper plants in response to two conditions of ozone (O₃) (0 and 100 ppm) under a treatment without and with rice bran enzymatic extract (RBEE). Values represent mean \pm SD, $n = 5$. Different letters indicate means that are significantly different from each other (two-way ANOVA, O₃ exposition \times RBEE treatment; HSD test, $P < 0.05$). O₃ exposition, RBEE treatment, and O₃ exposition \times RBEE treatment in the corner of the panels indicate main or interaction significant effects (* $P < 0.01$; ** $P < 0.001$).

Nevertheless, the activity of enzymes decreased both in an O₃ environment and when plants were treated with RBEE but no exposed to O₃, with the insignificant exception of the APX activity without ozone exposure (Figure 3B). In absence of O₃, the activities decrease 16, 26, and 17%, in CAT, GPX, and SOD, respectively. In O₃-exposed plants, the decreases were 41, 49, 10,

and 34% in CAT, APX, GPX, and SOD, respectively, being the APX activity the most affected.

To check the lipid peroxidation of plants, the content of MDA, commonly used as a marker of oxidative stress (Oszlányi et al., 2020), was measured in our leaf samples. As shown in Figure 4A, higher concentrations of MDA were recorded in

the C + O₃ plants, which presented a significant increase in MDA content compared to all other experimental plants. On the other hand, the plants sprayed with RBEE showed similar levels of lipid peroxidation to those of the control plants, showing the protective effect of RBEE treatment against oxidative stress caused by O₃ exposure.

All these positive effects of RBEE in plants in an O₃ environment were also reflected in the OSI (Figure 4B). The OSI shows that O₃-exposed plants treated with RBEE contain more similar stress levels to that of the control plants. These results support the protective effects of RBEE against O₃-induced oxidative damage. Furthermore, RBEE application in leaves did not produce any oxidative stress in pepper plants.

Mitogen-Activated Protein Kinase Genes Expression

This study also checked the expression of some MAPK genes involved in oxidative stress in plants (Liu and He, 2017). As suspected, expression of *CaMPK6-1*, *CaMPK6-2*, and *CaMKK5*

genes increased in leaves of O₃-exposed plants (Figure 5). RBEE did not give rise to the expression of these genes in plants in the absence of an O₃ environment. Surprisingly, however, after O₃ exposure, RBEE treated leaves showed a huge overexpression of these MAPK genes, these being expressions of 4.89, 55.31, and 6.39-folds higher than in the O₃-exposed control plant for *CaMPK6-1*, *CaMPK6-2*, and *CaMKK5* genes, respectively (Figure 5). This result could indicate that the O₃-oxidated RBEE produces the induction of gene expression by acting as a transcription inductor. However, this fact should be studied to understand the mechanism involved in this process.

DISCUSSION

Biostimulants have been defined as “a formulated product of biological origin that improves plant productivity as a consequence of the novel, or emergent properties of the complex of constituents, and not as a sole consequence of the presence of known essential plant nutrients, plant growth

regulators, or plant protective compounds” (Yakhin et al., 2017). Present results show a new product, an enzymatic extract from rice bran that protects against O₃-induced damage. O₃ treatment induces a decrease in net photosynthetic rate, chlorophyll content, and DF in pepper leaves which was partially reversed after foliar treatment with RBEE (Figures 1A,B, 2A, respectively). Thus, we can propose that RBEE may exert a biostimulant effect on pepper plants mainly based on its bioactive compounds.

Rice bran enzymatic extract, the enzymatically obtained extract from rice bran, shows a notable total antioxidant capacity (Revilla et al., 2009) and has been evaluated as a protector against lipid and protein oxidation in rat brain homogenate (Parrado et al., 2003). Additionally, we tested the antioxidant capacity of RBEE in two cell models: keratinocyte monolayers and reconstructed human epidermis both irradiated with UVB, and found that RBEE decreased lipid peroxidation in both systems (Santa-Maria et al., 2010).

Rice bran enzymatic extract is rich in prominent bioactive molecules. Many components of the extract may contribute to its antioxidant capacity. The most abundant phytochemical is γ -oryzanol, which is a natural antioxidant composed of ferulic acid esters of sterols and triterpene alcohols with high scavenging activity of free radicals, mainly mediated by ferulic acid moiety (Lemus et al., 2014; Minatel et al., 2016; Massarolo et al., 2017; Zduńska et al., 2018). RBEE also contains tocopherols (both tocopherols and tocotrienols) that act as antioxidants due to their ability to donate phenolic hydrogens (electrons) to lipid radicals (Xu et al., 2001). Polyunsaturated fatty acids which act as radical scavenging agents are also present in RBEE, contributing to the antioxidant activity. So, other natural substances such as *Rosa rubiginosa* oil (Franco et al., 2007), grape seed oil (Bail et al., 2008), and soybean-germ oil (Chen et al., 2019) are used for cosmetic purposes due to their polyunsaturated fatty acid content, which acts as a radical scavenging agent.

Rice bran enzymatic extract is also rich in PHs. PHs exhibit different antioxidant and free radicals scavenging activities (Li et al., 2008), mainly conferred by some nitrogenous compounds contained therein such as glycine, betaine, and proline (du Jardin, 2015). Moreover, PHs have shown an ability to enhance antioxidant mechanisms in plants (Gurav and Jadhav, 2013). It is worth noting that PHs, mainly those resulting from the enzymatic hydrolysis of protein substrates into low molecular weight peptides and free amino acids, have shown multiple biostimulant capabilities. Protein hydrolysates are included within the biostimulant classification (du Jardin, 2015). The direct effects in plants include modulating N uptake and assimilation, acting on signaling pathways in the root, regulating enzymes involved in this process (du Jardin, 2015), possessing hormonal activity similar to auxin and gibberellin (Colla et al., 2014), and producing antioxidant activity (Li et al., 2008; Gurav and Jadhav, 2013). In addition, when applied to soils, PHs have shown indirect effects on plant growth and nutrition by increasing the availability of nutrients and their acquisition by the roots – enhancing the microbial activity and biomass of the soil, soil respiration, and their fertility in general (du Jardin, 2015; Rodríguez-Morgado et al., 2015).

It is worth noting that mixture of these bioactive molecules, as is the case of RBEE, has been reported to greatly enhance the antioxidant activity of rice bran oil (Perez-Ternero et al., 2017).

According to the RBEE antioxidant capacity, we have selected an acute O₃ treatment as an abiotic stressor. O₃ is degraded in the apoplast into secondary ROS (Vainonen and Kangasjärvi, 2015) and high levels of ROS can lead to ROS stress that induces the enzymatic and non-enzymatic systems that protect cells from ROS (Sachdev et al., 2021). Accordingly all the enzymatic activities assayed – CAT, GPX, APX, and SOD – were induced after O₃ treatment. Induction was significantly reversed by the foliar treatment with RBEE (Figure 3). The effect on enzymatic activities could be correlated with the antioxidant effect of RBEE, thus the lipid peroxidation induced by O₃ treatment was significantly alleviated by RBEE (Figure 4A). Consequently, the antioxidant effect is reflected in the OSI values (Figure 4B).

Unlike other enzymes assayed, a surprising result was the induction of APX after the application of RBEE in plants not treated with O₃ (Figure 3B). We can speculate that this APX induction may be due to a hormetic effect induced by RBEE, stimulating a cellular system that could be essential for plant defense under stress. At the physiological level, hormesis is an adaptive response of an organism to a low-level stress factor accompanied by over-compensation when homeostasis is interrupted (Mattson, 2008; Calabrese, 2009; Wiegant et al., 2012). Hormesis is the cellular response in plants that occurs after an initial exposure to low levels of biotic or abiotic stressors – such as herbicides, temperature, chemicals, and radiation – which predisposes them to stimulate cellular defense mechanisms at subsequent sources of stress (Agathokleous and Calabrese, 2020; Berry and López-Martínez, 2020). For example, low doses of some herbicides such as 2,4-dichlorophenoxyacetic acid, glyphosate, and paraquat have been shown to trigger auxin production and antioxidant defense. The biostimulant-induced hormesis response of beneficial organisms allows plants to tolerate stress (Ahkami et al., 2017) through activation of secondary metabolisms and gene expression to recover homeostasis (Vargas-Hernandez et al., 2017). Application of biostimulants at right time can therefore facilitate increased plant growth while combined application of multiple biostimulants can be effective in reducing environmental drastic impacts (Dong et al., 2020).

In plants, the mechanism of hormesis is still unknown. The most probable pathways for hormetic responses are the induction of ROS by mild stress which leads to the activation of antioxidant defenses, stress-signaling hormones, or adaptive growth responses (Poschenrieder et al., 2013). Thus, induction of low and sub-toxic concentrations of ROS by mild stressors, such as which occurs as a result of foliar application of RBEE, has shown the ability to develop a hormetic effect, activating antioxidative defense and adaptive responses. RBEE is rich in 18C-unsaturated fatty acids (UFAs): oleic (18:1), linoleic (18:2), and α -linolenic (18:3) acids (Table 2). Besides their roles as ingredients and modulators of cellular membranes, reserves of carbon and energy, stocks of extracellular barrier constituents (e.g., cutin and suberin), or precursors of various bioactive

molecules (e.g., jasmonates and nitroalkenes), recent works have pointed the role of 18C-UFAs as regulators of stress signaling (He and Ding, 2020). Oleic acid has been implicated in plant immunity against pathogens (Mandal et al., 2012). Even more, linoleic acid may regulate plant defense through ROS production (Yaeno et al., 2004). In this context, we can assume that RBEE application may induce a mild increase in ROS due to UFAs content that underly the induction of APX activity.

Ascorbate peroxidase is an H_2O_2 -scavenging enzyme and is indispensable for the protection of chloroplasts and other cell constituents from damage by H_2O_2 and hydroxyl radicals (OH \cdot). APX has been identified in most higher plants and comprises a family of isoenzymes present in different plant cell compartments, including apoplast (Sofa et al., 2015). As compared to catalase, it is more vital in stress as it has a high affinity for hydrogen peroxide (Afzal et al., 2014). Accordingly, we have found that APX activity exceeds catalase activity 10 times (**Figures 3A,B**). After O_3 enters the leaves through the stomata, it rises to the apoplast where it is immediately degraded into secondary ROS. Detoxification of ROS in the apoplast can therefore be considered as an early line of defense against O_3 (Kangasjärvi et al., 2005; Castagna and Ranieri, 2009). APX uses ascorbate as its specific electron donor to reduce H_2O_2 to water. Ascorbate is believed to be the major redox buffer and ROS scavenger in the apoplast (Foyer and Noctor, 2009). Thus, we can speculate that pretreatment with RBEE induced ROS generation that slightly stimulates APX activity, probably at the apoplast, the gate of entrance, that facilitates posterior induction and consequently protection against O_3 exposure. The APX result could be working in tandem with the decrease in chlorophyll content and DF found in the same group of plants (**Figures 1B, 2A**). This effect could be due to linoleic acid present in RBEE as it has been shown that linoleic acid decreased the chlorophyll concentration and photosynthetic efficiency in *Cylindrospermopsis raciborskii* (Xu et al., 2016).

Protein phosphorylation mediated by protein kinase cascades is one of the most important post-translational modifications that coordinate response in cells. One relevant protein-kinase based amplification cascade is the MAPK cascade. The MAPK cascade is a complex signaling pathway hierarchically organized at least three sequentially acting serine/threonine kinases – a MAP kinase kinase kinase (MAPKKK), a MAP kinase kinase (MAPKK), and finally, the MAPK itself – with each phosphorylating, and hence activating, the next kinase. In this cascade, MAPKs phosphorylate specific substrate proteins, such as transcription factors and enzymes, and subsequently trigger cellular responses and rapidly transform upstream signals into appropriate intracellular responses (Liu et al., 2015). MAPK cascade is involved in many aspects of plant physiology, including cell division (Komis et al., 2011), plant growth and development (Xu and Zhang, 2015), plant resistance to pathogens (Bigeard et al., 2015) and insect herbivores (Hettenhausen et al., 2015), and plant response to abiotic stresses (Liu, 2012; Smékalová et al., 2014). It has been described as an interplay between MAPK cascade and ROS; so exogenous application of H_2O_2 or O_3 activates components of MAPK cascades. On the other hand, manipulating MAPK cascades results in initiation of ROS responses (Šamajová et al., 2013). In this context, the present

work analyses the role of the MAPK cascade in the protective effect of RBEE against O_3 damage.

The majority of MAPK and MAPKK members are constitutively expressed in pepper plants. In leaves, the transcript level of *CaMPK1* is the highest, followed by *CaMPK6-2*, and *CaMPK19-2*. Among MAPKK genes, *CaMKK5* exhibits the highest transcript levels. Under the challenges of heat shock, salt stress, or pathogen inoculation, most of the MAPKs and MAPKKs in the pepper genome were significantly transcriptionally modified (Liu et al., 2015). Accordingly, after O_3 exposure, we found induction of the studied MAPKs. It is worth noting the relevant role that MPK3/MPK6 play in ROS response and O_3 sensitivity. AtMPK3/AtMPK6 in *A. thaliana* (Ahlfors et al., 2004) and the orthologs SIPK/WIPK in tobacco (Marcus et al., 2000), have been found to regulate for O_3 sensitivity; in fact RNAi-mediated silencing of MPK6 renders the plant more sensitive to O_3 (Miles et al., 2005). In these lines we found increased CaMAPK6-1 and CaMAPK6-2 after pepper plants exposition to O_3 . Moreover, induction of CaMKK5 may be related to CaMAPK6-1 and CaMAPK6-2. It has been described in *Arabidopsis* that MKK5 was involved in MPK3/MPK6 activation in response to O_3 exposure (Vainonen and Kangasjärvi, 2015) and interestingly in pepper CaMPKK5 interacts with CaMPK3, CaMPK6-1, and CaMPK6-2 (Liu et al., 2015). But surprisingly, after O_3 exposure, RBEE treated leaves showed a huge expression of these MAPK genes, being higher than in the control plants under O_3 in *CaMPK6-1*, *CaMPK6-2*, and *CaMKK5* genes (**Figure 5**). As previously indicated, the MAPK cascade is involved in many aspects of plant physiology including the defense response against stress. The presence of multiple genes' family members in genomes of different plant species encoding for MAPKKKs, MAPKKs, and MAPKs, and the fact that one MAPK cascade may be associated with more than one upstream or downstream partner (Liu et al., 2015) made it difficult to elucidate specific mechanism mediated by MAPK modules. How ROS activates MAPK cascades still remains unclear. It is possible that plants not only use MAPK cascades to transduce ROS signaling to gene expression and sometimes cell death, but also initiate the negative feedback regulation by MAPK cascades to maintain ROS homeostasis. The different combinations of the three tiers of kinases, distribution, time point-dependent activation, strength, duration, and availability of substrates of MAPK cascades may determine the feed-forward or feed-back outcomes (Liu and He, 2017). However, our results unequivocally indicate that both the damage induced by O_3 and the activation of the protection systems against it induced by RBEE take place through the transcriptional induction of the MAPK cascade.

CONCLUSION

Rice bran enzymatic extract, an enzymatic extract of plant origin, reversed the O_3 -induced decrease in physiological parameters as net photosynthetic rate, chlorophyll content, and DF. Thus, the results of our study highlight the potential use of RBEE as an effective biostimulant plant protector against oxidative stress caused by O_3 . Present results also point out that MAPK cascade

is involved in both, O₃-induced damage and RBEE protection. However, more studies are needed to clarify how this kinase pathway is involved.

Thus, we contribute to the general efforts done in the last decade searching new non-chemical alternative products to protect crops against damages caused by environmental oxidative stress.

As the market indicates a growing interest in organically grown fruit, there is a need for biostimulants to counter the adverse effects of pathogenic fungi and fungal-like-pathogens. Four microbial pathogens (*Botrytis cinerea*, *Verticillium* sp., *Phytophthora* sp., and *Colletotrichum* sp.) which are the most often causes of strawberry diseases were selected. Five kinds of biostimulants (C1, C2, C3, C4, and C5) containing bacterial consortia were developed to combat the pathogens. The antagonistic effect of selected microorganisms against strawberry pathogens was observed. The effectiveness of various beneficial bacteria in combating fungal pathogens of cv. Honeoye strawberries was compared and the impact of their activity on fruit quality was assessed. The most significant effect on the strawberry firmness was found for the C2 consortium, which provided the strawberries infected with the pathogens group (MIX: *B. cinerea*, *Verticillium* sp., *Phytophthora* sp., and *Colletotrichum* sp.) with a 140% increase in maximum load in a puncture test compared to the positive control (C0). Strawberries contaminated with *Phytophthora* sp. after the application of Consortium C4 (C4) showed the largest increase (127%) in soluble solid content (SSC) when compared to the C0. Fruit contaminated with *Colletotrichum* sp. and *B. cinerea* after the application of C2 and Consortium 5 (C5), respectively, had the highest levels of anthocyanins and total phenolic content, when compared to C0. The largest increase, which reached as high as 25%, in D-galacturonic acid content was observed for the group of pathogens after Consortium 1 (C1) application. The extraction of strawberry pectin allowed for the study of the rheological properties of pectin solutions; on this basis, strawberry pectin from the control (NC) was distinguished as it showed the highest viscosity (0.137–0.415 Pas). Taking into account the individual effects of bacteria on strawberry pathogenic fungi and fungal-like-pathogens, it is possible to reduce the adverse effects of fungal disease and to improve the properties of strawberries by selecting the appropriate bacterial consortium. Interactions between microorganisms are often complex and not fully understood, which suggests the need for further research in this direction.

Keywords: antagonistic microorganisms, pectin, strawberry, organic fruit, biostimulants

INTRODUCTION

The strawberry is one of the most frequently preferred fruit by consumers due to availability year around and suitable for both organic and conventional production (Balci, 2021; Juric et al., 2021). Excessive pesticide use in conventional crops may lead to their accumulation in the fruit. For this reason, alternative control measures, which include the biopesticides or antagonistic microorganisms (Jensen et al., 2013). The organic farming system differs from the conventional one in prohibition of synthetic plant protection products (pesticides) and mineral fertilizers. The chemical plant protection products are replaced with organic fertilizers, which contain, among others, manure, compost, green manure, beneficial microorganisms (Ponder and Hallmann, 2019). In the context of organic fertilizers, the concept of biostimulants appears. Biostimulants are defined by the European Biostimulants Industry Council as “substance (s) and/or microorganisms whose function, when applied to plants or the rhizosphere, is to stimulate natural processes to increase/benefit nutrient uptake, nutrient efficiency, tolerance to abiotic stress, and quality of the crops” (European Biostimulants Industry Council [EBIC], 2021). It has been proven that biostimulants increase plant yield and improve fruit quality. Additionally, consumers are more interested in ecological products each year, bearing in mind the safety of food and the environment (Kovačević et al., 2015).

The microbiota present on healthy strawberries is complex and includes potential plant pathogens, human pathogens, mycotoxin-producing moulds and plant disease biocontrol agents (Jensen et al., 2013). Some of these microorganisms are antagonistic to the others. Notable bacterial antagonism against pathogenic fungi occurs with considerable frequency and is the result, among other causes, of the production of antibiotics and biosurfactants, as well as competition and parasitism (Berg et al., 2000). The mechanisms of action differ depending on the bacterial strain. The most common strawberry pathogens include fungi from the genera *Botrytis*, *Verticillium*, *Phytophthora*, *Colletotrichum*, *Penicillium*, *Alternaria*, *Cladosporium*, *Rhizopus*, *Aureobasidium*, and *Cryptococcus* (Tournas and Katsoudas, 2005). Bacterial populations on strawberry plants are dominated by *Pseudomonas* spp., *Stenotrophomonas* spp., *Bacillus* spp., and *Arthrobacter* spp. (Krimm et al., 2005).

One of the main strawberry postharvest diseases is grey mould which is caused by *Botrytis cinerea*. A grey coating appears on the leaves and fruit causing the plants to die off and the fruit to dry and rot (Jin et al., 2017). Research results suggest that the following microorganisms are active in combating grey rot: *Clonostachys rosea* (Cota et al., 2009), *Rhodotorula glutinis* (Srivastava et al., 2011), *Paenibacillus polymyxa* (Santiago et al., 2016), *Bacillus* sp. (Cruz et al., 2018), *Streptomyces* sp. (Kim et al., 2015), and *Pseudomonas* sp. (Haggag and Abo El Soud, 2012). The withering of strawberry plants is mainly caused by *Verticillium dahliae*, which attacks the plant's vascular system and blocks the transport of water and nutrients (Sowik et al., 2001). Research indicates that *P. polymyxa* (Zhang et al., 2018), *Bacillus* sp. (Milijasevic-Marcic et al., 2018), and *Streptomyces* sp. (Olanrewaju and Babalola, 2019) are disease-inhibiting

bacteria. Fungus-like pathogens of the genus *Phytophthora* including *Phytophthora megasperma*, *Phytophthora cryptogea*, *Phytophthora capsici*, *Phytophthora Citricola*, and *Phytophthora cactorum* can cause diseases of the root, crown and strawberry fruit. Infected plants suddenly lose healthy shoots. A relatively rare disease is red stele in strawberries (*Phytophthora fragariae*). Infected plants become stunted and the leaves turn yellow or red (Wilcox et al., 1993). *Streptomyces griseus* has shown promising results as an antifungal agent against *P. capsici*, as it produces numerous antibiotics that inhibit mycelium growth of *P. capsici*, *Pythium* spp., *Phytophthora* spp., *Rhizoctonia solani*, *Alternaria brassicicola*, and *Botrytis* sp. (Nguyen et al., 2015). The fungi belonging to the species of *Colletotrichum asianum*, *Colletotrichum fructicola*, *Colletotrichum tropicale*, *Colletotrichum dianesei*, *Colletotrichum karstii* (Lima et al., 2013), *Colletotrichum gloeosporioides* (Tang et al., 2019), and *Colletotrichum acutatum* (Moreira et al., 2014) cause anthracnose of fruit, which in the case of strawberries is manifested by the appearance of dry spots on immature fruit, and the browning and drying of flowers and shoots (Lima et al., 2013). It has been shown that the fungi *Aureobasidium pullulans*, *Diaporthe* sp., and *Nigrospora oryzae* inhibits the development of *C. acutatum* (Landum et al., 2016). Useful fungi and bacteria limit the growth and development of pathogens by activating antagonistic mechanisms such as parasitism, antibiotics, and competition (Poveda et al., 2020).

We investigated the impact of various biostimulants containing fungi and bacteria on the quality characteristics of strawberry fruit infected with microbial pathogens. The experiment included four fungal pathogens responsible for the most common strawberry diseases. Bacterial consortia with potentially antagonistic effects were applied to the infected plants infected with *B. cinerea*, *Verticillium* sp., *Phytophthora* sp., and *Colletotrichum* sp. The results allow for a preliminary selection of microorganisms that can be used to combat strawberry fungal diseases.

MATERIALS AND METHODS

Crop Conditions

The experiment was set up in triplicate for each of the 36 variants (Figure 1) and the research material consisted of strawberry cv. Honeoye. Each strawberry plant was grown in a separate pot without undercutting or root curling in a greenhouse at 23°C. Each pot contained 4 kg of soil collected from an organic experimental field of the Institute of Soil Science and Plant Cultivation - State Research Institute (Puławy, Poland) located in Grabów (Poland) and it was subjected to chemical and microbiological analysis. The soil was characterized as Cambisol with a loamy sand texture. Clover was used as a pre-crop. The soil composition was as follows: humus 1.9%, P₂O₅ 10.1 mg 100 g⁻¹ soil, K₂O 5.0 mg 100 g⁻¹ soil, Mg 10.6 mg 100 g⁻¹ soil, N-NO₃ 8.92 mg kg⁻¹ DM of soil, N-NH₄ 2.29 mg kg⁻¹ DM of soil, pH 5.9. Keramzite was placed at the bottom of each pot in a volume of 0.5 l. The soil was fertilized in autumn with manure (pH = 8.6, nutrient content: N 5.06 mg kg⁻¹, P₂O₅ 2.47 mg

kg^{-1} , K_2O 6.90 mg kg^{-1} , CaO 3.04 mg kg^{-1} , MgO 2.38 mg kg^{-1} , S 0.69 mg kg^{-1}) and potassium salt (LUVENA, 100 kg ha^{-1}). Bioilsa® (NaturalCrop, Poland) fertilizer was applied in a quantity corresponding to a dose of 150 kg ha^{-1} .

Plants were treated with five consortia (C1, C2, C3, C4, and C5) and a control (C0) was prepared, in which no consortia were applied (Figure 1). The consortia consisted of the following bacterial strains: AF117AB (*P. polymyxa*), Sp115AD (*Bacillus subtilis*), AF75AB2, Sp115AD, AF75BC (*Bacillus* sp.), AF75AA, AF75AD (*Streptomyces* sp.), JAFGU (*Lysobacter* sp.), and AF70AC (*Pseudomonas* sp.). The bacterial strains used in the experiment originated from the SYMBIOBANK collection of the Research Institute of Horticulture in Skierniewice and were selected based on a previous study as microorganisms with potentially beneficial properties in terms of plant biostimulation and protection. The bacterial consortia, with a population size of 10^8 cfu (colony-forming units) in 1 ml, were applied to the soil in a volume of 10 ml per pot directly to the roots at planting time and twice after planting at intervals of 3–4 weeks. The objects called “Consortium C0,” in which bacteria were not introduced, were the control for the ones containing bacterial consortia with their potential for plant biostimulation and protection, while NC objects constituted controls without pathogen contamination.

The next step was the infection of plants with five phytopathogenic fungi and fungus-like pathogens (BC, V, P, C, and MIX) and the submission of the control (NC) in which the plants were not treated with pathogens (Figure 1). Two days after plant inoculation with bacterial consortia, the plants were infected with the following pathogens: G277/18 (*Botrytis cinerea*), G296/18 (*Verticillium* sp.), G408/18 (*Phytophthora* sp.), G171/18 (*Colletotrichum* sp.). Strains of *B. cinerea*, *Phytophthora* sp., and *Verticillium* sp. were isolated from infected strawberry roots (Osztust et al., 2020), while *Colletotrichum* sp. was isolated from infected strawberry fruit (Malarczyk et al., 2020) at the Institute of Agrophysics of the Polish Academy of Sciences (Lublin, Poland). In the case of *B. cinerea* and *Colletotrichum* sp. the strawberry flowers were infected with 10 ml of pathogen suspension using an inoculum adjusted to 1,000 conidia in 1 ml. In contrast, *Phytophthora* sp. and *Verticillium* sp. were added to the soil as a pathogen inoculum suspension of 10^5 cfu ml^{-1} (10 ml was applied) and 10^4 cfu g^{-1} of soil, respectively.

At the harvest maturity stage, the strawberries (developed and grown, and the sepals easily detach from the stalk) were collected on March 23, 2019.

Firmness

Firmness is one of main parameter of texture which determine overall quality evaluation by consumers (Harker et al., 2003). For soft fruit puncture test is the most common method used for determination of firmness (Døving and Måge, 2002). Fresh fruit firmness (n) was determined by a puncture test by using a universal test machine (Lloyd LRX, Lloyd Instruments). The strawberry was placed on the platform of the device and the aluminium probe (3 mm diameter) was lowered with a constant plunger speed (20 mm min^{-1}) to a constant depth (6 mm). The maximum force required to penetrate the strawberry to a set

depth was a measure of tissue firmness (Fraeye et al., 2009). The test was carried out on twenty strawberries for each replicate of the variant. Average fruit firmness was expressed in terms of N.

Shape

The shape of the fruit is a hormone-regulated trait and many factors can alter the final shape including environmental conditions (Rey-Serra et al., 2021). The shape was determined in accordance with the method proposed by Ishikawa et al. (2018). The length (the longer dimension was measured from the fruit's tip to the base) and width (the shorter dimension of the fruit, was measured as a transverse measurement at the thickest point) of the fruit were determined. The quotient of length and width was calculated. Fruits are classified as flattened (quotient < 1), round (quotient = 1), or oblong (quotient > 1). The test was carried out on fifteen strawberries for each replicate of the variant.

Fresh Weight of Fruit

Fresh weight is the weight of the fruit on the day it is harvested. It is determined by a weight method to initially determine the size of the fruit (Reyes-Yanes et al., 2020). The purpose of determining the fresh weight is to obtain information on the effectiveness of the cultivation methods. Comparison the fresh weight, dry weight and shape provides information on the hydration level of the fruit and the tissue density (Miller et al., 2000). To determine the fresh weight of fruit (FWF), each fruit was weighed to three decimal places. The results were summed and averaged. The average fresh fruit weight was expressed in g.

Dry Weight of Fruit

The dry matter allows the determination of the product residue after the removal of water from it (Ozdemir and Topuz, 2004). The drying oven method is a validated standardized method that is readily available (International Organization for Standardization, 2000). Dry weight (DW) was determined according to the procedure described in standard PN ISO 1026:2000 (International Organization for Standardization, 2000). In Brief, 0.5 g of strawberries were taken from each variant in triplicate and weighed to the nearest 0.001 g. The strawberries were then placed in an oven at 105°C , after 24 h the fruit was weighed, placed in the oven for 2 h and weighed again. The procedure was repeated until no further weight loss was noted. The average dry weight of one fruit was expressed as a percentage of fresh weight.

Soluble Sugar Content

The soluble solid content (SSC) is a measure of the total soluble solid, which includes sugars, organic acids, amino acids, and more, and it is associated with consumer preference for fruit (Crisosto et al., 2003). The refractometric method is used because of the optical properties of sugars and sugar alcohols which are majority of soluble solids of most fruit (Magwaza and Opara, 2015). SSC was determined using a refractometer (PAL-BX/RI, ATAGO, Japan) and expressed in percentage terms. A minimum of five fresh strawberries were picked and juiced. One drop of juice was applied to the refractometer glass and the measurement

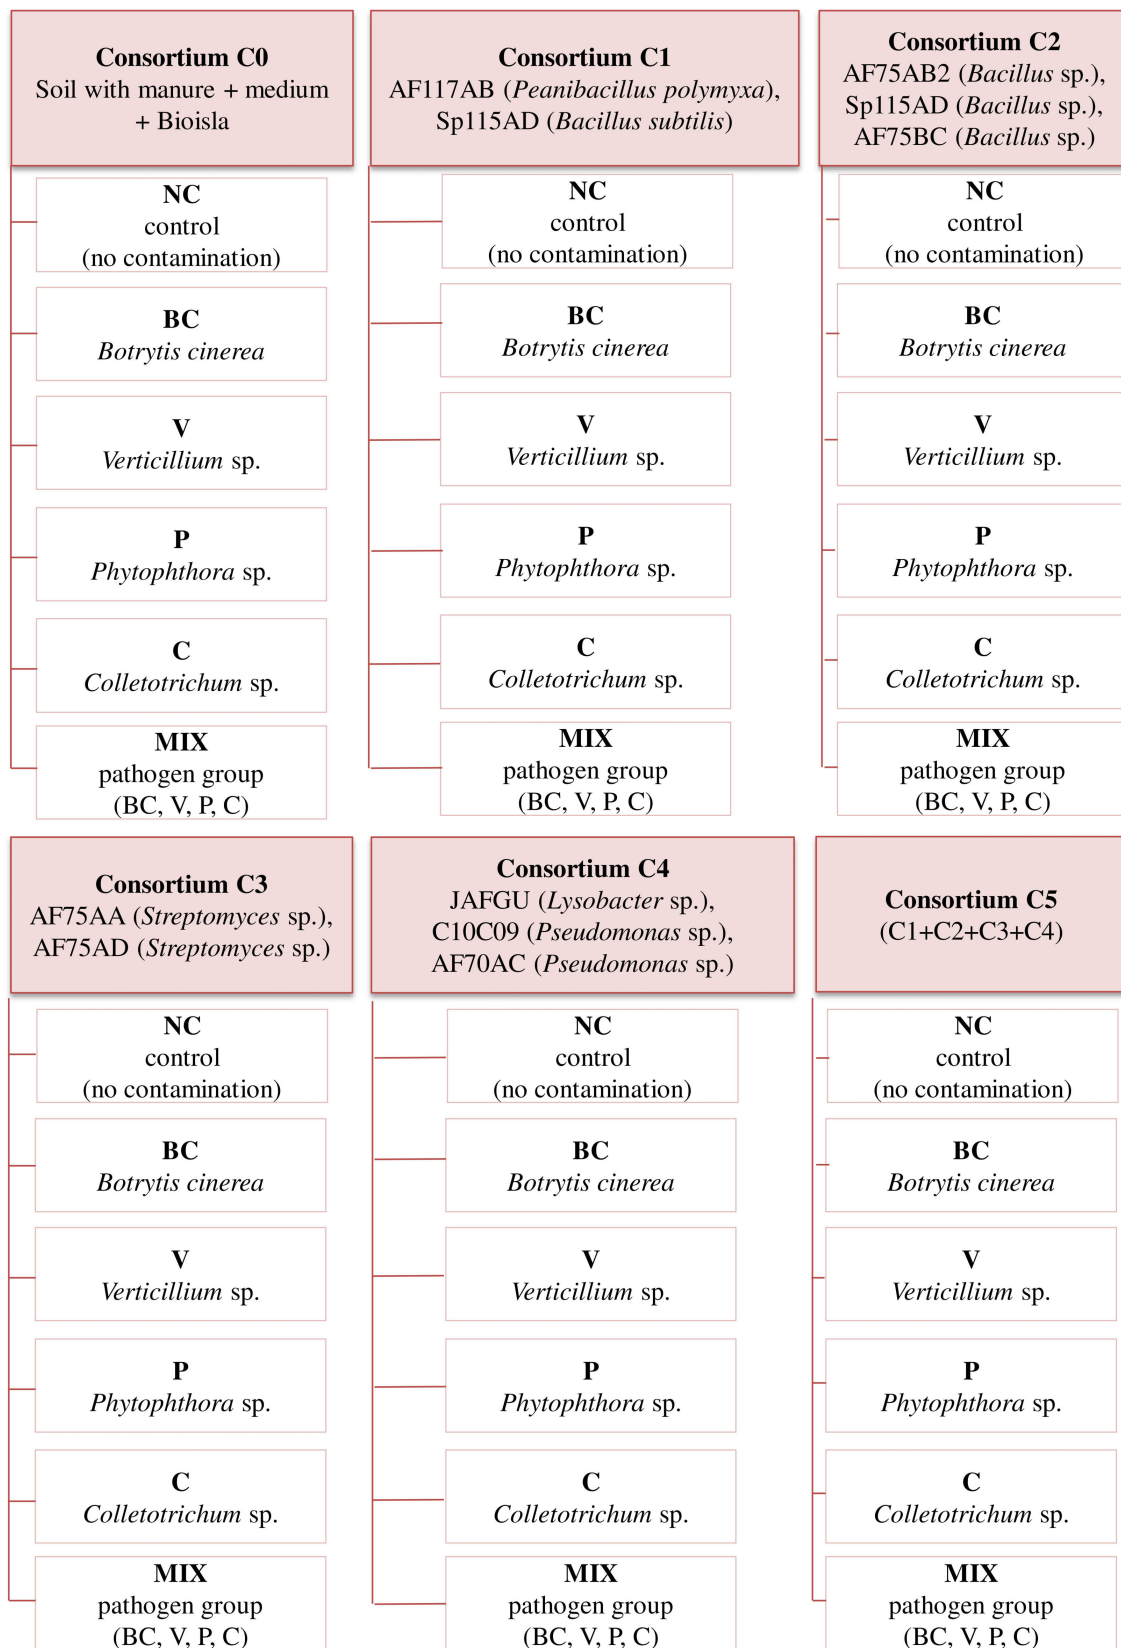

FIGURE 1 | Experimental design outlining 36 variants of the experiment.

was performed; the soluble sugar content was expressed in percentage terms. The measurement was performed in triplicate for each variant of the experiment.

Total Phenolic Content

Due to the strong antioxidant activity of most phenolic compounds in fruits, the total polyphenol content is determined for the evaluation of health-promoting properties. The Folin-Ciocalteu method has been used for many years and is still relevant today due to its high accuracy (Carmona-Hernandez et al., 2021). Phenolic compounds (PC) were determined according to the procedure proposed by Folin and Ciocalteu (1927) and Nunes et al. (2001), with some modifications. From each variant of the experiment, five fruit were taken in triplicate and then juiced. Then, 0.5 ml of the clear juice was diluted by adding 9.5 ml of deionized water. The resulting solution was spiked with 5 ml of Folin-Ciocalteu reagent (1:9 dilution) and 4 ml of sodium carbonate (0.075 g ml^{-1}). The mixture was left to stand for 30 min at 30°C , and then transferred to an ice bath (0°C) for 30 min. The absorbance of the solutions was measured at 760 nm. The content of phenolic compounds was determined using gallic acid solution as a standard, and the phenol concentration was expressed in $\text{mg } 100 \text{ g}^{-1} \text{ FW}$.

Anthocyanins Content

Anthocyanin is natural dye responsible for the color of the fruit and belongs to antioxidants which demonstrate health beneficial properties. The spectrophotometric method based on the reversible discoloration of anthocyanin depending on the pH is commonly used to measure the anthocyanin content (Johnson et al., 2020). The anthocyanins content (AC) was determined according to a previous procedure described by Nunes et al. (2001) and consisted of measuring the content of pelargonidin-3-glucoside [the main pigment in strawberries (Nunes et al., 2001)]. For each variant, 2 g of strawberry pulp was collected in triplicate. Subsequently, 18 ml of 0.5% (v/v) HCl in methanol was added to the pulp and the mixture was incubated in a refrigerator (4°C) for 1 h to extract the pigment. After incubation, the mixture was centrifuged and the supernatant was used to determine the anthocyanin content through the use of spectrophotometry at 520 nm. The anthocyanin content was calculated using the following formula: $A_{520} \times \text{dilution factor} \times [\text{molecular weight of pelargonidin-3-glucoside (PGN)}/\text{molar extinction coefficient (MEC)}]$, where $\text{PGN} = 433.2$, $\text{MEC} = 2.908 \times 10^4$. The result was expressed in terms of an average of three repetitions in terms of $\text{mg } 100 \text{ g}^{-1} \text{ FW}$.

Pectin Extraction

Pectin are one of the basic components of the cell wall. It has been shown that oxalate-soluble pectin play a significant role in shaping the texture of the fruit, which directly affects, among others, resistance to mechanical damage (Makarova and Shakhmatov, 2020). Strawberry pectin analysis was carried out according to the procedure proposed by Koubala et al. (2008) and Min et al. (2011) with some modifications. 1 g of pulp was taken in triplicate from each experimental variant. 35 ml of 0.25% ammonium oxalate ($\text{pH} = 4.6$) was added to the pulp and the

mixture was transferred to a water bath (85°C) for 1 h. After incubation, the mixture was centrifuged ($20,000 \times g$) for 10 min and the supernatant was collected. Three volumes of 96% ethanol were added to the supernatant and the solution was incubated in a refrigerator (4°C) for 24 h. The next step was to centrifuge ($20,000 \times g$, 10 min) the solution and discard the supernatant. The remaining residue contained pectin, it was washed twice with 96% ethanol, dried and used to determine the D-galacturonic acid content.

Galacturonic Acid Content

Content of galacturonic acid as the main component of pectin determines suitability of fruit for processing (gelling, production of ascorbic acid) (Ben Abdallah et al., 2018). The content of D-galacturonic acid (GalA) in strawberries was determined using a continuous flow analyser (CFA), SanPlus (Skalar, Netherlands) according to the procedure recommended by the manufacturer. The applied automatic colorimetric method of measurement of GalA content is based on a color reaction, where the color intensity is measured at a wavelength of 520 nm (Ognyanov et al., 2021). 10 mg of dried pectin was dissolved in 12 ml of deionised water. The resulting solution was diluted 10 times and the D-galacturonic acid content was determined. The result is expressed in $\text{g kg}^{-1} \text{ DW}$.

Rheological Properties

The rheological properties, which demonstrate the relationship between the structural, mechanical and sensory properties, are among the basic parameters of pectin (Xie et al., 2021). The rheological properties were measured using a Discovery HR-1 hybrid rheometer (TA Instruments, United States) with a cone-plate sensor. In brief, 1% aqueous solutions of strawberry pectin extracted with ammonium oxalate were prepared according to a procedure described elsewhere (Koubala et al., 2008; Min et al., 2011). For each variant of the experiment, pectin solutions were prepared in triplicate and each measurement was carried out at a temperature of $20 \pm 0.5^\circ\text{C}$. Viscosity was measured at a constant shear rate of 10 s^{-1} (three repetitions), and the flow curves were determined based on measurements at variable shear rates of 10 and 600 s^{-1} . Flow curves were described using the Ostwald-de Waele model as represented by the following equation:

$$\sigma = k\gamma^n$$

where σ is shear stress (Pa), k is consistency index (Pa s^n), γ is shear rate (s^{-1}) and n is flow behaviour index.

Antagonistic Properties of Consortia Against Fungal Pathogens

Antagonistic properties of consortia against fungal pathogens are determined in order to test the effectiveness of the tested bacterial consortia in combating fungal and fungal-like pathogens in the strawberry (Win et al., 2021). *In vitro* confrontations of four separate bacterial consortia and their mixtures (C5) against four selected phytopathogenic fungi and fungal-like-pathogens were set up using the plate culture method (Petri dish diameter 90 mm) with potato dextrose agar (PDA). Paper discs (5 mm diameter)

were surface sterilized with UV light, dipped in 30 µl of bacterial consortia suspension (10^8 cfu ml⁻¹) and placed in duplicates on Petri dishes inoculated with fungal pathogens. The pathogen inoculation included 150 µl of inoculum of a 7-day old culture of *B. cinerea* G277/18, *Phytophthora* sp. G408/18, *Verticillium* sp. G296/18, and *Colletotrichum* sp. G171/18 suspended with 10 ml of sterile water. The concentration of *B. cinerea* and *Colletotrichum* sp. was 10^3 jtk ml⁻¹, *P. cactorum* 10^5 jtk ml⁻¹, and *Verticillium* sp. 10^4 jtk g⁻¹. The pathogen-inoculated plates with discs soaked in bacterial consortia were incubated at 26°C in the dark. The observations were recorded 4 days after inoculation by measuring the fungal growth inhibition zone around the paper discs containing bacterial consortia.

Characteristics of Soil Used for Strawberry Cultivation

Characteristics of soil used for strawberry cultivation is a source of information about the processes during the growth and development of plants, which can have a direct impact on the quality of the fruit. Methods determining the content of proteins, enzymes, carbon and nitrogen in soil provide information on the level of soil degradation and allow the assessment of the importance of the biological consortia used (Wang et al., 2017). Soil samples were taken by complete randomization from a depth of 0–15 cm. The soil was dried at 23°C and sieved through a sieve with a mesh diameter of 2 mm. Total glomalin content (TG), easily extractable fractions of glomalin (EEG) (Wright and Upadhyaya, 1998), soil enzyme activity (dehydrogenase DHA) (Klein et al., 1964), acidic phosphatase (ACP), alkaline phosphatase (ALP) (Tabatabai and Bremner, 1969), as well as the carbon and nitrogen content in the biomass were determined in the samples.

Principal Component Analysis

Principal component analysis (PCA) is used to discover regularities between variables. It consists in determining the components which are a linear combination of the examined variables. PCA enables the identification of those initial variables that have a significant impact on the appearance of individual principal components (Yagmur and Gunes, 2021). In order to assess the relationship between the studied parameters, PCA analysis was performed using STATISTICA software (Statistica v.12, StatSoft Inc., United States).

Statistical Analysis

The obtained results were analysed with STATISTICA software (Statistica v.12, StatSoft Inc., United States) using a two-way analysis of variance (ANOVA) followed by the Tukey HSD test or Tukey for different N, F-Welch and RIR Tukey test for unequal numbers or ANOVA Kruskal–Wallis test; significant differences were determined at $P < 0.05$.

RESULTS AND DISCUSSION

Strawberries are in high demand because of their taste and health-promoting properties resulting from the presence of

antioxidants and vitamins. The development of organic farming and the promotion of a healthy lifestyle has significantly increased the demand for organically grown fruit. The recent guidelines of the European Green Deal and Biodiversity Strategy have led to the use of sustainable practices, such as organic farming, and to a reduction in the use of chemical pesticides (European Commission, 2019). These measures have led to fruit producers ensuring the high quality of their strawberries by using natural plant protection preparations. For this purpose, plant extracts, microbial consortia that antagonize strawberry pathogens (Ornelas-Paz et al., 2013) and plant protective hormones (Poveda, 2020) are both desirable and beneficial in terms of biocontrol. For economic reasons, it is important that ecological preparations not only increase the quality of the fruit, but also guarantee a plentiful harvest, reasonable production costs and that the market price of the fruit should be taken into consideration. Therefore, bacterial strains with potentially antagonistic properties against main fungal and fungal-like pathogens were selected for this study.

Strawberry Quality

The shape of strawberries has a significant influence over visual quality and consumer interest. Based on previous findings, auxin derived from achene is responsible for cell division and expansion (Zahedipour-Sheshglani and Asghari, 2020), this changes the shape of the strawberry. Consumers prefer round strawberries (Zahedipour-Sheshglani and Asghari, 2020). The change in shape from oblong (in C0) to round after the use of the appropriate consortium was noted in strawberry P (C4 and C5) and (Figure 2D), which makes them the most attractive to the consumer. Strawberry V (C4), P (C3), and MIX (C2) were distinguished by their flattened shape (Figures 2C,D,F). The remaining fruits were characterized as oblong.

An important parameter for assessing the quality of strawberries is firmness. Ensuring the proper firmness of the fruit allows for longer storage periods and facilitates transport over greater distances (Liu et al., 2019). The highest increase in firmness was observed for MIX-infected strawberries treated with C2, the maximum load in this case was on average 2.4 times higher than in the control (C0) (Figure 2F). A statistically significant increase in the maximum load value as compared to the control was also observed in the NC (C1), P (C4), and C (C5) groups (Figures 2A,D,E). It is assumed that the reason for the increase in the firmness of strawberries infected with selected pathogens could be the activity of bacterial consortia associated with the production of metabolites limiting mycelium growth and leading to an improvement in the quality and firmness of the fruit. Strawberries soften during ripening, mainly by degrading the middle lamina of the cell wall of the cortical parenchyma cells (Qin et al., 2017). One of the reasons for this degradation may be the activity of fungal pathogens attacking the fruit during ripening and storage (Ahmadi-Afzadi et al., 2013). The treatment of strawberries with *Hanseniaspora uvarum* yeast and infection with *B. cinerea* has been shown to preserve fruit firmness as compared to the control (Qin et al., 2017). The impact of the investigated bacterial consortia and fungal and fungal-like pathogens on the firmness of strawberries has not

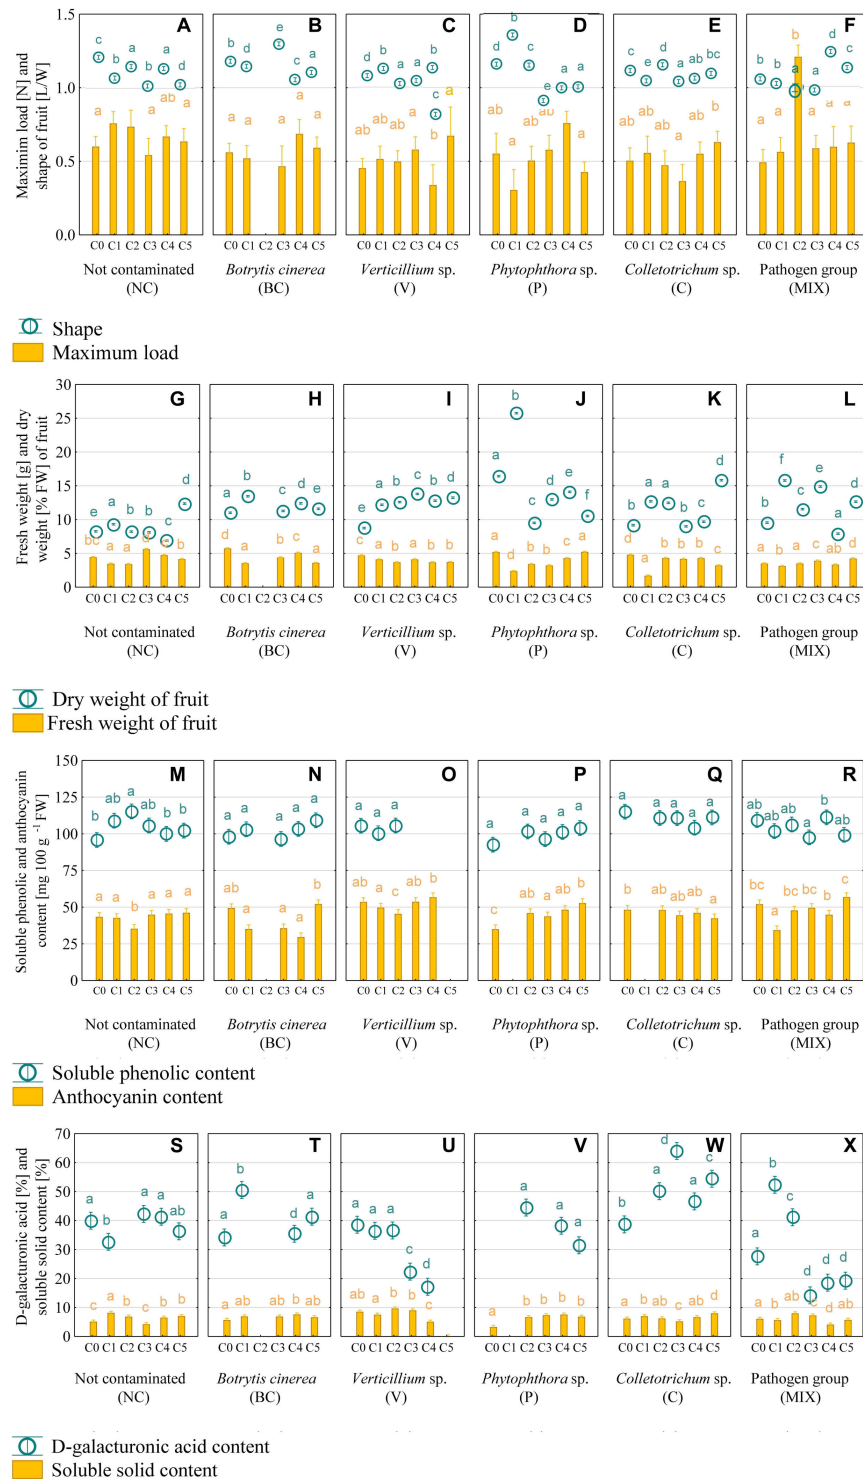

FIGURE 2 | Firmness of strawberries and shape (A–F), fresh and dry weight (G–L), soluble phenolic and anthocyanin content (M–R), and D-galacturonic acid and soluble solid content (S–X) in strawberry fruit. C0, control (not contaminated); C1, Consortium 1; C2, Consortium 2; C3, Consortium 3; C4, Consortium 4; C5, Consortium 5. A statistical analysis was performed for each pathogen group of plants separately. The data are means \pm SD ($n > 3$). Different letters (a–f) indicate the differences between consortia ($P < 0.05$) as determined by the following statistical test: ANOVA Tukey test for different N for maximum load (C–E) and shape (A–F); F-Welch test and RIR Tukey test for unequal numbers for (A,B,F), ANOVA and Tukey test HSD for fresh weight (G,H,L), dry weight (L), anthocyanin (N–Q), soluble phenolic (N–Q), D-galacturonic acid (W), soluble solid content (W,X); F-Welch and *post hoc* for fresh weight (I–K), dry weight (J,K), anthocyanin (M,R), soluble phenolic (M,R), D-galacturonic acid (S–U,X), soluble solid content (S–U); ANOVA Kruskal–Wallis test for dry weight (G–I), D-galacturonic acid (V), soluble solid content (V).

yet been investigated. The production of various metabolites that dissolve mycelium might play a role (Olanrewaju and Babalola, 2019). It is known that treating strawberries with beneficial microorganisms can improve the quality and properties of the stored fruit, including firmness (Fan et al., 2009). The antifungal activity of *Bacillus* sp. isolates against *C. acutatum* (Moreira et al., 2014) and *Phytophthora infestans* (Caulier et al., 2018), *Lysobacter* sp. and *Pseudomonas* sp. against *Colletotrichum* sp. (Tang et al., 2019), *S. griseus* against *P. capsici* (Nguyen et al., 2015) and *Lysobacter* sp. against *P. infestans* (Lazazzara et al., 2017) have been confirmed.

Fruit firmness is closely related to the dry matter content. Their soft texture and high water content make strawberry fruit susceptible to mechanical and physical damage which facilitates the penetration of microorganisms (Siebeneichler et al., 2020). In General, fruit with a higher tissue density exhibits a higher dry matter content and a greater degree of firmness compared to fruit with a lower tissue density (Tarantino et al., 2018). This relationship was observed for the strawberries NC (C1) and C (C5), with an increase in firmness and dry matter compared to the control (Figures 2A,E, 3A,E). An inverse relationship was observed in samples P (C4) and MIX (C2), fruit with a higher degree of firmness had a lower or comparable to the control dry content (Figures 2D,F, 3D,F). It is assumed that the decrease in the firmness of fruit with a high dry matter content is caused by a relatively high cell fragility, low turgor pressure or a low degree of adhesion between the adjacent strawberry tissue cells (Harker et al., 2000). Tissue hydration has a great impact not only on firmness, but also on fresh fruit weight. Studies have shown that strawberries may contain 84–92% water, depending on the variety and cultivation method (Liu et al., 2019). Only the C3 bacterial consortium increased the fresh matter content over the no contaminated (NC) strawberry by 63% (Figure 3G) and C3 and C5 consortia increased the fresh matter content in MIX-infected strawberry by 21% on average (Figure 3L). The higher fresh weight combined with the lower dry weight values indicate a higher water content in the strawberries belonging to these groups.

One of the factors determining consumer interest in strawberries is the SSC content, which is defined as the aggregate concentration of sugars (80–90% of the SSC), acids and other solutes in the cell juice (Mackenzie et al., 2011). The average content of SSC in the tested fruits was 6% (Figures 2S–X), which is the same as other studies which reported the content of SSC in strawberries to be within the range of 4–10% (Chen H. et al., 2018). In most cases, the SSC content was greater than or comparable to the control (C0) in strawberries treated with the bacterial consortia. A statistically significant decrease in the SSC value by 0.9–3.4% compared to the control (C0) was observed in groups V (C4), C (C3), and MIX (C1 and C4) (Figures 2U,W,X). The occurrence of differences in the content of SSC in the tested strawberries is natural and may result from differences in the cultivation method (Cao et al., 2015) consisting of treating the fruit with different bacterial consortia. The SSC content is influenced by various factors, such as genetics, climate, water management and cultivation practices. Positive correlations between the nutrient content, e.g.,

phosphorus and an increase in SSC content was noted for the strawberries (Valentinuzzi et al., 2015). This effect may occur due to the ability of bacteria to dissolve phosphates, which lowers soil pH and increases phosphorus availability through the production of organic acids. Moreover, an increase in the content of phosphorus in the fruit was shown after the treatment of strawberry seedlings with *Bacillus* sp. and *Klebsiella planticola* (Tomic et al., 2015).

Polyphenols and anthocyanins are responsible for the bright red colour of strawberries and play a key role as bioactive ingredients (de Andrade et al., 2019). The mean content of polyphenols in the tested fruit was in the range of 93–115 mg 100 g⁻¹, while the anthocyanins content was in the range of 31–57 mg 100 g⁻¹. The increase in polyphenol content was only observed in the NC group (C2) and was 20% greater than in the control (C0) (Figure 2M). None of the preparations used caused a statistically significant decrease in the content of polyphenols in strawberry cv. Honeoye. Unlike the case of polyphenols, a decrease in the content of anthocyanins in strawberry NC (C2), V (C2), and MIX (C1) was noted (Figures 2M,O,R). However, an increase in anthocyanin content at the level of 25–51% compared to the control (C0) occurred only in the group of *Phytophthora* sp. infected strawberries treated with C2, C3, C4, and C5 consortia (Figure 2P). It is predicted that the changes to the level of total phenolic compounds and anthocyanins may be due to the presence of pathogenic fungi, and fungal-like-pathogens, and beneficial bacteria. The bacterial synthesis of plant hormones or amino acids may enter the shikimic acid metabolic pathway, thereby acting as the precursors of phenolic acids (Cisternas-Jamet et al., 2020). The increase in anthocyanin content may be attributed to the release of anthocyanins from degraded cellular components (López-Ortiz et al., 2019), the activity of the enzymes responsible for the synthesis of anthocyanins and also the activity of microorganisms. Lingua et al. (2013) demonstrated the positive effect of bacteria of the genus *Pseudomonas* on the anthocyanin (cyanidine-3-glucoside and pelargonidine-3-glucoside) concentration in strawberries. However, the anthocyanin content shows a high degree of variability with respect to species, varieties, growth conditions and the degree of fruit ripeness (Todeschini et al., 2018).

The content of galacturonic acid (Figure 2), which is the main component of pectin, is important in fruit processing. Pectins have stabilizing and gelling properties, which is why they are used in the production of jam, juice, drinks, and jellies (Ben Abdallah et al., 2018). In addition, galacturonic acid is extracted from fruit for the synthesis of ascorbic acid (Agius et al., 2003). The content of galacturonic acid may vary; in a previous study, a ripe strawberry of the cultivar Chandler was found to contain about 330 mg of galacturonic acid g⁻¹ DW (Paniagua et al., 2017). The use of consortia resulted in an increase in the galacturonic acid content of ≥400 mg g⁻¹ DW (>40%) for strawberry grown in the following variants: BC (C1), C (C2, C3, C4, and C5), and MIX (C1 and C2) (Figures 2T,W,X), which was greater than the control (C0). Relatively large fluctuations in the content of galacturonic acid confirms the complexity of the processes caused by the activity of microorganisms, which are affected by

plant variety, growth conditions, pathogen infections and the consortia used.

Rheological Properties

The rheological properties of liquids determine the behaviour of the solution at all of the production stages, such as filling, mixing, packaging and removal from the package (Lee et al., 2009). Pectin solutions are used for the production of yoghurts, jelly, juices (Ke et al., 2020), paints, pastes and medicines (Jouini et al., 2018), due to their gelling, stabilizing and flavour-enhancing properties (Ke et al., 2020).

The viscosity of 1% solutions of strawberry pectin extracted with ammonium oxalate is shown in **Table 1**. The increase in viscosity as compared to the control (C0) occurred in NC (C3), BC (C1, C4, and C5), C (C2), and MIX (C2, C3, C4, and C5) strawberries. Also, contamination with pathogens (BC, V, C, and MIX) significantly lowered the viscosity of the strawberry pectin solutions in the controls (C0) as compared to the control of uninfected NC strawberries (C0). These results show that the use of appropriate consortia, dedicated to a specific pathogen, can increase the viscosity of pectin solutions. The decrease in viscosity

may be attributed to the activity of microorganisms that soften the fruit cell walls through pectin degradation (Mierczyńska et al., 2014). Viscosity depends, among other factors, on the molecular weight of the pectin molecules, their degree of methylation and pH, which may be affected by fungi and bacteria associated with strawberries at all stages of growth and ripening. It has been proven that viscosity increases with increasing pectin concentration (Chan et al., 2017).

The rheological data of the 1% pectin solutions were suitably adjusted by the Ostwald–de Waele model with a high coefficient of determination of $R^2 > 0.996$. Higher values of the coefficient k correspond to the higher viscosity of the samples. Based on the k -factor analysis, pectin solutions were obtained with a viscosity higher than that of the control (C0) in the NC (C3) and BC (C4 and C5) groups (**Table 1**). The antagonistic interactions of the microorganisms used led to the modification of pectin, an increase in apparent viscosity and the coefficient k , which is associated with an increase in the molar mass of pectin (Fracasso et al., 2018). The high molar mass of pectin promotes the formation of a gel structure (O'Donoghue and Somerfield, 2008). However, for some applications a lower viscosity may be seen as

TABLE 1 | Parameters of the Ostwald–de Waele model describing the rheological properties of 1% strawberry pectin solutions.

NC, control (no contamination); BC, *B. cinerea*; V, *Verticillium* sp.; P, *Phytophthora* sp.; C, *Colletotrichum* sp.; MIX, pathogen group (BC, V, P, and C); C0, control (no bacterial consortia); C1, Consortium 1; C2, Consortium 2; C3, Consortium 3; C4, Consortium 4; C5, Consortium 5. Different letters (a–f) indicate differences between experimental variants ($P < 0.05$) as determined by the Tukey HSD test. A statistical analysis was performed for each infected group of plants separately. Data are means ± SD ($n = 3$).

a positive property of the solutions due to pelargonidine lower energy consumption during processing (Venzon et al., 2015).

Flow curves reveal pseudoplastic, non-Newtonian behaviour due to the melt flow index values n ($n < 1$). The 1% pectin solutions tested are classified as shear thinned. Their viscosity decreases as the shear rate increases. Based on a previous study, the lower the n coefficient, the greater the degree of pseudoplasticity (Lee et al., 2009). The values of n for the tested solutions were in the range of 0.713–0.996. In comparison, the n values for 2% strawberry pectin solutions were 0.52, while for 5% strawberry pectin solutions they were

0.54 (Mierczyńska et al., 2017). Pseudoplastic fluid behaviour is important in the food industry (gelatinization of jellies and jams, thickening of juices and purees, and stabilization of liquids) (Grassino et al., 2016) and in medicine production (thickening of syrups or ointment, encapsulation of preparations) (Jouini et al., 2018).

The differences in the values of viscosity and in the flow of pectin solutions refers to the molecular properties of the samples, such as the chemical composition of neutral sugars, galacturonic acid content and the degree of pectin esterification (Fracasso et al., 2018). Microorganisms may have an indirect

effect on the chemical composition of the samples (Erturk et al., 2012). The use of beneficial microorganisms such as *Pseudomonas* sp., *Bacillus* sp., and *Azospirillum* sp. results in an increase in plant biomass and fruit yields (Erturk et al., 2012). In addition, it was found that beneficial fungi and plant growth-promoting bacteria show antagonism to the pathogens *C. acutatum*, *Macrophomina phaseolina*, and *Fusarium solani* in strawberry plants (Pastrana et al., 2016). Inoculation with beneficial bacteria in order to increase plant growth also has potential environmental benefits; it could reduce the use of agricultural chemicals and facilitate adaptation to sustainable management practices (Erturk et al., 2012).

Antagonistic Properties of Consortia Against Fungal Pathogens

In Petri dish-based assays carried out for the determination of the antifungal properties of the tested bacterial consortia, C4 and C5 did not show any clear zone of inhibition in the growth of the tested fungi, and fungal-like-pathogens or only indicated very weak inhibition (Table 2). The inhibitory effect was observed for C1, C2, and C3, with evident growth inhibition of all of the tested fungal pathogens in the case of C1 and C2, thereby confirming the antagonistic properties of the bacterial strains present in these consortia, which was observed in a greenhouse experiment. Other studies are consistent with the obtained results and confirm the antagonism of the tested bacterial consortia (contained *Bacillus* sp., *P. polymyxa*, and *Streptomyces* sp.) against strawberry pathogenic microorganisms (Chen P.H. et al., 2018; Li et al., 2021).

Influence of Microbial Activity on Soil Composition

The content of nutrients, proteins, and soil enzyme activity plays a key role in the functioning of the ecosystem. The cultivation of plants is accompanied by a decrease in soil productivity related to the depletion of nutrients, the release of toxic metabolites, and the development of pathogenic fungi (Gałazka, 2013). Total glomalin (TG) is one of the glycoproteins produced by arbuscular mycorrhizal fungi that live in symbiosis with plants and facilitate the uptake of water and nutrients from the environment. Easily extractable glomalin (EEG) has a more immunoreactive fraction than TG (Wright and Upadhyaya, 1998). For this reason, an increase in TG and EEG levels is desirable in the context of promoting plant growth. An increase in the TG content as

compared to the control (C0) was only observed in the strawberry NC (C5), while an increase in EEG content may be observed in the strawberry BC (C5) (Table 3).

The data shows the significant influence of the type of infectious pathogen and the bacterial consortium used on enzyme activity. The increase in acid phosphatase content as compared to the control (C0) characterized the strawberry fruit in the groups NC (C3, C4, and C5), BC (C2, C3, and C4), V (C1, C2, C3, and C4), and C (C2, C3, C4, and C5), while an increase in the content of alkaline phosphatase occurred in groups BC (C1 and C3), V (C3 and C4), P (C2, C3, C4, and C5), C (C4 and C5), and MIX (C2, C3, and C5) (Table 3). Increased phosphatase activity is associated with a higher content of organic matter in the soil (Singh et al., 2018). In contrast to phosphatase, a statistically significant increase in dehydrogenase content was observed in strawberry V (C1 and C3), C (C1, C2, C3, C4, and C5), and MIX (C2, C4, and C5) (Table 3). The increase in dehydrogenase activity may be explained by the greater availability of nutrients (Kanchikerimath and Singh, 2001).

Principal Component Analysis

The relationships between the parameters studied were analysed using the PCA method (Figure 3). The distribution of individual samples on the plane is shown in Figures 3A,C,E,G,I,K. The first two factors (PC1 and PC2) explain over 50% of the total variance among the analysed samples for all of the investigated variables. For all of the tested samples, the first axis (PC1) accounted for over 30% of the total variance. The samples that explain the PC1 and PC2 axis positively have the greatest impact on the tested infection factor. On this basis, we may distinguish C0 and C3 for the NC control (Figure 3A), C0 for BC (Figure 3C), C0 for V (Figure 3E), C5 for P (Figure 3G), C2 for C (Figure 3I), and C3 for MIX (Figure 3K). An analysis of the PCA1-PCA2 observation charts (Figures 3A,C,E,G,I,K) confirms the results of the analyses above; the need to select an appropriate consortium which acts antagonistically against individual pathogens in order to obtain the highest quality of fruit.

An analysis of the PCA variable charts allowed for the identification of certain dependencies between the examined parameters in all of the studied groups, a positive correlation was found between DW and SSC, which was consistent with the results of other studies (Jorquera-Fontena et al., 2014). The increase in the content of anthocyanins (AC) was accompanied by an increase in the content of phenols (PC)

TABLE 2 | Antifungal properties of the bacterial consortia used in the test expressed as the inhibition zone diameter (mm).

NC, control (no contamination); BC, *B. cinerea*; V, *Verticillium* sp.; P, *Phytophthora* sp.; C, *Colletotrichum* sp.; MIX, pathogen group (BC, V, P, and C); C0, control (no bacterial consortia); C1, Consortium 1; C2, Consortium 2; C3, Consortium 3; C4, Consortium 4; C5, Consortium 5. A statistical analysis was performed for each infected group of plants separately. Data are means ± SD (n = 3). Different letters (a–e) indicate differences between the experimental variants (P < 0.05) as determined by the following statistical tests: ANOVA Tukey (HSD) test (total glomalin: NC, BC, V, C, MIX; easily extractable glomalin: BC, V, C, MIX; dehydrogenase: BC, P, C, MIX; acid phosphatase: BC, P, C, MIX; alkaline phosphatase: NC, BC, P, MIX; carbon: NC, P, MIX; nitrogen: NC, P), F-Welch test and RIR Tukey test for unequal numbers (Total glomalin: P; easily extractable glomalin: NC, P; dehydrogenase: V, acid phosphatase: NC, V; alkaline phosphatase: V, C; carbon: BC, V, C; nitrogen: BC, V, C, MIX), ANOVA Kruskal–Wallis test (dehydrogenase: NC).

only in strawberries infected with *Phytophthora* sp. (Figure 3H). A positive correlation between the content of anthocyanins and polyphenols indicates a high antioxidant activity (Dembczyński et al., 2015). It was observed that an increase in total glomalin (TG) and easily extractable fractions of glomalin (EEG) in the soil were related to an increase in the level of nitrogen (NB) and carbon in biomass (CB) for the NC, V, and MIX groups (Figures 1B,F,L). Glomalin contains approximately 30% of soil carbon and is the main component of soil organic

matter (Gałązka, 2013), which is associated with a positive correlation between TG and EEG and CB. The growth of glomalin-producing bacteria (TG and EEG) requires a sufficiently high nitrogen concentration thereby explaining the positive correlation between TG, EEG, and NB (Gałązka, 2013). On the other hand, it is believed that an excessively high nitrogen level in the soil leads to a significant reduction in the activity of dehydrogenases involved in the transformation of soil

carbon. High dehydrogenase activity provides favourable conditions for the development of microorganisms in the soil environment (Koper and Siwik-Ziomek, 2006). A positive correlation between dehydrogenase activity (DHA) and CB was noted for the uninfected samples and those infected by *Verticillium* sp., *Colletotrichum* sp. and a mixture of pathogens (Figures 1B,F,J,L), which is consistent with the results of the studies by Turski and Wyczółkowski (2008). Our research confirms that there is only a positive correlation between acid phosphatase and alkaline phosphatase for the group infected with *Colletotrichum* sp. (Figure 3J). For the remaining groups studied, there is either a negative or an absence of any correlation between these enzymes. This situation may be explained by the development of soil microorganisms limiting the activity of certain enzymes. It is assumed that an excess of inorganic phosphorus inhibits the synthesis of phosphatases (Nahas et al., 1982).

CONCLUSION

The interaction of beneficial bacteria and pathogenic fungi or fungal-like-pathogens makes it possible to preserve the high quality of strawberry fruit. The beneficial effects of the selected consortia were confirmed by comparing the results produced by infected strawberries with those of a positive control. On this basis, Consortium C2, which is composed of *Bacillus* sp. strains, was singled out as one of the most effective against selected pathogens in terms of maintaining the firmness of strawberries contaminated with a group of pathogens. There was an increase in strawberry firmness as compared to the positive control after the use of selected antifungal consortia. The microorganisms contained in the consortia also influenced an improvement in the biochemical properties of the strawberries, such as the soluble solids content and anthocyanins content. The application of consortia C2, C3, C4, and C5 was accompanied by an increase in the SSC in the fruit infected with *Verticillium* sp. as compared to the control, thereby improving the flavour of the strawberries. Consortium C5 significantly increased the level of anthocyanins in strawberries contaminated with *Phytophthora* sp. and *B. cinerea*, and in the control, it also increased the health-promoting properties of the strawberries. The impact of the tested consortia on the pectin content of the strawberries was noted. In comparing the fruit samples with untreated beneficial microorganisms (C0), it may be seen that the group of pathogens (MIX) reduced the content of D-galacturonic acid and thus pectin to the greatest extent. The following consortia: C2 (the control), C1 (*B. cinerea*), C2, C3, and C5 (*Colletotrichum* sp.)

and C1 (the pathogens group) may be identified as causing the highest increase in the content of extracted pectin in infected fruit as compared to Consortium C0. The decrease in viscosity was related to the increase in pectin content, which is indicated by the negative correlation between these values for the aforementioned groups (*B. cinerea*, *Colletotrichum* sp., pathogens group). For consortia C2 (control), C3 and C5 (*Colletotrichum* sp.) and C1 (pathogens group) the viscosity decreased by more than one and a half times as compared to Consortium C0.

Based on our research results, we may conclude that the tested consortia show a high degree of antagonism toward the tested fungus and allow for high-quality fruit to be obtained. The use of bacterial consortia also has the potential for reducing environmental pollution and the amount of fungicide residues in the fruit. However, more research is still required to identify the most effective consortia for combating strawberry and other soft fruit fungal diseases.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article, further inquiries can be directed to the corresponding author.

Sweet sorghum [*Sorghum bicolor* (L.) Moench] is a highly productive, gluten-free cereal crop plant that can be used as an alternative energy resource, human food, and livestock feed or for biofuel-ethanol production. Phosphate fertilization is a common practice to optimize sorghum yield but because of high cost, environmental hazards, and soil fertility reduction, the use of chemical P fertilizer is discouraged. Due to this, the impetus to search for an inexpensive and eco-friendly microbiome as an alternative to chemical P biofertilizer has been increased. Microbial formulations, especially phosphate solubilizing microbiome (PSM) either alone or in synergism with other rhizobacteria, modify the soil nutrient pool and augment the growth, P nutrition, and yield of sorghum. The use of PSM in sorghum disease management reduces the dependence on pesticides employed to control the phytopathogens damage. The role of PSM in the sorghum cultivation system is, however, relatively unresearched. In this manuscript, the diversity and the strategies adopted by PSM to expedite sorghum yield are reviewed, including the nutritional importance of sorghum in human health and the mechanism of P solubilization by PSM. Also, the impact of solo or composite inoculations of biological enhancers (PSM) with nitrogen fixers or arbuscular mycorrhizal fungi is explained. The approaches employed by PSM to control sorghum phytopathogens are highlighted. The simultaneous bio-enhancing and biocontrol activity of the PS microbiome provides better options for the replacement of chemical P fertilizers and pesticide application in sustainable sorghum production practices.

Keywords: sorghum, phosphate solubilizers, microbiome, phytopathogens, antagonists, P-nutrition

INTRODUCTION

The constantly increasing human populations and regularly declining agricultural soils have placed extra pressure on sustainable agriculture systems to eliminate human food hunger worldwide (Díaz-Rodríguez et al., 2020). Globally, P fertilization is a common practice to improve sorghum production (Gemenet et al., 2016), but the intemperate application or unrelenting long-term utilization of chemical-P fertilizers cause environmental pollution and

reduce soil quality (Alori et al., 2017; Li et al., 2020). The efficiency of P solubilizer is very low (15–20%) due to its rapid fixation in acidic and alkaline soils, both of which are predominant worldwide (Aziz et al., 2014). Though the majority of global soils contain sufficient reserves of total P, most of it remains inaccessible, and soils thus become deficient in P. So, to maintain sorghum production, P fertilizers are applied regularly. The high cost of chemical-P fertilizer acts as a motivator in the quest for an alternative where naturally-occurring P sources such as rock phosphate (RP) serve as a P reservoir. Regrettably, RP is not easily available to plants in soils with a pH > 5.5–6, and farmers thus cannot use RP in sorghum fields (Gurdeep and Reddy, 2015). However, the microbial fertilizers, especially phosphate biofertilizers, augment the P use efficiency (PUE) and thereby improve plant P uptake. Collectively, the phosphate solubilizing microbiome (PSM) represents a group of soil organisms that make P available to plants from both inorganic and organic sources by solubilizing and mineralizing complex P compounds (Zaidi et al., 2009; Chawngthu et al., 2020). Among PSM inhabiting a particular environment, bacteria (Rezakhani et al., 2020), fungi (Elfiati et al., 2021), and actinomycetes (Saif et al., 2014) supply mineral nutrients especially P to various food crops including sorghum growing in different agroclimatic regions worldwide (Abawari et al., 2020; Chen et al., 2021). The PSM intervention in sorghum cultivation practices seems to be an incredibly attractive and highly promising approach to ameliorate sorghum production in P-deficient soil (dos Santos et al., 2017). Apart from supplying P, PSM plays an important role in suppressing the damaging impact of phytopathogens causing severe sorghum yield losses (Gopalakrishnan et al., 2015; Mitra et al., 2020). The PSM-mediated management of P nutrition and sorghum phytopathogens is considered an inexpensive and environmentally friendly biotechnological approach and appears to be a realistic substitute to chemical P fertilizers and hazardous pesticides (Saraf et al., 2014; Kumar et al., 2020). However, due to the competition among/between indigenous/introduced microbiome, soil environment, and other factors, the competence of PSM to survive and colonize in the rhizosphere is greatly challenged (Soumare et al., 2020). Despite this, the PSM, when applied as microbiological formulations in field/greenhouse, has been found to enhance the growth and yield of many food crops (Ahmed et al., 2017; Batool and Iqbal, 2019), including sorghum (Vijayalakshmi et al., 2020), by various direct and indirect mechanisms (Khan et al., 2014; Herrera-Quiterio et al., 2020).

Sorghum, a multipurpose cereal crop belonging to the family Poaceae, ranks fourth in terms of worldwide production after wheat, rice, and corn (Shoemaker and Bransby, 2010; Kumar et al., 2017a). It is typically cultivated in the semi-arid tropics (Almodares and Hadi, 2009) and has several economically important potential uses such as food (grain), feed (grain and biomass), biofuel (ethanol production), fiber (paper), fermentation (methane production), and fertilizer (Hasibuan and Nazir, 2017; Dar et al., 2018). Due to excessive pressure on the production of rice for human consumption, there is an urgent need to search for any nutrition-rich alternative food substitutes for rice to satisfy human food demands. Sweet sorghum in this context

can serve as a potential food alternative in many countries (Marles et al., 2018). Different approaches like crop rotation, use of resistant cultivars, and agrochemicals to combat phytopathogens have been adopted to enhance the yield and quality of sweet sorghum, but due to several reasons, especially the cost, technical difficulties, emergence of resistance among pathogens against toxic chemicals, residual toxicity to non-target organisms, or environmental pollution, the implementation of such methods/chemicals is discouraged in sorghum cultivation practices. The utilization of microbiological fertilizers particularly PSM is an alternative option to plant growth and production of sweet sorghum under biotic stress conditions. However, little research has been conducted and very little information is available on the ameliorative role of PSM in relation to the growth and yield of sorghum, particularly under biotic stressed conditions. Acknowledging the importance of human food and lack of information on the role of PSM in sorghum production in high throughput agricultural practices, this review attempts to provide the latest information on the biodiversity and physiological variations of PSM and its importance in sorghum P nutrition, biotic stress alleviation and yield optimization/stability in changing agro-ecosystems worldwide. This review further explains the mechanistic basis of disease suppression and highlights the potential role of single and/or composite PSM formulations in sorghum-soil systems. The understanding of the relationship between the PSM and related rhizobacteria and arbuscular mycorrhizal fungi may help in better management of P fertilization and biotic stress alleviation in sorghum growing in different agrosystems while reducing the risk of chemical pollution.

SORGHUM: FOOD, NUTRITIONAL COMPOSITION, AND HUMAN HEALTH

Sorghum, which is naturally gluten free, is a major cereal grown as a food and feed crop (Kumar et al., 2017b; Zhao et al., 2019). Sorghum is known by different names, such as great millet and guinea corn in West Africa; kafir corn in South Africa; dura in Sudan; jowar in India, and kaoliang in China. Among sorghum-producing countries, the United States is a major sorghum producer, but only a small fraction of grain is consumed here as human food; instead, it is mainly used as animal fodder. Worldwide, sorghum is consumed in various forms, such as alcoholic and non-alcoholic beverages, baked bread, tortillas, porridges, couscous, gruel, steam-cooked products, expanded snacks, cookies, etc. (Murty and Subramanian, 1982). Sorghum can also be processed into starch, flour, grits, and flakes and is used to produce a wide range of industrial products. Due to its nutritional importance, sorghum is incorporated into the human diet more specifically for people who are intolerant to wheat (Kulamarva et al., 2009). It is consumed mostly in northern China, India, and southern Russia, where about 85% of the crops are consumed directly as human food (Dicko et al., 2006).

Nutritionally, sweet sorghum is quite high (62%) in carbohydrates (Barcelos et al., 2016) and has a higher energy output than sugarcane, sugar beet, corn, and wheat

(Dar et al., 2018). Sorghum provides important minerals, vitamins, protein, and micronutrients essential for optimal health, growth, and development (Awika and Rooney, 2004; Kulamarva et al., 2009). Recently (Tasie and Gebreyes, 2020), observed proximate composition values such as moisture, ash, crude fat, crude fiber, and crude protein, and CHO in different sorghum varieties, which varied from 9.66 to 12.94, 1.12 to 2.29, 2.48 to 4.60, 2.17 to 8.59, 8.20 to 16.48, and 67.56 to 76.42, respectively. The highest mineral content in sorghum varieties was (mg/100g): P (368), Na (6), Mg (208), K (314), Ca (67), Fe (14), and Zn (6). The maximum tannin was recorded in Lalo (3,337 mg/100g) and Dano (2,474 mg/100g). Based on the high mineral value, sorghum varieties such as Miskir, Abshir, ESH-1, Meko-1, Red Swazi, and Karimtams can be considered for food product development. Sorghum also contains various phenolics like flavonoids (Shahidi and Naczk, 1995), which inhibit tumor development (Awika and Rooney, 2004), and antioxidants, which make the grain suitable for producing functional foods. It is a gluten-free cereal, which has importance in the occurrence of Celiac Disease (CD), an immunological response to gluten intolerance. The starches and sugars in sorghum are released more slowly than in other cereals (Léder, 2004) and it is thus beneficial for diabetic persons (Toomey, 1988).

WHY IS PSM SO IMPORTANT IN SORGHUM PLANT SYSTEMS?

Chemical fertilization (e.g., NPK) in agriculture is documented as a successful practice to manage soil fertility and concurrently to increase the quality and yield of cereal crops (Mojid et al., 2012; Saïdou et al., 2018), including sorghum (Sebnie et al., 2020), in different agro-ecological regions. Among plant nutrients, P is the major nutrient after N and is the second most deficient plant nutrient (Munir et al., 2004). Under a P-deficient environment, plants show altered growth and metabolism, and a reduction from 5 to 15% in crop yield has been reported (Shenoy and Kalagudi, 2005). So, to overcome the low P availability and to allow sorghum plants to grow normally, P fertilizers are used in cultivation practices (Roy and Khandaker, 2010). Sorghum requires high levels of chemical fertilizer for optimal growth, which causes a shift in the soil microbial community (Chu et al., 2007; Wang et al., 2018) and environmental degradation leading to human health problems (Adesemoye and Kloepper, 2009; Kang et al., 2011). These problems accentuate the need for new technologies in sorghum production systems to achieve sustainable production systems. The PSM of plant-growth-promoting microbes is of particular interest as it can, either alone or in combination with other related PGPR/AM-fungi, reduce the adverse impact of chemical fertilizers and simultaneously enhances plants' tolerance to environmental stress (Bhardwaj et al., 2014). Additionally, the PSM promotes root morphogenesis and gradually increases plant height, stem diameter, number of leaves per plant, leaf area, and yield along with protecting plants from phytopathogens attack (Pandey and Gupta, 2020). Also, P supplied either through solubilization or mineralization by PSM participates in cell division, growth of

new tissues and nucleic acid structure, protein synthesis regulation, respiration, signal transduction, macro-molecular biosynthesis, phospholipids, carbon metabolism and a wide range of enzymes, energy transfer, and photosynthesis (Kouas et al., 2005; Hameeda et al., 2008). To fulfill P demands, the PSM has been found to be very useful (Qarni et al., 2021). The PSM-sorghum plant synergy could, therefore, be of great practical importance in the management of P nutrition, biotic stress, and yield optimization. Once developed, the PSM formulation benefits sorghum in several ways due to its ability to (i) release P nutrients slowly and as per the need of plants; (ii) complement other minerals; (iii) supply essential agroactive biological enhancers to plants; and (iv) alleviate biotic stress (Khan et al., 2014; García-Fraile et al., 2015; Yadav and Sarkar, 2019). Broadly, the utilization of microbes mediated rock phosphate solubilization has multiple advantages over conventional chemical P fertilizers in sorghum cultivation practices. These advantages are as follows: (i) the PSM-based formulations are safer than chemical fertilizers; (ii) there is no chance of deposition of either toxic materials or microbiome in the food chain; (iii) the self-replicating ability of microbes evades the requirement for repetitive application; and (iv) they reduce dependence on pesticides. Put together, the PSM along with RP could be an incredibly strong strategy to advance the biological and physicochemical fertility of the soil, which eventually enhances the sorghum production at a low cost. While the literature regarding PGPR interactions with the top three cereals (maize, wheat, and rice) is quite sizeable, a search conducted using the words "PSM" and "sorghum" as keywords revealed very few papers in the scientific literature. Also, when searching PSM and sorghum diseases, very few scientific studies are available. Collectively, the amount of information regarding the interactions between PSM (bacteria/fungi/actinomycetes) and sweet sorghum is limited.

OVERVIEW OF PSM: DEFINITION, BIODIVERSITY, AND P-SOLUBILIZATION

A group of beneficial soil microbiomes, including bacteria, fungi, and actinomycetes, capable of mineralizing/solubilizing complex P into soluble forms are termed phosphate-solubilizing microorganisms (Tian et al., 2021). The PSM has been recovered from different ecological habitats (Table 1) using standard microbiological methods (Figure 1). *Pseudomonas* and *Bacillus* among bacteria and *Aspergillus* and *Penicillium* among fungi are the most efficacious P solubilizers (Li et al., 2016; Zhu et al., 2018). P-solubilizing fungi (PSF) are better P solubilizers than other PSMs due to their ability to do the following: (i) retain a P-dissolving ability after repeated subculturing; (ii) traverse longer distances more easily in any environment; and (iii) produce more organic acids (Venkateswarlu et al., 1984). Among mineral phosphate solubilization (mps) mechanisms, the organic acid (OA) theory is the most widely accepted mechanism of solubilization and supply of P to plants (Table 2). The OA lowers the pH of the environment and causes discharge of P ions from the P mineral by H^+ exchange for Ca^{2+} (Goldstein et al., 1993). The variation in pH and the amount of P solubilized

by PSM has also been unrelated (Asea et al., 1988), which suggests the involvement of mechanisms other than the OA in the P solubilization process which is influenced by many factors (Mohamed et al., 2018). The complex organic P compounds (phosphates, phospholipids, phytin etc.) in contrast are mineralized enzymatically by alkaline and acid phosphatases (Behera et al., 2017; Din et al., 2019), phytases (Din et al., 2019), and phospholipases (Walpola and Yoon, 2012) excreted by PSM.

Mechanisms Used by PSM to Facilitate Sorghum Plant Growth

Most of the cultivable soils in the world have insufficient elemental nutrients like P, N, K, and Zn, or these are unavailable to the plants. Also, poor agricultural practices, such as the disproportionate use of fertilizers, lead to undesirable effects such as soil fertility reduction. Indeed, a major part of chemical fertilizers applied to augment sorghum production is wasted further polluting the agroecosystem (Garnett et al., 2009). Below are some of the main mechanisms used by PSM to optimize the use of crop nutrients and help promote sorghum production.

Apart from supplying inherently P to plants, the P-dissolving microbiome benefits the plants by providing N through BNF, growth modulating enzymes, phytohormones, and antimicrobial compounds, which directly or indirectly affect the growth and development of sorghum (Table 3). The direct growth stimulation by PSM includes the acquisition of nutrients, such as P through solubilization/mineralization and N through N_2 fixation, phytohormone production, and facilitation of resource while indirectly they promote growth by suppression of plant pathogens and induction of resistance in host plants against pathogens (Figure 2).

The plant growth-promoting substances released by PSM include (i) phytohormones, such as indoleacetic acid (Lebrazi et al., 2020; Qarni et al., 2021) and gibberellin (Pandya et al., 2018; Kang et al., 2019), (ii) asymbiotic (Nosrati et al., 2014; Ayyaz et al., 2016) or symbiotic N_2 fixation (Muleta et al., 2021), (iii) biocontrol of phytopathogens through antifungal compounds and antibiotics (Olanrewaju and Babalola, 2019; Mitra et al., 2020) or lytic enzymes (Hamane et al., 2020; Naziya et al., 2020), and (iv) secretion of siderophores (Aallam et al., 2021) and HCN (Naziya et al., 2020; Boubekri et al., 2021). In addition to these biological enhancers, the phosphate dissolving bacteria (Kalam et al., 2020; Zhao et al., 2021), actinomycetes (Chukwuneme et al., 2020), and fungi (Ali et al., 2019) also release 1-aminocyclopropane-1-carboxylate (ACC) deaminase to protect plants from attack by pathogens. Phosphate solubilizing microbiota can also protect sorghum plants from biotic stress and stimulate growth indirectly by destructing the metabolism of attacking pathogens and/or stimulate the plant's immune system. Thus, the indirect mechanisms of PSM could be extremely useful and of great practical interest under field conditions because they provide a chance for growers to avoid the use of chemical biocides (Adesemoye and Kloepper, 2009; Khatoon et al., 2020) and, therefore, protect soils and crops from chemical toxicity.

PSM-SORGHUM INTERACTIONS: INOCULATION EFFECTS ON GROWTH, CROP NUTRITION, AND GRAIN YIELD

Application of microbes-based bio-fertilizers in agro-ecosystems is beneficial for plant growth and yield enhancement in both

conventional (Kalayu, 2019) and extreme environments (Kamali and Mehraban, 2020; Rizvi et al., 2020). Among microbial formulations, the research on PSMs impacting growth, crop nutrition, and yield of cereal crops under greenhouse/field trials are quite large (Table 4). The literature regarding PSM application in sorghum cultivation systems in different agroecological regions is, however, lacking. Considering this gap, the beneficial influence of PSM including PS bacteria (PSB), fungi (PSF), and actinomycetes (PSA) used either alone or in combination with other conventional PGPR or arbuscular mycorrhizal (AM) fungi is highlighted. A model explaining the ameliorative impact of the PSM on morphological, cellular, and physiological activities of the sorghum plant is presented in Figure 3.

Inoculation Effects of Single PSM

The inoculation of the P-solubilizing microbiome is considered a promising and inexpensive microbiological option, not to mention the most sustainable one, in food production systems because it increases the P bioavailability without destructing the soil-plant systems. Sorghum, considered a substitute to rice, adapts well to P deficient soils employing absorption and solubilization mechanisms including interaction with PSM. The direct application of RP either alone or/and followed by the inoculation of the PSM is however, a suitable alternative to

supply P to the growing sorghum crops. Recently (Mattos et al., 2020), evaluated the effect of PSB inoculation on two sorghum genotypes (BR007-efficient and responsive and SC283-efficient and non-responsive) with different P sources (RP and triple superphosphate, TSP). The sorghum genotypes were inoculated separately with the PSB *Bacillus* strains (B116 and B70) and were cultivated in greenhouse and field soils fertilized with TSP, RP, ½TSP + ½RP. The PSB inoculation significantly increased the root biomass and P content under greenhouse and grain yield and grain P content of genotype BR007 grown in the field but had no effect on genotype SC283. The application of PSB as P-bioinoculant with RP acted as a promising alternative to reduce the use of synthetic chemical fertilizers leading to sustainable production of sorghum. The findings of this experiment, however, suggested that the impact of PSB inoculation varied according to (i) sorghum genotype, (ii) P source, and (iii) phosphobacterial strains. A field experiment by (Shete et al., 2018) conducted for three consecutive rabi seasons applying a drought-tolerant PSB strain with or without N and P sources showed a variable effect on the growth and yield of rabi sorghum. The sorghum seed inoculated with PSB strain (Acc. No.1/2012) and 100% recommended N and 75% recommended P₂O₅ demonstrated the highest plant height (199.9 cm), grain yield (18.13 q/ha), stover yield (62.96 q/ha),

1,000 grain weight (28.86 g), P uptake (14.14 kg/ha), benefit: cost ratio (3.17) and PSB counts (4.67 × 10⁴) at flowering stage. The results firmly indicate a saving of 25% of chemical P fertilizer for rabi sorghum under dryland conditions. Seed inoculation with *Pseudomonas putida* strain 168 in other experiments resulted in the highest dried forage, maximum dry matter digestibility, and crude protein while *P. putida* strain 41 produced maximum water-soluble carbohydrates. Seed inoculation with bacterial strains alone (especially strain 168) increased nutrient uptake, plant growth and consequently enhanced the yield. Among the PSB strains, *P. putida* strain 168 was superior compared even to dual culture application suggesting the antagonism between the two PSB strains (Ehteshami et al., 2014). In a similar investigation, the PSB significantly increased the shoot growth, ear head weight, and P content in both roots and shoots, and the grain yield of sorghum rose under a greenhouse environment, compared to plants grown without bacterial cultures and treated with RP and single superphosphate (Vikram, 2007). The inoculation of PSF, *Aspergillus terreus*, and *Penicillium pinophilum* in association with the reactive phosphate rock (RPR) improved the shoot growth, P-uptake, and enhanced the dry matter yield of sorghum, when grown under greenhouse conditions. The PSF application increased the shoot dry matter yield by 30% while the plant

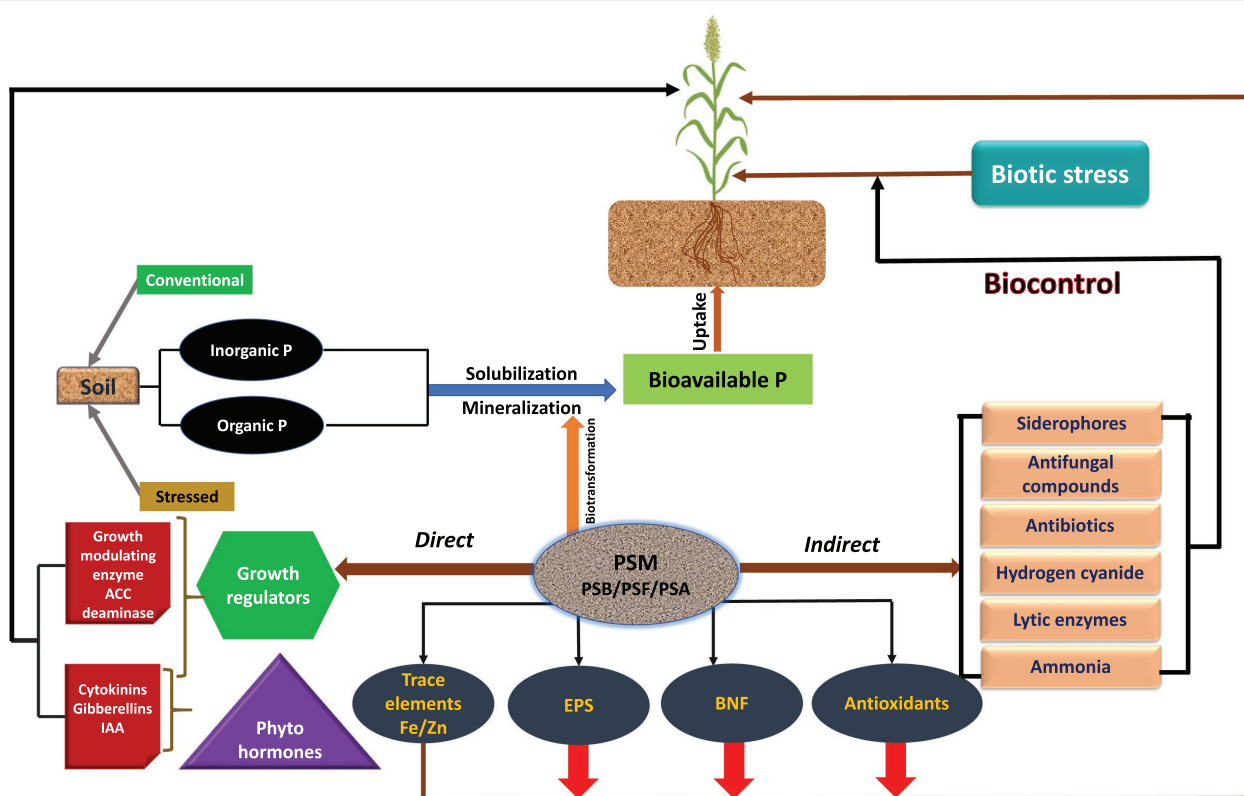

FIGURE 2 | Mechanism used by phosphate solubilizing microbiome (PSM) to facilitate sorghum plant growth.

height was enhanced by 42% compared to the uninoculated plants. The PSF inoculation, however, did not affect the root growth of sorghum plants. Moreover, the PSF substantially increased the P concentration by 61 and 71% in the absence and presence of RPR and 110 and 265% in the P accumulation of sorghum relative to the control, respectively. The PSF application, therefore, showed a more obvious beneficial impact on organ growth and sorghum P uptake (Steiner et al., 2016). A study conducted by Srinivasan et al. (2012) revealed that PSB identified using BIOLOG belonging to *Pseudomonas*, *Xanthomonas*, *Bacillus*, *Aerococcus*, *Alteromonas*, *Erwinia*, and *Enterobacter* while PSF identified as *Aspergillus* and *Penicillium* produced IAA and gibberellic acid (GA). The IAA produced by the bacterial cultures ranged between 0.74 and 9.53 $\mu\text{g } 25 \text{ ml}^{-1}$ while GA varied between 2.08 and 12.55 $\mu\text{g } 25 \text{ ml}^{-1}$. The amount of IAA secreted by the PSF differed from 2.33 to 8.69 $\mu\text{g } 25 \text{ ml}^{-1}$ and GA ranged from 3.44 to 14.80 $\mu\text{g } 25 \text{ ml}^{-1}$. Among the two P-solubilizers, PSF was superior to PSB in terms of P solubilization and increased maximally the stem girth, root length, root dry matter, and total dry matter of sorghum plants.

Inoculative Synergism Between PSM, N_2 Fixers, and AM-Fungi

The impact of mixed formulations of bio-enhancers belonging to two or more physiologically related/divergent groups has generally been excellent in promoting crop performance compared to single or mono culture applications

(Keller-Pearson et al., 2020; Dierks et al., 2021; Nogales et al., 2021). During composite application, the synergistic or additive effect of the interacting microbe is expected on growth, crop nutrition, and yield of crops. For example, bio-fertilizer organisms can improve the growth of a plant independently through N_2 fixation or through the production of growth hormones or synergistically through both mechanisms simultaneously. Therefore, a synergistic relationship promotes the growth, crop nutrition, and yield of plants more efficiently than solo culture because the microbial pairing allows the plants to achieve greater absorption of minerals (NPK) and other elements. However, little is known about the synergistic effect of PSM and other PGPR or AM-fungi on sorghum (Cobb et al., 2016). The combined effect of two or more PSM together or PSM with N_2 fixers or AM fungi on sorghum is reviewed and highlighted.

Composite Application of Phosphate Solubilizers

Some recent data by Rezakhani et al. (2020) indicate that the single-and dual cultures of PSB, *Pseudomonas* sp. FA1, and *Bacillus simplex* UT1 and different concentrations of silicon had variable impact on the morphological, nutritional uptake of P, Si and K, and physiological activities of *Sorghum bicolor* plant fertilized with soluble or insoluble P (RP; Rezakhani et al., 2020). In this sense, the RP-fertilized sorghum had better root and shoot biomass while the PSB strains and Si levels applied independently augmented all the measured bio-chemical

properties. Application of *Pseudomonas* sp. FA1 and *B. simplex* UT1 and Si with soluble P or insoluble P significantly enhanced P-use efficiency of sorghum plants. As a co-culture, both *B. simplex* and *Pseudomonas* sp. considerably increased the dry matter and P uptake of sorghum plants when raised with both forms of P fertilizer. While comparing the inoculation effects of the two PSB, *Pseudomonas* sp. was more efficacious than *B. simplex*. The composite culture of PSB with Si had the largest increase in P uptake and other growth indices. The results clearly suggest that the co-application of PSB and Si along with RP fertilization may serve as a substitute for chemical P fertilizer in sustainable sorghum cultivation practices. Studies by (Jisha and Alagawadi, 1996) revealed a variable impact of dual inoculation of PSB bacteria, *P. striata*, or *B. polymyxa* with the cellulolytic fungus, *Trichoderma harzianum*, on the nutrient uptake and yield of *Sorghum* grown in a vertisol treated with cotton stalks. Composite application of *B. polymyxa* or *P. striata* with *T. harzianum* increased the size and weight of the earhead, the number of spikelets per ear, and the straw and grain yield, and N and P uptake significantly relative to

uninoculated control and single PSB application. Grain yield was increased by 6–8% due to co-inoculation over mono P-solubilizers inoculation and by 28–30% over *T. harzianum* alone.

Synergism Between PSM and N₂ Fixers

Among phytonutrients, N and P are the two major nutrients that affect many important cellular processes like root elongation, proliferation and changes of root architecture, seed development, and maturity of plants growing both under conventional and stressful conditions (Liu et al., 2020; Patel and Panchal, 2020). The combined inoculation of PSM and N₂ fixers benefit plants better than either group of organisms used alone while substantially reducing the application of chemical fertilizers under field conditions (Gheliya et al., 2018; Li et al., 2020). Considering this (Afifi et al., 2014), in a field experiment conducted at Ismailia Agricultural Research Station, Agriculture Research Centre (ARC), Egypt, evaluated the impact of an associative N₂ fixer, *Azospirillum brasilense*, PSB *B. megaterium*, and potassium solubilizing bacterium (KSB) *B. circulans*, applied either alone or in combined forms and treated individually

Also, the NPK, crude protein, and total carbohydrates (%) were at maximum in sorghum grains. The *A. brasilense*, *B. megaterium*, and *B. circulans* when used together exhibited the highest grains yield (3.55 ton/fed) and 1,000 grains weight over control (full NPK). The findings clearly revealed that each bacterial strain could reduce the half doses of NPK through P and K solubilization and N-fixation processes. In a similar recent study, the impact of the asymbiotic nitrogen fixer (*A. chroococcum*) and P solubilizer (*B. megaterium*) on growth, yield parameters, and nutrient uptake of *Sorghum bicolor* grown under greenhouse conditions varied considerably (Vijayalakshmi et al., 2020). The formulations consisting of *A. chroococcum* and *B. megaterium* magnified the microbial populations in soil and through synergistic interaction increased the bioavailability of N and P and some other nutrients in the soil during sorghum harvest. The dual culture of N₂ fixer and P solubilizer applied with a 100% recommended dose of fertilizer (RDF) had a maximum beneficial impact on growth (plant height, length, and dry weight of root and shoot), nutrient uptake (NPK), and grain yield of sorghum compared to the uninoculated plants at harvest. The maximum number of grains (190/plant) and grain weight (5.23 g/plant) were observed with 100% RDF and combined formulations of *Azotobacter* with

PSB, which was followed by the 75% RDF with *Azotobacter* and PSB. A profound increase in the yield of sorghum was attributed as being largely due to the supply of N and P by the N_2 fixer and PSB to sorghum crops. This increase was well supported by enhancement in N (highest N 1.9%) and P (highest P uptake 0.41%) uptake by sorghum plants due to inoculation of *Azotobacter* with PSB along with 100% RDF at harvest compared to uninoculated and unfertilized control plants. In a similar greenhouse experiment (Alagawadi and Gaur, 1988, 1992), observed a significant increase in the yield of sorghum due to combined inoculation of PSB, *P. striata* or *B. polymyxa* and N_2 fixing *A. brasilense* which indicated a positive interaction between the dissimilar groups of bacteria. The yields were, however, markedly further enhanced by the application of 40 kg N as urea and 60 kg P_2O_5 (rock phosphate) per ha along with bacterial cultures over sole application of fertilizer or only bacterial inoculation. Due to this, it was suggested that 40 kg N could be saved and the whole quantity of super phosphate could be replaced by RP plus inoculation of *A. brasilense* and *P. striata* or *B. polymyxa*. The population counts of *Azospirillum* and phosphate-solubilizing bacteria in the rhizosphere of sorghum were higher in the respective inoculation treatments than in uninoculated treatments.

Synergism Between PSM and AM-Fungi

The AM-fungi during interaction receive sugars, amino acids, vitamins, and other organic substances from the host plant. In return, it absorbs minerals, especially P from the soil, and enhances the growth and yield of the host plant (Johansson et al., 2004). Agronomically, when the two dissimilar groups of beneficial organisms are applied in crop cultivation, the yield of many crops increases substantially (Saxena et al., 2013; Nacoon et al., 2020). Like other PGPR, AM-fungi and PSB interact synergistically wherein PSB solubilize sparingly available P compounds into orthophosphate that AM-fungi absorbs and transport to the host plants (Ordoñez et al., 2016). The reports on the inoculation effects of single or multiple PGPR on many cereal crops are numerous (Wahid et al., 2016; Naseri et al., 2018), but there is a scarcity of information on the synergistic effect of the PSM and AM-fungi on sorghum plants. Below, the role of composite application of PSM and AM fungi in the growth and yield promotion is highlighted.

Principally, AM-fungi provide nutrients to their host plants by producing hyphae that grow out from plant roots, effectively increasing the soil volume from which immobile nutrients can be acquired. So, mycorrhizal agricultural crops perform better and can be more productive compared with non-mycorrhizal plants. In addition, AM-fungi increase and improve the amounts of secondary compounds in plants (Mohamed et al., 2014). The synergy between AM-fungi and PSB with NPK fertilizer demonstrated variable growth and yield impact on greenhouse-grown sweet sorghum under saline conditions (Ramadhani and Widawati, 2020). The dual inoculation of AM-fungi and PSB in the presence of varying doses of NPK increased the plant height, the number of leaves, plant fresh weight, plant dry weight, and P of sweet sorghum plant. The AM-fungi and PSB applied with 25% NPK produced the highest increase in

all the biological features of sorghum plants, suggesting that the colonization between AM-fungi and PSB with NPK fertilizer could be a suitable and economical option for enhancing sorghum production even under saline conditions. The results of a study conducted by (Ziaeyan et al., 2016) showed that the plants inoculated with a combination of PSB and AM-fungi expressed synergistic effect to increase the efficiency of P fertilizer and growing conditions and yield of sorghum. The combined application of 25 mg P_2O_5 per kg of soil along with the PSB and AM-fungi maximally enhanced the biological attributes and therefore, could be recommended to save the P application in sorghum cultivation systems. Nitroxin, a bio-fertilizer prepared from a mixture of asymbiotic N_2 fixers *Azospirillum* and *Azotobacter* and AM-fungus (*Glomus mosseae*), mitigated the deleterious effects of stress by increasing the amounts of photosynthetic pigments, soluble proteins and osmotic regulation and decreasing electrolyte leakage in sorghum and, hence, increased the yield significantly. Mechanistically, the interacting bacterial genera had N_2 fixation, P solubilization, and iron releasing abilities, as well as the capability to secrete plant hormones such as auxin, cytokinin, and gibberellin and a growth modulating enzyme, ACC-deaminase, which together enhanced the yield substantially (Olanrewaju et al., 2017).

The interactions between PSM, N_2 fixers, and AM-fungi in terms of facilitating plant growth, nutrient uptake, and yield have been reported in numerous studies in the literature. The information regarding the inoculative effect of PSM, N_2 fixers AM fungi on sorghum is scanty. Widada et al. (2007) demonstrated that sorghum plants inoculated with PSB (*Pseudomonas* sp.), N_2 fixer (*Azospirillum lipoferum*), and AM-fungi (*Glomus manihotis* and *Entrophospora colombiana*) and grown in acid and P deficient soils improved the plant dry weight and nutrients (such as N, P, Fe, and Zn) uptake, which were enhanced further by dual inoculation of selected microbiome compared to the single inoculation. Dual inoculation of AM-fungi with PSB and AM-fungi and N_2 fixer increased plant dry weight by 112 and 64 times compared to the uninoculated plant, respectively. The selected rhizobacteria also improved plant colonization by AM-fungi. These results suggest that the tripartite interaction between PSB, N_2 fixer, and AM-fungi can be an excellent strategy for optimizing sorghum production since no antagonisms among interacting organisms were observed.

BIOTIC STRESS ALLEVIATION BY PSM

Pathogenic microorganisms are a major and continuing threat to food production and ecosystem stability worldwide. Yield, grain quality, and production stability of sorghum are constrained by various biotic (Kumar and Ram, 2014) and abiotic (Tari et al., 2013) stressors, resulting in poor marketability and utilization and causing severe economic losses. Among biotic factors, numerous fungal and bacterial diseases (Table 5) are of prime concern in sorghum-producing areas across the world. Attempts have been made to reduce pesticide use, develop stress-resistant varieties, enhance ecological fitness, and create

TABLE 5 | An overview of various diseases caused in sorghum following biotic stress.

Diseases	Causal organism	Major organs affected	Hotspot locations	References
Bacterial diseases				
Bacterial leaf streak	<i>Xanthomonas campestris</i> pv. <i>Holcicola</i>	Leaves	Wide geographical distribution	Wang et al., 2021
Bacterial leaf stripe	<i>Burkholderia andropogonis</i>	Leaves, flower buds, peduncles	Semi-arid and tropical regions	Mareya et al., 2020
Bacterial leaf spot	<i>Pseudomonas syringae</i>	Leaves	Argentina, Bulgaria, China, Hungary, India, Italy, Mexico, Africa, Rumania, Yugoslavia, Venezuela	Hernandez et al., 1992
Fungal diseases				
Anthraxnose	<i>Colletotrichum sublineolum</i>	All above-ground parts	United States, India, Mexico, Nigeria	Abreha et al., 2021
Charcoal rot	<i>Macrophomina phaseolina</i> (Tassi) Goid	Root and stalk	India, Africa, Australia, United States	Mahmoud et al., 2018
Downy mildew	<i>Peronosclerospora sorghi</i>	Seedling and leaves	Africa, Asia, Mexico, America	Prom et al., 2015
Covered kernel smut	<i>Sporisorium sorghi</i>	Kernels	Ethiopia, Africa	Nigusie and Ademe, 2020
Head smut	<i>Sporisorium holci-sorghi</i>	Panicle	Africa, Europe, North and South America, Mexico, Asia, Australia, New Zealand	Wagari, 2019
Loose kernel smut	<i>Sporisorium cruentum</i>	Kernels and panicles	Egypt	Moharam, 2018
Rust	<i>Puccinia purpurea</i>	Leaves	Nigeria, India, Mexico, United States	Wang et al., 2014
Rough leaf spot	<i>Ascochyta sorghi</i>	Leaves	China	Xu et al., 2019
Leaf blight	<i>Helminthosporium turcicum</i>	Leaves	Mexico, Brazil, India, Sudan, Nigeria, Niger, Kenya, and Ethiopia	Das and Rajendrakumar, 2016
Ergot	<i>Claviceps sorghi</i>	Spikelets	Israel	Shimshoni et al., 2017
Pokkah Boeng (twisted top)	<i>Fusarium subglutinans</i>	Leaf and top	India	Das et al., 2019
Zonate leaf spot	<i>Gloeocercospora sorghi</i>	Leaves	China	Jiang et al., 2018
Sooty stripe	<i>Ramulispora sorghi</i>	Leaves	United States	Brady et al., 2011
Grain mold	<i>Aspergillus</i> sp., <i>Penicillium</i> sp.	Grains	Asia and Africa	Das et al., 2020
Target leaf spot	<i>Bipolaris sorghicola</i>	Leaves	United States, India, Japan	Kimball et al., 2019

a sustainable production system in order to enhance efficiency, grain quality, and profitability (Sharma, 1985; Kumar et al., 2014). None of these approaches have, however, been completely successful due to several reasons such as the production cost, lethal impacts of agrochemicals, emergence of resistance among pathogens toward one or multiple biocides/pesticides, and lack of genetic resistance to sorghum varieties. These factors have generated interest among sorghum growers in employing biotechnological options, including the use of inexpensive PSM in the management of sorghum phytopathogens (Khasa, 2017; Nepomuceno et al., 2019; Mitra et al., 2020). The application of PSM in the abatement of phytopathogens has certain advantages, such as (i) not causing environmental hazards; (ii) precluding residual toxicity; and (iii) blocking the emergence of resistance among pathogens attacking sorghum. PSM controls the pathogen damage by one or simultaneous mechanisms through biocide compounds and optimizes the yields (Zaidi et al., 2014; Choudhary et al., 2016). The literature on the role of PSM in the management of phytopathogens affecting sorghum is, however, without doubt, lacking.

Mechanism of Disease Suppression

The PSM controls the phytopathogens attack by synthesizing pivotal molecules like siderophores (Sarr et al., 2020), antibiotics (Raaijmakers and Mazzola, 2012), lytic enzymes (Herrera-Quiterio et al., 2020), cyanogenic compounds (Munir et al., 2019), and through induction of systemic resistance (ISR; Audenaert et al., 2002). Due to this, the soil PSM improves the growth and grain yield of sorghum by suppressing the damaging impact of

biotic stresses. Below are some of the main mechanisms employed by PSM to manage phytopathogens and to boost sorghum yields.

Siderophores

Under iron-starved conditions, numerous PSMs, including bacteria, fungi, and actinomycetes, produce a wide range of siderophores (Maldonado et al., 2020; Aallam et al., 2021) with relatively low molecular weight (below ≈ 2 kDa) and ferric ion-specific chelating agents at neutral to alkaline pH to solubilize, capture, and transport inorganic iron to cell (Sandy and Butler, 2009). They are, therefore, exploited in the management of plant diseases (Verma et al., 2011; Jyothi et al., 2020). The siderophore positive rhizobacteria protect the plants from damages by preventing the iron acquisition (Estrella and Chet, 1998) and, hence, limiting the proliferation and root colonization by phytopathogens (O'sullivan and O'Gara, 1992).

Charcoal rot of sorghum caused by *Macrophomina phaseolina*, a soil- and seed-borne disease of sorghum, is endemic to tropical and temperate regions of the world (Kumar et al., 2016). Charcoal root causes considerable yield losses due to a lack of genetic-resistant sorghum varieties. Up to 64% yield losses are reported in India by this disease during the post-rainy season (Das et al., 2008). In order to control the attack of this phytopathogen (Gopalakrishnan et al., 2011), isolated siderophore-positive PSB, *Pseudomonas plecoglossicida*, *B. altitudinis*, *E. ludwigii*, *Acinetobacter tandoii*, and *P. monteillii* from the rhizospheres of a system of rice intensification (SRI) fields and tested their biocontrol activity against *M. phaseolina*. Interestingly, all PSB showed strong

antagonistic activity in dual culture assay, blotter paper assay, and *in vivo* greenhouse and inhibited the growth of *M. phaseolina*. No charcoal rot infection was observed in *P. plecoglossicida*-treated sorghum roots indicating the complete inhibition of pathogen whereas the roots treated with other isolates had 49–76% less charcoal rot infection compared to the control. All PSB increased root and shoot dry mass by 15–20% and 15–23% over control under greenhouse experiment. Also, all PSB adapted well to the sorghum rhizosphere as indicated by the reduction in charcoal rot disease. Similar antifungal activities (inhibition of growth, biomass, microsclerotia production, spore germination) of the secondary metabolites (antifungal volatile and siderophores) and the cell-free culture filtrates (CFCFs) of the selected fluorescent pseudomonad strains (SRB129, SRB288, and *Pseudomonas chlororaphis* SRB127) against the mycelial growth of *M. phaseolina* that varied from 30.5 to 76.5% in dual culture assay is reported (Das et al., 2008). The CFCF of the fluorescent pseudomonads @ 20% (v/v) significantly decreased the formation and germination of microsclerotia of *M. phaseolina*. Siderophore-positive bacterium *P. chlororaphis* (SRB127) controlled the charcoal rot of sorghum most efficiently under field conditions. As seed treatment, the bacterium reduced the charcoal rot incidence by >40% and crop-lodging by >20% and increased the sorghum grain mass. Under glasshouse conditions, the bacterium survived in the sorghum rhizosphere without any significant reduction in its population. Similarly, *Streptomyces* isolated from medicinal plant rhizosphere inhibited the fungal activity of phytopathogenic fungi *A. brassicicola*, *C. gloeosporioides*, *Fusarium oxysporum*, *P. digitatum*, and *S. rolfsii* through siderophores (Khamna et al., 2009). de Los Santos-Villalobos et al. (2012) reported the inhibition of *Colletotrichum* species (causing anthracnose in sorghum) due to the release of hydroxamate siderophore by *B. cepacia* in a Petri-dish bioassay test. Interestingly, even the lowest concentration ($0.64\mu\text{gml}^{-1}$) of siderophore inhibited the pathogen by 91%. Other phytopathogenic fungi capable of inflicting damage to sorghum for example, grain mold diseases of sorghum (*Aspergillus* and *Penicillium*) has also been controlled by siderophore rich culture and free supernatant of *Alcaligenes* sp., and *P. aeruginosa* (Sayyed and Patel, 2011). The siderophore based biological control measures, therefore, be adopted in sorghum cultivation practices due to reasons, as they are (i) inexpensive and non-destructive (safer) for the environment; (ii) self-replicating and do not require repeat application; and (iii) there is no emergence of resistance among target organisms (Sayyed et al., 2004).

Growth Modulating Enzyme

Production of 1-aminocyclopropane-1-carboxylate (ACC) deaminase by PSM is considered yet another most powerful management biological weapon for plants growing under abiotic stress (Glick, 2014). After infection by phytopathogens, ethylene, a stress hormone is produced in all higher plants, which causes senescence, chlorosis, abscission, and wilting in plants, worsening the detrimental impact of pathogens (Dubois et al., 2018; Sharma et al., 2019; Etesami and Glick, 2020). The damaging

impact of stress hormone can be annulled by the ACC deaminase, a multimeric enzyme, secreted by PSM bacteria (Zhao et al., 2021), fungi (Aban et al., 2017), and actinomycetes (Chukwuneme et al., 2020), which cleaves ACC (precursor of ethylene) to produce α -ketobutyrate and ammonia and thereby decreases the ethylene levels in host plants (Gupta and Pandey, 2019; Orozco-Mosqueda et al., 2021). The decrease in the levels of ACC and ethylene prevents the ethylene-mediated plant growth inhibition. PSM endowed with this capability can benefit the sorghum plants by reducing the stress and increasing plant growth (Santana et al., 2020). As an example, (Mareque et al., 2015) reported that the majority of the PSB, such as *Pantoea*, *Enterobacter*, *Serratia*, *Pseudomonas*, *Acinetobacter*, and *Stenotrophomonas* (Gammaproteobacteria phylum), *Achromobacter*, *Herbaspirillum*, and *Ralstonia* (Betaproteobacteria), *Rhizobium* (Alphaproteobacteria), *Chryseobacterium* (Bacterioidetes), *Bacillus*, *Staphylococcus*, *Brevibacillus*, and *Paenibacillus* (Firmicutes), and *Kocuria* (Actinobacteria), isolated from roots and stems of sweet sorghum plants exhibited ACC deaminase activity. Of these, ACC deaminase positive *Rhizobium* sp. UYSB13 and PSB bacterium *Pantoea* sp. UYSB45 showed a significant difference from the negative control in the stem height and dry weight (roots and shoots). Additionally, the ACC deaminase positive *Rhizobium* sp. UYSB12 and *Enterobacter* sp. UYSB34 significantly enhanced the root and the shoot dry weights of sweet sorghum.

Antimicrobials

The antibiotic-mediated inhibition of plant pathogens by rhizosphere-inhabiting biocontrol microorganisms is well (Babalola, 2010; Raaijmakers and Mazzola, 2012) are the most common and have been used in disease management through antibiotics, for example, the suppression of take all disease in wheat by 2,4-diacetylphloroglucinol (Weller et al., 2007). A variety of antibiotics have been identified: amphisin, 2,4-diacetylphloroglucinol (DAPG), oomycin A, phenazine, pyoluteorin, pyrrolnitrin, tensin, tropolone, and cyclic lipopeptides produced by pseudomonads (Raaijmakers and Mazzola, 2012; Saraf et al., 2014), and oligomycin A, kanosamine, zwittermicin A, and xanthobaccin produced by *Bacillus*, *Streptomyces*, and (Milner et al., 1996; Hashidoko et al., 1999; Mavrodi et al., 2012) diffusible products like 2, 4-diacetylphloroglucinol, phenazines, pyoluteorin, pyrrolnitrin, etc., or volatile compounds such as dimethyl disulfide, cyanogenic compounds, etc. (Olanrewaju and Babalola, 2019; Pandey and Gupta, 2020). One problem in depending too much on PSM-based antibiotics as biocontrol agents is, however, that with the increased use of PSM, phytopathogens may also develop resistance to microbe-mediated antibiotics in a manner similar to those exhibited for conventional antibiotics. This can though, be obviated by incorporating an HCN-positive PSM (Mahdi et al., 2020) with antibiotics producing PSM (Hamdali et al., 2008) so that the HCN-positive strain kills the pathogens while avoiding the emergence of antibiotic resistance among phytopathogens. The combination of HCN and antibiotics positive PSM looks a promising strategy that will synergistically control the phytopathogen attack.

Hydrolytic Enzymes

A number of hydrolytic enzymes, such as, cellulases, chitinase, β -1,3-glucanase, protease, lipase, and peroxidase, are released by the PSM (Liu et al., 2016; Nandimath et al., 2017). The cell wall of plant pathogenic fungi, for instance *F. oxysporum*, is mainly composed of β -1,3-glucan layers that are highly susceptible to lysis by β -1,3-glucanase. Following degradation, there occurs the leakage of inner cellular contents to the exterior environment and, finally, due to the osmotic imbalance, the pathogenic fungi collapses (Singh et al., 1999). For instance, some PSFs, such as *Acrocalymma* sp., *Otryobambusa fusicoccum*, and *Phoma* sp., produce lytic enzymes such as chitinases and glucanases (Silveira et al., 2021) and catalase and cellulases (Amin et al., 2020), and many PS actinomycetes such as *S. fulvissimus*, *Streptoverticillium olivovorticillatum*, *S. nogalater*, *S. longisporoflavus*, and *S. cellulosa* produce cellulase, chitinase, pectinase, lipase, and amylase (Nandimath et al., 2017), which lyse the cell walls of pathogenic fungi attacking sorghum. Similarly, number of PSB belonging to the genera *Chrysobacterium*, *Bacillus*, *Pseudomonas*, *Mycobacterium*, *Staphylococcus*, *Curtobacterium*, *Enterobacter*, *Agrobacterium*, *Ochrobactrum*, *Serratia*, *Stenotrophomonas*, and *Acinetobacter* produced lytic enzymes, such as proteases, celluloses, lipases, esterases, and amylases, which exhibited activity against *Fusarium*, *Aspergillus*, and *Colletotrichum* (Herrera-Quiterio et al., 2020). In a similar study, phosphate solubilizing *B. subtilis* BN1 isolated from the chirpine (*Pinus roxburghii*) rhizosphere exhibited strong antagonistic activity resulting in vacuolation, hyphal squeezing, swelling, abnormal branching, and lysis of *M. phaseolina*, *F. oxysporum*, and *R. solani*. The inhibition of fungal growth by *B. subtilis* BN1 was attributed due to the secretion of lytic enzymes, chitinase, and β -1,3-glucanase, which degrades the hyphae and digest the fungal cell wall (Singh et al., 2008). The CFCF of BN1 also showed a strong but concentration-dependent antifungal activity and completely inhibited the fungal growth at 60% CFCF concentration. *Pseudomonas putida* in yet another experiment demonstrated antifungal activity against *A. alternata*, *F. oxysporum*, and *R. solani* through chitinase, β -1,3 glucanase, salicylic acid, siderophore, and HCN (Selvakumar et al., 2009). The PS bacterium *Serratia marcescens* inhibited the growth of *Sclerotium rolfsii* (Ordentlich et al., 1988) while *Paenibacillus* sp. strain 300 and actinomycetes *Streptomyces* sp. strain 385 suppressed *F. oxysporum* fsp. *Cucumerinum*. Extracellular chitinase and laminarinase synthesized by *Pseudomonas stutzeri* degraded the mycelia of *F. solani* (Lim et al., 1991). These and other related studies that are not included in this review suggests that, in the absence of high level of genetic resistance in high-yielding sorghum varieties, the PSM as bio-antagonists could safely be used to effectively manage the biotic stresses of sorghum and hence to reduce losses in yield and quality of sorghum cultivated in different regions of the world.

CONCLUSION

The unwarranted and imprudent application of agrochemicals in sorghum cultivation practices and their hazardous impact on the soil environment warrants the use of a low-cost and

environmentally friendly P-solubilizing microbiome as a prospective alternative to P fertilizers and pesticides. Due to the exorbitant cost of chemical fertilizers, harmful impact of pesticides, and lack of high level of genetic resistance, the novel PSM discovered so far and discussed herein applied either alone or in synergism with compatible organisms can be a useful component in the management of P fertilization, yield optimization, and integrated sorghum disease management. The application of PSM-based (microphos) formulations in sorghum cultivation is likely to provide economic benefit to sorghum growers while reducing the risk of environmental pollution.

Future Prospects

The studies surveyed and presented herein are though directly relevant to improving food production, deciphering the detailed molecular and ecological relationships between PSM, N_2 fixers, and AM-fungi is indispensable to developing a better understanding of the synergistic relationship between three functionally divergent groups of the soil microbiome. Also, the rhizosphere competence and colonization effect of different PSM strains and their interaction with functionally unrelated plant beneficial bacteria should further be investigated under complex and variable natural conditions with the aim of producing “microphos: PSM based biofertilizer” to alleviate the biotic stresses and consequently augmenting sweet sorghum production in different agroecosystems. Continued research is, however, needed to develop novel strategies to ameliorate the yield and upgrade the efficiency of PSM to manage the attack of phytopathogens causing huge losses to sweet sorghum in variable agroclimatic conditions. To achieve this, scientists, institutions, and manufacturers need to work together to find solutions to nutrition and disease management and to optimize sorghum yield to eradicate hunger worldwide.

It is commonly known that exogenously applied melatonin can alleviate the impact of drought stress, but the mechanism used by melatonin to regulate stomatal behavior and carbon (C) and nitrogen (N) metabolism to increase drought resistance remains elusive. Herein, our aim was to investigate the influence of exogenous melatonin on the regulation of C and N metabolism in maize plants under water deficit. In this study, we analyzed stomatal behavior, the key components of C and N metabolism, and the gene expression and activity of enzymes involved in the C and N metabolism in maize plants. The results showed that the application of melatonin (100 μ M) significantly increased maize growth and sustained the opening of stomata, and secondarily increased the photosynthetic capacity in maize. Under drought stress, foliar application of melatonin induced the gene transcription and activities of sucrose phosphate synthetase, ADP-glucose pyrophosphorylase, phosphoenolpyruvate carboxylase, and citrate synthase, resulting in the enhancement of sucrose and starch synthesis and the tricarboxylic acid (TCA) cycle. This enhancement in sugar biosynthesis and the TCA cycle might lead to stronger N assimilation. As anticipated, NO_3^- reduction and NH_4^+ assimilation were also strengthened after melatonin treatment under drought stress. An increase was observed in some key enzymatic activities and transcription involved in nitrogen metabolism, such as that of nitrate reductase, nitrite reductase, glutamate synthase, and glutamine synthetase, in melatonin-treated, drought-stressed maize. Moreover, melatonin attenuated the drought-induced damage by reducing protein degradation and increasing the level of proline. Conclusively, our results indicate that exogenous melatonin enhances drought tolerance in maize *via* promoting stomatal opening and regulating C and N metabolism and related gene expression.

Keywords: maize, drought, melatonin, stomatal behavior, carbon and nitrogen metabolism

INTRODUCTION

Maize (*Zea mays* L.) is one of the most important grain crops cultivated worldwide but is extremely sensitive to drought stress (Li Z. et al., 2021). Water is a crucial environmental factor for crop production, and soil water deficits limit crop growth and yield (Yang et al., 2019). Water scarcity compromises economic output and food security worldwide, and in the past decade, global losses

in crop production due to drought totaled approximately \$30 billion (Riemann et al., 2015; Gupta et al., 2020).

Drought is complex abiotic stress, and a series of morphological, physiological, and biochemical changes take place during the response of plants to drought stress (Shah et al., 2020), which include plant growth (Todaka et al., 2017), leaf stomatal behavior (Indira et al., 2021), photosynthetic activity (Zhou et al., 2019), cellular redox homeostasis (Zhang et al., 2019), and metabolism homeostasis (Pinheiro and Chaves, 2011). These changes are usually interconnected. Specifically, osmotic stress caused by drought induces the accumulation of abscisic acid (ABA), which, at high levels, can promote stomata closure and decrease the internal carbon dioxide concentration (C_i) (Riemann et al., 2015; Kong et al., 2016; Zhou et al., 2019). Following stomatal closure and the decrease in C_i , the activity of the carboxylating enzyme Rubisco has been shown to decrease, which leads to electron accumulation and reactive oxygen species (ROS) overproduction, eventually resulting in oxidative damage and a series of subsequent side effects, such as leaf peroxidation, and degradation of chlorophyll, proteins, and nucleic acids (Campos et al., 2019; Sharma and Zheng, 2019; Sharma et al., 2020).

To cope with drought stress, the plants have evolved various metabolic adaptation mechanisms to defend against the adverse effects of stress, in which the coordinated regulation of carbon (C) and nitrogen (N) metabolism is one of the most important mechanisms (Ren et al., 2020). C and N metabolism are two of the most important metabolic processes in plants, and they are tightly related to each other (Yu et al., 2021). Metabolic processes involving C include reactions in photosynthesis and respiration (Cui et al., 2019). Photosynthesis and mitochondrial respiration provide C skeletons and an energy source for various biological processes, such as N assimilation and amino acid biosynthesis (Qiao et al., 2019). The growth and yield of plants are determined to a large extent by the capacity of photosynthesis (Cui et al., 2019). However, water deficit limits photosynthesis, which causes depletion of energy and sugar and diminishes plant production (Hu et al., 2020). N is a crucial structural component of nitrogenous compounds, such as amino acids, proteins, nucleic acids, chlorophyll, and enzymes (Qiao et al., 2019). Thus, N directly or indirectly affects plant photosynthesis through its effects on chlorophyll, photosynthetic rate, and the main enzymes of dark reactions and photorespiration (Zhong et al., 2019). The first step in N uptake and utilization is that nitrate reductase (NR) and nitrite reductase (NiR) convert nitrate (NO_3^-) into ammonium (NH_4^+) (Xie et al., 2019). Then, NH_4^+ is further assimilated to glutamate *via* glutamine synthetase (GS) and glutamate oxoglutarate aminotransferase (GOGAT) or glutamate dehydrogenase (GDH) (Rajasekhar and Oelmüller, 2010; Xie et al., 2019). Subsequently, glutamate acts as a donor of the amino group that distributes N to all other N-containing metabolites and macromolecules (Xie et al., 2019). The studies have shown that N assimilation plays a pivotal role in the acclimation of plant photosynthesis to drought stress (Xie et al., 2019; Zhong et al., 2019). Moreover, the C metabolism provides the energy and organic carbon skeletons for N assimilation and amino acid biosynthesis (Zhong et al., 2019). Therefore, the balance between

C and N metabolism provides essential contributions to drought tolerance (Liu et al., 2014; Ren et al., 2020).

Melatonin (N-acetyl-5-methoxytryptamine) is a new plant growth regulator that is widely found in bacteria, fungi, plants, and algae (Kanwar et al., 2018; Debnath et al., 2020). Previous reports demonstrated that melatonin is involved in multiple biological processes in plants, such as seed germination (Li C. et al., 2021), root growth (Boyko et al., 2020), flowering (Kolar et al., 2003), leaf senescence (Ahmad et al., 2020), increased photosynthetic capacity (Ahmad et al., 2019), and moderation of oxidative damage (Qi et al., 2018; Kaya et al., 2019, 2020; Siddiqui et al., 2020). Furthermore, many studies have shown that the antioxidant action of melatonin can substantially enhance the tolerance of plants under biotic and abiotic stresses, such as pathogen infections (Li et al., 2019), drought (Sharma et al., 2020), cold (Wang et al., 2020), heat (Wei et al., 2015), salt, and UV stress (Yao et al., 2020; Zhang et al., 2020). In addition, melatonin may enhance plant stress resistance by regulating C or N metabolism. A previous study has suggested that metabolites, such as carbohydrates, organic acids, and amino acids accumulate after the application of melatonin to increase cold stress tolerance in Bermuda grass (Hu et al., 2016). A recent study in cotton revealed that melatonin enhances pollen fertility by balancing the carbohydrates of drought-stressed anthers (Hu et al., 2020). However, most of these studies on melatonin-enhancing stress resistance focused only on C or N metabolism, and currently, there is no report that combined C and N metabolism to study how melatonin alleviates drought stress.

Given the essential contributions of C and N metabolism and melatonin to the drought resistance of maize and the regulatory role of melatonin on primary metabolism, we hypothesize that the melatonin-induced drought resistance of maize depends to a large extent on the coordinated modulation of C and N metabolism. Therefore, we investigated the possible role of melatonin in maize response to soil drought stress by determining the photosynthetic capacity, leaf stomatal behavior, the amounts of various metabolites related to C and N metabolism, and the gene expression and activities of some key enzymes involved in C and N metabolism. The current study aimed to explore how melatonin enhances drought tolerance by regulating the coordination of C and N metabolism. The results will contribute to further understanding of the role played by melatonin in alleviating drought stress.

MATERIALS AND METHODS

Plant Materials and Treatments

A pot experiment was conducted from May to August 2020 at the rainproof shed of the Maize Experimental Station of Northwest A&F University, Shaanxi, China. Maize (*Z. mays* L. “Shaandan 609”) seeds were sown in plastic pots of uniform size (diameter 26 cm and depth 38 cm), each filled with 15 kg air-dried soil and 10 g compound fertilizer containing 24% N, 6% P_2O_5 , and 10% K_2O . The soil water content is expressed as a percentage maximum of pot capacity (Ogbaga et al., 2014). All plants were watered to 85% before the seven-leaf stage. Afterward, half of the

pots were exposed to drought conditions. During this period, all pots were sprayed with either melatonin (100 μM) or distilled water at 8 p.m. every day. The sprayed melatonin solution was prepared by dissolving 1.15 g melatonin powder in 25 ml ethanol as a stock solution. Subsequently, a melatonin solution of the desired concentration was obtained by further dilution with distilled water, including 0.05% (v/v) Tween-20 as a surfactant. In the present study, the maize seedlings were subjected to four treatment regimes: (1) distilled water pretreatment plus ample water (Control, CK); (2) 100 μM melatonin plus ample water (MT); (3) distilled water pretreatment plus drought (DS); (4) 100 μM melatonin plus drought (DS + MT). The melatonin concentration (100 μM) applied in this study was chosen based on a study by Guo et al. (2020a). The experiment was stopped when the soil water content decreased to 50%, i.e., after drought for 6 days. At the end of the treatments, the fully expanded third leaf from the top of the plant was gathered, rapidly frozen in liquid nitrogen, and stored at -80°C for the following measurements.

Plant Growth Attributes

The plant leaf was measured with a tape measure on the last day of the experiment to calculate the leaf area, as described by Ahmad et al. (2019): leaf area = leaf length \times maximum leaf width \times 0.75. The aboveground plant parts from each group were sampled, and their fresh biomass was determined. Then, the aboveground parts of the maize plant were oven-dried at 105°C for 45 min and then maintained at 80°C for 48 h to obtain a stable dry weight. The amount of chlorophyll in the fully expanded third leaf from the top was determined using a SPAD-502 Plus chlorophyll meter (Plus, Konica Minolta, Japan).

To evaluate the water stress effects, measurements of the relative water content of leaves (RWC) were performed based on the method of Li et al. (2014) with some modifications. Briefly, a total of 1 g of fresh leaves tissue was immediately excised and weighed (fresh weight, WF), and again weighed after floating leaf segments on the water for 12 h in the dark (saturated weight, WS) and after oven-drying at 85°C for 24 h to a constant weight (WD). The RWC was calculated as follows:

$$\text{RWC}(\%) = [(WF - WD) / (WS - WD)] \times 100 \quad (1)$$

Determination of Gas Exchange Parameters and Chlorophyll Fluorescence

Gas exchange parameters, such as photosynthetic rate (P_n), intercellular CO_2 concentrations (C_i), stomata conductance (G_s), and transpiration rates (Tr) were recorded between 10:00 a.m. and 12:00 a.m. on the fully expanded third leaf from the top with an LI-6400XT portable photosynthesis system (LI-COR, Biosciences, Lincoln, NE, United States). During the measurement period, the photosynthetic photon flux density (PPFD) was controlled at $1,200 \mu\text{mol m}^{-2} \text{s}^{-1}$ (light saturation), the blocking temperature was at 25°C , the CO_2 concentration in the air entering the leaf chamber was at $400 \mu\text{mol mol}^{-1}$, and the

relative humidity was at 50–70%, according to Dai et al. (2020). Each treatment was replicated three times.

The eighth leaf was selected to evaluate chlorophyll fluorescence *via* the saturation pulse technique, using the Pulse Amplitude Modulated system (Dual-PAM-100, Heinz Walz, Effeltrich, Germany). The maximum efficiency of PSII photochemistry (Fv/Fm), quantum efficiency of PSII [Y(II)], quantum yield regulated energy dissipation of PSII [Y(NPQ)], the quantum yield of non-regulated energy dissipation of PSII [Y(NO)], and photosynthetic electron flows through PSII [ETR(II)] were imaged and calculated after adaptation in the dark for 30 min (Guo et al., 2020b).

Quantification of Carbohydrates

The amounts of sucrose, glucose, and fructose were determined by using high-performance liquid chromatography (HPLC) (Xu et al., 2020). Briefly, a frozen leaf sample (1.0 g) was ground in 5 ml of extraction buffer (ethanol: chloroform: water = 12: 5: 3), and transferred to a centrifuge tube containing 25 ml of ultrapure water. Then, the mixture was heated to 80°C in a water bath for 1 h. After cooling to room temperature, the mixture was centrifuged at $10,000 \times g$ for 15 min. The supernatant was filtered into a 50 ml volumetric flask, and the volume was brought to 50 ml with ultrapure water. This solution was used to quantitate the sugars, and the residue was used to quantitate the starch.

Starch was quantified in leaves with the Anthrone method as described by Hansen and Moller (1975). The starch was extracted with 20 ml of deionized water and heated in boiling water for 15 min using the residue obtained in the above extraction process. Then, the residue was extracted with 2 ml of 9.2 M perchloric acid and heated in boiling water for 15 min. After the mixture was centrifuged at $4,000 \times g$ for 15 min, the supernatant was brought to a final volume of 50 ml with distilled water. Then, 2.0 ml of the supernatant was mixed with 10 ml of anthrone reagent (1.0 g of anthrone dissolved in 500 ml 72% sulfuric acid) and boiled for 10 min. After this treatment, the tube was rapidly cooled to room temperature, and the absorbance was measured at 630 nm.

NO_3^- , NO_2^- , and NH_4^+ Measurements

The foliar NO_3^- , NO_2^- , and NH_4^+ were extracted from the tissue of each freeze-dried leaf by homogenizing with deionized water. The amount of NO_3^- was spectrophotometrically determined at 410 nm by nitration of salicylic acid, as previously described by Cataldo et al. (1975). The amount of NO_2^- was assayed by measuring the absorbance changes at 620 nm obtained by known concentrations of KNO_3 (Barro et al., 1991). NH_4^+ was quantified by measuring the absorbance changes at 620 nm based on Brautigam et al. (2007), with $(\text{NH}_4)_2\text{SO}_4$ as the standard.

Quantification of Soluble Protein, Free Amino Acids, and Proline

First, 0.5 g of leaf tissues were ground in 5 ml pre-cooled 50 mM phosphate buffer (pH 7.8). The homogenate was centrifuged at $12,000 \times g$ and 4°C for 20 min. The soluble protein concentration in the leaves was quantified using the Coomassie brilliant blue G-250 reagent according to Bradford (1976) with bovine serum

albumin (BSA) as a standard. The free amino acid content was determined by the ninhydrin method (Yemm et al., 1955), with glycine as the standard. Proline was determined according to the method of Ye et al. (2015). Briefly, 0.5 g of fresh leaves were homogenized in 5 ml of 3% aqueous sulfosalicylic acid. Then, the mixtures of 2 ml of supernatant, 2 ml of ninhydrin reagent, and 2 ml of glacial acetic acid were boiled for 30 min, cooled, and centrifuged at $10,000 \times g$ for 10 min. The absorbance was recorded at 520 nm, and the amount of proline was calculated according to a standard curve.

Enzymatic Activity Assay

Nitrate reductase (NR) and nitrite reductase (NiR) were measured in maize leaves (0.5 g), which were homogenized with 2 ml buffer containing 0.1 M Tris-HCl (pH 7.5), 10 mM cysteine, 1 mM ethylene diamine tetraacetic acid (EDTA), and 5 μ M flavin adenine dinucleotide (FAD). Then, the homogenate was centrifuged at $15,000 \times g$ for 20 min at 4°C, and all the extraction steps were performed on ice. The activities of NR and NiR were measured based on the method of Barro et al. (1991).

To determine the activities of glutamine synthetase (GS), glutamate synthetase (GOGAT), and glutamate dehydrogenase (GDH), corn leaves (0.5 g) were grounded in 3 ml buffer containing 50 mM Tris-HCl (pH 8.0), 2 mM Mg^{2+} , 2 mM DTT, and 0.4 M sucrose. Extracts were centrifuged at $10,000 \times g$ for 10 min at 4°C, and all operations were performed on ice. GS activity was determined according to the description of O'Neal and Joy (1973). GOGAT was measured as described by Matoh and Takahashi (1982). The activity of GDH was assessed as per Loyola-Vargas and de Jimenez (1984).

The frozen leaf samples (0.5 g) were extracted in 5 ml 100 mM Tris-HCl buffer (pH 7.0) containing 5 mM $MgCl_2$, 2 mM EDTA- Na_2 , 2 mM dithiothreitol (DTT), 2% β -mercaptoethanol, 0.2% BSA, and 2% polyvinylpyrrolidone (PVP), and the homogenates were centrifuged at $10,000 \times g$ and 4°C for 10 min. All the steps were performed on ice. After centrifugation, the supernatant was analyzed to determine if sucrose phosphate synthase (SPS), sucrose synthase (SuSy), acid invertase (AI), and alkaline invertase (NI) were present according to the method of Hu et al. (2020).

To determine ADP glucose pyrophosphorylase (AGPase) activity, 0.5 g maize leaf tissues were mixed with 50 mM HEPES-NaOH buffer, then centrifuged at 4°C for 10 min at $10,000 \times g$. The supernatant was used to determine the activity of AGPase according to Schaffer and Petreikov (1997). All extractions were carried out on the ice.

Citrate synthase (CS) activity in the frozen leaf samples (0.5 g) was extracted with 5 ml 200 mM Tris-HCl buffer (pH 8.2) containing 0.1% Triton X-100 and 10 mM erythorbic acid (Terrier et al., 2001). The samples were grounded in an ice bath, and the homogenates were centrifuged at $5,000 \times g$ for 20 min at 4°C. The supernatant was used to determine the activity of CS according to Johnson et al. (1994).

The frozen leaf samples (0.5 g) were grounded with 5 ml 100 mM phosphate buffer (pH 7.2–7.4) in an ice bath, and the homogenates were centrifuged at $3,000 \times g$ and 4°C for 20 min. The supernatant was then used for the enzymatic assay.

The activity of phosphoenolpyruvate carboxylase (PEPC) was determined using a detection kit (Jing Kang, Shanghai).

RNA Extraction and Real-Time Quantitative PCR Assay

The frozen leaf samples (approximately 100 mg) were grounded into powder under liquid nitrogen, and the total RNA of the different treatments was extracted using TRIzol reagent (Thermo Fisher, MA, United States). Then, 2 μ g of total RNA was reverse transcribed according to the instructions of the reagent manufacturer (HiScript II Q-RT SuperMix for qPCR, Vazyme, China). The primer sequences for RT-PCR were designed by Primer-BLAST (GenBank, NCBI) and are shown in Table 1. qRT-PCR was performed using the CFX96 real-time PCR detection system (Bio-Rad, Hercules, CA, United States) with SYBR Green I (Bio-Rad). The two-step PCR method was performed, and the PCR conditions were as follows: pre-denaturation at 95°C for 30 s, 40 cycles of 95°C for 5 s, and 60°C for 30 s. The results were calculated according to the $2^{-\Delta\Delta CT}$ method (Mohd et al., 2011). Three biological replicates were performed, and β -actin was used as an internal reference gene.

Statistical Analysis

ANOVA was performed for the results using SPSS 25.0 software, and then Duncan's multiple range test was carried out, with $P < 0.05$ indicating a significant difference. A SigmaPlot 10.0 was used to draw the figures. All the values are presented as the mean \pm SD.

RESULTS

Effects of Melatonin on Maize Growth Under Drought Stress

In the present study, we evaluated the effects of MT, drought stress, and their combination on the growth of maize to understand the role of melatonin in drought tolerance in maize plants. As shown in Figure 1, there were no significant effects on maize seedling growth between melatonin-treated and non-treated under the well-irrigated conditions. The water deficit caused a significant inhibition of plant growth, with the aboveground biomass accumulation and leaf area of non-treated maize seedlings decreasing by 36.0 and 42.0%, respectively, compared with control (Figures 1A,B). In comparison, exogenous melatonin application mitigated the drought stress, and the aboveground biomass accumulation and leaf area of melatonin-treated seedlings increased by 30.6 and 11.5%, respectively, compared with that of the non-treated seedlings (Figures 1A,B). Drought stress resulted in a sharp decrease in chlorophyll and the RWC, while the application of exogenous melatonin reversed these trends to some extent (Figures 1C,D). In relation to control, water deficit substantially reduced chlorophyll and the RWC by 30.17 and 40.19%, respectively. However, melatonin treatment caused significant recovery of chlorophyll and the RWC by

16.93 and 24.41%, respectively, compared with the drought stress treatment.

Effects of Melatonin on Stomatal Behavior Under Drought Stress

The SEM stomatal images showed that the stomata were almost completely closed by drought stress (Figure 2B), stomatal aperture exhibited a 72.3% decrease in comparison with control (Figure 3C). Moreover, drought stress also led to the stomata being shorter, narrower, and thinner. The stomatal length, width, and density in the plants that underwent

drought stress alone were 82.3, 76.7, and 79.1% of that of control, respectively (Figures 3A,B,D). Compared with the plants that received limited water, the stomata remained partially open in the melatonin-treated maize under drought stress (Figure 2D). Correspondingly, the stomatal aperture of melatonin-treated plants was 1.3-fold higher than that of stressed plants (Figure 3C). The melatonin-treated plants had longer and wider stomata under drought stress. The stomatal length and width in maize seedlings treated with melatonin were increased by 11.9 and 12.0%, respectively, in contrast to the drought stress-treated plants (Figures 3A,B). In addition, the stomatal length

FIGURE 2 | Effects of drought and exogenous melatonin on stomata in leaves. **(A)** Stomata from well-watered plants. **(B)** Stomata from drought-treated plants. **(C)** Stomata from well-watered plants that were also treated with 100 μ M melatonin. **(D)** Stomata from drought-treated plants that were also treated with 100 μ M melatonin. and width were not affected by the application of melatonin compared with the well-watered plants (**Figures 3A,B**), but the stomatal density of melatonin-treated plants under soil drought stress was less than that of control (**Figure 3D**). Under well-watered conditions, the application of melatonin decreased the stomatal aperture by 36.2%, but it had no effect on other characteristics of stomata (**Figure 3**).

Effects of Melatonin on Photosynthesis of Plants Under Drought Stress

Under well-watered conditions, the application of exogenous melatonin resulted in no obvious change in the ability to photosynthesize (**Figure 4**). After 7 days of drought stress, the P_n , C_i , G_s , and T_r were decreased by 58.3, 55.3, 70.4, and 51.7%, respectively, compared with control (**Figure 4**). In contrast, the exogenous melatonin-treated plants exhibited fewer negative effects of drought stress, with a decrease of only 46.0, 31.5, 50.0, and 31.2% for P_n , C_i , G_s , and T_r , respectively, compared with control (**Figure 4**). These data suggest that there was an increased photosynthetic performance for the melatonin-treated plants

compared with the non-treated plants under drought stress. In addition, the melatonin treatment increased the Rubisco activity from 25.5 to 38.31 $\text{mg g}^{-1} \text{h}^{-1} \text{FW}$, and the change in Rubisco activity was parallel with the expression of *ZmRCA1*, *ZmrbclL*, and *Zmrbcs* (**Table 2** and **Figure 5**). These results further support the ability of melatonin-treated plants to maintain photosynthetic C assimilation during drought stress.

To further investigate the alterations of photosynthesis in maize plants exposed to soil drought stress, multiple chlorophyll fluorescence parameters, such as F_v/F_m , $Y(\text{II})$, $Y(\text{NPQ})$, $Y(\text{NO})$, and $\text{ETR}(\text{II})$ were calculated (**Table 2**). The results of fluorescence measurement showed that the application of melatonin did not change the chlorophyll fluorescence parameters under the well-irrigated condition (**Table 2**). Compared with control, drought stress markedly reduced the F_v/F_m , $Y(\text{II})$, and $\text{ETR}(\text{II})$ by 7.0, 47.6, and 47.5%, respectively. However, melatonin application resulted in the significant reversal of the F_v/F_m , $Y(\text{II})$, and $\text{ETR}(\text{II})$ by 5.1, 50.9, and 53.7%, respectively. Moreover, the opposite effects were observed in $Y(\text{NPQ})$ and $Y(\text{NO})$, and the $Y(\text{NPQ})$ and $Y(\text{NO})$ of non-irrigated plants not treated with melatonin were 53.0 and 17.2% higher than the CK

seedlings. Compared with the untreated seedlings that underwent water restriction, melatonin treatment significantly decreased the Y(NPQ) and Y(NO) levels, with Y(NO) being decreased to the normal level.

Effects of Melatonin on Carbon Metabolites Under Drought Stress

Carbon metabolism is tightly linked with photosynthesis. To elucidate how melatonin regulates C metabolic homeostasis in maize under drought stress, we further measured the amount of carbohydrate and analyzed the activities of C-metabolizing enzymes in different treatments (Table 3 and Figure 6). Exogenously applied melatonin did not affect the amounts of soluble sugar, sucrose, starch, or fructose under normal conditions (Figure 6). In relation to control, there was a remarkable decrease in sucrose and starch in maize leaves (74.2 and 51.1% of control plants), when subjected to drought (Figures 6B,C). In contrast, melatonin treatment substantially increased the concentrations of sucrose and starch by 105.9 and 40.8%, respectively, compared with the drought-stressed plants (Figures 6B,C). Drought stress increased glucose and fructose levels by 97.9 and 66.4%, respectively, compared with control (Figures 6A,D). However, after 7 days of drought stress, the glucose and fructose in maize seedlings treated with melatonin were reduced by 18.7 and 20.5%, respectively, in contrast to the non-treated plants (Figures 6A,D).

Under normal growth conditions, all the C-metabolizing enzymatic activities that were evaluated in maize leaves were not altered by exogenous melatonin (Table 3). Compared with the control, soil water deficit caused considerable increases in SS and INV activity in melatonin-treated (1.3-fold and 1.7-fold of the control plants) and -untreated (1.7-fold and 2.7-fold of the control plants) maize seedlings, but the extent of increase of melatonin treatment was significantly lower than that of drought stress treatment (Table 3). In contrast to the control plants, water restriction resulted in a drastic decline of the activities of SPS, AGPase, PEPC, and CS by 34.9, 31.1, 22.0, and 40.5%, respectively. Compared with the drought stress treatment, the activities of SPS, AGPase, PEPC, and CS in melatonin-treated plants were increased by 60.5, 25.1, 53.6, and 33.6, respectively, with the activities of SPS and PEPC being notably higher than those of control. Furthermore, we found that the melatonin-mediated modulation of C-metabolizing enzymes was due to the induced expression of key genes encoding these enzymes, namely, *ZmSh1*, *ZmAgp1*, *Zmcts1*, *Zmps1*, and *ZmPEPC* (Figure 5).

Effects of Melatonin on Nitrogen Metabolism Under Drought Stress

Nitrogen metabolism is closely associated with chlorophyll fluorescence and C assimilation. Under the well-irrigated condition, exogenous melatonin application resulted in no remarkable changes in the amounts of primary N metabolites (Figure 7). Water stress led to a significant reduction of soluble protein, NO_3^- , and NO_2^- by 29.8, 31.9, and 25.5%, respectively, compared with control. However, in drought-stressed plants, the melatonin treatment increased soluble protein, NO_3^- , and NO_2^-

by 23.4, 18.9, and 15.1%, respectively (Figure 7). Under water deficit, free amino acids, NH_4^+ , and proline in untreated plants were increased by 56.1, 49.5, and 61.4%, while in melatonin-treated plants, these were increased by 23.2, 28.3, and 132.9%, respectively (Figure 7).

The activities of the six N metabolic enzymes were hardly affected by exogenous melatonin under the well-watered condition. Due to the suppression of the expression of *ZmNR*, *ZmNiR*, *ZmGln1-3* and *ZmGS2*, and *Zmfgs1*, which are the key genes encoding NR, NiR, GS, and GOGAT in drought-stressed plants, these enzymatic activities decreased by 36.8, 37.3, 40.4, and 31.9%, respectively, compared with that in the control plants (Table 4 and Figure 5). Exogenous melatonin-treated leaves exhibited higher NR, NiR, GS, and GOGAT activities than the drought-stressed leaves, and the expression of the respective genes was also higher in the melatonin-treated leaves compared with the drought-stressed plants (Table 4 and Figure 5). In contrast, withholding irrigation significantly increased the foliar GDH amination and GDH deamination activities compared with the control plants, with an average increase of 2.2- and 1.5-time (Table 4). The qRT-PCR analyses indicated that the transcript levels of *Zmgdh1*, a key gene encoding GDH, were also dramatically induced by drought stress (Figure 5). However, the GDH amination and deamination activities (79.4 and 68.1% of drought stressed plants, respectively) and *Zmgdh1* expression were notably inhibited by the addition of 100 μM melatonin compared with the drought stress treatment (Table 4 and Figure 5).

DISCUSSION

Exogenous Melatonin Enhanced Photosynthetic Carbon Assimilation by Promoting Stomatal Opening Under Drought Stress

Water deficit stress severely inhibits plant growth and development by affecting various aspects of plants physiology and biochemistry (Meng et al., 2014; Guo et al., 2020a; Gupta et al., 2020). Various types of research have demonstrated that exogenously applied melatonin can enhance drought tolerance in plants (Guo et al., 2020a; Hu et al., 2020; Khattak et al., 2021). Our results showed that the growth of maize was critically suppressed by water deficit because the drought-stressed plants exhibited lower values of leaf area and shoot dry weight compared with the control plants (Figure 1). In contrast, foliar-applied melatonin mitigates plant growth inhibition caused by drought stress, indicating that the exogenous melatonin application increased the tolerance to water deficit in plants (Figure 1). Moreover, we also observed that there was a reduction of the chlorophyll content and RWC after 7 days of drought stress, while melatonin treatment attenuated the decrease in chlorophyll content and RWC (Figure 1). Similar research results were observed in previous reports (Huang et al., 2019; Dai et al., 2020). These consequences may be due to the application of melatonin, which can facilitate photosynthesis.

Our results indicate that the water deficit significantly decreased photosynthetic activity in maize (Figure 4). Photosynthesis is the principal process of capturing light energy to synthesize carbohydrates, and it is closely related to the growth of plants. However, photosynthesis is sensitive to drought stress, and a water deficit notably inhibits photosynthesis in many plants (Velikova et al., 2018; Zhou et al., 2019; Sharma et al., 2020). In general, the decrease in photosynthetic activity is limited by the

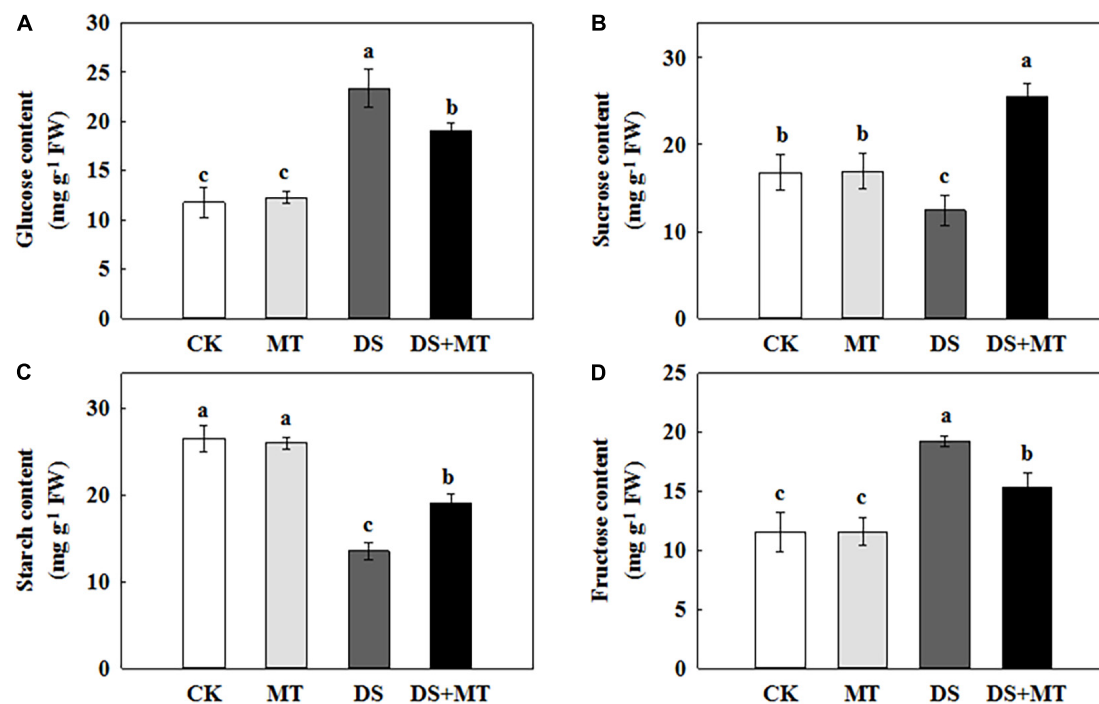

FIGURE 6 | Effects of drought and exogenous melatonin on the sugar content in leaves of maize. **(A)** Glucose content, **(B)** sucrose content, **(C)** starch content, and **(D)** fructose content. Values are the averages of three replicates \pm SD. Different letters indicate significant differences according to Duncan's multiple range tests ($P < 0.05$).

reduction in CO_2 diffusion to the chloroplast, which is induced by stomatal closure (Liu et al., 2013; Ye et al., 2016). The closure of stomata restricts the mesophyll transport of CO_2 , resulting in a decrease in the concentration of CO_2 in the intercellular airspaces of leaves. Low intercellular carbon dioxide (C_i) will decrease the activities of key enzymes, such as Rubisco to limit the photosynthesis rate (Flexas et al., 2006; Chaves et al., 2009; Zhong et al., 2019). As expected, our results confirmed that drought caused the stomata to close almost completely (Figure 2). The C_i and P_n level, and the activity of Rubisco, and the expression of several genes encoding key enzymes in Rubisco also decreased under the drought conditions (Figures 4, 5 and Table 2). These results further support the conclusion that the stomatal closure in water-stressed plants may be one of the reasons for the decrease in photosynthesis. However, the melatonin treatment increased the stomatal aperture and partially opened stomata under a water deficit (Figure 2). In addition, melatonin significantly increased stomatal density and stomatal length compared with water deficit stress (Figure 3). We speculate that in response to drought stress, an optimization strategy for stomatal structure and distribution would be beneficial. Similar research results were obtained in rape, with low stomatal width and high stomatal density observed in rape plants that experienced drought (Dai et al., 2020). Correspondingly, the higher Rubisco activity and P_n value were observed in melatonin-treated plants compared with the drought-stressed plants (Figures 3, 4 and Table 2), indicating that melatonin increased the C fixation and photosynthetic activity in maize plants under drought stress.

Chlorophyll fluorescence is an important indicator that can be used to characterize the photosynthetic capacity and energy conversion efficiency of PSII in plants (Mathur et al., 2019). Many studies have demonstrated that severe or long-term water deficit leads to photo-inhibition in the PSII reaction center (Huang et al., 2019; Zhou et al., 2019). Consistent with these findings, a large decrease in Fv/Fm , Y(II) , and ETR(II) was observed in drought-stressed plants (Table 2). Fv/Fm , Y(II) , and ETR(II) decreased, while Y(NPQ) and Y(NO) increased, indicating that drought stress-induced severe damage to the PSII complexes in maize seedlings. This was attributed to the fact that the limitation of ambient CO_2 diffusion to the site of carboxylation resulted in a relative excess of light energy and electron sinks, and led to photo-inhibition or photo-oxidation (Atkin and Macherel, 2009; Zhong et al., 2018). However, exogenous melatonin treatment can increase the photosynthetic efficiency and protect the maize plants from photo-inhibition caused by drought, because among plants exposed to drought stress, those treated with exogenous melatonin exhibited enhanced Fv/Fm , Y(II) , and ETR(II) , and decreased Y(NPQ) and Y(NO) levels (Table 2). Consistent with the current results, a previous study demonstrated that melatonin-treated tomato plants displayed significantly increased Fv/Fm and ΦPSII compared with the non-treated plants under water deficit conditions (Liu et al., 2015). Additionally, the application of melatonin produces a protective effect on chlorophyll (Campos et al., 2019; Li Z. et al., 2021). The amount of chlorophyll in melatonin-treated maize plants was higher as compared with the non-treated plants under drought

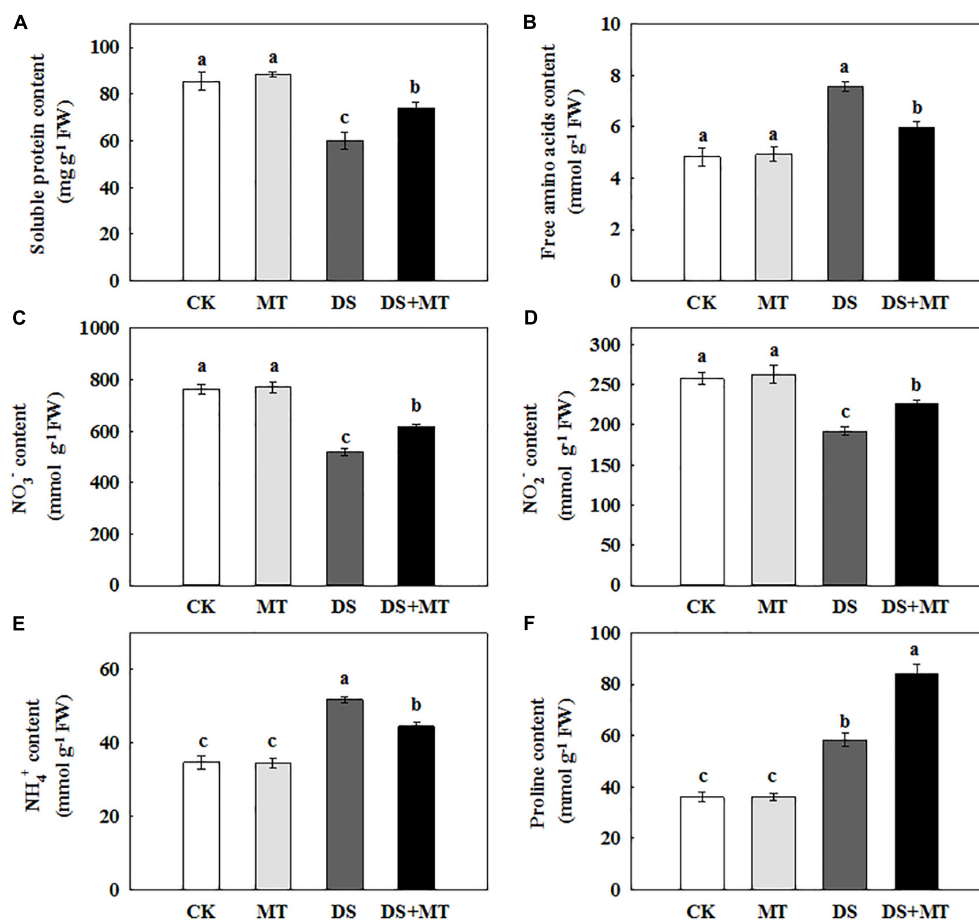

FIGURE 7 | Effects of drought and exogenous melatonin on soluble protein, free amino acid, inorganic N compounds, and proline content in the leaves of maize. (A) Soluble protein content, (B) free amino acid content, (C) nitrate (NO₃⁻) content, (D) nitrite (NO₂⁻) content, (E) ammonium (NH₄⁺) content, and (F) proline content. stress in this study (Figure 1C), confirming that exogenous melatonin slows damage to the photosynthetic apparatus.

Exogenous Melatonin Mitigated Drought Stress by Maintaining Carbohydrate Balance

In view of the inhibition of the photosynthetic capacity by soil water restriction, we observed that there was low carbohydrate synthesis in the drought-stressed maize plants (Figure 6). Plant growth and carbohydrate metabolism are closely linked because carbohydrates are the structural components and the energy source for the production and maintenance of biomass (Song et al., 2020). In higher plants, carbohydrates, such as sucrose and starch are created in photosynthetically active leaves (sources) and then exported to support sinks, which allow leaf expansion, and stem and root growth (Adams et al., 2013; Song et al., 2020). In the present study, we found that drought stress-induced a pronounced decrease in the activity and gene transcription of the main enzymes (AGPase and SPS) involved in starch and sucrose synthesis, leading to a lower starch and sucrose level in the

leaves (Figures 5, 7 and Table 3). This phenomenon is attributed to the growth inhibition observed in drought-stressed plants. Similar results were reported in soybean (Du et al., 2020). Along with the enhancement of the activity and gene transcription of AGPase and SPS (Table 3 and Figure 5), foliar spraying of melatonin facilitated starch and sucrose biosynthesis in maize leaves compared with the drought-stressed plants (Figure 6). These results demonstrated that melatonin treatment supports the growth of maize plants by the accumulation of additional photosynthates. The positive correlation between melatonin and carbohydrate synthesis was confirmed in the previous studies (Campos et al., 2019; Hu et al., 2020).

In addition, we observed that the levels of glucose and fructose were significantly enhanced in the water deficit-stressed maize plants compared with the control plants (Figure 6). Higher concentrations of glucose and fructose in the leaves of drought-stressed plants might be attributed to the enhancement of SS and INV activities (Table 3) because both enzymes can fragment sucrose into hexose sugars (Gandin et al., 2009). This phenomenon also partially explains why the sucrose content in the leaves decreased under a water deficit. Another possible

TABLE 4 | The effects of drought and exogenous melatonin on N-related enzymatic activities in leaves of maize.

Parameters	CK	MT	DS	DS + MT
NR activity (mmol NO ₂ ⁻ mg ⁻¹ h ⁻¹ FW)	0.37 ± 0.01 ^a	0.34 ± 0.02 ^a	0.23 ± 0.01 ^c	0.27 ± 0.01 ^b
NiR activity (mmol NO ₂ ⁻ mg ⁻¹ min ⁻¹ FW)	0.51 ± 0.03 ^a	0.53 ± 0.01 ^a	0.32 ± 0.01 ^c	0.43 ± 0.02 ^b
GS activity (mg g ⁻¹ h ⁻¹ FW)	70.46 ± 5.81 ^a	71.57 ± 5.86 ^a	42.11 ± 4.62 ^c	56.62 ± 4.26 ^b
GOGAT activity (mmol mg ⁻¹ Prot min ⁻¹)	3.98 ± 0.18 ^a	4.08 ± 0.15 ^a	2.71 ± 0.13 ^c	3.40 ± 0.15 ^b
NAD-GDH activity (nmol mg ⁻¹ Prot min ⁻¹)	4.20 ± 0.24 ^c	4.25 ± 0.31 ^c	9.38 ± 0.13 ^a	6.39 ± 0.21 ^b

The values are the averages of three replicates ± SD. Different letters indicate significant differences according to Duncan's multiple range tests ($P < 0.05$).

NR, nitrate reductase; NiR, nitrite reductase; GS, glutamine synthetase; GOGAT, glutamate synthetase; NAD-GDH, deaminating glutamate dehydrogenase; NADH-GDH, aminating glutamate dehydrogenase.

reason for the increase in glucose and fructose level is that drought stress inhibits the tricarboxylic acid (TCA) cycle. It has been reported that water restriction repressed the activity of the TCA cycle, which would reduce the oxidation of glucose and result in a depletion of the ATP pool (Nguyen et al., 2010; Hu et al., 2020). Our results are in agreement with this interpretation, as we found that drought stress decreased the activity and gene transcription of PEPC and CS, and increased the amounts of glucose and fructose in the leaves, compared with the control plants. However, recent research indicated that melatonin was involved in regulating the TCA cycle and could enhance energy production in water-stressed anthers (Hu et al., 2020). Our work further confirmed the protective role of melatonin on energy production in maize under drought stress. Exogenously applied melatonin increased energy production in drought-stressed plants (Figure 6). This increased energy can be further used for plant growth, thus promoting the growth of plants subjected to drought stress. Furthermore, the enhancements in the activities of the TCA cycle induced by melatonin under drought stress will provide more C skeletons and energy for the biosynthesis of downstream amino acids.

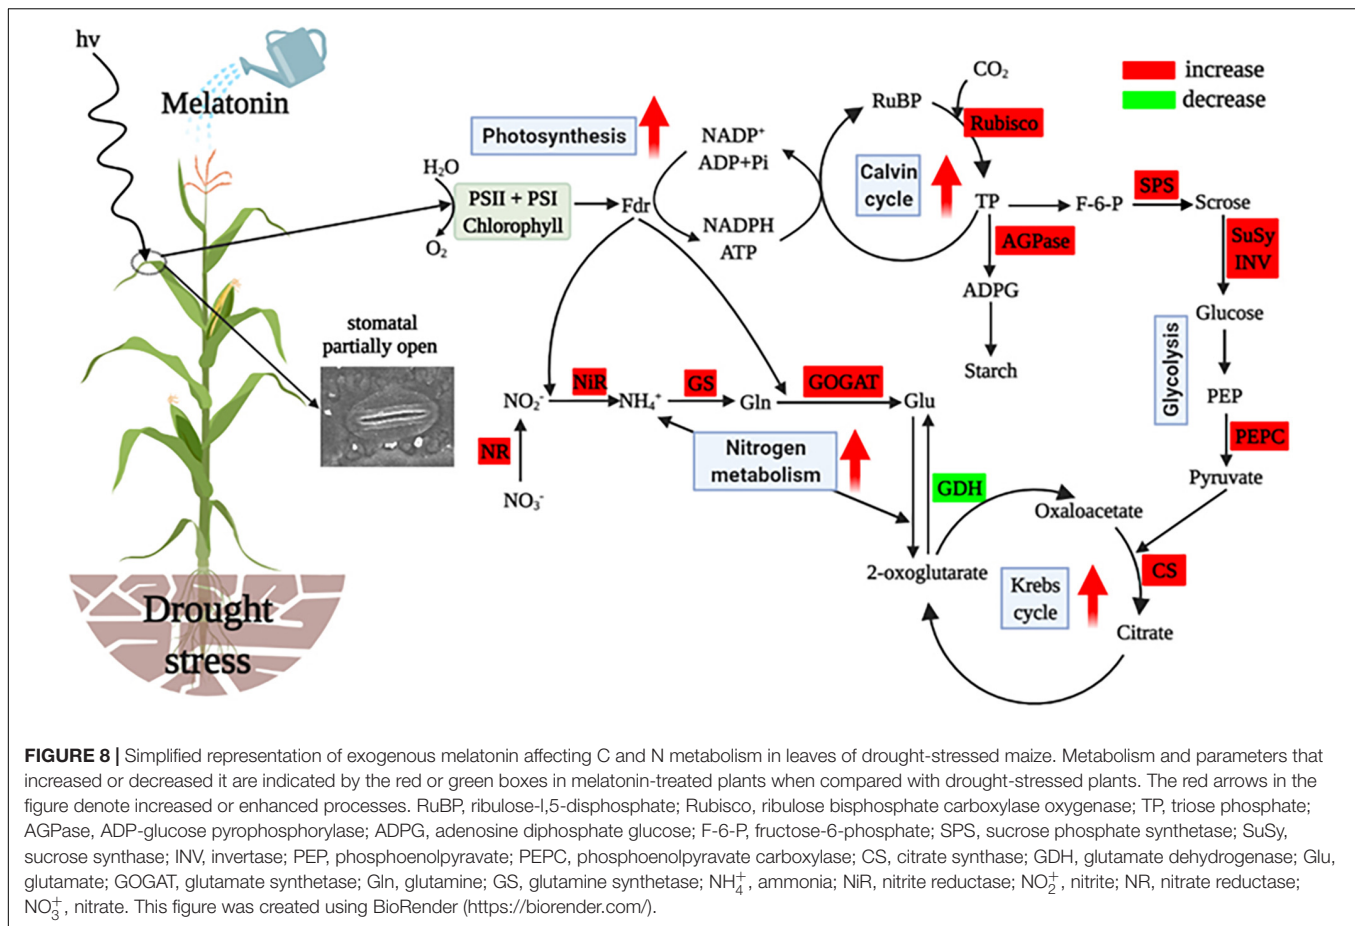

Exogenous Melatonin Improved Nitrogen Metabolism Under Drought Stress

Soil water deficit often causes a decrease in the activities of N assimilation enzymes and the synthesis of N-containing compounds to disrupt N metabolism (Zhong et al., 2018; Xie et al., 2019). In this regard, several previous studies have shown that drought stress can inhibit the uptake of NO₃⁻, resulting in a decrease in NR activity (Miranda-Apodaca et al., 2020; Ren et al., 2020). In this study, consistent with the decrease in NO₃⁻ and NO₂⁻ (Figure 7), drought stress triggered a marked diminution in NR and NiR activities, which reflects the decrease in the N assimilation capacity under a water deficit. Additionally, although the NR and NiR activities decreased under drought, it was also observed that NH₄⁺ accumulated in maize leaves (Table 4 and Figure 7). This increment can be explained by the glycine oxidation in activated photorespiration (Zhong et al., 2018). Under drought stress, the expression levels of the *ZmNR* and *ZmNiR* genes, which encode the NR and NiR enzymes, were enhanced in the melatonin-treated plants (Table 4 and Figure 5). Correspondingly, the melatonin-treated plants under drought stress exhibited higher NR and NiR transcription and activity

than untreated plants (Table 4 and Figure 5). In drought-stressed plants that were treated with melatonin, the increased NO₃⁻ and NO₂⁻ levels were in accordance with the increase in NR and NiR activities (Figure 7). In this context, induced NO₃⁻ reduction by melatonin treatment resulted in the maintenance of the osmotic pressure in photosynthetic cells (Zhong et al., 2019). Moreover, NO₃⁻ reduction is a process with a high energy requirement, and increased NO₃⁻ reduction in leaves would be facilitated due to the excessive energy derived from the photosynthetic apparatus (Sunil et al., 2013; Zhong et al., 2018).

The excessive accumulation of NH₄⁺ in plant leaves due to drought stress has a toxic effect on plants because a high level of NH₄⁺ triggers protein extrusion and cytosolic pH disturbances (Xie et al., 2019). In plants, NH₄⁺ must be assimilated via the GS/GOGAT cycle and GDH pathway into glutamine and glutamate (Liu et al., 2019). However, GDH has a lower affinity for NH₄⁺, and the GDH pathway is markedly activated only when the GS/GOGAT cycle is restrained (Xie et al., 2019). In this study, consistent with the transcription data of genes encoding GS and GOGAT (Figure 5), there were dramatically decreased GS and GOGAT activities in the plants exposed to drought (Table 4), and this could be another important reason for the accumulation of NH₄⁺. Those results are consistent with those reported previously (Jing et al., 2021). In contrast, our results show that melatonin mitigates the toxic effect of NH₄⁺, because the NH₄⁺ assimilation was notably strengthened in melatonin-treated drought-stressed plants by enhancing the activity and gene transcription of GS and GOGAT, and decreasing the GDH activity and *Zmgdh1* (Table 4 and Figure 5). This phenomenon can be explained by the enhancement of photosynthesis and the TCA cycle, which promotes the synthesis of the C skeleton and reduces the power and provides sufficient substrates and energy for the biosynthesis of amino acids. Thus, the GS/GOGAT cycle was enhanced in plants under drought, which subsequently promoted the synthesis of glutamate and other amino acids (Liang et al., 2018; Xie et al., 2019). These results indicate the positive impact of melatonin upon coordinated C assimilation and N metabolism in plants.

It was also observed that drought substantially increased the free amino acid and proline levels in the maize leaves compared with the control treatment (Figures 7B,F), and this may have occurred because N metabolism is involved in osmotic adjustment. The synthesis and accumulation of amino acids are often a strategy to enable plants to withstand

adverse environmental conditions because amino acids can serve as osmotica to maintain the stability of the cellular structure and cell osmotic pressure under drought conditions (Meng et al., 2014; Zhong et al., 2018). The treatment of melatonin dramatically enhanced the levels of soluble protein and proline, and vastly decreased the free amino acid content in maize leaves under water-limiting conditions (Figure 7). These results indicate exogenously applied melatonin in drought-stressed plants regulated cell turgor by producing additional substances that regulated osmolarity, maintained membrane integrity. Stability in protein synthesis can increase the resistance of plants to stress (Georgiadou et al., 2018). Most soluble proteins are enzymes that are involved in various metabolic pathways in plants (Sun et al., 2020). Thus, they are an important index for measuring the protein damage in the process of plant metabolism and are usually positively correlated with soil drought stress tolerance (Xie et al., 2019). In our experiments, soil drought stress significantly diminished the soluble protein content, indicating that water deficit led to protein degradation and protein damage (Figure 7A). Evidence has shown that the degradation of intracellular proteins (e.g., chloroplast proteins) is an important mechanism of the N remobilization under drought stress (Ren et al., 2020). During drought stress, the abundance and activity of enzymes that control N and C metabolism are affected by the degradation of

chloroplast proteins (Ishida et al., 2008). For example, drought stress-induced chloroplast proteins inactivation and degradation, resulting in an enhancement of the free amino acid content and the loss of function of plastid enzymes (e.g., GS) (Reguera et al., 2013). In our experiment, we found that the melatonin-treated plants had less proteins degradation than the non-treated plants under drought stress, along with an upregulated expression of *ZmGS2*, stabilized chloroplast function, and increased capacity for N assimilation. Taken together, exogenously applied melatonin plays a positive role in the coordination of C and N metabolism under drought stress.

CONCLUSION

Based on the analysis mentioned above, the present study suggests that water deficit critically disturbs the processes of C and N metabolism, resulting in inhibited crop growth. However, exogenously applied melatonin mitigated drought stress through coordinated regulation of C and N metabolism in maize. The protective effects of exogenous melatonin on maize were mainly due to ameliorated stomatal opening and photosynthetic activity of maize, which indirectly promoted the synthesis of photosynthetic end products and energy production, and enhanced N assimilation and NH_4^+ detoxification, and thus

consequently increased maize growth under the water restriction conditions (**Figure 8**). Overall, the results of this study provide valuable information for maize drought tolerance induced by melatonin and a new theoretical basis for the application of melatonin on crops grown in arid areas. Future research should explore the molecular mechanisms of functions of melatonin and the practical use of melatonin in crop production.

Chen Q, Qu Z, Li Z, Zhang Z, Ma G, Liu Z, Wang Y, Wu L, Fang F, Wei Z and Zhang M (2021) Coated Diammonium Phosphate Combined With Humic Acid Improves Soil Phosphorus Availability and Photosynthesis and the Yield of Maize. *Front. Plant Sci.* 12:759929. doi: 10.3389/fpls.2021.759929

Controlled release phosphorus (P) fertilizers and humic acid (HA) applications are two effective and significant techniques or measures for preventing P loss and enhancing maize development. However, the underlying physiological mechanism of how the controlled release P fertilizers combined with HA affect the maize production and P-use efficiency (PUE) remains unknown. The effects of applying coated diammonium phosphate (CDAP) and HA together on soil nutrient supply intensity, soil phosphatase activity, photosynthesis, endogenous hormone contents, and yield of maize, as well as PUE, were examined in this study. In a pot experiment, two types of P fertilizers—CDAP and diammonium phosphate (DAP)—as well as two HA application rates (0 and 45 kg ha⁻¹) and two P levels (60 and 75 kg P₂O₅ ha⁻¹) were utilized. Results showed that the key elements that influence the growth and yield of the maize were the availability of P content in soil, plant photosynthesis, and hormone levels. The combination of CDAP and HA had a greater impact on yield and PUE over the course of 2 years than either DAP alone or DAP combined with HA. Besides, using CDAP in combination with HA increased the yield and PUE by 4.2 and 8.4%, respectively, as compared to the application of CDAP alone at 75 kg P₂O₅ ha⁻¹. From the twelve-leaf to milk stages, the available P content in the soil was increased by an average of 38.6% with the combination of CDAP and HA compared to the application of CDAP alone at 75 kg P₂O₅ ha⁻¹. In addition, the application of CDAP combined with HA boosted the activities of ATP synthase, as well as the content of cytokinin (CTK), and hence improved the maize photosynthetic rate (Pn). When compared to the application of CDAP alone or DAP combined with HA, the Pn of CDAP + HA treatments was enhanced by 17.9–35.1% at the same P rate. In conclusion, as an environmentally friendly fertilizer, the combined application of CDAP and HA improved the intensity of the soil nutrient supply, regulated photosynthetic capabilities, and increased the yield and PUE, which is important for agricultural production, P resource conservation, and environmental protection.

Keywords: phosphorus use efficiency, economic benefits, phosphate release, endogenous hormone, phosphatase

INTRODUCTION

Phosphorus (P), as a structural element, is one of the essential macronutrients for plant growth and development (Johnston and Poulton, 2019; Ding et al., 2021). The P deficiency limits virtually all major metabolic processes, in plants, such as photosynthesis and respiration (Plaxton and Tran, 2011). However, agricultural production of over 40% of the world's arable land is limited by P deficiency (Balemi and Negisho, 2012; Zhu et al., 2018). Therefore, P fertilizers are commonly applied to meet crop demand. Because of sorption, precipitation (usually by interaction with Ca^{2+} and Mg^{2+} in calcareous soils, and Fe^{3+} and Al^{3+} in acidic soils), and microbial immobilization, the P-use efficiency (PUE) of most crops is only 10–15% (Castro and Torrent, 1998; Roberts and Johnston, 2015; Zhu et al., 2018). The applied P accumulates in soils and causes soil degradation and environmental concerns, such as water eutrophication (Leslie et al., 2017). Moreover, the detrimental effects of climate change on P transport in soil and lake eutrophication, such as global warming, drought, and heavy rainfalls, have been exposed (Piao et al., 2010; Fahad et al., 2016, 2020). China is the largest producer and consumer of P fertilizers in the world, but the reserve of phosphate rock, the main source of phosphate in fertilizer, is limited (Zhang et al., 2008; Ma et al., 2011). Therefore, effective P management is of importance for PUE improvement, resource reservation, and environmental protection.

Effective P management involving appropriate P fertilizers is vital for high PUE (Zheng et al., 2016; Tian et al., 2018). Many environmentally friendly methods for increasing P availability have been proposed, including the use of P-solubilizing microorganisms (Adnan et al., 2020; Wahid et al., 2020), partial acidification of rock phosphates (Sarkar et al., 2018), combined application of biochar and P fertilizers (Fahad et al., 2016), and foliar application of P fertilizers (Rafiullah et al., 2020). The application of controlled-release fertilizers is one of these methods. Controlled-release P fertilizers show high PUE in both acidic and alkaline soils. The PUE of controlled-release P fertilizers was reported to be higher than that of water-soluble P fertilizers (Sarkar et al., 2018). Coated diammonium phosphate (CDAP), a controlled-release P fertilizer, releases P according to the demand of the plant, which not only improves PUE and crop yield but also reduces the environmental risk posed by the excessive use of fertilizers (Cruz et al., 2017; Lu et al., 2019). Chen et al. (2020) demonstrated that compared to diammonium phosphate (DAP), CDAP significantly increased maize yield and PUE by 9.65 and 7.72%, respectively.

Humic acid (HA) applied to soil as an activator is also reported to increase the availability of soil P (Zhu et al., 2018). HA consists of aromatic and aliphatic structures harboring various functional groups (mainly oxygen-containing), such as carboxyl ($-\text{COOH}$) and phenolic hydroxyl ($-\text{OH}$). Studies have shown that HA application reduced P fixation, improved the efficiency of low and high solubility P sources, increased P availability, and improved PUE (Çimrin et al., 2010; Rosa et al., 2018; Shafi et al., 2020; Xu et al., 2021). HA improved soil structure by encouraging the formation of stable aggregates, which increased the productivity of soil crops (Zhou et al., 2019). In addition,

HA has been shown to improve certain aspects of growth in essential agronomic crops like soybean, wheat, rice, and maize (Calvo et al., 2014; Rosa et al., 2018). As a plant biostimulant, HA increases photosynthesis, reduces transpiration, stimulates root and shoot growth, and enhances stress resistance of plants (Canellas et al., 2013; Dantas et al., 2018; Xu et al., 2021), and is linked with changes in the hormone contents and enzyme activities and enhancement of H^+ -ATPase activity (Zandonadi et al., 2010; Calvo et al., 2014). However, since HA is a weak nutritional material, it cannot supply the nutrient requirements in crop production on its own.

Many research has been conducted on the effects of HA application, the combination of water-soluble P fertilizer and HA, and HA mixed with urea or controlled-release urea on soil quality, plant development, and fertilizer use efficiency (Shafi et al., 2020; Li Z. L. et al., 2021; Xu et al., 2021). Rosa et al. (2018) found that combining HA with phosphate fertilizers (e.g., single superphosphate) boosted root dry matter, and nutrient uptake increased the shoot dry matter output, as compared to biomass produced in soil that had not been treated with HA. To our knowledge, few studies on the effects of combining HA with controlled release P fertilizer on crop production have been conducted. We hypothesized that the combined application of CDAP and HA would improve crop growth, crop yield, and PUE. This study was aimed to: (1) investigate the effects of CDAP combined with HA on soil P availability, (2) understand the roles of photosynthesis and endogenous hormones in the increase of maize production when CDAP and HA are applied together, and (3) determine the factors that influence crop yield and PUE. Findings from this study should give a technological foundation for developing an effective fertilization strategy using controlled-release P fertilizers and biostimulants.

MATERIALS AND METHODS

Soil, Coated Diammonium Phosphate, and Humic Acid Used

The soil for the pot experiment was acquired from a field at the research farm of the National Engineering Laboratory for Efficient Utilization of Soil Fertility Resources (NELEUSFR), Shandong Agricultural University (SDAU), China. It is classified as Typic Hapludalf (Soil Survey Staff, USDA, 1999) or Typic-Hapli-Udic Argosols (Chinese Soil Taxonomy, CRGCST, 2001). Physical and chemical properties of the soil were as follows: pH: 7.83 (1:2.5 soil to water ratio), organic matter content: 12.10 g kg^{-1} , total P: 0.32 g kg^{-1} , available P: 13.50 mg kg^{-1} , NO_3^{--}N : 71.45 mg kg^{-1} , $\text{NH}_4^{+}\text{-N}$: 9.45 mg kg^{-1} , and available K: 92.32 mg kg^{-1} .

The controlled-release P fertilizer, the CDAP (17.2% N, 44.0% P_2O_5), was prepared by NELEUSFR, SDAU, China. The coating consisted of 10% of paraffin and 90% of polyurethane. Resin-coated controlled-release urea (43.0% N; 3-month release period) was purchased from Kingenta Ecological Engineering Group Co., Ltd., Shandong, China. The other fertilizers, urea (46% N), DAP (18.0% N, 46.0% P_2O_5), and potassium chloride (60.0% K_2O), were purchased from the local market. The HA (2.0-0%-3.0%

N-P₂O₅-K₂O) was purchased from Quanlin Jiayou Fertilizer Co., Ltd., Shandong, China. It had a pH of 5.40 (1:2.5 soil to HA ratio).

Pot Experiment

The pot experiment was carried out in the research farm of NELEUSFR, SDAU, China. With an average annual temperature of 13.2°C, the experiment location has a moderate continental monsoon climate. The following nine treatments were put up, each with four replications: (1) Control (no P fertilization); (2) P, 100% (DAP at 75 kg P₂O₅ ha⁻¹); (3) P, 80% (DAP at 60 kg P₂O₅ ha⁻¹); (4) CP, 100% (CDAP at 75 kg P₂O₅ ha⁻¹); (5) CP, 80% (CDAP at 60 kg P₂O₅ ha⁻¹); (6) P, 100% + HA (DAP at 75 kg P₂O₅ ha⁻¹ combined with HA); (7) P, 80% + HA (DAP at 60 kg P₂O₅ ha⁻¹ combined with HA); (8) CP, 100% + HA (CDAP at 75 kg P₂O₅ ha⁻¹ combined with HA); and (9) CP, 80% + HA (CDAP at 60 kg P₂O₅ ha⁻¹ combined with HA).

In each ceramic pot (36.0 cm in height, 30.0 cm in diameter), 1 kg sand was first placed in the bottom to improve aeration and to promote more oxygen supply to the root system (Li Z. L. et al., 2021), and then 20 kg of soil was placed on the top of the sand layer (Yu et al., 2021). Before usage, the test soil was air-dried, blended equally, and sieved. The sand (0.35–0.5 mm) used was purchased from the local market.

For the control treatment, nitrogen and potassium fertilizers were applied once as a basal fertilizer at 225 kg N ha⁻¹ and 150 kg K₂O ha⁻¹, respectively, whereas for the other treatments, nitrogen, P, and potassium fertilizers were applied at 225 kg N ha⁻¹, 75 or 60 kg P₂O₅ ha⁻¹, and 150 kg K₂O ha⁻¹, respectively (Zheng et al., 2016). These fertilizer rates were calculated based on the common practices in the area. For all treatments, both coated controlled-release nitrogen and conventional nitrogen were used to provide 60 and 40% of the total applied nitrogen, respectively (Zheng et al., 2016; Qu et al., 2020). HA was applied at 45 kg ha⁻¹.

On June 20, 2017, three seeds of maize (*Zea mays* L. cv. Zhengdan 958) were sown in each container. At the three-leaf stage, the seedlings were reduced to one. Agricultural management, such as pest and weed control, was performed as needed according to local practices. In 2018, the experiment was repeated using the same pots. Maize was planted on June 12, 2018, and harvested on September 26, 2018.

Maize ears were harvested after maturity on September 29, 2017, and September 26, 2018, respectively. To deactivate enzymes, kernels and plant samples were oven-dried at 105°C for 15 min, then dried at 65°C to a constant weight (Zheng et al., 2016; Gao et al., 2021). The biomass and yield of the maize were measured.

Sampling Analyses

To learn the nutrient release pattern of CDAP, 10 g of CDAP was placed in a glass bottle containing 200 ml distilled water and incubated at 25°C. The solution in the bottle was sampled at days 1, 3, 5, 7, 10, 14, 28, 42, 56, 70, 84, 98, and 112 and analyzed for N and P concentrations according to the National Standard of the People's Republic of China—Slow-Release Fertilizers (Liu et al., 2009). The functional groups of HA were identified with an FT-IR TENSOR analyzer (Bruker Co., Germany).

In 2017, at the growth stages of seedling (V3), six-leaf (V6), twelve-leaf (V12), and milk stages (R3) of soil samples were taken from 0 to 20 cm layer of each pot, air-dried, ground, and sieved to < 2 mm; plant height was measured from the soil surface to the top of the plant stem; the diameter of the maize stem was measured at the middle of the third node from the soil surface; The readings from the Soil Plant Analysis Development (SPAD) chlorophyll meter were taken between 09:00 and 11:00 a.m. (SPAD-502, Minolta, Japan). Soil available P was extracted with 0.5 M NaHCO₃ (pH = 8.5) and quantified using an automatic chemical analyzer (Smartchem200, AMS, Italy). Soil NO₃⁻-N and NH₄⁺-N were extracted with 0.01 M CaCl₂ (1:10 soil to water ratio) and measured with a continuous-flow injection analyzer (AA3-A001-02E, Bran-Luebbe, Germany; Houba et al., 1986; Dou et al., 2000). Soil available K was extracted with 1.0 M CH₃COONH₄ and determined using a flame photometer (Lu, 2000).

In 2018, at the V12 stage, the photosynthetic rates were determined between 09:00 and 11:00 a.m. using a LI-6400XT portable photosynthesis system (LI-Cor, Lincoln, NE, United States). Then, the fresh plant leaves, roots, and soil were sampled and frozen in liquid nitrogen for biochemical analysis. Contents of phosphoenolpyruvate carboxylase (PEPC), ADP-glucose pyrophosphorylase (AGPase), adenosine triphosphate (ATP) synthase, pyruvate phosphate dikinase (PPDK), auxin-indole-3-acetic acid (IAA), cytokinin (CTK), abscisic acid (ABA), and gibberellin (GA) of maize leaves were measured using the ELISA kit from Shanghai HengYuan Biological Technology Co., Ltd. (Shanghai, China) according to the manufacturer's instructions. Acid phosphatase (AP) and alkaline phosphatase (ALP) activities of maize root and soil were determined using the ELISA kit.

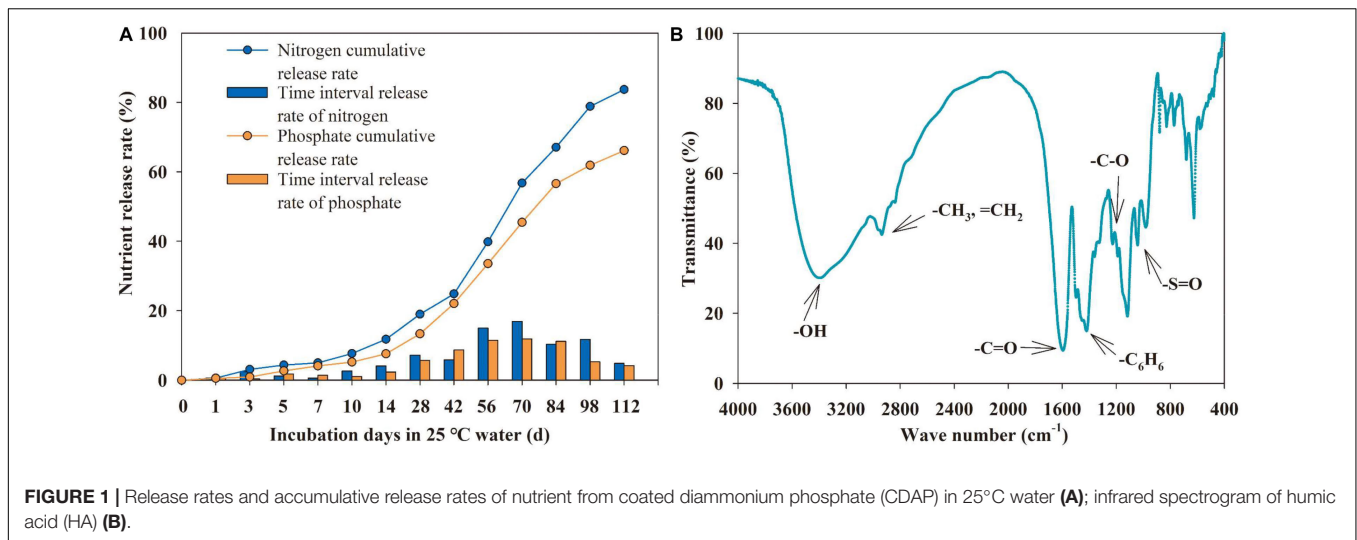

Total P content in the plant was measured using the molybdenum-antimony method after digestion with H₂SO₄-H₂O₂ (Lu, 2000). For the P fertilization treatments, PUE was calculated as follows (Devkota et al., 2013):

$$\text{PUE (\%)} = (\text{maize P uptake} - \text{maize P uptake in Control}) / \text{total P from fertilizer} \times 100\%$$

Statistical Analyses

Data were collected and analyzed with Microsoft Excel 2010, and figures were generated using SigmaPlot software (Version 12.5, MMIV, Systat Software Inc., San Jose, CA, United States; **Figures 1–7**) and Origin software (Version 2021b, OriginLab Corporation, MA, United States; **Figure 8** and Spearman's correlation analysis in **Figure 9**). Analysis of variance technique (one-way ANOVA) with mean separation using Duncan's test ($P < 0.05$) was performed with IBM SPSS Statistics 22 (SPSS Inc., IL, United States).

Origin software was used to determine the determinants on the application of different fertilizations in impacting maize yield and PUE using the chord diagram, principal component analysis, and Spearman's correlation analysis (Hou et al., 2019; Li R. C. et al., 2021). With the exception of the control treatment, data were collected and divided into four categories: (1) uncoated DAP treatments (Un-P; the mean value of P 100% and P 80% treatments); (2) coated DAP treatments (CP; the mean value of

CP 100% and CP 80% treatments); (3) uncoated DAP combined with HA treatments (P + HA; the mean value of P 100% + HA and P 80% + HA treatments); (4) coated DAP combined with HA treatments (CP + HA; the mean value of CP 100% + HA and CP 80% + HA treatments).

RESULTS

Nutrient Release Pattern of Coated Diammonium Phosphate and Functional Groups of Humic Acid

Under laboratory conditions in water (25°C), nutrient release from CDAP followed a linear pattern over time (Figure 1A). By

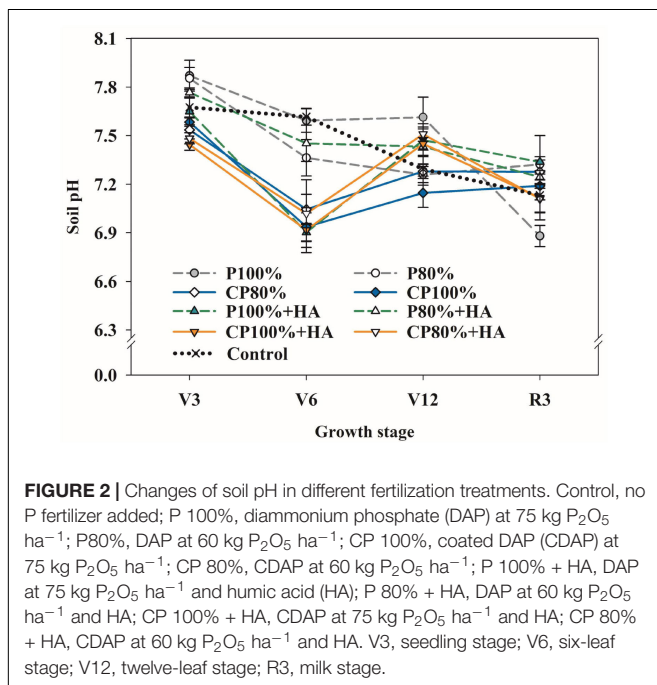

day 112, the cumulative release rates of P and N from CDAP reached 66.1 and 83.7%, respectively. The release of P and N was steady during the first 10 days (5.2 and 7.7% released, respectively), accelerated during the days 10–28 (8.1, 11.3% released, respectively), and slowed down afterward. However, the final cumulative release rates of P and N were different.

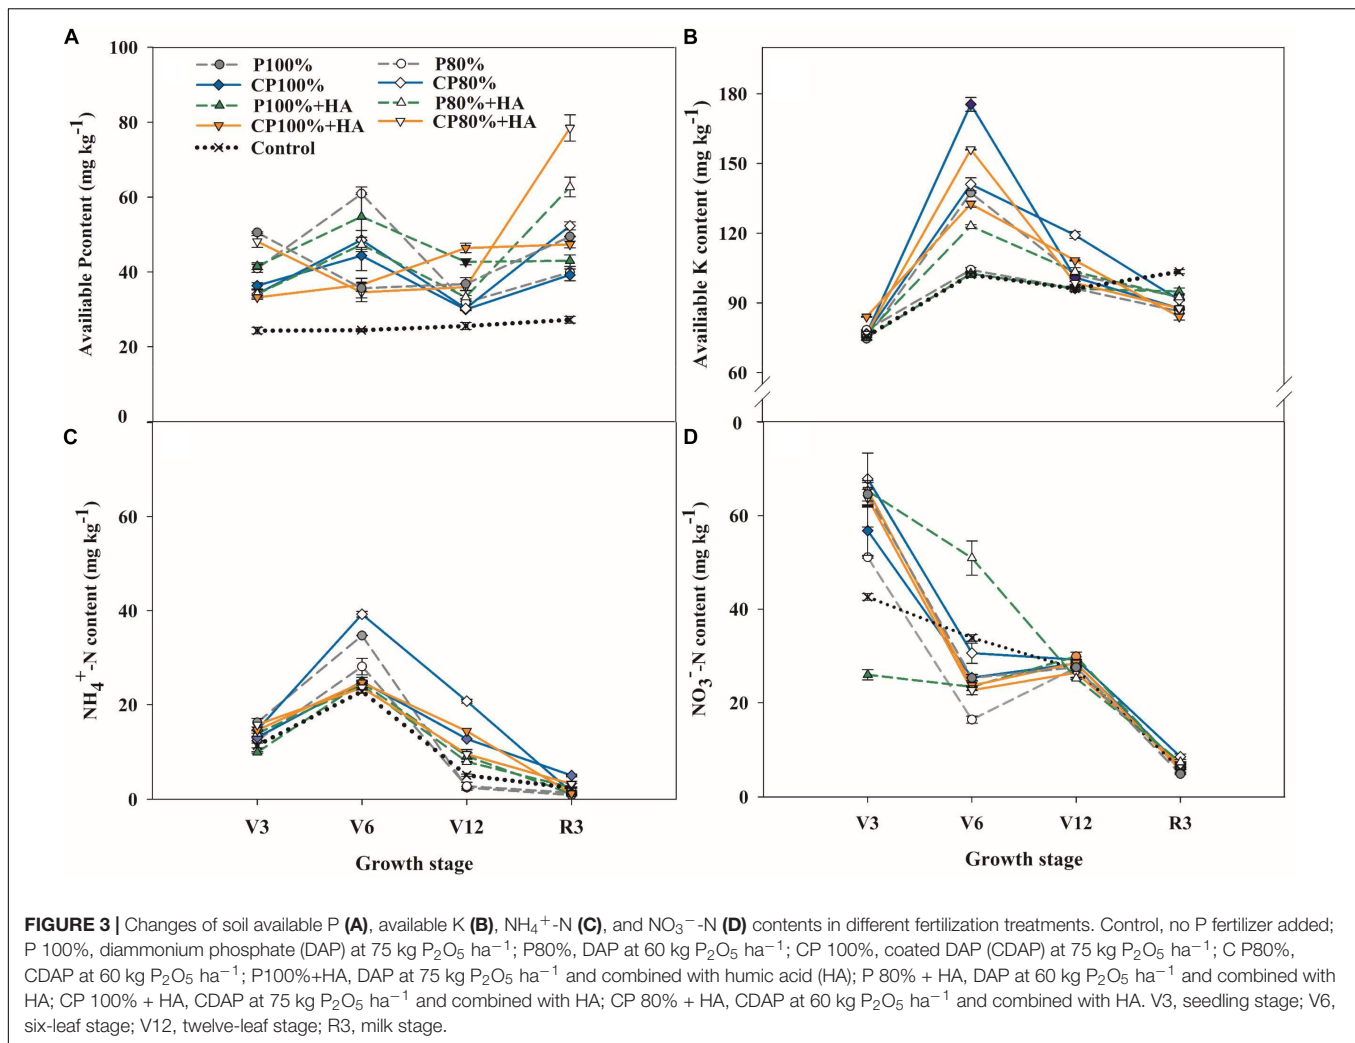

The FT-IR spectrum of HA displayed several characteristic peaks (Figure 1B). The peaks at 1,226 and 1,188 cm^{-1} are due to the existence of the C-O group. The peak at 1,117 cm^{-1} is attributed to the C-H stretching of the benzene ring or C-O stretching. The characteristic peak at 3,396 cm^{-1} corresponds to the stretching vibration of O-H in an aromatic ring (Sarlati et al., 2021).

Soil pH and Contents of Available Nutrients

The dominant form of orthophosphate ion present in the soil is pH dependent. At the V3 stage, the soil pH in CP 100%, P 100% + HA, and CP 100% + HA was 0.29, 0.22, and 0.10 units, respectively, lower than that in P 100% (Figure 2). The soil pH in CP 80%, P 80% + HA, and CP 80% + HA was significantly reduced by 0.33, 0.43, and 0.39 units, respectively, while that in P 80% was only reduced by 0.02 units compared to P 100%. The P 100% treatment resulted in the highest soil pH at the V12 stage. From the V12 to the R3 stage, the largest decrease in soil pH (0.7 units) occurred in P 100%.

Soil available P content was affected by the P fertilizers and fertilizer application rate (Figure 3A). The control treatment displayed the lowest soil available P content at the V3, V6, V12, and R3 growth stages. The application of CDAP significantly increased the soil available P content during the late growth stages of maize. At the V12 stage, soil available P content in CP 100%, P 100% + HA, and CP 100% + HA was 1.3, 8.0, and 16.7%, respectively, higher than that in P 100%. At the lower P application level (60 $\text{kg P}_2\text{O}_5 \text{ ha}^{-1}$), the CP 80%, P 80% + HA, and CP 80% + HA treatments significantly increased the soil available P content by 38.8, 50.6, and 19.5%, respectively, compared to the P 100% treatment. When

coated with polyurethane or applied together with HA, the DAP increased the soil available P content at the late growth stages of maize. At the V12 and R3 stages, soil available P content in CP 100%, P 100% + HA, and CP 100% + HA was 18.1, 35.7, and 61.8%, respectively, higher than that in P100%. The average soil available P content in CP 100% + HA was 47.8 mg kg^{-1} , significantly higher than that in CP 100% by 9.5%.

Soil inorganic N (NO_3^- -N and NH_4^+ -N) content (Figures 3C,D) was high at the early growth stages and decreased at the late growth stages of maize in all treatments. At the V6, V12, and R3 stages, soil inorganic N content in the treatments with combined application of P fertilizer (CDAP or DAP) and HA was higher than that in the treatments applied with DAP only. At the V12 stage, the inorganic N content in CP 100% and P 100% + HA was higher than that in P 100%. The highest inorganic N content was found in CP 80% while the lowest was in P 100% at the V12 stage. In the treatments with P fertilization, soil available K content was low at the V3 stage, which increased rapidly to the highest value at the V6 stage and then decreased afterward (Figure 3B). At the V6 stage, soil

available K content in CP 100% and CP 80% was 27.7 and 2.7%, respectively, higher than that in P 100%.

Acid Phosphatase and Alkaline Phosphatase Activities of Root and Soil

Phosphatase is a very important hydrolase that is ubiquitous in plants and soil. The root AP activity was increased by 11.6 and 17.2%, while the root ALP activity was increased by 24.7 and 89.5% in CP 100% and P 100% + HA, respectively, compared to P 100% (Figures 4A,B). The CP 100% + HA treatment increased the activities of root AP and ALP by 18.1 and 50.1%, respectively, compared to CP 100%. The root AP and ALP activities in CP 80% + HA were higher than those in CP 100%, though the P application rate was 20% lower in CP 80% + HA.

The highest soil AP activity was found in P 80% + HA, while the highest soil ALP activity was found in CP 100% (Figures 4C,D). There were no significant differences in soil AP activity between the treatments with $75 \text{ kg P}_2\text{O}_5 \text{ ha}^{-1}$. There were no significant differences in soil ALP activity between P 100% + HA and P 100%. The combined application of CDAP and HA did not have a clear effect on soil AP and ALP activities.

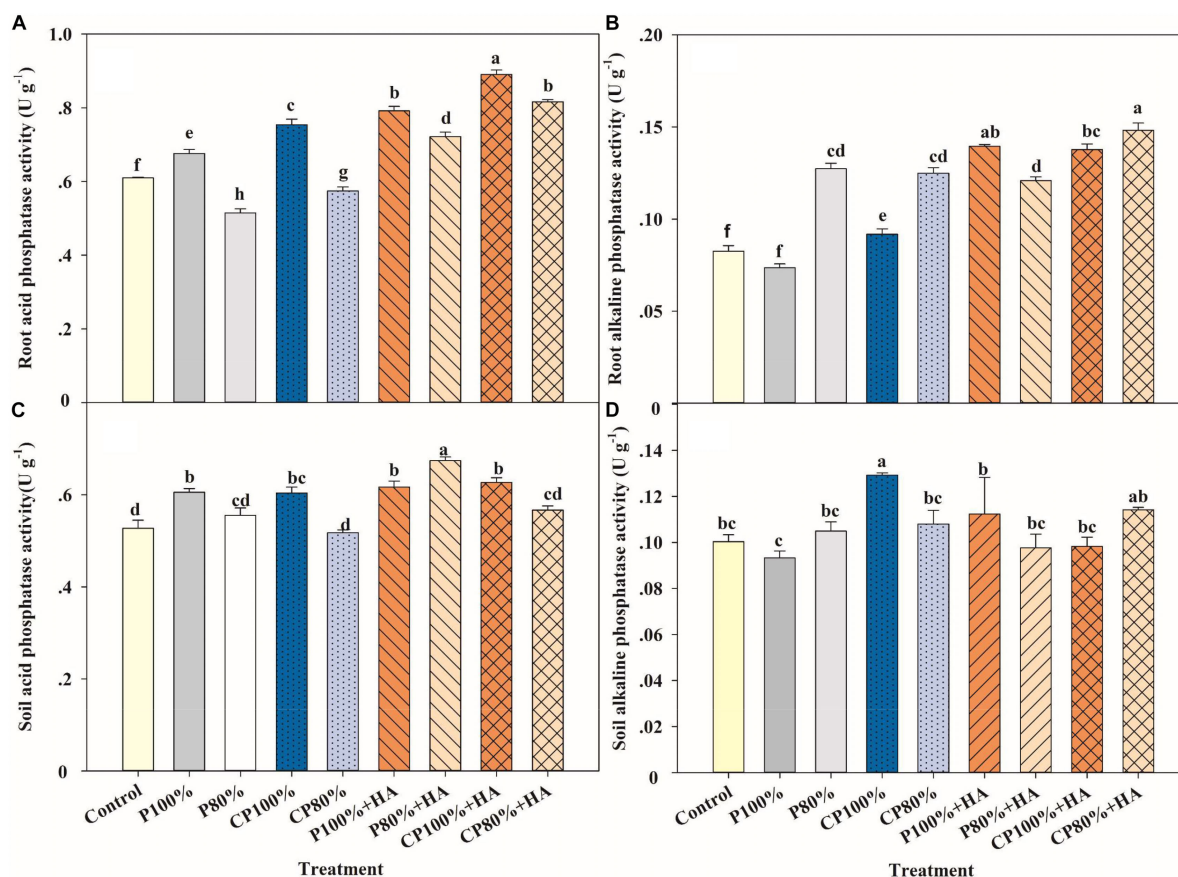

FIGURE 4 | Activities of root acid phosphatase (A), root alkaline phosphatase (B), soil acid phosphatase (C), and soil alkaline phosphatase (D) in different fertilization treatments at the twelve-leaf stage of maize. Control, no P fertilizer added; P 100%, diammonium phosphate (DAP) at 75 kg P₂O₅ ha⁻¹; P80%, DAP at 60 kg P₂O₅ ha⁻¹; CP 100%, coated DAP (CDAP) at 75 kg P₂O₅ ha⁻¹; CP 80%, CDAP at 60 kg P₂O₅ ha⁻¹; P 100% + HA, DAP at 75 kg P₂O₅ ha⁻¹ and combined with humic acid (HA); P 80% + HA, DAP at 60 kg P₂O₅ ha⁻¹ and combined with HA; CP 100% + HA, CDAP at 75 kg P₂O₅ ha⁻¹ and combined with HA; CP 80% + HA, CDAP at 60 kg P₂O₅ ha⁻¹ and combined with HA. Different letters above the bars indicate significant differences at $P < 0.05$ followed by Duncan's multiple range test.

Soil Plant Analysis Development Value, Photosynthetic Rate, and Photosynthesis Enzyme Activities

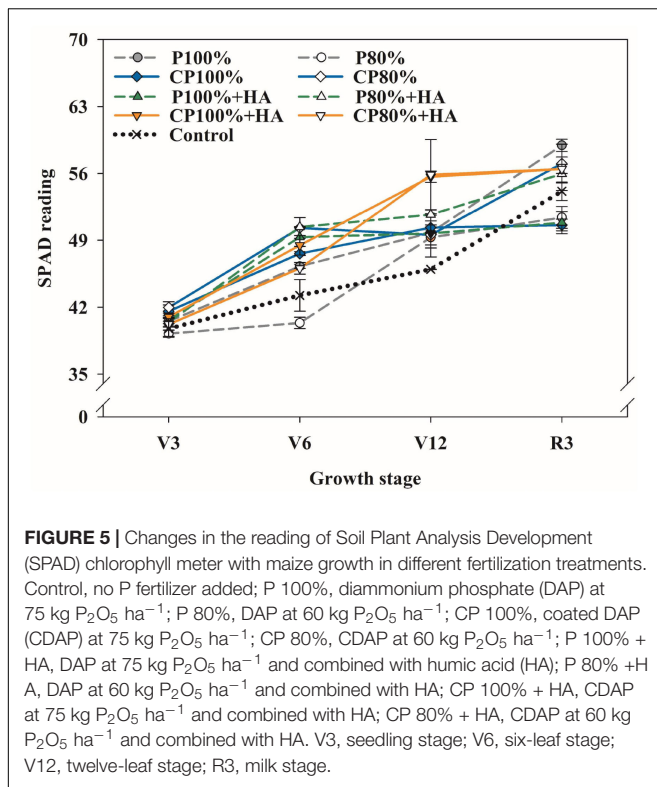

The readings from the SPAD value were employed to indicate the chlorophyll content of leaves, and the SPAD-502 chlorophyll meters were used to estimate it. All treatments exhibited an increasing trend in SPAD values over time (Figure 5). At the V12 stage, the SPAD value in the treatments with the application of CDAP, the treatments with the combined application of DAP and HA, and the treatments with the combined application of CDAP and HA were 2.1–8.4%, 4.9–7.9%, and 8.2–12.9%, respectively, higher than that in the treatments with the application of DAP at the same P rate. In addition, the SPAD value was significantly increased in CP 80%, P 80% + HA, and CP 80% + HA by 9.5, 12.5, and 21.1%, respectively, compared to P 100%, though 20% less P was applied in these treatments. The application of HA increased the leaf SPAD value of maize.

Photosynthesis is a fundamental physiological process of maize that uses light energy to accumulate organic matter. The combined application of CDAP and HA enhanced

photosynthesis at the V12 stage, a vital growth stage of maize (Figure 6). The photosynthetic rate in CP 100% + HA was the highest of all the treatments. For the treatments with 75 kg P₂O₅ ha⁻¹, the photosynthetic rate was in the order of CP 100% + HA > P 100% + HA > CP 100%. Of the treatments with 60 kg P₂O₅ ha⁻¹, P 80% + HA had the highest photosynthetic rate. Photosynthesis, a process that involves many enzymes, is strongly affected by the orthophosphate concentrations in cytosol and chloroplast. The different P treatments showed different effects on the activities of photosynthesis-related enzymes (Figure 6 and Supplementary Figure 1). Of all the treatments, P 80% had the lowest PEPC and PPDK activities (Supplementary Figure 1). The addition of HA significantly increased the activities of PEPC, ATP synthase, and PPDK.

Endogenous Hormones in Maize Leaf

Endogenous hormones serve a critical role in plant growth and development, even at very low levels. Figure 7 showed the contents of IAA, ABA, CTK, and GA in maize leaves during the V12 stage. Compared to P 100%, the CTK and GA contents

in CP 100% were increased by 32.4 and 21.1%, respectively. The P 100% + HA treatment increased IAA content by 34.6% and CTK content by 27.2%. The CP 100% + HA treatment increased IAA, CTK, and GA contents by 5.8, 46.4, and 21.5%, respectively. Moreover, the IAA and CTK contents were 30.5 and

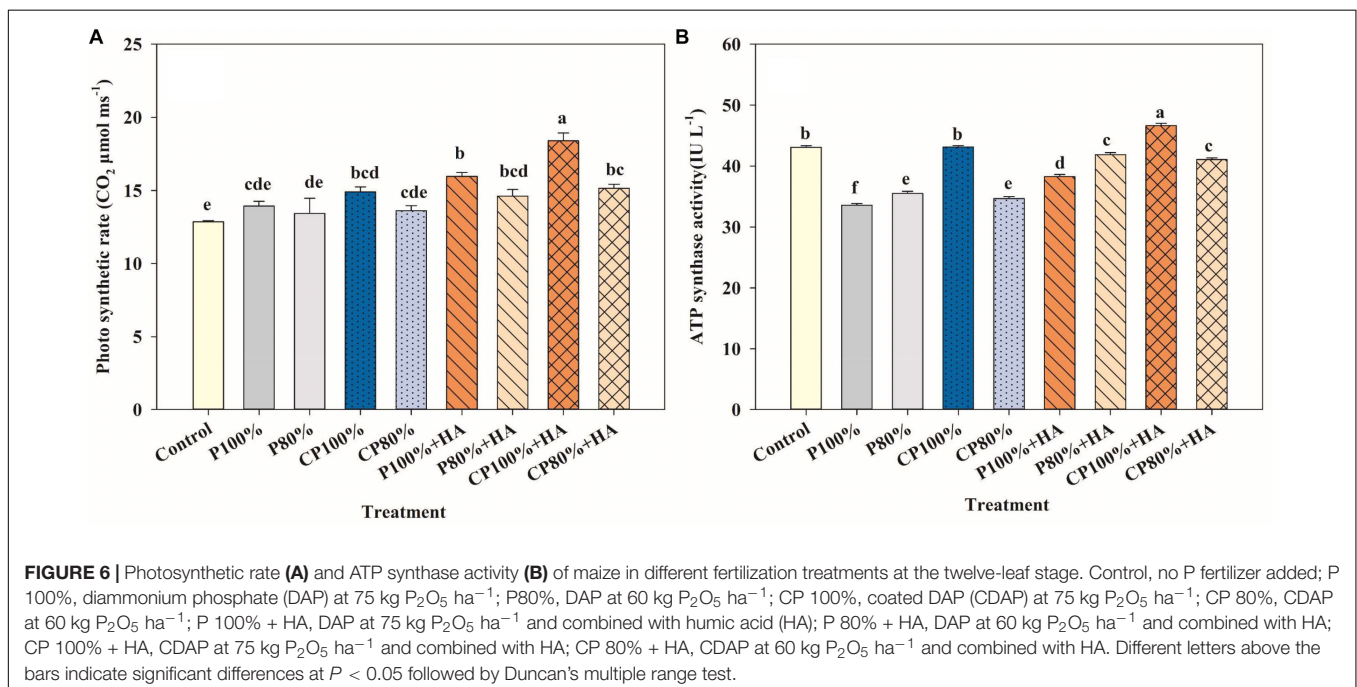

10.6%, respectively, higher in CP 100% + HA and 63.3 and 9.2%, respectively, higher in CP 80% + HA than those in CP 100%.

Maize Plant Height and Stem Diameter

Changes in plant height and stem diameter at different maize growth stages are presented in **Table 1**. The maize plants in the control treatment were the shortest with the slenderest stems at the V3, V6, V12, and R3 stages. Compared to P 100%, the treatments with CP 100%, P 100% + HA, and CP 100% + HA increased the plant height by 3.7, 7.3, and 9.9%, respectively, while CP 80%, P 80% + HA, and CP 80% + HA increased the plant height by 7.8, 6.6, and 10.1%, respectively. At the V3 stage, CP 100%, P 100% + HA, and CP 100% + HA increased the diameter of the maize stem by 10.4–20.0%, 10.1–15.1%, and 7.8–12.6%, respectively, compared to P 100%.

Maize Yield, P-Use Efficiency, and Net Profit of Maize Production

In both 2017 and 2018, the maize yield of the control treatment was significantly lower than that of the other treatments (**Table 2**). Compared to P 100%, the 2-year average grain yield in CP 100% and P 100% + HA was significantly higher by 13.5 and 10.3%, respectively, while that in CP 80% and P 80% + HA, the grain yield was higher by 11.0 and 10.0%, respectively. The grain yield in CP 100% + HA was 17.2 and 16.0% higher than that in P 100% in 2017 and 2018, respectively. In 2018, the highest yield was obtained in CP 100% + HA, which was 4.2 and 4.7% higher than that in CP 100% and P 100% + HA, respectively. The PUE of CDAP or DAP combined with HA was significantly higher than that of DAP (**Table 2**). The 2-year average PUE in CP 100%, P 100% + HA, and CP 100% + HA was 24.4, 13.8, and 27.8 percentage points, respectively, higher than that in P 100%. The

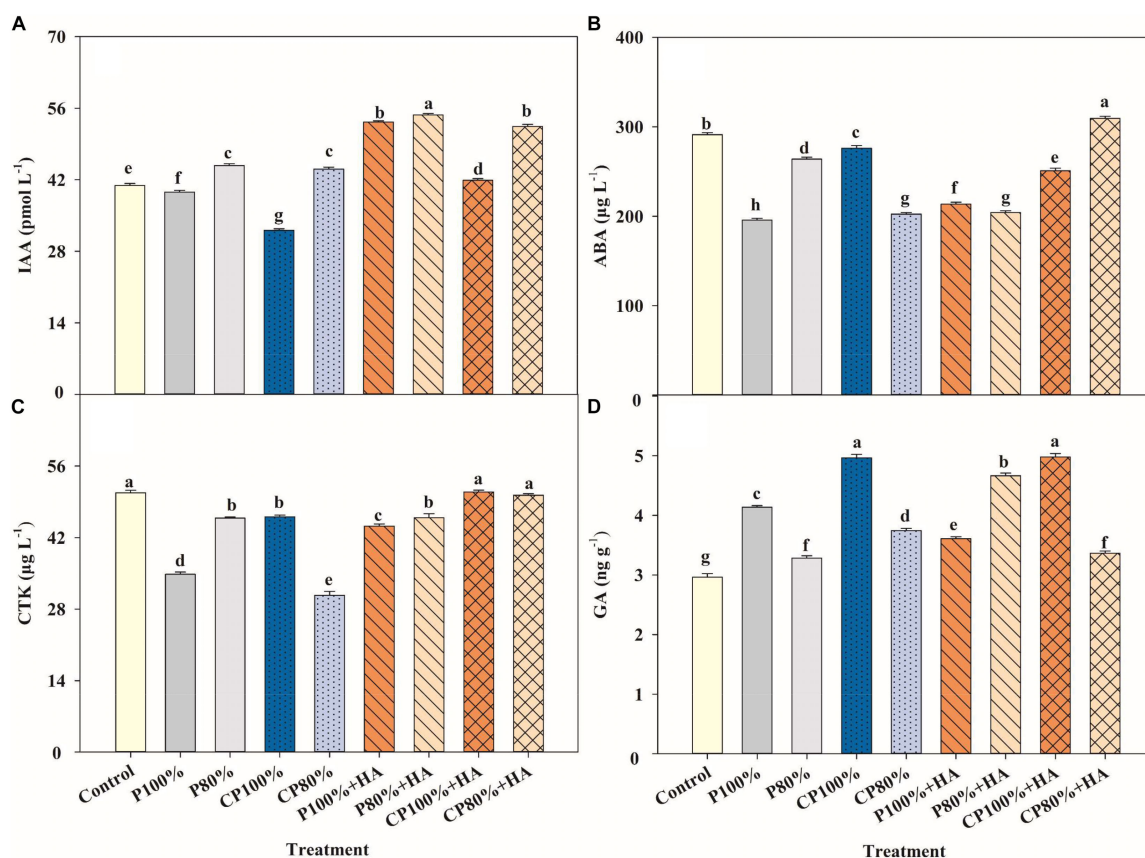

FIGURE 7 | Auxin indole-3-acetic acid (IAA) (A), abscisic acid (ABA) (B), cytokinin (CTK) (C) and gibberellin GA (D) contents of maize leaves in different fertilization treatments at the twelve-leaf stage. Control, no P fertilizer added; P 100%, diammonium phosphate (DAP) at 75 kg P₂O₅ ha⁻¹; P80%, DAP at 60 kg P₂O₅ ha⁻¹; CP 100%, coated DAP (CDAP) at 75 kg P₂O₅ ha⁻¹; CP80%, CDAP at 60 kg P₂O₅ ha⁻¹; P 100% + HA, DAP at 75 kg P₂O₅ ha⁻¹ and combined with humic acid (HA); P 80% + HA, DAP at 60 kg P₂O₅ ha⁻¹ and combined with HA; CP 100% + HA, CDAP at 75 kg P₂O₅ ha⁻¹ and combined with HA; CP 80% + HA, CDAP at 60 kg P₂O₅ ha⁻¹ and combined with HA. Different letters above the bars indicate significant differences at $P < 0.05$ followed by Duncan's multiple range test.

CP 80%, P 80% + HA, and CP 80% + HA treatments achieved a higher average of PUE than the P 100% treatment by 26.4, 20.7, and 27.4 percentage points, respectively.

When DAP was used in combination with HA, or when CDAP was applied alone or in combination with HA, the maize production cost was higher than when DAP was applied alone (Table 3). However, the application of CDAP, alone or together with HA, generally increased the maize grain yield. Of all treatments, CP 100% achieved the highest average net income. Compared to P 100%, the average net income of CP 100% and CP 80% was increased by 483.1 and 440.8 USD ha⁻¹, respectively, while that of P 100% + HA and P 80% + HA was increased by 287.1 and 321.5 USD ha⁻¹, respectively. The highest income was achieved by the CP 100% + HA treatment, which was 485.6 and 198.5 USD ha⁻¹ greater than that by the P 100% and P 100%+HA treatments, respectively.

Correlation Analysis

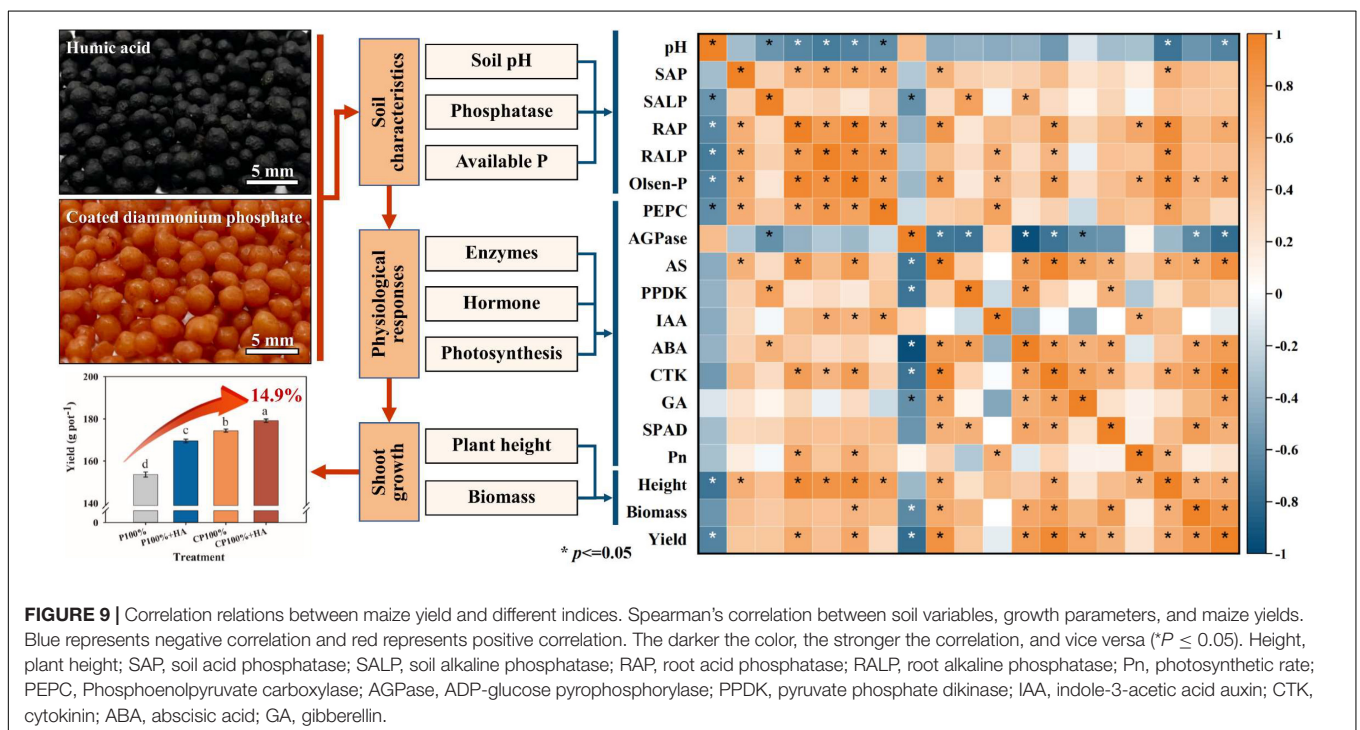

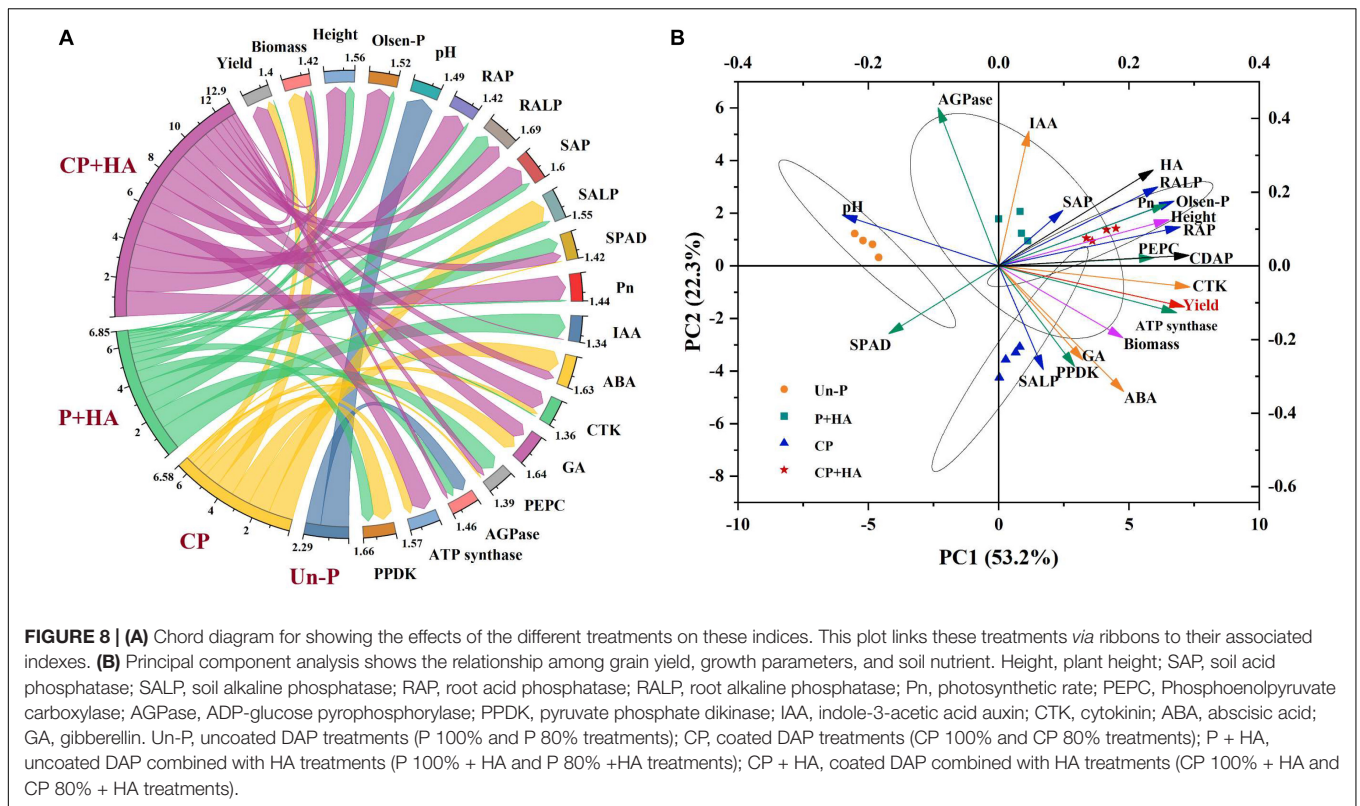

Correlation analysis showed that there was a positive effect with the application of CDAP in combination with HA on yield, biomass, height, available P content, soil AP, soil ALP,

root AP, root ALP, IAA, ABA, CTK, GA, PEPC, AGPase, and ATP synthase (Figure 8A). In addition, it was obvious that the contribution of the application of CDAP combined with HA respond to these indices than other treatments, including the combination of DAP and HA and application of CDAP and DAP, respectively. Principal component analysis revealed that the 21 parameters were divided into PC 1 (53.6%) and PC 2 (22.3%). PC 1 and PC 2 explained 53.2% of the differences among the 21 indicators (Figure 8B). In addition, pH and AGPase were distributed in the second quadrant, and they had a negative relationship with the other parameters mainly distributed in the first and fourth quadrants.

DISCUSSION

Effects of Coated Diammonium Phosphate on P Supply Intensity in the Soil Solution and Its Availability

It is important to balance fertilizer input and crop uptake in high-yielding maize production (Shoji et al., 2001; Geng et al., 2015).

The nutrient release curve of CDAP (Figure 1A) is similar to the sigmoidal nutrient uptake curve of maize (Bender et al., 2013). Lu et al. (2020) reported similar results pertaining to the nutrient release characteristics of CDAP that match with

the nutrient uptake requirement of maize much better than the conventional P fertilizer. Based on soil available P changes during maize growth (Figure 3A), it is speculated that CDAP had a longer P-release period in the pot experiment than in the

laboratory incubation (**Figure 1A**). First, the coating of CDAP was done by a polyurethane block copolymer containing soft and hard segments, with swelling properties for gradual nutrient release (Hou et al., 2015; Lu et al., 2016). Second, the nutrient release from coated fertilizers is greatly affected by humidity and temperature (Yang et al., 2011). Although soil temperature (26.1°C on average) during maize growth in the pot experiment was closer to the incubation temperature in the laboratory, soil

moisture was low compared with the moisture condition in laboratory incubation (Li et al., 2020), which might have greatly slowed down the P release. Our findings were in line with those of Zheng et al. (2016), who discovered changes in nutrient release characteristics between field soils and laboratory soils.

Sufficient nutrient supply is a requirement for high crop yield. In this study, the maize yield in CP 100% and CP 80% was increased by 13.5 and 11.0%, respectively, compared to P 100%

(Table 1). The coating of CDAP not only separates DAP from direct contact with the soil, thus preventing P from fixation by the soil *via* sorption, complexation, and precipitation (Roberts and Johnston, 2015) but also stops DAP from rapid dissolution and loss of surface runoff and subsurface flow (Hively et al., 2006; Holman et al., 2008). The V12 stage is a highly P-demanding growth stage of maize, during which a large amount of P is needed for grain development in the later stages (Bender et al., 2013). The application of CDAP increased the activity of phosphatase, AP in particular, in the root by 11.5–24.7% at the V12 stage (Figure 4), leading to higher P availability due to more organic P being hydrolyzed.

Additionally, the application of conventional P fertilizer (i.e., DAP) resulted in a higher soil available P content at the V3 stage (Figure 2), which would lead to a higher P content in the maize plant (Bender et al., 2013). However, high available P would inhibit the synthesis and the activity of phosphatase and in turn, would slow down the decomposition of protein-phytic acid-mineral element complex. Consequently, the availability of mineral elements would be decreased (Sarah et al., 2018). As CDAP released P into the soil solution at a rate that matches the maize demand, maize growth was not limited by P, resulting in a high grain yield.

Effects of Humic Acid on the P Availability and Maize Growth

Humic acid, as a P activator, accelerated P transformation into bioavailable forms. On the one hand, soil pH was lower in the treatments with combined application of HA and DAP than in the treatments with an application of DAP alone at the V3 stage. The presence of HA increases the altering of the root exudate profile and it also enhances the release of oxalate and citrate from maize roots, compared to maize not treated with HA (Canellas et al., 2008; Rosa et al., 2018;

Ma et al., 2021). Additionally, H⁺ is produced during HA decomposition (Hue, 1991), leading to an available P increase in calcareous soils with the dissolution of insoluble P compounds. On the other hand, the adsorption of HA generates a repulsive negative electric potential on the adsorption plane and a steric hindrance on the mineral surface, further inhibiting P binding on the soil surface (Wang, 2016). Additionally, HA complexes with Ca²⁺, Fe³⁺, and Al³⁺, reduce P precipitation with these cations. This was associated with the rich functional groups in HA, such as O-H in aromatic rings, C-O, and C-H in benzene rings (Figure 1B; Sarlaki et al., 2021). Furthermore, the application of HA increased the phosphatase (i.e., soil AP and root AP) activity (Figure 4) and in turn the amount of P released from the soil solid phase or from P fertilizers (Nardi et al., 2017; Zhu et al., 2018), leading to an increase in the available P content (Figure 3A). Therefore, HA protected P fertilizer to avoid wasting and improved the P availability in soil.

In addition to the P availability in soil, the HA use increased the growth of maize. As a biostimulant, HA possesses aliphatic and aromatic structures with various functional groups (mainly oxygen-containing). Its phenolic and quinone groups interact with enzymes in plant cell and stimulate plant metabolism, thereby promoting growth and improving crop yield (Fan et al., 2015). In this study, the photosynthetic rate of maize leaves at the key growth stage was enhanced by the application of HA (Figure 6). The application of HA improved photosynthesis by increasing the activities of PEPC, ATP synthase, and PPDK (Figure 6 and Supplementary Figure 1) and influenced the important metabolic pathways in photosynthesis, such as photosynthetic carbon assimilation, oxidative phosphorylation, and photosynthetic phosphorylation (Gao et al., 2017; Nardi et al., 2017).

The endogenous hormone plays a key role in regulating plant growth and developmental processes as well as in regulating plant responses to the external environment (Fahad et al., 2015a,b). The P 100% + HA treatment increased the IAA, ABA, and CTK contents in maize leaves by 34.6, 9.1, and 27.2%, respectively, compared to the P 100% treatment at the V12 stage. These results are in confirmation with the reports by Nardi et al. (2017). Nardi et al. (2002) suggested that humic-like substances behave as signaling molecules in the rhizosphere, eliciting the production of phytohormones. Moreover, HA stimulates the expression of *IAA5* and *IAA19*, two early auxin-responsive genes (Nardi et al., 2002). These phytohormones can act either locally (at the site of their synthesis) or transported to some other sites within the maize plant body to mediate growth and development responses of both under ambient and stressful conditions (Peleg and Blumwald, 2011; Fahad et al., 2015a). Furthermore, IAA and HA can enhance the synthesis and activity of plasma membrane H^+ -ATPase, an enzyme that converts energy for transmembrane transportation of nutrients including P, then energizes secondary ion transporters, and promotes the nutrient uptake of maize (Zandonadi et al., 2010).

Interactive Effects of Coated Diammonium Phosphate and Humic Acid

The interactive effect of CDAP and HA improved maize grain yield and PUE (Figure 9). The CDAP synchronized the P supply with plant demand. The HA increased the photosynthetic rate of maize to accumulate organic matter. Additionally, the functional groups of HA, such as $-COOH$ and $-OH$ (Figure 1B), adsorb to the soil surface and react with soil minerals, influencing metal speciation and solubility and reducing P fixation (Nardi et al., 2017; Sarlaki et al., 2021), which is conducive to meeting the P demand of maize in the early growth stage. Furthermore, some studies have shown that HA was capable of promoting root growth and modifying root architecture (Olaetxea et al., 2018) as well as modifying the gene expression of the main high-affinity root transporters of phosphate to increase the phosphate root uptake (Jindo et al., 2016; Olaetxea et al., 2018). Therefore, the combination of CDAP and HA was able to improve the overall P nutrition in maize plants. Besides, the contents of IAA and CTK in maize leaves were improved when treated with CDAP combined with HA. Meanwhile, the ATP synthase activity and the photosynthetic rate were improved (Figure 9) leading to better crop growth and grain development.

The interactive effect of CDAP and HA on maize yield was not significant in 2017. This may be because maize is a highly P-efficient crop and not very sensitive to P levels in soil (Ciarelli et al., 1998; Ci et al., 2012). However, the yield in CP 100% + HA was significantly higher than that in CP 100% in 2018. This is because the combination of CDAP and HA exerts beneficial effects on plant growth by improving the soil structure, fertility, and quality (Calvo et al., 2014; Raiesi, 2021; Xu et al., 2021), and two consecutive years of application eventually resulted in significant changes. The combination of CDAP and HA provides an HA-incorporated enhanced-efficiency P fertilizer

for environmentally friendly fertilization (Figure 9), and future research should include P-inefficient crops (e.g., wheat).

CONCLUSION

The application of CDAP combined with HA increased the soil available P content, improved the root acid phosphatase activity, ATP synthase activity, and cytokinin content, increased the photosynthetic rate, and plant height, and eventually increased the maize grain yield and PUE. When P was applied at $75 \text{ kg P}_2\text{O}_5 \text{ ha}^{-1}$, higher maize grain yield was obtained by CDAP-HA combination than by CDAP alone or DAP-HA combination, and in the second year of cultivation, these differences became bigger and significant. Even at $60 \text{ kg P}_2\text{O}_5 \text{ ha}^{-1}$, the combined application of CDAP and HA presented a higher grain yield and PUE in the second year than the conventional fertilization. Overall, the combined application of CDAP and HA is of significance in improving PUE, reducing P loss to the environment, ensuring food security, realizing sustainable utilization of land and fertilizer resources, and increasing the economic return of crops. Future studies should be conducted in different regions with various soil types and crops to develop an effective strategy of fertilization with controlled-release fertilizers and biostimulants (e.g., HA).

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/Supplementary Material, further inquiries can be directed to the corresponding author/s.

AUTHOR CONTRIBUTIONS

QC, ZGL, ZW, and MZ contributed to the conception and design of the study. QC, ZQ, ZL, ZZ, and GM organized the database. QC, YW, LW, and FF contributed to investigating and obtaining the resources. QC, ZGL, ZW, and MZ wrote sections of the manuscript. QC wrote the first draft of the manuscript. All authors contributed to the article and approved the submitted version.

FUNDING

This study was supported by the Key Research and Development Program of Shandong (Grant No. 2019GNC106011), the National Natural Science Foundation of China (Grant No. 41977019), and the Strategic Priority Research Program of the Chinese Academy of Sciences (Grant No. XDA28090200).

Salt stress severely threatens the growth and productivity of *Glycyrrhiza uralensis*. Previous results found that *Bacillus cereus* G2 enhanced several carbohydrate contents in *G. uralensis* under salt stress. Here, we analyzed the changes in parameters related to growth, photosynthesis, carbohydrate transformation, and the glycolysis Embden-Meyerhof-Parnas (EMP) pathway-tricarboxylic acid (TCA) cycle by G2 in *G. uralensis* under salt stress. Results showed that G2 helped *G. uralensis*-accumulating photosynthetic pigments during photosynthesis, which could further increase starch, sucrose, and fructose contents during carbohydrate transformation. Specifically, increased soluble starch synthase (SSS) activity caused to higher starch content, which could induce α -amylase (AM) and β -amylase (BM) activities; increased sucrose content due to the increase of sucrose synthase (SS) activity through upregulating the gene-encoding SS, which decreased cell osmotic potential, and consequently, induced invertase and gene-encoding α -glucosidase that decomposed sucrose to fructose, ultimately avoided further water loss; increased fructose content-required highly hexokinase (HK) activity to phosphorylate in *G. uralensis*, thereby providing sufficient substrate for EMP. However, G2 decreased phosphofructokinase (PFK) and pyruvate kinase (PK) activities during EMP. For inducing the TCA cycle to produce more energy, G2 increased PDH activity that enhanced CA content, which further increased isocitrate dehydrogenase (ICDH) activity and provided intermediate products for the *G. uralensis* TCA cycle under salt stress. In sum, G2 could improve photosynthetic

efficiency and carbohydrate transformation to enhance carbohydrate products, thereby releasing more chemical energy stored in carbohydrates through the EMP pathway-TCA cycle, finally maintain normal life activities, and promote the growth of *G. uralensis* under salt stress.

Keywords: salt stress, *Bacillus cereus* G2, photosynthesis, carbohydrate transformation, glycolysis, tricarboxylic acid cycle

INTRODUCTION

In plants, salt stress leads to reduced water uptake, excessive accumulation of toxic elemental ions, and production of reactive oxygen species (ROS) causing oxidative stress (Salimi et al., 2016; Ahmadi et al., 2018). This combination of osmotic, ionic, and oxidative effects promotes cellular damage, declines K^+ and Ca^{2+} efficiency, reduces photosynthetic rate, impairs metabolism, and ultimately inhibits plant growth and reduces productivity (Salimi et al., 2016; Brahimova et al., 2021). In response to salt-stressed condition, carbohydrate accumulation can be an important part of radical scavenging, osmo-protection, and carbon storage in plants (Keunen et al., 2013; Zhu et al., 2016; Li et al., 2020). Carbohydrates, as the products of photosynthesis, are not only the substrates for respiration but also important substances related to the growth and energy metabolism in plants (Raessler et al., 2010). Salt stress directly reduced CO_2 availability through diffusion limitation of stomata and mesophyll or change photosynthetic metabolism, and also affected oxidative stress and thus indirectly affected leaf photosynthesis (Chaves et al., 2008). Some studies showed that salt stress typically reduced the chlorophyll (Chl) content in plants (Khoshbakht et al., 2015; Ibrahim et al., 2017), while other studies reported increased Chl concentration with increasing salinity stress in salt-tolerant plants (Borghesi et al., 2011; Huang et al., 2015; Qiu et al., 2017). Salt stress caused inhibition of carbon assimilation by affecting the activities of carbon metabolism-related enzymes and the contents of carbohydrate (Li et al., 2020). The glycolysis (EMP) pathway-tricarboxylic acid (TCA) cycle serves as the primary pathway for carbohydrate catabolism, providing sufficient energy for the plant's life activities (Jiang, 2011). Moreover, salt stress led to the disorder of EMP metabolism, which posed a threat to plant respiration metabolism (Zhong et al., 2016). Salt stress also inhibited the TCA cycle, followed by a significant decrease in adenosine triphosphate (ATP) content, resulting in insufficient energy supply and further inhibition of plants' growth (Li et al., 2015, 2020). Thus, it can be concluded that plants exposed to salt stress are unable to maintain the required carbohydrate and energy levels, and, consequently, certain measures must be adopted to regulate carbohydrate metabolism in salt-stressed plants.

Plant endophytes have great potential to enhance plant growth and alleviate salt stress without harming the environment (Fan et al., 2020; Molina-Montenegro et al., 2020). Previous studies revealed that endophytes increased salt tolerance of plants by regulating carbohydrate metabolism (Ali et al., 2014; Ghaffari et al., 2016; Win et al., 2018). Specifically, wild-type bacterial endophytes significantly increased the total Chl contents of

tomato plants under salt stress (Ali et al., 2014). Endophyte (*Penicillium funiculosum* LHL06) significantly increased Chl contents and the photosynthesis rate of *Glycine max* L. under salt stress (Khan et al., 2011). Moreover, the endophytic fungus *Piriformospora indica* increased the starch concentration in barley plants under salt stress (Ghaffari et al., 2016). Therefore, carbohydrate regulation may be one of the important strategies for improving plant salt tolerance by endophytes. However, the deep mechanisms of endophytes on carbohydrate regulation in plants exposed to salt stress are largely unknown.

Glycyrrhiza uralensis Fisch., as an important windbreak and sand fixation plant in desert areas, widely grown in arid and semiarid regions of the world, especially in the harsh northwestern region of China, and suffers from salt stress year-round (Li et al., 2016; Wang C. et al., 2020). *Bacillus cereus* (G2), as an endophyte found by our laboratory, enhanced several carbohydrate contents in *G. uralensis* under salt stress, but the mechanism has not been thoroughly studied (Zhang, unpublished). During their seedling stage, plants are sensitive to adverse external factors; therefore, the seedlings stage is the optimum time to research plants' abiotic tolerance (El Atta et al., 2016). Therefore, in order to reveal the behind mechanism of G2 on carbohydrate metabolism in *G. uralensis* seedlings subjected to salt stress, this study analyzed parameters related to photosynthesis, carbohydrate transformation, and EMP pathway-TCA cycle at physiological biochemistry and transcriptome levels. This study not only provided valuable information for exploring the mechanism of G2 improving the salt tolerance of *G. uralensis*, but also laid the foundation for cultivating high-quality and high-yield *G. uralensis*.

MATERIALS AND METHODS

Plant Material

Glycyrrhiza uralensis seeds were collected from wild *G. uralensis* plants in Urad front flag, Inner Mongolia, China, in September, 2019. Healthy seeds were selected and stored in a kraft paper bag at 4°C until use.

Bacillus cereus G2 Material and Culture Suspension

Bacillus cereus (G2) was isolated from *G. uralensis* roots and identified by Sangon Biotech (Shanghai) Co., Ltd. This strain was deposited at the China General Microbiological Culture Collection Center under the accession No. CGMCC No. 16671, and under the accession No. MT803148 in NCBI.

The strain of G2 was cultured at 30°C for 2 days in a beef extract peptone AGAR medium, which contained 1-g L⁻¹ tryptone, 3-g L⁻¹ beef extract, 5-g L⁻¹ NaCl, and 16-g L⁻¹ agar, and the pH of the medium after autoclaving was 6.9–7.1. Then, G2 was grown in a sterilized LB liquid medium, which contained 2.5-g tryptone, 0.75-g beef extract, 1.25-g NaCl, and 250-ml distilled water, and the pH of the medium after autoclaving was 6.9–7.1. The bacteria culture suspension was incubated in a shaking incubator of 180 rpm at 28°C for 2 days.

Plant Growing Condition and Treatment

All of the seeds of *G. uralensis* were steeped with concentrated sulfuric acid (H₂SO₄) for 1.5 h, and then surface sterilized with 0.1% (v/v) H₂O₂ for 10 min, rinsed for three times in distilled water, and soaked in distilled water for 9 h at room temperature. Then, 75 water-absorbing, full-filled seeds were selected, blotted surface moisture, and sown evenly in each pot filled with 1,900-g high-pressure sterilized and a fully dried sand medium collected from native desert regions, which did not contain any nutrients. Then, pre-irrigated with 300 ml of distilled water as the control group (CK) or with 300 ml of distilled water containing 75-mM NaCl as the salt stress group (S). The above experiment was carried out in an indoor environment with natural light and an air temperature of 23–28°C during the day and night. After 35 days, G2 treatment was initiated when the third true leaf appeared in most of the *G. uralensis* seedling. The bacteria culture suspension with G2 was centrifuged at 8,000 rpm for 10 min, and it was washed in sterile distilled water, and the optical density (600 nm) of the bacterial strain was adjusted to 1 (~10⁸ cfu ml⁻¹) using sterile distilled water. Both CK and S groups were divided into two subgroups, and were watered either 300-ml distilled water or 300-ml of distilled water, containing 10⁸-cfu ml⁻¹ G2. Three replications per treatment were used, and each replication comprised two pots. All pots were randomly arranged and periodically rotated to minimize the effects of environmental heterogeneity.

At 10 days after G2 treatment, the plants were collected and used in subsequent experiments. Generally, three pots of each treatment, firstly, the numbers of plants per pot were recorded for calculation of the survival rate, and all the plants in the pot were taken out of the soil, and then growth indicators were recorded; then, the samples were oven dried at 60°C for 48 h and weighed. The rest three pots of each treatment – all seedlings were taken out of the soil between 9:00 a.m. and 10:00 a.m. and cleaned immediately with distilled water, and then parts of leaves were collected and mixed for determination of Chl contents, and the rest samples were immediately stored at –80°C to measure their physiological and biochemical characteristics.

Measurement of Photosynthetic Pigment Contents

About 0.2-g fresh leaves material of *G. uralensis* was extracted with 15 ml of a solution that contained ethanol and acetone (1:2, v/v) for 24 h at room temperature in the dark. To calculate the contents of Chl *a*, Chl *b*, and carotenoids (Car), the

absorbance was measured at 663, 645, and 470 nm, respectively (Wellburn, 1994).

Measurement of Carbohydrate Contents

About 0.2-g fresh *G. uralensis* seedlings material was homogenized in 2-ml 80% (v/v) ethanol, and then 80°C water bath for 30 min and centrifuged at 1,000 rpm for 5 min, and the supernatants were analyzed for total soluble sugar (TSS), sucrose, fructose, and starch contents. The TSS content was analyzed by anthrone colorimetry (Li et al., 2020), specifically 100-μL supernatant was mixed with 5-ml anthracite reagent, and incubation was performed for 10 min at 100°C, 630-nm colorimetric analysis. The contents of sucrose and fructose were analyzed by Tang (1999), as follows: Sucrose analysis: 400-μL supernatant added to 200-μL 2-M NaOH that was boiled for 5 min, and then added 3-ml 30% (v/v) HCl, 1-mL 1% m-dihydroxybenzene, which were 80°C water bathed for 10 min, 480-nm colorimetric analysis. The mixtures for the fructose analysis contained 100-μL supernatant, 0.2-ml 80% (v/v) ethanol, 0.8-ml 0.1% m-dihydroxybenzene, and 2.8-ml 30% (v/v) HCl, and then were 80°C water bathed for 10 min, 480-nm colorimetric analysis. The residues were extracted with 2 ml of 9.2-M perchloric acid, the volumes were adjusted to 10 ml in volumetric flasks, and the supernatants were analyzed to determine the starch contents by anthrone colorimetry (Gao, 2006).

Measurement of Carbohydrate Transformation-Related Enzyme Activities

About 0.2-g fresh *G. uralensis* seedlings material was homogenized in 2-ml water and centrifuged at 3,000 rpm for 10 min. Then, the amylase determination was carried out according to the method of Devi et al. (2007) with minor modification. α-Amylase (AM) activity was determined after destroying the β-amylase (BM) by heating the enzyme at 70°C for 20 min and estimating reducing sugars formed from 2% starch in a 50-mM sodium acetate buffer (pH 5.0) in the presence of 1-mM CaCl₂ at 37°C. BM was extracted with a 100-mM sodium acetate buffer (pH 3.6), containing 1-mM EDTA. The activity of BM was determined by estimating the reducing sugars formed after the enzyme action on 1% starch prepared in a 50-mM sodium acetate buffer (pH 5.0), containing 1-mM EDTA. The soluble starch synthase (SSS), granule-bound starch synthase (GBSS), and ADP-glucose pyrophosphorylase (AGP) were determined using reagent kits (Beijing Solarbio Science & Technology Co., Ltd.) according to the manufacturer's instructions. The GBSS, SSS, and AGP were determined by recording the increase of NADPH at 340 nm. The sucrose phosphate synthase (SPS) and sucrose synthase (SS) activities were measured using the m-dihydroxybenzene method (Tang, 1999) with minor modification. The mixtures for the SPS analysis contained 50-mM Tris-HCl (pH 7.0), 10-mM MgCl₂, 10-mM fructose-6-phosphate, 3-mM UDP-glucose, and 100 μL of crude enzyme. For the SS activity, the reaction mixtures contained 50-mM Tris-HCl (pH 7.0), 10-mM MgCl₂, 10-mM fructose,

3-mM UDP-glucose, and 100 μ L of crude enzyme. The invertase extraction and determination were carried out according to the method of Scholes et al. (1996). About 0.2-g fresh *G. uralensis* seedlings material was homogenized on an ice bath in 3 ml of extracting solution and centrifuged at 10,000 rpm for 10 min, and enzyme activity was detected in the supernatants. The amount of the compound formed by the reaction of reducing sugar with 3,5-dini-trosalicylic acid indicates its activity, and the absorbance is measured at 510 nm.

Measurement of Intermediate Contents in the EMP and Tricarboxylic Acid Cycle Pathway

The pyruvate (PA) and citrate (CA) contents were determined using reagent kits (Beijing Solarbio Science & Technology Co., Ltd.) according to the manufacturer's instructions. PA content was determined using 2,4-dinitrophenylhydrazine as the substrate to record the absorbance at 520 nm. CA content was determined by the reduction of Cr^{6+} at 545 nm.

Measurement of Enzyme Activities in the EMP and Tricarboxylic Acid Cycle Pathway

The hexokinase (HK), phosphofructokinase (PFK), and pyruvate kinase (PK) were determined using reagent kits (Beijing Solarbio Science & Technology Co., Ltd.) according to the manufacturer's instructions. HK was determined using glucose as the substrate to record the increase in absorbance at 340 nm caused by the enzymatic reduction of NADP^+ . PFK was determined using 6-phosphate-fructose as the substrate to record the decrease in absorbance at 340 nm caused by the enzymatic oxidation of NADH. PK was determined using phosphoenolpyruvate (PEP) as the substrate to record the decrease in absorbance at 340 nm caused by the enzymatic oxidation of NADH.

The malate dehydrogenase (MDH), pyruvate dehydrogenase (PDH), isocitrate dehydrogenase (ICDH), and succinate dehydrogenase (SDH) were determined using reagent kits (Beijing Solarbio Science & Technology Co., Ltd.) according to the manufacturer's instructions. The MDH activity was determined using oxaloacetate as the substrate to record the decrease in absorbance at 340 nm caused by the enzymatic oxidation of NADH. PDH catalyzed dehydrogenation of PA and reduced 2,6-DCPIP at the same time. The PDH activity was determined by recording a decrease in absorbance at 605 nm. The ICDH activity was determined by measuring ketoglutaric acid production at 340 nm, and the SDH activity was determined by recording the reduction rate of 2,6-DCPIP at 600 nm.

RNA Extraction, cDNA Library Construction, and RNA-Seq

Transcriptome sequencing was carried out by Beijing Baimeike Company. The experimental process followed the method provided by Oxford Nanopore Technologies (ONT), which mainly included the following steps: (i) *G. uralensis* seedlings collected of four treatments (CK, CK + G2, S, and S + G2)

were grounded, grouped by weight, and biologically replicated for RNA preparation. Three biological replicates per sample were used for the RNA-Seq experiments. (ii) Total RNA was extracted from the tissue using TRIzol reagent (Takara, Kyoto, Japan) according to the manufacturer's instructions. RNA purity was tested using the Nano Photometer spectrophotometer (IMPLEN, Westlake Village, United States). (iii) Library construction: primer annealing, reverse transcription into cDNA, plus switch Oligo; synthesis of complementary chains; DNA damage repair and terminal repair and magnetic bead purification. (iv) The cDNA libraries were sequenced using the Illumina NovaSeq 6000 platform.

Transcriptome Data Assembly

Filter the low-quality (length less than 500 bp, Qscore less than 7) sequence and ribosomal RNA sequence from the original landing sequence, and obtain the full-length sequence according to the presence of primers at both ends of the sequence. Polish the full-length sequence obtained in the previous step to obtain the consistent sequence. Contig comparisons with reference genomes or constructed contig sequences were performed to remove redundancy.

Transcription Quantification

Transcriptome sequencing can be simulated as a random sampling process. In order to make the number of fragments truly reflect the expression level of transcripts, it is necessary to normalize the number of mapped reads in the sample. CPM (counts per million) (Zhou et al., 2014) was used as an indicator to measure the expression level of transcripts or genes. The calculation formula of CPM was as follows (reads mapped to a transcript means the number of reads compared to the transcript; total reads aligned in the sample represent the total number of fragments compared to the reference transcriptome):

$$\text{CPM} = \frac{\text{reads mapped to transcript}}{\text{total reads aligned in sample}} \times 1,000,000$$

Quantification of Gene/Transcript Expression Levels and Differential Expression Analysis

Full length reads were mapped to the reference transcriptome sequence. Reads with match quality above 5 were further used to quantify. Expression levels were estimated by reads per gene/transcript per 10,000 reads mapped. For the samples with biological replicates: differential expression analysis of two conditions/groups was performed using the DESeq R package (1.18.0). DESeq provided statistical routines for determining differential expression in digital gene expression data using a model based on the negative binomial distribution. The resulting *p*-values were adjusted using the Benjamini and Hochberg's approach for controlling the false discovery rate. Genes with a *p*-value < 0.05 and fold change ≥ 1.5 found by DESeq were assigned as differentially expressed.

Reverse Transcriptase-Polymerase Chain Reaction and Quantitative Real-Time-Polymerase Chain Reaction

Reverse transcriptase-polymerase chain reaction RT-PCR and quantitative real-time-polymerase chain reaction (qRT-PCR) were performed on the same RNA pools, which were previously used in RNA-Seq for 10 key DEGs of carbohydrate metabolism in *G. uralensis*, respectively. Gene-specific primers were designed based on the sequencing data using the Primer-BLAST tool. The primer sequences used for conventional PCR and qRT-PCR analysis are listed in **Supplementary Table 1**. First-strand cDNAs were synthesized from 2 μ g of DNase-treated total RNA using RevertAid RT Reverse Transcription Kit (Servicebio, China). As for RT-PCR, target genes were amplified using a polymerase chain reaction (PCR) thermal cycler (ABI 2720, United States), photographed by FR-980B gel imaging system (FuRi Science & Technology Co., Ltd.), and analyzed with pixel quantitation software Image J 2 (Rawak Software Inc.). qRT-PCR was performed by Wuhan Servicebio Technology CO., LTD. using 2 \times SYBR Green qPCR Master Mix (High ROX). The reaction mixture (20 μ L) contained 2 \times ChamQ SYBR Green qPCR Master Mix 10 μ L, 1 μ L of primer, 1 μ L of template cDNA, 4 μ L of 50 \times ROX Reference Dye 1 and 7.6 μ L of ddH₂O. Amplifications were performed under the following conditions: 95°C for 10 min, followed by 40 cycles of 95°C for 15 s and 60°C for 60 s. Relative expression for each sample was calculated using the $2^{-\Delta\Delta C_t}$ methods with normalization to the internal control genes.

Statistical Analyses

All treatments have three replication operations presented as the mean \pm SD of each experiment. The one-way ANOVA was carried out, and physiological data were tested for significant treatment differences using Duncan's multiple range tests, and $p < 0.05$ was considered to be statistically significant. The correlation analysis of photosynthetic pigments contents, carbohydrates contents, enzymes activities, and intermediates contents of carbohydrate transformation and EMP pathway-TCA cycle in *G. uralensis* under four different conditions was determined. Principal component analysis (PCA) of the response variables photosynthetic pigments contents, carbohydrates contents, enzymes activities, and intermediates contents of carbohydrate transformation and EMP pathway-TCA cycle was performed to separate plants in different treatments. The first two principal components, which accounted for the highest variation, were then used to plot two-dimensional scatter plots. The qRT-PCR data were tested for significant treatment differences using the Student's *T*-test, and $p < 0.05$ was considered to be statistically significant. All statistical analyses were performed using SPSS Statistics 25, Origin 2018 Statistics, and GraphPad Prism 8.0.1.

RESULTS

Effect of *Bacillus cereus* G2 on the Growth Parameters of *Glycyrrhiza uralensis* Seedlings

The growth situation of *G. uralensis* seedling under all treatments (CK, CK + G2, S, and S + G2) is shown in **Figure 1A**. Salt stress significantly decreased plant height, leaf number, lateral root number, fresh weight, dry weight, and survival rate, but increased the root diameter. Interestingly, G2 significantly increased plant height, stem diameter, fresh weight, and dry weight of *G. uralensis* under salt stress (**Figure 1B**).

Effect of *Bacillus cereus* G2 on Carbohydrate Contents in *Glycyrrhiza uralensis* Seedlings

Salt stress significantly decreased the contents of TSS, starch, fructose, sucrose, and the ratio of sucrose/starch, while G2 significantly increased the contents of TSS, starch, fructose, and sucrose in *G. uralensis* under salt stress (**Figure 2**). TSS, sucrose, and fructose were very positively correlated with one another (**Figure 9** and **Supplementary Figure 1A**).

Effect of *Bacillus cereus* G2 on Photosynthesis in *Glycyrrhiza uralensis* Seedlings

Salt stress significantly increased Chl *a*, Chl *b*, and Chl *a* + *b* contents in *G. uralensis*. Interestingly, G2 significantly further increased the Chl *a* and Car contents in *G. uralensis* under salt stress (**Figure 3**).

In carbon fixation in the photosynthetic organisms pathway (**Table 1** and **Figure 4**) according to transcriptomic analysis, glyceraldehyde-3-phosphate dehydrogenase (NADP⁺) (GPD), ribulose-bisphosphate carboxylase small chain (Rubisco), and ribose 5-phosphate isomerase (RPI) A were differentially expressed in S vs. CK comparison. Specifically, the gene (*Glyur002595s00035357*)-encoding GPD, the genes (*Glyur000604s00024572* and *Glyur001973s00030832*)-encoding Rubisco, and the gene (*Glyur004632s00040687*)-encoding RPI were upregulated in S vs. CK comparison. However, G2 had no significant effect on the genes related to carbon fixation in the photosynthetic organisms pathway.

In the relationship between carbohydrates and photosynthetic pigments (**Figure 9** and **Supplementary Figure 1A**), fructose content was negatively correlated with Chl *a* and Chl *a* + *b* contents; the ratio of sucrose/starch was very negatively correlated with Chl *a* and Chl *a* + *b* contents, and negatively correlated with Chl *b* and Car contents.

Effect of *Bacillus cereus* G2 on Enzymes Related to Carbohydrate Transformation in *Glycyrrhiza uralensis* Seedlings

Salt stress significantly increased AGP activity but decreased SSS activity, while G2 significantly increased the activities of SSS, AM, and BM in *G. uralensis* under salt stress (**Figures 5, 8**). Salt stress significantly decreased the activities of SPS, SS, and NI, while G2 significantly increased the activities of SS, NI, and AI in *G. uralensis* under salt stress (**Figures 6, 8**).

In the starch and sucrose metabolism pathway (**Table 1** and **Figure 4**), β -glucosidase, β -fructofuranosidase (INV),

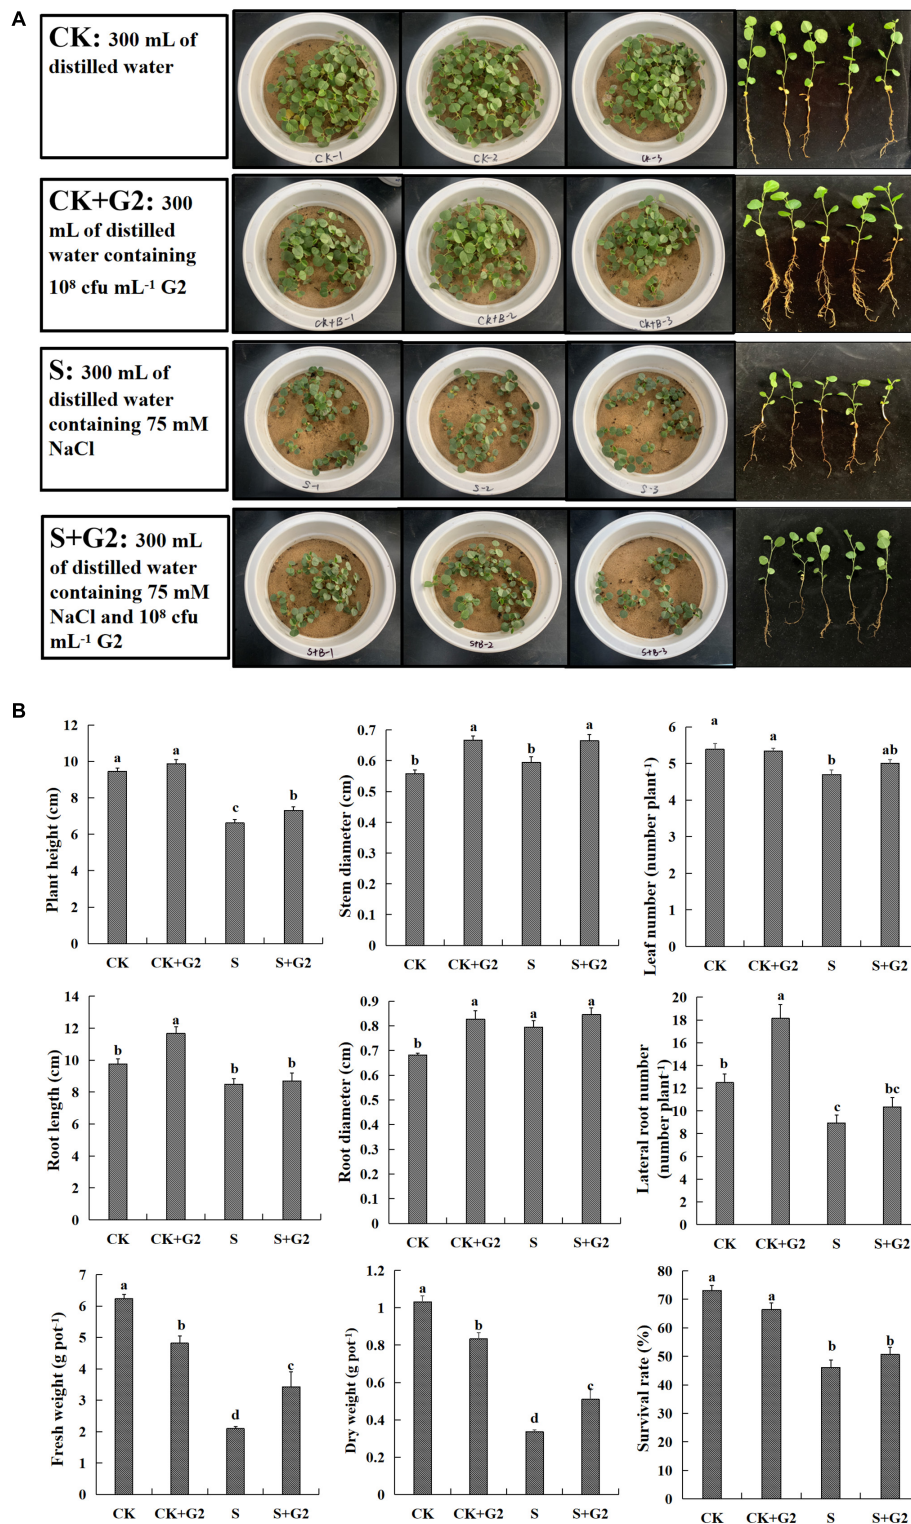

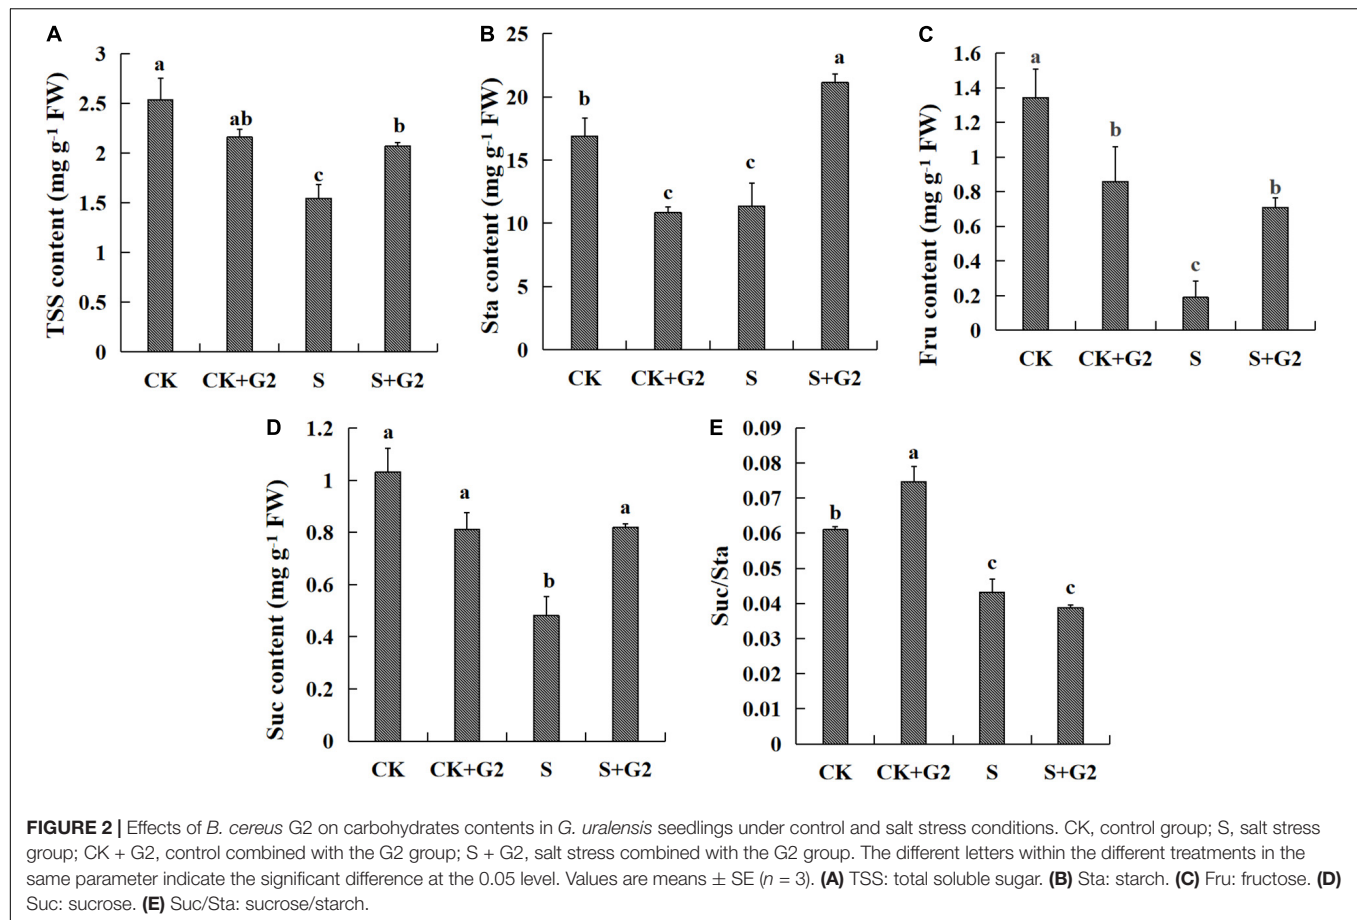

FIGURE 1 | (A) A part of the experiment layout of *Glycyrrhiza uralensis* Fisch. seedlings grown in control and salt stress conditions without or with *Bacillus cereus* G2. **(B)** Effects of *B. cereus* G2 on growth parameters of *G. uralensis* seedlings under control and salt stress conditions. CK, control group; S, salt stress group; CK + G2, control combined with the G2 group; S + G2, salt stress combined with the G2 group. The different letters within the different treatments in the same parameter indicate the significant difference at the 0.05 level. Values are means \pm SE ($n = 3$).

α -glucosidase, trehalose 6-phosphate synthase/phosphatase (TPS), BM, SS, and HK were differentially expressed under different treatments. Specifically, the genes

(*Glyur000779s00022830* and *Glyur000585s00027748*)-encoding β -glucosidase and the gene (*Glyur000324s00015431*)-encoding HK were upregulated, but the gene (*Glyur000214s00016036*)-encoding β -glucosidase, the gene (*Glyur000064s00005640*)-encoding INV, the genes (*Glyur000018s00003759* and *Glyur000231s00022077*)-encoding TPS and the genes (*Glyur000047s00004005* and *Glyur000067s00006388*)-encoding BM were downregulated in S vs. CK comparison. However, the gene (*Glyur000005s00001105*)-encoding α -glucosidase, the gene (*Glyur000018s00003759*)-encoding TPS, and the gene (*Glyur001957s00039090*)-encoding SS were upregulated in S + G2 vs. S comparison.

In the relationship between carbohydrate and carbohydrate transformation parameters (Figure 9 and Supplementary Figure 1B), TSS content was very positively correlated with SS and SPS activities and positively correlated with NI activity, and very negatively correlated with AGP activity. Starch content was very positively correlated with SSS and AM and positively correlated with the activities of GBSS and BM. Sucrose and fructose contents were very positively correlated with SS activity and positively correlated with NI activity, and very negatively correlated with AGP activity. The ratio of sucrose/starch was positively correlated with SPS activity and negatively correlated with the activities of GBSS and AM.

TABLE 1 | Regulation of carbohydrate metabolism-related DEGs in *G. uralensis* by salt stress or *B. cereus* G2.

Pathway	Enzyme name	Definition (EC)	Gene ID	Regulated

CK, control group; S, salt stress group; S + G2, salt stress combined with G2 group.
 “–” means normal.

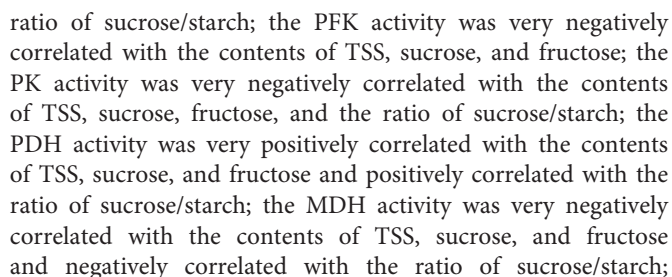

Effect of *Bacillus cereus* G2 on the Levels of Intermediates and Enzymes in the EMP Pathway-Tricarboxylic Acid Cycle of *Glycyrrhiza uralensis* Seedlings

In the EMP pathway, salt stress significantly decreased HK activity, while increased PFK and PK activities in *G. uralensis*. Interestingly, G2 only significantly increased HK activity under salt stress but decreased PK and PFK activities in *G. uralensis* under salt stress. As for the TCA cycle, salt stress significantly decreased PDH and SDH activities and CA content, but increased MDH activity in *G. uralensis*. Interestingly, G2 significantly increased PDH and ICDH activities and CA content, but decreased SDH activity under salt stress condition (Figures 7, 8).

In the EMP pathway-TCA cycle (Table 1 and Figure 4), HK, PFK, pyruvate decarboxylase (PDC), S-(hydroxymethyl)glutathione dehydrogenase/alcohol

dehydrogenase (ADH), aldehyde dehydrogenase (NAD⁺) (ALDH), pyruvate dehydrogenase E1 component beta subunit (pdhB), and dihydrolipoamide dehydrogenase (pdhD) were differentially expressed under different treatments. Specifically, the gene (*Glyur000324s00015431*)-encoding HK, the gene (*Glyur000219s00011582*)-encoding PFK, the genes (*Glyur000136s00007955* and *Glyur003994s00042985*)-encoding PDC, the gene (*Glyur000038s00004477*)-encoding ADH, the gene (*Glyur000698s00016570*)-encoding ALDH, the gene (*Glyur000278s00017282*)-encoding pdhB, and the gene (*Glyur000082s00007586*)-encoding pdhD were upregulated in S vs. CK comparison, while only the gene (*Glyur003994s00042985*)-encoding PDC was downregulated in S + G2 vs. S comparison.

In the relationship between EMP pathway-TCA cycle parameters and carbohydrates (Figure 9 and Supplementary Figure 1C), the HK activity was positively correlated with the

The results of PCA related to photosynthetic pigment contents, starch, and sucrose metabolism and EMP pathway-TCA cycle indexes that we measured revealed a closer association between biological replicates than between salinity or G2 treatments (**Supplementary Figures 2A,B**). PC1 explaining 42.9% of

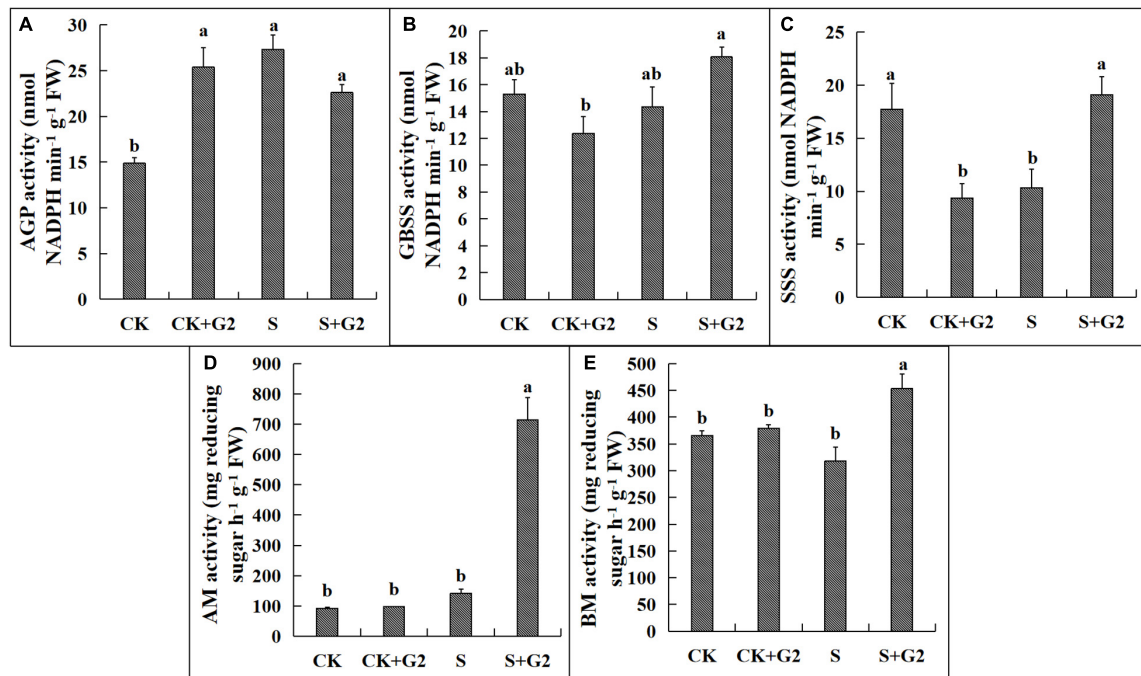

FIGURE 5 | Effects of *B. cereus* G2 on enzymes related to starch synthesis and decomposition in *G. uralensis* seedlings under control and salt stress conditions. CK, control group; S, salt stress group; CK + G2, control combined with the G2 group; S + G2, salt stress combined with the G2 group. The different letters within the different treatments in the same parameter indicate the significant difference at the 0.05 level. Values are means \pm SE ($n = 3$). total variation uncovered differences between plants of CK and S treatments, while PC2, accounting for 26.5% of total variation, distinctly separated the plants provided with S and S + G2 treatments. PC1 formation covers photosynthetic pigment contents, sucrose synthesis, and EMP indices, while PC2 formation covers starch synthesis and decomposition indices. PC1 clearly separated S-treated *G. uralensis* from control *G. uralensis* because of photosynthetic pigment contents, sucrose synthesis, and EMP indices. PC2 clearly separated S + G2-treated *G. uralensis* from S-treated *G. uralensis* because of starch synthesis and decomposition indices.

The results of PCA related to gene expression in carbon fixation in photosynthetic organisms, starch, and sucrose metabolism and the EMP pathway-TCA cycle pathway also revealed a relatively closer association between biological replicates than between salinity or G2 treatments (**Supplementary Figures 2C,D**). PC1 explaining 44.2% of total variation revealed differences between plants of CK and S treatments, while PC2 accounting for 19.2% of total variation distinctly separated the plants provided with S and S + G2 treatments, which is consistent with the result of the PCA in the physiological biochemical level. PC1 formation covered the genes related to the synthesis and decomposition of sucrose and fructose, while PC2 formation covers the genes-encoding pdhD, PFK, and PDC-2. PC1 clearly separated S-treated *G. uralensis* from control *G. uralensis* because of the genes related to the synthesis and decomposition of sucrose and fructose indices. PC2 clearly separated S + G2-treated *G. uralensis*

from S-treated *G. uralensis* because of the genes-encoding pdhD, PFK, and PDC-2.

The Polymerase Chain Reaction Expression Level of the Ley DEGs Related to Carbohydrate Metabolism in *Glycyrrhiza uralensis* Seedlings

To elucidate the correlation between mRNA transcript levels and gene expression levels and further analyze the carbohydrate metabolism-related genes expression level, transcriptional analysis of 10 DEGs in carbohydrate metabolism was conducted via RT-PCR and qRT-PCR in *G. uralensis* seedlings under four treatments (CK, CK + G2, S, and S + G2). The genes-encoding β -glucosidase, INV, α -glucosidase, BM, and SS in carbohydrate transformation and HK, PFK, pdhB, and pdhD in the EMP pathway-TCA cycle were used for this study. The RT-PCR results are shown in **Supplementary Figure 3**. The qRT-PCR results (**Figure 10**) showed that salt stress downregulated the genes-encoding INV, BM, and one of the gene-encoding β -glucosidase, while upregulated the genes-encoding HK, PFK, pdhB, pdhD, and one of the gene-encoding β -glucosidase in *G. uralensis* seedlings. G2 downregulated the genes-encoding INV, HK, PFK, pdhB, pdhD, and one of the genes encoding β -glucosidase, while G2 upregulated the genes encoding α -glucosidase under salt stress in *G. uralensis* seedlings.

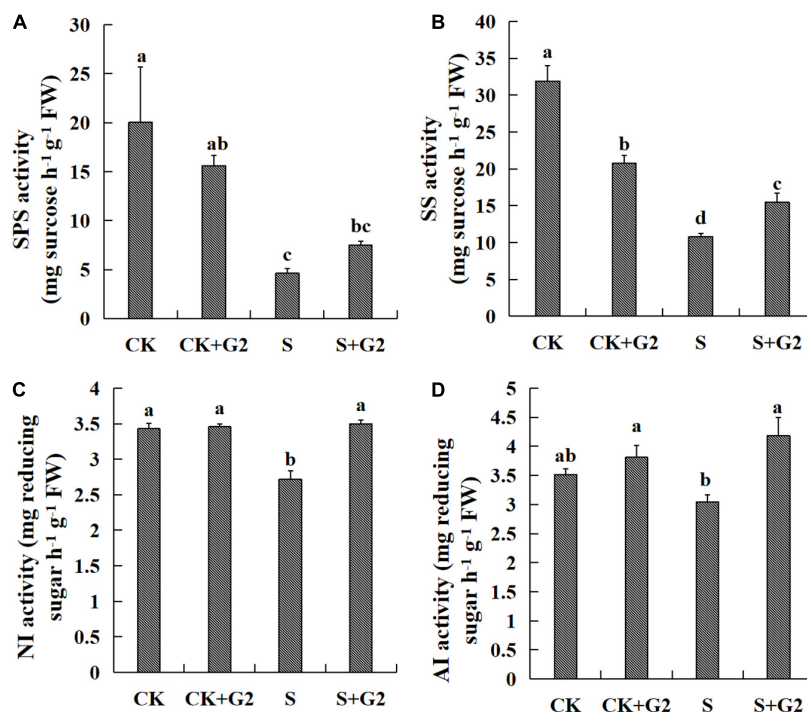

FIGURE 6 | Effects of *B. cereus* G2 on enzymes related to sucrose synthesis and decomposition in *G. uralensis* seedlings under control and salt stress conditions. CK, control group; S, salt stress group; CK + G2, control combined with the G2 group; S + G2, salt stress combined with the G2 group. The different letters within the different treatments in the same parameter indicate the significant difference at the 0.05 level. Values are means \pm SE ($n = 3$). (A) SPS: sucrose-phosphate synthase. (B) SS: sucrose synthase. (C) NI: neutral invertase. (D) AI: acid invertase.

DISCUSSION

Effect of G2 on Growth in *Glycyrrhiza uralensis* Under Salt Stress

Growth inhibition is the most frequent and significant effect of salt stress on plants, and it is mainly manifested as a decrease in biomass (Zhang et al., 2018). Present results also showed that salt stress inhibited the growth of *G. uralensis*, and this effect was partly reversed by G2 inoculation (Figure 2), agreeing with previous findings on wheat (*Triticum turgidum* subsp. *durum*) (Ibarra-Villarreal et al., 2021), soybean (*G. max* L.) (El-Esawi et al., 2018), and *Artemisia ordosica* (Hou et al., 2021). Specifically, G2 significantly increased plant height, stem diameter, fresh weight, and dry weight of *G. uralensis* seedlings under salt stress (Figure 1B).

Effect of G2 on Photosynthesis in *Glycyrrhiza uralensis* Under Salt Stress

Carbohydrate is produced during photosynthesis and acts as a substrate for respiration, which reflects the balance between plant carbon acquisition and expenditure (Liu et al., 2016). We mainly analyzed the genes in carbon fixation in photosynthetic organisms and the contents of photosynthetic pigments.

Our transcriptomic analysis showed that salt stress upregulated the genes-encoding RPI, Rubisco, and GPD in carbon fixation in photosynthetic organisms. The pathway of

carbon fixation in photosynthetic organisms is mainly divided into three stages: the carboxylation stage, the reduction stage, and the regeneration stage. In the carboxylation stage, Rubisco as the key enzyme in the first step converted ribulose-1,5-bisphosphate (RuBP) and atmospheric CO₂ into two molecules of 3-phosphoglycerate (3-PGA). Salt stress-induced stomatal closure generally causes a decline in the available CO₂; in this case, Rubisco uses O₂ that leads to the formation of 2-phosphoglycolate, which is a toxic two-carbon compound and inhibits at least two key enzymes of carbon metabolism, thus attenuates the net photosynthesis rate (Frukh et al., 2019). In our study, salt stress upregulated genes-encoding Rubisco; on the one hand, salt stress promoted the synthesis of 3-PGA, therefore promoted the energy storage process of photosynthesis at the substrate level; on the other hand, salt stress might promote the synthesis of 2-PGA, thereby weakening photosynthesis. However, the direction of Rubisco regulation depends on the partial pressure of CO₂ and O₂ in the environment, which need to be further analyzed. In the reduction stage, GPD catalyzes the reduction of 1,3-bisphosphoglycerate by NADPH to produce 3-phosphoglyceraldehyde (G3P) and NADP⁺; then, PGA can accept electrons from NADPH to decrease ROS production, and G3P can be used to synthesize starch in the chloroplast or can be transported to the cytoplasm for sucrose biosynthesis (Chintakovid et al., 2017). In this study, salt stress upregulated the gene-encoding GPD, therefore promoted the energy storage process of photosynthesis. However, whether the upregulation

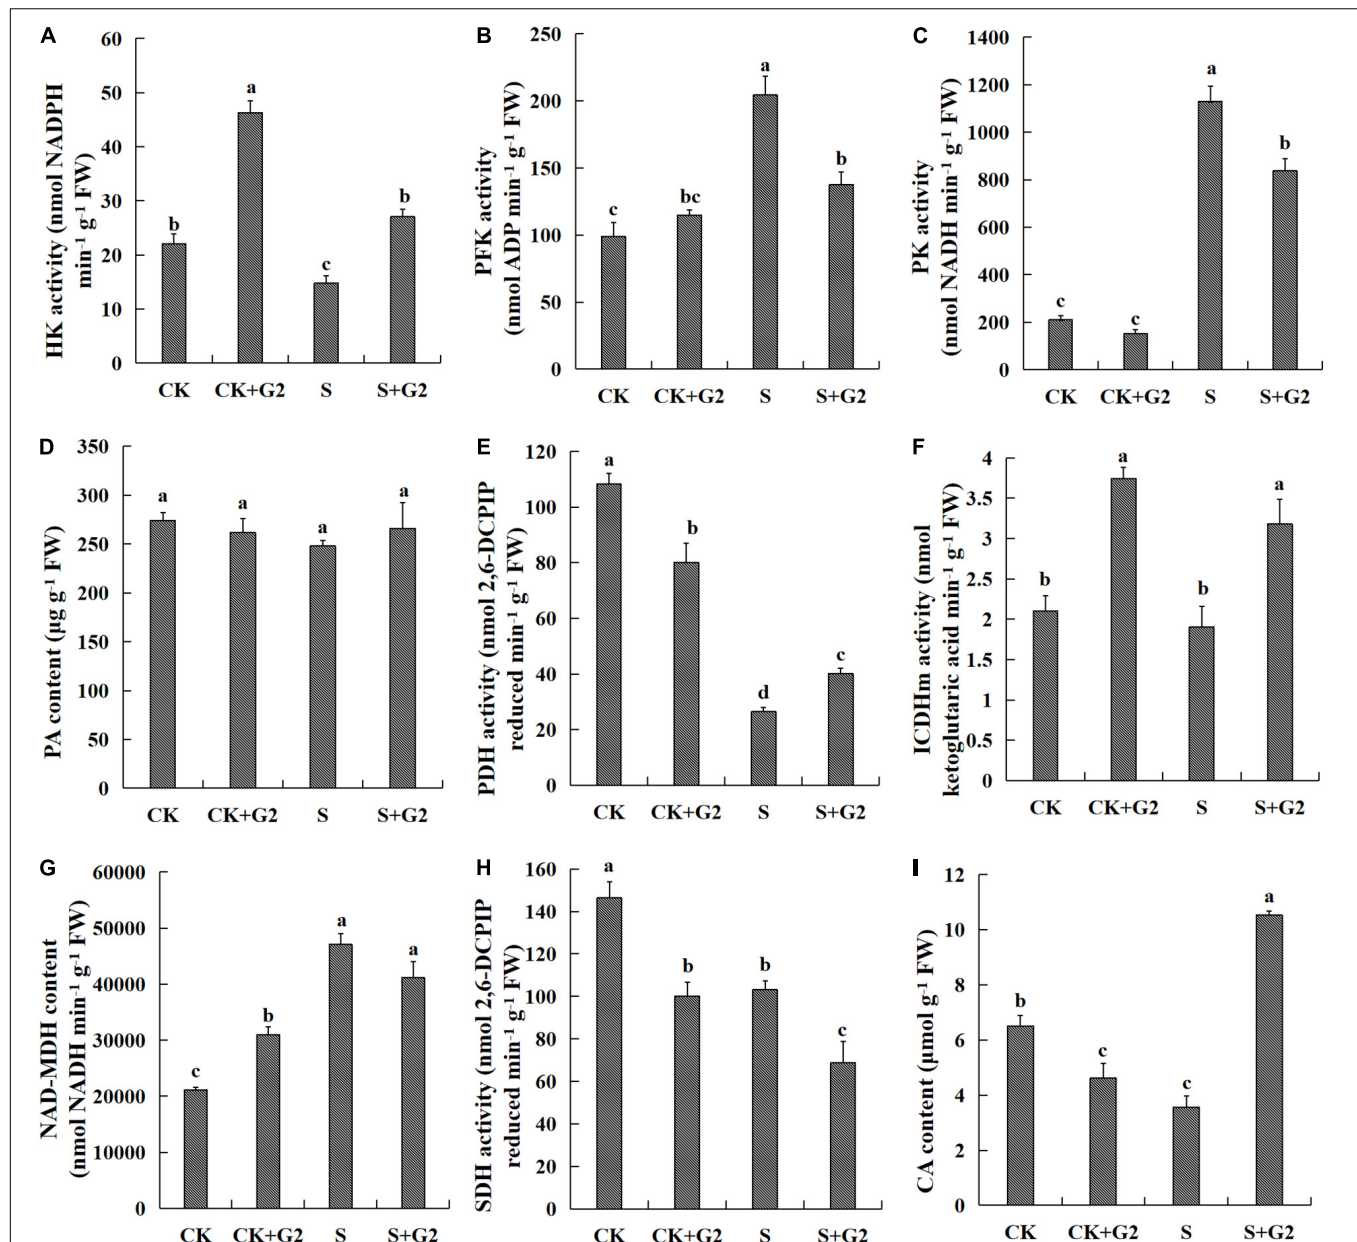

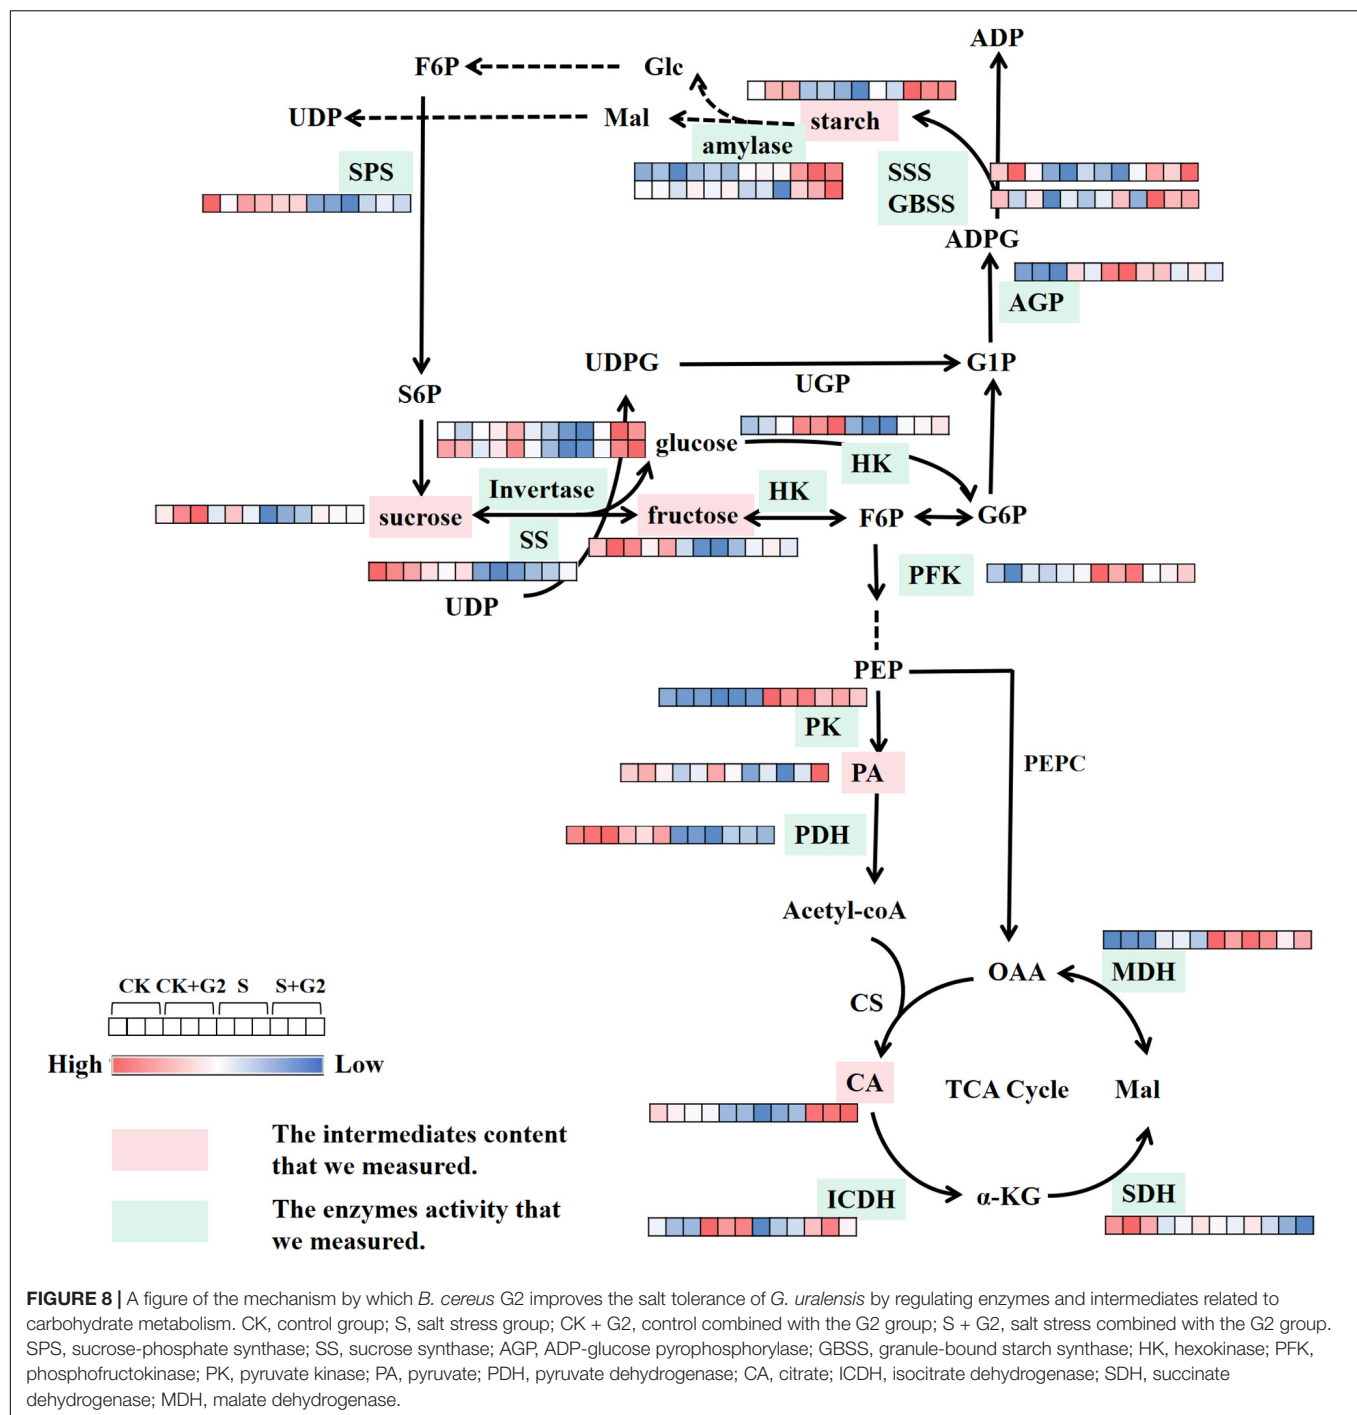

FIGURE 7 | Effects of *B. cereus* G2 on EMP-TCA-related enzyme activities and intermediate contents in *G. uralensis* seedlings under control and salt stress conditions. CK, control group; S, salt stress group; CK + G2, control combined with the G2 group; S + G2, salt stress combined with the G2 group. The different letters within the different treatments in the same parameter indicate the significant difference at the 0.05 level. Values are means \pm SE ($n = 3$). (A) HK: hexokinase. (B) PFK: phosphofructokinase. (C) PK: pyruvate kinase. (D) PA: pyruvate. (E) PDH: pyruvate dehydrogenase. (F) ICDH: isocitrate dehydrogenase. (G) MDH: malate dehydrogenase. (H) SDH: succinate dehydrogenase. (I) CA: citrate.

of the GPD gene under salt stress can help *G. uralensis* reduce the production of ROS and promote the synthesis of starch and sucrose remains to be confirmed by further studies. In the regeneration stage, RPI not only isomerizes ribose-5-phosphate into ribulose-5-phosphate but also helps in the regeneration of the Rubisco substrate (Moigne et al., 2020); therefore, the upregulation of the gene-encoding RPI could contribute to providing sufficient Rubisco substrates for *G. uralensis* seedling under salt stress. However, our results found that G2 had little

effect on the gene related to carbon fixation in photosynthetic organisms in *G. uralensis* under salt stress.

Salt stress generally reduced Chl content (Rabiei et al., 2020); however, some studies have reported increased Chl content with increasing salt stress in salt-tolerant plants (Borghesi et al., 2011; Huang et al., 2015; Qiu et al., 2017). In our study, salt stress also increased contents of Chl *a*, *b*, and *a* + *b* in *G. uralensis*, and then, maybe, leading to highly efficient photosynthesis in terms of light reaction, which is further supported by our

observation that *G. uralensis* leaves under salt stress exhibited greener compared to that under control conditions (Figure 1A). Interestingly, G2 further increased Chl *a* and Car contents in *G. uralensis* exposed to salt stress, which possibly helped improve the photosynthetic rate of *G. uralensis* and promote plants to resist oxidative stress caused by salt stress (Gururani et al., 2015), thus accumulating more photosynthetic products. Carbohydrates are important substrates of metabolism that helps the plants in various physiological events by regulating the

import of carbon to the metabolical sink (Aliche et al., 2019). In this study, salt stress resulted in a significant decrease in starch and TSS contents, and decreased *G. uralensis* growth and yield; in this case, *G. uralensis* thus could require the enhanced photosynthetic rate to synthesize more photosynthetic products to maintain the normal metabolism under salt stress, which may be the reason for the increase of Chl content under salt stress. Moreover, G2 significantly increased the starch and TSS contents in *G. uralensis* under salt stress, which could attribute

FIGURE 9 | Correlation analysis among *G. uralensis* photosynthetic pigment contents, starch and sucrose metabolism, EMP and TCA cycle indexes in the four treatments (CK, CK + G2, S, and S + G2). CK, control group; S, salt stress group; CK + G2, control combined with the G2 group; S + G2, salt stress combined with the G2 group. Chl a, chlorophyll a; Chl b, chlorophyll b; Car, carotenoids; AGP, ADP-glucose pyrophosphorylase; GBSS, granule-bound starch synthase; SSS, soluble starch synthase; AM, α -amylase; BM, β -amylase; SPS, sucrose-phosphate synthase; SS, sucrose synthase; AI, acid invertase; NI, neutral invertase; HK, hexokinase; PFK, phosphofructokinase; PK, pyruvate kinase; PDH, pyruvate dehydrogenase; ICDH, isocitrate dehydrogenase; SDH, succinate dehydrogenase; MDH, malate dehydrogenase; PA, pyruvate; CA, citrate; TSS, total soluble sugar; Sta, starch; Fru, fructose; Suc, sucrose.

to improve the photosynthetic rate caused by increased Chl a and Car contents.

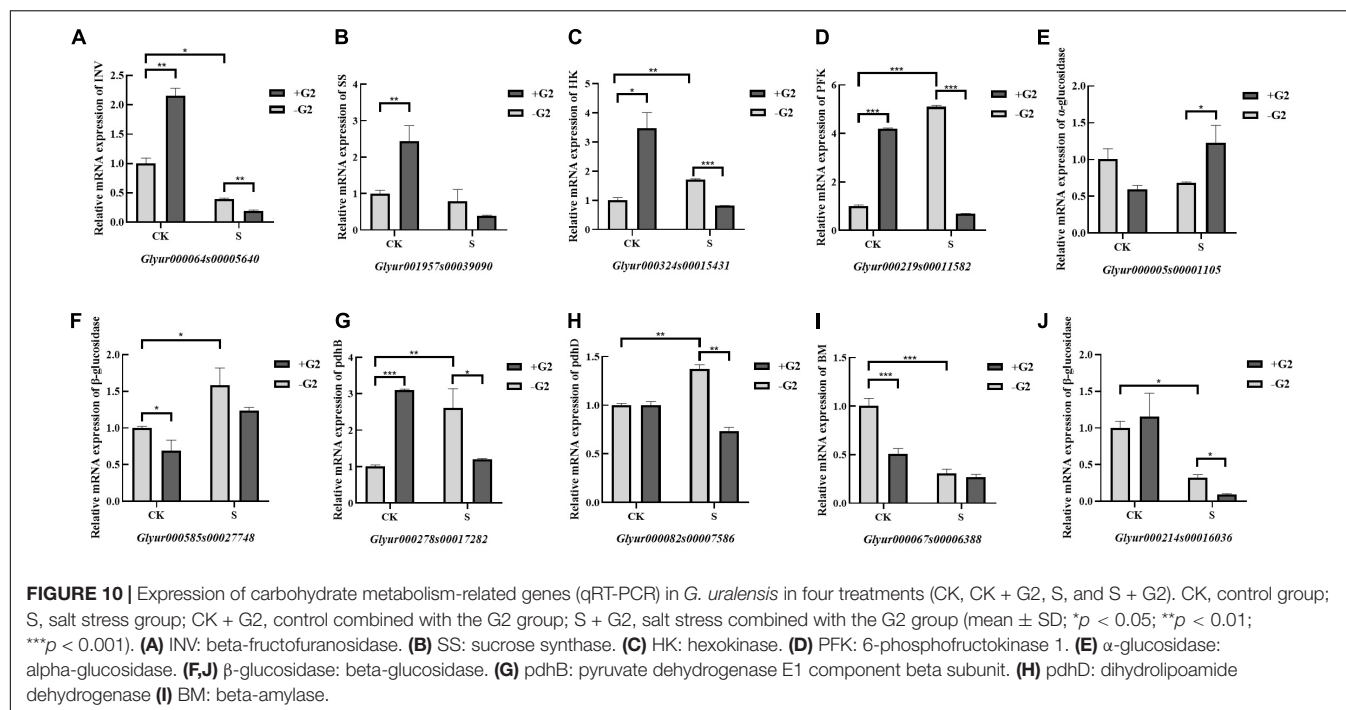

It was concluded that the G2 increased carbohydrate contents mainly by increasing photosynthetic pigments rather than by regulating the gene related to carbon fixation in photosynthetic organisms in *G. uralensis* under salt stress.

Effect of G2 on Carbohydrate Transformation in *Glycyrrhiza uralensis* Under Salt Stress

Carbohydrate contents are not only related to photosynthesis but also closely related to the key enzymes in its synthesis and decomposition. Maintenance of the balance among the production, translocation, partition, and use of carbohydrate is important for plants' normal growth. Starch, sucrose, and fructose are the important components of carbohydrate.

Starch is a major storage form of carbohydrate and an energy carrier in plant storage organs. In the present study, salt stress significantly decreased starch content, while G2 significantly

increased starch content in *G. uralensis* under salt stress (Figure 2). In starch synthesis, AGP catalyzes the conversion of glucose 1-phosphate and ATP to produce the precursor for starch biosynthesis, ADP-glucose (Sun et al., 2021), while GBSS and SSS catalyze the elongation of α -1,4-glucosidic bonds on amylose and amylopectin molecules, respectively, by the transfer of glucose from ADPG (Wu et al., 2020). Transcriptomic analysis showed that the genes related to starch synthesis had no differential expression in *G. uralensis* both in S vs. CK and S + G2 vs. S comparisons. However, different results were found when the activities of enzymes related to starch synthesis were measured. Specifically, salt stress significantly increased AGP activity but decreased SSS activity, while G2 significantly increased the activity of SSS in *G. uralensis* under salt stress (Figure 3), which could be the result of the combined action of all genes-encoding AGP and SSS. The results indicating that the decrease of starch under salt stress were mainly due to the inhibition of amylopectin synthesis, while the accumulation of starch by G2 under salt stress was also mainly due to the promotion of amylopectin synthesis. In starch decomposition, amylase catalyzes the hydrolysis of

starch to a mixture of smaller oligosaccharides (Baslam et al., 2020). Specifically, starch grains are attacked by AM to release linear and branched oligosaccharides, and then BM catalyzes branched oligosaccharides to release maltose disaccharides (Lloyd and Kötting, 2016). G2 had no effect on the genes-encoding AM and BM by transcriptomic analysis and the gene *Glyur000067s00006388* by qRT-PCR, but G2 increased AM and BM activities in *G. uralensis* under salt stress that helped starch hydrolysis and provided energy for subsequent life activities of plants, which could be the result of the combined action of all genes-encoding AM and BM. Furthermore, S + G2 treatment increased AM and BM activities, and the variation activity of AM was higher than BM, which was possibly due to excessive starch content required increased AM activity to decompose and produce linear and branched oligosaccharides, thus providing sufficient substrates for subsequent carbohydrate metabolism, whereas BM only catalyzed branched oligosaccharides. Moreover, starch content was very positively correlated with SSS and AM activities and positively correlated with BM activity (Figure 7), which also indicated that the decrease of starch content in *G. uralensis* under salt stress was mainly attributed to the decrease of SSS activity, while the increase of starch content by G2 in *G. uralensis* under salt stress was also mainly due to the increase of SSS activity firstly, and then the elevated starch required higher activities of amylase for decomposing, which thus improved the activities of AM and BM.

Sucrose is the main product of plant photosynthesis, which not only acts as a carbon and energy source but also plays a key role as a signaling molecule to regulate the growth of source and sink tissues and the sugar-mediated feedback repression of photosynthesis (Gil et al., 2013). In the present study, salt stress markedly decreased sucrose content, while G2

significantly increased sucrose content in *G. uralensis* under salt stress. SPS is responsible for the synthesis of sucrose from glucose and fructose, and AI, NI, and α -glucosidase catalyze the sucrose to glucose and fructose (Lombardo et al., 2011; Bilska-Kos et al., 2020), while SS has a dual role in the synthesis and hydrolysis of sucrose (Yang et al., 2020). In sucrose synthesis, salt stress had no significantly effect on the genes-encoding SPS and SS by transcriptomic analysis and the gene *Glyur001957s00039090* by qRT-PCR, but salt stress significantly decreased SS and SPS activities that inhibited the synthesis of sucrose, which could be the result of the combined action of all genes-encoding SS and SPS. G2 upregulated the gene *Glyur001957s00039090*-encoding SS by transcriptomic analysis, and G2 also increased SS activity in *G. uralensis* under salt stress that promoted the synthesis of sucrose, which suggested that G2 promoted the synthesis of sucrose, mainly by regulating SS activity resulted from upregulation of the gene *Glyur001957s00039090*. The activity of SS is highly correlated with sucrose content so that changes in SS activity may largely explain the reduced sucrose content in *G. uralensis* under S condition and the increased sucrose content in *G. uralensis* under S + G2 condition. In sucrose decomposition, salt stress downregulated the gene *Glyur000064s00005640*-encoding INV by transcriptomic and qRT-PCR analysis, and salt stress also decreased NI activity that inhibited the hydrolysis of sucrose, which indicated that salt stress inhibited the hydrolysis of sucrose mainly by regulating NI activity resulted from downregulation of the gene *Glyur000064s00005640*. However, G2 downregulated the gene *Glyur000064s00005640*-encoding INV by qRT-PCR analysis, but G2 increased NI and AI activities in *G. uralensis* under salt stress that promoted the hydrolysis of sucrose, which indicated

that gene *Glyur000064s00005640* is not the key gene that controlled NI and AI activities. Moreover, G2 upregulated the gene *Glyur000005s00001105*-encoding α -glucosidase by transcriptomic and qRT-PCR analyses, which suggested that G2 promoted the hydrolysis of sucrose under salt stress. Owing to sucrose accumulation under the S + G2 condition, the cell osmotic potential decreased. In order to avoid further water loss of leaves, G2 promoted sucrose hydrolysis and increased the accumulation of reducing sugar in *G. uralensis* under salt stress not only by upregulating invertase but also by upregulating α -glucosidase, thus could help *G. uralensis* produce more energy to cope with salt stress by facilitating sucrose hydrolysis. Correlation analysis results showed that sucrose content was positively correlated with NI activity, which indicated that the overmuch sucrose required higher NI activity for decomposition, which thus improved the activity of NI.

As for fructose, salt stress resulted in a significant decrease in fructose content, while G2 resulted in a significant increase in fructose content in *G. uralensis*. In fructose synthesis, invertases and α -glucosidase mentioned above can catalyze the cleavage of sucrose to glucose and fructose; therefore, these enzymes not only participate in sucrose hydrolysis but also contribute to the production of fructose. In the present study, salt stress downregulated the gene *Glyur000064s00005640*-encoding INV by transcriptomic and qRT-PCR analyses, and salt stress also decreased NI activity that inhibited the production of fructose, which indicated that salt stress inhibited the production of fructose mainly by regulating NI activity caused by downregulation of the gene *Glyur000064s00005640*. G2 downregulated the gene *Glyur000064s00005640*-encoding INV by qRT-PCR analysis, but G2 increased NI and AI activities in *G. uralensis* under salt stress that promoted the production of fructose, which indicated that gene *Glyur000064s00005640* is not the key gene that regulated NI and AI activities under the S + G2 condition, and the potential reason needs further studies. Moreover, G2 upregulated the gene *Glyur000005s00001105*-encoding α -glucosidase by transcriptomic and qRT-PCR analyses, which further verified G2 promoted the production of fructose under salt stress not only by upregulating invertase but also by upregulating α -glucosidase. In fructose decomposition, HK, as a key enzyme in EMP, can phosphorylate glucose and fructose and induce leaf senescence (Sun et al., 2021). In the present study, salt stress upregulated gene *Glyur000324s00015431*-encoding HK by transcriptomic and qRT-PCR analyses, but salt stress decreased HK activity that inhibited the phosphorylation of fructose. However, G2 downregulated gene *Glyur000324s00015431*-encoding HK by qRT-PCR analysis, but G2 increased HK activity in *G. uralensis* under salt stress that promoted the phosphorylation of fructose and thus provided sufficient substrates for EMP. These results suggested that the gene *Glyur000324s00015431* might not be the pivotal gene that controlled HK activity, and the reason needs further studies. The activity of NI is highly correlated with fructose content so that changes in NI activity may largely explain the reduced fructose content in *G. uralensis* under the S condition and the increased fructose content in *G. uralensis* under the S + G2 condition, and then the overmuch fructose

content required higher HK activity to decompose, which thus improved the HK activity.

In the starch and sucrose metabolism pathway, in addition to the genes mentioned above, the genes-encoding β -glucosidase and TPS in *G. uralensis* were affected by salt or G2. β -Glucosidase can catalyze the hydrolysis of the β -glycosidic linkage from the nonreducing end of isoflavone glucosides, disaccharides, oligosaccharides, aryl-glucosides, and alkyl-glucosides (Maitan-Alfenas et al., 2014). However, as a major component of the primary cell wall of many plant tissues, β -glucosidase may be involved in the production of signaling molecules through its specific hydrolytic activity, thus improving the plant's salt tolerance (Mostek et al., 2016). In our study, salt stress downregulated the gene *Glyur000214s00016036*-encoding β -glucosidase by transcriptomic and qRT-PCR analyses, but upregulated the gene *Glyur000585s00027748*-encoding β -glucosidase by transcriptomic and qRT-PCR analyses and the gene *Glyur000779s00022830*-encoding β -glucosidase by transcriptomic analysis in *G. uralensis*, which implied that β -glucosidase could involve in the starch and sucrose metabolism pathway through affecting hydrolytic activity. G2 downregulated the gene *Glyur000214s00016036*-encoding β -glucosidase by qRT-PCR analysis but had no significant effect on genes-encoding β -glucosidase by transcriptomic analysis in *G. uralensis* under salt stress; thus, the effect of β -glucosidase by G2 on *G. uralensis* remains to be further studied. TPS can catalyze UDP-glucose and glucose-6-phosphate to form trehalose 6-phosphate (Tre6P), and then trehalose 6-phosphate phosphatase (TPP) can catalyze trehalose from Tre6P (Wang P. et al., 2020). Overexpression of the TPS gene in plants can enhance the ability of plant cells to scavenge ROS, promote the low accumulation of O₂ and H₂O₂, thereby reducing cell death and enhancing salt tolerance and permeability of plants (Wang P. et al., 2020). In the present study, salt stress downregulated the genes (*Glyur000018s00003759* and *Glyur000231s00022077*)-encoding TPS, while G2 upregulated the gene *Glyur000018s00003759*-encoding TPS under salt stress in *G. uralensis* that may alleviate the oxidative stress caused by salt stress, thus improving the salt tolerance of *G. uralensis*.

Normal carbohydrate metabolism persists when plants grow unstressed conditions; in such a case, energy is stored in the form of starch, and the accumulation of TSS usually remains very limited. TSS concentrations are required for osmoprotection and carbon storage in plants subjected to salt stress (Neera and Amrit, 2018).

Effect of G2 on the EMP-Tricarboxylic Acid Cycle in *Glycyrrhiza uralensis* Under Salt Stress

The EMP pathway-TCA cycle plays an important role in the aerobic respiration of plants, providing ATP, reductants, and metabolites needed for plant growth and development (Jiang, 2011). Sucrose and starch are sources of the EMP substrate fructose (Li et al., 2020), and they store chemical energy that can be released in the form of ATP through the EMP pathway-TCA cycle (Bandehagh and Taylor, 2020), and our study found that G2 increased the sucrose, starch, and fructose contents, which

result in the EMP pathway being promoted from the substrate and energy level. In plants, HK, PFK, and PK are crucial for regulating the EMP pathway. HK is supposed to act as a sugar sensor and/or interact with other enzymes directly in supplying metabolic pathways (Kim et al., 2013). PFK is the rate-limiting enzyme in the EMP pathway because of its low catalytic efficiency and irreversible catalytic reaction (Wen et al., 2020). PK, a transferase involved in the final step of EMP, catalyzes PEP and adenosine diphosphate (ADP), resulting in one molecule of PA and one molecule of ATP. In our study, salt stress upregulated the gene *Glyur000324s00015431*-encoding HK by transcriptomic and qRT-PCR analyses, but decreased HK activity that inhibited the EMP process at the substrate level. However, G2 downregulated gene *Glyur000324s00015431*-encoding HK by qRT-PCR analysis, but increased HK activity in *G. uralensis* under salt stress. These results implied that the gene *Glyur000324s00015431* might not be the pivotal gene that regulates HK activity. The increase of HK activity by G2 could not only promote the EMP process at the substrate level but also help to alleviate the oxidative stress caused by the decrease of HK activity in *G. uralensis* under salt stress (Poór et al., 2019). Salt stress upregulated the gene *Glyur000219s00011582*-encoding PFK in transcriptomic and qRT-PCR results and also increased PFK and PK activity in *G. uralensis*, resulting in increased respiration in response to elevated energy requirements of *G. uralensis* from exposure to salt (Jacoby et al., 2011), which suggested that salt stress produced more energy by regulating PK and PFK resulted from upregulation of the gene *Glyur000219s00011582*. The increased PFK and PK activities may contribute to the acceleration of glucose catabolism, further produce more energy to remedy the inadequacy of energy caused by insufficient carbon sources, and, finally, maintain the *G. uralensis*'s normal life activities under salt stress, which is supported by the previous studies in tomato (Poór et al., 2019) and mangrove tree (Suzuki et al., 2005). However, G2 downregulated the gene *Glyur000219s00011582*-encoding PFK by qRT-PCR analysis and also decreased PFK and PK activities in *G. uralensis* under salt stress, which suggested that the EMP process was slowed down by regulating PK and PFK resulted from downregulation of the gene *Glyur000219s00011582*. In which case, the decrease of PFK and PK activities may be due to *G. uralensis*-elevated energy requirements from exposure to salt had been alleviated by G2. Additionally, an induced CA content can enhance the inhibitory effect of ATP and thus inhibit PFK activity (Sadka et al., 2019), which may help to explain why the process of EMP was slowed down.

In addition to the genes-encoding HK and PFK mentioned above, PDC, ADH, and ALDH-related genes in the EMP pathway were affected by salt or G2 in *G. uralensis*. There are three enzymes in the anaerobic metabolic pathway, PDC, ADH, and lactate dehydrogenase (LDH), in which PDC converted PA to acetaldehyde that was transformed to ethanol by ADH. Acetaldehyde and ethanol are harmful to plant cells (Pan et al., 2019). ALDH further oxidizes acetaldehyde into carboxylic acids that can help cope with salt stress (Tagnon and Simeon, 2017). In our study, all of the DEGs-encoding PDC, ADH, and ALDH were upregulated in S vs. CK comparison, indicating that salt stress could firstly cause to produce more acetaldehyde

and ethanol in *G. uralensis* by upregulating genes-encoding PDC and ADH and thus injure plant cells; in such a case, ALDH was upregulated timely for oxidizing excessive acetaldehyde into carboxylic acids that help *G. uralensis* cope with salt stress. However, only the gene-encoding PDC was downregulated in S + G2 vs. S comparison in *G. uralensis*, suggesting that G2 could protect plant cells from the impairment caused by toxic acetaldehyde and ethanol in *G. uralensis* under salt stress.

Pyruvate as the final product of the EMP pathway not only plays an important role in improving the salt tolerance of plants (Wu et al., 2013) but also links the EMP pathway with the TCA cycle. In our study, salt stress caused the PA production enzyme (PK) activity to increase and the PA decomposition enzyme (PDH) activity to decrease, but salt stress had no significant effect on PA content. This phenomenon may be due to the anaplerotic function of phosphoenolpyruvate carboxylase (PEPC) that replenished the TCA cycle with intermediates by catalyzing PA to produce oxaloacetate (Figures 4, 8), which finally ensured the normal progress of the TCA in *G. uralensis* under salt stress, which is supported by the results in peanut (*Arachis hypogaea* L.) (Pan et al., 2017). However, G2 caused the PA production enzyme (PK) activity to decrease and the PA decomposition enzyme (PDH) activity to increase, but had no significant effect on PA content in *G. uralensis* under salt stress, which may be due to G2 alleviated the inhibition to the TCA cycle from exposure to salt, and the TCA cycle can proceed normally, and the replenishment mechanism of PEPC was weakened, thereby reducing the consumption of PA in *G. uralensis* under salt stress.

The TCA cycle as the most effective way for an organism to obtain energy from the oxidation of sugar and other substances (Yu et al., 2021) can produce the largest amount of energy to plant and provide ATP and reductants for adaptive processes, such as ion exclusion, compatible solute synthesis, and ROS detoxification under salt stress (Che-Othman et al., 2019). Firstly, PDH as a bridge linking the EMP pathway to the TCA cycle can catalyze the oxidative decarboxylation of PA into acetyl CoA, which is the main input of energy in several steps of the TCA cycle (Saha et al., 2012). PDH complex is a complex consisting of three components: pdhB, dihydrolipoyl acetyltransferase (pdhC), and pdhD. In our study, salt stress upregulated the genes *Glyur000278s00017282* and *Glyur000082s00007586*-encoding pdhD and pdhB by transcriptomic and qRT-PCR analyses, but decreased PDH activity in *G. uralensis* that possibly inhibits energy production. However, G2 downregulated the genes *Glyur000278s00017282* and *Glyur000082s00007586*-encoding pdhD and pdhB by qRT-PCR analysis, but increased PDH activity in *G. uralensis* under salt stress that could provide energy for subsequent life activities of *G. uralensis*. These results indicated that the process of oxidative decarboxylation of pyruvate to acetyl-coA is complex, and the key genes regulating PDH need to be further identified. CA is the first organic acid generated in the TCA cycle, and the increase of CA content could help to resist the ionic stress in the plant (Torre-González et al., 2017). In our study, salt stress significantly decreased the CA content, while G2 significantly increased the CA content under salt stress, which potentially indicates an increased capacity for

acetyl-CoA-dependent synthesis of organic acid resulted from the increase of PDH activity in *G. uralensis* by G2. These results are supported by Che-Othman et al. (2019) for wheat. Moreover, CA can inhibit PFK activity by enhancing the inhibitory effect of ATP under S + G2 treatment, thus slowing down the EMP process in *G. uralensis*, which is strongly supported by the results from Sadka et al. (2019). The next three important steps in the TCA cycle are conversion of isocitrate to α -ketoglutarate catalyzed by ICDH, succinate to fumarate catalyzed by SDH with the generation of energy in the form of FADH₂, and malate to oxaloacetate catalyzed by MDH (Saha et al., 2012). Specifically, ICDH regulates nitrogen assimilation by maintaining the 2-oxoglutarate level (Bustamante et al., 2019), thereby linking C and N metabolism, and relates to plant antioxidants (Liu et al., 2010). In our study, G2 increased ICDH activity in *G. uralensis* under salt stress, which could affect C and N metabolism and antioxidant system. The accumulated CA under the S + G2 condition resulted from the increase of PDH activity needs higher ICDH to catalyze, thereby the ICDH activity was increased under the S + G2 condition. SDH plays a key role in mitochondrial metabolism both as a member of the electron transport chain and the TCA cycle (Araújo et al., 2011). Salt stress decreased SDH activity in *G. uralensis*, which could attribute to chloride that has a strong inhibitory effect on SDH activity, which is supported by Nunes-Nesi et al. (2013). However, G2 decreased SDH activity in *G. uralensis* under salt stress, which may attribute to the mitigation of chlorine toxicity. The TCA cycle is completed by MDH, which, as a salt-sensitive enzyme, is thought to play a protective role by counteracting the damaging effect of salt by increasing the malate through conformational change (Saha et al., 2012). Salt stress enhanced MDH activity in *G. uralensis*, and the more active MDH could offset the damaging effect of salinity by conformational changes, thus protecting *G. uralensis* from salt stress.

It was concluded that the G2 slowed-down EMP pathway may be attributed to the following reasons. Firstly, G2 alleviated the elevated energy requirements from exposure to salt, thereby decreased PFK and PK activities in *G. uralensis* under salt stress. Secondly, increased CA content inhibited PFK activity by enhancing the inhibitory effect of ATP under the S + G2 condition. Moreover, G2 increased HK activity, which may inhibit the production of ROS and increased ICDH activity, which may affect the production of plant antioxidants, thus possibly improving salt tolerance of *G. uralensis* by affecting the antioxidant system. PDH, as a key enzyme for major energy regulation in the TCA cycle, was promoted by G2 under salt stress in *G. uralensis*, which activated the TCA cycle, resulting in the production of large amounts of intermediates and energy to support *G. uralensis* growth under salt stress.

CONCLUSION

G2 improved Chl content in *G. uralensis* under salt stress, which may lead to highly efficient photosynthesis in terms of light reaction. Second, it increased carbohydrate contents in *G. uralensis* due to balanced regulation of related enzymes, thus

increased *G. uralensis* growth and yield under salt stress, and the increase of TSS content induced by G2 plays a protective role in osmoregulation in *G. uralensis* seedlings under salt stress. Third, it alleviated the elevated energy requirements from exposure to salt, thereby slowing down the EMP process in *G. uralensis* under salt stress. Fourth, it provided energy for the subsequent life activities of *G. uralensis* under salt stress through regulating the TCA cycle. Therefore, G2 can effectively regulate and accumulate carbohydrate, improve salt tolerance, and thereby promote the growth of *G. uralensis* seedlings under salt stress.

DATA AVAILABILITY STATEMENT

The data presented in the study are deposited in the GEO repository, accession number GSE187003 (<https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE187003>).

AUTHOR CONTRIBUTIONS

XX performed the experiment and wrote the manuscript. QW made the tables. XM modified the language. DL modified the details and made the figures. XZ provided the ideas and revised the manuscript. ZG revised the manuscript. All authors contributed to the article and approved the submitted version.

Methyl jasmonate (MeJA) and salicylic acid (SA) regulate the production of biologically active compounds in plants and stimulate the accumulation of plant aromatic substances. However, the underlying mechanisms of how MeJA and SA influence characteristic flavor compounds and the antioxidant activity of vegetables are poorly understood. Five MeJA and SA concentrations were used to investigate the dose-dependent effects of these phytohormones on the dry and fresh weight; chlorophyll abundance; the contents of vitamin C, soluble protein, and sugar, nitrate, total phenols, flavonoids, volatile components, and enzymatically produced pyruvic acid; and antioxidant activity in Chinese chive. We found that MeJA and SA at concentrations of 500 and 150 μ M, respectively, significantly increased the levels of total chlorophyll, phenols and flavonoids, vitamin C, and volatile components and significantly reduced the accumulation of nitrate. In addition, compared with the control, 500 μ M of MeJA significantly increased the soluble sugar and protein content, and 150 μ M SA significantly increased the dry and fresh weight of Chinese chive. Furthermore, these concentrations of MeJA and SA significantly increased the enzymatic pyruvate content and the amount of sulfide and aromatic volatile compounds and improved the characteristic flavor compounds. The 2,2-diphenyl-1-picrylhydrazyl radical scavenging capacity, Trolox-equivalent antioxidant capacity, and ferric-reducing antioxidant capacity were significantly improved after a preharvest treatment with 500 μ M MeJA and 150 μ M SA, which could improve the antioxidant activity, thus improving the postharvest quality and preservation characteristics of Chinese chives. Taken together, a preharvest treatment with 500 μ M MeJA and 150 μ M SA is optimal to improve the growth, quality, antioxidant activity, and flavor of Chinese chive, thereby enhancing its commercial value.

Keywords: methyl jasmonate, salicylic acid, antioxidant activity, quality, volatile compositions

INTRODUCTION

Fruits and vegetables contain a large amount of nutrients required by the human body, and their minerals, vitamins, and antioxidants are important for maintaining human health. As such, plants play a key role in maintaining a balanced diet and in well-being (Gbska et al., 2020). Phenols, carotenoids, alkaloids, and organosulfur compounds are the main phytochemical categories (Liu, 2004). Organosulfur compounds are the main flavor precursors of *Allium* plants, and they endow *Allium* vegetables with great nutritional and medicinal value (Jones, 2004; Yabuki et al., 2010). Flavonoids have antifungal activity in plants and are therefore involved in pathogen defense (Napal et al., 2009). Phenolics and flavonoids play an important role as antioxidants in raw food materials (Nayak et al., 2013; Ahmed and Eun, 2017). The nutritional value of vegetables is also greatly improved (Soppelsa et al., 2018).

Chinese chive (*Allium tuberosum* Rottler ex Spreng.) is a popular vegetable in China. As a commercial crop, Chinese chives are cultivated all over China (Mau et al., 2001). Similar to that of garlic (*Allium sativum* L.), Chinese chive has a distinctive odor due to volatile compounds and is rich in nutrients, such as vitamins, proteins, carbohydrates, and cellulose (Rose et al., 2005; Gao et al., 2018). Studies have shown that it is also rich in saponins, alkaloids, phenylpropanoid glucoside, polysaccharides, phenols, flavonoids, and sulfur compounds (Zhang et al., 2016; Tang et al., 2017). This is because Chinese chive can produce sulfur-containing metabolites-S-alk(alkene) cysteine sulfoxides (CSOs), which have an extremely high nutritional and medicinal value (Rabinowitch and Currah, 2002). CSOs are the main flavor precursors of *Allium* vegetables (Liu et al., 2021). The flavor of *Allium* plants is produced by the hydrolysis of CSOs by alliinase when the cells are ruptured, and the amount of pyruvate produced in the hydrolysis reaction is equivalent to that of CSOs, which can be used to evaluate the flavor of Chinese chive (Wall and Corgan, 1992). Chinese chive is a vegetable that has been used for both food and in medicine (Leelarungrayub et al., 2006; Bernaert et al., 2012). It has anti-inflammatory, anticancer, antibacterial, and antioxidant activities, which are mainly related to its sulfur-containing compounds (Rattanachakunsopon and Phumkhachorn, 2009; Hong et al., 2014; Zeng et al., 2017). Additionally, Chinese chives are considered as a health food that can improve the kidney function (Masuda and Mihara, 1988; Block et al., 1992), and they are used for sexual enhancement, nocturnal emission, abdominal pain, and diarrhea in traditional Chinese medicine (Jiangsu, 1979). Therefore, increasing the nutritional quality, antioxidant activity, and organosulfur compounds could be a good strategy to enhance the potential health benefits of *Allium* vegetables, including Chinese chives.

Jasmonic acid (JA) and methyl jasmonate (MeJA) and their derivatives are ubiquitous lipid-based plant hormones (Sheard et al., 2010). MeJA is a natural plant growth regulator, which has a wide range of physiological effects on plant growth, development, and abiotic tolerance, such

as postharvest preservation, quality improvement, secondary metabolite synthesis, and stress response (Meir et al., 1996; Delker et al., 2006; Donati et al., 2018). Based on these reports, MeJA treatment can regulate the antioxidant system, including phenolic substances and antioxidant-related enzymes, to regulate postharvest fruit quality and stress responses (Marjorie et al., 2016; Serna-Escolano et al., 2019; Min et al., 2021). Studies have also shown that MeJA can affect the biosynthesis of fruit components, such as carotene, chlorophyll, and vitamins (Saniewski and Czapski, 1983; Pérez et al., 1993; Wolucka et al., 2005). In addition, Shi et al. (2021) showed that MeJA induced the accumulation of tea (*Camellia sinensis* L.) aroma precursors and improved the quality of fresh leaves. Moreover, it has been observed that the application of MeJA significantly enhanced the flavor quality of fruits and vegetables, such as peaches (*Prunus persica* L. Batsch), strawberries (*Fragaria × ananassa* Duch.), sweet basil (*Ocimum basilicum*), and tomatoes (*Solanum lycopersicum* L. cv. Messina) (Ziosi et al., 2008; Fernando et al., 2010; Zhang et al., 2012; Misra et al., 2014). Salicylic acid (SA) can maintain plant growth and development and respond to abiotic stress (Miura and Tada, 2014). Studies have reported that the application of MeJA and SA increased the amounts of bioactive substances in oil palm seedlings (*Elaeis guineensis* Jacq.) and mangosteen (*Garcinia mangostana* L.) during cold storage, thereby enhancing their antioxidant activity (Arthy et al., 2018; Mustafa et al., 2018a). The exogenous application of SA increased the stomatal conductance of barley (*Hordeum vulgare* L.) leaves under drought stress, thereby increasing dry matter content (Habibi, 2012). Huang et al. (2010) showed that SA treatment induces the accumulation of flavonoids and carotenoids, thereby enhancing the antioxidant activity of preharvest navel oranges (*Citrus sinensis* Osb.). Li et al. (2019) found that SA treatment increased the flavonoid content in tea. Martínez-Esplá et al. (2018) showed that preharvest SA treatment increases the antioxidant compounds of plums (*Prunus salicina* Lindl.).

Previous studies on MeJA and SA have mostly focused on stress tolerance, postharvest quality, and the preservation of fruits (Kim et al., 2009; Ibrahim et al., 2018; Se et al., 2020). Despite being a Chinese characteristic flavor vegetable, few studies have been conducted on the flavor quality and antioxidant activity of Chinese chive compared with those on that of tomatoes, onions, and garlic. As such, there are no data on the effects of exogenous hormones on the volatile components of Chinese chives, and there are few reports on the effects of the exogenous application of MeJA and SA on the growth physiology, quality, and antioxidant activity of Chinese chives. We hypothesized that the preharvest application of MeJA and SA promotes the growth of Chinese chive, improves the quality, volatile content, and antioxidant activity, thus improving the characteristic flavor, postharvest quality, preservation characteristics, and its commercial value. The objective of this study was to determine the effects of preharvest MeJA and SA treatments on the growth physiology, quality, volatile content, and antioxidant activity of Chinese chive and to identify suitable spraying concentrations of these compounds for this crop for better Chinese chive cultivation.

MATERIALS AND METHODS

Plant Materials and Experimental Sites

The seeds of the Chinese chive cultivar “Chive God F1,” cultivated by the Fugou County Seed and the Seedling Research Institute of Henan Province, were used as the experimental material for this study. Seedlings were cultivated in Wushan (N 34°25′–34°57′, E 104°34′–105°08′), China, in the core demonstration area for Chinese chives, in May 2020. Wushan has a temperate continental semi-humid monsoon climate, with an annual average temperature of 10°C and a precipitation of 500 mm. The soil type at the test site was sandy loam, and the soil fertility was medium and uniform.

Methods and Treatments

The experiment was set up in a completely randomized design with 11 treatments and three replicates. The plot size for each planting area was 2.7 m × 3.3 m (plant, 460 holes). On May 21, 2021, Chinese chive seedlings were transplanted into a plastic greenhouse (10 m × 30 m) with a row spacing of 20 cm, a hole spacing of 10 cm, and three seedlings per hole. Each plot was treated with exogenous hormones: an aqueous solution of MeJA (containing 0.1% ethanol and 0.1% Tween-20) at five concentrations: 50, 150, 300, 500, or 800 μM; an aqueous solution of SA (containing 0.1% ethanol and 0.1% Tween-20) at five concentrations: 50, 150, 300, 500, or 800 μM; and a control solution (0 μM; containing 0.1% ethanol and 0.1% Tween-20). Three liters of the aqueous solution of each treatment was sprayed on the leaves of the Chinese chive between 7:00 and 8:00 every morning. All treatments were applied for 3 days in a row (June 16, 2021 to June 18, 2021). After 35 days (June 25, 2021), the Chinese chive had attained the commercial standard, and plants from all plots were collected. Fifteen holes (three plants per hole) were randomly selected from each plot, with five holes for each of the three biological replicates. All samples were immediately frozen in liquid nitrogen and stored at –80°C prior to analysis.

Growth and Photosynthetic Pigments Analysis

During harvest, 15 holes of Chinese chives (roots and shoots) were randomly selected from each plot within each treatment to record the fresh weight, and the dry weight was recorded after drying the plants at 105°C for 30 min, followed by 75°C for 72 h to a constant weight per a previously published method (Noreen et al., 2020).

The Chinese chive samples were taken using the same sampling method described above to determine the chlorophyll content. The photosynthetic pigments in the leaves were determined according to the method described by Arnon (1949) using the 80% acetone extraction technique. Briefly, a sample was obtained using a r puncher (0.5 cm diameter), 0.1 g of leaves was placed in a 25 ml test tube with a stopper, and 10 ml of 80% acetone was added, mixed well, sealed with a parafilm, and then chlorophyll was extracted in the dark for 48 h until the leaves turned white. The optical density of each extract was measured at 663 and 645 nm using a UV-1780 spectrophotometer

[Shimadzu Instruments (Suzhou) Co., Ltd., Suzhou, China]. The Chl.a, Chl.b, and total Chls (Chl.T) were calculated with the following formulas:

$$\text{Chl.a (mg g}^{-1} \text{ FW)} = [12.71 \times \text{D663} - 2.59 \times \text{D645}] \times (\text{V}/1000\text{W})$$

$$\text{Chl.b (mg g}^{-1} \text{ FW)} = [22.88 \times \text{D645} - 4.67 \times \text{D643}] \times (\text{V}/1000\text{W})$$

$$\text{Chl.T (mg g}^{-1} \text{ FW)} = [20.29 \times \text{D645} + 8.04 \times \text{D663}] \times (\text{V}/1000\text{W})$$

Where V and W represent the total volume of extract (ml) and fresh weight of the sample (g), respectively.

Nutritional Parameters Analysis

The vitamin C content was determined using the 2,6-dichloroindophenol stain method (Arya et al., 2000). The soluble protein content was determined using the Coomassie Brilliant Blue method (Bradford, 1976). The soluble sugar content was determined using the anthrone–sulfuric acid assay method (Wen et al., 2005). The nitrate content was determined according to Cataldo et al. (1975) with slight modifications.

Total Phenol and Flavonoid Analysis

The total phenol content was determined using the Folin-Ciocalteu method with a slight modification (Hand et al., 2017). Briefly, a crude extract of phenols (0.2 ml) was obtained by extraction with 50% methanol (0.2 ml), which was mixed with distilled water (4.8 ml), followed by Folin-Ciocalteu's phenol reagent (0.5 ml) and 20% sodium carbonate solution (2.5 ml). After incubating in water bath at 50°C for 30 min in the dark, the absorbance of the extract was measured at 760 nm using a UV-1780 spectrophotometer (Shimadzu Instruments, Suzhou, China). The results were compared with the calibration curve of gallic acid and expressed in milligrams of gallic acid equivalent (GAE) per gram of sample (mg GAE g^{–1}).

The flavonoid content was determined following the method of sodium nitrite-aluminum nitrate (Chang et al., 2002) with a slight modification. A crude extract of phenol (1 ml) was obtained by extraction with 50% methanol, which was evenly mixed with 50% methanol (1 ml) and 5% ammonium nitrite (0.5 ml). After incubating for 5 min, 10% aluminum nitrate (0.5 ml) was added. After incubation for 6 min, 4% sodium hydroxide (2 ml) was added. After incubating for 10 min, the absorbance of the extract was measured at 510 nm using a UV-1780 spectrophotometer [Shimadzu Instruments (Suzhou) Co., Ltd., Suzhou, China]. The results were compared with the rutin calibration curve and expressed as rutin equivalent (RE) mg (mg RE g^{–1}) per gram of sample.

Electronic Nose Analysis of Volatile Content

A portable electronic nose (PEN3) electronic nose (Airsense Analytics GmbH, Schwerin, Germany) was used to analyze the

volatile components of the samples. The PEN3 E-nose was equipped with a sensor array composed of 10 chemical sensing elements. The signal response of the sensor is expressed as (G/G0), which is defined as the ratio of the electrical conductivity of volatile matter to that of pure air (Cai et al., 2020). There were some differences in the types of sensitive substances, which could be detected by each sensor. **Table 1** lists the substance types and performance descriptions of the 10 sensors. The electronic nose analysis of the volatile components of Chinese chive was performed according to Jia et al. (2020), with a slight modification. Chinese chives were fully ground (1.5 g) in a headspace bottle using 0.75 g anhydrous sodium sulfate and distilled water (2 ml). The bottle was then heated in a magnetic mixer at 70°C for 15 min to equilibrate the internal headspace gas, and then the injection needle was inserted into the headspace bottle for measurement of volatile compounds. The detection conditions were as follows: flush time of 60 s, sensor zero-time of 5 s, presample time of 5 s, injection flow rate of 400 ml min⁻¹, and a measurement time of 120 s. Based on the data obtained at each time point, the average value of the stable maximum response of each sensor of three parallel samples was obtained, and a characteristic radar map was established.

Enzymatically Produced Pyruvic Acid in Chinese Chive

The content of enzymatically produced pyruvic acid in Chinese chive leaves was determined according to the method of Liu et al. (2021) with a slight modification. Briefly, the sample was divided into two portions. One part was extracted by grinding with ultrapure water and quartz sand. Then, 1 ml of the extract was added to 2 ml 8% trichloroacetic acid and 1 ml 0.1% 2,4-dinitrophenylhydrazine and mixed well. The mixture was incubated in a water bath at 37°C for 10 min, and then 5 ml of 1.5 M NaOH was added. The other part of the sample was placed in a boiling water bath for 10 min to inactivate alliinase, followed by the same method as described for the other section to determine the background

pyruvate levels. Absorbance was measured at 520 nm using a spectrophotometer. The enzymatically produced pyruvic acid was the pyruvic acid content in leaves minus the background pyruvic acid content. Pyruvate was determined using a standard sodium pyruvate curve.

Antioxidant Parameters Analysis

The total antioxidant capacity of Chinese chive was determined according to the kit instructions (Suzhou Keming, Suzhou, China), including 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging activity, ferric-reducing antioxidant power (FRAP), and 2,2'-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid (ABTS) radical scavenging activity. Briefly, using a precooled mortar, the leaf tissue was ground (0.1 g) in 1 ml of precooled extract. The homogenate was centrifuged at 4°C at 10,000 × g for 10 min, and the supernatant was collected for testing. According to the instructions of the DPPH radical scavenging activity and FRAP kits, the respective solutions were mixed and allowed to react at room temperature in the dark for 20 min and at room temperature for 20 min. A microplate reader (SpectraMax i3, Molecular Devices, Sunnyvale, CA, United States) was used to measure absorbance at 515 and 593 nm. The same extraction method was used to extract the supernatant from the sample to determine ABTS radical scavenging activity. When the tested substance was added to the ABTS+ solution, antioxidants reacted with ABTS+ and faded the reaction system. The change in absorbance was measured at 734 nm. The antioxidant capacity of the Chinese chive was quantified by the change in absorbance and Trolox was used as the control system.

Statistical Analysis

All experimental data were analyzed using IBM Statistical Product and Service Solutions (SPSS) Statistics version 21.0, and the statistical significance of treatment means was evaluated using Duncan's multiple range test ($p < 0.05$). All data were presented as mean ± SE. Data figures, correlation analysis, and principal component analysis (PCA) were generated using Origin Pro (2019b).

RESULTS

Effect of Methyl Jasmonate and Salicylic Acid Treatments on Dry and Fresh Weight of Chinese Chive

The application of SA treatment had a significant effect on the dry weight and fresh weight of the shoots and roots of Chinese chives (**Figures 1B,D**). The fresh weight of roots, shoots, and plants treated with 150 μM SA increased significantly by 69, 55, and 58%, respectively, and the dry weight increased by 85, 33, and 50%, respectively, compared with that of the control (0 μM). With the increase in the SA concentration, the dry and fresh weight of Chinese chives exhibited a decreasing trend. However, the application of MeJA had no significant effect on the dry and fresh weights of Chinese chives (**Figures 1A,C**).

TABLE 1 | Substance type and performance description represented by 10 sensors of electronic nose.

Array serial number	Sensor name	Substance types	Sensor performance description
1	W1C	Aromatic	Aromatic components, benzenes
2	W5S	Broadrange	High sensitivity, sensitive to nitrogen oxides
3	W3C	Aromatic	Sensitive aromatic components, ammonia
4	W6S	Hydrogen	Mainly selective to hydride
5	W5C	Arom-aliph	Aromatic components of short-chain alkanes
6	W1S	Broad-methane	Sensitive to methyl groups
7	W1W	Sulfur-organic	Sensitive to sulfides
8	W2S	Broad-alcohol	Sensitive to alcohols, aldehydes and ketones
9	W2W	Sulph-chlor	Aromatic components, sensitive to organic sulfides
10	W3S	Methane-aliph	Sensitive to long-chain alkanes

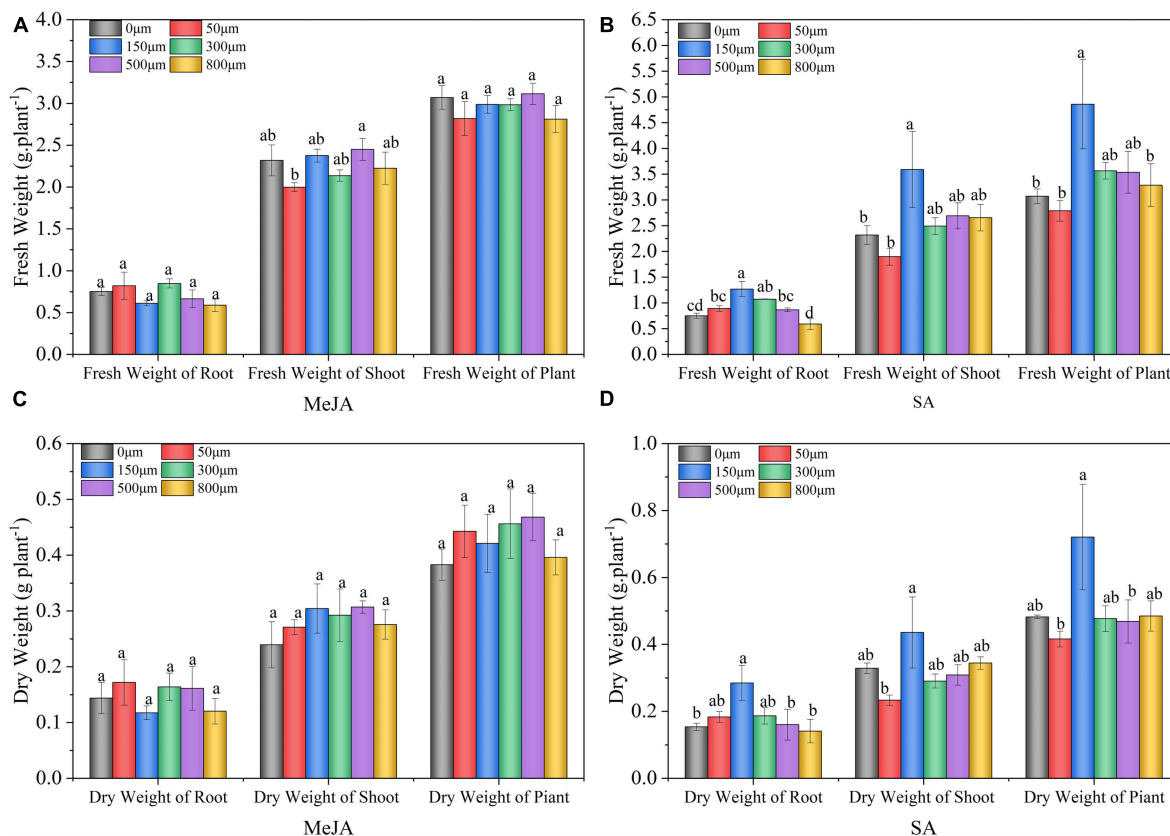

FIGURE 1 | Fresh (A,B) and dry weight (C,D) of Chinese chives affected by methyl jasmonate (MeJA) and salicylic acid (SA) treatments. Data represent the mean \pm SE ($n = 3$). Different lowercase letters indicate statistical significance by Duncan's multiple range test ($p < 0.05$).

Effect of Methyl Jasmonate and Salicylic Acid Treatments on Photosynthetic Pigment Contents of Chinese Chive

Compared with the control (0 μ M) treatment, 500 μ M MeJA significantly increased Chl.a and Chl.T by 5 and 8%, respectively, in Chinese chives (Figure 2A); however, 800 μ M MeJA significantly decreased Chl.a and Chl.T content. Treatment with 150 μ M SA significantly increased Chl.b and Chl.T content by 23 and 8%, respectively, compared with the control (0 μ M) (Figure 2B). When treated with 300–800 μ M SA, the content of Chl.a, Chl.b, and Chl.T in Chinese chives decreased significantly compared with the control (0 μ M).

Effect of Methyl Jasmonate and Salicylic Acid Treatments on Vitamin C, Soluble Sugar, Soluble Protein, and Nitrate Content of Chinese Chive

The contents of vitamin C, soluble sugar, and soluble protein in Chinese chives treated with MeJA were significantly higher than those in the control (0 μ M) (Figures 3A–C). The vitamin C, soluble sugars, and protein contents in Chinese chives treated with 500 μ M MeJA significantly increased by 44, 10, and 72%, respectively, compared with those in the control (0 μ M).

However, 50–500 μ M SA treatment had no significant effect on the soluble sugar content. SA at 800 μ M significantly decreased the vitamin C and soluble sugar content of Chinese chives (Figures 3A,B); however, there was no significant effect on the soluble protein content (Figure 3C). Compared with the control (0 μ M), treatment with SA (150–800 μ M) and MeJA significantly reduced the nitrate content of Chinese chive (Figure 3D).

Effect of Methyl Jasmonate and Salicylic Acid Treatments on Total Phenol and Flavonoid Content of Chinese Chive

The methyl jasmonate and salicylic acid treatments had significant effects on the total phenol and flavonoid contents of Chinese chive (Figure 4). Treatment with different concentrations of SA significantly increased the total phenol content (Figure 4A). After 150 μ M SA treatment, the total phenol content significantly increased by 29% compared with the control (0 μ M). However, treatment with different concentrations of MeJA significantly increased the total phenol content of Chinese chive (18.2%) at a concentration of 500 μ M. Treatment with different concentrations of MeJA and SA significantly increased the flavonoid content of Chinese chive compared with the control (0 μ M) (Figure 4B). The flavonoid

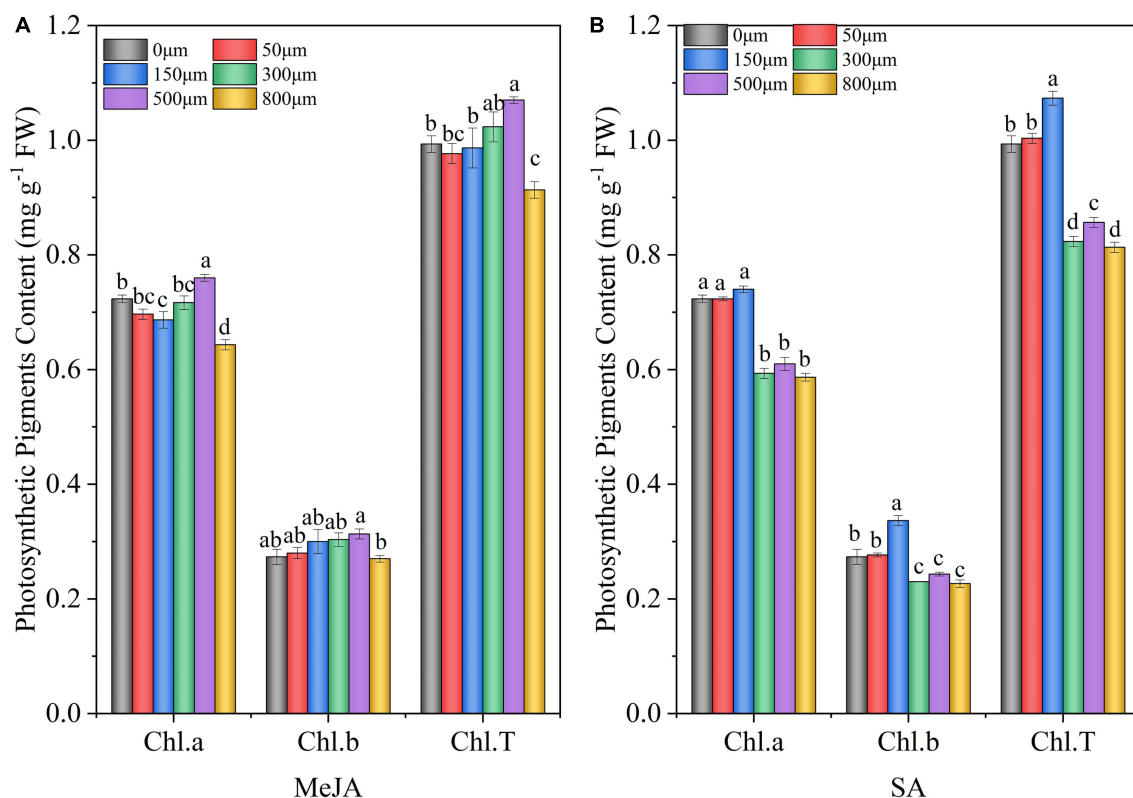

FIGURE 2 | Chlorophyll (Chl) Chl.a, Chl.b, and Chl.T contents of Chinese chives, as affected by MeJA (A) and SA (B) treatments. Data represent the mean \pm SE ($n = 3$). Different lowercase letters indicate statistical significance by Duncan's multiple range test ($p < 0.05$).

content in Chinese chive was significantly increased by 133% and 70 after treatment with 500 μ M MeJA and 150 μ M SA.

Effect of Methyl Jasmonate and Salicylic Acid Treatments on Volatile Composition and Flavor Intensity of Chinese Chive

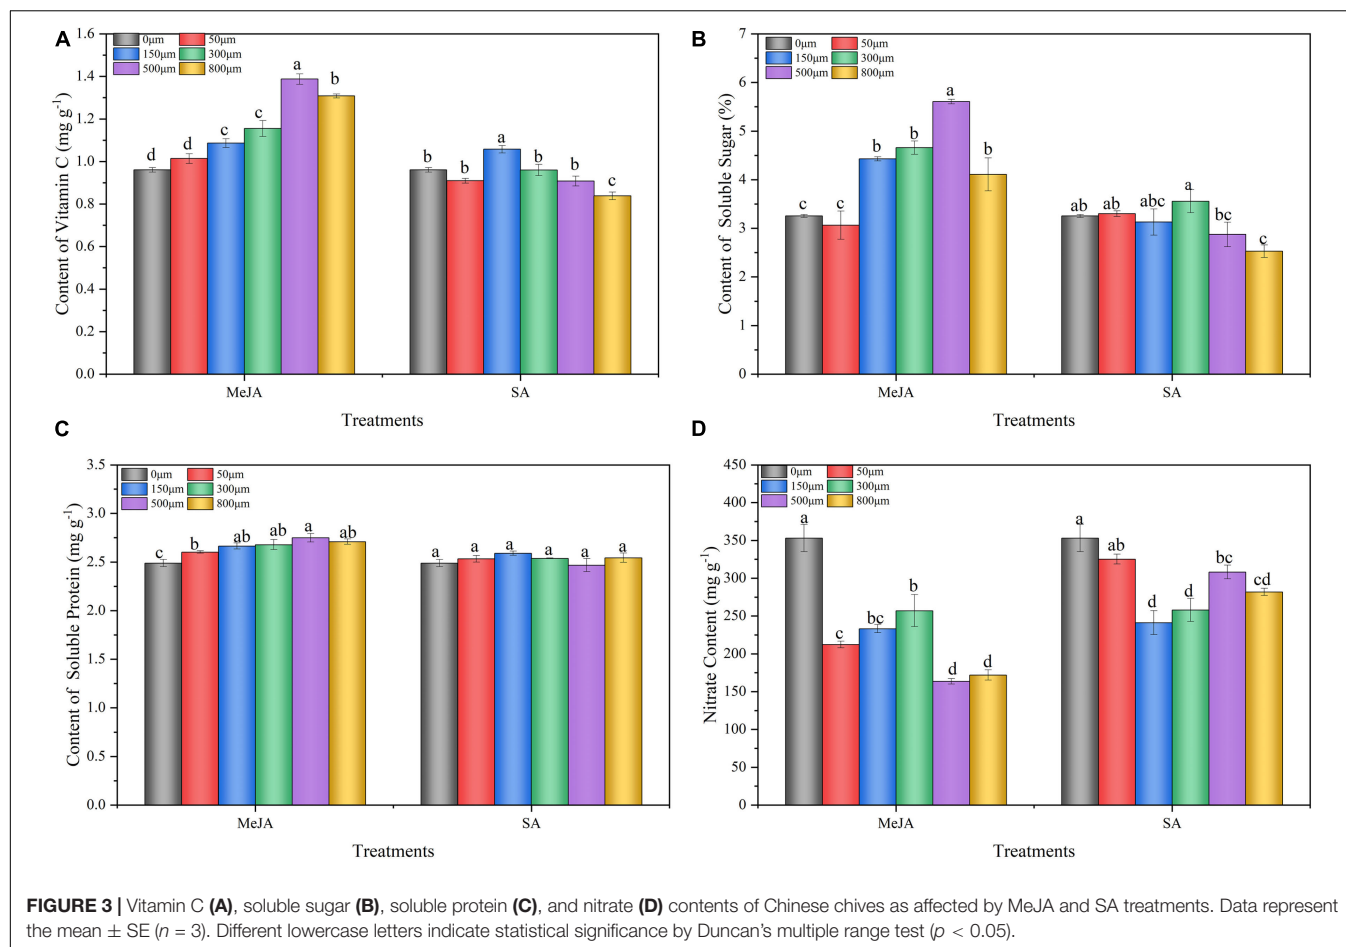

The 10 sensors of the electronic nose all responded to the volatile compounds of Chinese chive treated with different concentrations of MeJA and SA, and the responses of different sensors were differed (Figures 5A,B). The signal responses to the sensors were expressed by G/G_0 , which was defined as the ratio of the electrical conductivity of volatiles to that of pure air. The radar chart shows the response of the different sensors of the electronic nose to volatile substances in Chinese chive. In Figure 5, the relative resistivity (G/G_0) values of the W5S and W2W sensors were higher than those of the other sensors, indicating that the volatile components of Chinese chive, such as nitrogen oxides, aromatics, and organic sulfides, were more sensitive to the sensor. As can be seen from the radar map, the contours of 500 μ M MeJA and 50 μ M SA were the largest. After treatment with different concentrations of MeJA and SA, the outline of the radar map gradually changed, indicating that the composition of volatile compounds in Chinese chives changed. In addition, the heat map showed an increase or decrease in volatile content after MeJA and SA treatments compared with the control (0 μ M) treatment

(Figures 5C,D). With the exception of W1C and W5S, the relative resistivity of the other eight sensors treated with 500 μ M MeJA was increased compared with that of the control (0 μ M) sensors, which indicated that treatment with 500 μ M MeJA increased the amounts of most of the volatile components, such as sulfides, aromatics, and organic sulfides. Moreover, treatment with 50 and 150 μ M SA increased the amounts of characteristic aromatic substances, such as aromatics and sulfides, compared with the control (0 μ M).

The methyl jasmonate and salicylic acid treatments had a significant effect on the total flavor intensity (sulfur compounds) of Chinese chive, characterized by the pyruvate produced by alliinase (Table 2). Treatment with 500 μ M MeJA and 50 and 150 μ M SA significantly increased the enzymatic pyruvate content compared with the control (0 μ M).

Classification Model of Volatile Composition of Chinese Chive Using Principal Component Analysis

The principal component analysis was used to study the volatile components of Chinese chives treated with MeJA and SA (Figure 6). The first and second principal components captured most of the variation within the different MeJA and SA concentrations. The sum of the first two principal components treated by MeJA reached 95.2%, of which PC1 and PC2 explained

56.7 and 38.5% of the total variance, respectively (Figure 6A). The sum of the first two principal components treated by SA reached 96.3%, of which PC1 and PC2 explained 83.5 and 12.8% of the total variance, respectively (Figure 6B). In addition, it can be seen from the loading plot that W1W and W5C had strong loadings with the first and second principal component and W3C and W2W had strong loadings with the first and second principal component and thus were used as representative factors reflecting the volatile components of Chinese chives treated with different concentrations of MeJA and SA, indicating these treatments have considerable effects on the sulfide, organic sulfides, and aromatic volatile components of Chinese chive.

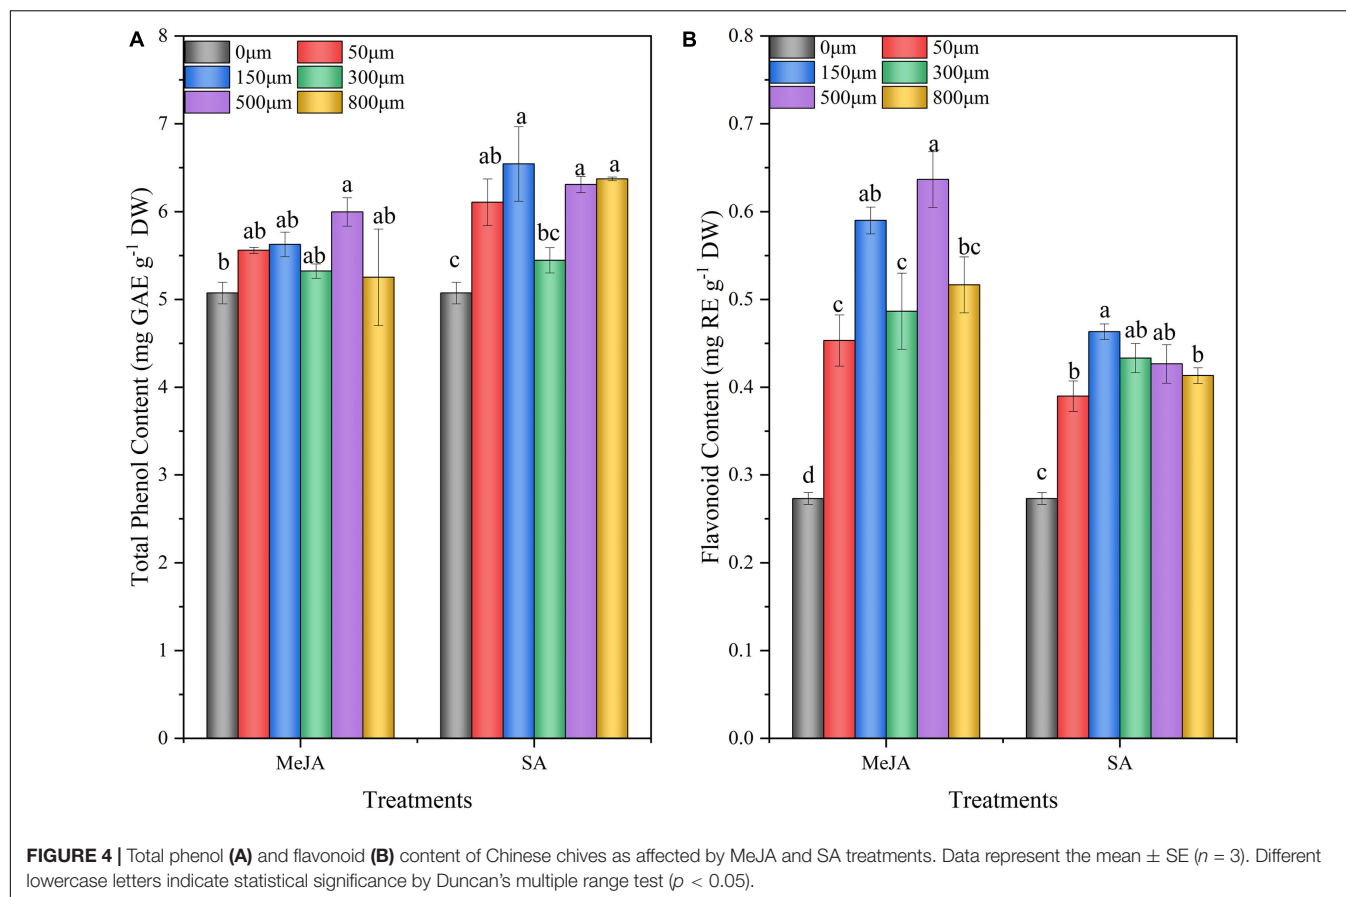

Effect of Methyl Jasmonate and Salicylic Acid Treatments on the Antioxidant Activities of Chinese Chive

The methyl jasmonate and salicylic acid treatments had a significant effect on the antioxidant activity of Chinese chives (Figure 7). All antioxidant activity determination methods, such as DPPH radical scavenging activity (Figure 7A), FRAP (Figure 7B), and ABTS radical scavenging activity (Figure 7C), indicated significantly higher antioxidant activity in MeJA (150–500 μM) and SA (150 μM)-treated Chinese chives than in the

control (0 μM). The highest scavenging capacity was recorded in Chinese chives treated with 500 μM MeJA and 150 μM SA. The scavenging ability of samples treated with 800 μM MeJA and 300–800 μM SA showed a downward trend.

Correlation Analysis and Principal Component Analysis

The correlation analysis of the parameters observed in this study showed that Chl.a had a significantly correlated with the Chl.T at $p < 0.01$ after MeJA and SA treatment, and Chl.b had a significantly correlated with soluble sugar and Chl.T at $p < 0.5$ (Figures 8A,B). DPPH had a significantly correlated with vitamin C and W1W after MeJA treatment ($p < 0.5$), and it had a significantly correlated with soluble sugar ($p < 0.01$); ABTS had a significantly correlated with FRAP and flavonoids ($p < 0.5$); soluble protein had a significantly correlated with flavonoids ($p < 0.01$); total phenols had a significantly correlated with flavonoids ($p < 0.5$) (Figure 8A); however, nitrate had a significantly negatively correlated with flavonoids and soluble proteins ($p < 0.5$). After SA treatment, the DPPH had a significantly correlated with vitamin C at $p < 0.5$; FRAP had a significantly correlated with soluble sugar and protein at $p < 0.5$; soluble protein had a significantly correlated with sugar and flavonoids at $p < 0.5$ (Figure 8B); however, nitrate had a

negatively correlated with flavonoids ($p < 0.5$), and negatively correlated with ABTS ($p < 0.01$).

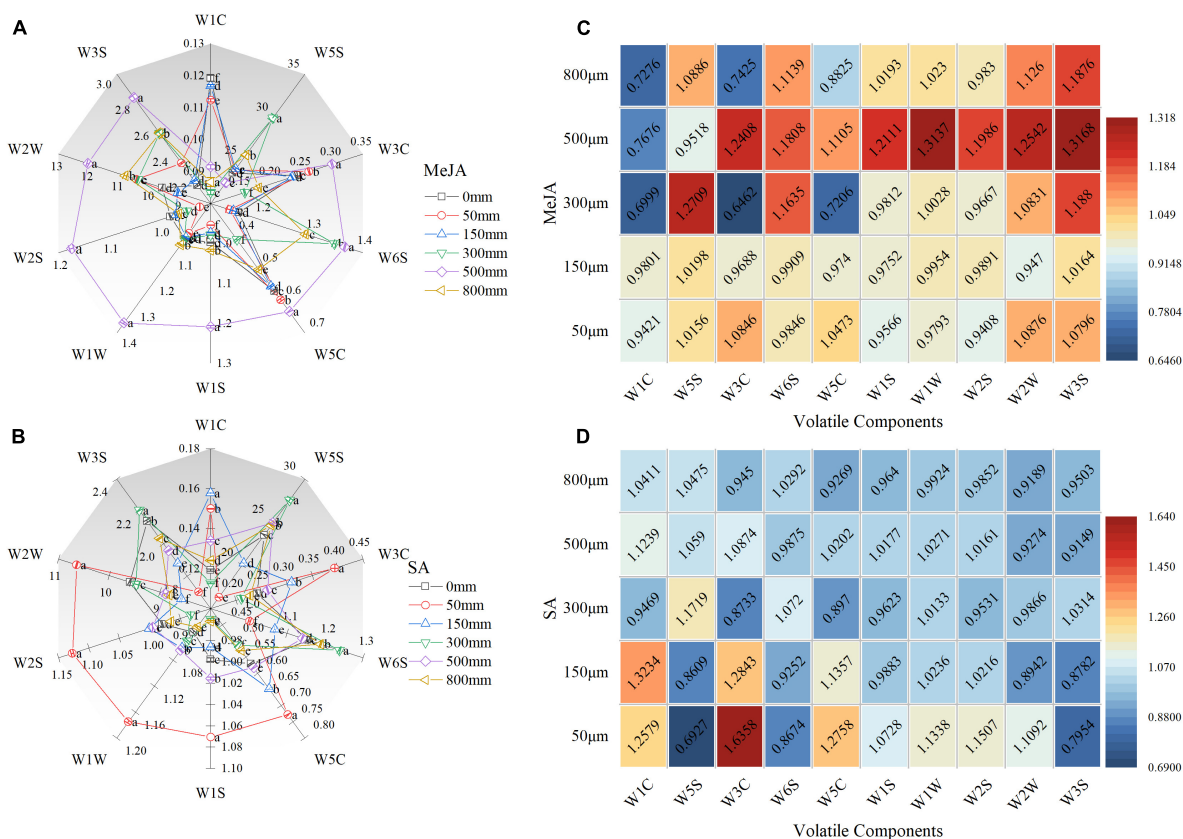

The PCA of the parameters observed in this study is shown in **Figures 8C,D**. The different concentrations of MeJA and SA treatments and various parameters constituted the corresponding groups. The sum of the first two principal components treated with MeJA reached 68.3% (**Figure 8C**). PC1 accounted for 50.5% of the total variance. PC2 accounted for 17.8% of the total variance. The sum of the first two principal components treated by SA was 61.3% (**Figure 8D**). PC1 accounted for 38.6% of the total variance. PC2 accounted for 23% of the total variance. In addition, it can be seen from the loading plot that flavonoids and Chl.a showed strong loadings with the first and second principal component, soluble sugar and Chl.a showed strong loadings with the first and second principal component and thus can be used as representative factors to reflect the effects of different concentrations of MeJA and SA on the growth physiology, quality, volatile content, and antioxidant potential of Chinese chive (**Figures 8C,D**).

DISCUSSION

Exogenous application of MeJA and SA can induce different biochemical, morphological, and physiological responses of plants (Huang et al., 2017). In our study, we found that MeJA

had no significant effect on the fresh and dry weights of Chinese chives (**Figures 1A,C**). Our results contradict the findings of Baek et al. (2021), who reported that MeJA treatment increased biomass in tomatoes. However, Kurowska et al. (2020) showed that the application of MeJA significantly reduced the first leaf sheath and dry leaf weight of barley seedlings. This suggests that different plants, tissue types, and developmental stages respond differently to MeJA. SA promoted plant growth by improving plant photosynthesis and significantly promoted the fresh and dry weight of shoot and root (Gururani et al., 2013). Our results showed that SA (150 μM) treatment significantly increased the fresh and dry weights of root, shoot, and plants (**Figures 1B,D**). Since the treatments were applied during the peak growth period of Chinese chive, the increase in fresh and dry weight could be attributed to the effect of SA on alleviating biotic and abiotic stresses in the plant, thus increasing net photosynthetic rate and productivity (Hasanuzzaman et al., 2017). In addition, we observed that both 800 μM MeJA and SA inhibited the growth of Chinese chive. This may be due to the effects of high concentrations of MeJA and SA on plants similar to abiotic stress, reducing plant photosynthesis and thus inhibits plant growth (Kang et al., 2012; Kurowska et al., 2020).

Among studies on the effects of JA on plant photosynthesis, the most controversial research is the effect on photosynthetic plant pigments (Shu et al., 2016). *Exogenous JA significantly inhibited photosynthesis in broccoli* (*Brassica oleracea* L.)

and tomato, but promoted *photosynthesis and chlorophyll accumulation in rapeseed* (*Brassica napus* L.) (Rahnamaie-Tajadod et al., 2017; Ding et al., 2018). In the present study, we found that the total chlorophyll content after 500 μ M MeJA treatment was significantly higher than that in the control (Figure 2A), which was similar to that reported by Ji et al. (2018) on maize seedlings (*Zea mays* L.). In addition, exogenous application of JAs increased photosynthetic pigments in a dose-dependent manner, thereby increasing photosynthetic efficiency (Sirhindi et al., 2020). The same results were shown in our study, where chlorophyll increased with increasing MeJA concentration (50–500 μ M). Previous studies have shown that SA application increased the chlorophyll content of wheat (*Triticum aestivum* L.) (Singh and Usha, 2003). Our results showed that treatment with 150 μ M SA significantly increased Chl.b and Chl.T content (Figure 2B), which was similar to that reported by Zhang et al. (2021). However, the high concentrations of MeJA (800 μ M) and SA (300–800 μ M) significantly reduced the total chlorophyll content. This may be due to the fact that the high concentrations of MeJA and SA can activate genes related to chlorophyll catabolism, which is related to the degradation of chlorophyll (Zhu et al., 2015). In addition, chlorophyll is the most prominent natural

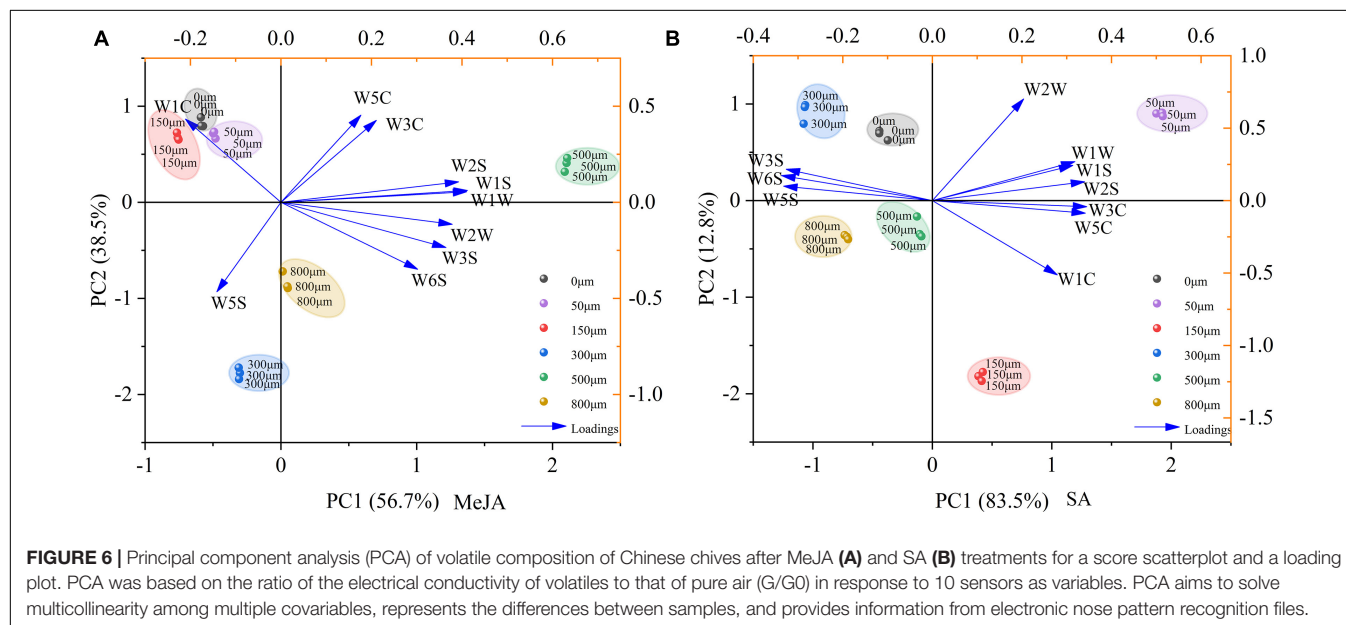

pigment in green vegetables and has significant antioxidant activity (Lanfer-Marquez et al., 2005). The chlorophyll can also reflect the senescence of plants and the maturity, color, quality, and freshness of fruits and vegetables through changes in its structure (Wang et al., 2005).

The nutritional properties of vegetables are not only protective compounds that maintain their quality, but also guarantee nutritional value (Mustafa et al., 2018b). The preharvest treatment of exogenous MeJA and SA simulated biological stress and increased phytochemical compounds in different crops (Ku and Juvik, 2013; Sariñana-Aldaco et al., 2020). Our results showed that the contents of vitamin C, soluble sugar, soluble protein, total phenol, and flavonoid in Chinese chives treated with MeJA (500 μ M) preharvest were significantly higher than those in the control (Figures 3A–C, 4), which was similar to the results of Min et al. (2021). The increase of total phenols and flavonoids in MeJA treatment may be due to the regulation of various physiological and metabolic processes, thus affecting the nutritional quality of crops. However, our results contradict the findings of Yamamoto et al. (2020), who reported that MeJA treatment significantly reduced flavonoids in citrus, indicating that MeJA has different regulation of bioactive substances in different crops, which is

TABLE 2 | Characteristic flavor of Chinese chives as affected by methyl jasmonate (MeJA) and salicylic acid (SA) treatments.

EPY ($\mu\text{g ml}^{-1}$)	0 mm	50 mm	150 mm	300 mm	500 mm	800 mm
MeJA	16.5 \pm 0.3d	29.9 \pm 0.8a	23.3 \pm 0.5b	24.3 \pm 0.7b	32.0 \pm 0.9a	20.5 \pm 0.6c
SA	16.5 \pm 0.3d	66.9 \pm 0.4a	67.6 \pm 0.5a	50.1 \pm 1.7b	23.0 \pm 0.5c	8.2 \pm 0.3e

worthy of further study. SA affects the phenylpropanoid pathway by inducing its key enzymes phenylalanine ammonia lyase and chalcone synthase, resulting in the accumulation of phenolic compounds (Ghasemzadeh et al., 2012). In the present study, we found that SA (150 μM) treatment significantly increased the content of vitamin C, total phenols, and flavonoids in Chinese chive (Figures 3A, 4). Flavonoids are widely found in plants and play important roles in antioxidant, anticancer, antibacterial, and antimutagenic effects, and they are also one of the antioxidants produced by plants for their own survival (Treutter, 2006; Ghasemzadeh et al., 2010; Sharma et al., 2014). The MeJA and SA treatments increased the contents of total phenols and flavonoids in Chinese chives, thus improving the antioxidant activity of Chinese chives. In addition, we observed that both MeJA and SA treatments reduced the nitrate content of Chinese chives (Figure 3D). This may be because the reduction in nitrogen (N) uptake as an immediate consequence after MeJA treatment and the concomitant reactivation of endogenous N from leaves to roots, thereby reducing nitrate accumulation in leaves (Rossato et al., 2002). In general, preharvest MeJA (500 μM) and SA (150 μM) treatments improved the nutritional quality and safety quality of Chinese chives.

The MeJA treatment can trigger biosynthesis of volatile secondary metabolites and non-volatile secondary metabolites (Cheong and Choi, 2003). A sensor equipped with an electronic nose can simulate human olfactory factors and specific fingerprints of volatile tissues (Schaller et al., 1998; Benedetti et al., 2008). We detected volatile components of Chinese chives

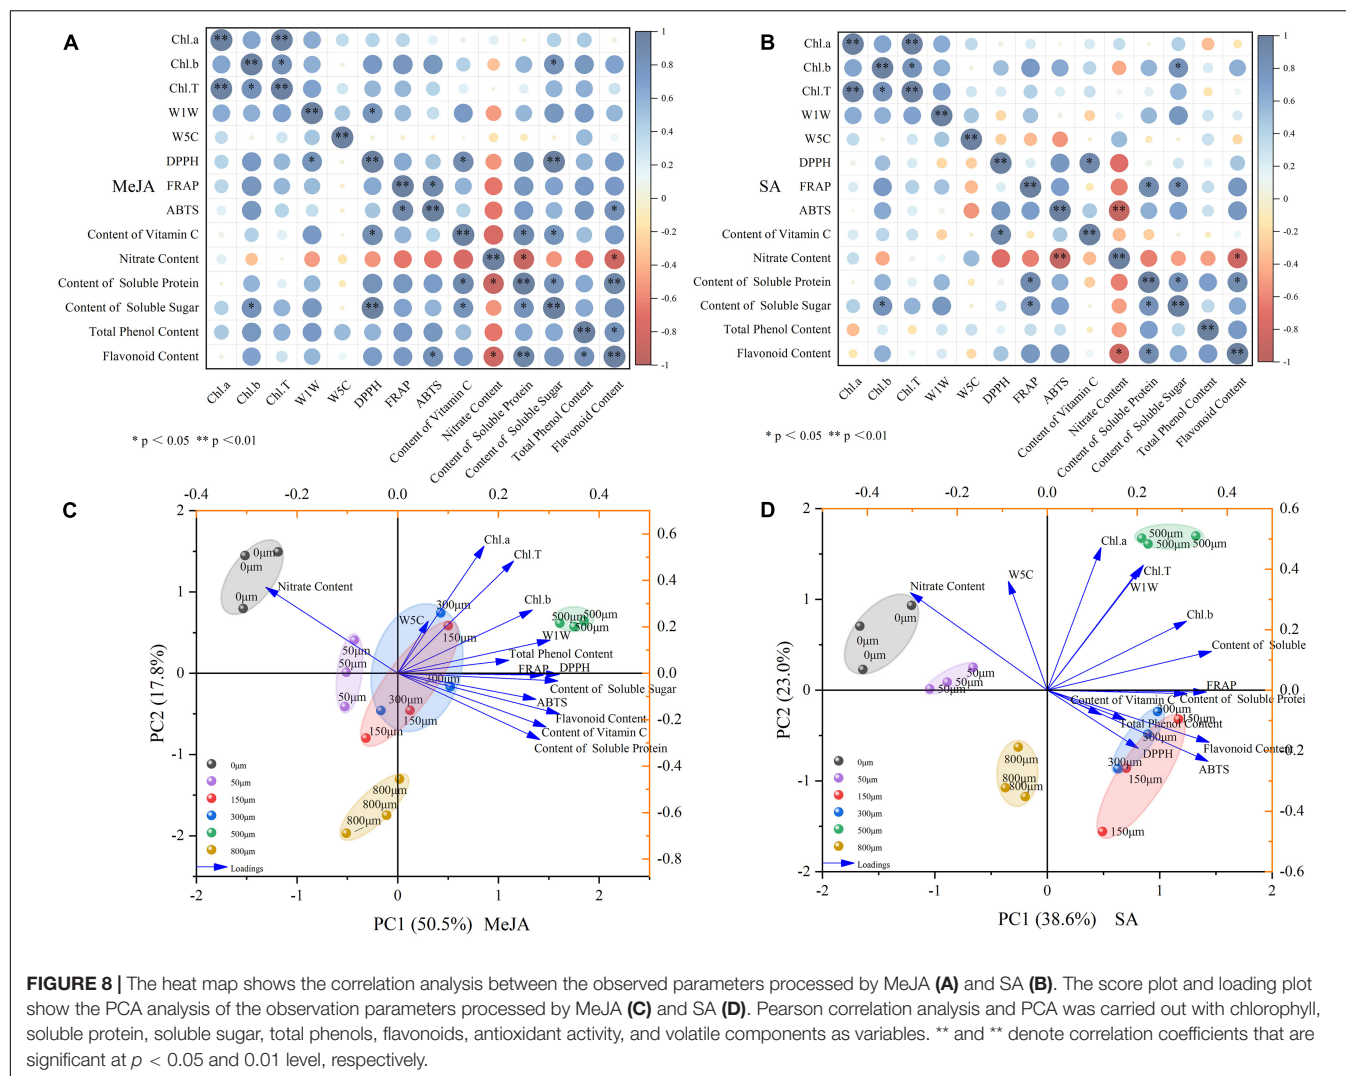

by electronic nose mainly nitrogen oxides (W5S), aromatics, and organic sulfides (W2W) (Figures 5A,B), which are more sensitive to the sensors of electronic nose and are characteristic aromatic substances of Chinese chives (Abbey et al., 2001). The volatile components of Chinese chives were dominated by methionine produced methyl sulfide, followed by Alliin produced allyl sulfide (Yabuki et al., 2010). The treatment with MeJA (500 μM) and SA (50 and 150 μM) increased the volatile composition of sulfur-containing compounds and enhanced the characteristic aromatic substances of Chinese chives. Meanwhile, we found that in addition to W1C and W5S, the relative resistivity of the other eight sensors treated with 500 μM MeJA was increased compared with that of the control sensors (Figure 5C), which indicated that treatment with this concentration of MeJA increased the content of most of the volatile components in Chinese chives, such as ammonia-based aromatic components (W3C), organic sulfides (W2W), hydrides (W6S), methyl groups (W1S), sulfides (W1W), alcohols, aldehydes, and ketones (W2S), short-chain alkane aromatic components (W5C), and long-chain alkanes (W3S). This may be because JA, as a lipid-based plant hormone, forms hydroperoxide through lipoxygenase pathway, and then oxidizes into short-chain aldehydes and ketones, increasing the hydride and aldehydes and ketones volatile components of Chinese chive (Li et al., 2010). Alcohols, aldehydes, and ketones have obvious odors (Tian et al., 2017), which may contribute greatly to the aroma of Chinese chive except aromatic hydrocarbons and sulfides. The aroma intensity of most long-chain alkanes is weak and contributes little to the aroma of food (Peng et al., 2014).

However, compared with the control, 500 μ M MeJA treatment increased the content of long-chain alkanes, which requires further study to determine the contribution of long-chain alkanes to aroma. The loading plots further indicated that different concentrations of MeJA and SA treatment had considerable effects on the volatile components compared with the control, such as sulfide, aromatic components (ammonia), short-chain alkane aromatic components, methyls, alcohols, aldehydes and ketones, organic sulfides (Figure 6). In addition, we found that 500 μ M MeJA and 150 μ M SA significantly increased the enzymatic pyruvate content (Table 2), which was consistent with the results of electronic nose testing that increased the content of organic sulfur compounds, thereby improving the flavor intensity of Chinese chives.

Previous studies have shown an increase in plant antioxidant activity after application of MeJA (Wang et al., 2008; Szymanowska et al., 2015), and this was similarly observed for DPPH, FRAP, and ABTS activity of the Chinese chive with MeJA application in this study (Figure 7). The improvement of antioxidant capacity of plants is related to the increase of phenols and other bioactive substances (Flores et al., 2015). In this study, the increase in the content of bioactive substances such as total phenols and flavonoids may be responsible for the improved scavenging and reducing abilities of Chinese chives

after MeJA (500 μ M) and SA (150 μ M) treatments. However, this contradicts the study that Mustafa et al. (2016) reduced the content of antioxidants by applying MeJA in carambola (*Averrhoa carambola*). This result indicates that the JA signal is involved in the balance of the redox reaction (Dong et al., 2010), which is worthy of further study. The antioxidant activities (DPPH, ABTS, and FRAP) after MeJA treatment had a significant correlation with organic sulfur compounds, vitamin C, flavonoids, and soluble sugars (Figures 8A,B). SA processing showed similar results. This further indicated that the improvement of antioxidant capacity of Chinese chive could be closely related to the increase in the content of bioactive substances. JA, MeJA, and SA are the most widely used elicitors that promote the production of more bioactive compounds in plants, which in turn improve the nutritional quality and antioxidant activity of plants (Baenas et al., 2014). PCA analysis showed that MeJA (500 μ M) and SA (150 μ M) positively regulate Chl.a, Chl.T, Chl.b, sulfides, total phenols, FRAP, DPPH, soluble sugar, ABTS, flavonoids, vitamin C, and soluble protein. In general, MeJA and SA enhance the bioactive substances content and antioxidant activity, thereby improving the medicinal value, postharvest quality, and preservation characteristics, thus increasing the commercial value of Chinese chives.

CONCLUSION

Our results suggest that preharvest treatments with 500 μM MeJA and 150 μM SA significantly increased the content of total chlorophyll, soluble sugar, total phenols and flavonoids, volatile components, and antioxidant activity of Chinese chive. In addition, 500 μM MeJA and 150 μM SA significantly increased the soluble protein content, and the dry and fresh weight, respectively. Simultaneously, 500 μM MeJA and 150 μM SA significantly increased the enzymatic pyruvate content, effectively increased the amounts of sulfide and aromatic volatile components, and improved the characteristic flavor compounds of Chinese chive. In addition, the antioxidant activity was improved after preharvest treatment with 500 μM MeJA and 150 μM SA, which could improve the postharvest quality and preservation characteristics, and therefore enhance the commercial value. In conclusion, preharvest treatment with 500 μM MeJA and 150 μM SA could be the best option for improving the growth

physiology, quality, antioxidant activity, and the flavor of Chinese chive.

Plant phenomics is becoming a common tool employed to characterize the mode of action of biostimulants. A combination of this technique with other omics such as metabolomics can offer a deeper understanding of a biostimulant effect *in planta*. However, the most challenging part then is the data analysis and the interpretation of the omics datasets. In this work, we present an example of how different tools, based on multivariate statistical analysis, can help to simplify the omics data and extract the relevant information. We demonstrate this by studying the effect of protein hydrolysate (PH)-based biostimulants derived from different natural sources in lettuce and tomato plants grown in controlled conditions and under salinity. The biostimulants induced different phenotypic and metabolomic responses in both crops. In general, they improved growth and photosynthesis performance under control and salt stress conditions, with better performance in lettuce. To identify the most significant traits for each treatment, a random forest classifier was used. Using this approach, we found out that, in lettuce, biomass-related parameters were the most relevant traits to evaluate the biostimulant mode of action, with a better response mainly connected to plant hormone regulation. However, in tomatoes, the relevant traits were related to chlorophyll fluorescence parameters in combination with certain antistress metabolites that benefit

the electron transport chain, such as 4-hydroxycoumarin and vitamin K1 (phyloquinone). Altogether, we show that to go further in the understanding of the use of biostimulants as plant growth promoters and/or stress alleviators, it is highly beneficial to integrate more advanced statistical tools to deal with the huge datasets obtained from the -omics to extract the relevant information.

INTRODUCTION

Changes in climate patterns are dramatically influencing some agricultural areas with special impact in arid, semi-arid, and coastal agricultural areas (Corwin, 2020). Soil salinity already covers 20% of total cultivated and 33% of the irrigated agricultural lands worldwide, and is expected to increase at a faster rate than now by the year 2050 (Mukhopadhyay et al., 2021). The high salt concentration in the soil reduces plant growth and, hence, yield in two ways: increasing the osmotic potential of the soil solution, making it harder for the plant to extract water, and accumulating into the root and shoot tissue at a concentration that can be toxic for the plant (Munns and Tester, 2008). The extent of salinity damage to the fitness and final yield of the crop can change according to the species. For example, lettuce (*Lactuca sativa* L.) reduces plant growth and yield under salt stress conditions (Moncada et al., 2020). However, tomatoes (*Solanum lycopersicum* L.) can maintain the fruit yield and increase their quality under moderate stress (Meza et al., 2020), whereas severe salt stress reduced tomato growth and provoked severe damages, especially in young seedlings (Ali et al., 2021).

To reduce the yield loss connected to salinity, scientists are moving toward the selection of more tolerant genotypes through breeding, genetic engineering, and marker-assisted selection (MAS) (Munns and James, 2000; Yamaguchi and Blumwald, 2005). However, these methods are expensive, time-consuming, and, in the case of genetic engineering, received with suspicion by the general public (Yamaguchi and Blumwald, 2005; Halford and Shewry, 2000). A more sustainable alternative is represented by the use of protein hydrolysates (PHs), a class of non-microbial plant biostimulants obtained from the partial hydrolysis of protein sources of plant or animal origin (Colla and Rouphael, 2015). Many works from the last years have enlightened the effects of PHs as stress alleviators on different crops growing in saline conditions (Van Oosten et al., 2017; Dell'Aversana et al., 2020; Di Mola et al., 2021). Nonetheless, it is important to remember that the effects of the PHs on crops can vary with the plant species or varieties, the time of the application, and the dose (Lisiecka et al., 2011).

Before a new potential PH-based biostimulant is put on the market, it is essential to test its effects in multiple conditions and on different crops. High-throughput automated platforms for plant phenotyping have proven to improve and speed up the biostimulant testing process (Rouphael et al., 2018). Different sensors can be implemented in high-throughput phenotyping platforms, allowing the user to monitor the effects of the PH applications on many morpho-physiological traits throughout

the entire crop life cycle (Paul et al., 2019a,b). As a result, we can define in which crop, developmental stage, and dosage the application is recommended. Besides, a deeper physiological study allows the characterisation of their mode of action. This information can be used for further possible applications.

The use of other -omic approaches, such as metabolomics, allows studying the biostimulant effect in a more complex manner, supporting, and integrating the phenomics data to better understand the biochemical processes activated in the plants by the biostimulants application. However, the data analysis and interpretation of the complex omics datasets can become another challenging bottleneck. Here, we investigated the mechanism of action of a set of 7 PHs in lettuce and tomato subjected to early and late salinity stress. We hypothesise that salinity will reduce plant growth and change the physiology of the plant in tomato and lettuce. However, the PH application will ameliorate the salt negative effect in both plant species. Besides, a deep data analysis using advanced statistical tools will allow us (i) to understand better the effect of the PHs on two species, lettuce and tomato, selected for their economic importance, their distinct architecture, and purpose, and their different sensitivity to salinity stress, (ii) to evaluate the biological translation from the results obtained in PH-primed *Arabidopsis* grown under salt stress (Sorrentino et al., 2021) to other crops under similar growing conditions, and (iii) to demonstrate the necessity of the use of statistical approaches to simplify complex omic datasets allowing identification of the traits relevant for the understanding of a biostimulant mechanism of action.

MATERIALS AND METHODS

Plant Material and Growing Conditions

Seeds of *Lactuca sativa* L. var. capitata (Salanova cv Aquino) and *Solanum lycopersicum* L. cv MicroTom were sown in 250 ml pots filled with 235 g of a mixture of sieved peat (Substrate 2, Klasmann-Deilmann GmbH, Geeste, Germany) and river sand in 1:1 proportion. All the pots were watered up to 55% of the soil relative water content (SRWC). The water holding capacity of the substrate was calculated as described by Junker et al. (2015). The covered pots were stratified at 4°C in the dark for two days. After that, the pots were moved to a climate-controlled growth chamber (FS-WI, Photon Systems Instruments, Czechia) under long-day conditions (16 h light/8 h dark). The climate conditions in the growth chamber were set at 21/19°C for day/night temperature with 60% relative humidity (RH) and

120 $\mu\text{mol m}^{-2} \text{s}^{-1}$ cool-white LED (6,500 K) and 5.5 $\mu\text{mol m}^{-2} \text{s}^{-1}$ far-red LED (735 nm) lighting. These conditions were kept constant throughout the entire experiment. The pots were kept covered with a plastic lid for the first 24 h to maintain the soil moisture before it was removed.

Selection of the Plants

Eight days after lettuce stratification and ten days after tomato stratification, when most of the germinated seedlings had reached the 2-true-leaf stage, a top view RGB picture of all plantlets was taken using the top view RGB2 camera in the PlantScreenTM Compact system (Photon Systems Instruments, Brno, Czechia). The plants with areas between the 1st and the 4th quartile of the normal distribution of the population were used for the experiment. In the tomato experiment, each variant counted 6 plantlets as biological replicates, with a total of 96 plants. For the lettuce experiment, each variant counted 8 plantlets as biological replicates, with a total of 128 plants.

High-Throughput Phenotyping

To investigate the effects of PHs application on the morpho-physiological parameters of lettuce and tomato grown under salt stress conditions, trays containing two pots with one plantlet each were automatically transported within PlantScreenTM Compact System on conveyor belts between the light-isolated imaging cabinets, weighing and watering station, and the dark/light acclimation chamber. The trays were measured thrice a week, ending with 10 phenotyping rounds distributed in 21 days for lettuce and 24 days for tomato (**Figure 1**), with the starting point before the first salt application (Day of Phenotyping 1, henceforth defined as DoP 1). The phenotyping protocol used was the same for both crops. Physiological measurements [Chlorophyll Fluorescence (ChlF) and Thermal Imaging (IR)], being sensitive to circadian rhythm regulation mechanisms (Cano-Ramirez and Dodd, 2018), were always performed in the morning. A single round measuring protocol consisted of an initial 15 min light-adaptation period inside the acclimation chamber, followed by IR, and red-green-blue (RGB) top view imaging (RGB2). Next, 15 min dark-adaptation was applied, followed by chlorophyll fluorescence kinetic imaging, RGB side view imaging (RGB1), and weighing and watering (**Figure 1A**). Due to the limited capacity of the phenotyping system for the lettuce experiment, the trays were divided into 3 blocks with 16 trays each. The measuring round for one block lasted for 2 h and 45 min. The PlantScreenTM Analyser software (PSI, Czechia) was used to automatically process, re-analyse, and export the data.

Biostimulants Selection and Application

Seven PHs obtained by enzymatic hydrolysis of vegetal-derived proteins were selected from a batch of eleven PHs that were previously screened for their mode of action (Sorrentino et al., 2021) and used for the experiment. They included PHs from different plant sources belonging to the botanical families of Fabaceae (O), Malvaceae (C), Brassicaceae (F), Solanaceae (B), and Gramineae (P), and two commercial products [Trainer[®] (D) and Vegamin[®] (H)], commercialised by Hello Nature Inc. (former Italtollina) (Anderson, IN, United States) and used

as positive controls. The PH was obtained through enzymatic hydrolysis of the dry biomass and was then analysed for their total nitrogen and carbon content. For a detailed description of the procedure, see Sorrentino et al. (2021) and Ceccarelli et al. (2021).

Biostimulants were applied to leaves through spraying once a week, using only distilled water for the controls or the given PH in a concentration of 3 mL/L for the treated plants. A total of 4 foliar applications of PHs were done throughout the experiment (**Figure 1B**). The first spraying (priming) was performed one day before the first salt application. Two hours before and after the spraying of the plants, the relative humidity in the growing chamber (FS-WI) was increased up to 80% to promote the stomata opening.

Due to the limited capacity of the phenotyping platform, the lettuce experiment was divided into two rounds, each consisting of 64 plants. The substances B, C, and F were tested in the first round, while D, H, O, and P in the second round.

Watering and Salt Treatment

All the pots were watered after each phenotyping round at up to 55% SRWC with a modified Hoagland solution [0.36 g/L Ca (NO₃)₂, 0.1 g/L KH₂PO₄, 0.80 g/L KNO₃, 0.04 g/L NH₄NO₃, 0.13 g/L MgSO₄, and 0.01 mg/L of MIKROM fertilizer (Cifo Srl, S.Giorgio di Piano (BO), Italy)] using the Weighing and Watering station in the PlantScreenTM Compact. The solution was freshly prepared before each watering round and the pH was adjusted to a value of 5.7.

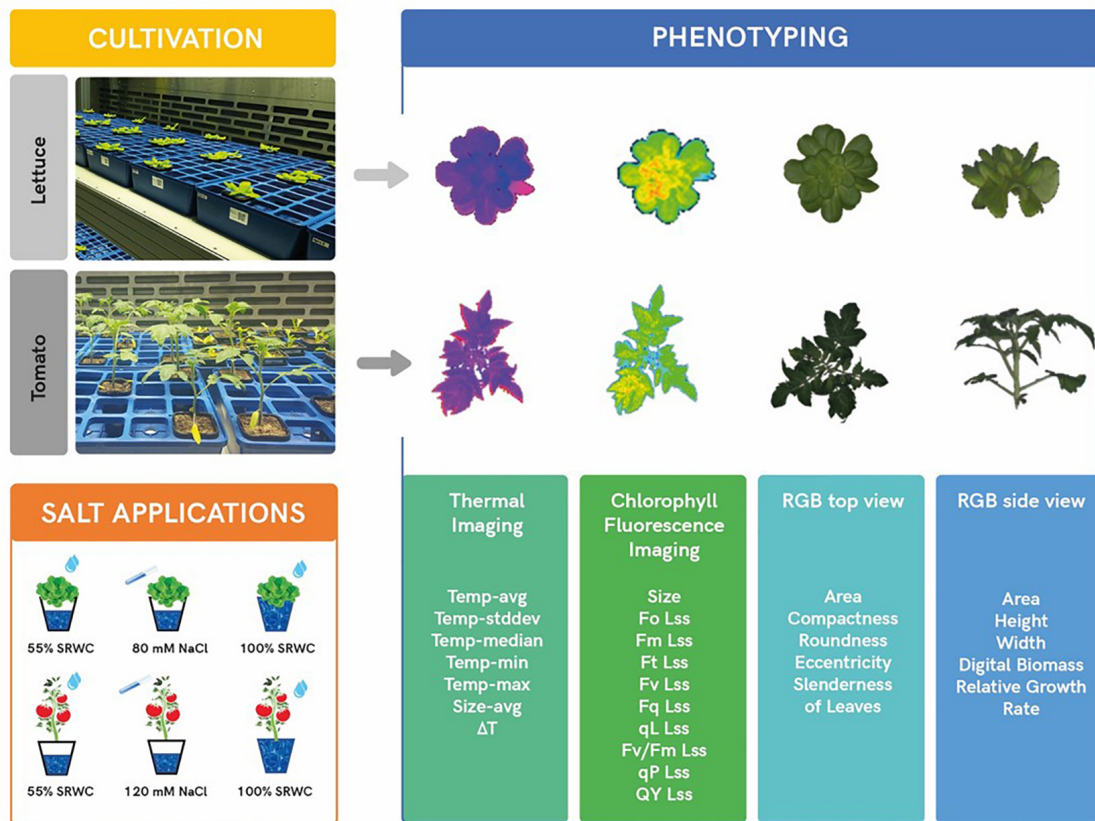

Starting from 2 weeks after stratification, the plants belonging to the stress group were subjected twice a week to salt application, ending with 6 applications for both crops (**Figure 1B**). In the lettuce assay, our objective was to reach a concentration of 40 mM NaCl in the soil, corresponding to moderate stress (Freitas et al., 2019). To avoid osmotic shock to the plants and NaCl accumulation in the soil, all the pots were first watered up to 55% of SRWC with plain nutrient solution. The plants belonging to the stress group were then given 40 ml each of an 80 mM NaCl solution (8.7 mS/cm). In the end, after a couple of hours from the salt application, all the plants were watered again of up to 100% of their SRWC to create drainage of the solution from the pot. The same setup was used with tomato, but in this case, the salt solution increased to 120 mM NaCl (14 mS/cm) to reach a concentration of around 60 mM NaCl in the pot, corresponding to moderate salt stress (Meza et al., 2020; **Figure 1B**). The two NaCl concentrations used in the experiments were the result of several preliminary tests conducted on both crops (data not shown).

Imaging Protocol and Data Analysis

Red-Green-Blue Imaging

Red green blue imaging using high-resolution top-view and side-view RGB cameras and an optimised image segmentation algorithm for automated analysis were used to calculate the number of plant-specific pixels throughout the whole experiment. The RGB images were processed as described by Awlia et al. (2016) and Paul et al. (2019a,b).

A

B

FIGURE 1 | Scheme of plant cultivation and phenotyping protocol. Plants were manually transferred from the cultivation chamber to PlantScreen™ Compact System for imaging using four different sensors (thermal camera, chlorophyll fluorescence, and top and side RGB). The resulting false-color, segmented images, and list of extracted parameters obtained from the sensors are shown (A). Timeline of plant cultivation (yellow bar) and phenotyping protocol (blue bar). Green dots show four-time points of the foliar application for the selected biostimulants and the orange dots show six timepoints for the salt treatment (B).

Projected shoot area (PSA) from the top (PSA_{top}) and the side view (PSA_{side}) was used to calculate the Digital Biomass (DM) of each plant (Rahaman et al., 2017):

$$\sqrt{PSA_{side}^2 \times PSA_{top}}$$

Digital Biomass, corresponding to the approximate volume, was then used to calculate the Relative Growth Rate (RGR),

where T_1 and T_2 indicate the time interval (days), while DM_1 and DM_2 indicate the corresponding digital biomass:

$$(\ln DM_2 - \ln DM_1) / (T_2 - T_1)$$

Relative growth rate (RGR) was calculated twice during the experiment: from DoP 0 to DoP 12 (**Early Phase**) for both crops, and from DoP 12 to DoP 21 for lettuce plants, or to DoP 24 for tomato plants (**Late Phase**).

Chlorophyll Fluorescence Imaging

To assess the effects of salt stress and biostimulants application on the photosynthetic performance of the plants, ChlF measurements were acquired using an enhanced version of the FluorCam FC-800MF pulse amplitude modulated (PAM) chlorophyll fluorometer incorporated into the PlantScreenTM Compact System (for more details, see Henley, 1993). After 15 min of dark adaptation, the light curve protocol, as described in Awlia et al. (2016), was used to quantify the rate of photosynthesis at different photon irradiances (Rascher et al., 2000). Four actinic light irradiances [Lss (Light steady-state) 1: 180 $\mu\text{mol m}^{-2} \text{s}^{-1}$; Lss2: 480 $\mu\text{mol m}^{-2} \text{s}^{-1}$; Lss3: 780 $\mu\text{mol m}^{-2} \text{s}^{-1}$ and Lss4: 1,080 $\mu\text{mol m}^{-2} \text{s}^{-1}$] with a duration of 60 s were used to quantify the rate of photosynthesis. The raw data were automatically processed using the PlantScreenTM Analyser software (PSI, Brno, Czechia). From the measured fluorescence transient states, the basic ChlF parameters were derived (i.e., F0, Fm, Ft, and Fv), which were used to calculate a range of parameters characterizing the plant photosynthetic performance (i.e., Fv/Fm, Fv/Fm', NPQ, and ΦPSII). We chose to evaluate the parameters obtained after the exposure of the plants to the light of intensity 480 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (Lss2) since they provide the highest discriminative power between control and stress plants.

Thermal Imaging

To determine the leaf temperature of the plants, we used the thermal imaging unit implemented into the PlantScreenTM Compact system, which allows assessing the canopy temperature from the top view. The thermal imaging unit incorporated in the PlantScreenTM Compact System consists of a light-isolated box with one top view camera mounted on a static frame and a temperature sensor to increase contrast for the image-processing step. The imaged area is 440 mm \times 340 mm (height \times width). To assess the Spatio-temporal variations in temperature over plant surface, we used an FLIR A615 thermal camera with 45 \circ lenses and a resolution of 640 \times 480 pixels and high-speed infrared windowing option and <50 mK thermal sensitivity (FLIR Systems Inc., Boston, MA, United States). The canopy temperature of each plant was automatically extracted with PlantScreenTM Analyser software (PSI, Brno, Czechia) by mask application, background subtraction, and pixel-by-pixel integration of values across the entire plant surface area.

To minimize the influence of the differences in environmental conditions and image acquisition timing among individual plants, the average canopy temperature of each plant (T_{avg}) was normalised with the actual temperature inside the Thermal Imaging box and expressed as canopy temperature depression or δT ($^{\circ}\text{C}$) (Hou et al., 2019).

Untargeted Metabolomic Analysis

At the end of the experiment, at DoP 21 and 24 in lettuce and tomato, respectively, the third true leaf of each plant was harvested and freeze-dried. The material from control plants and plants treated with the 7 PHs was used for the metabolomic analysis. Lyophilised plant material (50 mg for lettuce and 250 mg for tomato) was extracted in twenty volumes (w/v)

of methanol/water solution (70:30, v/v), acidified with 0.1% formic acid by Ultra-Turrax (Polytron PT, City, Switzerland), centrifuged, and then filtered through a 0.22 μm membrane as previously reported (Paul et al., 2019a,b). Untargeted metabolomics was performed using a 6,550 iFunnel quadrupole-time-of-flight mass spectrometer and a 1,200 series ultra-high-pressure liquid chromatographic system (UHPLC-ESI/QTOF-MS) from Agilent Technologies (Santa Clara, CA, United States) as previously described (Miras-Moreno et al., 2021). Briefly, 6 μL were injected and a reverse-phase chromatography was applied under a water-acetonitrile gradient elution (6 to 94% acetonitrile in 33 min). The mass spectrometer worked in positive ionisation (ESI+) and in SCAN mode for the acquisition of accurate masses ranging from 100 to 1,200 m/z. Four replicates were analysed for each treatment and samples were randomly sequenced. Quality Controls (QCs) were prepared by pooling all the extracts and were analysed throughout the chromatographic sequence using the same chromatographic conditions as samples but were acquired in data-dependent MS/MS mode (1Hz, 50–1,200m/z, 12 precursors per cycle) at different collision energies (10, 20, and 40eV).

Agilent Profinder B.07 (Agilent Technologies) software was used for mass (5-ppm tolerance), retention time (0.05min maximum shift) alignment, and for processing all the mass features from UHPLC-ESI/QTOF-MS raw data. The combination of monoisotopic mass, isotopes accurate spacing, and isotope ratio was used for annotation using the PlantCyc 12.6 database (Plant Metabolic Network)¹, as previously reported (Pretali et al., 2016; Schl  pfer et al., 2017). Only those compounds identified in 75% of the replications within at least one treatment were retained. Thereafter, MS/MS confirmations from QCs were carried out using the software MS-DIAL 4.24 (Tsugawa et al., 2015), formerly using MS/MS experimental spectra available in the software (Mass Bank of North America), and then using MS-Finder *in silico* fragmentation (Tsugawa et al., 2016). The annotation process corresponded to level 2 of confidence as set out in the COSMOS Metabolomics Standards Initiative (Salek et al., 2015).

Statistical Analysis

For the phenotyping data, statistical differences between treatments and time points were determined by Mixed model analysis (McCulloch and Searle, 2000; Boisgontier and Cheval, 2016) and multiple pairwise comparisons using *post hoc* Tukey's test (P -value <0.05). The statistical analysis was implemented in R studio (R GUI 4.0.3) using the "lmer" and "emmeans" packages (R Core Team, 2014; Bates et al., 2015; Russell, 2020). Then, to define the specificities of each crop and their response to the foliar application with PHs, and to go further in the mode of action, hierarchical clustering was applied with the use of "Ward's" linkage method to find similarities between crops, growth conditions, and the best and worse performed biostimulant and to identify clusters (Saxena et al., 2017). Finally, random forest classification was also applied to identify the significant variables for the treatment classification (Qi, 2012).

¹<http://www.plantcyc.org>

Concerning metabolomics, the software Agilent Mass Profiler Professional B.12.06 (from Agilent Technologies, Santa Clara, CA, United States) was used for data normalisation and baselining (Mimmo et al., 2017). Then, unsupervised hierarchical cluster analysis (HCA) based on fold-change heatmaps (Squared Euclidean distance) was used to naively describe patterns across treatments. Thereafter, supervised multivariate statistics were performed in SIMCA 13 (Umetrics, Malmo, Sweden), where orthogonal projection to latent structures discriminant analysis (OPLS-DA) was carried out. Each supervised model (separate models for tomato and lettuce, and then a comprehensive model for salt-stressed versus control plants), was validated by CV-ANOVA, checked for overfitting by permutation testing ($N = 200$), and then inspected for goodness-of-fit (R2Y) and prediction ability (Q2Y). After that, variable importance in projection (VIP) ranking was used to identify the most discriminant compounds in each OPLS-DA model. Finally, ANOVA (P -value < 0.01 , Bonferroni multiple testing correction) and fold-change (FC) analysis ($FC \geq 1.3$) were combined into Volcano Plots, and differential compounds were imported into the Omic Viewer Pathway Tool of PlantCyc (Stanford, CA, United States) software (Caspi et al., 2013) for biochemical interpretations.

RESULTS

Development of the Experimental Protocol for Salt and Biostimulants Applications

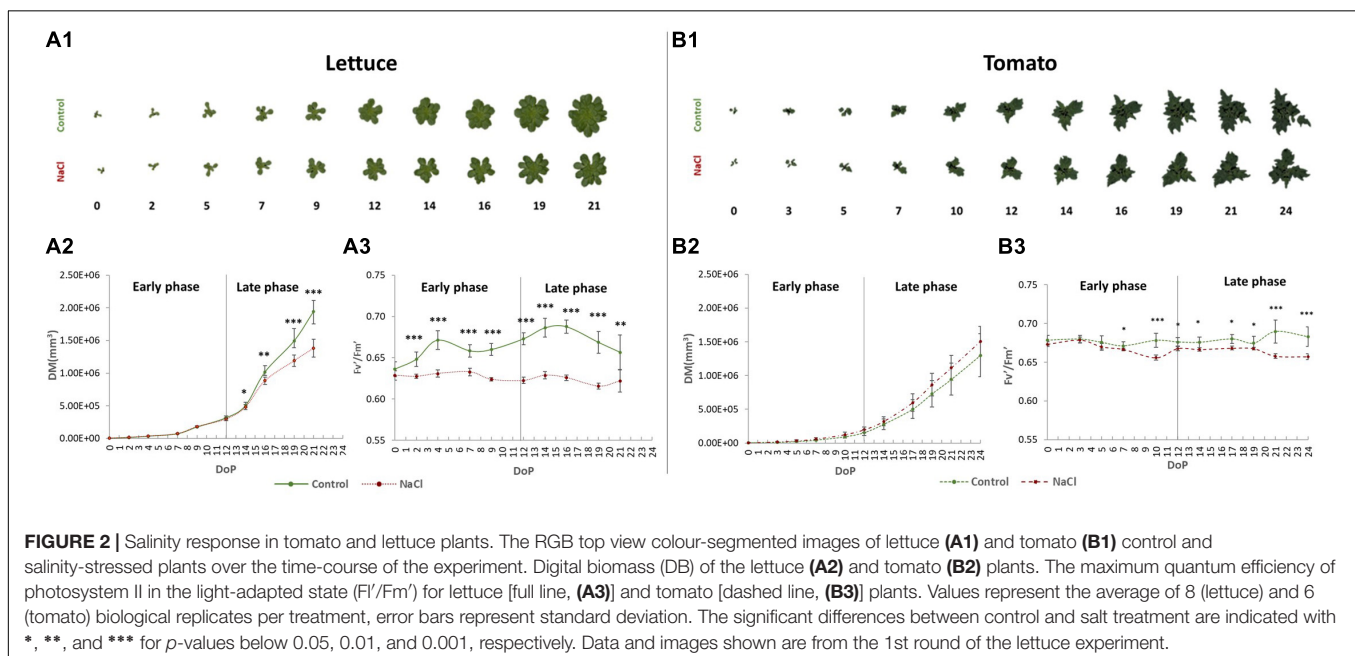

To effectively characterise the outcome of biostimulants applications on lettuce and tomato performance in the early vegetative growth phase, we first optimised the experimental

protocol for plant cultivation, mild-salt stress application, and the stress response quantification. The crops were analysed in independent experiments as they are very diverse in their tolerance to salinity, and two different concentrations of NaCl in the nutrient solution were used to water the plants as described in Materials and Methods (Figure 1). Lettuce and tomato plants were grown for 35 and 39 days, respectively, and this period corresponded to the complete head maturation in lettuce and the beginning of the flowering stage in tomatoes.

The PHs were applied *via* foliar spraying with solutions of 3 mL/L each (Figure 1; Di Mola et al., 2019a,b). The morpho-physiological traits of the plants were quantified dynamically throughout the trial to monitor their growth performance and physiological status. As a result, we could clearly distinguish two periods in the experiment, an early and late phase, in which the response of the plants to the salt stress and to the interaction with the biostimulants applications were diverse. It is well-known that plants respond to salt stress in two phases (Ugena et al., 2018): a rapid and osmotic phase, described here as the early phase (DoP 0-12), and a slower ionic phase due to the ion toxicity, referred to as the late phase (DoP 12-21 in lettuce or DoP 12-24 in tomato) (Figure 2).

Lettuce and Tomato Plants Have Different Physiological Responses to Mild Salinity

In lettuce, salt stress reduced plant growth in the later phase of the experiment after 4 salt applications (after DoP 14) (Figures 2A1,A2), and the reduction was similar in the lettuce plants from the first and second trials with 35 and 29% lower digital biomass (DB) than their correspondent controls, respectively (Supplementary Figures 1A1,B1). We further assessed other morphological parameters, such as roundness,

compactness, and slenderness of the leaves (SOL), showing that they did not differ between the rounds, but differed between the controls and salt-stressed plants in the late phase, with the less compact, round, and more SOL in the stressed lettuce (**Figure 2A1** and **Supplementary Figures 1A,B**).

The photosynthetic performance of the plants during the development and with the progression of the salt stress was also affected (**Figure 2A3** and **Supplementary Figures 1C,D**). In the two rounds that were analysed, the most significant differences were observed in the late phase between the controls and the NaCl-treated lettuce plants. We showed that the maximum quantum yield of PSII photochemistry for the light-adapted (F_v'/F_m') state and PSII operating efficiency (Φ_{PSII}) were significantly reduced in the stressed plants, whereas the non-photochemical quenching (NPQ) was increased compared to the controls (**Figure 2A3** and **Supplementary Figures 1C,D**). Altogether, our data demonstrate that in lettuce, only the late phase of salt stress imposition (after DoP12) was important to detect the differences in growth and in fluorescence-related parameters between treatments.

In tomato plants, the growth of the plant was not affected by the mild salt stress (**Figures 2B1,B2**). The remaining morphological parameters did not show differences between control and salt stress, except for the higher slenderness of the leaves (SOL) in salt-stressed plants during the transition from the early to late phase (**Supplementary Figures 2A1–A4**). Regarding the physiology, however, there were significant differences in several fluorescence-related parameters at the end of the early phase and late phase of the salt stress (**Figure 2B3** and **Supplementary Figure 2B**). In salt-stressed tomatoes, we observed a significant reduction in F_v'/F_m' and Φ_{PSII} , and increased NPQ values compared to the controls.

Protein Hydrolysates Specifically Improve Growth Performance of Lettuce Plants

In the following step, we analysed how the foliar application of selected PHs could modify the responses observed in salt-stressed and non-stressed plants. In lettuce plants, the substance P increased the DB at the late phase of stress after 3 foliar applications under both growth conditions (DoP13) (**Figures 3A1,A2**, **Supplementary Figure 3B1**, and **Supplementary Tables 1A,B**). The substances D and H also improved the DB, but only when plants were grown under salt stress conditions. Other morphological traits, such as roundness, compactness, or SOL, did not change (**Supplementary Figures 3A2–A4,B1–B4** and **Supplementary Tables 1A,B**). Similarly, the foliar application with substance P increased the RGR of the plants in the early phase under control conditions (**Figures 3A1,A2** and **Supplementary Figures 6A1,A2**). Other PHs did not modify the RGR of the plants compared to their respective controls (salt or control) in both the early and late phases. Interestingly, application of the PHs increased the final biomass (**Supplementary Figures 6B,C**), especially the dry weight of the aerial part of the plants when the substances B, C, E, and P were applied to plants grown under

control and salt stress conditions, or when the substance O was applied under control conditions.

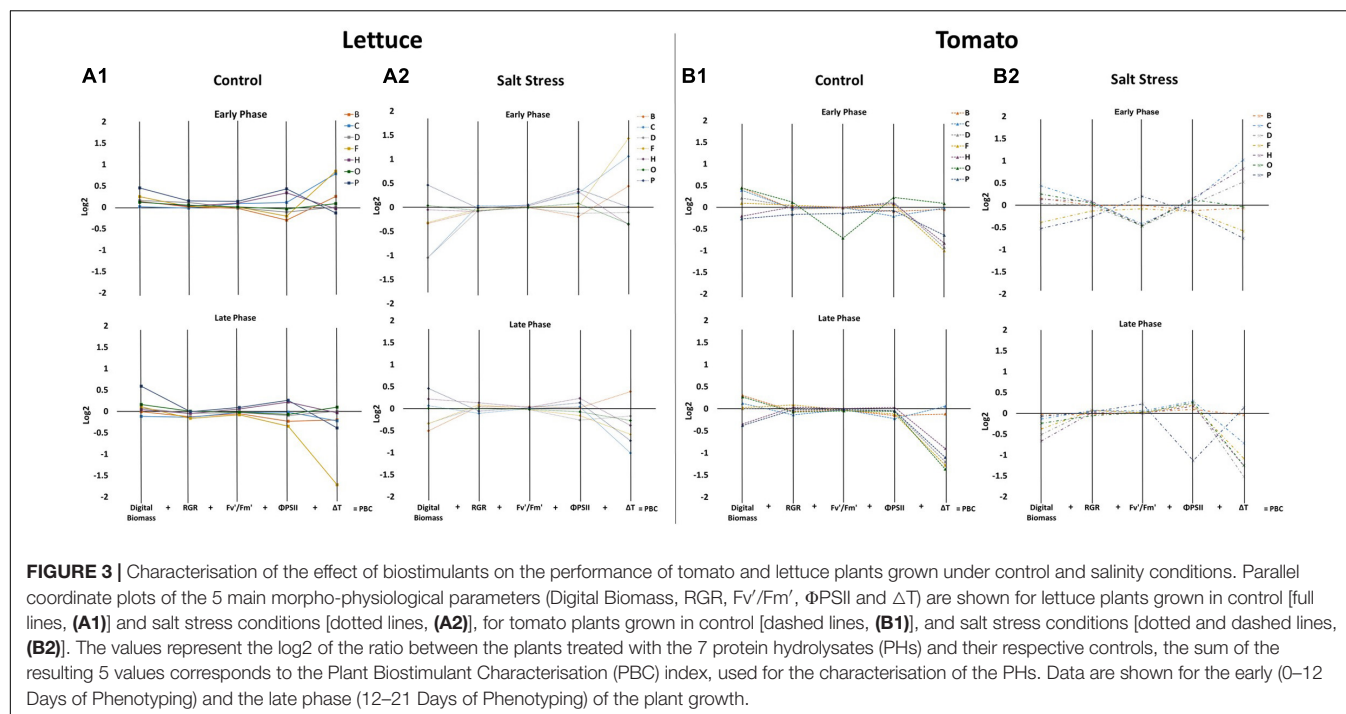

The application of biostimulants had a mild impact on the photosynthetic performance of the lettuce plants both under control and salt stress conditions. We showed that the plants treated with the substances P and H increased F_v'/F_m' and Φ_{PSII} values both under control and stress conditions, while we observed reduced NPQ levels along with the experiment (**Figures 3A1,A2**, **Supplementary Figures 3C,D**, **4C,D**, and **Supplementary Table 2A**).

In tomato plants, the application of PHs did not have any effect on the morphological traits; the differences in DB, RGR, and fresh and dry weight were only due to the growth conditions. Digital biomass (DB), along with the fresh weights of the plants, were similar in PH-treated plants and control plants during both phases of the experiment (**Figures 3B1,B2**, **Supplementary Figures 5A,B**, **7**, and **Supplementary Table 1C**). Similarly, no significant improvement of the photosynthetic efficiency of the plants was observed in tomato plants sprayed with PHs in any growth conditions (**Figures 3B1,B2**, **Supplementary Figures 5C,D**, and **Supplementary Table 2C**).

We have further analysed the impact of PHs applications on the leaf surface temperature profile of both crops using thermal image analysis. The salt stress significantly increased the temperature of the leaf surface in lettuce but not in tomato plants (**Supplementary Figure 8**). Similarly, the changes of the temperature by the application with biostimulants were more visible in lettuce than in tomato plants. We showed that the lettuce plants treated with the substances C and F had a significantly reduced surface temperature when grown both under control and stress conditions (**Figures 3A1,A2**, **Supplementary Figures 8A,B**, and **Supplementary Table 3A**). In tomatoes, the biostimulants reduced the temperature of the leaf surface after the first application in plants that were under control and salt stress conditions. However, in the late phase, they increased the temperature over the respective control in almost all the cases (**Supplementary Figure 8C** and **Supplementary Table 3A**).

Investigating the Mode of Action of the Protein Hydrolysates Through the Plant Biostimulant Characterisation Index

To simplify the results and to identify the specific mode of action of the 7 PHs, we used the Plant Biostimulant Characterisation (PBC) index as described previously (Ugena et al., 2018; Sorrentino et al., 2021). For the calculation of the PBC indexes, we selected the five traits (DB, RGR, F_v'/F_m' , Φ_{PSII} , and ΔT) that provided the highest discriminative power between the different treatments (**Supplementary Tables 1–3**). The PBC indexes for the Early Phase (from DoP 0 to 12) and the Late Phase (from DoP 12 to 21 in lettuce or from DoP 12 to 24 in tomato) were calculated independently since we could observe different responses of the plants treated with the 7 PHs in the two phases. To determine the index value, the log2 of the ratio between the biostimulant treated plants and untreated ones was determined for each crop and growth conditions, and then represented

in parallel plots (Figure 3). Then, the five obtained values represented in each parallel plot were summed to end with a unique number that represents the PBC index (for further detail see Sorrentino et al., 2021) which was included in Table 1. The calculated PBC index for each compound, growing condition, and phase of the trial could be negative (red) or positive (blue), providing information about the mode of action of that specific combination (Table 1). More in detail, the substances with positive PBC indexes (darker blue) in control conditions are characterised as plant growth promoters, whereas the negative (darker red) are plant growth inhibitors. Overall, our data clearly showed that in lettuce plants, the substance P was both the best growth promoter and stress alleviator, improving the fitness of the plants in all growing conditions and both stages of the trial. The second best was H, while the absolute worst was B (Table 1A). Some of the other PHs proved to be beneficial to the crop only in a specific growing condition and/or phase of the trial. For example, F showed an effect as a growth promoter, but only in the late phase of the experiment, while O acted as a stress alleviator in the early phase, but its effect faded in the Later Phase (Table 1A).

For tomato, the absolute best performer was the substance O, followed by D, F, and H, all acting as growth promoters and stress alleviators. Contrarily, the plants treated with the substance B showed the worst performances, especially in salt stress conditions (Table 1B).

The results obtained from the PBC index were also corroborated by a cluster analysis performed with the complete phenotyping data set (Figure 4). In lettuce, the plants treated with H and P were located in an independent cluster that was divided into two subclusters due to the growth conditions (control or salt) but independent of the stress and unstressed control plants

(Figure 4A). Contrarily, the rest of the substances were located with their respective controls that were only separated by the stress effect (Figures 4A,B). In tomato plants, except for the substances B and C, all PHs were beneficial for the plant fitness, especially when they were grown under salt stress conditions (Figure 4C). Altogether, we could conclude that H and P were the best growth promoters and stress alleviators, whereas B was a plant growth inhibitor.

The Applications of Protein Hydrolysates Activate Different Metabolic Pathways in Lettuce and Tomato Plants

An untargeted metabolomic analysis (UHPLC/QTOF-MS) was performed to understand the molecular mechanisms triggered by PH treatments in tomato and lettuce plants grown under either control or salinity conditions. The untargeted profiling allowed to putatively annotate more than 2,000 compounds; the whole list of metabolites, together with the composite mass spectra and individual abundances are provided as Supplementary Material (Supplementary Table 5A for lettuce, Supplementary Table 5B for tomato). The metabolomics dataset included a broad biochemical diversity, including metabolites from a large range of metabolic processes of primary and secondary metabolism. Multivariate statistics were applied to the metabolomic dataset highlighting the similarities or dissimilarities among the metabolomic profiles across treatments. At first, the unsupervised and supervised statistics were carried out separately, while considering the metabolomics datasets from lettuce and tomato. These statistics served as the first step of interpretation to point out the similarities or dissimilarities among all treatments.

TABLE 1 | Classification of 7 protein hydrolysates (PHs) using Plant Biostimulant Characterisation (PBC) index.

	(A) Lettuce				(B) Tomato			
	Control		NaCl		Control		NaCl	
	Early phase	Late phase	Early phase	Late phase	Early phase	Late phase	Early phase	Late phase
B	−0.38	−0.21	−1.04	−0.78	0.35	0.18	0.09	0.10
C	−0.54	−0.07	−1.73	1.01	0.17	−0.32	0.84	1.00
D	0.12	−0.10	−1.18	−0.42	1.27	1.14	1.14	1.33
F	−0.73	1.23	−1.77	0.15	1.21	1.24	0.92	1.00
H	0.63	0.30	0.53	1.00	0.73	0.63	1.36	0.77
O	0.15	−0.02	0.38	0.19	1.96	1.45	1.49	1.23
P	1.37	1.32	0.84	1.29	0.60	0.64	0.34	0.36

The PBC index values for each substance, in Early (0-12 Days of Phenotyping for both crops) and in Late Phase of the experiment (21-21 or 12-24 Days of Phenotyping for lettuce or tomato, respectively). The PBC index of the 7 studied PHs in lettuce (A) and tomato (B) plants under control and salinity conditions. White corresponds to 0, positive values are highlighted in blue and negative values are highlighted in red, the farther the value from 0, the darker is the corresponding hue.

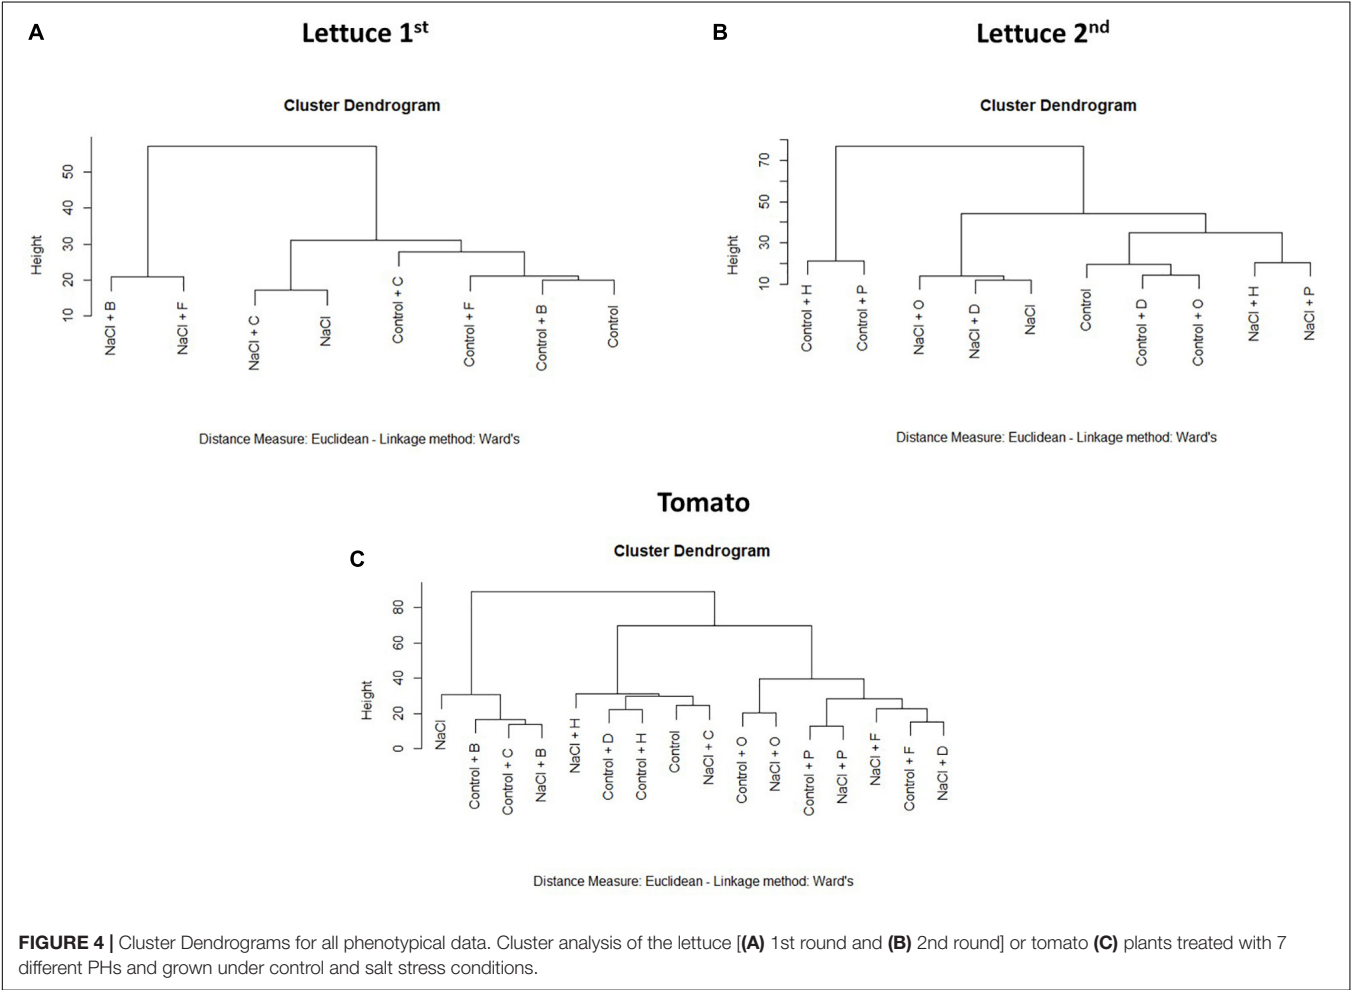

FIGURE 4 | Cluster Dendrograms for all phenotypical data. Cluster analysis of the lettuce [(A) 1st round and (B) 2nd round] or tomato (C) plants treated with 7 different PHs and grown under control and salt stress conditions.

When the lettuce plants were analysed, the unsupervised fold-change-based hierarchical clustering output (Figure 5A) naively evidenced that within each trial (first for PHs B, C, F, and second for D, H, O, P), the salinity application was the main clustering factor. Nevertheless, the score plot from the supervised OPLS-DA multivariate modelling (Figure 5B)

allowed to efficiently discriminate among the different groups of treatments, whereas control samples from the two different trials merged into the score-plot. The model was validated (P -value < 0.001), parameters of the OPLS-DA were excellent ($R^2Y = 0.983$, $Q^2Y = 0.935$), and overfitting was avoided through permutation testing. Therefore, discriminant compounds (VIP

score > 1.2 – **Supplementary Table 6A**) were exported and were considered. Overall, primary and secondary metabolites were equally represented among the VIP discriminants. In more detail, the most represented primary metabolites included carbohydrates, membrane lipids, hormones (mainly brassinosteroids, a cytokinin, and two gibberellins), and electron-carriers (quinol and quinones). Among secondary metabolites, the most represented compounds were phenylpropanoids, alkaloids, and isoprenoids. Exploring the OPLS-DA score plot (**Figure 5B**), the variants showed a clear distribution through all score spaces with a clear separation between stressed and non-stressed plants treated with the same PHs. Under non-saline conditions, the plants treated with B, C, and F presented metabolomic signatures similar to the untreated control, depicting a separated group of responses. However, a second group formed by the plants treated with H, O, and P, corresponding to the best performing biostimulants according to the phenotyping data, formed an independent group under control and salt stress conditions (**Figure 5B**).

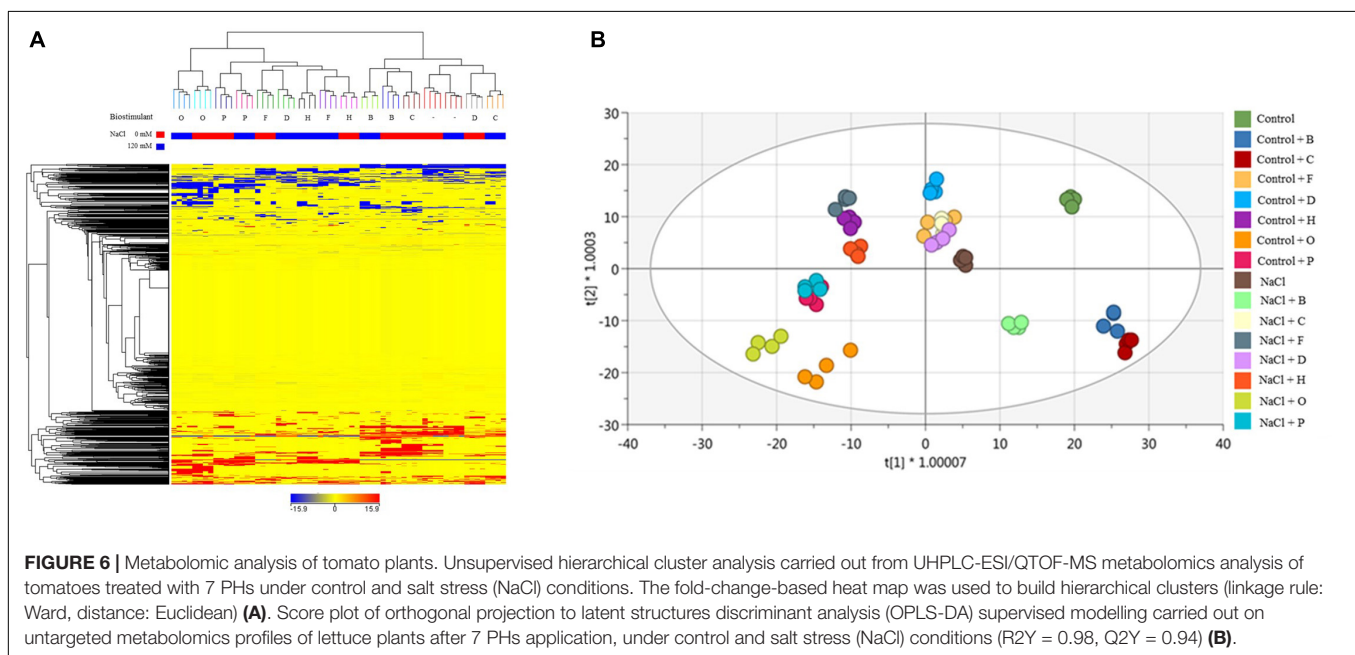

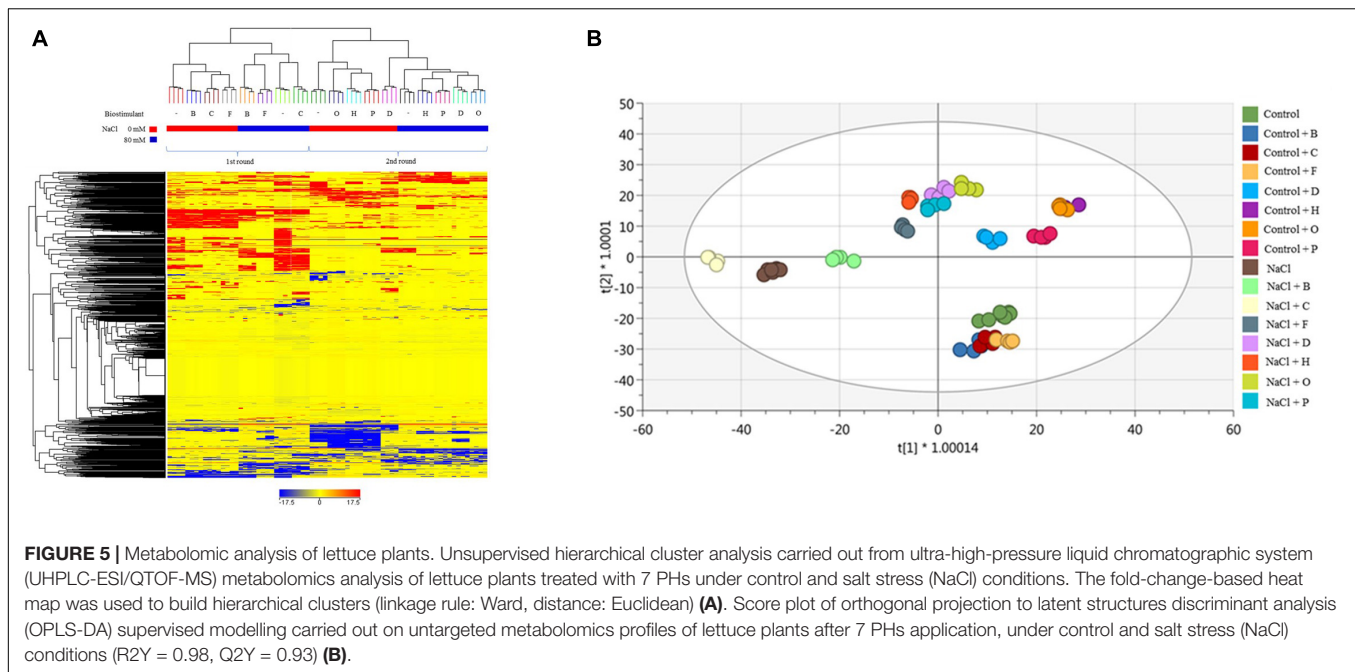

Different results were obtained in tomato plants. As a preliminary approach, unsupervised HCA (**Figure 6A**) suggests that salinity did not have a primary effect on metabolic signatures. Tomato samples clustered in two main groups, distinguishing PH treatments, with a cluster including O, P, F, and H, and a second group containing those plants treated with the substance B and C, more similar to untreated controls. These results were further confirmed by the OPLS-DA supervised statistics which allowed separating better the samples in the score space according to the combined treatments (**Figure 6B**). The model parameters of the OPLS-DA were excellent ($R^2Y = 0.981$, $Q^2Y = 0.941$), validation was adequate (P -value < 0.001), and overfitting could be excluded by permutation testing. Discriminant compounds (VIP score > 1.1 – **Supplementary Table 6B**) are mainly related to secondary metabolism (phenylpropanoids and to a lesser extent terpenoids and alkaloids), cofactors/electron carriers, and phytohormones (gibberellins, brassinosteroids, jasmonate, and IAA-conjugates). Primary metabolites range from carbohydrates, lipids, organic acids, and nucleic acid components. OPLS-DA evidenced that some PHs (O, P, H, D) were better able to minimize the differences between stressed and non-stressed plants, so the plants were grouped independently of the plant growth conditions. This feature might imply a hierarchically stronger effect of the biostimulant above salt stress, and thus, the ability of these PHs to well-play as stress alleviator on plant metabolism (**Figure 6B**).

Biochemical Insights on the Metabolomic Reprogramming Triggered by the Best and the Worst Performers Protein Hydrolysates

To further understand the differences between the mode of action of good and bad performing biostimulants, we analysed the plants treated with the best substance, H, as plant growth promotor and stress alleviator and with the worst, B, as growth inhibitor [according to the PBC indexes and the cluster analysis (**Figures 3, 4** and **Table 1**)]. The two corresponding

sub-datasets were then considered, including 669 compounds for lettuce and 1,090 for tomato. The HCA confirmed the strongest effect of salinity above the PH-treatments in lettuce, whereas PHs had a hierarchically stronger effect on tomatoes (**Supplementary Figures 9A,B**). Indeed, for lettuce, the two main clusters divided stressed from non-stressed plants, even though the metabolic profiles of control plants were more similar to B-treated plants. On the other hand, the metabolic signatures of tomato samples merged in two main clusters, one including H-treated plants and a second cluster grouped controls and B-treated. Consistent results were obtained by OPLS-DA where the separation of treatments could be observed in the score plot hyperspace (**Supplementary Figures 9A,B**). The OPLS-DA model was robust, being $R^2Y = 0.996$ and $Q^2Y = 0.987$ in lettuce (P -value < 0.001) and $R^2Y = 0.996$ and $Q^2Y = 0.977$ in tomato (P -value < 0.001). Thereafter, the Volcano plot analysis (P -value < 0.01, $FC \geq 1.3$) was applied to identify differential compounds. Overall, we evidenced that 414 (in lettuce, **Supplementary Table 7A**) and 261 compounds (in tomato, **Supplementary Table 7B**) were significantly modulated by treatments compared to control. The Pathway Tool analysis from PlantCyc was applied to simplify the interpretation in terms of plant metabolism. **Figures 7A, 8A** show the biosynthetic processes modulated by treatments, along with cumulate FC values. Overall, biosynthesis processes related to secondary metabolism were generally decreased in both crops (**Figures 7B, 8B**), except for tomato plants treated with PH B under non-stress conditions. In both species, N-containing compounds (mostly alkaloids), phenylpropanoids, and terpenes underwent the most evident modulation. In lettuce, several membrane lipids were impaired, such as long-chain fatty acid (also in the epoxy form) and sterols. Phytohormones were broadly affected by the treatments in lettuce, whereas in tomato, we evidenced a weaker impact (**Figures 7C, 8C**). The main modulations concerned gibberellins, which decreased in both crops. In treated lettuce, a reduction of brassinosteroids, auxin-conjugates (IAA-Ile, IAA-Leu, IAA-Asp), and N-glycosylated cytokinins were observed. The ethylene precursor (1-aminocyclopropane-1-carboxylate, ACC) down-accumulated only in control plants of lettuce treated with H-substance. In tomatoes, changes in cytokinin content with the main accumulation of trans-zeatin-O-glucoside-7-N-glucoside in response to PH B (either under control conditions or salt stress and to H in control conditions).

Similar results were obtained when the effect of the two PHs (B and H) was investigated with respect of their ability as growth improvers and stress alleviators by independently exploring non-stressed and salt-stressed plants. Two different OPLS-DA models were validated regardless of the plant species, one considering metabolomics data from salt-stressed plants and the other including non-stressed plants (**Supplementary Figures 10A,B**). Validation parameters were excellent in both models, showing a $R^2Y = 0.992$ and $Q^2Y = 0.964$ (P -value = 1.57×10^{-17}) for non-stressed samples and $R^2Y = 0.996$ and $Q^2Y = 0.949$ (P -value = 6.41×10^{-15}) for samples grown under salt stress. The strongest discriminant compounds were selected from each model through the VIP method

(VIP score > 1.20). A total of 310 (salinity, **Supplementary Table 8A**) and 333 (control, **Supplementary Table 8B**) metabolites were considered and exported along with their FC values into the Omic Viewer Pathway Tool of PlantCyc for interpretations (**Supplementary Figures 11A–C, 12A–C**). Half of the total discriminant compounds were classified as secondary metabolites. However, whereas B substance downregulated the accumulation of secondary metabolites (phenylpropanoids, terpenes, and N-containing compounds), H increased them along with the levels of others such as fatty acid/lipids, cofactors, and electron carriers.

Regarding phytohormones, several discriminant compounds were differentially modulated by the two PHs. Under non-stress conditions, brassinosteroids [3-dehydrotestosterone and (22S,24R)-22-hydroxy-5 α -ergostan-3-one] strongly down-accumulated in response to PH B but not to PH H, which, on the other hand, remarkably induced a strong accumulation of methyl (indol-3-yl) acetate (MeIAA), a storage form of IAA. Among cytokinins, two glycosylated forms of trans-zeatin accumulated by H applications, whereas only one (*trans*-zeatin-7-*N*-glucoside) in response to B. The PH-treated plants caused a depletion in the ethylene precursor [1-aminocyclopropane-1-carboxylate (ACC)],

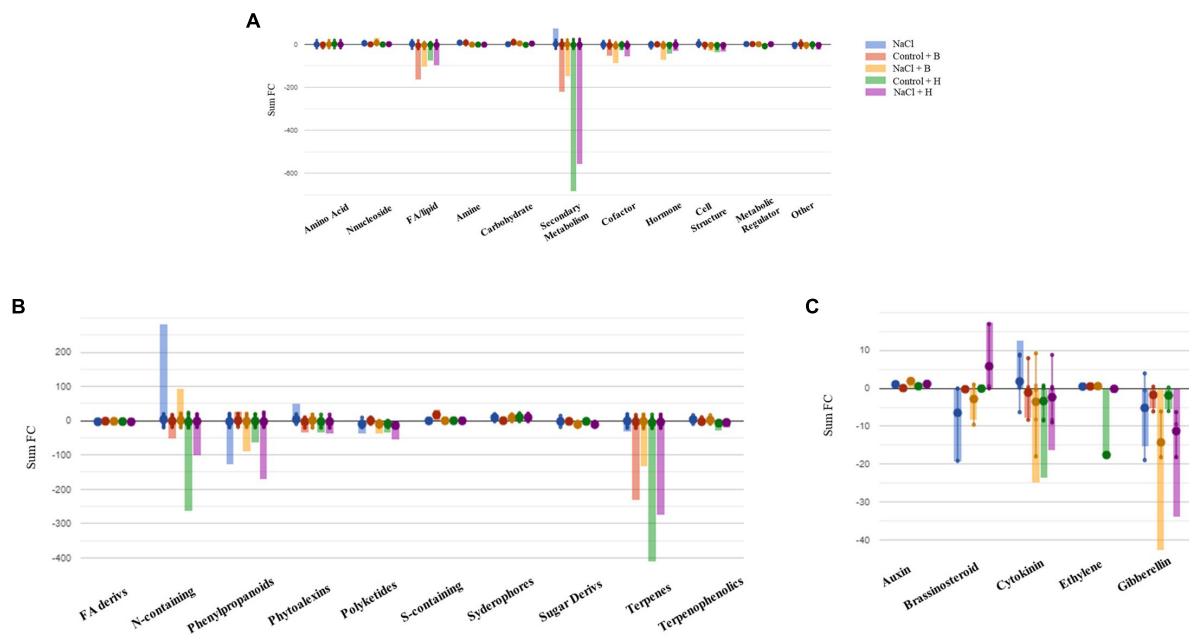

FIGURE 7 | Metabolic changes in lettuce plants. Metabolic processes (A), secondary metabolism (B), and (C) hormone biosynthesis were impaired by treatments in lettuce plants compared to control samples. Differential metabolites from the Volcano analysis (P -value < 0.01 , $FC \geq 1.3$) were elaborated using the Omics Viewer Dashboard of the Plant Cyc pathway Tool software (www.pmn.plantcyc.com). The large dots represent the average (mean) of all log Fold-change (FC) for metabolites, and the small dots represent the individual log FC for each metabolite. The x-axis represents each set of subcategories, while the y-axis corresponds to the cumulative log FC. but PH H had the strongest effect. Under salinity conditions, MeIAA showed the same modulations recorded in control plants. The only cytokinin found as discriminant (cis-zeatin) accumulated in response to the substance H.

Integrative Analysis of Phenomic and Metabolomics Datasets

The multivariate generalisation of the squared Pearson correlation coefficient was investigated through co-inertia (CIA) in terms of global similarity between the integrated phenotyping and metabolomic datasets (Supplementary Figure 13). The overall correlation between the two datasets was expressed as the RV coefficient. This is a measure of global similarity between the datasets and assumes values between 0 and 1. The closer to 1, the higher the similarity between the datasets (Robert and Escoufier, 1976). The overall similarity in structure between phenotyping and metabolomics data was higher in lettuce than in tomato with an RV coefficient equal to 0.37 and 0.29, respectively. However, the obtained RV for both crops reflected the lack of joint structure in these two datasets (phenomics and metabolomics). Altogether, we could say that according to the low synchrony obtained between the phenotypical and metabolomics data after CIA analysis, the changes in the metabolic content do not define the phenotype of the plants.

To deal with this low concordance between the two datasets, we decided to work with the phenotypical and metabolomic

data obtained from the plants treated with the substance H as plant growth promotor and stress alleviator, and with the substance B that worked as a growth inhibitor in both lettuce and tomato plants. As the first step, we used the random forest classification method to identify the most important phenotyping traits for each species. As a result, in lettuce, the importance was mainly focused on morphological traits, whereas in tomato the physiology was most relevant (Supplementary Tables 4A,B). Concretely, the volume represented as DB was the parameter with the highest discriminative power between treatments, followed by the physiological parameter, water use efficiency (WUE), related to water balance. However, in tomatoes, the most important parameters were related to the photosynthetic performance of the plant, with QY_max and QY_Lss4 as the main ones. The two crops respond in a different way to the changes in the growth conditions, where not only the growth conditions but also whatever treatment applied is included. Once defined, the main phenotypical traits, the correlated metabolites ($p < 0.05$) were identified performing a correlation matrix (Supplementary Tables 9A,B). For lettuce, many secondary metabolites, including alkaloids, terpenoids, and phenols or certain metabolites involved in amino acid metabolism (mainly degradation compounds) were negatively correlated with the volume of lettuce plants. However, this phenotyping trait was positively correlated with IAA, IAA-Asp, and L-arginine-succinate, among others. In tomato, however, QY_max was positively correlated to certain secondary metabolites, such as the phenol 4-hydroxycoumarin,

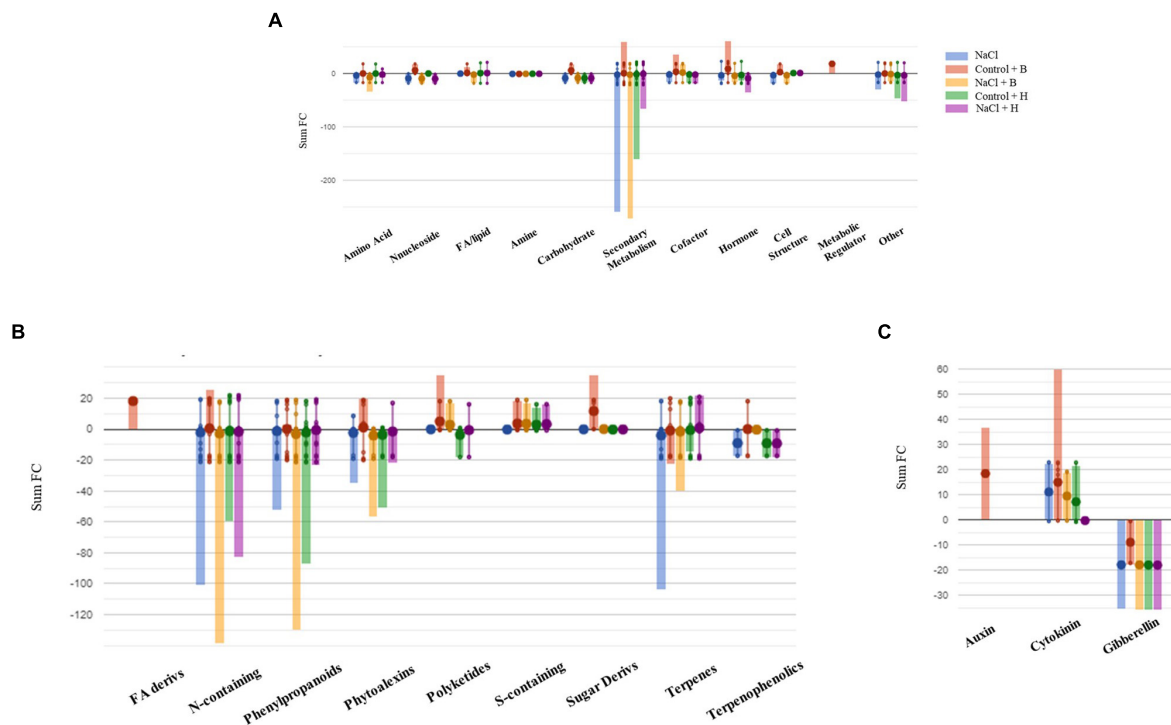

FIGURE 8 | Metabolic changes in tomato plants. Metabolic processes **(A)**, secondary metabolism **(B)**, and **(C)** hormone biosynthesis were impaired by treatments in tomato plants compared to control samples. and the vitamin K1 (phyloquinone), among others, and the carbohydrate D-erythrose 4-phosphate.

DISCUSSION

In the last years, the use of plant phenotyping approaches is becoming an efficient tool for characterizing the mode of action of biostimulants obtained from many different sources and in many plant species (Briglia et al., 2019; Danzi et al., 2019; Akhtar et al., 2020; Mutale-joan et al., 2020). Non-invasive approaches allow the simultaneous study of the crops grown under different growth conditions treated with biostimulant substances for a better understanding of their mode of action. To this end, our study could be another example of this type of study. We show that two distance crops, such as lettuce and tomato, differ in the response to salt stress alone or the interaction between the stress and the application of PHs based biostimulants. The PH application modified the kinetics of the curves for the different phenotyping traits, including plant growth, fluorescence-related parameters, and thermal imaging. This separated the plant response in the early and late phases, with it being more evident for lettuce than for tomato plants (**Supplementary Figures 1–8**). However, the effect was different for both crops and from

the one obtained in previous studies performed in Arabidopsis (Sorrentino et al., 2021). Whereas in lettuce, the biostimulant application induced changes during the early phase and after a low number of applications, in the case of tomato the changes were mainly visible at the late phase.

To go further in the understanding of the biostimulant mode of action, we probed the combination of phenotyping experiments with other omics, especially metabolomics, which can give additional information. In this context, the most difficult part is the data management, as both –omics approaches are ending with a huge amount of data to process and interpret. Thanks to the fast evolution of the data analysis based on multivariate statistical analysis, this is possible, and this aims to be a good example of such approaches. For that, the first step done was the clustering of the variants analysed independently for both lettuce and tomato using phenomic data (**Figure 4**). The high dimensionality of the data is a characteristic that creates many challenges in clustering and data analysis in general. The clustering tree is defined by the analysis of the L_K norm distances that depend on the value of K (Euclidean, Manhattan, Minkowski, etc.). The most often L_k norm used is Euclidean distance. In this regard, Aggarwal et al. (2001) showed some interesting results comparing different L_K norm distances. More specifically, they stress that the meaningfulness of L_K norm

($K = 1$ for Manhattan, $K = 2$ for Euclidean, etc.) is worse on high dimensions. This means that the Manhattan distance is preferred in situations where the number of traits (metabolomics or phenomics) is considerably large. That is the reason why Euclidean and Manhattan distances were both examined in this study. However, in this case, the results were not significantly different for both lettuce and tomato. One of the reasons for this result could be that there was a clear different response of the plant when the H or B substance was applied.

As the second step, after the performance of the metabolic analysis and data processing, the concordance between both datasets (phenomics + metabolomics) was performed using CIA analysis. This tool is becoming a particularly attractive method for the identification of relationships between large datasets, but it is mainly used in ecology or genetics (Bady et al., 2004; Genitsaris et al., 2016; Devarajan et al., 2021). However, there are not any case studies using this tool for integrating phenotyping data with other omics. In our study, we observed low values of the RV coefficient between both datasets (phenomics + metabolomics) (**Supplementary Figure 13**). This would mean that the metabolic profiling cannot explain the phenotypes of the plants, making the integration of both data more difficult. One of the reasons for this could be that the most of modulated metabolites were secondary metabolites, including alkaloids, phenylpropanoids, and terpenes (**Figures 7, 8 and Supplementary Table 7**). On the contrary, relevant molecules, such as plant growth regulators, are not so abundant and mainly appeared in lettuce. For example, in lettuce plants, there was a clear reduction of the conjugated forms of IAA, most probably to maintain the pool of IAA and thus allow the plant growth (reviewed by Ludwig-Müller, 2011). Besides, the precursor of ethylene, ACC, was also reduced in lettuce plants treated with the H substance when plants were grown under control conditions. It could mean that the H application can reduce the ethylene synthesis and with that, its negative effects (i.e., growth inhibition). However, recent studies also showed that ACC itself is enough to reduce the plant growth (Vanderstraeten et al., 2019).

To solve the low concordance between the phenotyping and metabolomic data, we decided to identify the most significant traits for each treatment (or treatment + biostimulant) among the phenotyping traits identified. For that, we used a random forest classifier. Such a tool is mainly used in plant science for machine learning approaches applied in image analysis (Barradas et al., 2021; Singh et al., 2016), but it has never been used for characterizing the biostimulant mode of action. Apart from a powerful classification method, the random forest has the advantage of revealing the significance of the traits used for identifying (classifying) treatments. This is done using the decrease in classification accuracy if a specific variable – trait is removed. The random forest classifiers applied for lettuce and tomato have high accuracy percentages (>95%), which makes them valid for the interpretation of the significant traits. The significant traits found for lettuce were the volume (based on the DB) and WUE. The most relevant result was the volume that positively correlated with the IAA levels (**Supplementary Table 9**). Higher IAA levels in leaves can improve cell extensibility and consequently induce leaf growth

(Veselov et al., 2002). Additionally, under stress conditions, the IAA accumulation can be a stress tolerance mechanism that permits the plant to keep growing (De Diego et al., 2012). Besides, this result could also explain the aforementioned reduction of the conjugation of IAA with certain amino acids observed in the plants treated with the H substance, and hence, their better growth under both control and stress conditions. The amide-linked IAA-amino acid conjugates are considered reversible storage forms with no or low biological activity (Mellor et al., 2016), with the Gretchen Hagen3 (GH3) family of auxin-inducible acyl amido synthetases as the enzymes converting IAA to IAA-amino acids. Thus, we could think that the application of the substance H in lettuce has downregulated the activity of GH3 to reduce auxin-conjugates and maintain the IAA levels as a stress response strategy.

In tomato, the most important trait was the QY_max, which was positively correlated to D-erythrose 4-phosphate (**Supplementary Table 9**), an intermediate in the pentose phosphate pathway, and the Calvin cycle that serves as a precursor in the shikimate pathway (Billakurthi and Schreier, 2020). This result could also explain the positive correlation with other metabolites product of this pathway, such as 4-hydroxycoumarin and vitamin K1 (phyloquinone). The hydroxycoumarins have been described as efficient antibacterial compounds that can improve plant stress resistance (Yang et al., 2018). Vitamin K1 has been detected inside thylakoid membranes as an electron carrier and is a key element within the photosystem I redox chain (reviewed by Lühje et al., 2013). Thus, it serves as a mobile carrier transferring the electrons across the plasma membrane and contributes to the maintenance of a suitable redox state of some important proteins embedded in the plasma membrane with protective functions against stress. The better performance in tomato plants can, thus, be related to the use of D-erythrose 4-phosphate as a precursor for the synthesis of antistress compounds from the shikimate pathway.

CONCLUSION

We assume that PH-based biostimulants improve the plant growth and salt stress response in crops, such as lettuce and tomato, through different mechanisms. For a better understanding of the mechanism of action, it was necessary to use powerful statistical tools which helped to simplify the results and, hence, their interpretation. Thus, we observed that for lettuce, the most interesting traits to study the PHs based biostimulants are those representing the aerial biomass (i.e., volume). These were correlated with altered levels of certain phytohormones, such as auxin and ethylene, and consequently with plant growth. However, in tomatoes, the chlorophyll fluorescence-related parameters were the most relevant defining the plant growth capacity and salt stress tolerance affecting also the stress-related metabolites from the shikimate pathway. We believe that these results corroborated the relevant role of the multivariate statistical analysis as a further step to uncover key traits and metabolites for a deeper understanding of the biostimulant mode of action.

Supplementary Figure 1 | Morphological and physiological parameters of lettuce plants under control and stress conditions. Digital biomass [DM, (A1-B1)], roundness (A2-B2), compactness (A3-B3), and slenderness of leaves [SOL, (A4-B4)] in lettuce plants grown under control or salt stress conditions for 21 days of phenotyping (DoP). Variations of maximum quantum yield of PSII photochemistry for the light-adapted state [Fv/Fm', (C1-D1)], PSII operating efficiency [Φ PSII, (C2-C3)] and non-photochemical quenching [NPQ, (C3-D3)]. The values were obtained after the exposure of the plants to a light intensity of

480 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (Lss2). Morphological and physiological values shown represent the average of 8 biological replicates per variant. Error bars represent standard deviation. The significant differences between control and salt treatment are indicated with *, **, and *** for *p*-values below 0.05, 0.01, and 0.001, respectively.

Supplementary Figure 2 | Morphological and physiological parameters of tomato plants under control and stress conditions. Digital biomass [DB, (A1)], roundness (A2), compactness (A3), and slenderness of leaves [SOL, (A4)] in tomato plants grown under control or salt stress conditions for 24 days of phenotyping (DoP). The maximum quantum yield of PSII photochemistry for the light-adapted state [Fv/Fm', (C1)], PSII operating efficiency [Φ PSII, (C2)], and non-photochemical quenching [NPQ, (C3)]. The values were obtained after the exposure of the plants to a light intensity of 480 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (Lss2). Morphological and physiological values shown represent the average of 6 biological replicates per variant. Error bars represent standard deviation. The significant differences between control and salt treatment are indicated with *, **, and *** for *p*-values below 0.05, 0.01, and 0.001, respectively.

Supplementary Figure 3 | Morphological and physiological parameters of lettuce plants treated with 7 different under control conditions. Digital biomass [DB, (A1-B1)], roundness (A2-B2), compactness (A3-B3), and slenderness of leaves [SOL, (A4-B4)] of lettuce plants treated with 7 PHs and grown under control conditions for 21 days of phenotyping (DoP). The maximum quantum yield of PSII photochemistry for the light-adapted state [Fv/Fm', (C1-D1)], PSII operating efficiency [Φ PSII, (C2-C3)] and non-photochemical quenching [NPQ, (C3-D3)]. The values were obtained after the exposure of the plants to a light intensity of 480 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (Lss2). Morphological and physiological values shown represent the average of 8 biological replicates per variant. Error bars represent standard deviation.

Supplementary Figure 4 | Morphological and physiological parameters of lettuce plants treated with 7 different under salt stress conditions. Digital biomass [DM, (A1-B1)], roundness (A2-B2), compactness (A3-B3), and slenderness of leaves [SOL, (A4-B4)] of lettuce plants treated with 7 PHs and grown under salt stress conditions for 21 days of phenotyping (DoP). The maximum quantum yield of PSII photochemistry for the light-adapted state [Fv/Fm', (C1-D1)], PSII operating efficiency [Φ PSII, (C2-C3)] and non-photochemical quenching [NPQ, (C3-D3)]. The values were obtained after the exposure of the plants to a light intensity of 480 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (Lss2). Morphological and physiological values shown represent the average of 8 biological replicates per variant. Error bars represent standard deviation.

Supplementary Figure 5 | Morphological and physiological parameters of tomato plants grown in control and salt stress conditions: PHs treated and untreated lettuce plants. Digital biomass [DM, (A1-B1)], roundness (A2-B2), compactness (A3-B3), and slenderness of leaves [SOL, (A4-B4)] of tomato plants treated with 7 PHs and grown under control and salt stress conditions for 24 days of phenotyping (DoP). The maximum quantum yield of PSII photochemistry for the light-adapted state [Fv/Fm', (C1-D1)], PSII operating efficiency [Φ PSII, (C2-C3)] and non-photochemical quenching [NPQ, (C3-D3)]. Values were obtained after the exposure of the plants to the light of intensity 480 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (Lss2). Morphological and physiological values shown represent the average of 6 biological replicates per variant. Error bars represent standard deviation. The significant differences between control and salt treatment are indicated with *, **, and *** for *p*-values below 0.05, 0.01, and 0.001, respectively.

Supplementary Figure 6 | Relative Growth Rate and final biomass of lettuce plants treated with PHs. Relative Growth Rate [RGR, (A1-A2)] of the different treatments over time, calculated for the early phase (from DoP 0 to DoP 12) and for the late Phase (from DoP 12 to DoP 21) in lettuce plants treated with 7 PHs grown under control or salt stress conditions. Total fresh (B1-B2) and dry (C1-C2) weight of the final aboveground biomass per variant. Values represent the average of the 8 biological replicates per variant. Error bars represent standard deviation. Different letters indicate significant differences according to the one-way ANOVA post hoc Tukey's test (*p* < 0.05).

Supplementary Figure 7 | Relative Growth Rate and final biomass of tomato plants treated with PHs. Relative Growth Rate [RGR, (A1-A2)] of the different treatments over time, calculated for the early phase (from DoP 0 to DoP 12) and for the late Phase (from DoP 12 to DoP 24) in tomato plants sprayed with 7 PHs,

grown under control conditions or salt stress. Total fresh (**B1–B2**) and dry (**C1–C2**) weight of the final aboveground biomass per variant. Values represent the average of the 6 biological replicates per variant. Error bars represent standard deviation. Different letters indicate significant differences according to the one-way ANOVA post hoc Tukey's test ($p < 0.05$).

Supplementary Figure 8 | Temperature of the leaves for lettuce and tomato plants under control and salt stress conditions. Canopy temperature depression measured on lettuce [(A1–A3, B1–B3), full and dotted lines] and tomato [(C1–C3), dashed and dotted + dashed lines] plants, untreated or treated with the biostimulant substances, grown under control or salt stress conditions. Values represent the average of the 8 biological replicates per treatment in lettuce and 6 biological replicates in tomato, error bars represent standard deviation. The significant differences between control and salt treatment are indicated with *, **, and *** for p -values below 0.05, 0.01, and 0.001, respectively.

Supplementary Figure 9 | Metabolomic analysis for the best (H) and worst (B) performing biostimulants. Unsupervised hierarchical cluster analysis carried out from UHPLC-ESI/QTOF-MS metabolomics analysis of lettuce (A) and tomato (B) plants treated with PH B or H, grown under control or salt stress conditions. The fold-change-based heat map was used to build hierarchical clusters (linkage rule: Ward, distance: Euclidean). Score plot of orthogonal projection to latent structures discriminant analysis (OPLS-DA) supervised modelling carried out on untargeted metabolomics profiles of lettuce (C) and tomato (D) plants after B and H application grown under control and salt stress (NaCl) condition.

Supplementary Figure 10 | Score plot of metabolomics profiles. Score plot orthogonal projection to latent structures discriminant analysis (OPLS-DA) supervised modelling carried out on untargeted metabolomics profiles of tomato and lettuce plants after B and H application grown under control (A) or salt stress (B) conditions.

Supplementary Figure 11 | Identified metabolites in control conditions. Metabolic processes (A), secondary metabolism (B), and hormone biosynthesis (C) were impaired by treatments in lettuce and tomato plants grown under control conditions. Differential metabolites (VIP score > 1.20) along with their fold-change (FC) values were elaborated using the Omic Viewer Dashboard of the PlantCyc pathway Tool software (www.pmn.plantcyc.com). The large dots represent the average (mean) of all log FC for metabolites, and the small dots represent the individual log FC for each metabolite. The x-axis represents each set of subcategories, while the y-axis corresponds to the cumulative log FC. FA/Lipid: fatty acids and lipids, Amine: amines and polyamines, Cofactor: cofactors, prosthetic groups, electron carriers, and vitamins, N-containing: Nitrogen-containing secondary metabolites, S-containing: Sulphur-containing secondary metabolites, Sugar Derives: sugar derivatives.

Supplementary Figure 12 | Identified metabolites in plant under salt stress conditions. Metabolic processes (A), secondary metabolism (B), and hormone biosynthesis (C) were impaired by treatments in lettuce and tomato plants grown under salt stress conditions. Differential metabolites (VIP score > 1.20) along with their fold-change (FC) values were elaborated using the Omic Viewer Dashboard of the PlantCyc pathway Tool software (<https://plantcyc.org/>). The large dots represent the average (mean) of all log FC for metabolites, and the small dots represent the individual log FC for each metabolite. The x-axis represents each set of subcategories, while the y-axis corresponds to the cumulative log FC. FA/Lipid: fatty acids and lipids, Amine: amines and polyamines, Cofactor: cofactors, prosthetic groups, electron carriers, and vitamins, N-containing: Nitrogen-containing secondary metabolites, S-containing: Sulphur-containing secondary metabolites, and Sugar Derivs: sugar derivatives.

Supplementary Figure 13 | Graphical output of co-Inertia analysis (CIA). Scatter plot of tomato (A) and lettuce (B) samples. Each sample is represented by an arrow whose length is proportional to the divergence between the phenomic and the metabolomic datasets. Eigenvalues of the co-inertia analysis for tomato (C) and lettuce (D). Correlation circles (E,F) showing the projections of the PCA axes (from the phenomic datasets) onto the axes of the co-inertia analysis (x axes) and projections of the PCA axes (from the metabolomic datasets) onto the axes of the co-inertia analysis (y axes). These four circles represent a view of the rotations needed to associate the two datasets for tomato (E) and the two datasets for lettuce (F).

Supplementary Table 1 | Pairwise comparisons test using mixed models for determining the significant differences between the means of the morphological parameters in lettuce (1st round, A, 2nd round, B) and tomato (C) plants treated with 7 PHs grown under control or salt stress conditions at different time points. The p -values below 0.05 are highlighted in green.

Supplementary Table 2 | Pairwise comparisons test using mixed models for determining the significant differences between the means of the photosynthetic parameters in lettuce (1st round, A, 2nd round, B) and tomato (C) plants treated with 7 PHs grown under control or salt stress conditions at different time points. The p -values below 0.05 are highlighted in green.

Supplementary Table 3 | Pairwise comparisons test using mixed models for determining the significant differences between the means of the difference between the canopy and air temperature in lettuce (1st round, A, 2nd round, B) and tomato (C) plants treated with 7 PHs grown under control or salt stress conditions at different time points. The p -values below 0.05 are highlighted in green.

Supplementary Table 4 | Importance of variables for lettuce (A) and tomato (B) plants based on the random forest classifier used for treatment classification based on a mean decrease in classification accuracy measure.

Supplementary Table 5 | Whole dataset produced from untargeted metabolomics carried out in lettuce (A) and tomato (B) plants treated with 7 PHs grown under control or salt stress conditions. Compounds are presented with individual intensities and composite mass spectra.

Supplementary Table 6 | Discriminant metabolites identified by the variable importance in projection (VIP) analysis following OPLS-DA modelling of the metabolome in lettuce (A) and tomato (B) plants treated with 7 PHs grown under control or salt stress condition. Compounds were selected as discriminant by possessing a VIP score > 1.20 .

Supplementary Table 7 | Differential metabolites derived from Volcano analysis ($p < 0.01$, FC ≥ 1.3) in lettuce (A) and tomato (B) plants treated with PH B, and PH H grown under control or salt stress conditions.

Supplementary Table 8 | Discriminant metabolites identified by the variable importance in projection (VIP) analysis following OPLS-DA modelling of the metabolome of lettuce and tomato plants treated with PH H and PH B grown under control (A) or salt stress (B) conditions along with their LogFC values in comparison to control samples. Compounds were selected as discriminant by possessing a VIP score > 1.20 .

Supplementary Table 9 | Correlation matrix between the most important phenotyping traits (according to the random forest analysis) and the metabolites for lettuce (A) and tomato plants (B).

Arbuscular mycorrhizal fungi are promoted as biofertilizers due to potential benefits in crop productivity, and macro- and microelement uptake. However, crop response to arbuscular mycorrhizal fungi (AMF) inoculation is context-dependent, and AMF diversity and field establishment and persistence of inoculants can greatly contribute to variation in outcomes. This study was designed to test the hypotheses that multiple and local AMF inoculants could enhance alfalfa yield and fatty acids (FA) compared to exotic isolates either single or in the mixture. We aimed also to verify the persistence of inoculated AMF, and which component of the AMF communities was the major driver of plant traits. Therefore, a field experiment of AMF inoculation of alfalfa (*Medicago sativa* L.) with three single foreign isolates, a mixture of the foreign isolates (FMix), and a highly diverse mixture of local AMF (LMix) was set up. We showed that AMF improved alfalfa yield (+ 68%), nutrient (+ 147% N content and + 182% P content in forage), and FA content (+ 105%). These positive effects persisted for at least 2 years post-inoculation and were associated with enhanced AMF abundance in roots. Consortia of AMF strains acted in synergy, and the mixture of foreign AMF isolates provided greater benefits compared to local consortia (+ 20% forage yield, + 36% forage N content, + 18% forage P content, + 20% total FA in forage). Foreign strains of *Funnelliformis mosseae* and *Rhizophagus irregularis* persisted in the roots of alfalfa 2 years following inoculation, either as single inoculum or as a component of the mixture. Among inoculants, *F. mosseae* BEG12 and AZ225C and the FMix exerted a higher impact on the local AMF community compared with LMix and *R. irregularis* BEG141. Finally, the stimulation of the proliferation of a single-taxon (*R. irregularis* cluster1) induced by all inoculants was the main determinant of the host benefits. Crop productivity and quality as well as field persistence of inoculated AMF support the use of mixtures of foreign AMF. On the other hand, local mixtures showed a lower impact on native AMF. These results pave the way for extending the study on the effect of AMF mixtures for the production of high-quality forage for the animal diet.

Keywords: biofertilization, *Funnelliformis mosseae*, *Rhizophagus irregularis*, microbial consortia, crop yield and quality, local and foreign AM fungal inocula, fatty acids (FAs)

INTRODUCTION

The management of soil biota is considered a key strategy to maintain and improve ecological services in agro-ecosystems (De Vries et al., 2013; Toju et al., 2018). The plant symbiotic arbuscular mycorrhizal fungi (AMF) support plant growth, productivity, and soil fertility (e.g., Smith and Read, 2008; Gianinazzi et al., 2010). However, the evidence of crop benefits following field application of fungal inoculum suggests that intensive agricultural practices, such as frequent and deep tillage, high P or N fertilizer rate, long fallow, and continuous cropping, have a negative impact on AMF abundance in soil (e.g., Jasper et al., 1989; Lekberg and Koide, 2005; Roldan et al., 2007; Duan et al., 2010; Higo et al., 2013; Sheng et al., 2013; van der Heyde et al., 2017). In the European Union (EU), AMF are cataloged as plant biostimulants according to the new Regulation (EU) 2019/1009, based on the functions of stimulating plant nutrition processes and tolerance to abiotic stresses and improving the quality of the agricultural product (EU, 2019). AMF represent an important segment of the global biostimulant market, estimated in 2018 at about \$ 2.0 billion (Rouphael and Colla, 2018). Despite the huge commercial interest in microbial and non-microbial plant biostimulants, associated with a growing body of research, the detailed molecular, cellular, and physiological mechanisms underlying plant-biostimulant interactions under different environments and management strategies remain largely unknown. Therefore, there is an urgent need to better elucidate the causal/functional mechanisms of biostimulants and their potential side-effects on the environment (e.g., invasiveness and threat to soil and plant biodiversity and ecosystem functioning, Hart et al., 2017).

In addition to the enhanced crop productivity (Lekberg and Koide, 2005; Pellegrino et al., 2011, 2015a; Pellegrino and Bedini, 2014), arbuscular mycorrhizal (AM) fungal addition through field inoculation can increase macro- and microelement content (Karandashov and Bucher, 2005; Veresoglou et al., 2012; Lehmann et al., 2014; Lehmann and Rillig, 2015; Ercoli et al., 2017a; Coccina et al., 2019; Pellegrino et al., 2020a) and nutraceuticals (Baslam et al., 2013; Saleh et al., 2020). Lekberg and Koide (2005), applying a meta-analysis approach on experimental results from field and glasshouse trials, demonstrated a large increase of mycorrhizal colonization in inoculation trials, suggesting that low inoculum potential can limit mycorrhizal colonization. Furthermore, they also showed that yield or biomass positive response to increased mycorrhizal colonization is non-linear, as management practices, site and climate, inherent inoculum potential, available soil P concentrations, and interactions between plant and fungal species modulate the plant response to increased mycorrhizal colonization.

In addition to abundance, AM fungal diversity can also limit AM fungal-derived benefits if different AM fungal species or isolates provide complementary benefits to the host plant (van der Heijden et al., 1998a,b; Verbruggen et al., 2010, 2013). Some pot studies with sterilized soil inoculated by a common bacterial community and AMF inocula have shown that plant growth and nutrient uptake were more promoted by diverse inocula, composed of a mixture of AM fungal taxa belonging

to different species of the same family (Edathil et al., 1996; van der Heijden et al., 1998a,b) or to different families (Thonar et al., 2014; Crossay et al., 2019; Parvin et al., 2020), than single-species inocula. These results are supported by a meta-analysis of Hoeksema et al. (2010) in which AM fungal inoculum complexity (multispecies and whole soil inocula vs. single species inocula) was positively related to plant benefits. Conversely, other studies showed that pot inoculation with multiple AM fungal species could not outweigh single inoculants in terms of plant biomass response, while plant diversity and nutrient uptake [e.g., phosphorus (P) and nitrogen (N)] were even decreased (van der Heijden et al., 2003; Jansa et al., 2008). However, due to the different functional traits among AMF (Munkvold et al., 2004; Thonar et al., 2011; Treseder et al., 2018), and because the interactions among AMF are not always synergistic (Koide, 2000; Jansa et al., 2008), the effectiveness of AM fungal mixed inocula have to be evaluated in the field, where a local microbial community (including AMF and many other microbial groups) is present. However, when a crude inoculum is applied (composed of AM fungal spores, roots, and soil), the method utilized for the production of different isolates may include their associated microbial communities and metabolites that are likely to have an effect on the inoculation outcomes, thus representing a confounding effect (Bianciotto and Bonfante, 2002).

However, the effectiveness of AM fungal inocula should be confirmed by pieces of evidence of their establishment and persistence in the field. Attempts to directly track inoculants in the field are few due to the fact that morphological methods (i.e., staining and counting at the microscope) cannot be applied because many AM fungal species colonizing the same root are morphologically indistinguishable, while current molecular markers can hardly distinguish among closely related taxa and the detection of specific fungal species isolates remains challenging in the field (Hart et al., 2015). An earlier study, based on the amplification of ca. 2,200-bp-long central stretch of the nuclear rDNA cistron and the barcoding of SSU-ITS2-LSU sequences (550, 200, and 580 bp, respectively), successfully tracked the establishment and persistence of two isolates of *F. mosseae* (IMA1 = BEG12 and AZ22C) in alfalfa up to 2 years (Pellegrino et al., 2012). Similarly, other studies using different molecular targets and approaches [e.g., the LSU of ribosomal RNA gene or the mitochondrial LSU DNA (mtLSU) and cloning and sequencing; a fragment of the RNA polymerase II gene (RPB1) and qPCR; mt cox3-rnl intergenic mtDNA region, and droplet digital PCR] could detect root establishment and persistence of some AM fungal isolates in field-inoculated crops up to 3 years (Farmer et al., 2007; Sýkorová et al., 2012; Thioye et al., 2019).

Alfalfa (*Medicago sativa* L.) is a perennial herbaceous legume and one of the most important forage crops in the world due to its high feeding value and yield potential (Radović et al., 2009). Moreover, alfalfa supports important functions in sustaining agricultural systems, such as diversification of crop rotations, conserving soil water, improving soil structure by the development of a large root system, and increasing soil fertility through biological N fixation (Carlsson and Huss-Danell, 2003; Hakl et al., 2017; Sun and Li, 2019). Alfalfa's global cultivation area exceeds 35 million ha (Radović et al., 2009) with an

estimated world production of around 436 million tons in 2006 (FAO, 2006). Alfalfa contains a high quantity of macro- and microelements, and a high amount of fatty acids (FA), such as linoleic acid (C18:2) and the α -linolenic acid (C18:3) (Boufaïed et al., 2003) that are fundamental for animal health (Radović et al., 2009). The composition of fats from food animals is a major human health concern, and particularly important is the content of total polyunsaturated FA (Σ PUFA), α -linolenic acid (ALA, 18:3), and linoleic acid (LA, 18:2), ALA, and LA belonging to the n-3 (omega-3) and n-6 (omega-6) fatty acid family, respectively (Calviello and Serini, 2010). An increase of PUFAs and conjugated linoleic acids (CLA), such as ALA and LA in the human diet, has been shown to reduce the risk of cardiovascular disease, diabetes, cancers, and obesity (Pariza et al., 2001). Since animals cannot synthesize ALA or LA *de novo*, their content in forage plants, among which alfalfa is one of the main sources, is of primary importance in producing beef and milk with high levels of omega-3 FA and CLA (Dhiman et al., 1999; French et al., 2000; Scollan et al., 2001; Pintus et al., 2013).

To our knowledge, no information is available about the role played by AMF in plant FA synthesis, despite the fact that C in the mycorrhizal roots, received by the host plant in the form of monosaccharides, is stored primarily as lipids and many of the genes induced in mycorrhizal roots are predicted to function in lipid metabolism (Rich et al., 2017; Roth and Paszkowski, 2017). This study was designed to test the following multiple hypotheses: (i) alfalfa yield and quality is limited by AM fungal diversity and multiple AM fungal inoculants could act in synergy to promote crop growth and FA concentration; (ii) environmental pressure could select for highly efficient AM fungi and therefore a mixture of native AM fungal isolates could provide greater benefits compared to an exotic mixture. Finally, we aimed to verify the persistence of inoculated AMF in the field, and which component of the AM fungal communities found in the plots was the major driver of plant traits. To these aims, a field experiment of AM fungal inoculation of alfalfa with single foreign isolates, a mixture of the foreign isolates, and a highly diverse mixture of local AMF was set up and plants and fungal traits were assessed for 2 years, together with the molecular assessment of inoculum persistence and native AM fungal communities.

MATERIALS AND METHODS

Fungal Material

The experiment compared five AM fungal inoculum treatments: (1) *Funneliformis mosseae* BEG 12, (2) *Funneliformis mosseae* AZ225C, (3) *Rhizophagus irregularis* BEG141, (4) a mixture of the above foreign isolates (Fmix) and (5) a mixture of local strains of AMF (Lmix). The Lmix was isolated from an alfalfa soil located in Manciano and was composed by *Funneliformis coronatum*, *Funneliformis geosporum*, *Funneliformis mosseae*, *Rhizophagus clarus*, *Rhizophagus irregularis*, *Glomus* sp., *septoglomus viscosum*, *Claroideoglomus etunicatum*, *Diversispora spurca*, *Acaulospora rugosa*, *Acaulospora cavernata*, *Acaulospora spinosa*, *Scutellospora aurigloba* and *Scutellospora calospora* (14 AM fungal species belonging to five families) (Pellegrino et al., 2020b). The

foreign AMF isolates were obtained from the collection of the Scuola Superiore Sant'Anna, Italy. Details about the geographical origin, collector, and original inoculum supplier are given in **Supplementary Table 1**.

The inocula of single foreign AM fungal isolates (BEG12, AZ225C, BEG141) were produced in 15 L pots (four pots for treatment). Each pot was filled with sandy soil and Terragreen (1:1 by volume) and 1.5 L of starting crude inoculum. The substrate was previously steam-sterilized (121°C for 25 min, on two consecutive days) to kill native AMF. The Fmix was obtained at the end of inoculum production, by mixing equal quantities of the foreign AMF isolates. The Lmix was produced in 15 L pots (four pots), by adding 1.5 L soil of the experimental site to 13.5 L of the substrate. Additional four 15 L-pots were set up for the inoculation of control plots, by mixing equal quantities of sterilized single foreign AM fungal inocula and soil from the experimental site (a total of 1.5 L) to 13.5 L of the substrate (mock inoculum). Sudan grass (*Sorghum sudanense* L.) was used as a host plant (10 plants per pot). All pots received 1.5 L of a deionized water filtrate from the single foreign AM fungal inocula, and from the soil of the experimental site. Although the amount of microbial filtrate used at the start of the propagation was very large to minimize the differences among AM fungal inoculants, we cannot exclude that the differences in socialization among AM fungal isolates and microbes could lead to the end of the production phase to distinct microbial communities in the inoculants. Pots were irrigated with tap water and supplied with half-strength Hoagland's solution every month (1.5 L per pot). After the 3-month growth, Sudan grass was harvested, and soil and roots were removed from the pots and air-dried. Then, the roots were cut, mixed with the soil, and stored in polyethylene bags at 4°C, until field inoculation. The AM fungal treatments were thus composed of AMF, microbes, soil, and roots, while the control was only composed of microbes, soil, and roots.

Experimental Site and Climatic Data

The experiment was carried out at Manciano (Grosseto), Italy (47° 16' 36.5" N–70° 14' 53" E; 447 m above sea level). Main soil physical and chemical properties were: 322.9 g kg⁻¹ sand, 308.5 g kg⁻¹ silt, 368.6 g kg⁻¹ clay (hydrometric method; Gee and Bauder, 1986); 7.1 pH (deionized H₂O 1:2.5 w/v); 28.7 g kg⁻¹ organic matter (Walkley–Black wet combustion method; Nelson and Sommers, 1982); 1.47 g kg⁻¹ total N (Kjeldahl digestion; Bremner and Mulvaney, 1982); 0.84 g kg⁻¹ total P (colorimetry using perchloric acid digestion; Olsen and Sommers, 1982); 8.3 mg kg⁻¹ available P (colorimetry using a solution of sodium bicarbonate; Olsen and Sommers, 1982); 163.2 mg kg⁻¹ exchangeable K (Thomas, 1982); 30.1 meq 100 g⁻¹ Cation Exchange Capacity (displacement with 0.1 M BaCl₂ triethanolamine, Hendershot and Duquette, 1986). The soil of the area is a *Haplic Calcisol*, according to the FAO classification system (IUSS, 2015), and an *Inceptisol*, according to the USDA classification (Soil Survey Staff, 1999). The climate of the site is cold, humid Mediterranean (Csa) according to the Köppen–Geiger climate classification (Kottek et al., 2006). Mean annual maximum and minimum air temperatures averaged over 1996–2015 are 20.2 and 9.3°C, respectively, and

annual precipitation was 769 mm (Vallebona et al., 2015). During the field experiment (November 2011–August 2013), maximum and minimum temperatures were 19.3 and 9°C, respectively, while total precipitation was 1,730 mm and had a peak of 207 mm during the 3rd decade of November 2012 (Supplementary Figure 1).

Field Experiment Setup

A 2-year field AMF inoculation experiment was set up with alfalfa (*Medicago sativa* L., var. Giulia) as the host crop. Conventional tillage was performed at the beginning of September 2011 and consisted of moldboard plowing (30 cm depth), disking twice (15 cm depth), and harrowing (20 cm depth) (Ercoli et al., 2017b). Plots of 25 m² size (5 m × 5 m) were designed within the field and hand inoculated with 0.4 kg m⁻² of inoculum, incorporated into the soil by hand hoeing at ca. 10 cm depth (19 October 2011). The mean number of spores/sporocarps per g of inoculum ranged from 10 to 25, corresponding to 4,000–10,000 spores/sporocarps per m². The plots were hand-seeded on 20 October 2011 with 5 g m⁻² of alfalfa seeds. The preceding crop was barley. Neither chemical fertilization nor chemical nor mechanical weed control was applied. Alfalfa was cut when regrowth at the crown was initiated, on June 20 and August 6, 2012 and on 17 June and 18 August 2013. The experiment design was a nested split-plot with three replicates. The main plot factor was the age of cultivation (first and second year), the sub-plot factor was the AMF inoculation (BEG12, AZ225C, BEG141, Fmix, Lmix, and mock inoculum as control), and the cut was a nested factor within the year of cultivation.

Sampling and Measurements

One month after crop emergence (December 2011), and at the beginning of spring growth in the two following years (2012 and 2013), six alfalfa plants from each replicated plot were sampled and AMF root colonization was assessed under a stereomicroscope (Olympus SZX 9, Olympus Optics, Tokyo, Japan), after clearing and staining with lactic acid instead of phenol (Phillips and Hayman, 1970), following the gridline intersect method (McGonigle et al., 1990). In both years and for both cuts, alfalfa shoots were harvested from one square meter for each replicated plot. A subsample of shoots was partitioned into stems and leaves, and dry weight was determined after oven drying at 75°C. Shoot N and P concentrations were determined by the Kjeldahl method and by the ammonium-molybdophosphoric blue color method, respectively (Jones et al., 1991). Protein concentration was calculated by multiplying the shoot N concentration × 6.25 (Lynch and Barbano, 1999). At the first cut of each year of cultivation, a root sample was extracted from the soil (about 100 g fresh weight) and assessed for AMF colonization applying the previously described procedure.

Fatty acids of alfalfa shoots from both cuts in the 2 years were extracted and methylated by a one-step procedure using toluene as solvent (Sukhija and Palmquist, 1988). Methyl nonadecanoate was used as an internal standard. Fatty acid methyl esters were quantified by gas chromatography using an HP 5890 chromatography (Hewlett Packard Co., Palo Alto, CA, United States), under the following conditions: 60-m × 0.32-mm

DB-23 capillary column, 0.25 µm film thickness, H₂ as a carrier gas, 2.8 cm³ min⁻¹ volumetric flow rate, injector split 1/100 at 240°C, septum purge vent at 2 ml min⁻¹, flame ionization detector at 250°C, and 15 kPa of heat pressure. The initial temperature was 150°C, which was increased by 5°C min⁻¹ up to 200°C. Fatty acid methyl esters in toluene were directly injected through the split injection port. The peak area of Fas was measured using a Turbochrom 3 analytical system (version 3.3; PE Nelson, Cupertino, CA, United States). Each peak was identified and quantified using pure methyl ester standards (Alltech, Deerfield, IL, United States). Total volatile fatty acids were calculated.

Extraction of Genomic DNA, PCR Amplification, Cloning, and Sequencing of Arbuscular Mycorrhizal Fungi Inoculants

In a further experiment, DNA was extracted from 50 spores of the foreign *F. mosseae* isolates BEG12 and AZ225C, from 20 spore clusters (ca. 25 spores each) of the foreign *R. irregularis* isolate BEG141 and from the roots of Sudan grass host plants grown in pots for the production of Lmix inoculum. Spores were crushed in microtubes on ice and the DNA was extracted using 50 µl of extraction buffer (100 mM Tris-HCl, 100 mM NaCl, 2 mM MgCl₂, and 2% Triton-X100, pH 8). Genomic DNA was extracted from a subsample of 100-mg fresh weight of roots collected from the Sudan grass pots (four replicates), using the Dneasy® Plant Mini Kit (Qiagen, Germantown, MD, United States). PCR amplification was performed using the primer pair NS31 and LSUGlom1, targeting a portion of the small subunit ribosomal RNA (SSU rRNA 18S) gene, the internal transcribed spacer (ITS1), the 5.8S, the ITS2, and a portion of the LSU rRNA gene (Pellegrino et al., 2012). The NS31/LSUGlom1 PCR amplicons were generated in volumes of 20 µl with 0.5 U of HotStarTaq DNA Polymerase (Qiagen, Germantown, MD, United States), 10 µM of each primer (NS31 /LSUGlom1), 0.2 mM of each dNTP, 1 mM of MgCl₂, and 1 × reaction buffer, using a touchdown thermal cycling on an S1000 Thermal Cycler™ (BIO-RAD, Hercules, CA, United States). The temperature profile was as follows: denaturation and enzyme activation at 95°C for 15 min, 20 cycles with denaturation at 95°C for 30 s, primer annealing for 1 min starting at 62°C and decreasing by 0.5°C per cycle to 52°C, extension at 72°C for 135 s and 20 cycles with denaturation at 95°C for 30 s, primer annealing at 52°C for 1 min, extension at 72°C for 135 s, and a final extension at 72°C for 10 min. The QIAquick (Qiagen, Germantown, MD, United States) purified PCR amplicons of DNA from the spore samples and the Wizard®SV (Promega Corporation, Madison, WA, United States) gel-purified amplicons of DNA from the root samples were ligated into the pGem®-T Easy vector (Promega, Corporation, Madison, WA, United States) to transform XL10-Gold® Ultracompetent *Escherichia coli* cells (Agilent Technologies, Milano, Italy). On average, sixty-five recombinant clones per amplicon library were screened for the ca. 2,200-bp-long NS31-Glom1 fragment on agarose gels [2% ultrapure agarose (VWR) stained with 0.5 µg ml⁻¹ ethidium

bromide]. The variable SSU, ITS2, and LSU fragments of the vector inserts (2.2 kb long) were sequenced from plasmids, using the GenElute™ Plasmid Miniprep Kit (Sigma-Aldrich, St Louis, MO, United States). Sequencing reactions were set up with the vector primers SP6 and T7 using the 3730XL Genetic Analyser automated sequencer (Life Technologies, Carlsbad, CA, United States) at the DNA Services of the University of Illinois in Chicago, United States.

Molecular Tracing of Arbuscular Mycorrhizal Fungi Inoculants in Roots of *M. sativa* Plants

At the onset of spring growth in 2013 (on the 2-year crop), 100 mg of fresh roots were collected from each replicate plot, and genomic DNA was extracted and amplified using NS31/LSUGlom1 primers, as described above. After screening on agarose, on average seventy recombinant clones were sequenced as described above. Plasmids (1184) were sequenced and phylogenetically identified targeting *F. mosseae* and *R. irregularis*, and other Glomeromycota taxa.

Statistical Analysis

All results except for AM fungal root colonization were analyzed by a three-way ANOVA using a general mixed model including crop age (Age), AM fungal inoculant (Inoc), and cut (Cut) as fixed factors. Given our experimental design, the effect of the year of growth is completely confounded with the crop age and thus it was not possible to discriminate the effect of climatic conditions from the effect of crop age. Plots-within-replicates were included as a random factor to account for grouping factors and repeated measures in the same plots (Onofri et al., 2016). AM fungal root colonization was analyzed by a two-way ANOVA using a general mixed model and including Inoc and crop stage (1 month, 1st year, and 2nd year) as fixed factors and plots-within-replicates as a random factor. The relative abundances of AM fungal phylotypes (native *F. mosseae* and *R. irregularis*, and other Glomeromycota) in roots were analyzed by a one-way ANOVA to test the effect of Inoc. Data were ln or arcsine-transformed when needed to fulfill the assumptions of the ANOVA. *Post hoc* Tukey-B significant difference test was used for comparison among treatments. Finally, one-way ANOVA was performed to test the effect of inoculants on plant growth, N and P content of forage, and on single and total fatty acid content accumulated over cuts and years (data were transformed, when necessary, as described above). Differences between means were determined using orthogonal contrasts: inoculated (+ Myc) vs. control, single AM fungal isolates vs. mixture inoculants (Single vs. Mixture), and foreign vs. local AM fungal mixtures (Fmix vs. Lmix). The means given in tables and figures are for untransformed data. Analyses were performed using the SPSS software package version 21 (SPSS Inc., Chicago, IL, United States).

To understand the functional relationship between AM fungal community within the roots of alfalfa and plant performance, and which were the phylotypes mainly responsible for the measured plant traits, a two-step approach was utilized: (i) a multivariate descriptive analysis of the AM fungal community within the roots

of the 2-year crop, and a multivariate descriptive analysis of the corresponding plant traits; (2) a test of the relationships between the biological community (AMF) and plant traits matrices. Thus, firstly, a non-metric multidimensional scaling analysis (nMDS) was done on the Bray-Curtis similarity matrix calculated on the fourth-root AM fungal relative abundances of phylotypes retrieved within the roots of inoculated and not-inoculated 2-year alfalfa (Kruskal, 1964). Moreover, the principal component analysis (PCA) was performed on the Euclidian distance matrix calculated on the square root of the plant traits (plant growth, N and P concentration of forage, and fatty acid composition) (Abdi and Williams, 2010). Then, a RELATE analysis, based on Spearman rank and 999 permutations, allowed to test the significance of the relationship between the two matrices ($\rho = 1$ perfect relationship) (Clarke and Warwick, 2001), while the BEST analysis, based on BioEnv methods (all combinations), Spearman rank and 999 permutations. Allowed to find the best descriptor of such relationship (Clarke et al., 2008). Finally, the Distance-based linear method (DistLM) analysis using a stepwise selection and the Akaike's information criterion (AICc) was applied to measure the significance and the variance explained by the best descriptor/s (Knorr et al., 2000), and the Distance-based redundancy analysis was used to plot the first and second axes of the DistLM (Legendre and Anderson, 1999). Analyses were performed using PRIMER 7 and PERMANOVA + software (Primer-e, Auckland, New Zealand) (Anderson et al., 2008; Clarke and Gorley, 2015).

Phylogenetic Analysis

The Glomeromycota affiliation of the sequences was verified in similarity searches using the Basic Local Alignment Search Tool (BLAST) in the National Center for Biotechnology Information (NCBI) database. No chimeric sequences were detected among the newly generated AM fungal SSU and ITS2-LSU sequences (1,324 sequences for each fragment). Here, 20 and 24 newly generated partial SSU (ca. 550 bp), ITS2 (ca. 165 bp) and LSU (ca. 400 bp) sequences of the isolates *F. mosseae* BEG12 and AZ225C, and 39 sequences of the native *F. mosseae* were aligned together with 17 public sequences of isolate BEG12 of *F. mosseae*, one sequence of the isolate *Funnelformis caledonium* BEG20, and one sequence of the isolate *Funnelformis geosporum* BEG11 using MAFFT online service (MAFFT version 7¹; Kuraku et al., 2013; Katoh et al., 2019). Moreover, 17 newly generated partial SSU (ca. 720 bp), 5.8S and ITS2 (ca. 430 bp), and LSU (ca. 365 bp) sequences of the isolate *R. irregularis* BEG141, and 40 sequences of the native *R. irregularis* were aligned together with five sequences of the isolate *R. irregularis* DAOM181602, three sequences of the isolate *R. irregularis* MUCL43194/DAOM197198, four sequences of the isolate *R. irregularis* DAOM229456, and two sequences of the isolate *R. irregularis* MUCL41833, and one sequence of the isolate *R. intraradices* FL208. The multiple alignments were separately computed for the SSU and ITS2-LSU fragments and then concatenated using SEAVIEW² (Gouy et al., 2010). Two

¹<https://mafft.cbrc.jp/alignment/server/large.html>

²<http://doua.prabi.fr/software/seaview>

phylogenetic trees (*F. mosseae* and *R. irregularis* trees) were built by neighbor-joining (NJ) analysis using built-in MEGA11³ (Tamura et al., 2021) and the Kimura 2-parameter model (Kimura, 1980). Branch support values correspond to 1,000 bootstrap replicates. The phylograms were drawn by MEGA 11 and edited by Adobe Illustrator 2021. Then, after having validated the DNA marker for the molecular discrimination among the foreign isolates of *F. mosseae* (12 and AZ225C) and *R. irregularis* (BEG141) and the native phylotypes of *F. mosseae* and *R. irregularis*, two further multiple sequence alignments were derived, including 478 and 332 newly generated sequences of *F. mosseae* and *R. irregularis*, respectively, derived from the roots sampled in the 2-year crop. Phylogenetic discrimination of non-native AM fungal strains relied on branch support of $\geq 70\%$. This approach of sequence analysis enabled to discriminate native from inoculated non-native strains through molecular barcoding and the phylogenetic divergence. The relative abundances of AM fungal intraradical communities (*F. mosseae* BEG12, AZ225C, BE141, native *F. mosseae*, native *R. irregularis*, and other Glomeromycota taxa) were calculated based on the ratio between the number of sequences affiliated to each phylotype and the total number of sequences of the clone library of each sample, and one-way ANOVA was performed to test the effect of inoculants and the *Post hoc* Tukey-B test was used for comparison among treatments. Cluster/Similarity Profile (SIMPROF) analyses were used to group the different samples into clusters based on their similarity/homogeneity of AM fungal intraradical communities (relative abundances of phylotypes) and to group the different phylotypes based on their similarity of occurrence. Relative abundance data were initially $\log(X + 1)$ transformed (Clarke and Warwick, 2001) and the Bray-Curtis similarity was calculated. The SIMPROF cluster analysis was performed to objectively define the groups within the dendrogram. Moreover, the relative abundances of the AM fungal phylotypes were represented by a shaded plot. The analyses were performed using PRIMER 7 and PERMANOVA + software (Primer-e, Auckland, New Zealand) (Anderson et al., 2008; Clarke and Gorley, 2015). All new sequences were uploaded in NCBI⁴ and are available under the submission numbers SUB10633042 (OL412293-OL412393) and SUB10648656 (OL441688-OL441757) for the SSU of *F. mosseae* and *R. irregularis*, respectively; SUB10638254 (OL435161-OL435261) for the ITS2 of *F. mosseae*; SUB10649136 (OL449343-OL449412) for the 5.8S-ITS2 of *R. irregularis*; SUB10638603 (OL422707-OL422807) and SUB10649570 (OL442685-OL442754) for the LSU of *F. mosseae* and *R. irregularis*, respectively.

RESULTS

Arbuscular Mycorrhizal Fungal Root Colonization

Arbuscular mycorrhizal (AM) fungal root colonization was influenced by the interaction of AM fungal inoculant and crop

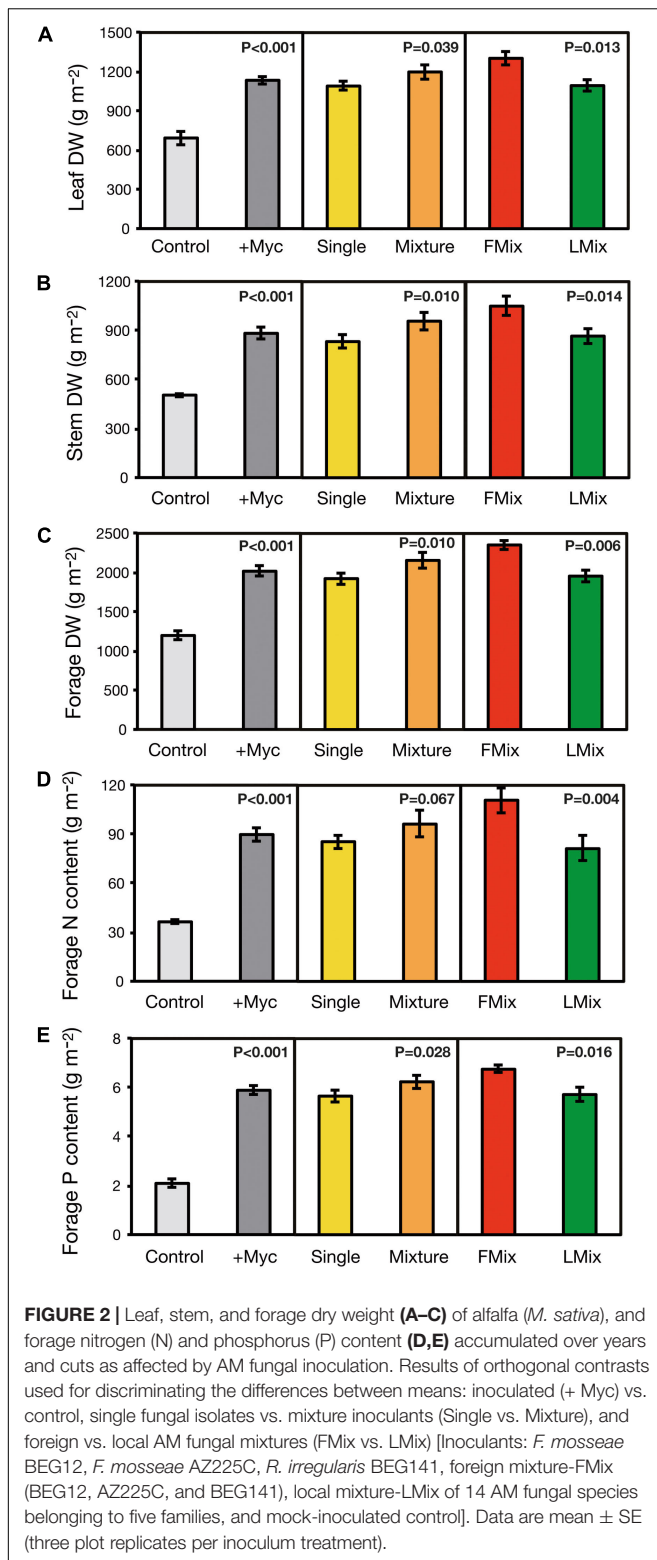

stage (Supplementary Table 2). Over time and with crop aging, root colonization increased with all treatments, but the rate of increase differed among control and inoculants (Figure 1). One month after seeding, AM fungal root colonization was higher with all inoculants compared with uninoculated control, ranging from 22% for BEG141 to 34% for Fmix. However, differences among inoculants were statistically not significant. Functional root nodules were observed in all plant samples without differences among treatments (data not shown). Similarly, at the beginning of the spring growth of the first year, root colonization was higher with all inoculants compared with the uninoculated control, and the range of variation among inoculants was small (from 37% for BEG141 to 41% for Fmix). At the onset of the spring growth of the second year, root colonization increased in the uninoculated control compared with the previous year, although the difference was statistically not significant. AM fungal root colonization in the 2-year plants did not further increase with all inoculants. At this crop stage, differences in root colonization among inoculation treatments were small (36–41%) and statistically not significant. Averaged over inoculants, root colonization was 30, 39, and 39% 1 month after seeding, at the onset of the spring growth of the first year and of the second year, respectively.

Plant Growth, Forage Yield, and N and P Content

Leaf DW accumulated over years and cuts was increased by 64% by inoculation and was 99% higher with inoculum mixture (Fmix and Lmix) compared with single inoculants (BEG12, AZ225C, BEG141), and 19% higher with Fmix than Lmix (Figure 2A). Calculating the quantity of stem DW accumulated over years and cuts, it is evident that it was increased by 75% by inoculation, and it was 15% higher with inoculum mixture compared with single inoculants, and 21% higher with Fmix than Lmix (Figure 2B). Forage DW accumulated over years and cuts was increased by 68% by inoculation, it was 12% higher with inoculum mixtures compared with single inoculants and was 20% higher with

³<https://www.megasoftware.net>

⁴<https://submit.ncbi.nlm.nih.gov>

FMix than LMix (Figure 2C). Forage N content accumulated over years and cuts was increased by 147% by inoculation, was unchanged when treated with inoculum mixture compared with single inoculants, and was 36% higher with FMix than with LMix

(Figure 2D). Forage P content accumulated over years and cuts was increased by 182% by inoculation, was 10% higher with inoculum mixture compared with single inoculants, and 18% higher with FMix than with LMix (Figure 2E). Details about plant growth, forage yield, and N and P content across years and cuts are given in **Supplementary Results** and **Supplementary Figures 2–4**.

Fatty Acid Profile

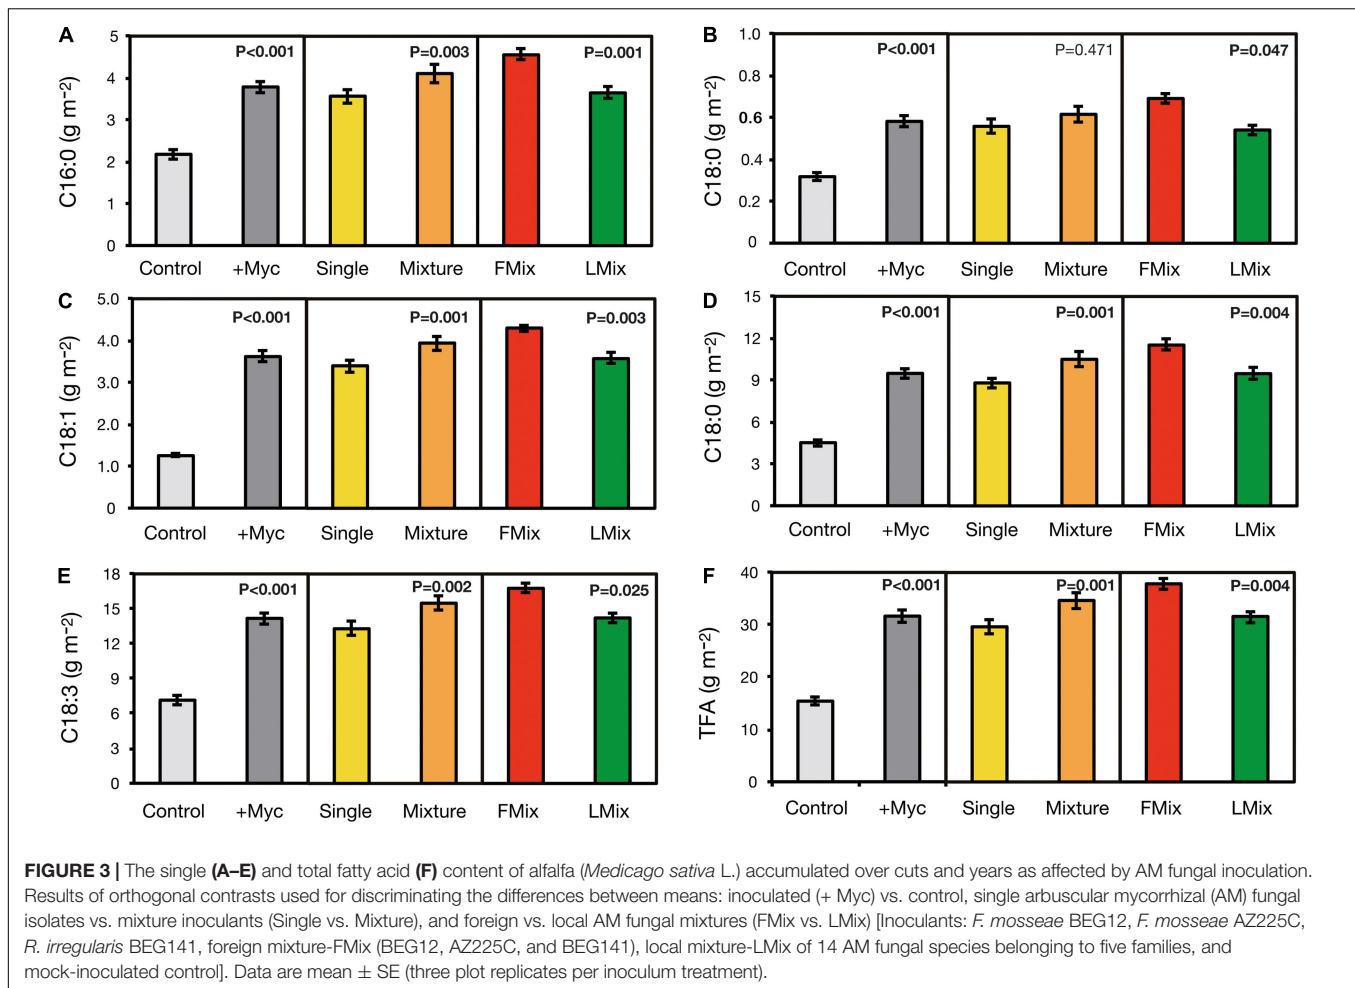

Arbuscular mycorrhizal (AM) fungal inoculation significantly influenced the forage FA profile of alfalfa (Supplementary Table 4). While nearly all FA examined had significant interactions between inoculation and age and between inoculation and cut, these interactions tended to be small compared with the sources of variation of inoculation. Therefore, these interactions are only reported in **Supplementary Tables 5, 6**, while the effect of inoculation, being of primary interest, is here illustrated. Fatty acids 18:3 (α -linolenic acid, omega-3) and 18:2 (linoleic acid, omega-6) were the predominant ones, comprising from 44 to 47% and 29 to 31%, respectively, of the total FA concentration in all treatment combinations (Supplementary Table 5). Fatty acids 16:0 and 18:1 were similar to each other in concentration, i.e., comprising from 11 to 15% and from 7 to 12% of the total FA, respectively, in all treatment combinations. Finally, FA18:0 had the smallest fraction, accounting for 2–3% of the total FA analyzed.

Arbuscular mycorrhizal (AM) fungal inoculation increased the concentration of all FA in forage compared with control, except for 18:0, and the increases were fairly similar across crop ages and cuts (Supplementary Table 5). Moreover, TFA, averaged over crop age and cut, were increased by 24% compared with uninoculated control. When significant differences occurred among inoculants, FMix was the most effective in increasing FA concentration in alfalfa forage.

Fatty acids content in forage of all FA accumulated over years and cuts was increased by AM fungal inoculation, and increases ranged from 74 to 189% in 16:0 and 18:1, respectively (Figure 3). Moreover, the content of all FA, except 18:0, was higher with inoculum mixture compared with single inoculants, and the increase ranged from 10 to 19% in 18:0 and 18:2, respectively. Finally, the content of all FA was higher when plants were inoculated with FMix than with LMix, and the increase ranged from 18 to 28% in 18:3 and 18:0, respectively. Similarly, TFA content was increased by 105% following inoculation and was 17% greater when inoculation was performed with an inoculum mixture than with a single inoculant and 20% greater when a mixture of foreign inoculants was applied, compared with a local one.

Molecular Discrimination Among Non-native and Native *F. mosseae* and *R. irregularis*

The c. 2,200-bp-long central stretch of the nuclear rDNA cistron, obtained using the PCR primers NS31 and LSUGlom1, provided sufficient phylogenetic resolution to discriminate the inoculated isolates from native strains of *F. mosseae* and *R. irregularis*.

However, similarly to Pellegrino et al. (2012), in the case of *F. mosseae* BEG12 and AZ225C, the discrimination was possible using the concatenated sequences of the variable 3' end of the SSU rRNA gene (ca. 550 bp), ITS2 (ca. 165 bp), and the variable 5' end of the LSU (400) rRNA gene (Figure 4A and Supplementary Figure 5). In the case of *R. irregularis* BEG141, the discrimination was possible using longer concatenated sequences of the variable 3' end of the SSU rRNA gene (ca. 720), the 5.8S and ITS2 (ca. 430 bp), and LSU (ca. 365 bp) (Figure 4B and Supplementary Figure 6). The sequences (obtained from spores) of the inoculated *F. mosseae* BEG12 and AZ225C, and *R. irregularis* BEG141 clustered distinctly from those of the native strains of both AM fungal species, amplified from the roots of Sudan grass grown in pots for the production of the Lmix inoculum (Figure 4 and Supplementary Figures 5, 6). The partial sequences of the nuclear rDNA cistron of the *F. mosseae* BEG12 isolate clustered into two phylogenetic subclusters, whereas those of *F. mosseae* AZ225C and *R. irregularis* BEG141 both grouped into only one cluster.

Reference sequences of *F. mosseae* BEG12 from NCBI clustered together with the sequences two phylogenetic subclusters of the inoculated *F. mosseae* BEG12 maintained in cultivation since 2010 at the AM fungal bank of the Institute of

Life Science (Scuola Superiore Sant'Anna, Pisa, Italy) (Figure 4A and Supplementary Figure 5). Since no reference sequences of SSU and ITS2 were available for *R. irregularis*, BEG141 and only three sequences available for LSU were included in the alignment as input for the tree building of four different isolates of *R. irregularis* and one of *R. intraradices* (Figure 4B and Supplementary Figure 6). The sequences of *R. irregularis* MUCL43194/DAOM197198 grouped into a unique, well-supported cluster, as well as the sequences of *R. irregularis* MUCL41833. Conversely, the sequences of *R. irregularis* DAOM181602 were grouped into two distinct clusters, as well as those of DAOM229456. The sequences of the local strain of *F. mosseae* were grouped into one cluster, whereas those of *R. irregularis* were more divergent and grouped into nine distinct clusters (Figure 4 and Supplementary Figures 5, 6).

Tracing Non-native and Native Strains of *F. mosseae* and *R. irregularis* in the Field

Using the validated molecular markers, foreign and local strains of *F. mosseae* and *R. irregularis* were successfully traced within the roots of the polyannual forage crop alfalfa 2 years following inoculation. However, AZ225C was the most persistent both as

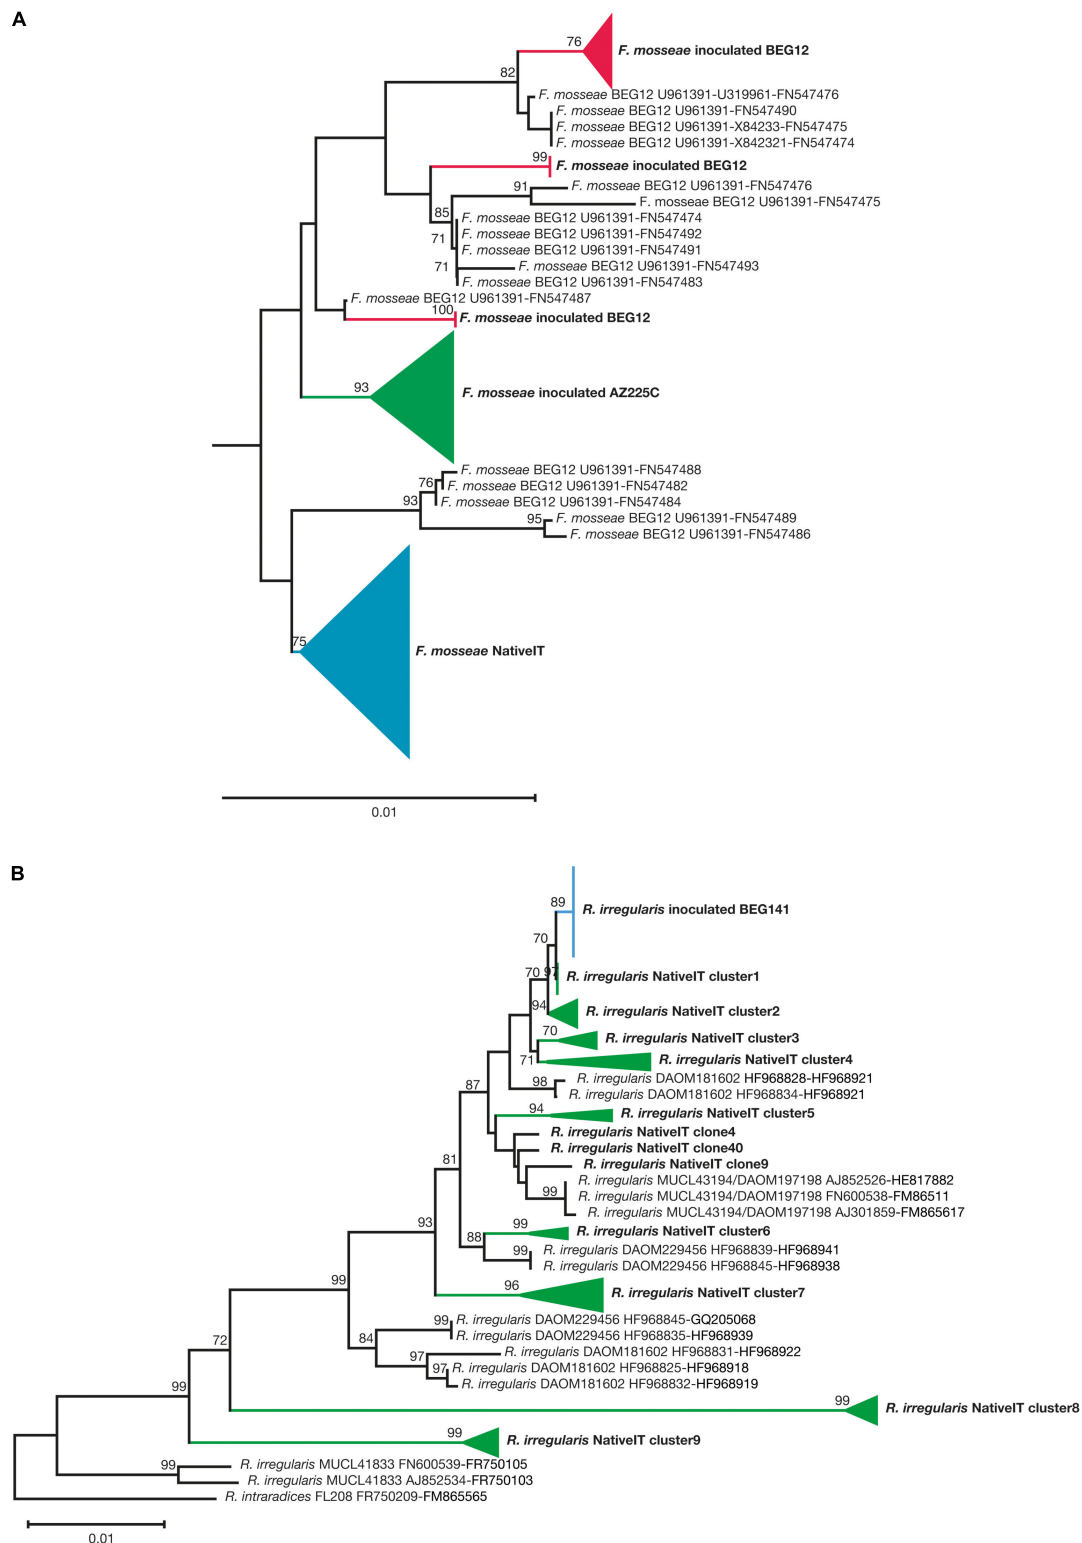

FIGURE 4 | Neighbor-joining (NJ) collapsed tree of the nuclear ribosomal rDNA sequences of *F. mosseae*, originating from local strains and the non-native inoculated isolates BEG12 and AZ225C (**A**). The tree is composed of 20 and 24 newly generated sequences of BEG12 and AZ225C, respectively, 39 native *F. mosseae* sequences, plus 17 sequences of BEG12 as reference. NJ collapsed tree of the nuclear ribosomal rDNA sequences of *R. irregularis*, originating from local strains and the non-native inoculated isolates BEG141 (**B**). The tree is composed of 17 newly generated sequences of BEG141 and 40 native *R. irregularis* sequences, plus 14 sequences of *R. irregularis* isolates as reference (DAOM181602, MUCL43194/DAOM197198, DAOM229456, and MUCL41833). The NJ *F. mosseae* tree is based (Continued)

FIGURE 4 | on concatenated sequences of the small subunit ribosomal RNA gene (SSU; ca. 550 bp), the internal transcribed spacer 2 (ITS2; ca. 165 bp) and the large subunit ribosomal RNA gene (LSU; ca. 400 bp). The NJ *R. irregularis* tree is based on concatenated sequences of the small subunit ribosomal RNA gene SSU (ca. 720 bp), 5.8S, and ITS2 (ca. 430 bp), and LSU (ca. 365 bp). Bootstrap values (based on 1,000 replicates) are shown at the nodes. The scale bar indicates substitutions per site. Clades formed by sequences of native and inoculated *F. mosseae* and *R. irregularis* strains are shown by colored branches and triangles. The concatenated sequences AJ245637-AJ239122-AJ5110241 of the isolate BEG11 of *Funneliformis geosporum* were used as an outgroup to root the *F. mosseae* tree, while the concatenated sequences FR750209-FM865565 of the isolate of *R. intraradices* FL208 were used as an outgroup to root the *R. irregularis* tree. The *F. mosseae* tree is outgroup-truncated. The newly generated sequences are highlighted in boldface, and their accession numbers are indicated in **Supplementary Figure 3**.

single inoculum or mixture, followed by BEG12 and BEG141 (**Supplementary Table 7**). This is also evidenced by the cluster analysis and the associated shade plot based on the AM fungal community found in the inoculated and control plots (**Figure 5**). Control replicates clustered together and separately from the inoculated plots, which were separated according to inoculation treatment, except for BEG141. Overall, local *F. mosseae* were similarly abundant to the other Glomeromycota taxa, but they were differently retrieved in the treated plots. In the BEG12 and AZ225C plots over 60% of the retrieved sequences were assigned to *F. mosseae* either inoculated or local, whereas in the BEG141 plots local *F. mosseae* accounted only for 7.4% (**Supplementary Table 7**). Comparing control and Lmix, local *F. mosseae* and other Glomeromycota taxa accounted for 44 and 37% of the total retrieved taxa in the control plots, while they accounted for 39 and 45%, respectively, in the Lmix plots. Finally, clusters 1–9 of local *R. irregularis* formed a unique group across the treated replicates, although clusters 5 and 6 were more abundant in the control, BEG12, and BEG141 plots.

These results are also supported by the NJ trees built focusing on *F. mosseae* and *R. irregularis* and by the relative abundance pie charts based on inoculum treatments (**Supplementary Figures 7, 8**). In detail, the NJ tree of *F. mosseae* clearly showed that the sequences retrieved in the alfalfa roots collected from the plots inoculated by BEG12, AZ225C, and Fmix clustered into three groups, phylogenetically affiliated to BEG12, AZ225C, and the local sequences of *F. mosseae*. Among these, 86% of the sequences affiliated to BEG12 were retrieved in the plots originally inoculated with this isolate, while the remaining were retrieved in the Fmix plots (14%) and no sequences were found in the other treatments. Similarly, 81% of the sequences affiliated to AZ225C were retrieved in the plots inoculated with AZ225C and 19% in the Fmix plots. Finally, the sequences phylogenetically affiliated to the native *F. mosseae* were retrieved in all the inoculated plots but were more abundant in the control plots, and their occurrence decreased progressively from Lmix (30%) to BEG141 (7%) (**Supplementary Figure 7**). As regard *R. irregularis*, the NJ tree showed that the sequences retrieved in the alfalfa roots collected from the treated plots were grouped into 10 clusters (**Supplementary Figure 8**), one cluster composed of sequences phylogenetically affiliated to BEG141 and the others composed by the sequences affiliated to the nine clusters of local *R. irregularis* strains initially found (**Figure 4B**). About 88% of the sequences affiliated to BEG141 were retrieved in the plots originally inoculated with this isolate, while the remaining were retrieved in the Fmix plots (12%) and no sequences were found in the other treatments. Regarding local *R. irregularis* clusters, the relative abundance of clusters 1, 4, and 6 differed among

treatments, while the abundances of the others did not change (**Supplementary Figure 8**).

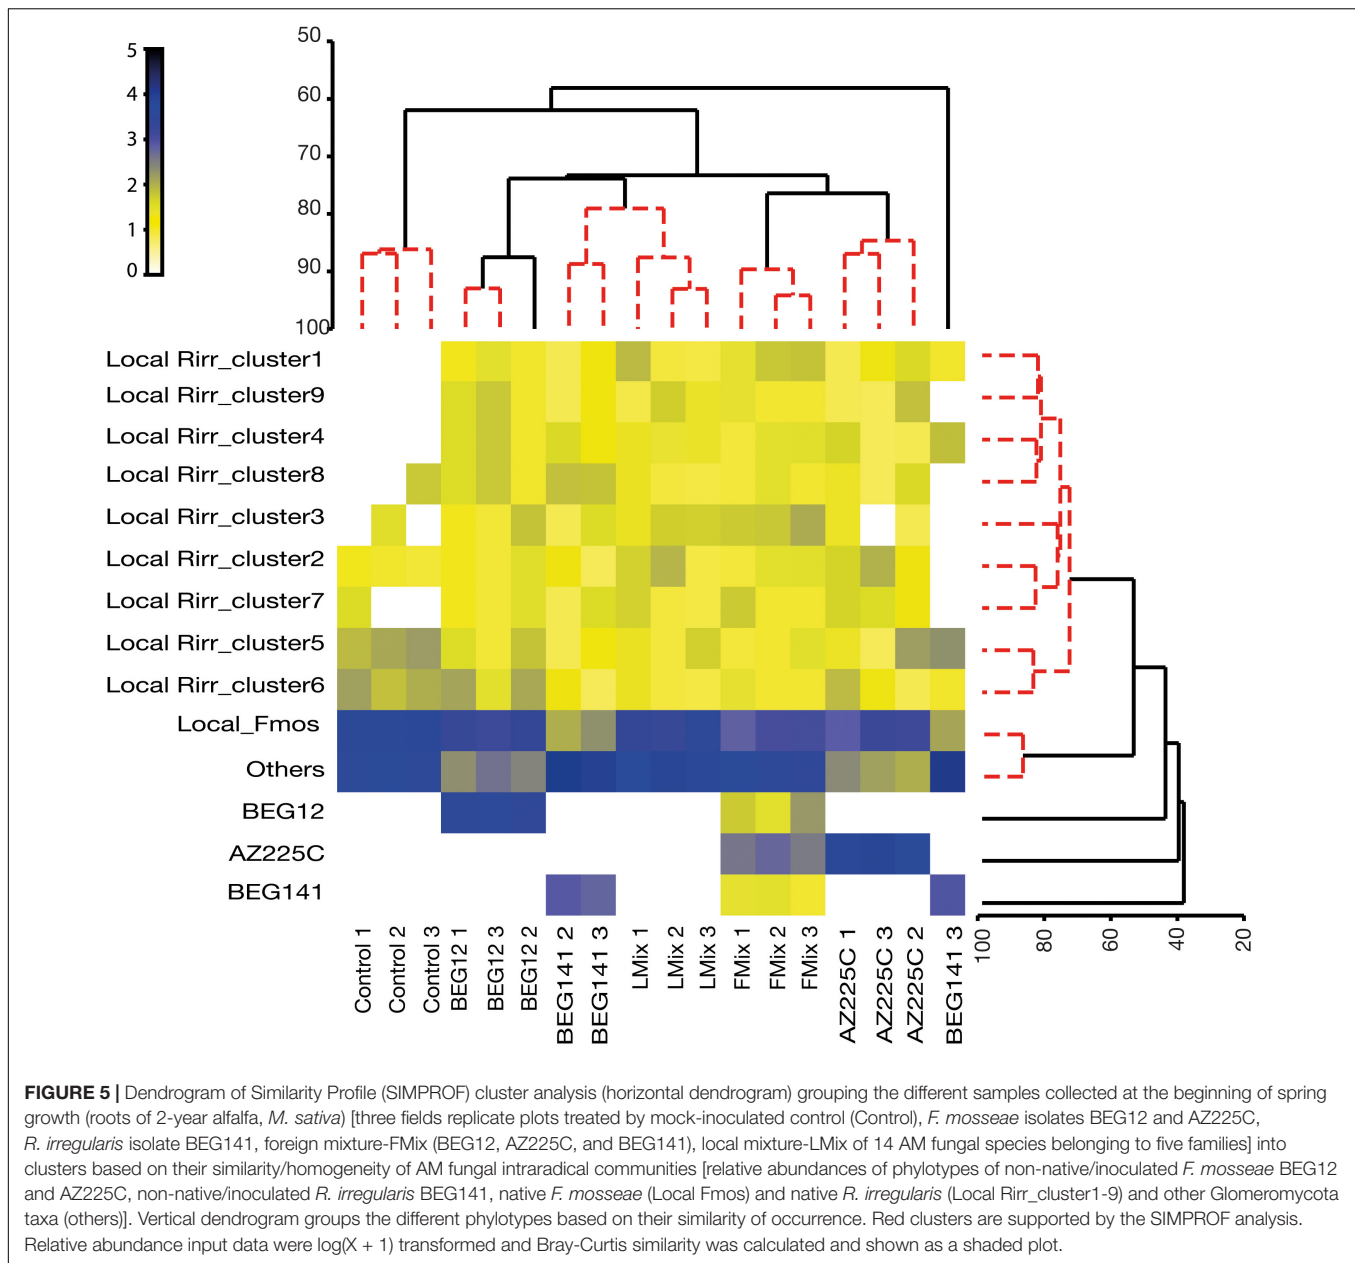

Exploring the Relationship Between the Components of Arbuscular Mycorrhizal Fungal Communities in Alfalfa Roots and Plant Traits

In the nMDS plot, representing the AM fungal communities within the roots of the 2-year alfalfa, the inoculum treatments were well separated along a first and second axis (**Figure 6A**), and the nMDS stress (0.09) supported this representation of the dissimilarity among samples. Moreover, the PCA, based on the corresponding plant traits, well separated the non-inoculated plots from the inoculated ones along the first axis, as well as the different inoculants along the second axis (**Figure 6B**). Overall, local *R. irregularis* clusters 1–4, and 7–9, and *F. mosseae* AZ225C and BEG12 were positively and strongly correlated with all plant traits. The relationship of the two matrices was also shown to be significant by the RELATE analysis, for which the ρ was equal to 0.46 and the significance level of sample statistic after 999 permutations were equal to 0.4% (**Figure 6C**). Nevertheless, the BEST analysis allowed us to highlight that together local *R. irregularis* cluster1 and cluster6 were the best predictors of the plant traits (correlation:0.656). Finally, although the marginal test of the DistLM analysis highlighted that many phylotypes were significantly correlated with the plant traits and explained a relevant part of the total variation (**Supplementary Table 8**), the local *R. irregularis* cluster1 alone was sufficient to describe the majority of the diversity inside the plant traits (49.2% of the total variance explained; $P = 0.003$). This is also detectable from the plot of the dbrDA of the DistLM axes (**Figure 6D**) showing that the increase in the abundance of the local *R. irregularis* cluster1 well explains the distribution of the samples in the multivariate space based on plant traits (**Figure 6B**).

DISCUSSION

Arbuscular Mycorrhizal Fungal Inoculation Enhances Alfalfa Yield and Fatty Acid Concentration in Forage

Overall, AM fungal field inoculation enhanced crop yield and FA concentration in both years of cultivation. AM fungal root colonization was greatly increased by inoculation and the effect was the highest at the beginning of crop growth. Indeed, already 1 month following inoculation, all inoculants reached the saturation (ca. 40%) within the roots of alfalfa, compared with

control having less than 10% of colonization. This suggests a high infectivity of the AM fungal inoculants under field conditions. This is in agreement with the root colonization pattern reported in a previous study on alfalfa field-inoculated with two single isolates of *F. mosseae* (IMA1 = BEG12 and AZ225C) (Pellegrino et al., 2012). In the study of Pellegrino et al. (2012), already 3 months after crop emergence, AM fungal colonization in the inoculated plants reached 30%, while in the control plots were low (3%), and the rate of colonization did not change with crop aging, supporting the high infectivity of the inoculants on alfalfa and a saturation level similar to the one in our research. Our data evidenced that native AMF occurring into control plots were less infective, because up to 2 years from crop seeding their presence in plant roots was still lower compared with inoculated

plots. Thus, these results support the high infectivity (54%–80%) found in a pot experiment with a 4-month-old alfalfa inoculated by *F. mosseae* IMA1 and AZ225C, and by *R. irregularis* IMA6 (= BEG141) (Avio et al., 2006). Other studies carried in pots with isolates of *F. mosseae* and *Rhizophagus intraradices*, reported in 8-month-old alfalfa plants root colonization up to 60% (Wang et al., 2020; Li et al., 2021). Thus, our results confirm the high mycotrophic behavior of this important forage crop previously described in controlled conditions.

In the first year of growth, the higher AM fungal root colonization detected in inoculated alfalfa compared with uninoculated controls was associated with a general improvement of plant growth, due to an increase of the growth of stems and leaves and consequently of forage. However, this

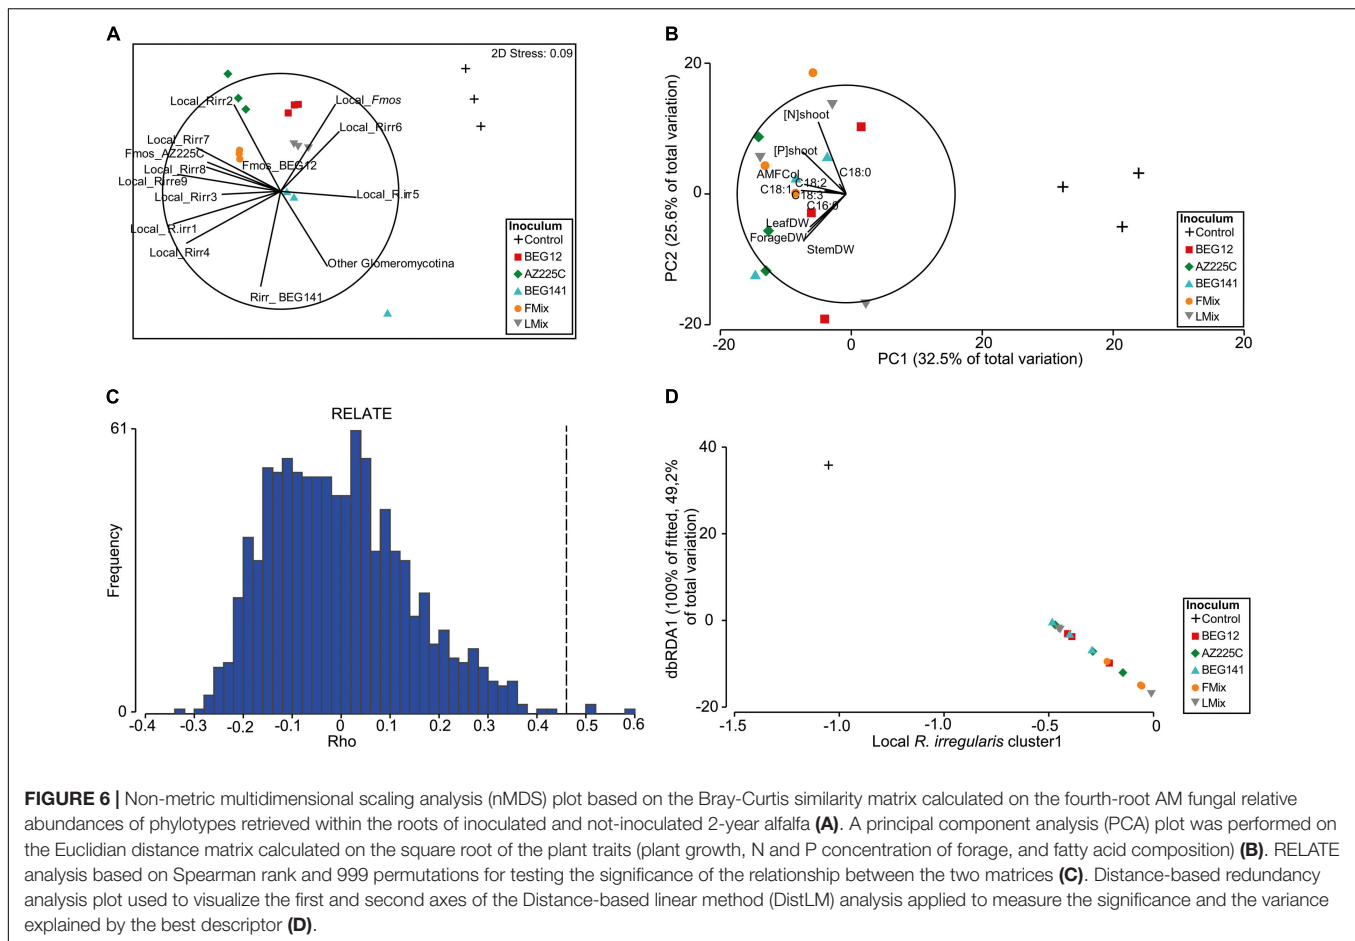

FIGURE 6 | Non-metric multidimensional scaling analysis (nMDS) plot based on the Bray-Curtis similarity matrix calculated on the fourth-root AM fungal relative abundances of phylotypes retrieved within the roots of inoculated and not-inoculated 2-year alfalfa (A). A principal component analysis (PCA) plot was performed on the Euclidian distance matrix calculated on the square root of the plant traits (plant growth, N and P concentration of forage, and fatty acid composition) (B). RELATE analysis based on Spearman rank and 999 permutations for testing the significance of the relationship between the two matrices (C). Distance-based redundancy analysis plot used to visualize the first and second axes of the Distance-based linear method (DistLM) analysis applied to measure the significance and the variance explained by the best descriptor (D).

fungal trait could not fully explain the variability in plant growth, since inoculants colonizing the roots of alfalfa at a similar rate differently influenced plant growth. In this regard, Lekberg and Koide (2005) found a significant but weak relationship between a change in mycorrhizal colonization and a change in yield. Therefore, while an increase in mycorrhizal colonization appears to be associated with an increase in yield, the mycorrhizal colonization cannot be the sole predictor of an increase in yield, and the characterization of the AM fungal components of the root community assemblages became essential for dissecting functionality (Vályi et al., 2016). Indeed, AMF taxa can greatly differ in the spread of external mycelium or hyphae architecture, thus affecting yield and nutrient uptake (Munkvold et al., 2004; Avio et al., 2006).

The positive effect of field AM fungal inoculation on N and P concentration in forage irrespective of inoculants is consistent with the results on Egyptian clover (*Trifolium alexandrinum* L.) and alfalfa (Pellegrino et al., 2011, 2012). A generalized positive effect of AM fungal inoculation on plant P concentration was reported by Lekberg and Koide (2005) taking into consideration 25 field trials. About the effect of AM fungal inoculation on plant N concentration, while a generalized increase was reported by Delavaux et al. (2017) looking only to greenhouse trials, the effect in the field is less clear and poorly studied

(Pellegrino et al., 2015a). However, in Pellegrino et al. (2011) a strong variability among AM fungal inoculants was reported on forage nutrient concentrations in pots where no other AMF occur. This suggests that the interactions of AM fungal inoculants with the native AM fungal community are likely to be responsible for the lack of differences in fungal physiological traits (van der Heijden and Scheublin, 2007). In addition, in the field, the outcome of the inoculation is influenced also by the disturbance history (i.e., reduced disturbance and shorter fallow) (Lekberg and Koide, 2005), and/or by soil nutrient availability (i.e., N and P) and soil pH (Han et al., 2020).

So far, a unique study in a field-grown crop analyzed the effect of AMF on fatty acid content and composition (Igíehon et al., 2021). In contrast with our results highlighting an increase in the amount of fatty acids, Igíehon et al. (2021) found a lower amount of fatty acids in seeds of soybean when plants were inoculated with AMF and no changes of fatty acids when soybean was inoculated with AMF plus strain of *Rhizobium* sp. However, similar to our results, the composition of polyunsaturated FA (PUFA), monounsaturated FA (MUFA), and saturated FA (SFA) was greatly modified by AMF and *Rhizobium* in comparison with the uninoculated control. Moreover, drought stress was shown to enhance the fatty acid contents in seeds of some inoculated soybean plants through upregulation and downregulation of

specific fatty acids (Hou et al., 2006; Igiehon et al., 2021). Under water-deficit conditions, plants colonized by mycorrhizal fungi have better growth than those that are not, and the response is more evident in perennial plants (Jayne and Quigley, 2014). Therefore, our results largely confirm the hypothesis that AM fungal inoculation supports plant growth and total fatty acid content in drought conditions, likely to occur in the area where our trial was run. A higher concentration of oleic acid (C18:1), linoleic acids (C18:2), and α -linolenic acid (C18:3), we found in all inoculated alfalfa plots, is a desirable quality in forage for animal nutrition, since these components are associated with several health and nutritional benefits (Radović et al., 2009; González-Fernández et al., 2020). The fatty acid auxotrophy of AMF is supported by recent studies showing that lipids synthesized by the host plants (e.g., palmitic, oleic, and myristic acids) are transferred to the fungi, lacking genes encoding fatty acid synthases (Stumpe et al., 2005; Trépanier et al., 2005; Sugiura et al., 2020). However, our results suggested that AMF, in addition to using fatty acids as C and energy source, can stimulate their synthesis in the aboveground part of the plant. This is in line with recent results reporting that AMF is involved in the stimulation of the synthesis of secondary metabolites plant (Baslam and Goicoechea, 2012; Zouari et al., 2014; Kaur and Suseela, 2020). Moreover, the use of AM fungi in pasture management could provide benefits for animals, derived products, and humans. In this regard, cows grazing in AM fungal inoculated pasture produced high-quality milk (Masoero et al., 2021).

Multiple Arbuscular Mycorrhizal Fungal Inoculants Act in Synergy to Promote Alfalfa Yield and Fatty Acids Concentration in Forage

In this study, mixed AM fungal inocula performed better than single inocula both in terms of plant growth, P uptake, and FA content and composition. However, no difference in AM fungal root colonization was reported. Several studies carried out in pot conditions with sterilized substrate showed that AM fungal mixed inocula promoted markedly plant performance (e.g., Edathil et al., 1996; Maherali and Klironomos, 2007; Thonar et al., 2014; Martignoni et al., 2021), whereas the few studies performed in the field do not allow to reach conclusive assessments (e.g., Powell, 1977, 1979; Clarke and Mosse, 1981; Pellegrino et al., 2011; Pellegrino and Bedini, 2014). Recently, some meta-analyses synthesized the literature on this topic, but merging the data obtained from lab experiments with the few obtained from the field (e.g., Rúa et al., 2016; Yang et al., 2017; Zhang et al., 2019). Significant differences were found in cereal yield (i.e., wheat, rice, and corn) if mixed inocula were compared with single inocula and substrate sterilization was not applied, whereas no differences were found if the substrate sterilization was applied with or without application of a microbial supplement (Zhang et al., 2019). These results may derive from complementarity among AM fungal species, which can provide a greater crop benefit (Koide, 2000; Thonar et al., 2014). A mixed and more complex inoculum can be more efficient across a range of soil parameters, climatic conditions, and host plants (species

or even varieties/genotypes) increasing plant nutrient uptake, decreasing nutrient losses, and improving soil aggregation. The greater efficiency of mixed inocula can be the result of a large variability among AM fungal taxa in foraging strategies and extraradical mycelium development (spread of the mycelium, hyphal architecture, or anastomosis frequency). This variability may enhance the ability of the inoculum to adapt and thus be more efficient and/or more persistent in many environments. Indeed, the structure of the AM fungal extraradical mycelium (ERM) that is largely variable among AM fungal species or even isolates among species was linked to specific functions (Munkvold et al., 2004; Avio et al., 2006; Thonar et al., 2011; Treseder et al., 2018). For example, a high positive correlation was highlighted between ERM interconnectedness (anastomosis frequency and number) and plant growth variables (total shoot biomass), or between anastomosis frequency and root P content (Avio et al., 2006). Moreover, a crop genotype inoculated with an AM fungal mixture may have a great probability to find among the AMF components the taxa with a higher host preference and a life history strategy adapted to local agricultural soil. In this regard, Wagg et al. (2015) using a model plant-mycorrhizal system, suggested that the fungal composition rather than the diversity of species may be more important in determining how plant species function within a community.

Multiple Arbuscular Mycorrhizal Fungal Inoculants Composed of Foreign Arbuscular Mycorrhizal Fungi Provide Greater Benefits to Alfalfa Compared to a Mixture of Local Arbuscular Mycorrhizal Fungi

Foreign isolates combined in the mixture performed better than the local-isolate mixture composed of 14 AM fungal species belonging to seven genera and five families. This is in agreement with the results recorded in the field by Pellegrino et al. (2011). On the contrary, Pellegrino and Bedini (2014) reported that the locally sourced AM fungal mixed inoculum was more effective than a foreign mixture inoculum. The greater effectiveness of foreign mixtures is in accordance with the results of the meta-analysis of Rúa et al. (2016) concluding that the geographic origin of plants relative to the origin of AMF and soil is important for describing the effect of inoculation on plant biomass. Indeed, if plants and soil are sympatric (i.e., locally sourced), but allopatric to the fungus (i.e., foreign origin), the positive effect of inoculation is greater than when all three components are allopatric. In agreement, Klironomos (2003) reported positive responses using local plants and fungi, and parasitic or no responses using foreign plant or fungal genotypes. Kiers et al. (2011) explained this concept by the bidirectionality of mutualism and the reward for individuals showing the best rate of exchange. Indeed, plants and fungi are able to detect variation in the resources supplied by their partners, allowing them to adjust their own resource allocation accordingly. In addition to this concept, the taxonomic resolution of the AM fungal diversity in the inocula is the main factor of plant functionality, as the

functional benefit was found at AM fungal family level, and not at species scale (Yang et al., 2017). Thus, an inoculum composed of many AM fungal families would allow maintaining a full complement of ecosystem functions, rather than an inoculum composed of many species belonging to the same or few families. Therefore, our hypothesis of greater host benefits from local AM fungal isolates than foreign isolates has to be rejected, probably due to the legacy of the agricultural practices (tillage, fertilization, pesticides, etc.) potentially selecting for less advantageous AM fungal strains. Finally, we would like to highlight, as previously mentioned, that in this study inoculants were composed of spores, roots, and soil (crude inoculum). Thus, during the process of production of the different AM fungal isolates and mixtures, AMF may have had socialized differently with the microbial community. This means that, although a significant microbial filtrate was applied at the start of the process of production to minimize microbial differences, at the end of the production phase the variabilities in crop response might be due not only to the AM fungal species identity but also to differences in microbial associated groups. Indeed, from the mycorrhizosphere and the spores of different AM fungal isolates many different bacterial taxa were detected (Bharadwaj et al., 2008). The multiple services provided by AMF were shown to be the result of the synergistic activity of the diverse bacterial communities living in the mycorrhizosphere, strictly associated with the spores and with the extraradical mycelium, which played many plant growth-promoting roles (e.g., nitrogen fixation, P solubilization, production of indole acetic acid, siderophores, and antibiotics) (Frey-Klett et al., 2007).

Molecular Discrimination of Foreign Inoculants and Native *F. mosseae* and *R. irregularis*

In this work, consistently with Pellegrino et al. (2012), the phylogenetic information contained in the polymorphic 3' end of the nuclear SSU rRNA gene, ITS2, and the 5' end of the LSU rRNA gene were sufficient for discriminating among foreign inoculants and local strains of *F. mosseae*. Moreover, the phylogenetic information contained in the 5.8S in addition to that contained in the partial SSU, complete ITS2, and partial LSU, allowed also to discriminate foreign inoculants and local isolates of *R. irregularis*. Thus, in our field site, these regions gave sufficient variation to reach a good resolution among closely related AM fungal isolates for both AM fungal species. Molecular discrimination of foreign inoculants might have been facilitated by the fact that both *F. mosseae* isolates BEG12 and AZ225C, and *R. irregularis* BEG141 have a distant origin. Indeed, *F. mosseae* isolates BEG12 and AZ225C are originated from United Kingdom and Arizona (United States), and *R. irregularis* BEG141 from France. Despite the fact that a high rDNA sequence polymorphism was proved within individuals (e.g., Hijri et al., 1999; Lanfranco et al., 1999; Jansa et al., 2002; Thiéry et al., 2012), other researchers (Krüger et al., 2009, 2012; Stockinger et al., 2010), similarly to our findings, proved that the combination of the highly polymorphic ITS region with variable SSU and LSU regions can be used to achieve phylogenetic species- and

strain-level resolution in AMF. In this regard, Farmer et al. (2007) could discriminate isolates of *R. irregularis* BEG141 and *C. etunicatum* BEG168, using only the variable domains of the LSU of ribosomal RNA gene, whereas more recent studies proved that other molecular markers (i.e., mtLSU, RPB1, and mt cox3-rnl intergenic mtDNA region) are even more efficient in the discrimination of foreign AM fungal isolates in the field (Sýkorová et al., 2012; Buysens et al., 2017; Kokkoris et al., 2019; Thioye et al., 2019). Very recently, to overcome the difficulties of the lack of consensus barcoding region for the determination of AM fungal taxa, Kolaříková et al. (2021) developed a fine and promising approach to sequence an AM fungal marker within the ribosome-encoding operon (rDNA) which covers all the three widely applied variable molecular markers (SSU, ITS, and LSU). In detail, they amplified a ca. 2.5 kb of the rDNA, spanning the majority of the SSU gene, the complete ITS region, and a part of LSU rRNA gene, and sequenced the PCR products using a PacBio platform and the Single-Molecule Real-Time sequencing. This approach proved to be able to obtain a robust phylogenetic assignment of several Glomeromycota lineages occurring in complex AM fungal assemblages, could overcome the site- and inoculation-specificity of the molecular approach we proposed.

Persistence of Inoculated Arbuscular Mycorrhizal Fungi in the Field and Effects on Native Arbuscular Mycorrhizal Fungi

Using the validated molecular approach, foreign strains of *F. mosseae* and *R. irregularis* were found to persist in the roots of the polianual forage crop alfalfa 2 years following inoculation with single-foreign isolate inoculum or the mixture of those isolates. Similarly, in potatoes, the inoculated *R. irregularis* BEG141 and *R. etunicatum* BEG168 were found to persist in roots 6 weeks following inoculation (Farmer et al., 2007). In this study, a nested PCR using taxon-specific primers, targeting the variable domains of the LSU of ribosomal RNA gene, and a cloning-sequencing approach was applied. Moreover, using other molecular markers, such as the mtLSU (cloning and sequencing approach) and a fragment of RPB1 (qPCR approach), Sýkorová et al. (2012) and Thioye et al. (2019) successfully traced two haplotypes of *R. irregularis* BEG140 in roots of field-inoculated *Phalaris arundinacea* and *R. irregularis* IR27 in roots of jujube (*Ziziphus mauritiana*), respectively. *Rhizophagus irregularis* BEG140 was reported to survive and proliferate up to 3 years in the field and was found more often in the inoculated than in control plots (Sýkorová et al., 2012), while *R. irregularis* IR27 was reported to persist in jujube tree roots up to 18 months. More recently, Buysens et al. (2017), using a qPCR approach and amplifying the mtLSU RNA gene, performed for the first time the absolute quantification in the field of the isolate *R. irregularis* MUCL 41833, and found a significant correlation between mtLSU_MUCL41833 and total, arbuscular and vesicular colonization of roots of three varieties of potatoes at three growing stages (i.e., flowering, before defoliation and harvest). Finally, Kokkoris et al. (2019) successfully traced the *R. irregularis* DAOM 197198 using specific primers, targeting the mt cox3-rnl intergenic mtDNA region, and a probe in a droplet

digital PCR. The inoculated isolate was found in all the plots (inoculated and non-inoculated) and its abundance increased over time, supporting the hypothesis of the spreading of the isolate beyond inoculated plots. Conversely, Berruti et al. (2017), using a next-generation sequencing-based on the amplification of only ca. 420 bp of the 18S V3-V4 hypervariable domains (SSU), found a lack of field persistence of the AM fungal components of microbial mixed inoculum in maize at the V8-9 stage. Therefore, long-term inoculation trials are needed for monitoring the evolution of the AM fungal native community and to track the persistence of the inoculated AMF.

In our study, among the foreign-inoculated AM fungal isolates, *F. mosseae* AZ225C was the most persistent both as single inoculum or mixture, followed by BEG12 and BEG141. This is in agreement with a previous study (Pellegrino et al., 2012), where at 2 years post-inoculation, the isolate AZ225C was more persistent in roots of *M. sativa* with respect to IMA1, although it declines from the establishment (i.e., 3 months following plant emergence; from 100 to 16%). In the previous study (Pellegrino et al., 2012), IMA1, despite still stimulating crop performance, did not persist after 2 years. This inconsistency proves the high site-specificity of the outcome of the inoculation related to climate, texture, and chemical properties of soil (Ciccolini et al., 2015; Pellegrino et al., 2015a,b, 2020a), or the genetic variability in AM fungal compatibility with different genotypes of the same plant species (*M. sativa* L. var. Giulia vs. cv. Messe) (Pellegrino et al., 2012). In this regard, a large variability in compatibility was proved for AMF in *Triticum turgidum* (Singh et al., 2012), and in *Triticum aestivum* L. (Pellegrino et al., 2020a).

Comparing mock-inoculated control and LMix, while the abundance of the local *F. mosseae* cluster was reduced, the abundance of the native *R. irregularis* clusters and other Glomeromycota taxa was promoted. The change of assemblages with LMix in comparison with those observed with single foreign inoculants of *F. mosseae* BEG12 and AZ225 (i.e., a strong decrease in the abundance of other Glomeromycota), supports the fact that inoculation with local AM fungal mixture or with the less persistent *R. irregularis* BEG141 determines a less environmentally impacting shift of the local fungal community. This is also associated with similarities in the outcome of the symbiosis in terms of plant performance (i.e., plant growth and nutrient and FA content).

The fact that sequences phylogenetically affiliated to the local *F. mosseae* were retrieved in all the inoculated plots, but were more abundant in the control plots, support the high ubiquity of this species (generalist) across a wide range of agro-climatic conditions and geographically areas (Öpik et al., 2006). Finally, no sequences similar to those of BEG12, AZ225C, and BEG141 were found in the roots of mock-inoculated alfalfa (controls) or the roots of alfalfa inoculated with LMix. This could support the absence of spreading of the inoculated AM fungal isolates, at least up to 2 years following inoculation and in such specific management, and in such a no-tilled polyannual forage. However, we cannot exclude a low fungal abundance as well as an insufficient sampling effort due to the used cloning and Sanger sequencing approach. Finally, since we inoculated crude inocula and the method of propagation cannot fully eliminate differences in microbial communities, we could not exclude that the outcome

of field persistence can be due not only to the identities of inoculated AMF but also to the associated microbes that might affect the establishment/persistence, with consequences in the soil/rhizospheric microbial communities.

Components of Arbuscular Mycorrhizal Fungal Communities in Alfalfa Roots Best Explain Plant Traits

Unexpectedly, although a high diversity in the composition of AM fungal assemblages was found among inoculated treatments, small differences were found in plant traits, such as growth and nutrient uptake, with the exception of FA. Total fatty acids (TFA) were increased with inoculum mixtures compared with single inoculants, while the content of the majority of FA was higher when plants were inoculated with FMix than with LMix. However, by relating the AM fungal assemblages within the roots of the 2-year alfalfa with the corresponding plant traits, the only change in abundance of the local *R. irregularis* cluster1 induced by all inoculation treatments was sufficient to describe the majority of the diversity inside the overall studied plant traits. Thus, we can speculate that the main determinant of the improved host benefit across the inoculation treatments is related to the stimulation of the proliferation of a single-taxa rather than to the increase in abundance of the inoculated isolates. Overall, these results suggest an environmental-driven selection for highly efficient AMF and support the use of native mixture inoculants having a lower risk of including invasive isolates (Hart et al., 2017).

CONCLUSION

The data presented in this study demonstrated that: (i) field application of AM fungal inocula improved alfalfa yield, nutrient and fatty acid concentration up to 2 years post-inoculation and enhanced AM fungal abundance in roots; (ii) multiple AM fungal inoculants can act in synergy to achieve the effects on crop yield and quality; (iii) a mixture of foreign AM fungal isolates provided greater benefits compared to local consortia; (iv) foreign strains of *F. mosseae* and *R. irregularis* persisted in the roots of the polyannual crop 2 years following inoculation either as single inoculum or as component of the mixture; (v) among inoculants, *F. mosseae* BEG12 and AZ225C and the foreign mixture exerted an higher environmental impact on the local AM fungal community compared with the local AM fungal mixture and *R. irregularis* BEG141; (vi) the stimulation of the proliferation of a single-taxa, such as the local *R. irregularis* cluster1, induced by all inoculation treatments was the main determinant of the improved host benefits, suggesting an environmental-driven selection for a highly efficient AM fungal strain. The results on crop productivity and quality as well as on-field persistence of inoculated AMF support the use of mixtures of foreign AM fungal isolates. On the other hand, taking into consideration the effects on the native AMF, the local AM fungal mixture shows a lower impact. These results pave the way for extending the study on the effect of exotic and native mixtures for the production of

high-quality forage for the animal diet, allowing to assess the fatty acid profile in milk or meat, and derived products, and finally to evaluate AM fungal benefits on human health.

DATA AVAILABILITY STATEMENT

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article/**Supplementary Material**.

AUTHOR CONTRIBUTIONS

EP conceived and designed the study and collected and analyzed the samples. EP and LE analyzed the data. EP, LE, and MN discussed the results. EP and LE wrote the manuscript. All authors reviewed and approved the manuscript before its submission.

Background: Biocontrol strategies are the best possible and eco-friendly solution to develop resistance against *O. furnacalis* and improve the maize yield. However, the knowledge about underlying molecular mechanisms, metabolic shifts, and hormonal signaling is limited.

Methods: Here, we used an axenic and a consortium of entomopathogenic *Beauveria bassiana* OFDH1-5 and a pathogen-antagonistic *Trichoderma asperellum* GDFS1009 in maize and observed that consortium applications resulted in higher chlorophyll contents and antioxidants activities [superoxide dismutase (SOD), peroxidase (POD), proline, protease, and polyphenol oxidase (PPO)] with a decrease in *O. furnacalis* survival. We performed a comprehensive transcriptome and an untargeted metabolome profiling for the first time at a vegetative stage in fungal inoculated maize leaves at 0-, 12-, 24-, 48-, and 72-h post insect infestation.

Results: The consortium of *B. bassiana* and *T. asperellum* leads to 80–95% of *O. furnacalis* mortality. A total of 13,156 differentially expressed genes were used for weighted gene coexpression network analysis. We identified the six significant modules containing thirteen candidate genes [protein kinase (GRMZM2G025459), acyl-CoA dehydrogenase (GRMZM5G864319), thioredoxin gene (GRMZM2G091481), glutathione S-transferase (GRMZM2G116273), patatin-like phospholipase gene (GRMZM2G154523), cytochrome P450 (GRMZM2G139874), protease inhibitor (GRMZM2G004466), (AC233926.1_FG002), chitinase (GRMZM2G453805), defensin (GRMZM2G392863), peroxidase (GRMZM2G144153), GDSL-like lipase (AC212068.4_FG005), and Beta-glucosidase (GRMZM2G031660)], which are not previously reported that are highly correlated with Jasmonic acid - Ethylene (JA-ET) signaling pathway and antioxidants. We detected a total of 130 negative and 491

positive metabolomic features using a ultrahigh-performance liquid chromatography ion trap time-of-flight mass spectrometry (UHPLC-QTOF-MS). Intramodular significance and real time-quantitative polymerase chain reaction (RT-qPCR) expressions showed that these genes are the true candidate genes. Consortium treated maize had higher jasmonic acid (JA), salicylic acid (SA), and ethylene (ET) levels.

Conclusion: Our results provide insights into the genetics, biochemicals, and metabolic diversity and are useful for future biocontrol strategies against ACB attacks.

Keywords: myco-synergism, *Ostrinia furnacalis*, *Beauveria bassiana*, *Trichoderma asperellum*, antioxidants myco-synergism triggers herbivory-induced defense

INTRODUCTION

Maize plants undergo several challenges during their growth, including pathogenic infections, environmental stresses, and insect attacks (Batool et al., 2020). Asian corn borer, *Ostrinia furnacalis* (Guenée), is among the most destructive insect pests of maize in Southeast and East Asia, especially China, causing an estimated yield loss of 6–9 million tons annually (He et al., 2003). Based on the importance of sustainable and eco-friendly agricultural practices (Guo et al., 2019), *O. furnacalis* control strategies have been shifted toward the application of biological control agents rather than harmful chemical pesticides (Mitchell et al., 2016; Batool et al., 2020). The *Trichoderma* spp. is traditionally viewed as a kind of biocontrol fungi against a range of plant pathogens (Dou et al., 2020), however, *Trichoderma* spp. has also been found with some functions against plant insects in different ways. More interestingly, in our previous study, we proved that *T. asperellum* and *Beauveria bassiana* are great entomopathogenic against *O. furnacalis* in maize (Batool et al., 2020). The plant herbivory response is a dynamic process that temporally and spatially regulates proteins, metabolic profiles, and transcript patterns (Ehrling et al., 2008; Barah and Bones, 2015). This suggests that it is essential to study the plant herbivory defense mechanisms at transcriptional and metabolic levels in response to insect-feeding and pre-inoculated entomopathogenic fungal strains (Li et al., 2016).

To combat herbivory, plants have evolved a broad range of defense mechanisms (Abebe, 2021). The morphological structures such as trichomes, waxy leaf surface, and numerous secondary metabolites act as the first barrier or the constitutive defense against herbivore attack. Plants have also developed an induced defense response, which affects the herbivore's survival, growth, and development directly through the production of defensive proteins and secondary metabolites, and indirectly through the secretion of volatile compounds to attract the pests (Guo et al., 2019). Plant-induced defense is initiated by the perception of insect-feeding-derived elicitor, and it is a sophisticated mechanism to balance the growth and defense. When plants are exposed to a herbivore attack, different receptors and transporters could be activated and pass the signals through different signal molecules to activate the genes involved in the biosynthesis of phytohormones such as jasmonic acid (JA), ethylene (ET), and salicylic acid (SA), secondary metabolites,

and defensive enzymes, which are toxic, repellent, interfere in the digestive system, survival, and nutrient absorption of insects (Qi et al., 2018). JA and SA accumulate and exhibit a major role in regulating the plant defense mechanisms against herbivory (Tzin et al., 2015; Guo et al., 2019). JA-induced signaling is primarily regulated upon insect feeding, whereas salicylic acid regulates the response to phloem-feeding insects (Tzin et al., 2015; Heideel-Fischer et al., 2018). Herbivory-induced defensive enzymes, including enzymatic [superoxide dismutase (SOD), peroxidase (POD), polyphenol oxidase (PPO), and protease] and non-enzymatic (proline) antioxidants in maize plants, help to develop resistance against a corn borer and are responsible for the regulation of plant defense mechanism through the production of secondary metabolites and reactive oxygen species (ROS) scavenging (Batool et al., 2020). *Trichoderma* is also capable of stimulating an induced systemic resistance (ISR) plant defense response against aphids, caterpillars, and nematodes, modulated by crosstalk between SA and JA (Di Lelio et al., 2021).

Entomopathogenic fungi have traditionally been assumed to help regulate insect populations. So far, they have aroused a limited interest as plant growth promoters, alongside of protecting plant from herbivores (González-Guzmán et al., 2020, 2021). However, some hypocrealean ascomycetes, such as *B. bassiana*, play other poorly understood ecological roles that might be useful in developing novel strategies for both increased crop production and crop protection (Sánchez-Rodríguez et al., 2018). Sánchez-Rodríguez et al. (2018) concluded in their study that *B. bassiana* successfully colonized the plant and boosted the spike production in wheat inoculated with seed-dressing and soil drenching methods and caused a 30–75% larval mortality after consuming the endophytically-colonized leaves. In their work, González-Guzmán et al. (2020) also examined the performance of two wheat varieties inoculated with entomopathogenic fungi including *B. bassiana* and *Metarhizium brunneum* by soil drenching and seed coating method and found an increased yield with no significant difference in plant heights. Their results support the seed-dressing method of inoculating with entomopathogenic fungi as a promising green technology for crop protection and enhancement with no negative effect on plant performance. Landa et al. (2013) identified the endophytic colonization of the Opium poppy plant by *B. bassiana* and concluded that it can protect the plant from stem gall wasp. The *B. bassiana*, *M. brunneum*, and *Isaria farinosa*

were also found to increase the iron (Fe) availability in soil differently depending on particle size, increased plant height, and inflorescences the production of sunflower grown (Raya-Díaz et al., 2017).

Advances in omics and quantitative biology offer several ways to identify gene networks and their regulatory mechanisms in living systems. One such promising approach is the RNA-Sequence-based weighted gene co-expression network analysis (WGCNA) (Langfelder and Horvath, 2008). The WGCNA is a useful method to identify modules/networks of coexpressed genes. Furthermore, the correlation of these modules with phenotypic traits was useful to detect the key genes within the networks (Umer et al., 2020). However, no such large-scale study regarding the synergistic interaction of *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009 in triggering the omics-based regulatory mechanisms of defense genes, biochemical enzymes, and phytohormones induced by the *O. furnacalis* herbivory, are available.

Here, we hypothesized that the consortium of entomopathogenic *B. bassiana* OFDH1-5 and pathogenic antagonistic *T. asperellum* GDFS1009 fungal inoculants can trigger the enhanced defense response in maize, then the normal herbivory-induced response by an enhanced expression of defense-related genes, antioxidants production, phytohormone synthesis, digestive enzyme inhibitors, etc. So, we performed the physiological, biochemical, transcriptome, metabolome, and phytohormonal level analysis in field-grown vegetative stage maize inoculated with *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009, singly and in the consortium at 0-, 12-, 24-, 48-, and 72-h under *O. furnacalis* feeding. By integrating differentially expressed genes (DEGs) and biochemical antioxidants through weighted gene coexpression network analysis (WGCNA), we revealed gene networks and key candidate genes linked to JA, SA, and ethylene biosynthesis pathway and production of antioxidants and insect cuticle and digestive enzyme inhibitors. Our results highlight the positive impact of *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009 on increasing the herbivory-induced defenses and restricting the survival and growth of *O. furnacalis*.

MATERIALS AND METHODS

Plant Growth and Treatments

Maize variety “Jingke 968” was planted in an open field located at the Gongzhuling Experimental Station of the Institute of Plant Protection, CAAS, Gongzhuling, China (43°30' N, 124°47' E; 224.9 m above sea level) on May 11, 2018, and May 06, 2019. The treatments include: (CK) untreated control, (BB-1) seed treatment with *B. bassiana* OFDH1-5, (BB-2) soil drenching with *B. bassiana* OFDH1-5, (TH-1) seed treatment with *T. asperellum* GDFS1009, (TH-2) soil drenching with *T. asperellum* GDFS1009, (BT-1) seed treatment with consortium of *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009, (BT-2) soil drenching with a consortium of *B. bassiana* OFDH1-5 + *T. asperellum* GDFS1009, and (IC) no inoculation. All

treatments except CK were infested with *O. furnacalis* larvae. Each treatment was replicated three times.

The *B. bassiana* OFDH1-5 (ACCC32726) sourced through Jilin Academy of Agricultural Sciences, Gongzhuling, China and the *T. asperellum* GDFS1009 (CGMCC NO. 9512) obtained from the School of Agriculture and Biology, Shanghai Jiao Tong University, Shanghai, China, were selected for this study based on the previous results (Batool et al., 2020). Fungal strains were grown and conidial suspensions of *B. bassiana* OFDH1-5 (1×10^9), *T. asperellum* GDFS1009 (1×10^9), and combined suspension of *B. bassiana* OFDH1-5 + *T. asperellum* GDFS1009 ($5.9 \times 10^5 + 8.4 \times 10^8$) in 1:1 were prepared as described by Batool et al. (2020). An interaction analysis to check the synergistic effect of two strains was performed based on laboratory pathogenicity analysis data (Supplementary Table 1). Surface-sterilized maize seeds were soaked in respective conidial suspension and placed in a shaker incubator (HWP-250) at $25 \pm 2^\circ\text{C}$ and 200 rpm for 12 h (Motholo, 2019), and then dried under a laminar air flow hood before planting (Cherry et al., 2004). For insect control-IC, control-CK, and soil drenching treatments BB-2, TH-2, and BT-2, seeds were soaked in a sterilized 1% (v/v) tween 80. For soil drenching treatments, 30 ml/plant fungal suspension was applied around the root zone after 1 week of germination.

Fifty plants per treatment were planted and replicated three times with 5 m spacing between rows. Plants of each treatment were planted 2.5 m apart from each other to hinder communication. The field conditions and management were consistent with the common local farming agricultural practices and covered with nylon netting to prevent insect immigration. All the plants selected for this experiment were healthy and developmentally similar.

Confirmation of Endophytic Colonization of Plants

To confirm the endophytic colonization of plants by fungal stains, a re-isolation method was used. Leaves were surface-sterilized in 1% sodium hypochlorite for 3 min, 70% ethanol for 1 min followed by washing with sterilized distilled water three times. Leaves were then cut into small segments by using sterilized scissors and placed on potato dextrose agar (PDA) plates. After incubation of 3–7 days at $25 \pm 2^\circ\text{C}$, the presence or absence of fungal growth from leaves was recorded and the colonization % was calculated (Quesada-Moraga et al., 2006).

Insect Infestation and Plant Sampling

The *O. furnacalis* neonates were obtained from the Institute of Plant Protection, CAAS, and reared on an artificial diet. Insect infestation for larval survival and maize damage rating was carried out at the vegetative and silking stage, representing 1st and 2nd generation infestation, respectively. Healthy plants were infested artificially with 60 neonates (<24 h old) on June 30 and June 25 for 1st generation infestation, and on August 10 and 6 for the 2nd generation infestation in 2018 and 2019, respectively. The infestation was done during the

evening to avoid exposure of neonate to direct sunlight and high temperature.

For antioxidants, chlorophyll, and molecular assays, 3rd instar larvae of *O. furnacalis* were placed on each leaf of healthy vegetative stage plants covered with small net cages to restrict their movement. Damaged leaves around the larval feeding site were collected in three replicates at 0-, 12-, 24-, 48-, and 72-h post infestation and immediately frozen in liquid nitrogen. Samples were stored at -80°C until further analysis (Guo et al., 2019).

Maize Damage Rating and Larval Mortality

When fifth instar *O. furnacalis* larvae were observed around the maize field of 1st generation on July 28 and 23 and of 2nd generation on September 9 and 4 (ready to harvest), maize plants were dissected to record the larval mortality rate (%), plant height, tunnel number, tunnel length, kernel number kernel weight, and fungal outgrowth on larval cadavers (Xie et al., 2015).

Measurement of Plant Antioxidants and Chlorophyll Content

Enzymatic antioxidants including POD, SOD, protease, polyphenol oxidase, proline content, and chlorophyll content were estimated in maize leaves at 0-, 12-, 24-, 48-, and 72-h post infestation. Detailed protocols are described in our previous article Batool et al. (2020).

Transcriptome Profiling and Bioinformatics Analysis

The RNA was isolated using the TIANGEN kit (Beijing, China), following the manufacturer's instructions. Sequencing libraries were generated using NEBNext UltraTM RNA Library Prep Kit for Illumina (New England Biolabs, Ipswich, MA, United States) according to the manufacturer's instructions, and index codes were added to attribute sequences of each sample. Library quality was assessed on the Agilent Bioanalyzer 2100 system. Clean reads were then mapped with the reference genome sequence by Hisat2 tools soft (Kim et al., 2015). Gene function was annotated based on database information. DEGs were identified using the DESeq2 with P -value < 0.05 (Wang et al., 2010). We used KOBAS software to test the statistical enrichment of DEGs in kyoto encyclopedia of genes and genomes (KEGG) pathways.

Weighted Gene Co-expression Network Analysis for Identification of Key Candidate Genes Involved in Maize Defense

Weighted gene coexpression network analysis (WGCNA) was performed in R (version 4.1.2) using default parameters to simplify genes into expressed modules to identify the defense-related hub genes (Langfelder and Horvath, 2008). The fragments per kilobase of transcript per million mapped reads (FPKM) values were normalized, and an adjacency matrix was constructed. The plant antioxidant and the chlorophyll analysis data, used as phenotypic data, were imported into the WGCNA

package, and correlation between antioxidants and chlorophyll data and gene modules were calculated using the default settings. The WGCNA package was used to convert the adjacency matrix into a topological overlap matrix (TOM). After constructing a network, the transcripts with identical expression patterns were grouped into one module, and eigengenes were also calculated for these modules. The genes from each module were exported using the default parameters for cytoscape export.

Validation of Intramodular Candidates Through Real Time-Quantitative Polymerase Chain Reaction

Validation of gene expression by RT-qPCR was carried out in three biological replicates on Applied Biosystems 7500 Fast Real-Time PCR System (Applied Biosystems, Foster City, CA, United States) using an SYBR Green (TAKARA Bio Inc., Japan) following the manufacturer's guide. The RNA was isolated using a TIANGEN kit (Beijing, China) and the complementary DNAs (cDNAs) were synthesized using the One-Step gDNA Removal and cDNA Synthesis SuperMix (TransGen Biotech Co., Ltd., Beijing, China) by using the user's manual. The amplification program followed was 95°C (15 s), followed by 40 cycles at 60°C (60 s), and 95°C (30 s). Actin (accession number-EU585777.1) was used as a reference gene. Fold changes of gene expression level were calculated using the $2^{-\Delta\Delta CT}$ method (Guo et al., 2019). Primers used are given in **Supplementary Table 4**.

Metabolome Profiling and Quantification of Phytohormones

Metabolite extraction and analysis were performed by using ultra-high-performance liquid chromatography-mass spectroscopy (UHPLC-MS, ExionLC, AB SCIEX; Waters, Manchester, United Kingdom) by following the protocol described by Yu et al. (2020). Quantification of SA, JA, and ET was done by following Guo et al. (2021). All the samples were collected as three biological replicates.

Data Analysis

Data collected from the maize physiological and biochemical experiments were analyzed using Statistix 8.1 software and the significance of $p < 0.05$ was applied. Alignment of RNA-seq data was done with HISAT2 software. Assembling of transcripts with mapped reads was done by using String Tie. To quantify the expression levels of transcripts for each sample, we used Asprofile software. The WGCNA was performed in R packages (version 4.1.2). Statistical comparisons of metabolite concentration were made using a SAS statistics package version 9.2 (SAS Institute Inc, 2015) and a significance level of $P < 0.05$ was applied.

RESULTS

Confirmation of Endophytic Colonization of Plants

By a re-isolation method, the mycelia growth of *B. bassiana* OFDH1-5 and *T. asperellum* GDSF1009 were observed growing

from leaf segments placed in PDA plates after 3 days, whereas, in the control treatment, no fungal growth was observed. In comparison with the soil drenching treatments, 19.6 and 15.9%, 42.2 and 39.44%, and 55 and 43.17% higher growth was recorded in seed coated treatment BB-1, TH-1, and BT-1 in 2018 and 2019, respectively (Table 1 and Figure 1).

Larval Survival Rate

The *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009 significantly affected the mortality rate of *O. furnacalis* larvae in both generations. In both generations, 89.38 and 92.28% of larval mortality was observed in BT-1 treatment (a consortium of both fungi) of 2018 and 2019, respectively, followed by 73.03 and 69.68% mortality was observed in BB-1, which was higher than IC. Plants inoculated with soil drenching method (BB-2, TH-2, and BT-2) showed relatively low mortality (60–65%, 40–50%, and 70–80%) in comparison with plants inoculated with seed treatment method (BB-1, TH-1, and BT-1) in 2018 and 2019, respectively (Table 2).

Maize Growth and Damage Rating

The consortium of *B. bassiana* OFDH1-5 + *T. asperellum* GDFS1009 has a positive effect on plant growth and damage rating. In Generation 1, the highest number of tunnels and tunnel lengths were recorded in the insect control treatment (IC), whereas this damage was reduced up to 86.3 and 94.6% in BT-1 in 2018, and 92.2 and 96.7% in 2019, respectively. The second lowest damage was recorded in BB-1 with 77.7 and 81.8% reduction in the number of tunnels and 91.3 and 93.8% reduction in tunnel lengths in 2018 and 2019, respectively. Similar results were recorded in generation 2 with the highest number of tunnels and tunnel lengths in IC and lowest (82.9 and 93% in 2018, and 84.9 and 95.6% in 2019) in BT-1 (Table 2).

Over the 2-year average, plant heights were reduced up to 25.65% in the insect control treatment (IC) compared to the

untreated control, while application of *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009 reduced the negative effect of *O. furnacalis* feeding and increased the plant heights up to 30.65, 29.1, and 34.5% in BB-1, TH-1, and BT-1, respectively. Less effect on plant height was seen in plants inoculated with the soil drenching method (Table 3). Additionally, the application of entomopathogenic fungi significantly increased the grain yield. The maximum increase in the average number of kernels per ear was recorded as 55.2 and 70.9% in BT-1, followed by 53.4 and 69.1% in BB-1, and 47.9 and 56.6% in TH-1 in 2018 and 2019, respectively. Similar patterns of increase in weight per 100 kernels were observed with 53.3 and 79.8% in BT-1, 46.2 and 65.7% in BB-1, and 36.1 and 43.4% in TH-1 in 2018 and 2019, respectively. In contrast, the maximum reduction in grain yield was recorded in insect control (IC) treatment with 20.6 and 29.1% in the number of kernels per ear, and 21.1 and 32.1% in weight per 100 kernels in the year 2018 and 2019, respectively, compared to untreated control (CK) (Table 3).

Larval cadavers were collected from the field to determine the percentage (%) of cadavers showing a fungal outgrowth collected from the field. The highest number of cadavers (%) with fungal outgrowth was observed as 87.33 and 91.83% in seed treated consortium treatment (BT-1) in 2018 and 2019, respectively, at Generation 1 infestation. Similarly, in Generation 2 infestation, 89.68 and 84.07% cadavers were detected in BT-1 with fungal outgrowth in 2018 and 2019, respectively, followed by 71–74% in seed treated with *B. bassiana* treatment (BB-1) (Table 4 and Figure 2). Based on agronomic field data, samples from BB-1, TH-1, BT-1 (inoculated through seed treatment method), and IC were used for further analysis.

Transcriptome Responses Triggered by *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009

For transcriptome profiling, four treatments (BB-1, TH-1, BT-1, and IC) in three replicates at 0-, 12-, 24-, 48-, and 72-h post *O. furnacalis* infestation were used to construct 60 cDNA libraries. A total of 458.04 Gb clean data was obtained and the clean data of each sample reached 5.71 Gb, and the Q30 base percentage was 93.24% and above. Clean reads were aligned with a designated reference genome (ZmB73_Ref-Gen_v4) and the comparison efficiency ranged from 79.13 to 89.36% (Supplementary Table 2). Based on the comparison results, the gene expression level analysis was performed and the differentially expressed genes were identified according to their expression levels $|\log_2(\text{fold-change})| > 1$ and an adjusted P -value < 0.05 in each pairwise comparison. The abundance of upregulated genes was higher than downregulated genes compared to all-time points (Supplementary Table 3). Identified genes in all samples were hierarchically clustered relative to control. The difference in color indicates high (red) and low (green) expressions (Figure 3A). The principal component analysis revealed the variability among transcriptome data of different samples. Clustering of samples away from each other and control group (IC) indicates a fungal inoculation and *O. furnacalis*-induced changes in gene expression specially

TABLE 1 | Percentage (%) endophytic colonization of plants by fungal isolates among different treatments in 2018 and 2019.

Treatments	Endophytic colonization (%)	
	2018	2019
CK	0 ± 0 ^f	0 ± 0 ^f
BB-1	85.02 ± 1.67 ^a	82.40 ± 0.73 ^b

Mean ± SD followed by different lowercase letters indicate significant differences among the treatments ($p < 0.05$). Treatments include: (CK) untreated control, (BB-1) seed treatment with *B. bassiana* OFDH1-5, (BB-2) soil drenching with *B. bassiana* OFDH1-5, (TH-1) seed treatment with *T. asperellum* GDFS1009, (TH-2) soil drenching with *T. asperellum* GDFS1009, (BT-1) seed treatment with consortium of *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009, (BT-2) soil drenching with a consortium of *B. bassiana* OFDH1-5 + *T. asperellum* GDFS1009, (IC) no inoculation.

in consortium treatment (BT) (Figure 3B). In total, 13,156 common DEG's were identified in all the combinations at different time points.

To explore the response of different processes in combined *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009 treatments,

we analyzed the KEGG enrichment analysis of common DEG's. The sets of DEG's were assigned to significant KEGG Pathways ($P > 0.05$) (Supplementary Figure 1), and the top enriched resistance related pathways in IC vs. BB, IC vs. TH, and IC vs. BT at 12-, 24-, 48-, and 72-h were listed in Figure 3C, which show

TABLE 3 | Differential effect of single and consortium of *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009 inoculation on maize yield under *O. furnacalis* attack in 2018 and 2019.

Mean ± SD followed by different lowercase letters indicate significant differences among the treatments ($p < 0.05$). Treatments include (CK) untreated control, (BB-1) seed treatment with *B. bassiana* OFDH1-5, (BB-2) soil drenching with *B. bassiana* OFDH1-5, (TH-1) seed treatment with *T. asperellum* GDFS1009, (TH-2) soil drenching with *T. asperellum* GDFS1009, (BT-1) seed treatment with consortium of *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009, (BT-2) soil drenching with a consortium of *B. bassiana* OFDH1-5 + *T. asperellum* GDFS1009, (IC) no inoculation.

uniquely induced genes enriched in a higher number of metabolic processes in consortium treatment (BT).

***B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009 Triggered Antioxidants and Chlorophyll Content in *O. furnacalis*-Induced Defense**

The antioxidant enzyme activities started to increase at 12-h in all the infested treatments and reached a maximum point

**FIGURE 2 |** Field collected dead larvae showing the existence of fungal outgrowth from the larval cadavers.

at 24-h of insect feeding and gradually decreased until 48-h, while polyphenol oxidase (PPO) reached the maximum at 48-h. The production of antioxidant enzymes was further triggered by entomopathogenic fungal treatments and the highest productions were observed in consortium treatment (BT-1). An increase of 132.5-, 385.3-, 100.6-, and 277.7-folds were recorded in SOD, POD, proline, and protease activities at 24-h of *O. furnacalis* feeding. In the case of PPO, a 522.7-fold increase was recorded at 48-h and the lowest enzyme activities were observed in IC treatment (Figures 4A–E).

Chlorophyll content was observed to be gradually decreased from 0-h to 72-h due to *O. furnacalis* feeding, but fungal inoculation increased the chlorophyll content. The maximum content of chlorophyll-a and chlorophyll-b were recorded in BT-1, followed by TH-1, and BB-1 compared to insect control (IC). Chlorophyll-a, chlorophyll-b, and carotenoid were reduced up to 80-, 86-, and 86.3-folds, respectively, in the insect control (IC) (Figures 4F–I).

Co-expression Network Analysis for the Identification of Hub Genes Involved in Maize Defense

The FPKM values of 13,156 common DEGs and plant biochemical parameters (SOD, POD, proline, protease, PPO, Chl-a, chl-b, carotenoids, and chl-a + b) at different time points were used for the weighted gene coexpression network analysis and the module trait correlations were calculated. Thirty-three gene modules were identified based on coexpression patterns. Each module is represented by a different color and presented as a cluster dendrogram and network heatmap (**Figures 5A–D**).

Among the 33 identified modules, only six showed significant correlations with the phenotypic data. The blue module with 326 genes showed significant correlations with SOD, proline, protease, and PPO with correlation coefficients (r^2) of 0.93, 0.82, 0.7, and 0.75, respectively. The darkgrey module possessing 149 genes showed positive correlations with POD ($r^2 = 0.84$), PPO ($r^2 = 0.73$), and protease ($r^2 = 0.95$). The green-yellow module, having 223 genes, showed significant positive correlations with POD ($r^2 = 0.71$), SOD ($r^2 = 0.81$), proline ($r^2 = 0.73$), protease ($r^2 = 0.71$), and PPO ($r^2 = 0.9$). Grey60 module consists of 57 genes, and it showed a positive correlation with carotenoids ($r^2 = 0.73$). Magenta module with 98 genes showed positive

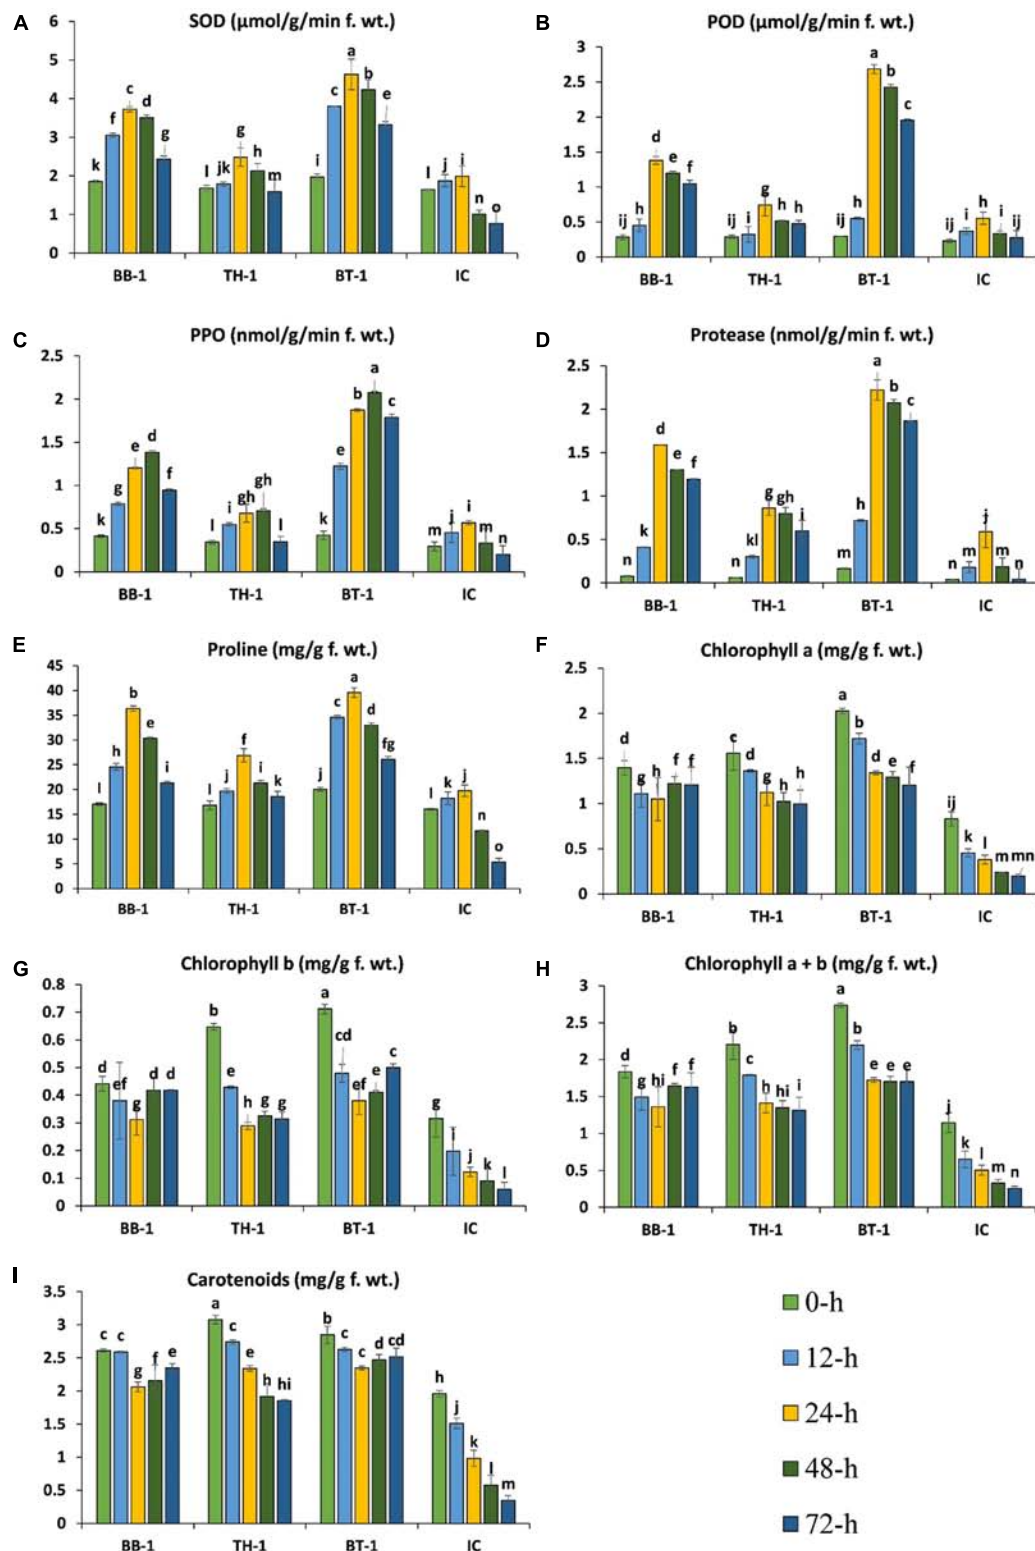

FIGURE 4 | *Beauveria bassiana* OFDH1-5 and *T. asperellum* GDFS1009 induced response of maize antioxidants and chlorophyll content under *O. furnacalis* attack. **(A)** Superoxide dismutase (SOD); **(B)** peroxidase (POD); **(C)** polyphenol oxidase (PPO); **(D)** protease; **(E)** proline; **(F)** chlorophyll a; **(G)** chlorophyll b; **(H)** chlorophyll a + b; **(I)** carotenoids. Different lowercase letters above each bar indicate significant differences among treatments ($p < 0.05$). FIGURE 5 | Weighted gene coexpression network analysis (WGCNA) analysis to identify key candidate genes involved in maize defense. **(A)** Cluster dendrogram and network heatmap of genes subjected to coexpression module calculation. **(B)** Sample dendrogram and module trait heatmap of each time point. **(C)** Hierarchical clustering presenting eleven modules having coexpressed genes. Each leaflet in the tree corresponds to an individual gene. **(D)** Module-trait associations based on Pearson correlations. The color key from green to red represents r^2 values ranging from -1 to 1. **(E)** Gene networks of six highly correlated modules with phenotypic traits. Genes in different red shape due to the highest weight within the module represents hub genes (key candidate genes) and are coded for gene descriptors based on annotation. Treatments include (BB-1) seed treatment with *B. bassiana* OFDH1-5, (TH-1) seed treatment with *T. asperellum* GDFS1009, (BT-1) seed treatment with a consortium of *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009, (IC) no inoculation.

correlations with POD ($r^2 = 0.82$) and with PPO ($r^2 = 0.93$). Salmon module with 145 genes showed a correlation with proline ($r^2 = 0.85$) (Figure 5D). The hub genes from these modules were selected by the cytoscape built-in extension, namely “CytoHubba,” visualizing the gene networks (Figure 5E). Furthermore, to find out the genes involved in maize defense within these gene networks, gene annotation information was extracted from maize reference genome (ZmB73_Ref-Gen_v4).

Real Time-Quantitative Polymerase Chain Reaction Validation of Intramodular Hub Genes

Selected hub genes were further validated by performing RT-qPCR at different time points, thus, narrowing down the number of selected genes. Finally, from 28 hub genes, we selected 13 key candidate genes with stable and consistent expressions responsible for maize defense against *O. furnacalis* (Figure 6). The RT-qPCR results were consistent with the RNA-seq data (Supplementary Figure 2). All the key candidate genes, along with other hub genes, are shown in Table 5.

B. bassiana OFDH1-5 and *T. asperellum* GDFS1009-Enhanced Expression of Key Candidate Genes in Maize Defense Response Against *O. furnacalis* Herbivory

Three key genes in the blue module were identified as protein kinase gene (GRMZM2G025459), which participates in the phytohormone signaling pathway to initiate a defense response and to regulate the expression of genes involved in ion homeostasis and oxidative stress responses, acyl-CoA dehydrogenase (GRMZM5G864319), which is involved in an alpha-linolenic acid metabolism of jasmonic acid pathway and thioredoxin gene (GRMZM2G091481), which acted as an important component of the signaling pathway in plant antioxidant networks. Similarly, in the salmon module, the Glutathione S-transferase was identified as a key gene (GRMZM2G116273), which plays a crucial role in plant oxidative stress response against high ROS (reactive oxygen species) levels generated by the insect attack.

Four genes, (GRMZM2G144153, AC212068.4_FG005, GRMZM2G392863, and GRMZM2G004466) were identified as key genes in darkgrey module. These genes were identified as glutathione peroxidase, GDSL-like lipase, defensin, and protease inhibitor. Glutathione peroxidase gene (GRMZM2G144153) is known to be activated upon a cell wall damage by insect feeding. In addition, it is also involved in the ROS scavenging, lignification of the cell wall, and synthesis of phenolic compounds. The GDSL-like lipase (AC212068.4_FG005) acts as an elicitor of systemic resistance linked with ET pathways. Upon insect feeding, its expression depending upon the ethylene signaling generates the systemic signals which translocate to other healthy parts of plants and propagate a systemic resistance throughout the plant. The defensin gene (GRMZM2G392863) has a great insecticidal property of inhibiting insect digestive enzymes; α -amylase play a crucial role in breaking down plant starch and hydrolyze proteins. Protease inhibitor genes

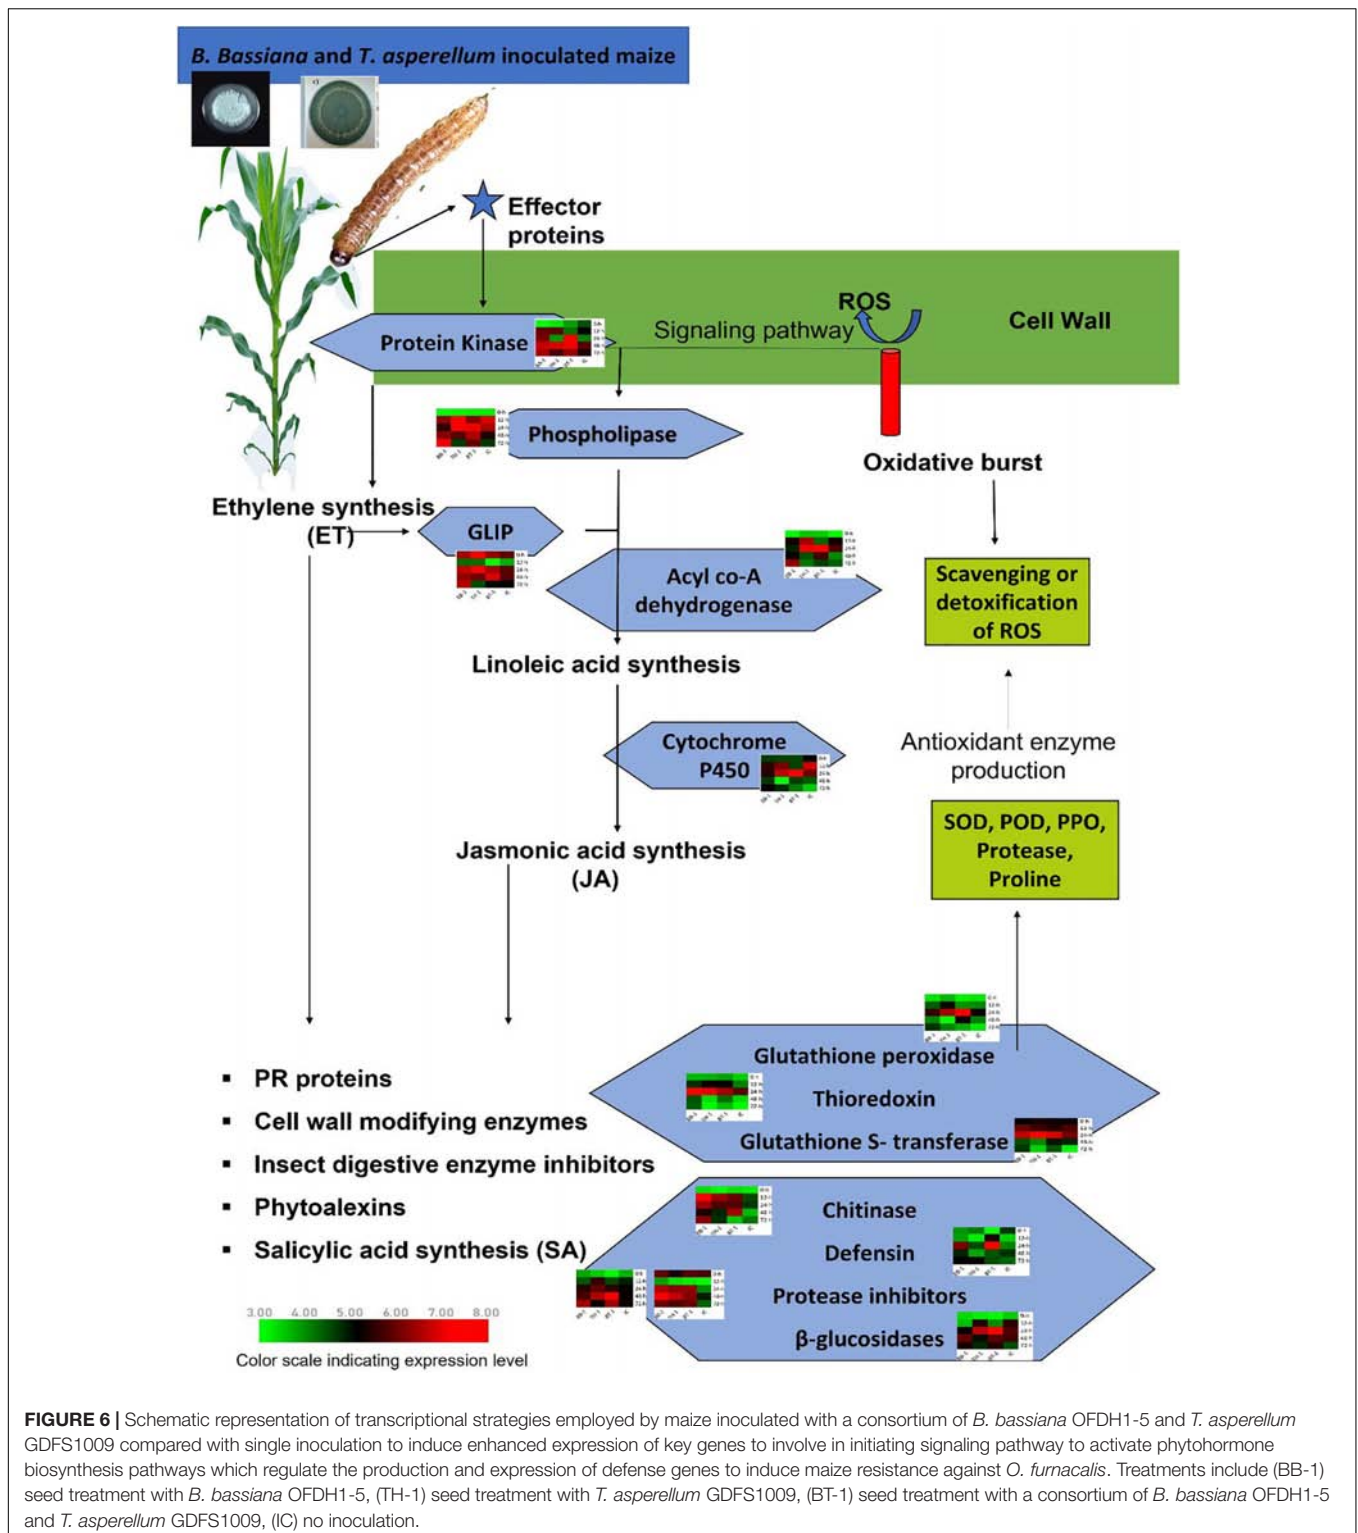

(GRMZM2G004466) were characterized as key genes. One more protease inhibitor gene (AC233926.1_FG002) was identified in the grey60 module as a key gene. They were found to participate in the reduction of insect growth, and, thereby, suppress the infection process by inhibiting extracellular proteases released by insects.

Patatin-like phospholipase gene (GRMZM2G154523) is responsible for the synthesis of linolenic acid, as a precursor of jasmonic acid biosynthesis pathway and chitinase gene (GRMZM2G453805), expressed by plants and acted as a self-defense mechanism against insect attack, were found as defense-related hub genes in the green-yellow module.

Beta-glucosidase 18 and cytochrome p450 (GRMZM2G031660 and GRMZM2G139874), which participate in various detoxification and biosynthetic pathways to protect the plant, were found as key genes in the magenta module. All genes showed differential expression patterns among all fungal-inoculated treatments, with the highest expression levels at 24- and 48-h post larval infestation specially in BT-1. The role and expression patterns of all key genes in maize defense response are shown in Table 5, Figure 6, and Supplementary Figure 2.

Metabolomic Adjustments Triggered by *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009

To obtain complete insights of *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009 inoculated maize under the *O. furnacalis* attack, we performed a comprehensive untargeted metabolomic analysis of all BB-1, TH-1, BT-1, and IC at 0-, 12-, 24-, 48-, and 72-h by UHPLC-QTOF-MS for the first time. The principal component analysis (PCA) analysis clearly showed the diversity among samples. Interestingly 0-h samples grouped indicating less diversity and other samples clustering away from control showed diversity in metabolomic data (Figure 7A). Through electrospray ionization (ESI) total of 7,367 NEG (negative) and 13,183 POS (positive) mass/retention time features were detected (Supplementary Data 4), and further 130 NEG and 491 POS differentially annotated and abundant metabolomic features were filtered based on different classes (Supplementary Data 5 and Figure 7B). Within the POS metabolic features, 9 fall in alkaloids and derivatives class, 26 in benzenoids, 3 in hydrocarbons, 194 in lipids and lipid-like molecule, 17 in nucleosides, nucleotides, and analogs, 47 in organic acids and derivatives, 11 in organic nitrogen compounds, 37 in organic oxygen compounds, 78 in organoheterocyclic compounds, 8 in organooxygen compounds, 57 in phenylpropanoids and polyketides and 1 each in hydrocarbon derivatives, organic compounds, organonitrogen compounds and lignans, neolignans, and related compounds. In the case of NEG metabolic features, 10 fall in benzenoids class, 15 each in nucleosides, nucleotide and analogs class and organic acid and derivative class, 1 in organic compounds, 16 in organic oxygen compounds, 13 in organoheterocyclic compounds, 6 in organooxygen compounds, 13 in phenylpropanoids and polyketides, and 41 in lipids and lipid-like molecules class

(Figure 7B). Through hierarchical clustering, metabolites were divided into five clusters. Obvious changes were seen in the abundance of all metabolites belonging to different classes with a higher abundance of malonic acid, succinic acid, threonic acid, and gluconolactone in cluster 1, silicristin and mulberrin

in cluster 2, etrogol and jasmonic acid in cluster 3, and betaine, L-threonine, L-carnitine, and thermophilin in cluster 5 were observed in a consortium treatment (BT-1). In cluster 4, all inoculated treatments have shown higher abundance as compared to control (IC) (Figure 7C).

***B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009-Enhanced Phytohormone Concentration Induced by *O. furnacalis* Herbivory**

To determine changes in stress-related phytohormones, we quantified JA, ET, and SA. A significant increase in the contents of phytohormones was recorded in all fungal inoculated treatments, but highest in consortium treatment (BT-1) at 24-h post infestation with an increase of 32.2, 37.4, and 77.5% in JA, SA, and ET, respectively (Figure 7D).

DISCUSSION

Ostrinia furnacalis is one of the most destructive insect pests of maize and it is responsible for major yield losses. It causes major damage at whorl stage plants by feeding in leaves and boring in maize stalk. Besides other pest control strategies, the biological control approach is of the highest interest because of its eco-friendly nature. The latest research proved that a consortium of biological control agents was effective against maize pests (Sarma et al., 2015; Batool et al., 2020). In our previous study (Batool et al., 2020), we have investigated and concluded that the entomopathogenic strain, *B. bassiana*, and

plant pathogen antagonistic strain, *T. asperellum*, have both strong synergistic potential and can be used in the consortium to enhance their biological control activity. They inhibit the insect survival and damage on maize plants by inhibiting the immune response of *O. furnacalis* at the transcriptome level. Based on our previous findings, in the present investigation, we further investigated the effect of *B. bassiana*, *T. asperellum*, and their consortium on insect survival, maize damage, and growth, at field level under natural environmental conditions. Furthermore, WGCNA was used for the first time in an entomopathogenically inoculated maize to integrate transcriptome and biochemical data and an untargeted metabolite profiling at the vegetative stage of maize to identify the candidate genes and metabolites associated with the regulation of defensive biochemical enzymes, and induction of maize resistance and maize defense pathways against *O. furnacalis*.

Both entomopathogenic/antagonistic fungi can colonize the plant endophytically and can induce a defensive response upon insect feeding as a challenge, thereby killing or arresting the growth of insects (Batool et al., 2020). Plants can provide a suitable environment for entomopathogenic fungi and their insecticidal activity can suppress the infection and facilitate plants by increasing insect resistance and plant growth (Gupta et al., 2016). Plant colonization largely depends upon the method of

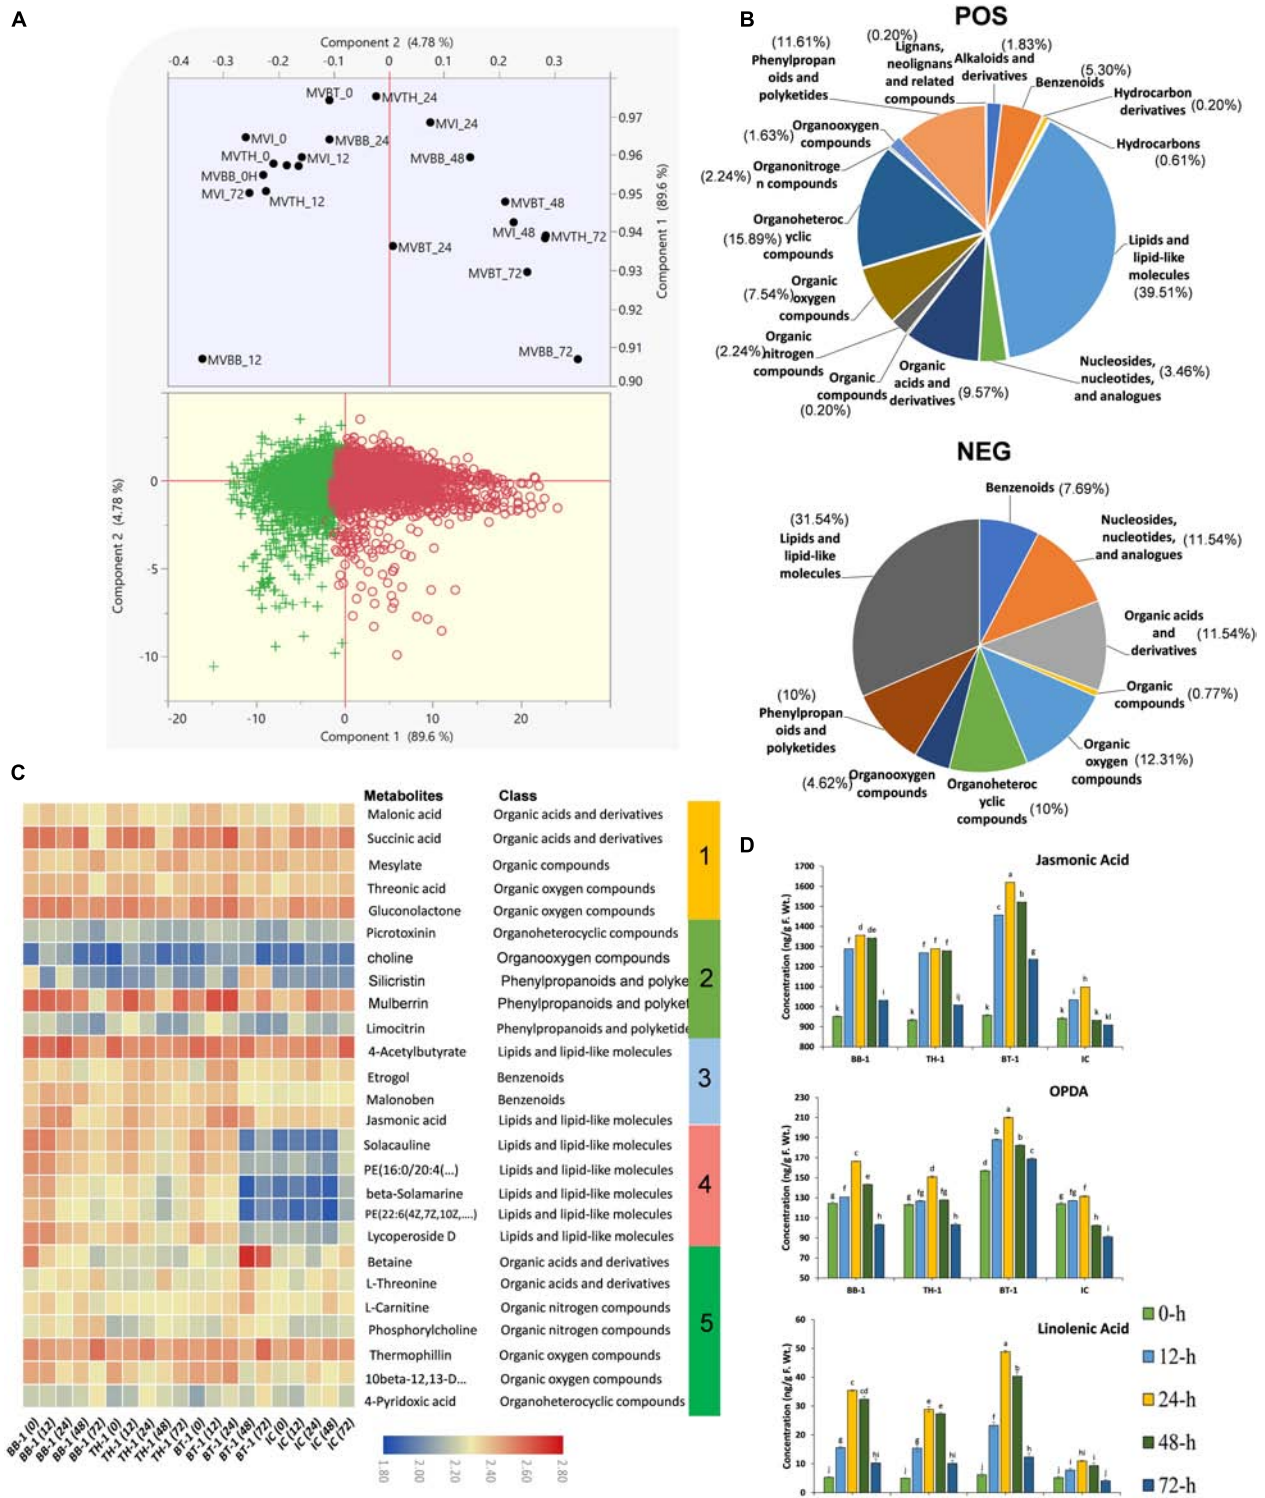

FIGURE 7 | Metabolome profiling of maize inoculated with single and consortium of *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009 and subjected to *O. furnacalis* attack. **(A)** PCA plot show divergence in metabolome data among treatments (MVBB, MVTH, MVBT, and MVI stands for BB-1, TH-1, BT-1, and IC, respectively). **(B)** Pie chart showing the percentage distribution of differentially annotated metabolites in different classes. **(C)** Hierarchical clustering of identified abundant metabolites. **(D)** Concentration of phytohormones in maize plants. Data is mean of three replicates and different lower-case letters above each bar indicate significant differences among treatments ($p < 0.05$). Treatments include (BB-1) seed treatment with *B. bassiana* OFDH1-5, (TH-1) seed treatment with *T. asperellum* GDFS1009, (BT-1) seed treatment with a consortium of *B. bassiana* OFDH1-5 and *T. asperellum* GDFS1009, (IC) no inoculation.

application and the seed treatment method was proven to be more effective (Batool et al., 2020). The seed treatment has the advantage of colonizing radical and plumule at the same time, as they are close to seed and can colonize the whole plant during its growth (Muvea et al., 2014). Our results were also in accordance with the findings of pathogenicity against *O. furnacalis* and reducing its survival, tunnel number and length, and increasing grain yield and plant growth in the consortium-treated Plants (BT-1). Some previous research also showed that the growth of entomopathogenic fungi in plants can prevent plant herbivory, and the *B. bassiana* have insecticidal activity against several insects including corn borers (Wagner and Lewis, 2000). *Trichoderma* is generally known for the function to induce the ISR of the whole maize plant against plant diseases and pest insects through colonization of maize roots (Rivas-Franco et al., 2020). The activity of *T. asperellum* was relatively low as compared to others, but its pathogenic activity was enhanced by the co-cultivation with *B. bassiana*. Shakeri and Foster (2007) also stated that the *Trichoderma* pathogenicity against borer larvae was lower and it can be increased by modifying them at the genetic level. *Trichoderma* could generate synergistic action with other biocontrol organisms, including the entomopathogenic fungi (Netzker et al., 2015), describing the use of consortium technique to enhance the activity through intercommunication.

In response to an insect attack, plants produce several defensive antioxidants including, SOD, POD, protease, PPO, and proline to scavenge ROS. These enzymes were considered the most important plant defense-related enzymes against herbivores (Guo et al., 2017; Batool et al., 2020). We also observed that antioxidant activities such as SOD, POD, PPO, protease, and proline were increased in all insect-infested plants, with a maximum increase at 24-h post infestation, while these enzyme activities were relatively higher in entomopathogenic fungal inoculated plants. The results revealed that these biocontrol agents enhanced the defense mechanism in plants by enhancing the production of defensive enzymes. Consortium treatment showed a maximum increase among all treatments. Some previous studies also reported the induction of SOD, POD, proline, protease, and PPO by biological control agents (Bano and Muqarab, 2017). PPO and protease play a defensive role against insect attack and induce resistance in plants (Joe and Muthukumaran, 2008). The chlorophyll content is one of the important components for plant growth and we observed that the chlorophyll content was increased in plants treated with entomopathogenic fungi compared to the insect control (IC). The same trend was recorded in previous studies (Bano and Muqarab, 2017; Batool et al., 2020). SOD is considered as the first enzyme in the scavenging process of ROS and its augmented scavenging action and detoxified by POD and act as a signaling agent to activate defensive genes in plants (Bano and Muqarab, 2017). Proline is best known as hydroxyl radical scavenger also serves as an energy source in plants. PPO is an important enzyme, which induces insect resistance in plants by participating in cell lignification and oxidation of polyphenols. Protease also has a defensive role against insect attacks (Batool et al., 2020).

With rapid development in bioinformatics, the weighted gene co-expression analysis (WGCNA) approach has been developed

to explore the functionality of transcriptome. WGCNA was used to detect the genes which co-express (Lin et al., 2019). The relationship between trait and module identifies the most vital hub genes, which supports an efficacious way to explore the in-depth mechanism of complex traits (Lv et al., 2020). Considering the importance of fungal inoculants against the control of *O. furnacalis*, plant yield, and maize defense through augmented production of enzymatic and non-enzymatic antioxidants. We also integrated these biochemical enzymes and compounds with plant transcriptome at 0-, 12-, 24-, 48-, and 72-h. We performed a transcriptome-based analysis to identify DEGs in different combinations. The DEGs were then analyzed by WGCNA along with biochemical parameters and 33 gene modules represented by different colors were identified. Among them, 6 were significantly correlated with SOD, POD, PPO, protease, proline, and chlorophyll content. All genes contained in modules were functionally annotated to identify hub genes and 28 hub genes were identified and validated through RT-qPCR. Finally, 13 genes were characterized as the key candidates that are involved in maize defense mechanism against *O. furnacalis* based on significant correlation of hub genes from the module with biochemical enzymes and chlorophyll content, and expression pattern of selected genes. Gamboa-Tuz et al. (2018) also identified stress related hub genes from papaya leaves and roots. Pan et al. (2020) correlated transcriptome through WGCNA to identify key genes in maize against herbivore.

Activity of Identified Candidate Genes in Phytohormone Signaling and Biosynthesis Pathways

Insect herbivores induce the expressions of genes associated with the phytohormone signaling pathway (Li et al., 2016). Plant recognizes herbivore damage as a primary signal and triggers the expression of defense related genes. Initially, when an insect starts feeding, the plant reacts to it by producing ROS and effector proteins to activate the expression of signaling molecules and initiate signaling pathways of systemic resistance (Almagro et al., 2009). We identified four such signaling related genes; protein kinase (GRMZM2G025459), GDSL-like Lipase (AC212068.4_FG005), Patatin-like phospholipase (GRMZM2G154523), and Cytochrome P450 (GRMZM2G139874), which showed a high response against *O. furnacalis* feeding in fungal inoculated treatments. The activity of GDSL-like lipase (GLIP) is highly dependent on the Ethylene ET- the pathway to generate systemic signals to produce GLIP in the uninfected part of the plants to protect it from the insect (Kwon et al., 2009). They also reported the reduction in the growth of *Pseudomonas syringae* by the accumulation of GLIP 1 in all parts of the plant. Patatin like phospholipase is a signaling molecule responsible for the release of linolenic acid from phospholipids to biosynthesize jasmonic acid (JA) (Ryu, 2004). Meijer and Munnik (2003) observed the presence of phospholipases in wounded tomatoes and many other plants. Dhondt et al. (2002) also found three lipase genes in response to external elicitor or infection before the accumulation of JA. Acyl co-A dehydrogenase gene (GRMZM5G864319) was also

identified as a candidate gene that participates in the linolenic acid metabolism of the JA biosynthesis pathway (Tang et al., 2015). Cytochrome P450 (CYP) participates in plant growth promotion and protection from biotic and abiotic stresses through detoxification and biosynthesis pathways. To date, the involvement of cytochrome p450 in different metabolic pathways including allene oxide synthesis in the jasmonic acid pathway, hormone metabolism, and biosynthesis of phytoalexin has been confirmed (Jun et al., 2015). *CYP74A* (allene oxide synthase, AOS) catalyzes the dehydration of hydroperoxide to an instable allene oxide in the JA biosynthetic pathway and plays an important role in wound-induced defense against biotic attacks (Park et al., 2002).

Gene Expression Regulating Antioxidant Enzyme Production

Biosynthesis of JA- and ET- activate the production of PR-proteins, cell wall modifying enzymes, salicylic acid synthesis, and phytoalexins as a defense response to induce systemic resistance. In the present investigation, the genes encoding defensive enzymes and proteins such as Thioredoxin (GRMZM2G091481), Glutathione Peroxidase (GRMZM2G144153), Glutathione S-transferase (GRMZM2G116273), Defensin like protein (GRMZM2G392863), protease inhibitor (GRMZM2G004466), protease inhibitor (AC233926.1_FG002), Chitinase (GRMZM2G453805), Beta-glucosidase 18 (GRMZM2G031660) were upregulated with higher expressions in consortium treatment (BT-1). The expression patterns of these genes coincide with the levels of biochemical enzymes produced in all treatments, which indicates that the over expressions of these genes may regulate higher production of enzymatic (SOD, POD, PPO, and Protease) and non-enzymatic (proline) antioxidants to initiate maize defense responses, such as lignification, suberization, insect growth inhibition, and scavenging of ROS.

Genes Mediating Redox Signaling

Enzymatic and non-enzymatic antioxidants reduce the level of ROS and SOD is considered as the first and most important enzyme in the scavenging process as it catalyzes O_2^- into H_2O_2 . The accumulation of the highest H_2O_2 is toxic for plants and POD detoxifies them (Bano and Muqarab, 2017; Batool et al., 2020). Peroxidases are the most important enzyme and they participate in different physiological processes of the plant (Almagro et al., 2009). Besides ROS scavenging, peroxidase encoding genes are also involved in lignin and suberin production to link the cell wall components. POD belongs to the PR-protein9 subfamily. The highest expression of POD increases the structure barrier and stops the infection. The expression of peroxidase genes in plants was induced by biotic and abiotic stresses (Sasaki et al., 2007). Thioredoxin genes were found to be associated with ROS scavenging enzymes such as ascorbate, POD, SOD, and catalase through disulfite bridge (Dos Santos and Rey, 2006). Moreover, Glutathione S-transferase detoxify electrophilic compounds in the scavenging process, also interact with plant thioredoxin (Yamazaki et al., 2004). Several stress conditions accumulate high ROS levels and resulted in the increased expression of the thioredoxin gene to participate in oxidative

stress-linked signaling to induce high levels of antioxidant enzymes in potato plants (Dos Santos and Rey, 2006).

Genes Inhibiting Insect Digestive Enzyme

Polyphenol oxidase is a plant antioxidant enzyme important for regulating insect feeding, growth, development and defense response against herbivory and its production can be associated with the expression of different proteins and enzymes that can restrict the nutrient uptake of insects and attack their digestive track, e.g., chitinase, protease inhibitors and α -amylase inhibitors (Abebe). The chitinase enzyme is very important and it inhibits insect chewing and killing by degrading the insect skeleton (Zhong et al., 2021). The highest expression of chitinase reduces the insect induced damage and survival rate. Bordoloi et al. (2021) also identified two chitinase genes viz. TEA028279 and TEA019397 in tea plants with high expression under stress conditions with jasmonate and salicylic acid in their promoter upstream region to degrade chitin, of insect's exoskeleton. Similarly, defensin gene also prevents the insect chewing by inhibiting insect's digestive enzyme such as α -amylase and protease and makes it difficult to breakdown plant starch. Defensin express continuously in leaves stomatal cells, cell wall, peripheral layer of root, seed, and flowers, which indicate that they play an important role in protecting all entry points of plants from pest and pathogens. Khairutdinov et al. (2017) reported the inhibition of α -amylase activity by *PsDef1* defensin gene in pine pest *Panolis flammea*. The inhibitory action of α -amylase by the defensin gene in *Sorghum bicolor*, *Vigna unguiculata*, and *Tephrosia villosa* have also been studied (Kovaleva et al., 2020). Similar to defensin, protease inhibitors and β -glucosidase are also important for inhibiting insect gut digestive enzymes like proteases to prevent its feeding. Guedes and Cutler (2014) reported the role of insecticidal protease inhibitors in tobacco, rice, oilseed rape, sugarcane, and brassica. Expressions of protease inhibitors have been detected in wounds and induce defense against plant herbivory and pathogen attack (Clemente et al., 2019). Maize, almond, and white mustard defensive β -glucosidases were shown to restrict the digestion of lepidopteran larvae (Vassão et al., 2018).

High accumulation of metabolites contributes to acclimation of maize pre-inoculated with entomopathogenic fungi in response to *O. furnacalis* stress. In our study, significant accumulation of organic acids, benzoxazinoids, phenylpropanoids and polyketides, and lipid-like molecules were observed with higher levels in consortium treatment. Benzoxazinoid is an important defensive secondary metabolite in maize defense against *O. furnacalis* (Guo et al., 2019). However, this untargeted metabolome profiling was performed for the first time in maize plants inoculated with a consortium of *B. bassiana* and *T. asperellum* in response to *O. furnacalis* attack. We found that the contents of benzoxazinoids were changed after insect attack but higher contents were seen in inoculated treatments as compared to control. Accumulation of organic compounds plays a key role in defense against biotic and abiotic stresses (Zhang et al., 2020). We found that the accumulation of metabolites belonging to benzoxazinoids,

lipid-like molecules, organic compounds and phenylpropanoids can be a common mechanism in plant adaptation to different stresses. JA contents, expression levels of genes involved in JA biosynthetic pathway and JA-dependent metabolite adjustment in lipid-like molecules, which plays a defensive role, increased during *O. furnacalis* feeding in consortium inoculated plants, indicating its enhanced protective mechanism in JA-dependent maize resistance to *O. furnacalis*. Similar findings were reported by Guo et al. (2019) in *O. furnacalis* induced direct and in direct defenses. Jasmonates are responsible for regulating nearly all biosynthetic pathways that lead to metabolites (Martínez-Medina et al., 2021). According to the significant impact of *B. bassiana* and *T. asperellum* on JA, significant changes in secondary metabolites were triggered. Similarly, previous research also reported a strong impact on plant metabolites, primary metabolism, and changes in defensive compounds (Martínez-Medina et al., 2021).

Among consortium of biocontrol agents used against pest attack, one acts as a stress inducer and the other acts as a control agent. The combined application of BCAs by different mechanisms effectively controlled the incidence of *Duponchelia fovealis* in strawberry plants (Araujo et al., 2020).

CONCLUSION

By comprehensive physiological, biochemical, transcriptomic, metabolomic, and phytohormone analysis in maize inoculated with *B. bassiana* and *T. asperellum*, applied singly and in the consortium, we revealed enhanced maize defenses against *O. furnacalis* herbivory. Our study indicates that consortium of *B. bassiana* and *T. asperellum* can synergistically suppress *O. furnacalis* immune response and enhance maize immune response in the field by directly inducing enhanced expression of defense genes and indirectly activating antioxidants and phytohormone production as compared to normal herbivory-induced defenses. They can regulate the coordinated gene network expression related to defense signaling and antioxidants response and within these networks, certain genes make a key contribution to trait variation. Higher phytohormone content diverse metabolome abundance in consortium treatments was also highlighted in our results indicating the importance of JA, SA, and ethylene in plant defense. The correlation between the expression of these genes and enzymatic (SOD, POD, PPO, and protease) and non-enzymatic (proline) antioxidants, phytohormone synthesis, and metabolite adjustments were identified the first time in *B. bassiana* OFDH1-5, *T. asperellum* GDFS1009 consortium inoculated maize against *O. furnacalis* attack. The advantages of fungal BCAs are economic mass

production, easy-to-use, sustainable control efficacy, and environmental safety suggest a bright future of mycoinsecticides in the world. Moreover, this study opens up new insight for future studies to focus on how certain changes in the gene networks and metabolites through biocontrol agents can affect above and below ground maize defense and other pathways. On the basis of current results, we believe that defense against ACB attack in maize is not a single gene-controlled process. Multiple genes are involved at the same time. Future research must focus on metabolic-gene clusters.

DATA AVAILABILITY STATEMENT

The datasets presented in this study is submitted in (<https://www.ncbi.nlm.nih.gov/bioproject>) repository, BioProject: PRJNA797234.

Bioeffector (BE) application is emerging as a strategy for achieving sustainable agricultural practices worldwide. However, the effect of BE on crop growth and quality is still controversial and there is still no adequate impact assessment that determines factors on the efficiency of BE application. Therefore, we carried out a network metaanalysis on the effect of BEs using 1,791 global observations from 186 studies to summarize influencing factors and the impact of BEs on crop growth, quality, and nutrient contents. The results show that BEs did not only improve plant growth by around 25% and yield by 30%, but also enhanced crop quality, e.g., protein (55% increase) and soluble solids content (75% increase) as well as aboveground nitrogen (N) and phosphate (P) content by 28 and 40%, respectively. The comparisons among BE types demonstrated that especially non-microbial products, such as extracts and humic/amino acids, have the potential to increase biomass growth by 40–60% and aboveground P content by 54–110%. The soil pH strongly influenced the efficiency of the applied BE with the highest effects in acidic soils. Our results showed that BEs are most suitable for promoting the quality of legumes and increasing the yield of fruits, herbs, and legumes. We illustrate that it is crucial to optimize the application of BEs with respect to the right application time and technique (e.g., placement, foliar). Our results provide an important basis for future research on the mechanisms underlying crop improvement by the application of BEs and on the development of new BE products.

Keywords: biostimulants, biofertilizers, sustainable agriculture, nutrient use efficiency, pH, PGPR

INTRODUCTION

The use of bioeffectors (BEs) has been proposed as a promising solution for the challenges of sustainable agriculture (Povero et al., 2016). A BE is defined as organic material and/or microorganisms applied to living plants or soil to enhance nutrient uptake, stimulate growth, improve stress tolerance and crop-quality traits, regardless of its nutrient contents (Van Oosten et al., 2017; Rouphael and Colla, 2018; Schütz et al., 2018; Ricci et al., 2019). Typical BEs include amino acids and other organic compounds, seaweed extracts, and botanicals as well

as microorganisms including fungi and bacteria. Numerous studies have demonstrated that the application of BEs is beneficial to plants in all developmental stages (Qiu et al., 2020; Roupael and Colla, 2020b) and may increase yield (Schütz et al., 2018).

Microbial products can directly influence nutrient availability in soil or nutrient uptake by plants. For example, N-fixing bacteria are able to sequester nitrogen (N_2) from the air, thereby increasing the pool of reactive N in the soil. Phosphate (P)-solubilizing bacteria (PSB) can transform phosphate from insoluble compounds to bioavailable ones by releasing protons, exudates, such as chelates, and other substances. Previous studies have determined that symbiotic arbuscular mycorrhiza fungi (AMF) promoted phosphate, nitrogen, and micronutrient acquisition through spatial enlargement of the influence of the rhizosphere (Watts-Williams and Cavigliaro, 2014). The stimulation of plant nutrient acquisition by BEs is beneficial, especially under nutrient-poor conditions and it reduces the dependency of agriculture on the application of inorganic fertilizers (Oldroyd and Leyser, 2020). Further, in high-input agricultural systems, the application of BEs can facilitate fertilizer and pesticide use without risking yield decline. Some plant growth-promoting microbes can alter the hormone balance in plants and improve plant performance. Meents et al. (2019), for instance, reported that the beneficial fungi *Piriformospora indica* increased auxin levels in plants thereby promoting root growth.

Besides selected microbial organisms, BEs also comprise a variety of processed substances from soil and plants, such as humic acids, amino acids, and extracts, from seaweeds and other plants. These products are diverse in terms of their potential influence on plants and the microbial community in the soil. Extracts can directly influence plant growth by bioactive compounds or indirectly by ameliorating soil characteristics (Shukla et al., 2018). By altering soil water holding capacity, they indirectly improve soil growing conditions and nutrient availability for plants (Khan et al., 2009). Extracts also interact with the soil microbial community and promote the function of beneficial fungi (e.g., AMF) by increasing infectivity, spore production, colonization, and hyphae growth (Khan et al., 2009). Humic and amino acids can stimulate the proton pump of the plant (Jindo et al., 2012), thereby supporting the plant's own nutrient solubilizing pathway and increasing nutrient availability in the rhizosphere. Additionally, the complexation of micronutrients by organic acids, reduction of Fe(III) to Fe(II), and the presence of organic radicals and phenolic compounds are further possible explanations for an increased nutrient availability in soil after the application of organic acids (Adani et al., 1998).

BEs have further been shown to improve plant tolerance to abiotic and biotic stress. Two main pathways are described: Firstly, beneficial microbes can adapt themselves to extreme conditions, such as salinity and cold temperatures (Selvakumar et al., 2008; Upadhyay et al., 2009). Microbes can then increase the tolerance of plants to abiotic stress by ameliorating plant performance under these conditions (Van Oosten et al., 2017). Secondly, microbes and natural compounds can produce substances that promote stress adaptation by the plant (Van Oosten et al., 2017).

Considering the recent public awareness on environmental degradation and pollution by agricultural production, the topic of BE-use in sustainable agriculture is becoming increasingly important. However, BEs as living organisms or natural extracts are influenced by edaphic and environmental factors after application. This leads to unreliable outcomes for farmers, thereby limiting their practical use and adoption. Despite decades of research on this topic, the efficiency of BEs varies widely among published studies (Schmidt and Gaudin, 2018). In particular, the pivotal factors determining the effects of BEs, such as crop specificity and mode of action, are still unclear. Moreover, most data from Chinese BE studies are not included in previously published metaanalyses.

The goal of this study was to systematically quantify the improvement of plant performance and other important indicators (e.g., quality, nutrient acquisition) *via* BE application in general, but also under given local agricultural conditions (e.g., pH, crop type). Another aim was to specify practical and efficient application strategies of BEs. To achieve these goals, a network metaanalysis was conducted to primarily determine whether BEs show a global positive effect on plant biomass, yield, aboveground nutrient content, nutrient use efficiencies, and quality indicators (protein- and soluble-solids content). Secondly, crucial factors that influence the efficiency of BEs were determined. Therefore, we analyzed variables, such as crop type, edaphic pH, and other aspects, in crop production on a global scale.

MATERIALS AND METHODS

Data Collection

In this metaanalysis, we compiled a global dataset by retrieving peer-reviewed studies published until December 2021 using Scopus by Elsevier, ISI-Web of Science, the search engines of Microsoft Academic, and Hohsearch (search engine of the University of Hohenheim, Stuttgart, Germany). Studies in Chinese were extracted from the China Knowledge Resource Integrated Database (CNKI). “Biofertilizer,” “biostimulant,” or “bioeffector” together with “nutrient” or “quality” were selected as keywords. This resulted in more than 2,000 possibly fitting studies. Studies were sorted by relevance prior to checking them. Literature searches were terminated if 20 studies in succession did not fit into the inclusion criteria defined below. We filtered the studies by the following inclusion criteria: (i) the standard errors and the number of replicates that were reported. These values were needed to calculate the effect sizes. (ii) The experiment had to be laid out in the soil. (iii) The only difference between the control and the treatment group was the BE application. (iv) Germination trials were excluded. (v) The study stated at minimum two predefined response variables. (vi) The agricultural crops were used for food, fodder, or biomass production. A PRISMA flowchart is included in the **Supplementary Materials (Supplementary Figure 1)**.

Preprocessing of Data

When data were available in graphs only, the program GetData Graph Digitizer (Ver. 2.22) was used to extract means and

standard errors. To convert the concentration of available N and P in soil from g kg^{-1} to kg ha^{-1} , the bulk density was estimated according to the United States Department of Agriculture – Natural Resources Conservation Service (2019). The effective root zone was determined as 0.5 m. If only the total N of the soil was analyzed, then the available N was estimated based on the calculation by Sponagel et al. (2005). When organic fertilizers were used and in case their nutrient composition was not analyzed, estimated nutrient contents were used from Herbert et al. (2019). If it could not be estimated, the study was not considered in the investigations of nutrient-use efficiency. Additionally, the shoot biomass for the calculation of nutrient use efficiencies was transformed into kg ha^{-1} by considering plant densities indicated in the papers or estimated based on a common agricultural practice (**Supplementary Table 1**). pH values were adapted in case it was measured in CaCl_2 or KCl, according to Reuter et al. (2008), to convert values to measurements in water. If the method was not given, it was assumed to be measured in water. For all the other measurements, methods were considered similar, and no transformation of the values was implemented.

The potential influencing variables BE, geographic region, application strategy, and application time were categorized. The BEs including microorganisms were categorized according to Schütz et al. (2018). Botanicals, as well as sea-weed extracts, were summarized as the group of “extracts.” Humic/amino acids formed another category. Substances not fitting into these categories were pooled in the group “others.” The combination treatment was subdivided into a dual combination, which included two different microorganism categories, a combination of more than two microorganism categories, and a mixture of microorganisms and non-microbes.

In the case of BE application, it is very likely that different effects must be expected for different management regimes. As nutrient balances vary largely across the world and locally adapted strategies are needed (Haygarth and Rufino, 2021), the World Bank (2019) classification of regions was applied to

account for this variation. This categorization of the countries was chosen as a broad indicator for the agricultural practice in the countries. According to the set of the experiment, we divided the data into pot and field trials. The grouping into perennial or annual did not happen according to the biological capability of growing several seasons, but according to the layout of the experiments. If the plants in the experiment had been growing for several seasons or the BE application was conducted for more than 1 year on the same plant, the study was identified as perennial.

Furthermore, the data were subdivided according to the application strategy. We identified four different modes of application. The BEs were applied either (1) to the seed, (2) in the soil, (3) to the seedling, or (4) by foliar application. Additionally, a combination of two or more above-mentioned modes of application was also considered. Concerning application time, we distinguished between a single application, before/at sowing or after sowing, or a multiple application. The pH range was divided into five subgroups, namely, ≤ 5.5 “strongly acidic,” $5.5 < \text{pH} \leq 6.5$ “slightly acidic,” $6.5 < \text{pH} \leq 7.5$ “neutral,” $7.5 < \text{pH} \leq 8.5$ “slightly alkaline,” $\text{pH} > 8.5$ “strongly alkaline.”

Statistical Approach

Determination of effect sizes is one option in metaanalyses to handle the variation of units and measurements and to enable the calculation of overall effects, thereby enabling the comparison of effects between studies (Sánchez-Meca and Marín-Martínez, 1998). For calculating the effect size, the treatment means were standardized by dividing them by their standard error. Additionally, the correction of bias according to Hedges (1981), which includes the repetition number, was added to the calculation. A logarithmic transformation was then applied to further stabilize the variance and counteract the right-skewness of the effect sizes. Effect sizes in the current study were calculated for the following traits: yield, shoot biomass, root biomass, aboveground nutrient content of N and P, nutrient

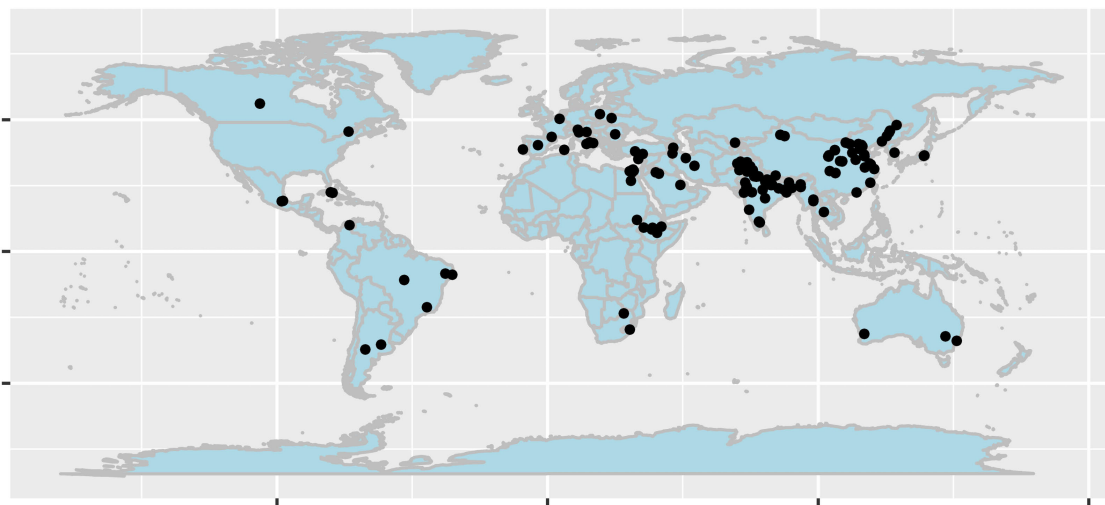

FIGURE 1 | Location of studies included in the data set. The figure was created by the R package ggmap (Kahle and Wickham, 2013).

use efficiency of N and P, as well as the quality parameters of protein and soluble solids content. We defined shoot biomass as the total aboveground plant material and yield as the main marketable product. Nutrient use efficiency was defined as the biomass divided through the total amount of available N and P in soil, respectively (available nutrient in soil + input through fertilizers).

Publication bias can strongly affect the results of metaanalyses, thereby altering or overestimating the outcomes (Levine et al., 2009). It was assumed that articles will be more likely to be published if they prove positive effects, similar to medical studies (Joobert et al., 2012). In our study, when a strong right skewness was observed, the statistical approach by Carrijo et al. (2017) was followed. Therefore, independently for every group of effect size, when the effect sizes of studies exceeded the mean plus three times the standard error, they were excluded from the analysis. After the exclusion, 186 out of 197 studies were used for the final analysis including a total amount of 1,791 observations. For the first time, 64 studies conducted in China (423 observations) were included. The locations of those studies when identifiable are shown in **Figure 1**. The 186 studies, which were finally included in the metaanalysis, are listed in the references.

It is important to consider the methodological quality of the studies as it could strongly influence the outcome of a metaanalysis (Moher et al., 1998). Therefore, we included the impact-factor of the journal, where the study was published as a covariate in our model. In later steps, the covariate was again removed from the model, as it was not significant in any case.

In the collected data structure, several treatments correspond to the same control. Therefore, to quantify the impact of each BE type of one study and still avoid correlation of effect sizes, a network metaanalysis was necessary using a linear mixed model described by Madden et al. (2016). This approach has the advantage that it enables us to compare treatments indirectly even if they never occurred together in the same study. A random study effect was included in the model as just a sample of available studies was chosen, and the aim of the analysis was to generalize our result for future studies to be published. The model can be described as follows:

$$Y_{ijklmnopqr} = \mu + b_j + \tau_i + (\alpha\tau)_{ik} + \beta_{li} + \gamma_{mi} + (\delta\tau)_{in} + \theta_{oi} + (\vartheta\tau)_{iq} + (\phi\tau)_{iq} + (\kappa\tau)_{ir} + e_{ijklmnopqr},$$

where μ is the intercept, b_j is the random effect of the j th study, τ_i is the main effect for the i th treatment (with levels control and treatment). β_{li} , γ_{mi} , and θ_{oi} are the effect of the l th application time, the m th BE, and the o th mode of application, respectively. These factors are nested within treatment, as in the control BEs were not applied at all. $(\alpha\tau)_{ik}$, $(\delta\tau)_{in}$, $(\vartheta\tau)_{iq}$, $(\phi\tau)_{iq}$, and $(\kappa\tau)_{ir}$ are the interaction effects of the i th treatment and k th testing system, the n th crop, p th perennial or annual, q th geographical region, and the r th pH-effect, respectively. We did not fit the main effects for these latter terms as we were only interested in the differences of control and treatment depending on these factors. The value $e_{ijklmnopqr}$ is the error of mean effect size $y_{ijklmnopqr}$ with a homogeneous error variance.

For all factors in the model above, our main focus was on the differences between control and treatment, and differences between these differences across treatments. Contrasts were used to calculate the difference of the differences between control and treatment. As the data were logarithmically transformed prior to analysis, differences correspond to ratios on the original scale. The back-transformed value from a difference of differences corresponds to an odds ratio.

To avoid overfitting, which means that additional non-significant factors in the model mask the effects of other factors, we performed a model selection. To implement this, we switched the method for variance component estimation to maximum likelihood. We then used the Akaike Information Criterion (AIC, Wolfinger, 1993) selection criterion to find the best model for our data. Since the AIC can only be used for comparisons of models which have identical data sets, an auxiliary dataset was created by omitting all observations for which data for at least one of the parameters of the full model was lacking. Afterward, the model selection was carried out using this auxiliary dataset. It was assumed that the best-selected model through the model selection is transmissible to the entire dataset later since studies were considered as random samples.

In none of the final models from the model selection, BE types were included as factors. Since one of our initial focuses was to investigate the differences between BE types, selected models of shoot and root biomass, yield, aboveground P as well as N content, and nutrient use efficiencies were expanded by the BE type. This resulted in slightly higher AIC and changed mean effects (**Supplementary Table 2**). Further analyses for all other factors were conducted with the non-expanded model and only BE types were investigated using the expanded model.

After finding the best model *via* AIC, the restricted maximum likelihood estimation was applied (Patterson and Thompson, 1971). Confidence limits were calculated for each difference between treatment and control and the contrasts of the differences among treatments. We considered estimates to be significantly different from zero when their p-Values were below or equal to 0.05, and in tendency when their p-Values were below or equal to 0.1. Afterward, differences and contrasts [as well as their lower and upper bounds of the confidence limit ($\alpha = 0.05$)] were backtransformed to the original scale for presentation purposes only. Standard errors were backtransformed using the approximate delta method (Xu and Long, 2005). Normal distribution and homogeneous variances of residuals (on the transformed scale) were checked graphically.

The illustration of the graphs was implemented in R with the package ggplot2 (Wickham, 2016). The figures depict the median and confidence limits of the subgroup analysis, as well as the overall effects, which we defined as the difference of the main effects τ_i , namely the difference of treatment and control factors.

RESULTS

The results of the model selection are shown in the **Supplementary Materials (Supplementary Table 3)**. In the root biomass investigation, no data was available for perennial

crops and field trials. Those parameters were therefore not considered in the analysis. The country grouping was also not relevant for the model of root biomass as experiments were exclusively laid out under controlled greenhouse conditions. A summary of the significant parameters in each model and the most important influencing factors for each indicator are provided (Supplementary Table 4).

Assessment of Bioeffector Effects on Crop Growth and Yield

As shown in **Figure 2A**, shoot biomass was significantly enhanced due to BE application by 26%. The variable soil pH influenced the outcome clearly (**Figure 2B**). A significant increase of biomass by BE application was observed in slightly acidic and strongly acidic soils, with strongly acidic soils showing the highest median of 58% increase. Regarding the mode of application, BE input *via* soil (38% increase) and foliar application (34% increase) as well as a combination of several different modes (48% increase) was more beneficial for plant biomass production than seed inoculation or application during early plant developmental stages (12% and 0.6% increase) (**Figure 2C**). **Figure 2D** illustrates that a significant increase of shoot biomass occurred in pot trials (33% increase). The efficiency of BE application differed among countries (**Figure 2E**), with middle-income economies obtaining the highest efficiencies (46% increase for lower-middle-income economies and 35% increase for upper-middle-income economies).

When adding the BE types to the model, non-microbial products attained the highest responses with a shoot biomass increase of 57%, 41%, and 42% for extracts, humic and amino acids, and the combination of microbes and non-microbial substances, respectively (**Figure 3A**).

The yield was significantly augmented by 30% (**Figure 4A**). Almost all crop types responded significantly to BE application, except the group “others.” Herbs and fruits increased in yield the most with 47% and 40% (**Figure 4B**). Pot-trials obtained a significantly higher yield increase than field trials with a 45% and 16% increase, respectively (**Figure 4C**). When investigating the expanded model, all BE types induced significant yield increases (**Figure 3B**), and the combination of microbes and non-microbial products stood out with an increase of 55% (**Figure 3B**).

Root biomass responded positively to BE application with an increase of 69% (**Figure 5A**). As shown in **Figure 5B**, in strongly acidic soils with pH levels < 5.5, root growth was extremely enhanced by 161%, whereas in other pH levels the effect was below the overall median. For strongly alkaline soils, data was limited in the dataset. Therefore, no definite statement can be given. The comparison of the mode of application resulted in significant increases for nearly every application mode, except the inoculation of the seedling (**Figure 5C**). The combination of several modes of application resulted in exceptionally high root growth with a 173% increase. The analysis of the model extended with the variable BE type led to no clear differentiation among the BE types except for AMF as well as the combination of

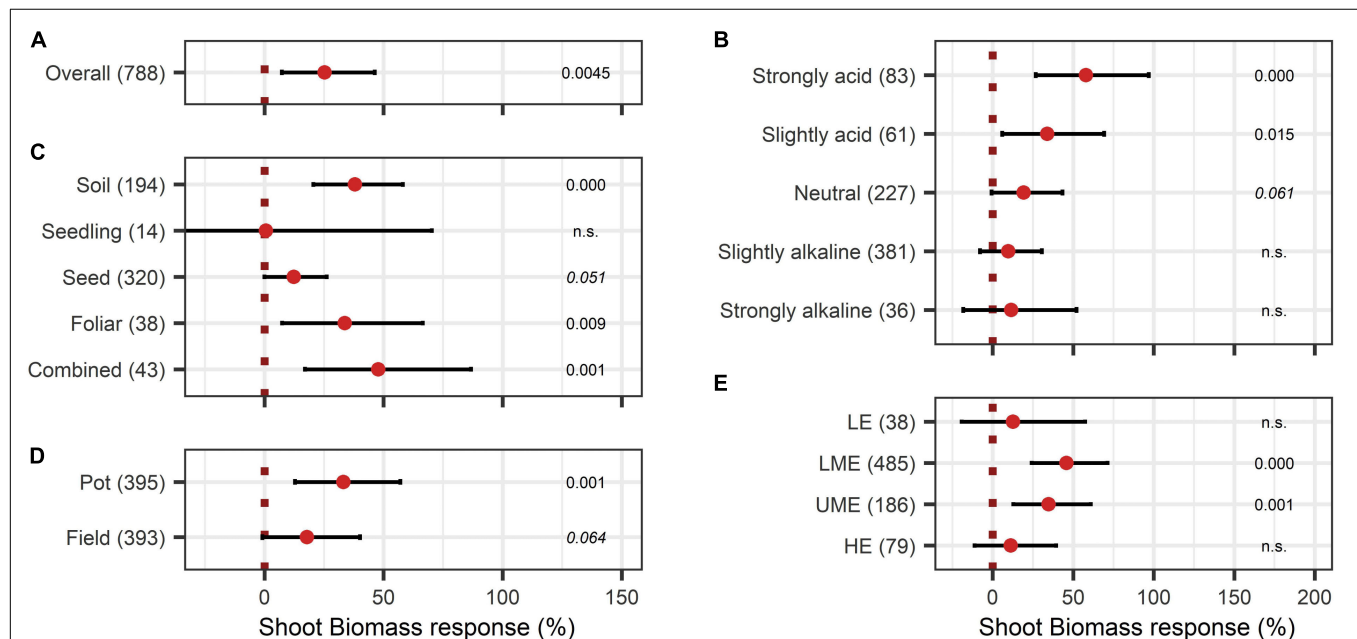

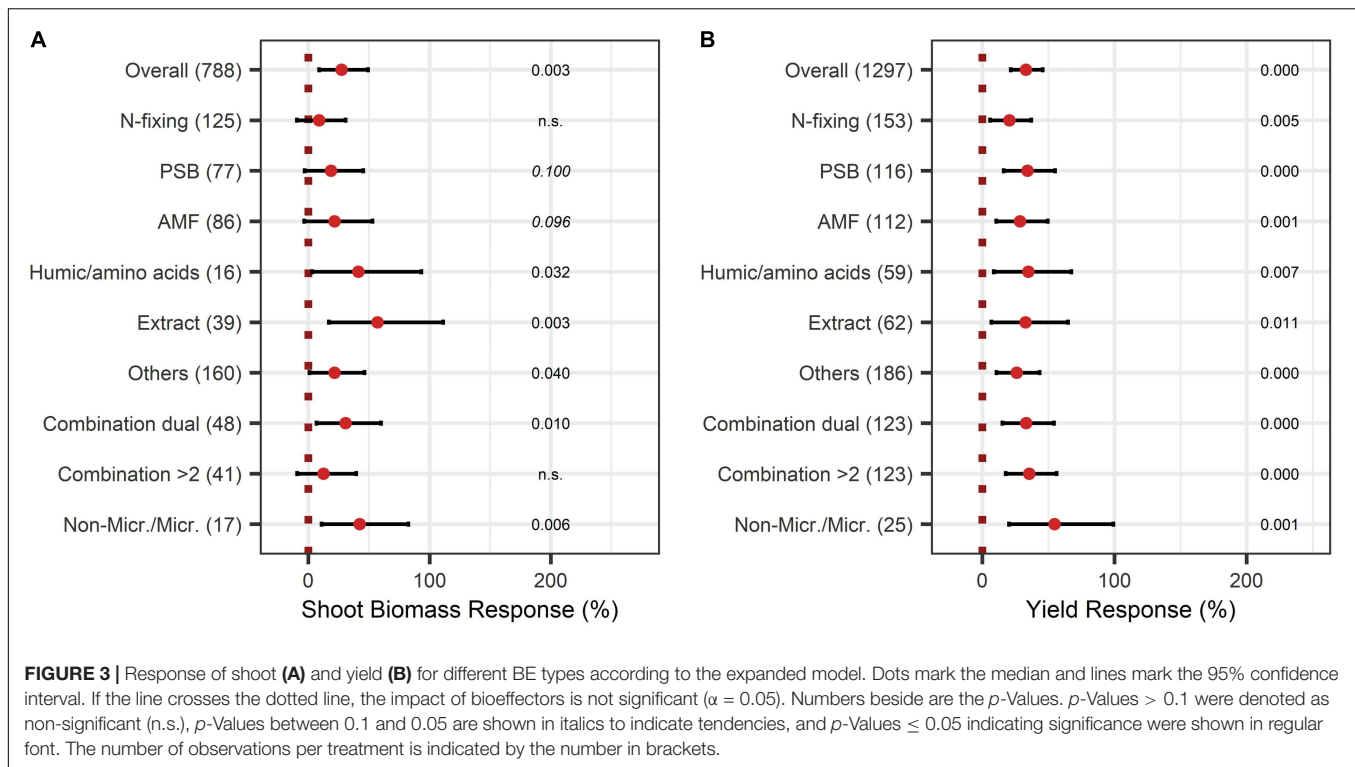

FIGURE 2 | Response of shoot biomass. **(A)** Overall biomass effect of all observations (median). **(B–E)** are subgroup analyses on biomass response: **(B)** pH categories, **(C)** mode of application, **(D)** test system, **(E)** country grouping (LE: low income economies, LME: lower middle income economies, UME: upper middle income economies, HE: high income economies). Dots mark the median, lines mark the 95% confidence interval. If the line crosses the vertical dotted line, the impact of bioeffectors is not significant ($\alpha = 0.05$). Numbers beside are the *p*-Values. *p*-Values > 0.1 were denoted as non-significant (n.s.), *p*-Values between 0.1 and 0.05 were shown in italics to indicate tendencies and *p*-Values ≤ 0.05 indicating significance were shown in regular font. The number of observations per treatment is indicated by the number in brackets.

microbes and non-microbial substances, which led to the highest root biomass improvements (Figure 5D).

Assessment of Bioeffector Effects on Crop Quality Indicators

Concerning the crop quality improving aspects after BEs application, soluble solids content and protein content were investigated. Soluble solids showed a positive increase with an overall BE effect of 55% (Figure 6A) and also, with BE application protein content strongly increased by 75% (Figure 7A). The content of soluble solids depended on the test system, crop type, and pH (Figure 6), whereas protein content was additionally affected by the mode of BE application, the geographic region, and if the plant was perennial or annual (Figure 7). Here, foliar application resulted in a strong increase in protein content by 157%, whereas seed and soil application led to increases of 45% and 105%, respectively (Figure 7F). Crop types, such as fruits and vegetables, for which quality aspects are important for selling, showed no significant increase in soluble solids content as well as in protein content by BE application (Figures 6C, 7C). In legumes, soluble solids content was significantly enhanced by 181% and protein content by 99% (Figures 6C, 7C). Protein content was more increased in perennial crops (138%) than in annual crops (29%) (Figure 7D). From slightly acidic to slightly alkaline environments, the median responses of soluble solids content were the most pronounced with increases from 53% to 73%, but significant responses could be obtained only in slightly alkaline conditions (Figure 6B). Additionally, protein contents were significantly increased in neutral environments by 180%, whereas increases were clearly lower in other soil pH ranges

(Figure 7B). The median increase of soluble solids content in the field (76%) compared to pot trials (37%) due to BE application was higher and more significant (Figure 6D), whereas for protein content, results were similar (74% for field and 77% for pot trials) (Figure 7G).

Assessment of Bioeffector Effects on Crop Nutrient Content and Nutrient Use Efficiency

The BE application showed significant improvements in aboveground nutrient content and nutrient use efficiency. The response of aboveground P content (40%) was slightly larger than the improvement of aboveground N content (28%) (Figures 8A, 9A). Crop types differed in their response to BE application regarding aboveground N and P content. Aboveground N content was especially enhanced in legumes (81%) (Figure 8B). Also, cereals and oilseed crops have the tendency to attain positive outcomes with an increase of 37%. For aboveground P content, differences were marginal among cereals, legumes, and fruits (61% to 87%) (Figure 9B). The application time after sowing led to the highest increase with regard to aboveground N and P content (64% and 73%) (Figures 8C, 9C). Both aboveground nutrient content responses did not differ in the test systems (Figures 8D, 9D). Soil (79%), foliar (49%), and a combination of different methods of application (90%) improved aboveground P content significantly (Figure 9E). In the case of aboveground N content, only soil application (104%) led to significant increases while seed application (29%) showed a tendency to increase N content (Figure 8E).

Dots mark the median and lines mark the 95% confidence interval. If the line crosses the dotted line, the impact of bioeffectors is not significant ($\alpha = 0.05$). Numbers beside are the p -Values. p -Values > 0.1 were denoted as non-significant (n.s.), p -Values between 0.1 and 0.05 are shown in italics to indicate tendencies, and p -Values ≤ 0.05 indicating significance were shown in regular font. The number of observations per treatment is indicated by the number in brackets.

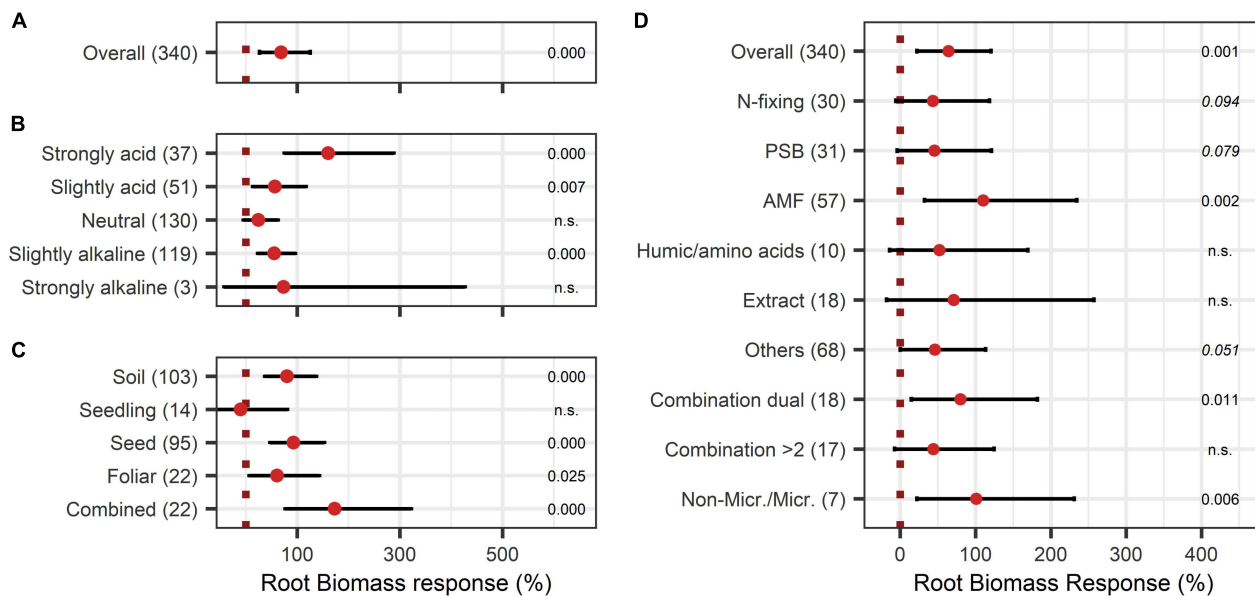

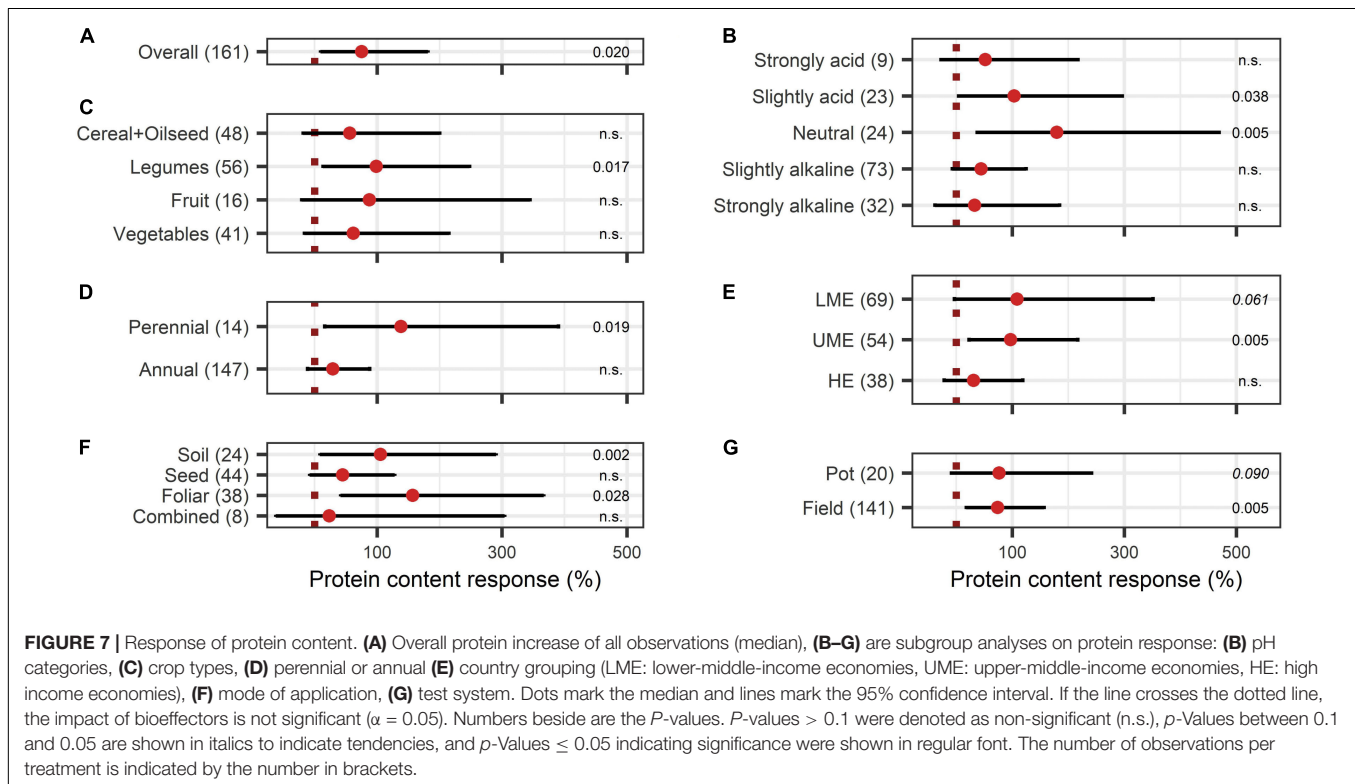

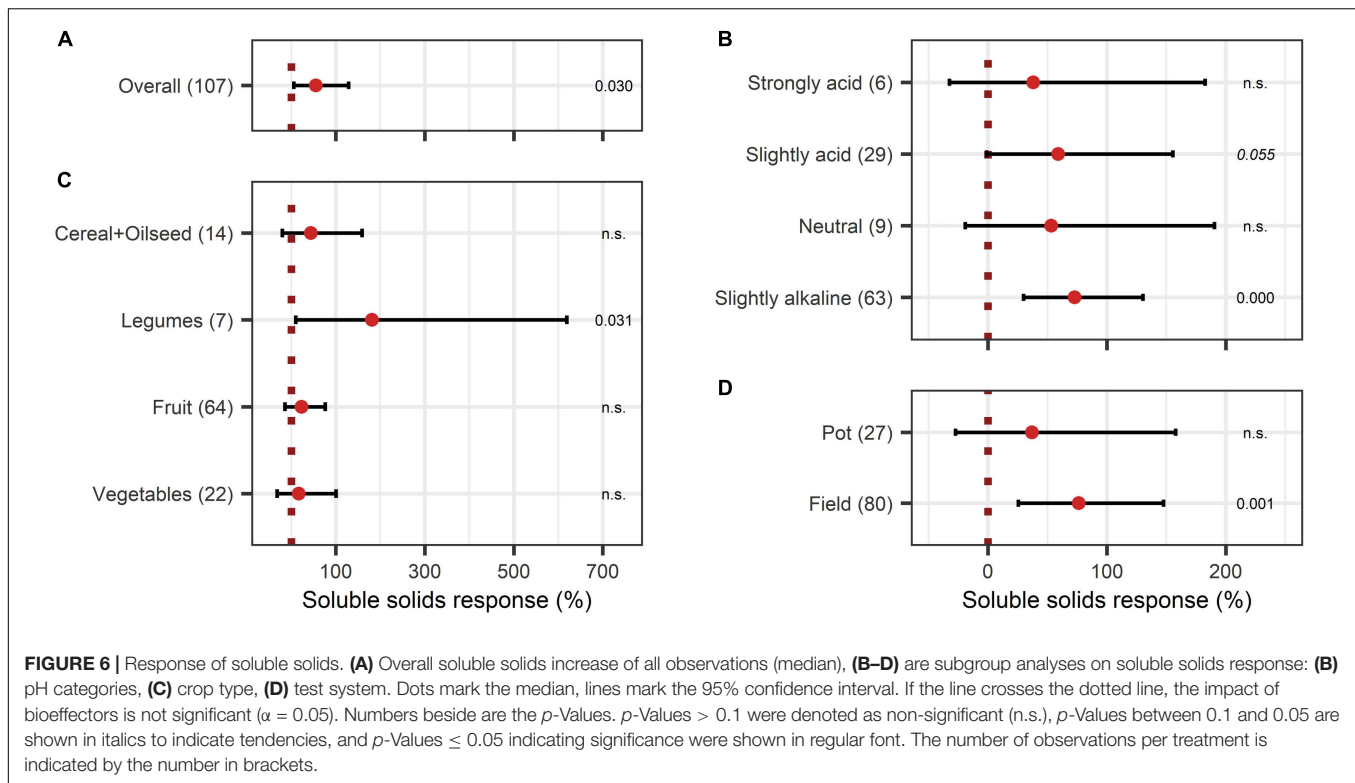

FIGURE 5 | Response of Root biomass. **(A)** Overall root biomass effect of all observations (median), **(B,C)** are subgroup analyses on root biomass response: **(B)** pH categories, **(C)** mode of application. **(D)** BE types and overall median according to the expanded model. Dots mark the median and lines mark the 95% confidence interval. If the line crosses the dotted line, the impact of bioeffectors is not significant ($\alpha = 0.05$). Numbers beside are the p -values. p -Values > 0.1 were denoted as non-significant (n.s.), p -Values between 0.1 and 0.05 are shown in italics to indicate tendencies, and p -Values ≤ 0.05 indicating significance were shown in regular font. The number of observations per treatment is indicated by the number in brackets.

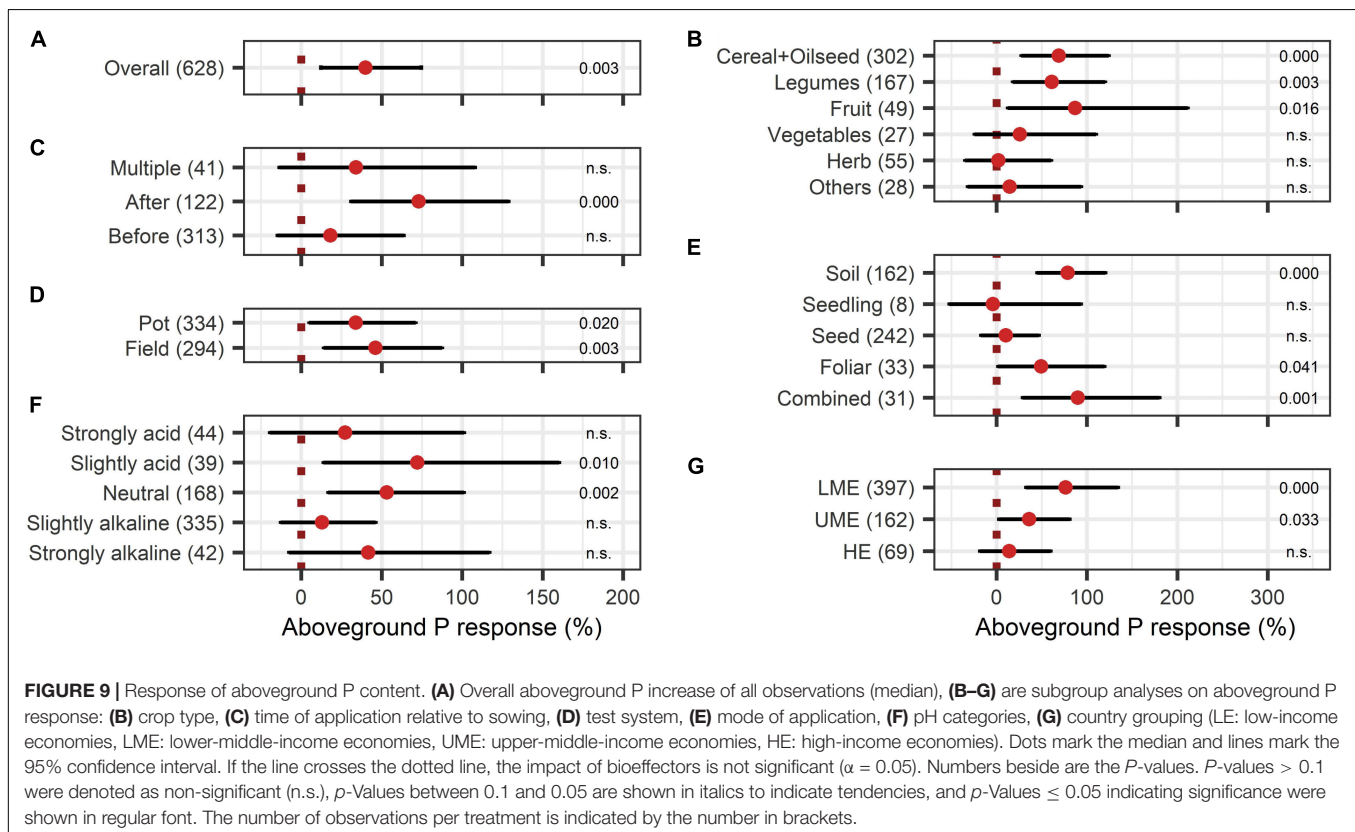

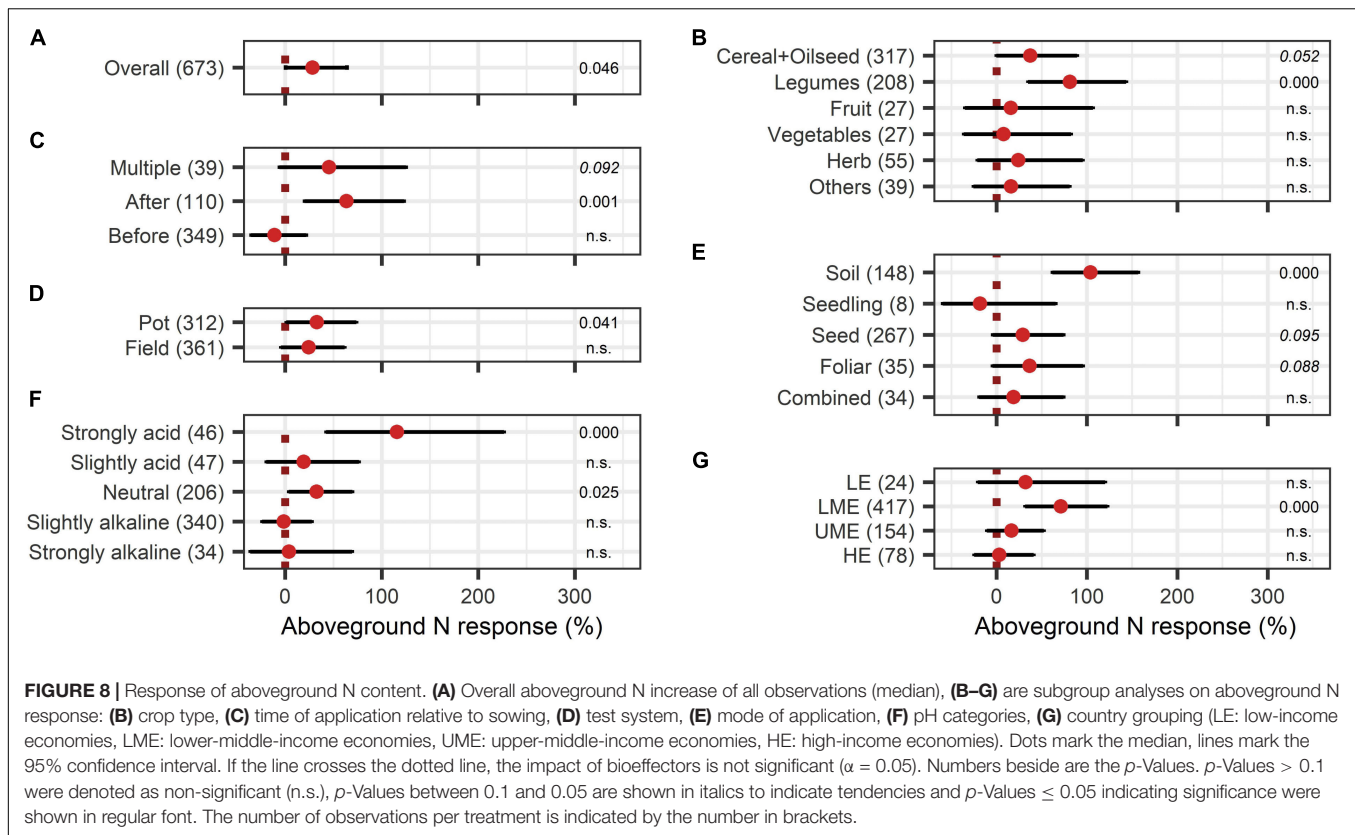

Aboveground N content was significantly enhanced in strongly acidic environments by BE application (116%) (**Figure 8F**). For aboveground P content, a tendency toward higher efficiencies

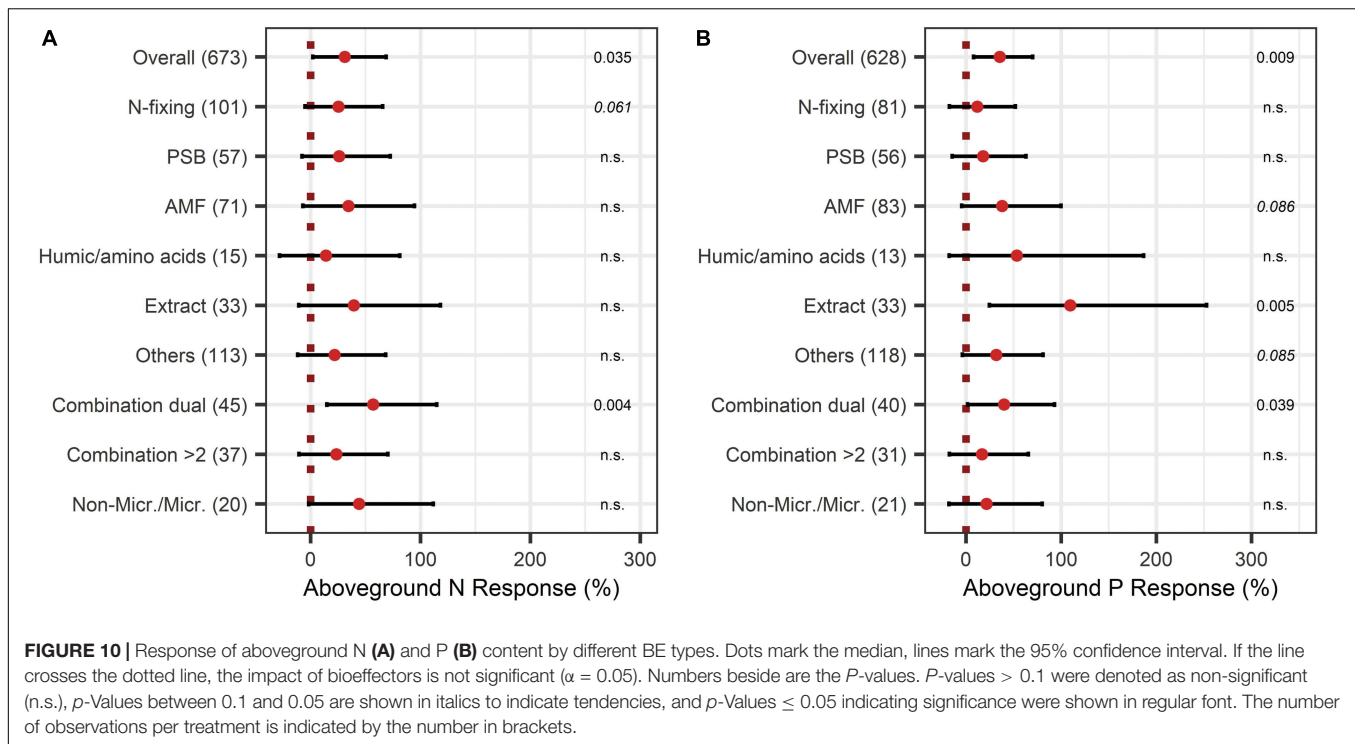

in lower pH levels was indicated; however, aboveground P content was again lower in strongly acidic soils (27% increase) compared to slightly acidic soils (72% increase) (**Figure 9F**).

For both nutrients, the highest improvements of aboveground content were achieved in lower-middle-income economies with 71% increases for N and 76% increases for P (Figures 8G, 9G).

In accordance with the increase of biomass, extracts improved aboveground P content by 110% when examining it with the extended model (Figures 10A,B). In the case of aboveground

P content, extracts and a dual combination treatment achieved significant positive results and AMF and others enhanced aboveground P content in tendency, whereas N was significantly increased by dual combinations and in tendency improved by N-fixing bacteria.

The overall effect of N-use efficiency was significantly enhanced by BE application with an increase of 36% (Figure 11A). Also, P-use efficiency was significantly improved by 22% (Figure 12A). To achieve enhanced nutrient-use efficiency, the application time needs to be considered for N, whereas the mode of application was the decisive factor for P. To increase N-use efficiency the most, an application time point after sowing should be preferred, which resulted in the highest improvements of 53% compared to 41% for multiple treatments and 17% for an application time before or at sowing (Figure 11B). For P-use efficiency, foliar application (40%) as well as soil application (39%) were the most suitable methods (Figure 12C). Moreover, N-use efficiency and P-use efficiency were dependent on soil pH. In both cases, the trend of higher efficiencies in lower pH levels was approximately visible (Figures 11C, 12B). While the test system (field or pot) did not alter the results for N-use efficiency (Figure 11D), pot trials (26%) showed a higher median than field trials (18%) for P-use efficiency (Figure 12D). In the models of N- and P-use efficiency, country grouping was included as a factor. The median response of BE application on N- and P-use efficiency was especially high in lower-middle-income (50% and 34%, respectively) and upper-middle-income countries (52% and 23%, respectively), whereas it was slightly reduced in low- (21% and 15%, respectively) and high-income economies (24% and 17%, respectively) (Figures 11E, 12E).

When the models of N-use efficiency were expanded by BE types, N-use efficiency was shown to be significantly improved by all BE types (Figure 13A). In particular, extracts and also humic and amino acids, and the dual combination treatment attained high responses for both nutrients, with 64%, 46%, and 45% for N-use efficiency (Figure 13A) and 109%, 54%, and 40% for P-use efficiency, respectively (Figure 13B). For the application of microbes, a combination of two different inoculants appeared to be more beneficial to improve N- and P-use efficiency than the application of only one BE type (Figures 13A,B).

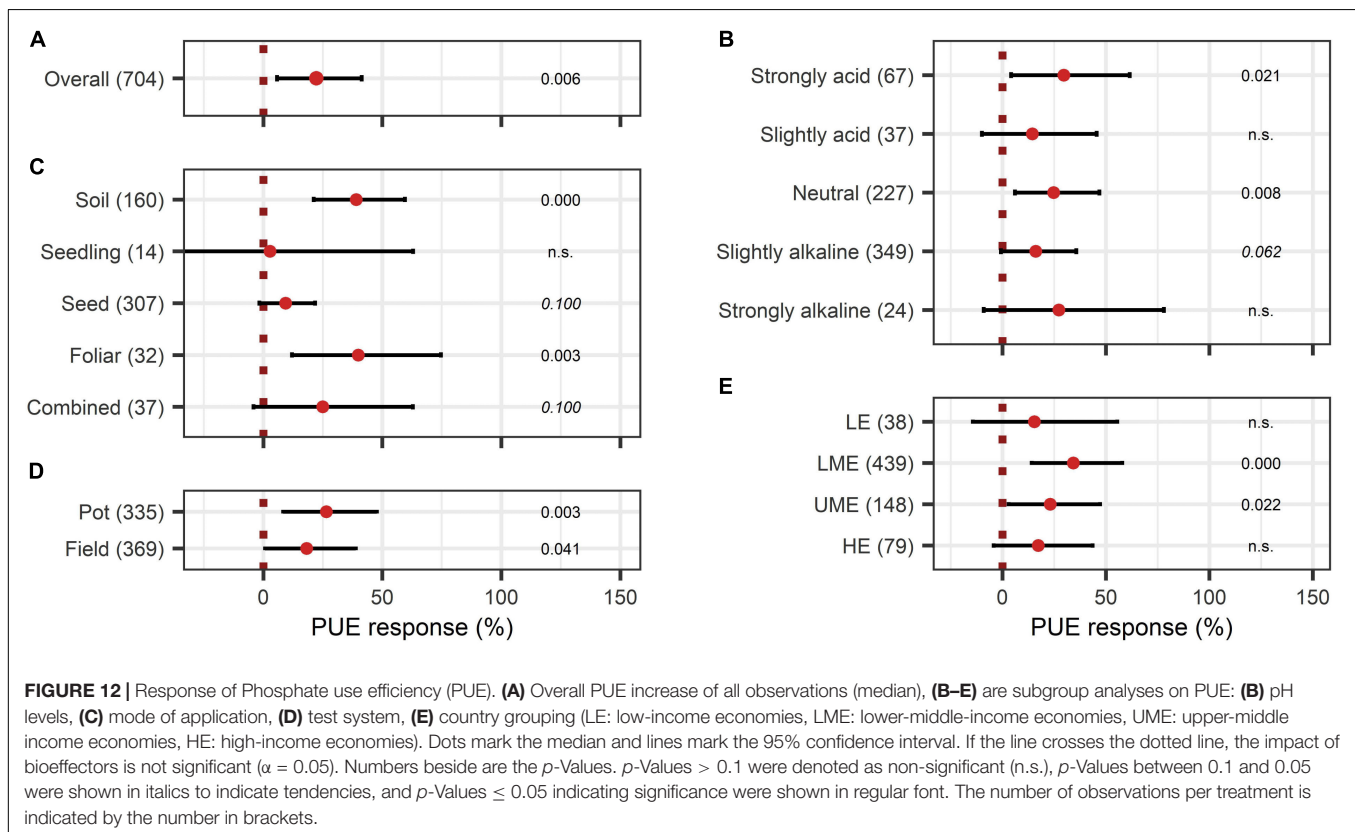

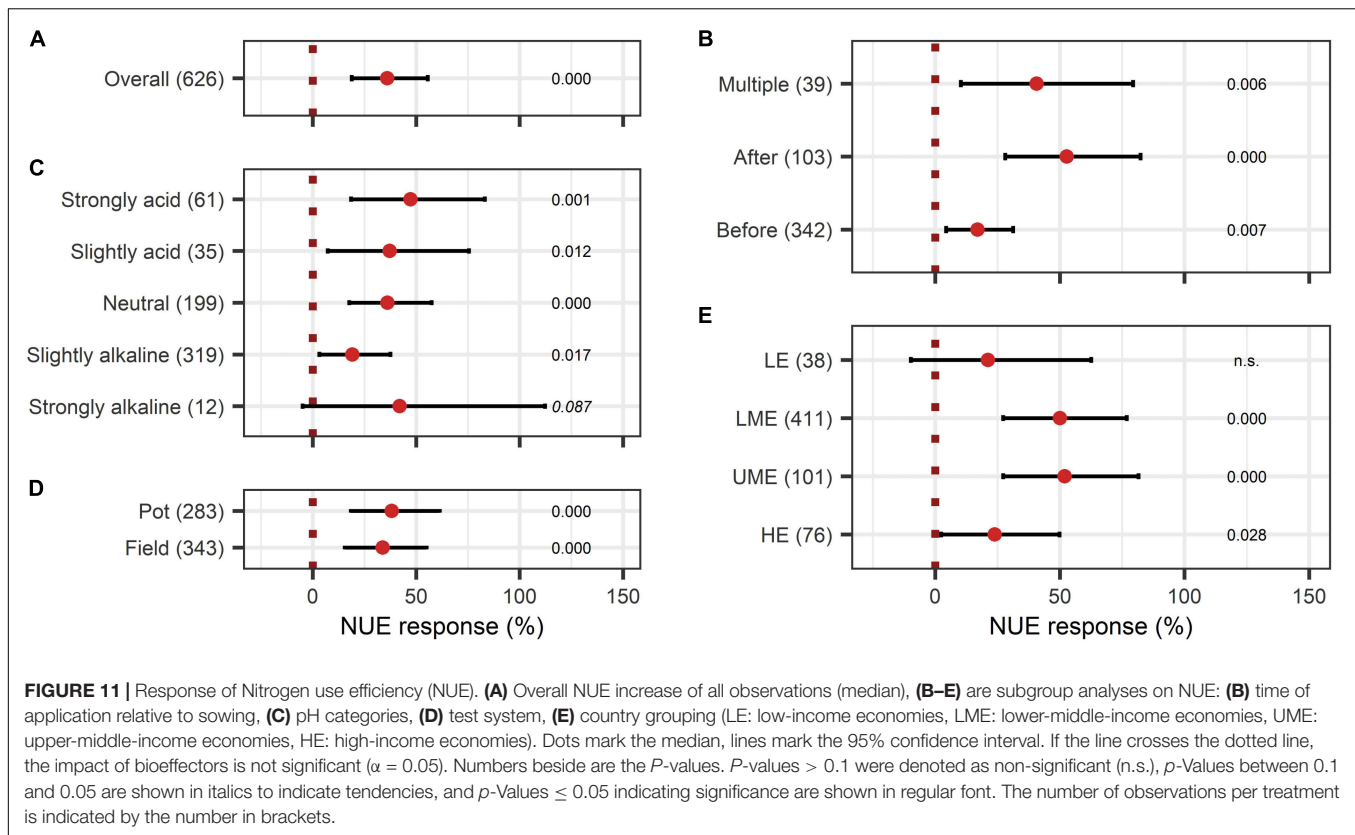

DISCUSSION

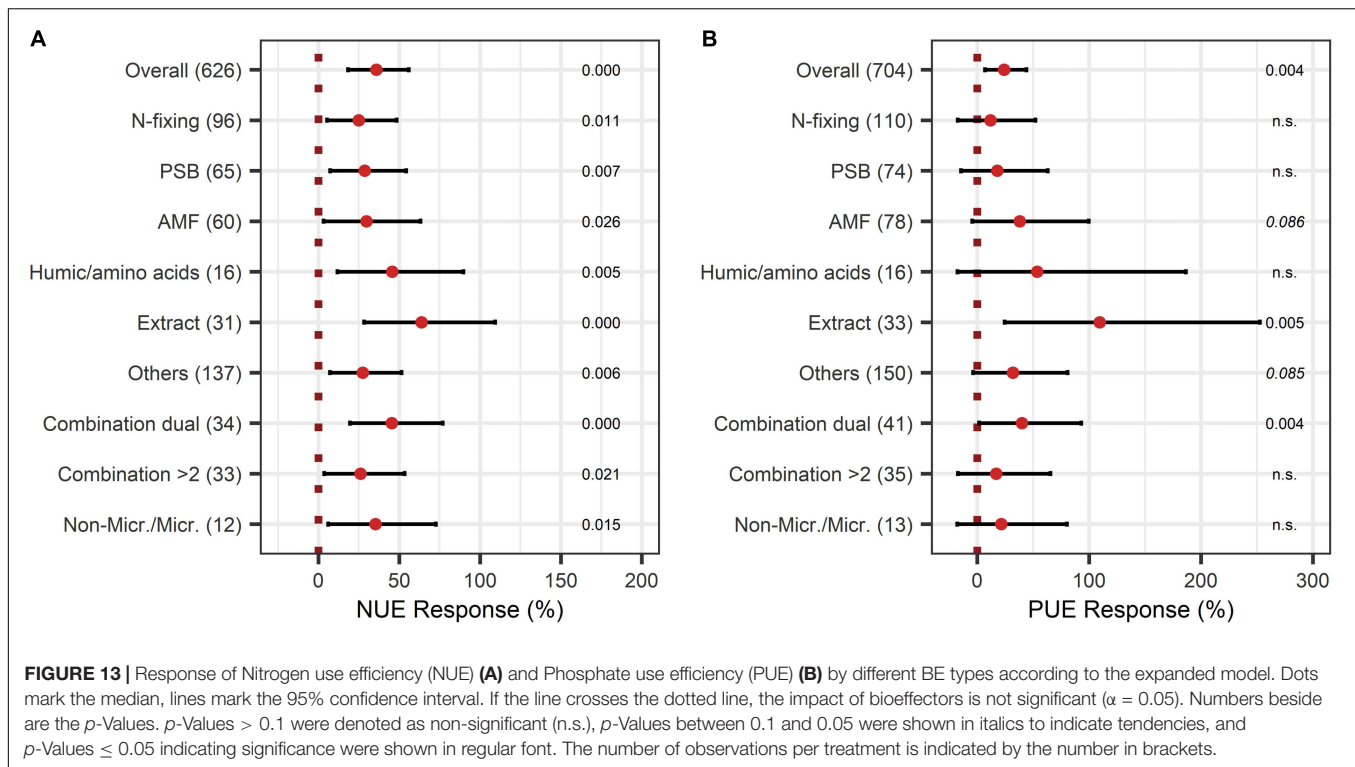

The General Impact of Bioeffectors

In this metaanalysis, BE application had a positive impact on the shoot and root biomass, yield, and analyzed quality indicators as well as on aboveground nutrient uptake.

Since the outcome of a metaanalysis strongly depends on the input data, it can be assumed that the current results could be slightly biased due to a higher chance of publication success for studies with positive BE effects and missing unpublished study data. But given the number of studies published on the positive impact of BEs, it is likely that the results indicate an existing effect but may overestimate the magnitude. The higher biomass translated directly into higher yields underlining the economic opportunity going along with BE application.

The benefit of BEs on nutrient uptake and nutrient use efficiency was already summarized by previous reviews (Kumar and Alope, 2020; Rouphael and Colla, 2020a,b). In the current study, the strong increase of plant macronutrient uptake by BE

application, in general, could be confirmed. Moreover, BEs can contribute to the production of high-quality food and fodder. In this study, they enhanced protein content and soluble solids content, which are some of the most important indicators for taste and nutritional value. These results agree with findings from previous studies, which investigated other quality indicators (Paradikovic et al., 2011; Maach et al., 2021).

The comparison of different BE types according to the categorization above was not included in any model for the analysis of plant growth or quality traits. One could hypothesize that the type of BE is not crucial for the success of the usage, which is consistent with recent findings from the metaanalysis by Lekfeldt et al. (2021). However, BEs are selected for studies based on the experimental setting and research question, and only a few studies directly compared BE types. Thus, the results of this analysis could be biased due to non-random selection of the BE types. The expansion of the selected models with BE types resulted in only slight increases of the AIC value. Significant deviations from the main effect of extracts and humic/ amino acids on shoot biomass, as well as the effect of a combination of microbial and non-microbial products on shoot biomass and yield, could be detected with the expanded model. Additionally, a combination of two different microbial strains could exploit synergies and increased biomass as well as aboveground N content, which was also highlighted by a recent review (Santoyo et al., 2021). The increase in aboveground P content and P-use efficiency by PSB was not outstanding. Raymond et al. (2020) suggested that P solubilizing capabilities of bacteria suffice to cover the demands of the bacteria, but not to support plant P acquisition. Therefore,

the improvement of aboveground P content might be caused by an improved spatial acquisition rather than an enhanced mobilization of bound phosphate in soil. Nevertheless, the P in the microbial biomass pool enters the nutrient cycle and becomes available to plants in the long term. The improvement of P nutrition through extracts, humic, and amino acids, however, did not go along with a proportional root growth increase. Thus, it cannot be related exclusively to enhanced spatial P acquisition. Other mechanisms and interactions related to the application of humic and amino acids and extracts need to be considered, such as humic-metal complexes, influence on soil biota, and increase of nutrient translocation (Anitha, 2020; Shukla and Prithiviraj, 2021). However, these mechanisms need to be clarified in future experimental studies.

In accordance with previous metaanalyses (Rubin et al., 2017; Schmidt and Gaudin, 2018), stronger positive effects on shoot biomass in pot trials than in field trials could be confirmed. This could also explain higher overall responses of root biomass compared to shoot biomass as root biomass was only investigated in pot experiments. Weinmann and Neumann (2020) suggested that BEs efficiency is higher in pot trials due to the limited soil volume, which leads to an artificially high concentration of the BE inoculant around the densely growing root. In contrast to pot trials, the root is not restricted in its growth direction in the field. This could hinder the establishment of symbiosis with BEs, as they are outcompeted by native microbial communities, which are spatially closer to the root (Weinmann and Neumann, 2020). However, in the results of aboveground N and P content, the higher efficiency of BEs in pot trials could not be identified. To clarify this contradiction, it would be helpful to reveal underlying

mechanisms to avoid results that are influenced by experimental approaches (e.g., higher application rates in pot trials, controlled conditions in the greenhouse) rather than by the test system.

Crop Types and Soil pH Determined the Effect Size of Bioeffectors

It was shown that the potential in achieving certain inoculation aims depends on the crop type as yield, aboveground nutrient contents, as well as quality traits response differed with the crop type. This may be the result of specialized symbiosis of plants and microbes to acquire nutrients in the soil, such as N-fixing bacteria and legumes, while other crop types lack this intense mutualistic interaction. In this study, the increase of aboveground N content in cereals and legumes indicates the development of more effective symbiosis with soil microorganisms, which is known to exist in these crop types (Rosenblueth et al., 2018). However, the potential amount of nitrogen fixation is lower in cereals than in legumes (Cooper and Scherer, 2012), which is also reflected by the results of this study.

Soil physicochemical characteristics can impact the success of BE application (Weinmann and Neumann, 2020). In this study, it was highlighted that the pH level of the soil strongly influences the outcome of a BE application. As mentioned above, most of the BEs can mobilize insoluble nutrients, such as P, in several ways. BEs act as a counterpart against nutrient fixation in soil by acidification, which is regarded as the most crucial impact of soil microbes (Raymond et al., 2020). However, the results imply that this mechanism is restricted to slight pH decreases as the efficacy of BEs decreased in almost any case in strongly alkaline soils. Additionally, the results from this analysis suggest that the highest benefit of BE application occurs in strongly acidic environments with the highest increase in shoot and root biomass. It also shows that the effectiveness of BE application to improve plant growth traits tends to increase with decreasing soil pH, especially for shoot biomass. In these soils, nutrients, such as P, become insoluble due to reaction with Al and Fe (Margenot et al., 2018). By an enhanced root growth, as demonstrated in this study, the acquisition of scarce soluble nutrients can be improved. BEs could support root growth in acidic environments by chelating detrimental Fe and Al-cations and forming metal-humic complexes (Khan et al., 2009; Anitha, 2020).

The Right Time and Right Way to Use Bioeffectors

It remains an open research question whether better-adapted application methods could improve the effectiveness of BE application. Application methods should be highly effective and easily adoptable in common agricultural schemes (Weinmann and Neumann, 2020). In the present metaanalysis, it was shown that investigated methods of application had a significant impact on growth parameters, quality traits, and aboveground nutrient content. Foliar and soil application seem to be the most promising application methods to achieve reliable growth gains, improve nutritional quality, and increase nutrient uptake. The application time influenced aboveground N and P content and N-use efficiency. Consistently, an application time after sowing

obtained highest efficiencies in all cases, in which application time was included in the model.

The country grouping provided a broad indicator for agronomical production regimes. Most of the investigated effects showed a dependency on management; however, in almost none of the cases the impact was negative, and for yield, country grouping was not included in the model. It could therefore be argued that the benefits from BE application are realizable in any region. Yet, differences in efficiency across countries could be detected regarding shoot biomass, aboveground N and P content, as well as N- and P-use efficiency. This may be due to different baselines of N- and P-use efficiency in the regions and therefore, varying improvement opportunities for growth and nutrient uptake. In the study of Omara et al. (2019), low-income economies and high-income economies obtained N-use efficiencies above the global average, while China and India, which contributed to a great extent to the data for this study, showed N-use efficiencies below the global average (Omara et al., 2019). One could hypothesize that BEs can especially support these countries with a low nutrient use efficiency, while in countries that already have a high efficacy, BEs cannot contribute much to ameliorate nutrient use efficiency even more.

CONCLUSION AND OUTLOOK

Reducing mineral fertilizer input while maintaining high yield levels is crucially important in sustainable agricultural production. As demonstrated in this study, BEs can contribute to achieve this goal by improving plant growth by 26%, yield by 30%, and P and N uptake by 40% and 28%, respectively. In contrast to studies focusing on single microbial BEs, we could show that non-microbial BEs and composite products with combinations of different microbial and non-microbial BEs are most promising as they increased biomass by 40%–60%. However, the results are not consistent. The application time, the application mode (e.g., foliar, placement, and combinations), and soil characteristics, especially the pH level, need to be considered to guarantee effective action of BEs. In summary, the effects of BEs on crop growth traits were strongest for the following: application after sowing; foliar application, a combination of several different application methods, and a soil application; as well as under acidic soil conditions especially regarding biomass response and nutrient uptake. Harmonizing BE types, application mode, crop type, and soil characteristics should be the focus of future studies. Further research is needed to clarify the mechanisms of non-microbial products, especially their influence on plant P uptake.

DATA AVAILABILITY STATEMENT

The data analyzed in this study is subject to the following licenses/restrictions: The datasets, SAS scripts and R scripts of the current study are available from the corresponding author on reasonable request. Requests to access these datasets should be directed to MH, m.herrmann@uni-hohenheim.de.

AUTHOR CONTRIBUTIONS

HY and MH conceptualized the study. MH and YW collected the data. JH and MH implemented the statistical analysis. MH drafted and wrote the manuscript. HY and TM complemented the work. HY, TM, and XC supervised the work. All authors read and revised the manuscript and approved the final version.

FUNDING

This study was financially supported by the Scientific Research Startup Foundation of Southwest University to HY (SWU019012) and the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – 328017493/GRK 2366 (Sino-German International Research Training Group AMAIZE-P). MH also would like to thank the Studienstiftung des Deutschen

Volkes for the financial support of her educational stay at the South West University in Chongqing (China).

ACKNOWLEDGMENTS

The authors would like to thank Drs. Xiaozhong Wang and Wushuai Zhang for the advice and Ms. Yue Wu for her support in the early stage of the project.

Identification and Characterization
of *Bacillus tequilensis* GYUN-300: An
Antagonistic Bacterium Against Red
Pepper Anthracnose Caused by
Colletotrichum acutatum in Korea.
Front. Microbiol. 13:826827.
doi: 10.3389/fmicb.2022.826827

Anthracnose is a fungal disease caused by *Colletotrichum* species and has detrimental effects on many crops, including red pepper. This study used *Bacillus tequilensis* GYUN-300 (GYUN-300), which exhibit antagonistic activity against the fungal pathogen, *Colletotrichum acutatum*. This pathogen causes anthracnose that manifests primarily as a fruit rot in red pepper. There have been little efforts to identify antagonistic bacteria from mushrooms; this strain of bacteria was identified as *B. tequilensis* using BIOLOG and 16S rDNA sequencing analysis. The genetic mechanism underpinning the biocontrol traits of GYUN-300 was characterized using the complete genome sequence of GYUN-300, which was closely compared to related strains. GYUN-300 inhibited mycelial growth and spore germination of *C. acutatum* under *in vitro* conditions. Important antagonistic traits, such as siderophore production, solubilization of insoluble phosphate, and production of lytic enzymes (cellulase, protease, and amylase), were observed in GYUN-300. These traits promoted growth in terms of seed germination and vigorous seedling growth compared to the non-treated control. When red pepper fruits were treated with GYUN-300, the preventive and curative effects were 66.6 and 38.3% effective, respectively, in wounded red pepper fruits; there was no difference between the preventive and curative effects in non-wounded red pepper fruits. Furthermore, GYUN-300 was resistant to several commercial fungicides, indicating that GYUN-300 bacterial cells may also be used synergistically with chemical fungicides to increase biocontrol efficiency. Based on *in vitro* results, GYUN-300 played a role to control anthracnose disease effectively in field conditions when compared to other treatments and non-treated controls. The results from this study provide a better understanding of the GYUN-300 strain as an effective biocontrol agent against red pepper anthracnose; this form of biocontrol provides an environment-friendly alternative to chemical fungicides.

Keywords: *Bacillus tequilensis*, anthracnose, fungicide resistance, fungal pathogen, genome sequence, microbial pesticide

INTRODUCTION

Red pepper (*Capsicum annuum* L.) is a vegetable crop belonging to the Solanaceae family, with the cultivation area of 33,373 hectares. The total production of chili pepper recorded as 92,756 tons in the year 2021 in Korea¹ (Kim et al., 2014). To meet the demands of a growing population, an increased production of red pepper along with other vegetables are required in Korea. Therefore, a large quantity of chemical pesticides is utilized annually to control various bacterial, fungal, and viral diseases on red pepper crops in Korea (Hong et al., 2015). Among all pathogens that cause diseases in red peppers, anthracnose caused by a wide range of *Colletotrichum* species results in serious losses of fruits during the pre- and post-harvest stages (Ali et al., 2016), while occasionally damaging the stem and foliage (Mishra et al., 2018; Mongkolporn and Taylor, 2018). To date, 24 *Colletotrichum* species infecting red peppers have been identified; the most common species are *Colletotrichum acutatum* and *Colletotrichum gloeosporioides*, which inflict serious damage to red pepper (Kim et al., 2008; Parisi et al., 2020). The fungal species of *Colletotrichum* cause anthracnose in several plants, including red peppers (Siddiqui and Ali, 2014). Anthracnose was responsible for a 10% annual reduction in pepper productivity in South Korea (Kim et al., 2008). Anthracnose in red pepper is associated with several *Colletotrichum* species, including *C. acutatum* (Harp et al., 2014), this may also infect other fruit and vegetable crops (Han et al., 2015). Red pepper anthracnose is typically characterized by dark brown to black, circular water-soaked spots with concentric rings of black acervuli developing beneath the skin of the fruit (Parisi et al., 2020); the spots are often numerous and coalesce, causing softening and fruit rot (Montri et al., 2009).

Anthracnose is usually controlled by the application of chemical fungicides in field conditions. The increased use of chemical fungicides has led to the development of resistance in fungal strains (Onyeka et al., 2006). In particular, *C. acutatum* is resistant to specific chemical fungicides, including carbendazim, benomyl, and copper oxide (Peres et al., 2002; Jayasinghe and Fernando, 2009). The continuous use of chemical pesticides increases public concern regarding the risks associated with hazardous residues on agricultural products and its adverse effects on biodiversity in ecosystems (Meena et al., 2020). In addition, disease control by chemical pesticides is cost-effective for farmers in developing countries (Wesseling et al., 1997; Bordoh et al., 2020). For these reasons, biological control using antagonistic microorganisms has emerged as environment-friendly alternative to control plant diseases (Köhl et al., 2019; De la Lastra et al., 2021). Antagonistic microorganisms produce a variety of secondary metabolites to combat plant pathogens (Hossain et al., 2015; Köhl et al., 2019; Cellini et al., 2021). They induce resistance against pathogen infections in plant tissues without direct antagonistic interactions with the pathogen itself (Sharma et al., 2019). Similarly, a previous study by Ali et al. (2015) reported that the red pepper anthracnose was suppressed

by an antimicrobial organic compound, propolis under post-harvest conditions. Additional indirect interaction with pathogens occurs during competition for nutrients and space, antibiotic production, colonization, induced systemic resistance (ISR), and parasitism against target plant pathogens (Kloepper et al., 2004; Kim et al., 2012); however, antagonistic microorganisms often do not exhibit consistent disease suppression compared to the commercial fungicides (Sang et al., 2013). Plant growth-promoting rhizobacteria (PGPR) are antagonistic to plant pathogens as they produce secondary metabolites, including siderophores, lytic enzymes, and antibiotics (Conn et al., 2008); they also produce plant growth regulators, such as indole-3-acetic acid (IAA), and solubilization of insoluble phosphates (Goswami et al., 2016).

There are several studies on antibiotic production by antagonistic microbes, such as *Bacillus* sp., *Pseudomonas* sp., and *Streptomyces* sp. (Beneduzi et al., 2012; Ngaliemat et al., 2021; Yang et al., 2021). *Bacillus* spp., produce spores, which may be used to develop an effective microbial biopesticide formulation in the form of a biocontrol agent (BCA). Previously, many studies have demonstrated that several secondary metabolites produced by antagonistic bacteria play key roles in controlling various phytopathogens (Han et al., 2015). To date, there have been no reports on the isolation of these bacteria from the edible mushroom, locally known as “Sanghwang.” It is a popular medicinal mushroom widely cultivated in China, Japan, and Korea (Chen et al., 2016). This is grown on different trees, such as Oak and mulberry (Sliva, 2010), and being used as a traditional medicine to treat various health disorders, such as inflammation, gastroenteric, lymphatic diseases, and cancers (Jang et al., 2015). This further may exhibits biocontrol potential against anthracnose caused by *C. acutatum* in red pepper. This study sought to meet two key objectives: (i) evaluate the potential efficacy of the selected PGPR strain, *Bacillus tequilensis* GYUN-300, as a BCA against red pepper anthracnose under *in vitro* and field conditions; and (ii) evaluate its complete genome sequence for determining divergent genomic characteristics among other *Bacillus* strains.

MATERIALS AND METHODS

Isolation of Antagonistic Bacteria From Mushroom

Fresh sanghwang mushrooms were purchased from the local traditional market and thoroughly washed with water in the laboratory. Thereafter, 5 g of mushroom was ground in 10 mL sterilized distilled water (SDW) and diluted to 10⁻⁸. Next, 100 µL of the diluted samples were plated onto nutrient agar plates; single colonies were selected 48 h after incubation at 28°C. Of the 20 total isolates obtained, only one isolate (i.e., GYUN-300) was selected for further study based on primary screening on *in vitro* antagonistic activity.

¹<https://kostat.go.kr>

Source of Fungal Pathogens Used

The pathogen *C. acutatum* KACC42403 as obtained from Korean Agricultural Culture Collection (KACC), Agricultural Microbiology Division, RDA, South Korea. Other two pathogens, *C. acutatum* ANBPC, and *C. acutatum* ANYPC, were isolated from the infected fruits. After cutting the small sections of the lesion from the infected fruit, they were surfaces sterilized in 70% ethanol for 30 s and were rinsed twice in SDW. Thus, surface sterilized tissues were placed onto potato dextrose agar (PDA) medium. The fungal colonies were obtained after incubating the plates at 25°C for 7 days. The isolates ANBPC and ANYPC were recovered from these colonies. The cultures were stored on PDA plates at 10°C for further use.

In vitro Antagonistic Activity of GYUN-300

Bacteria isolated from sanghwang mushrooms were diluted to 10^{-6} and 10^{-5} in SDW and placed onto tryptic soy agar (TSA) plates. Out of several bacterial isolates, only GYUN-300 was selected based on its *in vitro* antagonistic activity against *C. acutatum* isolates. The isolate GYUN-300 was maintained at −80°C in tryptic soy broth (TSB) with glycerol (20%) for long-term storage. To prepare bacterial suspensions, a culture from the −80°C stock was grown on TSA plates for 3 days at 28°C; single colonies were transferred to TSB and incubated for 48 h at 28°C under shaking conditions (150 rpm). Bacteria were pelleted after centrifugation for 5 min at $8,000 \times g$ and suspended in SDW to obtain a final concentration of 1×10^6 colony-forming units (CFU)/mL prior to application. The *in vitro* antifungal activity of bacterial cell suspensions of GYUN-300 was tested against *C. acutatum* isolates using a dual culture plate assay. Briefly, the fungal pathogenic isolates, *C. acutatum* KACC42403, *C. acutatum* ANBPC, and *C. acutatum* ANYPC were cultured on potato dextrose agar (PDA) medium for 7 days at 25°C to obtain mycelial plugs for the *in vitro* antagonism tests. The mycelial plugs (6 mm in diameter) of *C. acutatum* were placed onto the center of the PDA plates, and 10 μ L of antagonistic bacterial GYUN-300 cell suspensions (1×10^6 CFU/mL) impregnated on sterile paper discs (6 mm in diameter) were placed on the top, bottom, right, and left sides of the plate 30 mm away from the center of the plate; plates treated with SDW served as the non-treated control. The growth inhibition distance between the bacterial suspension and pathogen was measured 7 days after incubation at 25°C in comparison with the non-treated control. Each treatment consisted of five replicates (Petri dishes), and the experiment was carried out at least twice.

Preparation of Fungal Pathogen Inocula

Conidial suspensions (100 μ L) were spread onto PDA plates and incubated at 25°C for 7 days. The conidia were harvested by pouring SDW onto a PDA plate containing pathogenic fungi, and scraped. The suspensions were filtered through a double-layered cheesecloth. The concentration of spore suspensions was adjusted to 10^5 conidia/mL using a hemocytometer prior to its application.

Inhibition of Spore Germination of *Colletotrichum acutatum* Through Treatment With GYUN-300 Bacterial Cell Suspensions

Conidial germination and appressorium formation from *C. acutatum* were tested on a cover glass surface treated with GYUN-300 bacterial suspensions and its culture filtrate (CF) using a method described by Kim et al. (1998). Briefly, conidia from the cultures grown on PDA plates for 7 days were harvested and washed twice with ice-cold SDW. Conidial suspensions (10^6 CFU/mL) of 100 μ L were mixed into Eppendorf tubes containing bacterial cell suspensions of GYUN-300 or its CF, and incubated for 48 h at 25°C. Conidial germination and the formation of appressorium and primary hyphae in the GYUN-300 or its CF treatment were assessed at different durations (i.e., 8, 16, 24, 32, 40, and 48 h) in Petri dishes containing moist paper. At minimum, 50 measurements were carried out per structure with a ProgRes SpeedXT^{core} 3 Imager microscope using a differential interference contrast illumination.

Inhibition of Fungal Mycelial Growth by Volatile Compounds From GYUN-300

An I-plate assay (Sharifi and Ryu, 2016) and dual culture plate assays (Chaurasia et al., 2004) were carried out to evaluate the ability of the GYUN-300 strain to inhibit fungal growth through the production of volatile compounds. For the I-plate assay, one compartment of the I-plate contained TSA medium to inoculate GYUN-300, while the other side contained PDA to culture the fungal pathogen, *C. acutatum* KACC42403; the plate treated with SDW served as the non-treated control. Mycelial growth inhibition was observed 7 days after incubation at 25°C. For the dual culture plate assay, a Petri dish containing PDA medium was inoculated with a pathogenic mycelial plug on one side just 10 mm from the edge of the plate, and cell suspensions of GYUN-300 were used to inoculate the other side just 10 mm from the edge of the plate, by streaking on the same Petri dish without contacting the fungal pathogen. The inhibitory effect of GYUN-300 on fungal mycelia was measured 7 days after incubation at 25°C. Each test was conducted in triplicate, and three independent measurements were taken for each plate.

Identification of Antagonistic Bacteria Using MicroLog System

The putative *Bacillus* isolate was tested for the utilization of 95 carbon sources using the BIOLOG program (Jeon et al., 2003). Briefly, bacterial cells cultured on TSA medium for 24 h at 28°C were suspended in an inoculating fluid (i.e., 0.4% NaCl, 0.03% Pluronic F-68, and 0.01% gellan gum). They were inoculated onto GENIII MicroPlates (BIOLOG Inc., BiOLOG GP MicroPlate™, Hayward, CA, United States), and incubated at 28°C. After 24 h of incubation, turbidity in the wells was measured using a MicroLog™ 3-Automated Microstation system (BIOLOG, Hayward, CA, United States). Bacteria were identified using the MicroLog Gram-positive database (ver. 4.0; BIOLOG).

Molecular Identification of GYUN-300

The selective isolate, GYUN-300, was subjected to molecular identification based on the sequence homology of its 16S rDNA gene (Weisburg et al., 1991). The genomic DNA (gDNA) of GYUN-300 was isolated using a kit (BioFact Genomic DNA Extraction Kit, Biofact Co., Seoul, South Korea) as per the manufacturer's instructions. The 16S rDNA gene was amplified using polymerase chain reaction (PCR) with Taq DNA polymerase, and primers 27F (5'-AGA GTT TGA TCM TGG CTC AG-3') and 1492R (5'-GGY TAC CTT GTT ACG ACT T-3') were used for amplification. The thermal cycling conditions were: denaturation at 94°C for 5 min followed by 35 cycles at 94°C for 30 s, annealing at 55°C for 30 s, and extension at 72°C for 1 min. At the end of the cycle, the reaction mixture was held at 72°C for 10 min, and then cooled to 4°C. The PCR product was purified using a PCR gel purification kit (BIOFACT Co., Seoul, South Korea), according to the manufacturer's instructions. The purified PCR product was sequenced using an automated sequencer (Genetic Analyzer 3130; Applied Biosystems, Carlsbad, CA, United States), in which the same primers were used utilized. The sequence was compared with the reference bacterial species contained in a genomic database using the Basic Local Alignment Search Tool (BLAST) from the National Center for Biotechnology Information (NCBI). Sequence alignment and phylogenetic tree construction were carried out using the MEGA 4.0 program (BioDesign Institute, Tempe, AZ, United States).

GYUN-300 Whole-Genome Sequence Analysis and Annotation

Bacterial gDNA was extracted using a FastDNA™ SPIN Kit for Soil (MP Biomedicals, Santa Anna, CA, United States), according to the manufacturer's instructions. The concentration of extracted DNA was determined using a Qubit 2.0 fluorometer (Invitrogen, Carlsbad, CA, United States). The contamination of DNA or the cultured strain was tested by sequencing the 16S rRNA gene using an ABI 3730 DNA sequencing machine (Applied Biosystems, Foster City, CA, United States). The integrity of the gDNA was verified using agarose gel electrophoresis, and quantified using a Qubit 2.0 fluorometer (Invitrogen, Carlsbad, CA, United States). Then, sequencing libraries were prepared according to the manufacturer's instructions for 20 kb template preparation using the BluePippin Size-Selection System using PacBio DNA Template Prep Kit 1.0. Briefly, 10 µg of the gDNA was sheared to 20 kb using g-tubes (Covaris); they were then purified, end-repaired, and the blunt-end SMARTbell adapters were ligated. The libraries were quantified using a Qubit 2.0 fluorometer (Invitrogen, Carlsbad, CA, United States) and qualified using the DNA 12000 chip (Agilent Technologies, Waldbronn, Germany). Subsequently, the libraries were sequenced using PacBio P6C4 chemistry in the 8-well SMART Cell v3 in PacBio RSII.

The genome of the GYUN-300 strain was constructed *de novo* using PacBio sequencing data; sequencing analysis was carried out at Chunlab, Inc., PacBio sequencing data were assembled with PacBio SMRT Analysis 2.3.0, using the HGAP2 protocol (Pacific

Biosciences, Menlo Park, CA, Inc., United States); the resultant contigs of the PacBio sequencing data were prototyped using Circlator 1.4.0 (Sanger Institute). Gene-finding and functional annotation pipeline of the whole-genome assembly used in the EzBioCloud genome database, and the protein-coding sequences (CDSs) were predicted using Prodigal 2.6.2 (Hyatt et al., 2010). The gene encoding tRNA was identified using the tRNAscan-SE 1.3.1 (Schattner et al., 2005), while the rRNA and other non-coding RNAs were analyzed using the Rfam 12.0 database (Nawrocki and Eddy, 2013). The CRISPRs were detected by PilerCR 1.06 (Edgar, 2007) and CRT 1.2 (Bland et al., 2007). The CDSs were classified into groups based on their roles, referencing the orthologous groups² (EggNOG 4.5) (Powell et al., 2014). For more functional annotation, the predicted CDSs were compared with the Swissprot (UniProt Consortium, 2015), KEGG (Kanehisa et al., 2014), and SEED (Overbeek et al., 2005) databases using the UBLAST program (Edgar, 2007).

In vitro Enzyme Activity by Antagonistic Bacteria

The ability of bacteria to produce various enzymes, such as cellulase, protease, and amylase was tested under *in vitro* conditions. Cellulase production was assessed by inoculation of GYUN-300 cell suspensions on TSA media supplemented with 5 g/L carboxymethyl cellulose (CMC). Sterilized filter paper discs (6 mm diameter) impregnated with 10 µL bacterial cell suspensions were placed on Petri dishes at four sides 15–20 mm away from the edge of plates, then incubated at 28°C for 5 days. After pouring 0.1% Congo Red solution onto the surface of Petri dishes, and retained for 5–10 min; Plates were then de-stained using a 1 M NaCl solution. The development of a clear halo around the colonies indicated a positive reaction and the production of cellulase by bacteria. For protease activity, bacterial isolates were inoculated on gelatin media (i.e., gelatin 5 g, beef extract 3 g, protease peptone 5 g, agar 15 g, distilled water 1,000 mL); plates were then incubated at 28°C for 2–3 days. After dispensing plates with 1% tannic solution for 5 min for staining, they were washed with SDW; Protease activity was recorded through the development of a clear zone (halo) around the colonies, indicating that proteins were hydrolyzed by the bacteria. Amylase production was assessed through the inoculation of the GYUN-300 isolate on TSA media supplemented with 0.5% soluble starch. Sterile paper discs (6 mm) impregnated with bacterial cell suspensions were plated on solid media, and Petri dishes were incubated at 28°C for 2–3 days. After pouring iodine solution (0.3 g iodine and 0.6 g KI/L) on the surface of Petri plates, any clear halo development around colonies was indicative of a positive reaction and the production of amylase and degradation of starch by bacteria.

Determination of Siderophore Production and Phosphate Solubilization

The procedure developed by Schwyn and Neilands (1987) using Chrome Azurol S (CAS) media was used to evaluate

²<http://eggnogdb.embl.de>

the ability of bacteria to produce siderophores. Briefly, 10 μ L GYUN-300 bacterial suspensions were inoculated on iron-free King B solid media and incubated at 28°C for 2–3 days. Then, CAS agar (15 mL) was poured onto the GYUN-300 bacterial cultures, and after a few hours the plates were checked for the appearance of a halo around bacterial colonies, with a color change from blue to orange. The halo diameter was calculated by subtracting the diameter of the colony from the total diameter of the halo and the colony, a procedure developed by Gaur (1990) was used to determine the ability of bacteria to degrade the inorganic phosphates from the soil. Briefly, sterile paper discs (6 mm diameter) impregnated with 10 μ L of GYUN-300 bacterial suspensions were placed onto the surface of tricalcium phosphate medium (i.e., glucose 10 g, tricalcium phosphate 5 g, $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ 5 g, $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ 0.025 g, $(\text{NH}_4)_2\text{SO}_4$ 0.1 g, agar 20 g, distilled water 1,000 mL). After 15 days of incubation at 28°C, the appearance of a halo around the colony indicated phosphate solubilization. The phosphate solubilization ability was directly reflected by the halo diameter size; all experiments were carried out in triplicate.

Disease Control of Red Pepper Anthracnose by GYUN-300 Bacterial Suspensions

An indoor experiment was conducted to examine the preventive and curative effects of GYUN-300 bacterial suspensions on anthracnose in wounded and non-wounded red pepper fruits (cv. Geochanghan). Fully ripened red pepper fruits, procured from the field were selected for the experiment. Fruits were surface sterilized in 70% ethanol for 3 min, immersed in 1% NaOCl for 1 min, and rinsed 2–3 times in SDW; the surface-sterilized red pepper fruits were air-dried at room temperature. Nearly five wounds were inflicted on the surface of fruits using a sterile needle, and one set of non-wounded red pepper fruits were also used in this experiment. To test for preventive effects, wounded or non-wounded fruits were treated with antagonistic bacterial suspensions of GYUN-300 (10^7 CFU/mL) using a spray method (50 μ L per fruit). Fruits treated with chemical pyraclostrobin and SDW served as positive and negative controls, respectively. After sufficient drying at room temperature, 10 μ L of *C. acutatum* spore suspensions (10^5 conidia/mL) were inoculated on wounded or non-wounded sites, dried at room temperature, then placed in plastic square plates (40 cm \times 40 cm) containing filter paper under moist conditions. The disease index (DI), using the formula ($\text{DI} = \text{sum of disease ratings in fruits} / \text{total number of fruits assessed}$) was recorded 10 days after incubation at 25°C in comparison with a non-treated control, from which the control value (%) was calculated. To test for curative effects, wounded or non-wounded red pepper fruits were inoculated with 10 μ L of *C. acutatum* spore suspensions (10^5 conidia/mL), dried at room temperature, and placed in plastic square plates (40 cm \times 40 cm) containing wet paper to maintain the humidity. Plates were incubated at 25°C for 10 days, treated with antagonistic bacterial suspensions, and incubated at 25°C for another 4 days; then the disease index, from which the control value (%) was recorded.

Fruits treated with pyraclostrobin and SDW served as positive and negative controls, respectively.

Effect of Antagonistic Bacteria on Growth in Red Pepper Seed Germination

Red pepper seeds (cv. Geochanghan) used for growth promotion were purchased from the local market. Seeds were washed with tap water to remove the coated chemical fungicides and then surface-disinfected with 1% NaOCl for 10 min; they were then rinsed in SDW and dried completely on filter paper. The bacterial inoculum was prepared by culturing on TSA plates for 3 days at 28°C, and cell suspensions were prepared at 10^6 CFU/mL prior to inoculation. *Bacillus velezensis* AK-0 and *Serratia plymuthica* GYUN-8 were used as positive controls. They are commercially available in the market as biocontrol agents (BCAs), with names, Tangeokil and Serratan for AK-0 and GYUN-8, respectively in Korea. These BCAs are produced by Koreabio, Co. Ltd., South Korea; while seeds treated with SDW served as negative controls. Dried seeds were coated with bacterial cell suspensions (10^6 CFU/mL) by immersing for 30 min, placed between double-layered wet papers, and incubated in a growth chamber at 25°C for 6 days. Then, seed germination (root length in mm) was measured and compared to that of the non-treated control; this experiment was repeated at least once.

Growth Promotion Effect on Red Pepper Seedlings

To investigate the ability of GYUN-300 to promote growth, surface-sterilized red pepper seeds were sown in plastic trays (36 pots per tray) containing garden soil. After germination, 3-week-old red pepper seedlings were soil drenched with 25 mL of 3-days-old cultured bacterial suspensions (10^6 CFU/mL) of GYUN-300, GYUN-8, or AK-0. Observations of growth promotion were recorded once every 7 days up to 40 days of the growing period; Seedlings were watered once every 3 days. The average length (cm) of seedlings was measured; this measurement was constrained to the length of the aboveground biomass. Four replications were used per treatment; each replication consisted of 20 seedlings under greenhouse conditions.

Fungicidal Resistance Test to GYUN-300 Bacterial Suspensions

To investigate the fungicidal resistance to GYUN-300, 11 types of chemical fungicides currently used to control red pepper anthracnose in Korea were used (Supplementary Table 1). A single colony of GYUN-300 was inoculated into TSB and incubated under shaking conditions (180 rpm) at 28°C for 3 days. From this, 100 μ L of the suspensions were spread onto freshly prepared TSA plates. Sterile paper discs (6 mm in diameter) impregnated with 10 μ L of chemical fungicides at different concentrations (i.e., 0.5 \times , 1.0 \times , and 2.0 \times) were placed onto the TSA plates. Results were observed after 3 days of incubation at 28°C; the experiment was carried out in triplicate. Bacterial resistance to fungicides was determined based on the inhibition zone.

Field Evaluation of the Application of GYUN-300 on Disease Suppression of Red Pepper Anthracnose

A field experiment was conducted to investigate the biological control of red pepper anthracnose using GYUN-300 antagonistic bacteria in Korea. At first, the seedlings were raised in plastic trays (36 pots per tray) by placing a single seed per pot. Three-week-old red pepper seedlings were transplanted to a field belongs to Andong National University, located at Andong, Gyeongbuk Province, South Korea. Seedlings were planted at a distance of 100 cm between rows and 40 cm between plants. After preparing the field, the soil was fertilized with NPK before starting the transplantation. The planting row was covered with non-woven fabric material for weed control. Antagonistic microorganism treatments were grouped into three: soil drenching, foliar spray, and foliar spray + soil drench. The GYUN-8 and AK-0 bacteria were used as positive controls, Pyraclostrobin was used as chemical control, and water treatment was served as non-treated control. Bacterial cell suspensions prepared at a concentration of 10^7 CFU/mL were used for all treatments. The field was irrigated 10 days intervals. The first dose was administered on June 17, 2020, and a total of nine treatments were administered at 10 days intervals until August 31, 2020. The pyraclostrobin emulsion was used as chemical control, and tap water was used as negative control. The disease incidence (%) was calculated from the disease index ratings (Supplementary Table 2). Four replications were used per treatment; each replication consisted of 20 plants under field conditions.

Statistical Analysis

The data were subjected to analysis of variance (ANOVA) using SAS JMP software ver. 3. (SAS Institute Inc, 1995). The experiments were set up as completely randomized block designs under field conditions. Significant differences between treatment means were determined using the least significant difference (LSD) at $p < 0.05$. All experiments were carried out at least twice; data were analyzed separately for each experiment. The results of one representative experiment are shown.

RESULTS

In vitro Antagonistic Activity of GYUN-300

The GYUN-300 bacterium was tested for *in vitro* antagonistic activity against three fungal pathogenic isolates; *C. acutatum* KACC42403, ACPP014, and ACPP015, all of which cause anthracnose disease in red pepper fruits (Figure 1). The mycelial growth of all three pathogenic fungal isolates was inhibited at a greater level than the non-treated control. Among the three fungal isolates, the mycelial growth of isolate *C. acutatum* KACC42403 was greatly inhibited by GYUN-300 7 days after incubation at 25°C, when compared the growth inhibition of the other two pathogens. GYUN-300 was most effective with an average inhibition zone of

28, 25.3, and 25.5 mm against *C. acutatum* KACC42403, ACPP014, and ACPP015, respectively (Supplementary Table 3). The dual culture plate assay on the PDA medium exhibited greater inhibition of mycelial growth of *C. acutatum* KACC42403 on PDA plates 5 days after incubation at 25°C, while growth inhibition was not observed in the non-treated control (Figure 2).

Effect of GYUN-300 Cell Suspensions or Culture Filtrate Treatment on Conidial Germination of *Colletotrichum acutatum* Under *in vitro* Conditions

When conidial spores of *C. acutatum* KACC42403 were treated with GYUN-300 bacterial cell suspensions (10^6 CFU/mL) or their CF under *in vitro* conditions, there were different levels of damages in the conidia germination and germ tube lengths; these were compared to the non-treated control. Conidial spore germination analysis using a hemocytometer showed greater inhibition percentage of spores after 16 h incubation in GYUN-300 cell suspensions-treated conidia compared to CF-treated conidia. After 48 h of incubation, the conidial germination rate was 40 and 43% in the GYUN-300 cell suspension and its CF treatments, respectively (Figure 3A); while the spore germination increased drastically in the non-treated control. GYUN-300-treated conidia resting on the hard glass surface did not germinate, while from 16 h onward, water-treated conidia germinated and formed appressoria through germ tubes (Figure 3B). At 48 h, all conidia had germinated and appressoria were formed through germ tubes in the water-treated control; this did not occur with the GYUN-300-treated conidia. At 16 h itself, there was a suppression of conidial germination, resulting in gall-like formation on the hyphal wall without further leading to germination during 48 h of incubation. This result suggests that GYUN-300 cell suspensions played a role effectively in suppressing conidial germination of *C. acutatum* KACC42403 (Figure 3B).

Inhibitory Effects of Volatile Organic Compounds Produced by GYUN-300 on *in vitro* Fungal Growth of *Colletotrichum acutatum*

We tested the effect of bacterial volatile organic compounds (VOCs) released by GYUN-300 cells on the inhibition of mycelial growth of *C. acutatum* KACC42403 under *in vitro* conditions using the I-plate or dual culture plate assays. Exposing *C. acutatum* KACC42403 to VOCs released by GYUN-300 bacterial suspensions significantly inhibited fungal mycelial growth 7 days after incubation at 25°C (Figure 4). When bacterial cells colonized the entire Petri dish, fungal growth had been drastically reduced by 20% greater in I-plate assay in comparison with the growth reduction of the same fungal pathogen in the dual culture plate assay. This was because the spread of the bacterial inoculum was relatively lower than that observed in the I-plate assay; the specific VOCs involved are yet to be determined.

FIGURE 1 | *In vitro* antagonistic activity of *Bacillus tequilensis* GYUN-300 on the inhibition of *Colletotrichum acutatum* fungal stains in comparison with the non-treated control. Mycelial growth of fungal pathogens on potatoes dextrose agar plates was recorded 7 days after incubation at 25°C. The experiment was repeated at least once, with each treatment carried out in replicate.

Morphological Analysis of *Colletotrichum acutatum* in the Presence or Absence of GYUN-300 Cell Suspensions

Distinct morphological characterization of the mycelial growth of *C. acutatum* in the presence or absence of GYUN-300 cell suspensions were carried out *in vitro* using a dual culture plate assay (Supplementary Figure 1). The mycelium grown in the presence of GYUN-300 was elongated, where hyphae were formed producing gall-like formations on the mycelia. This was considered deformed mycelia, and mycelial growth was healthy without any signs of deformation when it was grown without the presence of the GYUN-300 cell suspensions.

Identification of Antagonistic Bacteria Using MicroLog System

The characteristics of GYUN-300 based on carbon source utilization and various chemical reagents assessed by the MicroLog system revealed that GYUN-300 was sensitive to various carbon sources, such as glycol-L-Proline, maltose, and D-fructose (Supplementary Table 4). By contrast, antibiotics, such as rifamycin SV, vancomycin, and minocycline, showed a negative reaction to the chemical substances (Supplementary Table 5). These traits were compared with *Bacillus subtilis*, where they were

found to have a 57% probability of occurring compared with the existing database. The bacteria was identified as *Bacillus* sp., based on carbohydrate and chemical utilization, as this method identifies specific bacteria by matching with carbon utilization in the database.

Molecular Identification of GYUN-300

The isolate GYUN-300 was characterized using 16S rDNA gene sequencing. Comparison of the specific sequence of the ribosomal gene with sequences deposited in GenBank (accession no. OK001770) suggest that the GYUN-300 isolate belonged to the *Bacillus* genus, and shared the highest homology with *B. tequilensis* (99.93%). In the phylogenetic tree, GYUN-300 was clustered with other *Bacillus* spp. and was closely related to *B. tequilensis* (Supplementary Figure 2); thus, molecular characteristics confirmed this species as *B. tequilensis*. In the phylogenetic tree, the isolate was clustered with other *Bacillus* species that was closely related to *B. tequilensis*.

GYUN-300 Whole-Genome Sequence Analysis and Annotation

PacBio RSII NGS equipment was used at a sequencing depth of 179.34× to obtain complete sequence data for GYUN-300. The generated raw data were assembled using the HGAP2 protocol to obtain a FASTA file consisting of one contig. In

FIGURE 2 | Dual culture plate assay for the *in vitro* inhibition of *Colletotrichum acutatum* mycelial growth using an antagonistic bacterium GYUN-300: **(A)** sterile paper discs loaded with bacterial suspensions (10^8 CFU/mL) placed onto the potato dextrose agar (PDA) plates containing pathogenic fungal spores; and **(B)** sterile paper discs (6 mm in diameter) loaded with sterilized distilled water (SDW) served as the non-treated control. The inhibition zone was measured 7 days after incubation at 25°C. The experiment was repeated at least once, with each treatment carried out in triplicates (Petri dishes).

genome analysis, GYUN-300 was identified as *B. tequilensis*, where its core genome coverage was 96.7%. The genome of the *B. tequilensis* GYUN-300 (GYUN-300) strain consisted of a circular chromosome of 4,220,345 bp, with 4,789 predicted protein-coding sequences (CDSs), 38 rRNA genes, 86 rRNA genes, and an average G + C content of 43.6% based on the NCBI Prokaryotic Genomes Automatic Annotation Pipeline (PGAAP) analysis (**Figure 5A** and **Table 1**); the full genome sequence was deposited in NCBI under the GenBank accession number OK001770. Comparative analysis between the genome sequences of GYUN-300 and four other *Bacillus* strains showed a similar genome (**Table 1**). The genome of the GYUN-300 strain was compared with the four closest known evolutionary relatives: *B. subtilis* subsp. *subtilis* NCIB 3610, *B. subtilis* subsp. *spizizenii* TU-B-10, and *B. subtilis* subsp. *inaquosorum* KCTC 13429. Most genes in GYUN-300 were associated with secondary metabolite biosynthesis, transport, amino acid metabolism, carbohydrate metabolism, and catabolism. The first outer circle in the gray of the genome map represents one contig, the second circle represents the forward, the third circle represents the CDSs on the reverse strand, and the fourth circle indicates the tRNA and rRNA positions (**Figure 5A**). In addition to the gDNA, it was determined that the genome was likely to have an additional plasmid form. The fifth circle represents the GC skew, used as a reference point; values higher than this are indicated in green, while lower values are indicated in red. The sixth circle is GC ratio metric, where values greater than the average GC ratio, were expressed in blue, and lower values were represented in yellow; the GC skew and GC ratio were expressed at 10 kb intervals.

Venn diagrams (**Figure 5B**) compare the common CDSs among *B. tequilensis* GYUN-300, *B. subtilis* subsp. *subtilis* NCIB 3610, and *B. subtilis* subsp. *spizizenii* TU-B-10. This section summarizes the unique protein-encoding genes from the total genes of GYUN-300 is presented here. There were 3637 common high-expression gene families shared among GYUN-300, NCIB 3610, and TU-B-10 (**Figure 5B**), while 391, 113, and 389 genes

were determined to be unique for GYUN-300, NCIB 3610, and TU-B-10, respectively. All predicted CDSs of GYUN-300 were compared in the clusters of orthologous genes (COG) database to identify homologous amino acid sequences. Each functionally annotated protein was assigned a COG number, representing a class of proteins; then, proteins were subjected to functional clustering analysis according to the COG function (**Figure 5C**). The detection of secondary metabolites from GYUN-300 was analyzed using antiSMASH (**Figure 5D**). A total of 12 biosynthetic gene clusters were detected in GYUN-300. Clusters 1, 3, 5, 7, and 12 showed 100% similarity to fengycin, sublancin 168 A, bacillibactin, subtilosinA, and bacillaene, respectively; cluster 10 showed 78% similarity to surfactin.

Production of Lytic Enzymes, Siderophore Production, and Phosphate Solubilization by Antagonistic Bacteria

The antagonistic bacterium, GYUN-300, was considered for the production of hydrolyzing enzymes, such as cellulase, protease, and amylase, under *in vitro* conditions (**Supplementary Figure 3A**). GYUN-300 was found to produce protease at a greater level with an average inhibition zone of 25 mm. By contrast, other enzymatic activities, such as cellulase and amylase, had inhibition zones of 18 and 23 mm, respectively. GYUN-300 displayed strong inhibitory activity against fungal pathogens and showed strong amylase activity (**Supplementary Figure 3A**). There was greater production of all three enzymes (i.e., cellulase, protease, and amylase) by GYUN-300 compared with the non-treated control (SDW); this was in terms of inhibition zones around inoculation sites on the solid media in Petri dishes through the degradation of various substrates, such as CMC, proteins, and soluble starch, respectively.

The capacity of GYUN-300 to produce siderophores was qualitatively observed using a CAS assay. The positive reaction

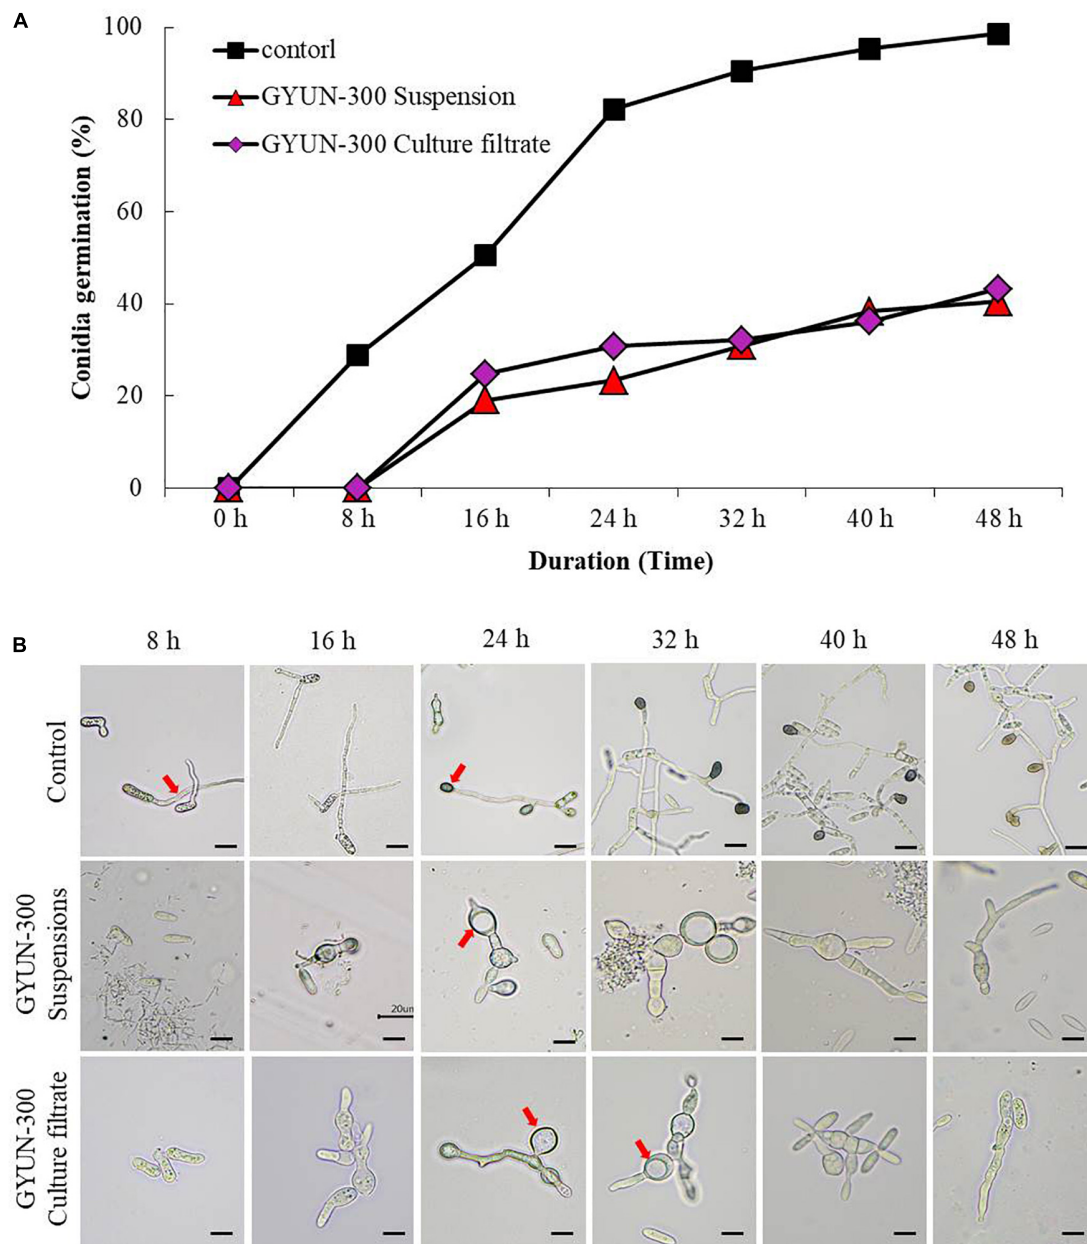

FIGURE 3 | Effect of bacterial cell suspensions and culture filtrate (CF) of *Bacillus tequilensis* GYUN-300 treatment on conidia germination rate (%) of *Colletotrichum acutatum* and microscopic observation: **(A)** Conidial germination rate (%) was suppressed by CF and bacterial cell suspensions, while the germination rate (%) was increased in the non-treated control; and **(B)** microscopic observations of *C. acutatum* fungal spore germination after GYUN-300 treatment during the incubation period from 8 to 48 h. The germination counting was carried out using a hemocytometer. Bar = 10 μ m. The experiment was repeated at least once, with treatments repeated in triplicate producing similar results.

of the qualitative assay results in a color change in the CAS agar medium from blue to orange around the inoculation site (**Supplementary Figure 3B**). The color changed from blue to light orange 4 days after incubating the plates at 28°C, while there was no color development around the non-treated control (SDW). This result suggests that siderophores produced by this bacterium helped to obtain dissolved iron by binding to Fe^{3+} ; this enables competition with pathogens for available iron, which

is essential for survival. The phosphate solubilization ability of the bacterium GYUN-300 was determined on tricalcium phosphate medium, where GYUN-300 solubilized the inorganic phosphate at a moderate level. This converted phosphorous into an available form, which is important as it is one of the major essential macronutrients for plant growth and development (**Supplementary Figure 3B**); there was no growth inhibition in the water-treated control.

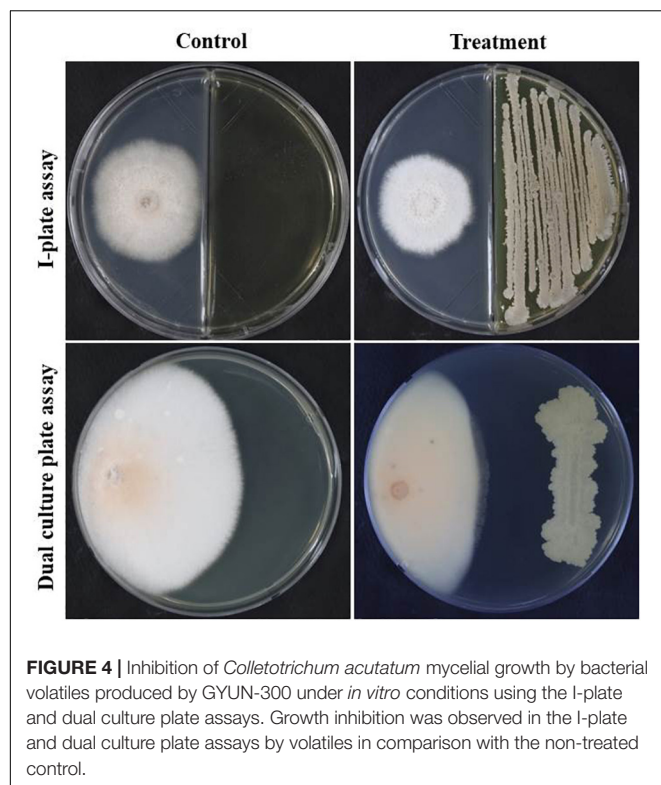

FIGURE 4 | Inhibition of *Colletotrichum acutatum* mycelial growth by bacterial volatiles produced by GYUN-300 under *in vitro* conditions using the I-plate and dual culture plate assays. Growth inhibition was observed in the I-plate and dual culture plate assays by volatiles in comparison with the non-treated control.

Control of Red Pepper Anthracnose by GYUN-300 Bacterial Suspensions

For anthracnose disease control by GYUN-300 bacterial suspensions, the red pepper fruits were treated with conidia suspensions on wounded or non-wounded fruits. In terms of preventive effects, where fruits were inoculated with pathogens after treatment with bacterial suspensions, the GYUN-300 bacterial treatment significantly ($P < 0.05$) controlled the anthracnose by 66.6%. This was higher than the chemical, GYUN-8, and AK-0 treatments, where they controlled the anthracnose by 56.6, 40, and 62.5%, respectively (Figure 6A). By contrast, in terms of the curative effect of wounded red pepper fruits, the GYUN-300 treatment controlled the anthracnose by 38.3%; this level of control was lower than the other treatments (Figure 6B). GYUN-300 treatment by the preventive method was better than the curative effect in wounded red pepper fruits. When GYUN-300 treatment was tested on non-wounded red pepper fruits, there was no significant difference in the control value among the three treatments. However, GYUN-8 treatment exhibited a greater control value (95.8%) than the other three treatments in terms of its protective effect (Figure 7A). In terms of the curative effects, the disease control using the chemical, GYUN-300, and AK-0 treatments was the same as that for the protective effects of non-wounded red pepper fruits; however, the GYUN-8 treatment exhibited less control than its protective effect (Figure 7B). The level of disease control with the non-treated control was zero in all treatments. These results suggest that the GYUN-300 strain is more effective as a preventive method compared to its curative effect.

Effect of GYUN-300 Treatment on Seed Germination and Growth Promotion in Red Pepper

A double-layered wet paper method was used to evaluate the growth promoting effect of GYUN-300 on red pepper seed germination under *in vitro* conditions. The average length of seedlings was higher in the AK-0 treated seedlings than other treatments (Supplementary Figure 4A). However, seedling length in GYUN-300 treated seedlings was higher than the non-treated control and GYUN-8-treated seedlings. The average seedling lengths were 31.7, 29.2, 39.6, and 25.3 mm, in the GYUN-300, GYUN-8, AK-0 treatments, and control, respectively. Similarly, the plant growth-promoting ability of GYUN-300 on red pepper seedlings was greater in terms of plant height compared to that in the non-treated control and other treatments, such as GYUN-8 and AK-0 (Supplementary Figure 4B); this indicates that GYUN-300 may be used for growth promotion.

Fungicidal Resistance to the Bacterium GYUN-300

The GYUN-300 strain was tested for resistance against various chemical fungicides under *in vitro* conditions. The bacterium GYUN-300 showed resistance against nine of the ten chemical fungicides tested in this study; while the bacterium showed sensitive to the fungicide Acibenzolar-S-methyl/Chlorothalonil, which inhibited bacterial growth on the TSA plates (Supplementary Table 6). This result suggests that most chemical fungicides used to control red pepper anthracnose do not affect GYUN-300 cell growth. These results suggest that GYUN-300 cells may be used synergistically with the chemical fungicides to control plant disease.

Effect of GYUN-300 on Disease Control of Red Pepper Anthracnose Under Field Conditions

Based on the *in vitro* results of disease suppression by GYUN-300, we tested the ability of GYUN-300 bacterial cells to suppress red pepper anthracnose caused by *C. acutatum* under field conditions. There was greater reduction in disease incidence (%) in the GYUN-300 treatment by foliar spray in comparison with the soil drench or combined application of soil drench + foliar spray (Figure 8). The disease incidence (%) was recorded as only 14% at both concentrations (500× and 100×) of GYUN-300 cell suspensions using a foliar spray method, while the disease incidence was 24.5% by combined method of spray + soil drench. On the other hand, the disease incidence was found at a greater level (56%) in both positive controls GYUN-8 and AK-0 by foliar spray method. Whereas, the disease incidence in chemical control (Pyraclostrobin) was observed as 46.1%, this is better than positive controls and non-treated control. Overall, all treatments with GYUN-300 showed better performance in controlling disease incidence (%) compared with the chemical treatments and non-treated control. These results suggest that

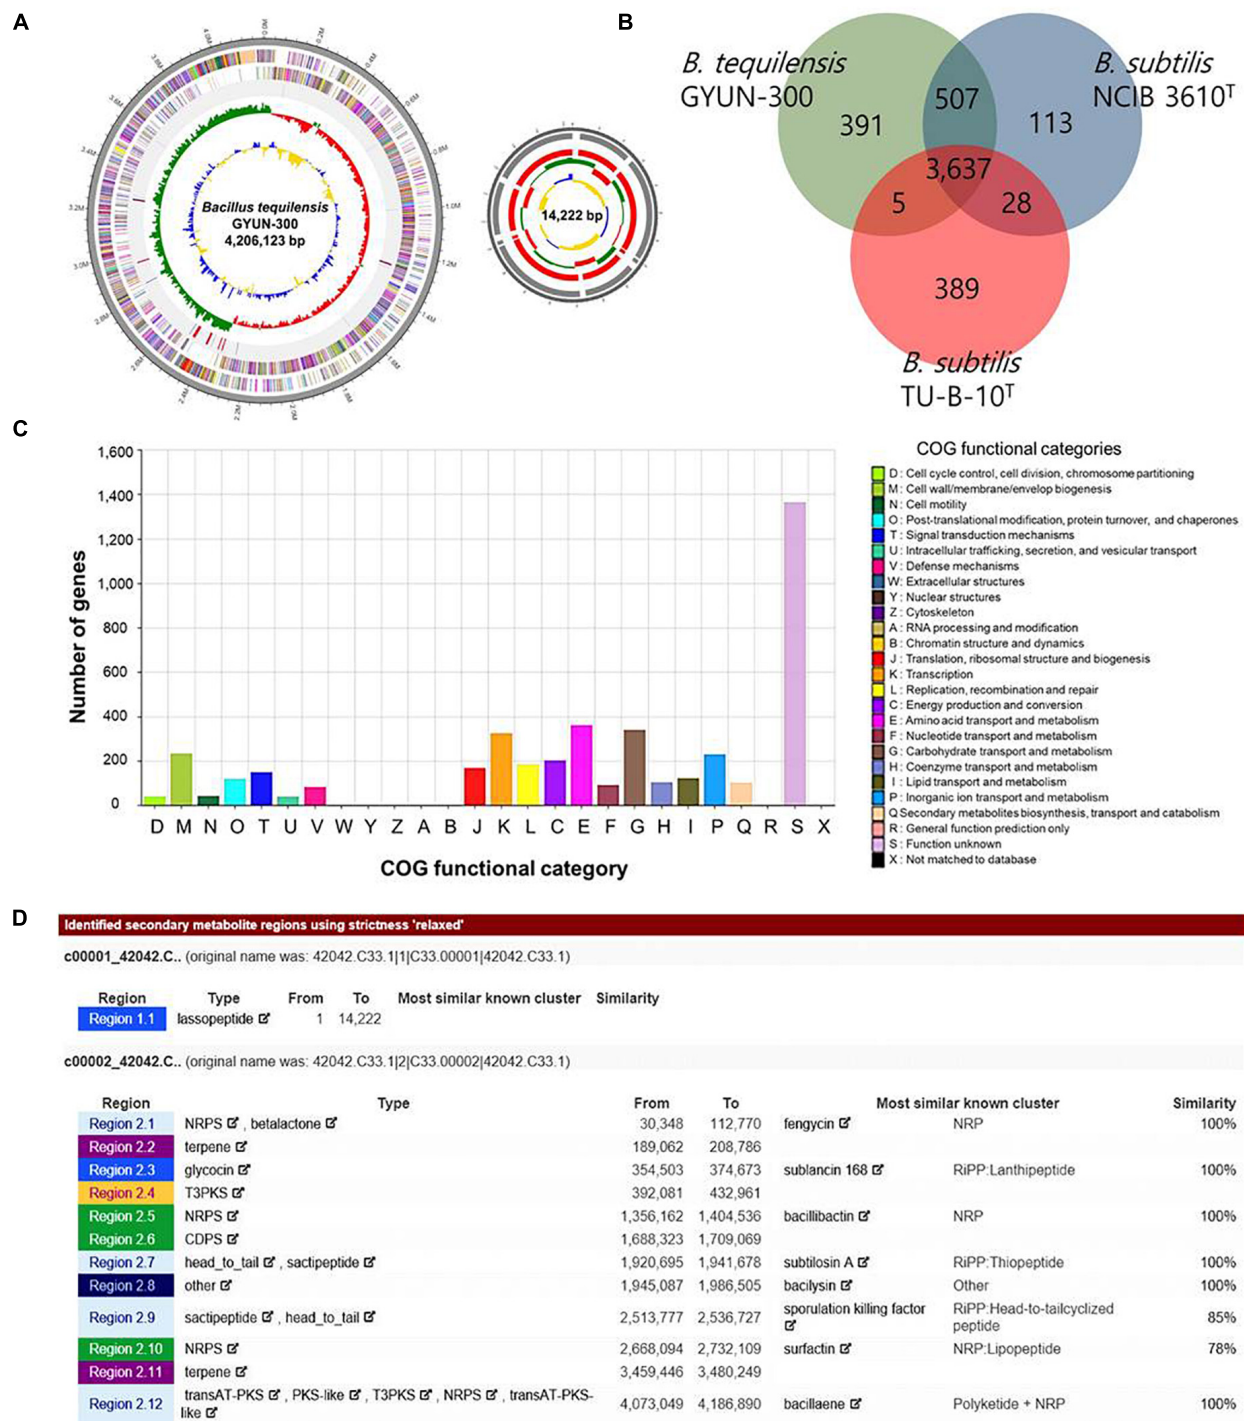

FIGURE 5 | Whole-genome map of *Bacillus tequilensis* GYUN-300 and annotation. **(A)** Marked characteristics shown from the outside to the center; coding sequence (CDS) on forward strand, CDS on reverse strand, tRNA, rRNA, guanine-cytosine (GC)-content, and GC skew. CDS genome consists of a single circular chromosome that is 4.2 mb in size, and represents one contig from the outer part of the circle; the second circle represents forward, the third represents reverse strand, and the fourth circle represents tRNA and rRNA positions; **(B)** distribution of orthologous genes in the *Bacillus tequilensis* GYUN-300, *B. subtilis* subsp. *subtilis* NCIB 3610^T, and *B. subtilis* subsp. *spizizenii* TU-B-10^T genomes. The Venn diagram shows the summary of unique SNPs from total genes of the *B. tequilensis* GYUN-300 strain. This analysis exploits all CDS of the genomes and is not restricted to the core genome; **(C)** the clusters of orthologous genes (COG) function annotation of *B. tequilensis* GYUN-300, and distribution of genes in different COG function categories; and **(D)** analysis of secondary metabolites of GYUN-300 using the antiSAMASH program.

TABLE 1 | Genomic features of the *Bacillus tequilensis* GYUN-300 genome and comparison with genomes of other *Bacillus* subsp. belonging to the *Bacillus subtilis* group.

Taxon name	Strain name	No. of contigs	Genome size	DNA G + C content (%)	No. of CDSs	No. of rRNA genes	No. of tRNA genes
<i>B. tequilensis</i>	GYUN-300	2	4 220 345	43.6	4,789	38	86
<i>B. subtilis</i> subsp. <i>subtilis</i>	NCIB 3610 ^T	2	4 299 822	43.3	4,329	30	88

GYUN-300 is a potential candidate for the biological control of red pepper anthracnose in Korea.

DISCUSSION

Bacillus species are widespread in and produce numerous antibiotic compounds that are active against several phytopathogens as an alternative to chemical fertilizers and synthetic pesticides (Shahid et al., 2021). In this study, we isolated the *B. tequilensis* GYUN-300 strain from fresh sanghwang mushroom, as it exhibits potent antagonistic activity against red pepper anthracnose caused by *C. acutatum* under *in vitro* and field conditions. Previously, several *Bacillus* species have demonstrated antagonistic activity against several *Colletotrichum* species, including *C. acutatum* (Han et al., 2015; Caulier et al., 2019).

This study describes the isolation, identification, and characterization of an antagonistic *Bacillus* sp. isolated from an edible mushroom. GYUN-300 was confirmed as *B. tequilensis* based on its morphology and the BIOLOG program results. Furthermore, the GYUN-300 strain was characterized by molecular analysis using 16S rDNA sequencing; this strain was identified as *B. tequilensis* GYUN-300. The GYUN-300 strain showed 99.9% homology with the reported database strains of other *B. tequilensis*. Anthracnose from *Colletotrichum* may cause considerable damage to various crops, including red pepper (Than et al., 2008; Kim et al., 2010); *Colletotrichum* spp. are frequently associated with several pepper diseases worldwide (Liu et al., 2016). There are limited reports on microbial-based control of anthracnose disease, and to the best of our knowledge, this is the first report on the use of the GYUN-300 as a potential BCA for red pepper anthracnose; this is also the first analysis of the whole-genome sequencing of GYUN-300. The results provide an understanding of the biocontrol mechanism of the GYUN-300 strain, providing a possible alternative BCA to control red pepper anthracnose in Korea.

It was found that treatment with GYUN-300 CF was equally effective as the cell suspensions in inhibiting the conidial germination of *C. acutatum* under *in vitro* conditions. Similarly, a recent study by Choub et al. (2021b) reported that the CF from *B. velezensis* CE100 exhibited antifungal activity against *Colletotrichum gloeosporioides* through the production of cyclic tetrapeptides from the CF. Another study reported that the CF from *B. subtilis* inhibited the growth and spore germination of *C. gloeosporioides* through mycolytic enzyme-mediated antagonism (Ashwini and Srividya, 2014).

Recently, Sarwar et al. (2018) reported that the growth of various phytopathogens, such as *Fusarium moniliforme*, *Fusarium oxysporum*, *Fusarium solani*, and *Trichoderma atroviride*, was suppressed by *Bacillus* spp. through the production of a broad spectrum of lipopeptide biosurfactants. This is supported by recent reports (Jayapala et al., 2019; Wu et al., 2019), which have demonstrated that *Bacillus* spp. played a role in producing antibiotic compounds to protect red pepper from anthracnose and wilt diseases caused by *Colletotrichum capsici* and *Rhizoctonia solani*, respectively. Zalila-Kolsi et al. (2016) reported that a few *Bacillus* species isolated from wheat rhizosphere soil exhibited *in vitro* antagonistic activity against several phytopathogenic fungi, including *F. graminearum*, which causes durum wheat disease.

The microscopic observations in this study indicate that the suppressive effects of bacterial suspensions of GYUN-300 and its CF may be due to antibiosis mechanisms. The GYUN-300 strain affected the conidial germ tube and mycelial morphology of *C. acutatum* KACC42403, causing severe damage to the fungal hyphae. Numerous studies have demonstrated the antifungal mechanisms of soluble non-volatile bioactive compounds, such as lipopeptides and proteins, produced by various *Bacillus* species against several soil-borne diseases (Zhang et al., 2020). Conversely, the suppression of mycelial growth of fungal phytopathogens caused by bacterial antagonists has been attributed to VOCs, involved in biocontrol interactions by *Bacillus* species against fungal pathogens, such as *Botrytis cinerea* (Sharifi and Ryu, 2016), *Penicillium expansum*, *Alternaria alternata* (Gao et al., 2018), and *C. gloeosporioides* (Chowdhury et al., 2015).

The whole-genome sequence of GYUN-300 was characterized; this consisted of a 4.22 Mb chromosome, and this genome was compared to other *Bacillus* species (Table 1). In particular, biocontrol-related genes and gene clusters involved in the antibiotic may produce differences in biocontrol targets and efficacy between GYUN-300 and other *Bacillus subtilis* strains. These results suggest that all other strains may prevent the host plant from the disease by genes involved in the synthesis of secondary metabolites and exhibit strong antifungal activities against various fungal phytopathogens (Pusztahelyi et al., 2015; Costa et al., 2019). *Bacillus* species produce cyclic lipopeptides (CLPs), known for their broad-spectrum antagonistic activity mediated by secondary metabolites (Kim et al., 2021). This may have contributed to antagonistic activity against *C. acutatum*. Whole-genome comparisons revealed that the GYUN-300 strain showed high similarity to *B. subtilis* subsp. *subtilis* NCIB 3610^T, *B. subtilis* TU-B-10^T, and *B. subtilis* subsp. *inaquosorum* KCTC

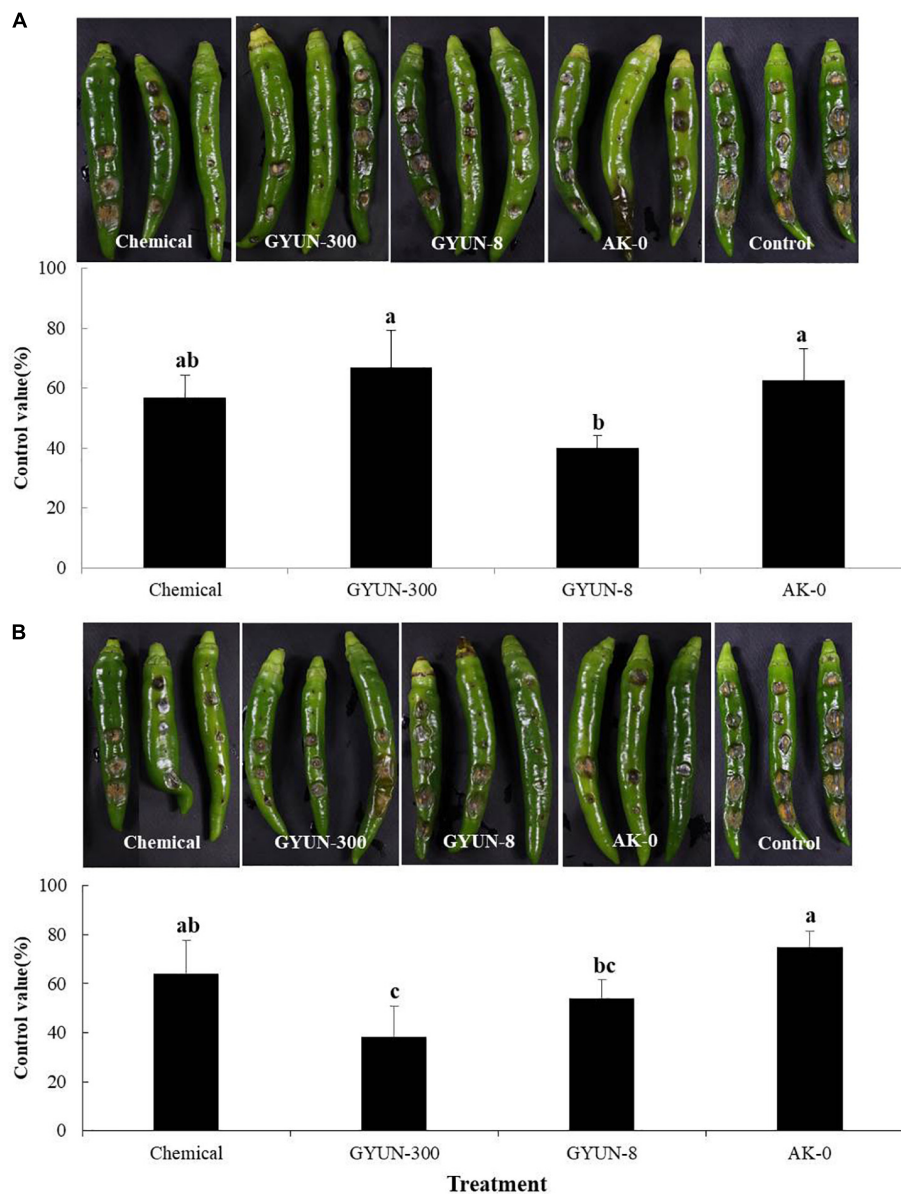

FIGURE 6 | Protective and curative effects of GYUN-300 on disease suppression of red pepper anthracnose in wounded fruits. **(A)** For protective effects, bacterial suspensions (10^7 CFU/mL) were sprayed on the detached green pepper fruits, followed by inoculation with *Colletotrichum acutatum* conidia suspensions (10^5 conidia/mL) on the same day. The disease severity (%) was recorded 10 days after incubation at 25°C. **(B)** For curative effects, symptom development was observed 10 days after pathogen inoculation with *C. acutatum* conidia suspensions (10^5 conidia/mL) on detached green pepper fruits, followed by treatment with bacterial suspensions (10^7 CFU/mL) using a spray method. Disease severity (%) was recorded 10 days after incubation at 25°C. The experiment was carried out two times with six replicates (fruits) per treatment, showing similar results. Bars with the same letters do not differ significantly between each other according to the least significant difference (LSD; $p < 0.05$).

13429^T strains currently used as BCAs in field conditions (Zhang et al., 2016; Gu et al., 2021). The COG database was used to functionally categorize predicted proteins from the distribution of genes (Galperin et al., 2015), and the COG categories were compared among the four strains, including GYUN-300. The COGs of the four strains showed highly similar distributions, suggesting that these strains have comparable biological characteristics. A total of 12 putative biosynthetic gene

clusters for secondary metabolites were detected in the GYUN-300 genome. Some are involved in the metabolism of amino acids, carbohydrates, lipid transport and metabolism, and catabolism of secondary metabolite biosynthesis (Zhang et al., 2016). These functions are important for antagonistic agents against various phytopathogens, including *C. acutatum*, which causes red pepper anthracnose. The genome of GYUN-300 was investigated for the presence of gene clusters involved in the biosynthesis of CLPs that

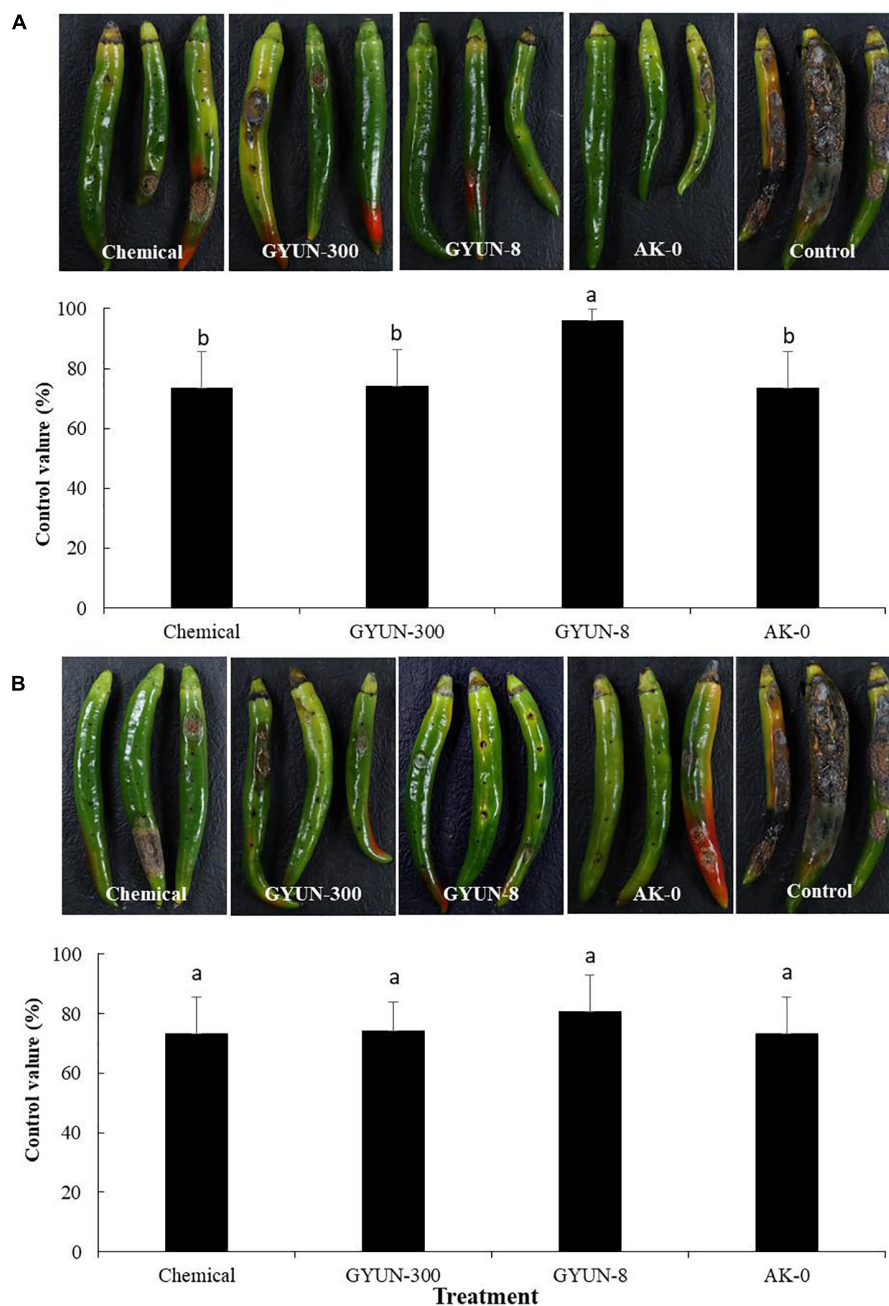

FIGURE 7 | Protective and curative effects of GYUN-300 on disease suppression of red pepper anthracnose in non-wounded fruits. **(A)** For protective effects, bacterial suspensions (10^7 CFU/mL) were sprayed on the detached green pepper fruits without wounding, followed by inoculation with *Colletotrichum acutatum* conidia suspensions (10^5 conidia/mL) on the same day. Disease severity (%) was recorded 14 days after incubation at 25°C. **(B)** For curative effects, symptoms were observed 14 days after pathogen inoculation with *C. acutatum* conidia suspensions (10^5 conidia/mL) on detached green pepper fruits without wounding, followed by treatment with bacterial suspensions (10^7 CFU/mL) using a spray method. Disease severity (%) was recorded 10 days after incubation at 25°C. The experiment was carried out two times with six replicates (fruits) per treatment, showing similar results. Bars with the same letters do not differ significantly between each other according to the least significant difference (LSD; $p < 0.05$).

were predicted by antiSMASH analysis; this is a web server and stand-alone tool for the automatic genomic identification and analysis of biosynthetic gene clusters.³

³<http://antismash.secondarymetabolites.org>

Furthermore, the GYUN-300 strain produced hydrolytic enzymes, such as cellulase, protease, amylase, and siderophores, as well as phosphate solubilization, which are common features of antagonistic bacterial isolates (Belbahri et al., 2017). Siderophores are powerful ferric iron-chelating

molecules produced by microorganisms that acquire iron, which is essential for crop growth. Siderophores differ from one another in their chemical structure and properties (Ahmed and Holmström, 2014), and have been suggested as environment-friendly alternatives to hazardous pesticides (Schenk et al., 2012). Siderophore-producing bacteria improve iron nutrition and slow down pathogen growth by limiting iron availability for pathogens (Nabila and Kasiamdari, 2021). However, the development of fungicide resistance in antagonistic bacteria is an increasing threat in plant disease management (Alizadeh et al., 2020). At times, the antagonistic bacteria in combination with agrochemicals are effective in suppressing pathogen growth at a greater level when compared with individual treatments under field conditions (Ons et al., 2020). This is in agreement with the results from this study, suggesting that GYUN-300 cell suspensions may be used in synergy with chemical fungicides.

The red pepper anthracnose disease was suppressed by GYUN-300 at a greater level in comparison with other positive controls, such as GYUN-8 and AK-0, and chemical control under field conditions. Similarly, a recent study by Choub et al. (2021a) reported that the field application of *B. velezensis* CE 100 culture broth resulted in a 1.3-fold and 6.9-fold decrease in anthracnose disease severity on walnut trees compared to the conventional and control groups, respectively. Previously, Park et al. (2001) reported to suppress the anthracnose disease in cucumber by the application of *Bacillus amyloliquefaciens* EXTN-1, and another strain *Bacillus vallismortis* BS07 suppressed the disease incidence (%) of anthracnose caused by *C. acutatum* on red pepper fruits at a greater level in comparison with the chemical control under field conditions (Park et al., 2013), which is in agreement

with our results. Additionally, our results are supported by a recent study (Prihatiningsih et al., 2019), which displayed the control of red pepper anthracnose using microencapsulated *B. subtilis* B298 by spray method under field conditions. On the other hand, recently our team (Kim et al., 2021) reported to show the disease control of anthracnose caused by *C. gloeosporioides* on fresh apples using a biocontrol agent *B. velezensis* AK-0.

In conclusion, the GYUN-300 strain isolated from the edible sanghwang mushroom exhibited significant antagonistic activity against red pepper anthracnose caused by *C. acutatum*. The strain was identified as *B. tequilensis* GYUN-300 based on whole-genome sequence analysis. The strain exhibits *in vitro* antagonistic activity and suppression of conidial germination and *in planta* disease control of anthracnose. GYUN-300 suspension treatment has also demonstrated to control red pepper anthracnose in field conditions in Andong, Gyeongbuk Province, South Korea. Whole-genome sequencing revealed that the core genome of GYUN-300 was very similar to various *B. subtilis* strains. The differences between the various *B. tequilensis* strains in terms of control targets and efficacies may be attributed to variations in genes or gene clusters responsible for the biocontrol mechanism. Several CLP products of this strain were determined by analyzing secondary metabolite BGCs using antiSMASH software. GYUN-300 possessed several biosynthetic compounds, which may play an important role in controlling red pepper anthracnose through a mechanism of antibiosis. Overall, the results of this study indicate that GYUN-300 shows as an eco-friendly BCA against phytopathogens. Future research should investigate the signaling pathways involved in the antagonistic effects of secondary metabolites against pathogenic fungi.

Improved nutrient use efficiency together with the use of biostimulants have been little explored thus far to improve fruit yield and quality in economically relevant crops. The aim of this study was to determine the additive or synergistic effects, if any, of the application of an enzyme hydrolyzed animal protein biostimulant (Pepton) combined with priming with low nitrogen (N) in the production and quality of greenhouse tomatoes. Biostimulant treatment (Pepton at a dose equivalent of 4 kg/ha) was applied by ferti-irrigation for 2 months during the vegetative phase both in controls (watered with nutrient solution) and nutrient efficient crop (NEC), in which plants were primed with low N by exposing them to a 30% N deficiency for 2 months, and then recovered for 1 month before fruit production. Foliar water and N contents, pigments, maximum PSII efficiency (Fv/Fm ratio), and phytohormones [including abscisic acid (ABA), salicylic acid (SA), jasmonic acid (JA), and cytokinins] were measured prior and at 4 and 8 weeks after the first application. Fruit production and quality [as indicated by total soluble sugars (TSS) and acidity (TA), and the contents of lycopene, vitamin E, and vitamin C] were measured 1 month later at harvest. Priming with low N availability (NEC plants) doubled ($p < 0.001$) fruit production (due to an increase in the number of fruits), tended to increase ($p = 0.057$) by 20% the amount of TSS and increased ($p < 0.05$) the contents of lycopene (by 90%) and vitamin E (by 40%). Pepton displayed a tendency, almost significant, to improve ($p = 0.054$) total fruit production both in control and NEC plants, thus showing an additive effect to low N priming in boosting fruit production. Pepton maintained fruit quality in terms of sugar

accumulation, total acidity and the contents of carotenoids, vitamins C and E. Pepton-related improvement in fruit production seemed to be related, at least partially, to an increased accumulation of cytokinins and photosynthetic pigments in leaves, which might favor vegetative vigor and ultimately fruit yield. In conclusion, Pepton application was effective in improving the yield of greenhouse tomatoes showing additive effect with low N priming, without negatively affecting fruit quality.

Keywords: biostimulant, cytokinins, nitrogen efficient crops, production, tomato

INTRODUCTION

Rising productivity to feed the escalating global population and increasing the use efficiency of the resources without harming the ecosystems are two of the greatest challenges that the agricultural sector is facing these days. Moreover, current agriculture has to face more frequent and long-lasting unfavorable environmental and soil conditions, which have a direct negative impact on crop productivity. A technological innovation proposed to solve these problems is the application of natural biostimulants that can enhance flowering, plant growth, fruit set, crop productivity, and nutrient use efficiency, while also improving abiotic stress tolerance (Rouphael and Colla, 2020). One of the main important nutrients for plant growth and development is nitrogen (N), which at the same time is one of the major limiting nutrients in most economically relevant crops (Flores et al., 2004; Padilla et al., 2018). Because of this, and to ensure high crop yield, it is very common among farmers to conduct excessive N applications that end up leaching into groundwater, threatening both the environment and human health (Padilla et al., 2018; Burri et al., 2019). Hence, it is of great importance to develop new techniques that help farmers optimize crop production, while using the minimum N input to reduce its harmful effects on the environment and human health.

Enzymatically hydrolyzed protein-based biostimulants may be an adequate approach to both raise productivity and increase the use efficiency of some nutrients such as N (Colla et al., 2014, 2017). Pepton 85/16® (Pepton) is a natural biostimulant obtained by the enzymatical hydrolysis of animal proteins that is available in a micro-granular form and highly soluble in water (APC Europe S.L., Spain). Pepton has been proved to have beneficial effects on crops under stress conditions such as intense cold or heat episodes, mild stress ambient field conditions, and water and nutrient stress. It has also been observed that it exerts a positive effect on the hormonal profile enhancing abiotic stress defenses (Polo et al., 2006; Marfà et al., 2009; Polo and Mata, 2018; Casadesús et al., 2019, 2020). However, little is still known about the possible effects of this biostimulant on plants under low nutrient availability conditions and the improvement of nutrient use efficiency. Priming with low N has been previously shown as a useful technique with a great potential to increase productivity since it can ameliorate nutrient use efficiency in wheat (Gao et al., 2019). However, to our knowledge, its potential beneficial effects on improving the yield and quality

of tomatoes, and most particularly in combination with biostimulant application, has not been explored thus far.

Tomato (*Solanum lycopersicum* L.) is one of the most cultivated crops with a cultivation area of 5.03 million hectares (FAOSTAT, 2019). Its fruits are highly valued by consumers due to their organoleptic characteristics and nutritional value, as they constitute an important source of vitamins C and E and lycopene, among other nutrients and antioxidants (Asensio et al., 2019). It is of great interest to increase the nutrient use efficiency of tomato plants, without affecting their production, since large amounts of fertilizer are usually applied to obtain their maximum yield (Abenavoli et al., 2016). Therefore, this work aimed to assess to what extent an enzymatically hydrolyzed protein-based biostimulant (Pepton) can improve fruit production and quality both in control and in low N primed conditions, and establish a mechanism of action, with an emphasis on the possible role of endogenous phytohormone contents.

MATERIALS AND METHODS

Experimental Design

Seeds of tomato plants (*Solanum lycopersicum* cv. Ailsa Craig) were obtained from the Experimental Field Facilities of the University of Barcelona (Barcelona, NE, Spain). Seeds were sown on 7th March 2019, in 1 L pots in a climate-controlled growth chamber (16 h day/8 h night, at 22°C), using a substrate based on 50% peat, 25% perlite, 25% vermiculite, CaCO₃ at 1 g/L and essential micronutrients at 0.05 g/L. On 8th April, seedlings were transferred to 3 L pots and placed in a glass greenhouse (25.6°C mean temperature, 33.8°C highest temperature average with an absolute maximum of 41.0°C, and 60.1% mean relative humidity) with 20 cm between pots. Then, on 10th June, four treatments were established including: Control plants without Pepton, Control plants with Pepton, Nitrogen Efficient Crop (NEC) without Pepton, and NEC with Pepton. Control plants were irrigated with 50% Hoagland nutrient solution (Hoagland and Arnon, 1950) throughout the experiment. In contrast, NEC plants were primed with low N by irrigating plants for 8 weeks with a nutrient solution deficient by 30% N relative to controls and then recovered with the same nutrient solution as used for controls (50% Hoagland solution). Pepton was applied by ferti-irrigation once every 2 weeks during the first 2 months at a dose equivalent of 4 kg/ha (0.2 g of Pepton dissolved in 0.5 L of

irrigation water), corresponding with the supplier recommendation for this crop. All applications were performed 1 h before sunset. All plants were subject to “topping” at week seven of starting treatments due to excessive growth in the greenhouse, so that this pruning caused the plants to stop flowering and setting new fruits.

Leaf samples were collected on 16th June (week 0), 16th July (week 4), and 13th August (week 8) at predawn (1 h before sunrise). In each sampling, one young, fully developed leaf from eight randomly selected plants per treatment was sampled. The apical leaflet was used to determine the chlorophyll fluorescence and the adjacent leaflet was used to determine the water, carbon (C), and N status, and the leaflet mass per area ratio (LMA). The other adjacent leaflet was immediately frozen in liquid N₂ and stored at −80°C for subsequent biochemical analyses. Fruit samplings from the same plants were performed between 4th September and 7th September. All fruits (from breaker to red ripe stages) of each plant were harvested for the estimation of yield. In addition, four ripe tomatoes on the red ripe stage were chosen for fruit quality analysis: one was frozen in liquid N₂ and stored at −80°C for subsequent biochemical analyses (total carotenoids, lycopene, and vitamins C and E) and three were used to analyze total soluble sugars (TSS) and titratable acidity (TA).

Pepton Composition

Pepton is an enzymatically hydrolyzed protein product that contains L-α amino acids (84.8%), free amino acids (16.5%), organic-nitrogen (12.0%), iron (3,000 ppm), and potassium (4.0%). The complete chemical composition of this biostimulant can be found in Polo and Mata (2018).

Total Production, TSS, and TA

Total production was estimated as the total amount of fruits produced per plant, the total biomass of fruits produced per plant and the fresh mass per fruit unit. The fresh mass of fruits was measured by weighing freshly harvested fruits. For estimating fruit quality, 1 ml of juice from a pool of three tomatoes was used to determine TSS using a digital refractometer HI 96801 (Hannah Instruments, Italy). Then, 10 ml of juice were diluted in 100 ml of MiliQ water and used for TA determination with 0.1 M NaOH and 1% phenolphthalein as an indicator to estimate citric acid content. The TSS/TA ratio was then calculated.

Fruit Total Carotenoids, Lycopene, and Vitamins C and E

For the quantification of total carotenoids, 100 mg of ground frozen fruit were extracted with acetone 80% (v/v) using ultrasonication (Branson 2510 ultrasonic cleaner, Branson, Danbury, CT, United States). The extract was then centrifuged for 10 min at 4°C and 13,000 rpm, and the supernatant was collected. The pellet was re-extracted until it was colorless, pooling at the end all the supernatants. Total carotenoids were

analyzed using UV/Visible spectrophotometry of double beam using a CE Aquarius UCE7400 (Cecil Instruments Ltd., Cambridge, United Kingdom). The absorbance of the supernatants was read at 470, 646, 663, and 750 nm, respectively. Carotenoid content was calculated following the equations developed by Lichtenthaler and Wellburn (1983).

Quantification of lycopene content was performed as described by Fish et al. (2002). Around 500 mg of ground frozen fruit were extracted with 800 µl MiliQ water, 1.5 ml acetone, 1.5 ml ethanol, and 3 ml hexane. The pellet was re-extracted with hexane until it was colorless. The absorbance of the supernatants was read at 503 and 800 nm.

The analysis of vitamin C was adapted from Takahama and Oniki (1992) and Queval and Noctor (2007). Around 100 mg of ground frozen fruit were extracted with 6% meta-phosphoric acid (w/v) and 0.2 mM DTPA using ultrasonication and centrifugation for 10 min at 4°C and 13,000 rpm. The contents of ascorbic acid (AA) and dehydroascorbic acid (DHA) were determined spectrophotometrically (xMark Microplate Spectrophotometer, Bio-Rad, Hercules, CA, United States) with quartz microplates reading the absorbance at 265 nm. Total ascorbate was calculated as the sum of AA + DHA.

For vitamin E analyses, 100 mg of ground frozen fruit were extracted with methanol and 5 ppm (w/v) of tocol as an internal standard. Extractions were performed as above. The extracts were then filtered with a hydrophobic PTFE filter of 0.22 µm (Phenomenex, Torrance, CA, United States) and injected into the HPLC system (consisting of a Waters 600 controller pump, a Waters 717 plus auto-sampler, and a Jasco FP-1520 fluorescence detector). Fluorescence detection was at an excitation wavelength of 295 nm and emission at 330 nm. The mobile phase was a mixture of *n*-hexane and 1,4-dioxane (95.5:4.5, v/v) at a flow rate of 0.7 ml/min. Tocochromanols were separated using an Inertsil 100A column (5 µm, 30 × 250 mm, GL Sciences Inc., Tokyo, Japan). A calibration curve was established with each of the tocochromanols analyzed using authentic standards from Sigma-Aldrich (Steinheim, Germany).

Leaf Water Status, C and N Contents, and LMA

Relative water content (RWC) was calculated using the formula $RWC = 100 \times (FW - DW) / (TW - DW)$, where FW is the fresh mass measured on the sampling date, TW is the turgid mass measured after rehydrating the leaves for 24 h in the dark at 4°C, and DW is the dry mass measured after oven-drying the leaves at 80°C until constant weight. Leaflet area was measured with a flatbed scanner and processed with ImageJ (1.52p, National Institutes of Health, Bethesda, MD, United States). The LMA was calculated as DW/Leaflet area.

For C and N analyses, 3 mg of dry leaflets were ground, weighed, placed in tin capsules, sealed and analyzed using an organic elemental analyzer (Thermo EA 1108, Thermo Scientific, Milan, Italy). Standard conditions recommended by the supplier were applied (Combustion reactor at 1,000°C, reactor chromatographic column at 60°C, helium flow 120 ml/min and 10 ml oxygen circuit at 100 kPa).

Photosynthetic Pigments and Chlorophyll Fluorescence

For total chlorophyll and carotenoid content measurements, methanolic extracts were prepared using 100 mg of frozen ground leaves and diluted 1:10 (v/v) with methanol. The absorbance of the supernatants was read at 470, 653, 666, and 750 nm using a UV/Visible spectrophotometer of double beam (CE Aquarius UCE7400, Cecil Instruments Ltd., Cambridge, United Kingdom). Chlorophyll a, chlorophyll b, and carotenoid contents were calculated following the equations developed by Lichtenthaler (1987).

The maximum efficiency of PSII photochemistry (or F_v/F_m ratio), an indicator of photoinhibition (Takahashi and Badger, 2011), was determined by measuring chlorophyll fluorescence from leaves by using a portable fluorimeter Mini-PAM II (Photosynthesis Yield Analyser, Walz, Germany) in dark-adapted leaves for 1 h, as described by van Kooten and Snel (1990).

Stress-Related Phytohormones and Cytokinins

Phytohormones, including the stress-related phytohormones, abscisic acid (ABA), salicylic acid (SA), jasmonic acid (JA), and the cytokinins, *trans*-zeatin (*t*-Z), and its riboside *trans*-zeatin riboside (*t*-ZR), were analyzed by the extraction of 100 mg of frozen ground leaves with methanol containing deuterium-labeled hormones, which were used as internal standards. The extracts were subject to ultrasonication and vortexing for 30 min. After centrifugation for 10 min at 4°C and 13,000 rpm, the supernatant was collected, and the pellet was re-extracted. The supernatants were then filtered with a hydrophobic PTFE filter of 0.22 µm (Phenomenex, Torrance, CA, United States) prior to analysis. Hormone levels were analyzed by UHPLC-ESI-MS/MS as described by Müller and Munné-Bosch (2011). Quantification was made considering the recovery rates for each sample by using the deuterium-labeled internal standards.

Statistical Analyses

Statistical analyses were performed by a three-way ANOVA for foliar analyses and a two-way ANOVA for fruit analyses. The Tuckey test was used as a *post hoc* method. In all cases, differences were considered significant at a probability level of $p < 0.05$ and a trending toward statistical significance at a probability level of p between 0.1 and 0.05 (Fisher, 1950; These et al., 2016). All statistical tests were performed with RStudio (Boston, MA, United States).

RESULTS AND DISCUSSION

Low N Priming and Pepton Application Improve Fruit Production

Biostimulants have been considered innovative tools that are able to improve plant growth and productivity and help alleviate the effects of abiotic stresses. Furthermore, some biostimulants, such as Pepton, that are enzymatically hydrolyzed animal protein-based biostimulants can promote circular economy

helping recycle animal waste products and reduce the use of limited resources of nature (Casadesús et al., 2020). Previous studies have shown that Pepton can improve crop performance against different abiotic stresses including water and temperature stress conditions. In the present study, fruit production was stimulated by the NEC treatment as compared to controls, whereas fruit size remained unaffected (**Figure 1**). NEC treatment increased the production of greenhouse-grown tomato fruits, estimated as total fresh matter of fruits per plant, by 1.7-fold, which was associated with an increase in the number of fruits per plant by 1.8-fold. However, no significant differences were observed for fruit size. A trend toward statistical significant effect ($p = 0.054$) was observed for fruit production in Pepton-treated plants, with an increase in fruit production by 32% relative to controls both in N-fed (Controls) and low N-primed plants (NEC; **Figure 1**). This increase in yield in both groups of plants supplemented with Pepton has an important economic relevance for producers with very positive return on investment. In a previous study, Polo and Mata (2018) found similar results, with a yield increased by 27% when Pepton was applied at similar doses (4 Kg/Ha) in gold cherry tomatoes growing under low stress ambient field conditions. N is a crucial nutrient for plant growth and development, so one might expect that plants with higher N availability (control, N-fed plants) would show increased fruit production, as previously observed in several economically important crops, including tomatoes (Warner et al., 2004). It is also true, however, that low N priming can be used in crops to improve nutrient efficiency, showing a great potential to increase yields (Gao et al., 2019). In the present study, we observed that plants have acclimated to a deprived nutrient availability during the vegetative growth for 2 months allowing them to become more efficient in their N use and, therefore, increase their total fruit production considerably. It is noteworthy, however, that aside from low N priming, the pruning of plants performed after 7 weeks of treatment may play a role in the observed effects. Topping might have caused a severe loss of aboveground biomass favoring fruit set and ripening, but at the same time reduced a significant amount of biomass previously consuming root N. Therefore, as pruning was performed just before the end of N deprivation, it may have had an impact on the recovery phase in the NEC treatment helping boost production relative to controls. In other words, NEC treatment may would not have had such a positive effect compared to controls if all plants had not been pruned.

The Positive Effects of Combined Low N Priming and Pepton Application on Fruit Production Did Not Negatively Affect Fruit Quality

Total soluble sugars and TA are important components of flavor exerting their effect not only through their content but also through their ratio (Xu et al., 2018; Navarro and Munné-Bosch, 2022). However, the effects of some nutrients' availability, such as a decrease in the N dose, on tomato quality are still controversial as it has been seen to both increase (Aziz, 1968; Bénard et al., 2009; Truffault et al.,

FIGURE 1 | Effects of low nitrogen (N) priming and Pepton application on fruit production in greenhouse-grown tomato plants. **(A)** Total fruit production per plant, **(B)** average fresh weight of ripen fruits, and **(C)** number of ripen fruits per plant, in Pepton-treated plants (P) or untreated controls (C) either fed with nitrogen in a 50% Hoagland solution (Control) or exposed to low nitrogen priming (NEC). NEC stands for Nitrogen Efficient Crop (these plants were exposed to a 30% N deficiency relative to controls for 2 months and then recovered for 1 month with the same nutrient solution used for controls before estimation of fruit production, see section Materials and Methods for details). Data are mean of $n = 8 \pm \text{SE}$. p values of two-way ANOVA are shown in the inlets and values of $p > 0.10$ were considered as not significant (NS).

FIGURE 2 | Effects of low nitrogen priming and Pepton application on fruit quality, in terms of soluble sugar accumulation and acidity, in greenhouse-grown tomato plants. **(A)** Total soluble sugars (TSS), **(B)** total acidity (TA), and **(C)** TSS/TA ratio in mature fruits of Pepton-treated plants (P) or untreated controls (C) either fed with nitrogen in a 50% Hoagland solution (Control) or exposed to low nitrogen priming (NEC). NEC stands for Nitrogen Efficient Crop (see **Figure 1** legend and section Materials and Methods for details). Data are mean of $n = 8 \pm \text{SE}$. p values of two-way ANOVA are shown in the inlets and values of $p > 0.10$ were considered as NS.

2019) and decrease (Hernández et al., 2020; Navarro and Munné-Bosch, 2022) the TSS/TA ratio. In the present study, fruit quality was improved by the NEC treatment, particularly,

a significant increase in the TSS/TA ratio was observed together with a trend toward statistical significant increase of TSS (**Figure 2**). Moreover, the quality of the tomato

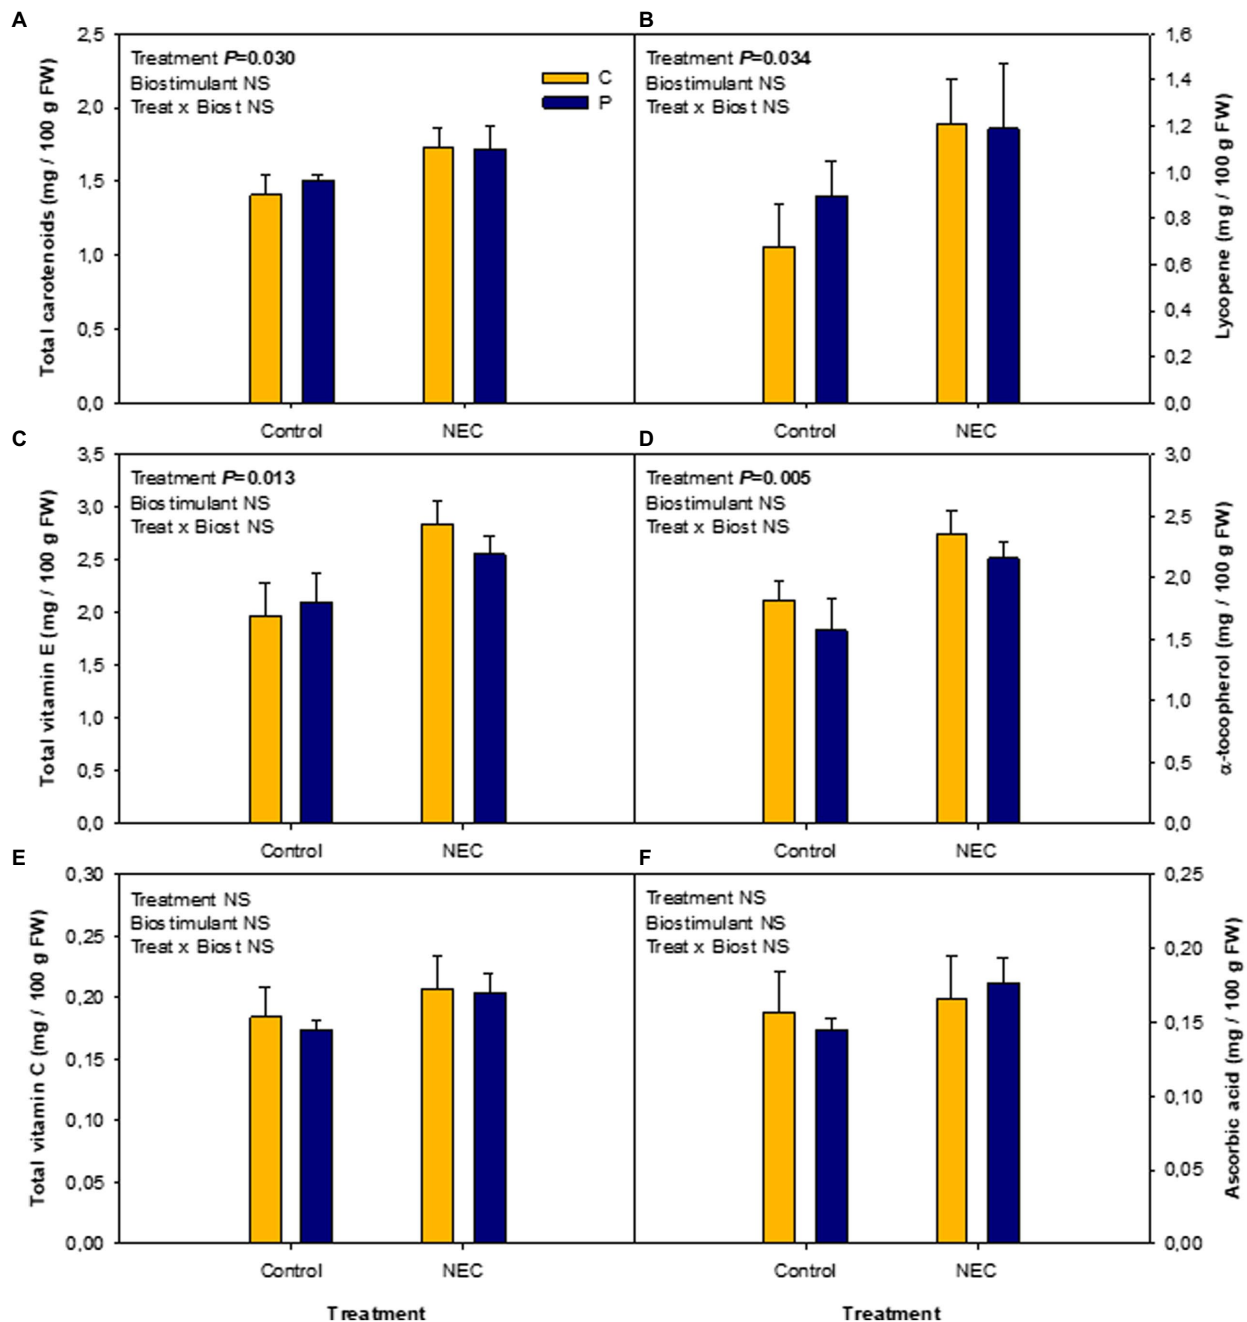

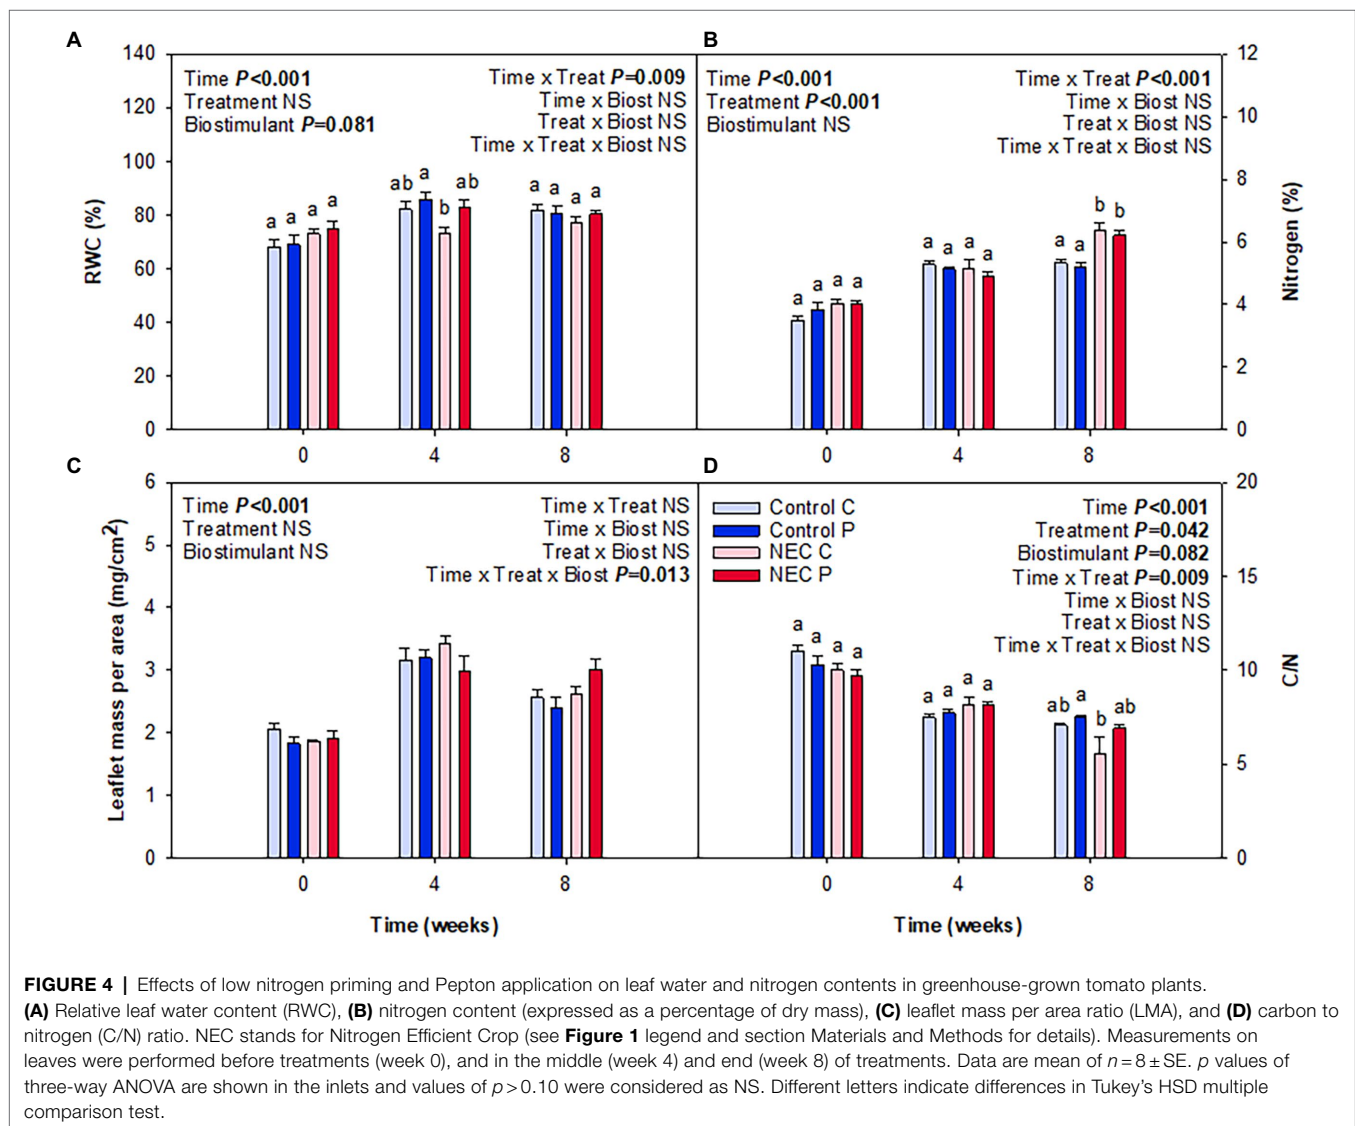

FIGURE 3 | Effects of low nitrogen priming and Pepton application on fruit quality, in terms of carotenoid, vitamin E, and vitamin C accumulation, in greenhouse-grown tomato plants. **(A)** Total carotenoids, **(B)** lycopene, **(C)** total vitamin E, **(D)** α -tocopherol, **(E)** total vitamin C, and **(F)** ascorbic acid contents in mature fruits of Pepton-treated plants (P) or untreated controls (C) either fed with nitrogen in a 50% Hoagland solution (Control) or exposed to low nitrogen priming (NEC). NEC stands for Nitrogen Efficient Crop (see **Figure 1** legend and section Materials and Methods for details). Data are mean of $n=8 \pm \text{SE}$. p values of two-way ANOVA are shown in the insets and values of $p > 0.10$ were considered as NS.

fruits was not affected by the application of Pepton, thus showing that this biostimulant can increase fruit yield without a negative impact on the TSS/TA ratio. Other quality parameters related to the antioxidant composition of the fruits, were also unaffected by the biostimulant, again indicating that it would be a great option to increase the

production without negative implications on the fruit quality (**Figure 3**). Furthermore, NEC treatment did improve the total carotenoids and vitamin E contents by increasing their major components, lycopene, and α -tocopherol, respectively. Total carotenoids and lycopene contents increased by NEC treatment by 18 and 52%, respectively, relative to controls.

Vitamin E in fruits also increased in response to the NEC treatment by 33% relative to the controls, mainly associated with an increase of α -tocopherol (Figure 3). In contrast, total vitamin C and ascorbic acid contents remained unaffected by treatments.

Effects of Low N Priming and Pepton Application on Fruit Production Differ on a Mechanistic Level

When analyzing water and N contents in leaves, it was observable that a significant increase of N content occurred due to the NEC treatment, especially at week 8 of treatment. This increase was reflected in the percentage of total N and the C/N ratio (Figure 4). Pruning during week 7 may have caused this effect. Despite plants suffering 30% N deficiency, the removal of a significant part of the aerial biomass may have largely alleviated stress and have

led to an improvement of N use in all treatments, but most particularly in those already suffering a N deficiency. Differences between NEC and control treatments were small but significant, with an increase in foliar N by 15% in the former compared to the latter. In contrast, Pepton treatment did not additionally increase foliar N contents, but showed a trend to improve the RWC ($p=0.081$), an effect that appeared to be more apparent before than after pruning (week 4 relative to week 8; Figure 4). The contents of photosynthetic pigments were also positively affected by either the NEC treatment, the biostimulant or both, depending on the parameter (Figure 5). The most striking effects were observed for the biostimulant combined with the NEC treatment. Pepton application significantly helped to maintain the contents of chlorophyll a+b and total carotenoids higher than in controls, an effect that was particularly observed at week 8 in NEC plants treated with Pepton (Figure 5). On the other side, NEC treatment alone

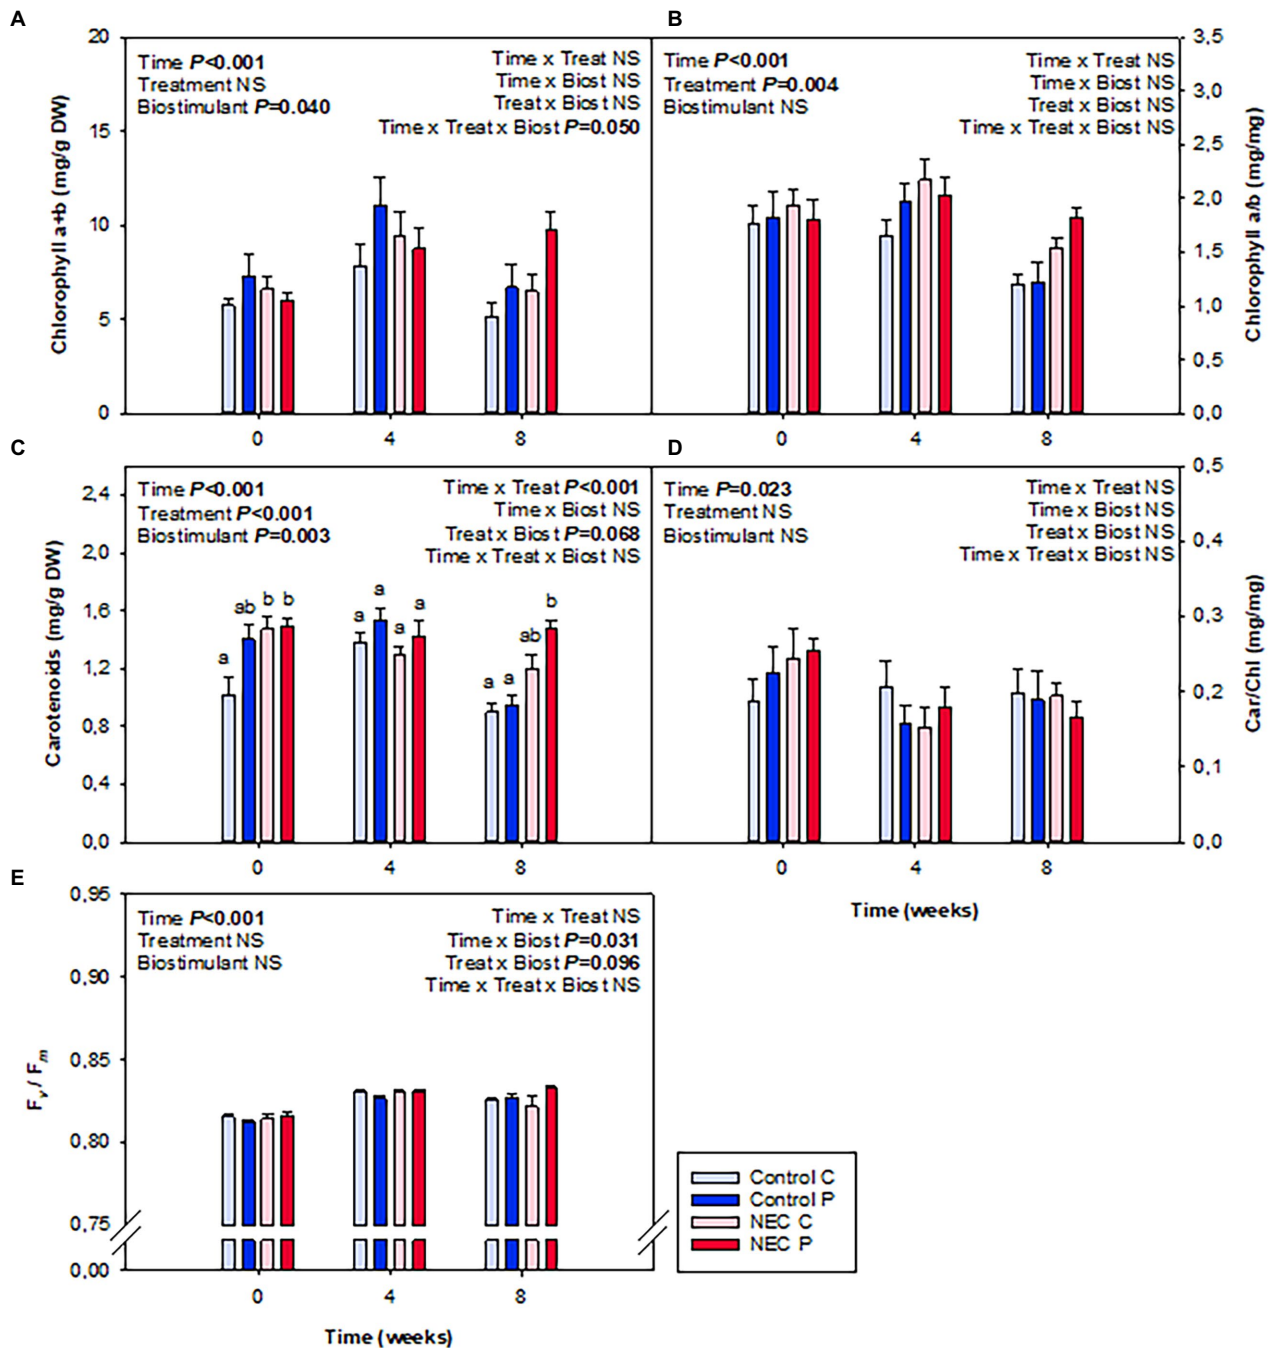

FIGURE 5 | Effects of low nitrogen priming and Pepton application on photosynthetic pigment contents and photoinhibition in leaves of greenhouse-grown tomato plants. **(A)** Chlorophyll a + b, **(B)** chlorophyll a/b ratio (Chl a/b), **(C)** carotenoids, **(D)** carotenoids/chlorophylls ratio (Car/Chl), and **(E)** maximum efficiency of photosystem II photochemistry (F_v/F_m), an indicator of photoinhibition. NEC stands for Nitrogen Efficient Crop (see **Figure 1** legend and section Materials and Methods for details). Measurements on leaves were performed before treatments (week 0), and in the middle (week 4) and end (week 8) of treatments. Data are mean of $n = 8 \pm \text{SE}$. p values of three-way ANOVA are shown in the inlets and values of $p > 0.10$ were considered as NS. Different letters indicate differences in Tukey's HSD multiple comparison test.

helped maintain carotenoids content and the chlorophyll a/b ratio high at week 8, but not as high as when combined with Pepton (**Figure 5**). This Pepton-related differential behavior in NEC plants may be attributed to an increased

endogenous concentration of cytokinins, and most particularly of the active form *t*-Z, but not of any of the stress-related phytohormones, ABA, SA, or JA (**Figures 6, 7**). NEC treatment had an impact on the endogenous content

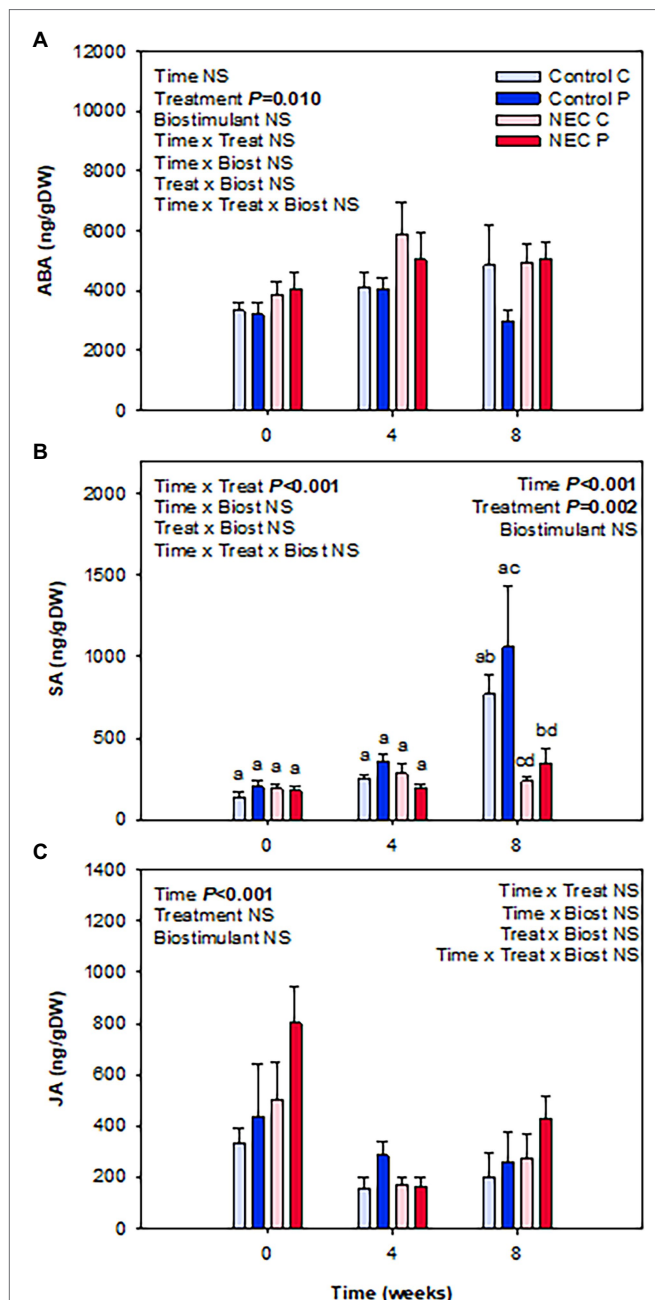

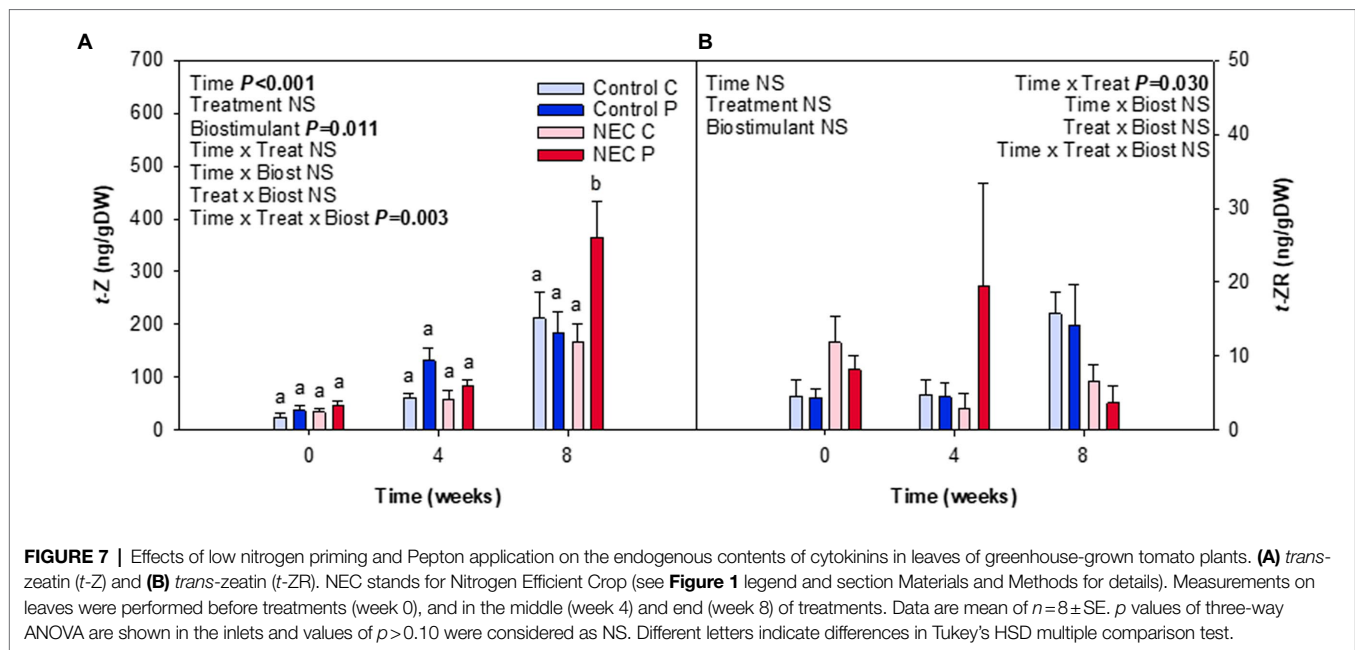

FIGURE 6 | Effects of low nitrogen priming and Pepton application on the endogenous contents of stress-related phytohormones in leaves of greenhouse-grown tomato plants. **(A)** Absciscic acid (ABA), **(B)** salicylic acid (SA), and **(C)** jasmonic acid (JA). NEC stands for Nitrogen Efficient Crop (see **Figure 1** legend and section Materials and Methods for details). Measurements on leaves were performed before treatments (week 0), and in the middle (week 4) and end (week 8) of treatments. Data are mean of $n=8 \pm \text{SE}$. p values of three-way ANOVA are shown in the inlets and values of $p > 0.10$ were considered as NS. Different letters indicate differences in Tukey's HSD multiple comparison test.

of ABA, which was most evident at week 4, but most particularly in the endogenous content of SA at week 8 (**Figure 6**). As SA is a well-known growth inhibitor (Abreu

and Munné-Bosch, 2009), reduced contents of SA in leaves of NEC may contribute to enhanced yields in low N-primed plants, an effect that occurred both with and without Pepton application. In contrast, Pepton doubled the endogenous contents of *t*-Z in combination with the NEC treatment (**Figure 7**), thus showing a possible link with the maintenance of chlorophyll contents (**Figure 5**). It is well-known that high cytokinins contents may have an anti-senescing effect and help maintain the photosynthetic apparatus active for longer (Müller and Munné-Bosch, 2021), which in this case might contribute to increase fruit yield in greenhouse-grown tomatoes subject to a combination of Pepton application and low N priming. It is interesting to note that this cytokinin-mediated effect was not observed for NEC only, thus indicating differential mechanisms of action upon the application of Pepton. It was only the combination of low N priming together with Pepton application that caused additive effects on yield, enhanced cytokinin contents and a maintenance of chlorophyll contents. It is tempting to speculate that the composition of peptides in Pepton may cause such an effect, since previous studies have shown a crosstalk between peptide and cytokinin signaling in plants (Leibfried et al., 2005; Fukuda and Higashiyama, 2011; Sakakibara, 2021), an aspect that warrants further investigations.

Another important point that needs consideration is the application and interpretation of statistical evaluation of results in the study of the application of biostimulants to improve crop yields and produce quality, either in the field or in controlled trials, as that performed in the present study. Statistical analyses generally rely on p values to demonstrate relationships and the traditional level of significance ($p < 0.05$) can indeed be negatively impacted by small sample size, bias, and random error, so that in psychology and biochemical research has sometimes evolved to include interpretation of statistical trends, correction factors for multiple analyses, and acceptance of statistical significance for $p > 0.05$ for complex relationships such as effect modification (These et al., 2016). We suggest that in very particular cases, where biostimulants may have relatively effects by themselves but they can indeed modify the effect of another treatment, as it occurred in our study with low N priming, it is suggested to consider p values close to 0.05 as showing a trend to significant effect and must not be disregarded. As shown in the present study, these effects may be out of the classical p value but at the same time represent important increases in yield that if confirmed under field conditions will lead to important economical revenues. It is therefore of value to include results with a trend to statistically significant results, so that these positive effects can be scalable and therefore adequately tested in the field in future studies. Furthermore, we strongly encourage research that relies on various yield and quality parameters, instead of using only one parameter, since any small unavoidable bias due to the intrinsic methodology used on the latter case can lead to equivocal interpretation of results.

CONCLUSION

It is concluded that priming with low N availability (NEC plants) doubled fruit production (due to an increase in the number of fruits), increased by 20% the amount of total soluble sugars and increased the contents of lycopene (by 90%) and vitamin E (by 40%). Furthermore, it is also stated that pruning the plants may have helped NEC treatment boost the production since there was a reduction of the root N-consuming biomass. Pepton treatment showed a trend to improve total fruit production both in control and NEC plants, thus indicating an additive effect to low N priming in boosting fruit production. Pepton maintained fruit quality in terms of sugar accumulation, total acidity, and the contents of carotenoids, vitamins C and E. Pepton-related improvement in fruit production seemed to be related, at least in part, to an increased accumulation of cytokinin and photosynthetic pigments in leaves, which might favor vegetative vigor and ultimately fruit yield. It should be noted that the observed effects may at least be partially attributed to the pruning that was carried out 7 weeks after treatment, thus it imperative to carry out future research to unravel the mechanisms underlying the interactive effects of low N priming with biostimulant application and pruning.

Plant Sci.* 13:860484. doi: 10.3389/fpls.2022.860484

Modern agriculture is facing multiple and complex challenges and has to produce more food and fiber to feed a growing population. Increasingly volatile weather and more extreme events such as droughts can reduce crop productivity. This implies the need for significant increases in production and the adoption of more efficient and sustainable production methods and adaptation to climate change. A new technological and environment-friendly management technique to improve the tolerance of quinoa grown to maturity is proposed using native microbial biostimulants (arbuscular mycorrhizal fungi; AMF) alone, in the consortium, or in combination with compost (Comp) as an organic matter source under two water treatments (normal irrigation and drought stress (DS)). Compared with controls, growth, grain yield, and all physiological traits under DS were significantly decreased while hydrogen peroxide, malondialdehyde, and antioxidative enzymatic functions were significantly increased. Under DS, biofertilizer application reverted physiological activities to normal levels and potentially strengthened quinoa's adaptability to water shortage as compared to untreated plants. The dual combination yielded a 97% improvement in grain dry weight. Moreover, the effectiveness of microbial and compost biostimulants as a biological tool improves grain quality and limits soil degradation under DS. Elemental concentrations, particularly macronutrients, antioxidant potential (1,1-diphenyl-2-picrylhydrazyl radical scavenging activity), and bioactive compounds (phenol and flavonoid content), were accumulated at higher levels in biofertilizer-treated quinoa grain than in untreated controls. The effects of AMF + Comp on post-harvest soil fertility traits were the most positive, with significant increases in total phosphorus (47%) and organic matter (200%) content under drought conditions. Taken together, our data demonstrate that drought stress strongly influences the physiological traits, yield, and quality of quinoa.

Microbial and compost biostimulation could be an effective alternative to ensure greater recovery capability, thereby maintaining relatively high levels of grain production. Our study shows that aboveground stress responses in quinoa can be modulated by signals from the microbial/compost-treated root. Further, quinoa grains are generally of higher nutritive quality when amended and inoculated with AMF as compared to non-inoculated and compost-free plants.

Keywords: biostimulants, root-shoot-grain circuit, seed quality, drought tolerance, antioxidants, pseudocereal, soil health, endogenous mycorrhiza

INTRODUCTION

By 2050, the world's population is expected to reach 9.7 billion, 34% higher than current levels. This will require raising overall food production by about 70% (FAO, 2017). Nearly all of this population increase will occur in many developing economies. This implies the need for significant increases in the production of several key commodities. Demand for (pseudo)cereals, for both food and animal feeds, will need to rise to some 3 billion tons, vs 2.1 billion today, by 2050. Major cereal crops, including wheat, rice, barley, and corn, are progressively failing to withstand the growing salinity and water scarcity present in marginal environments that are highly vulnerable to climate variability, such as shifts in growing season conditions (IPCC, 2014). Therefore, there is an urgent need to identify alternative ways to sustain and, possibly, increase agricultural production in areas where the cultivation of traditional crops has become greatly complicated and even sometimes uneconomic. Quinoa (*Chenopodium quinoa* Wild.) is an annual herbaceous pseudocereal crop originating from the Andean Mountains, where it has developed tolerance to several abiotic stresses (Di Fabio and Parraga, 2017). Quinoa grains—known as the “mother grain” of the Incan Empire—are a gluten-free alternative to starchy grains and have a low glycaemic index (Gordillo-Bastidas et al., 2016). Deemed the “Queen of Superfoods,” this plant was prized for its nutritional qualities as it contains all nine essential amino acids, carbohydrates, poly-unsaturated fatty acids, fiber, vitamins, and minerals (Ruiz-Lozano et al., 2016; Vilcacundo and Hernández-Ledesma, 2017). The grains also contain a large amount of phenolics, flavonols, and betalains (Abderrahim et al., 2015; Escribano et al., 2017). Such is the value of the plant that the UN marked 2013 as the International Year of Quinoa owing to its biodiversity and nutritional value and its role in providing food security and nutrition and poverty eradication, as well as its adaptability to thrive in a wide range of agroecosystems, as it grows at an exceptional range of altitudes, temperatures, humidities, and under different soil conditions (Bazile et al., 2013; Hussain et al., 2018).¹ Due to its superior nutritional profile and stress tolerance, interest in quinoa is increasing worldwide, although it is still an underutilized crop with few breeding programs (Massawe et al., 2016).

More frequent and severe droughts are expected across many regions in the 21st century (Schwalm et al., 2017). Drought has

a negative effect on growth, physiology, and yield (Fischer et al., 2017; Miranda-Apodaca et al., 2018). With climate change, growing alterations in the frequency, duration, and intensity of droughts and impending water disputes, the potential gains in welfare from selecting/cultivating effective drought-tolerant (DT) crops and using smart agronomical techniques, are enormous. In the past decade, total investment in drought-resistance research has clearly exceeded US\$1 billion (Lybbert and Bell, 2010b). Yet, (marginal) farmers—who are typically faced with poor soils, erratic weather and limited or no access to irrigation, and other inputs—may lack the control to perceive subtle differences in the value of competing varieties and their views of the relative yield benefit of DT varieties are conditioned by (1) drought pressure: if increased cost is not associated with benefit or if the yield is comparatively lower in DT varieties than in conventional varieties when water is plentiful and (2) if the relative benefits of DT varieties fade as drought severity increases (Lybbert and Bell, 2010a). Recently, Jarvis et al. sequenced the approximately 1.5-gigabase-long genome of *C. quinoa* (Jarvis et al., 2017). Using the information gained from the genome to improve quinoa production will require robust breeding efforts and fundamental research to identify the defenses mechanism used by quinoa.

To date, manipulating a plant's genetic makeup is a time-consuming option to enrich the new genetic variant. It is a tedious process and has several significant challenges under natural field conditions. Therefore, the demand for sustainable cropping systems has encouraged the search for technologies—from treated seeds and crop protection products to data analysis apps and precision spraying—and alternatives to increase crop production and quality/functionality with improved defense mechanisms, especially under stressful conditions. While farmer stakeholders may be able to afford to invest, small/marginal farmers have little or no access to affordable institutional credit. Further, farmers must learn how to best use these technologies to improve their farming business. To address these issues, there has been an upsurge in agricultural technologies and products. Different soil management practices that can enhance soil fertility, water availability, and the root zone could be efficient drought mitigation tools in irrigated and non-irrigated regions (Phillips et al., 2020).

In recent years, the use of plant biostimulants, either non-microbial or microbial, has become a popular option to enhance water and crop productivity and adapt crops to rapidly changing environmental conditions. The biofertilizer industry has witnessed a relatively stable market growth following the COVID-19

¹<http://www.fao.org/quinoa-2013/en/>

pandemic, with a similar trend of high demand existing in 2020. The global biofertilizer market is estimated to be worth US\$ 2.6 billion in 2021 and is expected to reach a value of US\$ 4.5 billion by 2026, at a compound annual growth rate (CAGR) of 12%. The need to increase food production combined with the imperative need to preserve natural resources has led to an upsurge in materials with low environmental impact but high efficiency, with natural-based substances being prioritized over synthetic inputs. The FAO recently recognized the potential of microbiomes in food production/safety, health enhancement, and environmental sustainability (FAO, 2019). Arbuscular mycorrhizal fungi (AMF) have been identified as microorganism targets that increase abiotic stress tolerance (Abdel Latef and Chaoping, 2011). More than two-thirds of terrestrial plants acquire mineral nutrients from the soil by the root pathway *via* root epidermal cells and root hairs, and the mycorrhizal pathway (Smith and Smith, 2011). AMF recruit distinct microbes into their hyphosphere to shape the “second genome of AMF,” which significantly contributes to soil organic nutrient mobilization and turnover (Zhang et al., 2021). By colonizing the rhizosphere/endo-rhizosphere of plants, these beneficial microorganisms promote growth through various direct and indirect mechanisms (Harrison, 2005; Maillet et al., 2011). In addition, AMF application induces antioxidant enzyme activity and osmolyte accumulation under various stressful conditions, including water shortage (Meddich et al., 2018; Ben-Laouane et al., 2019, 2020; Anli et al., 2020a; Boutasknit et al., 2020b). While plants are known to establish symbiotic relationships and the role of microorganisms in managing (a)biotic stresses is gaining importance, our understanding of those relationships under a stressful environment is rudimentary. Recent research has suggested that AMF should be combined with organic amendments to increase soil fertility (Anli et al., 2020a; Ben-Laouane et al., 2020; Boutasknit et al., 2020a, 2021a; Renaut et al., 2020). Organic compost is increasingly (re)used in (modern) agriculture as a mulch to provide surface protection and it also seems to be beneficial for field crops as an alternative to chemical fertilizer overuse (Raklami et al., 2019b). It is applied to increase plant and soil health, reduce nutrient losses by volatilization or leaching, prevent soil erosion, and improve soil water retention, soil carbon content, and the long-term fertility of agricultural soils. Many stormwater manuals continue to recommend compost as an organic matter source in bioretention soils (PGC, 2014; VTSM, 2017). Quality green composts can provide nutrients and improve physical soil conditions for plant growth (Cogger, 2005). Such composts contain important concentrations of nitrogen (N), phosphorus (P), and potassium (K⁺) as well as a wide range of micronutrients, including magnesium, copper, and iron (Meddich et al., 2015).

Our growing understanding of the interconnectedness of microbiomes and organic amendment in environmental and food systems suggests that soil biofertilizer innovations have the potential to improve sustainable food, feed, and biofuel production while embracing the principles of circularity. The role of organic compounds and microorganisms in plant growth, nutrient management, and biocontrol activity is very well established. Despite the promise of biofertilizer applications, the rush to develop them should be tempered by the need to fully understand the systems in which they function and

to characterize the biochemical pathways or interactions in crop systems. To the best of our knowledge, this is the first study to investigate the role of the dual application of AMF combined with compost on quinoa plants subjected to drought stress under field conditions. Moreover, quinoa seeds have potential health benefits and recent food trends and high demand have led to the adaptation and commercial production of quinoa seeds. Thus, the main objective of this research was to assess root reinforcement through a synergistic application of multiple soil biofertilizers (integrating organic amendments and native AMF) to mitigate the adverse effects of drought stress on the physiology, growth, yield, grain quality (antioxidant potential) of quinoa, and post-harvest agricultural soil fertility by regulating soil nutrient status and plant physiological processes. We hypothesized that “manipulating”/shaping the below-ground conditions in which plants grow could ultimately be beneficial. This study provides evidence toward selecting assemblages adapted to abiotic stress, improving resistance against stressors to promote the health and drought tolerance of plants.

MATERIALS AND METHODS

Growth Conditions of Plants in the Field, Biofertilizer Material, and Collection of Vegetal Samples

Quinoa (*Chenopodium quinoa* Willd.) cv. Titicaca has been used in this study based on its high nutritional value, early-maturity standard, top performance, and extensive cultivation (high potential of adaptation in the poor organic/mineral matters) in the Andean states, Sahel, the Middle East, and North African regions (Alvar-Beltrán et al., 2020; Miller et al., 2021; Fghire et al., 2022). Quinoa seeds were surface sterilized with sodium hypochlorite solution containing 0.02% Tween 20 for 10 min. After successive washings in sterile water, the seeds were placed on 1% agar plates containing 1/2 Murashige and Skoog (1/2 MS) medium and incubated in dark conditions at 30°C for 3 days. The uniform looking seedlings were transplanted in the field at a spacing of 20 cm (same row) × 80 cm (between rows) at Saada fields, Marrakesh, Morocco (31°37′39.9″ N and 08°07′46.7″ W), during February–June 2020. The climate of this location is semi-arid, with an average annual temperature of 19.6°C and an average annual rainfall of 250 mm (from September to June). Meteorological data (minimum and maximum temperature, minimum and maximum relative humidity, wind speed, solar radiation, and rainfall) were measured by iMETOS® ag weather stations installed in the field and presented in **Supplementary Figure S1**.

The fields have never been treated before with chemical fertilizers or other organic fertilizers. The physicochemical characteristics of the agricultural soil are reported in **Table 1**. All agronomic practices were performed uniformly for the quinoa plants, following the local cultural practices. We number the weeks according to the plants growing dates. Week 0 coincides with seedling emergence. Plants were subjected to two water regimes: 100% field capacity (FC; WW; well-watered regularly at 8 l/h) and 50% FC (DS; drought stress *ca.* 4 l/h) conditions

TABLE 1 | Physicochemical parameters of agricultural soil and compost used.

	Soil	Compost
Sand (%)	52	
Clay (%)	24	
Loam (%)	24	
pH	7.90±0.07	7.74±0.01
EC (mS cm ⁻²)	1.70±0.60	5.46±0.20
TKN (%)	0.15±0.01	1.32±0.01
NH ₄ ⁺ (%)	–	0.09±0.01
NO ₃ ⁻ (%)	–	0.31±0.01
TOC (%)	1.30±0.30	5.72±0.45
OM (%)	2.24±0.50	9.86±0.78
C/N	–	7.49±0.00

applied from week 1 until harvest. The field plots were irrigated at five-day intervals using drip irrigation system lines, with appropriate internal drippers, placed on the soil surface of each furrow. The WW plots received 100% FC of the weekly calculated crop evapotranspiration for the 5 days before each irrigation. Crop evapotranspiration was determined according to Xu et al. (2018) using potential evapotranspiration multiplied by the crop coefficient, which was adjusted according to crop growth stage.

We extracted and isolated an indigenous consortium of AMF isolated from the Tafilalet palm grove located 500 km southeast of Marrakesh (Morocco) and containing a mixture of 15 species: *Acaulospora delicata*, *A. leavis*, *Acaulospora* sp., *Claroideoglossum claroideum*, *Glomus aggregatum*, *G. claroides*, *G. clarum*, *G. deserticola*, *G. heterosporum*, *G. macrocarpum*, *G. microcarpum*, *G. versiforme*, *Glomus* sp., *Rhizophagus intraradices*, and *Pacispora boliviana* (Meddich et al., 2015). These species belong to five genera: *Glomus* (60% of the total community), *Acaulospora* (20%), *Claroideoglossum*, *Rhizophagus*, and *Pacispora* (all these three 6.7%). The number of AMF spores detected in this inoculum was 47 spores/100 g of the soil sample. The inoculum was enriched in propagules by co-cultivation with *Zea mays* L. as the host plant under controlled greenhouse conditions. Corn roots containing hyphae, vesicles, and spores were harvested, cut into small pieces and used as the inoculum. Inoculation of quinoa plants was performed by adding 2 g (/plant) of the inoculum (roots and substrate containing spores) to the quinoa root system. Non-mycorrhizal (NM) treatments received an equal quantity of both non-inoculated (and non-mycorrhizal) *Z. mays* roots to match “organic matter” in the pots and filtered inoculum in an attempt to restore other soil free-living microorganisms accompanying the AMF. The filtrate for each pot was obtained by passing the mycorrhizal inoculum in 20 ml of distilled water through a layer of 15- to 20-mm filter papers (Whatman, GE Healthcare, Buckinghamshire, United Kingdom).

The compost used in this study was prepared from green waste (quack grass) as described by Meddich et al. (2016).

The physicochemical properties of the compost are presented in Table 1. The compost was applied to the corresponding plot at a rate of 1.2 Kg/plot (10 t/ha).

Each water regime (WW or DS) comprised four treatments: (1) Control: non-inoculated and non-amended, (2) AMF: seedlings inoculated with the indigenous AMF consortium, (3) Comp: seedlings amended with compost, and (4) AMF + Comp: joint application of AMF and Comp. The experimental design was carried out as a split-plot based on a randomized complete block design with three replications. The fields were divided into 24 plots, 0.8 m wide separated from each other by 0.5 m; of six rows each (~ 60 plants per plot). Each plot was randomly assigned a watering regime (WW or DS) comprising biofertilizers (or not) treatments, with three replicates, for a total of 24 (2×4×3).

Harvesting, Plant Growth, and Yield Parameters

After 4 months of cultivation, at the harvest time and within each plot, individual plant samples were manually collected at the same time of the day (10 am to 1 pm). Ten representative plant samples from each plot were collected. Roots were collected using a shovel from 30 cm depth of each plant's system, avoiding brace roots, cutting using garden shears, and kept into an aluminum foil bag and then pooled. Roots were vortexed for 2 min in epiphyte removal buffer to remove rhizosphere soil, rinsed twice in root washing buffer, gently wiped, and placed in aluminum foil bags for the subsequent analyses.

The growth performance of quinoa plants was assessed by measuring the seed yield, shoot height (SH), root elongation (RE), biomass production (PDM; plant dry matter), and seeds dry matter (SDM). DM was obtained after drying samples at 80°C until the weight remained constant. Seed samples were cleaned and stored (4°C) for subsequent analyses. The tolerance index (TI) was calculated using the DMs according to the methods described by Parvez et al. (2020) using the following formula:

$$\text{Tolerance index (TI)}(\%) = \left(\frac{\text{DM}_{\text{stressed plants}}}{\text{DM}_{\text{well-watered}}} \right) \times 100$$

Mycorrhization Assessment

The harvested roots were washed with distilled water and cleared with 10% KOH at 90°C for 30 min. Then, they were rewashed and acidified with 2% HCl for 10 min and stained with Trypan blue at 90°C for 20 min, according to Phillips and Hayman (1970). Root fragments of 1 cm long were observed in the glycerol droplet. The microscopic assessment of mycorrhizal root colonization rates (F %: frequency and I %: intensity) was performed according to the method of Derkowska et al. (2008) using 20 randomly selected root fragments repeated five times for each sample.

$$\text{Mycorrhizal frequency (F)}(\%) = \left(\frac{\text{Infected root segments}}{\text{Total roots segments}} \right) \times 100$$

$$\text{Mycorrhizal intensity (I)}(\%) = \frac{(95n_5 + 70n_4 + 30n_3 + 5n_2 + n_1)}{\text{Total roots segments}}$$

Where n represents fragments with an index of 0, 1, 2, 3, 4, or 5 with the following infection rates: $100 > n_5 > 90$; $90 > n_4 > 50$; $50 > n_3 > 10$; $10 > n_2 > 1$; and $1 > n_1 > 0$.

Grain Mineral Composition Analysis

Mineral concentrations (K, Ca, and Na) in grain were determined after digestion using ICP/OES Ultima Expert (inductively coupled plasma/optical emission spectrometry, iCAP 6500 Duo, Horiba Inc., Burlington, ON, Canada). The total phosphorus in grains was determined according to the method described by Olsen and Sommers (1982).

Measurement of Chlorophyll and Carotenoids Concentration

The concentration of chlorophyll a , b , total chlorophyll, and carotenoids was determined using the method of Lichtenthaler (1987). Leaf tissue (100 mg) was homogenized in 80% pre-chilled acetone. After centrifugation at $10,000 \times g$ for 10 min, the supernatants were pooled and the absorbance of the extract was read at 480, 645, and 663 nm using a UV/visible spectrophotometer (UV-3100 PC spectrophotometer).

Total Soluble Sugars and Protein Quantification

The quantity of total soluble sugars (TSS) content was determined according to Kochert (1978) in 0.25 ml of the supernatant mixed with 0.25 ml of phenol and 1.25 ml of sulfuric acid. After 15 min, TSS content was determined by measuring the absorbance at 485 nm and calculated using the standard glucose curve.

Total soluble proteins were determined according to the technique described by Bradford (1976). Samples (1 g) were homogenized with 4 ml of 1 M phosphate buffer (pH 7.2) and then centrifuged at $18,000 \times g$ for 15 min at 4°C . The absorbance was read at 595 nm.

Stress Indicators (Malondialdehyde and Hydrogen Peroxide) Determination

Hydrogen peroxide (H_2O_2) concentration in seeds and leaves was determined by the method described by Velikova et al. (2000). Briefly, samples were homogenized with 5 ml 10% (w/v). Trichloroacetic acid (TCA) in an ice bath and then centrifuged at $12,000 \times g$ for 10 min at 4°C . The supernatant (0.5 ml) was recovered to determine the content of H_2O_2 and 0.5 ml of potassium phosphate buffer (10 mM, pH 7) and 1 ml of iodic potassium (1 M) was added. After 1 h of incubation, the absorbance at 390 nm was recorded and plotted against a standard H_2O_2 curve. The blank was made by replacing the sample extract with 10% TCA.

Lipid peroxidation as malondialdehyde (MDA) equivalent was evaluated in seeds and leaves tissues. MDA content was estimated by seed samples (0.1 g) in 3 ml of 0.1% (w/v) TCA

and centrifuged at $18,000 \times g$ for 10 min as described by Rao and Sresty (2000). Supernatant was mixed with 3 ml of 0.1% TCA containing 0.5% (w/v) thiobarbituric acid (TBA). The mixture was then heated in a water bath at 100°C for 30 min and immediately cooled in an ice bath. The absorbance was read at 440, 532, and 600 nm. The concentration of MDA ($\text{nmol g}^{-1} \text{ DW}$) was calculated by using the extinction coefficient of 155 mM cm^{-1} , and the results were expressed as nmol MDA equivalents per grams.

Preparation of Methanolic Extracts

Two grams of ground quinoa seeds was mixed with 50 ml of 80% (v/v) methanol at room temperature with frequent agitation. The mixtures were then left in a shaking incubator prior to filtration (Buckner funnel and Whatman No. 1) for 24 h and were then centrifuged at $3,500 \times g$ for 10 min at 5°C . The clarified extract was collected and then evaporated to dryness using a rotary evaporator at 40°C . Finally, the extract was reconstituted in sterile distilled water, freeze-dried, and stored at 4°C in an airtight container until further use.

Determination of Total Phenols and Flavonoids Content and 1,1-Diphenyl-2-Picrylhydrazyl Radical Scavenging Assay in Quinoa Grain

The total phenolic content (TPC) was measured using the Singleton et al. (1999) assay with slight modifications. To determine the total flavonoids, gallic acid standard was used to prepare the calibration curve. Briefly, a 250 μl aliquot of appropriately diluted methanolic extract solution (with distilled water) was placed in a test tube, to which 2.5 ml of 1 N Folin–Ciocalteu reagent solution was added. The mixture was incubated at room temperature for 3 min. Then, 250 μl of 10% sodium carbonate (Na_2CO_3) solution was added and kept in a dark place for 90 min. The absorbance of the extract solution and different concentrations of quercetin standard was measured at 760 nm. The TPC was calculated using an established formula and was expressed as milligrams of gallic acid equivalents (GAE) per g of quinoa sample DM (mg GAE/g DM).

The total flavonoids content (TFC) was determined using the colorimetric method described by Li et al. (2006). A quercetin standard was used to prepare the calibration standard curve to determine the TFC. A 0.5 ml aliquot of appropriately diluted methanol extract solution was taken in a test tube, to which 0.3 ml of 5% sodium nitrate solution was added. The mixture was kept at room temperature for 5 min. Then, 0.3 ml of 10% aluminum nitrate was added to each test tube, kept in a dark place for 6 min, and the reaction was stopped by adding 2 ml of 1 M sodium hydroxide. The absorbance of the extract solution and different concentrations of quercetin standard were measured at 510 nm. The standard calibration curve was prepared by plotting the concentration vs quercetin absorbance. Finally, The TFC was calculated using an established formula and was expressed as mg of quercetin equivalents.

The free radical scavenging activity of the quinoa seeds was assessed using the modified 1,1-diphenyl-2-picrylhydrazyl (DPPH)

radical scavenging assays of Athamena et al. (2010). A 50 µl aliquot of appropriately diluted methanol extract solution was placed in a test tube, to which 2 ml of freshly prepared 0.1 mM DPPH methanol solution was added. An equal amount of methanol was used as a control. After vigorously shaken incubation for 20 min in a dark place at room temperature, the absorbance of the extract solution and different concentrations of ascorbic acid standard were measured at 517 nm. The scavenging activity was calculated using the following formula:

$$\text{DPPH radical scavenging (\%)} = \left(\frac{A_{\text{control}} - A_{\text{sample}}}{A_{\text{control}}} \right) \times 100$$

The IC₅₀ (half-maximal inhibitory concentration) value was also calculated for the dose inhibition curve in linear range by plotting the extract concentration vs. the corresponding scavenging effect.

Antioxidant Enzymes Activities of Quinoa

Ground samples (100 mg) were mixed with 4 ml of 0.1 M sodium phosphate buffer (pH 7) containing 5% insoluble polyvinylpyrrolidone (PVPP) and 0.1 mM ethylene diamine tetraacetic acid (EDTA). The homogenate was centrifuged at 18,000 × g for 10 min at 4°C, and the supernatant was collected and used to measure antioxidant enzymes activities. Total soluble proteins were determined according to the technique described by Bradford (1976).

Superoxide dismutase (SOD, EC1.15.1.1) activity was assayed using the method of Beyer and Fridovich (1987). One unit of SOD activity was defined as the amount of enzyme leading to 50% inhibition of nitro blue tetrazolium (NBT) reduction at 25°C. The SOD activity was expressed at unit mg protein⁻¹ min⁻¹.

Ascorbate peroxidase (APX, EC1.11.1.11) activity was measured according to the method of Amako et al. (1994). APX was assayed as a decrease in absorbance at 290 nm for 1 min. The assay mixture contained 100 µl of extract sample, 50 mM potassium phosphate buffer (pH 7.6) including 0.2 mM EDTA, 100 µM H₂O₂, and 0.5 mM ascorbate. The reaction was initiated by adding the enzyme extract, and the decrease in absorbance was recorded. One enzyme unit was defined as µmol mg⁻¹ protein oxidized ascorbate per min.

Peroxidase (POX, EC 1.11.1.7) activity was measured using the guaiacol test by monitoring the change of absorbance at 470 nm. The activity was assayed for 3 min in a reaction solution containing 3 ml of 1 M potassium phosphate buffer (pH 7.0), 20 mM guaiacol, 40 mM H₂O₂, and 0.1 ml enzyme extract in a 3 ml volume (Polle et al., 1994). POX activity was determined by its ability to convert guaiacol to tetraguaiacol ($\epsilon = 26.6 \text{ mM}^{-1} \text{ cm}^{-1}$). One unit of POX activity was defined as an absorbance change of 0.01 unit min⁻¹.

Polyphenol oxidase (PPO, EC 1.14.18.1) activity was estimated by the method of Hori et al. (1997). The assay solution contained 20 mM catechol in 0.1 M phosphate buffer (pH 7). The reaction was started by adding 100 µl of the enzymatic extract. PPO activity was expressed in enzyme unit mg⁻¹ protein. One unit of PPO activity was defined as the amount of enzyme causing an increase in the absorbance of 0.001/min at 420 nm.

Soil Analyses

The physicochemical properties of agricultural field soil were analyzed at plant harvest on samples taken near the roots to assess the effect of compost and/or AMF applied alone or in combination with soil fertility. Five homogeneous rhizospheric soil samples at a 0–20 cm depth were collected for each treatment. The samples were dried and sieved to measure the pH, electrical conductivity (EC), total organic carbon (TOC), organic matter (OM), and assimilable phosphorus (AP). The pH and EC were measured in a diluted soil suspension 1/5 (v/v) using a pH meter HI 9025 and a conductivity meter HI-9033 (Hanna Instruments, Padua, Italy), respectively. Total TOC and OM were measured according to the method described by Aubert (1978), which consists of the oxidation of organic matter by potassium dichromate in the presence of sulfuric acid. The AP concentration was determined according to Olsen and Sommers (1982).

Statistical Analysis

Statistical analysis was carried out with the software package CoStat version 6.400 (CoHort Software). Data were analyzed by employing a three-way multivariate analysis of variance (MANOVA) followed by the Student–Newman–Keuls test using a significance level of 5% ($p \leq 0.05$). The normality of residuals was tested using the Shapiro–Wilk test. Mycorrhizal root colonization rates were arcsin-square root transformed to fit the assumption of normal distribution. Different lower cases indicate significant differences among treatments at $p \leq 0.05$. In order to integrate all the data, a complete dataset comprising all growth, physiological, and biochemical data was subjected to Principal Components Analysis (PCA). The PCA was performed using XLSTAT v. 2016 (Addinsoft, NY, United States). Initially, index values for each treatment were calculated by assessing the response of drought stress compared to its control value. The responses of all the traits under each treatment were combined and used as index values for PCA analysis. These index values were used to identify the correlation of response variable vectors and treatments across the ordination space. Percentage contributions of principal component (PC) variables are shown in **Supplementary Table S2**. The heatmap was performed using the software GraphPad® Prism v9.0 GraphPad (San Diego, CA, United States). Data are presented as mean ± standard error (SE) of three independent biological replicates.

RESULTS AND DISCUSSION

Drought remains one of the most damaging environmental stresses limiting crop production worldwide. Increasing food supply significantly in an unstable environment in the required timeframe is time-consuming. Hence, it is essential to find eco-friendly strategies that allow plants to withstand drought, focus on biomass and functionality, ensure food security, and mitigate the damage occurring in drought-prone areas. To our knowledge, this is the first study to summarize the extent to which the effect of single and multiple combinations of endogenous AMF and/or compost-based amendments are crucial to improve the fitness and health of quinoa—an immense industrial crop—under field drought conditions. Therefore, this

method could be used for designing a functionally reliable system which could be termed “plant probiotics.”

Effect of Drought Stress and Biofertilizers on the Root, Plant Growth, and Yield

The AMF infection frequency and intensity were estimated in the root system of quinoa plants (**Figure 1**). Under field conditions, the non-inoculated plants exhibited mycorrhizal infections with or without stress. The addition of AMF alone successfully infected quinoa roots and showed the highest root mycorrhizal frequency (57%) and intensity (44%) regardless of the water regime. The application of drought stress significantly ($p < 0.001$, **Supplementary Table S1**) reduced mycorrhizal frequency and intensity in all the treatments. The negative effect of drought on the AMF colonization of quinoa plants is in line with several studies showing that mycorrhizal infection decreased in drought-treated host plants (Baslam and Goicoechea, 2012; Meddich et al., 2015; Anli et al., 2020a). Drought induces inhibition of AMF spore germination and hyphal growth, thereby decreasing mycorrhizal colonization (Rydlová and Püschel, 2020). In addition, soil moisture plays a

vital role in spore germination and/or development (Püschel et al., 2021). The supply of compost significantly ($p < 0.001$, **Supplementary Table S1**) decreased mycorrhizal frequency by ca. 40 and 30% and intensity by ca. 50 and 30% in AMF-inoculated plants under non-stressed and stressed conditions, respectively. The application of organic amendments including compost and mineral nutrients may reduce AMF root colonization and activity owing to the release of mineralized P in the soil and/or diffusion of decomposition products, which reduces the establishment and maintenance of the symbioses (Gryndler et al., 2008; Baslam et al., 2011). Other studies, in contrast, have revealed that compost application could have a positive effect on AMF growth and sporulation (Cavagnaro et al., 2015; Anli et al., 2020a,b). There may be several reasons for this favorable effect of compost on AMF; N- and humic acid-rich compost (Gryndler et al., 2009), moderate level of soil assimilable P (Yang et al., 2017), and/or compost with no AM fungal spores that could outcompete the native microbial community once the compost is applied to the soil (Yang et al., 2018).

Several studies have been conducted which demonstrate the beneficial effects of AMF and/or compost on plant performance.

FIGURE 1 | Effects of water regimes (WW; well-watered or DS: drought stress) on AMF infection (A) frequency and (B) intensity of non-amended and non-inoculated quinoa (control) and quinoa inoculated with arbuscular mycorrhizal fungi (AMF) and/or amended with compost (Comp). Data are mean \pm SD. Means followed by the same letters are not significantly different at $p < 0.05$.

Here, we also showed that mycorrhizal symbiosis in the presence or absence of compost improved quinoa biomass and grain quality. In addition to the lower AMF colonization levels under drought stress, we observed higher growth traits in the treated plants relative to those in the control non-amended and non-inoculated plants. These results indicate that compost supply and AMF colonization improved the growth of treated plants. Drought stress jeopardizes plant growth and causes a series of physiological, biochemical, and molecular changes. A large number of studies have reported that biofertilizers enhance the ability of plants to tolerate drought stress through multiple mechanisms in leaves and below-ground, including soil structure improvement, increased formation of soil aggregates, and increases in soil nutrient and moisture retention. Plant nutrient and water absorption have been found to be accelerated due to the vast networks of extraradical mycelium, plant photosynthetic, and defense mechanisms which alleviate harmful reactive oxygen species (ROS) effects have been found to be improved and increases in the expression of drought-resistance genes have been observed (Mo et al., 2016). Here, we were interested in determining whether biofertilizer application would improve quinoa grain traits under drought stress.

The deleterious effect of water stress was observed on all growth parameters (shoot height, root elongation, and plant and grain dry weights) and quinoa yield cultivated under field conditions (Table 2). The results revealed that the growth traits and yield of plants were significantly ($p < 0.001$, Supplementary Table S1) reduced under water scarcity. However, biofertilizer application mitigated the negative effect of water deficit and improved the growth of quinoa as compared to the controls. The application of compost and AMF, separately or in combination, significantly increased plant biomass under stressed and non-stressed conditions compared to non-inoculated and non-amended plants. In fact, the highest plant growth values were obtained when the compost was combined with AMF (AMF+Comp). Under DS conditions, the AMF+Comp treatment increased plant dry weight (ca. 200%), grain dry weight (ca. 100%), shoot height (ca. 70%), root elongation (32%), and yield (ca. 100%) in comparison with stressed control plants.

The tolerance index data revealed that the quinoa variety used (Titicaca) was highly tolerant of water deficit (76%;

Table 2). Our results are in agreement with previous reports (Finlay, 2008; Anli et al., 2020a), showing that AMF inoculation combined with compost application yielded the highest values of plant growth parameters. The beneficial effect of mycorrhizal symbiosis and compost application on the growth of quinoa under drought could be explained by the greater uptake of low mobility nutrients, such as P and N contained in the substrate. Several studies have indicated that compost, AMF, and PGPR improve plant growth through the assimilation of immobile soil nutrients such as N and P (Tanwar et al., 2013; Baslam et al., 2014; Abdel Latef et al., 2016; Al-Karaki, 2016; Barje et al., 2016; Frosi et al., 2016; Yang et al., 2018; Raklami et al., 2019a; Anli et al., 2021). Previous reports have demonstrated that crops inoculated with AMF accumulated more N and P in leaves than non-mycorrhizal plants when subjected to drought stress (Meddich et al., 2015). Nadeem et al. (2014) showed that AMF could regulate mineral nutrition by solubilizing soil nutrients and producing plant growth regulators (i.e., hormones). This improvement in growth traits could also be due to the growth-promoting mechanisms employed by AMF through the production of phytohormones and the solubilization of minerals (Finlay, 2008). In addition, compost is used as a soil amendment in agriculture to improve organic C supply and increase the storage capacity of water and nutrients in the soil, resulting in a higher photosynthesis rate, growth, and plant stress tolerance (Anli et al., 2020a; Boutasknit et al., 2021b). In this study, growth improvement was accompanied by better quantitative productivity. The significant boost in yield was observed in plants inoculated with AMF and amended with compost.

Biofertilizers Enhanced Nutrient Uptake and the Concentration of Nutrients in Quinoa Grains

Cereal crops such as quinoa provide key nutritional elements to the human diet. However, abiotic stresses can negatively impact the concentration and distribution of nutrients in cereal grains. Indeed, P, K⁺, and Ca²⁺ contents were significantly ($p < 0.001$, Supplementary Table S1) decreased under water-deficit conditions. In contrast, Na⁺ uptake was significantly ($p < 0.001$, Supplementary Table S1) higher in stressed plants). Elemental

concentrations, particularly macronutrients, were greater in biofertilizer-treated quinoa grain than in untreated plants (Table 3). Under water-deficiency conditions, the dual application of AMF and compost showed the most significant increase in P, K⁺, and Ca²⁺ nutrients and a maximum decrease in Na⁺ (74%) content as compared to control plants under the same condition. This was followed by the application of AMF alone, which registered a significant increase in P and Ca²⁺ uptake. Cakmak reported that biofortification of cereals by using breeding or fertilizer techniques is considered a viable way to increase the concentrations of essential nutrients in the grain (Cakmak, 2008). Several studies showed that AMF inoculation affects the yield and nutrition of crops (i.e., bread and durum wheat, barley, sorghum, legume, and other food crops; Lehmann et al., 2014; Watts-Williams and Cagnano, 2014; Lehmann and Rillig, 2015), which has led to AMF being proposed as one part of the solution to food security (Thirkell et al., 2017), but there has been little focus on the effects on the grain. In our study, the highest elemental macronutrients in quinoa grain in decreasing order were P, K, and Ca. Phosphorus element plays critical roles in plant function, as it is a building block of nucleic acids and phospholipids. Our data showed that AMF-colonizing quinoa root systems supplemented with compost increased the P concentration by ca. 10× compared to untreated plants under both WW and DS conditions. Mycorrhizae are beneficial particularly for P nutrition since the influx of P in mycorrhizal roots can be 3–5× higher than the P influx in non-mycorrhizal roots (Smith and Read, 2008). This nutrient uptake is generally improved in AMF-treated plants (Smith and Smith, 2011) and is more important when different fungi colonize plant roots. Tian et al. (2013) reported that different AMF species act differently in terms of growth, P uptake, and P transporter gene expression in maize and that simultaneous root colonization with these species induces the greatest expression of P transporters. Watts-Williams and Gilbert (2021) showed higher macronutrient P, Mg, K, and S, and micronutrient Zn concentrations in mycorrhizal barley grain than in the mock-inoculated plants.

Furthermore, several studies have indicated that compost and AMF improve plant growth by absorbing immobile soil nutrients such as N and P (Baslam et al., 2014; Al-Karaki, 2016; Barje et al., 2016; Frosi et al., 2016; Raklami et al., 2019b). Colonization

by AMF results in the establishment of extensive hyphal networks and the secretion of glomalin, supplying plants with water and nutrients (P, N, K⁺, Ca²⁺, and Zn), which improves soil structure and hence productivity (Ben-Laouane et al., 2020). AMF extraradical hyphae can spread ~12 cm further beyond the root system, thus providing a greatly enhanced absorption area over roots, allowing plants to absorb root-inaccessible mineral nutrients (Bonfante and Anca, 2009; Kiers et al., 2011). Li et al. (1991) revealed that >75% of P acquired by mycorrhizal plants could be attributed to these extraradical hyphae. In addition, AMF modify root system elements, including morphology and diameter, and promote the development of a dense root system which improves plant functioning (Elsen et al., 2003). Under water-deficit conditions, plants improve in root fineness, root-shoot ratio, root number, and root hair length to mitigate the deleterious effects. Our data may suggest a modification in AMF-induced root morphology resulting in improved uptake, as observed, of mineral elements, including P, K, and Ca. The addition of compost to low OM soil can provide essential nutrients for plant growth and development and promote the plant's biological activity, which can further sustain the slow release of nutrients from the organic amendment (Scotti et al., 2015). The societal implications of these results are that from a human nutrition perspective (bioavailability), quinoa plants treated with AMF provide a more nutrient-rich grain, thus contributing to greater nutrition for consumers.

Biofertilizers Restore Abnormalities in Photosynthetic Machinery and Metabolite Content in Quinoa Grown Under Droughted-Field Conditions

The grain yield of cereals is determined by the synergistic interaction between source activity and sink (developing grains) capacity. A strong source with sufficient reserves is necessary for grain filling, and a high sink capability promotes reserve remobilization from the source to the sink (Camargo et al., 2016). We evaluated the protective role of compost-derived and rhizosphere-enriched AMF isolates application on chlorophylls as the major pigment used in photosynthesis under normal and drought conditions. Our results showed that concentration of Chl *a*, *b*, and total Chl significantly ($p < 0.001$; Supplementary Table S1) decreased under DS conditions

TABLE 3 | Seeds mineral composition of non-amended and non-inoculated quinoa (control) and quinoa inoculated with arbuscular mycorrhizal fungi (AMF) and/or amended with compost (Comp) subjected to different water regimes (WW; well-watered or DS: drought stress) after 4 months of cultivation.

(Table 4). One of the most important responses of plants to drought stress is the decline in concentrations of photosynthetic pigments, which may be due to a decrease in the protein, N, and Mg concentrations observed in the present study. A reduction in the chlorophyll content under water deficit suggests a breakdown of the chlorophyll structure and mechanisms of chloroplast dismantling (Rangani et al., 2016). Both Chl biosynthesis and degradation are linked with photosystem (PS) assembly and disassembly because Chl molecules are intimately integrated within PS subunits. The PS II light collection system in plants consists of several chlorophyll-binding proteins that perform essential functions, including the efficient collection of light energy for photosynthesis (Rangani et al., 2016). Concentrations of chlorophylls decreased in untreated and treated plants when subjected to drought. Concentrations of all pigments were significantly higher in treated plants than untreated plants. Applying biofertilizers induced a significant increase in the photosynthetic pigments as compared with non-inoculated with AMF and non-amended with compost. Indeed, the AMF and compost bicomination showed the highest values of these parameters under WW conditions. When water deficit was applied, all the biofertilizer treatments could maintain higher chlorophyll content than non-amended and non-inoculated control plants. A higher photosynthetic pigment under drought stress conditions suggests a better performance of the photosynthetic apparatus (Anli et al., 2020a; Ben-Laouane et al., 2020). Similar results were found in maize (Quiroga et al., 2017), quinoa (Ramzani et al., 2017), and date palm (Anli et al., 2020a). Hashem et al. (2019) showed that organic amendment and AMF mitigated the abiotic stress-induced decline in photosynthesis by improving chlorophyll biosynthesis. Several molecular and biochemical mechanisms have been proposed to explain the enhanced performance upon drought mediated by AM symbiosis and/or compost in the host plant (Fileccia et al., 2017; Balestrini et al., 2020).

Since pseudocereals, including quinoa, are broadleaf plants with seeds characterized by excellent nutrient profiles that can be ground into flour, providing a gluten-free alternative to

regular cereal-based flour; we next sought to analyze the carotenoids—can be not only provitamin A but also strong antioxidants with various health-promoting properties—soluble sugars, and proteins in the leaves (source) and seeds (sink). Water deficit resulted in a significant decrease in carotenoid (32 and 15%), sugar (52 and 33%), and protein (33 and 32%) concentrations ($p < 0.001$; **Supplementary Table S1**) in quinoa grains and leaves, respectively, as compared to non-stressed untreated plants (**Figure 2**). The supply of biofertilizers induced a significant increase in these parameters compared to untreated plants regardless of the water regime. Under drought stress, the most significant increases (220 and 111%) were recorded for TSS content in grains and leaves, respectively, in plants treated with dual AMF and compost application. Quiroga et al. found similar results regarding carotenoid content in maize (Quiroga et al., 2017). The synergistic effect of AMF and compost in improving the total content of carotenoids might be due, at least partially, to nutrient availability (Fileccia et al., 2017). Tang et al. (2015, 2016) suggested that quinoa seeds consumption over other cereals is a way to increase the intake of carotenoids. Copetta et al. (2011) observed that the use of AMF and compost improved the quality of plants by improving their organic (sugar and protein) osmolyte composition through increasing the photosynthetic machinery. The increase in protein and sugar concentration could be related to the increased mineral release from the compost and the improvement of its uptake by AMF, resulting in high phytohormone levels, thereby boosting the photosynthetic apparatus and source-sink dynamics. Previous studies showed that sugar metabolism genes tend to be upregulated in plants treated with beneficial microbes under abiotic stresses (Ahanger et al., 2014; Bárcana et al., 2015). Studies have revealed that enhancement of the accumulation of osmolytes, including proteins and sugars, is regulated through modulations in their assimilatory pathways with up- and downregulation of their synthesis and catabolism (Wu et al., 2017). Begum et al. (2019) suggested that the AMF inoculation of drought-stressed plants may have improved synthesis and downregulated the catabolism of osmolytes, resulting in significant increases in their accumulation. Ahanger et al. (2018) reported that crops exhibiting higher accumulation of osmolytes show improved tolerance and growth performance under stress through tissue water content and protein structure maintenance and functioning. Osmolyte accumulation is considered a ubiquitous response for accelerating water uptake under drought conditions, and the biofertilizer-mediated enhancement in their accumulation shown *herein* justifies the beneficial role of AMF and compost in improving the grain performance of quinoa under water-deficit conditions. Keunen et al. (2013) showed that sugars are key ROS scavengers and are assumed to regulate the interplay between ROS signaling and stress tolerance.

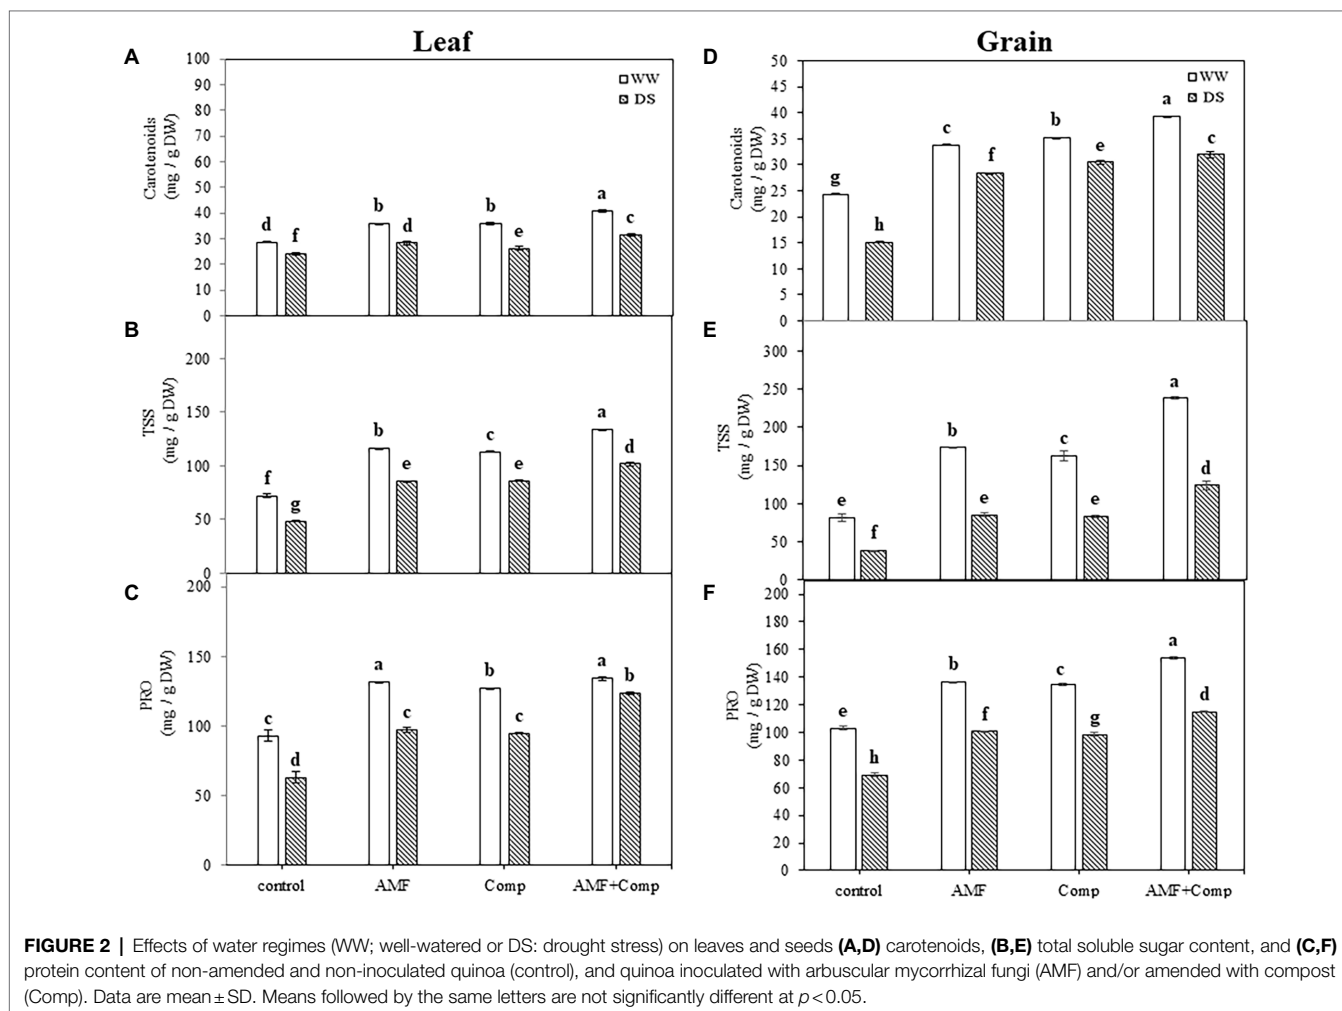

Biofertilizer Application Rescues Oxidative Stress Levels and Antioxidative Enzyme Activity in Quinoa Grains and Leaves

Drought stress and biofertilizers significantly ($p < 0.001$, **Supplementary Table S1**) affected MDA and H_2O_2 concentrations

TABLE 4 | Leaf chlorophyll content of non-amended and non-inoculated quinoa (control) and quinoa inoculated with arbuscular mycorrhizal fungi (AMF) and/or amended with compost (Comp) subjected to different water regimes (WW; well-watered or DS: drought stress) after 4 months of cultivation.

in quinoa leaves and grains (Figure 3). MDA and H_2O_2 concentrations were markedly increased in leaves and grains in non-treated plants, especially under DS conditions. Drought-induced oxidative damage resulting from increased ROS, including H_2O_2 , leads to lipid peroxidation and membrane dysfunction, thus affecting normal cellular functioning. The H_2O_2 generated at various sites in different plant organelles may diffuse through membranes, causing damage over long distances. Increased membrane damage, lipid peroxidation, in crops due to excessive generation of ROS has been well documented. Drought influences plant growth transitions by causing a surge in H_2O_2 accumulation and impeding membrane integrity (Singh et al., 2016). Stresses upregulate lipoxygenase activity and alter the poly-unsaturated fatty acid composition, leading to disruption in membranes' structural and functional integrity (Nahar et al., 2016). Lipid peroxidation levels in leaves and grains in the droughted cultures were decreased in the presence of AMF and/or compost. Similarly to MDA concentrations, H_2O_2 levels were significantly lower in the cultures inoculated with AMF and/or amended with compost than in non-AMF and compost-free plants. Quinoa inoculated with mixed AMF species and amended with compost, the dual combination, showed the lowest oxidative stress values

in leaves by 72 and 52% and grains by 70 and 50% in MDA and H_2O_2 , respectively. These could be attributed to reducing the ROS concentrations to minimal possible levels, thus protecting the major metabolic processes. A reduction in oxidative stress subsequently decreases the level of lipid peroxidation (Schützendübel and Polle, 2002), which is a process in which ROS obtain electrons from the lipid bilayer (cell membrane), leading to deleterious oxidation of most cell components. Maintaining low concentrations of ROS benefits tissues in regulating and integrating key developmental events, including cell proliferation, signaling, and programmed cell death (Neill et al., 2002; Miller et al., 2010).

Furthermore, the application of AMF and/or compost decreased the activity of the antioxidant enzymes in quinoa grains and leaves compared to untreated plants, regardless of the water regime applied. This decrease was more noticeable in the combined treatment for CAT (50 and 62%) and SOD (both 30%) activities in grains and leaves, respectively, under drought stress than in untreated plants (Figure 4). In contrast, in untreated quinoa plants, SOD, CAT, POX, and PPO activities were significantly increased ($p < 0.001$, Supplementary Table S1) under water shortage (Figure 4). The high antioxidant levels in quinoa grains and leaves grown in soil non-inoculated with AMF and non-amended

by compost, independently of the water regime, may be linked to the damaging effect of the high level of H₂O₂ and MDA content. Several studies have shown increased antioxidant activity in drought-stressed plants, which detoxifies ROS damage and alleviates oxidative stress (Gill and Tuteja, 2010; Shahid et al., 2014; Meddich et al., 2018). The significant increase in these enzymes limits cell damage and improves the antioxidant capacity of plants to defend themselves against stress, suggesting that AMF symbiosis and/or compost could help quinoa plants reduce the oxidative damage in response to water deficiency. Increased SOD activity prevents the generation of toxic hydroxyl radicals through the Haber-Weiss reaction, which can otherwise induce severe damage to the membrane and organelle functioning. CAT and peroxidases neutralize cytosolic H₂O₂ excess, while other enzymes, i.e., APX, AsA, and GSH act on the AsA-GSH pathway to neutralize plastidial and mitochondrial H₂O₂. In drought-stressed quinoa plants, biofertilizers mediated the upregulation of antioxidant functioning and redox homeostasis maintenance more than biofertilizer-treated plants under well-watered conditions and were thus able to prevent the harmful effects of drought stress to a considerable extent.

AMF and Compost Enhance the Bioactive Compounds of Quinoa Grains Under Droughted-Field Conditions

TPC, TFC, and DPPH were progressively influenced by drought stress and biofertilizer application. In this investigation, a significant decrease in the TPC (76%) and TFC (70%) under drought stress vs WW was observed in quinoa grains. However, the antioxidant activity determined by the DPPH radical scavenging activity

showed a significant increase (42%) in the untreated treatment (Figure 5). The application of AMF and compost, separately or in combination, increased these parameters significantly more than in stressed controls. Indeed, AMF-inoculated quinoa yielded the highest TPC improvement (525%) in grains under drought stress. It has been reported that AMF symbiosis under drought improves non-enzymatic antioxidant activities, which counteracts water-deficit effects in other cereals (Bahraminia et al., 2020). Previous studies demonstrated increased phenol and flavonoid content as drought severity increased (Gharibi et al., 2016; Siracusa et al., 2017). In plant tissues under control conditions, Robbins showed that phenylalanine produced widely dispersed phenolic acids, i.e., hydroxycinnamic acids (Robbins, 2003). The most common forms of flavonoids are glycoside derivatives, even though these compounds occasionally occur as a glycone in plants (Sarker and Oba, 2018). Flavonoids represent 60% of total dietary phenolic compounds, with the most predominant flavonoids being flavonols and the most prevalent naturally occurring flavonols being the glycosides of quercetin (Harborne and Williams, 2000). Moreover, our observation provides supportive evidence for a similar result for cereal grains (Adom and Liu, 2002; Ma et al., 2016; Kiani et al., 2021). As observed in this study, the induction of the synthesis of phenolic compounds by mycorrhization has also been shown by Hazzoumi et al. (2015), thus providing evidence of an active secondary metabolism. The increase in phenolic metabolism in response to mycorrhization would be responsible for the resistance of mycorrhizal plants to drought. The plants would respond more quickly and produce large quantities of phenolic compounds that can intervene in the defense reactions. Furthermore, phenols and flavonoids may be involved as signal

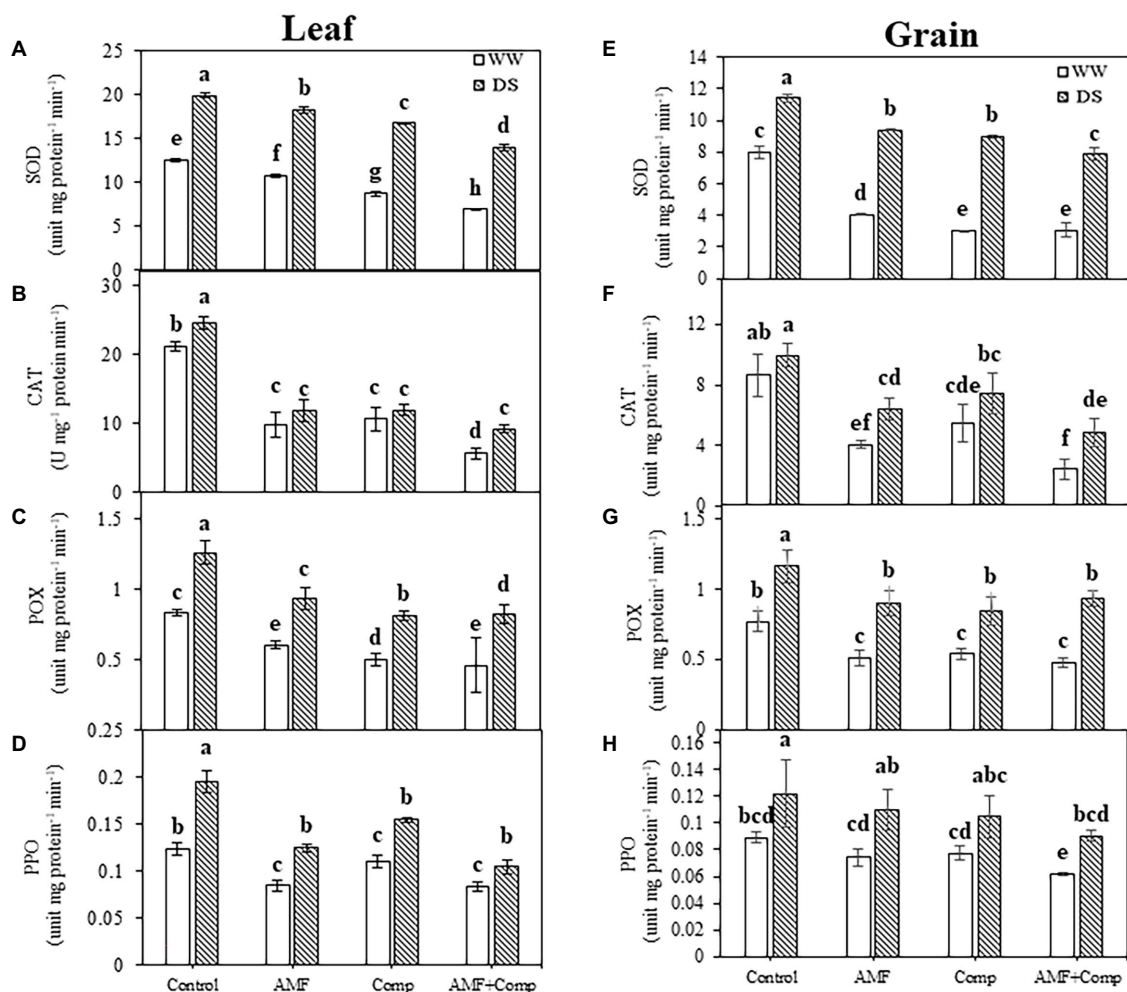

FIGURE 4 | Effects of water regimes (WW; well-watered or DS: drought stress) on leaves and seeds antioxidant enzyme activity **(A,E)** superoxide dismutase (SOD), **(B,F)** catalase (CAT), **(C,G)** peroxidase (POX), and **(D,H)** polyphenol oxidase (PPO) of non-amended and non-inoculated quinoa (control), and quinoa inoculated with arbuscular mycorrhizal fungi (AMF) and/or amended with compost (Comp). Data are mean \pm SD. Means followed by the same letters are not significantly different at $p < 0.05$.

molecules in plant-AMF interactions (Morandi et al., 1984), where some new phenolic molecules are produced during the establishment of AMF colonization (Charitha Devi and Reddy, 2002). Interestingly, Fiasconaro et al. reported that compost-treated soil increased TPC in peppers grown under drought conditions (Fiasconaro et al., 2019).

The high antioxidant activity induced by DPPH activity suggested the accumulation of phenolic compounds, which play an essential role in scavenging ROS under stressful conditions (Gengmao et al., 2015). Furthermore, high levels of phenols in plants can markedly improve their resilience during exposure to water stress and lead to better adaptation and survival (Liu et al., 2011). This accumulation of the essential non-enzymatic antioxidants, TPC and TFC, provides further evidence that phenol and flavonoid compounds play vital physiological and biochemical roles in cells, particularly in ROS scavenging and in helping overcome stresses (Tohidi et al., 2017; Sharma et al., 2019), and in particular, those evoked by oxidative stress during

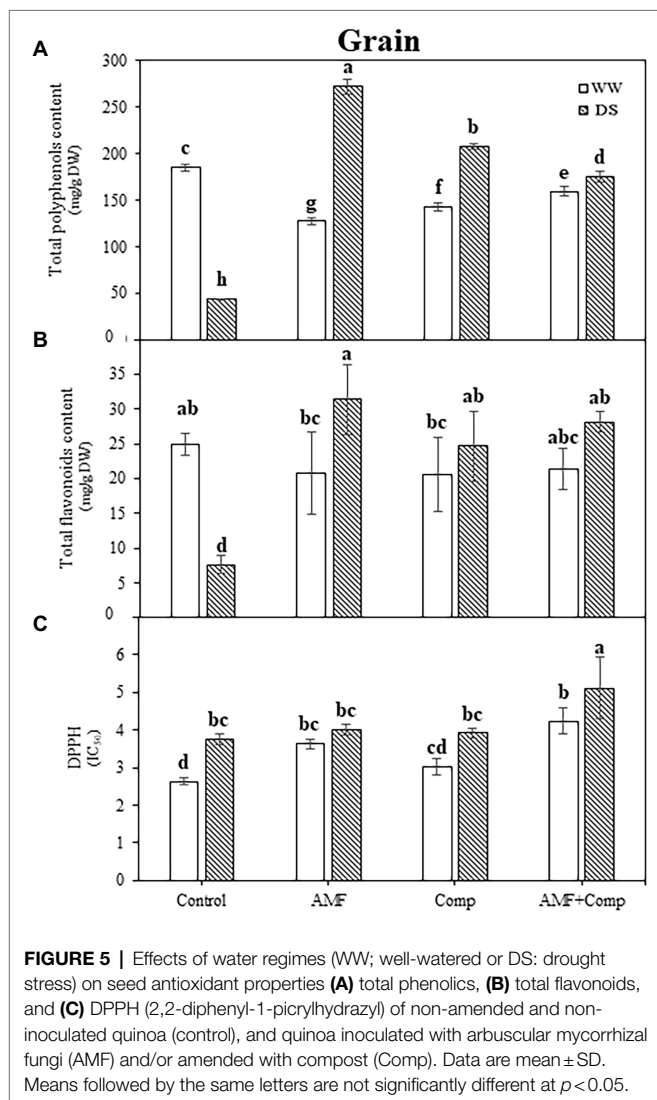

drought stress (Hura et al., 2007). From a societal and human nutrition perspective, the increase of these bioactive compounds in biofertilizer-treated quinoa grains could be very useful in preventing various diseases, including cancer and cardiovascular disease. Thus, the “empowerment of these compounds in plants, especially in grains, can limit human diseases (Uttara et al., 2009) and take the food industry to another level of quality/functionality.”

Biofertilizers Improved Soil Fertility Traits in Post-harvest Agricultural Soil

The results of soil analyses after the cultivation of quinoa and the application of the different treatments are shown in **Table 5**. Compared to the initial properties (**Table 1**), the soil TOC, OM, and P were significantly improved after biofertilizer application ($p < 0.01$, **Supplementary Table S1**). pH values decreased after the experiment in quinoa plants treated with AMF+Comp reaching a pH value of 7.7 under stressed conditions. The dual application

of biofertilizers significantly improved the concentrations of OM and TOC by *ca.* 200% and AP by ~50% under droughted-field conditions. The improved soil physicochemical properties after harvest under water deficit and biofertilizer application, especially

compost, could be due to the adequate and balanced quantity of nutrients and OM provided by this amendment and the processes launched by chemical and biological activity. Montiel-Rozas et al. showed that the application of organic amendments soil microbial activity, increasing OM degradation and mineralization processes (Montiel-Rozas et al., 2016). Similarly, Gaiotti et al. have highlighted that the inoculation with microorganisms and application of compost effectively improved soil quality, especially OM and mineral nutrition (Gaiotti et al., 2017). Moreover, AMF could promote soil quality *via* multiple mechanisms such as P solubilization, soil structure and aggregates *via* glomalin production (Ben-Laouane et al., 2020, 2021). Biofertilizers are not fertilizers in themselves but potentially enhance the release of naturally reserved nutrients in the soil (Schütz et al., 2018). Pii et al. (2015) showed that microbial inoculants enhance the decomposition process fostering the release of essential plant nutrients produced from the natural process of OM decomposition and which induce overall crop productivity. Thus, the application of nutrient-rich biofertilizers made from organic amendments and microorganisms that can induce such phenomena as P solubilization and mineral absorption is essential in the recovery of soil nutrients under water deficit and to enhance plant life growth and yield. Therefore, in this study, scaling up the biofertilizer formulation and application in field trial provided optimum growth conditions for maintaining the viability of the microorganisms, under unfavorable conditions, and added to the compost carrier to ensure that the nutrients are made available to the plant. Thus, the need to use a cheap and readily available organic matter coupled with indigenous microorganism strains should be an integral component of agricultural practice and industrial methods to enhance soil quality and essential nutrient content, due to the direct and indirect effects, and hence to increase yield performance and stimulate the concentration and distribution of nutrients in quinoa.

Principal Component Analysis and Heat Map Revealed the Potential of Biofertilizer Applications to Mitigate Drought and Support Better Quinoa Grains

The principle component analysis (PCA; Figure 6A) and heat map (Figure 6B) were performed to elaborate on the interactions

EC, electric conductivity; TOC, total organic content; OM, organic matter; and P, available phosphorus. Values represent the mean ± standard deviation (SD; n=3). Means followed by the same letters are not significantly different ($p \leq 0.05$).

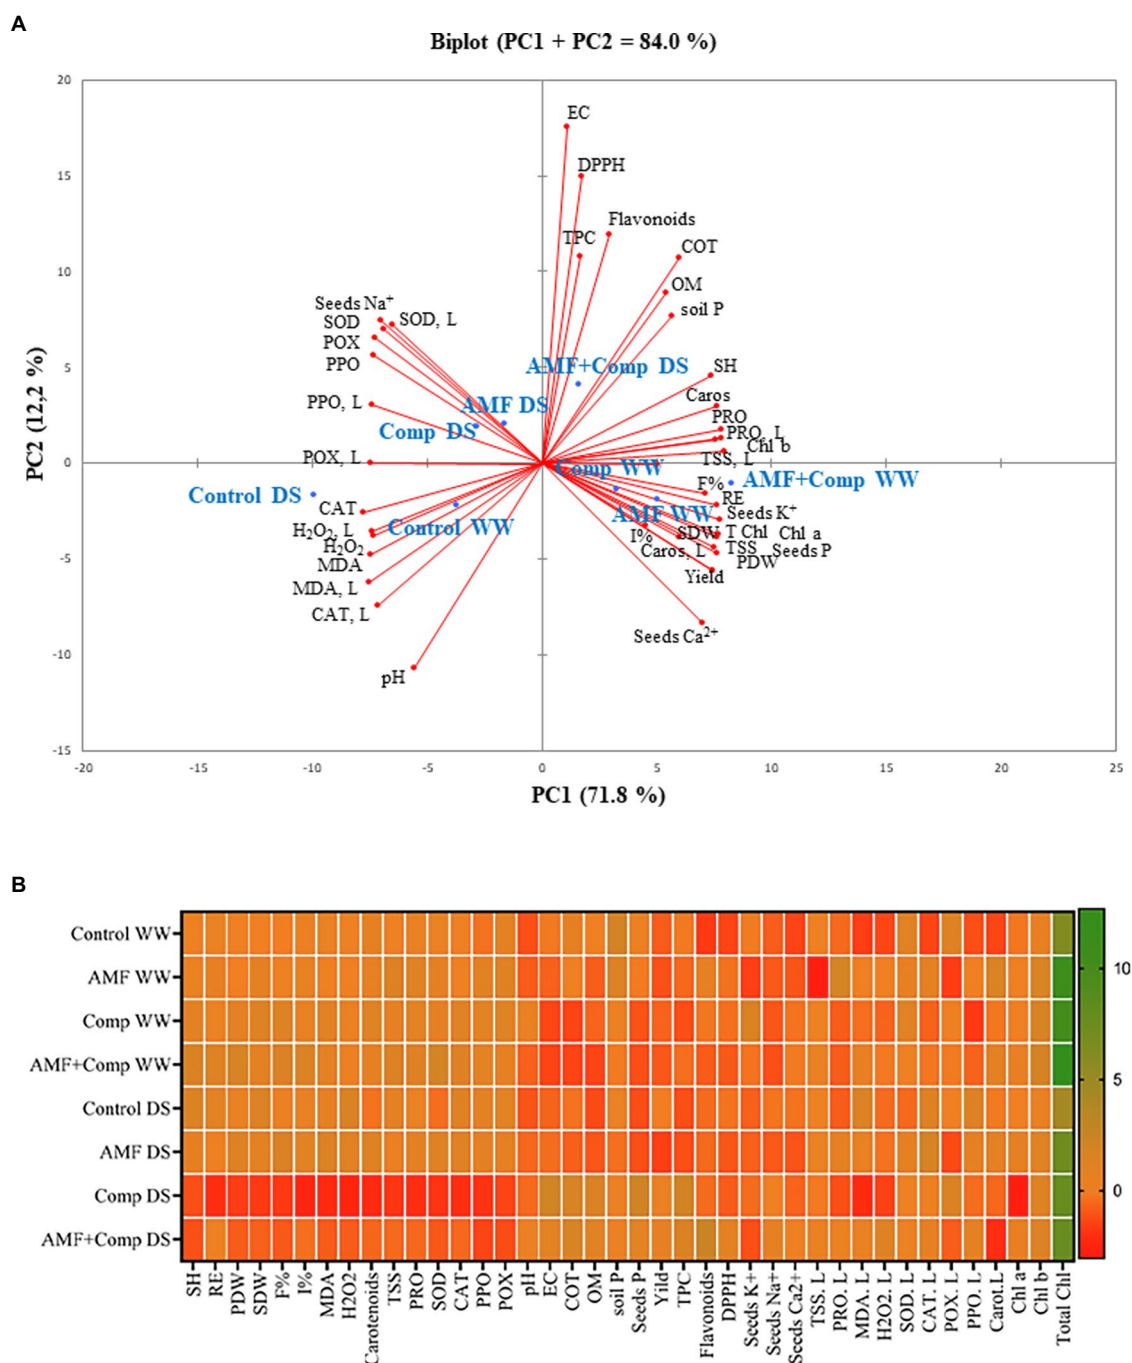

FIGURE 6 | The principal component analysis (PCA) **(A)** and heat map **(B)** measured variables and applied treatments. AMF, arbuscular mycorrhizal fungi consortium; AP, soil available phosphorous; Ca^{2+} , seed calcium; Caros, seed carotenoid; Caros, L, leaf carotenoid; CAT, seed catalase activity; CAT, L, leaf catalase activity; Chl, leaf chlorophyll; Comp, compost; DS, drought stress; EC, electrical conductivity; F%, AMF colonization frequency; I%, AMF colonization intensity; K^+ , seed potassium; Na^+ , seed sodium; OM, organic matter; P, seed phosphorus; PDW, plant dry weight; PPO, seed polyphenol oxidase activity; PPO, L, leaf PPO; POX, seed peroxidase activity; POX, L, leaf POX; Prot, seed protein; Prot, L, leaf protein; RE, root elongation; SDW, seed dry weight; SH, shoot height; SOD, seed superoxide dismutase activity; SOD, L, leaf SOD; TFC, seed total flavonoid; TOC, total organic carbon; TPC, seeds total phenol; TSS, seed total soluble sugar; TSS, L, leaf total soluble sugar; and WW, well-watered.

across the different treatments applied and traits. The PCA shows that treatments and variables were associated (83%) with the first (PC1) and the second (PC2) components, of which PC1 was the major component (71%; **Figure 6A** and

Supplementary Table S2). The heat map analysis indicates that the highest values of soil fertility (TOC, OM, and AP), plant growth (PH, RE, PDW, and SDW), yield, and grain traits (K, TSS, protein, and carotenoids) were found in

AMF + Comp-treated quinoa. DPPH radical scavenging activity and EC registered the highest values in the dual inoculation and compost under DS conditions. The single application of AMF was correlated with F%, I%, and grain P and Ca, under WW conditions, and with grain TPC and TFC under stressful conditions. Regarding irrigation, the drought stress conditions were associated mainly with low nutrient and bioactive compound content in grains, oxidative damage, and low soil fertility, leading to reduced grain quality and yield. In fact, the lowest values for these parameters were recorded in the controls under drought conditions, which showed the highest accumulation of Na⁺, oxidative stress markers (H₂O₂ and MDA), and detoxifying enzymes (SOD, CAT, PPO, and POX).

In general, our study demonstrates that the combination of AMF + Comp was the most efficient treatment to improve the yield and performance parameters of quinoa grains, principally regarding the concentration of the non-enzymatic antioxidants of phenolic and flavonoid compounds, under drought stress. Moreover, under the same condition, the dual combination improved plant growth, yields, and grain quality seemed to be influenced by the increase in grain nutrient status (P, K, and Ca²⁺).

CONCLUSION

Drought is the most important environmental stress factor that significantly reduces plant growth, biochemical processes, and crop production and nutritive quality worldwide. Taken together, our data suggest that drought stress limited quinoa growth, yield, and grain nutritional status/bioactive compounds and increased grain stress indicators. The overall conclusion of this study is that reinforcing the root system and altering the microbial population around the plant's rhizosphere, thereby disturbing the biological activities of the soils' ecosystem, increase the soil's traits, and in turn, quinoa yield/productivity and grain quality under normal and droughted-field conditions. AMF and the provision of green compost have an influential role in improving and preserving quinoa grain yield and functionality under water shortage conditions by boosting their bioactive compounds, including flavonoid and phenolic compound concentrations, ultimately improving the beneficial health effects for the final consumer. The potential of such native AMF + compost-based fertilizer applications could help plant growth, performance, and grain biofortification and mitigate global drought—a global mitigation strategy that farmers could implement as it is eco-friendly, cost-effective, easy to apply, and precludes the need for further subsidies.

Altogether, our results suggest that using a locally produced compost and water stress-adapted endogenous AMF can benefit the vegetative growth of crops and the quality of the

grain. This is an important finding since grain biofortification under water limitation is one of the main effects of climate change in agricultural areas worldwide, where the use of efficient biotechnological tools can partially counter the deleterious effects of drought. In the application of industrial biotechnology, it is more attractive and more promising to reveal the powerful features of natural consortia and organic amendments and combine to execute new functions. This knowledge is crucial to boost grain quality and bioactive compounds at the industrial and pharmaceutical levels and has the potential for extensive application with all the subsequent benefits for humanity.

DATA AVAILABILITY STATEMENT

The application of nanoparticles (NPs) has been proved as an efficient and promising technique for mitigating a wide range of stressors in plants. The present study elucidates the synergistic effect of iron oxide nanoparticles (IONPs) and silicon nanoparticles (SiNPs) in the attenuation of Cd toxicity in *Phaseolus vulgaris*. Seeds of *P. vulgaris* were treated with IONPs (10 mg/L) and SiNPs (20 mg/L). Seedlings of uniform size were transplanted to pots for 40 days. The results demonstrated that nanoparticles (NPs) enhanced growth, net photosynthetic rate, and gas exchange attributes in *P. vulgaris* plants grown in Cd-contaminated soil. Synergistic application of IONPs and SiNPs raised not only K⁺ content, but also biosynthesis of polyamines (PAs), which alleviated Cd stress in *P. vulgaris* seedlings. Additionally, NPs decreased malondialdehyde (MDA) content and electrolyte leakage (EL) in *P. vulgaris* plants exposed to Cd stress. These findings suggest that stress alleviation was mainly attributed to the enhanced accumulation of K⁺ content, improved antioxidant defense system, and higher spermidine (Spd) and putrescine (Put) levels. It is suggested that various forms of NPs can be applied synergistically to minimize heavy metal stress, thus increasing crop production under stressed conditions.

Keywords: growth, potassium, polyamines, antioxidant, stress, cadmium

INTRODUCTION

Mining operation, industrial waste, and pollutants emitted during agricultural and industrial operations (Palansooriya et al., 2020; Raghieb et al., 2020) release substantial quantities of toxic heavy metals (As, Cd, Hg, Pb) into the environment. The quantity of harmful heavy metals in the soil environment has steadily increased over time, which produces negative effects on plant growth and their developmental process, which is a great challenge for the sustainability of agriculture (Afzal et al., 2019). Among the numerous heavy metals, Cd content in the environment has risen owing to excessive use of chemical fertilizers and pesticides besides mining sources (Seshadri et al., 2016; Manzoor et al., 2019). Although the concentration of Cd reported in the environment is low, it is considered extremely toxic due to its higher mobility in media and living cells (Rahman and Singh, 2019; Kaya et al., 2020a), which is raising concerns for agriculture. It was reported that Cd exposure reduces seed sprouting, root elongation, shoot development, and the number of leaves per plant (Kaya et al., 2020b; Seifikalhor et al., 2020). In addition, it also results in the overproduction of reactive oxygen species (ROS) (Moradi-Marjaneh et al., 2019), which influence plant physiological, biochemical, and molecular characteristics (Raza et al., 2020). Plants can avoid, tolerate, and immobilize heavy metals in soil (Kumar and Prasad, 2018; Mei et al., 2020) by activating signaling molecules that regulate ROS production, phytohormone synthesis, and calcium calmodulin pathways (Bali et al., 2019). The activated pathways include the production of nitric oxide (NO), glutathione, phytohormones, and antioxidant enzymes (Dias et al., 2019; Rady et al., 2019), which lead to Cd chelation and reduced oxidative damage.

Nanoparticles (NPs) with a size of 100 nm exhibit unique properties such as increased reaction site, high surface activity, better catalytic efficiency, and unique magnetic characteristics (Yang et al., 2017, 2018; Wang et al., 2019), which have assisted in agriculture promotion by alleviating abiotic stress in plants (Adeel et al., 2019). Many researchers have reported that NPs improve seed germination, rhizome development, and quality of crops cultivated in stressed conditions (Ghafariyan et al., 2013; Palchoudhury et al., 2018; Kah et al., 2019). Nanotechnology research offers a new pathway for soil pollution remediation (Liu et al., 2021), since it has the potential to enhance plants' antioxidative defense systems, thus reducing the bioaccumulation of ROS in plants (Usman et al., 2020; Wang et al., 2020). As documented, NPs when applied in soil (Li et al., 2021) or sprayed *via* foliar (Toumey, 2020), results in a reduction of Cd and Pd toxicity in rice seedlings (Hussain et al., 2020). It was observed that the Si improved hydraulic conductivity in applied plants through enhancing K^+ concentration in xylem sap resulting in improved xylem hydraulic conductivity and osmotic gradient (Chen et al., 2016). Similarly, exogenously applied Fe modulates K^+ uptake and translocation in crop plants (Okturen Asri and Sonmez, 2014).

Potassium is a crucial phytonutrient required by plants for the maintenance of growth (Jaiswal et al., 2016), stomatal conductance, gaseous exchange (Hasanuzzaman et al., 2018), photosynthate production, and antioxidative defense system

(Xu et al., 2020). Approximately 10% of plant biomass is composed of K, which not only acts as a co-factor for various enzymes involved in photosynthesis and protein stabilization, but it also hinders Cd-translocation and escalates the production of crucial amino acids, carbohydrates, and nitrogenous compounds. Potassium improves plant stress tolerance by regulating the biosynthesis of polyamines (Karimi, 2017). Polyamines regulate physiochemical procedures of plants under normal conditions and also induce modification in the expression level of stress-responsive genes besides detoxifying metals by vacuolar compartmentalization (Spormann et al., 2021).

Considering the background information, we hypothesized that the synergistic effect of NPs can mitigate Cd stress; and regulate polyamine synthesis, K^+ metabolism, and antioxidant enzymes. Therefore, the objective of the present study was to explore the individual and combined role of IONPs and SiNPs application in mitigation of Cd toxicity through regulation of K^+ metabolism and antioxidant enzymes in *P. vulgaris* exposed to Cd-contaminated conditions.

MATERIALS AND METHODS

A total of 85 soil samples were collected (0–30 cm) from an agricultural field (2-ha area) in the vicinity of the campus site. The soil was sieved through a 4 mm mesh to remove plant parts, debris, then thoroughly mixed and conditioned for 1 week at 35% of water holding capacity (WHC) before the experiment. The physicochemical properties of the soil such as pH, electrical conductivity (EC), organic matter, and metal content (Cd, Zn, Fe, Ni, Pb) were measured using standard protocols (Bouyoucos, 1962; Page et al., 1982). The physicochemical properties of the soil were as follows; pH (7.13), EC (1.87), and organic content (0.45%). The total concentration of Cd, Zn, Fe, Ni, and Pb in soil was quantified as 5.87, 34.98, 37.91, 13.28, and 35.18 mg/kg, respectively. The soil was contaminated by mixing $CdCl_2$. Cadmium concentrations in the soil were kept as 0 mM $CdCl_2$, 1 mM $CdCl_2$, 1.5 mM $CdCl_2$, and 2 mM $CdCl_2$. Both IONPs and SiNPs were purchased from Alfa Aesar. A pilot project was carried out to find out the toxic concentration of Cd that affects the growth of *P. vulgaris*. A 10 mg/L IONPs and 20 mg/L SiNPs were found to be effective against selected Cd toxic levels. Iron oxide nanoparticles (IONPs) obtained from Alfa Aesar were having 99% purity, size 15–25 nm, and 4.67 density. Silicon nanoparticles obtained from Alfa Aesar were having 98% purity, size 40–100 nm, and 4.7 density. The solution used during the experiment was prepared using deionized H_2O .

Seed Priming With Iron Oxide Nanoparticles and Silicon Nanoparticles

Seeds of *P. vulgaris* were surface sterilized using 2.5% sodium hypochlorite solution for 2 min and then washed with deionized H_2O to remove chlorophyll (Chl) contents. IONPs and SiNPs were weighed and added in deionized H_2O followed by ultra-sonication for half-hour and their desired concentrations (IONPs = 10 mg/L) and (SiNPs = 20 mg/L) were achieved. After that sterilized seeds of *P. vulgaris* were soaked in an NP solution.

In the case of the control treatment, seeds were treated with deionized H₂O. In the next step, soaked seeds were dried and stored at 4°C for further experiments.

Seed Sowing and Greenhouse Conditions

The current study was executed at the university site (32°N, 74°E, 236m altitude). Ten seeds were sown in plastic pots of 40 × 45 cm containing 20kg treated soil. These pots were kept in the greenhouse condition with an average temperature of 20/15°C (day/night), average humidity of 50/70% late afternoon/morning, and a natural photoperiod. After germination, thinning was done and 8 plants were retained per pot. Regular weeding was done and plants were watered daily to uphold 70% of the field maximum moisture capacity throughout the growth period.

Determination of Growth and Leaf Relative Water Content

Plants were uprooted after 40 days and growth characteristics (root and shoot fresh weight, root and shoot dry weight) were estimated. Leaf relative water content (LRWC) values from *P. vulgaris* leaf samples were estimated using the following equation as given by Smart and Bingham (1974);

$$\text{LRWC}(\%) = \frac{\text{LFW} - \text{LDW}}{\text{LTW} - \text{LDW}} \times 100$$

Where LRWC = Leaf relative water content

LFW = Leaf fresh weight

LDW = Leaf dry weight

LTW = Leaf turgid weight

Estimation of Photosynthetic Pigments

Arnon method (1949) was used for the estimation of photosynthetic pigments. Approximately 100 mg leaf extract was mixed with 80% acetone and centrifuged for 5 min at 10,000 rpm. The optical density (OD) of filtrates was then measured using a spectrophotometer (Hitachi U-2001, Tokyo, Japan).

Determination of Malondialdehyde Content and Electrolyte Leakage

Malondialdehyde (MDA) content was determined according to the method of Cavalcanti et al. (2004). Briefly, 0.5 g samples were homogenized using mortar and pestle in 4 mL of trichloroacetic acid (TCA) (1% w/v) at 4°C. The homogenous mixture was then centrifuged for 20 min at 12,000 rpm to collect the supernatant. One milliliter of this supernatant was added to 3 mL of reaction mixture containing TCA (20% w/v) and thiobarbituric acid (0.5% w/v). The reaction mixture was incubated at 95°C for half-hour and the reaction was stopped by placing it in an ice bath. The absorbance value of the fraction was measured at 440, 532, and 600 nm.

The method of Blum and Ebercon (1981) was used for the determination of electrolyte leakage. A dry leaf sample (0.2 g) was floated in deionized H₂O (50 mL) for 24 h at room

temperature with shaking. The electrolyte content in the solution was quantified and recorded as CO. After 20 min of boiling the sample, the electrolyte content in the solution was recorded as C1. Electrolyte leakage was measured in percentage as per the following formula:

$$\text{Relative electrolyte leakage} = \frac{\text{CO}}{\text{C1}} \times 100$$

Determination of Antioxidant Enzymes

About 1 g leaf samples were homogenized in a solution of potassium phosphate buffer solution (100 mM), polyvinyl pyrrolidone (1% w/v), ethylenediamine tetraacetic acid (0.1 mM) and triton X-100 (0.5%). The homogenate was filtered through cheesecloth and centrifuged at 18,000 rpm for 20 min at 4°C. The resultant supernatant was used for the estimation of antioxidative enzymes and was stored at -80°C for analysis. The method of Aebi (1974) was used for the determination of catalase (CAT) activity. Briefly, potassium phosphate buffer (50 mM) and plant extract were used in the reaction (3 mL). To start the reaction, 10 mM H₂O₂ was added. 1 unit of CAT is defined as the number of enzymes, which release 1/2 of peroxide oxygen from 10 mM H₂O₂ solution in 100 s at 25°C. Superoxide dismutase (SOD) activity was measured according to the method of Beyer and Fridovich (1987). The reaction mixture (30 mL) for the determination of SOD was composed of potassium phosphate buffer (50 mM), methionine (9.9 mM), nitroblue tetrazolium (57 mM), and plant extract. The reaction mixture was started by light illumination. One unit of SOD is defined as the enzyme which causes a 50% decrease of SOD inhabitable reduction.

Determination of Proline Content

To determine proline content, dry leaf samples (0.5 g) were extracted in sulfosalicylic acid (3%) and then filtered (Bates et al., 1973). Afterward, 2 mL of leaf extract was mixed in ninhydrin solution (2 mL) and glacial acetic acid (2 mL). Plant samples were incubated at 100°C for 1 h and cooled in an ice bath. Four milliliters of toluene was vigorously added to the mixture. The absorbance value was calibrated at 520 nm using a spectrophotometer. Proline content was estimated using a standard curve.

Determination of Cadmium Content

Following Cd treatment, *P. vulgaris* seedlings were rinsed with deionized H₂O. Seedlings were dried at 80°C for 24 h. The plant material was digested in HNO₃:HClO₄. About 1 g plant sample was homogenized in 50 mM Tris (hydroxymethyl) aminomethane (Tris-HCl), 250 mM sucrose, and 1 mM DL-dithiothreitol. The homogenous mixture obtained was centrifuged at 3,000 rpm for 5 min for the isolation of the cell wall. The supernatant obtained was centrifuged at 20,000 rpm for 45 min. Cd was determined using ICP (ICP-AES, Thermo Elemental, United States) (Wang et al., 2009).

Determination of Nutritional Content

A flame photometer (Jenway PFP-7) was used for the determination of nutritional content (Mo⁺, Ca⁺, K⁺, Mn⁺) from

the digested plant samples. K^+ content was quantified with the help of a standard solution.

Determination of Gaseous Exchange

Assessments of gaseous exchange attributes, net CO_2 uptake, net photosynthesis (Pn), stomatal conductance (Gs), and transpiration rate (E), were performed at 10:00 a.m. at 27°C during the daytime on completely expanded leaves using a portable gas exchange system (Holá et al., 2010).

Determination of Polyamine Activity

The concentration of hydrogen peroxide produced during polyamine oxidation assisted in the estimation of polyamine oxidase (PAO) activity. The foliage plant sample was mixed with potassium phosphate buffer (0.1 mM at pH 6.5 in an pre-chilled mortar and pestle. The resultant supernatant (0.5 mL) was obtained by centrifugation of this mixture at 10,000 g at 4°C for 20 min followed by mixing with 4-aminoantipyrine/*N,N*-dimethylaniline solutions (0.4 mL), 0.2 mL horseradish POD (250 U/mL), and 5 mL of K_3PO_4 buffer (100 mM at pH 6.5). For the determination of polyamine oxidase, putrescine (30 mL of 20 mM) was homogenized in enzyme extract to initiate reaction according to Zhao et al. (2004).

Determination of Nitric Oxide Content

Nitric oxide activity was quantified using the nitric oxide detection kit (Solarbio Life Science, Beijing, China) following the manufacturer's instructions.

Estimation of Soluble Protein Content

Leaf samples (1 g) were extracted using KH_2PO_4 (4 mL at pH 6.8) following centrifugation at 3,600 rpm for 30 min. The resultant supernatant was collected and a 20 μ L aliquot of the extract was collected and homogenized with the Bradford color reagent (1 mL). The spectrophotometer calibration was carried out at 595 nm as per the procedure described by Bradford (1976).

Statistical Analysis

Data reported in the experiment was mean of 5 replicates. Statistical package XL-STAT was carried out for analysis of variance (ANOVA). Subsequently, Tukey's test was conducted to determine the significant differences among the values.

RESULTS

Effect of Iron Oxide Nanoparticles and Silicon Nanoparticles on Growth Attributes of *Phaseolus vulgaris*

Table 1 shows the role of IONPs and SiNPs, alone or in combination, on the growth of *P. vulgaris* seedlings grown in normal and Cd-contaminated soil. Synergistic application of NPs improved shoot fresh weight and root fresh weight by 39 and 40%, respectively, as compared to IONPs-only treated *P. vulgaris* seedlings grown in non-contaminated soil. When *P. vulgaris* seedlings were exposed to 2 mM $CdCl_2$, combined treatment of IONPs and SiNPs increased shoot fresh weight and root fresh weight by 45 and 19%, respectively, as compared to SiNP-treated *P. vulgaris* seedlings grown in Cd-contaminated media. Likewise, combined and synergistic treatments involving NPs enhanced root dry weight and shoot dry weight in *P. vulgaris* seedlings grown in normal and Cd-contaminated conditions (Table 1).

Effect of Iron Oxide Nanoparticles and Silicon Nanoparticles on Leaf Relative Water Content and Net Photosynthetic Rate of *Phaseolus vulgaris*

When *P. vulgaris* seedlings were grown in non-contaminated media, combined treatment of IONPs and SiNPs enhanced LRWC content by 9 and 4% in comparison with IONPs-only and SiNPs-only treatment, respectively. A similar trend of net

TABLE 1 | Effect of IONPs and SiNPs on root fresh weight, shoot fresh weight, root dry weight, shoot dry weight, leaf relative water content, and net photosynthetic rate of *Phaseolus vulgaris* grown in different concentrations of Cd.

Here IONPs, SiNPs, Cd0, Cd1, Cd2, Cd3 indicates iron oxide nanoparticles, silicon nanoparticles, 0 mM $CdCl_2$, 1 mM $CdCl_2$, 1.5 mM $CdCl_2$, 2 mM $CdCl_2$. Different letters indicate significant difference among the treatments ($P \leq 0.05$).

FIGURE 1 | Effect of IONPs and SiNPs on intercellular CO₂ concentration and stomatal conductance of *Phaseolus vulgaris* grown in different concentrations of Cd. Here IONPs, SiNPs, Cd0, Cd1, Cd2, and Cd3 indicate iron oxide nanoparticles, silicon nanoparticles, 0 mM CdCl₂, 1 mM CdCl₂, 1.5 mM CdCl₂, and 2 mM CdCl₂. Different letters indicate significant difference among the treatments ($P \leq 0.05$).

photosynthetic rate was observed in *P. vulgaris* seedlings exposed to different concentrations of CdCl₂ (Table 1).

Effect of Iron Oxide Nanoparticles and Silicon Nanoparticles on Gas Exchange Parameters of *Phaseolus vulgaris*

In the case of *P. vulgaris* seedlings grown in non-contaminated soil, synergistic application of IONPs and SiNPs increased intercellular CO₂ concentration and stomatal conductance by 8 and 18%, respectively, in comparison with alone application of IONP and SiNP treatment. When *P. vulgaris* seedlings were treated with 1 mM CdCl₂, 1.5 mM CdCl₂, and 2 mM CdCl₂, intercellular CO₂ concentration decreased by 20, 29, and 43%, respectively, as compared to Cd0 treatment. Synergistic application of IONP and SiNP increased intercellular CO₂

concentration in *P. vulgaris* seedlings grown in 1.5 mM CdCl₂ by 22 and 7%, respectively, in comparison with alone treatments of IONPs and SiNPs. Likewise, synergistic application of IONP and SiNP enhanced stomatal conductivity in *P. vulgaris* seedlings grown in Cd0-treatment and Cd-contaminated soil (Figure 1).

Effect of Iron Oxide Nanoparticles and Silicon Nanoparticles on Malondialdehyde Content and Electrolyte Leakage in *Phaseolus vulgaris*

Figure 2 shows that the application of IONPs and SiNPs reduced MDA content and EL leakage in *P. vulgaris* seedlings grown in non-contaminated and Cd-polluted soil. Synergistic application

FIGURE 2 | Effect of IONPs and SiNPs on MDA content and EL of *Phaseolus vulgaris* grown in different concentrations of Cd. Here IONPs, SiNPs, Cd0, Cd1, Cd2, and Cd3 indicate iron oxide nanoparticles, silicon nanoparticles, 0 mM CdCl₂, 1 mM CdCl₂, 1.5 mM CdCl₂, and 2 mM CdCl₂. Different letters indicate significant difference among the treatments ($P \leq 0.05$).

of IONPs and SiNPs reduced MDA content by 50 and 20% as compared to individual application of IONPs and SiNPs, respectively, in *P. vulgaris* seedlings grown in 1.5 mM CdCl₂-contaminated soil.

Electrolyte leakage was also reduced in *P. vulgaris* seedlings treated with combined application of IONPs and SiNPs, in comparison with individual treatments. In the case of *P. vulgaris* seedlings grown in 2 mM CdCl₂, combined application of IONPs and SiNPs reduced EL by 56 and 21%, respectively, in comparison with individual treatments of IONPs and SiNPs (Figure 2).

Effect of Iron Oxide Nanoparticles and Silicon Nanoparticles on Polyamine Content in *Phaseolus vulgaris* Seedlings

Figure 3 shows the effect of IONPs and SiNPs on spermidine (Spd) and putrescine (Put) content of *P. vulgaris* seedlings grown in normal and Cd-contaminated soil. Application of

IONPs and SiNPs, alone or in combination, escalated Spd and Put content in *P. vulgaris*. Combined treatment of IONPs and SiNPs enhanced Spd content by 91% as compared to individual application of SiNPs in *P. vulgaris* seedlings grown in 1 mM CdCl₂. Likewise, Put content also increased when *P. vulgaris* seedlings were treated with IONPs and SiNPs in combination. The combined application of IONPs and SiNPs enhanced Put content by more than one-fold in comparison with SiNPs-only treatment in *P. vulgaris* seedlings grown in 2 mM CdCl₂.

Effect of Iron Oxide Nanoparticles and Silicon Nanoparticles on Nitric Oxide and Proline Content of *Phaseolus vulgaris*

Nitric oxide and proline (Pro) content are considered as stress markers in plants. During the current study, IONPs and SiNPs enhanced nitric oxide and proline

FIGURE 3 | Effect of IONPs and SiNPs on PAs content of *Phaseolus vulgaris* grown in different concentrations of Cd. Here IONPs, SiNPs, Cd0, Cd1, Cd2, and Cd3 indicate iron oxide nanoparticles, silicon nanoparticles, 0 mM CdCl₂, 1 mM CdCl₂, 1.5 mM CdCl₂, and 2 mM CdCl₂. Different letters indicate significant difference among the treatments ($P \leq 0.05$).

content in *P. vulgaris* seedlings grown in normal and Cd-contaminated soil. In the case of *P. vulgaris* seedlings grown in control conditions, synergistic application of IONPs and SiNPs enhanced NO content by 44 and 50%, respectively, in comparison with individual application of IONPs and SiNPs. When *P. vulgaris* seedlings were exposed to 2 mM CdCl₂, combined application of IONPs and SiNPs enhanced NO content by more than onefold and 60% as compared to IONPs-only and SiNPs-only treatment. Similarly, IONPs and SiNPs also enhanced proline content in *P. vulgaris* seedlings grown in normal and Cd-contaminated conditions (Figure 4).

Effect of Iron Oxide Nanoparticles and Silicon Nanoparticles on the Activity of Antioxidant Enzymes in *Phaseolus vulgaris*

Figure 5 explains the role of IONPs and SiNPs on the activity of SOD and CAT in *P. vulgaris* seedlings grown in control and Cd-contaminated conditions. In the case of *P. vulgaris* seedlings grown in Cd0 treatment, combined application of IONPs and SiNPs improved the activity of SOD by 41 and 71%, respectively, in comparison with IONPs-only and SiNPs-only treatment. Synergistic treatment of IONPs and SiNPs enhanced

FIGURE 4 | Effect of IONPs and SiNPs on nitric oxide and proline content of *Phaseolus vulgaris* grown in different concentrations of Cd. Here IONPs, SiNPs, Cd0, Cd1, Cd2, and Cd3 indicate iron oxide nanoparticles, silicon nanoparticles, 0 mM CdCl₂, 1 mM CdCl₂, 1.5 mM CdCl₂, and 2 mM CdCl₂. Different letters indicate significant difference among the treatments ($P \leq 0.05$).

SOD content by 72 and 90% as compared to individual treatments of IONPs and SiNPs, respectively, in *P. vulgaris* seedlings grown in 2 mM CdCl₂. Likewise, combined treatment of IONPs and SiNPs enhanced CAT activity in *P. vulgaris* seedlings grown in normal and CdCl₂-contaminated conditions. The combined application of IONPs and SiNPs escalated CAT activity by 71 and 50%, as compared to IONPs-only and SiNPs-only treatment, respectively, in *P. vulgaris* seedling exposed to 2 mM CdCl₂.

Effect of Iron Oxide Nanoparticles and Silicon Nanoparticles on Cadmium Uptake of *Phaseolus vulgaris*

Table 2 shows that NP treatment reduced Cd uptake in *P. vulgaris* seedlings grown in CdCl₂-contaminated soil. Synergistic application of IONPs and SiNPs reduced Cd uptake by 68% in *P. vulgaris* seedling grown in 2 mM CdCl₂.

Effect of Iron Oxide Nanoparticles and Silicon Nanoparticles on Photosynthetic Pigmentation of *Phaseolus vulgaris*

Table 3 shows the role of IONPs and SiNPs on photosynthetic pigmentation of *P. vulgaris* grown in normal and Cd toxic conditions. IONPs and SiNPs orchestrated carotenoids content, Chl a, Chl b, and total Chl content in *P. vulgaris* seedlings.

Effect of Iron Oxide Nanoparticles and Silicon Nanoparticles on the Nutritional Content of *Phaseolus vulgaris*

Table 4 describes the role of IONPs and SiNPs on the nutritional content of *P. vulgaris* seedlings grown in normal and different concentrations of CdCl₂. A combined application of IONPs and SiNPs increased K⁺ content by 31 and 24%, respectively, as

FIGURE 5 | Effect of IONPs and SiNPs on SOD and CAT activity of *P. vulgaris* grown in different concentrations of Cd. Here IONPs, SiNPs, Cd0, Cd1, Cd2, and Cd3 indicate iron oxide nanoparticles, silicon nanoparticles, 0 mM CdCl₂, 1 mM CdCl₂, 1.5 mM CdCl₂, and 2 mM CdCl₂. Different letters indicate significant difference among the treatments ($P \leq 0.05$).

compared to IONPs-only and SiNPs-only treated *P. vulgaris* seedlings grown in non-contaminated potted soil.

DISCUSSION

Cadmium toxicity reduces the ability of plants to absorb key nutrients (Mg, Ca, P, K) and water content from soil (Yang et al., 2020). Potassium is considered as crucial for plant growth, development, and metabolomics (Hasanuzzaman et al., 2018) because it alleviates abiotic stresses (Raza et al., 2021) by restricting transportation and accumulation of heavy metals in plants (Kerchev et al., 2020). Additionally, potassium not only immobilizes heavy metal content (Liu et al., 2018) but also behaves antagonistically to Cd and detoxifies Cd within plants (Shamsi et al., 2008). Cadmium is a non-essential metal

and is involved in the hindrance of plant growth (Shah et al., 2020a) by causing a reduction in water content, biomass, fresh and dry weight of plants, as well as disruption in redox reaction (Raza et al., 2020). Potassium application stabilizes chlorophyll architecture, which leads to the regulation of photosynthate production (Hasanuzzaman et al., 2018). It was also documented that K⁺ application enhanced growth and yield in apple dwarf rootstock seedlings (Xu et al., 2020) via Cd assimilation by increased accumulation of K⁺ in plants (Norvell et al., 2000). In addition, the increase in K⁺ enhanced the activity of antioxidant enzymes and reduced MDA content in plants exposed to Cd toxicity. The results of the present study also indicated that synergistic application of IONPs and SiNPs enhanced K⁺ content in *P. vulgaris* seedlings grown in normal and Cd-contaminated soil. In the present study, IONPs and SiNPs treatment increased LRWC in *P. vulgaris* seedling

TABLE 2 | Effect of IONPs and SiNPs on root Cd content, shoot Cd content, translocation factor, and metal tolerance index of *Phaseolus vulgaris* grown in different concentrations of Cd.

Treatments	Root ($\mu\text{g g}^{-1}$ DW)	Shoot ($\mu\text{g g}^{-1}$ DW)
Cd0 + IONPs	ND	ND
Cd0 + SiNPs	ND	ND
Cd0 + IONPs + SiNPs	ND	ND
Cd1 + IONPs	0.013 \pm 0.002	0.05 \pm 0.0002
Cd1 + SiNPs	0.014 \pm 0.003	0.04 \pm 0.0001
Cd1 + IONPs + SiNPs	0.005 \pm 0.004	0.002 \pm 0.0003
Cd2 + IONPs	0.017 \pm 0.001	0.009 \pm 0.0001
Cd2 + SiNPs	0.015 \pm 0.003	0.007 \pm 0.0004
Cd2 + IONPs + SiNPs	0.019 \pm 0.008	0.005 \pm 0.0002
Cd3 + IONPs	0.021 \pm 0.005	0.003 \pm 0.0005
Cd3 + SiNPs	0.041 \pm 0.0003	0.006 \pm 0.0007
Cd3 + IONPs + SiNPs	0.049 \pm 0.002	0.029 \pm 0.0006

Here IONPs, SiNPs, Cd0, Cd1, Cd2, Cd3 indicates iron oxide nanoparticles, silicon nanoparticles, 0 mM CdCl₂, 1 mM CdCl₂, 1.5 mM CdCl₂, 2 mM CdCl₂.

(Table 1). Before, it was also reported that SiNP treatment enhanced gas exchange characteristics in plants exposed to Cd-contaminated media (Ur Rahman et al., 2021). Cadmium stress destabilized photosynthetic apparatus, yet IONPs and SiNPs application reduced injury to photosynthetic machinery. Iron

oxide nanoparticles increased root and shoot length in *Arachis hypogaea* plants (Rizwan et al., 2019). In the present research, it was noted also that synergistic application of IONPs and SiNPs increased photosynthesis and gas exchange characteristics in *P. vulgaris* seedlings.

Proline is crucial for the sustenance of metabolomics in plants (Ahmad et al., 2019). It was noted in the present investigation that *P. vulgaris* seedlings treated with IONPs and SiNPs showed an increased level of proline under Cd stress. The increased level of proline in NP-treated plants might lead to activation of proline synthesizing genes involved in the regulation of water content in plants.

Membrane stability is an essential characteristic required for the effective survival of plants under abiotic stress since damage to it will lead to cellular death. MDA is an indicator of cellular damage and membrane stability (Shah et al., 2020b). Under stress conditions, the generation of MDA and peroxidation of lipids increased causing damage to plants. In this study, Cd stress amplified MDA and EL in *P. vulgaris* plants grown in Cd-contaminated soil. Cadmium decreases the stability of membranous molecules due to the enhanced accumulation of ROS. Previous researchers revealed the role of IONPs and SiNPs in alleviating abiotic stresses in plants.

TABLE 3 | Effect of IONPs and SiNPs on carotenoids, total chlorophyll content, Chlb, and Chla of *Phaseolus vulgaris* grown in different concentrations of Cd.

Treatments	Carotenoids	Total Chlorophyll	Chlb	Chla

Here IONPs, SiNPs, Cd0, Cd1, Cd2, Cd3 indicates iron oxide nanoparticles, silicon nanoparticles, 0 mM CdCl₂, 1 mM CdCl₂, 1.5 mM CdCl₂, 2 mM CdCl₂. Different letters indicate significant difference among the treatments ($P \leq 0.05$).

The total antioxidant activity of a plant is a good indicator of how well the plant's antioxidant system is functioning in the presence of oxidative stress. Plants have a variety of antioxidative defense systems to deal with oxidative stress, particularly those produced by the generation of excess ROS as a result of abiotic stress. Superoxide peroxidase (SOD) is the first line of defense that is involved in the conversion of superoxide anion to peroxide. Catalase (CAT) is also a crucial antioxidant that plays an important role in plants' defensive approach to abiotic stresses. This enzyme is involved in the conversion of H_2O_2 to O_2 and H_2O . Current research reported that IONPs and SiNPs enhanced the activity of CAT in *P. vulgaris* seedlings exposed to Cd stress.

Nanoparticles reduced MDA levels, while they increased peroxidase (POD) and SOD activity in metal-stressed wheat plants (Sardar et al., 2022). Additionally, osmoregulators control the structure of organelles and macromolecules in plants by adjusting osmosis and aid in the reduction of Cd-induced toxicity in plants (Thind et al., 2021). In the present study, we also noticed that Cd inhibited the production of total soluble proteins and proline concentration in *P. vulgaris* seedlings. The findings of the present study were in line with the findings of Azizi et al. (2021). Application of NPs in the present study enhanced proline accumulation in Cd treated *P. vulgaris* seedlings. Enhanced accumulation of proline and soluble sugar may be due to augmented proline playing some vital roles in scavenging ROS, adjusting osmotic equilibrium and determining the membrane attributes in plants exposed to stress (Aswani et al., 2019). Many authors investigated the positive effect of NPs on the enhancement of proline accumulation under stress conditions in broad bean plants in addition to adjusted antioxidant enzyme activities, soluble sugars, and amino acids (Sadak and Bakry, 2020). Furthermore, Azimi et al. (2021) claimed that NP supply can decline salt stress in tomatoes by improving photosynthetic machinery, phenolics, and antioxidant enzyme activities and yield as well.

Cadmium phytotoxicity increased the formation of ROS and produced oxidative burst by interfering with the antioxidant defense system (Kamran et al., 2021), which promotes the MDA content due to the high accumulation of lipid peroxidation of the membrane. During the normal metabolism, the plants have established well-organized antioxidant enzyme defense mechanisms to eliminate the ROS (Fan et al., 2020). This is because SOD acts as the first line of defense in plants against ROS. Superoxide dismutase converts the O_2^- to less toxic H_2O_2 , and it forms the first line of defense in the antioxidant

system of plants; to this end, CAT scavenges the H_2O_2 to water and oxygen molecules (Orabi and Abou-Hussein, 2019). The ameliorative influence of the NPs on Cd stress was also assessed by Hussain et al. (2018) in the wheat plant. This apparently will promote antioxidant impairments by decreasing H_2O_2 and MDA content and enhancing the activities of SOD, CAT, and increased tolerance against abiotic toxicity (Sharma et al., 2019).

CONCLUSION

Cadmium toxicity enhanced oxidative stress in *P. vulgaris* seedlings. Application of IONPs and SiNPs escalated the activity of antioxidant enzymes besides incrementation in K^+ content. Additionally, synergistic application of IONPs and SiNPs increase NO content and Pro content in *P. vulgaris* seedlings grown in normal and CdCl_2 -polluted soil. Cd-stress alleviation is credited to increased activity of antioxidant enzymes and maintenance of PAs and K^+ metabolism. It is further added that mechanisms and molecules involved in the interaction of different NPs can be exploited for the mitigation of numerous stresses in plants.

doi: 10.3389/fpls.2022.837695

There has been much interest in the incorporation of organic molecules or biostimulants into foliar fertilizers with the rationalization that these compounds will enhance the uptake, or subsequent mobility of the applied nutrient. The objective of this research was to investigate the effects of an inositol-based plant stimulant on the mobility and accumulation of foliar-applied zinc (Zn) in wheat plants (*Triticum aestivum* L.). High-resolution elemental imaging with micro-X-ray fluorescence (μ -XRF) was utilized to examine Zn distribution within the vascular bundle of the leaf and whole grains. The inclusion of *myo*-inositol with Zinc sulfate, significantly increased Zn concentration in shoots in contrast to untreated controls and Zn sulfate applied alone. Foliar Zn treated plants increased Zn in grains by 5–25% with *myo*-inositol plus Zn treated plants significantly increasing grain Zn concentration compared to both Zn treated and non-treated controls. XRF imaging revealed Zn enrichment in the bran layer and germ, with a very low Zn concentration present in the endosperm. Plants treated with Zn plus *myo*-inositol showed an enhanced and uniform distribution of Zn throughout the bran layer and germ with an increased concentration in the endosperm. While our data suggest that foliar application of *myo*-inositol in combination with Zn may be a promising strategy to increase the absorption and mobility of Zn in the plant tissue and subsequently to enhance Zn accumulation in grains, further research is needed to clarify the mechanisms by which *myo*-inositol affects plant metabolism and nutrient mobility.

Keywords: biofortification, foliar fertilizer, biostimulant, wheat, zinc, μ -XRF

INTRODUCTION

Wheat (*Triticum aestivum* L.) is a cereal grass widely cultivated for their edible grains. Among widely cultivated food crops, wheat plays a particularly important role in daily energy intake, especially in the developing world. Modern wheat cultivars are however a poor source of micronutrients (e.g., Zn and Fe) and when used as a dominant part of daily calorie intake, a wheat based diet often fails to meet human Zn and Fe requirements (Cakmak et al., 2010). To meet human dietary needs in wheat dominant diets, it is estimated that grain Zn concentrations should

be increased from the current average of 20–35 mg kg⁻¹ to greater than 50 mg kg⁻¹ (Cakmak et al., 2010). Foliar fertilization can be used to effectively enrich Zn grain though the efficiency of transport of foliar applied Zn to grain is generally low (Erenoglu et al., 2011).

Foliar application of nutrients in crop plants is an important agricultural practice world-wide (Fernández et al., 2013). Foliar fertilization is essential where soil conditions such as high pH, limit the availability of soil applied fertilizers and where there is a need to ensure nutrient adequacy at critical stages of plant growth (Tian et al., 2015). Many factors may influence the efficacy of foliar fertilizers such as the physiological status and phenological stage of the plant, the mobility of the nutrient within the plant, or the presence of abiotic stresses (Fernández and Brown, 2013; Fernández et al., 2013). For example, Zn fertilizers, when applied *via* foliar fertilization, must readily penetrate the leaf and remain soluble to promote the translocation from leaves to phloem-fed tissues (White and Broadley, 2011; Saa et al., 2018). However, it has been reported that foliar application of common sources of Zn such as Zinc sulfate (ZnSO₄) and Zn-EDTA may not improve the mobility of Zn in plant tissues (Doolette et al., 2018). Thus, enhancing the efficiency of the foliar applied nutrients by adopting new strategies is of great importance not only from an economic, agronomic and environmental point of view, but also as a means to correct human nutrient deficiencies.

The use of plant biostimulants, such as inositol compounds, is emerging as a central feature in plant biochemistry and physiology (Yakhin et al., 2017). Inositol which is well known for acting as a stress-ameliorator in plants (Hu et al., 2018; Mukherjee et al., 2019) may also control multiple aspects of plant signaling and physiology (Jia et al., 2019). Previous reports suggest that exogenous application of inositol could not only alleviate stress but also alter gene expression involved in cell wall biosynthesis, regulation of phytohormones, redox reactions, and chromosome modifications (Chatterjee and Majumder, 2010; Donahue et al., 2010; Ye et al., 2016). In addition, some inositol isoforms (e.g., *myo*-inositol) may act as a strong chelator of metal cations possibly facilitating absorption and transport of nutrients. Given the important role of inositol in cellular functioning, especially its protective functions under biotic and abiotic stresses, surprisingly little is known about exogenous application of inositol in plants such as responses to nutrient availability and effects on mobility.

The development of new techniques that will help improve the efficacy of foliar applied nutrients by enhancing the absorption, translocation, and its utilization by plants with the ultimate goal of improving the quality and yields of crops is mandatory. Due to its capacity to potentially facilitate ion transmembrane transport, we hypothesize that *myo*-inositol applied in combination with Zn may increase its absorption, transport, and accumulation in plant tissues. Here, our goal was to provide comprehensive information on the mobility and distribution of foliar applied zinc, with or without *myo*-inositol, in wheat leaves and its accumulation and localization in grains using X-ray fluorescence

(XRF) synchrotron-based techniques which represents a powerful tool for characterizing *in vivo* nutrient mobility and distribution in plants.

MATERIALS AND METHODS

Plant Culture

Sterilized wheat seeds (*Triticum aestivum* L., cv. Patwin 515) were soaked in deionized water for 24 h and then germinated in containers filled with a soil mixture containing (% of volume) 40% peat, 35% silica clay, 20% perlite, and 5% gravel. 10-day-old seedlings of uniform height were transplanted into each 5L pot, one plant per pot, and the pots were transferred to a controlled environment greenhouse with day/night temperature of 25/20°C and day/night humidity of 70/85%. Lighting was provided by LED grow lights with 16-h day length. Plants were watered as needed with a nutrient solution [1.2 mM KNO₃, 0.8 mM Ca(NO₃)₂, 0.8 mM NH₄NO₃, 0.3 mM KH₂PO₄, and 0.2 mM MgSO₄, 12 μM Fe-EDTA, 0.25 μM Na₂B₈O₁₃·4H₂O, 1.5 μM MnSO₄, 0.25 μM ZnSO₄, 0.5 μM CuSO₄, and 0.04 μM Na₂MoO₄]. Each treatment and analyses were conducted in four biological replicates.

Foliar Treatments

During stem elongation (flag leaf ligule and collar visible) plants were treated with the following treatments: water sprayed control (no added Zn, “-Zn-CK”), zinc sulfate control (added Zn, “+Zn-CK”), *myo*-inositol (no added Zn, “-Zn+Ino”), and *myo*-inositol plus zinc sulfate (added Zn, “+Zn+Ino”). ZnSO₄ was applied at the final concentration of 250 mg L⁻¹, and *myo*-inositol was applied at the concentration of 0.25% v/v. The selected concentration was based on previous experiments (data not shown). *Myo*-inositol was selected due to its capacity to potentially facilitate ion transmembrane transport. The treatments were applied to the leaves of wheat 8 h before darkness (10 a.m.). The soil was covered to prevent inadvertent spray drift. Foliar application was repeated 15 days after initial application. To avoid the possibility that the effect of the foliar spray was a consequence of alleviation of secondary nutrient deficiency, all plants were grown with continuous and abundant soil nutrient.

Elemental Analysis

At plant maturity, shoot and grains were collected and prepared for elemental analysis. The wheat grains were removed from panicles and dehusked, and several dehusked grains were set aside for X-ray fluorescence (XRF) imaging. Leaves and grains were oven-dried at 65°C for 72 h and ground using a stainless-steel mill (0.2-mm screen). Ground, dry plant samples (0.1 g) were digested with concentrated trace-metal grade (TMG) HNO₃. Total concentrations of elements (i.e., Zn, Fe, Cu, and Mn) in the filtrates were analyzed using inductively coupled plasma mass spectroscopy (ICP-MS; Agilent 7500a, United States). Standard Reference Material (SRM) Tomato Leaves (NIST 1573a) were used to verify the results and gave excellent recoveries for all the elements of interest (≥94%).

Elemental Mapping

μ -X-Ray Fluorescence Sample Preparation

Mid-sections of leaves were obtained from plants treated with different foliar treatments. Leaf cross-sections (30 μm) were sectioned with a cryotome (LEICA, CM1850) at a temperature of -20°C . Single sections of each treatment were selected under light microscopy for their ultrastructural integrity and then freeze-dried under -20°C for 3 days prior to XRF analysis. The dehusked grains were set in epoxy (EPO-TEK 301-2FL) resin, cured, and cut into thin sections.

μ -X-Ray Fluorescence Analyses

X-ray fluorescence imaging of the grain and leaf thin sections was conducted at the Stanford Synchrotron Radiation Laboratory (SSRL) at beam lines 10-2 and 2-3. Experiments at Beam Line 10-2 were recorded at 10500 eV, using a 20 μm (H) \times 20 μm (V) beam spot size, a 20 μm \times 20 μm pixel size, and 200 ms dwell time per pixel. The incident X-ray beam of 2 μm at beam line 2-3 was focused using a pair of Kirkpatrick-Baez mirrors, and the incident beam was monochromatized using a Si(111) double-crystal monochromator. Micro-XRF maps were obtained by rastering the beam at 5 μm steps, with a count time of 100 ms per step. Fluorescence intensities of P, S, Cl, K, Ca, Mn, Fe, Ni, Cu, and Zn were monitored. Fluorescence signal intensities for Zn and any other elements were calculated with SMAK (Sam's Microprobe Analysis Kit, Version 1.5).

Experimental Design and Statistical Analysis

The experimental design was a randomized complete design with a full factorial structure. Each treatment and analyses were conducted in four biological replicates. Analysis of variance (ANOVA) was performed with SigmaPlot (Systat Software, Inc., Version 14.0). If significant differences ($P < 0.05$) were identified, a Tukey test was used to distinguish differences between the groups.

RESULTS

Grain Yield and Plant Biomass

Plant biomass and yield were determined at full plant maturity (Figure 1). Treatments did not significantly affect plant biomass (i.e., straw) or yield (i.e., whole grain mass) however the use of *myo*-inositol increased grain yield on average by up to 15% compared to -Zn-CK.

Total Zn Concentration in Shoots and Grains

All treatments affected shoot zinc concentrations (Figure 2). Shoot Zn concentrations ranged from 15.2 to 53.1 mg kg^{-1} and were significantly affected by both Zn treatments, with +Zn+Ino treated plants having significantly more zinc than the non-treated control (-Zn-CK) by nearly fourfold and significantly increasing shoot Zn by 13 mg kg^{-1} approximately 40% in contrast to +Zn-Ino treatments. Total zinc concentrations in shoots were lowest

for the control and *myo*-inositol treated plants, while shoot zinc in plants treated with zinc alone or applied with *myo*-inositol was significantly higher ($p = 0.001$).

Similar, though smaller trends were observed in the grains where Zn-treated plants both with and without *myo*-inositol had increased zinc concentration compared with non-treated control (Figure 2). In the absence of added zinc, *myo*-inositol had no effect on grain zinc levels, with the addition of both *myo*-inositol and Zn grain zinc levels increased by 20 ppm ($p < 0.05$). Zinc values in unpolished grains ranged from 55.5 to 75.6 mg kg^{-1} for -Zn-CK and +Zn+Ino treatments, respectively. On average, Zn treated plants increased zinc in grains by 5–25% with +Zn+Ino significantly increasing grain zinc concentration compared to both Zn-treated ($p = 0.018$) and non-treated controls ($p = 0.003$).

Distribution Patterns of Zinc in Leaf and Grain of Wheat Plants

Micro-XRF mapping was performed to investigate the effects of different foliar applied Zn and *myo*-inositol treatments on the distribution and localization of zinc in leaves of wheat at full plant maturity. The cross sections of wheat leaves are composed of upper and lower epidermis, parenchyma, and vascular tissue (xylem and phloem). Spatial imaging of zinc was also performed on cross-sections of unpolished wheat grains collected during plant harvest. The cross sections of unpolished wheat grains are composed of bran layer, endosperm, and germ. The normalized XRF intensities of each map indicates the relative distribution for each individual element.

X-ray fluorescence images showed that wheat leaves exhibited differential zinc distribution on plant tissue with a higher degree of distribution to the mesophyll and vascular tissues (Figure 3). When adjusted to the same relative scale, the zinc distribution on the +Zn-CK and +Zn+Ino treated plants was much more extensive and higher in fluorescence intensity than on the -Zn-CK and -Zn+Ino treated plants with +Zn+Ino treated plants showing a higher intensity when compared to +Zn-CK treated plants. This finding corroborates with the ICP-MS data (Figure 2), suggesting that *myo*-inositol applied *via* foliar spray in combination with Zn may facilitate solute movement into plant cells.

Images obtained from a longitudinal cross-section of wheat grains show the distribution of zinc (Figure 4). In -Zn-CK and -Zn+Ino treatments, zinc was distributed in highest concentration in the bran layer and germ, with a very small concentration present in the endosperm. For +Zn-CK and +Zn+Ino treated plants, zinc was also present in highest concentration in the bran layer and germ, but exhibited an increased concentration in the endosperm, with +Zn+Ino showing an enhanced and uniform distribution of zinc throughout the grain. Furthermore, intensity analysis across a single scan line through the grain confirmed that the peak of Zn intensities in the bran layer, endosperm, and germ was noticeably increased in the +Zn+Ino treatment.

FIGURE 1 | Grain yield (A) and plant biomass (B) of wheat treated with different foliar fertilizers. Data points and error bars represent means and SE of four replicates. Different letters denote significant differences ($p < 0.05$, $n = 4$).

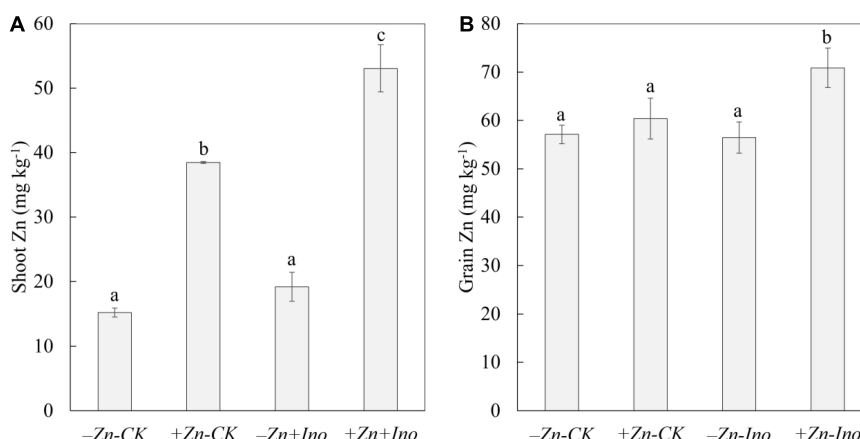

FIGURE 2 | Zinc (Zn) concentrations in shoots (A) and grains (B) of wheat plants treated with different foliar fertilizers. Data points and error bars represent means and SE of four replicates. Different letters denote significant differences ($p < 0.05$, $n = 4$).

All treatments showed the same pattern of distribution for other plant nutrients (data not shown). Iron, manganese, and copper follow a similar allocation pattern as zinc. Calcium was distributed throughout the grain with highest levels in the germ and bran layer, and lowest in the endosperm. Potassium and phosphorus follow a similar distribution pattern as calcium, with potassium being more abundant in the endosperm.

Plant Nutrients

Of the other plant nutrients analyzed (i.e., Fe, Mn, and Cu), none were significantly affected by the treatments compared to the -Zn-CK suggesting that foliar application of Zn and myo-inositol, alone or in combination, may increase total grain zinc in wheat without negatively affecting grain Fe, Mn, or Cu (Figure 5).

In the shoots, +Zn-CK treatment increased the concentration of Mn (155.9 mg kg⁻¹) and Cu (4.5 mg kg⁻¹), and slightly decreased Fe (21.7 mg kg⁻¹) concentration compared to the -Zn-CK (Mn: 148.8 mg kg⁻¹; Cu: 3.8 mg kg⁻¹, and Fe: 24.6 mg

kg⁻¹). -Zn+Ino also enhanced Mn (151.9 mg kg⁻¹) and Cu (3.9 mg kg⁻¹), and reduced Fe concentration (18.3 mg kg⁻¹). +Zn+Ino increased Mn concentration by 13% (168.5 mg kg⁻¹) and Cu by 15% (4.4 mg kg⁻¹) but did not affect Fe concentration (23.7 mg kg⁻¹).

In grains, +Zn-CK, -Zn+Ino, and +Zn+Ino decreased Mn concentration by 5% (71.2 mg kg⁻¹), 10% (68.0 mg kg⁻¹), and 4% (72.4 mg kg⁻¹), respectively, compared to the -Zn-CK (75.4 mg kg⁻¹). Fe and Cu concentration in -Zn-CK, +Zn-CK, -Zn+Ino, and +Zn+Ino treatments were consistent showing concentrations of 57.7 and 10.1 mg kg⁻¹, 56.1 and 9.3 mg kg⁻¹, 50.8 and 9.4 mg kg⁻¹, and 61.4 and 10.0 mg kg⁻¹, respectively.

DISCUSSION

Zinc sulfate (ZnSO₄) and Zn-EDTA are two common forms of foliar-applied Zn fertilizers (White and Broadley, 2009, 2011). However, low or limited mobility of zinc in leaves when applied

FIGURE 3 | Microscope cross section (A) and μ -XRF elemental maps (B–E) for Zn (red), Fe (green), and Mn (blue) of wheat leaf treated with different foliar fertilizers: –Zn-CK (B), +Zn-CK (C), –Zn+Ino (D), and +Zn+Ino (E). Pixel brightness for μ -XRF map (B–E) is displayed in RGB, with the brightest spots corresponding to the highest elemental fluorescence. Scale bar: 200 μ m. $n = 4$, representative images shown.

FIGURE 4 | Micro X-ray fluorescence (μ -XRF) elemental maps for Zn of grains collected from wheat plants subject to different foliar fertilizers: –Zn-CK (A), +Zn-CK (B), –Zn+Ino (C), and +Zn+Ino (D). Pixel brightness for μ -XRF maps (A–D) is displayed in RGB, with the brightest spots corresponding to the highest elemental fluorescence. Scale bar: 400 μ m. $n = 4$, representative images shown.

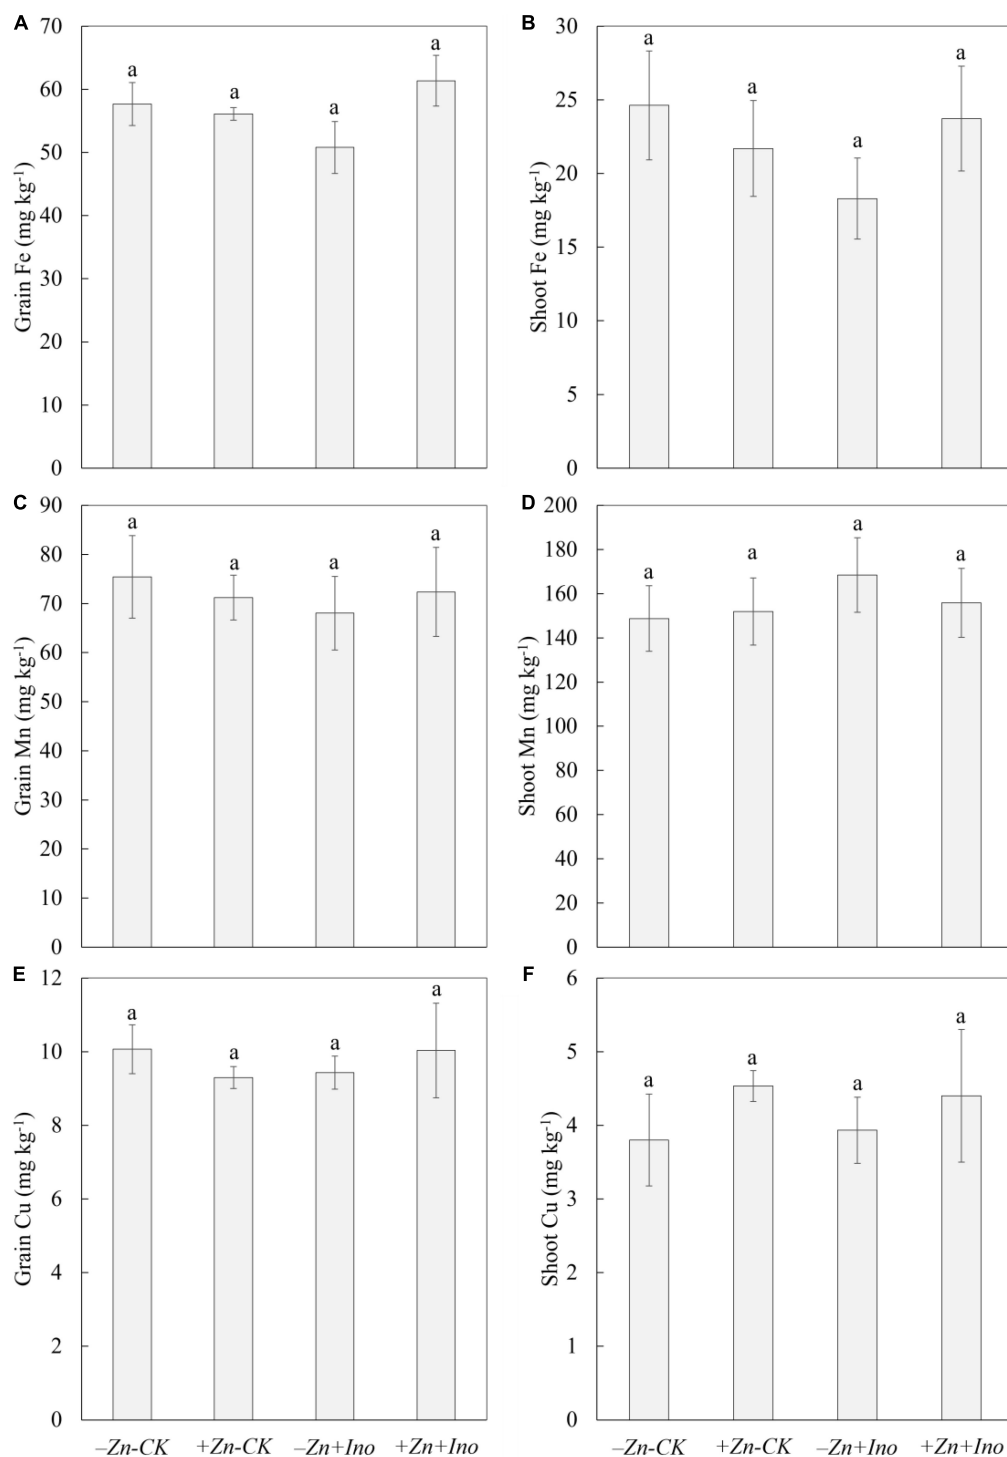

FIGURE 5 | Concentrations of Fe (A,B), Mn (C,D), and Cu (E,F) in leaves and grains of wheat plants treated with different foliar fertilizers. Data points and error bars represent means and SE of four replicates ($p < 0.05$, $n = 4$).

in the form of SO_4 (Tian et al., 2015) or chelated with EDTA (Doolette et al., 2018) has been reported. To improve the efficacy of foliar applied Zn, we focused on developing new strategies aiming to increase Zn transport from leaf surface to

phloem-fed tissues and subsequently improving its transport and accumulation in grains.

Results from the present study showed clearly increased accumulation of Zn in both leaf and grains of wheat after

the application of ZnSO_4 in combination with *myo*-inositol, while ZnSO_4 applied alone increased shoot Zn significantly but had only slightly increased Zn distribution and accumulation in grains (Figures 2–4). *Myo*-inositol applied alone slightly increased shoot Zn concentrations (Figure 2A) suggesting this product may also influence root Zn uptake or Zn transport of previously acquired Zn, this effect is being examined in separate experiments. The significant positive effect of +Zn+Ino on shoot (Figure 2A) and grain (Figure 2B) Zn concentrations and changes within organ Zn distribution suggests *myo*-inositol may alter both Zn penetration into the shoot tissue and the subsequent intercellular mobility of acquired Zn. While Zn has been reported as having a poor leaf penetration and low mobility in the phloem (White and Broadley, 2011), this study showed evidence that *myo*-inositol may improve Zn mobility in the plant tissue (Figure 3) resulting in greater phloem Zn transport, and higher grain Zn concentrations (Figure 4) than ZnSO_4 alone.

The role of inositol in plant metabolism is uncertain. Inositol may function in various plant signaling pathways, such as energy homeostasis, phosphate sensing, and immune responses (Williams et al., 2015). However, its existence and function in plants is newly emerging and little is known about its use as a plant stimulant. Inositol has been proposed to be an important component for stomatal regulation in plants as it is implicated in abscisic acid-mediated signaling (Perera et al., 2008). Recently, (Hu et al., 2018) showed that exogenous application of *myo*-inositol not only improved the photosynthetic activity and plant growth in *Malus hupehensis* plants, but also up-regulated stomatal apertures allowing those plants to modulate transpirational water losses and the uptake of CO_2 . While the mechanisms of absorption of solutes through the stomata are not very well understood (Fernández and Brown, 2013), it can be highly significant as the number of stomata contributing to uptake proved to be highly variable in the leaf surface (Eichert et al., 2008). For example, in *Vicia faba*, exogenously administered phosphatidyl-inositol induced stomatal opening and swelling in guard cell protoplasts (Lee et al., 2007). Thus, by up-regulating stomatal apertures, *myo*-inositol application may result in an improved distribution of permeability on the leaf surface possibly enhancing the diffusion of solutes into the stomatal pores. Li et al. (2019) studying the pathways in which foliar-applied ZnSO_4 moves through the sunflower leaf surface, considering the potential importance of the cuticle, stomata and trichomes, demonstrated that there is no indication that the stomata played a major role in the foliar absorption of ZnSO_4 . This corroborates our hypothesis where ZnSO_4 applied alone increased Zn in plant tissue only by twofold, while *myo*-inositol applied in combination with ZnSO_4 in the same concentration (250 mg L^{-1}) enhanced plant Zn by nearly fourfold compared to the control, possibly by modulating stomatal opening and increasing Zn absorption by the leaf.

An oxidized form of inositol is also the most common and important sugar implicated in polysaccharide synthesis for cell walls (Loewus and Murthy, 2000; Cui et al., 2013). In addition to cell wall biosynthesis, inositol and its derivatives provide components for other vital pathways such as, but not limited to,

biotic and abiotic stress response, plant growth and development, signaling transduction, and substrate transportation (Ye et al., 2016). Some recent studies have reported the benefits of non-foliar applied *myo*-inositol in plants under different conditions (Liu et al., 2006; Lee et al., 2007; Perera et al., 2008; Zhai et al., 2016; Belgaroui et al., 2018; Mukherjee et al., 2019). For example, in apple rootstock *Malus hupehensis*, root-applied *myo*-inositol alleviates salt-induced inhibition of growth not only acting in antioxidant defenses, but also mediating Na^+ and K^+ homeostasis and the osmotic balance (Hu et al., 2018). In contrast, very little is known regarding foliar application of *myo*-inositol and its possible benefits in plants. It has been reported that Zn is coordinated to P as Zn-Phytic acid (inositol-6-phosphate), which is composed of six Pi molecules linked to a *myo*-inositol, in roots and in leaves of *Arabidopsis lyrata* (Sarret et al., 2003; Bouain et al., 2014). According to Bouain et al. (2014), the occurrence of co-regulation of Pi–Zn nutrition in cells of intact plants may impact both P and Zn uptake and transport within a plant body. When exposed to a combination of ZnSO_4 and *myo*-inositol, wheat plants showed an increased accumulation of Zn in both shoots and grains. We speculated that the increased Zn concentration in response to *myo*-inositol application might be a gene-mediated response strategy related to ion transmembrane transport, leading to absorption of Zn as it has recently been shown that exogenous *myo*-inositol could alter gene expression and signaling transduction in plant cells (Ye et al., 2016). Furthermore, several genes related to substance transport in response to *myo*-inositol application were identified suggesting that *myo*-inositol might act as a regulator mediating the transportation of carbohydrates and other substances. However, no further evidence on its implication in the regulation of Zn transport and/or signaling has been discovered. Therefore, further research should focus on the role of *myo*-inositol in co-regulating Zn transport and signaling crosstalk.

On the basis of existing knowledge of inositol function in plants we propose two main mechanisms to explain the increased plant Zn accumulation and transport due to *myo*-inositol application (1) *myo*-inositol may have changed plant stomatal regulation and increased Zn absorption by wheat leaves; and (2) *myo*-inositol may have changed cell permeability by gene-mediated response strategy related to ion transmembrane transport, facilitating Zn absorption by the leaf. To our understanding, this is the first study utilizing μ -XRF to show visual evidence for the *in situ* investigation of Zn in wheat leaves and grains after foliar application of *myo*-inositol. We found that *myo*-inositol significantly affected Zn transport and distribution in leaf and grains of wheat. Additionally, *myo*-inositol treated plants increased plant yield by 5–15% compared to the controls. The results suggested that *myo*-inositol could affect the physiological status of plant cells and might also influence the mobility of Zn in the plant tissue. The observations above introduce many important points considering the form in which foliar applied Zn penetrates the leaf and how Zn is redistributed in leaf tissue when applied in combination with *myo*-inositol. While further research is required to better understand the specific absorption or uptake pathway of different foliar Zn fertilizers and/or plant stimulants, the results show

evidence that *myo*-inositol may improve the efficiency of foliar-applied ZnSO₄.

CONCLUSION

The diet of much of the world's population is based on cereals such as wheat that contain insufficient amounts of numerous nutrients (e.g., Zn, Fe, Cu, and Mn) to meet daily needs. Our results showed that foliar application of *myo*-inositol in combination with Zn may be a promising strategy to increase the absorption and mobility of Zn in the plant tissue and subsequently to enhance Zn accumulation in grains without affecting other essential metals such as Fe, Mn and Cu or decreasing grain yield. Further research is needed to clarify the mechanisms by which *myo*-inositol affects plant metabolism and to identify stimulant properties that can considerably increase grain micronutrients under a wide range of field conditions to maximize plant response to foliar applications.

(2022) A Meta-Analysis of Biostimulant
Yield Effectiveness in Field Trials.
Front. Plant Sci. 13:836702.
doi: 10.3389/fpls.2022.836702

Today's agriculture faces many concerns in maintaining crop yield while adapting to climate change and transitioning to more sustainable cultivation practices. The application of plant biostimulants (PBs) is one of the methods that step forward to address these challenges. The advantages of PBs have been reported numerous times. Yet, there is a general lack of quantitative assessment of the overall impact of PBs on crop production. Here we report a comprehensive meta-analysis on biostimulants (focus on non-microbial PBs) of over one thousand pairs of open-field data in a total of 180 qualified studies worldwide. Yield gains in open-field cultivation upon biostimulant application were compared across different parameters: biostimulant category, application method, crop species, climate condition, and soil property. The overall results showed that (1) the add-on yield benefit among all biostimulant categories is on average 17.9% and reached the highest potential via soil treatment; (2) biostimulant applied in arid climates and vegetable cultivation had the highest impact on crop yield; and (3) biostimulants were more efficient in low soil organic matter content, non-neutral, saline, nutrient-insufficient, and sandy soils. This systematic review provides general biostimulant application guidelines and gives consultants and growers insights into achieving an optimal benefit from biostimulant application.

Keywords: meta-analysis, biostimulant, crop yield, sustainable agriculture, open-field trial, climate, soil quality

INTRODUCTION

By 2050, the risk of hunger is predicted to rise by 30% due to climate change and the expected population increase (Van Dijk et al., 2021). To meet future food production requirements, the impact of climate change on crop production needs to be addressed. How we will achieve this ambitious goal is currently debated. Various conventional (e.g., fertilization) and novel bioengineering strategies (e.g., genetically modified crops) are extensively developed to boost crop production and ensure food security and safety (Bailey-Serres et al., 2019). As a general consensus is emerging synthetic fertilizers that cause environmental threats to the local and global ecosystems (Koli et al., 2019), plant biostimulants (PBs) are potentially a tool to mitigate climate change-induced stress and reduce the dependency on chemical fertilizers (Hunter et al., 2017). The European Commission aims to replace 30% of chemical fertilizers with bio-based alternatives by 2050 (Hansen, 2018). The application of PBs, is a more sustainable agricultural practice to preserve crop yield under reduced fertilizer conditions (Gupta et al., 2020). The global market value of PBs is expected to reach USD 3 billion in 2021, with a cumulative annual growth rate (CAGR) of about 13% until 2025 (EBIC, 2021). Nevertheless, there is no clear view of how efficient PBs really are.

The European Commission has categorized PBs under the framework of fertilizing products [Regulation (EU) 2019/1009, 2019]. Briefly, it states that PBs are products that stimulate plant growth and improve one or more additional functions: nutrient use efficiency, abiotic stress tolerance, crop quality traits, and availability of confined nutrients in the soil or plant rhizosphere. Furthermore, Regulation (EU) 2019/1009 cataloged two distinct categories based on whether the stimulatory bioactivity is of microbial or non-microbial origin, and this may require an even more refined classification (Rouphael and Colla, 2020). Within the most accepted subcategories, microbial PBs consist of arbuscular mycorrhizal fungi (AMF) and plant growth-promoting rhizobacteria (PGPR) (Rouphael and Colla, 2020). Commonly, 6 subcategories of non-microbial PBs are distinguished: chitosan (Chi), humic and fulvic acids (HFA), animal and vegetal protein hydrolysates (PHs), phosphites (Phi), seaweed extracts (SWE), and silicon (Si). More recently, an additional group of PBs that have received much attention are the plant extract-based PBs (PE) (excluding SWE) and are included as a separate class of PBs (Du Jardin, 2015; Bio4Safe, 2021). Aside from these complex mixtures of PBs, products with a single active compound are not included in this review because we consider that the majority of PBs are complex mixtures (Du Jardin, 2015; García-García et al., 2020). The European Biostimulant Industry Council (EBIC) proposed several general principles to regulate and justify the claims made by manufacturers with regards to PBs efficiency (Ricci et al., 2019). A European legal framework for PBs regarding standardization of sampling, denominations, marking, and test methods are currently under development and will be fully released in 2024 (CEN Technical Committees, 2021). Therefore, sufficient high-quality and credible experimental data is required from PBs producers to support the claims of PBs products and provide valuable practical advice for the users. Recently, a biostimulant database was launched for growers, gathering PBs product information, plant trials, and scientific data on crop quality, water nutrient use efficiency, and stress tolerance (Bio4Safe, 2021). However, an overall in-depth evaluation of PBs performance is still missing.

Crop yield enhancement is a popular claim listed in the product description of many PBs (Ricci et al., 2019). As various environmental factors and management practices influence yield performance (Liliane and Charles, 2020), empirical knowledge that depends on different experimental conditions is of critical value for the farmer. Because of the variability in agronomic management and environmental conditions, studies with similar or identical PBs have resulted in different effectiveness data (Schütz et al., 2018). As crop yield is a multi-trait property, meta-analysis has been conducted to gain insight into the impact of soil property (Oldfield et al., 2019), climate change (Challinor et al., 2014), and microbial PBs application (Schütz et al., 2018). Hence, effectiveness remains poorly understood to what extent these variables affect non-microbial PBs (designated as biostimulants in later text).

In this study, we performed a meta-analysis to (1) estimate crop yield improvement by biostimulants, (2) understand the relationship between crop yield and biostimulant application method, and (3) assess the impact of

environmental variables on the performance of biostimulants in open-field cultivation.

Literature Review

Thomson Reuters' Web of Science, Elsevier's Scopus, and Google Scholar were queried until July 2021 for peer-reviewed publications identified using the keywords "biostimulant AND crop AND (yield OR biomass)". Additional studies were also selected based on citations occurring in the selected papers and relevant reviews. Studies were selected for the analyses using five criteria: (1) crop yield data were obtained from open-field trials or walk-in tunnels (open on both sides), excluding pot and greenhouse experiments; (2) marketable crop yield was reported as it represents traceable agro-economic value; (3) the studies contained pairwise comparisons between single biostimulant-treated and corresponding non-treated control plants, using the same application method under the same geo-climatic and crop management; (4) the yield means, their standard deviation (SD), and the number of replications were provided separately; (5) the studies were written in English and available in full text. A total of 1,108 paired observations from 181 empirical studies (**Supplementary Data 1**) were identified after two rounds of screening of titles, abstracts, and full texts analyzed in this study following the PRISMA-P statement (**Supplementary Figure 1**) (Page et al., 2021).

Data Collection

Experimental crop yield data were collected from the original tables or extracted from the attached figures using WebPlotDigitizer (Rohatgi, 2020). The methodology section obtained other information, including the field site location, crop species, soil properties, biostimulant product information, application method, dose, frequency, and whether interannual studies were performed. All data were compiled in one dataset (**Supplementary Data 2**) after conversion to uniform metrics for each variable.

Moderator Variables

Four main groups of moderator variables were considered to investigate further potential crop yield effectors, including experimental-, plant-, climate-, and soil-related parameters. **Table 1** shows the classifications of all categorical moderators.

Biostimulant Categories and Methods of Application

The classification of biostimulants was based on the main bioactive substances: Chi, HFA, PHs, Phi, SWE, Si, and PE (Du Jardin, 2015; Rouphael and Colla, 2020). Detailed information about the available natural resources and the major bioactive compounds of these biostimulants are shown in **Supplementary Table 1**. Moringa leaf extract (MLE) was separated as a subgroup of interest, and the rest were other PE under the PE group.

The application methods are specified as foliar, soil, and seed treatment. Direct biostimulant application in the soil and introduction *via* irrigation water were considered soil treatments.

TABLE 1 | The description of classifications involved in categorical moderators.

Categorical moderators	Classifications involved
Climate categories ^a	A (Af, Am, As, Aw); B (BWk, BWh, BSk, BSh); C (Cfa, Cfb, Csa, Csb, Cwa); D (Dfa, Dfb, Dfc, Dsa).
Crop species in categories	Cereals (wheat, maize, oat, barley, rice, quinoa); Fruits (including nuts) (grape, mango, apricot, cherry, plum, mandarin, blueberry, apple, strawberry, pear, pistachio nut, papaya, citrus, sugarcane); Legumes (soybean, faba bean, black gram, common bean, pea, cowpea, mung bean, snap bean); Others (fennel, berseem clover, cardoon, dragonhead, geranium, sesame, lemon, hyssop, grass mixture, ryegrass, timothy, alfalfa, cotton, basil, honeysuckle, rape, vetch, chamomile, olive, zinnia, sugar beet, niger, milk thistle, meadow, mint, red clover); Root/tuber crops (potato); Vegetables (eggplant, rocket, tomato, okra, sweet pepper, onion, pepper, lettuce, garlic, broccoli, carrot, endive, cabbage, spinach, cucumber, celery).
Degree of soil pH	Strongly acid (5.1–5.5); Moderately acid (5.6–6.0); Slightly acid (6.1–6.5); Neutral (6.6–7.3); Moderately alkaline (7.9–8.4); Strongly alkaline (8.5–9.0).
Degree of soil salinity by ECe (dS/m)	Nonsaline (0–2.0); Slightly saline (2.1–4.0); Moderately saline (4.1–8.0); Strongly saline (>8.1).
Soil P Levels (ppm)	Very low (<16); Low (16–25); Medium (26–35); Optimal (>36).
Soil K levels (ppm)	Very low (<61); Low (61–60); Medium (91–130); Optimal (>131).

^aAccording to Köppen-Geiger climate classification (Peel et al., 2007) on main climates, A, equatorial; B, arid; C, warm temperate; D, snow; on precipitation: W, desert; S, steppe; f, fully humid; s, summer dry; w, winter dry; m, monsoonal; on temperature: h, hot arid; k, cold arid; a, hot summer; b, warm summer; c, cool summer.

Biostimulant application frequency indicates the total number of foliar applications, where “0” indicates continuous treatment with a specific time interval. The biostimulant application dose was only defined within dose-response studies, where “1” was used for the highest biostimulant concentration, “0” for non-treated conditions, and the other doses were expressed as corresponding relative concentrations. For interannual studies, annual crop cultivation was labeled as “0” while the rest of continuous crop production was marked as the order of successive years.

Crop Categories and Environmental Parameters

Cultivated crop species were grouped into 6 main crop categories (cereals, vegetables, fruits, legumes, root/tuber crops, and other crops) following the Food and Agriculture Organization of the United Nations (FAO) classification of agricultural crops (FAO, 2005). In addition, sugar crops (sugar cane and sugar beet), medicinal plants (e.g., cardoon, zinnia, and basil), oilseed crops (rapeseed and olive), grasses (e.g., alfalfa, ryegrass, and timothy), spice crops (cinnamon and fennel), and fiber crops (cotton) were added to the “other crops” class due to the limited number of relevant studies.

The locations, including city and country names, were converted to latitude and longitude with decimal degree coordinates. Next, the climate zone was categorized according to the Köppen-Geiger climate classification (Peel et al., 2007) using R software version 4.0.2 (R Core Team, 2020) equipped with package “kge” version 1.0.0.2 (Bryant et al., 2017). Finally, the geographical map of the identified studies was visualized using ArcMap (Esri, 2020). Four main climates (equatorial, arid, warm temperate, and boreal) and six subclasses (desert, steppe, monsoonal, summer dry, winter dry, and fully humid) are determined by vegetation and temperature and precipitation, were covered in this study. As regular irrigation was commonly applied during cultivation, studies with artificial drought stress experiments were excluded.

For soil physicochemical properties, soil texture was assigned to 12 classes according to the fractions of clay, silt, and sand

particles in the topsoil (0–30 cm), as described by the soil texture triangle (Soil Science Division Staff, 1993). Soil acidity and alkalinity, a measure for soil reaction, were expressed as soil pH measured in water or converted in CaCl₂ or KCl (Land Resources Management Unit Commission, 2010). The soil pH levels ranged from 3.5 to 8.4 and were split into six groups (strongly acid, moderately acid, slightly acid, neutral, moderately alkaline, and strongly alkaline) triangle (Soil Science Division Staff, 1993). Electrical conductivity (EC) of soil standard saturated paste extract (ECe), a measure for soil salinity, was represented as the standard EC, and EC measured in soil-water extracts were converted (Kargas et al., 2018). The degree of soil salinity was allocated into five levels (non-saline, slightly saline, moderately saline, and strongly saline) for all soils (Smith and Doran, 1997). The soil organic matter (SOM) was considered a critical indicator of soil health (Soil Health Institute, 2018). SOM was transposed from available soil organic carbon (SOC), which assumedly contributed to 58% of the mass of SOM (Edwards, 2021). Soil total nitrogen (N) indicates the percentage of organic and inorganic N forms (Marx et al., 1996). Furthermore, soil available nutrients for plant uptake are associated with three macronutrients, N, phosphorus (P), and potassium (K) content (ppm concentrations), where soil available N content (ppm) only includes plant-available nitrate- and ammonium-N (Horneck et al., 2011). For easier understanding in agronomy guide, soil fertility was interpreted to four levels (very low, low, medium, and optimal) based on available P and K concentrations and the expected yield potential without fertilization for most agronomic crops (Snyder et al., 1993).

Missing Values

If the studies only provided the dry biomass, the fresh weight was computed according to the calculated water contents (Spungen, 2005). When outcome errors were unavailable in the original text, the SD was estimated in percentage based on the mean SD of the existing studies per crop category (Schütz et al., 2018). The estimated SD for cereals was 4.25%, legumes 13.4%, root/tuber crops 9.51%, vegetables 9.67%, fruits 16.5%, and for

other crops (grasses and medical plants 8.84%, sugar crops 1.55%, oilseed crops 8.92%). Thus, more importantly, the availability of complete raw datasets combined with other descriptive records of trial-related conditions is critical for proper statistical analysis and justifying biostimulant claims of manufacturers (Ricci et al., 2019).

Data Analysis

The primary outcome of crop yield was defined as the fresh weight ($\text{kg}\cdot\text{m}^{-2}$) of marketable product, in the case of cereals, the seed or grain yield, shoot biomass for most vegetables or other crops, fruit yield for fruits, and tuber yield for root/tuber crops. The yield response (%) to biostimulant application was calculated using the Equation (1),

$$\text{Yield response (\%)} = \frac{\text{Yield}_{\text{with biostimulant}}}{\text{Yield}_{\text{without biostimulant}}} \times 100\% \quad (1)$$

where “Yield_{with biostimulant}” is the crop yield after treatment with a single biostimulant product and “Yield_{without biostimulant}” is the crop yield under non-treated control conditions. A meta-analysis was conducted in R with package “metafor” version 3.0-2 (Viechtbauer, 2010). First, the effect size was calculated with log-transformed ratios of the means and confidence intervals (CI) of each means, with yield response as the main outcome. The variables were assigned according to the major influencing factors of crop production. Next, random-effect models (RE) were fitted with categorical moderators using the restricted maximum-likelihood (REML) estimator method. For categorical moderators, forest plots were applied to visualize the meta-analyses. On the other hand, linear meta-regression analysis on continuous variables was conducted by fitting mixed-effect models (ME). The ME performance was evaluated by R^2 for variance explained (Nakagawa and Schielzeth, 2013). We also investigated the between-study heterogeneity by determining I^2 of each model (Inthout et al., 2016). To further explore the causes of heterogeneity, influence diagnostics was applied to remove outlier cases with large DFBETAS (indicating the change of SDs after study exclusion from model fitting). As a result, twenty-one of the 1,108 studies were removed. Additionally, to eliminate the systematic publication bias in meta-analysis, we evaluated the comprehensiveness of collected data by assessing the asymmetry of the funnel plot with the “regtest” function. Since the asymmetry test was not significant ($p > 0.05$) (Supplementary Figure 2), we thus addressed no issues on publication bias in our dataset and included all the data for this study.

RESULTS

Following a literature survey and selection using the quality criteria described previously, 1,087 paired observations in 180 studies were retained for data extraction and comparison. Most of these studies were performed in the Eurasian and Mediterranean regions under arid and warm temperate climates. The smaller subsection of studies was from the Americas and Southeast Asia, and a single study was conducted in Southern Africa and one in Australia (Figure 1).

PE Is the Most Efficient Biostimulant

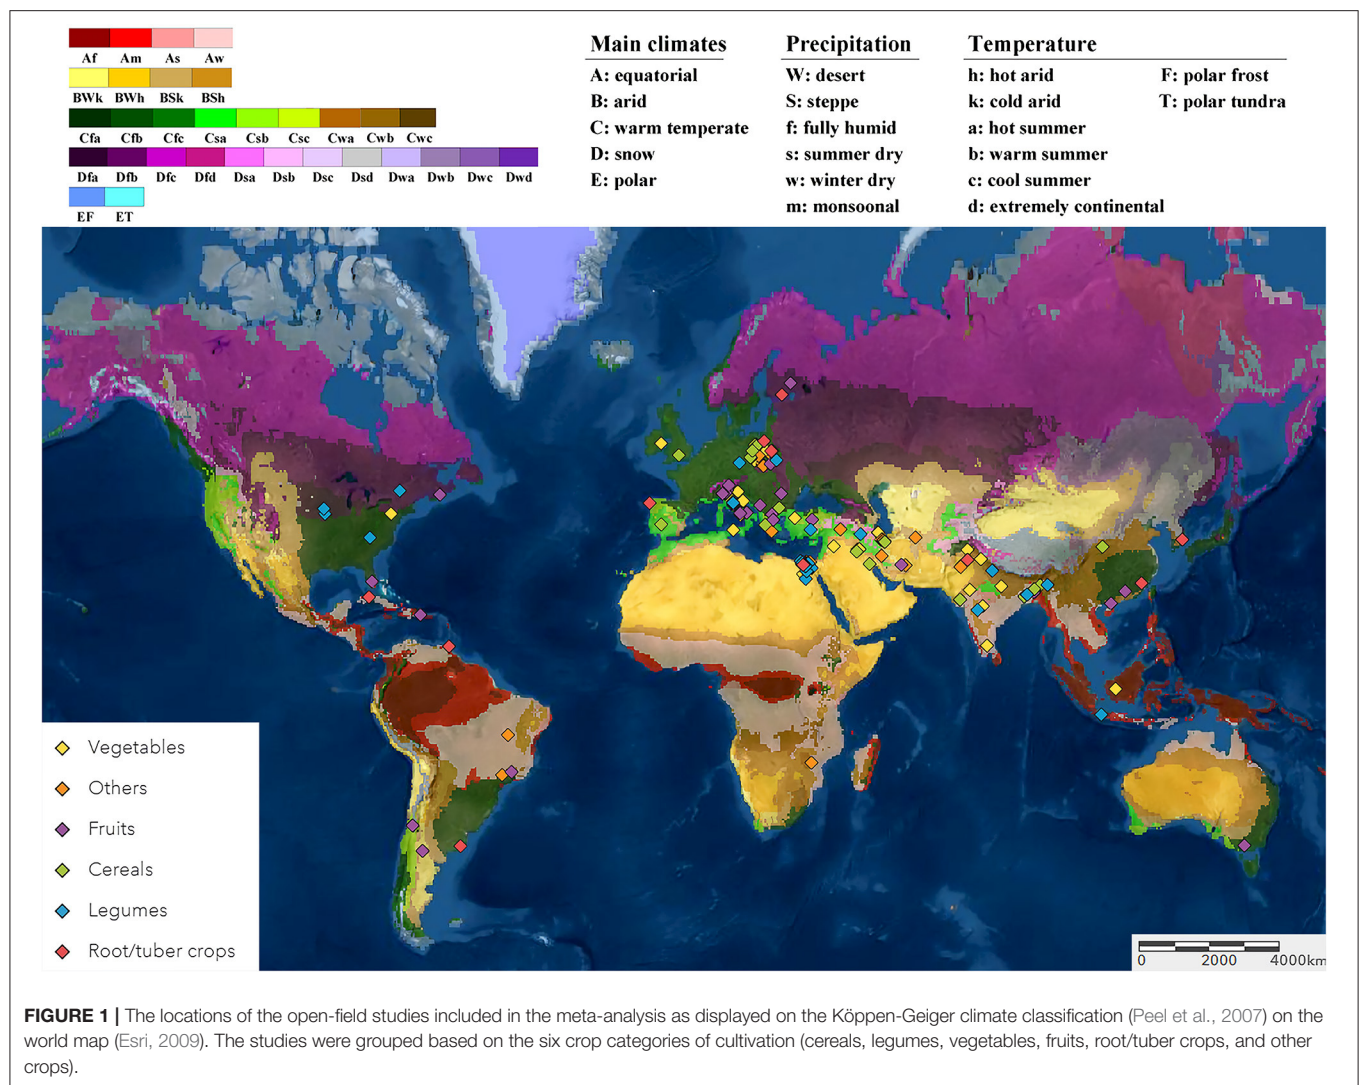

The average yield increases induced by reported biostimulant applications in open-field varied between 8.5 and 30.8% between the category (Figure 2). The overall average in crop yield response was 17.9% (CI 16.7–19.0%). The best performing category was PE, with a yield increase of 26.6% (CI 23.1–30.1%). Amongst MLE showed the highest improvement (+30.8%; CI 26.1–35.6%) while other PE (+22.3%; CI 17.2–27.3%). The biostimulant group with the lowest yield enhancement was Phi (+8.6%; CI 4.6–12.5%), and it was derived from the smallest dataset with 18 comparisons from three studies. The other four biostimulant categories, Chi, HFA, PHs, and SWE, showed an intermediate increase of 14.8–17.1%. Regarding the impact of the commercial status of biostimulants, non-marketed biostimulants tended to represent a stronger yield enhancement effect (+21.8%; CI 20.0–23.5%) than commercially purchased products (+14.4%; CI 12.7–16.0%). For SWE, commercial or non-commercial sources resulted in a similar yield increase of about 16.5–18.0%. The variation in results was the largest for Si, while SWE showed the most consistent yield increase.

Yield Effectiveness Affected by Biostimulant Application Method

Since the application methodology is an important efficacy determinant, the yield increase across different application methods (foliar, seed, and soil) and associated variables (frequency, dose, and interannual application) were compared (Figure 3). An unexpected result was that soil treatment, an indirect application method, resulted in the most substantial yield increase (+28.8%; CI 24.0–33.6%). Foliar treatments, representing over 85% of the studies, and seed application were similar in an average yield increase of about 17.0% (Figure 3A). In several studies, different dilutions of the biostimulant were tested. Here, we set the highest dose to “1” and calculated the effectiveness of dose responses (Figure 3B). The positive yield effect increased with higher doses, as was expected. However, the regression slope was very shallow, indicating that the doses applied were, in general, close to the saturation level. Single spray applications resulted in a comparably stronger yield increment (+14.9%; CI 12.3–17.6%) with subsequent sprayings of up to four times, resulting in only a slight further increase in yield reaching 16.6–18.6% (Figure 3C). More frequent spraying was counterproductive, with lower yield benefits between 11.3 and 14.3%. When comparing the use of biostimulant within annual or continuous crop production studies, a slightly higher yield improvement in the first 2 years of interannual cultivation was observed (~18.3–20.4%) rather than the single growth season (+16.7%; CI 15.0–18.4%) (Figure 3D). However, the efficiency of biostimulant application decreased in the third year (+12.9%; CI 10.6–15.3%) in interannual studies.

Vegetables Respond the Most to Yield Improvement

The effectiveness of biostimulant application was compared across different crop types: cereals, fruits, legumes, root/tubers, vegetables, and other crops (Figure 4). A sound comparison was

possible because the number of studies was similar across the different crop types. Vegetable crops showed the highest and roots/tubers the lowest yield benefit, differing by more than two-fold (+22.8% compared to +10.6%). Legumes were significantly better at responding to biostimulant applications than fruits, cereals, and other crops.

Yield Effectiveness Varied in Climate and Soil Properties

The impact of climate conditions on biostimulant performance was analyzed by comparing the yield increase across four main climate categories (equatorial, arid, warm temperate, and boreal) and six precipitation types (desert, steppe, monsoonal, summer dry, winter dry, and fully humid) (Figure 5). The effect of biostimulant was most positive in climates with seriously limited water availability (arid and desert). Moreover, yield gain showed a clear negative trend with increased precipitation, with fully humid climate conditions as the least favorable for biostimulant efficiency. Overall, water availability was revealed as a critical

factor, positively correlating with the effect of biostimulants. At the same time, temperature negatively impacted the more extreme side of the spectrum. Next, we compared soil physical and chemical parameters: textures, pH, salinity, and SOM (Figure 6). For most soil types, the average effect of biostimulant was within the same interval range. However, pure clay had a clear lower impact (+13.5%), even though soils with a high clay component were among the best scoring soils (e.g., silty clay loam; +26.3%) (Figure 6A). In general, regarding the soil pH levels, mild soil acidity or alkalinity were better than soils with a neutral or more extreme low or high pH (Figure 6B). Moderate alkaline soil reveals the highest potential response to biostimulant application. Soil salinity strongly positively correlated with biostimulant effectiveness (Figure 6C), in line with the water availability correlation shown in Figure 5. Finally, we compared biostimulant effectiveness across soils with different SOM content. Here, we found a robust negative trend between SOM and yield response after biostimulant application (Figure 6D). A negative correlation was also observed with

increasing soil total N (%) and soil available N content (ppm) (Figures 7A,B). Concerning soil P and K levels, the analysis revealed that biostimulants function better in poor soils deficient in P and K nutrients (Figures 7C,D).

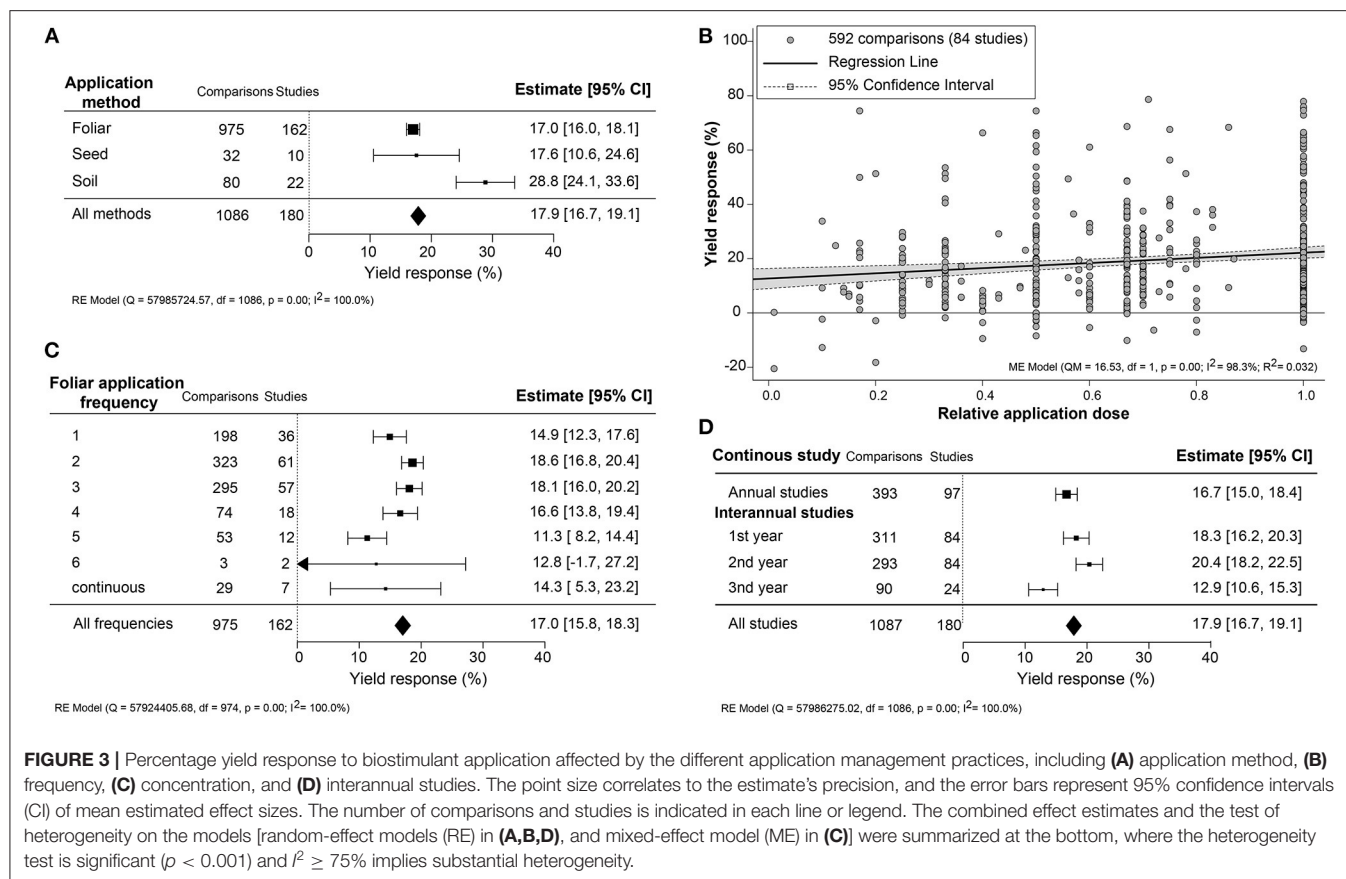

DISCUSSION

Biostimulant Effectiveness

A large body of published data demonstrates the positive impact of numerous types of biostimulants on a wide range of crops using different application methods under various conditions. However, for biostimulants to become standard practice, these products will require consistency and reproducibility in the beneficial effects they are claimed to have on crop production. A standardization for measuring the effectiveness of biostimulants is required to distinguish the good from the bad (Ricci et al., 2019). Variation in biostimulant effectiveness is expected as different crops respond differently to biostimulants, and the environmental conditions are likely also influencing the effects. Therefore, a one-to-one comparison of biostimulant effectiveness based on published data is not likely to be very reliable. In this study, we looked at the bigger picture and queried the literature

for data published on the effectiveness of biostimulants. To allow for sound comparisons, the study focused on biostimulants derived from natural resources categorized according to their origin and chemical properties (Geelen and Xu, 2020) and restricted to crop yield experiments in open fields that are closer to an application and commercialization target. The main result from the meta-analysis was that it revealed correlations between biostimulant effectiveness and impactors that have, insofar as we are aware, not previously been completely recognized.

Since most authors wish to report successful biostimulants, it is fair to assume that publications are biased toward the positive. This does, however, not prevent the identification of correlations between the effects and the materials and application conditions used. With the high yield gain found, one would expect widespread use of biostimulants in many crop production systems. This is currently not the case, and we, therefore, assume that the average yield increase reported here is an overestimation of what can be expected in a commercial context. Noteworthy here is that the efficiency of non-commercial products was 7% higher than commercial ones (Figure 2). Indeed, a more conservative estimation of the yield increase is warranted, and there is a need for a more systematic collection of yield data

to conclude the effectiveness of commercial crop production systems (Geelen and Xu, 2020). Previously, a meta-analysis focusing on humic substances under controlled environment and field studies reported an estimated just above 20% of the increase

in dry weight of shoot and root (Rose et al., 2014), which is close to the yield gain we found (+17.9%) (Figure 2). In the case of microbial PBs, Schütz et al. (2018) found that the yield benefit in field trials was between +8.5 and +20.0%. Taken together, the

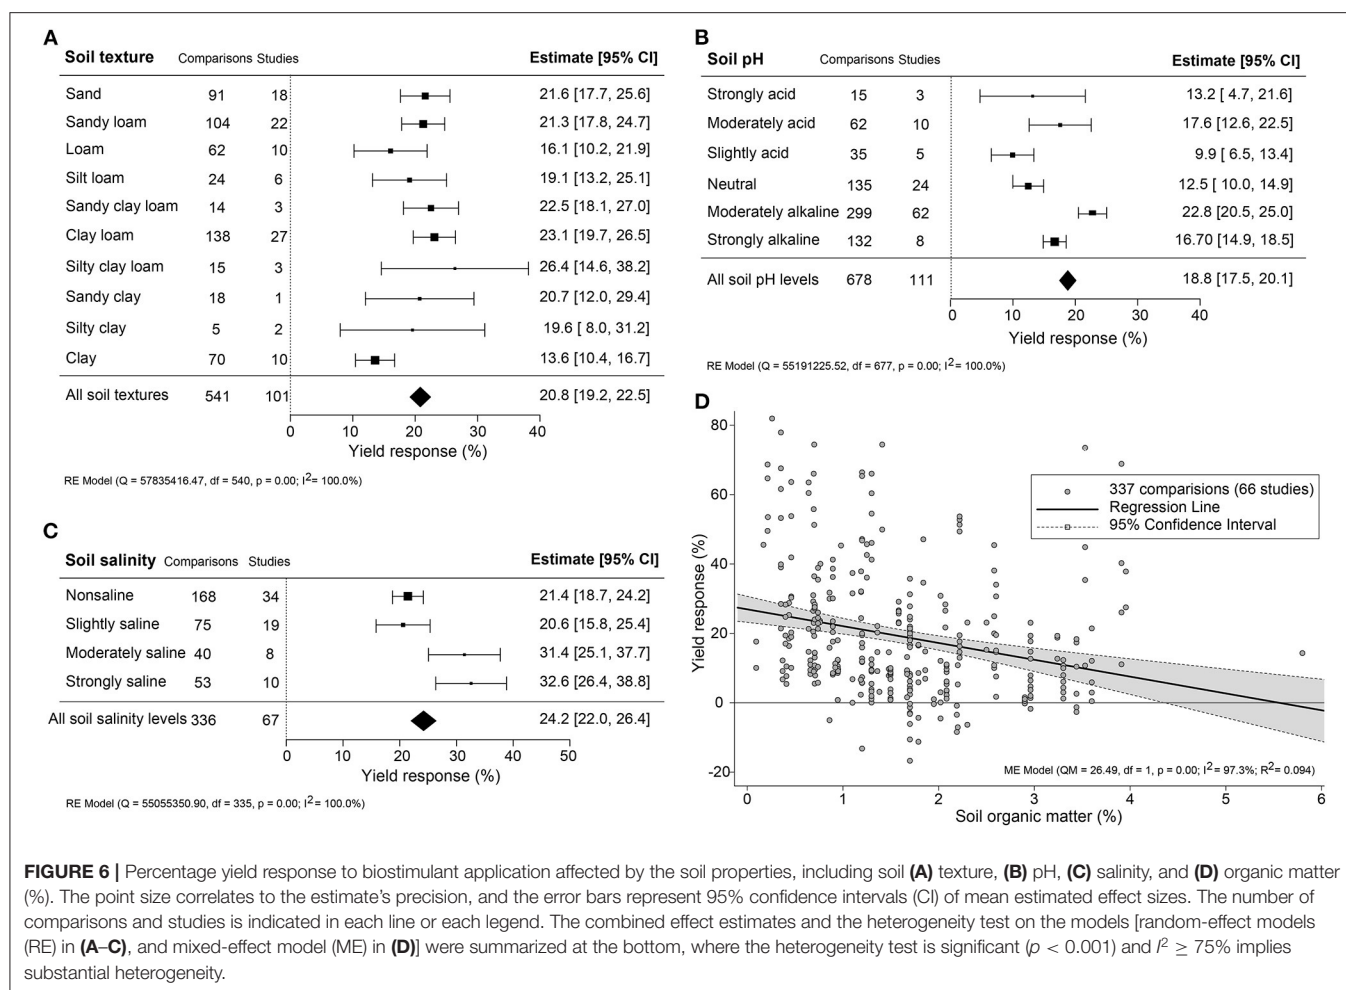

published data show some level of consistency across the different biostimulants analyzed. Chemical fertilizers also contribute to a yield gain, and here the average contribution was estimated to be around 40–60% (Stewart et al., 2005). Considering that biostimulants are commonly applied as supplements under conventional fertilization schemes and in many cases usually contain NPK fertilizers, the net positive effect of the bioactive ingredients is expected to be a considerable fraction of the total yield gain. Nevertheless, biostimulants sustainably improve the yield and provide a solution to reducing the dependency on synthetic fertilizer.

The extent of yield improvement varied across categories, with PE and MLE as the best performing biostimulants (Figure 2). MLE has been historically tested on many different crops displaying beneficial effects on seed germination, plant growth and yield, nutrient use efficiency, quality traits, and tolerance to abiotic stresses (Zulfiqar et al., 2020). The significant profitability and variability in MLE and other PE efficacy might be due to their complex composition of plant metabolites, containing many macro and mineral nutrients, osmoprotectants, and antioxidants (Soares et al., 2021). PE also likely contains plant hormones, which, in small quantities, are known to harbor the capacity to stimulate crop production (Harms and Oplinger, 1988). None of the MLE products used are, insofar we know, commercialized. This contrasts with SWE, for which more than 60% of the products analyzed are commercialized.

Moreover, from over 40% of the total dataset, we estimated the effect of SWE products with more confidence compared to the other biostimulant categories. The consistency in yield benefits linked with SWE application is likely a result of the standardization of SWE extraction and formulation methods. The use of SWE as a plant growth regulator can be traced back as far as the Roman Empire (Henderson, 2004), with the first commercial product marketed in 1952 (Milton, 1952). The technology of SWE production has developed into a mainstream hot-alkaline extraction method involving specific manufacturing conditions, allowing strong consistency in production and quality (Craigie, 2011). However, the more recently discovered biostimulants like PE show batch variations, and their processing methodology is not well-established (García-García et al., 2020).

While many biostimulants are typically complex mixtures, Phi and Si are simple inorganic salts. Despite their less complex chemical composition, the average effectiveness of Phi was the lowest, and that of Si showed the greatest variability. Compared to these products, PBs consisting of complex mixtures were more effective, and it will be a challenge to determine their mechanism of action. It also remains to be demonstrated whether the complex biostimulants exert stronger bioactivity because of synergistic interactions between bioactive ingredients (García-García et al., 2020). Therefore, further standardization in biostimulant production procedures is forecasted to improve

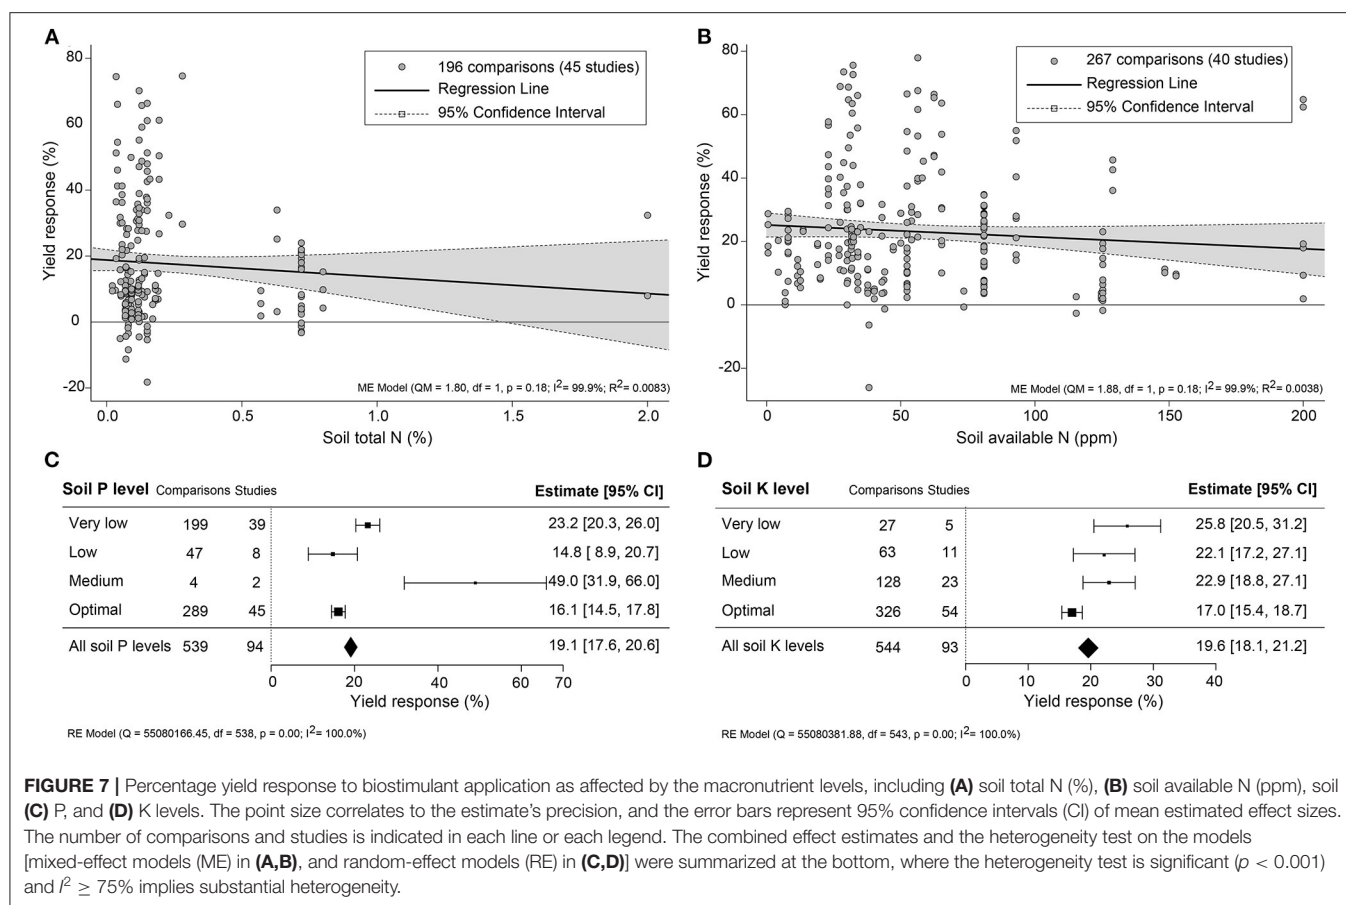

the consistency in effectiveness and reproducibility on yield gaining benefits.

Impact of Biostimulant Application Methodology

Biostimulants applied via soil resulted in about 10% higher yield benefits than foliar and seed applications (Figure 3A). This outcome is surprising as foliar and seed applications deliver the biostimulants directly to the plant, allowing faster uptake of the bioactive ingredients (Niu et al., 2021). For instance, surface spraying acts more directly and results in rapid responses to ripen fruits (Fernández and Eichert, 2009). Soil application of biostimulants likely has a different mode of action related to nutrient uptake efficiency or enhancing microbial activity on and around the crop. Nutrient availability is a major yield factor that can be improved by either providing higher levels of mineral or organic nutrients or by altering the microbial community interacting with the root system (Schütz et al., 2018; Kour et al., 2019; Oldroyd and Leyser, 2020). HFA, PHs, SWE, and PGPR have been shown to stimulate micro and macronutrient uptake efficiency, either by direct activation of ion transporters, mineral

utilization, or improving soil quality and mineral recycling (for an extensive review, see Halpern et al., 2015).

Foliar application is the favored method because it can be merged with conventional spraying practices. Remarkably, single biostimulant sprays were nearly as effective as multiple applications (Figure 3C). This suggests that the yield benefit is likely due to nutrient supply and other rapid-growth stimulation induced upon spraying the crop once or twice. Also noteworthy is that applications above 4 times resulted in a negative trend with lower efficiency. The diminishing returns of higher biostimulant application frequencies may be caused by changes in the uptake and assimilation rate of effective agents throughout the germination, vegetative, and reproductive plant developmental stages (Bulgari et al., 2019). Colla et al. (2015) recommended lowering the dosage when frequently applying biostimulant to avoid growth inhibition caused by overdose. In general, the efficiency of biostimulants depends on the plant's nutrient uptake rate, which is highest prior to maximum growth rates depending on the crop type (Jones et al., 2011; Nguyen et al., 2019). For example, SWE application was best during the tilling stage (Stamatiadis et al., 2021) and best during the seedling stage of sugarcane (Chen et al., 2021). Moreover, the sensitivity of plants

is regulated by their daily circadian clock that also may influence the effectiveness of the biostimulant (Belbin et al., 2019). It is thus suggested to spray biostimulants in the early morning or late afternoon because of the open stomata (Specialty Fertilizers, 2015). Summarily, we strongly advise following the optimized biostimulant application in crop management.

Comparison Between Crop Categories

Vegetable and legume crops showed the highest gain in yield upon biostimulant application (Figure 4). A previous meta-analysis study on the crop yield improvement via biofertilization with microbial PBs argued that vegetables require higher fertilizer concentrations for optimal growth, and legumes engage in symbiotic nitrogen fixation, which is stimulated upon the addition of microbial PBs (Schütz et al., 2018). As our analysis included only non-microbial PBs, the stronger legume response is not likely attributed to the stimulation of symbiotic interactions with nitrogen-fixing bacteria. It is currently unclear why vegetable and legume crops are more responsive to biostimulant application.

Biostimulants Are More Efficient Under Suboptimal Growing Conditions

Overall, biostimulants showed the strongest crop yield effects in soils of low quality (acid and alkaline soils, saline soils,

barren soils with low SOM, and P- or K-deficient soils) (Figures 6B–D, 7C,D). In these soils, the cation exchange capacity (CEC) is inherently nutrient-poor (Brown and Lemon, 2021). Soil rich in clay component or SOM, for instance, has a higher CEC value and typically retains higher levels of nutrients, and therefore supporting sustained crop growth and higher yield (Bayu, 2020). The yield gap of cultivation in poor soils is thus much larger than in fertile soils (Evans and Fischer, 1999). Therefore, we suggest combining biostimulant applications with “Integrated Fertility Management” to maximize yield potential and reduce crop loss risk under climate change scenarios.

Open-field production systems are exposed to variations in climate conditions and, therefore, at risk of abiotic and biotic stresses and degradation of the soil conditions (drought, salinity, nutrient deficiency) (Challinor et al., 2014; Mickelbart et al., 2015). Biostimulants are propagated as a solution to safeguard crop yield under suboptimal growth conditions (Yakhin et al., 2017). In agreement with this view, the effectiveness of biostimulant application was the highest under suboptimal growing conditions of arid climates with low precipitation conditions (Figure 5). A similar conclusion was made from a meta-analysis on the yield improvement using microbial PBs (Schütz et al., 2018). In arid climate conditions, crops are exposed to more extreme temperature

conditions, which strongly impacts crop fertility (Thakur et al., 2010; Deryng et al., 2014; De Storme and Geelen, 2014). How PBs can mitigate environmental stresses is not well understood. Exogenously applied compounds may elicit a stress response that prepares the plant for subsequent stresses caused by limitations in water, soil fertility, or unfavorable temperature conditions (Ahmad et al., 2019). Molecules that can elicit a stress response are present in biostimulants and have been shown to induce stress-related genes (Geelen and Xu, 2020; González-Morales et al., 2021). Phytohormones are also commonly present in biostimulants, and their interactions with plants are known to enhance osmolyte accumulation and tolerance to stress (Sharma et al., 2019). In addition, plant-derived biostimulants contain antioxidants and improve the adaptation to unfavorable growing conditions by eliminating reactive oxygen species (ROS) (Drobek et al., 2019). Therefore, the bioactive compounds in biostimulants may evoke either stress alleviation (e.g., suppression of ROS) or induce stress response factors that trigger the immunity against abiotic stresses (Brown and Saa, 2015), validating the hypothesis that biostimulants are more effective under suboptimal growth conditions.

CONCLUSIONS

This review underscores the importance of evaluating the biostimulant application methodology and the crop cultivation conditions. The study indicates that the impact of biostimulant application on crop yield depends on the type of products and application management. Our results also provide various environment-specific assessments of biostimulant performance in open-field conditions, which can be used to set up more effective farming practices for future biostimulant application strategies. In conclusion, biostimulants improve crop yield by reducing yield reductions under stress conditions. This approach can help improve food security for the growing world population under increasing climate change threats.

Designing Synergistic Biostimulants
Formulation Containing
Autochthonous
Phosphate-Solubilizing Bacteria for
Sustainable Wheat Production.
Front. Microbiol. 13:889073.
doi: 10.3389/fmicb.2022.889073

Applying phosphate-solubilizing bacteria (PSB) as biofertilizers has enormous potential for sustainable agriculture. Despite this, there is still a lack of information regarding the expression of key genes related to phosphate-solubilization (PS) and efficient formulation strategies. In this study, we investigated rock PS by *Ochrobactrum* sp. SSR (DSM 109610) by relating it to bacterial gene expression and searching for an efficient formulation. The quantitative PCR (qPCR) primers were designed for PS marker genes glucose dehydrogenase (*gcd*), pyrroloquinoline quinone biosynthesis protein C (*pqqC*), and phosphatase (*pho*). The SSR-inoculated soil supplemented with rock phosphate (RP) showed a 6-fold higher expression of *pqqC* and *pho* compared to inoculated soil without RP. Additionally, an increase in plant phosphorous (P) (2%), available soil P (4.7%), and alkaline phosphatase (6%) activity was observed in PSB-inoculated plants supplemented with RP. The root architecture improved by SSR, with higher root length, diameter, and volume. *Ochrobactrum* sp. SSR was further used to design bioformulations with two well-characterized PS, *Enterobacter* spp. DSM 109592 and DSM 109593, using the four organic amendments, biochar, compost, filter mud (FM), and humic acid. All four carrier materials maintained adequate survival and inoculum shelf life of the bacterium, as indicated by the field emission scanning electron microscopy analysis. The FM-based bioformulation was most efficacious and enhanced not only wheat grain yield (4–9%) but also seed P (9%). Moreover, FM-based bioformulation enhanced soil available P (8.5–11%) and phosphatase activity (4–5%). Positive correlations were observed between the

PSB solubilization in the presence of different insoluble P sources, and soil available P, soil phosphatase activity, seed P content, and grain yield of the field grown inoculated wheat variety Faisalabad-2008, when di-ammonium phosphate fertilizer application was reduced by 20%. This study reports for the first time the marker gene expression of an inoculated PSB strain and provides a valuable groundwork to design field scale formulations that can maintain inoculum dynamics and increase its shelf life. This may constitute a step-change in the sustainable cultivation of wheat under the P-deficient soil conditions.

Keywords: marker genes, *gcd*, *pqqC*, *pho*, *Ochrobactrum*, FESEM, bioformulations, FISH

INTRODUCTION

Phosphorus (P) is an essential key macro-nutrient for the optimal plant growth (Brito et al., 2020; Chandran et al., 2021) and a crucial element for various physiological and biochemical functions at plant cellular level (Bechtaoui et al., 2021). The complex dynamics of P in soil makes it a limited resource for plant uptake (Bindraban et al., 2020). To satisfy the rising P nutrition requirements of crops and to boost agricultural production, the conventional agriculture relies on agrochemicals, a practice that compromises the human and environmental health (Akanmu et al., 2021). Further, the global P input into croplands is expected to increase by up to 86% by 2050 (Mogollón et al., 2018), and thus sustainable means for P fertilization are urgently needed.

The application of bacteria that are beneficial for crop production, commonly termed as plant growth-promoting bacteria, has been adopted as a potent, biological alternative for the mineral fertilization. The bacterial inoculants can be used as biofertilizers and biostimulants to improve the soil nutrient availability, plant nutrient uptake and assimilation, and root growth, since their biological activities include, e.g., mineral and organic phosphate solubilization (PS), nitrogen fixation, siderophore, and indole-3-acetic acid production (Castiglione et al., 2021). Among the plant beneficial bacteria, the biofertilizer group phosphate-solubilizing bacteria (PSB) are promising candidates to satisfy the P requirements of the plants by converting unavailable soil inorganic (P_i) and organic (P_o) forms of phosphate into plant-available orthophosphates through dissolution and absorption (Chen and Liu, 2019). The P_i -solubilizing microorganisms secrete organic acids to dissolve phosphate minerals, whereas the organic phosphates are hydrolyzed by acid and alkaline phosphatases as well as phytases (Liu et al., 2020). In general, the application of PSB in soil decreases the pH locally and consequently makes the P bound in minerals available to the plant and strengthens the activity of other beneficial microorganisms (Etesami et al., 2021).

At present, the research on the genes of PSB related to P_i solubilization is mainly focused on *pyrroloquinoline quinone-glucose dehydrogenase* (*gcd*) and six redox-coenzyme *pyrroloquinoline quinone* genes *pqq A, B, C, D, E, F*, and *G* (Bhanja et al., 2021). By contrast, the organic phosphates are hydrolyzed by acid phosphatases, alkaline phosphatases, and phytases (inositol phosphate phosphatases) that are encoded by

phosphatase (*pho*) genes (Sarr et al., 2020). The knowledge on the genetic potential of PSB is still scanty, and the molecular studies to understand how PSB brings out the P solubilization are inconclusive (Liu et al., 2018).

In spite to the wide varieties of PSB, i.e., *Acinetobacter*, *Bacillus*, *Enterobacter*, *Ochrobactrum*, and *Pseudomonas*, there are still relatively limited studies on P-solubilizing pathways and expression patterns of genes related to phosphate-solubilizing that need to be further studied. For this reason, the first aim of this work was to construct primers and to provide expression analysis of key PS related genes, i.e., *gcd*, *pqqC*, and *pho* of selected PSB.

Although an elite strain with a high and consistent PS activity is an essential prerequisite for the development of successful inoculant, the non-biological components for bioformulations are still key bottlenecks in commercial development of the inoculants (Mendoza-Suárez et al., 2021). The choice of carrier material is fundamental, because carrier is the sole delivery vehicle of live microorganism from the production unit to the plants in the field (Vassilev et al., 2020). The main roles of a good carrier material are as follows: (i) To provide an optimal microenvironment for microorganisms to maintain microbial viability and longer shelf life without any need for special storage and (ii) to support the strain(s) competitive abilities with the usually much better adapted, native soil microflora (Soumare et al., 2020). Besides, the carrier material must be readily available, easily pulverized and sterilized, cost-effective, compatible with the environment, acquiescent to nutrient supplement, and un-harmful to the user (Koskey et al., 2021). The carrier materials can be organic [e.g., compost (CM), biochar (BC), peat, biogas, humic acid (HA), slurry, etc.] or inorganic (e.g., talc, perlite, lignin, zeolite, etc.) origin, or even synthesized from specific compounds (Mitter et al., 2021). The by-products from the food and agricultural industries are also important sources for the development of biostimulants. The PSB-based carrier materials can include extracts from food waste, manures, vermicomposting, aquaculture waste streams or even sewage treatments (Madende and Hayes, 2020).

Despite the great potential and long-term expedient effects, the biostimulants/biofertilizers still face major challenges that limit their use in agriculture. These challenges are often associated with limited shelf life and survival of inoculated strain in the field, in variable environments and with different host plants (Mitter et al., 2021). For this reason,

the various commercial bioinoculants did not function under field conditions with a similar efficacy as in greenhouse or laboratory conditions (Stamenkovi et al., 2018; Santos et al., 2019; Vassilev et al., 2020). Mostly, the reasons for that were inadequate formulations with carriers that did not support the survival and growth of the microorganisms and/or were not stable under field conditions (Fasusi et al., 2021). Furthermore, the simultaneous application of two or more plant growth promoting rhizobacteria (PGPR) as consortium can improve the plant growth and can cause substantial increment in the crop yield (Shahzad et al., 2017; Backer, 2018; Mpanga et al., 2019). Bacteria in the consortium can efficiently colonize in rhizosphere than single bacterium (Molina-Romero et al., 2021) and they not only reduce the application chemical fertilizers but also allow the plants to utilize P already present in the soil (Lobo et al., 2019). Hence, the second aim of this study was to design a successful bioformulation based on PSB consortium with optimal shelf life and agro-industrial by-products as sole carbon source/organic amendments. We expected that this approach is expedient for developing a robust and effective alternative for mineral P fertilization.

We hypothesized that (H1) the autochthonous PSB that can solubilize different unavailable forms of phosphate, may have the genetic potential to express key genes responsible for PS and improve root architecture concomitantly under P-deficient conditions. We assumed (H2) that designing biostimulants based on a PSB consortium and using different agro-industrial by-products as organic amendments could result in a product with a long shelf life and survival in the wheat rhizosphere. We also expected (H3) correlations between P solubilization from the different insoluble phosphate sources by PSB and increased soil available P, consequently also resulting in improved wheat root growth, and grain yield.

MATERIALS AND METHODS

The PSB and Evaluation of Their P-Solubilization Potential in Different Insoluble P Sources

The PSB *Enterobacter* spp. ZW9, ZW32 (GenBank accession numbers MK422617 and MK817561) and *Ochrobactrum* sp. SSR (GenBank accession number MK422612) used in this study were isolated from the wheat rhizosphere and characterized in our previous study (Yahya et al., 2021). These PSB are non-pathogenic, compatible with each other and were also submitted to DSMZ (<https://www.dsmz.de/>) culture collection under the accession numbers DSM 109610 and DSM 109592, DSM 109593 for *Ochrobactrum* sp. SSR, *Enterobacter* sp. ZW9 and *Enterobacter* sp. ZW32, respectively.

In the current study, an *in vitro* assay was carried out to assess the P-solubilization potential of P-solubilizing bacteria SSR, ZW32 and ZW9 in the presence of different insoluble P sources. The three PSB strains were cultured in rock phosphate (RP) broth medium (Nguyen et al., 1992) and phytate broth medium (Howson and Davis, 1983) supplemented with insoluble P sources, i.e., RP and phytate, respectively. The flasks were kept

at $28 \pm 2^\circ\text{C}$ and 180 rpm. An un-inoculated medium was used as a control. The P-solubilizing abilities of PSB were quantitatively estimated at 3, 5, 7, 10, and 15 days post-inoculation (DPI). To get the cell-free supernatant, the cultures were centrifuged at 4,000 rpm for 10 min at 4°C . The supernatant obtained was used for available P quantification as described by Murphy and Riley (1962) using the molybdenum blue method.

Expression Analysis of Genes Responsible for P-Solubilization in Soil Amended With RP Using Quantitative Real-Time PCR (qRT-PCR)

Based on the *in vitro* P-solubilizing efficacy and genetic potential (Table 1), *Ochrobactrum* sp. SSR was selected for expression analysis of PS-related genes as compared to the other two potential PSB (*Enterobacter* spp. ZW32 and ZW9). Therefore, a pot experiment was carried out in the soil amended with RP to evaluate the effect of SSR inoculation on wheat growth and root architecture concomitantly with expression of key PS related genes.

Effects of *Ochrobactrum* sp. SSR Inoculation on Wheat Plants and Soil Amended With RP

The PSB *Ochrobactrum* sp. SSR was evaluated for phosphate-solubilizing potential in soil amended with insoluble RP under the greenhouse conditions at National Institute for Biotechnology and Genetic Engineering (NIBGE), Faisalabad ($31^\circ 25' 0''\text{N}$ $73^\circ 5' 28''\text{E}$). Seeds of the wheat variety Faisalabad-2008 were surface sterilized with sodium hypochlorite (1.5%) and sequentially washed with sterile water. For the inoculum preparation, a single colony of SSR was grown in Luria-Bertani (LB) broth medium at $28 \pm 2^\circ\text{C}$ for 24–48 h. Sterilized seeds were inoculated with SSR (1×10^9 CFU ml^{-1}) for 30 min. Un-inoculated seeds dipped in LB medium were used as control. Two seeds per treatment were sown in cylindrical pots (10-cm diameter) filled with 300-g soil (loam texture, 0.57 % organic matter, pH 8, and 2 mg kg^{-1} available P) per pot.

The four biological treatments, i.e., T₁: SSR-inoculated seeds and soil amended with 45-mg P in the form of RP; T₂: Un-inoculated seeds and soil supplemented with 45-mg P in the form of RP; T₃: SSR-inoculated seeds and soil without RP; T₄: Un-inoculated seeds and soil without RP, each with six biological replicates, were arranged in a completely randomized design. All pots were provided with basic nutrient solution (Hoagland and Arnon, 1950) before sowing. Then T₁ and T₂ were provided with Hoagland without any P source while, T₃ and T₄ received Hoagland solution with complete nutrients. After germination, two plants per pot were grown and pots were watered as per requirement.

The plants were uprooted 30 days after sowing (DAS) and the plant growth parameters, i.e., root length, shoot length, plant dry, and fresh weight were determined. The root morphological parameters, i.e., root length (cm), root surface area (cm^2), root volume (cm^3), root length per volume (cm m^{-3}), root diameter (cm), number of crossings, number of forks, and tips were

measured by using a rhizoscanner (Epson photo scanner V-700, USA) accompanied with WinRHIZO software (Regent Int. Co., Ltd. Canada).

Plant P was analyzed by the tri-acid digestion method according to Tandon (1993). Rhizosphere soil was analyzed for available P by the Olsen method (Olsen, 1954) and alkaline phosphatase activity by following the *p*-nitrophenyl method (Tabatabai and Bremner, 1969).

Quantitative Real Time PCR (qRT-PCR)

To validate the persistence of inoculated PSB, wheat rhizosphere soil was collected from inoculated treatments of the pot experiment at 30 DAS and qRT-PCR was performed for expression analysis of PSB genes. Strain-specific (*Ochrobactrum* sp. SSR) primers for genes, i.e., glucose dehydrogenase (*gcd*), pyrroloquinoline quinone biosynthesis protein C gene *pqqC* and phosphatase (*pho*) responsible for P solubilization were used for expression analysis.

Primers Designing and Phylogenetic Analysis of PS-Related Genes

The primers for the amplification of *pqqC* genes of *Ochrobactrum* sp. SSR, encoding proteins involved in inorganic P solubilization were designed according to Rasul et al. (2021). The primers for *gcd* and *pho* gene of *Ochrobactrum* sp. SSR have been designed and reported in our preceding study (Rasul et al., 2021). The primers used in PCR amplification to evaluate the functionality and to authenticate the predicted sizes of amplicons (Table 1). The PCR conditions were 98°C for 3 min, followed by 35 cycles of 95°C for 60 s followed by 54°C for 60 s, 72°C for 60 s and final elongation at 72°C for 10 min. The amplified PCR-products were run on agarose gel (1%) at 80 V for 45 min. The PCR products were purified using PCR purification kit (QIAGEN Science, USA) and sequenced by MacroGen (Seoul, Korea). The obtained sequences were aligned and compared to sequences available at NCBI (<https://www.ncbi.nlm.nih.gov/>) and deposited to GenBank. Phylogenetic analysis was carried out by using

MEGA6 software by using maximum likelihood method (Kumar et al., 2016).

Primer Design for qRT-PCR

Gcd and *pqqC* primers for qRT-PCR were designed for *Ochrobactrum* sp. SSR and were used in PCR amplifications to verify the amplification of the predicted amplicon sizes (Table 1). The primers for *pho* gene were designed and reported in the previous study (Rasul et al., 2021). The *Gcd* gene was selected as reference gene to normalize and validate qRT-PCR experiment by screening relative expression (based on fold change values) of candidate genes, i.e., *pqqC* and *pho* genes.

The RNA Extraction and cDNA Synthesis

The RNA was extracted from the soil with FastRNA spin Kit (MP, Biomedical, USA) by following the manufacturer's instructions. The cDNA was synthesized using First-Strand cDNA Synthesis Kit (Invitrogen, California, USA). The quality and quantity of cDNA were analyzed using Nanodrop 2000 (Thermo 262 Scientific, United States).

Expression Analysis by qRT-PCR

Bio-Rad RT-PCR (Bio-Rad, Hercules, USA) with SYBR Premix ExTaq kit (Takara Bio, USA) were used for expression analysis. A 25-μL reaction mixture contained 12.5-μL SYBR Green Master, 0.2-μL forward primer (10 μM), 0.2-μL reverse primer (10 μM), 2-μL cDNA, and 10.1 μL deionized water. The amplification conditions were as follows: The initial denaturation at 95°C for 5 min, 35 cycles of 95°C for 30 s followed by 54°C for 30 s, and 72°C for 30 s. The melting curve was analyzed from 54°C to determine the primer specificity.

The data were calculated as described by Javaid et al. (2016) and the expression level of target gene *pqqC* and *pho* were normalized with the C_t -value of reference gene (*gcd*). All samples were analyzed in three replicates.

Designing of Bioformulations Based on PSB-Consortium and Organic Amendments

Four different carrier materials, i.e., BC, CM, filter mud (FM), and HA were used to design bioformulations with PSB consortium comprising of well characterized strains (*Ochrobactrum* sp. SSR, *Enterobacter* spp. ZW32, and ZW9). The BC was obtained from wheat straw by pyrolysis in an automated furnace at 350°C with a resident time of 1 h and at a constant heat rate, i.e., 10°C min⁻¹ (Abbas et al., 2020). The CM was derived from cow dung together with nitrogen-rich plant material and was obtained from Microbial Ecology Lab (NIBGE, Pakistan). The FM was obtained from decantation and filtration of sugarcane waste product (Suleman et al., 2018). The HA was extracted by alkali treatment of lignite as described by Ghani et al. (2021).

The standard procedures were followed for the characterization of carrier materials. The pH of the carrier materials was estimated by using pH meter (Phs-3c, Rex, China) according to Thomas (1996). The electric conductivity of soil was determined by using electric conductivity meter (DDS307A, Rex, Shanghai; Rhoades, 1993). The soil organic matter was estimated by Walkley black wet digestion method (Nelson and Sommers, 1996). Kjeldal method was used to measure total nitrogen (Bremner and Mulvaney, 1982). Elemental analysis of N and C was further validated by using CHNS analyzer (Perkin Elmer, Massachusetts, United States). The total P was determined by vanadate-molybdate method (Olsen, 1954).

The carrier materials were ground, sieved through 2-mm sieve and autoclaved. For the development of consortium, PSB strains, i.e., *Ochrobactrum* sp. SSR, *Enterobacter* spp. ZW32, and ZW9 were grown in LB broth medium separately at 28 ± 2°C for 24–48 h. The consortium (1 × 10⁹ CFU ml⁻¹) was developed by mixing equal volume of each of the bacterium that are grown in LB. The bacterial suspension was mixed uniformly and aseptically with the carrier material to allow an adequate evenness to the final mix. Each carrier was prepared aseptically by adding 300 ml of bacterial suspension to 700 g of carrier and mixed well. The negative controls were also prepared by aseptically adding 300 ml of un-inoculated LB broth to 700 g of carrier. Each bioformulation and negative controls were prepared in triplicates, stored in polythene bags and were incubated at 28°C until the sampling time (Pastor-Bueis et al., 2019).

Shelf Life Study of Bioformulations

The survival of the inoculated PSB was assessed in all tested formulation at different time intervals, i.e., after 15, 30, 60, 90, 180, and 270 days. Three samples from each formulation were collected at each sampling date and analyzed for survival of the PSB inoculum. The bacterial viability was estimated for each sample by four-fold serial dilutions on LB agar and NBRIP (National Botanical Research Institute's Phosphate) (Nautiyal, 1999) agar supplemented with tri-calcium phosphate as source of P. The mean values of PSB viable count per gram of carrier material was calculated at each time interval and plotted on logarithmic scale (Pastor-Bueis et al., 2019).

Morphological and Elemental Analysis of Bioformulations by Scanning Electron Microscopy With Energy Disruptive X-Ray Spectroscopy Microanalysis (SEM/EDS)

Morphology or surface features of PSB inoculated and un-inoculated bioformulations were observed using field emission scanning electron microscopy (FESEM). The predominant chemical elements were determined by element microanalysis through EDS with a JEOL SEM microscope JSM 6490-LV model at a voltage range 10–20 kV and 1,000–10,000 magnification (Shahzad et al., 2019).

In-vivo Evaluation of Bioformulations in Earthen Pots Under Net House Conditions

The bioformulations were evaluated for their impact on wheat grain yield and plant P content under net house conditions at NIBGE, Faisalabad (31°23'45.1"N, 73°01'3.4"E) in earthen pots through wheat-growing season November 2018 to April 2019. The seeds of wheat variety Faisalabad-2008 were surface sterilized as illustrated in preceding section. After sterilization, the seeds were pelleted with each bioformulation (@ 50-kg seeds kg⁻¹ carrier material), separately and kept for 30 min. Un-inoculated pelleted seeds (with carrier materials) were used as control.

The sowing was done in the earthen pots (30-cm diameter) filled with 12-kg soil (loamy texture, pH 8.2, soil available P 1.9 mg kg⁻¹ and organic matter 0.6%) and watered prior to sowing. The soil was supplemented with 80% recommended di-ammonium phosphate (DAP) dose (i.e., 20% reduced DAP). Eight treatments, six biological replicates, and four plants per pot were arranged in two factorial completely randomized design (Supplementary Table S2). Fertilizers were applied as per the recommendations, where DAP (150-mg kg⁻¹ soil) and urea (75-mg kg⁻¹ soil) in split doses were supplemented at the time of sowing and with first and second watering.

After 35 days of sowing plants were uprooted and multiple plant growth parameters (root length, shoot length, and plant dry weight) were evaluated. At maturity, plants were harvested and wheat yield parameters, i.e., number of tillers, grain yield, plant biomass, and plant height were recoded. Plant P content (Tandon, 1993), available P (Olsen, 1954), and alkaline phosphatase activity of soil (Tabatabai and Bremner, 1969) were analyzed by standard protocols.

In planta Evaluation of Bioformulation for Wheat Yield Parameters Under Field Conditions

Microplot Experiment

Based on the improved wheat yield and higher P-solubilizing potential in the net house experiment, the FM-based bioformulation was selected and evaluated in microplots at NIBGE. Each microplot was of the size of 1.5 × 1.5 m.

Three biological replicates for three treatments including seeds primed with bioformulation and soil supplemented with 80% of the recommended dose of DAP, i.e., 20% reduced dose and un-inoculated controls supplemented with 80 and 100% DAP

doses, respectively, were arranged in randomized complete block design. Seed pelleting of the wheat variety, Faisalabad-2008, was carried out as described in the previous section. The seeds were sown with the help of a dibbler in microplots. Fertilizers were applied as per recommendations (N: P, 15:100-kg ha⁻¹). The DAP and urea in split doses were applied at the time of sowing and subsequently with first and second irrigations.

Field Trial

A field trial was conducted to evaluate the selected bioformulation during winter season of November 2019–April 2020 at NIBGE, Faisalabad (31°23'45.1 "N, 73°01'3.4"E). Three biological replicates for three treatments, i.e., seeds primed with selected bioformulation provided with 80% recommended dose of DAP and un-inoculated controls supplemented with 80 and 100% doses of DAP, respectively were arranged in randomized complete block design. The seeds were sown by drill method in a plots size of 6 m × 6 m. Doses of fertilizers, treatments, and controls were similar to that applied in microplot experiment. While, standard agronomic practices were maintained throughout the experiment.

Estimation of Wheat Yield Parameters, Seed P, Available Soil P, and Phosphatase Activity

At maturity, the plants from both microplots and field trial were harvested and wheat yield parameters, i.e., number of tillers, grain yield, plant biomass, and plant height were recorded. Plant P content (Tandon, 1993), available P (Olsen, 1954), and alkaline phosphatase activity of soil (Tabatabai and Bremner, 1969) were analyzed by standard protocols.

Detection of Inoculated PSB

The survival of inoculated PSB was evaluated through the viable count method (Somasegaran and Hoben, 2012). The persistence of inoculated PSB was confirmed by fluorescent *in situ* hybridization (FISH) equipped with confocal laser-scanning microscopy (CLSM) (Amann et al., 1995). Inoculated *Ochrobactrum* sp. SSR was detected by hybridizing the Cy3-labeled ALF1b probe. While FLUOS-labeled probe "EUB338" was used for the total bacterial population (Manz et al., 1996). An Argon-Ion laser was used for excitation of FLOUS at 488 nm and Cy3 at 514 nm. FV10-ASW 1.7 software was used for imaging (Schneider et al., 2012).

The morphological characteristics and multiple plant growth promoting traits, i.e., phosphate solubilization, production of gluconic acid, and zinc solubilization of re-isolated PSB were compared to that of inoculated PSB (Yasmin et al., 2016).

Statistical Analysis

The data derived from *in vitro* experiments, pot experiment and field trials were statistically analyzed by ANOVA. The least significant difference (LSD) compared the variations between the treatments at 1 and 5% confidence level for lab assessments and field trials respectively, by using software STATISTIX-10 (Tallahassee, FL, USA). For the principal component analysis SPSS 23.0 software (SPSS Inc., USA) was used. Box

plots were generated for analysis of wheat yield parameters and soil parameters in an earthen pot experiment by using Origin Software 2020b (Origin Lab Corporation Northampton, MA, USA).

RESULTS

The PSB and Evaluation of Their P-Solubilization Potential in Different Insoluble P Sources

All tested PSB strains, i.e., *Ochrobactrum* sp. SSR, *Enterobacter* spp. ZW32, and ZW9 exhibited P-solubilizing activity in RP medium and phytate medium (**Supplementary Table S1**). The highest level of solubilized P from RP (112 µg ml⁻¹) was detected with SSR 15 DPI. The maximum P solubilization from phytate occurred 10 DPI for ZW32 and 3 DPI for ZW9 and SSR (**Supplementary Table S1**). The P released from phytate by SSR at 15 DPI (22 µg ml⁻¹) was considerably lower than from RP (112 µg ml⁻¹) (**Supplementary Table S1**).

Phylogenetic Analysis of Genes Responsible for P-Solubilization

The PQQ biosynthesis protein C related gene *pqqC* (GenBank under accession number OL342768) was amplified from genomic DNA of SSR. It showed 98% identity to *pqqC* nucleotide sequence of *Ochrobactrum* sp. (**Figure 1**).

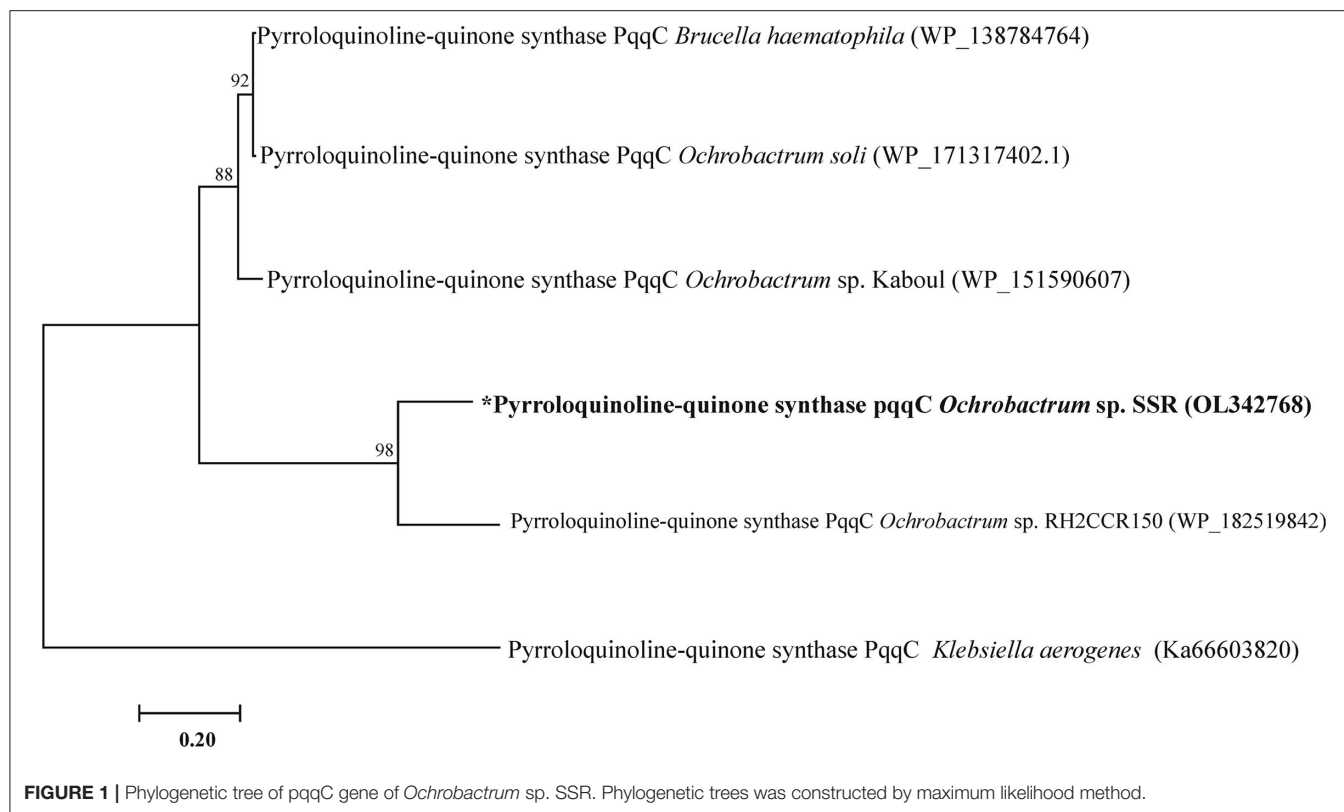

Expression Analysis of *gcd*, *PqqC*, and *pho* Genes by qRT-PCR

The persistence of *Ochrobactrum* sp. SSR in wheat rhizosphere was estimated by gene expression analysis of the *gcd*, *pqqC*, and *pho* genes. Among the tested treatments, the highest abundance of SSR was observed in RP amended soil. The supplementation of the soil with RP led to increased *gcd*, *pqqC*, and *pho* expression level (**Figure 2D**).

The relative expression level of *pqqC* and *pho* gene was 23-fold and 29-fold higher than reference gene *gcd* in SSR inoculated treatment supplemented with RP, while the expression level of *pho* gene was 3-fold higher than *pqqC* gene. On the other hand, the relative expression level of *pqqC* and *pho* gene was 17-fold and 23-fold higher, respectively, than the reference gene *gcd* in SSR inoculated treatment without RP (**Figure 2D**), while the expression level of *pho* gene was 6-fold higher than that of *pqqC* gene. Collectively, the SSR-inoculated treatment supplemented with RP showed high expression levels for *pqqC* and *pho* gene, i.e., 6-fold higher compared to inoculated treatment without RP (**Figure 2D**).

Effects of PSB Inoculation on Wheat Plants and Soil Amended With Rock Phosphate

The effect of *Ochrobactrum* sp. SSR on wheat variety Faisalabad-2008 was evaluated in soil either amended or not with RP under controlled conditions. Increases in shoot length, root length, plant fresh weight and dry weight were recorded in plants with SSR and soil amended with RP as compared to the un-inoculated control. These changes were significant in the presence and

absence of RP (Figures 2A,B; Table 2). The root morphological traits, i.e., root length, root volume, root surface area, root projection area, root tips and number of forks were also enhanced in inoculated plants (Figure 2C; Supplementary Table S3). Furthermore, we also observed increases in plant P (1.2–2.2%), available soil P (3.8–4.7 $\mu\text{g g}^{-1}$) and alkaline phosphatase activity (5.6–6.2 $\mu\text{moles g}^{-1}$ of soil h^{-1}) upon the treatment with the PSB (Table 2).

Shelf Life Study of Bioformulations

The survival of the three PSB, *Ochrobactrum* sp. SSR, *Enterobacter* spp. ZW32, and ZW9, was evaluated in bioformulations that were based on four carrier materials. These included BC, CM, FM, and HA. The PSB were less abundant in CM than other carrier materials at 15 DPI (Figure 3). All carriers maintained the inoculated PSB up to 180 DPI. However, after the course of 270 days, the FM showed significantly higher levels of the PSB than other carrier materials.

The inoculated PSB bacteria and the morphology of the bioformulations were investigated by FESEM. The PSB were detected in all four inoculated carrier materials (Figures 4A,D,G,J). Energy-dispersive X-ray spectroscopy was used to analyze the elemental composition of the surfaces of the bioformulations (Figures 4C,F,I,L). The data of SEM/EDS, CNHS, and biochemical analysis validates the presence of essential elements, i.e., N, K, C, and O in all tested carrier materials (Figure 4; Supplementary Table S4). However, it is also indicated that FM has more P than HA and CM. Only very

low amounts of heavy metals Cu, Fe, and Cd were detected in the tested carrier materials (Figure 5).

In-vivo Evaluation of Bio-Formulations in Earthen Pots Under Net House Conditions

All bioformulations enhanced the wheat plant growth in the pot experiment under net-house conditions up to variable extent (Figure 5). However, FM-based bioformulation showed significant increase in grain yield as compared to respective control, i.e., un-inoculated carrier material (Figure 5B). Seed P increased significantly in FM-based bioformulated plants compared to un-inoculated FM (Figure 5D; Supplementary Table S5), with concomitantly increased soil available P (6.23 $\mu\text{g g}^{-1}$ soil) and alkaline phosphatase activity (24 $\mu\text{moles g}^{-1}$ of soil h^{-1}) (Figures 5E,F; Supplementary Table S6).

The Performance of the Filter Mud Bioformulation in the Field

Based on the persistence of inoculum in FM, and the highly promising plant growth promoting effects of the PSB with FM in the earthen pot experiment, FM-based bioformulation was tested under field conditions. The FM-based PSB bioformulation enhanced not only wheat grain yield and plant biomass, but also seed P, soil available P, and soil alkaline phosphatase activity (Table 3).

A positive correlation was found between P-solubilization by SSR, ZW32, and ZW9 in presence of different insoluble P sources,

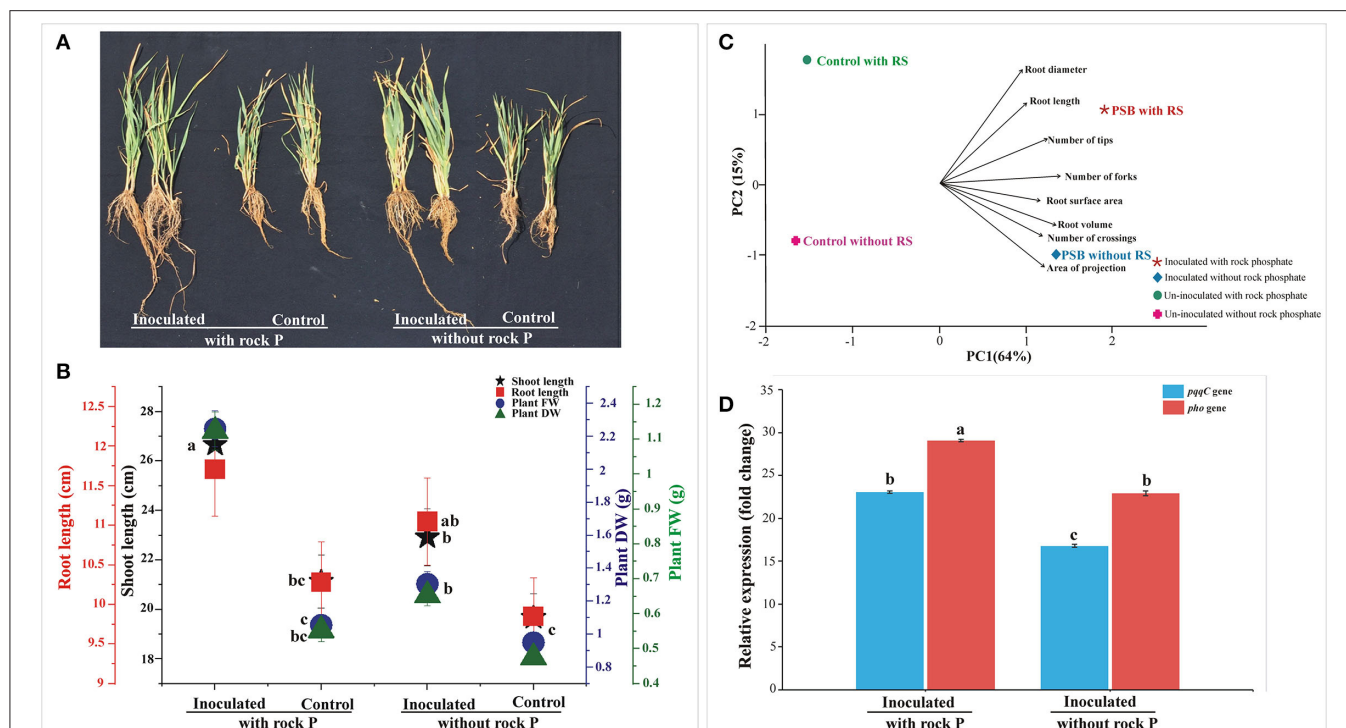

TABLE 2 | Evaluation of PSB on wheat grown in soil amended with unavailable form of P under controlled conditions.

Treatments	Fresh weight (g plant ⁻¹)	Dry weight (g plant ⁻¹)	Shoot length (cm)	Root Length (cm)	Plant P(%) ^a	Soil available P ^b	Phosphatase activity ^c
Inoculated with RP	2.25 ± 0.11 A	1.12 ± 0.06 A	26.67 ± 1.33 A	11.71 ± 0.59 A	2.25 ± 0.16 A	4.70 ± 0.23 A	6.24 ± 0.31 A
Control with RP	1.06 ± 0.05 C	0.55 ± 0.03 BC	21.13 ± 1.06 BC	10.28 ± 0.51 BC	0.94 ± 0.07 C	3.12 ± 0.16 C	3.03 ± 0.15 C

Evaluation of PSB on wheat growth, in soil amended with unavailable form of P under controlled conditions. The data were collected 30 DAS and shown as averages ± standard deviation of six replicates.

^aPlant P Content is given in % of the total plant weight, ^bSoil available P is represented by $\mu\text{g}/\text{gram}$ of soil weight. ^cSoil phosphatase activity is presented in $\mu\text{moles}/\text{g}$ of soil/h. The mean values followed by different letters are significantly different at $p > 0.05$ according to LSD.

and soil available P, soil phosphatase activity, seed P content, and grain yield of field grown inoculated wheat variety Faisalabad-2008 with 20% reduced DAP fertilization application (**Figure 6**). The PCA plot revealed correlation between different parameters, where the two principal components contributed up to 87% toward variance on x -axis (PC1 = 68%) and y -axis (PC2 = 19%). The plants inoculated with *Ochrobactrum* sp. SSR had significant (positive) impact on the grain yield, plant tillers, soil available P, soil phosphatase activity, seed P content of the wheat plants. No parameter was found to have negative effects by inoculation with the potential PSB.

Detection of Inoculated PSB

The presence of inoculated PSB in wheat rhizosphere soil from earthen pot experiment was confirmed by plating and counting the bacteria and FISH at 35 days after seeding (**Figure 7**). The root colonization was studied by FISH-CLSM of inoculated wheat roots. The FLUOS-labeled green probe EUB338 showed the total bacterial population (**Figure 7**). The Cy3-labeled ALF1b probe predominantly detects the presence of *Ochrobactrum* sp. SSR population in the PSB inoculated treatments as indicated by red cells (**Figures 7B–E**). Of note, the highest density of the red cells was observed in FM carrier material (**Figure 7D**).

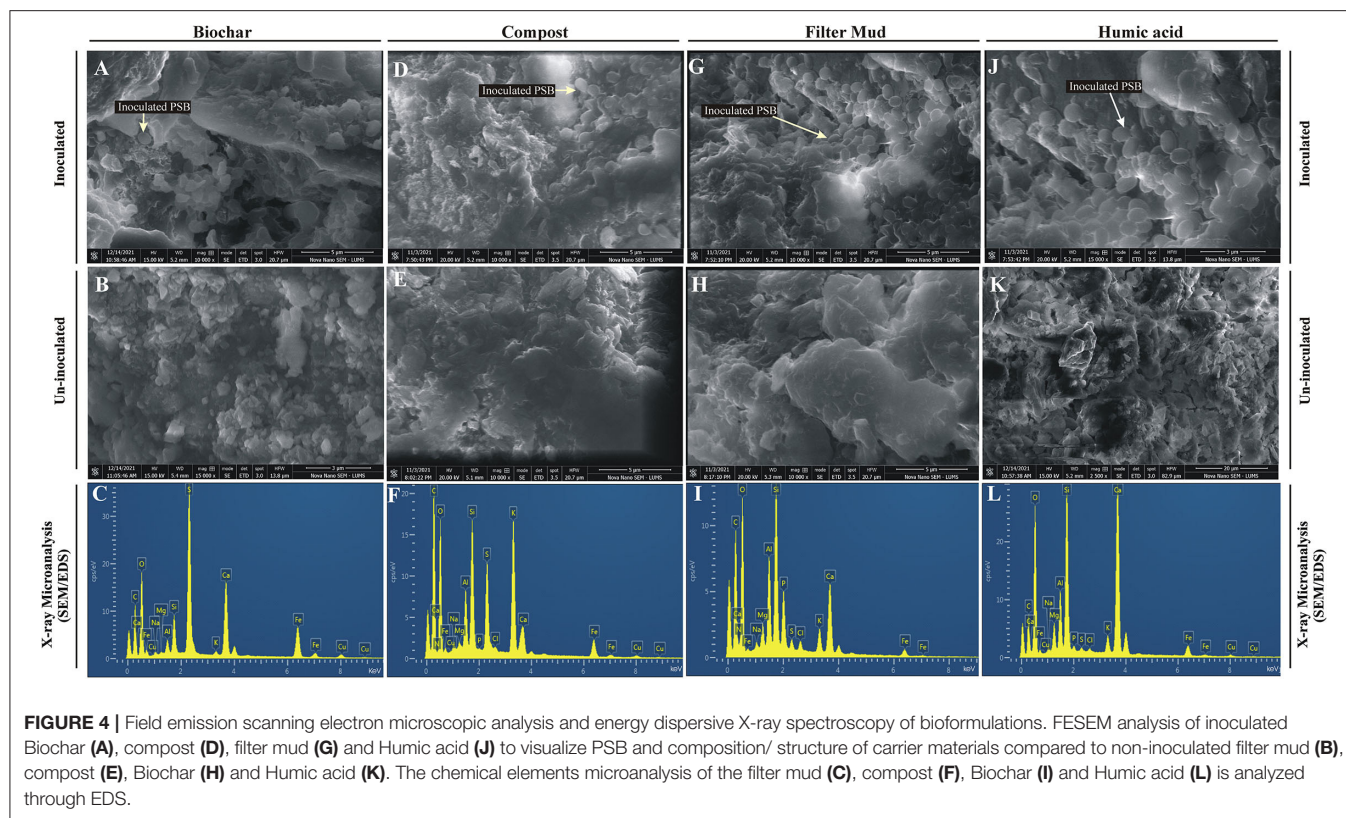

The re-isolated colonies of PSB, i.e., *Ochrobactrum* sp. SSR, *Enterobacter* spp. ZW32, and ZW9 were identified based on their morphological characteristics and plant growth promoting attributes, i.e., phosphate solubilization ($279\text{--}359 \mu\text{g ml}^{-1}$), gluconic acid production ($113\text{--}129 \mu\text{g ml}^{-1}$), and indole acetic acid production ($30\text{--}45 \mu\text{g ml}^{-1}$).

DISCUSSION

The development and use of the microbial inoculants has elicited great interest in the recent years since it presents a sustainable alternative for the application of chemicals fertilizes (Romano et al., 2020). However, the biofertilizer products still face major challenges, associated with the limited shelf life and the persistence of inoculant in different environments, and this limits their use in agriculture (Basu et al., 2021). To tackle this problem, we constructed a bioformulation that entails three plant growth promoting bacteria carried by FM. Our results suggest that the designed bioformulation has a long shelf life, is persistent in soil, and effective for both greenhouse and field applications.

The applied bacterial strains solubilized RP and phytate. Previously these bacteria were reported to solubilize P from tricalcium phosphate (Yahya et al., 2021). Our data supports the view that the utilization of multiple P sources by bacteria assures that they release P in different substrates and environments, and exhibit a strong potential for applications (Wan et al., 2020). We suggest that the successive analysis of TCP, RP and phytate solubilization by potentially novel plant beneficial bacteria provides a useful approach to obtain PSB that release P effectively in different soils.

To determine the genetic features of SSR that may contribute to the higher P solubilization, *pqqC* gene related to PQQ biosynthesis was amplified and analyzed phylogenetically. To this end new primers were designed that specifically amplify *pqqC* gene of *Ochrobactrum* genus. The *pqqC* encodes pyrroloquinoline quinone biosynthesis protein C, a well characterized enzyme that catalyze the final step of PQQ biosynthesis pathway. It is involved in oxidation and cyclization of 3a-(2-amino-2-carboxy-ethyl)-4 and 5-dioxo hexahydroquinoline dicarboxylic acid in the final step of PQQ biosynthesis (Meyer et al., 2011). In our previous studies, we revealed *gcd* (accession numbers MK883706), *pho* (accession

numbers MK883704; Rasul et al., 2021), and *pqqE* genes (accession numbers MT897167; Yahya et al., 2021) containing *Ochrobactrum* sp. SSR is multifaceted PSB. The *pqqC* and *pqqE* genes of strain SSR were amplified and known as most essential genes of PQQ operon. The biosynthesis of PQQ is only accomplished when the complex of gene products, i.e., pqq A, B, D, and F gets attached to pqqC at the C-terminal and with pqqE at the N-terminal (Bhanja et al., 2021). The amplification of these essential genes is the significant contribution and can provide novel insights into understanding the PQQ biosynthesis pathway in *Ochrobactrum* sp.

New primers for qPCR were designed and reported for the first time as marker genes to directly link the gene expression with phosphate-solubilizing activity. These primers were successfully applied for real time quantitative analysis of functional genes, i.e., *pqqC*, *pho* and *gcd* in inoculated soils of a pot experiment. We observed higher soil available P and soil phosphatase activities with concomitant increased expression of *pqqC* and *pho* genes related to SSR in RP amended soil as compared to inoculated soil with available P. This significant increase in soil available P corresponds to high rock P-solubilizing potential of *Ochrobactrum* sp. SSR *in vitro*. The SSR performed profoundly even in the absence of un-available P source but more efficiently in the presence of un-available P rock-phosphate as validated by higher expression level of marker genes, i.e., *pqqC* and *pho* relative to the *gcd* expression level. The developed qPCR primers are useful molecular tools to quantitatively trace functional gene expression and abundance of SSR that can be

linked to its P-solubilizing activity in the wheat rhizosphere. Our results are in line with globally coordinated nutrient addition experiments carried out in the UK, the USA, and South Africa by Widdig et al. (2019), which described that the P-solubilizing microbes can work more effectively in nutrient deprived soils. This leads to an increase in relative-abundance of PSB in plant rhizosphere. Similarly, a case study of rhizosphere soil from temperate beech forest revealed P-solubilizing efficacy of PSB get lowered in nutrient rich soils than soils with low nutrient availability (Nicolitch et al., 2016). Moreover, another study demonstrated that application of PSB in the soil significantly increased the soil available P and soil phosphatase activity in semi-arid soils with concomitant increased expression of *gdh* and *pqqC* genes in a microcosmic experiment (Saadoui et al., 2021).

The effects of PSB inoculation were not limited to phosphate solubilization only, but also extended to multiple root morphological traits, thus improving acquisition of P (Table 2). Inoculated wheat plants showed significant improvement in both above ground plant traits (i.e., plant P and shoot length) and belowground plant traits (i.e., root length, soil available P, and phosphates activity). This finding is consistent with the recent study by Elhaissofi et al. (2020), reported improved above and below ground parameters of PSB-inoculated wheat plants. The root morphological traits indicated root proliferation that significantly correlated with root/shoot P contents. This roots foraging and proliferation could lead to a greater P uptake.

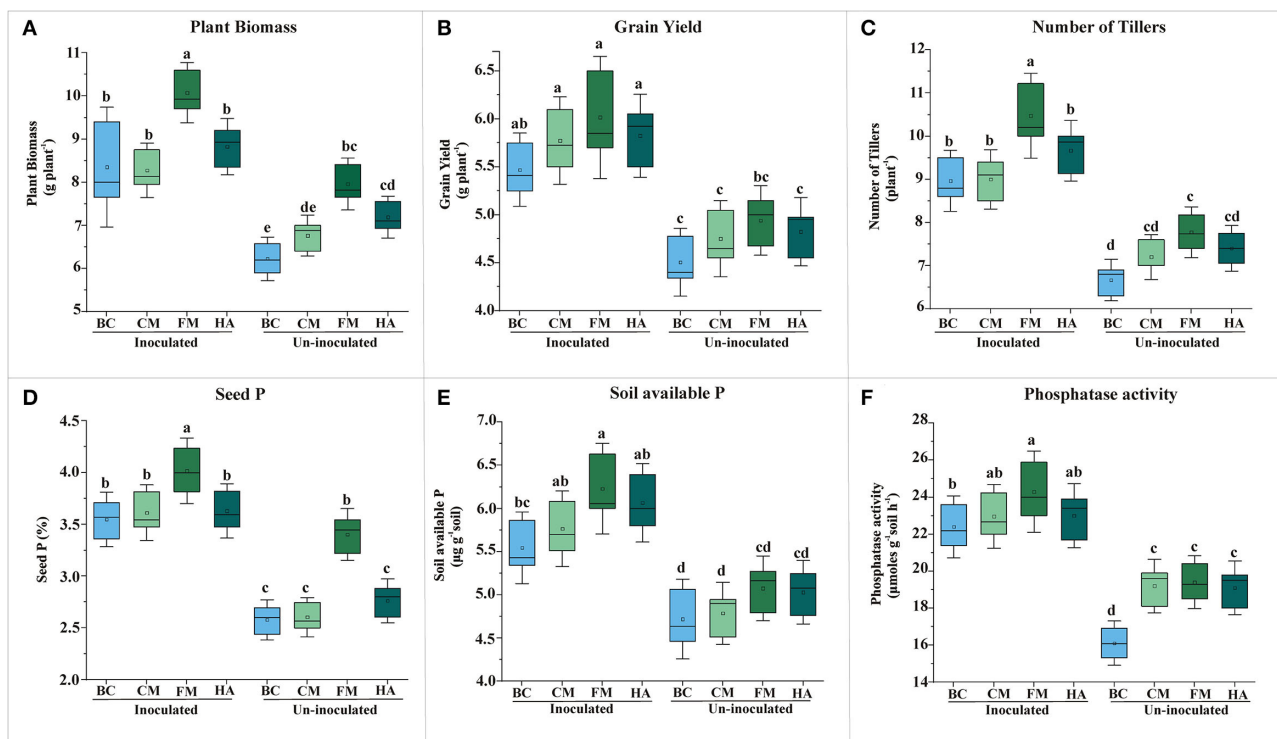

FIGURE 5 | Evaluation of PSB bioformulations for plant yield and soil P contents of wheat grown soil compared to un-inoculated controls. The effect of bioformulation on plant biomass (A), grain yield (B), number of tillers (C), seed P (D), available P of soil (E), and phosphatase activity (F). The mean values are an average of six biological replicates organized in completely randomized design. The mean values followed by different letters are significantly different at $p = 0.05$. BC, Biochar; CM, Compost; FM, Filter mud; HA, Humic acid.

TABLE 3 | Effect of Filter mud bioformulation and PSB consortium on plant growth and yield of wheat in microplots and field conditions.

Microplot trial	Treatments	No. of tillers (tillers plant ⁻¹)	Plant height (cm)	Plant biomass (kg plot ⁻¹)	Grain yield (kg plot ⁻¹)	Seed P content (%)	Soil available P (μg g ⁻¹ soil)	Phosphatase activity (μmoles g ⁻¹ soil h ⁻¹)
	Inoculated (80%)	13.33 ± 0.76 A	106.67 ± 5.03 A	2.36 ± 0.18 A	0.93 ± 0.04 A	4.15 ± 0.30 A	6.06 ± 0.28 A	26.63 ± 1.19 A

Wheat grown in microplots under net house and field conditions during winter wheat season 2018–2019. The FM bioformulation Inoculated and respective un-inoculated control were supplemented with 20% reduced application of DAP. Seeds were pelleted with FM bioformulation containing PSB consortium (1×10^9 CFU ml⁻¹). The mean values are an average of three biological replicates arranged in completely randomized design. The mean values followed by different letters are significantly different at $p > 0.05$ according to LSD. Area of each microplot was 2.25 m² with a total number of 54 plants grown in each microplot. Each treatment of field trial has plot size of 6 m × 6 m and seed rate was @123.5 kg ha⁻¹.

After the confirmation of genetic potential of SSR to solubilize recalcitrant-P, the present work is focused on designing the optimal inoculant formulation based on this elite strain SSR along with two other well-characterized and compatible PSB strains *Enterobacter* spp. ZW32 and ZW9 to develop consortium

for wheat to be applied under field conditions. Application of consortium can improve plant growth and increase the crop yield as compared to application of single bacterium (Backer, 2018; Mpanga et al., 2019). Although an elite PSB strains with consistent performance under field conditions

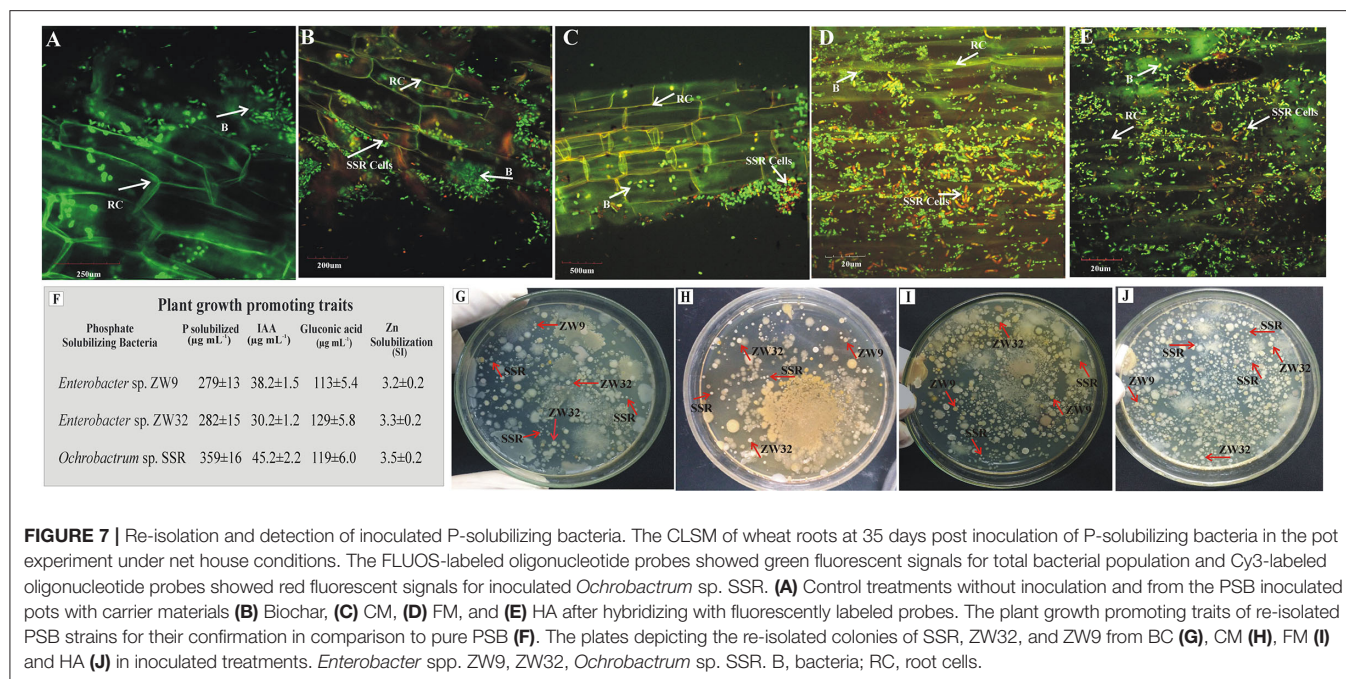

is essential for successful inoculant development, the non-biological components are still the key bottlenecks in commercial development of the inoculants (Pastor-Bueis et al., 2019; Mendoza-Suárez et al., 2021). Four different carrier materials, i.e., BC; CM; FM, and HA were used to design bioformulations with PSB-consortium based on autochthonous strain *Ochrobactrum* sp. SSR. Two other PSB strains used in consortium were well characterized *Enterobacter* spp. DSM 109592 and DSM 109593.

The elemental analysis of all carrier materials was performed with SEM accompanied with EDS. The data of SEM/EDS (Figure 4), CNHS, and biochemical analysis validates the presence of essential elements, i.e., N, K, C, and O in the tested carrier materials (Supplementary Table S4). However, P content of FM was higher than HA and CM. Non-significant amount of heavy metals Cu, Fe, and Cd were detected in all tested carrier materials. The essential heavy metals such as Cu, Fe, Mn, and Zn are required for various biochemical and physiological

processes of plant (Yan et al., 2020), but they may become toxic when present in excess. Therefore, the carrier materials with low amount of essential heavy metals are the potential candidates for the development of successful bioformulation.

The shelf-life assessment of well-characterized biostimulants revealed that all carriers maintained adequate survival of PSB to a variable extent up to 180 days period. The FM showed significantly higher bacterial load as compared to rest of the tested carrier materials predominantly up to 270 DPI (Figure 3). The persistence of inoculated PSB in carrier materials was further validated by FESEM. This indicates that FM-based carrier material provided more suitable microenvironment for inoculated PSB and maintained longer shelf life. This is an essential attribute of carrier materials for maintenance of microbial-viability without any special need of storage facility (Soumare et al., 2020). Besides, very few studies have focused on selection and development of

carrier materials and their effect on bioinoculum as most of studies emphasized on the performance of microbial inoculants (Koskey et al., 2021).

After designing of potential biostimulants with adequate shelf life, the next step was to evaluate the inoculants under field conditions. The FM-based bioformulation showed a pronounced effect on wheat growth as indicated by significant improved grain yield (16%) and seed P content (15%) with concomitant increased in soil available P (18%) under net house conditions (Figure 5). Under the field conditions, significant increase in grain yield (5%), plant biomass (10%), soil available P (7%), and soil phosphatase activity ($27 \mu\text{mol g}^{-1} \text{ soil h}^{-1}$) were observed in FM-based bioformulation compared to un-inoculated 80 and 100% controls (Table 3). The results are in line with some previous studies that shows the enhanced rice growth (Tahir et al., 2013) and wheat grain yield (Suleman et al., 2018) under agro-ecological conditions when seed pelleted with FM and PSB. Therefore, the FM can be adopted as a potent carrier material for the PSB aimed at improved soil nutrient availability, enhanced wheat grain yield, and decipher a key role as green alternative for imminent agricultural sustainability. Multiple traits of the PSB are directly involved in the bioavailability and P uptake by the plants. The PSB-enhanced nutrient-sensing capacity of the plants, which has already been made available by the secretion of bacterial organic acids (Chungopast et al., 2021; Yahya et al., 2021). The PSB modulates the morphology of root architecture and alleviates the P-stress by making P available in the soil and stimulating the plants to uptake P. This tripartite system could lead to improved crop vigor and yield.

The principal component analysis indicates a positive correlation between P solubilization by SSR, ZW32, and ZW9 in presence of different insoluble phosphate sources, and soil available-P, soil phosphatase activity, seed P content and grain yield of field grown inoculated wheat variety Faisalabad-2008 with 20% reduced application of DAP fertilizer (Figure 6). The agronomic performance of the potential inoculant tested under field trial, appraise the superiority of the inoculant. The various studies demonstrate that P-solubilizing microbes showed best effect with reduced application of DAP fertilizers (Suleman et al., 2018; Rosa et al., 2020; Rasul et al., 2021; Yahya et al., 2021).

The survival of inoculated PSB strains in wheat-rhizosphere was validated by viable count and FISH-CLSM, this shows that the inoculated PSB were rhizosphere-competent phosphobacteria. Furthermore, the plant growth promoting attributes of re-isolated PSB were compared to their pure cultures, indicates the persistence of inoculated PSB (Figure 7). The persistent colonization of PGPR in the rhizosphere is an indication that bacteria can carry out their functions (Hakim et al., 2021; Lopes et al., 2021) and form an association with local microbial community (Santoyo et al., 2021).

The ecological approach developed in the present study enabled us the development of biostimulators that can act as a soil conditioner in agriculture. These potential formulations can be a substitute to chemical fertilizers to optimize the use of natural phosphate in the world and improve resilience and yield of wheat crop. The deployment of such biostimulants containing multifaceted autochthonous *Ochrobactrum* sp. SSR and *Enterobacter* spp. ZW32 and ZW9 can offer a potential approach to mitigate P-induced stress in wheat plants. *Ochrobactrum*

sp. SSR exhibit pronounced potential in terms of modification of root morphology/architecture and increased real-time PS related genes expression to aid in transformation of insoluble P compounds into available forms for plant uptake, stimulate plant growth, and increase the crop yield.

CONCLUSIONS

This study provides a solid foundation to design well-characterized biostimulant formulation that deployed the multifaceted PSB and organic amendments based on agro-industrial by-products to improve the wheat growth and yield under P-deficient conditions. This is the first comprehensive research work that reports amplification of PS-related genes, i.e., *gcd*, *pqqC*, *pqqE*, and *pho* and real time expression of these genes by autochthonous *Ochrobactrum* sp. SSR, to release P from recalcitrant P forms. The successful biostimulant developed in this study is not only well-characterized but also extended the shelf life of highly efficient rhizosphere-competent P-solubilizers that ultimately led to sustainable wheat production for global food security.

Abd-Elkader DY, Mohamed AA, Feleafei MN, Al-Huqail AA, Salem MZM, Ali HM and Hassan HS (2022) Photosynthetic Pigments and Biochemical Response of Zucchini (*Cucurbita pepo* L.) to Plant-Derived Extracts, Microbial, and Potassium Silicate as Biostimulants Under Greenhouse Conditions. *Front. Plant Sci.* 13:879545. doi: 10.3389/fpls.2022.879545

There are many technological innovations in the field of agriculture to improve the sustainability of farmed products by reducing the chemicals used. Uses of biostimulants such as plant extracts or microorganisms are a promising process that increases plant growth and the efficient use of available soil resources. To determine the effects of some biostimulants' treatments on the photosynthetic pigments and biochemicals composition of zucchini plants, two experiments were conducted in 2019 and 2020 under greenhouse conditions. In this work, the effects of beneficial microbes (*Trichoderma viride* and *Pseudomonas fluorescens*), as well as three extracts from *Eucalyptus camaldulensis* leaf extract (LE), *Citrus sinensis* LE, and *Ficus benghalensis* fruit extract (FE) with potassium silicate (K_2SiO_3) on productivity and biochemical composition of zucchini fruits, were assessed as biostimulants. The results showed that *E. camaldulensis* LE (4,000 mg/L) + K_2SiO_3 (500 mg/L) and *T. viride* (10^6 spore/ml) + K_2SiO_3 (500 mg/L) gave the highest significance yield of zucchini fruits. Furthermore, the total reading response of chlorophylls and carotenoids was significantly affected by biostimulants' treatments. The combination of K_2SiO_3 with *E. camaldulensis* LE increased the DPPH scavenging activity and the total phenolic content of zucchini fruits, in both experiments. However, the spraying with K_2SiO_3 did not observe any effects on the total flavonoid content of zucchini fruits. Several phenolic compounds were identified via high-performance liquid chromatography (HPLC) from the methanol extracts of zucchini fruits such as syringic acid, eugenol, caffeic acid, pyrogallol, gallic acid, ascorbic acid, ferulic acid, α -tocopherol, and ellagic acid. The main elemental content (C and O) analyzed via energy-dispersive X-ray spectroscopy (EDX) of leaves was affected by the application of biostimulants. The success of this work could lead to the development of cheap and easily available safe biostimulants for enhancing the productivity and biochemical of zucchini plants.

Keywords: zucchini plants, beneficial microbes, plant-derived biostimulants, potassium silicate, phenolic compounds

INTRODUCTION

In agricultural performance, plant biostimulants are including different bioactive natural substances such as plant extracts, beneficial microorganisms, macroalgae seaweeds extracts, humic acid, fulvic acid, silicon, animal protein hydrolysate, vegetal protein hydrolysate, and bacteria belonging to the genera *Azotobacter*, *Rhizobium*, and *Azospirillum* (Chiaiese et al., 2018; Ricci et al., 2019).

In the recent years, the use of external preparations capable of stimulating plant growth by working on plant metabolism has become suitable for enhancing the efficiency of chemical fertilizers (Baroccio et al., 2017). Increasing yield is often associated with better-quality vegetables or fruits. According to the previous studies, biostimulants have a positive effect on the production of vegetables and fruits (Kocira et al., 2017; Goñi et al., 2018; Milić et al., 2018; Tarantino et al., 2018). In modern agriculture, biostimulants are the important strategies in the production of horticultural crops and consist of highly heterogeneous classes of compounds with a wide range of actions to improve quantitative and qualitative crops (Drobek et al., 2019).

Zucchini or squash (*Cucurbita pepo* L.), a highly polymorphic vegetable crop, is growing during the summer season in Egypt and all over the world (Ezzo et al., 2012; Mahmoud, 2016; Contreras et al., 2020), as a result of its economic importance and nutritional value. However, the increasing demand of consumers, in the local and international markets for fresh fruits of zucchini all year round, led to an increase in planting zucchini in the greenhouse (Formisano et al., 2020a,b). Zucchini is one of the most significant vegetable cash crops, especially, in newly reclaimed areas of Egypt, due to its high-yielding potential per unit area in the short-growing season. Therefore, improving the agricultural practices of zucchini production is of great economic interest. This may be achieved by applying simple applicable modern and low-cost strategies such as the use of silica compounds, *Trichoderma*, or plant-growth-promoting-rhizobacteria (PGPR) and plant extracts that stimulate the growth and development of this plant and then increase the productivity, which is safe for humans and environments (Savvas et al., 2009; Formisano et al., 2021; Novello et al., 2021).

Silicon (Si) is a biostimulant in the group of inorganic products. Foliar application of Si, as potassium silicates, is a relatively new technique of feeding vegetable plants, with several roles in plant physiology, regulation of ions uptake and increased tolerance of plants to various biotic and abiotic stresses (Artyszak, 2018). Moreover, Si stimulates the growth, development, and yield components of many vegetable species by correcting the levels of endogenous growth hormones (Artyszak, 2018).

Inoculating vegetable plants with *Trichoderma* or PGPR may be an effective strategy to stimulate the growth and development of plants as well as to minimize the use of synthetic fertilizers and agrochemicals. This strategy can improve plant tolerance for the abiotic stresses through induction of resistance by the production of phytohormones, enhancing soil productivity and volatile compounds that affect the plant signaling pathways (Kumar et al., 2020; Mannino et al., 2020). *Trichoderma* spp.

are free-living filamentous fungi in the soil, and some of them are the most potent agents for the biocontrol of soil-borne plant pathogens (Castiglione et al., 2021). *Trichoderma* can improve soil nutrient availability and promote plant growth and biostimulant (Velmourougane et al., 2019; Chen et al., 2021).

Plant extracts contain many bioactive compounds such as sugars, amino acids, proteins, nucleic acids, polysaccharides (Fernie and Pichersky, 2015), phenolic acids, and flavonoids (Sarker and Oba, 2018; Salem et al., 2021b). Foliar application of plant extracts leads to stimulating the root growth, photosynthetic capacity, and increasing the nutrient use efficiency, which ultimately leads to the growth promotion of vegetable crops (Bulgari et al., 2015). In addition, phenolic acids and flavonoids often play the important roles in the plant's defense against disease (Sarker and Oba, 2018). However, the plant extracts can be considered a good source of natural antioxidants and antimicrobial in both *in vitro* and *in vivo* (Di Mola et al., 2019; Souri and Bakhtiarizade, 2019; Godlewska et al., 2021). The raw materials resulting from the pruning processes of *Eucalyptus camaldulensis*, *Citrus sinensis*, and *Ficus benghalensis* trees are readily available in high quantities in Egypt. The growth of these trees under Egyptian conditions is very suitable and therefore economical in use. Further, the extracts from these trees were shown potential activities against the growth of bacteria and fungi (Nair and Chanda, 2007; Ekwenye and Edeha, 2010; El-Hefny et al., 2017; Bhawana et al., 2018; Salem et al., 2019; Abdelkhalek et al., 2020; Abo-Elgat et al., 2020; Afzal et al., 2020; Fatima et al., 2020).

The present research was carried out as an attempt to apply simple applicable modern, low-cost, and safe strategies through studying the effect of the use of some natural biostimulant with silicon on the productivity and bioactive component responses of zucchini plants, grown in clay soil, under drip irrigation in the greenhouse.

MATERIALS AND METHODS

A total of two consecutive experiments were carried out in the years 2019 and 2020 under a drip irrigation system in the greenhouse, at the Experimental Station Farm of the Faculty of Agriculture, Alexandria University, Abies, Alexandria, situated in Egypt, 31° 13' N latitude, 29° 59' E longitude.

Soil Analysis

Prior to the initial of the first experiment, soil samples of the experimental site up to 30 cm depth were collected and analyzed for some chemical and physical properties according to the standard procedures (Sparks et al., 2020). The main physical and chemical soil characteristics at the experimental site with clay soil were 46% sand, 24% silt, and 30% clay, electrical conductivity (EC): 2.60 dS m⁻¹, pH: 8, total nitrogen (N): 0.16%, phosphorus and potassium were 0.30 ppm and 0.33 m eq l⁻¹, respectively.

Experimental Work and Treatments

The current experiments were performed to study the effect of plant extracts, K₂SiO₃, and microbial inoculation with *Trichoderma viride* (10⁶ spore/ml) and *Pseudomonas fluorescens*

TABLE 1 | Treatments used in this study.

Treatment	Combination of biostimulants
Control	Without any microbial, plant extract, and potassium silicate
<i>T. viride</i>	<i>Trichoderma viride</i> (10 ⁶ spore/ml)
<i>T. viride</i> + K ₂ SiO ₃	<i>T. viride</i> (10 ⁶ spore/ml) + potassium silicate (500 mg/L)
<i>P. fluorescens</i>	<i>Pseudomonas fluorescens</i> (10 ⁸ CFU/ml)
<i>P. fluorescens</i> + K ₂ SiO ₃	<i>P. fluorescens</i> (10 ⁸ CFU/ml) + potassium silicate (500 mg/L)
<i>T. viride</i> + <i>P. fluorescens</i>	<i>T. viride</i> + <i>P. fluorescens</i> , individually (10 ⁶ spore/ml + 10 ⁸ CFU/ml)
<i>T. viride</i> + <i>P. fluorescens</i> + K ₂ SiO ₃	<i>T. viride</i> + <i>P. fluorescens</i> , individually (10 ⁶ spore/ml + 10 ⁸ CFU/ml) + potassium silicate (500 mg/L)
<i>E. camaldulensis</i> LE	<i>Eucalyptus camaldulensis</i> leaf extract (4,000 mg/L)
<i>E. camaldulensis</i> LE + K ₂ SiO ₃	<i>E. camaldulensis</i> leaf extract (4,000 mg/L) + potassium silicate (500 mg/L)
<i>C. sinensis</i> LE	<i>Citrus sinensis</i> leaf extract (4,000 mg/L)
<i>C. sinensis</i> LE + K ₂ SiO ₃	<i>C. sinensis</i> leaf extract (4,000 mg/L) + potassium silicate (500 mg/L)
<i>F. benghalensis</i> FE	<i>Ficus benghalensis</i> fruit extract (4,000 mg/L)
<i>F. benghalensis</i> FE + K ₂ SiO ₃	<i>F. benghalensis</i> fruit extract (4,000 mg/L) + potassium silicate (500 mg/L)

(10⁸ CFU/ml) as biostimulants on the growth, productivity, and bioactive of zucchini fruit that is grown in greenhouse conditions. Extracts were prepared from *Eucalyptus camaldulensis* leaves, *Citrus sinensis* leaves, and *Ficus benghalensis* fruits at the concentration of 4,000 mg/L as recommended in our previous work (Hassan et al., 2021).

AZIAD F1 cultivar was used in this study, and this cultivar was imported from the Sakata Tacky Company Japan vegetable seed. It is a desirable variety in the Egyptian market and bears low temperatures and high production (Abd Elmohsen et al., 2021). Zucchini seeds were sown in late September and in late December, in the first and second experiments, respectively. Within the same plantation row, the spacing between each plant and the other was set to be 30 cm, whereas the spacing between each line and the other was 1 m (3 plants/m²). The experimental layout was a randomized complete block design (RCBD), with three replicates. RCBD is used to control the variation in the experiment by accounting for spatial effects in the field or greenhouse, e.g., the variation in soil fertility or drainage differences in the field (Lauren, 2014). Each trial consisted of 13 treatments as shown in Table 1.

Each treatment was replicated three times, and each replicate consisted of 35 plants. Water irrigation was applied through the drip irrigation system. The drip irrigation system consisted of laterals GR of 16 mm in diameter with emitters at a 0.3-m distance. The emitters had a discharge rate of 4 L/h. The actual evapotranspiration of the zucchini crop (ET_c), under greenhouse at “Abies, Alexandria” area conditions, was calculated and adjusted at the start of each growth stage (Felefael and Mirdad, 2014). It was calculated by multiplying reference evapotranspiration (ET₀) for different growth stages through

both two experiments (from late September 2019 up to mid-December, 2019, in the first experiment and from late December and ended in late February 2020, in the second experiment) by a crop coefficient (K_C); $ET_c = ET_0 \times K_C$ (Allen, 1998; Razmi and Ghaemi, 2011) as shown in **Supplementary Table S1**. Irrigation frequency was every 5 days, to maintain soil water above 50% soil water depletion (Qassim and Ashcroft, 2002), which is the optimum level for zucchini plants.

The treatments of inoculation with *T. viride* were used as a drench to the plants' root area, were done through the addition of 50 ml suspension, which was mixed thoroughly with the soil, and then watered and left to ensure establishment and distribution in the soil. However, inoculation with *P. fluorescens*, *T. viride* + *P. fluorescens* and application of K₂SiO₃ and three extracts from *E. camaldulensis* LE, *C. sinensis* LE, and *F. benghalensis* FE were sprayed separately on zucchini plants. All treatments were added to the plants four times during the entire growing season of zucchini plants. The first addition was after 2 weeks from the sowing date, and then, the addition was done weekly. The spraying was done for each biostimulant separately, and *P. fluorescens* was sprayed before the spraying with K₂SiO₃ at an interval of 3 days. Ammonium sulfate (NH₄)₂SO₄, (20.5% N), phosphoric acid (58%), and potassium sulfate (48% K₂O) were the sources of N, P₂O₅, and K₂O, respectively. Nitrogen, phosphorus, and potassium fertilizers were fertigated at rates of 143, 167, and 238 kg N, P₂O₅, and K₂O/ha, respectively, which were injected directly into the irrigation water (fertigation) using a venture injector at one time weekly through a drip irrigation system in equal doses, starting from 2 weeks after planting. Climatic data, such as maximum and minimum air temperature (T_{maximum} and T_{minimum} °C) and relative humidity (RH%), were collected using Testo 175-H1 as shown in **Figure 1**.

Evaluation of Productivity

Zucchini fruits were harvested after 50 days from sowing, at a rate of two times a week. For each harvest, the number of fruits was counted and weighed for each treatment and then attributed to the hectare. The number and weight of fruits were recorded after each harvesting accumulatively. The number of fruits/hectare and the total productivity/hectare for each treatment were calculated.

Photosynthetic Pigments

Extraction of chlorophylls (a and b) and carotenoids from zucchini leaves was performed in ethanol 96% (v/v) in a proportion of 1:10 (w/v). The absorbance was read at 664 and 649 nm for chlorophylls a and b, respectively, as well as at 470 nm for carotenoids (Lichtenthaler, 1987; Campobenedetto et al., 2021).

Energy-Dispersive X-Ray Spectroscopy (EDX) Analysis

Energy-dispersive X-ray spectroscopy analysis was performed to measure the changes in the elemental chemical composition of zucchini leaves (nine leaves for each treatment) due to different treatments with treated with 500 mg/L K₂SiO₃ and

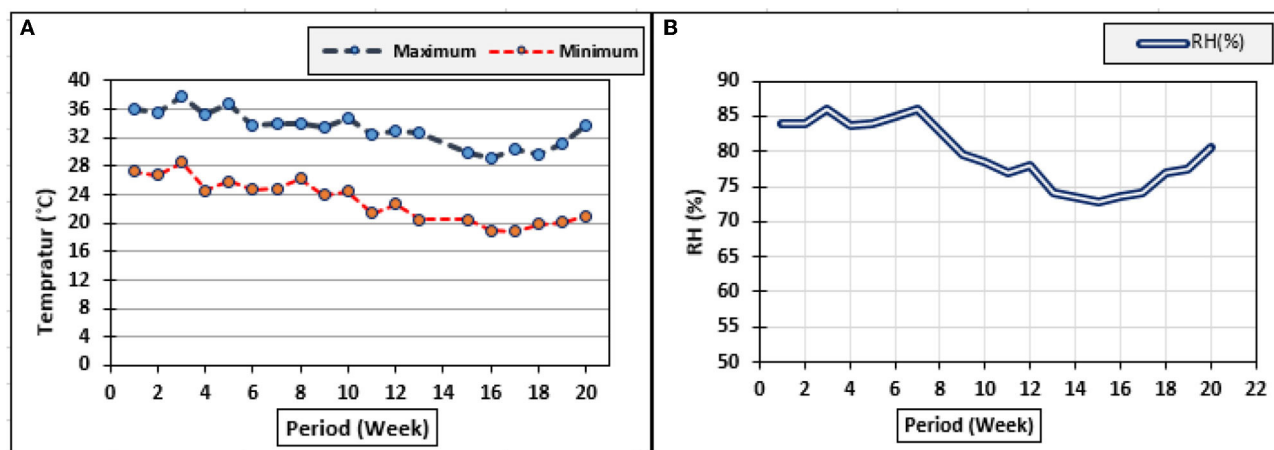

FIGURE 1 | The measured climatic conditions in the greenhouse during 2019 and 2020. **(A)** Minimum and maximum temperature (°C); **(B)** RH (%).

control treatment. Energy-dispersive spectrometry (EDX), JFC-1100E ion sputtering device (model JEOL/MP, JSMIT200 Series, Tokyo, Japan) with acceleration voltage of 20.00 kV to show the elemental composition at three points was used (Salem et al., 2021a).

2,2-Diphenyl-1-Picrylhydrazyl (DPPH) Radical Scavenging Activity

At 1 ml of 0.1 mM 2,2-diphenyl-1-picrylhydrazyl (DPPH), we added different concentrations of the prepared zucchini fruits' methanolic extracts. After vigorous shaking, the mixture was incubated for 30 min in the dark and at 25°C. The reduction of the radical DPPH resulting from the incubation with the different dilutions of zucchini methanolic extracts was monitored by reading the color decrease at 517 nm (Mannino et al., 2020). The percentage DPPH radical scavenging activity was calculated using the formula: Inhibition (%) = $[(A_{\text{control}} - A_{\text{sample}})/A_{\text{control}}] \times 100$, where A_{control} and A_{sample} are the absorbance of the control and treatments (Abd-Elkader et al., 2021).

Total Phenolic and Flavonoid Contents

Total phenolic content (TPC) was determined via Folin-Ciocalteu assay, as previously reported (Mannino et al., 2020). Quantification was performed using an external calibration curve with gallic acid (GA). Analyses were performed in triplicate, and data were expressed as millimole GA equivalents (GAE) per 100 g of FW., while the aluminum chloride colorimetric assay was used for total flavonoid content (TFC) determination and read at 510 nm using UV-Visible spectrophotometer Model UV 1601 version 2.40 (Shimadzu) (Marinova et al., 2005). Total flavonoids' content was expressed as mg catechin equivalents.

Fruit Extraction and HPLC Analysis of Phenolic Compounds

The extraction process was carried out on zucchini fruit samples treated with plant extracts and microbial with 500 mg/L K_2SiO_3 and control treatment. A sample was taken for each treatment

from the three replicates, about 15 fruits, then, all the fruits were grated and mixed well, and 30 g was taken then extracted by 60 ml methanol by the soaking method for 1 week (Ashmawy et al., 2020; Abd-Elkader et al., 2021). The extracts were then filtered through filter paper (Whatman no. 1) and then with a cotton plug. The extracts were concentrated and stored in brown vials in the refrigerator prior HPLC analysis. The phenolic compounds from the methanol extracts of each previous treatments were identified by the Agilent ChemStation [HPLC-(Agilent, Santa Clara, CA, USA)], which is composed of a quaternary pump and UV/Vis detector and C18 column (125 mm \times 4.60 mm, 5 μ m particle size). Chromatograms were obtained and analyzed using HPLC. Phenolic compounds were separated by employing a mobile gradient phase of water/acetonitrile/glacial acetic acid (980/20/5, v/v/v, pH 2.68) and acetonitrile/glacial acetic acid (1,000/5, v/v) with a flow rate of 1 ml/min and detected at 325 nm. All chemical standards (HPLC grade) were purchased from Sigma-Aldrich (St. Louis, MO, USA) (Hassan et al., 2021).

Statistical Analysis

All data were analyzed by implementing the CoStat software version 6.303 (CoHort Software 798 Lighthouse Ave. PMB 320, Monterrey, CA, 93940, USA) package through a two-way analysis of variance (ANOVA). A Tukey's honestly significant difference (HSD) test ($p < 0.05$) was used to separate the means (Steel and Torrie, 1980).

RESULTS

Productivity Parameters of Zucchini

Figure 2A shows that spraying of plants with K_2SiO_3 and biostimulants led to a significant increase in fruits number/ha compared to control. The fruits number/ha was significantly increased as zucchini plants were treated with *E. camaldulensis* LE and *E. camaldulensis* LE + K_2SiO_3 in the two consecutive experiments. In addition, plants sprayed with microbial and plant extracts were significantly increased the fruits number/ha

FIGURE 2 | Fruits number and total yield of zucchini as affected by biostimulant treatments. **(A)** Total number of fruits/ha and **(B)** The total yield (ton/ha) (means \pm S.E) of zucchini as affected by the extracts, microbial inoculations, and K₂SiO₃. Letters in the figure indicated that the means \pm S.E of treatments with the same letter/s were not significantly different according to Tukey's HSD level of probability.

as compared to the control treatment. Moreover, spraying plants with K₂SiO₃ at 500 mg/L with microbial or plant extracts were maximized the increase in fruits number/ha compared to biostimulant treatments without K₂SiO₃ in the two experiments.

The total yield/ha of zucchini fruits (Figure 2B) showed a significant difference among treatments with the highest values of 59.25 and 58 ton/ha, with the treatment of *T. viride* + K₂SiO₃, in the first and second experiments, respectively. *E. camaldulensis* LE + K₂SiO₃ treatment, also, gave a higher mean value in both experiments (56.67 and 56.34 ton/ha). It is noted

that the use of K₂SiO₃ with microbial and plant extracts as biostimulants led to an increase in total productivity/ha of zucchini in both experiments.

Photosynthetic Pigments

Table 2 presents the effect of K₂SiO₃ and plant extract or beneficial microbes as biostimulants on the content of photosynthetic pigments (total chlorophylls, chlorophylls a, b, and total carotenoids) of zucchini leaves. The results indicated a significant increase in the content of pigments as affected by

Letters in the figure indicated that the means ± S.E of treatments with the same letter/within the same column were not significantly different according to Tukey's HSD at a 0.05 level of probability.

the biostimulant treatments. It is clear from the results that the values obtained from the different photosynthetic pigments were affected by the different treatments of the biostimulant used. *T. viride* + K₂SiO₃, and *E. camaldulensis* + K₂SiO₃ treatments increased all the photosynthetic pigment contents, but the effect was most significant by the treatment *E. camaldulensis* LE + K₂SiO₃, in both experiments. In addition, Table 2 shows the application of the treatments *T. viride* and *E. camaldulensis* LE improved the chlorophyll pigment of leaves compared to the other treatments, in both experiments.

Elemental Compositions of Leaves by EDX Analysis

Table 3 and Figure 3 presents an EDX analysis to measure the changes in the elements' compositions of the leaves due to different treatments of biostimulants, which are six treatments in addition to the control. There was a significant effect of treatments on the elemental percentages with the highest values obtained with treatments *P. fluorescens* + K₂SiO₃, *T. viride* + *P. fluorescens* + K₂SiO₃, and *E. camaldulensis* LE + K₂SiO₃ on C, Mg, and Si elements. Also, there was a significant effect of treatments on elements N, P, and Ca percentages whereas the highest value was obtained by the plants treated with *T. viride* + K₂SiO₃. Moreover, the highest value of element K was obtained by treatment *E. camaldulensis* LE + K₂SiO₃.

DPPH Scavenging Activity

In Figure 4, all DPPH scavenging activity data of the zucchini fruits parameter were significantly influenced by the biostimulant applications. Our data indicated that the *E. camaldulensis* LE + K₂SiO₃ treatment increased the DPPH scavenging activity

mean value of zucchini fruits (75.93 and 76.21%) followed by *E. camaldulensis* LE (72.24 and 73.45%) in the first and second experiments, respectively (Figure 4). In addition, the combination of K₂SiO₃ with plant extract and microbial stimulants had no effect on improving DPPH in zucchini fruits, in both experiments.

Total Phenolic and Flavonoid Contents

Significant differences were found among the total phenolic contents of zucchini fruit samples in (Figure 5A), in both experiments. The values varied in a wide range with an average value of 150 to 300 mg GAE/100 g FW. In our two experimental conditions, the highest value was found with the treatment *E. camaldulensis* LE + K₂SiO₃ (300 mg GAE/100 g FW), followed by *E. camaldulensis* LE (289 mg GAE/100 g FW) and *T. viride* + *P. fluorescens* + K₂SiO₃ (287 mg GAE/100 g FW), whereas the lowest content was found in the control treatment.

The higher values of flavonoid content were recorded in biostimulant-treated zucchini plants with *T. viride* + *P. fluorescens* (104 mg QE/100 g sample), *T. viride* + *P. fluorescens* + K₂SiO₃ (110 mg QE/100 g sample), *E. camaldulensis* LE (116 mg QE/100 g sample), and *E. camaldulensis* LE + K₂SiO₃ (115 mg QE/100 g FW sample) treatments, with no significant difference among other treatments (Figure 5B). On the other hand, the spraying with K₂SiO₃ did not show any effects on the total flavonoids' content of zucchini fruits in both experiments.

HPLC Analysis of Phenolic Compounds in Zucchini Fruits

Table 4 presents the phytochemicals in terms of the phenolic compounds identified in the methanol extracts (MEs) of zucchini

fruits treated with plant extracts and microbial with K₂SiO₃ added only, which are six treatments in addition to the control treatment. The HPLC separation chromatograms are shown in **Supplementary Figure S1**. Ferulic (21.12 µg/ml), caffeic (19.63 µg/ml), and ellagic (18.33 µg/ml) acids were the most abundant compounds in zucchini fruit ME as affected by control. Zucchini fruit ME from plants treated with *T. viride* + K₂SiO₃ showed the presence of eugenol (35.16 µg/ml) and ellagic acid (17.36 µg/ml) as the main compounds. Eugenol (18.05 µg/ml) and caffeic acid (16.26 µg/ml) were the abundant compounds in ME from zucchini fruit treated with *P. fluorescens* + K₂SiO₃. Interestingly, α-tocopherol (22.01 µg/ml) with syringic acid (13.30 µg/ml) were the most abundant compounds in ME from fruits treated with *T. viride* + *P. fluorescens* + K₂SiO₃. The ME from fruits of the plants treated with *E. camaldulensis* LE + K₂SiO₃ identified *p*-coumaric acid (25.51 µg/ml), ferulic acid (20.11 µg/ml), and caffeic acid (18.87 µg/ml) as the abundant compounds. The ME of fruits from plants treated with *C. sinensis* LE + K₂SiO₃ identified pyrogallol (28.5 µg/ml), ferulic acid (18.09 µg/ml), and gallic acid (12.66 µg/ml) as the abundant compounds. Syringic (18.69 µg/ml) and caffeic (15.26 µg/ml) acids were the most abundant compounds in ME from fruits of zucchini collected from plants treated with *F. benghalensis* FE + K₂SiO₃.

DISCUSSION

The development of eco-friendly products to improve the growth and yield of horticulture has spurred a massive interest in commercial, especially in poor countries. The use of biostimulants has become increasingly common in modern agriculture and in the global market for the sale of agricultural products (Xu and Geelen, 2018). The biostimulants used may be a substance of natural origin or microorganisms that work or a mixture of them that improve the condition of crops and resist some pathogens and stress conditions to which plants are exposed without causing harmful side effects to the environment or humans (Du Jardin, 2015). The advantage of using biomass contained in plant extracts is its low cost (Tembo et al., 2018). Conversion of plant biomass in plant extracts, showing the action of biostimulants or plant growth, can be supportive to farmers in developing countries that cannot afford synthetic biostimulants, because of their high costs (Fite et al., 2020).

In this study, photosynthetic pigments and productivity were affected by the application of different biostimulants used. The results illustrated generally that *E camaldulensis* LE or *Trichoderma viride* with K₂SiO₃ increased the previous characters. *Eucalyptus* leaf extract increased photosynthetic pigments and the production of zucchini plants. These results might be due to many species of eucalyptus have high rich in carotenoids, carbohydrates, phenols, flavonoids, and antioxidants. Due to these compounds detected in *E camaldulensis* LE, it can be considered a biostimulant to enhance growth and productivity. Also, allelopathic activity and this activity can be the important catalysts in reducing diseases and increasing total yield (El-Rokiek et al., 2019). The

FIGURE 4 | DPPH (2,2-diphenyl-1-picrylhydrazyl) inhibition percentages (means \pm S.E) of methanol extracts from zucchini fruits as affected by the plant extracts, microbial inoculations, and potassium silicate biostimulants. Letters in the figure indicated that means \pm S.E of treatments with the same letter/s were not significantly different according to Tukey's HSD at a 0.05 level of probability.

induced metabolism of the photosynthetic pigments signified the increased growth parameters of the used leaf extract. In this response, the photosynthetic pigments of seedling broccoli significantly increased by *Eucalyptus* leaf extract (Mohsen et al., 2018). Furthermore, the application of *T. viride* seems to have affected photosynthetic pigments and the total yield characteristics of *Brassica* leafy crops similar to what has been shown for the control. *Trichoderma* is a genus of filamentous fungi that include several species described as biostimulants and/or biological control agents in agriculture (Velasco et al., 2021). Almost, microbial is widely used as a biofertilizer almost for all crops with or without amendments (Vinale et al., 2008; Schuster and Schmoll, 2010; Reynolds, 2016). Similarly, the PGPR increases both the growth parameters and yield attributes of onions and zucchini with the triple inoculation treatments (Tinna et al., 2020; Novello et al., 2021).

The role of microbial or *Trichoderma* in increased crop yield and quality was achieved mainly by the ability to degrade complex organic compounds present in the soil. Complex organic compounds were made available to plants in a simpler form, so that they could be absorbed (Khan et al., 2017; Thapa et al., 2020).

It is clear from previous studies that treating plants with silicon benefits their leaf structure by improving plant leaf erection, which leads to increased light interception and reduced self-shading, which leads to improved photosynthesis (Galindo et al., 2021). In this regard, silicon has a positive effect on chlorophyll pigments, which leads to an improvement in growth, which in turn affects the production of plants (Thorne et al., 2020; Salim et al., 2021). It is noted that there is an effect

of the use of biostimulants on the metabolism of plants and the final quality (Colla et al., 2015). Plant growth, quality, tolerance to abiotic and biotic stresses, photosynthesis, and using nutrients, fertilizers, and water are able to be enhanced by plant-derived biostimulants (PDBs) by modulating plant biochemical, molecular, and physiological processes (Rouphael and Colla, 2020b; Godlewska et al., 2021; Mosa et al., 2021b). Our previous work (Hassan et al., 2021) showed that the most abundant phenolic compounds in *Eucalyptus camaldulensis* LE were pyrogallol, caffeic acid, and *p*-coumaric acid, in *Citrus sinensis* LE were syringic and ferulic acids, and in *Ficus benghalensis* were gallic, *p*-coumaric, and syringic acids.

In addition, the application of biostimulants increased the biochemical compounds with potential effect on the nutrient content of plants. The shorter growing cycle of plants may result in biostimulation if the beneficial microbe has higher performance (i.e., *Trichoderma viride*), in improving the N uptake efficiency (Fiorentino et al., 2018). Moreover, the increase in the root system caused by the application of *Trichoderma* to the roots may have contributed to the increased N uptake of zucchini plants. This has also been observed when correlating the use of *Trichoderma* with the N content of leaves from several vegetable crops such as lettuce and tomato (Fiorentino et al., 2016; Sani et al., 2020).

Similar observations to our results were found after the use of microbial based on the enhanced yield by microbial inoculants has been linked in some cases to increased nutrient uptake and improved nutrient status of the cucumber and lettuce (Abdelaziz and Pokluda, 2009; El-Saady and Omar, 2017). Furthermore, some reports showed that *Pseudomonas* spp. was significantly

FIGURE 5 | Phenolic and flavonoid contents (means \pm S.E) of zucchini fruits as affected by the plant extracts, microbial inoculations, and potassium silicate biostimulants. **(A)** Total phenolic content and **(B)** total flavonoid content. Letters in the figure indicated that the means \pm S.E of treatments with the same letter/s were not significantly different according to Tukey's HSD at a 0.05 level of probability.

increased the uptake of P, Fe, Ca, and manganese (Mn) in some vegetables, e.g., eggplant and tomato (Calvo et al., 2014; Chrysargyris et al., 2020).

Some studies that are similar to our results were found after the use of PDBs in agriculture leads to an improvement in the crop's quality with an increase in bioactive components (Di Mola et al., 2019). It can be said that biological stimulants have a positive effect on a number of chemical properties of fruits and vegetables. It is evident that the use of several types of PDBs has potential effects on the development and quality of several plant

species, for example, tomato (Souri and Bakhtiarzade, 2019), rocket (Di Mola et al., 2019), and zucchini (Hassan et al., 2021).

Consistence with the present findings, PDBs as the foliar application were enhanced the total phenolic contents, antioxidant activity, and nutrient contents of tomato plants compared to the control (Chiaiese et al., 2018). Furthermore, these findings, generally, agreed with those previously reported on spinach and broccoli (Fan et al., 2011; Kałuzewicz et al., 2017), where they concluded that the use of biostimulants enhanced the phenolic content.

nd, not detected; ME, methanol extract.

Foliar application of Si has biostimulation effects, and also, it can be used by plants to augment their defenses against the entrance of toxic ions *via* the root apoplast (Verma et al., 2021b).

The phenolic contents were ranged between 96.2 and 117.3 mg GAE/100 g of FW, as affected by different biostimulant treatments. Other studies showed that the average phenolic content of zucchini fruits of was 8.67 mg GAE/g FW (Hamissou et al., 2013).

Zucchini plants treated with the following treatments *T. viride* + K_2SiO_3 , *P. fluorescens* + K_2SiO_3 , *T. viride* + *P. fluorescens* + K_2SiO_3 , *E. camaldulensis* LE + K_2SiO_3 , *C. sinensis* LE + K_2SiO_3 , and *F. benghalensis* FE + K_2SiO_3 showed several phenolic compounds (myricetin, syringic acid, *p*-coumaric acid, eugenol, vanillin, caffeic acid, 4-hydroxybenzoic acid, pyrogallol, gallic acid, ascorbic acid, ferulic acid, α -tocopherol, salicylic acid, catechol, ellagic acid, and protocatechuic acid) in the methanol extract with different concentrations compared with the control treatment. These phenolic compounds or PDBs are playing the important roles in regulating plant metabolic processes (Boudet, 2007; Lin et al., 2016; Mosa et al., 2021a). Simple phenolic acids such as hydroxybenzoic and hydroxycinnamic acids are derived from phenylpropanoid pathway (Mandal et al., 2010).

This study clarified the importance of the role played by Si element as a biostimulant in spraying on zucchini plants and increasing the efficiency of plant extract or microbial biostimulant. Si improves the growth of the plant by role defending the plant by increasing some different biochemical mechanisms in plants such as antimicrobial enzymes, flavonoids, and pathogen-related proteins (Verma et al., 2021a), chlorophyll

pigments, and antioxidants (Thorne et al., 2020; Salim et al., 2021). Studies have also shown that one of the beneficial properties of Si is its positive effects on abiotic stress tolerance and resistance to pathogens and diseases and thus has an effective role in improving overall productivity (Savvas and Ntatsi, 2015; Abd-Elkarim et al., 2017; Shwethakumari et al., 2021).

Plant-derived biostimulants have a positive effect on crop and vegetable plants; however, to improve their efficacy and optimize their inclusion in the industrial processes, the understanding of their action mechanism should be amended (Brown and Saa, 2015; Backer et al., 2018; Rouphael and Colla, 2020a).

CONCLUSION

The results of this study highlight the importance of biostimulant application to mitigate the effects of yield and biochemical. The potential use of some leaf extracts or microbial with K_2SiO_3 as a biostimulant was tested in zucchini plants on plant photosynthetic pigments, productivity, bioactive component, and elements content parameters that were evaluated after its use. The productivity of zucchini plants was increased by the foliar application of the treatments *T. viride* + K_2SiO_3 or *E. camaldulensis* LE + K_2SiO_3 as well as the content of the leaves of photosynthesis pigments. HPLC analysis of phenolic compounds in zucchini fruits and elements content of leaves was affected by biostimulants (microbial and plant extract with silicon). Total phenolic contents and DPPH scavenging activity were increased significantly in plants treated with *E. camaldulensis* LE + K_2SiO_3 .

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/**Supplementary Materials**, further inquiries can be directed to the corresponding author/s.

Humic acid-enhanced phosphate fertilizer (HAP) is widely applied in Chinese agriculture due to its high efficiency. Although the structural composition and physicochemical properties of humic acid (HA) are significantly altered during HAP production, a clear understanding of the mechanisms underlying the biological effects of HA extracted from HAP fertilizer (PHA) on plant growth is still lacking. In the current study, we extracted PHA from HAP and assessed its effects on the dry biomass, phosphorus (P) and nitrogen (N) uptake, and P absorption rate of maize seedlings when supplied at different concentrations (2.5, 5, 10, and 25 mg C L⁻¹) in the hydroponic culture. The root vigor, root plasma membrane H⁺-ATPase activity, and root nitrate reductase activity were also determined as the representative indicators of the root capacity for nutrient absorption, and used to clarify the mechanism by which PHA affects the maize growth and nutrient absorption. The results showed that the dry biomass, phosphorus uptake, nitrogen uptake, and average phosphorus absorption rates were significantly higher by 14.7–27.9%, 9.6–35.1%, 17.9–22.4%, and 22.1–31.0%, respectively, in plants treated with 2.5–5 mg C L⁻¹ PHA compared to untreated controls. Application of 10–25 mg C L⁻¹ raw HA resulted in similar stimulatory effects on plant growth and nutrient absorption. However, higher levels of PHA (10–25 mg C L⁻¹) negatively impacted these indicators of plant growth. Furthermore, low PHA or high raw HA concentrations similarly improved root vigor and root plasma membrane H⁺-ATPase and nitrate reductase (NR) activities. These results indicate that lower concentrations of PHA can stimulate maize seedling growth and nutrient absorption to an extent that is comparable to the effect of higher concentrations of raw HA. Thus, the proportion of HA incorporated into HAP could be lower than the theoretical amount estimated through assays evaluating the biological effects of raw HA.

Keywords: humic acid-enhanced phosphate fertilizer, humic acid, biological activity, maize, concentration

INTRODUCTION

Field application of humic acid-enhanced phosphate fertilizer (HAP) has been shown to increase crop yields and phosphorus (P) use efficiency when compared to conventional phosphate fertilizers (Li et al., 2017; Ma et al., 2019). Its higher performance is due to the effects of humic acid (HA) on P bioavailability, stimulation of plant growth, and nutrient absorption (Eyheraguibel et al., 2008; Yang et al., 2019; De Hita et al., 2020). However, only trace amounts of HA are present in HAP (i.e., typically lower than 0.5% w/w) (Zhao et al., 2020), suggesting that HA provides a greater contribution toward stimulating root growth and nutrient absorption than toward modulating P bioavailability (Eyheraguibel et al., 2008; Rose et al., 2014). Thus, the in-depth study of the bioactive effects of HA in HAP (PHA) on the production of plants cultivated in hydroponics is beneficial to clarify the mechanism that HA enhances the efficiency of phosphate fertilizer, and provides an important reference for HAP production (Urrutia et al., 2013).

Many studies have suggested that HA shows strong biological activity in promoting plant growth and the absorption of macronutrients, such as nitrogen (N) and P (Canellas et al., 2010; Jannin et al., 2012; Shah et al., 2018; De Hita et al., 2020; Jindo et al., 2020), and that these effects can be modulated by variations in the structural composition, molecular weight, and concentrations of different compounds in heterogeneous HA. For example, HA that is structurally enriched in carboxyl groups and hydrophobic structures has been reported to increase the root surface area, whereas HA with a greater proportion of aromatic and carbonyl groups have been linked to the increase of root number and diameter (García et al., 2016). Alternatively, HA composed of more smaller molecular components is reportedly most effective for inducing the absorption, transport, and assimilation of NO_3^- (Albuzio et al., 1986; Nardi et al., 2000; Zanin et al., 2018; Pizzeghello et al., 2020), while HA containing a higher proportion of high molecular components has been described as a potent positive regulator of root growth in other studies (Zandonadi et al., 2007; Canellas et al., 2009). Thus, the chemical structure of HA affects its function as a plant growth stimulator, while it is uncertain which chemical structure is predominantly available.

It is well-established that high temperature can substantially alter the structural composition of HA (Zhou et al., 2019), while a lot of heat is generated by exothermic neutralization reactions between phosphoric acid and alkaline compounds during the production of phosphate fertilizers (Peng and Xiang, 2017). Hence, the incorporation of HA into the phosphate fertilizer can change its structure, which has been verified by our previous study (Jing et al., 2020). The change likely leads to differences in the effects and potency of PHA on plant growth compared to carbon equivalent concentrations of HA. Whether PHA also maintained the bioactive effects on plant growth as HA was of great significance for revealing the enhancement mechanism of PHA on the efficiency of phosphate fertilizers.

Additionally, HA concentration can also serve as an important factor that determines its effect on the stimulation of plant growth. Pizzeghello et al. (2020) identified a positive, linear,

and concentration-dependent relationship between biomass production and HA concentration (ranging from 0 to 1 mg C L^{-1}) in garlic. However, work by Rose et al. (2014) indicated that plant biomass production followed a bell-shaped distribution with increasing HA concentration. Likewise, Garcia et al. (2016) observed adverse effects on the root of *Brachiaria* following the application of high concentrations of HA, which can be attributed to redox imbalance. Most of the previous studies focused on the influence of individual factors while overlooking the comprehensive contributions of structural properties, the molecular weight of constituent compounds, and concentration in the mechanistic analyses of the HA effects on plant growth.

The objective of this study is to determine the biological activity of PHA, identify the possible mechanisms by which HAP enhances plant growth and nutrient absorption, and provide a reference for the amount of HA incorporated into phosphate fertilizer. To this end, we extracted PHA from HAP and conducted a series of hydroponic experiments to assess the effects of 2.5–25 mg C L^{-1} of HA or PHA on biomass production, P and N uptake, and P absorption rate in maize. We also examine representative indicators of the root capacity for nutrient absorption, including root vigor and root plasma membrane H^+ -ATPase activity, as well as root nitrate reductase activity as an indicator of nitrogen metabolism for biomass production.

MATERIALS AND METHODS

Preparation of HA and PHA

Humic acid was extracted from weathered coal (45°23' N, 119°15' E; Huolinhe, Tongliao, Inner Mongolia Autonomous Region, Northeast China) according to the method conducted by Zhang et al. (2017). Subsequently, HAP incorporated with 0.5% HA was manufactured, and PHA was extracted from HAP and purified as described by Jing et al. (2020). In brief, 56.03 g of potassium hydroxide was added to the mixture containing 0.50 g of HA and 46.47 g of phosphoric acid (85% in v/v) under continuous stirring, and the reaction product was immediately pulverized and grounded through a 0.85 mm sieve to obtain the HAP fertilizer. Ten samples were prepared to achieve enough amounts of HAP for the extraction of PHA. HAP was dissolved in deionized water at a solid–liquid ratio of 1:10, and the pH of the mixture was adjusted to 1.0 using 6 M HCl. After standing for 24 h, the solution was centrifuged. The insoluble portions were collected and thoroughly washed four times with deionized water at a solid–liquid ratio of 1:10 and then oven-dried at 50°C to obtain PHA.

The phosphorus content of HA and PHA was determined using inductively coupled plasma emission spectrometer (5110 ICP-OES, Agilent Technologies Inc., USA) after wet digestion with $\text{H}_2\text{SO}_4\text{--H}_2\text{O}_2$ (Kalra, 1998). The contents of carbon, hydrogen, oxygen, nitrogen, and sulfur in HA and PHA were determined using an element analyzer (Vario Micro Cube, Elementar Analysensysteme GmbH, Germany). The relative proportions of C-containing functional groups and the molecular weight distributions of HA and PHA were determined using solid-state ^{13}C nuclear magnetic resonance spectrometer (Bruker

TABLE 1 | Elemental composition, relative proportions of C-containing functional groups, hydrophobicity index, and the percentage of the fractions with molecular weight <3,500 Da in all the detected molecular weights of HA and PHA.

AVANCE III HD 400 MHz, Switzerland) and gel permeation chromatography (GPC, Shimazu LC-20A, Japan) as described by Jing et al. (2020). The data of the above parameters are presented in **Table 1** and **Supplementary Figure S1**.

Hydroponic Maize and Experimental Design

Maize hybrid ZD958, a dominant high-yield hybrid in North China, was used in this study. Hydroponic experiments on maize seedling growth were conducted in an artificial climate chamber (28°C day/21°C night, 16 h/8 h light/dark period, 300 μmol m⁻² s⁻¹ light intensity, and 70% relative humidity) at the Dezhou experimental station, Chinese Academy of Agricultural Sciences. Before hydroponic culture, maize seeds were presoaked and pregerminated as described by Jing et al. (2020), and then the endosperm of seedlings was removed, and each plant was transplanted to containers filled with Hoagland nutrient solution (pH = 6.1) (Mao and Shen, 2011) containing HA or PHA at different concentrations. According to the previous studies by our group and others (Jing et al., 2020; Rosa et al., 2021), the concentration gradient of HA or PHA was set as 2.5, 5, 10, and 25 mg C L⁻¹. The nutrient solution with 0 mg C L⁻¹ of HA or PHA was set as a control. Six replicates were arranged for each treatment. During the incubation period, the nutrient solution was renewed every 72 h.

Sampling and Laboratory Analyses

During the incubation, the volume of initial and replaced nutrient solution was accurately measured, and meanwhile, the sampling of nutrient solution was conducted for the further P concentration analysis. The P concentration in the sampled nutrient solution was determined by the vanadium molybdate yellow colorimetric method (Haslemore and Roughan, 1976). Then, the P absorption rate of the plant was calculated according to formula (1).

On the 30th day after seed germination, the plant was harvested and divided into roots and shoots. All replicates for each treatment were split into two halves. One-half was stored in liquid nitrogen to retain freshness, and the remaining half was oven-dried at 105°C for 30 min and then at 75°C for 48 h to determine the dry biomass of the plants.

The fresh samples were used to measure the physiological traits as follows. The root vigor was evaluated by TTC (2, 3, 5-triphenyltetrazolium chloride) reduction method (Chen et al., 2006). The root plasma membrane (PM) H⁺-ATPase activity was determined by using Plant H⁺-ATP ELISA Kit (Jianglai Biological, Shanghai, China). The root nitrate reductase (NR) activity was assayed by monitoring the nitrite formation by the colorimetric method, as indicated by Jaworski (1971). The oven-dried samples were ground using a ball mill (MM400, RETSCH, Germany), and the P and N content was determined after wet digestion with H₂SO₄-H₂O₂ (Kalra, 1998). The P content was determined using the vanadium molybdate yellow colorimetric method (Johnson and Ulrich, 1959), and the N content was determined using the Kjeldahl method (Bremner, 1960).

Calculations and Statistical Analysis

Based on the decrease in the amount of P in the nutrient solution per unit time, the P absorption rates (mg day^{-1}) of a plant can be calculated as:

$$P \text{ absorption rate} = \frac{C_1 \times V_1 - C_2 \times V_2}{D} \quad (1)$$

where C_1 and C_2 are the concentrations of P (mg/ml) in the initial and replacement of nutrient solution, respectively; V_1 and V_2 are the volumes of initial and replacement of nutrient solution (ml), respectively; and D is the number of days that the nutrient solution was used, and D was 3 days in this study.

All values are shown as the mean of all replicates. The variance among different treatments was analyzed by using SAS 9.1 (SAS Institute Inc., NC, USA). The differences in maize traits between HA and PHA treatments at the same concentration were compared with two independent sample *t*-tests, while the differences between different HA or PHA concentrations were evaluated by performing an analysis of variance (ANOVA) with the least significant difference (LSD) ($\alpha = 0.05$). LSD was also used to assess the interaction between the type and concentration of HA and PHA. We conducted a structural equation model (SEM) to explore the direct and total effects of root vigor, and root PM H^+ -ATPase and root NR activities on the nutrient absorption, and Pearson correlation analysis was used to explore the relationship between nutrient absorption and root vigor or root PM H^+ -ATPase activity. Graphs were compiled by using Origin 2021 (Origin Lab Corporation, MA, USA).

RESULTS

PHA Shows Stronger Stimulatory Effects on Maize Biomass Production Than HA at Low Concentrations

To better understand the effects of PHA on the growth of maize plants, we first compared biomass production between maize plants treated with different concentrations of HA or PHA. The results showed that humic acid type, the concentration, and the interaction between type and concentration significantly impacted the accumulation of maize dry biomass ($P < 0.01$) (Supplementary Table S1). HA led to 16.6% and 30.7% higher total dry biomass than control plants at 10 and 25 mg C L^{-1} ($P < 0.05$), respectively, although it had no significant impact on total dry biomass at the concentrations of 2.5 or 5 mg C L^{-1} (Figure 1A). In contrast, application of 2.5 or 5 mg C L^{-1} PHA significantly increased total dry biomass by 14.7 and 27.9%, respectively, compared to the untreated controls ($P < 0.05$), but resulted in a significant decrease in biomass of 14.5 and 24.6% at 10 and 25 mg C L^{-1} concentrations, respectively ($P < 0.05$). A comparison of HA and PHA at the equivalent carbon concentration showed that biomass production was significantly higher under PHA treatment at low concentrations (i.e., 2.5–5 mg C L^{-1}) ($P < 0.05$), whereas HA application provided significantly stronger effects than PHA at higher concentrations (i.e., 10–25 mg C L^{-1}) (Figure 1A). In addition, quantification of root biomass

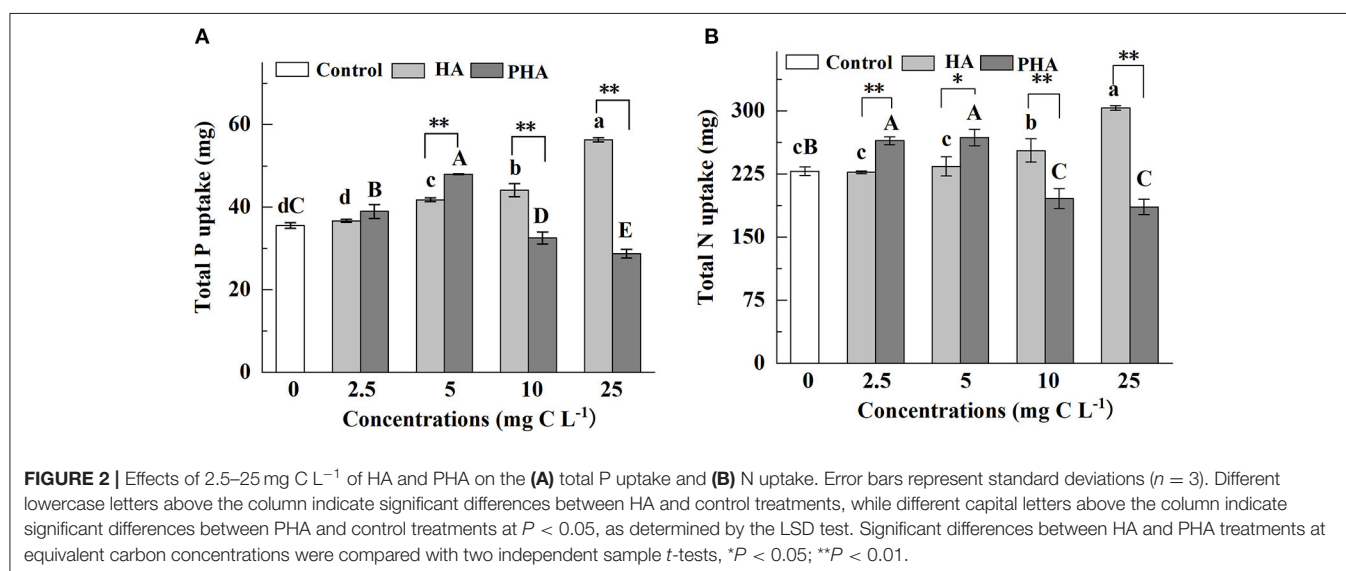

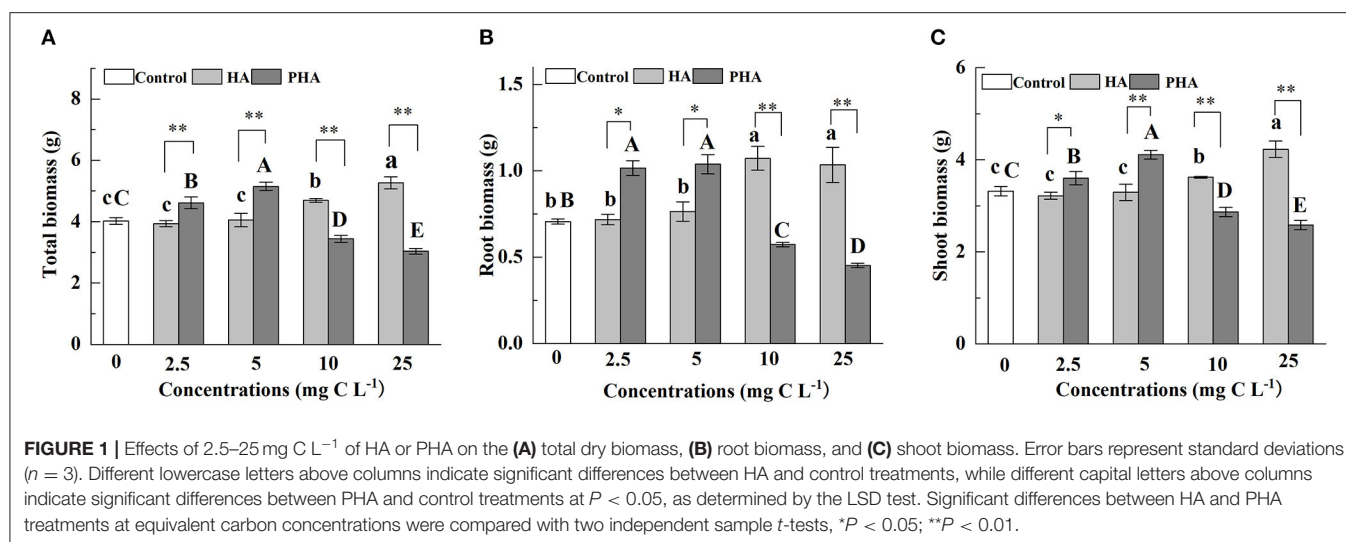

and shoot biomass under HA or PHA treatments recapitulated the effects of different concentrations on total dry biomass (Figures 1B,C). Taken together, these results indicated that PHA provided stronger stimulatory effects on biomass production in maize at lower concentrations than HA.

PHA Provides Its Maximal Effects on Nutrient Uptake at Lower Concentrations Than HA

Given that PHA application led to increased biomass accumulation in both above- and below-ground plant organs, we next measured P and N uptake under exposure to different concentrations of PHA or HA (Figures 2A,B). The results indicated that humic acid type, concentration, and the interaction between type and concentration significantly impacted P or N uptake ($P < 0.01$) (Supplementary Table S1). Although HA had no significant impact on P or N uptake at low concentrations (i.e., 2.5–5 mg C L^{-1}) ($P > 0.05$), at high concentrations of HA (i.e., 10–25 mg C L^{-1}), the uptake of both macronutrients was significantly greater than that observed in the untreated control plants ($P < 0.05$) (Figures 2A,B). Conversely, PHA treatments significantly enhanced nutrient uptake at lower concentrations (i.e., 2.5–5 mg C L^{-1}) ($P < 0.05$), but significantly reduced P and N uptake at higher concentrations ($P < 0.05$) relative to that observed in controls (Figures 2A,B). Maximum nutrient uptake for each treatment was observed at 25 mg C L^{-1} HA and 5 mg C L^{-1} PHA, with 58.5 and 35.1% higher P uptake corresponding to these respective treatments (Figure 2A), and 32.9 and 17.5% higher N uptake, respectively, compared to that of controls (Figure 2B).

At equivalent carbon concentrations, nutrient uptake was significantly higher under PHA treatments than that under HA treatment at low concentrations ($P < 0.05$), although no significant differences were identified between HA and PHA treatments in P uptake at 2.5 mg C L^{-1} ($P > 0.05$). At high concentrations (10–25 mg C L^{-1}), nutrient uptake was significantly higher in plants treated with HA compared to those subjected to PHA treatment ($P < 0.05$) (Figures 2A,B). Moreover, nutrient uptake by roots and shoots under different concentrations of HA or PHA was generally consistent with total P or N uptake (Supplementary Figures S2A–D).

We then compared the rates of P absorption by maize under different concentrations of HA or PHA over 30 days of cultivation (Figure 3A). During the cultivation, the average rates of P absorption increased along with HA concentration by 4.9, 10.5, 26.7, and 27.2% at 2.5, 5, 10, and 25 mg C L^{-1} , respectively, compared to that in the untreated controls (Figure 3B). In contrast, average P absorption rates increased by 21.9 and 30.6% over that in controls under treatment with 2.5 and 5 mg C L^{-1} PHA, respectively. However, average P absorption rates were lower than the rates observed in control plants, by 5.8 and 40.5% on average, under 10 and 25 mg C L^{-1} PHA, respectively (Figure 3B). Comparison of treatments at equivalent carbon concentrations indicated that average P absorption rates by maize were significantly higher in PHA than HA at 2.5 or 5 mg C L^{-1} , but significantly higher in HA compared to PHA at 10 or 25 mg C L^{-1} .

L⁻¹ (*P* < 0.05). These results suggested that the positive effects of PHA on nutrient uptake were strongest at lower concentrations than those conferred by HA treatment.

PHA Provides Maximal Stimulatory Effects on Root Nutrient Absorption Capacity at Lower Concentrations Than HA

Since root vigor and root plasma membrane (PM) H⁺-ATPase activity are known as representative indicators related to nutrient absorption by roots (Azevedo et al., 2019; Huang et al., 2021), we measured these traits in order to assess the effects of PHA on the capacity of root to absorb nutrients. The results showed that HA treatments resulted in significantly increased root vigor and root PM H⁺-ATPase activity at concentrations of 10 or 25 mg C L⁻¹ compared to the control treatments, but had no significant impact on these indicators at 2.5 or 5 mg C L⁻¹ (*P* > 0.05) (Figures 4A,B). In agreement with our experimental results, both indicators were significantly higher at 2.5–5 mg C

L⁻¹ of PHA than that in controls (*P* < 0.05) (Figures 4A,B). However, at 10–25 mg C L⁻¹ of PHA, root vigor was significantly lower than that of control plants (*P* < 0.05) (Figure 4A), and root PM H⁺-ATPase activity was not significantly different from controls (Figure 4B). Notably, at 2.5 or 5 mg C L⁻¹, root vigor and root PM H⁺-ATPase activity were significantly higher in PHA treatments than in HA treatments, but significantly higher in HA than PHA at 10 or 25 mg C L⁻¹ (*P* < 0.05). These results suggested that both PHA and HA application could lead to higher root vigor and root PM H⁺-ATPase activity than that observed in the absence of either treatment, but with maximal effects conferred at lower concentrations of PHA compared to HA.

Concentration of PHA With Largest Stimulation on Root Nitrate Reductase Is Lower Than That of HA

Since nitrate reductase (NR) activity in roots is an important indicator to assess nitrogen metabolism, we investigated whether

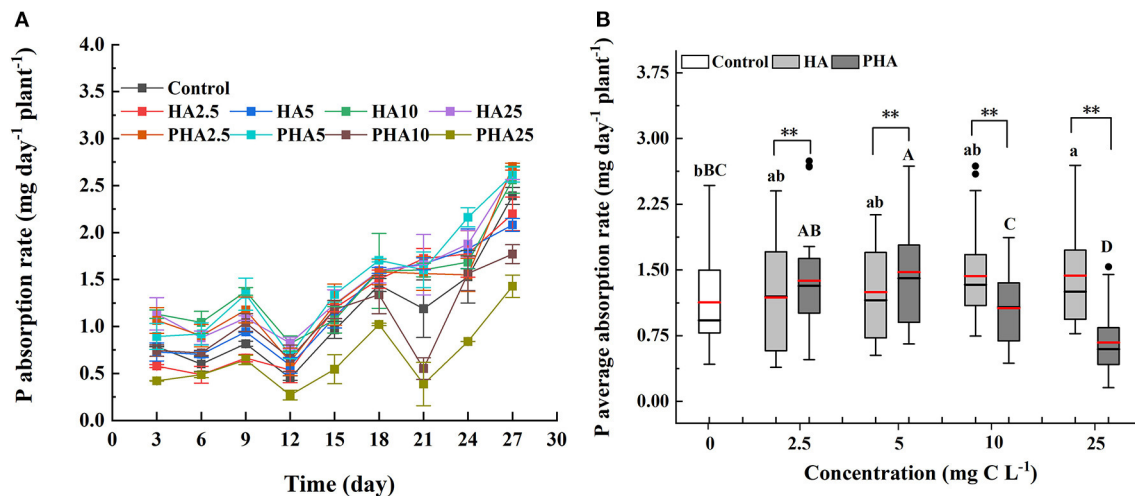

FIGURE 3 | Effects of 2.5–25 mg C L⁻¹ of HA and PHA on **(A)** P absorption rate over time ($n = 3$) and **(B)** average P absorption rate ($n = 27$). **(B)** Black lines, median value; red lines, mean value; lower and upper edges of the boxes, 25th and 75th percentiles of all data; bars, 5th and 95th percentiles of all data; dots in outside the boxes, <5th and >95th percentiles of all data. Different lowercase letters above the column indicate significant differences between HA and control treatments, while different capital letters above the column indicate significant differences between PHA and control treatments at $P < 0.05$, as determined by the LSD test. Significant differences between HA and PHA treatments at equivalent carbon concentrations were compared with two independent sample t -tests, $**P < 0.01$.

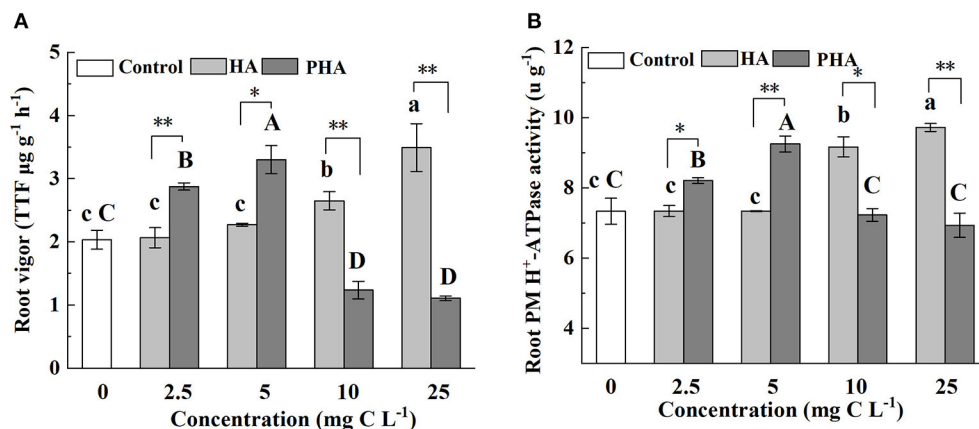

FIGURE 4 | Effects of 2.5–25 mg C L⁻¹ of HA and PHA on **(A)** root vigor and **(B)** root plasma membrane (PM) H⁺-ATPase activity. Different lowercase letters above the column indicate significant differences between HA and control treatments, while different capital letters above the column indicate significant differences between PHA and control treatments at $P < 0.05$, as determined by the LSD test. Significant differences between HA and PHA treatments at equivalent carbon concentrations were compared with two independent sample t -tests, $*P < 0.05$; $**P < 0.01$.

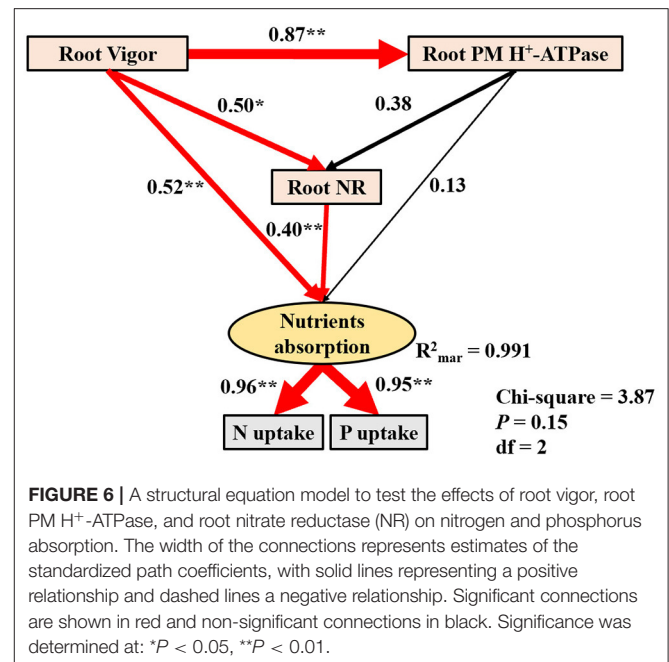

and how different concentrations of HA or PHA affected this activity. The results showed that root NR activity was significantly higher than that in control plants at high concentrations of HA (i.e., 10–25 mg C L⁻¹) ($P < 0.05$), but not significantly different from controls at 2.5 mg C L⁻¹ ($P > 0.05$) (Figure 5). However, compared to the NR activity detected in the untreated control plants, the application of 2.5–5 mg C L⁻¹ of PHA resulted in significantly elevated root NR activity, while higher concentrations (10–25 mg C L⁻¹) of HA significantly decreased root NR activity ($P < 0.05$) (Figure 5). As evident in the above-mentioned comparisons between equivalent treatments, root NR activity was significantly higher in PHA treatments than in HA treatments at low concentrations, but higher in HA treatments

than PHA at high concentrations ($P < 0.05$). These results indicated that both PHA and HA could increase root NR activity at different concentrations.

DISCUSSION

Modification of Humic Acid via Its Incorporation Into Phosphate Fertilizer Lowers the Concentration Required to Stimulate Maize Growth

In this study, we show that the stimulatory effects on plant growth and nutrient absorption by HA or PHA are affected

by their concentration (Supplementary Table S1), and the concentration of PHA required to significantly increase dry biomass and nutrient absorption is lower than that of HA, which could be explained by differences in the structural characteristics of HA and PHA. Compared with HA, PHA was characterized by the presence of more low-molecular-weight compounds and a higher hydrophobicity index, and less number of carboxylic groups (Table 1). Previous reports showed that HA with a larger proportion of low-molecular-weight compounds exhibits higher potency in promoting the growth of garlic (*Allium sativum* L.) plantlets than HA containing a larger proportion of high-molecular-weight compounds at concentrations ranging from 0 to 5 mg C L⁻¹ (Pizzeghello et al., 2020). Similarly, HA with strong hydrophobicity and more carboxylic groups shows greater beneficial effects on root growth, root area, root mitotic site, and root PM H⁺-ATPase activity (Jindo et al., 2012) at lower concentrations than HA with low hydrophobicity, which requires higher application rates to achieve the same results on plant productivity (Monda et al., 2018). These findings are supported by our results that show lower concentrations of PHA can provide similar stimulatory effects on plant growth as higher concentrations of HA (Figures 1A, 2A,B), which can be attributed to PHA containing a greater percentage of low-molecular-weight components than HA (Table 1, Supplementary Figures S1C,D), while incongruity with the fact that PHA has less carboxyl groups than HA. The result is also inconsistent with the view that HA-mediated promotion of root growth seems to be more closely related to HA mobility, molecular conformation, and functional group distribution than to molecular weight (Olaetxea et al., 2018). The above incongruity might be attributed to the fact that there was a greater variation of the molecular weight distribution between

PHA and HA than that of the carboxyl group content (Table 1). Additionally, the result of this research also suggests that the actual quantity of HA, added during the preparation of HAP, that is required to obtain optimal effects on plant growth could be less than that determined by theoretical calculations based on the biological effects of raw HA.

PHA Can Improve Root Vigor and Root Nitrate Reductase Activity to Enhance Absorption of Macronutrients

The increase in nutrient uptake is usually attributed to the enhancement of root physiological indexes, such as root vigor, root PM H⁺-ATPase activity, and root nitrate reductase (NR) activity (Olaetxea et al., 2018; Azevedo et al., 2019; Zhou et al., 2022), while the primary factor varied for different environmental conditions. Therefore, we constructed a structural equation model to analyze inherent relationships between nutrient uptake and root physiological traits affected by HA or PHA. Our model showed that nutrient absorption (P or N) is directly positively influenced by root vigor (Figure 6), which indicated that PHA application enhances nutrient absorption through improved root vigor when compared to HA.

The higher absorption of P or N in PHA is also directly stimulated by root NR activity (Figure 6), since root NR catalyzes the first step in the reduction of nitrate N to organic forms in plants, and increasing NR activity promotes N accumulation (Cordeiro et al., 2011). This is consistent with previous results that higher root NR activity and more nutrient uptake were observed in maize treated with low-molecular-weight HA (Vaccaro et al., 2015; Zanin et al., 2018). Moreover, root NR activity also has positive effects on P absorption (Figure 6), implying that enzymes associated with N metabolism also

contribute to P uptake. This co-regulatory effect on N and P uptake could be explained by the requirement of both essential macronutrients in plant biomass production, for example, nucleic acid and nucleoprotein synthesis (Marschner, 2012). Overall, PHA can improve P or N uptake by enhancing root vigor and stimulating root NR activity.

In addition, previous studies have also reported that the positive effect of HA on root PM H⁺-ATPase activity is the main factor affecting nutrient absorption (Xu et al., 2012; Olaetxea et al., 2018; Azevedo et al., 2019). However, in this study, root PM H⁺-ATPase activity had no significant impact on nutrient absorption ($P > 0.05$) (Figure 6). Further correlation analysis revealed that P or N uptake shares a generally positive correlation with root vigor and root PM H⁺-ATPase activity ($P < 0.001$, $n = 27$), although the correlation coefficients for uptake and root vigor (P uptake, $R^2 = 0.90$; N uptake, $R^2 = 0.94$) are higher than those observed for uptake and root PM H⁺-ATPase activity (P uptake, $R^2 = 0.88$; N uptake, $R^2 = 0.85$), implying that nutrient uptake is more strongly affected by root vigor than PM H⁺-ATPase activity. This result is supported by the lack of significant effects on nutrient absorption by root PM H⁺-ATPase activity in our structural equation model.

CONCLUSION

This study has clearly demonstrated that PHA retains the bioactive effects of raw HA in stimulating maize seedling growth and P or N absorption. HA or PHA appears to increase nutrient absorption by enhancing root vigor and stimulating root NR activity. However, lower concentrations of PHA can

provide similar stimulatory effects on plant growth and nutrient absorption as higher concentrations of HA. These results have indicated that the actual proportion of HA being incorporated into HAP for optimal effects on maize growth and macronutrient uptake could be lower than that determined through the assays that evaluated the biological effects of raw HA.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

AUTHOR CONTRIBUTIONS

BZ conceived and designed the study. JJ and SZ conducted the experiments and wrote the main manuscript. LY, YL, and CC contributed to data interpretation. All authors were involved in revising the manuscript.

FUNDING

This work was financially supported by the National Key Technologies R&D Program of China during the 13th Five-Year Plan period (2016YFD0200402).

The floating raft constitutes a valuable system for growing herbs as it effectuates high yield and prime functional quality. However, the pressing need for advancing sustainability in food production dictates the reduction of chemical fertilizer inputs in such intensive production schemes through innovative cultivation practices. In this perspective, our work appraised the productive and qualitative responses of two “Genovese” basil genotypes (Eleonora and Italiano Classico) grown in a floating raft system with nutrient solutions of varied electrical conductivity (EC; 2 and 1 dS m⁻¹) combined with root application of protein hydrolysate biostimulant at two dosages (0.15 and 0.3 0 ml L⁻¹ of Trainer®). The phenolic composition, aromatic profile, and antioxidant activities (ABTS, DPPH, and FRAP) of basil were determined by UHPLC/HRMS, GC/MS, and spectrophotometry, respectively. “Eleonora” demonstrated higher number of leaves (37.04 leaves per plant), higher fresh yield (6576.81 g m⁻²), but lower polyphenol concentration (1440.81 μg g⁻¹ dry weight) compared to “Italiano Classico.” The lower EC solution (1 dS m⁻¹) increased total phenols (+32.5%), ABTS, DPPH, and FRAP antioxidant activities by 33.2, 17.1, and 15.8%, respectively, and decreased linalool relative abundance by 5.5%. Biostimulant application improved crop performance and increased total phenolic concentration in both genotypes, with the highest phenolic concentration (1767.96 μg g⁻¹ dry weight) registered at the lowest dose. Significant response in terms of aromatic profile was detected only in “Eleonora.” Our results demonstrate that the application of protein hydrolysate may compensate for reduced strength nutrient solution by enhancing yield and functional quality attributes of “Genovese” basil for pesto.

INTRODUCTION

The ongoing quest for a healthy lifestyle and modern-day awareness exemplified in “*we are what we eat*” usher consumers to dietary schemes characterized by regular consumption of fruits and vegetables. The association between high consumption of healthy foods and low incidence of chronic disorders is attributed to the beneficial effects of the phytochemical antioxidants typical of plants (Teklić et al., 2021). Phytochemicals are classified into three groups according to their metabolic pathway: phenylpropanoids, alkaloids, and terpenoids (El-Nakhel et al., 2019). Better known as secondary metabolites, these biomolecules, crucial in defense and functional environment-plant interaction (Verma and Shukla, 2015), have always been a natural and indispensable resource for cosmetic, pharmaceutical, and agri-food industries (Mahajan et al., 2020; Ciriello et al., 2021b). Minor plant species, such as herbs, due to a heterogeneous and not fully explored reservoir of secondary metabolites, have rekindled the interest of both consumers and academics (Kwon et al., 2020; Alexopoulos et al., 2021). Basil (*Ocimum basilicum* L., *Lamiaceae*) is an irreplaceable ingredient for traditional Italian dishes (“pesto” and pizza “Margherita”) and the pharmaceutical sector (Barátová et al., 2015; Ciriello et al., 2021a,b) due to the biosynthesis of low molecular weight organic compounds (i.e., monoterpenes and phenylpropanoids), responsible for its distinctive aroma (Dias et al., 2016). On the other hand, the outstanding nutraceutical value of basil is mainly attributable to a heterogeneous phenolic profile (rosmarinic acid, chicoric acid, caffeic acid, and p-coumaric acid) that, like aroma, is strongly affected by the interaction between genotype and environment (Jakovljević et al., 2019; Ciriello et al., 2021b). To date, phenolic compounds have become among the most investigated natural molecules (Dias et al., 2016). In addition to having a considerable impact on quality attributes (flavor and color), they possess antioxidant, antifungal, and antimicrobial properties, such as being considered multitarget drugs with potential applications in the agri-food sector as surrogates for artificial preservatives (Filip, 2017). Increasingly extreme environmental conditions combined with the demand for high-quality agricultural production have led the growers to alternative cropping systems (Alexopoulos et al., 2021; Ciriello et al., 2021a; Teklić et al., 2021). In this context, the soilless growing system is a viable strategy for the conversion and redevelopment of abandoned urban and peri-urban areas to full-scale green farms (Wortman, 2015). Among hydroponic systems, the floating system is undoubtedly the one that best lends itself to the production of aromatic herbs such as basil (Ciriello et al., 2020, 2021a). This growing system, in addition to being more economically sustainable (lower production and set-up costs), would guarantee, in line with today’s market demands, a higher production all year round with standardized characteristics (Bonasia et al., 2017; Prinsi et al., 2020; Aktsoglou et al., 2021; Žlabur et al., 2021). In addition, the potential to control and manipulate the composition of the nutrient solution (NS) would positively change secondary metabolism by enhancing the phytochemical properties of grown horticultural products (Scuderi et al., 2011; Maggini et al., 2014; El-Nakhel et al.,

2019; Prinsi et al., 2020; Aktsoglou et al., 2021). The unclear effects of dilute NS (nutrient stresses) on leafy vegetable yield parameters (Fallico et al., 2009; El-Nakhel et al., 2019; Ciriello et al., 2020; Hosseini et al., 2021) have prompted growers to use concentrated NS that exceed crop needs (Yang and Kim, 2020). Consistent with the guidelines of the European Commission, the need to reduce chemical input while improving yield and quality in intensive production environments has prompted the agricultural sector to become increasingly interested in biostimulants (Carillo et al., 2019; Kerchev et al., 2020; Teklić et al., 2021). The combination of hydroponic and biostimulants appears to be a promising ecological strategy for controlled environment production of high-quality vegetables. Colla et al. (2015) reported that plant protein hydrolysates (PH’s) are innovative strategies to address the above challenges. Recent work by Rouphael et al. (2021) pointed out that the use of PH’s by foliar application improved the production performance of “Genovese” basil in protected cultures. The effectiveness of these natural products (derived from agricultural by-products) is also confirmed in the work of Caruso et al. (2019) and Cristofano et al. (2021) on arugula (*Eruca sativa* Mill.) and lettuce (*Lactuca sativa* L.), respectively. These results are attributable to bioactive molecules (amino acids and signaling peptides) that exert a plethora of physiological and growth effects on plants while inducing up-regulation of increasingly sought-after secondary metabolites (Colla et al., 2017; Ertani et al., 2017; Caruso et al., 2019). The possibility of sustainably increasing resource use efficiency (Rouphael et al., 2021) by partially ameliorating environmental drawbacks associated with overfertilization makes the application of PH’s in floating raft systems (FRS) even more attractive. The complete absence of interactions between the roots and the agricultural soil makes the FRS suitable for studying *in vivo* the real plant responses to biostimulant integration (Tsouvaltzis et al., 2020). To date, there is a lack of information in the literature on the application mode recommended for this cropping system. However, considering that PH’s improve the uptake, assimilation, and translocation of nutrients through modifications of the root system, the possibility of applying the biostimulant directly in contact with the root system (in NS) could further enhance its potential. The benefits of biostimulus on production and quality in a soilless superintensive system could be an effective tool to reduce chemical fertilizer inputs, and to improve economic and environmental sustainability. Our work aimed to evaluate the use of a PH in a NS at two different doses to assess the effects on the production performance and quality of two Genovese basil genotypes (Eleonora and Italiano Classico) grown in a FRS with two different nutrient concentrations (1 and 2 dS m⁻¹).

MATERIALS AND METHODS

Plant Material, Experimental Design, and Growth Conditions

The experimental trial was carried out in a passive ventilation greenhouse at the experimental site of the Federico II University

of Naples - Department of Agriculture (DIA) located in Portici (Naples, Italy; lat. 40°51'N, long. 14°34'E; 60 m above sea level), during the summer growing season in 2020. The experimental design was trifactorial in which two "Genovese" basil (*Ocimum basilicum* L.) genotypes [(1) Eleonora, Enza Zaden, Enkhuizen, Noord-Holland, The Netherlands: erect stem, large green, slightly serrated leaves; suitable for open field cultivation; intermediate resistance to *Peronospora belbahrii* and (2) Italiano Classico, La Semiorto Sementi, Sarno, SA, Italy; erect stem, medium height with bright green, slightly blistered "spoon" leaves] were grown in a FRS with two different concentrations of NS (1 dS m⁻¹-Half Strength and 2 dS m⁻¹-Full Strength) and two doses of biostimulants (0.15 and 0.30 mL L⁻¹) plus an untreated control (hereafter B_{0.15}, B_{0.30}, and Control, respectively). The treatments were performed in triplicate and arranged in a completely randomized block design. On 9 June (18 days after sowing), at the phenological stage of 2–3 true leaves, basil seedlings were transplanted into 54-hole polystyrene trays (52 × 32 × 6 cm; upper hole diameter: 4.5 cm; bottom hole diameter 3 cm; volume: 0.06 l) at a density of 317 plants m⁻². The experimental design comprised 36 experimental units, each consisting of a 54-hole tray floating in a 40-liter tank filled with 35 l of NS. The oxygenation of the NS was provided by a submersible pump (Aquaball 60, Eheim, Stuttgart, Germany).

Nutrient Solutions Management, Biostimulant Application, and Harvest

The NS (half strength and full strength) were prepared from osmosis water. The half strength NS was obtained by halving the macronutrient concentration of the full strength stock NS (14.0 mM nitrate, 1.5 mM phosphorus, 3.0 mM potassium, 1.75 mM sulfur, 4.5 mM calcium, 1.5 mM magnesium, and 1.0 mM ammonium). Micronutrient concentrations were for both solutions 15 μM iron, 9 μM manganese, 0.3 μM copper, 1.6 μM zinc, 20 μM boron, and 0.3 μM molybdenum. During the trial, the pH was continuously monitored and maintained at values of 5.8 ± 0.2. At transplanting, a legume PH (Trainer- Hello Nature USA Inc., Anderson, IN 46016) was applied to the NS at two different doses (0.15 mL L⁻¹ and 0.30 mL L⁻¹). The biostimulant used, which was free of plant hormones (Rouphael et al., 2018; Paul et al., 2019), contained soluble peptides and amino acids such as Ala, Arg, Asp., Cys, Glu, Gly, His, Ile, Leu, Lys, Met, Phe, Pro, Ser, Thr, Trp, Tyr, and Val, which comprised 5% of the total nitrogen content along with soluble sugars and phenols. At the end of the experiment, 25 plants per experimental unit were sampled to determine biometric parameters such as the number of leaves per plant and fresh yield. The harvested plant material was then placed in a ventilated oven at 60°C until a constant weight was reached to determine the dry yield and the percentage of dry matter (DM = 100 × dry weight/fresh weight). Instead, a homogeneous pool of 20 plants per experimental unit was sampled and placed immediately at -80°C for future qualitative analysis. A plant material sample was freeze-dried (Alpha 1–4, Martin Christ Gefriertrocknungsanlagen GmbH, Osterode am Harz, Germany) and finely ground with a KM13 rotating blade grinder (Bosch, Gerlingen, Germany).

CIELab Color Space Determination

At harvest, color coordinates were recorded on the adaxial surface of ten healthy and fully expanded leaves per experimental unit using a Minolta Chromameter CR-400 portable colorimeter (Minolta Camera Co. Ltd., Osaka, Japan). As described by the International Commission on Illumination (CIE), the color was expressed by L, a*, and b* coordinates by which the Chroma and Hue angle were determined as follows:

$$\text{Chroma} = \left[(a^*)^2 + (b^*)^2 \right]^{0.5}$$

$$\text{Hue angle} = \tan^{-1} b^* / a^*$$

Determination of ABTS, DPPH, and FRAP Antioxidant Activities

The antioxidants activities were determined following the protocols described by Graziani et al. (2021). For the determination of ABTS antioxidant activity a stock solution was prepared by mixing 44 ml of potassium persulfate (2.45 mM) with 2.50 ml of aqueous solution (7 mM) of 2,2'-azinobis-(3-ethylbenzothiazoline-6-sulfonate) radical (ABTS*) and placed at 20°C (room temperature) for 12 h. The ABTS solution was diluted (1:88) with ethanol until it reached an absorbance of 0.700 ± 0.005 at 734 nm. After that, a 1 ml aliquot of ABTS solution was added to 100 ml of the filtered sample and incubated at room temperature for 2.5 min. For the antioxidant 2,2-diphenyl-1-picryl-hydrazyl (DPPH) activity, 1 ml of methanolic solution of DPPH 100 μM (absorbance of 0.90 ± 0.02 at 517 nm) was added to 0.2 ml of diluted leaf extract and incubated at room temperature for 10 min. For ferric reduction/antioxidant power (FRAP) antioxidant activity determination a FRAP reagent was prepared by mixing 1.25 ml of 2,4,6-triaryl-triazine (TPTZ; 10 mM) in 40 mM Hydrochloric acid, 1.25 ml of 20 mmol ferric chloride in water, and 12.5 ml of 0.3 M sodium acetate (pH 3.6). An aliquot of 2.850 ml of FRAP reagent was added to 0.015 ml of leaf extract and incubated at room temperature for 4 min. The absorbances of the ABTS, DPPH, and FRAP assays were measured with a UV-VIS spectrophotometer (Shimadzu, Japan) at 734, 517, and 593 nm, respectively. Results were expressed as mmol Trolox equivalents kg⁻¹ dry weight (dw) of the sample. All determinations were made in triplicate.

Determination of the Polyphenol Profile by Ultra-High Performance Liquid Chromatography and Orbitrap High-Resolution Mass Spectrometry Analysis

Extraction of Polyphenolic Compounds

Polyphenolic compounds were extracted as described by Corrado et al. (2021). Briefly, 0.1 g of finely ground and freeze-dried leaves was extracted in 5 ml of an aqueous methanol solution (60:40, v/v). Then, the obtained solution was sonicated and centrifuged at 4,000 rpm for 15 min, and 0.05 ml of supernatant was collected, filtered, and analyzed.

Quantification of Phenolic Compounds

Quantification and separation of phenolic compounds were performed by UltraHigh-Pressure Liquid Chromatography (Dionex UltiMate 3,000 UHPLC, Thermo Fisher Scientific, Waltham, MA, United States) coupled to the Q Exactive Orbitrap LC–MS/MS Mass Spectrometer (Thermo Fisher Scientific, Waltham, MA, United States) as described by El-Nakhel et al. (2021). The polyphenols were separated by using a Luna Omega PS (1.6 m, 50 × 2.1 mm, Phenomenex, Torrance, CA, United States) at 25 °C. The mobile phase was a two-phase solution containing water (phase A) and acetonitrile (phase B). Both mobile phases contained 0.1% formic acid (v/v). Polyphenolic compounds were eluted using the following gradient schedule: 0–1.3 min 5% B, 1.3–9.3 min 5–100% B, 9.3–11.3 min 100% B, 11.3–13.3 min 100–5% B, 13.3–20 min 5% B. The flow rate was 0.2 ml min⁻¹. For all compounds of interest, an ESI source (Thermo Fisher Scientific, Waltham, MA, United States) was used in negative ion mode, with full ion (MS) and all ion fragmentation (AIF) scanning events. Data acquisition and processing were performed with Quan/Qual Browser Xcalibur software, v. 3.1.66.10 Xcalibur, Thermo Fisher Scientific, (Thermo Fisher Scientific, Waltham, MA, United States). Polyphenols were expressed as $\mu\text{g g}^{-1}$ dw.

Determination of Volatile Compounds

The extraction and quantification of volatile compounds (VOCs) were performed by gas chromatography combined with the mass spectrometer technique (GC/MS) after solid phase microextraction (SPME), as described in detail by Ciriello et al. (2021b).

Extraction of Volatile Compounds by the SPME Technique

An aliquot of 0.5 g of frozen sample was placed in glass vials with a screw cap and placed on a heated stirrer (30°C for 10 min) to facilitate the migration of volatile compounds into the headspace. The adsorption of VOCs was performed by introducing a divinylbenzene/carboxane/polydimethylsiloxane fiber 1 cm long and 50/30 μm thick; Supelco® (Bellefonte, PA, United States) into the headspace for 10 min.

Quantification of Volatile Compounds

SPME fiber containing the adsorbed analytes was introduced into the split-splitless injector of the gas chromatograph (GC 6890 N; Agilent, Santa Clara, CA, United States) coupled to the mass spectrometer (MS 5973 N; Agilent, Santa Clara, California, United States). The thermal desorption of the analytes occurred at 250 °C for 10 min. The oven temperature was maintained at 50°C for 2 min and increased from 50°C to 150°C at 10°C/min and from 150°C to 280°C at 15°C/min. The injection and ion source temperatures were 250°C and 230°C, respectively, and helium (99.999%) was used as a carrier gas with a flow rate of 1 ml min⁻¹. The gas chromatograph was equipped with a capillary column (30 m × 0.25 mm) coated with a 0.25 μm 5% diphenyl/95% dimethylpolysiloxane film (Supelco®, Bellefonte, PA, United States). The mass spectrometer was set at 70 eV. Identification of VOCs identification was performed using the National Institute of Standards and

Technology (NIST) Atomic Spectra Database version 1.6 (U.S. Department of Commerce, Gaithersburg, Maryland, United States).
