The experiment consisted of a randomized block design with three factors: Cultivar-CV, Biostimulant-B, and Nutrient Solution Concentration-NSC. Analysis of variance (ANOVA) was conducted for the main effects and their interactions. In the absence of significant interactions, significant main effects for factors applied at only two levels (CV and NSC) also denote significant differences between the two means. In the case of significant two-way interactions (CV × B, B × NSC, and CV × NSC), interaction means were compared using the Tukey–Kramer HSD test with statistical significance determined at the $p < 0.05$ level. All data are presented as mean ± standard error. Statistical analysis was performed using IBM SPSS 20 (Armonk, NY, United States) package for Microsoft Windows 10. Statistical processing was performed using IBM SPSS 20 (Armonk, NY, United States) package for Microsoft Windows 10.

RESULTS

Yield and Yield Parameters

Regarding the main yield parameters, the cultivar factor significantly influenced all the parameters reported in **Table 1**, except the dry yield. Although “Eleonora” had the highest number of leaves and the highest fresh yield, “Italiano Classico” was characterized by a higher percentage of dry matter. Biostimulant treatment significantly influenced all yield parameters compared to the Nutrient Solution Concentration that affected dry yield and dry matter (**Table 1**).

Biostimulant treatment showed a linear increase in leaf number, fresh yield, and dry yield as a function of the dose used (Control > B_{0.15} > B_{0.30}), in contrast to dry matter, which showed the highest value at B_{0.15}. Regarding the CV × B interaction for both “Eleonora” and “Italiano Classico,” the B_{0.30} dose determined, compared to the Control, an average increase of 13.65 and 21.38% in the number of leaves and dry yield, respectively. The dry matter did not show the same trend since, in “Eleonora,” the highest value was obtained at B_{0.15}, while in “Italiano Classico,” the highest values were obtained at B_{0.15} and B_{0.30}. The CV × B interaction did not influence fresh yield that was significantly influenced by the B × NSC interaction (**Figure 1**). Regardless of the NSC, the use of the biostimulant increase fresh yield (**Figure 1**) and dry yield (**Table 1**). However, for the full strength solution (FS; 2 dS m⁻¹), a linear increase of the above two parameters was observed as the concentration of the biostimulant increased. The highest dry matter values were obtained at B_{0.15} for both half strength [HS; 1 dS m⁻¹; (7.67%)] and FS (7.88%) nutrient solutions. On the contrary, the highest values were already observed at B_{0.15} for the HS nutrient solution, which did not show significant differences compared to the B_{0.30} dose. The CV × NSC interaction showed significant differences only for dry yield and dry matter. In “Italiano Classico,” the use of the FS increases by 4.82 and

**Significant effect at the 0.01 level.

***Significant effect at the 0.001 level.

3.40% dry yield and dry matter, respectively. The same trend was observed in “Eleonora” only for dry matter (+1.60%).

CIELab Colorimetric Parameters

Except for the Hue angle, significant differences were observed between genotypes for leaf colorimetric characteristics (Table 2). “Italiano Classico” showed the highest values of L, a*, b*, and Chroma. Greenness (a*) was the only parameter influenced by the biostimulant, with the highest value obtained at B_{0.30}. The different NSC influenced the colorimetric parameters L, a*, and Hue angle, as opposed to b* and Chroma. The latter were significantly affected by the CV × B and CV × NSC interactions (Table 2). The CV × NSC interaction also influenced

the a* and Hue angle parameters. The biostimulants in the HS solutions did not affect a* and Hue angle, compared to the FS nutrient solution, where the B_{0.15} and B_{0.30} doses increased these parameters, compared to the Control. The CV × NSC interaction showed significant differences only for the parameters L and b*. In both “Eleonora” and “Italiano Classico,” the use of HS increased L; the opposite trend was observed for the b* in Eleonora, while no significant differences were registered in “Italiano Classico.”

Phenolic Acids

The total phenols were influenced by the factors under investigation and their mutual interactions (Table 3). Chicoric acid was the

predominant compound, followed by feruloyl tartaric acid, salvianolic acid K, rosmarinic acid, caftaric acid, salvianolic acid L, and chlorogenic acid. “Italiano Classico” showed the highest content of chicoric acid, salvianolic acid K, rosmarinic acid, salvianolic acid L, and chlorogenic acid, while “Eleonora” showed the highest concentration of feruloyl tartaric acid. B and NSC treatments significantly affected the entire phenolic profile (Table 3). Specifically, the biostimulant at B_{0.15} dose increased the total phenols by 35.63% compared to the Control. Similarly, the HS increased the total phenol by 32.50%, compared to the HS one. CV×B interaction affected all the parameters reported in Table 3. The B_{0.15} dose increased caftaric acid, feruloyl tartaric acid, salvianolic acid K, salvianolic acid L, and total phenols for both genotypes, compared to the Control. On the other hand, the highest chicoric acid values were obtained from the Italiano Classico × B_{0.15} combination (1290.32 μg g⁻¹ dw) and Italiano Classico × B_{0.30} (1309.98 μg g⁻¹ dw). In comparison, the lowest value was obtained from the combination Eleonora × B_{0.30} (11.68 μg g⁻¹ dw). Except for the most and least representative phenolic acids (chicoric and chlorogenic acids, respectively), all phenolic acids were affected by the B×NSC interaction. The B_{0.15}×HS combination provided the highest total phenol concentration (2045.94 μg g⁻¹ dw) and feruloyl tartaric acid, salvianolic acid L, salvianolic acid K, and caftaric acid, while the highest concentration of rosmarinic acid was obtained from the Control × HS combination. Compared to the CV×NSC interaction, for both “Eleonora” and “Italiano Classico,” the HS,

compared to the FS, increased total phenols by 53.99 and 15.95%, respectively. Except for caftaric acid, the highest concentration of all phenolic acids was recorded for both genotypes in the HS.

Antioxidant Activities

The results of the ABTS, DPPH, and FRAP assay are presented in Table 4 and are expressed as Trolox equivalents mmol kg⁻¹ dw. The CV factor did not result in any significant differences for all antioxidant activities, in contrast to what was observed for the B and NSC factors. Specifically, application of Biostimulant at B_{0.15} dose increased ABTS, DPPH, and FRAP by 32.37, 31.37, and 19.80%, respectively, compared to B_{0.30} dose. Relative to the effect of nutrient solution concentrations, HS resulted in a significant increase in all antioxidant activities compared to FS. The CV×B and B×NSC interactions did not result in significant differences for all parameters reported in Table 4, compared to the CV×NSC interaction where differences were observed only for DPPH antioxidant activity. In “Italiano Classico,” the different nutrient solution concentration did not lead to significant differences for this parameter (DPPH). In contrast, in “Eleonora,” the FS reduced DPPH by 27.32%, compared to the HS.

Volatile Compounds

The percentages of the main volatile compounds are shown in Table 5. Linalool was the predominant compound, followed by eucalyptol, α-Bergamotene, eugenol, 1-Octen-3-ol, and β-cis-Ocimene. Except for eugenol, all volatile compounds detected were significantly affected by CV. “Eleonora” recorded the highest content of eucalyptol, α-Bergamotene, 1-Octen-3-ol, and β-cis-Ocimene, while “Italiano Classico” showed the highest value of linalool (Table 5). The biostimulant influenced the whole aroma profile with the highest content of linalool and eucalyptol obtained at B_{0.30} and B_{0.15} doses, respectively. The same compounds increased with increasing NSC (HF>HS) while the highest values of α-Bergamotene, eugenol, and β-cis-Ocimene were obtained using the HS solution. The CV×B interaction affected the entire profile of volatile compounds (Table 5). For “Eleonora,” the B_{0.30} dose increase linalool by 27.33%, compared to the control, in contrast to “Italiano Classico,” where the application of the biostimulant did not result in significant differences. Furthermore, for “Eleonora,” the B_{0.15} dose increased eucalyptol and 1-Octen-3-ol. The highest values of α-Bergamotene, eugenol, and β-cis-Ocimene were obtained from the Eleonora × Control combination. Relative to the B×NSC interaction, at both nutrient solution concentrations, the B_{0.30} dose increase linalool (+11.81%, on avg.) compared with Control. Regardless of dose, the biostimulant in the HS reduced eugenol and α-Bergamotene. The highest values of 1-Octen-3-ol (2.95%) were obtained from the combination of B_{0.15}×HS combination. Except for eucalyptol, all volatile compounds were affected by the CV×NSC interaction (Table 5). For “Eleonora,” the FS increased linalool and 1-Octen-3-ol, compared to the HS. The opposite trend was observed for α-Bergamotene, eugenol, and β-cis-Ocimene. For “Italiano Classico,” only linalool was affected by the different nutrient concentrations, with the highest values recorded by the Italiano Classico × FS combination.

Principal Component Analysis

A principal component analysis (PCA) for yield, visual and quality attributes was conducted to further explore differences between the two “Genovese” basil genotypes (Eleonora and Italiano Classico), grown in a FRS with two different concentrations of NS (1 dS m⁻¹-Half Strength [HS] and 2 dS m⁻¹-Full Strength [FS]) and two doses of biostimulants (0.15 and 0.30 mL⁻¹, compared to an untreated control). The first two principal components (PCs) explained 60.7% of the cumulative variance, with PC1 and PC2 accounting for 36.1 and 24.6%, respectively (Figure 2). PC1 was positively correlated with all target polyphenols, volatile compounds as well as the antioxidant assays. Also, PC1 correlated negatively with the visual attributes (L, a*, b*). Furthermore, PC2 correlated positively with the three antioxidant activities and target polyphenols

(Figure 2). Based on the angle between vectors of the examined variables, cichoric acid, chlorogenic acid, total phenols, DPPH and FRAP were found to be positively and significantly correlated among them (angle <90°) and negatively correlated with eucalyptol (angle >90°; Figure 2). The PC1 and PC2 score plot discriminated tested treatments into different cluster groups. On the positive side of PC1, “Italiano Classico” fertigated with HS and treated with 0.15 mL⁻¹ of PH delivered basil leaves of premium quality with high concentration of target polyphenols and antioxidant activities. At the lower right quadrant, “Eleonora” supplied with HS solution, showed the highest aroma profile, while the “Eleonora” cultivar fertigated with FS (irrespective of the biostimulant treatment) was positioned in the lower left quadrant distinguished by the poorest nutritional value (Figure 2).

DISCUSSION

The PH's in Nutrient Solution Boosted Basil Yield

Soilless systems are increasingly used to maximize the yields of premium quality vegetables. Among these, the FRS is

characterized by ease of use, low management costs and high functionality, allowing early production with standard characteristics even on a large scale. The surprising yield obtained in the present study confirms the high efficiency of the FRS for basil cultivation compared to soil cultivation. Compared to the results obtained by Zheljazkov et al. (2008) on 38 basil

cultivars grown in the open field, we recorded average yields approximately 15 times higher. This result is attributable to a better allocation of water and nutritional resources and the high density adopted (317 m⁻²; Ciriello et al., 2020). Regardless of the growing system, genetic material plays a crucial role in the productive response of basil (Žlabur et al., 2021). It should be noted that “Eleonora” showed better adaptability to the selected cropping system, producing more leaves per plant, and thus providing a higher fresh yield than “Italiano Classico,” which, in contrast, had a higher dry matter percentage (Table 1). In hydroponic systems, yield is primarily determined by the formulation of the NS, and to this end, numerous studies have focused on seeking optimal mineral levels to achieve *ad hoc* crop-specific “recipes” (Hosseini et al., 2021). For example,

some studies have shown reduced yields in spinach (*Spinacia oleracea* L.; Cocetta et al., 2014) and lettuce (Hosseini et al., 2021) when grown in nutrient solutions with suboptimal mineral concentrations. Moreover, in our study, we did not observe any significant change in fresh yield in basil grown in HS (1 dS m⁻¹) and FS (2 dS m⁻¹) nutrient solutions. Our result is in line with the observations of Hosseini et al. (2021), who reported reductions in fresh yield in basil and lettuce grown on nutrient solutions with lower EC of 0.9 dS m⁻¹ and corroborated the studies of Walters and Currey (2018) on “Sweet,” “Lemon,” and “Holy” basil, which did not observe yield increase with EC between 1 and 4 dS m⁻¹. This shows that excess nutrients in the solution provide no benefit in terms of basil yield and negatively affect resource efficiency,

economic viability, and environmental sustainability of hydroponic systems. The pressing need to ensure high yields of high-quality vegetables by adopting efficient and environmentally friendly cultivation methods makes the application of biostimulants in NS a promising ecological strategy. In our study, the application of PH's (Trainer[®]) in the NS increased the fresh yield, the dry yield, and the number of leaves proportional to the dose used (Table 1). These results highlight that applying the biostimulant directly to the NS is a beneficial strategy to increase yield in hydroponic systems, as also shown by Cristofano et al.

(2021) in lettuce. The beneficial effects of PH's on yield parameters, also obtained in arugula (Caruso et al., 2019; Giordano et al., 2020), celery (*Apium graveolens* L.; Consentino et al., 2020) and basil (Rouphael et al., 2021), can be attributed to the peptides and bioactive amino acids characteristic of commercial formulations (Rouphael et al., 2021). Peptides, involved in cell differentiation and division, due to recognized hormone-like activity, modify root architecture and growth, improving uptake and crop yield (Li et al., 2016; Colla et al., 2017; Kim et al., 2019). The above effects are also attributable to amino acids

(easily absorbed by roots) that are involved in essential signaling processes in addition to performing physiological functions (Tsouvaltzis et al., 2020). These molecules found in Trainer[®] could have promoted nitrogen uptake in the rhizosphere and regulated key transcription factors and photosynthesis (Alfosea-Simón et al., 2021). In contrast to what was observed for the yield, the higher accumulation of dry matter in plants treated with the biostimulant (Table 1) is not widely supported in the literature. As an example, Caruso et al. (2019) recorded results comparable to ours in arugula, while Consentino et al. (2020) obtained opposite results in celery. In spinach, Rouphael et al. (2020) observed no significant difference for this parameter. The contrasting results highlight how the effects of biostimulants depend on factors such as time and mode of application, growth conditions, and genotype (Teklić et al., 2021). In line with the above, although the biostimulant, on average, increased the fresh and dry yield, integration of the PH's into the FS and HS solutions showed dose-dependent responses. While, for the FS, increasing the dose led to linear increases in fresh and dry yields, there was no apparent dose-dependent effect for the HS. Under these operating conditions, the above points out that the impact of the biostimulant could also be influenced

by the mutual interaction between the application dose and the concentration of the NS.

Different Genotypes Impacted Visual Attributes of Basil Leaves

Color is a characteristic of light measurable in terms of wavelength and intensity, related to the observer's perception and to the light conditions under which it is observed, able of influencing consumer choice about food quality (Pathare et al., 2013). In basil, the bright green color of the leaves and the attraction of consumer interest is a critical industrial requirement for the preparation of a "pesto" sauce, as it reduces the use of artificial colorants (Ciriello et al., 2021b). Although the basil genotypes tested all belonged to the "Genovese" cultivar, CIELab colorimetric parameters (L, a*, b*) showed cultivar-dependent variations, with "Italiano Classico" recording the highest values of all above parameters, confirming the results of Ciriello et al. (2020) on the same basil genotypes grown in FRS. The higher values of L (brightness) and a* (greenness) in "Italiano Classico" are consistent with Chroma values, indicating a higher color intensity perceived by the consumer. The latter parameters (L and a*) were also influenced by the

NSC. In particular, the FS increased leaf brightness (higher L) and greenness (higher a^*) compared to the HS, although it did not show any productive differences (Table 2). As argued by Fallovo et al. (2009), the more intense green leaf color could be attributed to a higher chlorophyll content (data not shown) related to the higher nitrogen levels of the FS (2 dS m^{-1}). Our color results showed that applying the biostimulant at the highest dose ($B_{0.30}$) in the NS increased only the parameter a^* , compared to the Control, in agreement with Consentino et al. (2020). This result could be related again to the increase induced by biostimulants in chlorophyll content, as observed by Vernieri et al. (2006) and Aktsoglou et al. (2021) in arugula and peppermint (*Mentha × piperita*), respectively. However, Caruso et al. (2019) and Giordano et al. (2020), despite observing an increase in SPAD (an indirect index of chlorophyll content), did not record a change in color in arugula after the application of PH's. These results confirm once again how the effects of biostimulants differ primarily by species, but also by dose, mode of application, and different growth and development conditions.

Impact of Interactions Between Investigated Factors on Basil Quality Attributes

The inability to “escape” from possible environmental threats has “bound” plants to passive defense mechanisms based on the production of specialized metabolites that have allowed their survival over time (Trivellini et al., 2016). In medicinal plants, specialized metabolites are characterized by significant structural and chemical diversity that uniquely confers the desired technological and nutritional attributes (Dias et al., 2016; Filip, 2017). Although we had used “Genovese” genotypes characterized by a similar phenolic profile in our study, the concentration of total phenolic acids differed considerably (Table 3). The higher total phenolic concentration in “Italiano Classico” (Table 3), also obtained in other works conducted under different growth conditions, again demonstrates how the accumulation of these compounds is strongly influenced by genetics (Žlabur et al., 2021). Despite this, the antioxidant activities reported in Table 4 were not affected by the effect of the cultivar. The explanation for this could lie in the fact that between the two genotypes tested there was only a 9.4% difference in the concentration of total phenols, but it could also be due to the synergistic effects between polyphenols and other chemical constituents, such as ascorbic acid and carotenoids that contribute to overall antioxidant activity (Graziani et al., 2021). The data in Table 3 clearly show the influence of genetics on the diversity of the phenolic profile of the basil genotypes. Although rosmarinic acid is referred to as the most represented phenolic acid in basil (Kiferle et al., 2013; Filip, 2017; Ciriello et al., 2020), in our study, both “Eleonora” and “Italiano Classico” were characterized by a predominant concentration of chicoric acid. The influence of genotype on the predominant biosynthesis of chicoric acid was also confirmed by Kwee and Niemeyer (2011) in basil. The authors showed that 9 basil varieties out of 15 tested had the highest absolute concentration of chicoric acid. Furthermore, it is important to note that the discrepancy with the results reported

in the literature is attributable not only to the genetic material but also to the different extraction methods and solvents used to determine the phenolic acids and the different growth conditions adopted (Filip, 2017). Regardless of the cultivar, the present work confirms that basil leaves contain, in addition to high levels of chicoric acid, significant amounts of salviolanic acids K and L. The important and recognized pharmacological properties of salviolanic acid could further increase the nutraceutical value of basil (Prinsi et al., 2020). The change in the entire phenolic profile in response to changing concentrations of NS (Table 3) confirms that nutritional stress can affect the biosynthesis and accumulation of specialized metabolites (Mahajan et al., 2020). The use of a HS increased the levels of the entire phenolic profile in both genotypes compared to what was observed in the FS, similar to what was observed in basil (Jakovljević et al., 2019), lettuce (El-Nakhel et al., 2019), artichoke (*Cynara cardunculus* subsp. *scolymus* L.), and cardoon (*Cynara cardunculus* L.; Roupahel et al., 2012). The increase in the phenolic profile showed the same trend as the ABTS, DPPH, and FRAP assays (Table 4), indicating how the limitation of nutrition induced an improvement in antioxidant activity. This result and the increase in the phenolic profile are probably related to the halving of nitrate in the HS, which as observed by Chishaki and Horiguchi (1997) has a more significant influence on the accumulation of phenolic acids than potassium and phosphorus deficiency. Low nitrogen levels would stimulate phenylpropanoid metabolism, inducing the accumulation of phenylalanine ammonia-lyase (PAL) and other critical enzymes involved in the biosynthesis of phenolic compounds (Fritz et al., 2006; Wada et al., 2014; Mahajan et al., 2020). This would suggest that low nitrogen levels, by decreasing growth requirements, would promote the accumulation of specialized metabolites (Prinsi et al., 2020). However, in our study, we did not observe a reduction in fresh yield at HS (Table 1), which justifies the high phenolic concentration as a result of ex novo synthesis rather than a deceleration of primary metabolism by increased activity of PAL or its substrate (phenylalanine; Gershenzon, 1984). Similarly to the yield parameters (Table 1), the application of the biostimulant in the NS significantly increase the phenolic concentration in basil. A probable reason for elucidating this interesting result could be related to the increase in production due to a better photosynthetic activity mediated by the biostimulant, which would have promoted secondary metabolism (Colla et al., 2017). However, the bioactive signal molecules characteristic of PH's, in addition to providing the plethora of physiological effects mentioned above, may have triggered the induction of the production of specialized metabolites. Based on a recent work (Kisa et al., 2021), in which a positive influence was observed on basil secondary metabolism after applying amino acids, our results could be traced to the composition of Trainer®, which is characterized by the presence of these organic molecules. One of the crucial functions of amino acids and molecules derived from them is their ability to serve as precursors for specialized plant metabolites, acting both as substrates and as activators of key enzymes such as chorismate mutase, creating points of interconnection in the biosynthesis of phenolic compounds (Feduraev et al., 2020; Kisa et al., 2021). Interestingly,

regardless of the cultivar and concentration of the nutrient solution, among the biostimulant doses tested ($B_{0.15}$ and $B_{0.30}$), the highest accumulation of total phenolics was obtained after application in the nutrient solution of the lowest dose ($B_{0.15}$) of the biostimulant, confirming that this result was not dose dependent. The justification behind the above could stem from the fact that at dose $B_{0.30}$, the biostimulant prioritized production over secondary metabolism. The variability in the composition of essential oils among basil types gives this aromatic herb a multitude of uses. The non-unique aroma of basil is determined by the various compounds that constitute its essential oils, mainly terpenoids (synthesized through the mevalonate pathway and the 2-methyltritol 4-phosphate pathway) and phenylpropanoids (synthesized through the shikimate pathway; Dudai et al., 2020; Mahajan et al., 2020). The distinctive aroma of “Genovese” basil and its derivative products (such as pesto sauce) is attributable to the dominant presence of critical aromatic molecules such as linalool and the complete absence of mint (menthol) and anise (estragole; Ciriello et al., 2021b). Not surprisingly, in the basil genotypes tested, linalool was the predominant, a compound that, in addition to uniquely characterizing the flavor of the “Genovese” genotypes, also has documented therapeutic properties (Mughal, 2019). However, the differences found in “Eleonora” (higher content of 1-Octen-3-ol, eucalyptol, β -cis-Ocimene, and α -Bergamotene) and “Italiano Classico” (higher content of linalool) in the full aroma profile reported in **Table 5** underscore the significant impact of genotype. These differences could be due to the different leaf morphology, the density of oil glands, vegetative growth, and biosynthesis of volatile odorous compounds (Khammar et al., 2021). Compared to the latter, the higher content of linalool but lower contents of eucalyptol and β -cis-ocimene contents, recorded in “Italiano Classico,” compared to “Eleonora,” highlights a clear genotypic effect on gene expression that regulates the conversion of its sole precursor (geranyl pyrophosphate) from the enzymes linalool synthase, 1,8-cineole synthase and β -cis-ocimene synthase (Chang et al., 2007). The basil genotypes tested showed a different response to the biostimulant (**Table 5**). As seen in peppermint and spearmint (*Mentha romana* L.; Aktsoğlu et al., 2021), biostimulant in the NS did not result in any significant difference in the composition of the aroma profile of Italiano Classico. On the one hand, this result could indicate a low sensitivity of the cultivar to the biostimulant and, on the other hand, it could result from the use of insufficient doses to induce alterations in the overall composition of volatile oils. On the contrary, in “Eleonora,” there was a significant effect on the whole aromatic profile caused by the application of the biostimulant. We observed a direct correlation between increasing the dose of biostimulant and the linalool content, contrary to what was observed for eugenol, β -cis-Ocimene and α -Bergamotene, which instead decreased regardless of the dose used. Since plant nutrition is known to influence the content of volatile oils (Aktsoğlu et al., 2021), it is not surprising that the use of NS at different concentrations resulted in significant differences in basil flavor profile (**Table 5**). As with the biostimulant, different responses were observed for the NSC between the two basil genotypes used in the present study. In “Italiano Classico,” the different

NSC changed only the content of the most represented compound (linalool), while in “Eleonora,” all compounds, except eucalyptol, were significantly affected by the different availability of nutrients in the nutrient solution. In any case, in both genotypes, the more concentrated nutrient solution (FS) increased the linalool content. As also seen on *Salvia sclarea* L. (Sharma and Kumar, 2012), the higher availability of nutrients, especially nitrogen, led to an increase in the linalool content, as nitrogen, involved in the biosynthesis of primary and secondary metabolites, could positively interact in its metabolic pathway, confirming our results (Khammar et al., 2021).

CONCLUSION

The challenge imposed on the agricultural sector to provide nourishment to a growing population has led to alternative production techniques such as hydroponics. However, the urgent need to reduce chemical inputs in alternative cropping systems has paved the way for biostimulants, which currently represent an environmentally sustainable strategy for horticultural production. Under the experimental conditions of our study, the varietal comparison showed that “Eleonora” provided the highest fresh yield (6576.81 g m^{-2}). At the same time, “Italiano Classico” had the highest total phenol concentration ($1590.04 \mu\text{g g}^{-1} \text{ dw}$). The use of NS with different concentrations did not result in significant differences in fresh yield, regardless of the cultivar, but positively impacted the aroma and phenolic profile. Specifically, the HS increased total phenols by 32.5%, compared to the FS that ensured the highest content of eucalyptol (22.0%) and linalool (53.4%). The application of biostimulants in the NS increased all biometric parameters (such as the number of leaves, fresh and dry yield) and the linalool content proportionally to the dose used, while the highest total phenol concentration was obtained from the lowest dose ($B_{0.15}$). Based on the excellent results achieved, the application of biostimulants in NS turned out to be a valid strategy to reduce chemical input. For this reason, it should also be investigated on other leafy crops to define a new production technique that can improve both yield and quality.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

AUTHOR CONTRIBUTIONS

Cucumber wilt caused by *Fusarium oxysporum* f.sp. *cucumerinum* (*Foc*) is a highly destructive disease that leads to reduced yield in cucumbers. In this study, strain YB-04 was isolated from wheat straw and identified as *Bacillus subtilis*. It displayed strong antagonistic activity against *F. oxysporum* f.sp. *cucumerinum* in dual culture and exhibited significant biocontrol of cucumber *Fusarium* wilt with a higher control effect than those of previously reported *Bacillus* strains and displayed pronounced growth promotion of cucumber seedlings. *B. subtilis* YB-04 could secrete extracellular protease, amylase, cellulase, and β -1,3-glucanase and be able to produce siderophores and indole acetic acid. Inoculation with *B. subtilis* YB-04 or *Foc* increased cucumber defense-related enzyme activities for PPO, SOD, CAT, PAL, and LOX. However, the greatest increase was with the combination of *B. subtilis* YB-04 and *Foc*. Sequencing the genome of *B. subtilis* YB-04 showed that it had genes for the biosynthesis of various secondary metabolites, carbohydrate-active enzymes, and assimilation of nitrogen, phosphorous, and potassium. *B. subtilis* YB-04 appears to be a promising biological control agent against the *Fusarium* wilt of cucumber and promotes cucumber growth by genomic, physiological, and phenotypic analysis.

Keywords: *Fusarium oxysporum* f.sp. *cucumerinum*, biocontrol agent, genome sequencing and assembly, *Bacillus subtilis*, growth promotion

INTRODUCTION

Cucumber (*Cucumis sativus* L.) is an important vegetable crop worldwide. Cucumber wilt caused by *Fusarium oxysporum* f.sp. *cucumerinum* (*Foc*) is one of the most destructive diseases of cucumber that can lead to severe losses in yield and quality (Zhou et al., 2017). *Foc* enters root tissues by direct penetration or wounds causing visible symptoms, including necrotic lesions, vascular and root wilt, and ultimately death (Ahn et al., 1998). It can survive up to 20 years in soil (Zhao et al., 2017). Furthermore, there are no commercially available cucumber cultivars with resistance

against *Fusarium* wilt. Therefore, biological control of cucumber *Fusarium* wilt using antagonistic microorganisms has been considered to be a promising alternative.

Beneficial microorganisms can be used as biological control agents (BCAs) against different plant diseases. Many of these are species of *Bacillus*, which are also plant growth-promoting bacteria (PGPB) that can improve plant growth by producing secondary metabolites, such as fengycin, surfactin, bacillaene, and macrolactin, siderophores, and indole acetic acid (IAA) and secreting hydrolases to suppress plant pathogens and promote plant growth (Blake et al., 2021). More importantly, *Bacillus* species have several advantages, such as rapid growth, spore production, safe, non-pathogenic nature, and adaptation to broader environmental conditions (Nayak, 2021). However, there are several problems in the field application of microbial agents, including lack of high-efficiency biocontrol, relatively short shelf life, and variable control effectiveness. Therefore, understanding the growth-promotion and biocontrol mechanisms of beneficial microorganisms can significantly contribute to improved application efficacy of BCAs.

One way to better understand these organisms is through whole genome sequencing allowing for the discovery of genes for the production of bioactive compounds responsible for biocontrol and growth promotion (Bauman et al., 2021). For instance, sequencing the complete genome of the BCA *Bacillus velezensis* 9912D revealed gene clusters for secondary metabolite synthesis, including several potentially new lantibiotics (Pan et al., 2017). Similarly, the complete genome of *Bacillus subtilis* 7PJ-16 revealed genes for biosynthesis of antimicrobial metabolites and promoting plant growth traits, indicating its ability to act as a BCA and PGPB (Xu et al., 2019). The genome of *B. subtilis* 9407 showed that it had genes for the biocontrol mechanism against bacterial fruit blotch, including genes for a newly identified subtilisin A, bacilysin, and bacillaene (Gu et al., 2021).

In this study, strain YB-04 was isolated from wheat straw. A number of BCA and PGPB traits were screened for YB-04 in culture. The genome of strain YB-04 was sequenced to identify a number of genes associated with BCA and PGPB traits. Plant growth promotion of cucumber seedlings by soil inoculation of YB-04 was assessed based on chlorophyll content and growth of shoots, roots, stems, and leaves. Biocontrol activity by YB-04 against *Fusarium* wilt of cucumber was assessed based on disease severity and disease index. Furthermore, the activities of cucumber defense-related enzymes activities, both by YB-04 alone and in combination with *Foc* inoculation, were examined. The discovery and characterization of *B. subtilis* YB-04 indicate that it is a promising BCA and PGPB of cucumber.

MATERIALS AND METHODS

Isolation of Strain YB-04 and *in vitro* Antagonism Test

Strain YB-04 was isolated from wheat straw and cultured in LB broth by a dilution plate method at 37°C, collected from a field (E113°97', N35°05') at the Henan Academy of

Agricultural Sciences in Xinxiang, Henan, China in June. *Foc* was obtained from the College of Plant Protection, Henan Agricultural University. Antagonistic activity against *Foc* was performed by a dual culture where *Foc* was grown on PDA at 28°C for 5 days, and then 5 mm agar plugs were excised and transferred to the center of another PDA plate. Strain YB-04 was placed 3 cm away from the edge of the Petri dish, and the growth rate of *Foc* was measured relative to the control, which was *Foc* without strain on a plate (Xu et al., 2020).

Biocontrol Efficiency of Strain YB-04 Against Cucumber *Fusarium* Wilt and Growth Promotion on Cucumber Seedlings

Strain YB-04 was cultured in LB broth for 24 h at 37°C with shaking at 180 rpm and harvested by centrifugation (4,000 × g for 5 min), washed once with LB broth, and adjusted to 10⁸ CFU/ml based on OD at 595 nm. *Foc* was grown on PDA at 28°C for 5 days, and then ten 5 mm agar plugs were excised and transferred to 100 ml PDB. The broths were incubated at 28°C in a shaker at 180 rpm for 3 days. The *Foc* cultures were filtered through 4 layers of sterile gauze, and the filtered spores were adjusted to 10⁵ spores/ml using a hemacytometer (XB-K-25, Qiujiang, Shanghai, China).

Cucumber seeds of cultivar Chuancui No. 3 were surface-sterilized in 75% ethanol (v/v) for 30 s and then rinsed with sterile water three times. The seeds were air-dried and each seed was planted in a separate pot (10 cm high, 10 cm diameter) filled with a 400 g sterilized mixture of soil. The plants were grown in the greenhouse at 25°C with a 16 h light/8 h dark photoperiod. After 10 days, each pot of cucumber seedlings was treated as follows: (1) drenching with 15 ml of YB-04 suspension; (2) first drenching with 15 ml of YB-04 suspension and 24 h of later drenching with 15 ml *Foc* spore suspension; (3) first drenching with 15 ml of 0.1% hymexazol and 24 h later drenching with 15 ml *Foc* spore suspension; (4) drenching with 15 ml of sterile distilled water; or (5) drenching with 15 ml of sterile distilled water and 24 h later drenching with 15 ml of *Foc* spore suspension. Each treatment was performed using 12 plants with 3 replicates. At 20 and 45 days post inoculation (dpi) with YB-04, chlorophyll content, shoot height and fresh weight, root length and fresh weight, stem thickness, and leaf area were measured, and disease severity and disease index were recorded for plants inoculated with *Foc* at 45 days post YB-04 inoculation (Chen et al., 2010). In brief, disease severity was assessed using a 0–4 disease scale; 0 = leaf asymptomatic; 1 = leaf wilting below 1/4 of cucumber seedling; 2 = leaf wilting in 1/4 to 1/2 of cucumber seedling; 3 = leaf wilting above 1/2 of cucumber seedling; 4 = the whole plant was wilted and died. The disease index was calculated using $DI = [(0 \times N_0) + (1 \times N_1) + (2 \times N_2) + (3 \times N_3) + (4 \times N_4)] / T \times 4 \times 100$, where N is the number of cucumber seedlings for each disease score and T is the total number of cucumber seedlings. Disease incidence = $[N_1 + N_2 + N_3 + N_4] / T \times 100\%$. Control efficacy = $(DI \text{ of control} - DI \text{ of treatment}) / DI \text{ of control} \times 100\%$. The chlorophyll content of leaves was measured by using a SPAD-502 Plus chlorophyll content meter (Konica

Minolta, Tokyo, JP). Root length and shoot height were measured with a ruler. The fresh weight of root and shoot was recorded with an analytical balance (ME203E, Mettler Toledo, Shanghai, China). Stem thickness was measured at 2 cm from the crown with a vernier caliper (MNT-200, Shanghai Meinaite Metals Instruments Co., Shanghai, China).

Determination of Defense Enzyme Activities in the Cucumber Leaves

After 20 days post YB-04 inoculation, leaves were harvested and stored at -80°C . In brief, 0.5 g leaves were ground in liquid nitrogen, and 1 ml of extraction buffer was added. After centrifugation at $8,000 \times g$ for 10 min, the supernatant was removed for enzyme assays. Enzyme activities were measured using assay kits for PPO (Cat. No. BC0195), SOD (Cat. No. BC0175), CAT (Cat. No. BC0205), PAL (Cat. No. BC0215), and LOX (Cat. No. BC0325) following the procedures of the manufacturer (Solarbio, Beijing, China). Absorbance was determined by using a plate reader (Tecan Spark, Tecan, Switzerland).

Detection of Plant Growth-Promoting Bacteria and Biological Control Agents Traits

Protease activity was detected with single colonies of YB-04 grown at 30°C for 5 days on skim milk agar (0.1 g CaCl_2 , 5.0 g NaCl, 10.0 g skim milk, 10.0 g peptone, and 18.0 g of agar per liter, pH 7.2). Protease activity was observed as clear zones around the colonies (Kazanas, 1968). Amylase activity was detected with single colonies grown at 30°C for 48 h on starch agar (10.0 g soluble starch, 10.0 g tryptone, 5.0 g glucose, 5.0 g NaCl, 5.0 g beef extract, and 18.0 g of agar per liter, pH 7.2). Lugol's iodine solution (1% iodine in 2% potassium iodide w/v) was added to the starch agar plate, and amylase activity was observed as a colorless halo (Al-Naamani et al., 2015). Cellulose activity was assayed with single colonies grown for 7 days at 30°C on carboxymethylcellulose agar (5.0 g CMC-Na, 0.1 g $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.25 g $(\text{NH}_4)_2\text{SO}_4$, 0.25 g K_2HPO_4 , and 18.0 g of agar per liter, pH 5.5). The plates were flooded with 1% (m/v) Congo Red, and then washed with sterilized distilled water, and cellulose activity was detected as a clear zone (Teather and Wood, 1982). The β -Glucanase activity was assayed with single colonies grown at 30°C for 2 days on β -glucan agar (0.05 g glucose, 0.5 g yeast extract, 1 g peptone, 0.5 g NaCl, 0.01 g Congo Red, and 18.0 g of agar per liter, pH 7.0). The β -Glucanase activity was indicated by a clear zone around the colonies (Teather and Wood, 1982). Siderophore production was determined with single colonies grown at 30°C for 2 days in the dark on Chrome Azurol S blue agar (10 ml 20% sucrose solution, 30 ml 10% acid hydrolyzed casein, 1 ml 1 mmol/L CaCl_2 , 5 ml 0.1 mol/L phosphate-buffered saline (pH 6.8), 50 ml CAS dyeing solution, and 18 g of agar per liter, pH 7.2). Siderophore production was indicated by a change from blue to orange around the colonies (Schwyn and Neilands, 1987). IAA production was measured with single colonies grown at 30°C for 2 days on L-tryptophan nutrient broth (3 g beef extract, 10 g peptone, 5 g NaCl, 0.5 g L-tryptophan per liter,

pH 7.2). After centrifugation at $14,000 \times g$ for 10 min, 1 ml of supernatant was mixed with 2 ml of Salkowski stain, and then kept at room temperature in the dark for 30 min (Glickmann and Dessaux, 1995). All of the above reagents were of analytical grade and produced by China National Pharmaceutical Group Corp., Shanghai, China.

Genome Sequencing and Assembly of Strain YB-04

Strain YB-04 was grown in LB broth for 16 h at 37°C by shaking at 180 rpm. Genomic DNA was extracted with a Mini-BEST Bacterial Genomic DNA Extraction Kit Ver. 3.0 following the manufacturer's instructions (Takara, Beijing, China). An approximately 10 kb insert sequencing library was constructed and sequencing was performed using the PacBio Sequel II system (Pacific Biosciences, Menlo Park, CA, United States) by Frasergen (Wuhan, Hubei, China). Sequencing reads were *de novo* assembled by using HGAP4 (Chin et al., 2013) and the Canu (v.1.6) (Koren et al., 2017) software. The depth of genome coverage was analyzed by using the align tool (BLASR, v0.4.1) (Chaisson and Tesler, 2012). The assembled complete genome sequence was deposited in NCBI GenBank (Accession number CP072525). A circular map of the genome was constructed by using Circos (v0.64) (Krzywinski et al., 2009).

Genome Annotation of Strain YB-04

The genome of strain YB-04 was annotated using Glimmer (v3.02) (Delcher et al., 2007). The tRNA and rRNA genes were identified by tRNAscan-SE (v2.0) (Lowe and Eddy, 1997) and RNAmmer (v1.2) (Lagesen et al., 2007), respectively. Functional descriptions of putative protein encoding genes were done by BLASTx with an *E*-value threshold of $1e-5$ using the NCBI Non-Redundant protein database (NR), Swiss-Prot, Clusters of Orthologous Groups (COG), Kyoto Encyclopedia of Genes and Genomes (KEGG), and Gene Ontology (GO).

Phylogenetic Relationship of Strain YB-04

The 16S rRNA gene sequences of strain YB-04 and *B. velezensis* FZB42, *B. velezensis* YB-130, *B. subtilis* H1, *B. subtilis* 168, *B. licheniformis* SRCM103583, *B. licheniformis* ATCC 14580, *B. altitudinis* CHB19, *B. altitudinis* GQYP101, *B. pumilus* SF-4, and *B. pumilus* ZB201701 were obtained from the genomes (GenBank IDs: CP000560.2, CP054562.1, CP026662.1, NC_000964.3, CP035404.1, CP034569.1, CP043559.1, CP040514.1, CP047089.1, and CP029464.1, respectively). A tree of the 16S rRNA gene sequences was constructed with MEGA 7.0 using the Neighbor Joining method (Kumar et al., 2016). Average Nucleotide Identity (ANI) was calculated using an ANI calculator (Yoon et al., 2017).

Analysis of Genes Encoding CAZymes and Gene Clusters Responsible for the Biosynthesis of Secondary Metabolites

Protein-coding genes in the genome of strain YB-04 were aligned with the carbohydrate active enZYme (CAZy) database

Treatment	Disease incidence (%)	Disease index	Control efficacy (%)
FOC	95.07 ± 0.41a	107.51 ± 0.4a	
FOC + 0.1% Hymexazol	3.48 ± 0.15b	13.24 ± 0.14b	87.68 ± 0.08a
FOC + YB-04	2.42 ± 0.21c	8.69 ± 0.09c	91.92 ± 0.12a

Data are the mean ± standard deviation (SD); different letters (a–c) in the same column indicate significant difference at p -values < 0.05 level.

(Lombard et al., 2014) using dbCAN2 (Zhang et al., 2018) and HMMER (v3.1b2) (Finn et al., 2011) with an E -value threshold of $1e^{-15}$. Identification of gene clusters for the synthesis of

secondary metabolites was analyzed by using antiSMASH5.0 (Blin et al., 2019).

Statistical Analysis

Statistical analysis was performed using SPSS v21.0 by one-way analysis of variance (ANOVA). Means were compared with Duncan's multiple range tests at a probability of $p \leq 0.05$.

RESULTS

Isolation of YB-04 and Wilt Disease Biocontrol Activity *in vitro* and *in vivo*

Dilution plating from surface-sterilized wheat straw yielded numerous colonies with different colony appearances. Twenty strains were purified and screened for antagonistic activity against *Foc* in dual culture and reduced wilt severity of cucumber inoculated with *Foc* in the greenhouse (data not shown). Strain YB-04 was selected based on having the greatest antagonistic activity against *Foc* in culture (Figure 1) and reduced wilt severity of cucumber seedlings at 20 days after *Foc* inoculation (Figure 2). Disease incidence, disease index, and control efficacy at 45 dpi revealed that YB-04 significantly reduced wilt symptoms caused by *Foc* to levels slightly less than the chemical fungicide hymexazol (Table 1).

Growth-Promotion Activity of Strain YB-04

At 20 and 45 dpi with strain YB-04, there was a significant increase in chlorophyll content, height and fresh weight of shoot, root length and fresh weight, stem thickness, and leaf area compared to non-treated cucumber seedlings (Figure 2 and Table 2). At 20 dpi, the greatest increases were observed for the fresh weight of shoots and roots at 115.91 and 334.88%, respectively. At 45 dpi, the greatest increases were observed for shoot height and leaf area at 79.03 and 49.07%, respectively.

At 20 and 45 dpi with strain YB-04 and *Foc* inoculation, there was also a significant increase in chlorophyll content, height, and fresh weight of shoot, root length and fresh weight, stem thickness, and leaf area compared to that of the *Foc* inoculated cucumber seedlings (Figure 2 and Table 2). This was also observed with the *Foc* inoculated seedlings treated with hymexazol. However, strain YB-04 treatment of the *Foc*-inoculated seedlings resulted in significantly higher chlorophyll content, shoot height and fresh weight, root length and fresh weight, and leaf area than *Foc*-inoculated seedlings with hymexazol. However, there was no significant difference in the stem thickness of *Foc*-inoculated seedlings with strain YB-04 or hymexazol at 45 dpi.

Effect of Strain YB-04 on Activities of Defense-Related Enzymes in Cucumber Seedlings

At 20 dpi with strain YB-04, cucumber seedlings showed significantly higher activities of SOD, CAT, PAL, and LOX,

but not PPO, compared to non-treated seedlings (Table 3). Inoculation with *Foc* also significantly increased those enzyme activities, except PPO, compared to seedlings without *Foc* inoculation. The highest activities were observed with *Foc* inoculation and strain YB-04 treatment, which was significantly higher for all the enzymes compared to *Foc* inoculation. However, the activities of PAL and CAT significantly increased but LOX,

PPO, and SOD significantly decreased with *Foc* inoculation and hymexazol treatment compared to *Foc* inoculation.

Detection of *in vitro* Antifungal and Growth-Promoting Traits

Strain YB-04 could secrete protease (Figure 3A), amylase (Figure 3B), cellulose (Figure 3C), and β-1, 3-glucanase

(Figure 3D). In addition, it could produce siderophores (Figure 3E) and indole acetic acid (Figure 3F).

Genome Sequencing, Assembly, and Identification of Strain YB-04

A total of 387,797 high-quality sequencing long reads with a mean length of 10,962 bp and an N50 of 13,374 bp were generated from the genomic DNA of strain YB-04 by the Pacbio sequencing platform. Total base pairs were 4,251,215,058 bp with an 882.47X genome coverage. The YB-04 genome consisted of a

single circular chromosome of 4,156,177 bp with a GC content of 43.83% (Figure 4). There were 4,325 protein-coding genes covering 88.62% of the genome with an average gene length of 851.6 bp, which included 87 tRNAs, 30 rRNAs (5S, 16S, 23S), and 22 sRNAs. Four gene islands, three CRISPRs, and four prophages were detected (Supplementary Tables 1–3). For the predicted protein encoding genes, 99.70, 90.73, 75.45, 64.30, and 53.87% could be annotated with the NR, Swiss-Prot, COG, GO, and KEGG databases, respectively (Supplementary Table 4).

A phylogenetic tree based on 16S rRNA gene sequences of strain YB-04 and 10 other *Bacillus* isolates showed that strain YB-04, *B. subtilis* 168, and *B. subtilis* H1 clustered (Figure 5). Strain YB-04 and *B. subtilis* 168 had the maximum ANI value of 98.74%, followed by *B. subtilis* H1 with 98.65%, which is higher than the cutoff of 95–96% for bacterial species identity. ANI values between strain YB-04 and the 8 other *Bacillus* species ranged from 71.05 to 77.22% (Figure 6). Therefore, strain YB-04 was identified as *B. subtilis*.

Genome Analysis of Selected Genes of *Bacillus subtilis* YB-04

The genome of *B. subtilis* YB-04 had 111 genes identified as putative CAZymes, namely, 2 auxiliary activities (AAs), 7 polysaccharide lyases (PLs), 15 carbohydrate-binding modules (CBMs), 19 carbohydrate esterases (CEs), 24 glycosyltransferases (GTs), and 51 glycoside hydrolases (GHs) (Figure 7 and

Supplementary Table 5). Six of those were classified as both GHs and CBMs.

There were 13 gene clusters predicted to be responsible for the biosynthesis of secondary metabolites. At 100% similarity, there was each matching gene clusters for bacillaene, fengycin, bacillibactin, subtilin, subtilosin A, and bacilysin synthesis. There was also one gene cluster with 82% similarity to that for surfactin synthesis. There were 6 biosynthetic gene clusters with no similarity in the antiSMASH database that appeared to be novel biosynthetic gene clusters of secondary metabolites. Based on their matches to the antiSMASH database, these were one gene cluster

each for types of lanthipeptide-class-i, Type III PKS, tRNA-dependent cyclodipeptide synthases, other unspecified ribosomally synthesized, post-translationally modified peptide products, and two gene clusters, each encoding for terpenes (Table 4).

The genome of *B. subtilis* YB-04 contained predicted genes for an ATP-dependent phosphate uptake system *PstABCS*, *phoPR* operon for regulating *Pho* regulon in response to phosphate limitation, and alkaline phosphatase genes of *phoA* and *phoD* for phosphorus acquisition (Table 5). It also contained the *nasABCDEF* gene cluster for nitrite transport and reduction. Additionally, there were the potassium uptake system *ktrABCD*,

a putative gamma-glutamylcyclotransferase *YkqA* for potassium assimilation, and a putative potassium efflux channel *yugO*.

DISCUSSION

Fusarium wilt disease caused by *Foc* is one of the most devastating soil-borne diseases of cucumber, resulting in severe yield losses throughout the world (Zhou et al., 2018). While the use of BCAs to control plant diseases and PGPBs to improve plant growth is considered to be promising (Radhakrishnan et al., 2017; Koskey et al., 2021), new strains are needed to screen for greater efficiency, shelf life, and consistency. As part of that, an in-depth analysis of growth promotion and biocontrol traits will help in developing them into successful microbial products.

In this study, *B. subtilis* YB-04 was found to be a BCA with antagonistic activity against *Foc* in dual culture and significantly reduced *Fusarium* wilt caused by *Foc* at levels comparable to hymexazol, which is used to control the disease in China. It was also a PGPB with pronounced growth promotion on cucumber seedlings. Previously, *B. subtilis* B579, *B. subtilis* MBI600, and *B. subtilis* B068150 were also shown to significantly reduce cucumber *Fusarium* wilt and promote cucumber growth (Chen et al., 2010; Li et al., 2012; Samaras et al., 2020). Compared to those bacteria, the percentage reduction in the *Fusarium* wilt of cucumber by *B. subtilis* YB-04 was greater than those achieved by *B. subtilis* B068150, *B. subtilis* B579, or *B. subtilis* MBI600. The percentage of increased growth-promotion based on the shoot and root fresh weight and plant height by *B. subtilis* YB-04 was greater than those achieved by *B. subtilis* B579 or *B. subtilis* MBI600. Thus, *B. subtilis* YB-04 appears to be more effective as a BCA and PGPB than some of the previously described *B. subtilis* tested on cucumber.

To act as a BCA against plant pathogenic fungi, bacteria possess a number of mechanisms including synthesis of hydrolytic enzymes, production of antibiotics, and induction of systemic resistance (Morales-Cedeño et al., 2021; Saeed et al., 2021; Xu et al., 2021). In this study, *B. subtilis* YB-04 had all of those mechanisms. Hydrolytic enzyme activities including protease, amylase, cellulase, and β -1, 3-glucanase were present in pure cultures, and they can break down chitin, glucans, and other polymers in fungal cell walls, thus inhibiting the growth of fungal pathogens (Naglot et al., 2015; Li et al., 2019). Other *B. subtilis* BCAs with similar enzymes include *B. subtilis* BCC6327, *B. subtilis* ZIM3, and *B. subtilis* LR1 (Thakaew and Niamsup, 2013; Banerjee et al., 2017; Dai et al., 2020). Furthermore, a large number of CAZyme genes were found in the genome of *B. subtilis* YB-04, also suggesting that it has a strong capability to be antagonistic against fungal plant pathogens based on the potential degradation and use of fungal polymers as nutrient sources (Banani et al., 2015; Chen et al., 2018; Sui et al., 2020). In addition, gene clusters were found to be responsible for the biosynthesis of known secondary metabolites, including bacillaene, fengycin, bacillibactin, subtilin, subtilosin A, bacilysin, and surfactin, indicating antibiotic production by *B. subtilis* YB-04, which is common in *Bacillus* species (Xu et al., 2019; Su et al., 2020). Other *B. subtilis* BCAs found to produce antibiotics or have genes for antibiotic production included *B. subtilis* BSD-2 for lanthipeptide (Liu et al., 2016). Surfactin and fengycin can also be elicitors of induced systemic resistance in plants (Romero et al., 2007; Ongena et al., 2010). Many studies have reported that plant defense enzymes play important roles in disease resistance (Prasannath, 2017; Ji et al., 2020; Xu et al., 2021). Induction of the activities of defense-related enzymes in leaves following soil inoculation with *B. subtilis* YB-04 and *Foc* indicates a form of systemic resistance. Defense-related enzymes activities for PPO, SOD, CAT, PAL, and LOX could be induced by inoculation with *B. subtilis* YB-04 or *Foc* alone and the greatest increase was with the combination of *B. subtilis* YB-04 and *Foc*. Other *B. subtilis* BCAs causing host induction of defense-related enzyme activities include *B. subtilis* B579, *B. subtilis* SL-44, and *B. subtilis* CBR05 (Chen et al., 2010; Chandrasekaran and Chun, 2016; Wu et al., 2019).

All the growth parameters of cucumber seedlings measured in this study were increased with *B. subtilis* YB-04 treatment. Importantly, growth parameters were all increased much more in infected seedlings with *Foc* treated with *B. subtilis* YB-04 than those infected with *Foc* and treated with hymexazol. This indicates that *B. subtilis* YB-04 can improve plant growth while providing disease control, which would be an advantage over using hymexazol that did not promote growth. This was similar to *Pseudomonas aeruginosa* CQ-40 that controlled tomato gray mold caused by *Botrytis cinerea* and promoted the growth of tomato seedlings, whereas pyrimethanil only controlled the disease with a prevention effect of up to 64.71% (Wang et al., 2020).

To act as a PGPB, bacteria have a variety of mechanisms including the production of enzymes and siderophores for nutrient acquisition and phytohormones to promote growth, and enzymes to reduce the negative effects of various abiotic stresses

TABLE 4 | List of the putative gene clusters encoding for secondary metabolites by antiSMASH in the *B. subtilis* YB-04 genome.

Clusters	Types	Genomic locations	Most similar known clusters	Similarity
Cluster 1	NRPS	349,833–413,272	Surfactin	82%
Cluster 2	Terpene	1,124,835–1,145,348		
Cluster 3	Lanthipeptide-class-i	1,699,549–1,725,648		
Cluster 4	transAT-PKS,PKS-like,T3PKS,transAT-PKS-like,NRPS	1,747,915–1,862,664	Bacillaene	100%
Cluster 5	NRPS, betalactone	1,920,534–2,002,654	Fengycin	100%
Cluster 6	Terpene	2,073,306–2,095,204		
Cluster 7	T3PKS	2,142,940–2,184,037		
Cluster 8	NRPS	3,179,833–3,229,574	Bacillibactin	100%
Cluster 9	lanthipeptide-class-i	3,377,840–3,404,065	Subtilin	100%
Cluster 10	CDPS	3,523,308–3,544,054		
Cluster 11	Sactipeptide	3,768,784–3,790,395	Subtilosin A	100%
Cluster 12	Other	3,797,486–3,838,904	Bacilysin	100%
Cluster 13	RIPP-like	4,040,385–4,053,116		

TABLE 5 | Genes responsible for nitrogen, phosphorous, and potassium assimilation identified in the strain YB-04 genome.

Function	Gene	UniProt accession No.	Description	Best hit in YB-04	Identity
Phosphate assimilation	<i>phoA</i>	P19406	Alkaline phosphatase 4	orf00986	99.35%
	<i>phoR</i>	P23545	Alkaline phosphatase synthesis sensor protein PhoR	orf03027	99.48%
	<i>phoP</i>	P13792	Alkaline phosphatase synthesis transcriptional regulatory protein PhoP	orf03028	99.58%
	<i>phoD</i>	P42251	Alkaline phosphatase D	orf00275	99.49%
Phosphate transport	<i>pstS</i>	P46338	Phosphate-binding protein	orf02500	99.67%
	<i>pstC</i>	A0A6M4JLF7	Phosphate transport system permease protein	orf02499	99.35%
	<i>pstB1</i>	P46342	Phosphate import ATP-binding protein PstB 1	orf02496	99.62%
	<i>pstB2</i>	P46341	Phosphate import ATP-binding protein PstB 2	orf02497	99.63%
	<i>pstA</i>	A0A6M3ZE53	Phosphate transport system permease protein	orf02498	100.00%
Nitrate/nitrite assimilation	<i>nasD</i>	P42435	Nitrite reductase	orf00344	99.26%
	<i>nasE</i>	P42436	Assimilatory nitrite reductase [NAD(P)H] small subunit	orf00343	100.00%
	<i>nasA</i>	P42432	Nitrate transporter	orf00347	99.50%
	<i>nasC</i>	P42434	Assimilatory nitrate reductase catalytic subunit	orf00345	98.03%
	<i>nasB</i>	P42433	Assimilatory nitrate reductase electron transfer subunit	orf00346	97.54%
	<i>nasF</i>	P42437	Uroporphyrinogen-III C-methyltransferase	orf00342	97.30%
Potassium assimilation	<i>ktrC</i>	P39760	Ktr system potassium uptake protein C	orf01561	100.00%
	<i>ykqA</i>	P39759	Putative gamma-glutamylcyclotransferase YkqA	orf01560	96.75%
	<i>ktrD</i>	O31658	Ktr system potassium uptake protein D	orf01445	100.00%
	<i>yugO</i>	Q795M8	Putative potassium channel protein YugO	orf03270	100.00%
	<i>ktrB</i>	O32081	Ktr system potassium uptake protein B	orf03241	99.10%
	<i>ktrA</i>	O32080	Ktr system potassium uptake protein A	orf03240	99.10%

(Glick, 2012; Saeed et al., 2021). *B. subtilis* YB-04 produced siderophores that can improve iron uptake and alleviate harmful effects of iron on plants that have been associated with enhanced plant growth (Haas, 2003; Dimkpa et al., 2009). The genome of *B. subtilis* YB-04 also contained genes responsible for nitrogen, phosphorous, and potassium assimilation. Plant growth and development depend on macronutrients, such as nitrogen, phosphorous, and potassium, that are mostly obtained from the soil and can be made more available to plants by soil microbes that have the ability to solubilize nutrients and transfer them to plants (Glick, 2012; Rana et al., 2020). Finally, *B. subtilis* YB-04 produced IAA, which may be taken up by the cucumber seedlings stimulating the transcriptional expression of IAA responsive

genes and enhancing biomass (Spaepen et al., 2014; Jiang et al., 2020).

In summary, *B. subtilis* YB-04 appears to be an effective BCA against cucumber *Fusarium* wilt and an effective PGPB of cucumber seedlings. The BCA mechanisms could include induced systemic host resistance as indicated by greater host defense-related enzyme activities, and direct pathogen inhibition through secretion of extracellular enzymes and antibiotics. The PGPB mechanisms could include nutrient acquisition *via* siderophores and enzymes for fixing nitrogen and solubilizing potassium and phosphorus, and direct plant growth enhancement through increased amounts of indole acetic acid. Compared to other *B. subtilis* strains used as cucumber

Fusarium wilt BCAs and PGPBs in cucumber, *B. subtilis* YB-04 is a more effective BCA than all those reported thus far and is a more effective PGPB than most reported so far. Thus, it appears to be a very promising novel beneficial *B. subtilis* strain for cucumber production.

DATA AVAILABILITY STATEMENT

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article/**Supplementary Material**.

AUTHOR CONTRIBUTIONS

LY and WX conceived the research and designed the experiments. QY, XX, FY, XD, and WX performed the experiments and analyzed the data. WX prepared the manuscript draft. PG, BT,

and LY critically revised the manuscript. All authors approved the final version of the manuscript.

FUNDING

This research was funded by the Central Government Guiding Local Projects (2020[44]), the Special Project for Science and Technology Innovation Team of Henan Academy of Agricultural Sciences (2022TD25), and the Outstanding Youth Science and Technology Fund of Henan Academy of Agricultural Sciences (2022YQ06).

Less nutrient availability and drought stress are some serious concerns of agriculture. Both biotic and abiotic stress factors have the potential to limit crop productivity. However, several organic extracts obtained from moringa leaves may induce immunity in plants under nutritional and drought stress for increasing their survival. Additionally, some rhizobacterial strains have the ability to enhance root growth for better nutrient and water uptake in stress conditions. To cover the knowledge gap on the interactive effects of beneficial rhizobacteria and moringa leaf extracts (MLEs), this study was conducted. The aim of this experimental study was to investigate the effectiveness of sole and combined use of rhizobacteria and MLEs against nutritional and drought stress in wheat. Nitrogen-fixing bacteria *Pseudomonas aeruginosa* (Pa) (10^8 CFU ml⁻¹) was inoculated to wheat plants with and without foliar-applied MLEs at two different concentrations (MLE 1 = 1:15 v/v and MLE 2 = 1:30 v/v) twice at 25 and 35 days after seed sowing (50 ml per plant) after the establishment of drought stress. Results revealed that Pa + MLE 2 significantly increased fresh weight (FW), dry weight (DW), lengths of roots and shoot and photosynthetic contents of wheat. A significant enhancement in total soluble sugars, total soluble proteins, calcium, potassium, phosphate, and nitrate contents validated the efficacious effect of Pa + MLE 2 over control-treated plants. Significant decrease in sodium, proline, glycine betaine, electrolyte leakage, malondialdehyde, hydrogen peroxide, superoxide dismutase (SOD), and peroxide (POD)

concentrations in wheat cultivated under drought stress conditions also represents the imperative role of Pa + MLE 2 over control. In conclusion, Pa + MLE 2 can alleviate nutritional stress and drought effects in wheat. More research in this field is required to proclaim Pa + MLE 2 as the most effective amendment against drought stress in distinct agroecological zones, different soil types, and contrasting wheat cultivars worldwide.

Keywords: PGPR, agroecological zones, drought stress, *Pseudomonas*, nitrogen-fixing bacteria, biofertilizers, bioinoculants

INTRODUCTION

Crop production is always under pressure to increase and sustain the food demands, considering the estimated increase in global population that might increase from the current 7.7 billion to approximately 9.6 billion in the year 2050 (Zulfiqar et al., 2020). Moreover, constantly changing climatic conditions are the other major challenge for sustainable crop production (Wheeler and Von Braun, 2013). Several abiotic and biotic stress factors such as temperature, water-logging, salinity, drought, weed, and pest infestations critically limit crop production (Parajuli et al., 2019). Climate change leads to widely drought-affected areas, such as tropics (Grover et al., 2011).

Water constitutes approximately 80–90% of the total biomass of herbaceous plants and is crucial in almost all plant physiological processes, a principal means of nutrients and metabolite transport (Lisar et al., 2012). Water scarcity is one of the leading plant stress factors. A drought effect reduces cell turgor and water potential causing adversities in carrying out plant's normal physiological functions (Lisar et al., 2012). In fact, water is the key determining factor for crop growth and productivity, thus playing an essential role in species distribution and evolution (Ngumbi and Kloepper, 2016).

The induction of drought stress tolerance has been described by several physiological and biochemical changes (Shukla et al., 2012). In spite of these tolerance strategies including elaborated antioxidative activities, losses to crop production are increasing rapidly. Chemical fertilizers are largely being used to increase agricultural production, which is a matter of concern due to their improper use and potential adverse effects on human health and environment (Ruzzi and Aroca, 2015; Jiménez-Gómez et al., 2018). Expensive agrochemicals and synthetic fertilizers are commercially undesirable (Colla et al., 2015). Hence, to maintain and increase the yield, it is crucial to devise some efficient, low-cost, less time taking, and environment-friendly techniques to cope with drought conditions and achieve a sustainable agricultural system (Venkateswarlu and Shanker, 2009; Zulfiqar et al., 2019).

Several microorganisms, mainly bacteria, colonize the plant root zone (Kaushal and Wani, 2016; Barnawal et al., 2019). The beneficial associations between microbes and roots are an important determinant of soil texture, water conservation, and plant health. Plant growth-promoting rhizobacteria (PGPR) improve nutrient uptake by roots, growth, and consequently crop yield by causing biochemical changes in the plant body, meanwhile protecting from a variety of other plant diseases (Khan et al., 2020; Singh et al., 2021; Soumare et al., 2021).

Furthermore, improvement in soil texture and fertility enhances crop production (Nardi et al., 2009).

Moringa leaf extract (MLE), as a plant biostimulant in the foliar application, enhances the growth of plants that are grown even under abiotic stress conditions (Semida and Rady, 2014). *Moringa oleifera* Lam belongs to the Moringaceae family and native to the subcontinent (Shahzad et al., 2013). Moringa leaves are rich in both micronutrients and macronutrients, i.e., N, P, Ca, K, Na, Zn, Mg, B, Cu, Mn, and Fe (Yasmeen et al., 2014). These mineral nutrients can supplement the nutritional demands of stressed grown crops and help in decreasing the use of agrochemicals and synthetic fertilizers (Zulfiqar et al., 2020). Spraying MLE diluted solution on plant leaves seems to have a considerable positive impact, i.e., delay in senescence, higher sugar contents, increased plant height, and bigger fruits and seeds (Yasmeen et al., 2013a; Nasir et al., 2014). This validates the potential effects of MLE to be used to improve plant vigor specifically in suboptimal environmental situations like drought stress as a foliar application. MLE foliar spray increased approximately 20–35% yield of several plants (Yasmeen et al., 2012).

Wheat (*Triticum aestivum* L.) is one of the most important cereal crops worldwide, considering its production and human consumption. Wheat supplements almost one-third of the total global population. Harvesting more yields to meet the future food demands of the increasing population is a major agricultural concern at all times. Different environmental factors contribute to crop yields (Yasmeen et al., 2012; Fasiha Amjad et al., 2021). Wheat in Pakistan experiences severe abiotic constraints during all developmental stages (Rashid et al., 2018), and drought stress is the main limiting factor among abiotic stresses for wheat yield (Budak et al., 2013; Mutumba et al., 2018).

Previously, the effects of exogenous applied MLE and treating plants with nitrogen-fixing bacteria (NFB) were studied solely on wheat grown at high temperatures. This study covers the knowledge gap in the combined use of NFB and MLE under normal and heat stress situations. In earlier studies, treating plants with rhizobacteria and the effects of foliar sprayed MLE were assessed solely on wheat grown under drought stress conditions by considering their ameliorative implications on various physiological and biochemical attributes but their combined implications are still not confirmed.

Therefore, this study aimed to investigate the best treatment combination for alleviation of heat stress in wheat. Anaj 17 genotype was selected because it is one of the latest genotypes developed in the past 5 years in Pakistan and it performed well under abiotic stress conditions so we wanted to check

its response to the application of MLE and rhizobacteria. It is hypothesized that the combined use of MLE and NFB might be a better approach than the sole application to improve wheat growth attributes under heat stress. This study was conducted to analyze the ameliorative and best co-application of applied amendments in alleviating the drought stress effects on wheat plants. It is hypothesized that MLE and rhizobacterial combined application might be an effective approach to improve wheat attributes than their sole applications in drought effects. In earlier studies, treating plants with rhizobacteria and the effects of foliar sprayed MLE were assessed solely on wheat grown under drought stress conditions by considering their ameliorative implications on various physiological and biochemical attributes but their combined implications are still not confirmed. Therefore, this study is conducted to analyze the ameliorative and best co-application of applied amendments in alleviating the drought stress effects on wheat plants. It is hypothesized that MLE and rhizobacterial combined application might be an effective approach to improve wheat attributes than their sole applications in drought effects.

MATERIALS AND METHODS

Experimental Site and Design

The wheat crop was sown at the experimental site of the Government College University Faisalabad (30°–31.5° N and 73°–74° E, 184.4 m above sea level). A greenhouse pot experiment was carried out from November to January. The experimental layout was a randomized complete block design (RCBD) that was replicated three times.

Soil Characteristics

The clay loam soil (8–12 inches in depth) collected from the experimental site of the Government College University Faisalabad was air-dried and sieved through a 2-mm sieve. The collected soils were sterilized through solarization, by covering the soil with a thin layer of plastic sheet. The heat from the sun builds up the temperature of the soil to kill most of the bacteria, weeds, and pests (Stapleton et al., 2008). Some soil chemical characteristics that were analyzed before the experiment include EC 7.78 (d Sm⁻¹), pH (water) 7.3; organic matter contents 1.38%; available N 0.032 ppm, available P 5.93 ppm, and available K 32.3 ppm.

Seed Collection and Sterilization

A well-adapted wheat genotype Anaj 17, which performs well under abiotic stress conditions, was selected. Seeds were disinfected using 95% ethanol and washed using 70% sodium hypochlorite solution followed by rinsing with distilled water three times.

Treatments

The treatments (two sets of pots) were as follows: (i) control (untreated with foliar spray, no bacterial inoculation), (ii) *Pseudomonas aeruginosa* (Pa) (strain) [inoculation with Pa], (iii) MLE 1 [foliar sprayed MLE at 1:15], (iv) MLE 2 [foliar

sprayed MLE at 1:30], (v) Pa + MLE 1 [inoculation with Pa bacteria + foliar sprayed MLE at 1:15], and (vi) Pa + MLE 2 [inoculation with Pa bacteria + foliar sprayed MLE at 1:30].

Fertilizer and Seed Sowing

At the start of the experiment, the soil was fertilized with a basal dose of N–P–K fertilizer (0.51–0.45–0.38 N–P–K g) using urea (46% N), sulfate of potash (50% K₂O), and diammonium phosphate (46% P₂O₅, 18% N) [24]. Initially, ten seeds were sown in each pot containing 12 kg clay loamy soil (25 cm diameter × 30 cm height), and after complete emergence, they were thinned to six plants per pot.

Moringa Leaf Extract, Pa (Strain), and Establishment of Drought Stress

An aerobic PGPR strain of free-living soil nitrogen-fixing bacteria; Pa (Pa strain) isolated from the rhizosphere of wheat roots growing in local field areas by serial dilution method was used in this study. The serial dilutions up to 10⁻⁷ were spread on Luria-Bertani (LB) agar plates at 37°C temperature and inoculated overnight. Bacterial growth was determined by measuring optical density at 600 nm using a spectrophotometer (Gontia-Mishra et al., 2016). Before inoculation, the seeds were coated with 20% gum Arabic as an adhesive and immersed in a bacterial suspension of 10⁸ CFU ml⁻¹ strength just before 15 min of sowing. After 20 days of seed sowing, one set of pots (half number) was shifted to canopies for the imposition of drought stress. Well-watered conditions were maintained at 70 FC (70% field capacity), while drought stress was maintained at 45 FC (45% field capacity). The plants that remained were kept at different water regimes until harvesting.

Fresh and disease-free moringa leaves were collected and rinsed with water. Notably, a 100-g leaf sample was extracted in 1 L distilled water (1:10 w/v) for 15 min (Yasmeen et al., 2013b). Later, MLE was filtered and diluted with distilled water at two concentrations: MLE 1 = 1:20 v/v and MLE 2 = 1:30 v/v. Some chemical properties of moringa leaves are total chlorophyll = 3.79 mg g⁻¹ FW, carotenoids = 1.58 mg g⁻¹ FW, total phenolics = 1.68 μmol g⁻¹ FW, mg g⁻¹ FW, nitrogen = 14.13 mg g⁻¹ DW, phosphorous = 2.98 mg g⁻¹ DW, potassium = 11.97 mg g⁻¹ DW, and calcium = 16.8 mg g⁻¹ DW. The extracts were freshly prepared before their application. Distilled water was sprayed on control plants in both applications. MLE was sprayed to a pot-grown wheat twice after 25 and 35 days of sowing date (50 ml per plant) after the establishment of drought stress. Tween-20 surfactant was used in a foliar spray (0.1% v/v).

Harvesting and Measurement of Growth Attributes

Harvest was done after 45 days of planting. Root and shoot fresh weights (FWs) and lengths were measured immediately after harvest at the experimental site. Fresh samples were stored at -30°C in a biomedical refrigerator for fresh analysis. Three samples per treatment were oven-dried (65°C) for 3 days to

determine their dry weights (DWs) and ionic content analysis using the acid digestion method.

Photosynthetic Pigments

The chlorophyll contents of wheat leaves were determined as described by Dere et al. (1998). Notably, 0.2 g of leaves (randomly collected) were extracted in 10 ml methanol (96%) using a homogenizer at 1,000 rpm for 1 min, then filtered, and centrifuged for 10 min at 2,500 rpm. The supernatant was separated and used to determine chlorophyll contents at 666 (chlorophyll a), 653 (chlorophyll b), and 470 nm (total carotenoids) wavelengths using a spectrophotometer (Model SM1200; Randolph, NJ, United States).

Measurements of Stomatal Conductance (gs)

Stomatal conductance (gs) of fully developed leaves (three plants per treatment) was measured by putting them in a portable infrared gas analyzer chamber (Analytical Development Company, Hoddeson, United Kingdom). The measurements were made 6 days after the first MLE foliar spray.

Leaf Biochemical Analysis

Fully expanded leaves from each replicate were taken, wrapped in aluminum foils, immersed in liquid nitrogen, and transferred into plastic zipper bags. These samples were stored at -80°C for further analysis. Following, biochemical analysis was performed using a spectrophotometer (Model SM1200; Randolph, NJ, United States).

To determine osmolytes as sugars and non-enzymatic antioxidants, 50 mg of dried leaves were homogenized in 10 ml of 80% ethanol and filtered followed by the re-extraction in 10 ml ethanol, and a 20 ml of the final volume was maintained. This obtained solution was used to evaluate flavonoids (Lewis et al., 1999), soluble sugars (Dubois et al., 1956), proteins (Bradford, 1976), and proline (Bates et al., 1973) contents. Glycine betaine (GB) was assessed by following the method of Holmström et al. (2000).

Mineral Content

For the determination of P contents in wheat molybdate/ascorbic acid, the blue technique was used, and nitrate contents were assessed by Kowalenko and Lowe (1973) method using a spectrophotometer (Model SM1200; Randolph, NJ, United States). K concentration was determined using a flame photometer. Ca and Na ions were evaluated by Atomic Absorption Spectrum (AAS; Shimadzu instruments, Inc., Spectra AA-220, Kyoto, Japan).

Statistical Analysis

Statistical analysis of data was performed using a *post-hoc* test, which was performed to measure specific differences between treatments using the Duncan's Multiple Range Test (DMRT) in a completely randomized block design. The significant differences between treatment means were determined using analysis of variance and mean separation at a 5% significance

level ($p \leq 0.05$). In addition, the Pearson correlation of different wheat attributes under drought stress and well-watered conditions was performed. Logarithmic data transformation to obtain near-normal distribution was implemented before analysis, where required.

RESULTS

Length, Fresh Weight, and Dry Weight of Roots and Shoot

All applied treatments had a significant positive effect on root and shoot FWs, DWs, and lengths under control and drought stress conditions (Figure 1). In this regard, Pa + MLE 1 and Pa + MLE 2 were proved significantly efficient amendments in increasing root FW and shoot FW of wheat plants during drought conditions. Furthermore, MLE 2 enhanced root DW and shoot DW at 45 FC compared with control (70 FC). The treatments MLE 2, Pa + MLE 1, and Pa + MLE 2 had a more significant effect on root length and shoot length as compared with the control under drought stress. A significant difference was observed between the given amendments and control plants which signify their effectiveness in drought stress environments.

Photosynthetic Pigments

All photosynthetic pigments such as chlorophyll a, chlorophyll b, total chlorophyll, and carotenoids were significantly affected when subjected to drought stress conditions (45 FC) as compared with well-irrigated conditions (70 FC) (Figure 2). All applied amendments significantly improved plant photosynthetic pigments over the control. Pa + MLE 1 and Pa + MLE 2 treatments were remained efficient in increasing chlorophyll a and chlorophyll b at 45 FC over control-treated wheat plants (70 FC). Furthermore, MLE 2 differed significantly better for the enhancement of total chlorophyll contents at 45 FC than 70 FC. Treatments MLE 2, Pa + MLE 1, and Pa + MLE 2 were significantly different for wheat carotenoid contents under drought stress as compared with the control. A significant difference was observed in MLE at both concentrations and Pa for all studied parameters in all treatment levels. The above results signify the value of given amendments in enhancing the efficiency of water uptake and use by the grown plants.

Flavonoids, Phenolics, Total Soluble Sugars, Total Soluble Proteins, and Stomatal Conductance

Flavonoids, phenolics, total soluble sugars, total soluble proteins, and stomatal conductance of wheat plants were significantly affected in drought stress (45 FC) compared with well-watered plants (70 FC) (Figure 3). Both sole and combined applications of Pa and MLE significantly increased plant total soluble sugars, total soluble proteins, and stomatal conductance over the control. Pa + MLE 1 and Pa + MLE 2 treatments were remained efficient in decreasing flavonoids and phenolics at 45 FC over 70 FC. Moreover, MLE 2 differed significantly better than MLE 1 and

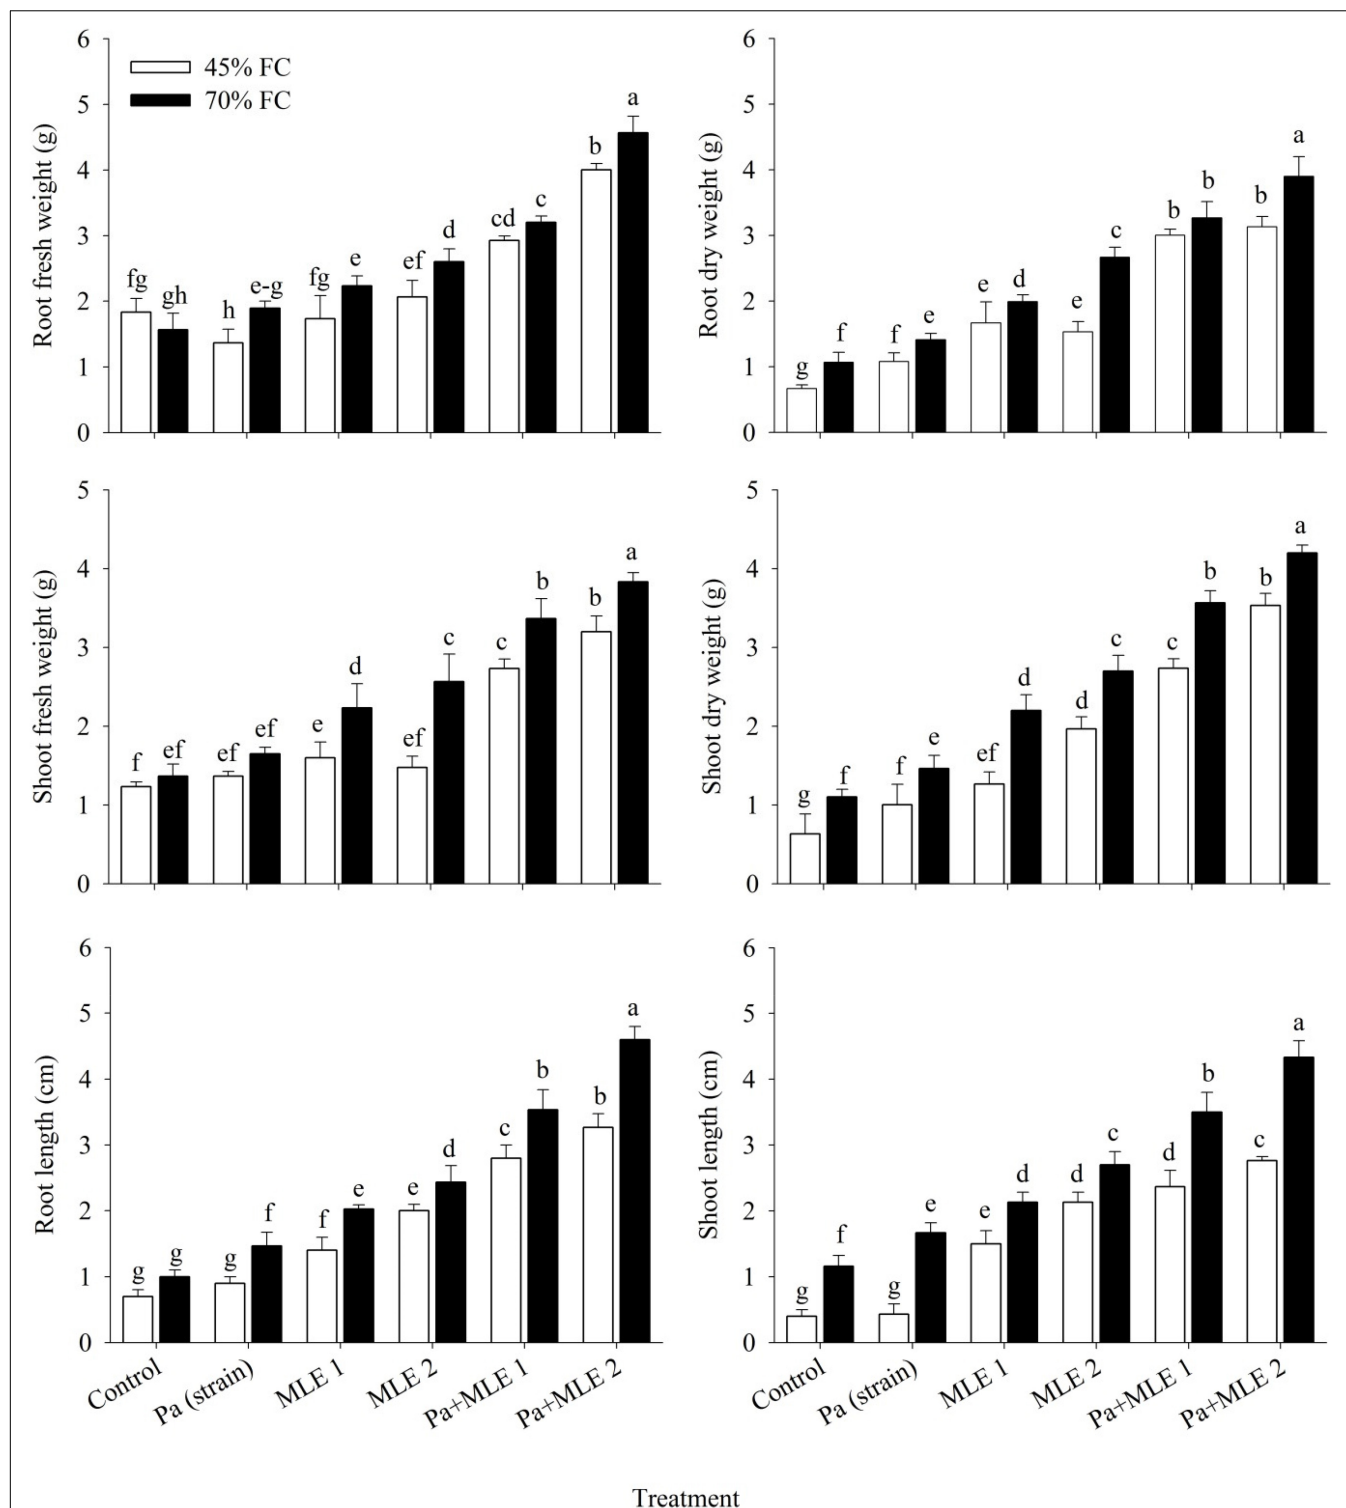

FIGURE 1 | Impact of sole and combined applications of *Pa* and moringa leaf extract (MLE) on different growth attributes of wheat plants under 45 FC and 70 FC irrigation levels. Different bars represent the mean values of three replicates. Error bars represent standard error (SE). Different letters on bars indicate significant difference at $p \leq 0.05$ [70 FC = well-irrigated, 45 FC = drought stress condition; C = control, *Pa* (strain) = *Pseudomonas aeruginosa* inoculated plants, MLE 1 = foliar-applied MLE at 1:15, and MLE 2 = foliar-applied MLE at 1:30]. Means with the same letters within the column are not significantly different.

FIGURE 2 | Impact of sole and combined applications of Pa and MLE on different photosynthetic pigments of wheat plants under 45 FC and 70 FC irrigation levels. Different bars represent the mean values of three replicates. Error bars represent SE. Different letters on bars indicate significant difference at $p \leq 0.05$ [70 FC = well-irrigated, 45 FC = drought stress condition; C = control, Pa (strain) = *P. aeruginosa* inoculated plants, MLE 1 = foliar-applied MLE at 1:15, and MLE 2 = foliar-applied MLE at 1:30]. Means with the same letters within the column are not significantly different.

Pa either in sole or combined applications at 45 FC than 70 FC, while, MLE 2, Pa + MLE 1, and Pa + MLE 2 were significantly efficient in decreasing flavonoids and phenolics of wheat plants under drought stress as compared with the control. These results prove the effectiveness of these amendments in increasing the water uptake efficiency of wheat plants.

Oxidative Stress Indicators, Enzymatic Antioxidants, and Ionic Contents

Ionic nutrient contents increased significantly in plants that were irrigated at 70 FC compared with plants irrigated with water to reach only 45 FC (Table 1). However, in contrast, different oxidative stress indicators such as sodium, proline, GB, electrolyte leakage (EL), malondialdehyde (MDA), and hydrogen peroxide (H_2O_2) increased significantly in plants subjected to 45 FC water conditions. Furthermore, antioxidant enzyme [superoxide dismutase (SOD) and peroxide (POD)] activities were increased in drought stress.

All additives had significant positive improvements in ameliorating drought effects in wheat. These amendments were

more detectable when the dose of MLE foliar application was increased. Pa and MLE decreased sodium, proline, GB, EL, MDA, H_2O_2 , and SOD and POD contents significantly. Also, they increased calcium, potassium, phosphate, and nitrate concentrations in plant tissues. It is worth mentioning in this study that sole and combined applications of either MLE or Pa were better in decreasing the oxidative stress indicators and increasing nutrient contents of wheat, and this signifies the success of these ameliorating treatments for drought stress. Pa + MLE 1 and Pa + MLE 2 recorded the least oxidative stress indicators and enzymatic antioxidant activities during more nutrient assimilation in plants.

All values are the means of three replicates \pm SD. Different labels represent significant different alphabets using the least significant difference (LSD) test. [70 FC = well-irrigated conditions, 45 FC = drought stress conditions; C = control, Pa (strain) = *P. aeruginosa* inoculated plants, MLE 1 = foliar applied MLE at 1:15, and MLE 2 = foliar applied MLE at 1:30] [GB = glycine betaine, EL = electrolyte leakage, MDA = malondialdehyde, H_2O_2 = hydrogen peroxide, SOD = superoxide dismutase, and POD = peroxide].

FIGURE 3 | Impact of sole and combined applications of *Pa* and MLE on flavonoids, phenolics, total soluble sugars, total soluble proteins, and stomatal conductance of wheat plants under 45 FC and 70 FC irrigation levels. Different bars represent the mean values of three replicates. Error bars represent SE. Different letters on bars indicate significant difference at $p \leq 0.05$ [70 FC = well-irrigated, 45 FC = drought stress condition; C = control, *Pa* (strain) = *P. aeruginosa* inoculated plants, MLE 1 = foliar-applied MLE at 1:15, MLE 2 = foliar-applied MLE at 1:30, and S.C. = stomatal conductance]. Means with the same letters within the column are not significantly different.

Pearson Correlation

A significant positive correlation exists between plant morphological attributes and photosynthetic pigments (**Figure 4**). This might, in turn, improve plant vigor and consequently improved plant growth. Also, the total soluble sugars, total soluble proteins, stomatal conductance, and ionic contents were increased with the given amendments. However, oxidative stress indicators, enzymatic antioxidants, flavonoids, and phenolics increased under drought stress conditions recorded significant negative correlations with plant growth parameters.

DISCUSSION

This study evaluates the effect of MLE (MLE 1 = 1:20 v/v and MLE 2 = 1:30 v/v) and PGPR strain (Pa) on drought stress tolerance ability of wheat (Anaj 17 genotype) under two irrigation regimes (45 FC and 70 FC). The use of organic or biofertilizers as a global initiative instead of costly chemical fertilizers is addressed by several researchers (Talaei et al., 2014; El-Naggar et al., 2015; El-Serafy, 2018; Rahimi et al., 2019). Plant-derived biostimulants that trigger abiotic stress tolerance to ameliorate stress-induced yield reduction involve many different mechanisms, and most of these involve phytohormones and upregulated antioxidant defense systems (Bulgari et al., 2017; Sadasivam et al., 2017).

The highest dry matter contents in both root and shoot were obtained with the combined application of Pa + MLE 2 mixture that agrees with previous findings describing that soil beneficial bacteria can promote plant growth in abiotic stress conditions. Durán et al. (2016) had similar results on lettuce inoculated with *Bacillus* sp. and *Klebsiella* sp. and concluded that inoculated plants have more DW than non-inoculated ones. In this sense, Glick et al. (2007) said that this increase in the dry matter might be the enzyme 1-aminocyclopropane-1-carboxylate (ACC) deaminase enzyme activity of bacteria to lower the stress-induced ethylene levels, leaving α -ketobutyrate and NH_4^+ available to the plants. Moreover, according to the study by Sánchez López (2011), auxins, i.e., indole-3-acetic acid (IAA), have a stimulatory effect on secondary root development that contributes to the total biomass of the plant by increasing nutrient and water absorption in moisture deficit conditions. The results from this study are in accordance with those claimed by Mishra et al. (2012) that an increase in auxin concentration stimulates adventitious root formation and thus increases root surface area and total plant biomass, proclaiming a morphological strategy of plants to tolerate drought with the help of bacterial strains.

Photosynthetic pigment contents are considered a valuable physiological indicator for evaluating the damage caused by stress intensity. The wheat genotype in this study had more chlorophyll contents when supplemented with Pa and MLE with the highest value recorded in their combined treatment at both water regimes. This alteration is directly related to plant macronutrient contents such as nitrogen. The reactive oxygen species (ROS) produced during abiotic stress cause the reduction of chlorophyll contents by damaging photosynthetic machinery (Manivannan et al., 2007). Similar to our results, Ahmadi et al. (2013)

also found a significant increase in chlorophyll contents by inoculating wheat with different bacterial strains (*Pseudomonas* sp. and *Azospirillum* sp.).

This study indicates that the increase in mineral nutrient contents of wheat is due to the use of biostimulants that enhanced drought stress tolerance. The inoculation with *P. aeruginosa* and MLE applied separately and in combination increased levels of sodium, calcium, potassium, phosphate, and nitrate in wheat submitted to drought. This might be due to the nutrient solubilization by added microorganisms due to the production of ACC deaminase (Mutumba et al., 2018). In addition, Römheld and Kirkby (2010) considered potassium as a key element in reducing water stress by adjusting osmoregulation in cells as a compatible solute. Zulfiqar et al. (2020) reported enhancement in soil nutrient availability and improvement in fruit quality induced by plant-derived biostimulants in stress conditions. The increase in plant nutritional status and vigor is due to improved soil microbial activity (Colla et al., 2015) and the presence of some chelating agents that enhance nutrient solubility in soil (Abou Chehade et al., 2018).

Induced tolerance by plant growth regulators is triggered by external stress factors and enhancement in plant sterols by reducing EL and regulating membrane stability (Lucini et al., 2015), thus providing an antioxidant defense system. Results of this experimental study indicate that Pa and MLE significantly improve growth, biochemical, antioxidant, and ionic attributes of wheat. Rhizobacteria potentially increase plant vigor by increasing atmospheric nitrogen fixation ability of roots and mineral absorption.

In accordance with our findings, previous studies also validate drought stress effects that consequently increase ROS that activate plant enzymatic and non-enzymatic antioxidant systems in order to balance the cellular redox state (Zulfiqar et al., 2020). Kumar et al. (2019) reported seed priming that involves plant growth regulators inducing sugar-triggered plant immunity (called “sweet immunity”—immunity by sugar compounds) having a positive priming effect on antioxidant systems. Results of our study validate that the antioxidant contents were improved using MLEs as a bioactive compound. Furthermore, a study by Rashid et al. (2018) confirmed the presence of a primary growth regulator, zeatin (a cytokinin derivative) that provided abiotic stress tolerance. Moringa extract constitutes considerable quantities of secondary metabolites, antioxidants, and osmoprotectants (Rehman et al., 2015). MLE's growth-promoting and abiotic stress tolerance inducing effects justify its use as a potential alternative to synthetic chemical fertilizers for improving wheat productivity (Nasir et al., 2016; Brockman and Brennan, 2017; Merwad, 2018; Younis et al., 2018). MLE aqueous solutions are very easy to make, cost-effective, and environment-friendly and can be used by the farmers effectively for increasing their crop yields. This study clearly reveals that all studied growth, biochemical, ionic, and antioxidant constituents of wheat plants were improved by using either of the two given amendments. Pa and MLE reduced all investigated oxidants and oxidative stress indicators. It is worth mentioning in this study that these supplementary amendments might antagonize each other's effects to some extent in their combined applications, as their sole applications had lowered physiological, biochemical, and ionic attributes. Thus, constitutive effects, i.e., Pa and MLE,

at both concentration levels were more elaborated, thus inducing drought tolerance in wheat.

CONCLUSION

The application of both nitrogen-fixing bacteria (Pa strain) and foliar sprayed MLE either in sole or combined treatments can alleviate nutrient and drought stress effects. Nevertheless, the combined application of Pa and MLE 2 (Pa + MLE 2) can efficiently improve wheat growth attributes, photosynthetic pigment contents, and nutrient uptake under drought stress. The combined supplementation of Pa and MLE had more significant positive effects compared with their sole applications. Pa + MLE 2 was also efficient in decreasing oxidative stress indicators and enzymatic antioxidants of wheat under drought stress. There is a need for more investigations at field levels by considering the effect of other environmental constraints to effectively validate these findings.

A survey of plant-based wastes identified sunflower (*Helianthus annuus*) bark extract (SBE), produced via twin-screw extrusion, as a potential biostimulant. The addition of SBE to Arabidopsis (*Arabidopsis thaliana*) seedlings cultured *in vitro* showed a dose-dependent response, with high concentrations causing severe growth inhibition. However, when priming seeds with SBE, a small but significant increase in leaf area was observed at a dose of 0.5 g of lyophilized powder per liter. This optimal concentration of SBE in the culturing medium alleviated the growth inhibition caused by 100 mM NaCl. The recovery in shoot growth was accompanied by a pronounced increase in photosynthetic pigment levels and a stabilization of osmotic homeostasis. SBE-primed leaf discs also showed a similar protective effect. SBE mitigated salt stress by reducing the production of reactive oxygen species (ROS) (e.g., hydrogen peroxide) by about 30% and developing more expanded true leaves. This reduction in ROS levels was due to the presence of antioxidative agents in SBE and by activating ROS-eliminating enzymes. Polyphenols, carbohydrates, proteins, and other bioactive compounds detected in SBE may have contributed to the cellular redox homeostasis in salt-stressed plants, thus promoting early leaf development by relieving shoot apical meristem arrest. Sunflower stalks from which SBE is prepared can therefore potentially be valorized as a source to produce biostimulants for improving salt stress tolerance in crops.

Keywords: *Helianthus annuus*, plant extract, biostimulant, *in vitro* assay, salt stress, antioxidant

INTRODUCTION

Substantial losses in biomass accompany crop production and downstream processing because of inadequate harvesting methods and a lack of valorization of by-products (Parfitt et al., 2010). To reduce the ecological footprint of agricultural practices, the Food and Agriculture Organization of the United Nations (FAO) identified two primary targets: “agricultural sustainability” and “global

food losses" (FAO, 2021). In view of these targets, we urgently need to transform agricultural waste into value-added products. Crop waste is a natural resource for refining and recovering bioactive ingredients (Van Tang, 2017). Indeed, various molecules are abundant in unused biomass, some of which can be developed as plant biostimulants (PBs) (Xu and Geelen, 2018; Huang et al., 2021). The development and commercialization of PBs is a rapidly growing business, estimated at USD 3.2 billion in 2021 with a projected compound annual growth rate (CAGR) of 12.1% (Markets and Markets, 2021). Strikingly, plant extract-based PBs exhibited the highest effectiveness in yield enhancement of field crops (Li et al., 2022). Compared with synthetic chemical additives for crop improvement, PBs derived from natural resources like plant byproducts are poised to encompass a lower environmental risk and impact (Kumar et al., 2019). PBs are more likely to pass the regulatory restriction of fertilizers from natural origins imposed by legislation (Regulation [EU], 2019).

The main methods of PBs application are foliar spraying, seed priming, and soil drenching (Verified Market Research, 2021). Hence, most primary screening assays are designed to screen putative biostimulant activity starting from seed germination and the growth responses of seedlings (García-García et al., 2020). The monitoring of seedling growth allows for *in vitro* assays under controlled conditions, short evaluation periods, and assessment of a broad spectrum of responses (Colegate and Molyneux, 2007). Subsequent bioassays are dedicated to monitoring specific plant responses. For example, seed priming tests report the effect of chemical reagents on seed germination and early seedling development (Lutts et al., 2016). *Arabidopsis* (*Arabidopsis thaliana*) seedlings grown *in vitro* are widely used to study the effects of exogenous chemicals on root and shoot growth (Trinh et al., 2018). An alternative to growth assays is measuring the longevity of mature leaf discs punched from mature leaves that normally senesce in a matter of days (Chiu et al., 2021). *In vitro* bioassays also allow for the quantitative impact of stress responses, and the combining of the results from multiple assays provides a reasonable indication for possible biostimulant activity under field conditions.

Plant-based raw materials are typically rich in diverse metabolites (Zulfikar et al., 2020). Various plant extracts have also improved stress tolerance, often attributed to antioxidants (De Diego and Spíchal, 2020). Polyphenols, abundant in many plant extracts, are a class of bioactive antioxidants that scavenge *in vitro* and *in vivo* reactive oxygen species (ROS) (Stagos, 2020). For instance, many polyphenols are found in various bark byproducts from woody species such as oak and willow (Drózd and Pyrzynska, 2017; Dou et al., 2018; Tanase et al., 2019). Sunflower (*Helianthus annuus*) seeds and florets are also rich in polyphenols with antioxidant activity (Karamać et al., 2012; Ye et al., 2015). The trichomes isolated from the surface of sunflower stems contain many flavonoids, which are typically showing antioxidant activity (Brentan Silva et al., 2017).

Sunflower is an annual crop produced for its seed and is the fourth most important oilseed crop responsible for 10% of the world's edible plant-derived oil (Dantas et al., 2017). The leaves and stems are usually not harvested and left on

the field as organic compost. The worldwide production of sunflower foliage and stems is an estimated 15.2 megatons per year (United Nations Industrial Development, 2007). Because of this substantial amount of biomass, stem material is considered a source of fiber used in biocomposite panels and other fiber-rich materials. The stalks are separated into the bark (external "woody" part, 90% w/w), which is rich in lignocellulose, and the pith (internal part, 10% w/w) (Evon et al., 2018; Verdier et al., 2020). In addition to fiber, the stalks can potentially be refined through the advanced twin-screw extrusion technology and used for various added-value applications in the agrochemical industry.

This study shows that (1) sunflower bark extract (SBE) can be produced as a side stream during twin-screw extrusion of fiber from stems; (2) SBE is a complex mixture of water-soluble molecules, several of which have bioactivity on plant growth; (3) exogenous application of SBE mitigates salt stress-induced growth inhibition of *in vitro* grown *Arabidopsis* salt.

MATERIALS AND METHODS

Sunflower Stalk Collection and Bark Extraction

Sunflower stalks were collected with a forage harvester with the assistance of Ovalie Innovation in Autumn 2018 (Samaran, Gers department, southwest France). The stalks were stored in a ventilated box and dried with ventilated air at 40°C for 24 h. The bark was mechanically separated from the pith using a three-step procedure: (1) grinding of stalks using a hammer mill (Electra Goulu N, France) fitted with a 32 mm sieve; (2) de-dusting of the ground material using a vibrating sieve shaker (Ritec 600, France) equipped with a 1 mm screen; (3) aspiration of pith particles. Pith and bark particles were separated based on their differential density (i.e., 30 and 140 kg/m³, respectively).

Here, the twin-screw extrusion technology was used as an innovative technique for the thermo-mechanical and organic solvent-free extraction of biomolecules (Evon et al., 2018; Vandenbossche et al., 2019). The bark was then fractionated into a pulp and a liquid extract made of water-soluble compounds using a co-rotating and co-penetrating twin-screw extruder (Clextral Evolum HT 53, France). The extruder barrel (1.9 m in length) consisted of eight modules, each 4D in length (D is the screw diameter, i.e., 53 mm), except for module 1, which had an 8D length. A filter section consisting of six hemispherical dishes with 1 mm diameter perforations outfitted on module 7 enabled filtrate collection. During the liquid/solid fractionation process, bark with 10.0 ± 0.1% moisture content was fed at the level of module 1 using a gravimetric feeder. Water was injected at the end of module 2 using a piston pump at a liquid/solid ratio of 2.9 (i.e., 10.2 and 29.6 kg/h for the inlet flow rates of bark and water, respectively). For optimal operation, a specific screw configuration was applied. Bilobe paddles (BL22) were positioned in module 5 to favor strong mixing between the liquid and the solid. In addition, reversed pitch screws (CF2C) were positioned in module 8, immediately downstream from the filtering sieves to separate the liquid (i.e., the filtrate)

and solid (i.e., the pulp) phases continuously by compression action. The temperature was set at 80°C in module 2, at 100°C along the extracting zone (modules 3–6), and 110°C in the pressing part (module 8). The rotation speed of the screws was set at 250 rpm.

The filtrate collected at the bottom of the filtration module (module 7) was centrifuged to remove the small solid particles and driven through the filter. Then, the clarified filtrate was concentrated by partial water evaporation and freeze-dried, producing SBE as a powder product stored in the dark at 4°C until use.

Chemical Characterization of Starting Sunflower Bark and Sunflower Bark Extract

The moisture and dry matter contents of solids in the starting sunflower bark were determined according to ISO 665:2000 (ISO, 2000). The mineral content of starting bark was quantified according to ISO 749:1977 (ISO, 1977), and lipids were assessed according to ISO 659:2009 (ISO, 2009). Cell wall polymers, including cellulose, hemicellulose, and lignin, were quantified using the ADF–NDF method (ADF for acid detergent fiber, and NDF for neutral detergent fiber) of Van Soest and Wine (1967, 1968). After 1 h of boiling in water, water-soluble compounds were calculated from biomass losses.

Inside the SBE, the soluble protein and digestible carbohydrate contents were analyzed by colorimetric methods (Deans et al., 2018). Total phenolics content (TPC) was estimated by the Folin–Ciocalteu method (Sánchez-Rangel et al., 2013). The total flavonoid content (TFC) was measured following two aluminum complexation methods using quercetin and rutin as reference flavonoids (Pekal and Pyrzynska, 2014). The total *in vitro* antioxidant capacity (TAC) of SBE was determined using the 2,2-diphenyl-1-picrylhydrazyl (DPPH) and the 2,2'-azino-bis (3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) assay (Xiao et al., 2020). Trolox (TE) was used as a standard antioxidant to calculate the equivalent antioxidant capacity of samples. The DPPH assay was slightly modified (Xiao et al., 2020). A total of 20 µl sample was added with 100 µl 200 mM DPPH and 80 µl 50 mM Tris–HCl buffer (pH 7.4).

Chemical Profiling of Sunflower Bark Extract Using UHPLC-PDA-High-Resolution Mass Spectrometer Analysis

Sunflower bark extract was dissolved in water at 1 mg/mL and pushed through a 0.22 µm filter (Millix-GV, Millipore). Samples were subjected to ultra-high-performance liquid chromatography (Acquity UPLC) coupled to a PDA detector (UPLC eLambda 800 nm) and a SYNAPT G2-S High-Resolution Mass Spectrometer (HRMS) (Waters, Milford, MA, United States). Prepared samples were chromatographically separated on an ACQUITY UPLC BEH C18 column (1.7 µm, 2.1 mm × 150 mm) protected by an ACQUITY UPLC BEH C18 VanGuard Precolumn (1.7 µm, 2.1 mm × 5 mm) (Waters). The mobile phase A was 0.1% formic acid in water (solvent A) and the mobile phase B was 0.1% formic acid in acetonitrile

(solvent B) at a flow rate of 0.35 mL/min with following gradient: 95% A–5% B (0–18 min), 100% B (18–25 min), 95% A–5% B (25.1–30 min). PDA data was recorded between 220 and 550 nm. Ions were detected in the positive electrospray ionization (ESI+) and negative electrospray ionization (ESI–) modes. The ESI conditions were set as follows: capillary voltage of 3.0 kV (ESI+)/2.0 kV (ESI–), source temperature of 120°C, cone voltage of 30 V (ESI+)/40 V (ESI–), and desolvation temperature of 500°C with a desolvation gas flow of 800 L/h. The collision-induced dissociation (CID) was set at 4 eV for precursor ion, and MS/MS fragment ion information was obtained with a collision energy ramp from 8 to 40 eV. The HRMS was calibrated between 50 and 1200 Da with a sodium formate solution prior to analysis. The injection volume was set at 5 µl, and each sample was analyzed in duplicate. All data were recorded at resolution mode (20,000 FWHM) in centroid full scan MS^E mode (data-independent acquisition, DIA). A 200 pg/µl leucine enkephalin solution was continuously infused during analysis to perform lockmass correction (*m/z* 556.2771 in positive ion mode and *m/z* 554.2615 in negative ion mode) during analysis. Blanks containing only the mobile phase without any sample were injected between each batch of samples.

To determine the chemical composition of SBE, the raw MS/MS data were processed for feature detection and alignment with MS-DIAL software version 4.48 (Blaženović et al., 2017). The detailed settings are listed in **Supplementary Table 1**, and are adapted from Lee et al. (2019). To gain a high confidence in the peak identification, only the features present in both runs from the same sample were considered for alignment correction. Next, aligned features meeting the criteria were selected with a total weighted similarity score of over 60 (overall library-matching score based on retention time, accurate mass, isotope ratio, and MS^E spectra) (Tsugawa et al., 2015). Then, we searched these chosen features for further compound prediction in MS-FINDER software version 3.50 (Tsugawa et al., 2016) among online metabolites databases, including PlantCyc (plant), KNApSACK (natural product), FoodDB (Food), ChEBI (Biomolecules), and PubChem (Biomolecules), with the agreement of identification confidence levels (level 3) (Schymanski et al., 2014). In each feature, the predicted formula and structure with the top total score were reported as the final candidate compound (Tsugawa et al., 2019). Finally, the identified compounds were assigned taxonomy based on their chemical characterization represented as InChIKey (International Chemical Identifier) in ChemOnt ontology via ClassyFire (Djoumbou Feunang et al., 2016).

Pesticide Residue Detection in Sunflower Bark Extract

Lyophilized powder of SBE was analyzed for the presence of over 500 pesticide residues (Regulation [EC], 2005, 2009) (Primoris, Belgium). Briefly, the pesticide(s) were extracted from the crude sunflower bark material with acidified acetonitrile (QuEChERS extraction) or acetonitrile with 0.5% acetic acid. Pesticides were quantitatively determined using LC–MS/MS and GC–MS/MS, respectively. No chemicals above the maximum residue levels were reported (data not shown).

Plant-Based Bioassays Using Arabidopsis as the Model Plant Root Development

Arabidopsis (Col-0) seeds were chlorine gas-sterilized for 3 h (Lindsey et al., 2017), sown on full strength Murashige and Skoog medium, and vernalized for 3 days at 4°C (Trinh et al., 2018). Next, the plates were exposed 8 h to light (room temperature 21.4°C, 40–60% humidity, light intensity 140 $\mu\text{mol m}^{-2} \text{s}^{-1}$, 14/10 h day/night photoperiod) and transferred to the dark for another 3 days to induce etiolation. Then, uniform-size of 3 DAG (days after germination) seedlings were transplanted onto the growth medium and incubated vertically for 10 days. For the dose-response experiment, the medium was supplemented with 0.1, 0.5, 1, 2, 3, 3.67, 4, and 5 g/L SBE. For the time-course analysis of primary root development, the medium was supplemented with 1 g/L or 3 g/L SBE and incubated for 6, 12, and 24 h after etiolation. Seedlings were scored for the numbers of adventitious roots (ARs), junction roots (JRs), and lateral roots (LRs) under a binocular microscope (Olympus, SZX9, Tokyo, Japan). The primary root length (PRL) was measured by image analysis using ImageJ software version 1.53n (Schindelin et al., 2012) coupled with the “NeuronJ” plugin (Meijering et al., 2004). Each treatment consisted of three plates, and each plate contained 10 seedlings.

Shoot Growth

Arabidopsis shoot growth in response to SBE application was evaluated using a shoot assay adapted from De Diego et al. (2017). Briefly, seedlings were grown as described in the root assay and, at 3 DAG, transferred to 24-well tissue culture plates (VWR, CA, United States) containing Murashige and Skoog medium (4 mL per well) supplemented with 0.5 g/L SBE and 100 mM NaCl. Since at 100 mM NaCl, *Arabidopsis* rosettes are more compact (Claeys et al., 2014), we assessed the shoot growth at 13 DAG by measuring the green surface area using ImageJ. Each data point corresponds to 16 seedlings per treatment. The electrolyte leakage (also called conductivity) from seedlings was measured with a conductivity meter (inoLab Cond level 1) (Jiang et al., 2017).

Floating Leaf Disc

The senescence leaf disc assay was modified from Ghosh et al. (2015) and Chiu et al. (2021). *Arabidopsis* was cultivated in Jiffy-7® peat pellets (Jiffy Products International AS, Norway) in a growth room (room temperature 18°C, less than 70% relative humidity, light intensity 100 $\mu\text{mol m}^{-2} \text{s}^{-1}$, 16/8 h day/night photoperiod). The chlorophyll content in fully expanded rosette leaves of the same developmental stage was determined by the SPAD-502 chlorophyll meter (Konica Minolta, Tokyo, Japan). Leaves with SPAD values from 25 to 35 were harvested from healthy plants at 30 DAG. Around 20 leaf discs were punched with a 7 mm cork borer and floated on a 5 mL solution in each petri dish (55 mm diameter). Each treatment consisted of six individual plates. Distilled water (dH₂O) was considered the blank, while 200 mM NaCl was considered the salt treatment. For exogenous SBE treatment, leaf discs were pretreated with 5 mL of dH₂O or 0.5 g/L SBE for 1 day before incubating

in the blank or salt solution for another 2 days. The plates were sealed with 3M Micropore tape (3M, St. Paul, MN, United States) and placed in the growth room (room temperature 25°C, 40–60% humidity, light intensity 200 $\mu\text{mol m}^{-2} \text{s}^{-1}$, 24 h light photoperiod). After incubation, the leaf disc samples were first wrapped in dust-free tissue paper, then homogenized into powder with liquid nitrogen, and stored at –80°C for further analysis. Photosynthetic pigments of chlorophyll *a* (Chl *a*), chlorophyll *b* (Chl *b*), and carotenoids (Car) were assessed from frozen samples using a microplate reader (Tecan Infinite M200), according to Chiu et al. (2021). Malondialdehyde (MDA), as a biomarker of lipid peroxidation, was analyzed via the thiobarbituric acid (TBA)-reactive substances assay following (Hodges et al., 1999).

True Leaf Development

The true leaf assay was adapted from Rosa and Scheid (2014). *Arabidopsis* seeds were sown directly on the treated medium and vernalized as mentioned before (Trinh et al., 2018). Since the addition of NaCl (100 mM) in the medium induced moderate salt stress (Claeys et al., 2014), medium supplemented with 0.5 g/L SBE was prepared with or without 100 mM NaCl for the exogenous SBE application. The plates were positioned horizontally for germination in the light without etiolation and early leaf development monitoring for 10 days. The germination rate and the early development phenotypes were recorded daily at the same time each day. At 2 DAG, seed germination was evaluated by checking if the radicle was visible after testa rupture. Later, at 10 DAG, the successful emergence and expansion of the first pair of true leaves were determined by a binocular microscope at 20× zoom. If the side-view width of the true leaf had expanded larger than the hypocotyl diameter, it was then scored as a plant with expanded true leaves (Supplementary Figure 1). The percentage (%) of seedlings with true leaves was calculated following Equation 1:

$$\% \text{ plants with true leaves} =$$

$$\frac{\text{Number of seedlings developed with true leaves}}{\text{Number of germinated seedlings}} \quad (1)$$

This assay was performed as nine replicates for each treatment, and each plate contained 25 seeds. The harvested samples at 10 DAG were pooled into four biological replications and stored at –80°C for further analysis. The fresh weight of whole seedlings was measured and subsequently dried at 65°C for 48 h in an oven for dry biomass determination. In addition, the conductivity and MDA content in seedlings were measured as mentioned above to evaluate plasma membrane damage.

Hydrogen peroxide (H₂O₂), as one of the main ROS products, was quantified based on potassium iodide (KI) oxidation (Junglee et al., 2014). To detect *in situ* H₂O₂, histological staining with 3,3'-diaminobenzidine (DAB) on whole seedlings was performed as previously described (Daudi and O'Brien, 2012). The seedlings were imaged via an Olympus BX51 microscope (Olympus, Tokyo, Japan) equipped with differential interference contrast (DIC) optics at 10× zoom. The relative DAB staining intensity was calibrated in pseudo color and quantified in

TABLE 1 | Contents of soluble protein, digestible carbohydrate, polyphenols, and *in vitro* antioxidant capacity in SBE.

Parameters	SBE
Soluble protein content (mg g DW ⁻¹ BSA equivalent)	14.91 ± 0.41
Digestible carbohydrate content (mg g DW ⁻¹ D-glucose equivalent)	6.91 ± 0.53
Total phenolic content (TPC) (mg g DW ⁻¹)	AsA equivalent CHA equivalent 6.46 ± 0.79 29.68 ± 0.81
Total flavonoid content (TFC) (μg g DW ⁻¹)	QE equivalent Rutin equivalent 9.70 ± 0.29 15.93 ± 2.01
Total antioxidant capacity (TAC) (mg g DW ⁻¹ TEAC)	IC ₅₀ DPPH assay IC ₅₀ ABTS assay 20.66 ± 0.67 117.34 ± 3.34

Values are represented as mean ± SD (n = 3). SBE, sunflower bark extract; DW, dry weight; BSA, bovine serum albumin; AsA, ascorbic acid; CHA, chlorogenic acid; QE, quercetin; TEAC, trolox equivalent antioxidant capacity; DPPH, 2,2-diphenyl-1-picrylhydrazyl; ABTS, 2,2'-azino-bis (3-ethylbenzothiazoline-6-sulfonic acid).

four tissues, inclusive of cotyledons, hypocotyls, shoot apical meristems (SAMs), and root, using ImageJ coped with the “Colour Deconvolution 2” plugin (Ruifrok and Johnston, 2001; Landini et al., 2021).

The antioxidant enzyme activity was then determined following a semi high-throughput protocol (Fimognari et al., 2020) with the adapted extraction method (Noctor et al., 2016). About 300 mg grounded sample was extracted with 2 mL extraction buffer (0.1 M phosphate buffer plus 1 M EDTA; pH 7.5) and 50 mg polyvinylpyrrolidone (PVP). The mixture was centrifuged for 10 min at 4°C. Next, the total protein content was quantified in the desalted supernatant by Wizard® SV minicolumns using a spectrophotometer (DeNovix Inc., United States). Finally, the enzyme kinetic assays were performed for the activity measurement of ascorbate peroxidase (APX, EC:1.11.1.11), catalase (CAT, EC:1.11.1.6), glutathione reductase (GR, EC:1.8.1.7), glutathione S-transferase

(GST, EC:2.5.1.18), monodehydroascorbate reductase (MR, EC:1.6.5.4), (cytoplasmic) peroxidase (POX, EC:1.11.1.5), and superoxide dismutase (SOD, EC:1.15.1.1). The antioxidative enzyme capacity, indicating the rate of catalyzed reaction by the enzyme, was calculated as a unit per mg of protein (Vanhoudt, 2014).

Statistical Analysis

The treemap was generated indicating the chemical classification of compounds identified in SBE by R software version 4.1.1 (R Core Team, 2021) coupled with “treemap” package version 2.4-3 (Tennekes and Ellis, 2021). Non-parametric Kruskal–Wallis test was used with *post hoc* Dunn’s analysis (α = 0.05) for variances in root numbers of different types. PRL was normalized and fitted in a 5-parameter logistic model of dose-response analysis using “nplr” package version 0.1-7 (Commo and Bot, 2016). The half-maximal-effect concentration (EC₅₀) was calculated on

The compounds were detected and tentatively identified via UHPLC-PDA-HRMS under ESI+ and ESI– modes. SBE, sunflower bark extract; ESI+ (–), positive (negative) electrospray ionization; RT, retention time; NA, not available.
¹The ontology information of identified features (class, subclass, and parent level 1) was retrieved by InChIKey according to ChemOnt chemical taxonomy (Djombou Feunang et al., 2016).
²The top-ranking score of the candidate compound was selected in the MS-FINDER program (Tsugawa et al., 2016).

the PRL inhibition effect by getEstimates function (Venturelli et al., 2016). Dynamic growth models of plant leaf area were fitted in exponential growth curves illustrating the early development patterns. One-way ANOVA analysis was applied with *post hoc* Tukey HSD test ($\alpha = 0.05$) to compare the treatment difference for other plant traits. Besides, two-way ANOVA analysis was used for two independent variables: the addition of growth media and timepoints. The statistical analysis of the remaining parameters and data visualization were performed with GraphPad Prism software version 8.0.2 (GraphPad, San Diego, CA, United States).

RESULTS

Preparation of Sunflower Bark Extract and Chemical Analysis

Aqueous extraction of sunflower bark was obtained using a twin-screw extruder as described in the materials and methods. **Supplementary Table 2** shows the chemical composition of the starting bark materials, with the insoluble fraction constituting 88% of the bark containing 50% cellulose and 15% lignin. The high content in lignocellulose promoted the separation into fiber (pulp) and a liquid filtrate, which contained the water-soluble compounds. The chemical composition and antioxidant activity of the freeze-dried liquid filtrate (SBE) contained 1.5% (w/w) soluble protein and 0.7% (w/w) carbohydrate (**Table 1**). The polyphenol content (TPC and TFC) per gram dry biomass of SBE was 6.46 mg AsA equivalents and 29.68 mg CHA equivalents with phenolic acids, and 9.70 μ g QE equivalents and 15.93 μ g rutin equivalents with flavonoids. TAC of SBE was represented as IC₅₀ from *in vitro* antioxidant assays, which were 20.66 and 117.34 TE equivalents in the DPPH and ABTS assay, respectively.

The low molecular weight primary and secondary metabolites were characterized by untargeted metabolic profiling using UHPLC-PDA-HRMS. It resulted in 2369 LC–MS features in the ESI+ mode and 814 under the ESI– mode (the chromatograms are shown in **Supplementary Figure 2**, all the identified compounds are listed in **Supplementary Data 1**). A total of 26.03% of the ESI+ and 57.97% of the ESI– detected peaks were tentatively identified. These compounds were classified according to 35 distinct categories of plant metabolites (**Figure 1**). The lipids and lipid-like molecules, organic acids, phenylpropanoids and polyketides, benzenoids, and organoheterocyclic compounds formed the five most extensive groups representing half of the classified metabolites. SBE was particularly rich in compounds across chemical superclasses of phenylpropanoids and polyketides, organic acids and derivatives, and benzenoids, of which polyphenols are well-known antioxidants with cytoprotective activity (Kiokias et al., 2020; Šamec et al., 2021). Thereby, we further focused on the diverse proportions of non-flavonoid and flavonoid compounds of interest under the phenylpropanoids and polyketides superclass in SBE. Eleven polyphenol classes involved 20 subclasses, and 45 tentatively identified compounds were illustrated in **Table 2**.

Sunflower Bark Extract Inhibited the Primary Root Growth of Non-stressed Arabidopsis Seedlings in a Dose-Response Manner

The root tip is a sensory organ that evaluates the presence of mineral nutrients and physical obstructions, adapting its growth in response to the conditions by altering the growth rate and orientation of cell division and expansion (Svolacchia et al., 2020). Hence, the primary root is very susceptible to environmental conditions, and its plasticity facilitates the detection of slight changes in the composition of the growing medium (Malamy, 2005). To test the impact of SBE application on root growth, root length (PRL) and branching (AR, LR, and JR) of *in vitro* grown Arabidopsis seedlings were determined (Supplementary Figure 3). Significantly less AR was formed when treated with SBE at higher doses. A strong reduction in LR number was observed at SBE levels from 1 g/L, while the effect on JR formation was more complex with a promotion up to 1 g/L SBE but a reduction from a higher concentration above 1 g/L. Furthermore, the EC_{50} of SBE inhibition of PRL was 0.63 g/L (Figure 2). Since root growth often shows an adaptive behavior to exogenous stimuli, the inhibition of PRL was examined at different time intervals after transfer to the medium containing SBE. Growth inhibition was observed 24 h after treatment with 1 g/L SBE, while at 3 g/L SBE inhibition occurred 6 h after treatment (Supplementary Figure 4). To avoid secondary effects following primary root growth inhibition, SBE was applied at 0.5 g/L in the subsequent assays (Supplementary Figure 3).

Priming With Sunflower Bark Extract Did Not Alter Germination Rate but Stimulated Shoot Growth

We did not observe a notable change in shoot growth after transferring 3 DAG Arabidopsis seedlings to SBE containing medium (Figure 3B). In addition to the seed priming experiment, there was no impairment of seed germination rate after 2 days

in any of the treatments (Supplementary Figure 5). After 4 days, however, we observed a slight, statistically significant increase in the leaf area of seedlings grown on SBE containing medium (Figure 4A).

Sunflower Bark Extract Alleviated Shoot Growth Inhibition Under Salt Stress

Biostimulants typically show a more pronounced effect in plants grown under stress (Rouphael and Colla, 2020). The impact of SBE was therefore assessed under conditions of salt stress. As the suppression of shoot growth by NaCl was very notable (Claeys et al., 2014), the projected leaf area was used as a proxy for determining the effect of SBE. In the shoot assay, the shoot growth was severely inhibited in the presence of 100 mM NaCl, showing a reduced petiole length, smaller cotyledons, and delayed or even arrested emergence of the first true leaves (Figure 3A). In the presence of SBE, the NaCl-stressed seedlings generated a significantly larger green surface area than in control salt-stressed plants (Figure 3B). NaCl causes osmotic stress and ionic imbalances, affecting the integrity of the plasma membrane (Dubois and Inzé, 2020). Therefore, the seedlings were collected after 13 DAG to determine the electrolyte leakage (Figure 3C). Salt stressed plants grown on SBE containing medium showed much lower conductivity than the control plants, suggesting that SBE treatment protected the plants from cell membrane damage.

We then put more attention to early true leaf development in seed priming treatment. SBE did not influence the germination rate of Arabidopsis under salt stress conditions (Supplementary Figure 5). Since we noticed that shoot growth was enhanced in SBE containing medium, a time-course analysis was performed to determine this response in more detail (Figure 4). On 100 mM NaCl-containing medium, shoot development was significantly reduced, while this growth inhibition was strongly alleviated when SBE was included in the medium (Figure 4A). Under normal conditions, all plants expanded their first true leaves at 10 DAG, while in the presence of NaCl, only 20% of the plants produced expanded true leaves. However, the number of salt-stressed plants with expanded true leaves increased to around 80% when treated with SBE (Figure 4B). The addition of SBE advanced true leaf development by about 2 days, and the effects were already noticeable from 3 DAG when NaCl-induced anthocyanin accumulation as a red discoloring of the cotyledons and at the upper hypocotyl margin was observed. While less intense red coloring was shown in the presence of SBE (Figure 4C).

Sunflower Bark Extract Preserved Photosynthesis Pigments and Stabilized the Cell Membrane Under Salt Stress

The Arabidopsis response to salt stress includes a reduction in growth, reflected in lower fresh weight and dry weight (Figures 5A,B), and a bleaching effect that entails a decline of pigments, the photosynthetic chlorophyll, and carotenoids (Leschevin et al., 2021). These pigments were quantified, and chl_{a+b} was reduced twofold, whereas carotenoids were down by about threefold in 10 DAG salt-stressed seedlings (Figures 5C,D).

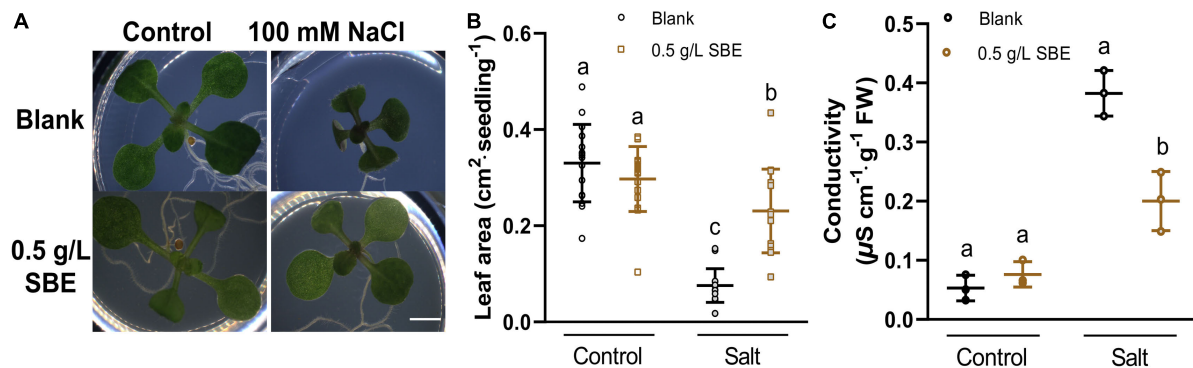

FIGURE 3 | Salt stress alleviation of SBE treatment in the Arabidopsis shoot assay. **(A)** Phenotypes of representative seedlings at 13 DAG grown on multiwell plates. Bar = 2 mm. The changes of **(B)** leaf area ($n = 16$) and **(C)** conductivity ($n = 4$) of 13 DAG seedlings. Error bars indicate SDs of the means. Different letters represent significant differences between treatments using Tukey's HSD test ($p < 0.05$). SBE, sunflower bark extract; DAG, days after germination.

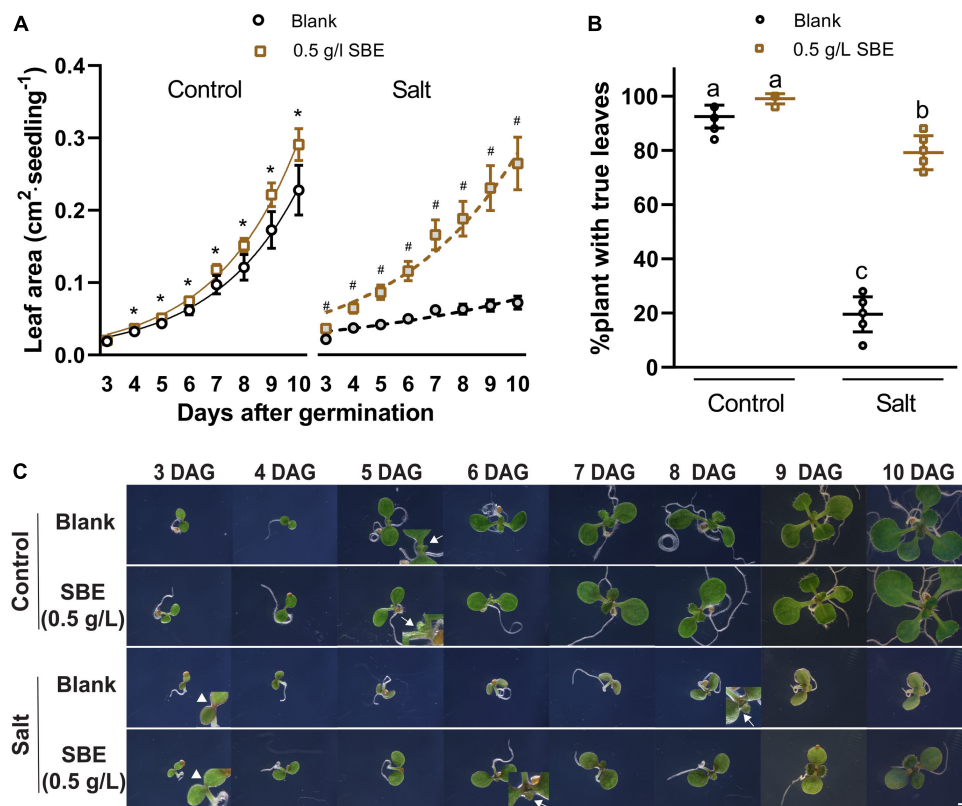

FIGURE 4 | Salt stress alleviation of SBE treatment in the Arabidopsis true leaf assay. **(A)** The dynamic growth of leaf area from 3 DAG to 10 DAG. Error bars indicate SDs of the means ($n = 9$). Different letters represent significant differences between treatments using Tukey's HSD test ($p < 0.05$). Fitted lines were exponential curves of dynamic leaf area growth. The symbols * and # represent significant differences between treatment with or without SBE addition under control or salt stress conditions at the same time point, respectively ($p < 0.05$). Both salt treatments were significantly different from the two non-stress treatments at every time point (label not shown). **(B)** The percentages of plants successfully developed with true leaves at 10 DAG. **(C)** Phenotype changes of representative seedlings from 3 DAG to 10 DAG focusing on the center of two cotyledons under binocular 6.3× zoom. Bar = 2 mm. Arrows without tails indicate salt stress alleviation by SBE addition on anthocyanin accumulation at the cotyledon edges of 3 DAG seedlings. Arrows with tails showed the earliest starting time point of visible true leaves. SBE, sunflower bark extract; DAG, days after germination.

This protective effect of SBE was accompanied by diminished salt stress-induced electrolyte leakage (Figure 5E) and MDA overaccumulation (Figure 5F).

To investigate whether SBE exerts a priming protective effect on mature leaves, punched leaf discs from fully developed leaves were pretreated for 1 day with SBE or water as a control

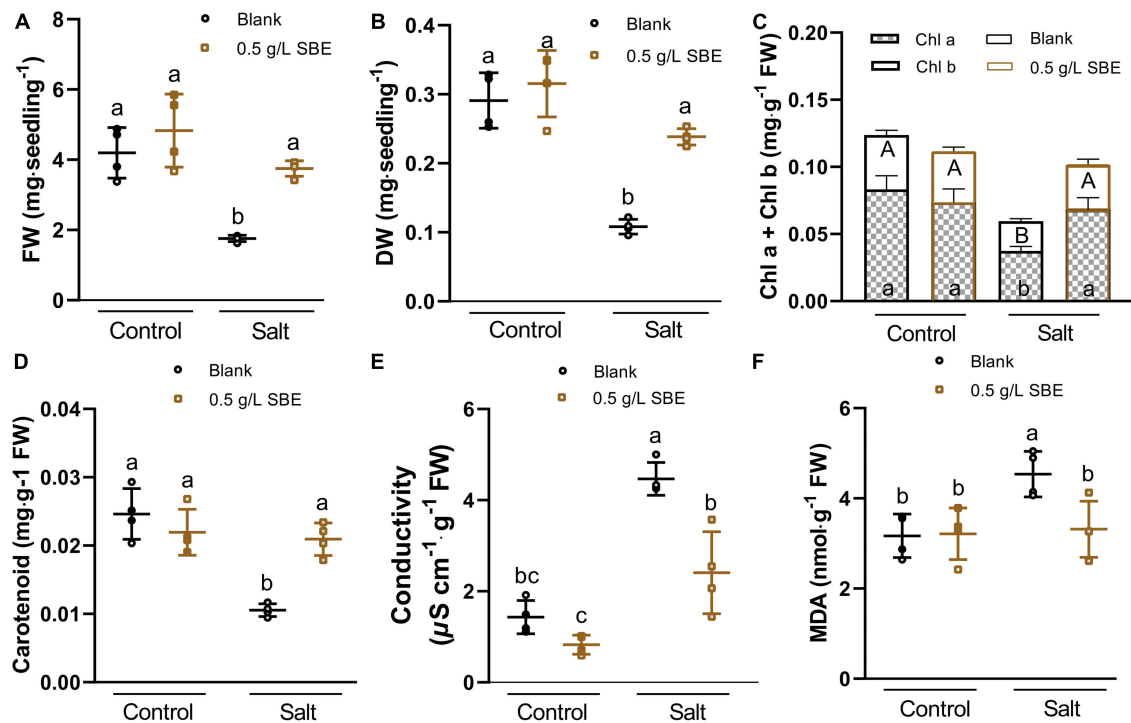

FIGURE 5 | Salt stress alleviation of SBE treatment on the physiological traits of 10 DAG Arabidopsis in the true leaf assay. **(A)** Fresh weight, and **(B)** dry weight of the whole seedlings at 10 DAG. The changes of photosynthetic pigments containing **(C)** chlorophyll a and b, **(D)** carotenoid content, **(E)** conductivity, and **(F)** MDA content. Error bars indicate SDs of the means ($n = 4$). Different letters represent significant differences between treatments using Tukey's HSD test ($p < 0.05$). SBE, sunflower bark extract; DAG, days after germination; FW, fresh weight; DW, dry weight; Chl a, chlorophyll a; Chl b, chlorophyll b; MDA, malondialdehyde.

(Figure 6A). Next, the leaves were floated for 2 days on a solution with or without 200 mM NaCl. The SBE pretreated leaves maintained a higher level of chl_{a+b} and carotenoid content under salt stress conditions (Figures 6B,C). Similar to the salt-stressed seedlings, SBE pretreatment dampened the accumulation of MDA production induced by salt (Figure 6D).

Sunflower Bark Extract Mitigates NaCl Toxicity by Suppressing Hydrogen Peroxide Overaccumulation

Salinity-induced osmotic and ionic stress affects cellular redox homeostasis by H₂O₂ overproduction causing oxidative damage to proteins and lipids (Munns and Tester, 2008; Huang et al., 2019). We, therefore, asked if SBE scavenges ROS in salt-stressed plants. The H₂O₂ levels more than doubled in salt stress seedlings at 10 DAG (Figure 7A). The salt-induced increase in H₂O₂ was reduced to about 60% by SBE application (Figure 7A). ROS reduction was already apparent after 3 DAG upon ROS staining with DAB (Supplementary Figure 6 and Figure 7B), which coincides with the earliest time point when SBE started showing a significant improvement in shoot growth on NaCl containing medium (Figure 4C). The relative DAB staining intensity in plants grown in the presence of SBE was lower than in plants without SBE (Figure 7B). The quantification of DAB intensity in the cotyledons, hypocotyl, root, and SAM showed that the dampening effect of SBE occurred in all seedling organs

(Figure 7C). H₂O₂ levels were relatively higher in the root and SAM than in cotyledons and hypocotyl. The SBE mediated reduction of ROS was most pronounced in the SAM in line with the protective effect of SBE on true leaf development under salt stress conditions.

Next, we asked whether SBE neutralizes ROS formation via the overactivation of antioxidant enzymes that are part of the plant defense system (Apel and Hirt, 2004; Bobrovskikh et al., 2020). To this end, the activity of the antioxidant enzymes was measured in control and salt-stressed seedlings grown with or without SBE supplement (Figure 8). In control conditions, no difference in antioxidant enzymes activity was investigated. SBE treatment of salt-stressed plants significantly increased the activity of CAT, APX, and POX (Figures 8B–D), which directly participate in eliminating ROS pathway by catalyzing the conversion from H₂O₂ to H₂O (Dumanović et al., 2021). In contrast, SOD, GR, GST, and MR were not significantly altered by SBE treatment (Figure 8A and Supplementary Figure 7).

DISCUSSION

This study on the analysis of potential biostimulant activity is a major step in valorizing sunflower stalks. Here, we report that SBE, a side stream obtained during fiber isolation by twin-screw extrusion, contains polyphenols and other bioactive molecules that activate ROS scavenging enzymes, thereby suppressing the

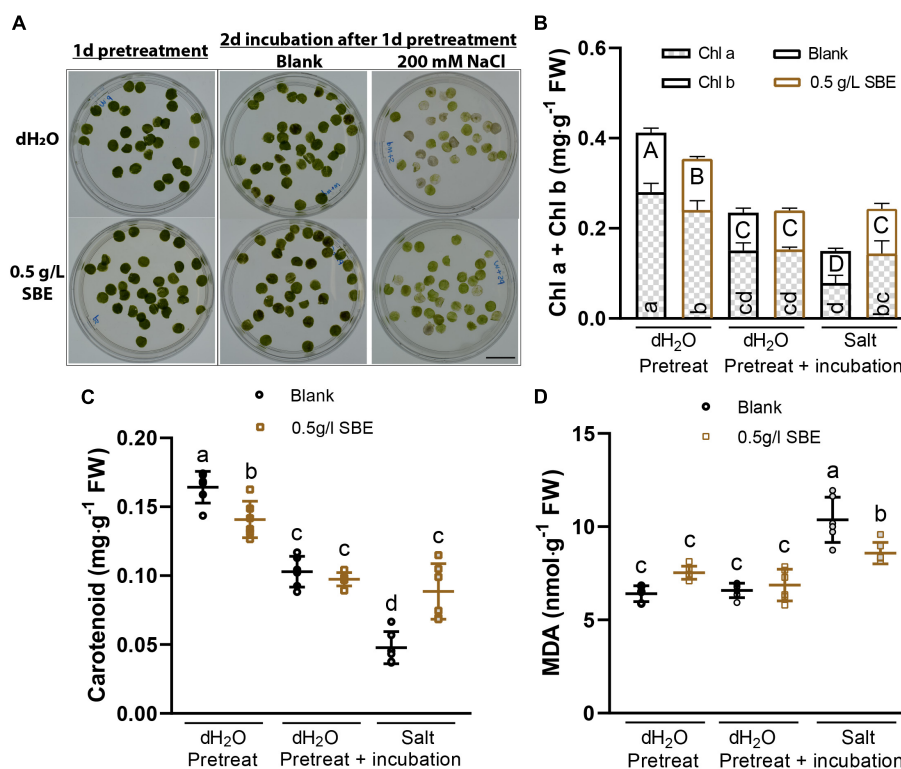

FIGURE 6 | Salt stress alleviation of SBE pretreatment on expanded *Arabidopsis* leaves in the leaf disc assay. **(A)** The representative image of treated leaf discs was taken before sampling. Bar = 2 cm. Photosynthetic pigments contain **(B)** chlorophyll a and b, and **(C)** carotenoid content. **(D)** MDA content. Error bars indicate SDs of the means ($n = 6$). Different letters represent significant differences between treatments using Tukey's HSD test ($p < 0.05$). SBE, sunflower bark extract; DAG, days after germination; FW, fresh weight; Chl a, chlorophyll a; Chl b, chlorophyll b; MDA, malondialdehyde.

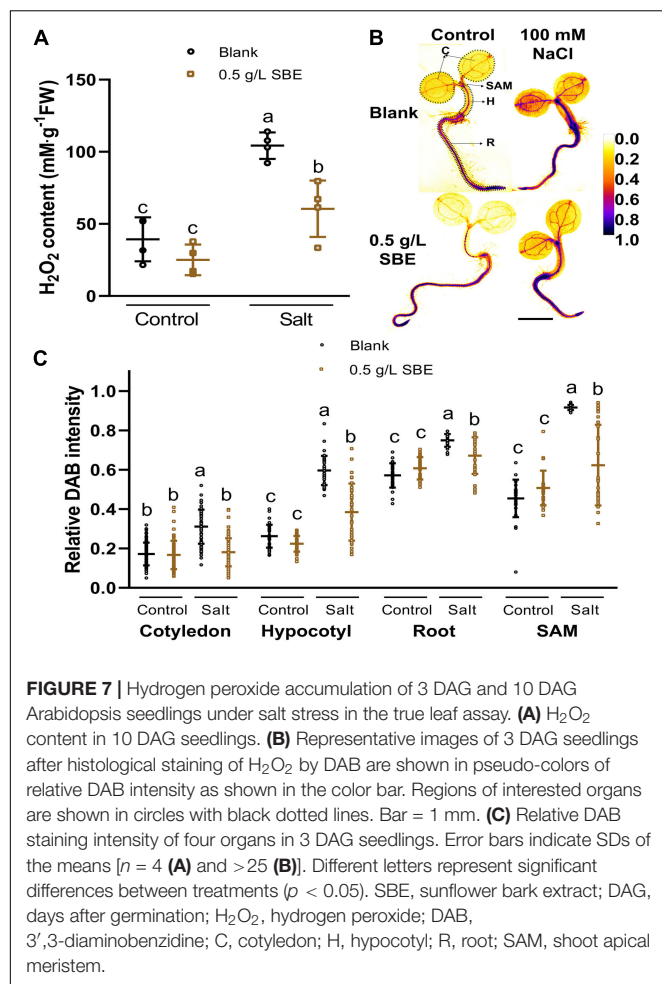

oxidative damage to *Arabidopsis* seedlings grown on the NaCl-containing medium. Together, the results suggest that SBE is a potential source of biostimulant.

The twin-screw extrusion method is an extraction technique for separating insoluble parts (e.g., fibers) from solvent-soluble molecules in a single step. The solvent, thermal and mechanical actions are customized to extract fiber-rich plant biomass from crop waste such as sunflower stems (Evon et al., 2018; Vandenbossche et al., 2019). The extrusion method is an ecofriendly biorefinery process that meets the criteria of “green chemistry” extraction of natural products (Chemat et al., 2012). Yet, the bark extract is not economically valorized from the sunflower fiber part. SBE is an aqueous extract adhering to the guidelines of the European directive for certification of natural substances without pesticide residue and, as such, can be used to produce a novel biostimulant.

The outer bark constitutes about 90% dry weight of the whole stalk, indicating that it is much denser than the pith (Xu et al., 2020). The stems contain a considerable amount of polyphenols (Kamal, 2013). The chemical composition of an aqueous extract from sunflower bark has not yet been reported. An estimation of phenolics content (TPC) in SBE (Table 1) was obtained by applying a modified Folin–Ciocalteu assay to quantify TPC values against CHA (Sánchez-Rangel et al., 2013). However, the TFC values for evaluating “total” flavonoid content

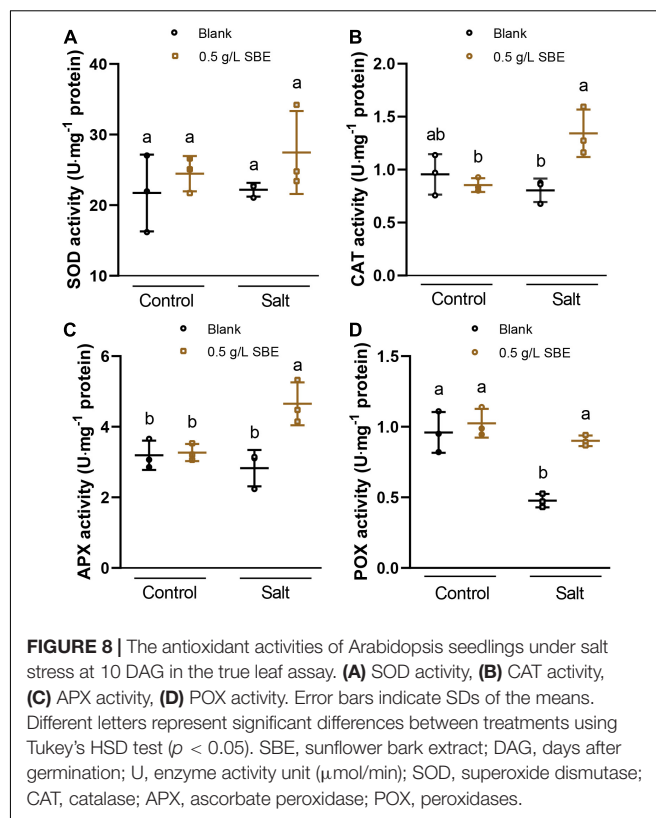

are not adequate based on aluminum complex reaction as the two procedures we performed are specific for different flavonoid structures (Pekal and Pyrzynska, 2014). In this situation, it is not possible to compare the accurate polyphenol content across the studies using different protocols. Therefore, to improve the coverage of present plant metabolites in SBE besides polyphenols, UHPLC-PDA-HRMS was performed for more precise detection and identification (Lai et al., 2018). Thanks to the validated algorithm increasing the accuracy of compound identification (Tsugawa et al., 2016), MS-DIAL combined with MS-FINDER is recommended to match MS^c spectra *in silico* for untargeted metabolomics (Blaženović et al., 2017; Vaniya et al., 2017). Our study thus provides the chemical composition of SBE, to some degree, revealing the plant metabolomics with both colorimetric and UHPLC-PDA-HRMS analysis.

Sunflower bark extract shows conspicuously *in vitro* activity, completely inhibiting primary root growth at doses above 1 g/L (Supplementary Figure 3). This strong growth inhibition contrasts with the growth-promoting effects observed in salt-stressed plants treated with more diluted SBE. Sunflowers produce a diverse set of allelochemicals that either positively or negatively affect the growth of other plant species (Macías et al., 2002). Some of these allelochemicals were already identified in sunflower stalks (Maheswari et al., 2019). Allelopathic activity in sunflower was closely linked with the presence of polyphenols

and terpenes (Rawat et al., 2017). Sunflower aqueous shoot extract partially inhibited rapeseed and *Cephalaria* seedling growth (Hamad, 2017). Natural polyphenols were extensively reported to induce cytotoxicity in plant normal cells as well as cancer cell in dose-dependent manners (Rasouli et al., 2016; Perveen, 2017). These or other allelopathic compounds are likely also present in SBE and could be responsible for the primary root growth inhibition at high doses and may also prime to trigger a plant defense response, a property of many biostimulants (Kerchev et al., 2020).

However, at 0.5 g/L, SBE protected Arabidopsis from oxidative damage induced by a moderate concentration of NaCl in the medium (Figure 4). Also, allelopathic extracts from *Levisticum officinale* Koch were recently identified to have a positive performance on soybean yield (Szparaga et al., 2021). One of the reasons is that some polyphenols have antioxidant activity and play a role in controlling oxidative stress in plants (reviewed in Ferdinando et al., 2012; Šamec et al., 2021). For example, quercetin suppressed the ROS toxicity of paraquat in seedlings of Arabidopsis, tobacco, and duckweed (Kurepa et al., 2016) and heavy-metal stress in Arabidopsis (Zhang et al., 2017). Recent evidence shows that flavonoids are active as cytoprotective antioxidants preventing mitochondrial signaling that regulates

autophagy and apoptosis (Kicinska and Jarmuszkievicz, 2020). Phenolic acids are also stress-relieving molecules due to their high antioxidative properties (Šamec et al., 2021), namely, caffeic and sinapic acids enhance salt tolerance in wheat seedlings when exogenously applied (Kaur et al., 2017). The reduction in ROS levels mediated by SBE is likely due to the antioxidant activity of polyphenols and possibly other molecules within a non-toxic concentration range.

Next to polyphenols, SBE contained digestible carbohydrates and soluble protein. Sugars released from carbohydrates function as energy metabolites, osmoprotectants, and signaling molecules and mitigate stress responses in plants (Rook et al., 2006; Krasensky and Jonak, 2012). Likewise, several amino acids derived from proteins have been proved to be precursors of secondary metabolites and signaling molecules tightly related to plant responses under stress (Batista-Silva et al., 2019). These water-soluble primary compounds may support plant stress adaptation and complement the ROS suppressing activity of the above-mentioned bioactive agents.

The true leaf development assay in Arabidopsis is a sensitive method for evaluating DNA damaging agents (Rosa et al., 2013). High concentrations of NaCl induce ROS formation in germinating eggplant leading to DNA damage (Kiran et al., 2020). In particular stem cells in germinating seeds and in shoot meristems are highly susceptible to DNA damage causing an arrest in leaf development (Fulcher and Sablowski, 2009). We speculate that the accumulation of H_2O_2 in SAM causes oxidative damage, including DNA damage and that this prevents

the development of the first true leaves in our experiments (Figure 7C). Polyphenols suppress ROS overaccumulation by neutralizing free radicals with donated electrons or hydrogen atoms with concomitant formation of stabilized phenolic radicals (Dumanović et al., 2021). In addition, polyphenols activate ROS scavenging enzymes (Kerchev et al., 2020). These enzymes function in plant defense and regulate cell growth and cell death (Mhamdi and Van Breusegem, 2018). Therefore, SBE will likely affect shoot growth under salt stress by activating ROS scavenging enzymes.

In future experiments, fractionation of SBE into less complex mixtures will be necessary to define the extent of synergism between the different bioactive molecules. Plant extract-based biostimulants are typically mixtures of bioactive compounds (García-García et al., 2020), which may explain why certain extracts are active despite the applied low dilutions. Given that the large biomass of sunflower stalks is currently underused, we anticipate that it is a suitable resource for biostimulant development and will contribute to valorization of the stems. Further studies will also focus on the consistency and reproducibility of bioactivity across separate harvested materials.

CONCLUSION

Taken together, we demonstrated that SBE can be refined from sunflower bark using water as an extraction solvent in a twin-screw extruder and that it contains bioactive molecules that act as protectants against salt stress by maintaining cellular redox homeostasis. The results highlight the potential of SBE as a source for biostimulant production that can be used for seed biopriming, soil, and foliar application. Future studies are underway to test the effectiveness of SBE biostimulant under field conditions on various crops. The characterization of the bioactive ingredients is a critical target to unravel the chemical structure and underlying mode of action.

Pseudomonas sp. strain 1008 was isolated from the rhizosphere of field grown wheat plants at the tillering stage in an agricultural plot near Pergamino city, Argentina. Based on its *in vitro* phosphate solubilizing capacity and the production of IAA, strain 1008 was formulated as an inoculant for bacterization of wheat seeds and subjected to multiple field assays within the period 2010–2017. *Pseudomonas* sp. strain 1008 showed a robust positive impact on the grain yield (+8% on average) across a number of campaigns, soil properties, seed genotypes, and with no significant influence of the simultaneous seed treatment with a fungicide, strongly supporting the use of this biostimulant bacterium as an agricultural input for promoting the yield of wheat. Full genome sequencing revealed that strain 1008 has the capacity to access a number of sources of inorganic and organic phosphorus, to compete for iron scavenging, to produce auxin, 2,3-butanediol and acetoin, and to metabolize GABA. Additionally, the genome of strain 1008 harbors several loci related to rhizosphere competitiveness, but it is devoid of biosynthetic gene clusters for production of typical secondary metabolites of biocontrol representatives of the *Pseudomonas* genus. Finally, the phylogenomic, phenotypic, and chemotaxonomic comparative analysis of strain 1008 with related taxa strongly suggests that this wheat rhizospheric biostimulant isolate is a representative of a novel species within the genus *Pseudomonas*, for which the name *Pseudomonas pergaminiensis* sp. nov. (type strain 1008^T = DSM 113453^T = ATCC TSD-287^T) is proposed.

PGPR, *Pseudomonas pergaminiensis* sp. nov., wheat, biostimulant, agronomic efficiency, genome mining, phylogenomics

Introduction

The rhizosphere of terrestrial plants harbors complex assemblages of bacteria that are fundamental for the nutrition, health, and tolerance to biotic and abiotic stresses of the plant host (Mendes et al., 2013), being this interkingdom association a consequence of a long co-evolutionary history that shaped the current plant holobionts (Rosenberg and Zilber-Rosenberg, 2016; Lyu et al., 2021). Those plant-beneficial bacteria are collectively referred to as plant growth-promoting rhizobacteria (PGPR), a concept introduced in the late 70's (Kloepper et al., 1980). Although the taxonomic composition of the rhizosphere microbiome is certainly influenced by the plant genotype, soil features, agronomical practices, and environmental factors (Philippot et al., 2013), there are ubiquitous bacterial groups that are hallmark components of the rhizosphere niche, such as members of the *Streptomyces*, *Flavobacterium*, *Bacillus*, *Burkholderia*, and *Pseudomonas* genera (Mendes et al., 2011; Rey and Dumas, 2017; Imade and Babalola, 2021; Kavamura et al., 2021).

In particular, *Pseudomonas* spp. strains display a strong preference for the rhizosphere habitat in comparison to bulk soil, a feature that has been revealed by both culture-dependent and culture-independent approaches (Molina et al., 2000; Agaras et al., 2012; Tao et al., 2020; Chiniqy et al., 2021). The relative ease to isolate and culture *Pseudomonas* strains in the lab, together with the identification and characterization of a number of genetic and biochemical traits that may significantly contribute to the growth and health of the host plant, has fostered the exploitation of a number of *Pseudomonas* isolates for the development of agricultural inputs to increase the yield of different crops. The latter represents a promising conceptual solution to the worldwide demand of eco-friendly alternatives to the questioned utilization of chemical inputs in agriculture (Backer et al., 2018; Höfte, 2021; Müller and Behrendt, 2021).

A group of isolates of the genus *Pseudomonas* that have become plant biocontrol models, like *Pseudomonas protegens* CHA0, *Pseudomonas synxantha* 2–79, *Pseudomonas chlororaphis* PA23, or *Pseudomonas simiae* WCS417, have the ability to protect the roots of colonized plants from diverse phytopathogens, either through the production of antimicrobial compounds and/or by inducing systemic resistance in the plant (Ramette et al., 2011; Duke et al., 2017; Zhang et al., 2020; Höfte, 2021; Pieterse et al., 2021). On the other hand, rhizospheric isolates like *P. fluorescens* SS101 or *P. fluorescens* SBW25, do not show biocontrol capacity at all, but display plant growth-promoting traits like strong root competitiveness, stimulation of root growth and/or modulation of hormone homeostasis (Park et al., 2015; Shinde et al., 2019), and fall within the definition of plant biostimulants (Du Jardin, 2015). Usually, the *in vitro* characterization of such indirect (biocontrol) or direct (biostimulant) traits has been further mined at the genetic and/or genomic level, to unravel the underlying molecular

determinants (Paterson et al., 2017; Agaras et al., 2018; Biessy et al., 2019; Pieterse et al., 2021), which may ultimately lead to biotechnological improvements of the identified plant-beneficial traits (Haskett et al., 2021).

Nevertheless, only a few thoroughly characterized *Pseudomonas* isolates with plant-beneficial traits have been registered worldwide as active ingredients for the production of commercial agricultural inputs (Basu et al., 2021; Höfte, 2021), a fact that most likely reflects the hurdles existing in the transition from the lab to the field (Backer et al., 2018). Here, we report the isolation of the *Pseudomonas* sp. isolate 1008 from the rhizosphere of field-grown wheat, which proved to be a highly efficient biostimulant of wheat crops in field assays under agronomical conditions. Further, we have determined its full genome sequence, explored its plant-beneficial genetic traits, and carried out phylogenomic, phenotypic and chemotaxonomic comparative analyses with related taxa, which strongly support that strain 1008 is a plant-biostimulant representative of a novel *Pseudomonas* species.

Materials and methods

Strain isolation and characterization

Root systems of wheat plants (stage Z.20; tillering) with their surrounding soil were sampled in a productive plot in the vicinity of Pergamino city, Province of Buenos Aires, Argentina (33° 56' 41" S, 60° 34' 04" W) (Figure 1a). Care was taken to avoid damaging the root systems. The plants were placed in clean plastic bags, leaving them open to avoid anoxic conditions, and were transported to the laboratory for processing without delay (Figure 1b). The aerial parts were cut, and the root systems were gently brushed to remove loosely adhered soil (Figure 1c). Each root system with its tightly associated rhizospheric soil was placed in an Erlenmeyer flask containing sterile demineralized water (pH 6.8–7) and agitated for 30 min at 200 rpm. Thereafter, aliquots of the suspensions were serially diluted with sterilized water, plated on *Pseudomonas* agar F (Merck Millipore) and incubated at 28°C for 48 h. The colonies that showed fluorescence upon exposure of plates to UV light (Figure 1d) were re-streaked for ensuring purity and preserved for subsequent characterization and preliminary identification. Colonies of interest were first screened on the basis of the conventional physiological tests according to Bergey's Manual of Determinative Bacteriology (Palleroni, 2015) to select candidate isolates of the species *Pseudomonas fluorescens* or closely related species (i.e., Gram-negative rods that grow in cetrimide agar: positive; oxidase test: positive; glucose fermentation: negative; motility: positive; fluorescent pigments in *Pseudomonas* F medium: positive; fluorescent pigments in *Pseudomonas* P medium: negative; growth at 41°C: negative; gelatin hydrolysis: positive). Phosphate solubilization, a feature

sought for the selection of candidates for the formulation of biofertilizer inoculants, was applied as the second screening criterion in agarized Pikovskaya's medium (Pikovskaya, 1948). The phosphate solubilizing isolates preliminarily identified as *P. fluorescens* were further tested with the bioMérieux API 20 NE Gallery System. The isolate 1008, which is the subject of this study and that was originally designated as a *P. fluorescens* representative on the basis of the aforementioned biochemical and physiological tests, was selected for further characterization and development of a commercial formulation for agronomical purposes.

Phenotypic assays

Strain 1008 was routinely grown on *Pseudomonas* agar F (Merck Millipore) or nutrient agar (NA; 4% w/v blood agar base, 0.5% w/v yeast extract; Biokar). Liquid cultures were grown in tryptone soybean broth (TSB; Laboratorios Britania) or nutrient yeast broth (NYB; 2.5% w/v nutrient broth, 0.5% w/v yeast extract; Biokar), with shaking (200 rpm). In all cases, incubation temperature was 28°C. The strain was stored at −80°C as a suspension of an overnight NYB culture containing 20% w/v of glycerol. Solubilization of mineral phosphate was qualitatively assessed in agarized medium containing inorganic phosphate (Pikovskaya, 1948). The presence of a clear halo around the bacterial colonies was determined after 5 days of growth. Phosphate solubilization was quantified in liquid Pikovskaya medium with 5 g/L of $\text{Ca}_3(\text{PO}_4)_2$ (Pikovskaya, 1948) modified by buffering with 100 mM Tris and adjusting the pH to 8.0 with HCl. Samples from triplicate cultures were withdrawn to assess soluble phosphate concentration. In total, 1 mL of the cell suspension was centrifuged at $12,000 \times g$ for 20 min at 4°C, and the P content in the supernatant was determined by the molybdenum blue method (Murphy and Riley, 1962). Zinc solubilization was qualitatively assessed in agarized Pikovskaya's base medium containing 1% w/v ZnO (Tagele et al., 2019). The presence of a clear halo around the bacterial colonies was determined after 48 h of growth. Extracellular protease and phospholipase C (lecithinase) activity were qualitatively assessed in skimmed milk agar or in egg yolk agar, respectively, as reported previously (Sacherer et al., 1994). Intracellular and extracellular phosphatase activities were determined enzymatically by following the hydrolysis of *p*-nitrophenyl phosphate in reactions buffered at pH 5.5 or pH 9.0 (for acid and alkaline phosphatase, respectively), as reported (Tabatabai and Bremner, 1969). Cellular siderophore production was qualitatively studied in CAS agar plates (Schwyn and Neilands, 1987). Hydrogen cyanide production was detected using the picrate filter paper method (Egan et al., 1998). Indoleacetic acid (IAA) production was analyzed in the supernatant of cultures grown for 24 h in tryptophan-amended medium (20 mg/100 ml) by colorimetry with the

Salkowski reagent, as described elsewhere (Bric et al., 1991). The capacity of strain 1008 to inhibit the growth of phytopathogenic fungi was assessed with the dual culture assay on PDA plates (Muller et al., 2018). Analysis of cellular fatty acids and metabolic profiling in Biolog GenIII plates were carried out by DSMZ Services, Leibniz-Institut DSMZ - Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH, Brunswick, Germany.

Transmission electron microscopy

Cells of strain 1008 from early stationary-phase cultures in NYB were negatively stained with a solution of 2% w/v uranyl acetate for 5 min and directly observed at a magnification of 15,000–40,000 \times with a JEOL/JEM 1200 EX II transmission electron microscope at the Microscopy Service of the School of Veterinary Sciences (National University of La Plata, La Plata, Argentina). The dimensions of cells were analyzed in digitalized images with ImageJ¹.

Field assays

Field assays were carried out in three different locations in the Argentine Pampas, close to the cities of Pergamino, Junín, and Ferré (Figure 1a). The properties of the soil in each location are: typic Argiudoll – silt loam, for Pergamino; typic Hapludoll – loam/silt loam, for Junín and Ferré (Agaras et al., 2020). In the period 2010–2016, the annual average temperature ranged between 15.7 and 19°C, with an average monthly temperature range of 10 to 23 °C; the annual average rainfall ranged between 656 and 1,681 mm, with an average monthly rainfall range of 26 to 182 mm (Supplementary Table 1). The chemical analyses of soil samples (contents of organic carbon, nitrate, organic nitrogen, total nitrogen, and extractable phosphorus, and pH) were determined by Laboratorio SueloFértil (Pergamino, Buenos Aires²) using standardized agronomical protocols.

For evaluating the impact of seed inoculation with a commercial formulation based on strain 1008, seeds of different cultivars of wheat (*Triticum aestivum*) (Supplementary Table 2) were treated with the formulated inoculant Rizofos® following the instructions of the manufacturer (Rizobacter Argentina S.A.). Briefly, seeds were treated at a ratio of 0.8 ml of inoculant plus 0.2 ml of Premax R® bacterial protectant per 100 g of seeds in a rotary mixer at room temperature during 2 min. Seeds were immediately sown or stored at temperatures below 25°C in the dark for a period of up to 15 days before sowing. Non-treated seeds served as control. When indicated (Supplementary Table 2),

Isolation and microbiological characterization of *Pseudomonas* sp. strain 1008. (a) Geographic location of the wheat field plot sampled for isolation of *Pseudomonas* strain 1008 (1, Pergamino), and of the experimental field assays for evaluation of the performance of the inoculant based on strain 1008 (1, Pergamino; 2, Ferré; 3, Junín). (b) Wheat plants sampled at tillering stage. (c) Loosely adhered soil was gently brushed away from the root system. (d) Fluorescent colonies developed on *Pseudomonas* agar F upon plating of dilutions of rhizospheric suspensions. (e) Gram staining of cells from a pure culture of strain 1008. (f) Streaks of strain 1008 on Pikovskaya agar with calcium triphosphate as P source. (g) Close up of a macrocolony of strain 1008 and the surrounding calcium triphosphate solubilization halo on Pikovskaya agar. (h) Transmission electron micrograph showing cells of strain 1008 grown for 24 h in nutrient yeast broth at 28°C and 200 rpm. Note the flagella with a typical polar location. (i) Colony phase variants of strain 1008 on nutrient agar plates. The larger colonies correspond to phase variant 1 (j,k) whereas the smaller colonies correspond to phase variant 2 (l,m). The colony morphotype of each variant is clearly distinct under magnifying lens (k,m).

seeds had been previously treated with the commercial fungicide Compinche® (Rizobacter Argentina S.A.), containing difenoconazole and metalaxyl-M as active principles. Genotypes, seed treatments and fertilizer applications were those recommended by regional agronomical advisers (Supplementary Table 2).

Each treatment had three replicates per location in a completely randomized block design, with a plot size of 9 m²

(6 m × 1.5 m, with 7 furrows). Sowing dates, plant densities and fungicide seed treatments were adjusted to the selected genotypes and the regional recommendations [Supplementary Table 2; (Agaras et al., 2020)]. At harvest, the number of plants and of spikes per m², and grain yield (kg/ha) were recorded. When indicated (Supplementary Table 2), the number of tillers per m², the tiller and spike dry weight, and the NDVI (Normalized Difference Vegetation Index, shown as the average

value per m², during tillering), were determined during early crop stages (Benedetti and Rossini, 1993).

Statistical analysis of field assays

The data set comprises twenty-five field assays under no-till management across seven campaigns, heterogeneously distributed in three geographical locations. In addition to the main effect of seed bacterization with the Rizofos® formulation containing live cells of strain 1008, the experimental plots included: the effect of seed pre-treatment with (or without) the fungicide Compinche®; five wheat genotypes (Baguette 601, Klein Tigre, Klein Rayo, Klein Yará, and Buck SY 300); and two different forecrops (soybean or cereal/soybean). Thus, we considered that there were five additional effects that could be influencing the impact of wheat seed bacterization. First, we applied ANOVA to evaluate if those effects interacted with seed bacterization. Upon confirming that the interactions between bacterization and every additional effect were not significant, we applied Generalized Linear Mixed Models (GLMM; Di Rienzo et al., 2011) to evaluate the global effect of seed bacterization with strain 1008 on crop yield using Infostat v. 2020 software (Di Rienzo et al., 2020). GLMM were fitted to analyze the data (with $n = 150$ for grain yield, plant number and spike number per m²; $n = 114$ for tiller number; $n = 34$ for tiller dry weight; $n = 102$ for tiller fresh weight; $n = 48$ for spike fresh weight), considering locations, seasons, crop genotypes, forecrops and seed pre-treatment with fungicide as random effects, and amending the variance structure to achieve homoscedasticity when corresponded (Casanoves et al., 2007; Harrison et al., 2018). The fitted models were evaluated with Akaike's (AIC) and Schwarz's (BIC) Information Criteria, looking for the lowest values for selecting the best model. Likelihood ratio between models was applied when AIC and BIC criteria were not sufficient to select the best model (Di Rienzo et al., 2011). Finally, ANOVA tests were performed on each of the 25 field trials to specifically evaluate the impact of seed bacterization (Di Rienzo et al., 2020). If appropriate, Fisher's LSD multiple comparison method was applied to evaluate significant differences among average values. In all cases, statistics were done at $p < 0.05$. Multivariate analyses were conducted using Principal Component Analysis (PCA) of grain yield, plant number and tiller number per m² ($n = 150$, Infostat v. 2020).

DNA isolation and genome sequencing

Genomic DNA of strain 1008 was extracted with the Zymo ZR Soil Microbe DNA MiniPrep kit (Zymo Research), according to the manufacturer's guidelines. gDNA concentration and quality were assessed by UV spectrophotometry with Nanodrop ND-1000. A sample of 15 µg of gDNA in 10 mM Tris.HCl (pH

8.0) was submitted to Macrogen Inc. (Korea) for whole genome *de novo* sequencing with the PacBio RS System. Upon quality control analysis (fluorescence-based quantification, agarose gel and microfluidic electrophoresis), the gDNA was processed according to a guide for preparing SMRTbell template for sequencing on the PacBio RS System. The templates were sequenced using SMRT® sequencing. Sequencing resulted in a total of 134,530 subreads, with an average length of 9,422 bp, totaling around 1,27 Gb, which represents 192× coverage of the genome.

Genome assembly and annotation

The raw data generated from PacBio RS II sequencing was utilized for whole-genome sequence assembly. The assembly and annotation approach was performed as described recently with smaller modifications (Wibberg et al., 2020, 2021). In brief, the assembly was performed using canu v1.6 (Koren et al., 2017) resulting in a single, circular contig. This contig was then polished based on PacBio reads using quiver 2.1 (Chin et al., 2013) and adjusted to *dnaA* as the first gene. The finished genome sequence was annotated with Prokka (Seemann, 2014) and imported into the annotation platform GenDB (Meyer et al., 2003). The annotated circular and gapless chromosome of 6,609,162 bp and a GC content of 60.7% was deposited into the NCBI database under the accession number CP078013.

Phylogenomic analysis

The phylogenetic position of strain 1008 within the genus *Pseudomonas* was inferred by a set of complementary studies based on comparative sequence analysis of single or multiple genes, and of genome properties: comparative analysis of whole genome average nucleotide identity (ANI) and tetranucleotide usage pattern (Tetra) in the JSpeciesWS server (Richter et al., 2015); average amino acid identity (AAI) at the EDGAR server (Dieckmann et al., 2021); 16S rRNA based gene tree, genome-based phylogenetic tree, and digital DDH at the Type (Strain) Genome Server (TYGS) (Meier-Kolthoff and Göker, 2019).

Genome mining

The presence of sequences related to integrated plasmids and prophages was studied with NCBI VecScreen³, PlasmidFinder 2.1 and PHAST tools (Zhou et al., 2011; Carattoli et al., 2014). MGEfinder and ICEfinder were used to identify mobile genetic elements (Liu et al., 2018; Durrant et al., 2020). oriTfinder was used to identify DNA transfer-related

³ <https://www.ncbi.nlm.nih.gov/tools/vecscreen/>

modules (Li et al., 2018). Genomic islands were searched with IslandViewer 4 (Bertelli et al., 2017). Acquired genes and/or chromosomal mutations mediating antimicrobial resistance were inspected using the Resistance Gene Identifier tool⁴ at the Comprehensive Antibiotic Resistance Database (Alcock et al., 2020). The presence of CRISPR/Cas elements was studied with CRISPRCasFinder and CRISPRMiner2 (Couvin et al., 2018; Zhang et al., 2018). antiSMASH v6.0 was used for predicting secondary metabolite biosynthetic gene clusters (Blin et al., 2021). Bacteriocin gene clusters were mined with BaGel4 (Van Heel et al., 2018). A list of genes related to direct and indirect plant growth promotion mechanisms, as well as for rhizosphere competence and interactions with plant cells and other microbial species, was compiled from recent works (Berendsen et al., 2015; Biessy et al., 2019; Anderson and Kim, 2020; De Vrieze et al., 2020; Keswani et al., 2020; Singh et al., 2021) and surveyed in the genome of strain 1008 by using BlastN and BlastP webservices at the NCBI webpage⁵. Type IV secretion system components were identified with OriTfinder (Li et al., 2018). Type VI secretion system components were identified with SecRet6 (Li et al., 2015).

Availability of biological material

The type strain, originally designated as 1008, was deposited in the Leibniz Institute DSMZ - German Collection of Microorganisms and Cell Cultures GmbH (DSMZ, Braunschweig, Germany) and in the American Type Culture Collection (ATCC, Manassas, VA, United States), under the accession numbers DSM 113453 and ATCC TSD-287, respectively.

Results

Isolation and characterization of a phosphate-solubilizing *Pseudomonas* isolate with plant growth-promoting features from field-grown wheat roots

Field-grown wheat plants at the tillering stage were sampled in an agricultural plot nearby the city of Pergamino (Buenos Aires province, Argentina; Figure 1a) to generate a collection of rhizobacterial isolates with potential to be formulated as an agricultural input. Rhizospheric suspensions were plated on *Pseudomonas* agar F, and fluorescent colonies with different morphological features were subjected to an initial set of phenotypical tests to retain those *P. fluorescens* candidates on the

basis of Bergey's determinative manual. Upon further screening for phosphate-solubilizing potential, one isolate designated as 1008 was retained for further characterization of plant-growth promoting features (Figure 1 and Table 1). The results of the bioMérieux API 20 NE Gallery System for strain 1008 were consistent with an isolate representative of the *P. fluorescens* lineage (Supplementary Table 3), which was also supported by the sequence of its 16S rDNA gene (Supplementary Figure 1).

Strain 1008 was selected by its phosphate-solubilizing activity in a first screening on agar plates (Figures 1f,g and Table 1). In liquid Pikovskaya medium after 24 h of growth at 28°C and 200 rpm, strain 1008 was able to solubilize an average of 22% of the insoluble calcium triphosphate (final soluble P content of 45 mg per 100 ml). It was also able to mineralize P from two types of phosphate rocks (of Chinese and Chilean origin) achieving a final soluble content of 46 mg P per 100 ml. In addition to insoluble sources of P, strain 1008 solubilized zinc in a modified Pikovskaya medium containing ZnO (Table 1 and Supplementary Figure 2A).

The production of indole acetic acid (IAA)-like compounds was first detected qualitatively as a positive reaction to the Salkowski reagent in cells grown in agarized medium supplemented with 5 mM tryptophan (Table 1). The production of IAA was confirmed by HPLC-MS/MS analysis of liquid cultures. Strain 1008 produced IAA in a tryptophan-dependent manner reaching up to 46,7 mg/100 ml after 48 h of growth (Supplementary Figure 2E). The production of extracellular proteolytic and lecithinase activities were revealed in qualitative plate assays (Table 1 and Supplementary Figures 2B,C). Spectrophotometric enzymatic assays revealed the production of both acid and alkaline phosphatases, with a major fraction of the activity detected in acid conditions (586 µg *p*-nitrophenol/mg bacteria.h) of which 83% was located intracellularly. By contrast, 82% of the total alkaline phosphatase activity (10 µg *p*-nitrophenol/mg bacteria.h) was detected in the culture supernatant.

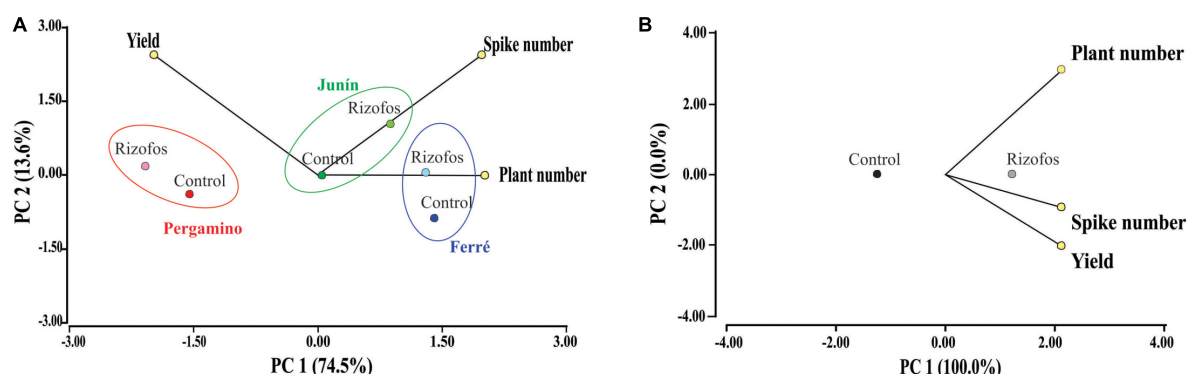

FIGURE 2

Agronomic efficiency of *Pseudomonas* sp. strain 1008. Principal component analyses of wheat parameters measured for 25 field assays (for details, see [Supplementary Table 2](#)). Data were partitioned by seed bacterization treatment with *Pseudomonas* sp. strain 1008, and by location (A); or, only by seed bacterization treatment (B). (A) In each location, wheat grain yield and the number of spikes per m² mainly explain the seed bacterization effect. Together, PC1 and PC2 explain > 85% of the total variance. PC1 explains the geographical effect, whereas PC2 explains the bacterization effect for each geographical site. (B) Seed bacterization clearly influenced the three measured variables, explaining the whole variance. In both plots, “Rizofos” refers to the seed bacterization treatment.

Strain 1008 produced soluble and diffusible iron-chelating compounds detected in CAS plates ([Table 1](#) and [Supplementary Figure 2D](#)) and it was not able to grow on ACC as the sole C source in defined medium, thus disclosing the lack of ACC deaminase activity under the tested conditions ([Table 1](#)). Finally, strain 1008 did not produce hydrogen cyanide and did not inhibit the growth of a variety of phytopathogenic fungi or an oomycete in dual culture plates ([Table 1](#) and [Supplementary Figure 2F](#)).

Pure cultures of strain 1008 in NYB medium revealed polarly flagellated cells typical for the *Pseudomonas* genus, with average dimensions of 1.9 ± 0.4 μm long and 0.9 ± 0.1 μm wide ([Figure 1h](#)). Cells showed on average 1 or 2 polar flagella of up to 10 μm long ([Figure 1h](#)). Interestingly, strain 1008 showed evidence of colony phase variation in solid medium ([Figures 1i–m](#)). The identity of both phase variants was confirmed by 16S rDNA sequencing ([Supplementary Figure 3](#)). Whereas the colony morphotypes were clearly distinct ([Figures 1i–m](#)), both colony phase variants were undistinguishable at the cellular level ([Supplementary Figure 3](#)).

To summarize, strain 1008 was isolated from the rhizosphere of field grown wheat plants at the tillering stage and preliminary typed as a member of the *P. fluorescens* subgroup on the basis of phenotypical tests and its 16S rDNA sequence ([Supplementary Figure 1](#); see below). *In vitro* assessment of plant growth-promoting traits revealed that strain 1008 had features that may directly impact on plant growth (such as an improvement of P availability to plant roots and production of IAA). For this reason, strain 1008 was formulated as an inoculant for wheat seed treatment and subjected to multiple field assays to evaluate its performance as a plant biostimulant.

Agronomic efficiency of *Pseudomonas* sp. strain 1008

The impact of treating wheat seeds with Rizofos®, a commercial formulation based on *Pseudomonas* strain 1008, was evaluated in a series of 25 field assays carried out in the period 2010–2017 ([Supplementary Table 2](#)). This dataset involved seven campaigns in two or three locations ([Figure 1a](#)), a total of five wheat genotypes, two different forecrops, two treatments with antifungals (Compinche®, or none), and two treatments with strain 1008 (Rizofos®, or none), under no-till management. The variables that were measured in all 25 assays were grain yield, number of plants and number of spikes per m² ([Supplementary Table 2](#)). These were used to carry out multivariate analyses.

By considering all classifiers (location, campaign, genotype, seed treatment with antifungals, forecrop, and treatment with Rizofos®), we did not find a general impact of any of the factors ([Supplementary Data 1](#)). If location and treatment with Rizofos® were only considered for data classification, the effect of inoculation was clear-cut, specifically based on the contribution of grain yield and spike number ([Figure 2A](#)). The impact of location was more evident in the plant number per m² ([Figure 2A](#)). If we only consider the impact of seed inoculation with Rizofos® in a principal component analysis, the PC1 explained 100% of the variability, with those plots in which seeds were treated with Rizofos® showing the highest values for the three variables (number of plants and of spikes per m², and grain yield) ([Figure 2B](#)). This global analysis of the field assay dataset thus indicated that all factors other than seed treatment with Rizofos® did not strongly influence the data behavior. Thus, we next proceeded to apply a generalized linear mixed model, in which all factors (except for seed treatment with

TABLE 2 Agronomic efficiency of *Pseudomonas* sp. strain 1008.

Variable	n	Control	+Rizofos®	SE	P-value

Output of GLMM applied to analyze the impact of wheat seed bacterization with *Pseudomonas* sp. strain 1008 (Rizofos®) in field assays. Adjusted average values for non-bacterized (Control) and bacterized (+Rizofos®) treatments and associated standard error (SE) are shown. Fisher's LSD test ($\alpha = 0.05$) was applied for multiple comparisons, *p*-value correction was not applied. See [Supplementary Data 1](#) for more details of the GLMM analysis. *The model could not be built. Different superscript lowercase letters (a, b) denote statistical meaningful differences between treatment average values. n.s., there was not significant statistical difference among control and treatment with Rizofos.

Rizofos®) were considered as random effects. This allowed us to evaluate the impact that treatment of seeds with the inoculant based on strain 1008 had on the different variables recorded in the field trials (Table 2 and [Supplementary Data 1](#)).

Overall, the variables that responded better and with statistical support to the seed treatment with Rizofos® were grain yield (+8%), number of spikes (+5%), and tiller fresh weight (+8%) (Table 2). It is worth mentioning that we did not detect an interaction between the application of fungicide (Compinche®) and seed treatment with Rizofos® for any of the variables recorded in the field trials ([Supplementary Data 1](#)). In other words, the positive effects of seed inoculation with Rizofos® were not influenced by the application of the fungicide Compinche. With regards to the location of the field trials, the highest yields were registered nearby Pergamino, although there was no interaction between the location and seed inoculation with Rizofos® ([Supplementary Data 1](#)).

When the effect of Rizofos® was analyzed for each of the individual field assays by means of a simple ANOVA, we found that in 18 out of 26 cases (70%), the bacterization of seeds significantly increased the yield of wheat with $p < 0.05$ ([Supplementary Table 4](#)). If the statistical significance is relaxed at $p < 0.1$, the application of Rizofos® showed a positive yield response in 100% of the 26 field trials ([Supplementary Table 4](#)).

In summary, the application to wheat seeds of an inoculant formulated with live *Pseudomonas* sp. strain 1008 showed a robust positive impact on the grain yield in the field across a number of campaigns, soil properties, seed genotypes, and with no significant impact of the simultaneous treatment of the seeds with a fungicide.

Genomic properties of *Pseudomonas* sp. strain 1008

Prompted by the possibility to uncover the genetic basis for the biostimulant behavior of strain 1008 on the one hand, and

to permit a more confident taxonomic positioning of the strain, we determined its genome sequence. The 6.6 Mb genome of this plasmid-free strain is composed by a circular chromosome with a GC content of 60.72% and is predicted to contain 6,000 protein-coding genes, five ribosomal operons and 67 tRNA genes (Table 3 and Figure 3). The size and informational content of strain 1008' genome is slightly above the average for the genus (6.3 Mb and 5,775 CDS⁶, as of July 2021).

One integrative and conjugative element (ICE) of 115 kb is present in the chromosomal region 3,036,538–3,151,403 (Figure 3 and [Supplementary Figure 4](#)). It has a GC content

6 www.pseudomonas.com

TABLE 3 Description of the sequenced, assembled, and annotated whole genome of *Pseudomonas* sp. strain 1008.

Sequencing technology	PacBio RS chemistry sequencing
Polymerase subread bases	1,267,610,607 bp
Total subreads	134,530
Average subread length	9,422 bp
Average reference coverage	192×
Bio-project number	PRJNA741525
NCBI Accession number	CP078013
Genome size	6,609,162 bp
G + C content	60.72%
Chromosome	1
CDS	6,000
Coding density	89%
rRNA operons	5
tRNAs	67
Max. CDS length	14,115 bp
Mean CDS length	980 bp
Genes with COG identified	3,951
Hypothetical proteins (COGs R or S)	34%

of 56.12% (−4.6% with respect to the chromosome average; [Table 3](#) and [Supplementary Figure 4](#)) and is flanked by perfect direct repeats of 16 bp at positions 3,036,538 – 3,036,553 (*attL*) and 3,151,388 – 3,151,403 (*attR*). This ICE encodes 91 proteins comprising a likely functional T4SS apparatus with its own relaxase and T4-coupling protein ([Supplementary Figure 4](#)). No integrated plasmids were detected, and no *oriT* or relaxase sequences were found outside the ICE region. A search at the Comprehensive Antibiotic Resistance Database using the Resistance Gene Identifier tool revealed four ORFs related to efflux pumps of the RND and MFS families ([Supplementary Table 5](#)), typical of pseudomonads ([Pasqua et al., 2019](#)). One intact 38 kb-prophage of the *Pseudomonas* phiCTX family ([Hayashi et al., 1990](#)) flanked by *attL-attR* sites was identified in between positions 1,778,760 – 1,816,567 ([Figure 3](#)). The prophage has a GC content of 57.4% and encodes 41 ORFs ([Supplementary Figure 5A](#)). Importantly, the *ctx* gene encoding a eukaryotic cell pore-forming toxin, originally described for the phiCTX phage of *P. aeruginosa* hosts ([Hayashi et al., 1990](#)), is not present in the prophage region of strain 1008 ([Supplementary Figure 5A](#)). A second but incomplete prophage region is present in positions 3,466,884 – 3,483,655 (16.7 kb; [Supplementary Figure 5B](#)), and it most likely represents a phage remnant. Importantly, according to the PathogenFinder tool of the Center for Genomic Epidemiology ([Cosentino et al., 2013](#)), the genome of *Pseudomonas* sp. strain 1008 corresponds to a microorganism not pathogenic for humans ([Supplementary Figure 6](#)). In support of the latter conclusion, strain 1008 did not show evidence of toxicity toward the nematode *Caenorhabditis elegans* and the springtail *Folsomia candida*, when applied into soil following standardized protocols ([Supplementary Data 2, 3](#)). Strain 1008 was neither pathogenic in a murine model following intranasal and oral inoculation of 1×10^8 cells ([Supplementary Data 4](#)).

The chromosome of strain 1008 contains minimal orphan CRISPR arrays, three of which seem to be derived from foreign genetic material and two appear to be a self-targeting spacer originated from the own chromosome ([Supplementary Table 6](#)). However, no CRISPR-associated (Cas) proteins were detected, so disregarding the functionality of these CRISPR loci.

Finally, a number of transposable elements were identified ([Figure 3](#) and [Supplementary Table 7](#)), including single copies of IS66-, IS21-, and IS1182-like elements within the ICE, and one composite transposon bracketed by two IS3 elements located just downstream the ICE. In addition, three copies of IS3 were detected in the rest of the chromosome ([Figure 3](#) and [Supplementary Table 7](#)).

The bacterial genome available in public databases with the highest similarity at the DNA sequence level to that of *Pseudomonas* sp. strain 1008 is by large that of *Pseudomonas azotoformans* F77 (GenBank accession CP019856), with an ANIm = 99.08% along a 94.4% of chromosomes alignment.

We will deepen on the taxonomical implications of this finding in the next section. As expected, there is a substantial degree of synteny along both chromosomes, except for the fact that strain F77 lacks a large region of about 200 kb in the middle of the replicon, mapping to positions 3,100,000 – 3,300,000 in the chromosome of strain 1008 ([Figure 3](#) and [Supplementary Figure 7](#)). This gap in the F77 genome may be partially explained by the insertion of the mobile genetic elements detected in the chromosome of strain 1008 (specifically, the ICE and the composite transposon; [Figure 3](#) and [Supplementary Figure 7](#)).

Genome mining of plant growth-promoting, rhizosphere colonization and competitiveness traits of *Pseudomonas* sp. strain 1008

The complete genome of *Pseudomonas* sp. strain 1008 was annotated with state-of-the-art tools and mined to search for genetic determinants of direct and indirect plant growth-promotion, rhizosphere colonization, and competitiveness (see section “Materials and Methods”). An exhaustive list of the identified genes and operons of interest for this work is presented in [Supplementary Table 8](#), and the physical location of a number of relevant genes/operons is shown in [Figure 3](#).

Pseudomonas sp. strain 1008 does not have the genetic capacity to carry out biological nitrogen fixation ([Supplementary Table 8](#)), a feature that, within the genus, is only restricted to the species *Pseudomonas stutzeri* ([Silby et al., 2011](#)) and to a few number of uncharacterized isolates ([Li et al., 2017](#)). Neither it has the genetic determinants for a complete denitrification pathway, only bearing one copy of *napA* encoding the periplasmic nitrate reductase, and the *nirBD* operon encoding subunits of the periplasmic nitrite reductase ([Supplementary Table 8](#)). However, the genome of strain 1008 is equipped with a number of genes encoding enzymes that may substantially contribute to the acquisition of phosphorus from extracellular inorganic and organic sources ([Figure 3](#) and [Supplementary Table 8](#)). For instance, we identified homologs of *acpA* (acid phosphatase), *alkP* (alkaline phosphatase), *ygiF* (inorganic triphosphatase), *phoD1* and *phoD2* (phosphatases), *phoX* (phosphatase), *ppx* (exopolyphosphatase), the *phn* operon (C-P lyase for organophosphonate utilization), and *phyPf* (phytase of the β -propeller type) ([Figure 3](#) and [Supplementary Table 8](#)). Of these, the polypeptides encoded by *phyPf*, *acpA*, *phoD1*, *phoD2*, and *phoX*, contain signal peptides for their export across the plasma membrane (of the Sec/SPI type for the phytase, and of the TAT system for the rest). Additionally, there is one full *pqq* operon encoding enzymes for the biosynthesis of pyrroloquinoline quinone (PQQ). This redox coenzyme is required for the activity of glucose dehydrogenase, an enzyme whose critical role in the solubilization of inorganic phosphates has been demonstrated ([De Werra et al., 2009](#)).

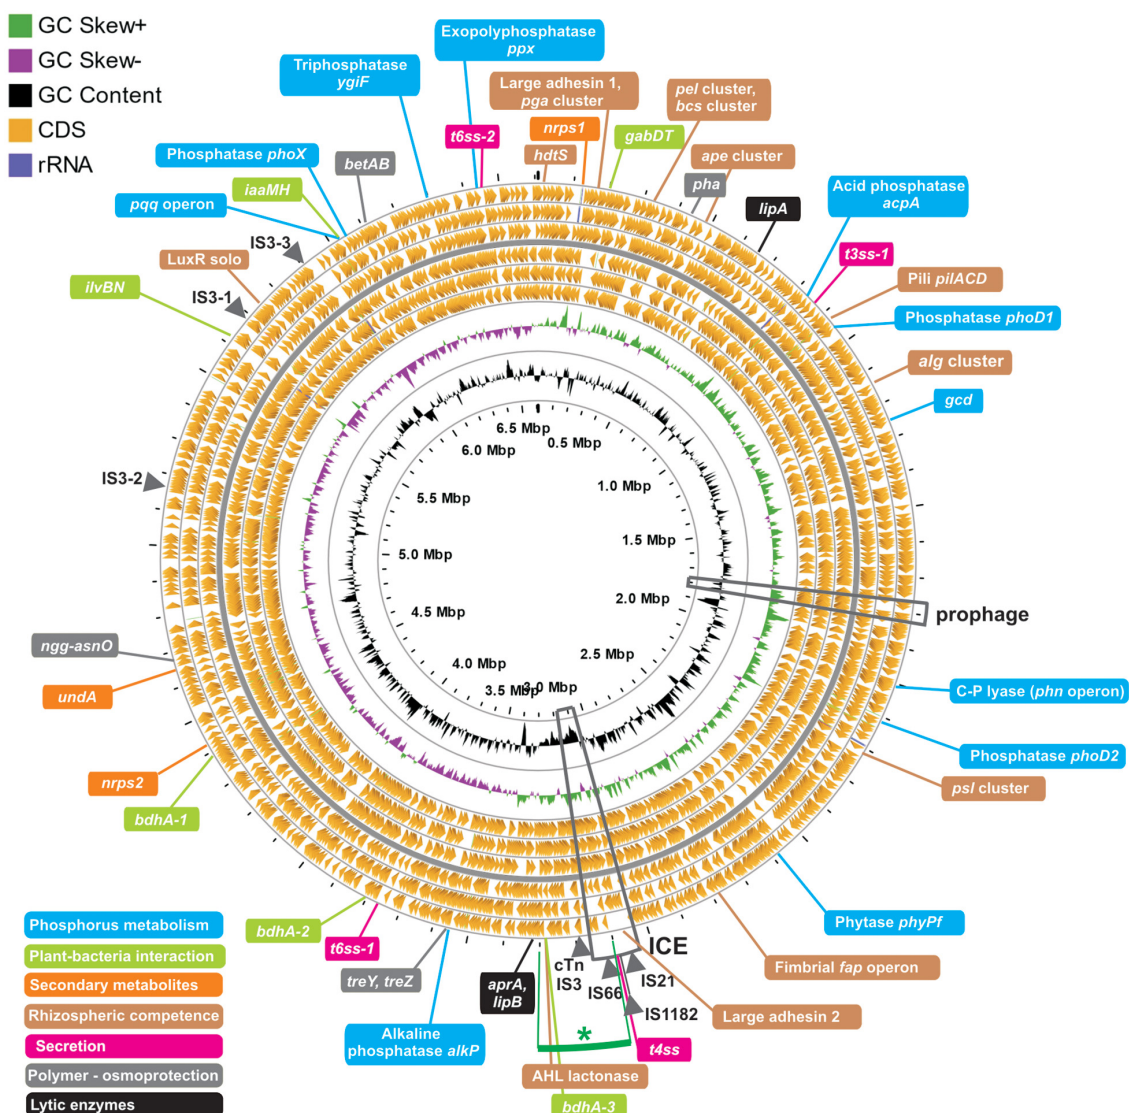

FIGURE 3

Characteristics and features of the genome of *Pseudomonas* sp. strain 1008. The circular map of the 6.6 Mb chromosome was performed with the GCview server (<http://cgview.ca/>). The circles represent, from outside to inside: rings 1–6, protein coding genes in the three different reading frames, oriented in the forward (rings 1–3) and reverse (rings 4–6) orientations, respectively. Ring 7 shows GC skews, with positive and negative values being indicated with green and purple colors, respectively. Ring 8 shows G + C% content plot (black). The innermost ring indicates absolute chromosome coordinates. Positions of mobile genetic elements are indicated with arrowheads in the outermost ring. The location of an intact prophage and of an integrative and conjugative element (ICE) are indicated with boxes. Finally, the position of a number of genetic loci related to plant growth promotion and rhizosphere competitiveness are indicated with colored lines, following the reference colors of the legend positioned at the lower left corner.

The corresponding glucose dehydrogenase gene *gcd* was also identified (Figure 3 and Supplementary Table 8).

In pure cultures, strain 1008 produces IAA and this is stimulated by the addition of tryptophan (Supplementary Figure 2). Of the known pathways for the biosynthesis of auxin (Spaepen et al., 2007), we could only detect two genes probably constituting an operon encoding the enzymes for the IAM pathway: namely, the tryptophan-2-monooxygenase *IaaM* and the indole-3-acetamide hydrolase *IaaH* (Figure 3

and Supplementary Table 8). On the other hand, we did not find the cluster of genes for IAA catabolism (*iachABICDEFG*). In addition to IAA, the genome of strain 1008 revealed its genetic potential to produce the volatile compounds acetoin and 2,3-butanediol (Figure 3 and Supplementary Table 8), which have been reported as plant biostimulants and inducers of systemic resistance (Chung et al., 2016). Under stress conditions plants produce and accumulate GABA, but its production has to be controlled because high levels of GABA can impair cell

TABLE 4 Overall genome relatedness indices derived from pairwise genomic comparison between *Pseudomonas* sp. strain 1008 and type species with the highest similarity of 16S rDNA sequences.

Type strain	16S ¹	ANiB (%) ²	ANIm (%) ³	dDDH ⁴
<i>P. lurida</i> LMG 21995	99.02	90.30 (79.9)	91.73 (79.8)	67.6 (64.2 – 70.8)
<i>P. marginalis</i> pv. <i>marginalis</i> ICMP 3553	98.79	90.02 (76.7)	91.41 (77.8)	61.6 (58.3 – 64.8)
<i>P. extremorientalis</i> LMG 19695	98.57	89.92 (79.5)	91.22 (80.0)	66.9 (63.5 – 70.1)
<i>P. azotoformans</i> LMG 21611	99.85	89.88 (81.3)	91.22 (91.9)	66.6 (63.2 – 69.8)

¹% identity along a 1,325 bp amplicon sequence from *Pseudomonas* sp. strain 1008, based on BlastN. ²Pairwise average nucleotide identity calculation based on Blast (ANiB) with the % of aligned genome sequence in between parentheses. ³Pairwise average nucleotide identity calculation based on MUMmer (ANIm) with the % of aligned genome sequence in between parentheses. ⁴Digital DNA–DNA hybridization (dDDH) estimate values (%) based on *in silico* DDH according to formula d_6 [a.k.a. GGDC formula 3, TYGS server; (Meier-Kolthoff et al., 2013; Meier-Kolthoff and Göker, 2019)]; model-based confidence intervals are specified in between parentheses. Shaded cells indicate the highest scores for every genomic feature. n.d., not determined.

elongation and plant stress resistance (Li et al., 2021). The identification of *gabT* and *gabD* homologs, encoding GABA aminotransferase and succinate-semialdehyde dehydrogenase involved in GABA degradation, and the *gabP* gene, encoding the GABA permease (Figure 3 and Supplementary Table 8), suggests that strain 1008 can acquire and metabolize GABA in the rhizosphere, thus indirectly modulating root GABA levels.

The type three secretion system (T3SS) is a complex protein structure evolutionary derived from the flagellar apparatus that spans the cytoplasmic and outer membranes of bacteria and the cell envelope of the eukaryotic host to deliver effectors directly into its cytosol (Galan et al., 2014). Thus, T3SSs play an important role in plant cell-bacterial interactions, with an outcome of virulent or mutualistic association, essentially depending on the nature of the transported effectors (Zamioudis and Pieterse, 2012). We have detected one T3SS locus of the Hrp-1 type in the genome of strain 1008 (Figure 3 and Supplementary Table 8). The T3SS cluster is highly similar and syntenic to those of the plant-beneficial strains *P. simiae* WCS417 and *P. fluorescens* SBW25 (Supplementary Figure 8). Based on the lack of plant virulence of strain 1008, this T3SS gene cluster -if functional- may be instrumental for induction of systemic resistance and/or modulation of other physiological responses in root cells (Stringlis et al., 2019).

Notably, the genome of strain 1008 lacks biosynthetic gene clusters (BGCs) responsible for the production of antimicrobial compounds that are hallmarks of biocontrol strains of the species *P. protegens*, *P. chlororaphis*, *Pseudomonas donghuensis*, or *P. putida* (namely, 2,4-diacetylphloroglucinol, pyrrolnitrin, pyoluteorin, polyynes, phenazines, hydrogen cyanide, and 7-hydroxytropolone, among others; Supplementary Table 8 and Figure 3). The sole exceptions are the presence of the *undA* gene, encoding an enzyme for the production of the antifungal volatile 1-undecene (Rui et al., 2014), and of a homolog of the *ycaO*

gene involved in posttranslational modification of ribosomally synthesized peptides (Burkhart et al., 2017) (Figure 3 and Supplementary Table 8). The number of identified BGCs of the NRPS and PKS type is also remarkably low, just two orphan NRPS clusters and none PKS clusters (Supplementary Table 8). Homologs of the broadly distributed genes in *Pseudomonas* species encoding the extracellular metalloprotease A (*aprA*), the extracellular phospholipase C (*plcN*), and two extracellular lipases (*lipA*, *lipB*) were identified. By contrast, no chitinase gene was detected. Strain 1008 neither possesses genes for characterized insecticidal proteins (Kupferschmied et al., 2013).

In terms of iron scavenging, we identified the *pvd* gene cluster for the biosynthesis of pyoverdine. In fact, spectroscopic signals in the UV-visible range typical of pyoverdine were detected in supernatants from cultures of strain 1008 in iron-deficient medium (Supplementary Figure 2G). Besides the pyoverdine gene cluster, we found genes encoding the hemophore protein HasA and the corresponding hemophore receptor. Interestingly, we did not detect the genes for biosynthesis of the siderophore achromobactin, but we identified one gene encoding a putative achromobactin receptor (Supplementary Table 8). No other genetic determinants for the production of additional siderophores were found. With regards to the transport of iron complexes, the genome of strain 1008 bears five genes encoding putative ferric-pyoverdine receptors and 13 genes for TonB-dependent receptors (six of which are located adjacent to iron-metabolism genes; Supplementary Table 8).

Effective colonization of the rhizosphere is key to execute direct and indirect mechanisms of plant growth-promotion (Lugtenberg and Kamilova, 2009). Our current studies on the root colonizing ability of strain 1008 point to a strong competitiveness to access the rhizoplane of wheat in natural soil in the presence of indigenous microorganisms and irrespective

of its initial location (bulk soil or seeds), although the survival of strain 1008 in bulk soil is severely limited in the absence of plant roots (unpublished data). The abilities to adhere to surfaces and establish biofilms, as well as to compete with other rhizobacteria, are critical factors to colonize the rhizosphere. In this sense, the genome of strain 1008 is endowed with the genetic capacity to produce polysaccharides commonly found in the extracellular matrix of biofilms (e.g., alginate, Psl, and Pel), as well as for the biosynthesis of a set of macromolecules mediating surface adhesion (cellulose, PGA adhesin, Fap amyloid fimbriae, and two large adhesins of the ShlA/HecA/FhaA family) (Figure 3 and Supplementary Table 8). The rhizosphere niche colonization by strain 1008 may be facilitated by its swimming motility driven by the flagellar apparatus (Figure 1) encoded by the flagellar operons, as well as by twitching motility associated with pili (Supplementary Table 8).

Strain 1008 lacks canonical *luxIR* genes for AHL production and global coordination of gene expression according to cell density, but it possesses one AHL synthase gene of the *hdtS* type, one LuxR-solo gene, and one AHL-lactonase encoded within the ICE region (Figure 3 and Supplementary Table 8). This implies that strain 1008 would be able to respond to its own and/or to foreign AHLs, and/or to interfere with cell–cell communication of other rhizobacteria. Finally, we identified genes for production of metabolites that confer protection to cells against different types of stress, namely osmotic stress [*betAB*, *ngg-asnO*, and *treY/treZ*, for betaine, NAGGN and trehalose biosynthesis, respectively; (Kurz et al., 2010)], oxidative stress [*ape* cluster for aryl polyene production; (Schoner et al., 2016)], and general stress [*pha* genes for polyhydroxyalkanoates; (Lopez et al., 2015)] (Figure 3 and Supplementary Table 8). Collectively, the expression of these genes may confer increased fitness in the rhizosphere to strain 1008.

An interesting bacterial strategy to compete with non-kin cells is the type VI secretion system (T6SS), a contractile nanoweapon to inject toxins directly into the cell membranes, periplasm, or cytoplasm, leading to killing of competitor cells if they do not have the matching immunity protein (Ryu, 2015). The injected T6SS effectors have different biochemical activities, but the nanomachine and their injected toxins are not harmful for plant cells (Lucke et al., 2020). The genome of strain 1008 contains two complete T6SS loci, and a number of potential effector toxins of the *tse5* (four copies) and *vrgG* (three copies) types (Figure 3 and Supplementary Figure 9 and Supplementary Table 8). Besides the genetic determinants of the T6SS nanomachines, strain 1008 contains genes encoding bacteriocins (Ghequire and De Mot, 2014; Jackson et al., 2018): we identified functional homologs of S-pyocins of the *pys1* (for a colicin-like rRNAse) and PA3865 (for a tRNAse) types, as well as two copies of putative CDI toxins related to PA0041 and PA2462 proteins from *P. aeruginosa*, and three copies of a gene encoding a putative bacteriocin of the DUF692 family. It would

be interesting to evaluate the functionality of the two detected T6SS loci in standard bioassays for antibacterial activity.

The broadly conserved global regulatory cascade of *Pseudomonas* species known as Gac-Rsm is fundamental to coordinate different traits for colonization of plant tissues, production of secondary metabolites and the interaction with eukaryotic organisms sharing the niche with pseudomonads (Ferreiro et al., 2018; Sobrero and Valverde, 2020). The genome of strain 1008 contains all the essential and accessory genetic elements delineating a functional Gac-Rsm cascade, including the GacS-GacA two-component system, the GacS-modulating histidine kinases RetS, LadS, and PA1611-like, three ortholog RNA binding proteins of the Rsm family (RsmA, RsmE, and RsmI), and the two cognate non-coding regulatory RNAs RsmY and RsmZ (Supplementary Table 8).

Phylogenomic, phenotypic and chemotaxonomic comparative analysis of *Pseudomonas* strain 1008 and related taxa

The first attempt to assign a taxonomic position to *Pseudomonas* sp. strain 1008 by comparative analysis of a 1,325 bp partial sequence of the PCR amplified 16S rDNA gene indicated that the isolate had >98.4% of sequence identity with several species belonging to the *P. fluorescens* subgroup within the *P. fluorescens* lineage (Table 4 and Supplementary Figure 1). For a more detailed analysis of its phylogenetic positioning, we drew on the complete genome sequence of strain 1008. A pairwise genome comparison with a set of type species having highly similar 16S rDNA sequences revealed that the closest taxonomic species was *Pseudomonas lurida* (Table 4). However, the calculated ANIb and ANIm values for strain 1008 were far below the current accepted threshold of 95% for species definition (Jain et al., 2018). In addition, the dDDH values calculated for each close relative species with respect to strain 1008, were all below 70% (Table 4), the cutoff for delimiting species (Meier-Kolthoff et al., 2013). These findings firmly suggested that strain 1008 may be a representative of a novel *Pseudomonas* species within the *P. fluorescens* subgroup.

To get further support for this hypothesis we profited on the genome-based taxonomy service provided by the DSMZ Type (Strain) Genome Server (TYGS; Meier-Kolthoff and Göker, 2019). In agreement with the ANI similarity and dDDH data (Table 4), the TYGS analysis reinforced the finding that strain 1008 is a representative of a novel species of *Pseudomonas* (Figure 4 and Supplementary Figure 8).

When the relatedness of the genome of strain 1008 was analyzed by comparison to all *Pseudomonas* genomes available in public databases, we found that the highest similarity indexes corresponded to the genome of *P. azotoformans* strain F77 (NCBI accession CP019856), with ANIb and AAI

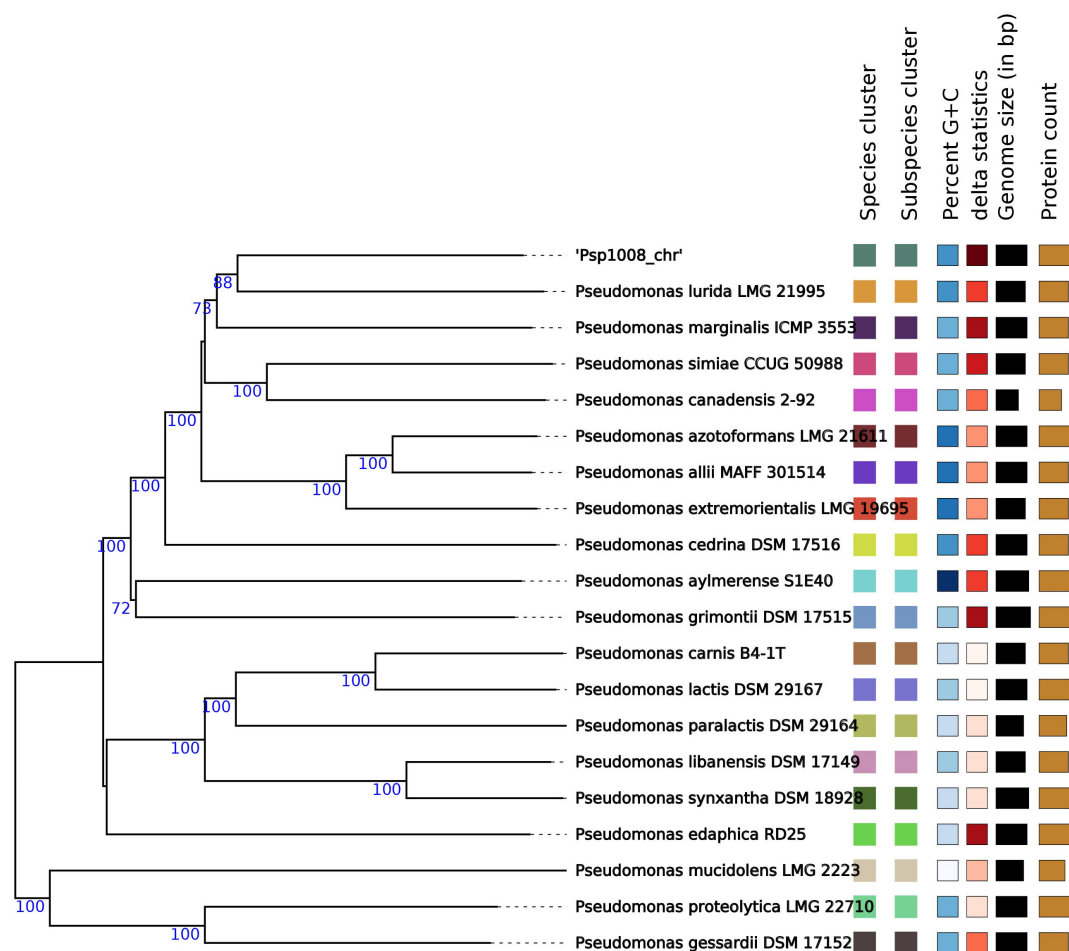

FIGURE 4

Genome BLAST Distance Phylogeny (GBDP) tree of *Pseudomonas* sp. strain 1008. The phylogenetic tree was constructed with the type (Strain) Genome Server (Meier-Kolthoff and Göker, 2019), which produces a GBDP tree by approximating intergenomic relatedness using the MASH algorithm among all type strain genomes in the TYGS database and by extracting and comparing 16S rRNA gene sequences with >14,990 type strains using BLAST as a proxy to identify the 50 closest type strains to calculate precise distances. The tree itself was constructed using FastME version 2.1.4 to infer a balanced minimum evolution tree with branch support. The tree represents only the *Pseudomonas* spp. most closely related to strain 1008. Bootstrap support values are shown at the nodes. The leaf label "Species cluster" assigns a different color to denote genomes from different type species.

(average amino acid identity) values of 99.02 and 99.64, respectively (Figure 5). However, the genomic similarity between the type strain of the *P. azotoformans* species (LMG 21611) and strain 1008 (Table 4 and Figures 4, 5) is not consistent with this finding, thus raising doubts about the taxonomical positioning of *P. azotoformans* F77. In fact, the ANIm and AAI analyses of all available genomes of isolates designated as members of the *P. azotoformans* species (including that of the species type strain), clearly support the fact that both strains 1008 and F77 are representatives of a novel species distinct from *P. azotoformans* and from closely related type species (Figures 4, 5). In addition to the evidence provided by genomic metrics, the comparison of the composition of whole-cell fatty acids and of key biochemical activities between strain 1008 and closely

related taxa (Tables 5, 6), also provide phenotypic support for the separate species status that was shown by the phylogenomic analysis.

Based on the evidence described above demonstrating that strain 1008 represents a newly derived branch in the phylogenomic tree of the *P. fluorescens* lineage (Figures 4, 5), we propose a new taxonomic entity with the name "*Pseudomonas pergaminensis*" sp. nov.

Description of *Pseudomonas pergaminensis* sp. nov.

Pseudomonas pergaminensis (per ya mi 'nen sis), N.L. masc./fem. adj. pergaminensis, belonging to Pergamino county

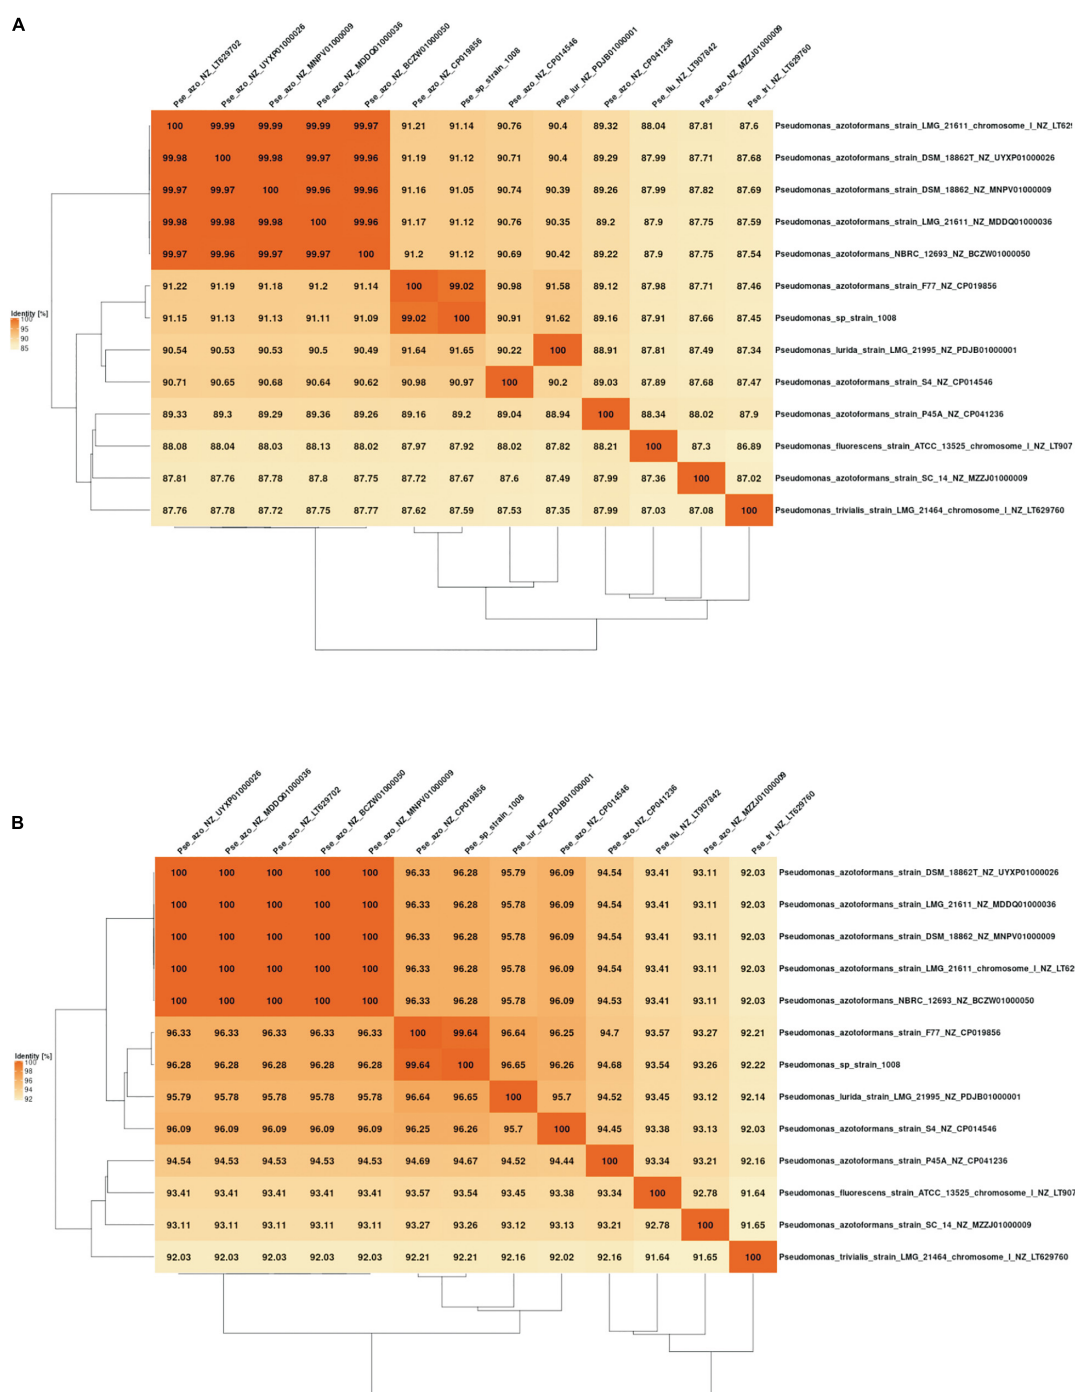

FIGURE 5

Overall genome relatedness derived from pairwise genomic comparison between *Pseudomonas* sp. strain 1008 and type species and isolates with the highest similarity of 16S rDNA sequences. (B) Average amino acid identity matrix generated with the AAI matrix tool of the EDGAR platform (<https://edgar3.computational.bio.uni-giessen.de/cgi-bin/edgar.cgi>).

(Province of Buenos Aires, Argentina), from where the type strain was isolated.

Cells of strain 1008^T are Gram-reaction negative, aerobic, oxidase positive, rod-shaped bacteria ranging between

0.6–1.1 mm wide × 1.2–3.2 μm long, non-endospore-forming rods. Grows on *Pseudomonas* agar F at 28°C forming circular colonies <2 mm, with smooth borders, opaque, of light beige color, and creamy texture. It may give rise to

phase-variant colonies. Growth occurs at 4–35°C but not at 37°C. Strain 1008^T grows in a pH range from 6–9, and with a NaCl concentration of up to 1% w/v. Results from tests using API 20 NE Gallery System show that the following substrates are utilized: D-glucose, D-arabinose, D-mannose, D-mannitol, N-acetyl-D-glucosamine, D-gluconate, capric acid, adipic acid, malic acid, and citrate. Using the Biolog GenIII system, tests positive for the utilization of the following additional substrates: dextrin, D-fructose, D-fructose-6-phosphate, D-galactose, D-fucose, L-fucose, L-rhamnose, L-galactonic acid lactone, D-galacturonic acid, D-glucuronic acid, glucuronamide, acetic acid, quinic acid, γ -amino butyric acid, formic acid, and Tween-40 (**Supplementary Data 5** and **Supplementary Figure 10**). The major cellular fatty acids are C_{16:0} (30.4%), C_{16:1w7c} (29.5%), C_{18:1w7c} (15.3%), C_{17:0cyclo7c} (9.1%), C_{12:0} 2OH (4.3%), C_{12:0} 3OH (3.7%), C_{10:0} 3OH (3.0%), and C_{12:0} (2.3%) (**Supplementary Data 6**). It is able to solubilize mineral phosphates and zinc oxide, to produce IAA and siderophores, to secrete proteases and phospholipases, but not chitinases. The strain 1008^T was isolated from the rhizosphere of field grown *Triticum aestivum*, in Pergamino, Buenos Aires province, Argentina, in 2003. The genomic DNA G + C content of the type strain is 60.72%. The full genome sequence of the strain 1008^T has been deposited at the NCBI GenBank under accession number CP078013. The type strain is 1008^T (= DSM 113453 = ATCC TSD-287).

Discussion

The urgent need of sustainable and eco-friendly strategies to mitigate the impact of agrochemical industry and its massive application has boosted research on plant-biostimulant microorganisms, whereas at the same time, it has exposed frequent inconsistencies between the plant-beneficial potential of isolated microorganisms studied under lab conditions and their efficiency in the field (Timmusk et al., 2017; Backer et al., 2018; Basu et al., 2021). Such hurdles may be partially reduced if the microorganisms are isolated from plant tissues of the target crop and are applied in the geographical area of origin (Armada et al., 2018; Müller and Behrendt, 2021). *Pseudomonas* sp. strain 1008 was isolated from the rhizosphere of healthy field-grown wheat plants, as a bacterium able to increase the availability of phosphate to plant roots and to produce auxin (**Figure 1** and **Supplementary Figure 2**). Based on these traits, strain 1008 was formulated as an inoculant for its application on wheat seeds before sowing and tested in a series of field trials at three different locations around the isolation site, across several campaigns involving different wheat varieties (**Figure 1a** and **Supplementary Tables 1, 2, 4**). Collectively, the results of the whole set of field trials strongly support the use of this biostimulant bacterium (Du Jardin, 2015) as an efficient agricultural input for promoting the yield of wheat (**Table 2** and **Supplementary Table 4**). The fact that a single seed

bacterizing shot with live *Pseudomonas* sp. strain 1008 resulted in an average increase of wheat yield of 8% (median = +9.7%; **Table 2** and **Supplementary Table 4**), suggests that seedling establishment and its early development are critical stages that are strongly responsive to the presence of the bacterium and its physiological activities, and whose beneficial effects are largely transduced all along the growth cycle of the plant. Recently, it has been proposed that domestication and breeding strategies have worked against the maintenance of plant genes promoting interactions with plant-beneficial bacteria (Valente et al., 2020). In this regard, bacterization of commercial wheat seeds with strain 1008 may represent a way to by reinstate key microbial functions in the rhizosphere of seedlings by compensating the reduced ability of modern wheat varieties to interact with PGPR (Perez-Jaramillo et al., 2016; Valente et al., 2020).

Physiological and genomic plant-beneficial traits of *Pseudomonas* sp. strain 1008

In vitro, strain 1008 was capable of solubilizing phosphate from pure calcium triphosphate and from mineral phosphate rocks, mineralizing phosphate from organic esters, solubilizing zinc from ZnO, producing siderophores and extracellular lytic enzymes of the phospholipase and protease types (**Table 1** and **Supplementary Figure 2**). All these features may cooperatively contribute to enhancing nutrient availability in the rhizosphere of wheat plants.

The closest related strain to *Pseudomonas* sp. 1008 described in the literature is the isolate F77 (**Supplementary Figures 7, 8**). Strain F77 was originally assigned to the *P. azotoformans* species, but on the basis of our phylogenomic analysis this species ascription should be revised (**Figure 5**). Strain F77 was reported as a strong biomineralizer of aluminum and iron from biotite minerals, being this feature fully dependent on the activity of the product of the *gcd* gene, encoding the periplasmic glucose dehydrogenase enzyme (Wang et al., 2020). In pseudomonads, glucose dehydrogenase drives the oxidation of glucose into gluconic acid in a reaction that requires the PQQ cofactor (Miller et al., 2010). Gluconic acid may be further oxidized in the periplasm to 2-ketogluconic acid by the activity of the product of the *gad* gene (gluconic acid dehydrogenase) (Miller et al., 2010). This pathway of glucose uptake leads to acidification of the cell environment, which indirectly facilitates solubilization of mineral phosphates. In fact, genetic data confirmed the absolute requirement of *gcd*, *gad* and *pqq* genes for solubilization of calcium triphosphate by the biocontrol rhizospheric strains *P. fluorescens* F113 and *P. protegens* CHA0 (De Werra et al., 2009; Miller et al., 2010). *Gcd* can also oxidize xylose (Dvorak and De Lorenzo, 2018), another abundant sugar present in plant root exudates. The genome of strain 1008 encodes *gcd*, *gad*, and *pqq* homologs (**Figure 3** and **Supplementary Table 8**), thus providing genomic support for the observed

capacity to solubilize mineral phosphates. Acidification of the extracellular environment in the rhizosphere has been found to contribute to local suppression of root immunity upon recognition of bacterial inducers of ISR, an effect that for certain rhizospheric *Pseudomonas* species required PQQ biosynthesis and gluconic acid production (Yu et al., 2019). Thus, root colonization by strain 1008 may also be promoted through this mechanism of ISR modulation associated with the control of extracellular pH driven by PQQ-dependent acidification (Yu et al., 2019), which in parallel contributes to solubilization of mineral phosphates.

Additionally, several genes of strain 1008 encode phosphatases acting on organic phosphate esters, some of which are predicted to be secreted (i.e., a β -propeller-phytase, the acid phosphatase AcpA, and the phosphatases PhoD1, PhoD2, and PhoX). Notably, strain 1008 has an *alkP* homolog, encoding an alkaline phosphatase, that is also present in only two out of the 613 complete genomes available in the PseudoDB database: the phylogenetically closest isolate “*P. azotoformans*” strain F77 and *Pseudomonas extremorientalis* BS2774, the latter being a member of a subgroup whose type species is also closely related to strain 1008 (Table 4 and Figure 4). Altogether, the repertoire of genes related to the metabolism of inorganic and organic sources of phosphates present in the genome of strain 1008 (Figure 3 and Supplementary Table 8) suggests its potential as a phosphorus biofertilizer in the rhizosphere of wheat.

Pseudomonas sp. strain 1008 produces auxin in a tryptophan-dependent manner (Table 1 and Supplementary Figure 2). In bacteria, five different tryptophan-dependent pathways for IAA biosynthesis have been reported (Spaepen et al., 2007). By contrast, the genetic basis for the tryptophan-independent production of IAA is unknown (Spaepen et al., 2007). We could not identify the *ipdC* (IPA pathway), *oxd* and *nha1* (IAOc/IAN pathway), and *tdc* (TPM pathway) genes in the genome of strain 1008. We detected, however, a putative operon highly resembling the *iaaMH* tandem of the IAM pathway (Figure 3 and Supplementary Table 8). Given that the gene responsible for the fifth biosynthetic pathway involving a tryptophan side-chain oxidase (TSO) is yet unknown (Spaepen et al., 2007), we cannot rule out the presence of a *tso* homolog in the genome of strain 1008. Besides auxin, the genome of strain 1008 has the potential to produce other phytostimulators, such as the volatiles 2,3-butanediol and acetoin [two compounds known to be involved in plant growth stimulation (Ryu et al., 2004; Chung et al., 2016)], and the cofactor PQQ, which in addition to its role in phosphate solubilization, it has been reported to act a phytostimulator with antioxidant properties in tomato and cucumber (Choi et al., 2008). With regards to modulation of plant hormone homeostasis during abiotic stress responses, the genome of strain 1008 does not encode a *bona fide* ACC deaminase gene *acdS*, but it encodes the GABA permease GabP and the GABA catabolic enzymes GabD-GabT (Figure 3 and Supplementary Table 8). Thus, strain 1008 may

TABLE 5 Comparison of the relative abundance (%) of major cellular fatty acids of *Pseudomonas* sp. strain 1008 and its closest phylogenetic relatives (see Table 4 and Figure 4).

Fatty acid	16:0	16:1 w7c	18:1 w7c	17:0 cyclo w7c	12:0 2OH	12:0 3OH

Data were retrieved from BacDive (<https://bacdive.dsmz.de/>) and from the literature (Dabboussi et al., 1999; Behrendt et al., 2007; Von Neubeck et al., 2017; Lick et al., 2020). +, positive reaction; +w, weak positive reaction; —, negative. n.r., not reported.

contribute to attenuate the GABA-mediated response to abiotic and biotic stress (Li et al., 2021) in the rhizosphere of colonized plants, in a way comparable with bacterial ACC deaminase to limit ethylene production by plant tissues (Gamalero and Glick, 2015). All these genetic traits directly related to phyto-regulation suggest that cells of *Pseudomonas* sp. strain 1008 colonizing the rhizosphere of wheat may have a key role in promoting root system development locally and contributing systemically to modulation of plant responses to stresses.

With regards to indirect mechanisms of plant growth promotion, strain 1008 was unable to produce HCN [a volatile compound responsible for the inhibition of diverse phytopathogens (Blumer and Haas, 2000)] and to antagonize several phytopathogenic fungi and one oomycete *in vitro* (Table 1 and Supplementary Figure 2). These findings provide stronger support toward a direct plant biostimulatory effect, rather than to an indirect biocontrol-based mechanism, as the main contribution of strain 1008 to the promotion of wheat growth and yield in the field. In this regard, mining of the full genome sequence of strain 1008 clearly indicated that this isolate was not evolved to fight pathogens with secondary metabolites typical of biocontrol PGPR, like antibiotics, antimetabolites, and lipopeptides of NRPS origin (Figure 3 and Supplementary Table 8) (Keswani et al., 2020). However, the capacity to induce systemic resistance cannot be discarded for strain 1008, as typical general elicitors of ISR like LPS, flagella and siderophores of the pyoverdine type (Pieterse et al., 2014) are structural and functional components of strain 1008 (Figure 1, Supplementary Figure 2, and Supplementary Table 8). Furthermore, the genome of strain 1008 encodes genes for the production of the volatile compounds 2,3-butanediol and acetoin (Figure 3 and Supplementary Table 8), which are also elicitors of ISR (Pieterse et al., 2014; Silva Dias et al., 2021). In addition, it has been recently proposed that certain plant-beneficial rhizobacteria may engage into a feedback loop. The recognition of key MAMPs by the plant immune system triggers a defense reaction that stimulates bacterial production of IAA, thus reinforcing development of lateral roots and ISR itself on the plant side, but also promoting root colonization by the rhizobacterium (Tzipilevich et al., 2021). It would be interesting to explore if the IAA-producer strain 1008 can also enter into such a virtuous loop with plant roots.

The compendium of genes and operons detected in the genome of *Pseudomonas* sp. strain 1008 that are potentially involved in biofertilization and phytostimulation as the main underlying mechanisms for promotion of wheat yield in the field, as well as those genetic determinants potentially relevant for rhizosphere colonization and competitiveness (Figure 3 and Supplementary Table 8), set the basis for designing functional genetics screens and gene expression profiling of strain 1008, in order to provide experimental support linking the functional relevance of the cataloged genetic repertoire

of plant-beneficial traits in the rhizosphere. An important issue that has to be considered when aiming to link gene functions to PGPR mechanisms and, by transition, to agronomic efficiency in the field, is that plant-beneficial rhizospheric microbes may display a set of concurring mechanisms that contribute to the overall robust performance in the field, as it has been addressed for the agronomic response of different crops to the inoculation with *Azospirillum brasilense* [i.e., the “multiple mechanisms hypothesis” (Bashan and De-Bashan, 2010; Cassán et al., 2020)]. This hypothesis may explain the overall positive impact of strain 1008 on the yield of wheat across a number of field assays carried out in different locations, with different seed genotypes and across different campaigns (Figure 2 and Supplementary Table 2). Under this scenario, we have preliminary data indicating that strain 1008 promotes early root development of wheat in natural soil, and that induces root branching and expression of auxin-responsive reporter fusions in *Arabidopsis thaliana* (unpublished data). These effects would be consistent with the observed production of auxin by strain 1008 (Supplementary Figure 2) and with the identification of an operon encoding the auxin biosynthetic proteins IaaM-IaaH of the IAM pathway (Figure 3 and Supplementary Table 8); together, these clues would point to auxin production in the rhizosphere as one of the possible mechanisms of strain 1008 contributing to the promotion of root development in the field. However, and importantly, such hypothesis needs to be challenged with targeted mutation of the *iaaMH* genes; the same reasoning applies to all other genetic traits with potential relevance in the field that were identified in the genome of strain 1008 (Figure 3 and Supplementary Table 8).

Strain 1008 is a representative of the proposed novel species *Pseudomonas pergaminensis*

The initial taxonomic assignment of strain 1008 indicated that the isolate belonged to the *P. fluorescens* lineage, with its 16S rDNA sequence being 98.4–99.1% similar to those of different type species within this large and complex cluster of the *Pseudomonas* genus (Table 4 and Supplementary Figure 1). On the basis of the full genome sequence, we concluded that isolate 1008 represents a novel species of the genus *Pseudomonas* (Figure 4 and Supplementary Figure 8). Moreover, our genomic comparative analysis led us to conclude that this novel proposed species for strain 1008, must also include the aluminum- and iron-weathering isolate F77, which had been originally typed as a *P. azotoformans* isolate (Wang et al., 2020), and that shares an overall genomic relatedness with strain 1008 of 99.08% at the nucleotide level, and of 99.64% at the amino acid level (Figure 5). The phenotypic and chemotaxonomic features of strain 1008 confirmed its

differentiation from related taxa (Tables 5, 6, Supplementary Datas 5, 6, and Supplementary Figure 10). The results from this polyphasic approach support the classification of 1008^T as a novel species of *Pseudomonas*, and the name of *Pseudomonas pergaminensis* is thus proposed for this strain.

Conclusion

We report the isolation, physiological characterization, and genomic analysis of a wheat rhizospheric strain representative of a novel species of the genus *Pseudomonas*, that showed a robust positive effect on the yield of field-grown wheat upon its application as a formulated inoculant on seeds. *In vitro* and genomic traits strongly suggest that *Pseudomonas pergaminensis* 1008^T acts as a plant biostimulant, rather than as a biocontrol bacterium. Full genome information will be useful for functional characterization of the mechanisms underlying the robust performance of strain 1008 in the field.

Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article/Supplementary Material.

Author contributions

MD and TB isolated, characterized, and developed the commercial formulation of strain 1008. FN designed, implemented, and monitored field trials. GGA and WC supervised research and the agronomical evaluation of the commercial formulation. BA performed the statistical analysis of agronomical data and prepared DNA for genome sequencing. DW carried out genome assembly, annotation, and a set of comparative genomic tests. CV carried out genome mining, phylogenomic analysis, organized datasets, elaborated article structure, and wrote the manuscript. All authors contributed to manuscript revision, read, and approved the submitted version.

Funding

This work was supported by Rizobacter Argentina S.A. and by research grants from Universidad Nacional de Quilmes (PUNQ 1306/19, Argentina) and CONICET (11220150100388CO and 11220200101442CO, Argentina). Bioinformatics support by the BMBF-funded project “Bielefeld-Gießen Center for Microbial Bioinformatics—BiGi (Grant Number: 031A533)” within the German Network for Bioinformatics Infrastructure (de.NBI) is gratefully acknowledged. BA and CV are members of CONICET.

Conflict of interest

MD, TB, FN, and WC, were employed by Rizobacter Argentina S.A. GGA was employed by Indrasa Biotecnología S.A.

The remaining authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

The authors declare that this study received funding from Rizobacter Argentina S.A. The funder had the following involvement in the study: isolation and characterization of the bacterial strain; development of the commercial formulation tested in field assays; design, implementation, and monitoring of the agronomical evaluation of the formulation in field trials.

To ensure food security given the current scenario of climate change and the accompanying ecological repercussions, it is essential to search for new technologies and tools for agricultural production. Microorganism-based biostimulants are recognized as sustainable alternatives to traditional agrochemicals to enhance and protect agricultural production. Marine actinobacteria are a well-known source of novel compounds for biotechnological uses. In addition, former studies have suggested that coral symbiont actinobacteria may support co-symbiotic photosynthetic growth and tolerance and increase the probability of corals surviving abiotic stress. We have previously shown that this activity may also hold in terrestrial plants, at least for the actinobacteria *Salinispora arenicola* during induced heterologous symbiosis with a wild Solanaceae plant *Nicotiana attenuata* under *in vitro* conditions. Here, we further explore the heterologous symbiotic association, germination, growth promotion, and stress relieving activity of *S. arenicola* in tomato plants under agricultural conditions and dig into the possible associated mechanisms. Tomato plants were grown under normal and saline conditions, and germination, bacteria-root system interactions, plant growth, photosynthetic performance, and the expression of salt stress response genes were analyzed. We found an endophytic interaction between *S. arenicola* and tomato plants, which promotes germination and

shoot and root growth under saline or non-saline conditions. Accordingly, photosynthetic and respective photoprotective performance was enhanced in line with the induced increase in photosynthetic pigments. This was further supported by the overexpression of thermal energy dissipation, which fine-tunes energy use efficiency and may prevent the formation of reactive oxygen species in the chloroplast. Furthermore, gene expression analyses suggested that a selective transport channel gene, *SIHKT1,2*, induced by *S. arenicola* may assist in relieving salt stress in tomato plants. The fine regulation of photosynthetic and photoprotective responses, as well as the inhibition of the formation of ROS molecules, seems to be related to the induced down-regulation of other salt stress response genes, such as *SIDR1A*-related genes or *SIAOX1b*. Our results demonstrate that the marine microbial symbiont *S. arenicola* establishes heterologous symbiosis in crop plants, promotes growth, and confers saline stress tolerance. Thus, these results open opportunities to further explore the vast array of marine microbes to enhance crop tolerance and food production under the current climate change scenario.

KEYWORDS

Salinispora heterologous symbiont, marine actinobacteria, coral actinobacteria, plant salt stress, plant biostimulant, photoprotective response

Introduction

Plant biostimulants (PBs) based on microorganisms have emerged as sustainable alternatives to traditional agrochemicals by enhancing plant stress tolerance and increasing crop yields and quality under suboptimal conditions. Nowadays, PBs are becoming essential components of strategies to mitigate the effects of climate change. In their native environments, plants live and grow with many symbiotic microorganisms. However, intensive cultivation practices and the indiscriminate use of fertilizers and agrochemicals, which at one point increased the ecological success of plants, have modified the natural microbiota of crop soils. Microorganism-based PBs take advantage of the symbiotic microorganisms that typically occur in nature and reintroduce them into empty crop soil, which enables plants to withstand environmental changes that threaten the global crop industry (Shameer and Prasad, 2018).

Currently, one of the principal problems that affects crop productivity is soil salinization. Soil salinization has increased due to the over-irrigation and over-fertilization of high-yield cropping systems, which have affected 931.67 million hectares worldwide as of 2018 (Mukhopadhyay et al., 2021). The resulting high salt concentrations in soils produce osmotic stress and cause imbalances in water and nutrient uptake by plants (Arif et al., 2020). Moreover, a high influx of Na^+ ions into the plant cells results in the displacement of K^+ ions from many enzymes and cofactors, which affects plant metabolism (Abdelaziz et al., 2019). Both

ionic and osmotic stressors promote the accumulation of reactive oxygen species (ROS) and cause oxidative stress, which can damage DNA, proteins, and lipids (Shahid et al., 2020). These plant stressors affect germination, photosynthesis, growth, flowering, and many other physiological processes responsible for the low crop yields associated with saline soils (Parihar et al., 2015).

Plants have evolved complex survival responses to cope with salinity that involve coordination among many physiological and genetic processes, such as controlling water loss through stomata pore regulation, ion sequestration, metabolic and osmotic adjustments, and the activation of enzymatic and non-enzymatic mechanisms of the antioxidant system to maintain cellular redox homeostasis (Orsini et al., 2011; Abo-Ogiala et al., 2014; Adem et al., 2014; Geilfus et al., 2015; Soares et al., 2019). However, natural plant responses are not always sufficiently able to cope with stress. To our knowledge, no reliable process is available to fully restore saline soils (Shankar and Evelin, 2019). However, the inoculation of plants with certain microorganisms can increase their salt tolerance and enable them to be cultivated under saline stress conditions. Rodriguez et al. (2008) elegantly demonstrated a process, which they defined as habitat-adapted symbiosis (HAS), in which endophytic symbionts of native halophytes enable saline-sensitive plants to grow in saline soils. Since then, HAS strategies employing various halophytes from different saline habitats have been explored to relieve salt stress in salt-sensitive plant species. Some examples of HAS species that confer resistance to salt stress in plants

are the halophilic bacteria *Stenotrophomonas rhizophila*, which inhabits the halophyte *Lygeum spartum* that is native to the desert environments of Algeria; *Bacillus atrophaeus*, which is an endophyte of the halophytes *Suaeda mollis* and *Salsola tetrandra* that are native to Algeria Salt Lakes; *Jejubacter calystegiae*, which is found in the halophyte *Calystegia soldanella* that is found on sandy beaches in South Korea; and many fungus-like microorganisms like *Neocamarosporium chichastianum*, *N. goegapense*, and *Periconia macropinosa*, which has been isolated from the desert halophyte *Seidlitzia osmarinus* collected at Hoz-e Soltan Salt Lake in Iran (Jiang et al., 2021; Kerbab et al., 2021; Moghaddam et al., 2021; Dif et al., 2022). Some of these HAS species have been successfully employed in PB formulations.

Recently, it was shown that the marine actinobacteria *Salinispora arenicola* could establish a symbiotic relationship with seedlings of the wild-tobacco *Nicotiana attenuata* under *in vitro* conditions (Ocampo-Alvarez et al., 2020) and relieve saline stress during germination and early growth. As *S. arenicola* is a saline habitat symbiont that relieves saline stress in the saline-sensitive *N. attenuata*, it partially fulfills the HAS definition. However, the native habitat of *S. arenicola* is marine, and it is found within *Porites* corals where it establishes what seems to be three symbiotic trophic interactions between the coral and *Symbiodinium* sp., a phototrophic alga. Therefore, *S. arenicola* is better defined as a habitat-adapted heterologous symbiont (HAHS). Nevertheless, the potential of this HAHS species to relieve salt stress and any associated mechanisms remain unexplored in terrestrial plants of agricultural interest.

All HAS possess specific mechanisms to ameliorate saline stress in plants. A common HAS mechanism is the production of osmolytes, such as proline, trehalose, glycine betaine, or exopolysaccharides, which directly ameliorate osmotic stress by decreasing the internal osmotic potential of plants cells (Bano and Fatima, 2009; Upadhyay et al., 2012; Timmusk et al., 2014; Upadhyay and Singh, 2015). Other HAS mechanisms involve activating antioxidant systems, such as enzymes, biochemical compounds, and secondary metabolites that counteract the induced oxidative stress (Hashem et al., 2016). Moreover, several HAS also regulate phytohormone activity or biosynthesis. For example, ACC (1-aminocyclopropane-1-carboxylate) deaminase activity lowers the level of the stress-related phytohormone ethylene, thus avoiding the down-regulation of genes involved in plant growth (Glick et al., 2007). Another mechanism to cope with salinity in plants is the overexpression of specific ionic channels that counterbalance the K^+/Na^+ proportion, such as high-affinity Na^+ and K^+ transporters (i.e., High-affinity K^+ , *HKT*; Na^+/K^+ antiporters, *NHX*; or inward-rectifier K^+ channel/transporters, *AKTs*; Arif et al., 2020). Different mechanisms produce different levels of protection, which may lead to improved germination, photosynthesis, growth, flowering, or yield under saline conditions.

Tomato (*Solanum lycopersicum*) is an agriculturally important crop, and its responses to salt stress have been abundantly reported. Some of the most recognizable effects of salinity in tomato plants are reduced growth; decreased dry weights (DW) of roots, stems, and leaves; and leaf senescence (Munns, 2002; Zribi et al., 2009). Growth reduction is a consequence of Na^+ accumulation due to a decline in the water potential, which affects photosynthetic activity (Iyengar and Reddy, 1996; Hanachi et al., 2014). Stomatal closure is probably the first plant protection response against desiccation and a direct factor that immediately controls carbon fixation in the case of C3 plants. Long-term exposure to saline treatments in tomatoes has been shown to result in a notable and progressive decline in photochemical processes and a notable increase in non-photochemical quenching (NPQ) that protects the plant from an overreduction of the quinone electron acceptor (QA; Zribi et al., 2009).

In this study, the properties of the marine actinobacteria *S. arenicola* as a PB and bio-protector under normal and saline conditions were evaluated in tomato plants. First, the nature of the interaction between the tomato plants and *S. arenicola* was established. Then, the potential of this actinobacteria to relieve induced salt stress during germination and plant growth was explored based on the assumption that the HAHS *S. arenicola* may possess specific activities that could alleviate salt stress in tomato plants. Finally, the photosynthetic performance, pigment composition, osmolyte content, and changes in the antioxidant properties of tomato plants were explored while scouting for changes in the expression of genes potentially involved in different mechanisms induced by salt stress conditions. Overall, our results support the potential of this marine actinobacterium to be used as a crop PB and protective agent against salt stress.

Materials and methods

Biological samples

Salinispora arenicola strain X29 (GenBank accession number MT002753¹) was isolated from *Porites lobata* obtained from the Tropical Central Pacific coral reef system (19° 5' 55.21" N, 104° 23' 24.47" W and 19° 3' 28.87" N, 104° 15' 40.25" W) and cryopreserved at −70°C in 15% glycerol (Ocampo-Alvarez et al., 2020) until use.

The bacterial suspension used to treat Tomato plants was prepared as follows: *S. arenicola* X29 was cultivated on A1 medium (Mincer et al., 2002) under agitation at 210 rpm and 28°C for 5 days and then centrifuged at 10,000 × g for 5 min. The supernatant was discarded, and the pellet

¹ <http://www.ncbi.nlm.nih.gov/genbank/index.html>

was weighed and resuspended with distilled water to a final concentration of 1 mg/mL.

All experiments were conducted using tomato plants (*S. lycopersicum* L. cv. Rio Fuego; Kristen Seed, San Diego, CA, United States). Tomato seeds were cleaned by immersion on a 10% v/v household soapy solution for 1 min and washed thrice with sterile distilled water. They were then disinfected with 3% sodium hypochlorite for 10 min and washed thrice with sterile distilled water. Subsequently, the seeds were either treated with *S. arenicola* X29 or not and then sown in phytagel-agar media for the germination and fluorescence *in situ* hybridization (FISH) experiments or with peat moss in germination trays and later treated at the seedling stage with *S. arenicola* X29 for subsequent plant response analyses (Figure 1). The plants were grown at all times in an artificial climate growth chamber (Thermo Fisher Scientific, Waltham, MA, United States) at 28/17°C and with a 16:8 h day/night photoperiod (155–300 $\mu\text{m s}^{-1} \text{m}^{-2}$).

Root *Salinispora* colonization

Tomato seeds were cleaned as previously described and incubated for 2 h in 3 mL of *S. arenicola* X29 culture or water (i.e., control) right after cleaning (Figure 1). Then, the seeds were sown in sterile plates with solid plant growth media [6 g L^{-1} phytagel (Sigma-Aldrich, St. Louis, MO, United States) and 3.2 g L^{-1} Gamborg's B-5 Basal Medium with Minimal Organics (Sigma-Aldrich)], with or without 100 mM NaCl (SIGMA, Merck KGaA, Darmstadt, Germany). Seeds were then incubated at 28/17°C with a 16:8 light/dark photoperiod (155–300 $\mu\text{m s}^{-1} \text{m}^{-2}$) in a growth chamber. After 30 days, the roots were harvested, fixed with formaldehyde, and stored at -20°C until needed for Giemsa staining and FISH hybridization.

Giemsa-stained roots were then observed under a light microscope (Olympus BX41; Olympus, Tokyo, Japan; Muresu et al., 2010). FISH was performed according to the methods of de-Bashan et al. (2011) and Palacios et al. (2019). Three probes labeled with FAM dye, which have been previously reported, were used to target eubacteria: EUB-338-I (5'-GCT GCC TCC CGT AGG AGT-3'), EUB-338-II (5'-GCA GCC ACC CGT AGG TGT-3'), and EUB-338-III (5'-GCT GCC ACC CGT AGG TGT-3'; Amann et al., 1990; Daims et al., 1999). The samples were visualized with a BX41 epifluorescence microscope (Olympus) using a FITC filter at 550/570 nm (excitation/emission; Olympus America, Melville, NY, United States).

Germination assays

The tomato seed germination assay was conducted according to the standard protocol of the international society for seed bioassays (ISTA), which was modified by adding the

actinobacteria or A1 medium (i.e., controls) as previously described. Approximately 800 surface-sterilized seeds were mixed with 3 mL of *S. arenicola* X29 suspension culture or A1 medium (control) for 2 h (Figure 1). Under sterile conditions, the seeds were transferred into Petri dishes containing wet Whatman no. 5 filter paper (Whatman International Limited, Maidstone, United Kingdom).

The salt stress experiment was run with 8 mL of 100 mM NaCl or sterile distilled water (control). Four groups, each containing 100 seeds, were included in each experiment. The seeds were incubated in a growth chamber at 28°C with a 16:8 light/dark photoperiod (155–300 $\mu\text{m s}^{-1} \text{m}^{-2}$). Seed germination was measured every day for 8 days and only when the radicle was at least 2 mm long. The germination percentage was determined using the following formula:

$$\% \text{ Germination} = \frac{\text{number of germinated seeds}}{\text{total number of seeds}} \times 100$$

Germination was followed daily for 8 days after sowing. The seed germination data were fitted to the Gompertz equation: $f = a \left(\exp^{-\exp\left[-\left(\frac{d-d_0}{b}\right)\right]} \right)$, where a represents the maximum germination percentage and d_0 represents the half time of maximum germination. Germinated seeds were grown for five additional days (13 days after sowing), and the morphological properties of the seedlings were analyzed. Specifically, the plumule and radicle lengths (cm) of the seedlings were measured, and the dry weight of the seedlings was determined after oven drying at 50°C to a constant weight. Nitrogen, carbon, and polyphenol content were determined in seedlings to evaluate any nutritional or antioxidant benefits induced by the actinobacteria.

Nitrogen and organic carbon percentages were determined according to the methodology established by the Association of Analytical Chemists (955.04; Association of Official Analytical Chemist, 1990). Total polyphenol content was evaluated with the Folin-Ciocalteu colorimetric method with a gallic acid standard (Singleton and Rossi, 1965).

Treatment of plants with *Salinispora arenicola* for growth, photosynthesis, metabolite, antioxidant capacity, and gene expression analysis

Tomato seeds were germinated in peat moss as previously described without further treatment. Fifteen-day-old seedlings were washed with distilled water to remove peat moss. The roots were incubated for 3 min in the *S. arenicola* X29 suspension at a bacteria concentration of 1 mg/mL or water (control). The treated seedlings were transplanted into pots with 500 g of soil mixture composed of vermiculite, peat moss, and soil (1v:1v:1v; Figure 1).

FIGURE 1

Experiment outline. **(A)** Root *Salinispora* colonization and germination assays of tomato (*Solanum lycopersicum*) plants. Seeds were sterilized, directly inoculated with *S. arenicola* X29, and sown and cultured in phytagel-agar plates. Growth and plant response analyses. **(B)** Tomato seedling roots were inoculated on day 15. On day 30, the plants were treated for 8 days with increasing NaCl concentrations and analyzed on day 39.

Salt stress treatment

Fifteen days after treatment with the *S. arenicola* suspension, a set of tomato plants was irrigated with increasing concentrations of saline water (150, 200, 250, and 300 mM NaCl) every second day. Photosynthetic performance and morphological parameters were analyzed for all treatments 9 days after inducing salt stress with saline water irrigation (Day 39, Figure 1). Whole leaf samples were collected, flash-frozen with liquid nitrogen, and stored at -70°C for metabolite, pigment, enzyme, or gene expression analyses.

Photosynthetic performance analysis

Chlorophyll-*a* fluorescence was measured with a non-intrusive pulse-amplitude modulated (PAM) chlorophyll-fluorometer (Junior-PAM, Heinz Walz GmbH, Effeltrich, Germany). All photosynthetic parameters from the fluorescence measurements were obtained as described by Schreiber (2004) (Supplementary Table 1). Two standard protocols (i.e., induction curves and rapid light response curves) were used to obtain all photosynthetic parameters for our experiments. Both protocols were performed on the second youngest,

attached, fully expanded, and healthy leaves of at least six plants per treatment. The light guide of the Junior-PAM was positioned at the midpoint of the adaxial side of the leaf for both fluorescence protocols. The protocols were initiated after 30 min of dark adaption.

The NPQ induction curves began with a saturating pulse of 10,000 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ (800 ms) to measure maximum fluorescence when all PSII reaction centers were closed. This pulse was followed by 40 s of darkness to reestablish a basal F_0 measurement, after which the leaf was subjected to 20 min of high actinic light (1,500 $\mu\text{mol photon m}^{-2} \text{ s}^{-1}$). Saturating light pulses (SP) were emitted during this lighting period every 30 s. The rapid light curves (RLCs) were set with 12 light levels (each turned on for 30 s): 25, 45, 65, 90, 125, 190, 285, 420, 625, 820, 1,150, and 1,500 $\mu\text{mol photon m}^{-2} \text{ s}^{-1}$. As in the induction curve experiments, the RLCs began with a saturating light pulse of 10,000 $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$ (800 ms) to measure maximum fluorescence when all PSII reaction centers were closed. All experiments began early in the morning and were completed before noon. The induction curve and RLC parameters were obtained from the automatic data output of the Junior PAM software.

Photosynthetic pigments

Photosynthetic pigments were extracted and measured using the method described by Zapata et al. (2000) following the recommendations of Osuna-Ruiz et al. (2019). Pigments were extracted from 300 mg of fresh frozen leaves in 90% acetone for 24 h at 4°C and then centrifuged at $3,220 \times g$ for 10 min. The supernatants were recovered and stored at -20°C until use. Pigment quantification was performed with a 1200 Infinity HPLC system (Agilent Technologies, Santa Clara, CA, United States) coupled to a diode array detector (DAD) with a C-8 column (ZORBAX 4.6 mm \times 100 mm, 3.5 μm particles). The mobile phases consisted of eluent A (methanol:acetonitrile:pyridine 0.25 M, 50:25:25, v:v:v) and eluent B (acetonitrile:acetone, 80:20, v:v) delivered with the following gradient scheme (A%/B%, min): 100/0, 0; 60/40, 22; 5/95, 28; 5/95, 38; and 0/100, 40. The flow rate was fixed at 1 mL per min. All solvents were HPLC grade (Tedia, OH, United States). Pigments were identified by comparing their retention times with standards (DHI, Hørsholm, Denmark). Pigment coefficients were calculated to evaluate the photosynthetic and photoprotective status of whole-treated plants. Total chlorophyll was obtained by the sum of Chl *a* + Chl *b* and was used as a proxy for photosynthetic capacity. The chlorophyll ratio was obtained by dividing Chl *a* by Chl *b* and was used as an estimator of LHCII antenna size and the light acclimation state. The pool size of the xanthophyll cycle pigments ($\sum XC$) was obtained by the sum content of the three xanthophyll pigments [i.e., violaxanthin (Vx), antheraxanthin

(Ax), and zeaxanthin (Zx)] and was used to estimate the photoprotective capacity to dissipate thermal energy. The percentage of xanthophyll cycle pigments in deepoxidated state DEPS was obtained by the formula $\left(\frac{[Zx] + 0.5[Ax]}{\sum XC} \right) \times 100$ and was used to assess the actual photoprotective state of the $\sum XC$ pool. The β -carotene:total chlorophyll ratio, $\frac{\beta-car}{Chl a+b}$, was used as a proxy of the antioxidant capacity.

Total phenol, flavonoid, proline, and reducing sugar content

Phenol, flavonoid, and reducing sugar content were determined from acidified ethanol extractions conducted with fresh frozen leaves (six plants per treatment) that were pulverized and lyophilized (ILSHIN BIOBASE Table Top Freeze Dryer). A total of 25 mg of lyophilized leaves was extracted in 70% ethanol (acidified with 0.1% HCl) for 24 h at 4°C in the dark. The mixture was centrifuged at 4°C for 20 min at $10,000 \times g$, and the supernatant was collected for metabolite analysis.

Total polyphenol content was determined using the Folin-Ciocalteu (F-C) colorimetric method adjusted for micro-determination (Cao et al., 2020) with some modifications. A 100- μL aliquot of the sample extract and 500 μL of F-C reagent were mixed and incubated at room temperature for 5 min. Afterward, 400 μL of Na_2CO_3 (15%) was added to the solution. The mixture was incubated at 45°C for 10 min. A total of 200 μL of the reaction mixture was placed into a 96-well plate. The absorbance was measured at 730 nm in a microplate reader (MultiskanTM GO Microplate Spectrophotometer, Thermo Fisher Scientific, Waltham, MA, United States) after mixing and an 80-min incubation in the dark. A standard curve using gallic acid was recorded (10–200 $\mu\text{g/mL}$). Phenol content was expressed as gallic acid equivalents (GAE, mg) per gram of DW (mg GAE/g DW).

The reducing sugar assay was conducted according to the methodology of Negulescu et al. (2012) with some modifications. A 100- μL aliquot of the sample extract was added to 1,000 μL of DNS reagent (3,5-dinitro salicylic acid, Sigma Aldrich) and mixed. The samples were incubated for 10 min at 100°C. Subsequently, the mixture was allowed to cool to room temperature for 4 min, and 200 μL was placed in a microplate. The absorbance was read at 540 nm with the MultiskanTM GO microplate reader (Thermo Fisher Scientific). A glucose calibration curve ranging from 1–10 mg/mL was used.

The proline assay was conducted as described by Palmeros-Suárez et al. (2015). Briefly, leaves were harvested, flash-frozen in liquid nitrogen, pulverized, and lyophilized. A total of 25 mg of powdered tissue from each sample was mixed with 100 μL of the proline extraction buffer [80% ethanol, 100 mM HEPES *N*-(2-Hydroxyethyl)piperazine-*N'*-(2-ethane sulfonic acid) buffer at pH 7.4, and 5 mM MgCl_2]. The mixture was incubated at

4°C for 10 min with shaking and then centrifuged at $10,000 \times g$ at 4°C for 10 min. The supernatant was transferred to a new tube and concentrated by vacuum centrifugation using a Maxi Dry Lyo (Heto-Holten, Allerød, Denmark). The precipitate was dissolved in 100 μ L of HEPES buffer (100 mM, pH 7.4) with $MgCl_2$ (5 mM). A 100- μ L aliquot of the former solution was added to 200 μ L of a solution containing glacial acetic acid 60% (v/v), ethanol 20% (v/v), and ninhydrin 1% (w/v). The mixture was boiled at 95°C for 20 min, cooled to room temperature, and the optical density was recorded at 520 nm in the MultiskanTM GO microplate reader (Thermo Fisher Scientific).

Antioxidant capacity

Antioxidant capacity was measured according to the methodology of Brand-Williams et al. (1995) following the recommendations of Rubio-Ochoa et al. (2019). A total of 100 μ L of each sample extract and 900 μ L of 0.1 M of the stable radical 2,2-diphenyl-1-picrylhydrazyl (DPPH[•] in 70% ethanol) were mixed for 30 min at room temperature in the dark. Subsequently, a 250- μ L aliquot of each sample was placed in the 96-well MultiskanTM GO microplate (Thermo Fisher Scientific) and read at 515 nm. The result was expressed in micromol equivalents of Trolox per gram of tissue (DW) using a calibration curve ranging from 1–1,000 μ M/mL.

Salinity responsive gene expression assay

Total RNA was extracted from leaves obtained from a pool of three plants using TRIzol Reagent (Invitrogen, Carlsbad, CA, United States) following manufacturer recommendations. The cDNA was obtained from 2 μ g of RNA using GoScript reverse transcriptase (Promega, Madison, NJ, United States) and oligo-dT (15) primers. qPCR amplifications were performed using SYBR[®] Green detection in 96-well plates in a StepOnePlus System (Applied Biosystems, Foster City, CA, United States). Reactions were prepared in a total volume of 15 μ L with 1.5 μ L of cDNA template (1:10), 7.5 μ L SYBR[®] Select Master Mix (Applied Biosystems), and forward and reverse gene-specific primers (300 nM). The cycling conditions were set as follows: initial denaturation step at 95°C for 5 min, followed by 40 cycles of denaturation at 95°C for 10 s, and annealing at 60°C for 30 s. A melting curve analysis was used to evaluate reaction specificity. The RT-qPCR system software automatically determined the baseline and cycle threshold (Ct). Relative expression was calculated using a comparative cycle threshold method (Livak and Schmittgen, 2001) and *SIGADPH* and *SIEF1 α* as endogenous reference genes. Primers for *SIGADPH* and salinity responsive genes were reported

by Devkar et al. (2020) and *SIEF1 α* by Wang et al. (2020) (Supplementary Table 2).

Statistical analysis

The data sets were analyzed by a one-way ANOVA and *post hoc* Tukey HSD tests after both normality and homogeneity of variance were tested with Shapiro–Wilk and Bartlett tests, respectively. When these assumptions were not met, a permutational ANOVA (PERMANOVA) was used. All statistical analyses were conducted in Sigma Plot v. 12 (Systat Software, Inc., Chicago, IL, United States) and PRIMER + PERMANOVA software (Version 7.0.13; PRIMER-e, Plymouth, United Kingdom).

Results

Tomato root colonization by *Salinispora arenicola*

In a previous study (Ocampo-Alvarez et al., 2020), a close interaction between *S. arenicola* and *Nicotiana attenuata* roots was observed *in vitro*. To confirm the presence of such interactions in tomato plants in this study, tomato seeds inoculated with *S. arenicola* and controls (bacteria-free) were grown under either saline or salt-free conditions and analyzed by Giemsa staining and FISH (Figure 2). Colonization of *S. arenicola* was observed in the central zone of the seedling roots. Under salt-free conditions, we found the bacteria interacting with the epidermal cells of roots (Figures 2E,F). Interestingly, bacterial colonization was more markedly observed under saline conditions on root hairs (Figures 2G,H). The control seedlings showed no presence of any bacteria (Figures 2A–D), which confirms that *S. arenicola* interaction occurs in tomato plants and that the site of this interaction changes from epidermal cells to root hairs based on salinity conditions. As *S. arenicola* is a bacteria found in saline habitats with the capacity to sustain a heterologous symbiotic relationship with plant roots, hereinafter it is referred to as a HAHS.

Salinispora arenicola increases the germination percentage of tomato seeds under salt stress conditions

Once the interaction between *S. arenicola* and the tomato plants was confirmed, the effects of this HAHS on germination competence were evaluated (Figure 3). With salt-free irrigation, no differences were observed in germination kinetics between the HAHS-treated and control seeds with

FIGURE 2
Colonization of *Salinispora arenicola* on tomato root hairs. Samples underwent Giemsa staining (A,C,E,G) and Fluorescence *in situ* Hybridization (FISH; B,D,F,H). Arrows indicate the presence of habitat-adapted heterologous symbiont (HAHS) bacterial cells in samples of plants inoculated under control (Ctrl; without NaCl) and NaCl conditions (100 mM).

FIGURE 3
Germination kinetics of HAHS-treated and control tomato seeds under saline conditions. Symbols represent the daily average germination percentage of four replicates with 100 seeds. Seed germination data were fitted to the Gompertz equation: $f = ae^{(-e^{-(\frac{d-d_0}{b})})}$. Seeds inoculated under control (Ctrl) or habitat-adapted heterologous symbiont (HAHS) conditions with water free of NaCl or with 100 mmol NaCl (+NaCl) irrigation. Statistical significance was analyzed by a univariate analysis of variance. Lowercase letters denote statistical differences (pairwise test) among treatments for each parameter.

TABLE 1 Growth and biochemical characteristics of habitat-adapted heterologous symbiont (HAHS)-treated (B) and control (C) tomato seedlings under salt stress conditions.

	Ctrl	HAHS	NaCl	HAHS + NaCl
Plumule (cm)	6.61 ± 0.24 ^b	9.29 ± 1.18 ^c	3.84 ± 0.46 ^a	4.51 ± 0.40 ^a
Radicle (cm)	6.00 ± 0.40 ^b	7.35 ± 0.24 ^c	3.40 ± 0.21 ^a	3.96 ± 0.64 ^a
% N	5.09 ± 0.01 ^b	5.19 ± 0.01 ^b	3.74 ± 0.03 ^a	4.72 ± 0.09 ^c
% C	43.42 ± 0.09 ^b	38.72 ± 0.14 ^d	31.20 ± 0.30 ^a	41.02 ± 0.19 ^c
Polyphenols (mg/kg)	901.81 ± 6.37 ^b	600.01 ± 1.71 ^d	356.97 ± 5.52 ^a	1,582.53 ± 14.17 ^c

Ctrl, control; HAHS-free; HAHS = *S. arenicola*; NaCl = HAHS-free and NaCl condition (100 mM); and HAHS + NaCl = *S. arenicola* and NaCl condition (100 mM).

~90% seed germination. Salinity delayed the germination kinetics in both HAHS-treated (HAHS+NaCl) or HAHS-free seeds (NaCl). However, although NaCl treatment caused a delay in seed germination, HAHS-treated seeds reached the maximum germination percentage (~90%) at the end of the germination assay as did the control seeds. In comparison, HAHS-free seeds with NaCl treatment only reached ~60% germination. Salt stress affected tomato seed germination, but treatment with *S. arenicola* alleviated this stress by the end of the experiment.

Additionally, in the germinated seedlings, we measured %N, %C, and polyphenol (mg/Kg) content and the radicle and plumule heights on day 13 (Table 1). Salinity decreased the plumule and radicle lengths of both HAHS-treated and HAHS-free seedlings. Interestingly, treatment with *S. arenicola* significantly increased both length measurements under conditions of no salt stress. Seedling plumule and radicle lengths correlated nicely with nitrogen content (Pearson $r \approx 0.8$), although the relationships with polyphenols and carbon showed different patterns. Polyphenol content decreased in the control tomato seedlings under salt stress conditions but increased in the plants treated with *S. arenicola* under salt stress. The high polyphenol content in HAHS-treated tomato seedlings could be related to the enhanced antioxidant activity that protected tomato seeds during germination. This is supported by the high correlation between the germination percentage and polyphenol content (Pearson correlation: $r = 0.95$). Furthermore, high correlations were found between %N and %C content and germination (Pearson correlation: $r = 0.97$, 0.94 , respectively).

Growth promoting activity of *Salinispora arenicola* with saline and salt-free irrigation

Tomato plant seedlings (15 days after germination; DAG) were submerged in either an *S. arenicola* suspension (HAHS-treatment) or water (control) before being transplanted into pots with soil and allowed to grow for 15 more days (Figure 1B). Afterward, groups of plants of each treatment were irrigated for 8 days with increasing NaCl concentrations

up to 300 mM, which resulted in another two treatments: HAHS+NaCl and NaCl. Plant response parameters (i.e., plant length from the bottom to the main apex and the number of leaflets) were recorded 1 day after the last irrigation treatment (day 9 after the first irrigation). Results showed a clear and significant effect of *S. arenicola* in promoting tomato plant growth (Figure 4). With simple irrigation (salt-free), we found increases in growth of 27.2% in the shoots and 42.3% in the roots of plants treated with *S. arenicola* compared to those of the controls. In addition, leaflets and compound leaves increased in number by 20.9% and 36.3%, respectively (Figure 4).

Saline irrigation showed a slight decrease in all analyzed phenotypes for both control and HAHS-treated plants (Figure 4). Interestingly, HAHS-treated plants under salt stress conditions grew higher than control plants grown without saline stress, with a slight difference in shoot length (5.7%) and a notable difference in root length (21.1%; $P = 0.001$). Moreover, we still observed that HAHS-NaCl plants substantially outgrew bacteria free-plants under saline conditions (NaCl), with 26.8% and 42.2% differences in shoot and root lengths, respectively, and differences of 17.1% and 24.6% in the number of leaflets and compound leaves, respectively (Figure 4). Overall, although growth was affected by salinity in both control and HAHS-treated plants, *S. arenicola*-treated plants outperformed the control plants, which further suggests induced salt-tolerance activity by the actinobacteria.

Salinispora arenicola enhances photosynthetic performance and photoprotection

In line with the growth results obtained with simple water irrigation, HAHS-treated plants exhibited enhanced photosynthetic performance compared to HAHS-free plants in the form of an ~25% larger electron transport rate (ETR_{MAX}), a marginally but statistically significant increase in the maximum photochemical quantum yield of PSII (F_V/F_M ; c. 2%), and ~15% higher dissipation of absorbed energy in the PSII antenna through a thermal dissipation pathway (NPQ; Figure 5A).

FIGURE 4

Salinispora arenicola enhances the growth of tomato plants under normal and salt stress conditions. Phenotype measurements of 39 DAG plants grown with either NaCl-free irrigation or saline irrigation that were either inoculated with a habitat-adapted heterologous symbiont (HAHS) bacterium or not (control; Ctrl). Statistical significance was determined using a permutational ANOVA (PERMANOVA; $p = 0.001$). Lowercase letters denote statistical differences (pairwise test) among conditions.

The yield coefficients of the absorbed energy distribution [effective photochemical quantum yield, $Y(II)$; the non-regulated quantum yield of fluorescence emission from PSII, $Y(NO)$; and light-regulated quantum yield of non-photochemical fluorescence quenching, $Y(NPQ)$] confirmed the bacterial benefits to photosynthetic performance. HAHS treatment induced a 40% increase of $Y(II)$ compared to that of the control plants and a drop in the non-regulated $Y(NO)$ and regulated $Y(NPQ)$ energy distribution pathways in HAHS-treated compared to those of HAHS-free plants. This points to an increased capacity of HAHS-treated plants to allocate light-derived energy into the carbon assimilation pathway induced by the actinobacteria (Figure 5B).

Interestingly, when plants were irrigated with a saline solution, the photosynthetic parameters followed an interesting pattern of change with respect to those observed under non-stressed conditions in HAHS-free and HAHS-treated plants (Figure 5A). For HAHS-free plants, salt-stress induced no effect on F_V/F_M , although a reduction of ~9% in NPQ and an increase of ~20% in ETR_{MAX} were observed. On the other hand, HAHS-treated plants showed no increase in F_V/F_M , but in contrast, a significant increase in NPQ (~74%) and a decrease in ETR_{MAX}

(~7%) under saline stress was observed when compared to those of the control plants. This agrees with the observed changes induced by saline stress in yield coefficients, which showed a decrease in the proportion of $Y(NO)$ of ~17%, a marginal reduction in $Y(II)$ of ~7%, and a high increase in $Y(NPQ)$ of ~42% in HAHS-treated plants (Figure 5B).

Photosynthetically related pigments and metabolites

The photosynthetic changes suggested the activity of photosynthetic and photoprotective-related pigments and metabolites. Pigment composition (Figure 6) and metabolite content (Table 2) were assessed in plant leaves collected 1 day after the last saline irrigation treatment. An increase in light collector molecules (Chl *a* by 11% and Chl *b* by 6%) was observed in HAHS-treated plants under salt-free irrigation (Figure 6 and Supplementary Table 3), which provides evidence of extended photosynthetic performance induced by the actinobacterium. The increase was higher in Chl *a* than Chl *b*, which was reflected in the Chl *a/b* ratio. Moreover, the

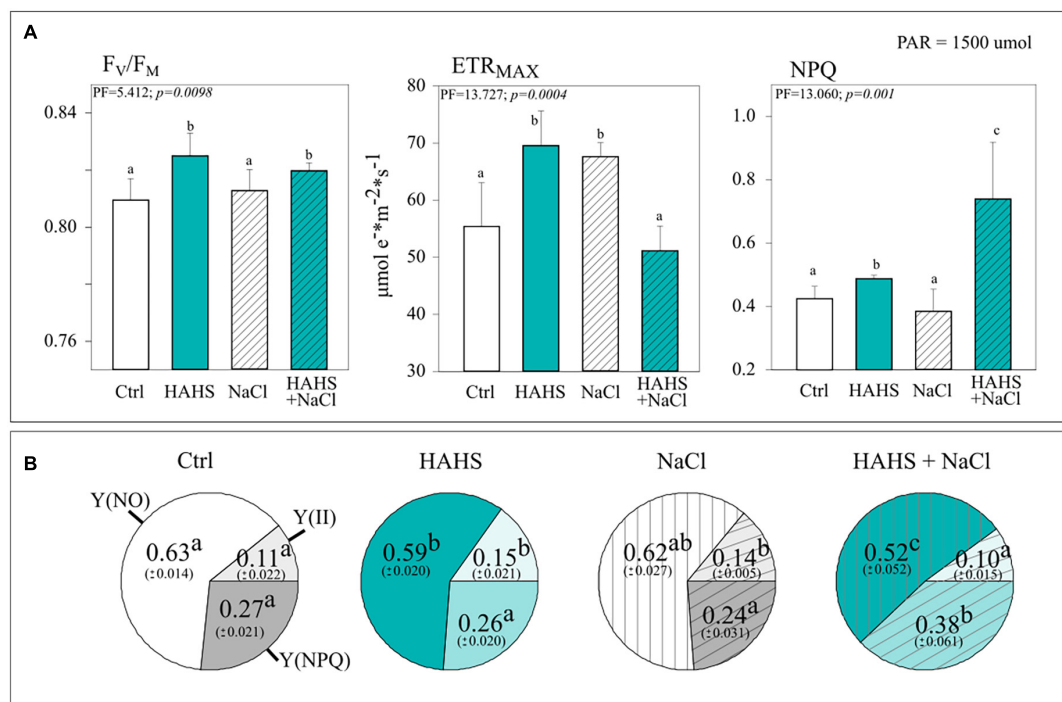

FIGURE 5

Salinispora arenicola enhances quantum yield and photoprotection under saline stress. (A) Photosynthetic performance parameters and (B) Yield coefficients of the absorbed energy distribution. Parameters were measured with a non-intrusive pulse-amplitude modulated (PAM) device ($n = 6$) 39 days after germination (DAG) in plants grown with either NaCl-free or saline irrigation and inoculated with a habitat-adapted heterologous symbiont (HAHS) bacteria (turquoise bars) or not (control; C, white bars). F_v/F_m , Maximum photochemical quantum yield of PSII; ETR_{MAX} , Maximum electron transfer rate; NPQ, Stern-Volmer type non-photochemical fluorescence quenching; Y(NO), Quantum yield of non-regulated heat dissipation and fluorescence emission; Y(II), Effective photochemical quantum yield of PSII; Y(NPQ), Quantum yield of light-induced non-photochemical fluorescence quenching. Statistical significance was determined separately for each irrigation scheme using a univariate analysis of variance (ANOVA; $p = 0.001$). Lowercase letters denote statistical differences (pairwise test) among conditions.

Xanthophyll cycle pool size $\left[\sum \left(\frac{XC}{Chl\ a+b} \right) \right]$ was reduced by 8% in HAHS-treated plants compared to that of the control plants, which was also likely due to the higher content of chlorophyll molecules. The photoprotective pigment zeaxanthin, which is related to the light-regulated energy dissipation mechanism, was not affected, although the antioxidant molecule beta-carotene increased ~60% in HAHS-treated plants.

In HAHS-free plants, salt stress caused a significant reduction in all analyzed pigments [chl *a* (~21%), chl *b* (~22%), Zeaxanthin (~11%), and Beta-carotene (~19%)] and on the xanthophyll cycle pool size (~16%). In contrast, treatment with HAHS prior to saline stress partially lessened the reduction in light collector molecules (chl *a* down to 12% and chl *b* to 17%) and the xanthophyll cycle pool (down to 6%) with respect to those of the control conditions. Furthermore, the content of Zeaxanthin and Beta-carotene was enriched up to 2 and 40%, respectively, which suggests induced zeaxanthin-related photoprotective and beta-carotene-related antioxidant activity by the actinobacterium *S. arenicola*.

Antioxidant metabolites, such as proline and phenol, and DPPH antioxidant activity tended to increase in plants under

salinity as a strategy to mitigate stress by reducing the cellular osmotic potential and free radical scavenging. We found an increase in all of these parameters after saline irrigation. However, the increase was onefold lower in HAHS-treated plants than in untreated plants for both proline and DPPH (Table 2). This result implies that the symbiotic bacteria may reduce oxidative and osmotic stress and thus alleviate responses upstream, perhaps by inducing cation-transporters or reducing ROS formation.

Studies have also reported changes in sugar accumulation after saline stress (Yin et al., 2010), which are likely a consequence of a metabolic reconfiguration and redistribution of resources or an effect of photosynthetic changes. We observed a significant reduction in the content of reducing sugars (~50%) when HAHS-free plants were treated with saline water (Table 2). This reduction was not observed in HAHS-treated plants. Sugar content reduction in untreated plants may be due to the observed decrease in photosynthesis (El-Beltagi et al., 2017). Overall, metabolic changes suggest that the symbiotic bacteria may lessen oxidative and osmotic stress and thereby protect plant metabolism.

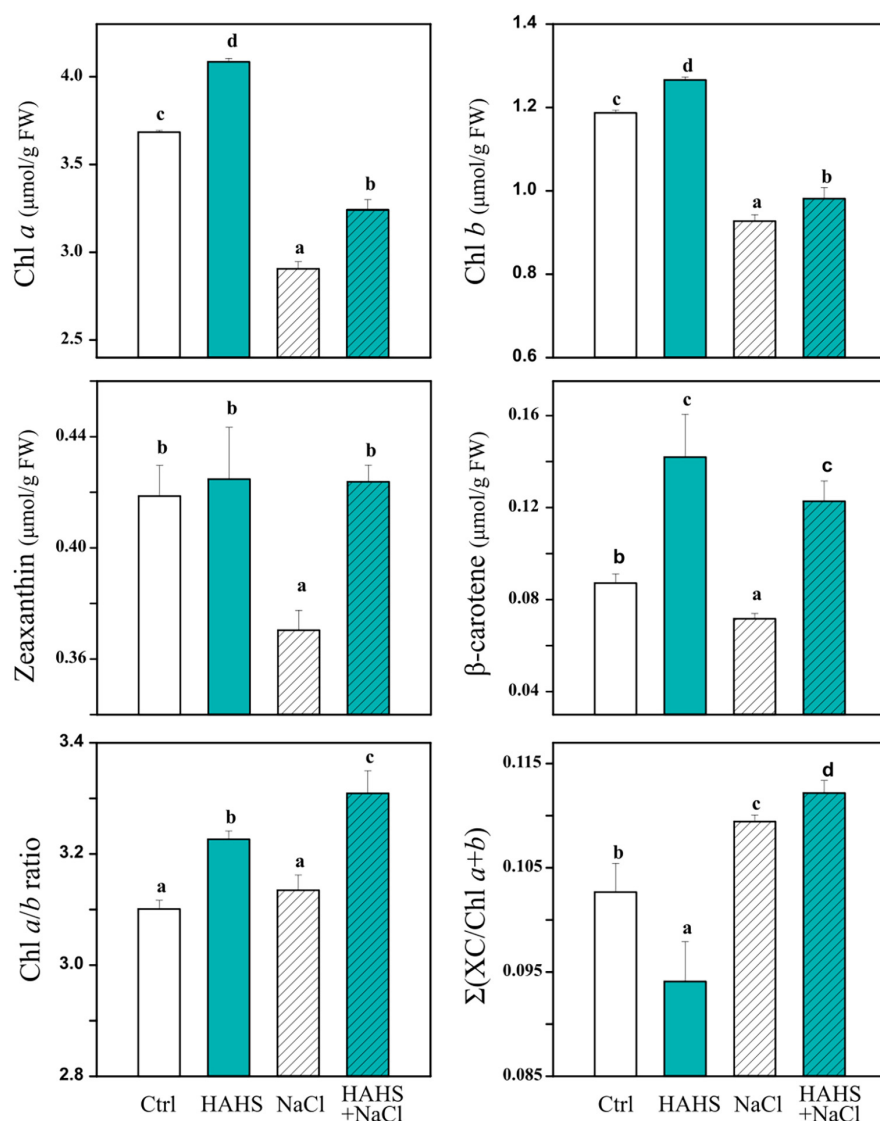

FIGURE 6

Salinispora arenicola induces changes in photosynthetically related pigments under normal and saline conditions. Plants ($n = 4$) 39 days after germination (DAG) were grown with either normal irrigation (white boxes) or saline irrigation (NaCl; gray boxes) and inoculated with a habitat-adapted heterologous symbiont (HAHS; B, turquoise) or not (control; C, black). Statistical significance was determined separately for each irrigation scheme using a univariate analysis of variance (ANOVA; $p = 0.001$). Lowercase letters denote statistical differences (pairwise test) among conditions.

TABLE 2 Proline, phenolics, antioxidant activity, and reducing sugars in tomato plant leaves.

	Ctrl	HAHS	NaCl	HAHS + NaCl
Proline	37.39 ± 1.53 ^a	35.68 ± 1.14 ^a	133.55 ± 3.23 ^b	93.08 ± 1.46 ^c
Total phenolics	5.03 ± 0.22 ^a	4.75 ± 0.28 ^a	5.47 ± 0.33 ^b	5.30 ± 0.16 ^b
DPPH antioxidant activity	3.64 ± 0.48 ^a	3.17 ± 0.45 ^a	6.50 ± 0.30 ^c	5.94 ± 0.34 ^b
Reducing sugars	41.67 ± 1.34 ^c	35.34 ± 0.92 ^b	27.33 ± 0.70 ^a	33.27 ± 2.29 ^b

DPPH is a water soluble, stable radical 2,2-diphenyl-1-picrylhydrazyl; DPPH Antioxidant activity (μg Trolox/g FW), proline (μg/mg FW), reducing sugars (mg/g FW), total phenolics (mg GAE/g FW), and flavonoids (mg/g FW) in six-week-old tomato plant leaves. Ctrl = control, habitat-adapted heterologous symbiont (HAHS)-free; HAHS = *S. arenicola*; NaCl = HAHS-free and NaCl (100 mM); and HAHS+NaCl = *S. arenicola* and NaCl (100 mM). Values are mean ± standard deviation ($n = 6$). Different letters indicate significant differences according to Tukey tests ($P < 0.05$).

Salinispora arenicola modulates salinity responsive gene expression

To obtain insights into the possible mechanism responsible for alleviating saline stress, the expression of the following five genes was assessed: *SIHBF7*, a transcription factor regulator of salt tolerance; *SIRD29B*, a gene involved in early responses to desiccation; *SISDR1A*, a responsive gene involved in ABA biosynthesis; *SIHKT1,2*, a cation transmembrane transporter involved in Na^+/K^+ homeostasis; and *SIAOX1b*, a gene related with oxidative stress-related genes and ROS scavenging (Figure 7). Most of the genes were upregulated under salt stress conditions, with or without bacteria, except *SIRD29B*, which did not show any changes in expression. Interestingly, the expression of *SIHKT1,2* increased in HAHS-treated plants regardless of whether or not they were subjected to salt stress. *SIHKT1,2* encodes a Na^+/K^+ transporter and plays a crucial role in salinity tolerance mechanisms by alleviating osmotic stress. On the other hand, *SIAOX1b* and *SIHBF7* decreased their expression by half under salt stress conditions in HAHS-treated plants when compared to that of control plants under the same stress conditions. Therefore, HAHS treatment may induce changes that prime plants to better respond to salt-induced osmotic stress to avoid oxidative stress.

Discussion

The indiscriminate use of agrochemicals coupled with the projected increases in population growth and soil salinity are expected to negatively impact the native microbiota of soils, and thus sustainable alternatives must be explored for plant agriculture. In this study, we show a growth-promoting and induced saline resilience effect in tomato plants by the marine actinobacteria *S. arenicola*. This actinobacterium established an endophytic symbiosis with tomato plant roots (Figure 2). The presence of this actinobacteria on tomato seeds relieved the inhibitory effect of salt on tomato germination and enhanced tomato plant growth under normal irrigation conditions (Figures 3, 4). Although salt-induced growth inhibition was still observed with HAHS-treated tomato plants, we observed enhanced quantum yield and photoprotective mechanisms (Figure 5). These changes appeared with increased quantities of photosynthetic pigments like Chl *a*, Chl *b*, β -carotene, and zeaxanthin along with increased amounts of reducing-sugars compared to those present in HAHS-free plants, which suggests improved photoprotection and a specific NPQ mechanism at play. Interestingly, we observed reductions in proline osmolyte and antioxidant activity in plant leaf tissues compared to that of the control plants under saline conditions (Figure 6 and Table 2), which implies that the bacterial treatment might ameliorate the underlying causes that induce these responses.

Furthermore, after scouting for the possible mechanisms involved in these responses based on gene expression, only two genes with significant differences in expression between HAHS-treated and HAHS-free plants were identified (Figure 7). The expression of *SIHKT1,2*, which is involved in ion-transporter encoding, was found to be significantly higher in HAHS-treated plants than in HAHS-free plants under both normal and saline conditions. *SIHKT1,2* expression may explain the ameliorated responses in HAHS-treated plants to salt stress by restoring the K^+/Na^+ balance and relieving osmotic stress.

Microscopic analysis showed that *S. arenicola* established a stable symbiotic interaction with tomato plants (Figure 2). Interestingly, this interaction was observed to change with the salinity conditions of the substrate. Under salt-free conditions, *S. arenicola* was found on epidermal roots cells, while we observed them mainly distributed on root hairs under saline conditions. Both epidermal root cells and root hairs have been recognized as active interaction sites for microbes. The roles of root hairs in plant exudation in part determine the growth of symbiotic bacteria (Mercado-Blanco and Prieto, 2012). Furthermore, an evaluation of the effect of saline stress conditions on root exudation patterns in barley plants by Knipfer et al. (2021) revealed higher water exchange by exudation in the root hair region compared to the mature region (epidermal and endodermal cells) under saline stress, whereas higher water exchange occurs in mature regions in the absence of saline stress. Similar phenomena could occur in tomato roots under saline stress, with an increase in exudation in the root hair region that produces chemotaxis of *S. arenicola* and improves colonization in this region. Moreover, *Salinispora* is an obligate halophile (Mincer et al., 2002). Therefore, it is also possible that *S. arenicola* could migrate out of the plants or to more superficial cells, such as root hairs, in salty soil. In non-salty soil, the bacteria would likely prefer deeper cells to escape low-salinity soil. However, it would be interesting to further explore and define the specific reasons behind this behavior.

Tomato seeds exposed to salt stress showed delayed germination and a reduction in the percentage of germinated seeds. Salt stress disrupts germination by decreasing water uptake due to changes in the hydraulic potential or the activity of phytohormones, such as gibberellins (GAs) and abscisic acid (ABA; Liu et al., 2018). However, HAHS-treated seeds under saline conditions showed the same overall germination percentage as that of control plants, although with a slight delay. GAs activate amylase enzymes that make endosperm energy available in the embryo for germination; however, salinity is known to affect amylase activity (Liu et al., 2018). The recovery of the germination percentage in HAHS-treated seeds may be explained by the high production of saline-stable glycosyl hydrolases by *S. arenicola*, including α -amylase, endoglucanases, and endomanases, which are seen in the *S. arenicola* genome (CNS-205, T00613; Penn and Jensen, 2012) and published in the Kyoto Encyclopedia of Genes and Genomes

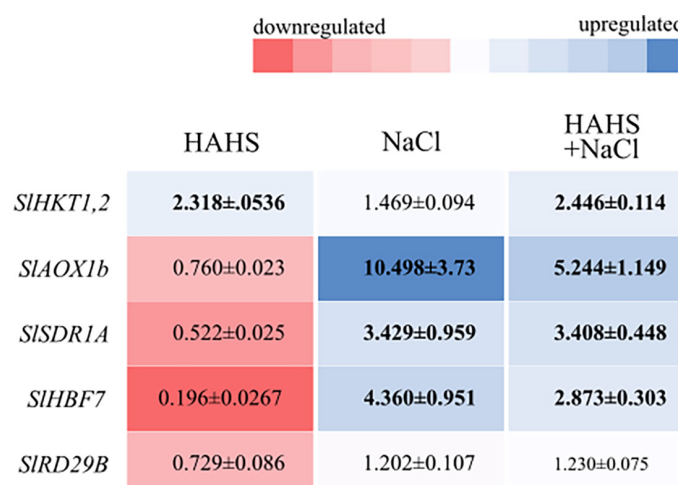

FIGURE 7

Salinispora arenicola modulates the expression of saline response genes in tomato plant leaves. Shade plot showing up- (blue) or downregulated (red) saline responsive genes in plants in the habitat-adapted heterologous symbiont (HAHS), HAHS + NaCl, and NaCl treatments. Gene expression was normalized to control expression. Black numbers inside the colored blocks indicate changes in expression at least 50% lower or higher than that of the control.

database². Therefore, even if GAs are not produced in sufficient concentrations due to low water uptake during imbibition under saline conditions, the enzymes necessary for germination could be provided by the HAHS *S. arenicola*.

Salt exposure also affected the growth of tomato plants, independent of the bacterial treatment. However, HAHS-treated plants were healthier, with thicker stems, greener leaves, and fewer senescent leaves than those of HAHS-free plants. It is possible that the initial effect on growth and perhaps nutrition by HAHS treatment prior to saline irrigation may have prepared the plant to better cope with salt stress conditions. This is consistent with the onset of arrested growth. However, we observed increased photoprotection parameters, such as NPQ, and a reduction in Y(NO) and ETR_{MAX} in HAHS-treated plants under salt stress conditions. ETR_{MAX} increased in HAHS-free plants under salt stress conditions, although this does not seem to be consistent with the observed arrested growth. It could be argued that the electron flow in these plants was directed toward an alternative electron sink pathway, such as photorespiration (Figure 8). Photorespiration is considered to be a significant electron sink pathway for C₃ plants under saline stress (Di Martino et al., 1999; Hossain and Dietz, 2016). Abscic acid-mediated stomata closure is one of the first responses to salt stress (Zhao et al., 2021). Stomata closure decreases the availability of CO₂ in leaves and increases the probability of RuBP oxygenation by Rubisco, which leads to photorespiration (Kalaji et al., 2011). Photorespiration is an energy-expensive process that affects plant growth (Walker

et al., 2016). Therefore, although an increase in ETR_{MAX} was observed in NaCl-treated plants, it does not necessarily translate to increased photosynthesis and growth. HAHS-treated plants seem to prevent this scenario by redirecting quantum energy to dissipation mechanisms, as evidenced by the increase in NPQ, which is consistent with the increase in zeaxanthin pigment. The onset of this NPQ mechanism (Figure 8) allows the plant to reduce PSII pressure and prevent oxidative damage through the reduction of the un-regulated dissipation of energy [Y(NO)], which may result in ROS production at the photosynthetic antenna.

To avoid damage caused by the overproduction of ROS, plants employ an arsenal of antioxidant defense mechanisms, one of which involves the synthesis of molecules with antioxidant properties, such as polyphenols (Salem et al., 2014; Zhao et al., 2015). Antioxidant production is often observed as a plant tolerance mechanism to cope with salt stress (Soares et al., 2019; Akyol et al., 2020). Salt stress affects the electron transport chain, which may favor the formation of potentially harmful ROS that are then scavenged by antioxidants (Ahanger et al., 2017; Numan et al., 2018). Inoculation with several plant growth-promoting rhizobacteria (PGPR), such as *Sphingobacterium* BHU-AV3 in tomato plants, increases phenols and antioxidative enzymes and directly alleviates the induced oxidative stress (Kohler et al., 2009; Hashem et al., 2016; Vaishnav et al., 2020). As expected, phenols and the overall antioxidant activity in plant leaf tissues increased with salt stress in tomato plants. However, no significant changes were observed in phenols or antioxidant activity between HAHS-treated and HAHS-free plants (Table 2) that would improve the performance of the HAHS-treated plants in our experiment.

FIGURE 8

Model of habitat-adapted heterologous symbiont (HAHS)-induced changes in the light reactions of photosynthesis and associated alternative electron transfer pathways. The light energy distribution (pink side) and electron transport (blue side) of the light reactions of photosynthesis are shown. In the control plants, the photochemical energy flows to NADPH, mainly via the linear electron flow (LEF) pathway. Reduced Y(NO) and increased Y(II) indicate a lower probability of non-regulated dissipation but a higher probability of energy conduction to photochemistry as observed for HAHS-treated plants. As a result, plants exhibited higher F_v/F_m values and high plant growth. An increase in Chl content, the Chl a/b ratio, and beta-carotene but a reduction of XC/Chl $a+b$ suggests a reduction of antenna size and an increase of PSII reaction centers in agreement with the increase in photosynthetic performance. High ETR_{MAX} with a small antenna and no PSII damage indicates highly efficient energy consumption in the Calvin cycle induced by HAHS interaction. Plants under salt stress without HAHS did not exhibit differences in Y(NO) or Y(NPQ) dissipation, indicating that no induced protective mechanism was present in the antenna. However, a significant increase in Y(II) linked to lower plant size was found, suggesting that a salt-induced mechanism in tomato plants without HAHS is related to the activation of alternative sinks such as photorespiration. Induced stomatal closure due to saline stress reduces CO_2/O_2 ratio increases the photorespiration probability. Photorespiration reduces the energy destined for photosynthetic Calvin Benson cycle, thereby affecting plant growth. In plants treated with HAHS under saline conditions, the HAHS protects plant photosynthesis by increasing the regulated thermal energy dissipation Y(NPQ) pathway, which decreases the potential for ROS formation in the LHCII antenna. This is also reflected in high F_v/F_m values compared to those of the control and control + NaCl plants. PsBS, pigment-binding protein associated with photosystem II (PSII); VDE, Violaxanthin De-Epoxidase; XC, Xanthophyll cycle pigments (Zx+Ax+Vx); Zx, Zeaxanthin; Ax, Antheraxanthin; Vx, Violaxanthin; LHC, Light-Harvesting Complex; PSII, Photosystem II; OEC, oxygen-evolving complex; PQ, Plastoquinone; PQH, Plastoquinol; AOX, Alternative Oxidase; Cyt b6/f, Cytochrome b6/f; PC, Plastocyanin; PSI, Photosystem I; ROS, Reactive oxygen species; ETR_{MAX} , Maximum electron transfer rate; Y(NO), Quantum yield of non-regulated heat dissipation and fluorescence emission; Y(II), Effective photochemical quantum yield of PSII; Y(NPQ), Quantum yield of light-induced non-photochemical fluorescence quenching.

It is likely that the higher NPQ levels observed in HAHS-treated plants under salt stress may contribute to avoiding ROS formation and thus reducing oxidative stress beforehand. Therefore, although antioxidant activity and metabolites were equivalent in plants with or without HAHS treatment, oxidative stress may have been reduced in HAHS-treated plants. Further experiments that analyze ROS production, ROS half-life times, and other antioxidant metabolites are needed to answer this question.

The presence of bacteria alone induced a drop in reducing sugars even though ETR_{MAX} was enhanced. An increase in ETR_{MAX} suggests an increase in sugar production. However, it is likely that the rate of sugar consumption also increased in HAHS-treated plants, with sugars being redirected to growth and development (as suggested by the high shoot and root lengths and the number of branches) to sustain the symbiotic relationship with the bacteria. The symbiotic consumption of photosynthetically produced sugars has been demonstrated for other root symbiotic interactions, such as mycorrhizal

interactions (Schweiger et al., 2014). On the other hand, salt-stress conditions lowered the sugar levels in HAHS-free plants. This was also observed in ETR_{MAX} levels, which were increased by salt stress in HAHS-free plants. However, considering that growth was inhibited, the flow of the electrons at ETR_{MAX} may follow alternative electron sink pathways. Moreover, the rapid secretion of photosynthetically produced molecules other than sugars, such as osmolytes, can lead to high ETR_{MAX} but low growth rates (Demmig-Adams et al., 2017). Interestingly, salt stress conditions had no significant effect on reducing sugars in HAHS-treated plants. This may be due to a reduction in ETR_{MAX} by redirecting quantum energy to dissipative NPQ mechanisms and a decrease in the sugar used, as suggested by the reduced growth. This coordinated response may favor the plant by avoiding energy waste and oxidative stress.

Proline accumulation in the leaves and roots is considered to be a salt-sensitive trait in tomato plants that may be used to select varieties with different degrees of tolerance (Gharsallah et al., 2016). Many reports have shown that the

proline concentration increases in the shoots of plants grown under saline conditions (Vicente et al., 2004; Amini and Ehsanpour, 2005; Roy et al., 2014). Plants accumulate proline as a non-toxic and protective compatible solute, which participates in cytosolic osmotic adjustments and balances osmotic pressure differences between the cytosol and vacuoles (Parida and Das, 2005; Munns and Tester, 2008; Kamanga et al., 2020). Additionally, proline acts as an energy supplier and a signaling/regulatory molecule that can activate responses involved in the adaptation process, which helps to improve salinity tolerance (Maggio et al., 2002). In agreement with this, our experiments showed increased proline levels when plants were exposed to salt stress conditions, although this increase was lower in HAHS-treated plants (Table 2). As with any stimuli response mechanism, a quantitative level of damage or impact must induce a protective response of a similar scale. In this case, a lower response in HAHS-treated tomatoes does not necessarily mean a lower capacity to protect against the damaging effects of salt, as suggested by the observed growth and photosynthetic performance (Figures 4, 5). Instead, this could be due to lower adverse effects produced by Na^+ ions. A potential hypothesis is that the activation of ion transporters ameliorates some of the adverse effects of Na^+ . Which is line with many other studies that have shown that the activation of HKT1 transporters under saline stress conditions increases salinity tolerance in plants (Rodríguez-Navarro and Rubio, 2006). This aligns well with the observed overexpression of *SIHKT1,2* in HAHS-treated plants with regular or saline irrigation (Figure 7). The increased expression of *SIHKT1,2* in HAHS-treated plants, even in the absence of salt stress, could serve as a mechanism that prepares the plants to withstand stress by ameliorating other stress responses. In agreement with this, HKT1 induction has been proposed as a protective mechanism to salinity stress conditions in halophytes (Rodríguez-Navarro and Rubio, 2006) or in salt sensitive plants, where growth promoting bacteria (Zhang et al., 2008) and synthetic bacterial community (Schmitz et al., 2022) induced HKT1 expression. However, *SIHKT1,2* gene behavior in response to HAHS even in salty or regular conditions, needs further investigation. Additionally, the decreased expression of *SLAOX1b* and *SIHBF7* under saline conditions in HAHS-treated plants compared with those of the control plants indicates lower damage caused by free radicals and other salt-related effects. *Salinispora* is endemic to marine ecosystems, and *Salinispora* strains offer a vast array of potential benefits to their ubiquitous hosts. These strains are recognized for their antimicrobial activity (Cardoso-Martínez et al., 2015; Chase et al., 2021), ability to modify microbiotas (Tuttle et al., 2019), and ability to degrade recalcitrant materials. The particular strain used in this study was isolated from corals. However, many other strains have been obtained from other marine sources, including ascidians (Steinert et al., 2015), seaweeds (Jensen et al., 2005), soft corals (Louka et al., 2022), and sponges (Kim et al., 2005), which suggests that *Salinispora*

is a ubiquitous symbiont. However, we were surprised to find that this actinobacterium was able to sustain a stable interaction with a terrestrial plant, although *S. arenicola* is closely related to several terrestrial actinobacteria (Trujillo et al., 2014). Thus, the ability to sustain this interaction may be due to a conserved mechanism present among terrestrial or marine actinobacteria or an evolutionary memory in *S. arenicola* metabolism that allows it to interact with terrestrial plants. A better understanding of the interactions between *S. arenicola* and terrestrial plants may allow us to identify the fundamental mechanisms necessary for sustaining symbiotic relationships, promoting growth, and alleviating saline stress. We define this interaction as a habitat-adapted heterologous symbiosis following the guidelines of Rodríguez et al. (2008). However, ecological interactions are not always positive. For example, Chhun et al. (2021) demonstrated that *S. arenicola* could inhibit the growth of some marine phototrophs. Therefore, it is essential to further study actinobacteria interactions to mitigate any potential side effects in terrestrial plants.

Data availability statement

The original contributions presented in this study are included in the article/Supplementary material, further inquiries can be directed to the corresponding author.

Author contributions

HO-A, AB-E, and RH-H designed and formulated the concept of the study. AB-E, RH-H, RP-R, CS-H, PP-S, EJ-C, OP, FC, ML-G, MH-O, LM-M, and HO-A performed part of the measurements in laboratory and interpreted part of the results. AB-E, IM-C, FR-Z, and HO-A carried out the analysis of the data. AB-E, RH-H, IM-C, and HO-A draft the manuscript with contributions of CS-H and PP-S. All authors approved the final manuscript.

Funding

This work was partially financed by a PRODEP project (UDG-PTC-1460) provided to HO-A, the Universidad de Guadalajara (P3E-2021; awarded to HO-A); the FORDECYT-PRONACES CONACYT Project (1576/2019) awarded to HO-A, AB-E, OP, and FC; and a CONACyT grant (INFR-2012-01188065). AB-E acknowledge CONACYT for its support through the program *Investigadoras e Investigadores por México* (No. 2196).

Acknowledgments

We thank the volunteer biology students Olmedo Valadez Leonardo and Sánchez González Ian Cristian for their help in the lab. We also thank Asdrúbal Burgos for the discussions and valuable comments on the draft. We are grateful to Andrea Liévana MacTavish for her English language review and Carolina Mateos-Salmón for the illustration in **Figure 1**.

Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

An ever-increasing population has issued an open challenge to the agricultural sector to provide enough food in a sustainable manner. The upsurge in chemical fertilizers to enhance food production had resulted in environmental problems. The objective of the current study is to assess the utilization of biostimulants for sustainable agricultural production as an alternative to chemical fertilization. For this purpose, two pot experiments were conducted to examine the response of radish against individual and combined applications of biostimulants. In the first experiment, the effects of chemical fertilizer (CK), glycine (G), lysine (L), aspartic acid (A), and vitamin B complex (V) were studied. The results demonstrated that V significantly improved the transpiration rate (81.79%), stomatal conductance (179.17%), fresh weight (478.31%), and moisture content (2.50%). In the second experiment, tested treatments included chemical fertilizer (CK), Isabion® (I), glycine + lysine + aspartic acid (GLA), moringa leaf extract + GLA (M1), 25% NPK + M1 (M2). The doses of biostimulants were 5g L⁻¹ glycine, 1g L⁻¹ lysine, 2g L⁻¹ aspartic acid, and 10ml L⁻¹ moringa leaf extract. The photosynthetic rate improved significantly with GLA (327.01%), M1 (219.60%), and M2 (22.16%), while the transpiration rate was enhanced with GLA (53.14%) and M2 (17.86%) compared to the CK. In addition, M1 increased the stomatal conductance (54.84%), internal CO₂ concentration (0.83%), plant fresh weight (201.81%), and dry weight (101.46%) as compared to CK. This study concludes that biostimulants can effectively contribute to the sustainable cultivation of radish with better growth and yield.

KEYWORDS

biostimulants, fertilization, glycine, radish, vegetable production

Introduction

The main challenge the world is facing today is to feed its increasing population using less and highly efficient inputs (Bashir et al., 2021). It is estimated that by 2050 the population will increase to 9.7 billion; this demands a 70% increase in food production to feed such a huge population (Del Buono, 2021).

On the other hand, the key factors influencing crop productivity are limited available land, climate change, the genetic potential of crops, and depletion of natural resources (Maja and Ayano, 2021). The Green Revolution was a promising approach to food security, but in the long run, its adverse impact on agriculture, human health, and the environment were observed worldwide (John and Babu, 2021).

There is rampant overuse of chemical fertilizers and about 1.9×10^{11} tons of them are used globally (Wan et al., 2021). Conventional agricultural patterns that include excessive use of fertilizers and pesticides have increased crop production but have negatively impacted food quality and environmental sustainability (Chouhan et al., 2021). The excessive use of chemical fertilizers contributes to groundwater and atmospheric pollution, poor food quality, increased input cost with lower outputs, deterioration of the soil quality and fertility status, reduced nutrient efficiency, susceptibility to pathogens, nutrient leaching, greenhouse gases emission, and other abiotic stresses (Rahman and Zhang, 2018; Godlewska et al., 2021; Wan et al., 2021).

To improve crop yield, quality, and environmental sustainability, various breeding programs have been attempted. The need for sustainable and modernized agriculture makes it imperative to improve plant growth and development functions, stimulate plant metabolism, and improve environmental safety (Bashir et al., 2021). Biostimulants are organic/ inorganic substances gaining popularity due to their incredible benefits for better plant growth and development. They are involved in the stimulation of plant physiological processes and improved plant shoot/ root growth. They minimize chemical fertilizer use, are cost-effective, enhance plant's tolerance to biotic and abiotic stresses, boost yield, and, more importantly, offer an environmentally friendly approach (Bashir et al., 2021; Rehim et al., 2021; Bell et al., 2022; Samuels et al., 2022). European Biostimulant Industry Council (EBIC) reported that biostimulants improve the nutrient use efficiency and uptake in plants, counteract the influence of biotic and abiotic stresses, and improve crop quality (Bashir et al., 2021). Based on their origin, biostimulants are generally classified as humic, amino-acid/nitrogen-containing, inorganic, chitosan/ biopolymers, beneficial microbes, seaweed, and botanical extracts (Samuels et al., 2022).

One of the beneficial effects of biostimulants to be identified recently is crop yield enhancement. Moringa leaf extract is a potent bio-stimulator that improves plant growth and yield. It contains essential nutrients, sugars, amino acids, phytohormones, vitamins, and antioxidants. It benefits the plants by improving seed germination, nutrient status, growth and yield processes, fruit quality, chlorophyll content, and biometric attributes (Abd El-Mageed et al., 2017; Arif et al., 2022). Moreover, using biostimulants also promotes nutrient uptake, enzymatic activity, crop physiology, green leaf pigment, plant metabolism, and molecular processes (Rehim et al., 2021).

The use of amino acid-based biostimulants positively impacts the plants' metabolic processes and favors sustainable agriculture (Alfosea-Simón et al., 2020). In addition, animal-based protein hydrolysates significantly increase the gaseous exchange and chlorophyll fluorescence (Cristiano and De Lucia, 2021). Without chemical fertilizers, the foliar application of biostimulants, vitamins, and coenzyme Q10 significantly improves the radish root-shoot biomass under green-house conditions (Rehim et al., 2021). Radish is of various cultivars, including shapes (oval, round, spindle, icicle, cylindrical, long, conical, half long), color (white, red, pink, black, purple), and flavor. The crop is cultivated worldwide on a large scale; its extensive cultivation is better due to its taste, high nutritional content, low calories, and myriad health benefits (Godlewska et al., 2021). In Asia, it is one of the most economically important crops; it is cultivated for its soft leaves and root, which is consumed raw, dried, pickled, or simmered (Lee and Park, 2020). Radish has also been reported to reduce health risks associated with cancer, stone formation, constipation, jaundice, and anxiety (Godlewska et al., 2021). As per published data, biostimulants play a vital role in the yield enhancement of various vegetables along with controlled chemical fertilization. Still, there is a considerable gap in identifying the potential benefits of biostimulants for morpho-physiological parameters of radish. This makes the current study timely and important to identify the influence of biostimulants on sustainable agriculture.

Considering the positive effects of biostimulants on plant growth, development, and yield, the present study was undertaken with the following objectives: (i) identify the physiological response of radish against individual and combined use of biostimulants, (ii) estimate the efficacy of biostimulants on crop morphology, and (iii) find an alternative to minimize the use of chemical fertilizers. We hypothesized that the use of biostimulants will not just only improve the radish production but will also enhance the photosynthetic rate and other related physiological indices.

Materials and methods

Two pot experiments were conducted to assess the role of biostimulants on radish yield, morphology, and physiology. A brief description of each experiment is given below.

Experiment 1

The experiment was conducted from September to December 2021 at the research area of the Department of Soil Science (30.258° E, 71.515° N), Bahauddin Zakariya University, Multan, Pakistan. The climate of the Multan region is semi-arid to arid. The pots were lined with plastic sheets and filled with

15 kg soil having the following physicochemical properties: pH 7.7, EC 0.5 dS·m⁻¹, organic matter 0.4%, saturation percentage 34%, texture loam, nitrogen (N) 221 mg kg⁻¹, phosphorus (P) 8.2 mg kg⁻¹, and potassium (K) 30.1 mg kg⁻¹.

The experiment consisted of five treatments with three replications in a completely randomized design (CRD). The tested treatments were: recommended chemical fertilizer (CK; N 61.8 kg ha⁻¹, P 49.4 kg ha⁻¹, K 61.7 kg ha⁻¹), glycine (G; C₂H₅NO₂), lysine (L; C₆H₁₄N₂O₂), aspartic acid (A; C₄H₇NO₄), and vitamin B complex (V; vitamin B1, B6, B12). The doses of biostimulants were maintained the same according to the crop's N requirements (61.8 kg ha⁻¹). G, L, and A were purchased from Sigma Aldrich, while V was purchased from Martin Dow Market Ltd.

Six radish seeds (cultivar "Mino early long white," Nongwoo Bio) were sown in each pot on 24 September 2021. Smaller seedlings were later eradicated, and only two plants per pot were maintained. The foliar application was performed four times in the morning on sunny and windless days (15 October, 25 October, 5 November, and 15 November). Plants were harvested on 9 December 2021. Regular manual weed eradication and irrigation practices were maintained during the growth period. Plant samples (rosette and root) were collected after harvesting for further analysis.

Experiment 2

The experiment was conducted between October 2021 and January 2022 at the research area of the College of Agriculture (30.97° E, 70.96° N), Bahauddin Zakariya University, Bahadur Sub-campus Layyah, Pakistan. The region has a desert climate with usually no rainfall, and similar to experiment one, the pots were lined with plastics sheets and filled with 8 kg soil (pH 7.8, EC 0.1 dS·m⁻¹, organic matter 0.7%, saturation percentage 28%, texture sandy loam, N 450 mg kg⁻¹, P 7.1 mg kg⁻¹, and K 62.34 mg kg⁻¹).

The experiment comprised five treatments with three replications in a completely randomized design (CRD). The treatments included: recommended chemical fertilizer (CK; N 61.8 kg ha⁻¹, P 49.4 kg ha⁻¹, K 61.7 kg ha⁻¹), Isabion® (I), glycine + lysine + aspartic acid (GLA), moringa leaf extract + GLA (M1), 25% NPK + M1 (M2). The doses of biostimulants were 5 g L⁻¹ glycine, 1 g L⁻¹ lysine, 2 g L⁻¹ aspartic acid, and 10 ml L⁻¹ moringa leaf extract. Whereas, Isabion® was used as recommended by the manufacturer. G, L, and A were purchased from Sigma Aldrich, while I was purchased from Syngenta, Pakistan. Moringa leaf extract was prepared at the laboratory. Fresh moringa (50 g) leaves were weighed and soaked in 200 ml distilled water for 12 h, then sonicated, centrifuged, and stored supernatant for further use.

Similar to experiment one, six seeds were sown in each pot on 21 October 2021, and two healthy plants were maintained.

Four foliar applications of biostimulants were applied on 16 November, 26 November, 6 December, and 16 December 2021. The crop was harvested on 13 January 2022, and plant rosette and root samples were collected for further analysis.

Gaseous exchange parameters

Gaseous exchange parameters (photosynthetic rate, transpiration rate, internal CO₂, and stomatal conductance) were measured at vegetative maturity (ten days before harvesting) using an infrared gas analyzer (IRGA; Analytical Development Company, Hoddesdon, UK). Readings were taken between 8:00 and 9:00 a.m. The IRGA chamber was attached to a fresh expanded radish leaf and logged for ten seconds (Scafaro et al., 2018; Zaheer et al., 2020).

Photosynthetic pigments

To determine the chlorophyll a + b content, fresh leaf samples (0.5 g) were collected and cut into fine pieces (<0.25 mm²). The samples were dipped in ethanol (96% v/v) for chlorophyll extraction and placed in darkness for 24 h. Afterward, the spectrophotometer was used to determine the chlorophyll a + b contents by measuring absorbance at 665 and 649 nm. The following equation was used to calculate the chlorophyll a + b contents (mg g⁻¹).

$$\text{Chlorophyll a + b} = \frac{(5.1 \times A_{665} + 20.24 \times A_{649}) \times V}{m}$$

Where A₆₆₅ and A₆₄₉ is the absorbance value, V is the volume of solution (liters), and m is the weight (g) of the sample used (Yuan et al., 2016).

Leaf greenness index

The leaf greenness index was measured using SPAD 502 Plus Chlorophyll Meter (Konica Minolta, Osaka, Japan). Three fully expanded fresh leaves from each pot were selected, and the readings were measured three times. The average was calculated to estimate leaf greenness.

Fresh and dry weight

Plant samples (rosette and roots) were collected and washed at harvest, and fresh plant weight was measured. Later on, the samples (root and rosette) were oven-dried at 65°C until a constant weight was achieved. The plant dry weight was measured using a weighing balance and recorded in grams.

Moisture content

The moisture content in samples was determined using the following formula.

$$\text{Moisture content (\%)} = \frac{(\text{Fresh weight} - \text{Oven dry weight})}{\text{Fresh weight}} \times 100$$

Where fresh weight is the weight of plant samples at the time of harvest, and oven-dry weight was obtained after drying the samples at 65°C until a constant weight was achieved. A weighing balance was used for weighing, and readings were taken.

Biometric analysis

The biometric analysis of radish included root diameter and length. After harvest, the radish was washed, and its length was measured using a measuring tape.

Whereas, the diameter of radish was determined using Vernier calipers.

Statistical analysis

Data sets were represented as means \pm standard deviation (SD), and CRD was the basis of the analysis of variance (ANOVA). The least significant difference (LSD) test was used for comparison at a 5% probability level. Statistical softwares R-studio® and Statistix 9® were used for statistical analysis. Microsoft Excel 2016 was used for data processing and visualization. Pearson correlation analysis was performed using R-studio.

Results

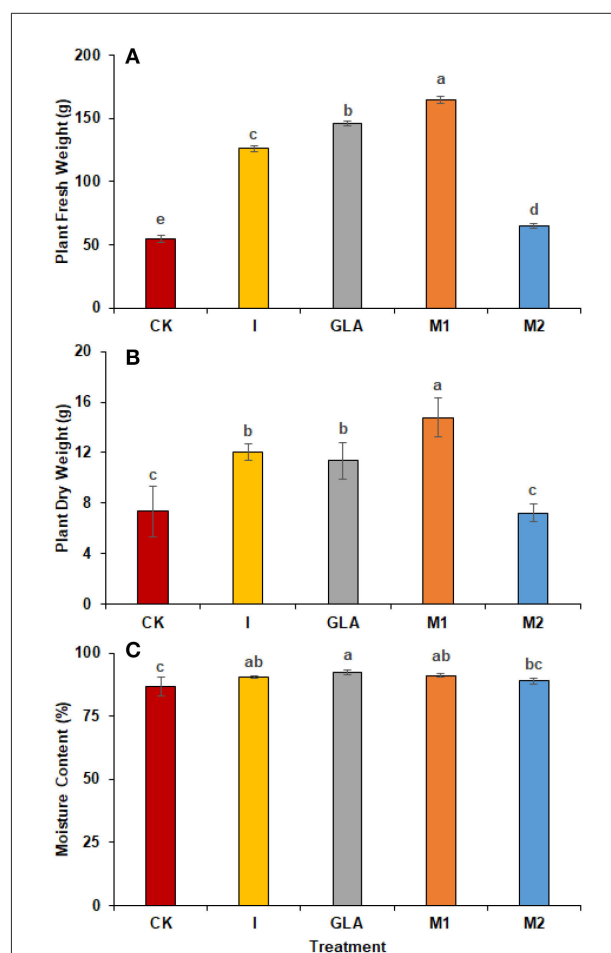

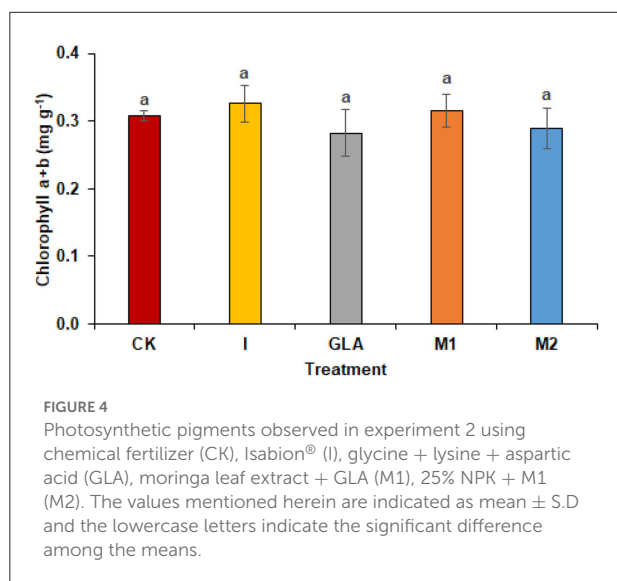

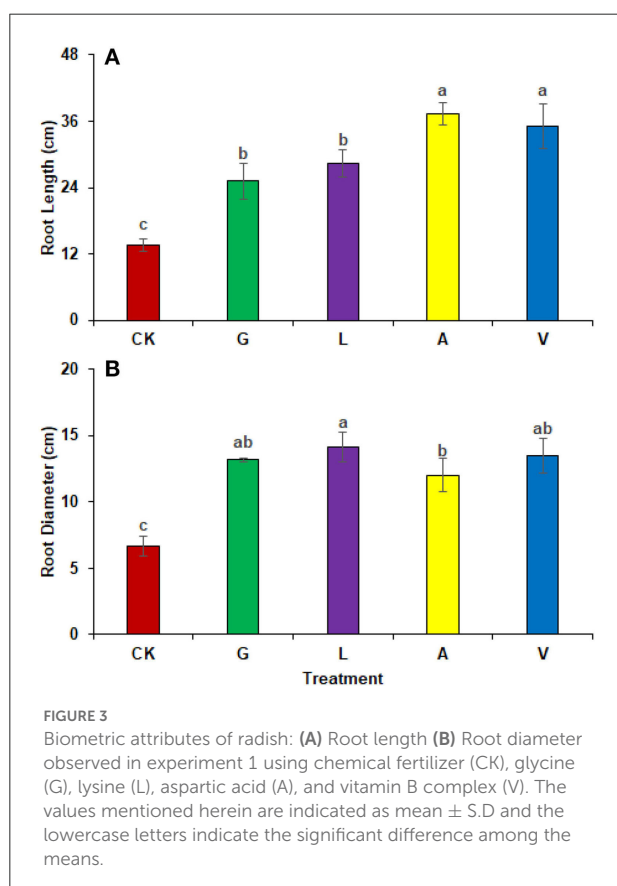

The radish growth performance improved significantly with the use of biostimulants. In our experiments, the control group contained plants sprayed with the recommended dose of chemical

fertilizers (CK). All the treatments are compared with CK.

Experiment 1

Gaseous exchange parameters

Photosynthetic rates showed insignificant changes with the identified values as $4.03 \mu\text{mol m}^{-2} \text{s}^{-1}$ in CK, $4.23 \mu\text{mol m}^{-2} \text{s}^{-1}$ in G, $4.00 \mu\text{mol m}^{-2} \text{s}^{-1}$ in L, $4.61 \mu\text{mol m}^{-2} \text{s}^{-1}$ in A, and $3.78 \mu\text{mol m}^{-2} \text{s}^{-1}$ in V respectively. Transpiration rate was significantly increased with the application of V (81.79%), followed by A (47.77%), L (36.77%), and G (1.17%), respectively, compared with CK. The identified values were $0.97 \text{ mmol m}^{-2} \text{s}^{-1}$ in CK, $1.17 \text{ mmol m}^{-2} \text{s}^{-1}$ in G, $1.33 \text{ mmol m}^{-2} \text{s}^{-1}$ in L, $1.43 \text{ mmol m}^{-2} \text{s}^{-1}$ in A, and $1.76 \text{ mmol m}^{-2} \text{s}^{-1}$ in V

respectively. Stomatal conductance was also increased with a similar trend where V showed the highest increase (179.17%), followed by A (141.67%), L (87.50%), and G (47.92%). The values observed were $0.16 \text{ mmol m}^{-2} \text{ s}^{-1}$ in CK, $0.24 \text{ mmol m}^{-2} \text{ s}^{-1}$ in G, $0.30 \text{ mmol m}^{-2} \text{ s}^{-1}$ in L, 0.39 in A, and $0.45 \text{ mmol m}^{-2} \text{ s}^{-1}$ in V. Internal CO_2 concentration was significantly improved with the application of biostimulants. The highest increase was observed with G (15.04%), L (14.69%), V (13.81%), and A (11.70%), respectively, compared with CK. The values reported were $379.00 \mu\text{mol mol}^{-1}$ in CK, $436.00 \mu\text{mol mol}^{-1}$ in G, $434.67 \mu\text{mol mol}^{-1}$ in L, $423.33 \mu\text{mol mol}^{-1}$ in A, and 431.33 in V.

Photosynthetic pigments

The foliar application of biostimulants on radish increased the photosynthetic pigments in leaves. Chlorophyll contents were improved significantly with the application of A (45.81%), followed by V (43.89%), L (41.28%), and G (16.01%) as compared to CK (Figure 1A). The identified values were 1.15 mg g^{-1} in CK, 1.33 mg g^{-1} in G, 1.62 mg g^{-1} in L, 1.68 mg g^{-1} in A, and 1.65 mg g^{-1} in V, respectively. The SPAD measurements demonstrated that G enhanced (9.91%) the greenness index of the leaves, while the values observed were 47.31 in CK, 52.00 in G, 46.70 in L, 45.37 in A, and 46.99 in V (Figure 1B).

Fresh and dry weight

A significant improvement in plant total fresh and dry weights were observed with the application of biostimulants. The identified values were 121.33 g in CK, 466.67 g in G, 441.67 g in L, 695.00 g in A, and 701.67 g in V, respectively. The most significant change in fresh plant weight was observed in radish plants receiving V (478.31%), followed by A (472.82%), G

(284.63%), and L (264.02%) (Figure 2A). In addition, plant dry weight improved significantly in A, followed by L, V, and G (364.73, 337.90, 364.73, and 212.50%) compared to the CK (Figure 2B). The identified values were 11.33 g in CK, 34.78 g in G, 48.74 g in L, 51.72 g in A, and 48.61 g in V.

Moisture content

The use of biostimulants influenced radish moisture contents. The moisture contents were higher in V (2.50%), followed by A (1.94%), and G (1.92%) as compared to CK. Whereas, the identified values were 90.80% in CK, 92.55% in G, 88.97% in L, 92.56% in A, and 93.07% in V respectively (Figure 2C).

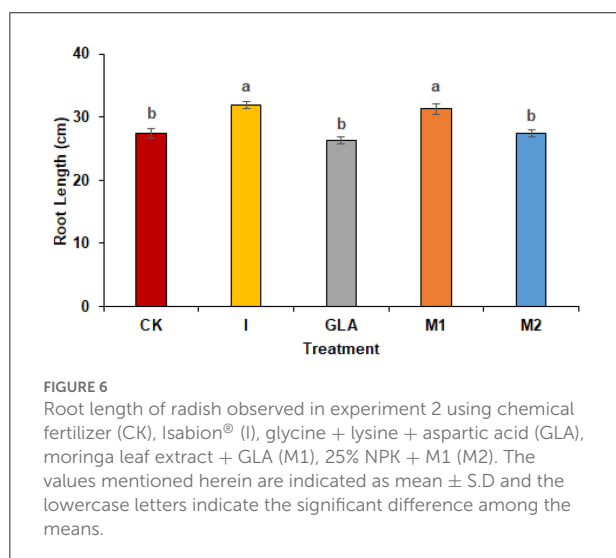

Morphological analysis

The biostimulants influenced the root length and diameter significantly. Root length was increased significantly with A (172.86%), followed by V (157.50%), L (107.27%), and G (84.10%) in comparison with CK. The identified values were 13.67 cm in CK, 25.17 cm in G, 28.33 cm in L, 37.30 cm in A, and 35.20 cm in V, respectively (Figure 3A). Similarly, root diameter was increased with L (111.89%), V (102.40%), G (97.40%), and A (79.91%) as compared to CK. The values observed were 6.67 cm in CK, 13.17 cm in G, 14.13 cm in L, 12.0 cm in A, and 13.50 cm in V, respectively (Figure 3B).

Experiment 2

Gaseous exchange parameters

Similar to experiment one, biostimulants significantly improved the plants' physiology in experiment two (Figure 4). Photosynthetic rates were significantly enhanced with GLA (327.01%), M1 (219.60%), and M2 (22.16%), respectively. The identified values were $3.64 \mu\text{mol m}^{-2} \text{ s}^{-1}$ in CK, $3.42 \mu\text{mol m}^{-2} \text{ s}^{-1}$ in I, $15.54 \mu\text{mol m}^{-2} \text{ s}^{-1}$ in GLA, $11.63 \mu\text{mol m}^{-2} \text{ s}^{-1}$ in M1, and $4.45 \mu\text{mol m}^{-2} \text{ s}^{-1}$ in M2 respectively. The transpiration rate was significantly improved with GLA (53.14%) and M2 (17.86%) compared to the CK. The identified values were $4.46 \text{ mmol m}^{-2} \text{ s}^{-1}$ in CK, $4.31 \text{ mmol m}^{-2} \text{ s}^{-1}$ in I, $6.83 \text{ mmol m}^{-2} \text{ s}^{-1}$ in GLA, $4.03 \text{ mmol m}^{-2} \text{ s}^{-1}$ in M1, and $5.26 \text{ mmol m}^{-2} \text{ s}^{-1}$ in M2 respectively. In addition, the stomatal conductance was enhanced significantly with M1 (54.84%) followed by GLA (43.01%), and internal CO_2 concentration was improved with M1 and M2 (0.83 and 1.93%, respectively) compared to CK. Whereas, the values of stomatal conductance were $0.31 \text{ mmol m}^{-2} \text{ s}^{-1}$ in CK, $0.30 \text{ mmol m}^{-2} \text{ s}^{-1}$ in I, $0.44 \text{ mmol m}^{-2} \text{ s}^{-1}$ in GLA, $0.48 \text{ mmol m}^{-2} \text{ s}^{-1}$ in M1, and $0.28 \text{ mmol m}^{-2} \text{ s}^{-1}$ in M2 respectively. Moreover, the values of internal CO_2 concentration were $363.33 \mu\text{mol mol}^{-1}$ in CK,

344.67 $\mu\text{mol mol}^{-1}$ in I, 338.67 $\mu\text{mol mol}^{-1}$ in GLA, 366.33 $\mu\text{mol mol}^{-1}$ in M1, and 370.33 in M2.

Photosynthetic pigments

The photosynthetic pigments of radish leaves showed non-significant results with the spraying of biostimulants. Chlorophyll a + b was highest in I (5.11%) and M1 (1.47%) as compared to CK. The identified values were 0.31 mg g^{-1} in CK, 0.33 mg g^{-1} in I, 0.28 mg g^{-1} in GLA, 0.31 mg g^{-1} in M1, and 0.29 mg g^{-1} in M2 respectively (Figure 4).

Fresh and dry weight

A significant increase in plant total fresh and dry weights were observed with the application of biostimulants. The highest plant fresh weight was achieved in plants receiving M1 (201.81%), followed by GLA (167.06%), I (130.47%), and M2 (18.29%). The identified values were 54.67 g in CK, 126.00 g in I, 146.00 g in GLA, 164.00 g in M1, and 64.67 g in M2, respectively (Figures 5A,B). In addition, plant dry weight was significantly improved in M1, followed by I and GLA (101.46%, 63.84%, and 54.93% higher than CK). The observed values were 7.33 g in CK, 12.01 g in I, 11.36 g in GLA, 14.77 g in M1, and 7.22 g in M2 (Figure 5C).

Moisture content

Moisture contents were also influenced by the use of biostimulants and were significantly improved with GLA (6.51%) followed by M1 (5.16%) and I (4.48%) as compared to CK. The identified values were 86.59% in CK, 90.47% in I, 92.23% in GLA, 91.06% in M1, and 88.82% in M2 respectively (Figure 6).

Morphological analysis

Radish length was influenced significantly by the use of biostimulants and was shown by I (16.52%) followed by M1 (14.09%) and M2 (0.35%) as compared to CK. The values observed were 27.42 cm in CK, 31.91 cm in I, 26.33 cm in GLA, 31.28 cm in M1, and 27.52 cm in M2, respectively (Figure 7).

Pearson correlation

Photosynthesis is strongly positively correlated with transpiration rate and moderately associated with stomatal conductance. It has a weak negative correlation with internal CO_2 assimilation and chlorophyll content. Transpiration showed a strong negative association with internal CO_2 assimilation, chlorophyll content, fresh weight, and dry weight. Moreover, a weak positive correlation was observed between stomatal conductance and root diameter. Stomatal conductance

showed a strong positive association with root length and a weak positive relationship with root diameter. Internal CO_2 concentration strongly correlates with chlorophyll content, fresh weight, and dry weight. In addition, a moderate positive relation with root diameter was observed. Chlorophyll content showed a strong positive correlation with fresh and dry weight, moderate relation with root diameter, and a weak association with moisture content. Plant fresh weight had a strong positive relation with dry weight and moderate association with moisture content, root length, and diameter. Moreover, dry weight had a strong positive correlation with root diameter, moderate correlation with root length, and a weak association with moisture content. Root length and diameter were also positively correlated with each other (Figure 7).

Discussion

An increasing population along with climate change has threatened agricultural production. Today's need is to develop new sustainable products to increase production and yield and support organic farming (Godlewska et al., 2021). In this scenario, biostimulants can play an environment-friendly role to increase crop productivity, which is associated with the minimal use of chemical fertilizers. In the current study, individual and the combined application of biostimulants showed a potential to improve radish morphology, growth, and yield.

Our results demonstrated an increase in leaf gas exchange attributes. The use of biostimulants improved the transpiration rate, stomatal conductance, and internal CO_2 in plants (Figures 8, 9). Biostimulants can potentially improve water-use efficiency in plants (Jiménez-Arias et al., 2022), which also increases turgor pressure in radish leaf guard cells and increases gaseous exchange attributes. Leaf greenness and chlorophyll are essential in transmitting and absorbing solar energy (Ahmad et al., 2021). The results showed that amino acid-based biostimulants significantly improved the chlorophyll content (Figures 1, 4). The increased pigments with biostimulants can be associated with water and ion use efficiency, better stomatal conductance, photosynthetic capacity, and bioactive compounds, i.e., vitamins (Ali et al., 2020), amino acids, and mineral nutrients (Bahmani Jafarlou et al., 2022). In addition, moringa leaf extract also improves chlorophyll content with its induced sink capability through the supply and translocation of photo-assimilates from leaves to other parts of a plant that improve fruit quality (Arif et al., 2022).

In addition, the use of biostimulants showed a positive response to radish yield and growth. The results determined that the use of A, V, and M1 significantly improved the radish yield and production (Figures 2, 5). Whereas a low yield was observed with the combined use of biostimulants and mineral fertilizers. The amino acid-based biostimulants positively impact plant physiology and metabolism, while the interaction of

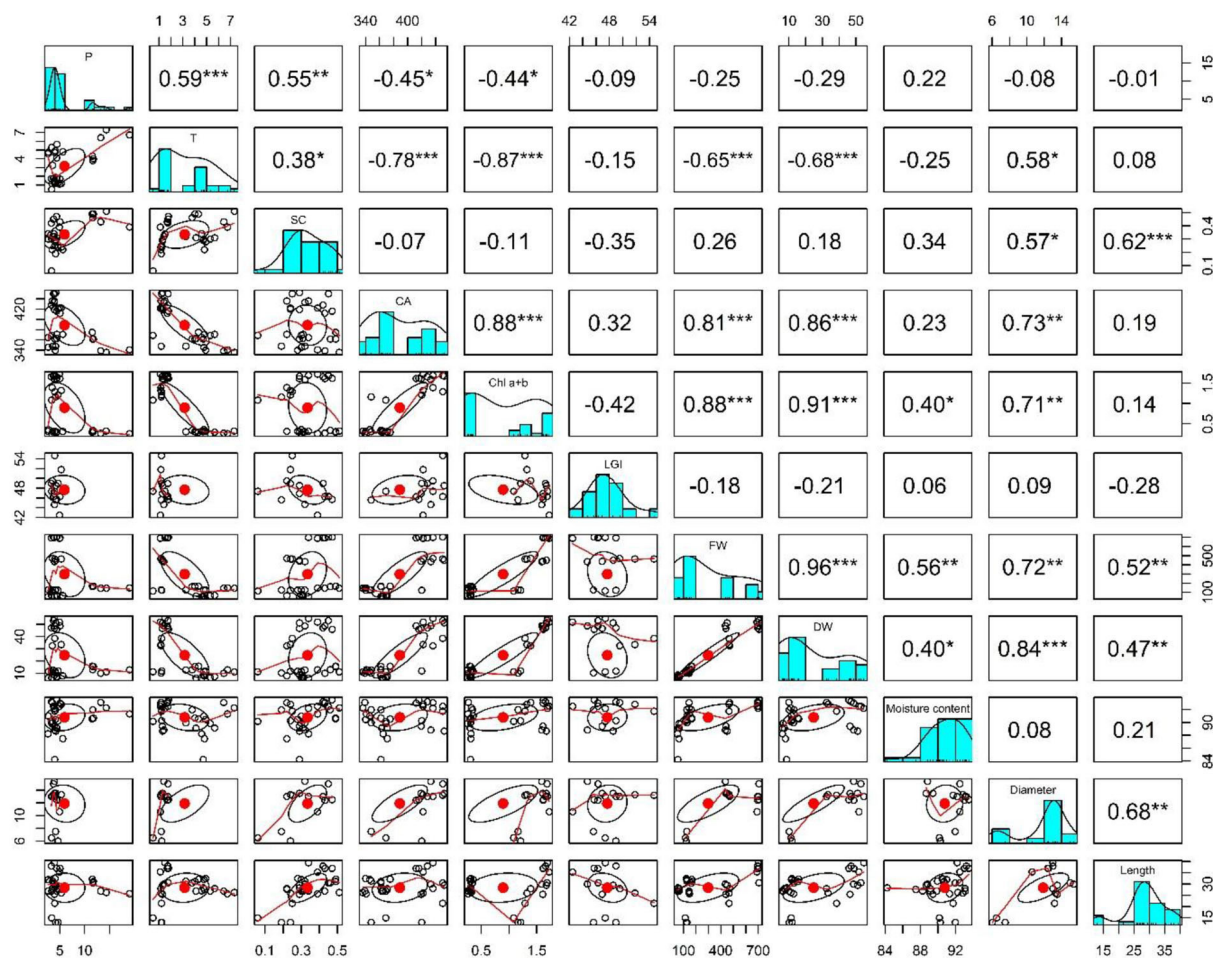

FIGURE 7

Pearson correlation indicating the relation between assessment parameters: P is Photosynthetic rate, T is Transpiration rate, SC is Stomatal conductance, CA Internal CO₂ concentration, Chl a+b is Photosynthetic pigments, LGI is Leaf greenness indexes, FW is Plant fresh weight, DW is Plant dry weight, Moisture content is Moisture content, Diameter is Root diameter, and Length is Root length. The * indicates weak relationship, ** shows strong, and *** shows very strong relationship.

biostimulants when applied in combination is still unknown (Alfosea-Simón et al., 2021). Plants can produce amino acids and vitamins, but it requires considerable energy; therefore, if applied exogenously, they can save energy and improve their development at different growth stages (Popko et al., 2018). In addition, improved yield can also be related to the potential of Vitamins B₁ and B₆ to develop resistance in plants against oxidative stress (Asensi-Fabado and Munné-Bosch, 2010). Biostimulants also act as signal-transducing molecules and benefit plant physiological processes that contribute to higher yield and biomass (Khan et al., 2019).

The results of both experiments also suggest that foliar application of amino acids and vitamins improves the radish root morphology (Figures 3, 6). Previous literature reported that root growth is also stimulated with the application of biostimulants having vitamin B-complex (Rehim et al., 2021). Vitamins B₁ is a cofactor that contributes significantly to

improve primary metabolic processes in plants (glycolysis, tricarboxylic acid cycle, and pentose phosphate pathway) that ultimately increases plant growth performances (Soppelsa et al., 2019). In addition, free amino acids are small molecules easily absorbed by plant leaves and roots and promote endogenous biosynthesis of plant hormones that ultimately regulate plant phenological processes (Caruso et al., 2019). Foliar application of amino acids improves plant growth, yield, and morphology in beans and radish (Kocira et al., 2020; Rehim et al., 2021). Amino acids are involved in synthesizing organic compounds and phytohormones (auxin and gibberellin) and enhancing macro and micronutrient uptake, contributing to better crop productivity (Kocira et al., 2020). Moreover, glycine has a better potential to release N molecules than urea (McCoy et al., 2020).

Although the use of chemical fertilizers contributes a lot to improving crop productivity and yield, it has adverse

effects on the soil, water, and environment. The results of our study demonstrated that the foliar application of biostimulants has a promising role in improving crop yield, physiology, and morphology. Moreover, it is an

innovative method for the sustainable cultivation of radish. However, the long-term impact and effects of biostimulants on soil properties and field conditions need to be explored.

Conclusion

The demand for food and a safe environment is gaining attention from the scientific community, and sustainable agriculture needs effective chemical fertilizers, genetically improved plants, and growth-promoting biostimulants. Biostimulants are a rich source of biologically active compounds and can potentially improve plant metabolic processes to achieve better crop quality, yield, and productivity. The study concludes that the foliar application of biostimulants increases gaseous exchange activities and chlorophyll content in radish as well as the plant's morphology, and its fresh and dry biomass, which can be conclusive evidence to reduce chemical fertilizers. However, further studies regarding field conditions, long-term uses and impacts, effects on soil mineral status, nutrient use efficiency, and plant biochemical properties are the identified research gaps. In addition, the mechanistic approaches behind the improved results with the combined use of biostimulants need attention.

Co-inoculation of arbuscular mycorrhizal fungi (AMF) and bacteria can synergically and potentially increase nitrogen use efficiency (NUE) in plants, thus, reducing nitrogen (N) fertilizers use and their environmental impact. However, limited research is available on AMF-bacteria interaction, and the definition of synergisms or antagonistic effects is unexplored. In this study, we adopted a response surface methodology (RSM) to assess the optimal combination of AMF (*Rhizoglyphus irregularis* and *Funneliformis mosseae*) and *Bacillus megaterium* (a PGPR—plant growth promoting rhizobacteria) formulations to maximize agronomical and chemical parameters linked to N utilization in maize (*Zea mays* L.). The fitted mathematical models, and also 3D response surface and contour plots, allowed us to determine the optimal AMF and bacterial doses, which are approximately accorded to 2.1 kg ha⁻¹ of both formulations. These levels provided the maximum values of SPAD, aspartate, and glutamate. On the contrary, agronomic parameters were not affected, except for the nitrogen harvest index (NHI), which was slightly affected (*p*-value of < 0.10) and indicated a higher N accumulation in grain following inoculation with 4.1 and 0.1 kg ha⁻¹ of AMF and *B. megaterium*, respectively. Nonetheless, the identification of the saddle points for asparagine and the tendency to differently allocate N when AMF or PGPR were used alone, pointed out the complexity of microorganism interaction and suggests the need for further investigations aimed at unraveling the mechanisms underlying this symbiosis.

biostimulants, *Bacillus megaterium*, *Rhizoglyphus irregularis*, *Funneliformis mosseae*, nutrients uptake, plant growth promoting rhizobacteria

Introduction

Nitrogen (N) represents a major nutrient for plants, being an essential component of proteins, nucleotides, chlorophyll, and a broad range of secondary metabolites. Cereals grains, providing 60% of the food necessary to feed the world's population, require significant inputs of N to achieve optimum yields. Nevertheless, N availability can represent a limiting condition since nitrate (NO_3^-) and ammonium (NH_4^+), representing the readily available N pool, account for only 2% of total soil N content (Moreau et al., 2019).

At the same time, the increasing use of synthetic N fertilizers over the last decades has posed concerns about the contamination of surface and groundwater bodies by nitrate, the impairment of biodiversity, and the emission of greenhouse gases (Ahmed et al., 2017). In line with the EU “Farm to fork” strategy, which aims at increasing the agricultural land managed under organic farming by 25%, scientific efforts are being done to maintain (or even increase) crop productivity by efficiently using organic fertilizers, which have been recognized to increase N losses very often, especially if applied inappropriately (Maris et al., 2021). Such an increase in N use efficiency can significantly minimize N losses and the consequent adverse impacts on ecosystems while decreasing costs for organic fertilizers (Galloway et al., 2014).

All the pathways of N cycling in soils mainly depend on the edaphic conditions, agronomic management, climate, crop genetics, and finally determines N availability, transfer, transformation, and losses (Congreves et al., 2021). Many scientific contributions have reported best agronomic practices and breeding solutions to enhance NUE, commonly defined as the plant biomass accumulation per unit of soil N available (Peng et al., 2006; van Bueren and Struik, 2017; Anas et al., 2020). N assimilation by plants involves the GS–GOGAT pathway, for which glutamine, asparagine, glutamate, and aspartate are upstream key intermediates; once incorporated into organic compounds, N is then distributed to a broad range of different N-containing compounds. Over the last two decades, biotechnological engineering of the amino acid metabolism has led to promising results for the improvement of NUE, especially the content of glutamine, asparagine, glutamate, and aspartate has been adopted as an interesting target to carry out these studies, being involved in plant N utilization and storage after assimilation (Dellero, 2020; The et al., 2021). Recently, especially in a framework of sustainable crop production, the inoculation with beneficial microorganisms has gained importance in such plant NUE increase (Di Benedetto et al., 2017; Verzeaux et al., 2017; Dalla Costa et al., 2021).

Arbuscular mycorrhizal fungi (AMF) have been reported to increase NUE by developing the symbiotic association with most terrestrial plants, favoring access to N uptake in a larger soil volume (Verzeaux et al., 2017). Interestingly, the

specific up-regulation of NO_3^- and NH_4^+ transporters has been observed in AMF colonized roots compared with the non-colonized plants (Courty et al., 2015; Garcia et al., 2016). In cereals such as sorghum, maize, and rice, AMT3.1 plant NH_4^+ transporter transcripts were specifically up-regulated following the mycorrhizal colonization (Koegel et al., 2017). Similarly, higher NUE has been observed following beneficial associations with N₂-fixing bacteria such as Rhizobia, *Frankia* sp., and Cyanobacteria, and some other diazotrophs like *Azospirillum* spp., *Herbaspirillum* spp., and *Paenibacillus* spp. Interestingly, a community of mycorrhizosphere bacteria living strictly associated with AMF has been suggested to encompass improved crop performances, acting synergistically with AMF (Oldroyd et al., 2011; Santi et al., 2013; Udvardi and Poole, 2013; Agnolucci et al., 2015; Kollah et al., 2016; Mus et al., 2016; Rosenblueth et al., 2018). In this regard, a high degree of specificity between bacteria and AMF has been proposed, and this tripartite association can potentially increase NUE in plants (Tajini et al., 2012; Giovannini et al., 2020; Paul et al., 2020).

The dynamic assembly of the rhizosphere microbial community depends on a large set of factors and is driven by an intricate set of belowground chemical communications (van Dam and Bouwmeester, 2016; Qu et al., 2020). However, very little information is available in the literature regarding optimizing AMF-bacteria co-inoculation to manipulate rhizomicrobiome and improve plant performance.

The present study aimed at optimizing the co-inoculation between mycorrhiza and *Bacillus megaterium* using the response surface methodology (RSM), with reference to enhanced N utilization in maize (*Zea mays* L.). The RSM approach has been chosen to account for the interaction(s) between the fungal and bacterial inoculum in the framework of the complex rhizosphere community. Similarly, different plant-based indices of NUE (i.e., NHI and NUtE; López-Bellido and López-Bellido, 2001) and yield of maize have been considered to account for the different assimilation, metabolization, mobilization processes, as well as the translocation to reproductive portions, to overcome the temporal and spatial edges of NUE indices (Congreves et al., 2021).

Materials and methods

Experimental site and microorganism inoculation

The field experiment was conducted over one maize cropping season—between May 2021 and September 2021—at the CERZOO experimental research station in Piacenza (45°00′21.6″N, 9°42′27.1″E; altitude 68 m a.s.l.), Northern Italy. At the experimental site, the climate is temperate (Cfa following Köppen classification), with an average annual temperature of

13.2°C and cumulative annual precipitation of 837 mm (20-yr data). The soil is a fine, mixed, mesic Udertic Haplustalf based on the Keys to Soil Taxonomy (Soil Survey Staff 2014). The physicochemical properties of soil (0–30 cm soil layer) measured before starting the experiment were: organic matter content 27 g kg⁻¹; pH H₂O 7.8; bulk density 1.36 g cm⁻³; sand 127 g kg⁻¹; silt 445 g kg⁻¹; clay 428 g kg⁻¹; soil total N 1.3 g kg⁻¹; available P (Olsen) 32 mg kg⁻¹; exchangeable K (NH₄⁺ Ac) 294 mg kg⁻¹, and cation exchange capacity 30 cmol⁺ kg⁻¹. Biostimulant treatments consisted of a seed dressing with the powder AMF-based product Aegis Sym irriga® (*Rhizoglossus irregulare* BEG72 and *Funneliformis mosseae* BEG234, 700 sp g⁻¹ each species) formulation, or the PGPR Bactrium® (*Bacillus megaterium* BM77 e BM06, 5 × 10⁹ CFU/g each species) liquid formulation, all from Athens, Agrotecnologia Naturales SL (Tarragona, Spain). The seed dressing was homogenized with maize seeds using an automated mixer.

To assess the effect of different doses of AMF and bacteria on yield and NUE in maize, nine different types of seed dressing were prepared as all the possible combinations of the three doses of AMF (low: 0.1 kg ha⁻¹; medium: 2.1 kg ha⁻¹; and high: 4.1 kg ha⁻¹) and three doses of *B. megaterium* (low: 0.1 kg ha⁻¹; medium: 2.1 kg ha⁻¹; and high: 4.1 kg ha⁻¹). As a result, the present field experiment was set up as a randomized complete block (RCB) design with 9 treatments and 4 replicates (blocks). Each plot was 28 m²: 10 m long and 2.8 m wide (4 maize rows at a 0.7 m inter-row distance). Before planting maize, the seed dressing was carried out in the Lab separately for each treatment. In brief, each level of the 3 × 3 AMF-*B. megaterium* doses were manually mixed with maize seeds (at around 82,000 seeds ha⁻¹). Then, maize was planted with a common two-row plot seeder on 7 May 2021. Maize cropping management followed principles reported by the regulation (EU) 2018/848 on the organic farming production methods. To represent local practice under organic farming, a 170 kg N ha⁻¹ slurry distribution was applied to all the plots before soil tillage (autumn 2020), and no fertilizer was applied during the cropping cycle of maize. To prevent water stress, maize was sprinkler-irrigated three times at doses of 30, 40, and 45 mm. Harvesting took place on 20 September 2021 with a plot-scale combination.

SPAD measurement

On 13 August, relative chlorophyll concentrations, defined as SPAD value, were estimated between 02:00 p.m. and 03:00 p.m. using a SPAD-502 chlorophyll meter (Minolta, Tokyo, Japan). The average value of five measurements of three leaves was taken as the maize SPAD value per plot.

Asparagine, glutamine, aspartate, and glutamate content in leaves

On 13 August, the ninth leaf of five plants per plot was sampled and stored at −20°C. The frozen samples were used to determine the content of four amino acids, namely, asparagine, glutamine, aspartate, and glutamate.

Initially, the five leaves per plot were ground together with liquid nitrogen using a pestle and mortar to obtain a homogeneous and representative final sample. Two aliquots (2 × 1 g) per plot were extracted in 10 ml of 50% methanol, 50% deionized water, and 0.01% formic acid using an Ultra-Turrax (Ika T-25, Staufen, Germany) and successively centrifuged (12,000 × g).

The different extracts were diluted 1,000-fold with deionized water and then filtered in the HPAEC vials using 0.20 µm syringe filters until instrumental analysis. The amino acid content of the hydroalcoholic leaf extracts was then investigated through High-Performance Anion Exchange Chromatography with Pulsed Amperometric Detection (HPAEC-PAD). The analyses were carried out on a Dionex ICS-5000 + instrument (Thermo Fisher Scientific, Waltham, the United States) provided with an electrochemical cell consisting of a gold-working electrode and a pH-Ag/AgCl reference electrode. The separation was performed using a Thermo Scientific™ Dionex™ AMINOPAC™ PA10 Analytical column (2 × 250 mm). The chromatographic runs were executed in a total time of 80 min, with multi-gradient elution consisting of a mobile phase of deionized water (eluent A), 250 mM aqueous sodium hydroxide (eluent B), and 1 M sodium acetate solution (eluent C). The flow rate was 0.25 ml/min, and the injection volume was 25 µl, with a column and detector compartment temperature at 30°C. Gradient elution consisted of 0–12 min with 80% of eluent A and 20% of eluent B; 12–16 min with 68% of eluent A and 32% of eluent B; 16–40 min with 36% of eluent A, 24% of eluent B, and 40% of eluent C. Also, a 40 min of equilibration phase was considered, using 80% of eluent A and 20% of eluent B. The amino acids were detected by an ICS-5000 + electrochemical detector in integrated pulsed amperometric detection mode applying the following waveform potentials and durations: E1 = 0.13 V (t1 = 0.40 s), E2 = 0.33 V (t2 = 0.210 s), E3 = 0.55 V (t3 = 0.460 s), E4 = 0.33 V (t4 = 0.560 s), E5 = −1.67 V (t5 = 0.580 s), E6 = 0.93 V (t6 = 0.590 s), and E7 = 0.13 V (t7 = 0.600 s). For the quantification step, a calibration curve (R² > 0.98) of the four amino acids was prepared by appropriately diluting an amino acid standard mix (2.5 µmol/ml in 0.1M HCl solution, provided by Merck, Darmstadt, Germany), considering the following concentration range: 25-10-5-2.5-1 µM (**Supplementary Figure 2**). The chromatographic system was controlled through the Thermo Scientific™ Dionex™ Chromeleon™ software

version 7.0 for the instrumentation command, chromatograms acquisition, and processing.

Maize yield and agronomic nitrogen use efficiency indices

At the BBCH 89, maize yield was measured by manually harvesting 8 m² per single plot. Plants were weighed and separated into grain and biomass (stalks). A 100-g sub-sample of each grain and biomass sample was oven-dried at 65°C until constant weight to measure dry matter content. Grain and biomass N-uptake were calculated by multiplying grain and biomass yield by their N-concentrations, determined by the Dumas combustion method with an elemental analyzer varioMax C:N (VarioMax C:NS, Elementar, Germany).

The two following N-efficiency parameters were calculated for each treatment according to López-Bellido and López-Bellido (2001): (i) N harvest index (NHI;%) as the ratio of N in grain to N in total plant biomass; and (ii) N-utilization efficiency (NUE; kg kg⁻¹) as the ratio of grain yield to total plant N-uptake.

Statistical analysis

Data analysis was performed with Rstudio 3.6.1 software (R Core Team, 2013). On each NUE parameter, two different two-way ANOVA ($p < 0.05$) were carried out. The first ANOVA was focused on the differences between treatments, thus, the combination of AMF and bacterial doses, as well as the block, were considered as factors, respectively, represented by 9 and 3 levels. The response profiles not impacted by the microbial inoculations were plotted as box plots using the *ggplot* package to represent the data distribution according to treatments (Wickham and Chang, 2007). Successively, the second ANOVA was performed to study the effects and the interactions of the AMF and bacteria factors.

After that, response-surface analysis was performed with the *rsm* package (Lenth, 2009). According to Kumar et al. (2020), the face-centered composite design (FCDD) was used and two independent variables with three levels were selected: AMF (x₁: 0.1 kg ha⁻¹; 2.1 kg ha⁻¹; 4.1 kg ha⁻¹) and *B. megaterium* (x₂: 0.1 kg ha⁻¹; 2.1 kg ha⁻¹; 4.1 kg ha⁻¹). A full factorial design of 27 experimental runs with 12 cube points, 12 axial points, and 3 center points was chosen (Table 1), while SPAD values, amino acid concentrations, and other NUE parameters were considered response profiles for modeling. The experimental runs were randomized to minimize the effect of unexpected variability on the observed responses. The following second-order quadratic

model was used to develop the optimization and predictive model:

$$Y = \beta_0 + (\beta_i^*x_1) + (\beta_j^*x_2) + (B_{ij}^*x_1^*x_2) + (\beta_i^*x_1^2) + (\beta_j^*x_2^2); \quad (1)$$

where Y is the predicted response profile, β_0 , β_i , β_j , and β_{ij} are the interactive regression coefficients, and x₁ and x₂ are the AMF and *B. megaterium* doses, respectively.

Results

Analysis of variance revealed a significant effect of the treatments on maize in terms of SPAD value and amino acid concentrations (Table 2). Interestingly, the highest value of SPAD (62.95 ± 1.41) was found with the intermediate dose of AMF and *B. megaterium*, corresponding to 2.1 kg ha⁻¹ of each inoculum. Similarly, the same result was obtained for aspartate, whose highest concentration (0.81 ± 0.38 μM) was registered at the same treatment level, showing a content 4.7- and 3.5-folds higher than those, respectively, registered with the lowest (0.1 kg ha⁻¹) and the highest (4.1 kg ha⁻¹) doses of both inocula. Surprisingly, asparagine and glutamine concentrations reached the maximum concentration (respectively, 2.95 ± 0.52 and 0.86 ± 0.13 μM) at 2.1 + 2.1 kg ha⁻¹ AMF-*B. Megaterium* combination, then decreased with the increasing dosage of AMF and raised again at the highest levels of mycorrhizal and bacterial inocula. At final, the inoculum with 2.1 + 4.1 kg ha⁻¹ of AMF and *B. megaterium* combined reflected a higher glutamate content (0.82 ± 0.14 μM).

However, the ANOVA did not reveal a significant effect of the treatments for the considered agronomic parameters, except for NHI, which seemed to be slightly affected (p -value of < 0.10) and indicated a higher N accumulation in grain following 4.1 and 0.1 kg ha⁻¹ of AMF and *B. megaterium* inoculation (Table 2). Box plots (Figure 1) provided high-level information regarding data symmetry, variance, and outliers, allowing comparisons between different treatments.

Overall, biomass and biomass N-uptake values showed a similar trend, with 2.1 + 2.1 kg ha⁻¹, 2.1 + 4.1 kg ha⁻¹, and 4.1 + 4.1 kg ha⁻¹ doses of mycorrhizal and bacterial inocula that tended to increase maize performances. Biomass N-concentration tended to be the highest under 0.1 + 2.1 kg ha⁻¹, 2.1 + 0.1 kg ha⁻¹, and 4.1 + 4.1 kg ha⁻¹ doses of mycorrhizal and bacterial inocula.

Grain yield values showed a tendency to be increased under 0.1 + 2.1/4.1 kg ha⁻¹, 2.1 + 2.1 kg ha⁻¹, and 4.1 + 0.1 kg ha⁻¹ doses. Moreover, grain N-concentration tended to be higher (1.51 ± 0.16%) in the absence of mycorrhizal inoculation (0.1 + 4.1 kg ha⁻¹ of AMF and *B. megaterium*). At last, the

highest NUT value was obtained with 4.1 kg ha⁻¹ and 2.1 kg ha⁻¹, respectively, of AMF and *B. megaterium* dose.

A prediction model was developed for those indices being significantly affected (*p*-value of < 0.05) by AMF and *B. megaterium* treatment. The quadratic equations of the final models are given below Eqs. 1–5:

$$Y_{\text{SPAD}} = 62.57 + 0.81x_1 + 0.89x_2 - 0.39x_1x_2 - 4.39x_1^2 - 3.42x_2^2 \quad (2)$$

$$Y_{\text{ASPARTATE}} = 0.69 + 0.05x_1 + 0.02x_2 - 0.09x_1x_2 - 0.33x_1^2 - 0.09x_2^2 \quad (3)$$

$$Y_{\text{GLUTAMATE}} = 0.69 + 0.09x_1 + 0.08x_2 - 0.03x_1x_2 - 0.22x_1^2 - 0.07x_2^2 \quad (4)$$

$$Y_{\text{ASPARAGINE}} = 2.89 + 0.28x_1 - 0.02x_2 - 0.16x_1x_2 - 0.87x_1^2 + 0.17x_2^2 \quad (5)$$

$$Y_{\text{GLUTAMINE}} = 0.80 + 0.23x_1 + 0.09x_2 - 0.19x_1x_2 - 0.27x_1^2 + 0.14x_2^2 \quad (6)$$

Regarding the SPAD value, the model showed a high coefficient of determination ($R^2 = 0.9$) and a high *F*-value (224.9), while the *p*-value was < 0.05 and no significant lack of fit values (> 0.05) were found. Similarly, a high-predictive model was found for glutamine concentration, exhibiting $R^2 = 0.8$, *F*-value = 8.75, and a *p*-value of < 0.05. Glutamate, asparagine, and aspartate models showed lower R^2 , being 0.5, 0.6, and 0.4, respectively, corresponding to 4.3, 6.4, and 3.9 *F*-values.

TABLE 2 Two-way ANOVA on SPAD value, amino acid concentrations, and agronomic parameters observed in the maize crop following AMF and *B. megaterium* treatment.

Values are presented as mean ± standard error (SE). Bold values denote statistical significance at the $p < 0.05$ level. The “*” symbolizes the interaction of the two factors (AMF and bacteria) within ANOVA.

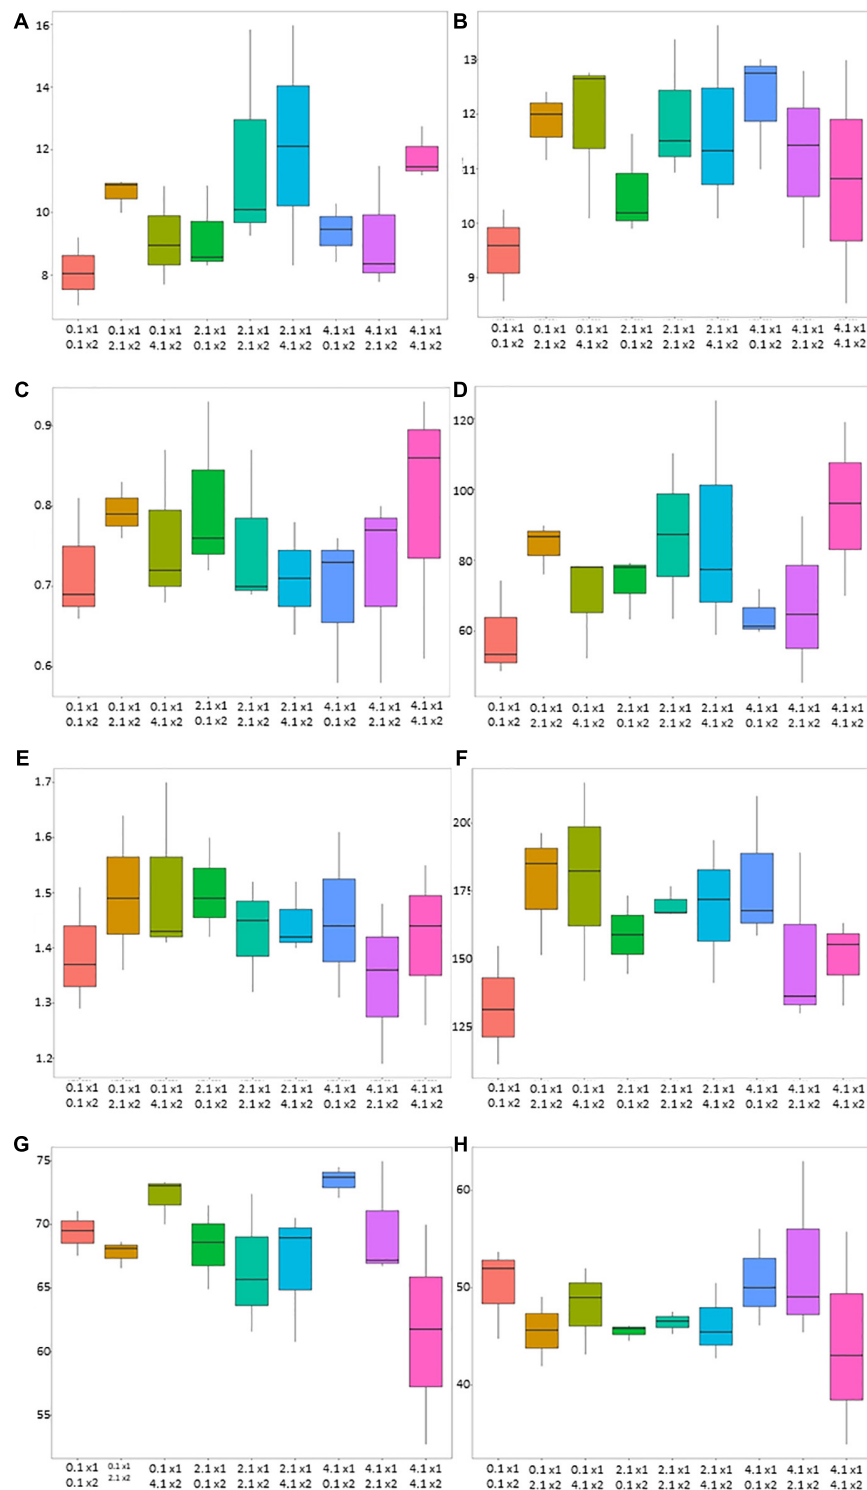

FIGURE 1

Box plot diagrams of agronomic parameters for AMF and *Bacillus megaterium* treatments on maize (*Zea mays* L.). The X-axis describes the combination of AMF and *B. megaterium* doses (0.1 kg ha⁻¹, 2.1 kg ha⁻¹, and 4.1 kg ha⁻¹) while the Y-axis represents the values for maize biomass (mg ha⁻¹) (A), grain yield (mg ha⁻¹) (B), biomass nitrogen concentration (%) (C), biomass nitrogen-uptake (kg ha⁻¹) (D), grain nitrogen concentration (%) (E), grain nitrogen-uptake (kg ha⁻¹) (F), NHI (G), and NutE (H). Each box line corresponds to the median of the data while the ends of the box show the upper (Q3) and lower quartiles.

However, in all the three cases, the p -value was < 0.05 , and a significant lack of fit was not provided (> 0.05).

The final regression analysis equations were used for plotting 3D response surface and contour plots which represented the interaction of the input factors—AMF and *B. megaterium*—to trace the stationary point of each variable for the desired response (Figure 2 and Supplementary Figure 1). This stationary point was a maximum for SPAD value, aspartate, and glutamate, indicating a maximum response of these profiles obtained with mycorrhizal and bacterial-specific doses (Figure 2). The RSM optimized values for maximum SPAD value (62.66) were 2.27 ka ha^{-1} for AMF and 2.35 ka ha^{-1} for *B. megaterium*. Moreover, 2.22 and 2.24 ka ha^{-1} indicated the optimized doses of mycorrhizal and bacterial inocula to reach the highest aspartate content (0.69), while 2.41 ka ha^{-1} and 3.31 ka ha^{-1} obtained the maximum glutamate concentration. Concerning asparagine and glutamine, the stationary point was represented by a saddle point (2.91 and 0.85), which consisted of an inflection point of the response surface and was, respectively, achieved with 2.40 ka ha^{-1} and 2.36 ka ha^{-1} , and with 2.99 ka ha^{-1} and 2.03 ka ha^{-1} of AMF and *B. megaterium* inocula. The contour plots of the fitted response surfaces allowed us to visualize the behavior of the fitted surface around the stationary point (Supplementary Figure 2). Each plot displayed a color image overlaid by the contour lines of constant responses in a two-dimensional space.

Discussion

The choice of the best AMF-bacteria combination to improve NUE and thus ensure efficient and sustainable food production has become a burning question in the perspective of developing new strategies for the ecological transition of agriculture (Agnolucci et al., 2019). *B. megaterium* and AMF are both supposed to be potential bio-fertilizer agents able to play a key role in plant growth promotion. Their single and dual inoculation has revealed beneficial emerging properties in plant symbiosis, mostly translated into enhanced plant growth, yield, and abiotic stress tolerance (Ortiz et al., 2015; Khalid et al., 2017). RSM allows testing of multiple factors with complex interactions, modeling the system mathematically and using a limited number of experimental trials. However, despite the presence of studies based on the application of RSM models to improve plant growth, yield, and NUE, the statistical optimization of the best performing inoculum which can boost plant N acquisition is still limited in literature (Peng et al., 2014; Gundi et al., 2018; Naili et al., 2018; Mazumdar et al., 2021).

Several studies have shed light on the ability of AMF or PGPR to increase plant NUE, reporting higher grain and biomass values, as well as higher levels of N_{UE},

in different crops. In maize, clear evidence of improved NUE have been observed following inoculation with bacterial strains of *P. fluorescens* S3X and *C. necator* 1C2 (Pereira et al., 2020), *Bacillus megaterium* (Ganugi et al., 2022), and other. Concerning AMF, positive results were reported by single inoculation with *R. irregularis* BEG72 and *F. mosseae* BEG234, and coupled application of *Rhizophagus irregularis* and *Bacillus* spp. (Adesemoye et al., 2008).

Nevertheless, understanding the specific mycorrhizal and bacterial synergic action requires considerable study since PGPR-AMF affinity and colonization efficiency seem to be strongly related to the fungus species and origin. Marulanda-Aguirre et al. (2008) found different results for *B. megaterium* when inoculated on lettuce (*Lactuca sativa* L.) coupled with *Glomus constrictum* autochthonous, *G. constrictum* from a collection or commercial *G. intraradices*. In addition, this study highlights how an optimized mycorrhizal-to-bacterial inoculation rate on maize seeds at planting might be a success factor for the establishment and effectiveness of an AMF-PGPR symbiosis. Interestingly, our optimization aimed at enhancing maize NUE revealed similar RSM values for maximum SPAD, aspartate, and glutamate concentrations, which correspond to the intermediate doses of AMF and *B. megaterium*. Together with indicating a treatment effect on these NUE indices, this point confirmed the tripartite synergy between plants, mycorrhizae, and microbial communities for plant nutrition. Such synergy can be translated into a significant increase in N acquisition compared with the single inoculation of AMF or *B. megaterium* (Hestrin et al., 2019). However, the identification of saddle points for asparagine and glutamine pointed to the complexity of microorganisms' interactions. The presence of such intricate microbial interactions indicates the need for further deep analyses, focused on experimental runs at points along this path, using the observed response values for guidance on where to locate the next factorial experiment (Lenth, 2009; Jan et al., 2021).

Despite the lack of significant treatment effect on most of the agronomic parameters, our data revealed interesting trends which is worth exploring in the future. On the one hand, it seems that maize plant biomass and biomass N-uptake could be increased by the concomitant action of AMF and *B. megaterium* at > 2.1 . On the other hand, grain yield, grain N-uptake, and NHI showed a tendency to be increased preferentially by the single action of either AMF or *B. megaterium*, while lower values were registered under co-inoculation conditions. This latter statement was further corroborated by the fact that NHI (which was close to being significantly affected by the treatments) had the highest values with 4.1 kg ha^{-1} of AMF or *B. megaterium*, alternatively. These results suggest that (i) combining AMF and *B. megaterium* at a significant dose ($> 2 \text{ kg ha}^{-1}$) may have the potential to enhance plant tissues growth toward vegetative biomass, and (ii) if AMF and

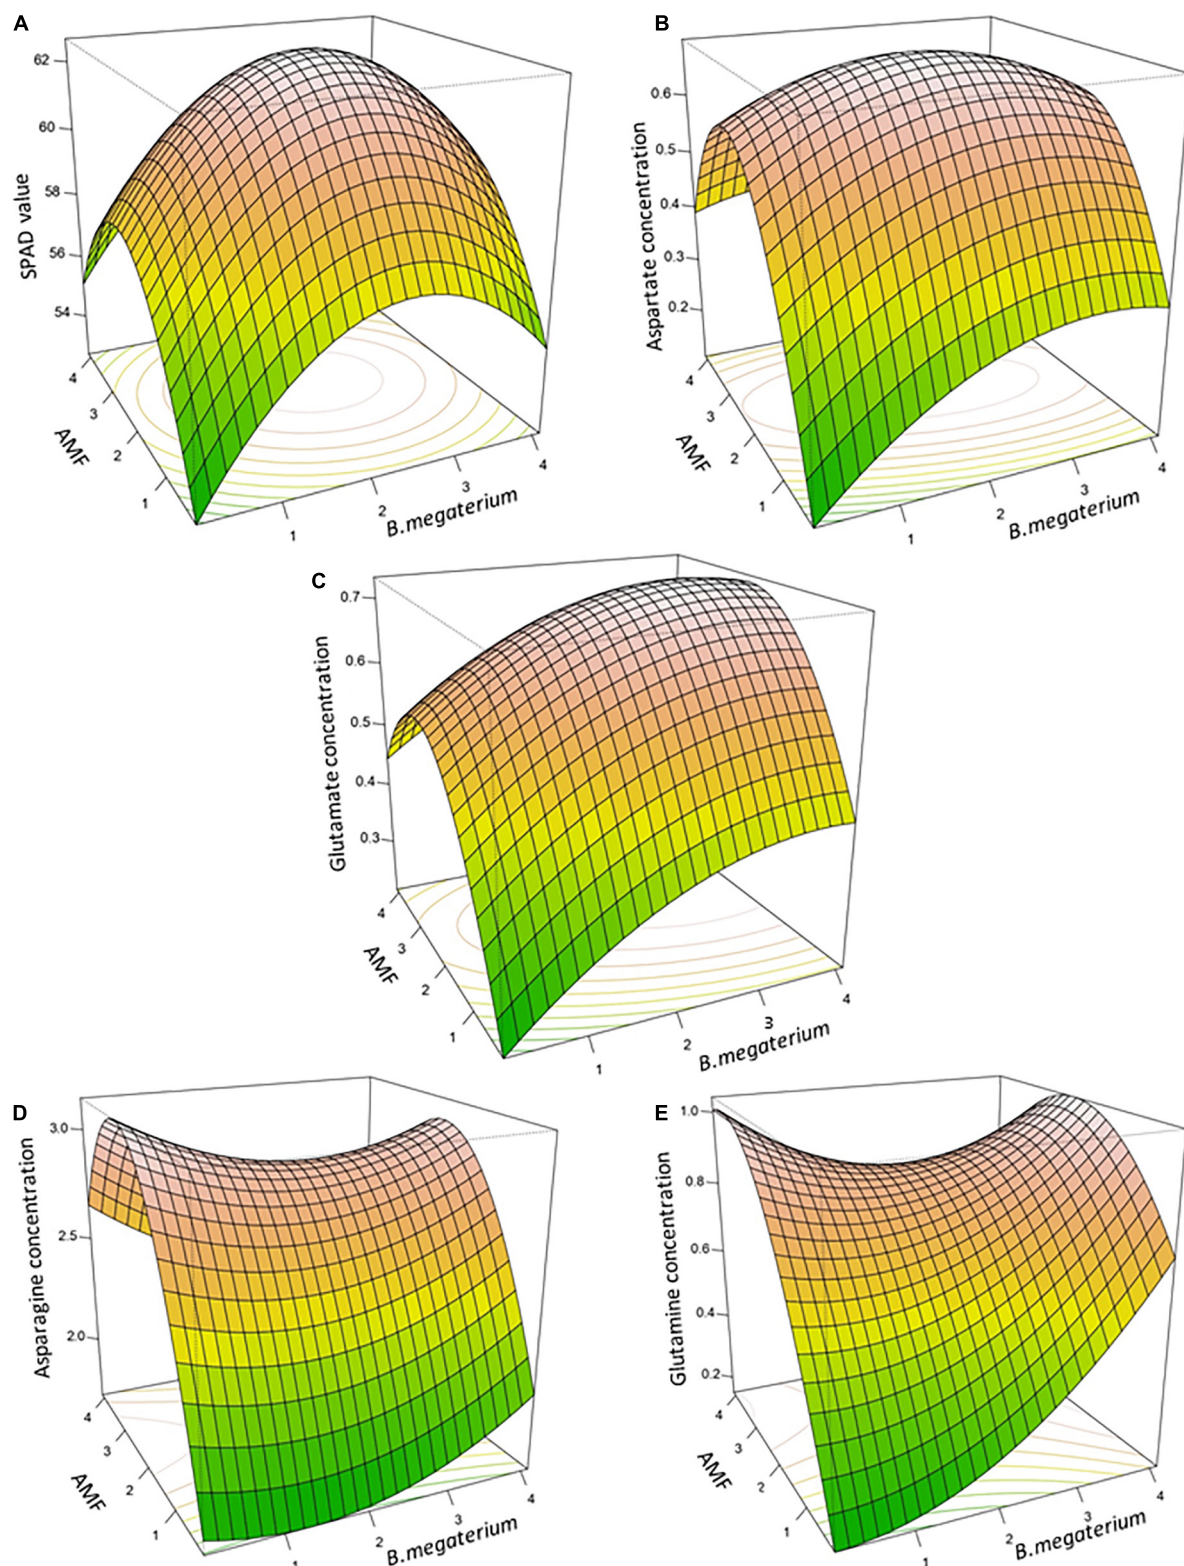

FIGURE 2

The three-dimensional response surface plots for interactive effects of *B. megaterium* and AMF co-inoculation on SPAD value (A), aspartate concentration (B), glutamate concentration (C), asparagine concentration (D), and glutamine concentration (E) in maize.

B. megaterium are inoculated alone, it is likely that grain-related agronomic parameters could benefit more than biomass-related ones. In fact, distinct effects provided by AMF, PGPR, and their co-inoculation in terms of drought resistance and essential oil yield have been previously reported in myrtle (Azizi et al., 2021). Similarly, it was reported that symbiotic efficiency may be hindered by interaction(s) with other biofertilizers together with being impacted by agro-practices (Kuila and Ghosh, 2022). In another work, Pacheco et al., evaluated the effect of AMF and *Pseudomonas putida* (PSB) single and co-inoculation on P uptake, productivity, and P concentration in maize (Pacheco et al., 2021). Interestingly, these authors reported that the microbial inoculants enhanced plant P uptake, that the presence of PSB increased biomass per unit of P taken up, and that the microbial inoculants altered P allocation within the plant, reducing grain P concentration (Pacheco et al., 2021). This distinct effect of the microbial inoculants on biomass production and nutrients allocation agrees with the results from Lozano Oliv  rio Salvador and co-workers, who observed specific effects in terms of dry weight, symbiotic efficiency, chlorophyll content, and nitrogen accumulation when AMF or rhizobacteria were applied with compost to soybean (Salvador et al., 2022).

Despite the fact that mechanisms underlying the effect of single and combined inoculum are still unknown, amino acid metabolism represents an interesting target for crop NUE improvement, being actively involved in plant NtE (Dellero, 2020). In particular, the glutamine synthetase/glutamate:2-oxoglutarate aminotransferase (GS/GOGAT) cycle represents the major route for plant ammonia assimilation, followed by asparagine synthetase (ASN) and glutamate dehydrogenase (GDH) (Harrison et al., 2000). Accordingly, experimental studies on maize have pointed out the increased concentration of aspartate and glutamate following *R. irregularis* and *Gigaspora margarita* inoculation (Matsumura et al., 2013; Hu and Chen, 2020), while the enhanced activity of ammonium assimilating enzymes (GS and GDH) have been detected with *Azospirillum* bacterial treatment (Ribaud   et al., 2001).

Here, for the first time, we reported how different rates of mycorrhiza-to-*Bacillus* co-inoculation may be considered—to some extent—as a driver of differential N partitioning between grain and vegetative biomass in the maize plant. This should be considered to address future studies to shed light on how such biotic interactions may steer plant physiology toward grain rather than vegetative tissues N accumulation.

Nevertheless, it should be stated some important aspects of the experiment. At first, it must be pointed out that the *Aegis Sym irriga*® product is predominantly but not totally made by AMF, being associated—as the most commercial inocula—to other bacteria. For this reason, the effect of this inoculum on plant-based indices of NUE, as well as that obtained following its interaction with the PGPR product, is not necessarily ascribable to the exclusive presence of mycorrhiza.

Second, to further complicate matters, plant responses should be studied under a wide range of soil-climate conditions, including different soil types and soil fertility, and temperate to dry climates. Particularly, physico-chemical soil properties, such as nutrient availability, pH, structure, organic matter content, and texture, can affect the release of plant root exudates and, consequently, the availability and the interactions with soil microbial communities (Neumann et al., 2014). It is likely that plant-microbe symbiosis is profoundly influenced by external environmental conditions, namely, temperature and moisture (Cheng et al., 2019). As consequence, it should be clarified that our results are strictly related to a specific pedoclimatic experimental context and, for this reason, maximum and saddle points for each NUE index cannot be certainly considered as absolute values exactly reproducible under different plant growth conditions.

Equally, the lack of significant effects in some agronomic indices may be reasonable because of the peculiar temperate and fertile conditions underlying the study, which is why it would be unreasonable to draw a conclusion about a lack of general effect of microbial inocula on the plant NUE. Notwithstanding, the application of prediction models may considerably contribute to advancements in the agricultural sector, particularly, under challenging factors interaction conditions.

Data availability statement

The original contributions presented in this study are included in the article/**Supplementary material**, further inquiries can be directed to the corresponding author.

Author contributions

PG, AF, VT, and LL conceived the ideas and designed the methodology. PG, AF, GR, and PB collected the data. PG, GR, and PB analyzed the data. PG, AF, PB, VT, and LL wrote the original draft. AF and LL critically revised the original draft. All the authors gave final approval for the publication.

Funding

This project was funded by the Emilia-Romagna region, Italy, in the framework of the Regional Development Program PSR 2014-2020, Measure 16.1.01–Focus Area 4B (project 5150325 – INBIOS: Sviluppo di un approccio INtegrato a base di BIOstimolanti per la sostenibilit   delle produzioni agrarie).

Acknowledgments

We thank the “Romeo ed Enrica Invernizzi” Foundation (Milan, Italy) for the kind support to the metabolomic facility at the Università Cattolica del Sacro Cuore.

Conflict of interest

PB was employed by company oloBion-OMICS LIFE LAB.

The remaining authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Biostimulants have become an asset for agriculture since they are a greener alternative to traditionally used plant protection products. Also, they have gained the farmers' acceptance due to their effect on enhancing the plant's natural defense system against abiotic stresses. Besides commercially available complex products, small molecule-based biostimulants are useful for industry and research. Among them, polyamines (PAs) are well-studied natural compounds that can elicit numerous positive responses in drought-stressed plants. However, the studies are merely focused on the vegetative development of the plant. Therefore, we aimed to evaluate how drenching with putrescine (Put) and spermidine (Spd) modified the maize production and the yield quality parameters. First, a dosage optimization was performed, and then the best PA concentrations were applied by drenching the maize plants grown under well-watered (WW) conditions or water deficit (WD). Different mechanisms of action were observed for Put and Spd regarding maize production, including when both PAs similarly improved the water balance of the plants. The application of Put enhanced the quality and quantity of the yield under WW and Spd under WD. Regarding the nutritional quality of the grains, both PAs increased the carbohydrates content, whereas the contribution to the protein content changed by the interaction between compound and growth conditions. The mineral content of the grains was also greatly affected by the water condition and the PA application, with the most relevant results observed when Spd was applied, ending with flour richer in

Zn, Cu, and Ca minerals that are considered important for human health. We showed that the exogenous PA application could be a highly efficient biofortification approach. Our findings open a new exciting use to be studied deep in the biostimulant research.

drenching, mineral nutrition, polyamines, yield, *Zea mays*

Introduction

Plants are sessile organisms exposed to a rapidly changing environment. They respond to external stimuli, which might result in plant acclimation to specific growing conditions. When this is impossible, growth becomes inhibited and, later, may die. Abiotic stresses are the principal cause of severe yield losses of 50–80%, depending on the crop and geographical location (Zhang et al., 2018). The global climate change projections forecast an increase in extreme weather events' occurrence, frequency, and severity (FAO, 2018). The incidence of abiotic stresses such as drought will raise and compromise the yield of the crops, especially in arid and semiarid areas. Drought is multidimensional stress affecting plants at various developmental stages, including the plant's production (Blum, 1996). One of the most promising methods to cope with the inevitable abiotic stresses is the application of biostimulants to enhance plant resilience to environmental perturbations (Van Oosten et al., 2017). Their action relies on the “preparation” effect (priming or hardening) that their application exerts on the plants (Gebremedhn and Berhanu, 2013; Maiti and Pramanik, 2013; Savvides et al., 2016). Biostimulants have been proved to improve plant growth and photosynthesis efficiency by modifying the plant metabolism under abiotic stress conditions (Paul et al., 2019; Sorrentino et al., 2021). Moreover, the recent recognition of biostimulants as an independent group of agricultural inputs by the European Union and their contribution to more sustainable agricultural practices forecasts a growing interest in these substances (Ben Mrid et al., 2021).

Typically, biostimulants are a mixture of several substances, such as protein hydrolysates or seaweed extracts; this has been seen as a great opportunity by some companies to join the circular economy trend since they can give a second life to waste and by-products (Xu and Geelen, 2018). However, these products present the disadvantage of lack of uniformity between the batches and the problematic identification of the active substances (Yakhin et al., 2017). Studying pure organic active compounds as biostimulants will lead to a better standardization, the quality control of formulation, and an understanding of their mode and mechanism of action (García-García et al., 2020). While the effectiveness of biostimulants has been widely researched and summarized in extensive reviews

(Battacharyya et al., 2015; Bulgari et al., 2015, 2019), there is a limited information available on how their application might affect the final yield and quality.

Maize (*Zea mays* L.) is one of the most important cereal crops for human nutrition in large parts of the world (Huma et al., 2019) and an essential grain used as livestock feed in the world (Loy and Lundy, 2018). Drought negatively affects the plant growth, the dry biomass content, and the yield (Anjum et al., 2017; Kim et al., 2019). The water deficit during maturation might cause problems in the grain filling stage (Zhang et al., 2019) and reduce the quality parameters such as starch, proteins (Barutcular et al., 2016), or mineral content (Aqaei et al., 2020). Maize kernel mainly comprises carbohydrates, protein, and oil (Chaudhary et al., 2014). Starch accounts for approximately 70% of the kernel weight (Orhun et al., 2013). According to the release and absorption of glucose in the intestines, starch is divided into the following three categories: Rapidly and slowly digestible starch and resistant starch; the last category has particular importance for human nutrition since its consumption has been linked to a decrease in the risk of developing type 2 diabetes and colon cancer (Hoebler et al., 1999). Protein content varies from 8 to 11% of the kernel weight on common varieties of maize (Landry and Moureaux, 1980). However, the nutritional value is poor for monogastric and human consumption due to the low content of essential amino acids such as lysine, tryptophan, and threonine (Li and Vasal, 2015). The discovery of the opaque-2 gene and its link with higher lysine and tryptophan was the beginning of the Quality Protein Maize (QPM) research, which produced hybrids whose kernels had a significant increment on the mentioned amino acids. Nevertheless, the yield was reduced in these hybrids, and their agronomical performance was deficient (Chaudhary et al., 2014). The kernel mineral composition is strongly affected by the environmental factors, soil moisture, and fertility, but it is mainly genotype dependent, with the vast variety of differences as the most significant contributor to the reported variance (Feil et al., 2005; Menkir, 2008).

The development of nutritionally enhanced food crops using traditional breeding practices and modern biotechnology approaches is known as “biofortification” (Chaudhary et al., 2014; Garg et al., 2018). The first main achievements in this field were the lysine and tryptophan enriched maizes or

vitamin A-rich orange sweet potato; much effort is put into transgenic research, although traditional breeding practices are best accepted (Garg et al., 2018). Given the exposed facts, we decided to test biostimulants as an alternative approach for maize biofortification due to their effect on plant metabolism and stress tolerance. With this aim, we applied two polyamines (PAs) with proven efficiency as stress alleviators, putrescine (Put), and spermidine (Spd) (Li et al., 2015, 2018; Marcińska et al., 2020; Islam et al., 2022), although the dose was optimized to the specific cultivar of maize used. The maize plants were treated with the two PAs *via* drenching, which has been proven to have positive results toward drought stress (Jiménez-Arias et al., 2019) because drenching provides a more extended period of continuous uptake of the supplemented substance than the foliar application (Parkunan et al., 2011). Some reports also revealed that the drench application improves soil fertility by increasing the availability of minerals, soil aeration, and water holding capacity and promotes the development of essential microbes (Battacharyya et al., 2015; du Jardin, 2015). We expect that applying PAs by drenching will improve maize's biofortification and stress tolerance.

Materials and methods

Plant material, growth conditions, and dose optimization

A local plant nursery provided a local forage variety of maize from Gran Canaria Island (*Zea mays* L. c.v. Lechucilla) in a 150-socket nursery tray. One week after sowing, the plants were placed in a growth chamber under controlled conditions with a temperature of 22°C, a photoperiod of 16-h light and 8-h dark, with a light intensity of 300–400 $\mu\text{mol m}^{-2} \text{s}^{-1}$, and a relative humidity around 60–70%. Plants in stage V1 were used for the dose optimization experiments when the lowermost leaf had a visible leaf collar (Zhao et al., 2012).

Putrescine and spermidine were purchased from Sigma-Aldrich (Put CAS number 333-93-7; Spd CAS number 124-20-9). In the direct application-optimized doses of both chemicals under two water regimes in the nursery tray, 20 plants were used as biological replicates per variant (treatment \times growth condition), as described in Jiménez-Arias et al. (2022). The nursery experiment ensured the suitability of the plant for the root treatment. The treatments were applied directly to the roots of stage V1 plants, consisting of 5 ml of a half-strength Hoagland solution (Hoagland and Arnon, 1938) for the controls or containing the tested substances at the following five concentrations: 0.01, 0.1, 0.5, 1, and 2 mM for the treated plants. Twenty plants per variant were grown under a water limitation of 50% of the field capacity for a week. The two harvesting times were performed; at the dry period's beginning and end. The

whole plant, including the aerial part and roots, was harvested. The dried weight (DW, mg) of the 20 plants was recorded after being oven-dried at 85°C for 48 h to calculate the relative growth ratio (RGR) (Hoffmann and Poorter, 2002),

$$\text{RGR} = (\ln \text{DW}_2 - \ln \text{DW}_1) / (t_2 - t_1), \quad (1)$$

where DW_1 and DW_2 corresponded to the dry weights of maize seedlings at times t_1 and t_2 (beginning and end of the water deficit).

The plant water use efficiency (WUE, mg ml^{-1}) was calculated considering all the amount of water provided during the experiment timespan (Kuglitsch et al., 2008).

$$\text{WUE} = \text{Plant biomass} / \text{Total irrigation} \quad (2)$$

Greenhouse experiment

Once the data was evaluated for the dosage optimization, an additional study with maize variety was conducted at a greenhouse property of the Escuela de Capacitación Agraria de Tacoronte (Tenerife), Canary Islands (28°29'47.0"N 16°25'12.0"W) from June 2021 to August 2021. The ambient conditions were recorded daily (Supplementary Table 1). The average maximum and minimum temperatures were 30 and 22°C, respectively, with an average relative humidity of 80% (Supplementary Table 1). The soil is classified as clay-loam (35% clay, 27% silt, and 38% sand), and the experiment was organized in randomly distributed blocks of 20 m^2 blocks with three replicates, each block containing 80 plants. The seeds were sown in nursery trays and transplanted to the field after 15 days of the sowing. The irrigation was calculated according to the FAO (Rao et al., 2016), taking into account the evapotranspiration rate (ET_o) provided by a nearby meteorological station, property of the island council, Cabildo de Tenerife (Supplementary Table 1). The soil humidity was monitored within the wet-bulb with the TEROS 12 FDR sensor (METER Group, Pullman, WA, United States). The treatments consisted of 20 ml of water for the controls or of 0.1-mM Put (CAS No.: 333-93-7) or 0.5-mM Spd (CAS No.: 124-20-9) for the treated plants; both compounds purchased from Aldrich Chemical Co. (St. Louis, MO, United States). The treatment was applied manually using a backpack sprayer with a dispenser. The solutions were applied directly to the wet soil, between the irrigation emitter and the plants, to ensure the direct availability of the root system. The treatments were applied twice, 2 and 4 weeks after the transplanting. After the second application, the water restriction for the drought variant started, and these conditions were maintained until the harvest of the maize cobs. The plants did not receive additional fertilization or protective treatment during the experiment. The weeds were manually removed every 7–10 days to avoid competition for the water.

Biomass, yield, and water status measurement

In 15 and 30 days after the onset of the water restriction, the relative water content (RWC, %) was calculated (Barrs and Weatherley, 1962). A total of 20 disks of 1-cm diameter per variant were excised from the last fully expanded leaf and immediately weighted to register the fresh weight (FW, mg). After that, the disks were submerged in distilled water for 24 h to determine the turgid weight (TW, mg). Finally, the disks were oven-dried at 85°C for 48 h to register the dry weight (DW, mg). The RWC for each disk was calculated as

$$\text{RWC} = (\text{FW} - \text{DW})/(\text{TW} - \text{DW}) \quad (3)$$

The yield-related parameters were evaluated at the harvest, 45 days after the onset of the stress. The number of adequately developed maize cobs per plant and variant was counted. Ten random plants per variant were selected to determine morphometric parameters such as plant length (from insertion to the soil until the base of the flower) and width (at the middle of the stem length), and the length and width of the last fully developed leaf. The cobs to evaluate production were also obtained from the selected plants. The cobs were weighed to record the fresh weight and then oven-dried at 65°C for 1 week to reduce the possible bias due to the different moisture levels. The dry cob weight, the number and total weight of all kernels per cob, and the weight of 100 kernels (in triplicate from each cob) were registered. The total yield considering 40,000 plants ha⁻¹ for the used plantation frame was also calculated using the following equation with the following formula:

$$\begin{aligned} \text{Yield ha}^{-1} &= \text{Average kernel weight/Cob} \times \\ &\text{Average cob number/Plant} \times \text{Estimated plants ha}^{-1} \end{aligned} \quad (4)$$

The Harvest index (HI) was also calculated from the total kernel weight (total KW) per cob and the average cob fresh weight (average cob FW) as follows:

$$\text{HI} = \text{Total KW/Average Cob FW} \quad (5)$$

The production water use efficiency (WUEp) in maize was also estimated (Kiziloglu et al., 2009). The accumulated effective crop evapotranspiration (ETc, mm) was calculated through the experiment (Supplementary Table 1). This term corrects the deficiencies of the ETo values by a Kc factor that depends on the moisture soil level, crop characteristics, and the stage of the crop vegetative cycle (6). For maize, the Kc values are estimated at 1.2 in the initial phases to 0.6 at the final stages (FAO).

$$\text{ETc} = \text{ETo} \times \text{Kc} \quad (6)$$

The WUEp (kg mm⁻¹) was then calculated as the ratio between the accumulated ETc and the final yield (kg ha⁻¹).

Protein, carbohydrates, and mineral composition of the maize flour

All kernels from the selected cobs were ground to a fine powder to evaluate quality parameters. A 50 mg of the powder per sample was used for the total protein content calculated using the Kjeldahl Method (Kirk, 1950), multiplying the total nitrogen content by 6.25. An additional 100 mg of the powder was used to determine total carbohydrates using the phenol sulfuric acid method modified in multi-well plates (Jiménez-Arias et al., 2019). Finally, 1 g of the flour powder per sample was used to analyze the mineral content (Ca, Mg, K, P, Na, Cu, Zn, and Fe). Each sample was converted to ash in a muffle stove at 480°C and mineralized by the dry method with 6 N HCl. The mineral levels were determined by ICP OES Avio 500 (Perkin Elmer, Waltham, MA, United States).

Data analysis

All plant growth and production parameters were used to calculate the Plant Biostimulant Characterization Index (PBCI), a visual and helpful tool to reduce all considered variants into a single number a for better biostimulant characterization (Ugena et al., 2018; Sorrentino et al., 2021). The PBCI was used to select the best-performed concentrations in the first experiment (dose optimization) and evaluate the PA application impact on maize production.

The data were evaluated using different statistical approaches. First, using Infostat software, the normality of the variables was assessed with the Shapiro–Wilks test. After that, a two-way ANOVA ($p \leq 0.05$) followed by multiple comparisons with LSD posthoc test was used for parametric data and Kruskal–Wallis test ($\alpha = 0.05$) for nonparametric data. The multivariate statistical analyses with the yield-related parameters were also carried out for better visualization. One principal component (PC-Dim) analysis and matrix correlation were constructed in RStudio v.2021.09.1+372 using the packages *factoextra*, *ggplot2*, and *corrplot*.

Results

Nursery tray dose optimization

The dose optimization was performed in nursery trays following the protocol established by Jiménez-Arias et al. (2022). The parameters considered to evaluate the efficiency of the dose were the plant weight (shoot and root), the RGR (%), and WUE (Supplementary Table 2). Table 1 displays the heatmap from the computed parameters, transformed with the log2 and relativized to the untreated maize seedlings. The drenching with Put at 0.5 and especially 0.1 mM enhanced the plant biomass (weight), RGR (%), and WUE compared to untreated seedlings

TABLE 1 Heatmap summarizes the parameters estimated in maize seedlings treated with Put or Spd at five concentrations (0.01, 0.1, 0.5, and 1 or 2 mM) grown under water limitation (50% field capacity).

Compound	Concentration	Biomass	RGR	WUE	PCBI
Put	0.01	−0.003	−0.001	−0.003	−0.008
	0.1	0.050	0.026	0.059	0.135
	0.5	0.014	0.008	0.017	0.039
	1	−0.033	−0.018	−0.039	−0.091
	2	−0.021	−0.011	−0.025	−0.057
Spd	0.01	−0.089	−0.049	−0.106	−0.244
	0.1	−0.085	−0.046	−0.101	−0.232
	0.5	−0.044	−0.024	−0.052	−0.120
	2	−0.078	−0.042	−0.092	−0.212
	1	−0.119	−0.066	−0.143	−0.328

The studied parameters were plant dried weight (Plant W, mg), relative growth ratio (RGR, %), and water use efficiency (WUE, mg mL^{−1}). The table represents the ratio (log2) between the original values of each variant and the untreated plants (Control). The right panel shows the obtained PCBI values. Blue indicates a stress alleviator; orange indicates a stress inductor.

when grown under a water limitation of 50% field capacity, ending with a positive PCBI value (Table 1). Contrarily, the application of Spd did not improve the seedlings performance under the same growth conditions (Table 1 and Supplementary Table 2). The plants treated with 0.5-mM Spm presented less negative PCBI (Table 1). Thus, we selected 0.1-mM Put and 0.5-mM Spd to evaluate their impact on maize production under optimal and water deficit conditions.

The application of polyamines enhanced the RWC in maize plants

The changes in soil water content were recorded through the experiment and represented in Figure 1A. The plants under well-watered conditions were irrigated according to their water requirements estimated by FAO's reference evapotranspiration (ET_o) (Supplementary Table 1). The water supply was reduced by 20% of the crops water requirements for the water stress variants. As a result, we observed that the volumetric water content in the well-watered plants was maintained between 1.7 and 1.6 m³ m^{−3} (Figure 1A). However, in the stress variant, the water was drastically reduced to a volumetric water content of 1.4 m³ m^{−3} for the first four days and maintained for additional 15 days. After that, it fluctuated between 1.3 and 1.1 m³ m^{−3}.

The water status of the plants was estimated twice by the RWC, at 15 (t₁) and 30 (t₂) days after the water restriction onset (Figures 1B,C). According to ANOVA, there was a significant interaction between growth conditions and treatment for RWC_{t₂} but not for RWC_{t₁}. The water restriction reduced the RWC_{t₁} in all plants compared to well-watered ones. However, the application of Put and Spd increased the RWC_{t₁} values compared to their respective controls. The Put and Spd applications kept the same trend, with an RWC_{t₁} of 4 and 2.6% for WW and 9 and 4% for WD conditions,

respectively, compared to the corresponding untreated plants (Supplementary Table 3). Interestingly, no differences in RWC_{t₂} were observed among variants; only the untreated plants significantly reduced the RWC_{t₂} to 80% (Figure 1C and Supplementary Table 3). Thus, Put and Spd applications increased significantly RWC_{t₂} to 14.9 and 15.8% in the maize plants, respectively, compared to the untreated plants under WD (Supplementary Tables 1, 3).

The application of Spd by drenching reduced the biomass-related parameters under water limitation

The biomass production was evaluated by monitoring several parameters such as stem diameter, the plant length (measured from the transition to the roots, up to the emission of the anthers), length and width of the flag leaf, and the ratio length/width (L/W) for the flag leaf (Figure 2 and Supplementary Table 4). The parameters were then represented in a parallel coordinate plot, and the values were used for the PCBI calculation. None of the treatments enhanced plant biomass production in any water regime, so all presented negative PCBI values (Figure 2). The parallel coordinate plot illustrated that only Put slightly enhanced the biomass production under WW conditions; the rest of the treatments and growth conditions presented a negative effect. The thicker stem was reported for the WW control plants, with Put plants having the thinnest stem for both irrigation conditions. Interestingly, the Spd-treated plants were the only ones keeping the stem thickness irrespectively of the growth conditions (Figure 2 and Supplementary Table 4). The water limitation slightly reduced the plant height, flag leaf length, and width without significant differences (Supplementary Table 4). Overall, the highest plant length and leaves were found in the Put treated maizes under WW conditions, while the shortest plants were reported for the WD with Spd application. Regarding the leaf L/W ratio, the highest values were reported for Put and Spd in WW conditions, followed closely by the Control treatment and Put under WD (Figure 2 and Supplementary Table 4). The lowest L/W ratio was observed in the maize plants treated with Spd under WD, confirming that this treatment modified the plant stress response and hence, the growth profile.

Put enhanced yield and WUEp under optimal conditions, and Spd under water limitations

As a first step in evaluating maize's yield, the total number of cobs produced per variant was counted and represented in Figure 3A. The Put application was the most effective treatment

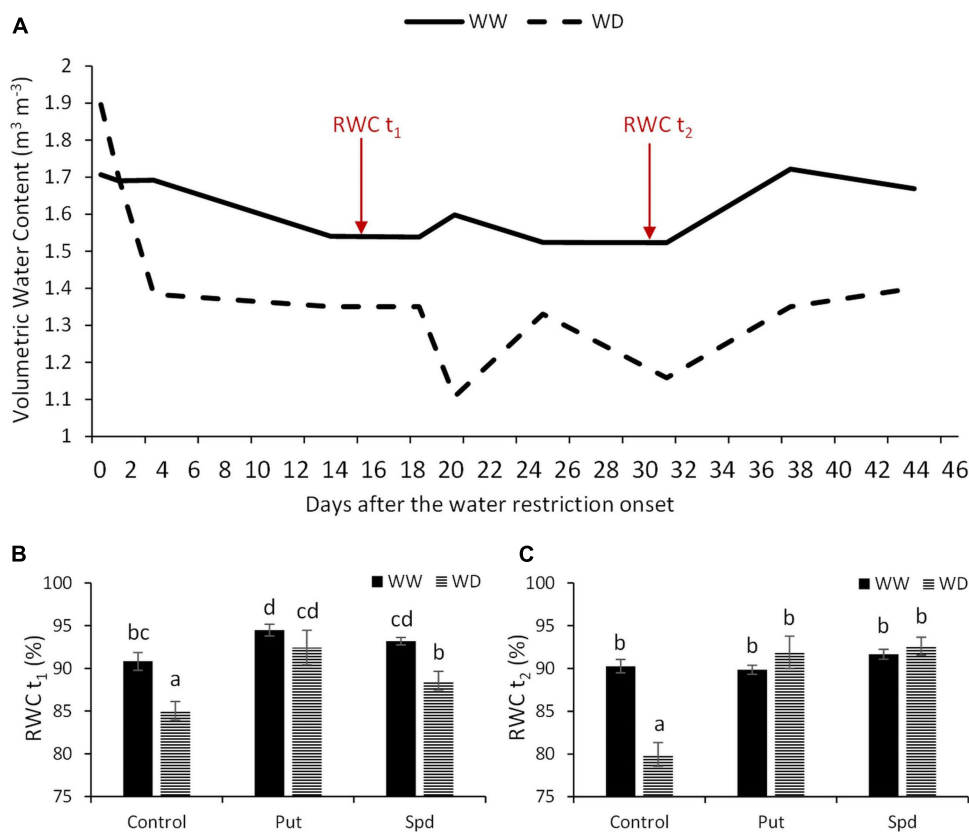

FIGURE 1 Water-related parameters in maize plants under optimal conditions and water limitation. **(A)** Volumetric water content of the soil ($\text{m}^3 \text{m}^{-3}$) measured with the FDR soil moisture sensor from the onset of the water restriction. Red arrows indicate the two dates (t_1 , t_2), when the relative water content (RWC, %) was measured in the maize plants untreated (Control) and treated with 0.1-mM Put or 0.5-mM Spd under optimal conditions (WW) or water deficit (WD). **(B)** RWC_{t_1} of the plants, t_1 corresponds to 15 days after the onset of the stress. **(C)** RWC_{t_2} (%) of the plants, t_2 corresponds to 30 days after the onset of the stress. Mean \pm SE; $N = 24$. Different letters for the RWC values indicate the significant differences according to the LSD test after two-way ANOVA ($p \leq 0.05$).

FIGURE 2 Parallel coordinate plot and PBCI regarding the biomass-related parameters. Stem diameter (mm), plant length (cm), flag leaf length and width (cm), and length/width ratio (L/W) of maize plants treated with 0.1-mM Put or 0.5-mM Spd under optimal conditions (WW) or water deficit (WD). The plot represents the ratio (\log_2) between the original values of each variant and the untreated plants under WW conditions. The right panel shows the obtained PBCI values. Orange color indicates stress inductor.

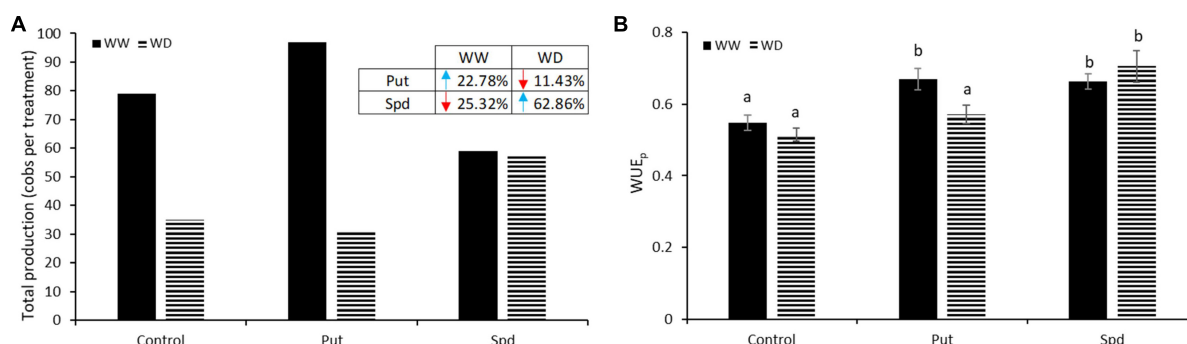

FIGURE 3

Total production and WUE_p in PA treated maize plants. **(A)** Total production expressed as the sum of all cobs produced per variant in maize plants untreated (Control) and treated with 0.1-mM Put or 0.5-mM Spd grown under well water (WW) or water deficit (WD). Enclosed in the left upper table, the percentage of increment (blue, upside arrow) or reduction (orange, downside arrow) of Put and Spd treatment relative to the respective control in WW and WD conditions. **(B)** Water use efficiency calculated as the ratio between the fresh biomass production and the ET_o adapted to maize crop with the FAO Kc. Different letters indicate the significant differences between the treatments and the growth conditions according to the LSD test after two-way ANOVA; $p < 0.05$.

under WW, so its plants increased the total production by 22.78%, with 97 cobs compared to 79 obtained in the controls. On the other hand, Spd reduced the production to only 59 cobs. Water limitation reduced the final yield in all treatments, except in Spd treated plants that maintained similar production as observed under WW conditions (Figure 3A) and enhanced the production by 62.78% compared to control plants under WD. However, the Put application reduced plant production by 11.43% (Figure 3A).

Crop physiologists initially considered WUE as the amount of carbon assimilated and crop yield per unit of transpiration (Viets, 1962), although the definition evolved to biomass or marketable yield produced per unit of transpiration. In this sense, this parameter is essential to better characterize the productivity of crops, especially in a water scarcity scenario. In this work, the production WUE was calculated to understand better the relationship between plant production and the water used (Figure 3B). A significant interaction between treatment and growth condition was obtained according to ANOVA ($p = 0.002$). In control plants, no differences in WUE_p were observed among growth conditions. However, the PA treatments enhanced the WUE_p of the treated plants under WW conditions, but only Spd application improved this parameter under WD (Figure 3B). These results pointed to WUE_p increase induced by PAs as one of the primary factors conditioning maize yield under optimal and water limitation conditions.

Other parameters related to the cobs and kernel production were also determined (Supplementary Table 5). Among them, the fresh weight and length of the cobs and the final yield per hectare considering the kernel were the production-related parameters that showed a significant interactive effect on the treatment and growth conditions according to ANOVA ($p \leq 0.05$). The treatment with Put and Spd improved the fresh cob weight but reduced the length compared to the controls

under WW, but not under WD (Figure 4 and Supplementary Table 5). Contrarily, the PA treatments reduced the cob length in both growth conditions except for Spd under WD. Polyamines significantly increased the yield per hectare ($1.5 \times 10^6 \text{ g ha}^{-1}$ for Put and $1.6 \times 10^6 \text{ g ha}^{-1}$ for Spd) compared to untreated plants ($1 \times 10^6 \text{ g ha}^{-1}$) under WD conditions, reaching the level of the WW plants (Figure 4 and Supplementary Table 5). Regarding the harvest index (HI), Put-treated plants under WD overcame the levels of controls under WW conditions.

To integrate the production data, two additional PBCIs were estimated (right panel, Figure 4). As a final result, we observed that Put improved maize yield (positive values for PBCI) under WW and WD conditions. However, Spd only enhanced maize production under WD conditions and negatively affected the plants under WW (right panel, Figure 4). Altogether, the PA application by drenching enhances the quality of maize production, especially under water restrictions.

Polyamines application modifies the quality of the maize flour

As the final step, we evaluated the percentage of carbohydrates (CH) content and protein in the kernel powder obtained from each treatment and growth conditions (Figure 5 and Supplementary Table 6). According to ANOVA, both parameters were affected by the interaction between the treatment and growth conditions. Under WW conditions, the PA application did not change the carbohydrate content (Figure 5A). The reduced water availability significantly decreased the CH content for the control treatment; curiously, both PA treatments resulted in significantly higher CH content than the WD control, leveling it up to the control treatment under WW conditions (Supplementary Table 6). The water

FIGURE 4

Parallel coordinates plot representing \log_2 of the production parameters relativized with the control of each growth condition; cobs per plant (Cobs/Pl), cobs fresh (Cob FW), and dry weight (Cob DW) (g), length [L(K)] (kernels in a line), circumference [circ. (K)] (kernel circumference) and diameter (diam.) (mm), the weight of 100 kernels (100 K DW) (g) and the total kernel weight (Total KW) (g), the total number of kernels (Total K), the yield per hectare, considering the dry kernel production [$\text{Yield(K)} \text{ ha}^{-1}$], harvest index (HI) (Total dry kernels weight/Average cob fresh weight), and the WUE in maize plants untreated (Control) and treated with 0.1-mM Put or 0.5-mM Spd grown under well water (WW) (A) or water deficit (WD) (B). The right panel represents the PBCI, which summarizes the plot in a single number positive (Blue color) for growth promotor or negative (orange) for stressor.

availability significantly affected the protein content (%), with higher values for the kernels from the controls under WD than under WW conditions (Figure 5B). The PA application presented a different pattern (Supplementary Table 6). Also, Put significantly increased the protein content under WW conditions but reduced them under WD compared to the respective controls. Contrarily, Spd did not affect the protein content under WD but significantly reduced it under the protein content compared to the controls under WW conditions (Figure 5B).

The mineralogical profile of the flour obtained from the dry grains was also analyzed (Table 2 and Supplementary Table 7). Significant changes were observed in the flour mineral compositions due to the treatment, growth conditions, and their interaction. As Na, P, and Cu were the most sensitive parameters because their changes were due to the interaction between the treatment and the growth conditions ($p \leq 0.006$, $p \leq 0.001$, and $p \leq 0.047$, respectively). The treated plants presented the biggest changes in Cu, mainly due to a significant increment in those treated with Spd (Table 2 and Supplementary Table 7). The WD conditions significantly reduced the Na levels of

the non-treated plant, but the application with Put and Spd kept them at the same levels as the WW-variants. The water restriction significantly induced the P, K, and Mg accumulation in the plants under WD, except the Spd treated ones that kept the lower values observed in the flour from the WW plants. The opposite situation was observed for Ca, where only the Spd-treated plants from WD kept the levels of the WW ones (Table 2 and Supplementary Table 7). Altogether, the PA application modifies maize flour's chemical and mineral composition. However, the changes are also highly influenced by the growth conditions.

The multivariate statistical analysis uncovers the different effects of Put and Spd in maize

To better visualize and integrate the biomass, productivity, hydric status of the plants, and the kernel nutritional profile, we performed a principal component analysis (PCA) and correlation matrix (Figure 6). The two first PCs explained 67.3%

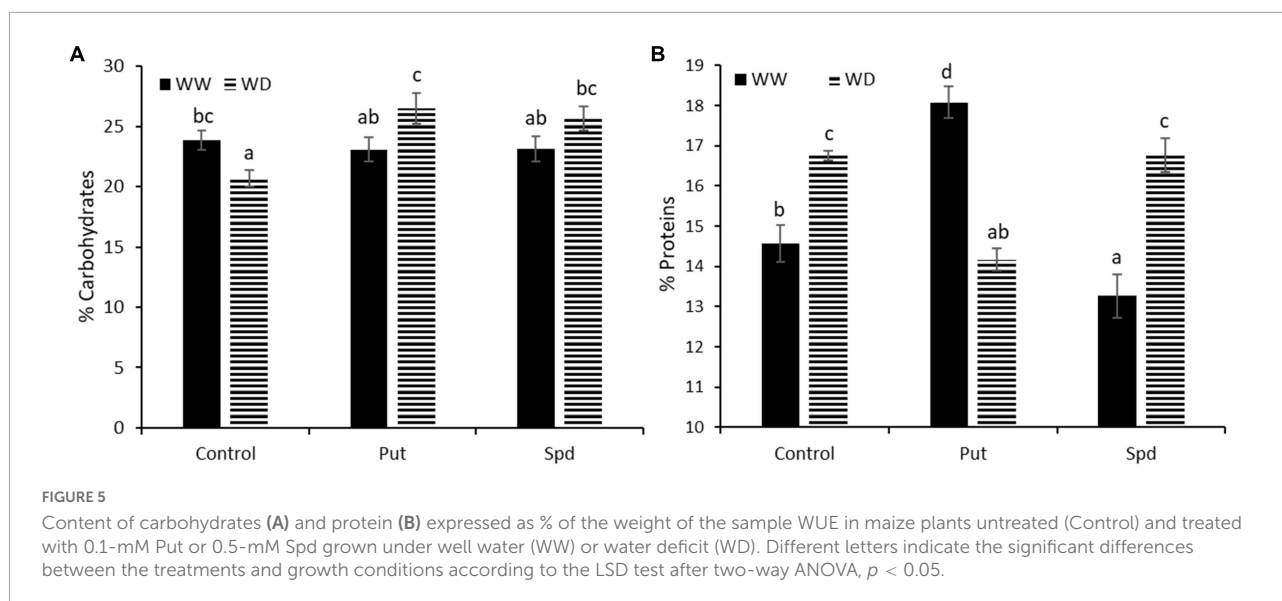

TABLE 2 Heatmap containing the log2 values of the different mineral elements content (ppm) in maize plants untreated (Control) and treated with 0.1-mM Put or 0.5-mM Spd grown under optimal conditions (WW) or water deficit (WD).

Growth conditions	Treatment	Ca	Fe	K	Mg	Na	P	Zn	Cu
WW	Control	0 ab	0 a	0 ab	0 ab	0 b	0 ab	0 a	0 a
	Put	0.58 ab	-2.00 a	-0.42 a	-0.24 a	0.00 b	-0.15 a	-1.77 a	0.77 a
	Spd	0.20 ab	0.38 a	-0.27 ab	-0.11 a	-0.07 b	0.14 bc	1.45 b	0.31 a

The values are relative to the control treatment under WW. The different letters indicate significant differences according to the LSD test after two-way ANOVA, $p = 0.05$. Blue indicates accumulation and red reduction.

(Dim1 = 42%; Dim2 = 25.3%) of the total model variation. As the first result, Dim1 separated the non-treated plants due to the irrigation regime (Figure 6A). However, whereas stressed Put treated plants were located close to the irrigated plants, Spd was located opposite to these plants, pointing to a different mechanism of action between these two PAs. Put treated plants under WD strongly correlated with the leaf biomass expressed as flag leaf length/width ratio and the Zn and Fe levels. This result was also evident in the negative correlation between Fe, p, K, and Mg with many production-related parameters, the plant RWC and Ca in the flour, observed in the correlation matrix (Figure 6A). Contrarily, Spd-treated plants under WD presented longer (Cob_L) and heavier (Cobs_FW) cobs, with higher content of Cu in the flour (Figure 6A). It is worth mentioning that the growth condition affected CH and protein content, presenting a higher correlation with the RWC, the kernel-related parameters, and the final yield. The PA-activated strategy conditioned the biomass production (vegetative or reproductive biomass) and the composition of the final product; in this case, the quality of the flour.

Discussion

Nowadays, the research topics need to focus on understanding how the principal abiotic stresses such as drought affect crop yield. Besides, due to the promising biostimulant efficiency to mitigate the plants' stress effect, new evidence is needed to know if they provide any quantitative or qualitative benefit in the final yield. This study aimed to evaluate using the major PAs as small molecules-based biostimulants to improve maize production under optimal and water restriction conditions. Their impact on maize biofortification is also investigated. A recent review has reported the relevance of these compounds in regulating plant tolerance/resistance to stress abiotic/biotic (Ramazan et al., 2022). When used PAs as a foliar application, the concentration range of 0.1–1 mM elicited positive responses in stressed plants (De Diego and Spíchal, 2020). In this work, we investigated their application *via* fertirrigation because it is considered an efficient agricultural method to enable plants to cope with the consequences of the water limitation during the growth and fruit production

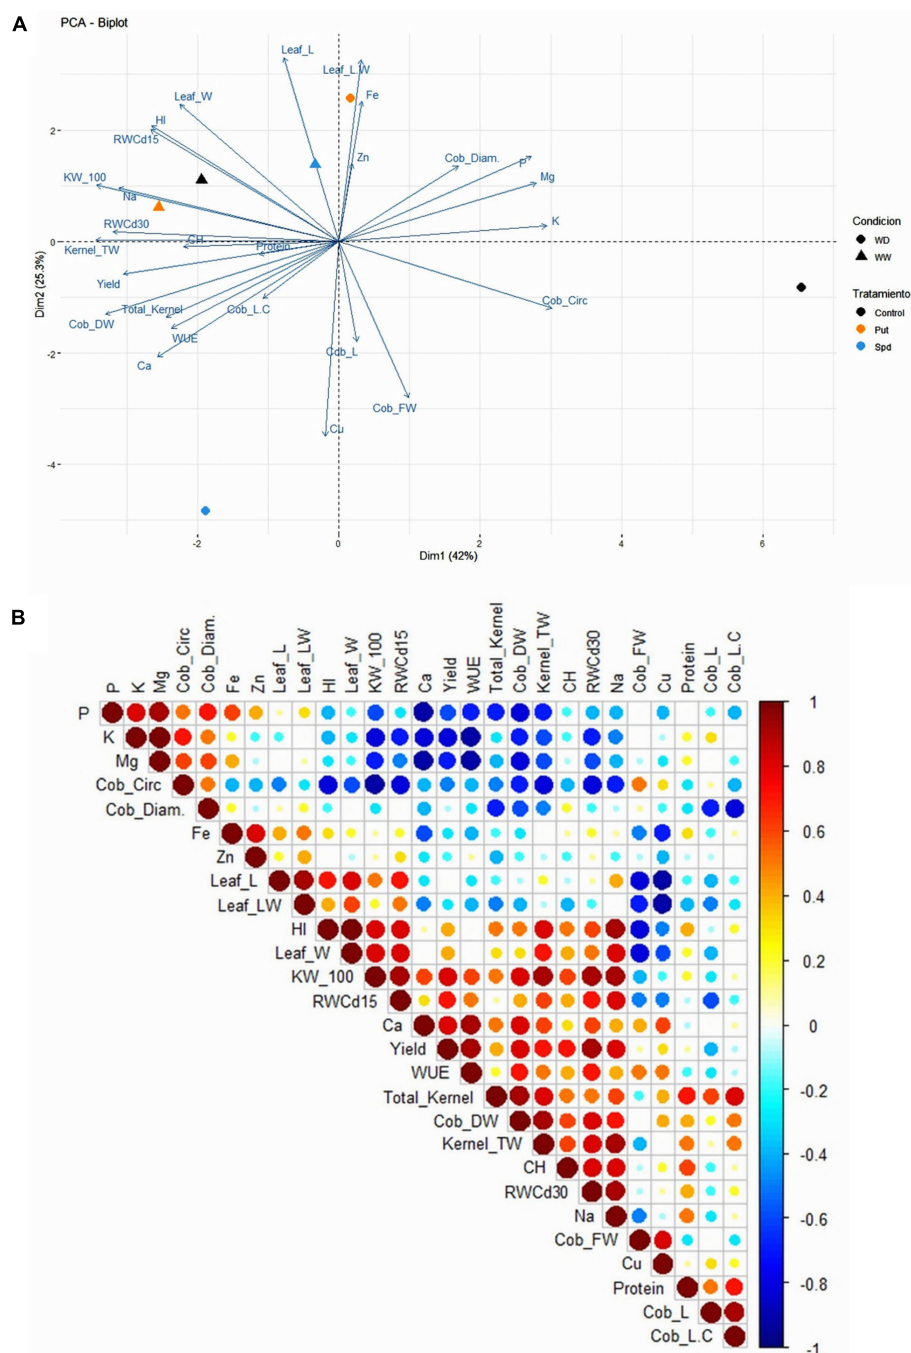

FIGURE 6

Principal component analysis (A) and correlation matrix (B) of the studied biomass parameters [flag leaf length (Leaf_L), flag leaf width (Leaf_W), and flag leaf length/width ratio (leaf_LW)], relative water content at 15 and 30 days after the stress onset (RWC 15d and RWC30d), productivity parameters [cob length (Cob_L), cob circumference (Cob_circ.), cob diameter (Cob_diam.), cob fresh weight (Cob_FW), cob dry weight (Cob_DW), weight of 100 kernels (KW_100), total number of kernels per cob (Total_Kernel); total weight of the kernels per cob (Kernel_TW), harvest index (HI), yield, water use efficiency (WUE), protein content (Protein), carbohydrates content (CH), and mineralogical profile of the kernels (P, K, Mg, Fe, Zn, Ca, Na, and Cu) in maize plants untreated (Control) and treated with 0.1-mM Put or 0.5-mM Spd grown under well water (WW) or water deficit (WD).

(Agliassa et al., 2021). The main reason is that the fertirrigation provides the plant with a longer nutrient uptake window than foliar application (Parkunan et al., 2011). However, it

must be considered that different application methods can trigger different responses in the plants (Paul et al., 2019), so optimizing the dose for the root treatment was an essential step,

ending with 0.1-mM Put and 0.5-mM Spd the most effective concentrations (Table 1).

The application of PAs reduced the RWC losses when plants are subjected to water limitations (Figure 2) compared to untreated plants. Many studies have also obtained similar results and reported that the PA-induced better water balance is due to decreasing the stomatal conductance and increasing proline, anthocyanins, and soluble phenolics levels, improving membrane properties and enhancing the activity of catalase and superoxide dismutase (Farooq et al., 2009; Hassan et al., 2018). Their application has also been described as improving plant osmotic adjustment mechanisms (Choudhary et al., 2022). However, the improvement in the water balance did not influence the plant biomass but instead reduced it in the PA-treated plants (Figure 3). Similar results were also observed in other maize species (Li et al., 2018) and crops (Ullah et al., 2012; Liu et al., 2018). One possible explanation is that this type of treatment simulates moderate stress in the plants, so-called hardening, to be ready for fighting future adverse conditions (Duarte-Sierra et al., 2020).

The “no improvement” of the plant growth might also be an energy-saving mechanism to redirect the PA-induced/accumulated resources to the enhancement of the production of the crop. This concept has already been proposed for fruit tree management, where the application of plant growth retardants has been explored to reduce vegetative growth and obtain higher production (Köhne, 1989). According to this assumption, we expected that both PA treatments improved maize production under WW and WD. However, different responses were observed; Put enhanced the total maize yield under WW but reduced it under WD (Figure 3). Despite the reduced total maize yield, drenching with 0.1-mM Put ended with a positive PBCI under WD due to a higher number of cobs per plant, higher kernel weight, or yield per ha (Figures 4, 7A and Supplementary Table 5). The exogenous application of PAs, including Put, has improved flowering and yield in many plant species (Reviewed by González-Hernández et al., 2022) and wheat production (Mostafa et al., 2010). These results could partially explain the higher number of cobs per plant. Besides, the exogenous application of 0.1-mM Put enhanced yield in winter wheat under WD and the plant biomass (Gupta and Gupta, 2011; Gupta et al., 2012). Besides, the long-term application of Put on salt-stressed rice stimulated the morphogenesis of reproductive structures, enhancing the yield compared to the unstressed plants (Ndayiragije and Lutts, 2007). This positive effect of Put was also observed in the vegetative development and yield of barley salt-stressed plants (Seleem et al., 2021). Pál et al. (2018) also suggested that Put pretreatment induces acclimation processes under controlled conditions. These results agree with ours, so the Put-treated plants presented the best growth and yield under control conditions, and they had higher biomass production and some productive parameters under WD (Figures 4, 6A, 7A).

Overall, the PA addition enhanced the production, in agreement with the findings of Liang and Lur (2002), who demonstrated that aborted maize kernels had lower endogenous PA levels. However, a much higher yield was obtained with Spd than with Put under WD (Figures 3, 4 and Supplementary Table 5). This could be because the vital biological processes, such as embryogenesis and seed settings, have been related more to the levels of Spd than Put (Feng et al., 2011; Chen et al., 2019a). The benefit of Put could be only due to its condition as a precursor of Spd synthesis (Feng et al., 2011). Furthermore, a recent study showed that high endogenous levels of Put but not of Spd could condition grain filling of wheat, and hence, yield, under drought because it induced the accumulation of endogenous ethylene and ABA in the grains, which worsened the adverse stress effects (Liu et al., 2016). Controversial results were also obtained in wheat where the exogenous Spd and Put applications had an opposite effect on florets; while Spd inhibited the floret degeneration, Put enhanced it, resulting in a reduction of fertile floret number (XiaoKang et al., 2016). Another study demonstrated that pretreatment with Spd improved the grain yield of salt-stressed rice plants (Saleethong et al., 2013). However, this response must be concentration-dependent and conditioned by the endogenous levels of the different PA forms and their crosstalk with other phytohormones. For example, the crosstalk between ethylene and PAs has also been reported to condition the seed setting in maize (Feng et al., 2011). These authors also demonstrated that high levels of PAs are needed to avoid aborted kernels. It is well known that ethylene and PAs compete for the same precursor S-adenosyl-methionine (SAM), the methionine-activated form (Podlešáková et al., 2019). This could explain that high PAs and low ethylene levels promote plant flowering and embryogenesis (reviewed by Chen et al., 2019a), where Spd is the leading PA form regulating these processes.

From our knowledge of yield quality in maize, no study focused on the impact of PAs as small molecule-based biostimulants exist in the research literature. Our work demonstrated that PA application improved both yield quantity and quality. The first two parameters analyzed were the CH and protein content (%) in the flour powder obtained from the seeds (Figure 5 and Supplementary Table 6). Regarding CH, it was shown that the crosstalk between PAs and the ethylene pathway could condition plant yield and determine the grain filling and carbohydrate translocation in cereals (Yang et al., 2017). Therefore, we expected PA supplementation to induce a good CH transport, enhancing the kernel set and the final yield. As a result, WD reduced the CH content compared to the WW conditions in untreated plants, as previously observed by Hussain et al. (2020) and Abbas et al. (2021). However, opposite results were also published. For example, it has been reported that drought during the vegetative stage of maize plants induced an increment in glucose and amino acids on the grains (Harrigan et al., 2007) or did not affect

the CH content (Barutcular et al., 2016). Interestingly, the PA application increased the flour CH content in the plants under WD conditions over the levels of the WW plants (Figure 5A and Supplementary Table 6). Besides, clear evidence was found about a positive correlation between CH, the leaf RWC, and the Na content, which also positively correlates with the weight of 100 kernels and the total kernels weight (Figure 6B). It can be because the application of PAs under stress has been reported to protect the photosynthetic apparatus (ensuring the synthesis of photosynthates) and increase the osmotic adjustment of the plants under stress conditions (Chen et al., 2019b; Jing et al., 2019). Moreover, Xu et al. (2016) suggested that PA might be involved in the starch biosynthesis in kernels during post-anthesis when the soil is drying. Therefore, it is not surprising that those treatments reported the same yield as the proper irrigated plants and were higher than the WD control plants.

Low water availability increased the protein content in the flour, as described by Lu et al. (2015), Barutcular et al. (2016), and Abbas et al. (2021). However, other studies showed no alterations in the protein content by the water restriction (Hussain et al., 2020). Our work showed that the PA levels could be a relevant factor in determining the protein content in the flour. However, the opposite responses were obtained by the Put or Spd applications under both WW and WD conditions (Figure 5B). There is a direct link between the source–sink ratio during the filling stage and the final protein content in the kernels (Borrás et al., 2002). As mentioned above, Spd is considered essential for a good grain filling. Its exogenous application reduced the production and the flour protein content under WW conditions, whereas it improved the yield but not the protein level under WD (Figures 4, 5B). Contrarily, the Put application enhanced the production and protein content under WW but reduced both under WD. In wheat, the Spd application may affect grain filling by regulating protein synthesis and posttranslational modification, together with a better antioxidative response under drought conditions (Li et al., 2020). This way, the maize–Spd treated plants could deal better with the water limitations, ensuring better production under this adverse condition.

On the other hand, Put exogenous application induced the increment of N content in cotton plants (*Gossypium barbadense* L.) under control conditions and salt stress (Darwish et al., 2013). Our results partially agree since we only reported a protein increment under control conditions. The different behavior observed for Put and Spd applications in the plant growth and yield quantity and quality could be because they regulated the PA synthesis, the conversion, and the terminal catabolism differently. In this regard, it has been proved that at least the synthesis of Spd and Spm *via* the activity of the spermine synthase (SPMS, E.C.2.5.1.22) and spermidine synthase (SPDS, E.C. 2.5.1.16) could condition the flowering (reviewed by Chen et al., 2019b). In addition to the SPDS, the activity of other enzymes related to the PA synthesis, such as

ornithine decarboxylase (ODC, E.C. 4.1.1.17) and S-adenosyl-L-methionine decarboxylase (SAMDC, E.C. 4.1.1.50) have also been positively correlated with the grain filling rate (Yang et al., 2020). The PA oxidation *via* polyamine oxidases has been reported to regulate the plant reproductive phases (reviewed by Yu et al., 2019). In this last case, the back conversion from thermospermine or spermine to Spd was the most often identified step conditioning fertility and floral development. Cao et al. (2010) suggested that Spd, among Put and Spm, might be more closely involved in the physiological changes of the maize kernel development. Altogether, it is clear that the effect of the PA application in maize production is due to the endogenous levels and the interconversion between the different PA forms. The further studies are needed focusing on the enzymatic changes to clarify the mode of action of these compounds.

As the last step, we analyzed the mineral content of the flour. Only the limitation of water availability has induced controversial results regarding the flour mineral composition. For example, some studies did not see any effect (Feil et al., 2005), whereas others observed a reduction in K, P, and Fe (Abbas et al., 2021). Contrarily, Avila et al. (2017) reported the increment of P and Mg on grains of maize plants subjected to water limitations. These contrasting results point to a complex response of the plants that affect the metabolism in the grains and condition their mineral composition, which is regulated by the interaction of variety, genotype, and stress intensity. Our study showed that the application with PAs modified the composition under WW and WD (Table 2, Supplementary Table 7, and Figure 7B). Only the Spd treatment increased the Zn content in WW plants, whereas all applications enhanced the Cu under WW and WD. These two minerals have been reported to accumulate under drought stress (da Ge et al., 2010; Avila et al., 2017). Zn deficiency reduces plant growth and nutritional quality (Liu et al., 2019). In a previous experiment with wheat, it was proposed that the increment of N supply also contributed to an enhancement of the Zn concentration in the grains (Kutman et al., 2010).

Copper is also needed for the growth and development of maize and is an essential cofactor for many metalloproteins and various enzymes involved in different physiological and cellular processes such as oxidation and reduction reactions (Rajput et al., 2018). Besides, both minerals are considered essential for human health (White and Broadley, 2009; Garg et al., 2018). It is worth mentioning that the deficiencies in Cu also play a vital role in COVID-19, altering the disease outcomes and prognosis (Altooq et al., 2022). In this context, crop biofortification by applying compounds or fertilizers increases attention to assure plant and human health. Our results showed that a simple PA application could improve the content of these two minerals in the flour, especially when the plants are treated with Spd (five times more Cu under WD or three times more Zn under WW). Additionally, the Spd application also induced a significant

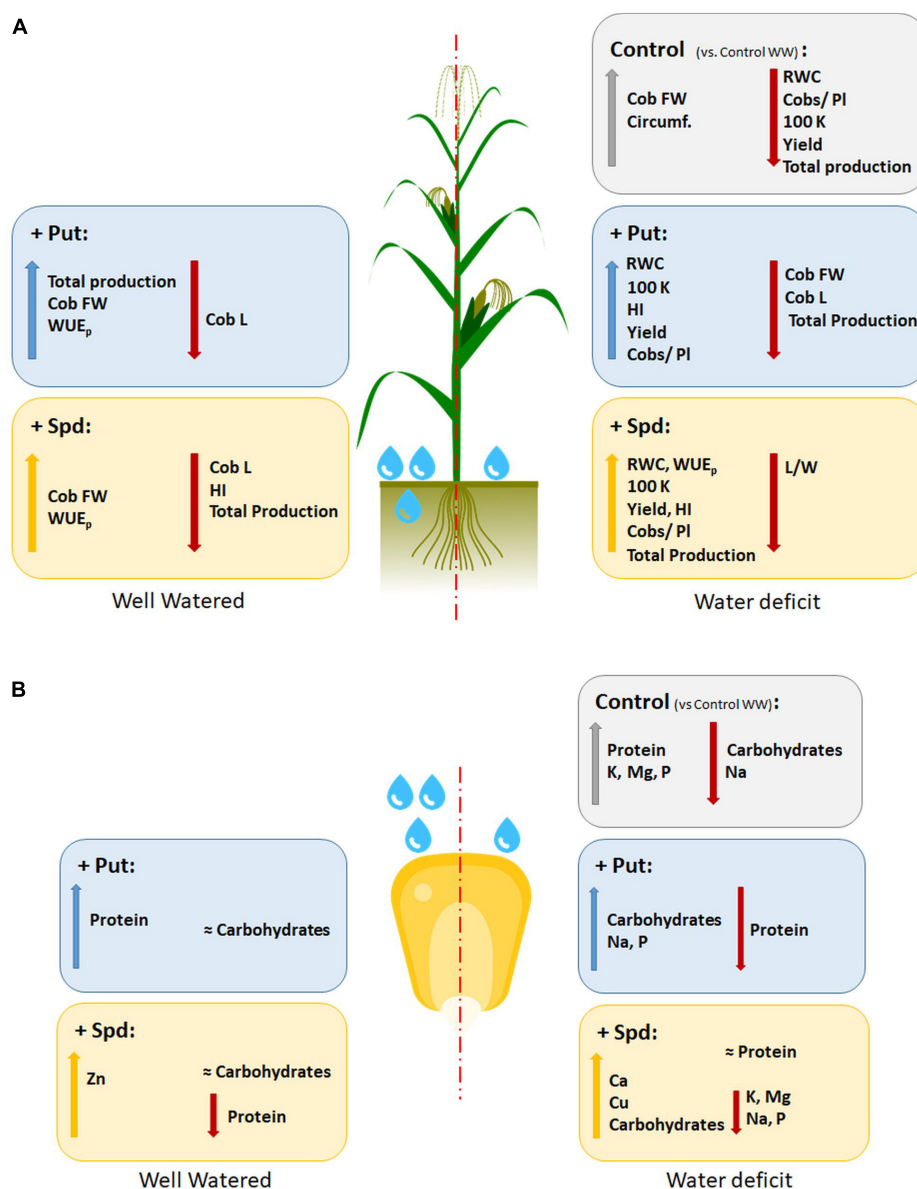

FIGURE 7

Summary of the variation of the observed parameters in maize plants untreated (Control) and treated with 0.1-mM Put or 0.5-mM Spd grown under well-water (WW) or water deficit (WD). Bold formatting of the font means the statistical effect on the increment or reduction; the total production is expressed as the sum of every cob produced per treatment and condition. The parameters displayed are the water use efficiency (WUE); leaf relative water content (RWC); flag leaf length/width ration (L/W); cob fresh weight (g) (Cob FW); cob length, as kernels in the longitudinal line (Cob L); cob circumference, as the kernels in the perimeter at the center of the cob (circumf.); average cobs produced in a plant (Cobs/pl); the weight of 100 kernels (g) (100 K); harvest index (HI); yield (10^6g ha^{-1}) (Yield); % of carbohydrates; % of protein; and minerals (ppm) such as Ca, Zn, K, Mg, Na, P, and Cu.

accumulation of Ca. However, it is evident that product and crop specificities exist, so it is expected to respond differently to the treatments according to the genotype (Shahrajabian et al., 2021). From the human nutritional point of view, higher Ca content is an advantage because a recent study associates a dietary low calcium intake with a higher risk of all-cause mortality (Yoo et al., 2022). Altogether, we demonstrate that the exogenous application of PAs improves plant performance under stress

conditions and can also be an efficient biofortification approach (Figure 7), especially in the case of Spd.

Conclusion

The polyamine application by drenching can improve maize production under optimal and stress conditions. However,

different polyamines induced different responses, conditioned by the growth conditions. Putrescine was the most effective treatment under well-watered conditions because it enhanced the fruit production, the WUE, and the content of Ca and Cu. The spermidine application showed better results under water deficit, with better water balance, water use efficiency, higher production, and better nutritional composition of the flour by increasing carbohydrates content, Cu and Ca. These results point to polyamine supplementation as an exciting approach for crop biofortification. Nevertheless, due to the different effects of genotype and product specificities, a higher effort should be put into elucidating and characterizing the use of these substances for crop and site-specific locations.

Data availability statement

The original contributions presented in this study are included in the article/**Supplementary material**, further inquiries can be directed to the corresponding author.

Author contributions

AH, DJ-A, AB, and NDD designed the idea of the project. AH, DJ-A, and SM-S performed the experiments. AH and NDD analyzed the data and wrote the manuscript. All authors agreed with the last version of the manuscript.

Funding

This work was funded by the project “Plants as a tool for sustainable global development” (Registration No: CZ.02.1.01/0.0/0.0/16_019/0000827) within the program

Research, Development, and Education (OP RDE), and by the project AHIDAGRO 450 (MAC2/1.1b/279), Cooperation Programme INTERREG-MAC 2014-2020, with European Funds for Regional Development- 452 FEDER.

Acknowledgments

We thank Natalia Usenco for her technical support during field sample processing.

Plant growth-promoting rhizobacteria are important for improving plant iron nutrition, but the interactions among inoculants, host plants and soil microorganisms have not been greatly explored. *Rahnella aquatilis* JZ-GX1 was applied to treat the increasingly serious iron deficiency chlorosis in *Cinnamomum camphora*, and the resulting improvement in chlorosis was determined by assessing the contents of chlorophyll, active iron, Fe²⁺ and antioxidant enzymes in leaves, the effects on the soil microbial community and the metabolism in the rhizosphere by high-throughput sequencing techniques and liquid chromatography–mass spectrometry (LC–MS). The results showed that inoculation with JZ-GX1 significantly increased the chlorophyll content of *C. camphora*, which promoted the redistribution of active iron in roots and leaves, increased the activities of superoxide dismutase (SOD), peroxidase (POD), catalase (CAT) and ascorbate peroxidase (APX), and thus reduced membrane damage in iron-deficient *C. camphora* caused by reactive oxygen species. According to genome prediction and ultra-performance liquid chromatography–mass spectrometry (UPLC–MS) analysis, the JZ-GX1 strain could secrete desferrioxamine (DFO), and the concentration of DFO in *C. camphora* rhizosphere was 21-fold higher than that in uninoculated soil. The exogenous application of DFO increased the SPAD and Fe²⁺ contents in leaves. In addition, the inoculant affected the fungal community structure and composition in the *C. camphora* rhizosphere soil and increased the abundances of specific taxa, such as *Glomus*, *Mortierella*, *Trichoderma*, and *Penicillium*. Therefore, *R. aquatilis* JZ-GX1 application promoted iron absorption in *C. camphora* trees by secreting DFO and alleviated iron deficiency chlorosis through interactions with the local fungal community.

KEYWORDS

Cinnamomum camphora, iron deficiency chlorosis, *Rahnella aquatilis*, microbial community, desferrioxamine

Introduction

Iron is one of the most important trace elements in many living organisms and mainly exists as Fe^{2+} and Fe^{3+} in nature (Liu et al., 2017). The transformation between these forms is an important redox process in living cells, and the availability and content of iron play important roles in the growth and development of plants (Ferreira et al., 2019). Although iron is abundant in the Earth's crust, ranking fourth among all elements on the Earth's surface, the solubility of iron in soil is very low due to oxidation by oxygen in the atmosphere, drought and the alkalinity of semidry calcareous soil; thus, the absorption of iron by plants is difficult (Zhou et al., 2016). The concentration of free soluble iron in soil is $<10^{-17}$ M, which is markedly lower than the optimal value for plant growth (Arikan et al., 2018). Plants growing in these soils often show iron deficiency chlorosis, which seriously affects the yield of crops (Aras et al., 2018). Therefore, iron deficiency stress has become a global problem. Over the years, researchers have also introduced many control measures to solve this problem, including soil application, trunk injection, and foliar spraying of various inorganic, organic and chelated iron fertilizers (Farshchi et al., 2021). However, these methods have many problems, such as causing slight damage to trees and environmental pollution and high cost; thus, no economic and effective method for the prevention and control of iron deficiency chlorosis in plants has been developed (Li M. et al., 2021).

A large number of microorganisms are found in plant rhizosphere soil, and among these, the bacteria beneficial to plants are called plant growth-promoting rhizobacteria (PGPR). Many studies have shown that PGPR can secrete a series of substances, including siderophores, organic acids, and volatiles, to help plants cope with iron deficiency stress (Radzki et al., 2013; Martinez-Medina et al., 2017). For example, Liu et al. (2017) effectively controlled the yellowing associated with iron deficiency in peanuts and peaches through the use of siderophore-producing bacteria. Aras et al. (2018) studied the effect of PGPR on the uptake of iron by peach trees in calcareous soil and found that the absorption and transport of malic acid released by bacteria in the rhizosphere effectively reduced the pH of leaves and that the organic acid secreted by *Azospirillum brasilense* significantly reduced the pH of cucumber hydroponic nutrient solution and increased the activity of Fe^{3+} reductase in cucumber roots. However, the mechanisms through which microorganisms promote plant iron absorption are currently mostly limited to the phenotypic and physiological responses of host plants, and few studies have investigated the changes in indigenous soil microbial communities after inoculation with exogenous bacterial agents. The effects of most microorganisms on plants in nature are accomplished through interactions (Niu et al., 2021). Due to the influence of biological and environmental factors, the effects of inocula are often not ideal. The interaction between the plant rhizosphere and microorganisms is very complex. Whether a single exogenous bacterial agent can adapt to the indigenous microbial community and exert its plant growth-promoting

characteristics is currently unclear. Therefore, understanding the interactions among plants, inocula and local microorganisms is of great significance.

In recent years, with the rise and development of genomics technology, an increasing number of studies have used genomic, transcriptome, metabolome and microbiome sequencing techniques to comprehensively and deeply study the interaction mechanisms between PGPR and plants or the soil microbial community (Gamez et al., 2019; Luo et al., 2020; Yang et al., 2020; Ye et al., 2020; Priya et al., 2021). For example, Li F. et al. (2020) combined transcriptome and microbiome analyses and revealed that the rare fungus *Mortierella capitata* can promote crop growth directly by altering root gene expression levels and indirectly via interaction with indigenous rhizosphere bacteria. Tao et al. (2020) combined high-throughput sequencing, culturable microbiome, key microbial return and community interaction experiments and found that *Bacillus amyloliquefaciens* W19 enhanced multispecies root colonization in coordination with specific probiotic *Pseudomonas* populations in the tomato rhizosphere in the treatment of tomato bacterial wilt to ultimately result in the formation of a probiotic community that effectively helps plants resist pathogen infection. Tsai and Schmidt (2017) showed that coumarin secreted by plants is favorable for the interactions between plants and microbial communities under iron restriction. These special metabolites change the composition of root microorganisms and are necessary for plant iron uptake and immune regulation mediated by microbial communities.

Cinnamomum camphora, which belongs to Lauraceae, is the main component of subtropical evergreen broad-leaved forests and a famous tree species in landscapes (Zhong et al., 2019). Due to its good appreciation, pruning resistance, strong sprouting ability and excellent cultural value, *C. camphora* has become one of the dominant tree species in landscaping, has been widely used in parks, green spaces, street trees and courtyard greening (Chen et al., 2020) and has played an important role in improving the ecological environment of cities. *Cinnamomum camphora* contains unique chemicals and is affected by few diseases and insect pests, but due to heavy planting, lack of management and the area not suitable for the growth of the species, *C. camphora* etiolation is becoming increasingly serious in many places (Zhou H. et al., 2017; Duan et al., 2020). *Cinnamomum camphora* iron deficiency etiolation is generally characterized by varying degrees of leaf yellowing, poor tree potential, white and thin leaves in severe cases, scorched and withered spots on the tip and edge of leaves, and vulnerability to frost injury; the yellowed leaves are initially locally distributed only on the crown, and the number then increases gradually, resulting in yellowing of the whole crown, withering of shoots, sparseness of branches and leaves, shrinking of the crown, gradual exhaustion and death, which seriously affects the economic and ecological benefits of the species (Kong et al., 2020a).

The etiolation of *C. camphora* is pervasive and widespread. Researchers usually explore the cause of the disease from the perspective of the soil pH and element content, whereas the

microbial community in the underground part of *C. camphora* has rarely been investigated. In this study, nontargeted metabolic technology based on LC-MS was used to characterize the secretion and metabolism of *Rahnella aquatilis* JZ-GX1 in the rhizosphere of *C. camphora* and to identify the key substances that may affect the uptake of iron by *C. camphora*. From the point of view of soil microecology, we aimed to clarify the mechanism through which *R. aquatilis* JZ-GX1 alleviates the etiolation of *C. camphora*. A microbial amplification technique was also used to explore the effect of the JZ-GX1 strain on the community structure and composition of bacteria and fungi in the rhizosphere of *C. camphora* and to explore the soil microbial inducement that may lead to the etiolation of *C. camphora* with the aim of providing a scientific solution for the management of the disease.

Materials and methods

Plant materials, growth conditions and pot experimental design

Rahnella aquatilis JZ-GX1 (CCTCC M2012439) was isolated from the rhizosphere soils of *Pinus massoniana* in Guangxi, China, and identified by 16S rRNA sequencing (GenBank No. KC351183.1). This bacterial strain was inoculated into Luria-Bertani (LB) liquid medium and incubated in an orbital shaker (200 rpm) at 28°C for 18 h. Bacteria were collected by centrifugation at 8,000 rpm and 4°C for 15 min. The centrifuge tubes were washed with 0.1 M phosphate-buffered saline (PBS, pH 7.2), and the bacteria were then diluted to obtain 1×10^7 CFUs/ml for microbial inoculation (Kong et al., 2020b).

Three-year-old *C. camphora* seedlings were purchased from a nursery and planted in plastic pots ($\Phi 15 \times 20$ cm) containing 2 kg of saline-alkali soil. The soil properties were as follows: pH 8.2; organic matter, 7.89 g/kg; available N, 37.61 mg/kg; available P, 16.07 mg/kg; available K, 153.01 mg/kg and effective Fe, 6.14 mg/kg. All the plants were cultured at 25°C under a 12-h light/12-h dark cycle until the seedlings started to exhibit yellowing. Subsequently, 60 *C. camphora* seedlings were selected, divided into three groups (20 plants per group) and administered one of the following treatments: (1) 0.1 M PBS, (2) 1.2% iron sulfate (FeSO_4), and (3) 10^7 CFUs/mL *R. aquatilis* JZ-GX1 suspended in PBS. The plant roots in each pot were inoculated with 50 ml of the treatment solution, and the plants were then watered daily until harvesting of the plant tissues. The harvested samples were used for various physiological and biochemical analyses.

Determination of the Chl and Fe concentrations in *Cinnamomum camphora* plants

After 30 days, the concentrations of Chl in the leaves were determined according to the method described by Zhang et al.

(2009). Fresh leaf tissue (0.5 g) was extracted with 2 ml of 95% (v/v) ethanol for 24 h in the dark. The concentrations of Chl a, Chl b, and carotenoids in the extract were determined by reading the absorbances at 665, 649, and 470 nm, respectively, with a spectrophotometer (UNICOWFUV-2000, Unico, United States).

After harvest, the plants were separated into leaves, shoots and roots. Approximately 0.2 g of plant material was individually digested in 1 mol/L HCl at a 1:10 ratio (v/v) for the extraction of active Fe (Koseoglu and Acikgoz, 1995). Improved NH_4F masking method was used for the extraction of Fe^{2+} from the fresh samples. The concentrations of active Fe and Fe^{2+} in the digested solution were then determined with O-phenanthroline spectrophotometry (Ni et al., 2015).

Determination of the MDA, EL, O_2^- , and H_2O_2 levels in leaves

To analyse the mitigation of microbe-mediated iron deficiency stress in planted soil, the stress-related levels of malonaldehyde (MDA) and reactive oxygen species (ROS) in leaves were investigated (Chen et al., 2015). Young leaves on the top of the *C. camphora* trees were collected after 3, 5, 10, and 20 days of the different treatments. Malonaldehyde was extracted from leaves with 10% trichloroacetic acid, and its concentration was determined based on the absorbances at 450, 532, and 600 nm (Xu et al., 2008). The formation rate of O_2^- (Elstner and Heupel, 1976) and the level of H_2O_2 (Mukherjee and Choudhuri, 1983) in leaves were determined based on the absorbances at 530 and 436 nm, respectively. The values of electrolyte leakage (EL) were determined according to the method reported by Jiang and Zhang (2001).

Determination of antioxidant enzyme activity in leaves

To verify the levels of O_2^- and H_2O_2 , ROS-scavenging antioxidant enzymes were extracted from leaves according to methods described by Liu et al. (2010). The activities of superoxide dismutase (SOD), catalase (CAT), peroxidase (POD) and ascorbate peroxidase (APX) were determined based on the absorbances at 560, 240, 470, and 340 nm, respectively (Beauchamp and Fridovich, 1971; Aebi, 1984; Zhu et al., 2004; Li J. et al., 2020). To calculate the activities of antioxidant enzymes, the protein content in each of the enzyme extracts was determined based on the absorbance at 595 nm (Bradford, 1976).

Prediction of secondary metabolites of *Rahnella aquatilis* JZ-GX1

The complete genome sequence of *R. aquatilis* JZ-GX1 has been deposited in the NCBI under GenBank accession number

SAMN18652319, and the secondary metabolites of the JZ-GX1 strain were predicted using antiSMASH online prediction software.¹ The complete gene cluster information for siderophore synthesis in the JZ-GX1 genome was determined and mapped. The secondary metabolites of JZ-GX1 and other bacteria were compared and analyzed (Blin et al., 2019).

Gene expression related to siderophore biosynthesis of JZ-GX1 under Fe deficiency

Strain JZ-GX1 was inoculated into 20 ml of MSA medium (per liter: 20 g of sucrose, 2 g of L-asparagine, 1 g of K_2HPO_4 , 0.5 g of $MgSO_4 \cdot 7H_2O$) with or without $20 \mu M$ $FeCl_3 \cdot 6H_2O$ for 24 h and centrifuged at 12,000 rpm for 5 min. The bacterial cells were collected, rinsed with sterile water, frozen in liquid nitrogen, and stored at $-80^\circ C$ for RNA isolation. Total RNA of JZ-GX1 was extracted using a bacterial RNA extraction kit (Jiancheng Bioengineering Institute, Nanjing, China). After the detection of RNA quality and concentration, cDNA samples were prepared using HiScript II Q Select RT SuperMix for RT-qPCR (CAT: 11202ES08; Yeasen, Shanghai, China). The expression levels of related genes were calculated using ABI 7500 software (Applied Biosystems, United States), and *atpD* was used as an internal control (Li P. et al., 2021). These gene primers are shown in Supplementary Table S1.

Ultra-performance liquid chromatography–mass spectrometry spectrometric analysis

The crude siderophore extract of *R. aquatilis* JZ-GX1 was syringe-filtered using a $0.22\text{-}\mu m$ nylon filter. Filtrates were injected into a UHPLC instrument (U3000, Thermo Scientific, Germany) with a Waters BEH C18 Column (150×2.1 mm, $1.7 \mu m$, United States) at $35^\circ C$, and the instrument was connected to a mass spectrometer (TripleTOF® 5600+, AB Sciex, United States). The mobile phase consisted of acetonitrile:0.1% formic acid- H_2O at a ratio of 5%:95% with a 0.3 ml/min flow rate.

The positive and negative ion modes of electrospray ionization (ESI) were detected. The source conditions of ESI were as follows: Ion Source Gas 1 (Gas1): 50 charge; Ion Source Gas 2 (Gas2): 50 magical; Curtain Gas (CUR): 25; Source Temperature: $500^\circ C$ (positive ion) and $450^\circ C$ (negative ion); Ion Sapary Voltage Floating (ISVF): $5,500$ V (positive ion) and $4,500$ V (negative ion); TOF MS scan range: $100\text{--}1,200$ Dajia; ion scan range product ion scan range: $50\text{--}1,000$ Da; MaOF 0.2 s; MS scan accumulation time: 0.01 s; secondary mass spectrometry was performed by information-dependent acquisition (IDA). Using high sensitivity

mode, declustering potential (DP): ± 60 V, collision energy: 35 ± 15 eV.

Identification of metabolites in the rhizosphere soil of *Cinnamomum camphora*

Rhizosphere soil of *C. camphora* with and without inoculation with the JZ-GX1 strain was extracted in prechilled methanol (3 ml), sonicated for 30 min and centrifuged for 20 min at $4,000 \times g$. The supernatant was passed through a $0.22\text{-}\mu m$ filter for liquid chromatography combined with mass spectrometry (LC–MS) analysis at Wenxin Biotechnology Co., Ltd. (Nanjing, China; Wan et al., 2018). In brief, the extracts were separated using an ultra-performance liquid chromatography (UPLC) system (Waters Corporation, Japan). The UPLC column was an ACQUITY UPLC BEH C18 column (100 mm \times 2.1 mm, $1.7 \mu m$), which was maintained at $35^\circ C$ and treated with a multistep gradient for product elution over the course of 30 min at 0.4 ml/min. The gradient was composed of A (formic acid-water, containing 0.1% formic acid) and B (formic acid-acetonitrile, containing 0.1% formic acid) as follows: 0–5 min, 5% B; 5–50 min, linear gradient from 5% to 100% B; 50–60 min, 100% B. The time-of-flight mass spectrometry (TOF-MS) parameters were as follows: positive and negative ionization modes; the ion source temperature and solvent removal temperature were $120^\circ C$ and $450^\circ C$, respectively; the He carrier gas was 800 L/h; the MS scanning range was $50\text{--}1,000$ MHz/z; and the resolution was 30,000 (Yang et al., 2020).

Before the identification of metabolites, the original data were analyzed by peak identification, alignment, deconvolution and normalization. Following data evaluation, including quality control and principal component analysis (PCA) analysis, OPLS-DA, a supervised multivariate method, was used to maximize metabolome differences between sample pairs. Differentially accumulated metabolites (DAMs) were set at fold change (FC) > 2 or FC < 0.5 and OPLS-DA VIP ≥ 1 . Volcano map construction and unsupervised PCA clustering of the identified metabolites were performed using Ezinfo 3.0. The MetaboAnalyst 4.0 software was employed to build heatmap diagrams. Subsequently, the KEGG² were used to construct the metabolic pathway.

High-throughput sequencing and analysis of 16S rRNA and internal transcribed spacer regions

To investigate the effects of strain JZ-GX1 on the rhizosphere microbial community, six samples were randomly selected on the 30th day from three replicates of the inoculated and uninoculated

¹ <https://antismash.secondarymetabolites.org/>

² <http://www.genome.jp/kegg/>

treatments, and two soils from the same replicate were mixed to obtain one composite sample. After removing 0–5 cm of topsoil, the soil around the root system was gently shaken off. The soil attached to the root surface was then evaluated as rhizosphere soil. The fresh soil samples were stored at -80°C before DNA extraction and microbial community analysis. Soil DNA was extracted from 0.60 g of fresh soil using a Fast DNA[®] Spin Kit for Soil (MP Biomedicals, CA, United States). Two universal primer sets (515F/909R and ITS1F/ITS2) were used: the former was used to amplify the prokaryotic 16S rRNA V4 region, and the latter was used to amplify the fungal internal transcribed spacer (ITS) region (Blaalid et al., 2013). The data were analyzed with the free online platform of the Majorbio Cloud Platform,³ and the obtained prokaryotic and fungal sequences were deposited in the Sequence Read Archive (SRA) with the accession number PRJNA733870.

Estimation of root fungal colonization frequency

The 1-cm long root segments were cleared with 10% KOH solution for 100 min at 95°C , bleached with 10% hydrogen peroxide for 15 min, acidified with 0.2 mol/L hydrochloric acid for 1 h, and finally stained with 0.05% (w/v) trypan blue in lactophenol for 3 min. After microscopic observation (Zeiss Microscope System Standard 16; Carl Zeiss Ltd.; Germany), the AMF colonization rate was expressed as the percentage of the number of fungal colonized root segments over the total number of observed root segments (Yang et al., 2021).

Data analysis and processing

The data were subjected to analysis of variance (ANOVA) followed by Duncan's multiple comparison test with SPSS 21.0 software (IBM Inc., Armonk, NY, United States), or independent samples t-test to determine significant differences ($p < 0.05$). Graphs were generated using GraphPad Prism 8.0 (GraphPad Software, Inc., United States).

Results

Rahnella aquatilis JZ-GX1 alleviated iron deficiency chlorosis in *Cinnamomum camphora*

Chlorophyll is one of the most important pigments related to photosynthesis and is widely used to evaluate the status of iron stress in plants. The application of JZ-GX1 strain significantly improved the etiolation of *C. camphora* resulting from iron

deficiency (Figure 1A). Compared with CK, FeSO_4 and inoculation treatments significantly increased the chlorophyll b, total chlorophyll and carotenoid contents of iron-deficient *C. camphora*. Among these treatments, the inoculation treatment exerted the best effect, as observed by 154.03%, 186.64%, and 80.07% increases in these contents, respectively, but had little effect on the content of chlorophyll a (Figure 1B).

Active iron is a form of iron directly absorbed and utilized by plants that can more effectively affect the iron nutritional status of plants. The iron content of *C. camphora* seedlings grown in alkaline soil was significantly lower. The FeSO_4 treatment significantly increased the content of active iron in roots, whereas the JZ-GX1 treatment significantly increased the content of active iron in leaves, but the two treatments exerted no significant effect on active iron in stems (Figure 1C). The supply of exogenous inorganic iron sources and microbial inoculant not only increased the content of active iron in *C. camphora* but also affected the content of Fe^{2+} . In contrast to the active iron, the JZ-GX1 treatment did not increase the content of Fe^{2+} in roots but significantly increased the content of Fe^{2+} in stems and leaves of *C. camphora* (Figure 1D), which indicated that the JZ-GX1 strain promoted the transfer of Fe^{2+} from roots to leaves.

Rahnella aquatilis JZ-GX1 reduced oxidative damage in *Cinnamomum camphora* leaves

Under normal circumstances, the production and scavenging of ROS in plants are in a dynamic equilibrium, but iron deficiency inhibits the antioxidant system and increases the production of ROS, and these effects damage electron transport in chloroplasts and mitochondria and consequently cause oxidative stress in plants. The level of ROS in *C. camphora* leaves increased gradually, peaked on the 10th day, and then decreased, and the JZ-GX1 treatment decreased the contents of O_2^- and H_2O_2 (Figures 2A,B). Electrolyte leakage analysis showed that the CK group exhibited relatively stable EL during the detection period, whereas the JZ-GX1 treatment showed some fluctuations, but the value obtained with the JZ-GX1 treatment was generally lower than that of CK (Figure 2C). Malonaldehyde is the final product of membrane lipid peroxidation in plant cells. Compared with CK, the addition of JZ-GX1 strain significantly decreased the MDA content in leaves at all tested time points with the exception of 20 days (Figure 2D).

Rahnella aquatilis JZ-GX1 enhanced the activities of antioxidant enzymes in *Cinnamomum camphora* leaves

The exposure of plants to external environmental stress leads to the production of ROS and subsequent oxidative damage. The scavenging of ROS in plants is mainly performed by some enzyme systems and antioxidants, and SOD, POD, CAT, and APX are

³ www.majorbio.com

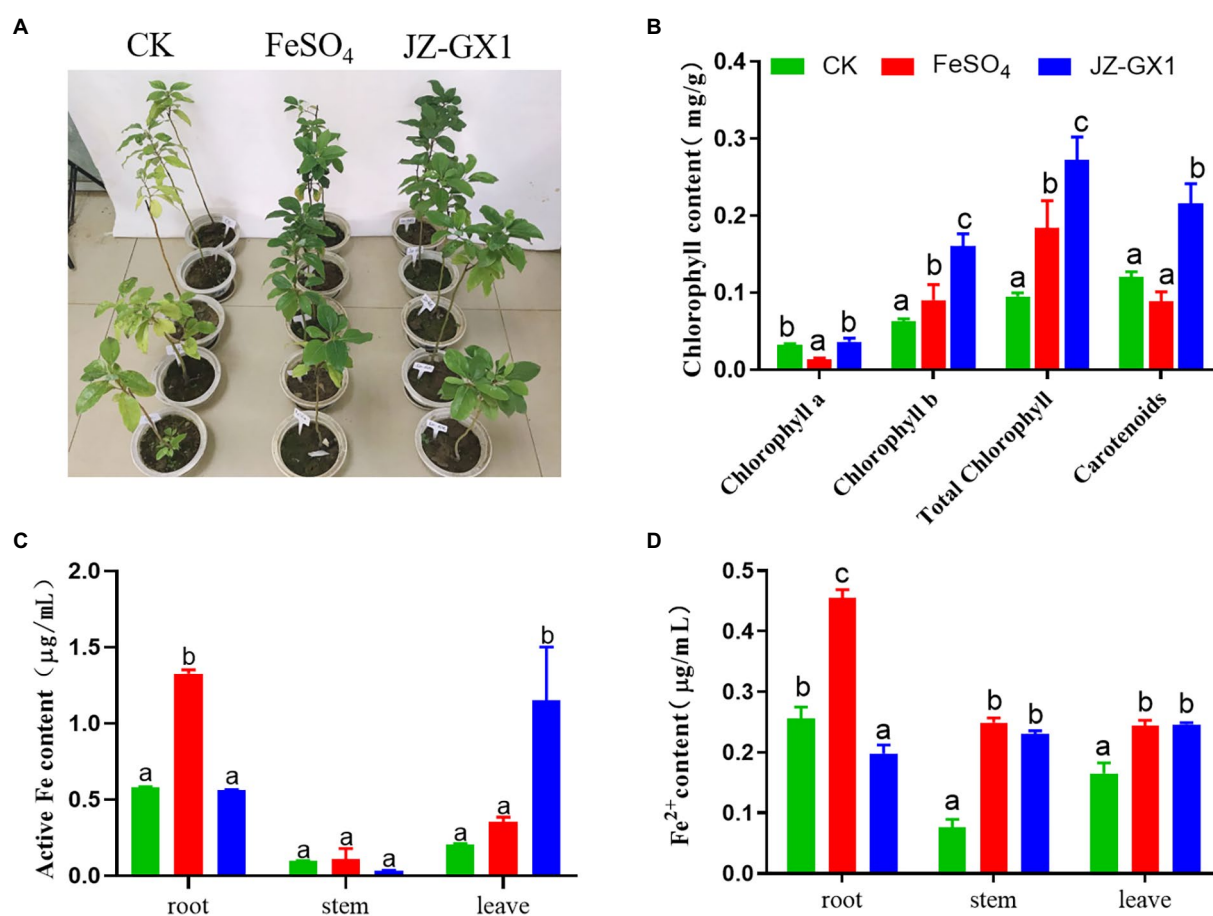

FIGURE 1
Effects of *Rahnella aquatilis* JZ-GX1 on the phenotype (A), chlorophyll content (B), active iron content (C) and Fe²⁺ content (D) of *Cinnamomum camphora*. important ROS-scavenging enzymes in plants. In this study, the effect of inoculation of JZ-GX1 strain on SOD enzyme activity was not obvious, only higher than that of CK on the 5th day, but lower than that of CK at other time points (Figure 3A). After the application of JZ-GX1, the activities of POD, CAT, and APX increased during culture, reached maximal levels on the 5th day, were 40.57%, 42.75%, and 21.63% higher than those obtained with the CK, respectively, and then decreased gradually but remained higher than those in the CK (Figures 3B–D).

Rahnella aquatilis JZ-GX1 secreted desferrioxamine

To explore the potential key substances of JZ-GX1 that promote iron uptake by *C. camphora*, we predicted its secondary metabolites according to its whole genome. The results showed that JZ-GX1 strain could synthesize and secrete siderophores. The comparison found that the siderophore synthesis gene cluster of JZ-GX1 strain exhibited high homology (100%) with the known

DFO E synthesis gene cluster dfoJACS of *Pantoea agglomerans* (Figure 4A). In addition, at transcription level, Fe deficiency induced the upregulation of *dfoJ*, *dfoA*, *dfoC*, and *dfoS* genes in JZ-GX1 (Supplementary Figure S1).

Moreover, the supernatant organic extracts of strain JZ-GX1 were analyzed by UPLC–MS in the positive ion mode, and the mass spectrum showed a molecular ion peak at m/z 561.3599 ($[M + H]^+$), with a retention time of 4.19 min (Figure 4B), which was similar to that of the standard DFO (m/z 561.3000 ($[M + H]^+$), retention time of 4.34 min; Figure 4C). Based on the mass spectra, the compound was also identified as DFO (Supplementary Figure S2).

Application of *Rahnella aquatilis* JZ-GX1 changed the metabolite profiles in the rhizosphere soil of *Cinnamomum camphora*

To evaluate the metabolic changes in the secretions from *C. camphora* roots induced by the JZ-GX1 strain, a nontargeted

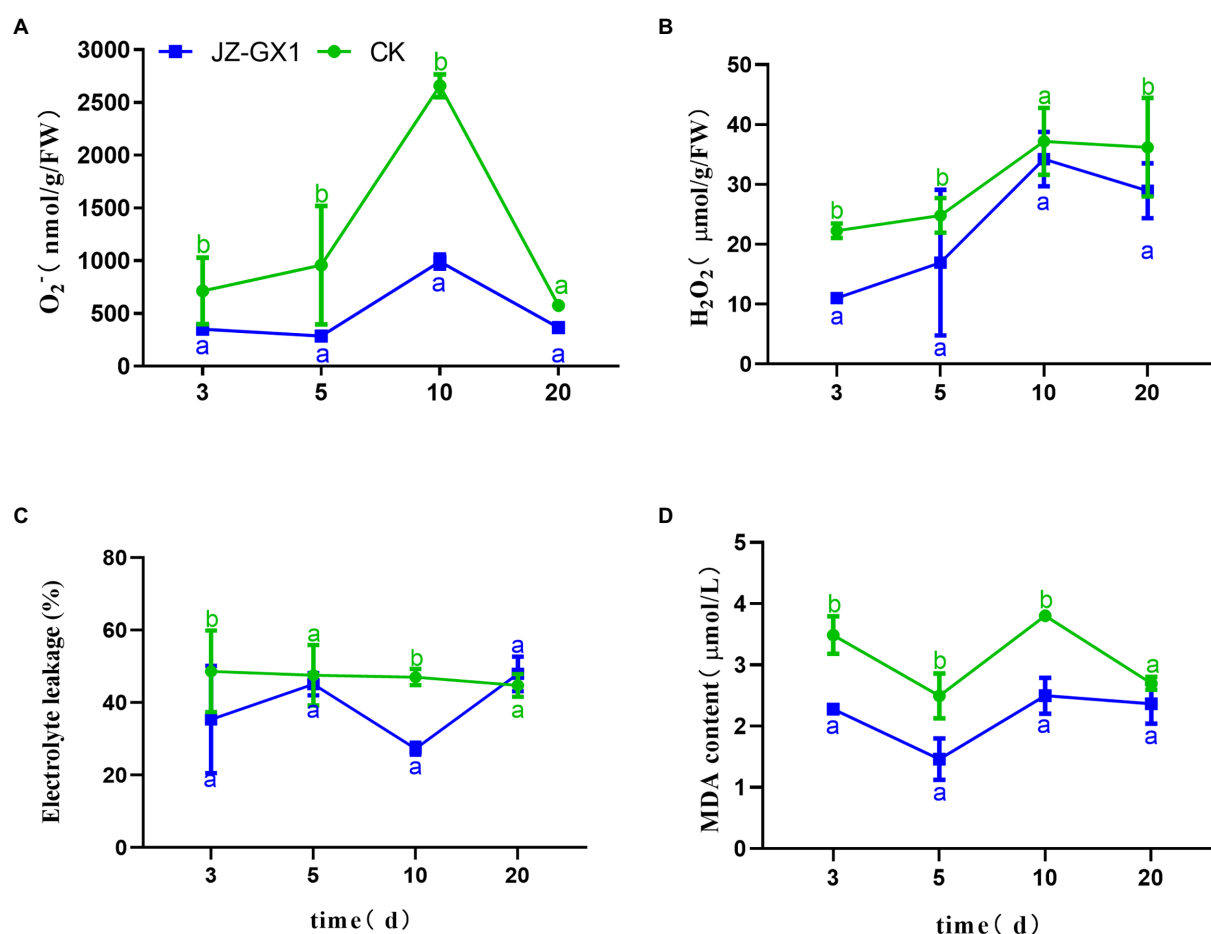

FIGURE 2

Effects of *Rahnella aquatilis* JZ-GX1 on the O_2^- (A), H_2O_2 (B), EL (C) and MDA levels (D) in *Cinnamomum camphora* leaves. Data are the means \pm SE. Different letters indicate statistically significant differences ($p < 0.05$) among treatments (t-test).

metabolomics detection of rhizosphere soils from etiolated and green *C. camphora* was performed based on UPLC–MS. A PCA analysis explained the metabolites of the two treatments were obviously separated on PC1, and the contribution rate of PC1 was 46.6%, the contribution rate of PC2 was 28.1%. The results from the same group of samples were concentrated, which indicated good repeatability between groups (Figure 5A). As seen in the volcano plot, a total of 381 metabolites were changed by the JZ-GX1 treatment, including 271 with increased expression and 110 with decreased expression (Figure 5B).

The main differential metabolites included phenolic acids, such as 3-O-cis-coumaroylmaslinic acid and 3-trans-caffeoyltormentic acid; amino acids, such as Arg, Cys, and His; glutinosone; tacrolimus; and other substances, such as lipoyllysine, arginyl and DFO (Figure 5C). Among the representative compounds showing significant differences, DFO exhibited 21.53-fold higher abundance in the JZ-GX1-inoculated group than in the uninoculated group (Figure 5D). According to the relatively large changes in metabolites, pathway enrichment analysis showed that the affected KEGG

metabolic pathways mainly included glycolysis/gluconeogenesis, biosynthesis of isoflavonoids and phenylpropanoids, porphyrin and chlorophyll metabolism, tryptophan metabolism and biosynthesis of antibiotics (Figure 5E).

Desferrioxamine promoted iron absorption by *Cinnamomum camphora*

To explore the effects of DFO on iron absorption by *C. camphora* trees, three different concentrations of DFO were applied. The results revealed that compared with the treatment without DFO, different concentrations of DFO alleviated the iron deficiency-induced yellowing of *C. camphora* (Figure 6A). Desferrioxamine concentrations of 10, 100, and 500 μ M significantly increased the SPAD value in leaves (Figure 6B). The Fe^{2+} content treated with a low concentration of DFO (10 μ M) was significantly higher than that obtained with the two other concentrations (Figure 6C).

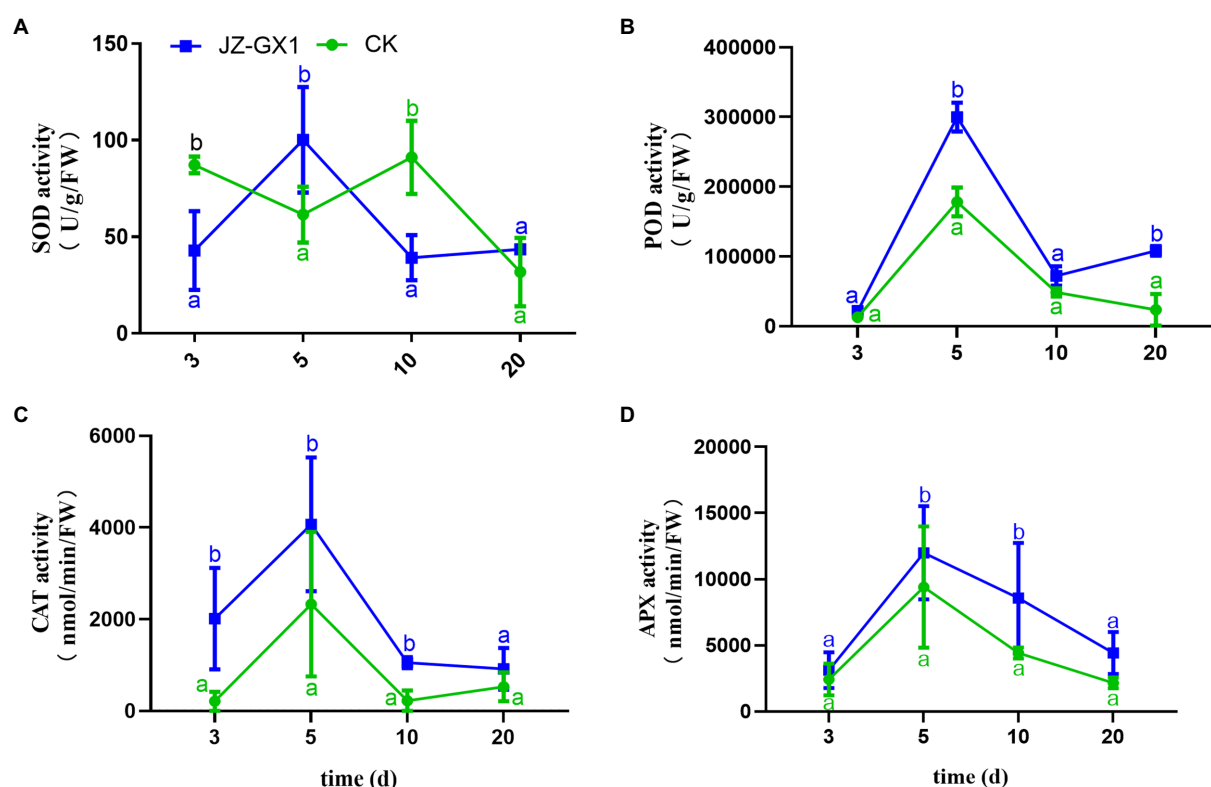

FIGURE 3

Effects of *Rahnella aquatilis* JZ-GX1 on SOD (A), POD (B), CAT (C) and APX enzyme activities (D) in *Cinnamomum camphora* leaves. Data are the means \pm SE. Different letters indicate statistically significant differences ($p < 0.05$) among treatments (t-test).

Effects of *Rahnella aquatilis* JZ-GX1 on microbial community composition and structure in rhizosphere of *Cinnamomum camphora*

The operational taxonomic unit (OTU) number analysis revealed a decrease in rhizosphere bacterial and fungal diversity on inoculation treatment, and the α -diversity was not affected by JZ-GX1 strain inoculation (Table 1). Regarding microbial community composition, the application increased the relative abundances of *Acidobacteriota* and *Verrucomicrobia*, slightly decreased the abundances of *Chloroflexi* and *Cyanobacteria*, and did not affect other phyla (Figure 7A). The analysis of fungal flora showed that application of the inoculum increased the relative abundances of *Basidiomycota*, *Mortierellomycota* and *Glomeromycota*, decreased the relative abundances of *Ascomycota* and *Rozellomycota*, and greatly increased the number of unclassified fungi in the rhizosphere soil of iron-deficient *C. camphora* (Figure 7B). According to the fungi functional guild (FUNGuild) prediction, the JZ-GX1 treatment also decreased the relative abundances of saprotrophic fungi, plant pathogens and animal pathogens and increased the

proportions of arbuscular mycorrhizal fungi and orchid mycorrhizal (Figure 7C). The root system of *C. camphora* inoculated with JZ-GX1 formed a typical mycorrhizal structure, and a large number of arbuscules and vesicles were observed (Figures 8B–E), while the roots of most uninoculated plants were not infected by mycorrhiza (Figure 8A). The hypha colonization rate increased by 270.37% compared to CK (Figure 8F). These results indicated that the application of the JZ-GX1 strain greatly disturbed the community structure of the rhizosphere fungi of *C. camphora*.

Identification of specific fungal genera

The histogram presented in Figure 9A showed the composition of the fungal community in the rhizosphere soils of etiolated and green *C. camphora* at the genus level. Compared with those of untreated plants, the application of the JZ-GX1 strain decreased the relative abundances of *Rozellomycota*, *Nectriaceae*, *Agaricomycetes*, *Neocosmospora*, *Paraphoma*, and *Plectosphaerella* and significantly increased those of *Mortierella*, *Saitozyma*, *Penicillium*, and *Trichoderma* (Figure 9B). These microbes may be an important feature of

the ability of the JZ-GX1 strain to alleviate *C. camphora* etiolation.

Discussion

Rahnella aquatilis JZ-GX1 reduces oxidative damage in *Cinnamomum camphora* under alkali stress by activating the antioxidant system

Under normal physiological conditions, ROS in plants are in a dynamic balance of being continuously produced and scavenged, but the exposure of plants to biotic or abiotic stress destroys this balance and increases the level of ROS (Pflugmacher et al., 2010; Wan et al., 2015; Wu et al., 2021). These increases in ROS (including H_2O_2 and O_2^-) can lead to cell membrane damage and EL and subsequently to membrane lipid peroxidation, and the degree of membrane lipid peroxidation can be reflected by the MDA content (Guo et al., 2019). In this experiment, we found that iron deficiency led to increases in the H_2O_2 and O_2^- contents in *C. camphora* leaves, which was consistent with the results obtained by Zhou C. et al. (2017) and Song et al. (2018) for peanut and chrysanthemum.

Superoxide dismutase, POD, and CAT are important active oxygen-scavenging enzymes in plants that can reduce the damage caused by membrane lipid peroxidation (Qin et al., 2018). Superoxide dismutase can catalyse the disproportionation of the

superoxide anion to H_2O_2 , and H_2O_2 is then decomposed into H_2O by CAT and APX (Wang et al., 2012). Peroxidase, an enzyme that is widely found in plants, contains iron in a porphyrin ring and has limited specificity. This enzyme can catalyse the decomposition of intracellular peroxidation products and plays an important role in maintaining the normal physiological function of leaves (Nounjan et al., 2021). Iron is an important cofactor in the synthesis of many enzymes. Once iron deficiency leads to decreased POD and CAT activities, plant cells accumulate more H_2O_2 (Hassan et al., 2020). In this study, the application of JZ-GX1 increased the activities of four antioxidant enzymes, reduced the production of ROS (H_2O_2 and O_2^-) and the accumulation of MDA, and effectively alleviated the oxidative stress caused by iron deficiency. In addition, due to the redox characteristics of iron ions, bioavailable Fe^{2+} is easily oxidized, and the application of JZ-GX1 improved the antioxidant capacity of trees and stabilized the transport of Fe^{2+} in plants to promote the transfer of Fe^{2+} from roots to stems and leaves compared with that observed in the CK treatment.

Desferrioxamine secreted by *Rahnella aquatilis* JZ-GX1 promotes iron absorption by *Cinnamomum camphora*

Plant growth-promoting rhizobacteria play important roles in plant growth and development and disease control and help plants cope with various abiotic stresses (such as salt, heavy metal, and drought stresses; Qin et al., 2018;

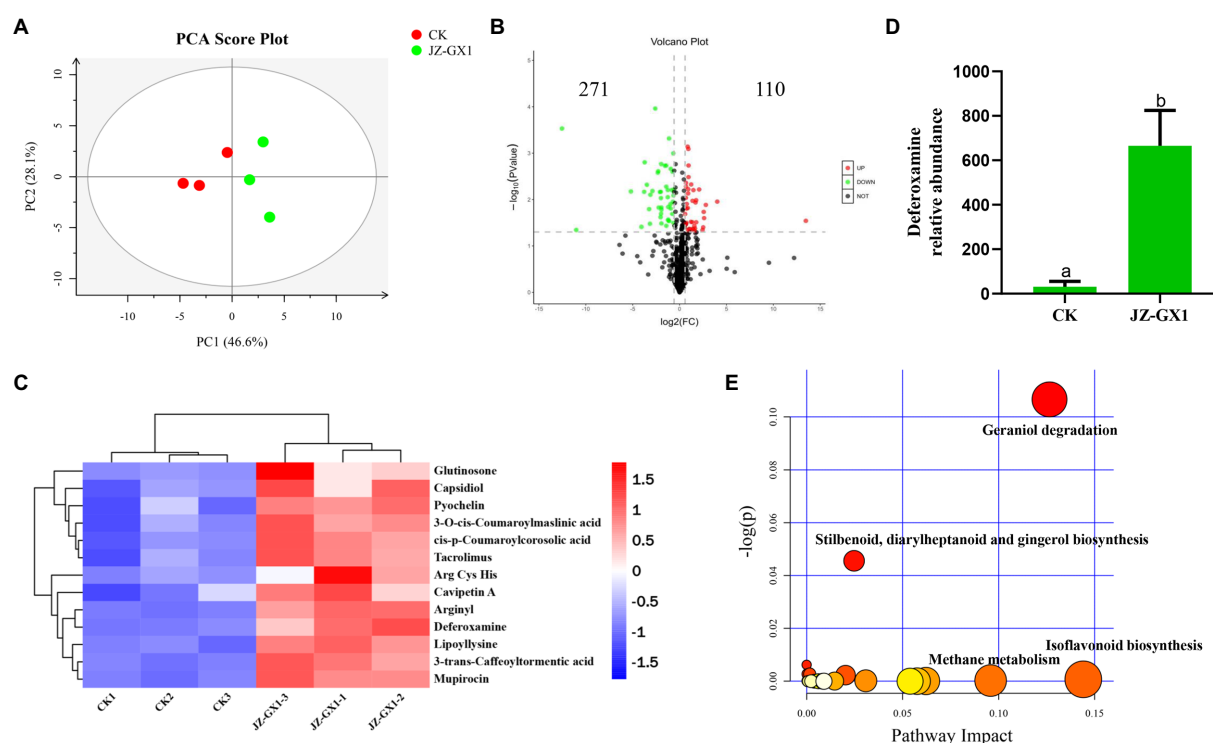

FIGURE 5

PCA analysis of the metabolites for positive mode. PC1 and PC2 are the first two principal components (A), volcano plot (B), heatmap analysis for the identified metabolites with significant difference being selected by PLS-DA (VIP >1, $p < 0.05$) (C), DFO relative abundance (D) and KEGG pathway analysis of the rhizosphere soil in etiolated and green *Cinnamomum camphora*. The size and color of each point represents the number of metabolites enriched in a particular pathway and the $-\log_{10} p$ -values, respectively. A larger pathway impact and $-\log_{10} p$ -values shows a greater degree of enrichment (E).

Guo et al., 2020; Hassan et al., 2020). To date, most studies have focused on the secretion of active substances *in vitro* and the host responses of microorganisms, but no in-depth study has investigated how microorganisms function in complex soil environments. In this study, based on whole genome prediction and UPLC-MS spectrometric analysis, it was shown that JZ-GX1 strain could secrete DFO, and the abundance of DFO in inoculated soil was 21-fold higher than that in uninoculated soil. Desferrioxamine was the first siderophore isolated from *Streptomyces*, is the most effective iron fertilizer known thus far (Pierwola et al., 2004; Liu et al., 2019) and has been widely used as the iron source of peanut, cucumber, tobacco, wheat and other plants (Yehuda et al., 2003, 2012; Fernandez et al., 2004). Desferrioxamine secreted by JZ-GX1 strain may contribute to the iron absorption of *C. camphora*.

Iron deficiency chlorosis of *Cinnamomum camphora* may be related to the relative abundance of soil pathogenic fungi

For a long time, the physiological etiolation of *C. camphora* was considered to be related to high pH and low available iron

content in soil, but the microbial flora of etiolating plant soil was ignored. The plant root microbiome is considered the second genome of plants and plays an important role in plant growth and development (Wozniak and Galazka, 2019; Cao et al., 2020). We hypothesize that the physiological etiolation of *C. camphora* may be related to the relative abundance of pathogenic fungi in its rhizosphere soil, and this hypothesis was proven by FUNGuild function prediction analysis. Iron is the core of many metabolic processes, particularly in alkaline environments, and is thus the focus of severe competition among organisms (Aznar et al., 2014). To survive, a pathogen competes for insoluble Fe^{3+} in soil; thus, the plant has less soluble iron, which results in iron deficiency chlorosis in leaves (McCully et al., 2019). In addition, a KEGG metabolic pathway analysis of soil metabolism revealed that some macrolides were highly enriched in the treatment group. JZ-GX1 promoted the secretion of antibiotics by other microorganisms, this effect could be a consequence of the change in the microbial abundance of specific taxa. Meanwhile, it cannot be excluded that DFO could also be produced by some of the microorganisms whose growth was stimulated by JZ-GX1. Therefore, exogenous beneficial microorganisms can adjust the community and structure of indigenous

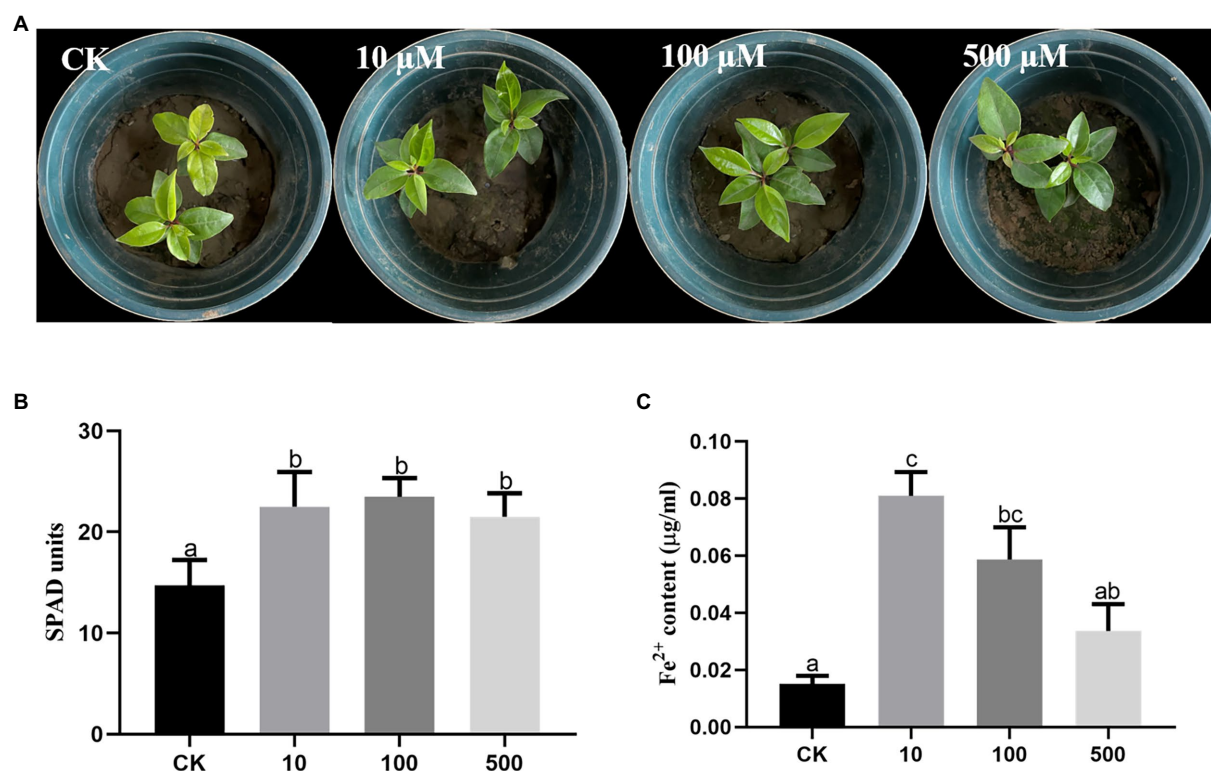

FIGURE 6 Effects of different concentrations of DFO on the growth of *Cinnamomum camphora* under iron deficiency. Plant phenotype (A), SPAD (B) and (C) Fe²⁺ content. microorganisms; this results in a decline in pathogen abundance, plants no longer lack iron, and the physiological etiolation can be alleviated.

Rahnella aquatilis JZ-GX1 regulates specific soil fungal communities by secreting DFO

Studies conducted in recent years have found that siderophores can promote the growth of some unculturable microorganisms and change the microbial community (Xavier, 2011). In view of the high abundance of DFO obtained with the JZ-GX1 treatment in this study, we speculated that the

rapid and stable secretion of DFO by JZ-GX1 into the environment provides not only abundant absorbable iron but also excessive siderophores, resulting in relatively high iron concentration niches, which are beneficial to the growth of other microorganisms using homologous siderophores. Studies have shown that some fungi of *Mortierella* and *Trichoderma* can secrete hydroxamic acid siderophores, and DFO belongs to this type of siderophore (Zhao et al., 2014). Therefore, we hypothesize that the observed increases in the *Mortierella* and *Trichoderma* populations may depend on the increase in DFO abundance found in the group inoculated with the JZ-GX1 strain. In addition, the excessive secretion of DFO-bound Fe³⁺ by the JZ-GX1 strain will bring excessive redox pressure to the environment. This type of siderophore

can be recognized, absorbed and utilized by only the producer's own specific receptors on the cell membrane and not by other microorganisms, thus inhibiting the growth of some microorganisms that cannot use it (Maindad et al., 2014; Yu et al., 2017). This mechanism may explain how the JZ-GX1 strain promotes plant development as a provider of iron in the rhizosphere. Therefore, in the future, the composition of fungi and bacteria in soil can be changed by adding biological fertilizer to the plant rhizosphere, and this strategy might provide a feasible biological method for the treatment of *C. camphora* etiolation from a microbial community perspective.

Conclusion

Plant growth-promoting rhizobacteria have been widely shown to promote plant growth and stress resistance. In this

study, the exogenous application of JZ-GX1 increased the contents of chlorophyll, active iron and the activities of antioxidant enzymes in leaves. After a comprehensive analysis of the microbial community structure and metabolic response of *C. camphora* rhizosphere soil after inoculation, this study proposed the possible mechanism of interactions among *R. aquatilis* JZ-GX1, native microflora and plants (Figure 10). After entering the low-iron rhizosphere soil, the JZ-GX1 strain first secretes DFO to chelate insoluble Fe^{3+} for its own needs. The Fe^{3+} -DFO complex directly provides an iron source for iron-deficient *C. camphora*. On the other hand, the removal of Fe^{3+} may limit the growth of pathogens and increase the abundances of some specific microorganisms (such as *Glomeromycota* and *Mortierella*). The mycorrhizae formed by these microorganisms indirectly promote the ability of plants to absorb iron and ultimately alleviate the etiolation of *C. camphora* caused by iron deficiency.

FIGURE 10

Putative model of the mechanism through which *Rahnella aquatilis* JZ-GX1 alleviates the iron deficiency-induced etiolation of *Cinnamomum camphora* by reprogramming the rhizosphere microbial community and increasing the content of DFO in soil. The JZ-GX1 strain secretes DFO to chelate insoluble Fe^{3+} , then the Fe^{3+} -DFO complex directly provides an iron source for iron-deficient *C. camphora*. At the same time, the removal of Fe^{3+} may limit the growth of pathogens and increase the population of *Glomeromycota* and *Mortierella*. The mycorrhizae formed by these microorganisms alleviate the etiolation of *C. camphora* caused by iron deficiency.

and Xiaoqiang Jiao*

National Academy of Agriculture Green Development, Department of Plant Nutrition, Key Laboratory of Plant-Soil Interactions, Ministry of Education, China Agricultural University, Beijing, China

Phosphorus (P) supply and planting density regulate plant growth by altering root morphological traits and soil P dynamics. However, the compensatory effects of P supply and planting density on maize (*Zea mays* L.) growth and P use efficiency remain unknown. In this study, we conducted pot experiments of approximately 60 days to determine the effect of P supply, i.e., no P (CK), single superphosphate (SSP), and monoammonium phosphate (MAP), and different planting densities (low: two plants per pot; and high: four plants per pot) on maize growth. A similar shoot biomass accumulation was observed at high planting density under CK treatment (91.5 g plot⁻¹) and low planting density under SSP treatment (94.3 g plot⁻¹), with similar trends in P uptake, root morphological traits, and arbuscular mycorrhizal colonization. There was no significant difference in shoot biomass between high planting density under SSP (107.3 g plot⁻¹) and low planting density under MAP (105.2 g plot⁻¹); the corresponding P uptake, root growth, and P fraction in the soil showed the same trend. These results suggest that improved P supply could compensate for the limitations of low planting density by regulating the interaction between root morphological traits and soil P dynamics. Furthermore, under the same P supply, the limitations of low planting density could be compensated for by substituting MAP for SSP. Our results indicate that maize growth and P use efficiency could be improved by harnessing the compensatory effects of P supply and planting density to alter root plasticity and soil P dynamics.

KEYWORDS

maize, phosphorus supply, planting density, phosphorus use efficiency, root morphological traits, soil P dynamics

Introduction

Phosphorus (P) is an essential nutrient for plant growth and development, as well as an important factor limiting sustainable maize production (Bindraban et al., 2020; Muhaba and Dakora, 2020). Mineral P fertilizers are critical in ensuring food security (Nedelciu et al., 2020); however, P use efficiency is extremely low owing to poor P mobility (Heuer et al., 2017). Although increasing planting density is a common agronomic measure for increasing P use efficiency (Jia et al., 2018; Zhang et al., 2021), it results in reduced space for root growth. The primary mechanism for P acquisition in maize production is the morphological expansion of root systems (Zhou et al., 2019a). The low mobility of P and the compression of root space have made efficient P use under high planting density conditions difficult (Shao et al., 2018). Allowing root systems to fully develop their biological potential and increase soil P uptake will be critical to improving P use efficiency in intensive maize production.

The spatial expansion of maize roots becomes severely compressed and the competition among plant roots growing closely at high planting densities is severe due to the extent of overlap among rhizospheres, which may result in nutrient deficiencies (Thorup-Kristensen and Kirkegaard, 2016; Li et al., 2019). High planting densities decrease the number of nodal roots, lateral root density, and root biomass per unit volume of soil (Shao et al., 2018; Niu et al., 2020). In addition, root system size can be reduced at high planting density due to plant competition. The root crown angle can become more vertical to adapt to a small growing space at high planting densities (Shao et al., 2018; Tomasi et al., 2020). Furthermore, maize roots adapt to obtain P in small spaces by becoming thinner and longer, extending into soil spaces with limited carbohydrates. The root-soil contact area also increases to enhance P acquisition (Lynch et al., 2022). Root foraging for P is determined by changes in root morphology in response to soil environmental conditions, and plant productivity and P uptake may be affected by planting density due to differential competitiveness.

The plastic response of the root system is not only limited by growth area but also largely affected by P supply at high planting densities (Wang et al., 2020; Postma et al., 2021). According to Semchenko (2020), resource capture is the primary driver of root changes. Maintaining an adequate P supply in the root zone can help the root system and mycorrhizal infection expand into the soil space and acquire soil P (Deng et al., 2017). Planting density and P supply interactions can maximize the efficiency of maize roots in mobilizing and acquiring P (Schneider et al., 2019). Indeed, P supply has the potential to considerably improve P use efficiency in crop production by activating soil P (Soltangheisi et al., 2018). Initial and residual P effects are influenced by the solubility of P fertilizer, which varies widely (Gong et al., 2022). However, it is

unclear whether maize dry-matter accumulation loss caused by low planting density may be compensated for by regulating root plasticity and soil P dynamics through altered P supply.

This study aims to determine the compensatory mechanisms of P supply and planting density on maize root morphology, soil P dynamics, and P uptake. The specific goals of the study were to (1) evaluate the growth and P uptake of maize under different P supplies and planting densities, and (2) to examine whether maize growth limitation due to low planting density may be compensated for by altering P supply.

Materials and methods

Experimental design

A greenhouse pot experiment was conducted from May to July 2021 at the Quzhou Experimental Station of the China Agricultural University (36°51'57"N, 150°0'37"E), in Quzhou County, Hebei Province, China. Calcareous loam soil was collected from the Quzhou Long-Term Fertilizer Station (36°52'21"N, 115°03'15"E) of the China Agricultural University. The soil was air-dried and then sieved to pass through a 2-mm mesh. The soil type is calcareous fluvo-aquic soil from the North China Plain. The basic physical and chemical properties of the soil are as follows: pH value, 8.0; soil organic carbon content, 12.5 g kg⁻¹; total nitrogen content, 1.3 g kg⁻¹; soil Olsen-P content, 4.3 mg kg⁻¹; and soil available potassium content, 194 mg kg⁻¹. The soil properties were measured using the methods specified by Bao (2001).

The experiment was laid out in a 3×2 complete factorial design. Three P supply treatments were used: no P (CK), single superphosphate (SSP), and monoammonium phosphate (MAP). Two planting densities were tested: low (two plants per pot) and high (four plants per pot). Each of the six treatment combinations were replicated four times for a total of 24 pots. Each pot was 30 cm in diameter and 40 cm in height. A treatment rate of 150 kg P ha⁻¹ was applied using the different P supplies, SSP and MAP. In the fertigation treatments, urea and muriate of potash were used as sources of nitrogen and potassium, respectively. Both nitrogen and potassium were applied at a rate of 150 kg ha⁻¹. All fertilizers were incorporated and completely mixed with soil at planting.

Maize Zhengdan 958 seeds was used in this study; they were surface sterilized in 10% (v/v) H₂O₂ for 0.5 h, washed with deionized water, a supersaturated solution of calcium sulfate (CaSO₄) was soaked for 1 day, and germinated in a dish with an aerated cover with wet filter paper for 3 days at 25 °C. Pots were watered daily to field capacity (18%, w/w) by watering every day. Temperatures ranged from a minimum of 20 °C at night to a maximum of 30 °C during the day.

Plant harvest and sample analysis

The plants were harvested 60 days after planting. Shoots and roots were separated and shoots were first oven-dried at 105 °C for 0.5 h and then dried at 75 °C for 4 days to constant weight. The dry samples were weighed, crushed, and homogenized. Shoot P concentration was determined according to the standard vanadomolybdate method (Murphy and Riley 1962).

The root samples were carefully and thoroughly washed in a large volume of deionized water and then scanned using the EPSON root scanning software (Epson Expression 1600 pro, Model EU-35; Epson, Tokyo, Japan) at 400 points per inch. The WinRHIZO software (Pro2004b, version 5.0; Regent Instruments Inc., QC, Canada) was used to measure total root length. Lateral root density was calculated by dividing the number of lateral roots per 5 cm of the primary root by the 5-cm length of the primary root (Wu et al., 2019). Arbuscular mycorrhizal colonization analysis was performed according to the method of Trouvelot et al. (1986). Fine roots were cut into 1-cm-long segments and thoroughly mixed. Root samples were cleared with 10% (w/v) potassium hydroxide (KOH) at 90 °C for 2 h, and mycorrhizal colonization was stained using trypan blue. All roots were dried at 75 °C for 3 days and then weighed to calculate root dry biomass. The root/shoot ratio was defined as the ratio of root dry mass to that of the shoots (Marziliano et al., 2015).

Rhizosphere soil was taken from a 0–2-mm distance around the roots and collected by clearing the roots of debris; the rhizosphere soil was the loosely attached soil particles that were removed from around the roots (Cui et al., 2020; Zhou et al., 2022). Soil samples were then air-dried and passed through a 2-mm mesh sieve. Soil P fractions were analyzed sequentially and extracted using the Hedley method (Hedley et al., 1982). Soluble P is extractable with water and NaHCO₃ (water-extractable P and NaHCO₃-extractable P), which is considered labile P, and are immediately available to plants. Moderately

labile P is extractable with NaOH (NaOH-extractable P), which is available to plants. Recalcitrant forms, such as HCl-extractable P and residual P, are considered non-labile P and are only available to plants over long time periods (Cross and Schlessinger, 1995).

Statistical analysis

A two-way analysis of variance (ANOVA) test was used to examine the effects of P supply, planting density and their interacting effects on variables. All statistical analyses were performed using the SPSS statistical software (SPSS 20.0; SPSS Inc., Chicago, IL, USA). Significant differences among means were separated by the least significant difference test at the $P \leq 0.05$ probability level. The graphs were constructed using Sigmaplot (version 10.0; Systat Software Inc., San Jose, CA, USA).

Results

Shoot biomass and P content

Shoot biomass was significantly influenced by P supply and planting density ($P < 0.01$, Table 1; Figure 1A), and was higher for MAP-treated plants than for SSP or CK-treated plants at both planting densities. The high planting density concurrently improved shoot biomass: high shoot biomass was obtained under the high planting density condition, regardless of the P source. However, soil P supply intensity and planting density had complementary effects on shoot biomass. P supply intensity compensated for the reduction in shoot biomass due to the low planting density. Similar root biomass levels were recorded at the low planting density under the SSP treatment (91.5 g plot⁻¹) and at the high planting density under the CK treatment (94.3 g

TABLE 1 Two-way analysis of variance of phosphorus (P) supply, planting density, and their interaction.

Parameters	P supply		Planting density		P supply × Planting density

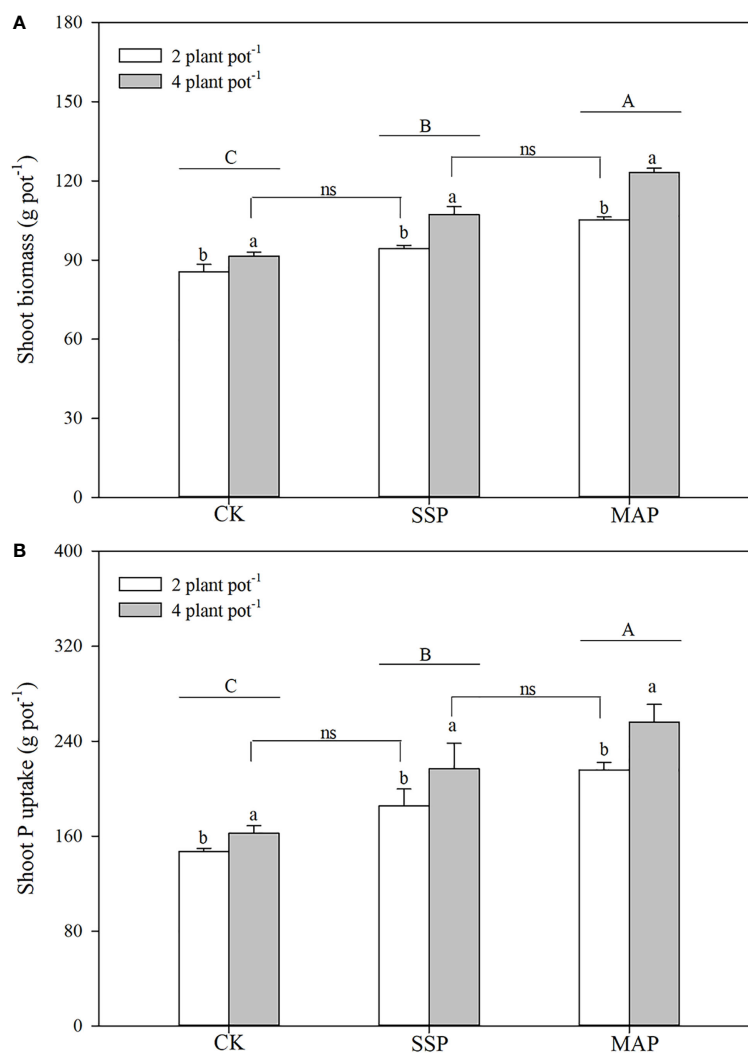

FIGURE 1

Shoot biomass (A), shoot phosphorus (P) content (B) under two planting densities and three P fertilizer sources, no P (CK), superphosphate (SSP), and monoammonium phosphate (MAP). Different lowercase letters represent a significant difference among different planting densities at the $P < 0.05$ level, and different uppercase letters represent significant differences among different P fertilizer sources at the $P < 0.05$ level; ns indicates no significant difference at the 95% confidence interval between the two treatments.

plot⁻¹). A strong complementary effect was also found between P source and planting density. A reduction in shoot biomass due to low planting density was compensated for by substituting the MAP for the SSP treatment under the same P supply. Higher shoot biomass was recorded for the high planting density under the SSP treatment (107.3 g plot⁻¹), which was equivalent to the shoot biomass recorded for the low planting density under the MAP treatment (105.2 g plot⁻¹).

Shoot P content was strongly influenced by both P supply ($P < 0.01$) and planting density ($P < 0.01$), increasing in tandem with planting density (Table 1; Figure 1B). Shoot P content was higher in high planting densities than in low planting densities. The shoot P content observed in the low planting density under

the SSP treatment was equivalent to the shoot P content observed in the high plant density under the CK treatment. This finding indicated that, although the shoot P content was limited by the low planting density, it was compensated for by P supply intensity. The shoot P content differed significantly by P source; regardless of planting density, the shoot P content was significantly higher when the MAP treatment was applied than when SSP was applied. Similar complementary effects of P sources and planting density on the shoot P content were observed. There were no significant differences in the shoot P content between the high planting density under the SSP treatment and the low planting density under the MAP treatment.

Root morphological traits

P supply and planting density significantly influenced maize root biomass ($P < 0.01$, Table 1; Figure 2A). P supply had a greater influence on root biomass in the MAP treatment than in the CK or SSP treatments, and root biomass increased as planting density increased. No significant differences were observed between the low planting density under the SSP treatment and the high planting density under the CK treatment. There was a strong complementary effect between P source and planting density on root biomass. A similar root biomass accumulation was observed at the high planting density in SSP-treated pots and the low planting density in MAP-treated pots.

Maize root length was also affected by P supply and planting density ($P < 0.01$, Table 1; Figure 2B); specifically, it was higher in the MAP-treated pots than in both the SSP- or CK-treated pots, regardless of the planting density. Furthermore, maize root length increased with planting density for both of these P sources.

However, there was no significant difference in the root length between the low planting density under the SSP treatment and the high planting density under the CK treatment. Root length in SSP-treated pots at the high planting density was equivalent to that in MAP-treated pots at the low planting density.

The root/shoot ratio and lateral root density were significantly altered by P supply and planting density ($P < 0.01$, Table 1; Figures 2C, D). Thus, the root/shoot ratio and lateral root density of plants grown in SSP- and MAP-treated pots were significantly greater than those grown in CK-treated pots. However, there was no significant difference in the root/shoot ratio or lateral root density between the SSP and MAP treatments at either planting density. The effect of planting density on the root/shoot ratio and lateral root density under MAP supply was negligible. Similar to root length, there was no significant difference in the root/shoot ratio or lateral root density between the low planting density under SSP and the high planting density under the CK treatment. Similar root/shoot ratio values and lateral root densities were observed at the

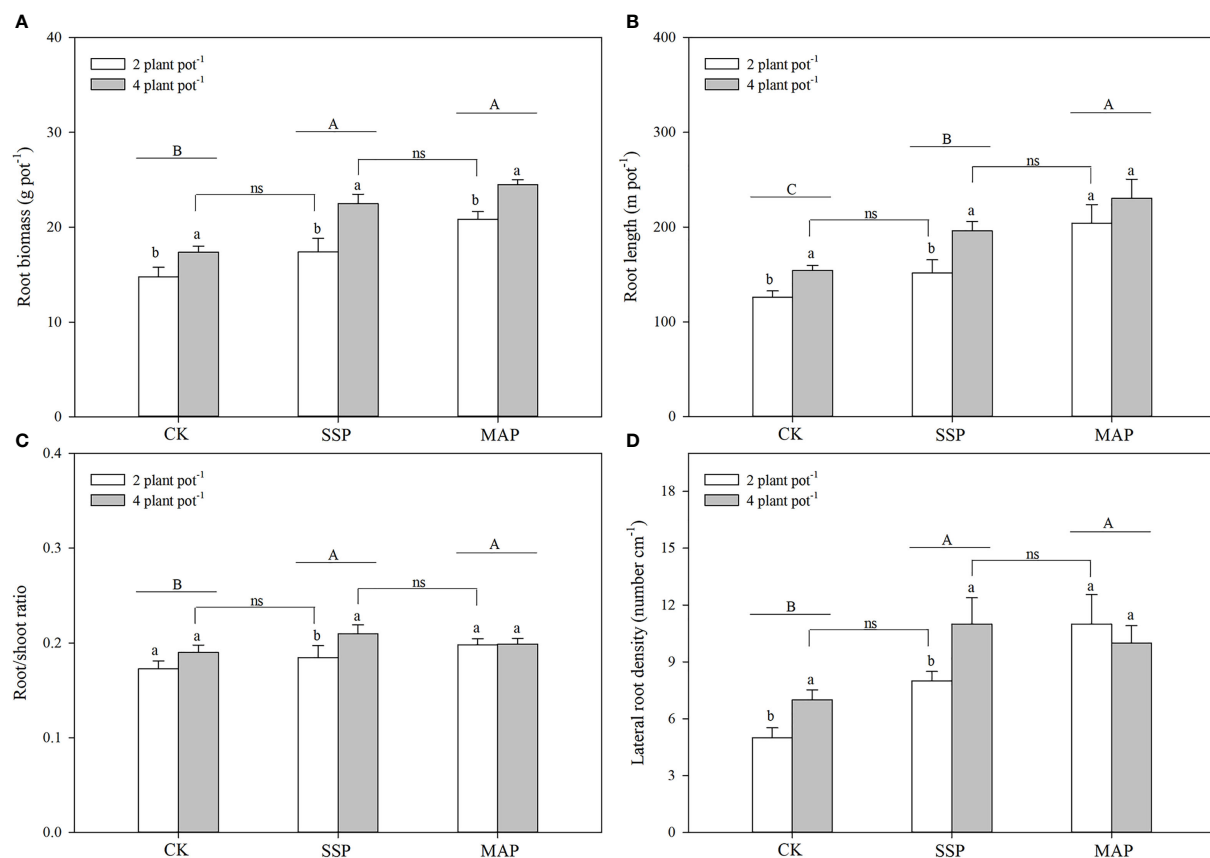

FIGURE 2 Maize root biomass (A), root length (B), root/shoot ratio (C), and lateral root density (D) under two planting densities and three P fertilizer sources, no P (CK), superphosphate (SSP), and monoammonium phosphate (MAP). Different lowercase letters represent a significant difference among different planting densities at the $P < 0.05$ level, and different uppercase letters represent significant differences among different P fertilizer sources at the $P < 0.05$ level; ns indicates no significant difference at the 95% confidence interval between the two treatments.

high planting density under SSP and the low planting density under the MAP treatment.

Phosphorus fractions in the rhizosphere soil of maize

The labile P fractions accounted for only 2–8% of total P (Figure 3A). Labile P in the rhizosphere soil of maize was significantly altered by P supply and planting density ($P < 0.01$, Table 1; Figure 3B). The amount of labile P in maize plants grown with SSP or MAP was significantly greater than that of maize plants grown without P, while there was no significant difference in labile P between the SSP and MAP treatments, regardless of planting density. However, labile P in the rhizosphere soil of maize, in the high planting density under MAP was significantly greater than that of the low planting density treatment. There was no significant difference between the high planting density under the

SSP treatment and the low planting density under the MAP treatment.

The moderately labile P fractions accounted for only 0.4–4% of total P (Figure 3A). Changes in the moderately labile P content of maize rhizosphere soil were mostly consistent with those for the labile P content among the treatments (Figure 3C). Moderately labile P in the maize rhizosphere soil significantly increased when P was supplied, compared with the CK treatment. A higher moderately labile P content in the maize rhizosphere soil was observed at the high planting density under the MAP treatment, whereas no significant difference was detected in moderately labile P between the high planting density under the SSP treatment and the low planting density under the MAP treatment.

The non-labile P fractions accounted for 88–98% of total P (Figure 3A). P supply and planting density had little effect on the non-labile P content in maize rhizosphere soil (Table 1; Figure 3D). However, the non-labile P content at the low planting density under the CK treatment was equivalent to

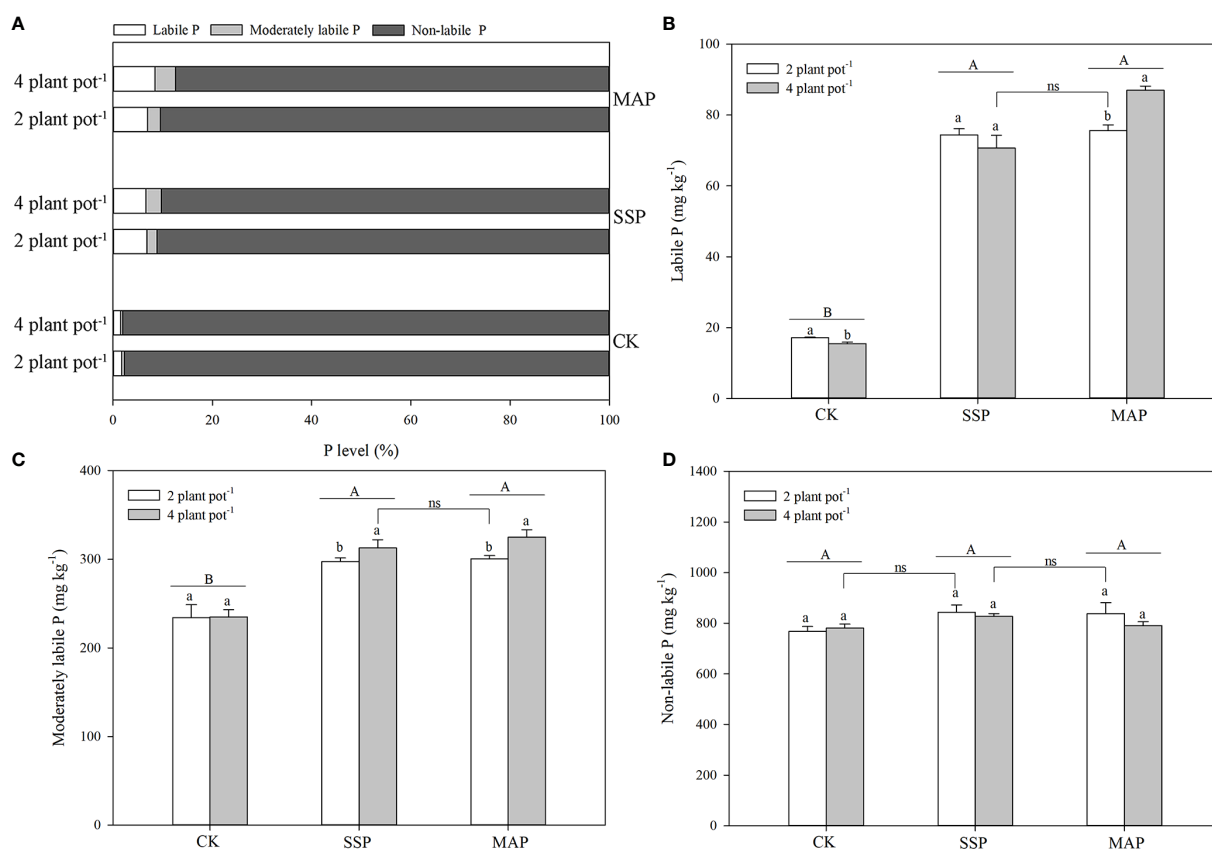

FIGURE 3

Proportions of labile, moderately labile, and non-labile P fractions under phosphate sources and cover crops under two planting densities and three P fertilizer sources (A). Labile P (B), moderately labile P (C), and non-labile P (D) under two planting densities and three different P fertilizer sources, no P (CK), superphosphate (SSP), and monoammonium phosphate (MAP). Different lowercase letters represent a significant difference among different planting densities at the $P < 0.05$ level, and different uppercase letters represent significant differences among different P fertilizer sources at the $P < 0.05$ level; ns indicates no significant difference at the 95% confidence interval between the two treatments.

that at the high planting density under the SSP treatment. Similarly, the non-labile P content was higher at the high planting density under the SSP treatment than at the low planting density under the MAP treatment.

Arbuscular mycorrhizal colonization

The arbuscular mycorrhizal (AM) colonization was significantly altered by the P supply and planting densities (Table 1; Figure 4). Specifically, AM colonization decreased with P supply regardless of the planting density. The effect of AM colonization at the high planting density was greater than that at the low planting density in both SSP and MAP treatments. However, there was no significant difference in AM colonization between the high planting density under the SSP treatment and the low planting density under the CK treatment.

Discussion

Several studies have investigated the effects of P supply or planting density on maize growth (Zhang et al., 2019; Gong et al., 2021). This study confirmed prior findings by demonstrating strong interaction effects between P supply and planting density. However, little is known about whether the negative effects of low planting density on shoot biomass accumulation and P uptake can be offset by increasing P

supply. P plays an important role, and aboveground biomass accumulations are a response to P availability (Cheng et al., 2020; Nkrumah et al., 2021). Shoot biomass accumulation and P uptake can be increased by intensifying the P supply or changing the P source at low planting density. Similar levels of root biomass accumulation were observed at a low planting density under SSP conditions and at a high planting density under the CK treatment. These findings suggest that limited aboveground dry-matter accumulations in maize caused by low planting density are compensated for by increasing P supply intensity. It is unclear whether substituting MAP for SSP can compensate for a low shoot biomass accumulation and P uptake caused by a low planting density. The SSP treatment resulted in a high shoot biomass accumulation and P uptake at a high planting density, which were equivalent to those at the low density under MAP treatment. These findings indicate that limited aboveground dry-matter accumulations in maize at low planting densities could be compensated for by substituting MAP for SSP.

Low planting density reduces the leaf area index and the interception of photosynthetically active radiation by the canopy, resulting in a decrease in the accumulation of aboveground dry-matter (Zhang et al., 2021). Consistently, we found that at low planting densities, shoot biomass accumulation and P uptake were lower than at high planting densities. This finding in the present study was similar to those in previous studies (Du et al., 2021; Gong et al., 2021). P supply may affect root architecture and morphology, and could facilitate the establishment of a better root system (Williamson et al.,

FIGURE 4

Arbuscular mycorrhizal (AM) colonization under two planting densities and three P fertilizer sources, no P (CK), superphosphate (SSP), and monoammonium phosphate (MAP). Different lowercase letters represent a significant difference among different planting densities at the $P < 0.05$ level, and different uppercase letters represent significant differences among different P fertilizer sources at the $P < 0.05$ level; ns indicates no significant difference at the 95% confidence interval between the two treatments.

2001). It may also affect P uptake by maize plants (Hopkins and Hansen, 2019; Pongrac et al., 2020). In this study on maize, root architecture, root biomass, root length, root/shoot ratio, and lateral root density were all significantly higher under P supply than under the CK treatment. Consistent with a previous study (Zhang et al., 2017), AM colonization decreased when P supply intensity increased. A high P supply intensity may have contributed to the selection of less beneficial AM species (Saia et al., 2015). These changes in maize roots effectively increased the amount of P accessible to maize plants, supporting previous findings (Gong et al., 2021). Root growth may explain the complementary effects of P supply and planting density on shoot biomass and P uptake (Zhang et al., 2014; Gong et al., 2021). The proportion of labile P and the moderately labile P content in the SSP treatment was higher than that in the CK treatment in both planting densities tested. Labile P and moderately labile P contents were transformed into other more available forms of P for plant uptake under the SSP treatment at low planting densities, compared with that under the CK treatment at high planting densities. Our study provides substantial evidence for the complementary effects of P supply intensity and planting density on shoot biomass and P uptake.

Increasing planting density is an effective method for improving output yield in agricultural systems (Li et al., 2021; Zhou et al., 2019b). A similar shoot biomass accumulation and P uptake were observed for the same P supply intensity at a high planting density under the SSP treatment and at a low planting density under the MAP treatment. Furthermore, the values of maize root-architecture components, such as root biomass, root length, root/shoot ratio, and lateral root density, were equivalent under the MAP treatment combined with a low planting density to those observed under the SSP treatment combined with a high planting density. MAP could provide readily available P to plants, and contribute indirectly to improved root growth and development because of the beneficial starter effects of MAP (Chien et al., 2011; Gong et al., 2022) because MAP is produced from ammonia and phosphoric acid, and phosphate (PO_4^{3-}) and ammonium (NH_4^+) are released upon dissolution. NH_4^+ and PO_4^{3-} ions are macronutrients that enhance root elongation (Weligama et al., 2008; Lu et al., 2019). When MAP was applied, shoot biomass and P uptake were higher than when SSP was applied at the same planting density. Low shoot biomass accumulation and P uptake due to low planting density may be compensated for by substituting MAP for SSP through exploiting the biological potential for enhancing P use efficiency. This implies a compensatory effect between P source and planting density.

Conclusions

In this study, P supply and planting density significantly modified root morphology and soil P dynamics, thereby influencing shoot biomass accumulation and P uptake. A similar shoot biomass accumulation was observed at a low planting density under SSP treatment and at a high planting density under CK treatment, with similar trends in P uptake, root morphological traits, and AM colonization. The reduction in aboveground dry-matter accumulation was fully compensated for by P supply at a low planting density. Additionally, at the same P supply level, shoot biomass accumulation and P uptake at a high planting density under SSP were equivalent to those observed at a low planting density under the MAP treatment, indicating that the reduction of aboveground dry-matter accumulation in the low planting density was fully compensated for by substituting MAP for SSP. These results contribute to our understanding of the biological potentials that can be exploited to enhance P use efficiency by optimizing the types and intensities of P fertilizer. Furthermore, our study provides new insights into the compensatory effects of P supply and planting density on maize production.

Ensuring food and nutritional security, it is crucial to use chemicals in agriculture to boost yields and protect the crops against biotic and abiotic perturbations. Conversely, excessive use of chemicals has led to many deleterious effects on the environment like pollution of soil, water, and air; loss of soil fertility; and development of pest resistance, and is now posing serious threats to biodiversity. Therefore, farming systems need to be upgraded towards the use of biological agents to retain agricultural and environmental sustainability. Plants exhibit a huge and varied niche for endophytic microorganisms inside the *planta*, resulting in a closer association between them. Endophytic microorganisms play pivotal roles in plant physiological and morphological characteristics, including growth promotion, survival, and fitness. Their mechanism of action includes both direct and indirect, such as mineral phosphate solubilization, fixating nitrogen, synthesis of auxins, production of siderophore, and various phytohormones. Medicinal and aromatic plants (MAPs) hold a crucial position worldwide for their valued essential oils and several phytopharmaceutically important bioactive compounds since ancient times; conversely, owing to the high demand for natural products, commercial cultivation of MAPs is on the upswing. Furthermore, the vulnerability to various pests and diseases enforces noteworthy production restraints that affect both crop yield and quality. Efforts have been made towards enhancing yields of plant crude drugs by improving crop varieties, cell cultures, transgenic plants, etc., but these are highly cost-demanding and time-consuming measures. Thus, it is essential to evolve efficient, eco-friendly, cost-effective simpler approaches for improvement in the yield and health of the plants. Harnessing endophytic microorganisms as biostimulants can be an effective and alternative step. This review summarizes the concept of endophytes, their multidimensional interaction inside the host plant, and the salient benefits associated with endophytic microorganisms in MAPs.

plant-microbe interaction, plant growth promotion, secondary metabolites, stress tolerance, medicinal plants, endophytic microorganisms

Introduction

Plants perform a range of fundamental functions in helping all distinct forms of living beings and release chemical signals to communicate with them. The roots give anchorage to the plant in soil and assist in the acquisition of water and nutrients, as well as produce chemical compounds that induce various types of interactions. This constitutes mutualism with the microorganisms that include fungi in mycorrhizal associations, endophytes, and plant growth-promoting rhizobacteria (PGPRs) as well as parasitism with pathogenic microorganisms, other plants, and herbivores (Badri et al., 2009). The plant roots discharge tremendous quantities of chemical compounds to fight pathogens and attract advantageous microorganisms (Badri and Vivanco, 2009). Such plant-microbe interactions occur at different trophic levels within a sophisticated arrangement of communities (Yan et al., 2019). Approximately 470 million years ago, the evolution of aquatic plants into terrestrial organisms was made possible by cooperating with soil microbes, and many of those microbe-plant interactions still persist (Bhattacharya and Medlin, 1998; Palmer et al., 2004; Ni et al., 2012; Williams et al., 2013). Some plant-microbe interactions are commensalism, where no harm is done to the plant, but the microbe gains some advantage. Several distinct interactions are advantageous to both partners (e.g., they are called mutualistic). Lastly, another group of microorganisms are pathogens and parasites to their host plants. In all the incidents, the microbe and the plant have established the ability to communicate. The microorganism recognizes and responds to the chemical signaling molecules produced by the plants. This usually results in the discharge of microbial compounds that are in turn identified by the plant, thereby generating a two-way “communication” that uses a molecular lexicon. Once a plant-microbe relationship begins, microbes and plants continue to observe their partner’s physiology and coordinate their activities accordingly.

Medicinal and aromatic plants (MAPs) hold a crucial position within people’s healthcare systems throughout the world. Until the arrival of advanced medicines, an oversized population in emerging nations has traditionally relied upon the products obtained from plants, particularly from forests. Numerous medicinal and aromatic crops are being exploited for economic uses. Approximately 12.5% of the more than 422,000 plant species have been universally documented for

medicinal properties; however, only a couple of hundreds are known to be in cultivation (Schippmann et al., 2002). There is a need to grow MAPs to maintain their steady supply and conservation amidst decreasing stocks from natural sources and rising global interest. Apart from increasing farmers’ income, MAPs cultivation also acts as insurance crops against the climate extremes. Its cultivation for essential oils and several phytopharmaceutically important compounds is an age-old aspect of agriculture; conversely, owing to the high demand for natural products, commercial cultivation of MAPs is on the upswing. Furthermore, the vulnerability to various biotic and abiotic perturbations (phytopathogens, drought, water-logging, salinity, temperature, etc.) enforces noteworthy production constraints to diminish both yield and overall quality of the crops. Until the arrival of today’s medicine, a large part of the population in developing nations traditionally depended on the products obtained from plants, particularly from forests, for administering human and livestock ailments. Some efforts have been made towards enhancing yields of plant crude drugs by improving crop varieties, cell cultures, transgenic plants, etc., but these are highly cost-demanding and time-consuming measures. Thus, it is vital to evolve efficient, eco-friendly, cost-effective simpler approaches for improvement in yield and health of the plants.

Plant growth-promoting endophytic microorganisms inhabit and proliferate inside the plants without any distinct symptoms of any diseases *in-planta* (Bacon et al., 2002), and their mechanism includes both direct and indirect actions such as mineral phosphate solubilization (Verma et al., 2001), fixing nitrogen (Alishahi et al., 2020), synthesis of auxins (Patten and Glick, 2002), production of siderophore (Lodewyckx et al., 2002), and various phytohormones (Costacurta and Vanderleyden, 1995). As many abiotic stresses induce multiple physiological disturbances, which include stomatal closure and stunted plant growth, this ultimately results in lesser crop yield. It has been well reported that ACC (1-aminocyclopropane-1-carboxylic acid) deaminase-containing microbes lower the effect of stress induced by higher ethylene levels of the host plant (Penrose et al., 2001; Sessitsch et al., 2005; Glick, 2005; Sun et al., 2009; Rashid et al., 2012). Therefore, microbial treatments can protect plants from the damaging effects of environmental perturbations (Ali et al., 2014). Changes in climatic conditions such as rainfall, ambient CO₂, and varying temperatures affect

agriculture through countless constraints resulting in either low yields or sometimes death of the plants. This review reveals the role of endophytes in improving agricultural sustainability, which can serve as a valuable approach toward green cultivation of MAPs and cost-effective drug production.

Endophytes: Microbial entities for plant fitness

Endophytes, the Greek word having “endon” (within) and “phyton” (plant), was coined by De Bary (1879) for “any organism occurring within plant tissues”. Bacon and White (2000) have defined endophyte in the broadest and widely accepted manner that states that endophytes include those microbes colonizing living plant internal tissues and not causing any instant, obvious ill effects. Thus, most precisely, endophytes refer to microorganisms (fungi, bacteria, actinomycetes, etc.) that spend at least a part of their life cycle establishing a relationship with a plant that remains asymptomatic (Vanessa and Christopher, 2004). Microorganisms that require living cells to grow and complete their life cycle are known as “obligate” while the others that mainly thrive on the outside of the plant tissues are termed as “epiphytes” and sometimes may enter the plant endosphere, called “opportunistic” (Hardoim et al., 2008). In this interaction, both plant and endophytic microbes live together, providing profound benefits to each other (Ting et al., 2009). These endophytes are often rhizospheric in nature, and preferable sites for their attachment and subsequent entry into the host plant could be apical root zone with thin-walled surface root layers and basal root zones with small cracks (Gagné, 1987). They proliferate in the entire host plant (Hallmann et al., 1997a), and reside within the cells, vascular tissues, or intercellular spaces (Patriquin and Dobereiner, 1978; Jacobs et al., 1985; Bell et al., 1995). Endophytic microbes could also enter through the stomata and vertically transmit from parent to offspring *via* seeds while roots have maximum colonization through epidermis formed by lateral root emergence (Roos and Hattingh, 1983; Agrawal and Shende, 1987). Which community of microbes are friends and which are foes? It is decided by the immune system of the plant itself (Zeilinger et al., 2016). The “balanced antagonism” with asymptomatic colonization between the host plant and endophytic microbes clearly shows that endophytes can live within the plant without activating any host defense mechanism and improves its self-sustenance through the production of the plant-like substances (Schulz et al., 1999; Schulz and Boyle, 2005).

The study of plant–microbe interactions helps us acknowledge natural events that influence our daily lives and could benefit befalling in sustainable resources, a smaller influence on the atmosphere and surroundings, and control of

environmental pollution. The benefits of using these interactions for biotechnological applications are huge. The utilization of the pre-existing plant–microbe interactions for the promotion of growth of the plant and biocontrol diminishes the use of unnatural synthetic pesticides and fertilizers, resulting in lowering input costs and, more importantly, reducing the influence of chemical nutrients and pesticides on existing useful flora and fauna (Boddey et al., 2003; Elmer and Reglinski, 2006; Whipps and Gerhardson, 2007). The production of beneficial compounds of industrial and pharmaceutical importance through plant–microbe symbiosis reduces the requirement to supply expensive catalysts and precursors and is energy-saving (Wu et al., 2007; Del Giudice et al., 2008). Remediation by traditional methods is costly and laborious; however, plant–microbe remediation approaches are incredibly efficient and less interfering (Anderson et al., 1993). The carbon sequestration by the plant–rhizosphere methods is probably a sustainable approach for reducing atmospheric carbon (Wu et al., 2009).

As the name implies, endophytic microorganisms live within a plant in the intercellular spaces of various plant parts such as stems, roots, petioles, leaves, etc., without imposing any apparent symptoms of disease or ill health. The symbiotic relationship of the host and its endophytes has been studied in detail and is explained as the plant partner protecting and feeding the endophytes, which, “in return”, produce certain substances with bioactive capabilities (antiviral, plant growth promotion, antibacterial, antifungal, insecticidal, etc.) to augment the growth and competitiveness of the former under natural conditions. These endophytic entities defend their host plants from pathogens by secreting bioactive secondary metabolites under unfavorable environments (Azevedo et al., 2000; Strobel, 2003). The endophytic organisms are now recognized as a vital part of biodiversity, the allocation of endophytic microflora varies with the difference according to its host. Zhang et al. (2006a) suggested that almost all of the vascular plants are known to harbor endophytic entities, especially those with medicinal values that are thought to be related to the formation of therapeutic products. Endophytic microbes are not entirely explored yet, but several investigations present them as an enormous therapeutic compound source. Worldwide, about 300,000 plants grown in an unexplored region are a host of at least one or more endophytic microbes (Araújo et al., 2001). Therefore, functionally diverse endophytes’ occurrence offers a key role in ecosystems at the most plentiful biodiversity (Strobel, 2003). Survival of the endophytic microbes inside the host cell can be for a long duration. The ability of these microbes to produce bioactive secondary metabolites makes them interesting candidates to be studied and exploited in biotechnological aspects (Casella et al., 2013) to add on to the existing wealth of secondary metabolites. Such interest has been reflected in a number of recent reviews showcasing the secondary metabolite-producing abilities of these wonder

microbes (Müller, 2015). The growth and yield of several medicinal plants have been reported to be enhanced by many endophytes (Barnawal et al., 2012; Barnawal et al., 2014), especially by gene expression modulation regulated in important secondary metabolites' biosynthesis. They have also been reported to impart tolerance to the plants against a range of biotic and abiotic stresses (Pandey et al., 2016a; Pandey et al., 2016b; Lata et al., 2018).

Chemical fertilizers' indiscriminate use for boosting the productivity of crops is drastically destroying soil and environmental health (Tilman, 1998). Even then, the use of fertilizers is likely to increase further in agriculture to feed the ever-growing huge population (Vitousek et al., 1997; Frink et al., 1999). In the current scenario of global climate change, sustainable agriculture production proves to be a significant challenge. Some approaches such as the integration of microbes associated with plants in agriculture enhance the growth of the plant through different modes and alleviate several biotic and abiotic perturbations (Tanaka et al., 2005; Vega et al., 2008; Lata et al., 2018), and may serve as rescue practices under such situations.

Colonization of the endophytic microorganisms in plants

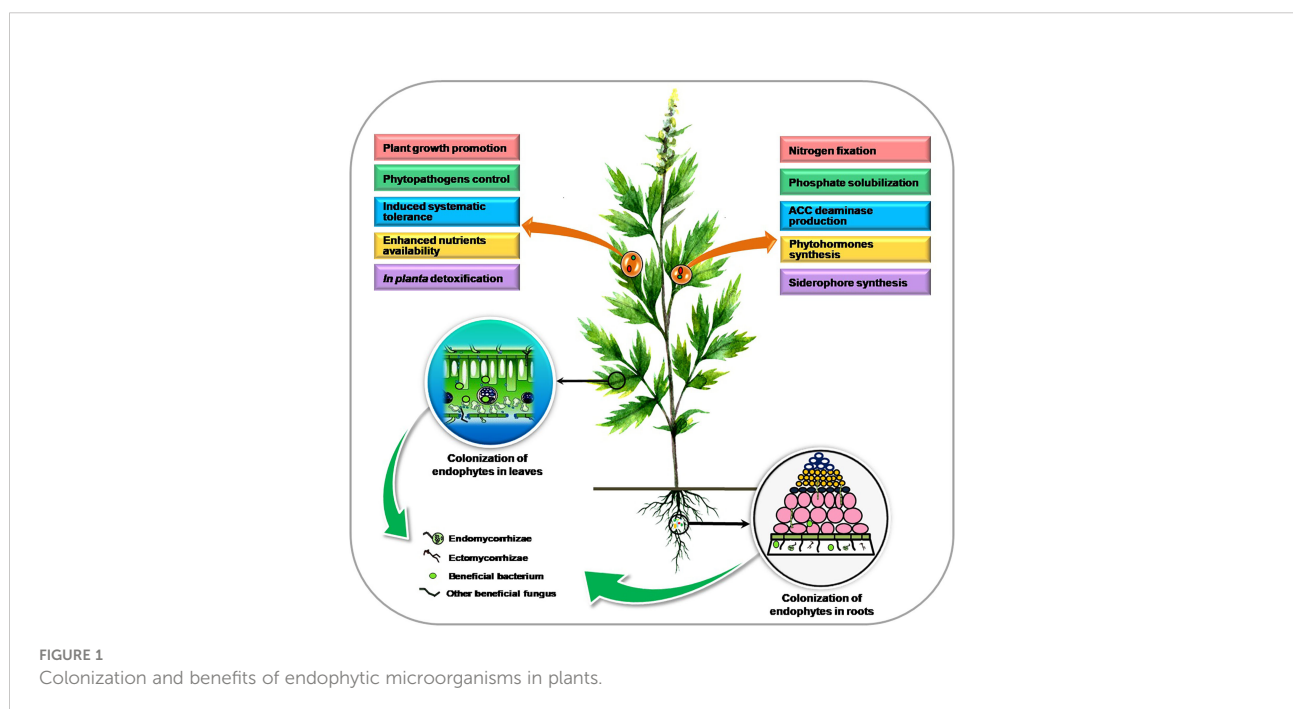

Plants exhibit a huge and varied niche for microorganisms inside the *planta* resulting in a closer association between them. Endophytes inhabit the internal plant tissue comprising different

bacterial and fungal species that collectively form the “plant endomicrobiome” and can trigger various physiological responses in the plant. Colonization and benefits associated with endophytic microorganisms in plants are presented in Figure 1.

Colonization of the bacterial endophytes

Bacterial endophytes, sometimes considered a part of the population of rhizospheric microbes (Marquez-Santacruz et al., 2010), are present in various tissues such as the stem, root, leaf, tuber, and fruit, of different agricultural, horticultural, and forest species. As the endophytic bacteria are directly in contact with the plant tissues, they have the benefit of greater advantage than rhizospheric bacteria from the plants and offer more benefits to the plant other than bacteria in the rhizospheric region and outside the plants (Araujo et al., 2002). The wide-ranging and recurrent occurrence of such endophytic bacterial populations indicates that healthy plants recruit more endophytic populations (Hardoim et al., 2015) and provide these organisms with a huge and somewhat uncharted ecological niche.

The colonization of host-associated microbes occurs horizontally from the surroundings and might be vertical *via* parent to the progenies (Santoyo et al., 2016). Endophytic bacteria have several ways to enter inside the host plant tissues. Except for those microbes that are already established

inside the seeds of the plant (Truyens et al., 2014), the most frequent point of entry of endophytic bacterial endophytes inside the host plant is *via* the cracks on the roots and wounded root tissues formed as a result of growth and development of the plant (Sprent and De Faria, 1989; Sørensen and Sessitsch, 2006). This allows leakage of plant metabolites, which attract more bacteria towards it (Hallmann et al., 1997a). Other points of entry of endophytes could be lenticels present in root and shoot periderm (Scott et al., 1996), radicles of germinating seeds, or lateral root hair cells. For example, Hallmann et al. (1997b) showed that *Enterobacter asburiae* JM22, an endophytic bacterium in cotton plants, produces enzymes capable of hydrolyzing cellulose in the cell wall, assisting the entry of the bacterium inside the host plant.

Autofluorescent proteins (AFP) could be an important method as well as a tool for the visualization of the biofilm to study plant-microbe interaction. These visualization techniques also include gene expression studies using GFP (green fluorescent proteins) in which the GFP gene is integrated into the chromosome of bacteria and a plasmid containing GFP cloned cells which are visualized by confocal or epifluorescence or laser scanning microscopy (Villacieros et al., 2003; Germaine et al., 2004). In the β -glucuronidase (GUS) reporter system, staining helps in the visualization of bacterial movement and gene expression in the rhizosphere and phyllosphere, and entrance and site of pathogens can be studied by IVET (*in vivo* expression technology) (Preston et al., 2001; Leveau and Lindow, 2001; Zhang et al., 2006a).

Colonization of the fungal endophytes

For the recruitment of the endophytes, the host plant establishes symbiosis with large soil microbial diversity. Initially, attachment of the endophytic fungi might occur on the surface of roots and form structures called appressorium (Yedidia et al., 1999). After that, these attachments penetrate the outer root system and internally colonize the plant tissues (Viterbo and Chet, 2006; Nogueira-Lopez et al., 2018). Endophytic fungi mostly use two types of diffusion patterns; in the primary mechanism, fungi are vertically transmitted into progeny seed from maternal plants by which the offspring gets infected (Gagic et al., 2018). The endophytic fungi transmission among the host plants and the offspring is brought about under appropriate environmental conditions when infected seeds germinate and the endophytic fungi present inside the seed enter the seedlings after the germination of seeds (Hodgson et al., 2014).

Generally, endophytic fungi initiate from the nutrient-rich atmosphere of the rhizosphere, which also has insects and animal feeding processes, and air floating fungal spores

(Rodriguez et al., 2009; Sasse et al., 2018). Many of the endophytic fungal microbes are transmitted through spores or hyphal fragments horizontally in aboveground tissues, by insects or herbivores (biotic) or rain or wind (abiotic dispersion agents) from plant to plant, thus establishing communication of fungal endophytes between several plant hosts (Wiewiora et al., 2015).

Microscopic observations of tomato roots on early colonization by the endophytic fungus *Trichoderma* illustrated no disturbance in cell integrity during this process (Chacón et al., 2007). However, in cucumber roots colonized by endophytes, various phenomena such as enhanced chitinase activity, necrosis of the penetration peg, and fluorescent products' formation in the intercellular spaces were observed. This phenomenon might be due to copious extracellular enzyme production by endophytic fungi (Suryanarayanan et al., 2012).

How endophytic microorganisms benefit the plants

Not much information exists about the mechanisms of endophyte-mediated plant growth enhancement. Endophytes can mediate plant growth improvement both directly and indirectly (Figure 2). As rhizospheric bacterium initiates its development into endophytes, it is supposed that endophytes can maintain their characteristics inside the host plant.

Direct beneficial mechanisms

Endophytic microbes help host plants directly in many ways to promote the plant's growth by improving the uptake of essential nutrients, which ultimately increases overall crop yield (Muthukumarasamy et al., 2002). A typical example is nitrogen fixation by particular endophytes in leguminous crops (Stacey et al., 2006). Additionally, several researchers have stated that endophytic bacteria effectively associate with non-leguminous crops to form a synergistic association intended for nitrogen fixation (Bhattacharjee et al., 2008; Saravanan et al., 2008; Mattos et al., 2008; Govindarajan et al., 2008; Oliveira et al., 2009). Plant growth enhancement may occur *via* many approaches that include plant hormone production, like gibberellins, IAA (indole-3-acetic acid), ethylene, and cytokinin regulation and activity. Many endophytes have shown to exhibit an activity of enzyme ACC (1-aminocyclopropane-1-carboxylate) deaminase to modulate physiology by reducing ethylene content (Hardoim et al., 2008; Barnawal et al., 2012) since ethylene in plant growth inhibitive hormone. In previous studies, *Burkholderia phytofirmans*, a plant growth-promoting endophytic strain, has been proven to enhance the yields of numerous crops (Lazarovits and Nowak, 1997; Sharma and Nowak, 1998; Sessitsch et al., 2005; Barka

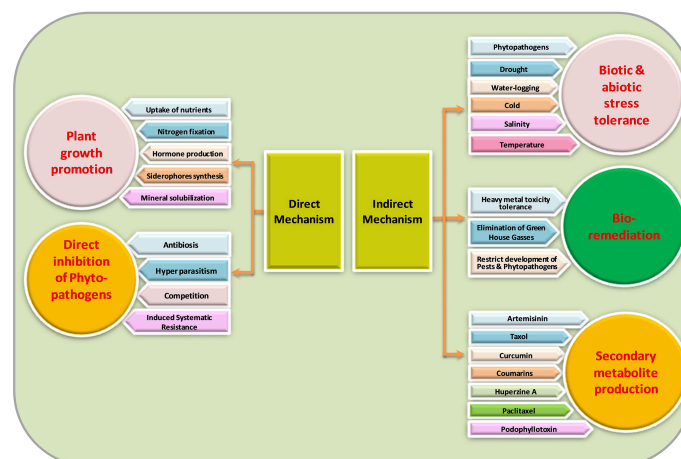

FIGURE 2
Mechanism of action of endophytic microorganisms.

et al., 2006). Similarly, Mattos et al. (2008) showed that *Burkholderia kururiensis*, an endophytic bacterium, enhances IAA hormone production. *Penicillium citrinum* strain generated a large amount of physiologically active gibberellins than *Gibberella fujikuroi* (wild type), which offers to generate a biologically active source of gibberellic acid (GA3) (Khan et al., 2008). Various studies showed that a variety of fungal endophytes promoted height, biomass, and tiller number in numerous crops (Spiering et al., 2006; Zhang et al., 2007; Lowe et al., 2008). *Stagonospora* spp., a seed-borne endophytic fungus, increased the yield of *Phragmites australis* (Cav.) Trin. ex Steud. (Ernst et al., 2003), and endophytic fungus promoted growth in peppermint (Mucciarelli et al., 2003). Some examples of endophytic microbes' associated benefits in medicinal and aromatic plants are presented in Table 1.

Indirect beneficial mechanisms

Plants muddle through various unfavorable environmental conditions or abiotic stresses like cold, drought, hyper-salty situations, or pathogenesis. Endophytic microbes help the plant conquer such perturbations through some indirect mechanisms, which also promote the buildup of secondary metabolites (including drugs or important medicinal components) in plants.

The endophytic microbes support the host plants to defeat the before-mentioned stresses by some indirect mechanisms. They are also effective in bioremediation by various means, like they decrease heavy metal stress (Zhang et al., 2012), eliminating harmful greenhouse gases (Stępniewska and Kuźniar, 2013), and restricting the development of pests on plants (Azevedo et al., 2000). Endophytic microbes also support phytoremediation by

reducing metal phytotoxicity. Simultaneously, for plants containing endophytes with requisite metabolic capabilities and degradation pathways for reducing phytotoxicity and magnifying degradation, the plant–endophyte relationships can be equipped to remediate wastelands and groundwater (Weyens et al., 2009). Rajkumar et al. (2009) reported that endophytic bacteria assist in promoting the extraction of heavy metals. Endophytes are also effective in the degradation of polyaromatic hydrocarbon (PAH). Radwan (2009) documented the phytoremediation of oily soils using rhizobacteria, which appears to be a cheap and environmentally friendly method of cleaning the environment.

Tolerance to biotic stresses

Endophytic microorganisms have the ability to enhance plant resistance systems against pathogen infestation through antagonistic activity (Miller et al., 2002; Gunatilaka, 2006). Many studies showed that endophytes have a crucial role in regulating the gene expression of the host, modulating physiological responses and plant defense-related pathways (Van Bael et al., 2012; Estrada et al., 2013; Salam et al., 2017). Khare et al. (2016) illustrated that jasmonic acid and salicylic acid could greatly contribute to plant stress responses against phytopathogens. Ren and Dai (2012) described that inoculation with *Gilmaniella* sp. AL12 induces jasmonic acid defense responses against pathogenic fungi in *Atractylodes lancea* (Thunb.) DC. The gibberellins produced by endophytes enhance insect and phytopathogens' resistance via salicylic and jasmonic acid pathways (Waqas et al., 2015a). An endophyte, *Fusarium solani*, elicits induced systemic resistance against a fungal pathogen, *Septoria lycopersici*, by stimulating gene expression

linked to the pathogenesis (Kavroulakis et al., 2007). Foliar endophytic fungi, *Colletotrichum tropicale*, inoculated in *Theobroma cacao* (L.) enhance tolerance to *Phytophthora* (Mejía et al., 2008). The endophytic bacteria produce several antimicrobial compounds that can increase the resistance of the plants to various phytopathogenic fungi, bacteria, nematodes, etc. Endophytic *Pseudomonas putida* BP25 associated with black pepper inhibits a range of phytopathogens, viz., *Rhizoctonia solani*, *Phytophthora capsici*, *Gibberella moniliformis*, *Pythium myriotylum*, *Radopholus similis*, and *Colletotrichum gloeosporioides* by the production of several compounds (Sheoran et al., 2015). *Macrophomina phaseolina* causes charcoal rot disease in different crops and has been reported to be restricted by siderophore-producing *Rhizobium* (Arora et al., 2001). An endophyte, *Pseudomonas fluorescens*, having antagonistic effects against *Verticillium* was isolated by Mercado-Blanco et al. (2004) from olive plant roots. Yong et al. (1994) established the role of endophyte *Fusarium* spp. in the enhancement of growth and terpenoid content in *Euphorbia pekinensis* Rupr.

The endophytic fungus *Phomopsis cassia* associated with *Cassia spectabilis* enhances tolerance against phytopathogenic fungi *Cladosporium sphaerospermum* and *C. cladosporioides* by producing cadinane sesquiterpenoids, which are toxic to pathogens (Silva et al., 2006). Similarly, Wang et al. (2012) reported that an endophyte, *Chaetomium globosum* L18, inhibits pathogenic fungi by synthesizing some toxic chemicals in *Curcuma wenyujin* Y. H. Chen & C. Ling. In another study, Cao et al. (2009) identified endophytic microbes *Choiromyces aboriginum*, *Stachybotrys elegans*, and *Cylindrocarpum* associated

produces cell wall-degrading enzymes to kill pathogenic fungi in *Phragmites australis* (Cav.) Trin. ex Steud. Furthermore, an endophytic fungus, *Trichothecium roseum*, has a toxic chemical, “trichothecin”, which enhances tolerance to pathogenic fungi in *Maytenus hookeri* Loes. (Zhang et al., 2010). Similarly, *Bacillus subtilis* and *Myxormia* sp. also enhance tolerance against pathogenic fungi *Fusarium oxysporum* and *F. solani* in *Angelica sinensis* (Oliv.) Diels (Yang et al., 2012).

Endophytic microbes *Chaetomium cochliodes*, *Cladosporium cladosporioides*, and *Trichoderma viride* enhance insect resistance in creeping thistle via producing some chemicals toxic to pathogens (Gange et al., 2012). Similarly, Sumarah et al. (2010) reported that fungal endophytes enhance resistance against *Choristoneura fumiferana* insect in red spruce (*Picea rubens* Sarg.). An endophyte, *Leucocoprinus gongylophorus*, increases insect resistance by synthesizing some chemicals antagonistic to ants’ fungal symbiont (Bittleston et al., 2011). Furthermore, the endophyte *Chaetomium* Ch1001 associated with cucumber enhances tolerance against root-knot nematode by producing abscisic acid affecting the motility of the second-stage juveniles of insects (Yan et al., 2011). According to the study undertaken by Gómez-Vidal et al. (2009), endophytes *Beauveria bassiana*, *Lecanicillium dimorphum*, and *L. cf. Psalliotae* increase insect resistance to *Phoenix dactylifera* by modulating the expression of cell division-related proteins in the host plant. Strobel et al. (1999) reported that in thunder god vine (*Tripterygium wilfordii* Hook. f.), an endophyte, *Cryptosporiopsis* cf. *quercina*, produces “cryptocin” and “cryptocandin” toxic to pathogenic fungi

Pyricularia oryzae in host plant. Daungfu et al. (2019) recently identified several endophytes, *Bacillus subtilis* LE24, *Bacillus amyloliquefaciens* LE109, and *Bacillus tequilensis* PO80, isolated from citrus plant having antagonistic effects against pathogens, which might be helpful in the biocontrol of pathogens. All these findings strongly confirm that the presence of endophytes in the host has the potential to increase their tolerance to pathogens through several mechanisms. Conversely, in resistance stimulation to disease facilitation, the process wherein endophytes invade plant tissues affects endophyte–pathogen interactions, perhaps producing facilitation (positive induction of pathogens), negatively strengthening host resistance, or having no effect at all (Suryanarayanan et al., 2009; Schmidt et al., 2014; Adame-Alvarez et al., 2014). These require further research for confirmation.

Tolerance to abiotic stresses

Abiotic stressful conditions, viz., drought, water-logging, salinity, cold, heat, and heavy metal toxicity, may cause adverse effects on soil and environmental health (Wang et al., 2003; Khare and Arora, 2015). Endophytes have a vital function in increasing tolerance against abiotic perturbations in plants (Wani et al., 2016). Waqas et al. (2012) reported that stomatal closure mediated by abscisic acid (ABA) might have a key function in the regulation of plant growth by reducing other abiotic stresses, including osmotic stress.

Under drought stress, an endophytic bacterium, *Sinorhizobium meliloti*, upregulated FeSOD and Cu/ZnSOD, promoting drought tolerance in *Medicago sativa* (L.) (Naya et al., 2007). Similarly, *Arbuseular mycorrhiza* improves nutrient absorption and modifies *Salvia*'s metabolic activities to boost drought tolerance (Meng and He, 2011). An endophytic microbe, *Trichoderma hamatum* DIS 219b, delayed drought-induced alterations in stomatal conductance and net photosynthesis, promoting drought tolerance in *Theobroma cacao* (L.) (Bae et al., 2009). According to Sziderics et al. (2007), a fungal endophyte, *Piriformospora indica*, enhances osmotic stress tolerance via encoding enzyme ACC oxidase and lipid transfer protein. Wang et al. (2009) reported that *Arbuseular mycorrhiza* and *Penicillium griseofulvum* reduce injury of water stress by increasing the activity of protective enzymes and osmotica contents, thereby enhancing tolerance against salt and drought stress in *Glycyrrhiza uralensis*. Liu et al. (2011) reported that soluble protein concentration and peroxidase activity (POD) are altered by *Chaetomium globosum* and *Botrytis* sp. Under salt stress in *Chrysanthemum morifolium* (Ramat.) Hemsl. A fungal endophyte, *Yarrowia lipolytica*, promotes salinity stress tolerance in *Euphorbia milii* Des Moul. (Jan et al., 2019).

Moreover, ABA-mediated signaling pathways and their biosynthesis during salinity stress are altered by several microbes in the plant endosphere and may help plant growth. *B. phytofirmans* (PsJN) altered gene expression for a cell surface signaling element, which passes signals to bacteria about the alteration in environmental conditions and consequently improves their metabolism (Sheibani-Tezerji et al., 2015). Fernandez et al. (2012) reported in PsJN bacterized grapevine that stress-induced gene expression in addition to metabolite levels improved over control at a lower temperature by balancing carbohydrate metabolism. Recently, de Zélicourt et al. (2018) reported that *Enterobacter* sp. (SA187), an endophyte, colonizes *Arabidopsis* root and shoot tissues and stimulates tolerance against salt stress by synthesizing KMBA (2-keto-4-methylthiobutyric acid). Márquez et al. (2007) reported that at high soil temperatures, *Curvularia protuberata*, an endophytic fungus, has been linked to *Dichanthelium lanuginosum* for its survival. Wan et al. (2012) reported that endophytes can also reduce the heavy metal-promoted oxidative injury. Earlier studies suggested endophytic bacteria's function in enhancing tolerance to metal toxicity through diverse mechanisms such as sequestration, intracellular accumulation, and extracellular precipitation or alteration of toxic metal ions to a minimum or non-toxic form (Ma et al., 2016; Mishra et al., 2017). Luo et al. (2012) discovered that a bacterial endophyte, *Bacillus* sp. SLS18, reduces heavy metal toxicity via root tillers and biomass accumulation in *Solanum nigrum* (L.) and *Phytolacca acinosa* Roxb. Recently, Domka et al. (2019) identified an endophytic fungus, *Mucor* sp., which enhances metal toxicity tolerance in *Arabidopsis arinosa* (L.) Lawalrée. Some examples of endophytes enhancing the tolerance of crop plants against abiotic and biotic stresses are presented in Table 2.

Endophytic microorganisms producing secondary metabolites/bioactive compounds in the host plant

The diversity of bioactive compounds varies according to the habitats of the host plants; for example, in a tropical rain forest, limited resource availability leads to great competition among plants and their endophytes; thus, selection pressure is at the peak, resulting in the production of many novel molecules as compared to temperate forests (Reddell and Gordon, 2000). Isolation of indigenous microbes from different plant parts and their interaction with the host plant may divulge applicant microbes to promote plant growth and as biocontrol agents. Such microbial inoculants have the potential to provide resistance against environmental perturbations without affecting the indigenous microbial equilibrium (Palaniyandi et al., 2013).

TABLE 2 Host medicinal plants with enhanced defense responses conferred by endophytic microorganisms.

Endophytic microorganisms	Host plant	Type of stresses	Mechanism	References
<i>Bacillus subtilis</i> , <i>Myxormia</i> sp.	<i>Angelica sinensis</i> (Oliv.) Diels	Pathogenic fungi: <i>Fusarium oxysporum</i> and <i>F. solani</i>	Produce some chemicals toxic to pathogens	Yang et al., 2012

<i>Sinorhizobium meliloti</i>	<i>Medicago sativa</i> (L.)	Drought stress	FeSOD and Cu/ZnSOD are upregulated	Naya et al., 2007
<i>Pseudomonas koreensis</i> AGB-1	<i>Miscanthus sinensis</i> Andersson	Heavy metal toxicity (Zn, Cd, As, and Pb)	Through extracellular sequestration, increased catalase and SOD activities in plants	Babu et al., 2015
<i>Beauveria bassiana</i> , <i>Lecanicillium dimorphum</i> , L. cf. <i>Psalliotae</i>	<i>Phoenix dactylifera</i> (L.)	Insect	Modulate the expression of cell division-related proteins in host	Gómez-Vidal et al., 2009
<i>Choiromyces aboriginum</i> , <i>Stachybotrys elegans</i> , <i>Cylindrocarpon</i>	<i>Phragmites australis</i> (Cav.) Steud.	Pathogenic fungi	Produce cell wall-degrading enzymes to kill pathogenic fungi	Cao et al., 2009
150 foliar fungal endophytes	<i>Picea rubens</i> Sarg.	Insects: <i>Choristoneura fumiferana</i>	Produce some chemicals toxic to insects	Sumarah et al., 2010
<i>Arbuseular mycorrhiza</i>	<i>Salvia miltiorrhiza</i> Bunge	Drought stress	Increase the absorption of nutrient and alter metabolic activities in host	Meng and He, 2011
<i>Bacillus</i> sp. SLS18	<i>Solanum nigrum</i> (L.), <i>Phytolacca acinosa</i> Roxb.	Heavy metal toxicity (Mn and Cd)	Accumulation of root tillers and biomass	Luo et al., 2012
<i>Trichoderma hamatum</i> DIS 219b	<i>Theobroma cacao</i> (L.)	Drought stress	Delayed drought-induced changes in stomatal conductance and net photosynthesis	Bae et al., 2009
<i>Cryptosporiopsis</i> cf. <i>quercina</i>	<i>Tripterogium wilfordii</i> Hook.f.	Pathogenic fungi: <i>Pyricularia oryzae</i>	Produce cryptocin and cryptocandin toxic to pathogens	Strobel et al., 1999

Many endophytic microbes can synthesize a notable variety of secondary metabolites like antioxidant, anticancer, immunosuppressive, antidiabetic, antioomycete, antifungal, antibacterial, antiviral, and nematicidal agents (Gunatilaka, 2006; Zhang et al., 2006b; Verma et al., 2009; Aly et al., 2011). Shimizu (2011) reported that endophytic actinobacteria synthesize antibiotics, which is useful in plant growth promotion and improves the tolerance of plants to stress. Endophytes also have been in the limelight during the last

decade or so because of their capability in producing several secondary metabolites that are bioactive (Tan and Zou, 2001; Schulz et al., 2002; Strobel, 2003; Prado et al., 2013). These compounds extracted from endophytes belong to the various chemical groups like xanthenes, terpenoids, phenols, steroids, benzopyranones, isocoumarins, chinones, cytochalasins, tetralones, and enniatines (Schulz et al., 2002). Sometimes, these endophytic microbes may cause variation in well-known structural compounds like fungal steroids, ergosterol, or plant

hormone indole-3-acetic acid (Lu et al., 2000). Several endophytes can also be attributed to providing protection of plants against pests because of the compounds occurring in them (Poling et al., 2008).

There are many reports that have shown that host secondary metabolism can be induced by endophytes, but such interaction has not been much explored. Qawasmeh et al. (2012) reported that when endophytes (from the Clavicipitaceae family) interact with grasses, there is a production of phenolic compounds, which are mainly defense-related. However, secondary metabolites could remain unchanged or get reduced depending on which type of endophyte interacts with the host plant. A well-known example of a high-demanding anticancerous molecule is “taxol” isolated from *Taxomyces andreanae*, a taxol-producing fungal endophyte of *Taxus* species (Stierle et al., 1995). An example showed that bacterial endophytes have methanol dehydrogenase genes, which were known to express furanone biosynthesis and localized especially in vascular tissues of strawberry receptacles and plant achenes cells (Nasopoulou et al., 2014). Likewise, Koskimäki et al. (2009) have reported that fungal endophyte *Paraphaeosphaeria* sp. increased the accumulation and biosynthesis of flavan-3-ols phenolic acids and oligomeric proanthocyanidins in *Vaccinium myrtillus*. In *Artemisia annua* (L.), an endophytic bacterium, *Pseudonocardia* sp., has been reported to increase artemisinin synthesis by upregulating the cytochrome P450 monooxygenase (CYP71AVI) and cytochrome P450 oxidoreductase (CPR) genes, and this also activated a defense mechanism (Wang et al., 2006). It has also been found that endophytes may act as upregulators of the specific gene expression for tissue-specific roles, e.g., foliar endophytes enhanced primary metabolites, crop yields could be increased by root endophytes, and endophytes isolated from the capsule could upregulate key genes of benzyloisoquinoline alkaloid (BIA) biosynthesis in *Papaver somniferum* (L.) (Pandey et al., 2016a). Tiwari et al. (2010) found an improved content and yield of essential oils in holy basil. In the Chinese medicinal plant *Atractylodes lancea* (Thunb.) DC., the endophytic bacterium *P. fluorescens* could enhance the generation of ROS (reactive oxygen species), which resulted in an increase of sesquiterpenoids (Zhou et al., 2015). Endophytic bacteria *Aranicola proteolyticus*, *Bacillus cereus*, *B. thuringiensis*, *B. licheniformis*, and *Serratia liquefaciens* recovered from *Pinellia ternata* (Thunb.) Makino could produce inosine and guanosine alkaloids similar to their host plant in fermentation media (Liu et al., 2015). Tiwari et al. (2013) found that endophyte *Micrococcus* sp. and *Staphylococcus sciuri* inoculated plant had significantly higher amounts of ajmalicine, serpentine, and vindoline in *Catharanthus roseus* (L.) G. Don. Kumar et al. (2014) reported that the endophytic bacterium *Azotobacter chroococcum* could enhance the yield of curcumin in rhizomes of turmeric.

Endophytic microflora encompasses a high potential for the synthesis of an ample range of unidentified, undepicted novel

secondary metabolites within or without host plants. It is needed to identify which type of mechanism or cryptic genes and what circumstances for the evolution of the genome are involved in the synthesis of novel compounds in endophytes as well as *in-planta*. Some examples of endophytes producing secondary metabolites in host plants are presented in Table 3.

Phytoremediation

Phytoremediation is the most efficient and eco-friendly system for restoring natural soil conditions when various environmental pollutants have contaminated it. In the past two decades, endophytes' usage in the phytoremediation of diverse environmental pollutants has received more attention (Sheng et al., 2008; McGuinness and Dowling, 2009; Weyens et al., 2009; Weyens et al., 2010; Hur et al., 2011; Segura and Ramos, 2013; Wei et al., 2014; Anyasi and Atagana, 2018). Such research has shown the potential of plant-microbe interaction in the restoration of polluted regions and may be helpful in designing efficient environmental pollutant removal systems. One of the reasons could be attributed to the complicated relationship between endophytes and their hosts. In contrast, the other reason has to do with the fact that it is practically impossible to comprehend the mechanisms of existence and situations of endophytes to be able to replicate them. It is impractical to exaggerate the role of endophytes in both management and harnessing the natural environment. Unfortunately, the holistic view of these taxa has been constrained by them. Such constraints include the fact that the process of isolation of endophyte relies on culture dependence, while several microorganisms exist that cannot be cultured. This emphasizes nonculture-dependent innovation as the barrier to understanding endophytes.

Agronomic practical application of endophytic microorganisms

The most frequently used inoculation technique in agriculture includes the use of endophytes; culture, facilitated by a carrier, is combined with the synthetically manufactured sticky seeds and sown. Moreover, several commercial formulations include liquid cultures directly applied or with the granular fertilizer or seed applications. Other techniques have also been used, including seed priming, seed coating, foliar spraying, root dipping, pelleting, and direct soil application (O'Callaghan, 2016). Given the presence of endophytic microbes, seed inoculation can accomplish this goal. Still, its effectiveness is constrained by the lengthy engaging period, subsequent physical abrasion, and competition with other soil microbes. Root dipping or seedlings treated with microbial

suspension are also susceptible to contamination and handling issues. The application of endophytes in bulk populations is made possible by pelleting or direct soil application. However, there is still an issue with the lack of homogeneity in the field and exposure to environmental perturbations. Despite using every conventional method, the microbes still need to endure for a few weeks before they may enter the plant after root hair emergence. Even while some endophytes' facultative character suggests the prospect of further colonization if they can endure in the rhizosphere, the ecological constraint exists. Seed priming with a predetermined duration can help the microbe's entrance during imbibitions. However, several scientific and technical

difficulties are still associated with applying endophytes to seeds *via* coatings, sprays, granules, and capsules. Moreover, a seemingly simple procedure like plate counting also seems to have some technical problems, e.g., the "viable but not culturable" bacteria may not be detected by plate counting.

The formulation should facilitate the microorganism's penetration and colonization of the host while minimizing dosage and cost. It should also increase microbe establishment in the soil and close to or on the plant. The application of endophytes requires a thorough knowledge of the physicochemical and biological environment, including the phyllosphere, soil, seed surface, and rhizosphere, as well

as the cultivation and formulation of the biologicals to prolong shelf life. In the context of mycorrhiza, progress has been made in understanding the molecular plant–microbe interaction that needs to be integrated into novel formulation and application strategies. In other circumstances, such endophytic entomopathogenic fungi do not clearly understand how they invade and colonize. Basic research studies only use straightforward water-spore mixtures instead of more advanced and practical application methods.

Furthermore, designing formulations having high microbial inoculant concentration and survivability during storage is crucial for developing potent inoculants. Since it is impossible to test out every potential combination of parameters throughout the formulation process, it is challenging to determine the most critical variables. Nevertheless, it is challenging to maintain sterility throughout the formulation process for an extended period, which could lead to contamination. Even though we can find entomopathogenic fungi in nature in this form, their poor recovery rate from plants reveals that these organisms do not occur naturally.

Conclusion

Plant–microbe interactions benefit the all-embracing vicinity of agricultural applications. Microorganisms are abundantly present in nature and primarily colonized *in-planta*. Plant–endophyte interaction is mostly considered beneficial, having profound effects on the physiology of the host plant and the overall performance by promoting growth, development, and imparting fitness to the host plants against different biotic and abiotic stresses. They play a vital function in agricultural sustainability by providing eco-friendly inputs to enhance crop productivity and quality while minimizing harmful chemical fertilizers. The study of these plant–microbe interactions helps us acknowledge natural events that influence our daily lives and could benefit befalling in sustainable resources, a smaller influence on the atmosphere and surroundings, and control of environmental pollution. The benefits of using these interactions for biotechnological applications are huge. The utilization of the pre-existing plant–microbe interactions for the promotion of growth of the plant and biocontrol diminishes the use of unnatural synthetic pesticides and fertilizers, resulting in lowering input costs and, more importantly, reducing the influence of chemical nutrients and pesticides on existing useful flora and fauna. Moreover, the production of beneficial

compounds of industrial and pharmaceutical importance through plant–microbe symbiosis reduces the requirement to supply expensive catalysts and precursors and is energy-saving. In recent years, MAPs are being paid considerable attention worldwide due to their vast economic potential, primarily in the field of herbal medicine. Until the arrival of advanced medicines, an oversized population in emerging nations has traditionally relied upon the products obtained from plants. Furthermore, about 12.5% of the more than 422,000 plant species have been universally documented for medicinal properties; however, only a couple of hundreds are known to be in cultivation. There is a need to grow MAPs to maintain their steady supply and conservation amidst decreasing stocks from natural sources and rising global interest.

Limitations and further investigations

Endophytic microorganisms are tissue specific in nature; their establishment and functionality within the host are affected by several factors such as tissue type, host's genotype, and surrounding conditions. The lack of knowledge about the widespread presence of endophytic microorganisms' communities in plant tissues has been a hindrance in advancing research on endophytes in various fields. It should be noted that the development of successful endophyte application technologies would fully depend on improving our understanding of how they enter and colonize *in-planta*. Consequently, to guarantee reproducibility, reliable methods of endophytic inoculum delivery should be developed for better productivity of MAPs. Leveraging the relationship between plants and endophytes can be crucial for advancing sustainable development (Ryan et al., 2008); extensive research investigations are required to accept or refute this hypothesis. Therefore, in-depth future studies are needed to demonstrate an improved comprehension of the organism in its host to advance the viability of endophyte-assisted biological applications, especially in the field. The persistent reliance on the deployment of a generic method in their processing was inferred to be a hindrance to the capability to fully grasp the interaction between endophytes and their host concerning their utilization in biological activities. Since most organisms prefer to eschew them due to transformations, they cannot be recognized using those general techniques. Thus, using complex molecular processes in their processing will lead to a better understanding and enable the use of the endophytic application in agriculture/food processing, medicine, and environmental management.

Author contributions

AK and AT conceived and planned this review article. AT and PP wrote the original draft of the manuscript. ST helped in review and data collection. PP prepared the figures. All authors reviewed and agreed on the final version.

Acknowledgments

We are thankful to the Director of CSIR-Central Institute of Medicinal and Aromatic Plants for providing the necessary facilities to carry out the research work. AT is grateful to the Department of Science and Technology, India for the INSPIRE fellowship.

The ever-increasing human population associated with high rate of waste generation may pose serious threats to soil ecosystem. Nevertheless, conversion of agricultural and food wastes to biochar has been shown as a beneficial approach in sustainable soil management. However, our understanding on how integration of biochar obtained from different wastes and mineral fertilizers impact soil microbiological indicators is limited. Therefore, in the present study the effects of agricultural (AB) and food waste derived (FWB) biochars with and without mineral fertilizer (MF) on crop growth and soil health indicators were compared in a pot experiment. In particular, the impacts of applied amendments on soil microbiological health indicators those related to microbial extracellular (C, N and P acquiring) enzymes, soil basal as well as different substrate induced respirations along with crop's agronomic performance were explored. The results showed that compared to the control, the amendment with AB combined with MF enhanced the crop growth as revealed by higher above and below ground biomass accumulation. Moreover, both the biochars (FWB and AB) modified soil chemical properties (pH and electric conductivity) in the presence or absence of MF as compared to control. However, with the sole application of MF was most influential strategy to improve soil basal and arginin-induced respiration as well as most of the soil extracellular enzymes, those related to C, N and P cycling. Use of FWB resulted

in enhanced urease activity. This suggested the role of MF and FWB in nutrient cycling and plant nutrition. Thus, integration of biochar and mineral fertilizers is recommended as an efficient and climate smart package for sustainable soil management and crop production.

nutrient cycling, sustainable crop production, waste recycling, food security, agriculture

Introduction

The world's population has been increasing exponentially and is expected to turn up to 9.6 billion until 2050 (Tripathi et al., 2019) and is projected to be linked with a 60% increase in food demand (Boretti and Rosa, 2019). This overwhelming pace of human population, high food consumption and agricultural waste production will put pressure on the global agriculture which may outcome in negative environmental and socio-economic aspects. In fact, the higher food production and waste generation due to human consumption are concomitantly linked and approximately 1/3rd of the food produced is annually wasted around the globe (Kibler et al., 2018; Ishangulyyev et al., 2019). It has been estimated that the annual amount of this food waste is approximately 1.3 billion tons globally (Gustavsson et al., 2011). A big part of this amount (56%) is produced by developed world while the rest (44%) is being generated by the less developed countries (Bond et al., 2013; Lipinski et al., 2013). However, a big part of the wasted food material is lost, incinerated or buried in the landfills, causing soil and water pollution which is another of the main global concerns (Parry et al., 2007; Abiad and Meho, 2018). In this way, only in USA, around US\$90 billion–US\$100 billion a year is lost (Lundqvist et al., 2008). Therefore, the situation demands for the safer utilization of food and viable approaches to deal with the wasted materials to ensure the food security and environmental protection.

Several types of organic (including food and agricultural) wastes are generated worldwide with the potential to be utilized as soil amendments for enhancing soil health and crop production (Toscano et al., 2013; Sayara et al., 2020; Naveed et al., 2021). However, direct application of such wastes may cause risks to soil health, especially to soil chemical and microbiological characters (Urrea et al., 2019). Therefore, bioconversion of agricultural and food wastes to non-hazardous and stable soil amendments is a viable alternative. This will not only reduce the risks associated with environmental burdens, but also ensures the safe disposal and utilization of end product as sustainable soil amendments (Sulok et al., 2021; Brtnicky et al., 2022). Conversion of agricultural and food

wastes into biochar (a C rich) product produced by the pyrolysis is an effective way in this regard too. Biochar has been reported to enhance soil fertility, improve soil health and ultimately increasing crop yields (Ahmad et al., 2020; Karimi et al., 2020; Rasool et al., 2022). We took advantage of converting the collected food and agricultural wastes into biochars and utilized them for this study.

It has been recognized that intensive agricultural practices, injudicious use of chemical fertilizers, removal of crop straw and heavy tillage operations have resulted in the loss of soil fertility and degradation of arable lands (Sonmez et al., 2016). Currently, farmers heavily rely on the use of chemical fertilizers and crop protection chemicals to produce higher crop yields (Mustafa et al., 2019). This behavior of farmers has aggravates the soil degradation and its productive capacity as the higher use of chemicals and fertilizers deteriorate the environmental resources and cause soil salinity, eutrophication and heavy metal pollution in arable soils (Bouraoui and Grizzetti, 2014; Ali et al., 2019; Zulfiqar et al., 2022). To entail these challenges, researchers are focusing on developing alternative strategies, which ensure high crop yields without negative effects on the soil quality and water resources (Bais-Moleman et al., 2019; Tan et al., 2021; Kang et al., 2022; Wali et al., 2022). Nevertheless, chemical fertilizers have shown a potential to increase crop yields by modifying soil properties, the sole utilization of chemical fertilizers have been questioned in the face of climate change (Srivastav, 2020; Meena et al., 2020). In this respect, the combination of biochar together with mineral fertilizers could be an effective strategy to enhance soil health and crop biomass yields while keeping the mineral fertilizers at low levels. Previously many studies have shown the improvements in crop yields and soil fertility under the application of either chemical fertilizers or biochar (Atkinson et al., 2010; Khadem and Raiesi, 2017) or the combination of both (Singh et al., 2019a; Singh et al., 2019b). Most of these studies have shown the variable effects of biochar derived from various sources on soil properties (Prendergast-Miller et al., 2014; Hussain et al., 2017; Mohan et al., 2018) and agronomic and physiological responses of crops (Carter et al., 2013; Kuppasamy et al., 2016; Singh et al., 2020). Majority of these studies have only focused on soil physico-chemical properties

and the role of applied biochar amendments on soil microbiological attributes those related to (soil extracellular enzymes and soil basal as well as substrate induced respirations) remained relatively unexplored till date. Moreover, the comparison of effects of biochars (derived from agricultural and food wastes) with and without mineral fertilizers on crop's photosynthetic efficiency remained neglected in the past. Therefore, we compared the effects of two types of biochars with and without mineral fertilizers on soil physico-chemical and microbiological properties and how they respond to crop growth and physiology. We considered the soil extracellular enzymes activity and microbial respiration as soil health indicators and crop's photosystem efficiency as agronomic performance respectively for evaluating the effects of applied biochars together with mineral fertilizer. The specific objectives of the present study were to (i) compare and analyze the effects of produced biochars with and without mineral fertilizer on soil basal and substrate induced respirations and extracellular enzymes, and (ii) assess the growth and physiological responses of crop under applied amendments.

Materials and methods

Procurement and preparation of biochars

For the purposes of pot experiment, the food waste biochar (FWB) was prepared in two steps. The first step involved the pre-treatment process, which consists of two consequent steps i.e., the dried food waste (dry matter approx. 90%) was mixed with 25% of spruce sawdust and subsequently the mixture was pelletized at a briquetting press for the production of pellets type JGE 260 with a matrix at a size of 6 mm of extrusion holes and a pellet length of 40 mm. The second step was the heat treatment of the samples, whereby thermal pyrolysis (TP) was performed in laboratory, small-scale conditions, in a small-scale TP unit working under 600°C. This unit works discontinuously, and the maximum capacity is around 5 kg·batch⁻¹ of feedstock. The glass condenser attached to the pyrolyzer was used for the separation of gaseous products and the pyrolysis oil. The input weight of feedstock samples was 3 000 g·batch⁻¹. The feedstock was placed into the TP unit in a stainless-steel cylindrical reactor. During the experiments, the

residence time was 340 - 410 minutes, and the temperature did not exceed 600°C.

Moreover, commercial biochar from agricultural waste was purchased from the manufacturer (Sonnenerde GmbH, Austria). This biochar was produced with a high-technology production unit Pyreg500 from grain husks, sunflower pods and pulp mud. The process temperature was set up at 650°C. The chemical composition of applied biochars is given in (Table 1).

Experimental design and treatments

The growth substrate used for the pot experiment was prepared by mixing a silty clay loam (USDA Textural Triangle) Haplic Luvisol (WRB soil classification) collected at field near the town Troubsko (Czech Rep., 49°10'28"N 16°29'32"E) with a fine quartz sand (0.1–1.0 mm; ≥95% SiO₂) in a weight ratio of 1:1. The soil properties were as follows: total C 14.0 g·kg⁻¹, total N 1.60 g·kg⁻¹, available P 0.10 g·kg⁻¹, available S 0.15 g·kg⁻¹, available Ca 3.26 g·kg⁻¹, available Mg 0.24 g·kg⁻¹, available K 0.23 g·kg⁻¹; pH (CaCl₂) 7.3.

One kilogram of this growth substrate was mixed with 32 g (equivalent to 40 t·ha⁻¹) of a particular biochar (Table 1) and filled to experimental plastic pots (volume 1 L, top diameter 11 cm, bottom diameter 9 cm, height 13 cm). Control treatment was left without the addition of biochar. The mineral fertilizer (MF) NPK (16:16:16) was dissolved in demineralised water and applied on soil surface of specific variants in dose equal to 0.1 g N·kg⁻¹ of soil. Following biochar treatments were applied in the presence and absence of mineral fertilizer; (i) control (no biochar) (ii) foodwaste biochar (FWB) with and without mineral fertilizer (hereinafter referred to as FWB+MF) and (iii) agricultural waste derived biochar (AB) with and without mineral fertilizer (hereinafter referred to as AB+MF). The experimental treatments are shown in (Table 2). Each treatment was carried out in 3 replicates (pots).

Pot experiment

The pot experiment with lettuce (*Lactuca sativa* L. var. *capitata*) took place in growth chamber Climacell EVO (BMT, Czech Rep.) under controlled conditions: full-spectrum LED lighting, light intensity 20,000 lux; photoperiod 12 h;

temperature 18/22°C (night/day); relative humidity 70%. Lettuce seeds were sprouted on wet filter paper for two days and then five of them were sown to the depth of approximately 2 mm in each pot. After sowing, each pot was watered with 100 mL of distilled water. The 10-day-old seedlings were reduced to one plant per pot. Pot placement in the growth chamber was randomized. Soil humidity was controlled, and water content was maintained during the experiment at approximately 60% of water holding capacity. The pots were variably rotated once per week. The plants were harvested 8 weeks after sowing.

Plant biomass and photosynthesis characteristics measurements

At harvest time, determination of photochemical efficiency of photosystem II (PSII) of lettuce plants was carried out. The quantum yield of the PSII (Φ_{PSII}) was determined (at light intensity 2400 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$) by the fluorometer PAR-FluorPen FP 110-LM/S (Photon Systems Instruments, Drásov, Czech Republic) and the software FluorPen 1.1 was used for the analysis of the measured data. Determination of normalized difference vegetation index (NDVI) was carried out too with PlantPen NDVI 310 (Photon System Instruments, Drásov, Czech Republic). The spectral reflectance of chlorophyll pigments, expressed as NDVI, is a measure of chlorophyll content (Garty et al., 2001) and its integrity (Castro and Sanchez-Azofeifa, 2008) and correlates with photosynthetic rate (Garty et al., 2001). Then, the lettuce shoots were cut at ground level, and the roots were gently cleaned of soil and washed with water. Fresh aboveground (AGB) and root biomass were estimated gravimetrically by weighing on the analytical scales.

Soil analysis for microbiological soil health indicators

A mixed soil sample was taken from each pot after harvesting the lettuce. Soil samples were homogenized by sieving through a sieve with mesh size 2 mm. Air dried samples were analyzed for pH

(ISO 10390, 2005) and electric conductivity (EC) (Hardie et al., 2012). Freeze-dried samples were used for the analyses of enzymatic activities: β -glucosidase (GLU), phosphatase (PHOS), urease (URE) and N-acetyl- β -D-glucosaminidase (NAG) (ISO 20130, 2018). The samples stored at 4 °C were used for determination of dehydrogenase activity (DHA) using standard method based on triphenyltetrazolium chloride (TTC) (Małachowska-Jutysz and Matyja, 2019), soil basal respiration (BR) and substrate induced respirations (IR) – D-glucose (Glc-IR), L-alanine (Ala-IR) and L-arginine (Arg-IR) (Campbell et al., 2003) using MicroResp[®] device (The James Hutton Institute, Scotland).

Statistical analyses

The obtained data were statistically analyzed using the one-way analysis of variance (ANOVA). Treatment means were compared using Tukey HSD *post-hoc* test (at significance level $p = 0.05$).

To evaluate the effects of applied amendments, principal component analysis (PCA) was plotted for observed variables and observations using Rstudio.

Results

Plant growth and chlorophyll fluorescence

The application of biochars with and without mineral fertilizer (MF) differently affected the plant growth and photosynthetic parameters. The plant fresh above ground biomass (AGB-fresh) was significantly highest under AB+MF as compared to control and other treatments (Figure 1A). This trend was followed by MF alone and food waste biochar with mineral fertilizer (FWB+MF). The highest root fresh weight (Root-fresh) was observed under the application of AB+MF which was followed by FWB+MF relative to control (Figure 1B). The quantum yield of the electron transport of the PSII (Φ_{PSII}), which expresses the real capacity of the PSII for photochemical reactions, was relatively increased by MF application. There was no significant increase found for Φ_{PSII} , which acts as a measure of the overall efficiency of PSII reaction centers in light, under applied amendments (Figure 1C). The spectral reflectance of chlorophyll pigments, expressed as NDVI (Figure 1D) was correlated with Φ_{PSII} values (Figure 1C).

Soil chemical properties

The application of food waste biochar with and without mineral fertilization significantly enhanced the soil pH as compared to control (Figure 2A). The highest pH values were

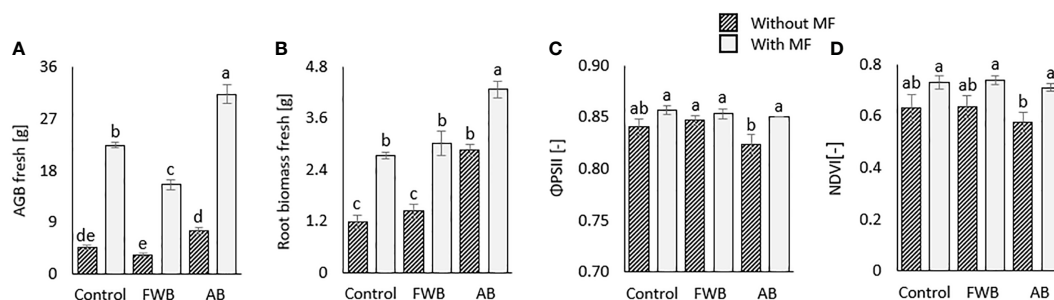

FIGURE 1

Values are mean of three replicates. Different lowercase letters indicate statistical significance at $p < 0.05$.

observed in soils receiving FWB, FWB+MF and AB, while the lowest was found under MF control which was statistically similar with the pH value under AB+MF application (Figure 2A). Remarkable variations were however observed for soil electrical conductivity (EC) under the applied biochars with and without MF. Specifically, the highest EC was observed under the application of FWB+MF and FWB without MF (Figure 2B) which were statistically significant as compared to other treatments and control.

Soil extracellular enzymes activities

The highest dehydrogenase activity (DHA) was observed under the sole application of MF (Figure 3A). All other amendments except AB significantly reduced DHA as compared to control (Figure 3A). Similar to DHA, the same treatment i.e., MF resulted in highest glucosidase (Glu) and phosphatase (PHOS) activities (Figures 3B, C). All other

amendments resulted in reduced activities of Glu and PHOS as compared to control. Regarding urease, the significantly highest activity was recorded under the application of FWB and AB without MF as compared to control (Figure 3D). Moreover, the MF alone enhanced N-acetyl-glucosaminase (NAG) activity as compared to other treatments (Figure 3E), while no clear trend was observed for aryl sulphatase activity under applied treatments (Figure 3F).

Soil basal and substrate induced respiration

The application of food waste and agricultural biochars with and without mineral fertilization considerably affected the basal as well as substrate induced respirations (SIR). A significantly highest increase in soil basal respiration (BR) was observed under the sole application of MF and AB (Figure 4A) as compared to control and other treatments. The application of

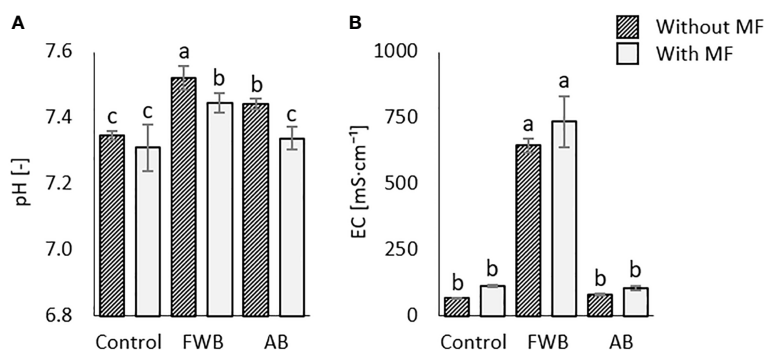

FIGURE 2

Values are mean of three replicates. Different lowercase letters indicate statistical significance at $p < 0.05$.

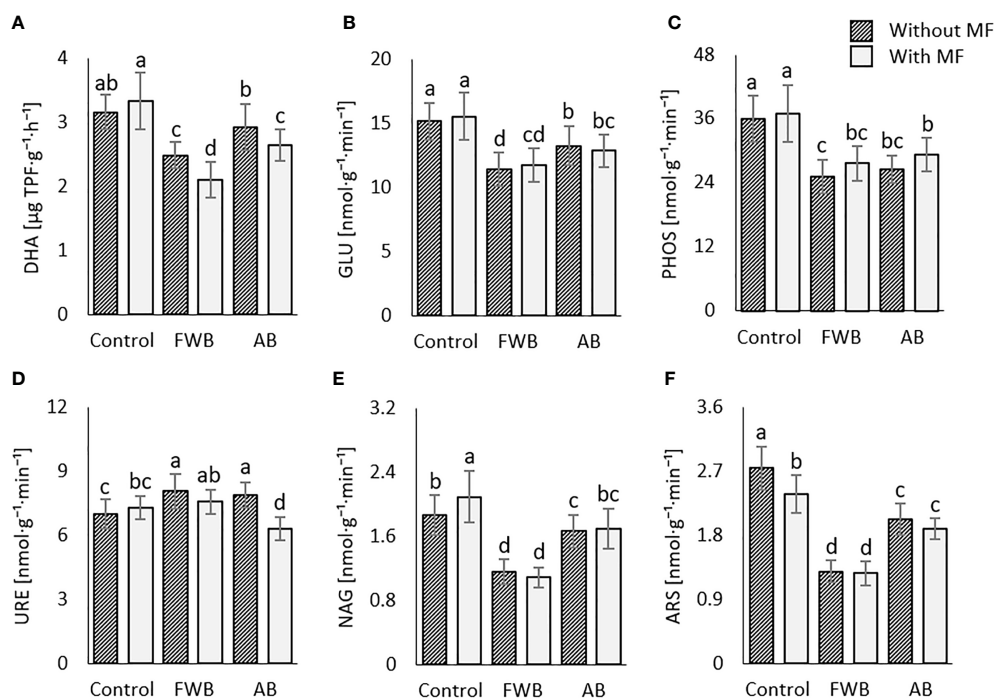

FIGURE 3

Comparative effects of applied food waste (FWB) and agricultural waste biochar (AB) with and without mineral fertilization (MF) on (A) dehydrogenase activity; (B) glucosidase activity; (C) phosphatase activity; (D) urease activity; (E) N-acetyl-glucosaminase activity and (F) aryl-sulphatase activity. Values are mean of three replicates. Different lowercase letters indicate statistical significance at $p < 0.05$.

AB without MF resulted in significantly highest glucose-induced respiration (Glu-IR) and alanine-induced respiration (Ala-IR) respectively as compared to control (Figures 4B, C). This trend was followed by the application of MF alone. However, the sole application of MF enhanced the arginine-induced respiration (Arg-IR), which was significantly highest as compared to other treatments (Figure 4D).

Results from principal component analysis

The score and loading plots of principal component analysis (PCA) regarding the observed soil and plant characteristics are shown in (Figure 5). The extracted components (Dim1 and Dim 2) maximally (82.7%) accounted for the observed variations in the data set. The applied amendments were successfully separated by the principal components (as marked by different colors). This suggests the positive influence of applied amendments on the observed parameters. The treatments MF, AB and AB+MF were distributed in components 1 and FWB and FWB+MF were distributed in component 2 of the PCA (Figure 5). This clearly indicated the differential roles of applied amendments on the listed soil and plant parameters.

As indicated by the PC1, the applied MF was found as the most influential treatment on most of the measured soil enzymes in the present study. While PC2 showed FWB and FWB+MF as most influential treatments regarding soil chemical properties (pH and EC). The most displaced parameters were soil pH, EC and plant chlorophyll fluorescence parameters Φ_{PSII} and NDVI, suggesting the differential effects of applied amendments on soil characteristics and plant growth and physiology.

Discussion

Agricultural and food wastes derived biochars have been regarded as alternative sources for enhancing soil chemical, physico-chemical and biological health and crop growth and development. However, the sole utilization of biochar does not always result in an increase in soil fertility and crop biomass. The present study, therefore, aimed to compare the effectiveness of agricultural and food wastes derived biochars with and without mineral fertilization for improving soil chemical, physico-chemical and biological properties related to microbial soil health indicators and crop growth. The results revealed that the application of agricultural biochar with mineral fertilization enhanced crop biomass (Figure 1). This enhancement might be

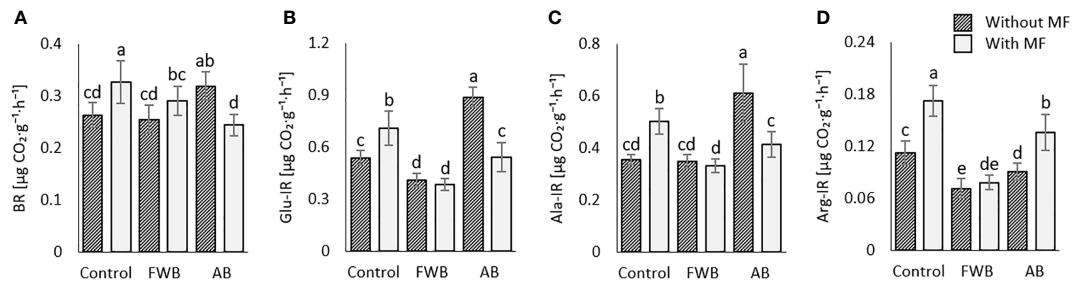

FIGURE 4

Values are mean of three replicates. Different lowercase letters indicate statistical significance at $p < 0.05$.

associated with the increased acquisition of readily available plant nutrients under the applied biochar plus mineral fertilizer combination (Sadaf et al., 2017). Similarly, Jeffery et al. (2017), reported enhanced crop growth and yield. The authors stated that the enhancement of crop growth and yield is mainly related to enhanced soil nutrients under biochar application. These results are further substantiated by the findings of Lai et al. (2017) and Dong et al. (2015), who reported enhanced crop biomass and yield under applied biochar. In our work, the highest increase in biomass accumulation was observed under combined application of biochar with MF (Figures 1A, B), which

agrees with the results of Ali et al. (2020), who reported higher crop biomass accumulation under combined application of biochar and nitrogenous fertilizers. This comparatively higher crop performance observed in the present study under AB+MF and FWB+MF revealed that integrated use of biochar and mineral fertilizers could be a suitable approach for enhancing crop production in a similar pattern observed by Singh et al. (2019a).

The higher crop growth might also be related to enhanced physiological parameters of crops under applied biochar and mineral fertilizer treatments (Qian et al., 2019; Ali et al., 2021).

FIGURE 5

Principal component analysis of the observed microbiological and chemical soil health indicators and crop biomass and physiological parameters under the influence of applied food waste (FWB) and agricultural waste biochar (AB) with and without mineral fertilization (MF).

Despite the fact that we found no significant variations in the plant physiological parameters (Φ PSII, NDVI), their relative increase in MF fertilized treatments (Figures 1C, D) confirms the direct dependence of chlorophyll content and photosynthesis on nutrient availability, especially nitrogen (Huang et al., 2004; Mu and Chen, 2021). This shows that the applied biochars were unable to cast any additional benefit on crop's physiological parameters, however, their combination with mineral fertilizers shows the potential to increase plant growth, as demonstrated also by other studies (Kizito et al., 2019; Li et al., 2020; Ndoung et al., 2021; Liu et al., 2022). The improved crop performance under combined application of biochars and mineral fertilizers could be due to the improved crop nutrient and water availability coming from fertilizer and the mechanisms of biochar on retention and exchange of these nutrients on biochar surfaces which lead consistent supply of nutrients to crops (Agbna et al., 2017; Singh et al., 2019b; Faloye et al., 2019). On the other hand, the reduced or lower crop growth performance under sole application of biochar might be due to the clogging of micropores and reduced availability of crop nutrients (Singh et al., 2019b).

Soil chemical and physico-chemical properties are important determinants of soil quality. It has been shown that biochar application results in the modification of soil chemical properties mainly pH and electrical conductivity and soil nutrient status (Joseph et al., 2020; Holatko et al., 2022). We found enhanced soil pH under the application of food waste biochar (FWB) with and without MF (Figure 2A). This enhanced soil pH under biochar addition is related to the higher pH of the biochar itself and its liming effect as has been previously reported by many researchers (Ali et al., 2020; Hammerschmidt et al., 2022). Moreover, the highest increase in EC under FWB+MF treatment than control (Figure 2B) might be the outcome of direct release of nutrients from MF which could be retained on the biochar surfaces and resulted in increased soluble salts in soil solution eventually showing higher EC. This is further supported by the results of PCA (Figure 5) suggesting FWB with and without MF as most influential treatments for soil chemical properties observed here. Moreover, higher pH and EC might be due to the higher porosity and surface area of biochar which together with applied fertilizers might have improved the soil physico-chemical properties through nutrient retention on biochar surfaces resulting in higher pH and EC (Jaafar et al., 2015). Our results are in line with Ali et al. (2021) who reported enhanced soil physico-chemical properties due to the application of biochar and N fertilizers.

Soil extracellular enzymes mediate the cycling of C, N and P in agroecosystems and are important determinants of soil organic matter decomposition (Bilen and Turan, 2022). We found differential responses of applied organic amendments with and without MF on various soil enzymes involved in C, N

and P cycling (Figures 3A–F). In most of the cases, application of MF enhanced soil enzyme activities. Our findings agree with Tian et al. (2016) reporting enhanced soil enzyme activities under the application of mineral fertilization. Both mineral fertilization and biochar have been recognized to improve soil extracellular enzyme activities. The enhancement of enzyme activities under MF in the present study could be related to the increased availability of limiting nutrients to microbes as speculated by Zhang et al. (2014). Moreover, it has been acknowledged that the application of mineral fertilizers causes rapid mineralization of native soil organic matter (Foley et al., 2005; Liu et al., 2010), which is reflective in the findings obtained on enhanced activity of nutrient mineralizing enzymes under MF application in the present study (Figure 3). Moreover, Lehman et al. (2011) postulated that the alterations of soil pH due to biochar addition might affect the activities of enzymes especially phosphatases. Furthermore, in line with our findings, Song et al. (2020) in another study reported enhanced activity of C and N acquiring enzymes under the influence of mineral fertilization and biochar additions (Figure 3). Thus, the higher enzyme activities under applied amendments are suggestive for increased nutrients (C, N, P) mineralization in this study.

Soil respiration is one of the biological soil health indicators and is of significant concern in the face of climate change (Singh et al., 2019b). Considerable variations were observed for soil basal, and substrate induced respirations in soils subjected to various amendments (Figures 4A–D). The soil basal and SIR are considered active indicators of soil microbial biomass (Hassink, 1993). The sole application of MF yielded highest BR and Arg-IR while the amendment with AB without MF enhanced Glu-IR and Ala-IR in the present study (Figures 4A–C). We ascribe the higher BR and Arg-IR to increased utilization of nutrient sources by microbes and their proliferation under the application of MF and arginine (substrate). Moreover, the role of biochar in improving SIR has been well studied in many studies (Gul et al., 2015; Karimi et al., 2020). The enhanced SIR under AB in the present study might be related to an enhanced substrate availability and release of other biologically active compounds (Hermann et al., 2019). Moreover, biochar porosity provides the microbes with essential microenvironment, water and aeration, thereby enhancing their activity (Gul et al., 2015; Xu et al., 2016; Hermann et al., 2019). Generally, higher soil respiration is observed in biochar treated soils which further gets increased or decreased depending on biochar types and the amount of labile carbon present (Jones et al., 2012; Brunn et al., 2014; Mohan et al., 2018). The increase in Glu-IR and Ala-IR in the present study under applied AB treatment might reveal higher microbial activity due to the presence of more labile C (Hussain et al., 2017). Moreover, the higher variations observed for soil enzymes (Figure 3) and soil respiration (Figure 4) under applied

amendments might be associated with the large differences in C: N ratios of applied biochars (Table 1). This could have caused large variations in microbial growth and nutrient turnover and hence caused variations on observed microbial attributes.

Conclusion

Comparison and analysis of food and agricultural wastes derived biochar in combination/absence of mineral fertilizer revealed differential responses of soil microbial indicators and plant growth and physiological alteration. The study demonstrated that agricultural waste derived biochar enhanced crop growth and its combination with mineral fertilizers had the potential to improve its physiological attributes in terms of chlorophyll fluorescence indicators. This shows that the integration of biochar with mineral fertilizers could be a sustainable approach for enhancing crop production. The food waste derived biochar on the other hand, was found to enhance soil chemical properties owing to its alkaline nature and higher nutrient contents. Furthermore, the mineral fertilizer was most influential strategy in improving soil basal respiration and C, N and P cycling enzymes which suggests the role of fertilizers in nutrient cycling as indicated by the principal component analysis as well. It is thus concluded that, the application of food and agricultural waste derived biochars not only helps in waste recycling but also help in modification of soil bio-chemical properties together with mineral fertilizers. Based on findings, it can be concluded that a combination of biochar and mineral fertilizers is a viable approach for sustainable soil management and crop production in agro-ecosystems. However, further studies taking into account the functional groups characterization and surface chemistry of biochars derived from various wastes are required to deepen our understanding on the mechanisms by which biochar affects soil quality attributes and improve crop performance.

Current and continuing climate change in the Anthropocene epoch requires sustainable agricultural practices. Additionally, due to changing consumer preferences, organic approaches to cultivation are gaining popularity. The global market for organic grapes, grape products, and wine is growing. Biostimulant and biocontrol products are often applied in organic vineyards and can reduce the synthetic fertilizer, pesticide, and fungicide requirements of a vineyard. Plant growth promotion following application is also observed under a variety of challenging conditions associated with global warming. This paper reviews different groups of biostimulants and their effects on viticulture, including microorganisms, protein hydrolysates, humic acids, pyrogenic materials, and seaweed extracts. Of special interest are biostimulants with utility in protecting plants against the effects of climate change, including drought and heat stress. While many beneficial effects have been reported following the application of these materials, most studies lack a mechanistic explanation, and important parameters are often undefined (e.g.,

soil characteristics and nutrient availability). We recommend an increased study of the underlying mechanisms of these products to enable the selection of proper biostimulants, application methods, and dosage in viticulture. A detailed understanding of processes dictating beneficial effects in vineyards following application may allow for biostimulants with increased efficacy, uptake, and sustainability.

KEYWORDS

biological agents, biostimulants, grapevine, organic, vineyard, viticulture, wine

Introduction

Grape (*Vitis vinifera*) production has increased globally over the last decade from 65 million to 77.8 million tons. The world's vineyards totaled 7.4 million hectares in 2018, of which ~4.5% were cultivated with organic approaches (i.e., refraining from pesticides and chemical fertilizer use and promoting sustainable cultivation practices). About 88% of organic vineyards are located in Europe, primarily in France, Italy, and Spain. There is a need, and increasing demand, for more ecologically-sustainable agricultural products as outlined by the United Nations Sustainable Development Goals (SDGs). For production to support demand despite current anthropogenic climate change (Roka, 2022), more research on sustainable food systems is urgently needed.

Higher yields are necessary for sustainable food security on a finite land basis (Godfray et al., 2010; Foley et al., 2011). According to Renaud-Gentié (Seufert et al., 2012), the yield ratio between organic and conventional agricultural production per unit area is 0.75. To close this yield gap while simultaneously satisfying consumer preference for organic products, improved techniques for organic grape farming are required.

Additionally, grape varieties often require specific environmental conditions, historically located in very narrow latitudinal zones (30–50°N and 30–40°S) with minimal temperature extremes (Nesbitt et al., 2018). Due to the high environmental sensitivity of *Vitis vinifera*, a strong correlation between meteorological conditions propelled by global warming (e.g., heat waves, extreme precipitation, droughts, hailstorms, and windstorms) and low grape yield and wine quality has been reported (Santos et al., 2020).

Biostimulants are substances or microorganisms applied to plants, which enhance nutrition use efficiency, abiotic stress tolerance, and crop quality traits, using mechanisms that do not directly add fertility to the soil (du Jardin, 2015), and in the EU the marketing of biostimulants is regulated by specific provisions (Regulation EU 1009, 2019). Initially, these technologies were primarily utilized in organic farming, with later uptake in both conventional and integrated systems

(Rouphael and Colla, 2020). The application of biostimulant technologies is now a well-known tool, though poorly-researched strategy to enhance plant growth and prevent pests and diseases (Gutiérrez-Gamboa et al., 2019; Cataldo et al., 2022; Monteiro et al., 2022; Olavarrieta et al., 2022).

Biocontrol agents (BCAs) are organisms antagonistic to crop pests. Synthetic pesticides, mainly fungicides, are widely used in viticulture. However, pesticide residue contamination of grapes and grape products (raisins, juices, and wines) is widely studied and may be detrimental to consumer health (Walorczyk et al., 2011). An EU report (EFSA, 2021) has shown increased pesticide residue levels in primary commodity food products since 2016. Table grape products are of particular concern, in which 66% of products were contaminated, and 14.3% of products tested contained more than five different pesticide residues. In a sample of dried vine fruits, 28 pesticides were detected (Cabrera and Pastor, 2021). When testing grape leaves, 37.9% had residues above the allowed maximum residue levels (MRL). Gava et al. (2021) highlighted the importance of tracing contamination from the originating vineyard to the wine. Of additional concern is that these residues can affect alcoholic fermentation, change product flavor, and pose a toxicological risk to the consumer as well as those involved in the production chain.

This review presents a series of different biostimulant materials and biological control agents utilized in sustainable vineyards (their main effects on *Vitis vinifera* are summarized in Figure 1). Additionally, the origin of the materials, the application methods, and the underpinning functions/mechanisms of each material are described. The limitations of current practices and alternative approaches to aid future studies of the interaction between viticulture and global climate change are also addressed.

Biostimulant materials

Protein hydrolysates

Protein hydrolysates (PHs) refer to mixtures of polypeptides, oligopeptides, and amino acids that are manufactured from

FIGURE 1

An overview of the main effects of biological control agents (BCAs), protein hydrolysates (PHs), seaweed extracts (SE), pyrogenic materials, humic substances (HS), plant growth-promoting rhizobacteria (PGPR), and mycorrhizae applied in viticulture.

protein sources using partial hydrolysis (Schaafsma, 2009). They are produced by either acid and/or alkaline hydrolysis (Schaafsma, 2009), enzymatic hydrolysis (Colla et al., 2015), or from by-products of plant or animal origins (Meggio et al., 2020). In horticulture, more than 90% of PH utilized is derived from animal origin, while plant-derived PHs are relatively novel (Colla et al., 2015). Animal-derived PHs often contain higher amounts of total amino acids compared to plant-derived PHs (Ertani et al., 2009). Plant-derived PHs contain carbohydrates and phenols, which enhance plant oxidative stress defenses, as well as aid in energy metabolism (Colla et al., 2015). PHs can be further subdivided into two categories: (1) protein fractions with a relatively high content of specific amino acids, such as glutamine peptides and cysteine/glycine and tryptophan peptides; and (2) bioactive peptides with specific amino-acid sequences (i.e., 3 to 20 amino acids), which are usually hydrophobic (Schaafsma, 2009). In general, the effects of PHs on plant physiology are closely related to the stimulation of carbon and nitrogen metabolism, hormone activity, and nutrient supply and uptake by plants (Figure 1). Moreover, it has been demonstrated that PHs can stimulate the plant microbiome which can promote plant growth and development by enhancing water and nutrient uptake as well as their adaptation to biotic and abiotic stresses (Colla et al., 2017, and sources reviewed within).

The effects of PHs on grapevine growth are reviewed in Table 1. PHs are known to regulate gene expression involved in the transport of nutrients, and the signaling and metabolism of reactive oxygen species, thereby enhancing plant stress tolerance (Meggio et al., 2020). For example, PHs can effectively improve grapevine tolerance to water deficit (Boselli et al., 2019; Meggio et al., 2020). A study by Boselli et al. (2019) showed that PH-treated grapevines contain higher levels of anthocyanins, often observed under water stress conditions (Castellarin et al., 2007). Therefore, PHs may be able to mimic water stress conditions in grapevine and reduce water loss due to evapotranspiration (Boselli et al., 2019).

In addition, PHs act as signal compounds to trigger plant defense responses (Boller, 1995). Grapevine is highly susceptible to various pathogens (Lachhab et al., 2014). In particular, downy mildew (*Plasmopara viticola*) and powdery mildew (*Erysiphe necator*) are the most widespread and devastating grapevine diseases worldwide (Gauthier et al., 2014; Nesler et al., 2015). Frequent fungicide applications (i.e., every 7–10 days in season) are often required to control these diseases, a practice which not only dramatically increases production costs but also negatively impacts the environment and human health (Jones et al., 2014). Plant defense by-products may be an attractive alternative to chemical pesticides (van Aubel et al., 2014). Elicitors including PHs are not toxic to plants and are recognized by plant membrane receptors, meaning they are often freely able to mobilize an array of plant defenses (Boller and Felix, 2009). PHs contain a large variety of bioactive peptides, which may act

as plant growth regulators, antioxidants, and biostimulants (Colla et al., 2014), as well as directly influence numerous biological processes evoking hormonal and immunological responses (Ito et al., 2006; Phelan et al., 2009). Therefore, PHs can trigger signaling events involved in grapevine immunity (Gauthier et al., 2014). Some studies (Gauthier et al., 2014; Lachhab et al., 2014) report reduced symptoms of downy mildew and gray mold (*Botrytis cinerea*) on grapevine following applications of PHs derived from soybean and casein. PHs may improve plant nutrient uptake through modification of root architecture, by complexation of nutrients such as Zn (Ertani et al., 2018), or stimulation of microbial and enzymatic activities (Colla et al., 2015) – e.g., increased activity of N₂-fixing, P-solubilizing, and indoleacetic acid-producing bacteria was observed in lettuce (Colla et al., 2015) and tomato (Colla et al., 2014) after application of PHs. The application of PHs also increases the activity of both nitrate reductase and glutamine synthetase in roots and leaves (Ertani et al., 2009). Nitrate reductase reduces nitrate to ammonia, and glutamine synthetase catalyzes the ATP-dependent amination of glutamate to produce glutamine, thereby facilitating assimilation or re-assimilation of nitrogenous sources originating from a wide variety of anabolic or catabolic processes (Ertani et al., 2009). Applications of different PHs have been observed to increase grapevine yield, correlated with PH organic N content (Bosselli et al., 2019).

Further research on the effects of PHs on viticulture should be explored, especially the impact on microbial communities living in the rhizosphere or phyllosphere (aboveground plant surfaces inhabited by microbes), which has received little study (Colla et al., 2015 and Colla et al., 2017).

Seaweed extracts

Biostimulants can also be produced from marine macroalgae (i.e. seaweed extracts; SEs). In the last decade, the application of SEs in agriculture has gained traction and several seaweed species (such as brown seaweeds *Ascophyllum nodosum*, *Ecklonia maxima*, and *Laminaria* spp, and red seaweeds *Kappaphycus alvarezii*, and *Gracilaria edulis*) are currently used in commercial production of biostimulants (Yakhin et al., 2017; El Boukhari et al., 2020). SEs have been successfully explored in arable cropping, including viticulture (Table 2). The most common method of applying SEs in vineyards is foliar spraying, although the extracts can be applied directly to the soil (Mancuso et al., 2006; de Carvalho et al., 2019). Like most biostimulants, SEs may increase crop productivity and improve fruit quality in both stressed and non-stressed conditions (Deolu-Ajayi et al., 2022). The vegetative shoot growth stage of the crop is frequently targeted for SE application to stimulate growth and boost crop vitality by modulating underlying biochemical processes, which are also

TABLE 1 An overview of the main effects of protein hydrolysates (PHs) applied in viticulture.

Crop variety	Applied material and properties	Dosage, the form of application, and stage of plant development	Experimental condition	Effects	Reference
Table grape inoculated with either <i>B. cinerea</i> (100 conidia/wound) or natural infections.	- PH derived from soybean. - PH derived from casein.	- 20 μ L in the wound (3 x 3 mm) 24 h before inoculation. - Spraying at preharvest (0.8 and 1.6 g L ⁻¹ on vines every 15 d) or a combination of a pre- (0.8 g L ⁻¹) and postharvest treatment (200 mL).	-Organic vineyard cultivation during the 2012/2013 season, planted in 1998 in Fumane, Valpolicella, Verona, Italy.	- Significant reduction of gray mold incidence by 67% (soybean PH) and 54% (casein PH) at a low application dose (0.8 g L ⁻¹). - In the field, PH derived from either soybean or casein reduced gray mold incidence by 65 and 92% respectively compared to water control.	Lachhab et al. (2016).
Grapevine plantlets (<i>Vitis Vinifera</i> cv Marselan) inoculated with <i>Plasmopara viticola</i> .	- PH derived from soybean. - PH derived from casein.	- 10 mL of each PH per plant was sprayed on 8-week-old grapevine plantlets.	-Greenhouse conditions.	- Application of PH derived from either soybean or casein reduced downy mildew infected leaf surface by 76% and 63% as compared to the control, respectively. - Both PHs acted as elicitors to enhance grapevine immunity against pathogen attack.	Lachhab et al. (2014).
Grape cultivar (<i>Vitis Vinifera</i> L., cv Corvina).	- PH derived from soybean. - PH derived from casein. - PH derived from lupin.	-Spraying at two concentrations; 1.6 and 6.4 g L ⁻¹ at every 10 d three times, from fruit-set to bunch closure.	- Field experiments were carried out over 5 growing seasons (2012 to 2016) in an organically managed vineyard of <i>Vitis vinifera</i> L. cv. Corvina, 24-year-old vines located in the Valpolicella area, Italy.	- All treatments significantly ameliorated the total anthocyanin content of berries compared to the control. - The greatest effect was obtained by soybean-derived PH. - All PHs reduced plant water loss.	Boselli et al. (2019).
Grapevine (<i>Vitis Vinifera</i> L., cv Sauvignon Blanc).	- A novel PH biostimulant (APR).	-A concentration of 0.5 g L ⁻¹ PH was added to the soil or pot as a soil drench.	-Pot experiment approximating field-conditions in a tunnel at the “L. Toniolo” Experimental Farm of the University of Padua in Legnaro, NE Italy in 2018.	- Application of PHs to roots before imposing water deprivation mitigated consequences of stress by sustaining the growth of younger vegetative organs, and limiting the extent of cell dehydration.	Meggio et al. (2020).
Grapevine (<i>Vitis Vinifera</i> cv. Marselan) inoculated with <i>Plasmopara viticola</i> .	- Laminarin (Lam), a β -1,3 glucan polymer from the algae <i>Laminaria digitata</i> - The chemically sulfated form of Lam, PS3.	-Lam and PS3 solution (5 g L ⁻¹) were sprayed on upper and lower leaf faces until the run-off point.	-Greenhouse pot experiment	- PS3 triggered a long-lasting plasma membrane depolarization of grapevine cells. - PS3 and Lam shared a common stress-responsive transcriptome profile, which resulted in induced resistance against <i>P. viticola</i> .	Gauthier et al. (2014).
Grapevine (<i>Vitis vinifera</i> L.).	- nutrient broth PH - a natural derivative from peptone via meat (1.9 g L ⁻¹) and yeast extract (0.7 g L ⁻¹).	- 5.0 (2010), 3.0 (2011), and 3.0 g L ⁻¹ (2013) of PH -Treatment was applied weekly with a motorized backpack mist blower.	-Field trials were carried out in 2010, 2011, and 2013 at S. Michele all'Adige (Italy) in a vineyard planted in 1997.	-PH controlled powdery mildew on grapevine across seasons (comparable to standard fungicide treatments) both on leaves and bunches across three different years.	Nesler et al. (2015).

important at the reproductive stage (Figure 1). SEs may also enhance microbial biodiversity, but information about this effect on the plant microbiome is scarce (El Boukhari et al., 2020).

Physiologically, SEs boost nutrient assimilation and plant growth under non-stressed conditions. Spraying wine grapevines with any of three commercial SEs (Maxicrop, Proton, and Algi-power) increased both macro- and micro-nutrient uptake from the soil (Turan and Köse, 2004; Table 2). Similar mineral uptake induction in wine grapevines was reported by Mancuso et al. (2006) and de Carvalho et al. (2019) when SEs were applied, resulting in a subsequent

increase of dry weight by ~ 27% and fruit yield by ~ 24% (Table 2). Foliar application of either an *Ascophyllum*-derived seaweed extract or the commercially available extract “SUNRED” improved fruit quality and shortened the ripening time of wine grape (Frioni et al., 2018; Table 2) and table grape (Deng et al., 2019; Table 2) cultivars. The enhancement in fruit quality may be linked to an accumulation of anthocyanins and phenolic compounds, especially in the berry skin, which was also observed (Frioni et al., 2018; Deng et al., 2019).

During drought stress and water deprivation in controlled greenhouse experiments, foliar application of a seaweed indole-

TABLE 2 An overview of seaweed-based (SEs) biostimulants applied in viticulture.

Crop variety	Product details and seaweed species	Bioactive substance	Experimental conditions	Application and dosage	Physiological effects	References
<i>Vitis vinifera</i> L. cv. Karaerik	Commercial biostimulant “Maxicorp” containing <i>Ascophyllum nodosum</i> . Commercial biostimulant “Proton” (seaweed species not specified). Commercial biostimulant “Algipower” (seaweed species not specified).	Not Specified.	Greenhouse experiment with 1-year-old grapevine saplings grown in 20 cm diameter pots. Four increasing fertilization levels, including a control without any nutritional element, were used.	Foliar spray of seaweed biostimulants at individual concentrations of 0.5, 1, and 2 g L ⁻¹ . A total of 4 applications occurring every 15 days were performed. The initial treatment was applied to 2-week-old plants.	Increased macro- (nitrogen, phosphorus, potassium, calcium, and magnesium) and micronutrient (iron, zinc, magnesium, and copper) plant uptake.	Turan and Köse (2004).
<i>Vitis vinifera</i> L. cv. Sangiovese.	Not specified.	IPA (Indole-3-propionic acid) extract.	Greenhouse experiment with 1-year-old <i>V. vinifera</i> cv. Sangiovese grafted onto <i>V. berlandieri</i> x <i>riparia</i> ‘420A’ in 25 cm ² pots. Water stress was introduced by stopping irrigation for 6 days and restoring it after the dry period.	Biostimulant was applied at a rate of 10 g L ⁻¹ , with foliar sprays occurring 2 times weekly for the duration of the experiment. *A fertilizer NPK 9-5-4 was combined with the biostimulant treatment.	Significant increase in nitrogen, phosphorus, potassium, and magnesium uptake, and also in total dry weight. In water deficit conditions, plants showed faster recovery of their leaf water potential.	Mancuso et al. (2006).
<i>Vitis vinifera</i> L. cv. Niagara Rosada.	Commercial biostimulant “Acadian LSC” containing <i>A. nodosum</i> . <i>Hypnea musciformis</i> . <i>Lithothamnium</i> sp. <i>Sargassum vulgare</i> .	Not Specified	A field trial in an established vineyard in Lavras, Brazil. The vineyard was cultivated with the espalier method and has clayey soil.	Foliar application of the biostimulants at 6 g L ⁻¹ . Each biostimulant was applied 4 times: 20 days after dormancy, at blooming, fruit set, and veraison.	Significant increase in potassium, boron, and zinc; as well as an estimated yield increase of 24.15% (equivalent to 2.72 t ha ⁻¹) compared to the control. Significant increase in magnesium and zinc, but no significant increase in crop yield. Significant increase in boron only, and a 13.17% yield increase equivalent to 1.46 t ha ⁻¹ . Significant increase in magnesium, but no significant increase in crop yield.	de Carvalho et al. (2019).
<i>Vitis vinifera</i> L. cv. Sangiovese.	A commercial biostimulant “Acadian marine plant extract powder” containing <i>A. nodosum</i> .	Not specified.	Field trial (2013) in Umbria, Italy growing only the Sangiovese cultivar. The vineyard has a vertical shoot-positioned trellis cultivation system, and loamy soil.	- Foliar application for all 3 cultivars at 1500 g ha ⁻¹ , 5 times during the growing season, beginning 2 weeks before grape veraison and occurring every 10-14 days.	Improved fruit color of the Sangiovese cultivar.	Frioni et al. (2018).
<i>Vitis vinifera</i> L. cv. Pinot Noir.			Field trial (2014) in an established vineyard with both Pinot Noir	- An additional treatment with 3000 g/	Increased vegetative parameters of both

<i>Vitis vinifera</i> L. cv. Cabernet Franc.			and Cabernet Franc, located in Benton Harbour, Michigan, USA. The vineyard has a vertical shoot-positioned trellis cultivation system, and sandy loam soil.	ha of the biostimulant was performed on only the Sangiovese cultivar.	grape cultivars. Shortened ripening time in only Pinot Noir.	
<i>Vitis vinifera</i> L. cv. Red globe.	Application of commercial biostimulant "SUNRED" containing an unspecified seaweed extract.	Not specified.	Field trial (2015/2016) in Pengshan county, Meishan, China. The cultivation method and soil were not specified.	Foliar biostimulant treatments of 0.6, 0.8, and 10 g L ⁻¹ were each applied twice: at the start of veraison and 5 days later.	Improved grape color at the different biostimulant concentrations.	Deng et al. (2019).
<i>Vitis vinifera</i> L. cv. Chardonnay.	Commercial biostimulant "Seasol" containing brown seaweeds <i>Durvillaea potatorum</i> and <i>A. nodosum</i> .	Not specified.	Field trials (2012/2013 and 2013/2014) near Kenley, Australia. The vineyard uses a double-wire cordon trellis system of cultivation and has calcareous loamy sandy soil.	Drip irrigation of 10 L ha ⁻¹ of biostimulant per application, with 8 and 4 applications at the 1 st and 2 nd field trials respectively. Biostimulant was first applied at the woolly bud and budburst growth stages respectively, and treatments occurred every 20-30 days.	Significant increase in grape yield by 13.8% (equivalent to 1.6 t/ha) compared to the control.	Arioli et al. (2021).
<i>Vitis vinifera</i> L. cv. Semillon.			Field trials (2012/2013 and 2013/2014) near Balranald, Australia. The vineyard uses a double-wire cordon trellis system, and has calcareous loamy sandy soil.	Drip irrigation of 5 L ha ⁻¹ of the biostimulant with 3 applications in both field trials. Treatments were applied at the budburst, flowering, and fruit set growth stages.	The yield increased by 10% (equivalent to 1.3 t/ha) compared to the control.	
<i>Vitis vinifera</i> L. cv. Merlot.			Field trial (2013/2014) near Loxton, Australia. The vineyard uses a double-wire cordon trellis system and its soil type is calcareous loamy sand.	Drip irrigation of 5 L ha ⁻¹ of the biostimulant with 3 applications. Treatments were applied at the budburst, flowering and fruit set growth stages.	The yield increased by 17.6% (equivalent to 1.8 t ha ⁻¹) compared to the control.	
<i>Vitis vinifera</i> L. cv. Merlot.			Field trial (2014/2015) at Tharbogang, Australia. The vineyard uses a single-wire cordon trellis system and has duplex soils ranging from loamy sand to clay loam.	Drip irrigation of 10 L ha ⁻¹ of the biostimulant with 4 applications. Treatments were applied at the budburst, flowering, fruit set, and veraison growth stages.	The yield increased by 11% (equivalent to 0.5 t ha ⁻¹) compared to the control.	
<i>Vitis vinifera</i> L. cv. Cabernet Sauvignon.			Field trial in (2016/2017) at Tharbogang, Australia. The vineyard uses a double-wire cordon trellis system and has duplex soils ranging from loamy sand to clay loam.	Drip irrigation of 10 L ha ⁻¹ of the biostimulant with 3 applications. Treatments were applied at 4-cm growth, flowering, and fruit set.	The yield increased by 10.7% (equivalent to 0.7 t ha ⁻¹) compared to its control.	
<i>Vitis vinifera</i> L. cv. Montepulciano.	Not specified.	Laminarin.	Field trials (2012 and 2013) at Camerano, Italy grown according to the Guyot trellis system. Biostimulant treatment started at the inflorescence growth stage.	Foliar spraying with 1 L ha ⁻¹ of commercial biostimulant "Frontiere" in each of the 11 treatments, and treatments occurred weekly.	The biostimulant had no significant reduction of grapevine downy mildew.	Romanazzi et al. (2016).
<i>Vitis vinifera</i> L. cv. Moscato.	Not specified.	Laminarin.	Greenhouse conditions with ~ 60-day old transplanted grape plants in 4 L pots. Plants were inoculated twice with powdery mildew pathogen (<i>Erysiphe necator</i>).	- Treatment with 2 g L ⁻¹ of a commercial biostimulant "Vacciplant" per timepoint. Biostimulants were applied at 6 time points occurring every 7-9 days: 2 treatments occurred prior to 1 st pathogen inoculation, another 2 before 2 nd pathogen inoculation, and 2 last treatments after the 2 nd pathogen inoculation.	Reduction in Powdery mildew disease severity in the grape plants.	Pugliese et al. (2018).

(Continued)

TABLE 2 Continued

Crop variety	Product details and seaweed species	Bioactive substance	Experimental conditions	Application and dosage	Physiological effects	References
			Field trials (2016 and 2017) at Piedmont, Italy, in an established vineyard with an espalier cultivation method and “Guyot” pruning.	<ul style="list-style-type: none"> - A fungicide methiram was simultaneously used on the plants. Treatment with 2000 g/ha per timepoint. Biostimulant treatment was applied at 9 individual time points, occurring every 8–10 days. - A fungicide methiram was simultaneously used on the plants. 		

3-propionic acid (IPA)-derived extract induced faster recovery of leaf water potential and stomatal kinetics (Mancuso et al., 2006). Different wine grape cultivars treated with a commercial seaweed biostimulant “Seasol” *via* soil fertigation, showed an average fruit yield increase of 14.7% across five locations with varying environmental conditions (Arioli et al., 2021; Table 2). Yield increase occurred irrespective of heat and/or cold stress in a single growing season (Arioli et al., 2021). The performance of the field experiments suggests an essential soil-crop interaction for increased productivity (Arioli et al., 2021). Unfortunately, analyses of the soils and the applied extracts were not reported and therefore, cannot support this hypothesis. Moreover, variations in the SE dosage in different fields in this study prevent further conclusions regarding the direct effect soil type (and properties) may have on SE, as well as the overall impact on crop productivity in the presence of the biostimulant.

Although SEs reduce the effects of crop diseases (Shukla et al., 2019) and non-seaweed-derived biostimulants also contribute to disease prevention in viticulture (reviewed in Gutiérrez-Gamboa et al., 2019), the specific use of SEs to mitigate diseases of grapevine has not been extensively studied. Treatment with a commercial seaweed-derived biostimulant “Vacciplant” caused a reduction in the effects of powdery mildew disease in both greenhouse experiments and field trials (Table 2). Grapevine disease severity was reduced by ~ 65% and 52% in greenhouse and field experiments, respectively (Pugliese et al., 2018). Thus, there is still potential for the application of seaweed-derived biostimulants in viticulture for disease control, especially considering the need for reduced agrochemical reliance in the coming decades.

Bioactive compounds have biological activity in plants, some of which result in increased crop productivity and resilience to stress. While the presence of bioactive compounds in seaweed has long been suspected of having stimulatory effects on plants, including complex polysaccharides (absent in arable crops, e.g. alginate, laminarin, and fucoidan), phytohormones, sterols, and osmolytes (Yakhin et al., 2017), speculations remain regarding underlying mechanisms. This is perhaps due to current research focusing on growth promotion, rather than also investigating

and linking the role of these bioactive compounds to specific mechanisms. Further research is needed, and will also provide essential information for biostimulant optimization. Of note is that changes in mineral concentration due to foliar application of SEs do not always enhance crop productivity. Only two of four SEs tested caused a significant increase in grapevine yield (de Carvalho et al., 2019; Table 2), indicating that SEs must be tested independently to establish their benefits. Conflicting observations may be explained by variations in biochemical composition among seaweed species and their derived extracts, linked to the environmental conditions of the cultivation sites as well as harvesting times (Khairy and El-Shafay, 2013). Overall, the application of SE is beneficial for crops in both stressed and non-stressed conditions and thus may be attractive for wider adoption in viticulture.

Humic substances

Humic substances (HS) are an important carbon compartment present in soils, waters, and sediments. Although researchers are not in complete agreement as to how HS are formed and structured, a growing body of evidence indicates they may serve as biostimulants of plant growth. HS biostimulants are available commercially in the form of products based on humic acids (HA), fulvic acids (FA), or a mixture of both (HA+FA). Efficacy is related to the product’s chemical composition, the form of extraction and application, the applied concentration, and the stage of development of the crop (Canellas et al., 2009; Zandonadi et al., 2013; Olivares et al., 2017; Jindo et al., 2020). Effects of HS application in plants often include the activation of plasma membrane H^+ -ATPase and the alteration of the primary and secondary metabolism, generally resulting in increased root growth, nutrient uptake, rate of photosynthesis, and attenuation of stress associated with salinity, drought, or metal toxicity (Zandonadi et al., 2007; Dobbss et al., 2018; Jindo et al., 2020) (Figure 1). It is suggested that some biostimulant effects of HS originate from their impact on structural and physiological modifications in

roots and shoots related to nutrient assimilation and soil distribution (Canellas et al., 2015). Also, HS can simultaneously regulate the transcription and activity of some plant hormones following addition to the rhizosphere (Souza et al., 2022). Recently, it has been demonstrated that HS can alter the plant microbiome by favoring the recruitment of beneficial microorganisms after application (da Silva et al., 2021).

Despite a limited number of studies involving the specific use of HS in grape cultivation, several effects are consistently observed (Table 3). These include increases in photosynthetic rate, total soluble solids, total chlorophyll, and average berry size and weight (Ferrara and Brunetti, 2008 and Ferrara and Brunetti, 2010; Ibrahim and Ali, 2016; Popescu and Popescu, 2018; Irani et al., 2021). For example, Popescu and Popescu (2018) noted increased photosynthetic rate and total soluble fruit solids in cultivars 'Feteasca Regala' and 'Riesling Italian' planted in Romania, following foliar application of HA (40 and 50 mL L⁻¹) previously extracted from vermicompost. The increase was attributed to a higher concentration of carotenoids in the leaves. Ferrara and Brunetti (2010) reported an improvement of parameters associated with fruit quality (e.g. increase in total soluble solids, °Brix, and the °Brix/titratable acidity ratio, and a decrease in tartaric acid) due to the application of HA (100 mg L⁻¹, extracted from the soil in Apulia, Italy) at full-bloom. In the cultivar 'Italy', six applications of HA (derived from different origins) increased chlorophyll content, °Brix value, and berry size (Ferrara and Brunetti, 2008). The authors attributed these effects to the presence of 6% nitrogen in the humic matrix. However, the increase in berry size might also be the result of the hormone-like activity of HA (i.e., auxin, gibberellin- and cytokinin-like activity), which is useful for organic seedless table grape production where the application of synthetic hormones is not permitted. In Egypt, Ibrahim and Ali (2016) applied HA (Greenhum Company, Italy) in both February and March to the cultivar 'Superior Seedless'. Chlorophyll content, berry weight, and total fruit volume significantly increased after HA was respectively applied to leaves (5.0 g L⁻¹) or to the soil (5 and 7.5 g L⁻¹, 2.5 g L⁻¹). In Spain, Sánchez-Sánchez et al. (2006) reported increased iron and phosphorus levels and reduced sodium in the leaves of cultivar 'Italy' following treatment with solutions containing HA+FA. Recently in Iran, Irani et al. (2021) applied FA (0.5%) *via* leaf spray or HA (20 g plant⁻¹) *via* irrigation, and observed the alleviation of drought stress, increased nutrient absorption, and concentration of proline (an important stress signaling molecule), carbohydrates, and soluble proteins. Additionally, HA and FA application resulted in greater berry weight, productivity, and concentration of total soluble solids (Irani et al., 2021).

Protocols outlining best practices in terms of vineyard HS application practices and optimal concentrations are yet to be developed, and research regarding potential negative structure-activity interactions has yet to be conducted. Despite these shortcomings, the beneficial effects of HS on grapevines are

evident, generally resulting in increased production, increased fruit quality, and an expansion of the plant's ability to tolerate environmental stresses.

Pyrogenic materials

Pyrogenic materials are obtained by pyrolysis of plant biomass, a thermal decomposition process occurring at relatively high temperatures in the absence of oxygen. These materials represent a sustainable source of biostimulants with a long tradition in agriculture (Ogawa and Okimori, 2010). Pyrogenic materials include biochar (solid C-rich residue of pyrolysis), and pyroligneous acid (also known as wood vinegar, the aqueous fraction obtained from the condensation of pyrolysis vapors). Biochar is highly aromatic, porous, and possesses a chemically recalcitrant structure. It is generally used as a soil amendment, due to potential agronomic and environmental benefits associated with enhanced soil fertility and long-term soil C sequestration (Woelf et al., 2010; Lehmann et al., 2011). Pyroligneous acid consists of a mixture of a large number of oxygenated organic compounds (including acids, alcohols, ketones, phenols, furans, and ethers) and hydrocarbons with antioxidant and antimicrobial properties. Pyroligneous acid has potential as a plant growth and germination biostimulant, antioxidant and free-radical scavenger, pesticide, and antimicrobial agent (Mungkunkamchao et al., 2013; Grewal et al., 2018).

Biochar is more commonly used than pyroligneous acid in vineyards, either alone or in combination with compost (Figure 1 and Table 4). There is contrasting information in the literature regarding biochar's impact on vineyard productivity. A recent meta-analysis by Payen et al. (2021) showed that biochar application increased soil organic C, at a rate of 8.96 Mg CO₂-eq ha⁻¹ yr⁻¹. The authors also postulated biochar application might lead to enhanced vineyard productivity, but additional long-term investigations are needed to support this statement. Several authors (Baronti et al., 2014; Genesio et al., 2015; Maienza et al., 2017) have reported increased productivity in biochar-amended vineyards, associated with enhanced physicochemical properties of the amended soils, increased soil water availability, and growth of fine root biomass (Amendola et al., 2017). However, there were no significant differences in grape quality. Conversely, other reports indicate only minor effects on soil physicochemical properties following biochar application over a three-year period, which did not significantly affect vineyard fertility (Schmidt et al., 2014; Sánchez-Monedero et al., 2019). Although these authors did observe benefits following the addition of biochar-blended compost to the soil, effects were similar to those in control vineyards amended with conventional compost without biochar.

Biochar may also act as a biostimulant when used as a carrier of inoculum for microorganisms (Hale et al., 2015; Głodowska

TABLE 3 An overview of the main effects of humic substances (HS) applied in viticulture.

Crop variety	Applied material and properties	Dosage, the form of application, and stage of plant development	Experimental condition	Effects	Reference
<i>Vitis vinifera</i> cv. Italia.	HA+FA commercial (Mol). Functional groups (with Nuclear Magnetic Resonance ^{13}C): 90.7% of fulvic acids with three main portions that consisted of 10% aliphatic C, 73% aromatic C and 16.9% carboxylic C.	Two applications were carried out on the soil, in mid and late March.	Field cultivation. Twelve-year-old plants; drip-irrigated.	An increase in Fe and P absorption, as well as a decrease in Na absorption; Increased berry weight.	Sánchez-Sánchez et al. (2006) .
<i>Vitis vinifera</i> cv. Italia. Grapevines were grafted onto 1103 P (<i>V. berlandieri</i> x <i>V. rupestris</i>).	HA was extracted from soil or organic compost. 54.91% of C; 4.91% of H; 6.73% of N; 32.67% of O; C/N ratio of 9.52; Total acidity of 5.0 meq g $^{-1}$ of C; Phenolic acidity of 2.2 meq g $^{-1}$ of C and carboxyl 2.7 meq g $^{-1}$ of C	5 and 20 mg L $^{-1}$, via leaf spray. Six applications with a 21-day interval.	Field cultivation. Forty-five-year-old plants; drip-irrigated.	Increased berry size and reduction in titrable acidity; Increase in N content, total chlorophyll content, yield, and soluble solids (°Brix).	Ferrara and Brunetti (2008) .
<i>Vitis vinifera</i> cv. Feteasca Regala (henceforth RF) and cv. Riesling Italian (henceforth RI). Grapevines were grafted on rootstock hybrid Kober 5 BB (<i>Vitis berlandieri</i> x <i>Vitis riparia</i>).	Commercial HA (BioHumusSol Company Ltd.). 14.5 g humic substances L $^{-1}$, 19 ppm nitrate nitrogen (NO $_3$ -N), 104 ppm ammonium nitrate (NH $_4$ -N), 22.5 ppm P, 132 ppm K, 39 ppm Ca, 75 ppm Mg, 75 ppm Na	30, 40, and 50 mL L $^{-1}$, via leaf spray, one application at the pre-bloom and fruit set the phenological stage.	Field cultivation. Non-irrigated.	Increase in the total leaf area, yield, and total soluble solids (50 mL L $^{-1}$); Increase in photosynthesis rate, chlorophyll a and b, and carotenoids (40 e 50 mL L $^{-1}$)	Popescu and Popescu (2018) .
<i>Vitis vinifera</i> cv. Italia. Grapevines were grafted onto 1103 P (<i>V. berlandieri</i> x <i>V. rupestris</i>).	HA extracted from soil. 52.46% of C; 5.77% of H; 5.4% of N; 35.66% of O; C/N ratio of 11.33; Total acidity of 5.0 meq/g of C; Phenolic acidity of 2.2 meq/g of C and carboxyl 2.7 meq/g of C	100 mg L $^{-1}$ via spray foliar.	Field cultivation. Drip-irrigated.	Increased berry weight; Increase in total soluble solids (°Brix); decrease of tartaric acid.	Ferrara and Brunetti (2010) .
<i>Vitis vinifera</i> cv. Superior seedless.	Commercial HA (Humatic 8500).	One, two, or three applications.	Field cultivation. Eleven-year-old plants; drip-irrigated.	Increase in total soluble solids, yield, and fruit quality with four HA applications.	Ibrahim and Ali (2016) .
<i>Vitis vinifera</i> cv. Yaghouti.	HA (K $_2$ O 10%; HA 55%; FA 15%) or FA Total nitrogen 3%; K $_2$ O 10%; FA 50%; chlorine 4.3%.	Application of HA with irrigation water at a concentration of 20 g per vine, two times (bud swell and millet-sized berry). Application of FA as a foliar spray at a concentration of 0.5% two times (millet-sized berry and 2 weeks later).	Field cultivation. Ten years old (plants); drip-irrigated.	Increase in berry weight, yield, total soluble solids, proline, and soluble carbohydrates (both HA and FA; under water stress conditions or not). Increase in N, P, K, Zn, and Fe content (leaf). In the plants with and without water stress, only the N content was not increased.	Irani et al. (2021) .

et al., 2016; Hardy and Knight, 2021), as a suppressor of plant disease (Graber et al., 2010; Debode et al., 2020), and as a coating for novel biochar-fertilizer composites (Joseph et al., 2013) or slow-release fertilizers (An et al., 2020). However, these

applications have not been fully explored in vineyards. Hale et al. (2015) demonstrated in a soil incubation experiment that biochar might support high population densities of the plant growth-promoting rhizobacteria (PGPR) *Enterobacter cloacae*.

TABLE 4 An overview of the main effects of pyrogenic materials in viticulture.

Crop variety	Pyrogenic material	Properties	Application and dosage	Experimental condition	Effects	Reference
<i>Vitis vinifera</i> L. (cv. Pinot Noir).	Biochar from 80% various hardwoods and 20% various coniferous wood chips at 750°C.	Soil organic amendment.	8 t ha ⁻¹ of biochar (d.w.).63.2 t ha ⁻¹ biochar-compost (d.w.), biochar added at 20% before composting process.	Field trial (3 years),rainfed vineyard (25-35 years old).	No relevant effects on plant growth parameters of vine or vine health are caused by biochar and biochar-compost.Minor effects on grape quality only in the first year of trial.	Schmidt et al. (2014).
<i>Vitis vinifera</i> L. (cv. Merlot, clone 181; rootstock 3309 Couderc).	Biochar from orchard pruning at 500°C.	Soil organic amendment.	16.5 t ha ⁻¹ of biochar (d.w.) applied in two consecutive years.	Field trial,rainfed vineyard (20 years old).	After 3 years: Increased soil water holding capacity and plant available water content. After 5 years: Increased vineyard production with no detrimental effects on grape quality. After 5 years: No negative impact on soil microbial community, and no retention of toxic compounds (PAH and heavy metals). After 7 years: Biochar is effective in restoring degraded soil functionality. The effects persist after 7 years of following a one-time application.	Baronti et al. (2014). Genesio et al. (2015). Maienza et al. (2017) Giagnoni et al. (2019).
<i>Vitis vinifera</i> L. (cv. Grenache).	Biochar from grapevine trunks at 550°C.	Soil organic amendment.	5 t C ha ⁻¹ of biochar.5 t C ha ⁻¹ biochar-compost.	Field trial (2 years),rainfed vineyard (20 years old).	Improvement in the N nutrient status of vines after application of 'compost' and 'compost x biochar' treatments in year two.	Ubalde et al. (2014).
<i>Vitis vinifera</i> L. (cv. Pinot Blanc). <i>Vitis vinifera</i> L. (cv. Ribolla Gialla). <i>Vitis vinifera</i> L. (cv. Sauvignon).	Biochar from oak at 650°C.	Soil organic amendment.	10.9 t C ha ⁻¹ of biochar (d.w.).10.9 t C ha ⁻¹ of biochar: compost (d.w.), biochar added at 10% before composting process.	Field trial (3 years),3 rainfed vineyards.	Biochar enhanced soil water availability, but had no significant effects on soil nutrient availability, grape yield, or must quality.Biochar-blended compost had a similar effect as conventional compost.	Sánchez-Monedero et al. (2019).
<i>Vitis vinifera</i> L. (cv. Shiraz)	Not available.	Soil organic amendment.	8.5 t ha ⁻¹ of biochar.	Field trial (4 years),rainfed vineyard	No significant effect on yield and vegetative growth	Botelho et al. (2020)
<i>Vitis vinifera</i> ssp. <i>vinifera</i> .	Biochar from maize corn cob rachis at 450 -500°C.	Soil organic amendment.	5 t C ha ⁻¹ of biochar.	Field trial (2 years),rainfed vineyard (25 years old).	Reduced soil microbial biomass for at least two years after application.No significant effects on the community composition of soil microbes or microarthropods.	Andrés et al. (2019).
<i>Vitis vinifera</i> L. (cv. Montepulciano).	Biochar from orchard pruning at 500°C.	Soil organic amendment.	10 t ha ⁻¹ of biochar (d.w.).	Field trial (1 year), rainfed vineyard (15 years old).	Increased organic carbon, available water content, and formation of a large fraction of macro aggregates.Increased fine root biomass with no significant effect on the production of arbuscular mycorrhizal fungi.	Amendola et al. (2017).
<i>Vitis vinifera</i> L. (cv. Chardonnay).	Biochar from orchard pruning at 500°C.	Soil organic amendment.	30 t ha ⁻¹ biochar (fresh weight).	Rhizobox.	Enhanced soil physicochemical soil properties and increased soil water content during the harsh summer period.Promoted earlier root production and lowered the number of fibrous roots.	Montagnoli et al. (2021).
<i>Vitis rotundifolia</i> L. (Muscadine grape cv. Alachua).	Biochar from southern yellow pine at 400°C.	Soil organic amendment.	0, 5%, 10%, 15%, and 20% of biochar (d.w.).	Greenhouse study in pots.	Enhanced soil water and nutrient status, and improved plant P and Mg uptake, with no significant differences in plant physiological performance. Improved soil physical properties and stimulation of fine root development.	Chang et al. (2021a). Chang et al. (2021b).
<i>Vitis vinifera</i> L.	Biochar from dairy manure at 400°C.	Soil organic amendment.	2 g and 5 g of biochar kg ⁻¹ soil.	Pot experiment (2 months).	Enhanced plant growth and soil properties under water stress conditions.	Kanwal et al. (2018).
<i>Vitis vinifera</i> L. (cv. Pinot noir).	Not available.	Soil organic amendment.	2% of biochar (d.w.).	Pot experiment.	Enhanced soil water availability under water shortage.No significant impact on soil N availability.	Petrillo et al. (2020).

(Continued)

TABLE 4 Continued

Crop variety	Pyrogenic material	Properties	Application and dosage	Experimental condition	Effects	Reference
<i>Vitis vinifera</i> L.	Biochar from gasification of vineyard pruning at 900–950°C.	Growing media component for nursery grapevine production.	0, 10%, 20%, 40% vol. of biochar.	Greenhouse study in pots.	BC applied at 10% enhanced plant-growth response, particularly expressed at the shoot stage.	Ronga et al. (2019).
<i>Vitis vinifera</i> L. (cv. Grüner Veltliner).	Biochar from softwood chips and cereal husk at 480°C.	Remediation of Cu-polluted soils.	1 to 6 kg m ⁻² of biochar (d.w.).	Greenhouse study in soil columns.	Biochar enhanced Cu mobilization in a neutral vineyard soil but reduced the ecotoxicologically relevant Cu ²⁺ fraction.	Soja et al. (2018).
<i>Vitis vinifera</i> L. (cv. Chardonnay).	Biochar from poultry litter at 550°C.	Fungal-disease suppression and control of nematode population.	6.9 t ha ⁻¹ of biochar (d.w.).	Field trial (3 years), vineyard (5 years old).	Decreased plant-parasitic nematode population, and increased free-living (non-plant-parasitic) nematode population. Possible role of biochar porous structure protecting bacteria and fungi from predators.	Rahman et al. (2014).
<i>Vitis vinifera</i> L. (Red Globe).	Bamboo biochar.	Microbial inoculum (<i>Pseudomonas putida</i>).	250 – 500 g biochar per tree (d.w.). 12.5 g biochar mL ⁻¹ inoculum.	Field trial (1 year), vineyard (8 years old).	Inoculated biochar improved the yield and quality of the grapefruit. Enhanced soil properties and altered soil microbial community structure.	Wei et al. (2020).
<i>Vitis vinifera</i> L. (Red Globe).	Wood vinegar from a hardy rubber tree at 550°C.	Inhibition of grey mold infection (<i>Botrytis cinerea</i>) during grape storage.	Grapes soaked in wood vinegar diluted 600, 400, and 200 times for 15 s and left to air-dry.	Laboratory conditions.	Inhibitory effect on the disease <i>Botrytis cinerea</i> during grape storage by stimulation of antioxidant defense-related enzymes.	Chen et al. (2020).

d.w., dry weight.

Interestingly, chemical properties of the biochar (particularly pH and N content) affected initial inoculum survival, but physical properties (surface area and porosity) were mainly associated with later survival after soil application (Hale et al., 2015). Biochar did not negatively affect rhizobacterium activity, which may occur due to bacterial signaling compounds or bacteria-derived plant growth hormones binding to the biochar surface. Depending on feedstock and pyrolysis conditions, certain biochars with large surface area or high pH can adsorb or hydrolyze signaling molecules, disrupting soil microbe cell-to-cell communication (Gao et al., 2016).

Similarly, Zhu et al. (2017) reported that biochar could modify communication between rhizosphere microbial communities and plant roots, affecting plant response to soil-borne pathogens (Harel et al., 2012; Akhter et al., 2015). Graber et al. (2010) proposed that induced resistance against pathogens observed in both tomato and pepper following biochar application may be due either to a shift in soil microbial populations following biochar addition, or to the release of chemicals from biochar toxic to pathogens. The utilization of beneficial microorganisms as biostimulants is discussed in greater detail below, and other mechanisms by which biochar can act as a disease-suppressing agent have been previously summarized by Bonanomi et al. (2015) and Graber et al. (2014).

Pyroligneous acid is often applied as a foliar spray or soil drench (Mungkumchao et al., 2013), or in combination with biochar (Zhang et al., 2020). Zhang et al. (2020) demonstrated the benefit of applying biochar and pyroligneous acid for increased blueberry yield and nutritional quality, by enhancing soil organic matter and nutrient availability. In terms of vineyard pest management, Chen et al. (2020) studied the ability of pyroligneous acid to inhibit grey mold (*Botrytis cinerea*) infection of table grape cultivar 'Red Globe'. The application of diluted pyroligneous acids (200- and 400-fold dilution) improved grape resistance to grey mold, likely through stimulation of antioxidant defense-related enzyme activities, including those of superoxide dismutase, peroxidase, and ascorbate peroxidase. However, other investigations of pyroligneous acid use in vineyards are lacking.

The application of biostimulants from pyrogenic materials may help vineyards adapt to climate change, especially in a scenario of water shortage which may be particularly detrimental to viticulture (Maienza et al., 2017). Fascinatingly, the positive impacts of biochar on vineyard soil fertility are maintained in the long term (7 years), even after a single application (Giagnoni et al., 2019). This benefit has also been identified for improving the growth and symbiotic performance of other plants (lupin, *Lupinus angustifolius*) under drought stress conditions (Egamberdieva et al., 2017).

Microorganisms as biostimulants

Plant growth-promoting rhizobacteria

Certain prokaryotic soil microorganisms can establish beneficial relationships with plants. Coined ‘plant growth-promoting rhizobacteria’ (PGPR) (Kloepper and Schroth, 1979), these microbes can enhance plant growth and development through several direct and indirect processes, performed at different plant growth stages (Vorholt, 2012; Ruzzi and Aroca, 2015; Castellano-Hinojosa and Bedmar, 2017). According to Chauhan et al. (2015), the main PGPR traits are biofertilization and phytostimulation (through the excretion of phytohormones such as indole-3-acetic acid [IAA], cytokinins, and gibberellins), tolerance to biotic and abiotic stress (via 1-aminocyclopropane-1-carboxylate [ACC] deaminase activity), and biopesticide and biocontrol activity (production of antibiotics, lytic enzymes, hydrogen cyanide [HCN], and volatile organic compounds [VOCs], among others) (Chauhan et al., 2015; Kumar-Jha and Saraf, 2015; Goswami et al., 2016; Oleńska et al., 2020). Additionally, PGPRs can have synergistic interactions with the endophytic grape microbiome (Vandana et al., 2021).

Bacteria must first be isolated and cultured prior to their utilization as PGPRs. For use in viticulture, several authors have isolated viable PGPRs from the microbiome of *Vitis vinifera* L., which may then be re-applied as biostimulants in vineyards (Compant et al., 2011; Pinto and Gomes, 2016; Rezgui et al., 2016; Pacifico et al., 2019). The effectiveness of these PGPRs depends on several factors including environmental conditions, soil characteristics, and even crop variety (Pacifico et al., 2019). Nevertheless, PGPRs are a feasible tool for use in vineyards to effectively promote plant growth and protection (Figure 1).

Most studies of PGPRs in viticulture are focused on the initial stages of crop development in specific vine cultivars. Additionally, few studies testing strains at a field scale can be found (Table 5). Under *in vitro* and/or greenhouse conditions, Muganu et al. (2015); Köse et al. (2015), and Velásquez et al. (2020a) noted a wide variety of PGPR strains (*Ensifer*, *Burkholderia*, *Pseudomonas*, and *Bacillus*) were able to promote growth and root callusing percentage in four different *V. vinifera* cultivars: ‘Beyaz Çavus’, ‘Italia’, ‘Cabernet Sauvignon’, and ‘Chardonnay’. Köse et al. (2003) observed *Bacillus* strains BAI6 and OSU142 increased rooting in 41B (a hardy cross between old-world *V. vinifera* and new-world *V. berlandieri*) rootstocks. Similarly, Sabir (2013) and Sabir et al. (2017) applied *P. putida* BA-8 and *B. simplex* T7 to 41B hybrids and recorded a promotion of graft callusing, scion shoot growth, nursery survival rate, and fruitfulness. Salomon et al. (2016) tested a combination of strains *B. licheniformis* and *P. fluorescens* in order to improve the growth of *V. vinifera* cultivar ‘Malbec’ in greenhouse conditions. Also in a greenhouse, the cytokinin and auxin-producing *B. megaterium* M3 was applied in combination

with *Agrobacterium rubi* A18 and *Alcaligenes eutrophus* Ca-639 to *V. vinifera*, grafted onto 41 rootstocks. Growth enhancement and increased grapevine pruning residue weight were noted (Salomon et al., 2017).

In a rare field-scale experiment, Rolli et al. (2017) applied several bacteria from the genera *Paenibacillus*, *Pseudomonas*, *Bacillus*, *Delftia*, and *Achromobacter*, to *V. vinifera* cultivars ‘Syrah’ and ‘Sauvignon’. Increased plant growth, number of grape branches, and grape production were recorded. Veliksar et al. (2017) applied strains of *Azotobacter*, *Pseudomonas*, and *Bacillus* to two *V. vinifera* cultivars in Moldova, and observed improved photosynthetic activity, as well as reduced mineral fertilizer requirements. Erdogan et al. (2018) achieved similar improvements with combinations of a wide range of PGPR strains in grafted rootstocks of *V. berlandieri* and *V. riparia* in Turkey. In China, Lu et al. (2020) observed enhanced growth and final grape quality, following the application of *P. putida* Rs-198 to a perennial variety.

In addition to general growth and quality enhancement, inoculation with PGPRs may also induce grape tolerance against biotic and abiotic stresses. For example, the application of phosphate-solubilizing bacteria isolated from the *Vitis* rhizosphere resulted in improved plant development when grown in saline-alkaline soils (Liu et al., 2016). Salomon et al. (2014) observed both drought alleviation and production of defense compounds in the grape cultivar ‘Malbec’. Barka et al. (2006) found that *Burkholderia phytofirmans* PsJN could effectively protect Chardonnay grapes against cold stress.

Other studies focus on using PGPR strains to alleviate heavy metal stress. Funes-Pinter et al. (2018) identified *B. licheniformis*, *Micrococcus luteus*, and *P. fluorescens* as effective species for elevating growth and fruit yield in plants when grown in the presence of arsenic (As III). Veliksar et al. (2019) used strains of *Agrobacterium radiobacter*, *P. putida*, and *B. subtilis* to increase resistance against high soil concentrations of copper, and reduce the amount of mineral fertilizer needed.

Microorganisms may also be used as biocontrol agents against fungal pathogens in vineyard soils. For example, several studies have applied bacterial strains in order to protect vineyards from the common vine pest grey mold (*Botrytis cinerea*). Miotto-Vilanova et al. (2016) and Verhagen et al. (2010) found that several strains belonging to the *Pseudomonas*, *Burkholderia*, *Microbacterium*, *Kocuria*, and *Terribacillus* genera harbored plant growth and phytopathogen-control traits against *B. cinerea*. Andreolli et al. (2016) and Rezgui et al. (2016) also tested strains of *P. protegens* and *B. subtilis* against fungal pathogens, with the latter obtaining good results in field trial conditions. These studies show that a vast myriad of bacterial-borne traits can be effective for biocontrol, including the production of antibiotics, terpenes, pigments, and proteases, as well as inducing resistance against biotic stresses. As an indication of the high potential for PGPRs to combat plant biological stress, Asghari et al. (2020) applied *Pseudomonas* and

TABLE 5 An overview of the main effects of plant-growth-promoting rhizobacteria (PGPR) applied in viticulture.

Crop variety	PGPR strains	Properties	Application and dosage	Experimental condition	Effects	Reference
<i>Vitis vinifera</i> L. cv. Cabernet Sauvignon.	<i>Bacillus aryabhattai</i> JY17. <i>Bacillus aryabhattai</i> JY22.	Phosphate solubilization.IAA.Siderophore.ACC deaminase.Chitinase.HCN (JY22).	Inoculation with 50 mL (10^8 CFU mL ⁻¹) into the middle part of the seedling roots.	Greenhouse, transplanted after 3-4 leaves had grown on the seedlings, 28 L pots.	Increased plant height, stem thickness, root and shoot dry weight.	Liu et al. (2016).
<i>Vitis berlandieri</i> hybrids (41B and 1103P).	<i>Pseudomonas putida</i> BA-8. <i>Bacillus simplex</i> T7.	Cytokinin synthesizer. Auxin synthesizer.	Scion node dipped into bacterial suspension (10^9 CFU mL ⁻¹) for 1h.	Controlled greenhouse, and rootstocks.	Increased graft callusing, scion shoot growth, cane hardening, and nursery survival rate and fruitfulness	Sabir (2013).
<i>Vitis vinifera</i> L. (Malvasia bianca lunga).	<i>Burkholderia</i> spp. strain IF25.	Biostimulation.Phosphate solubilization.Siderophores.IAA production.	Bi-nodal shoots dipped into 50 µL of bacterial inoculum.	<i>In vitro</i> .	Induced advanced rooting and high rooting percentage.	Muganu et al. (2015).

Pantoea sp. and noted lowered gall formation produced by *Agrobacterium tumefaciens*.

As shown above, PGPRs have so far primarily been researched *in vitro*, and in greenhouse trials. Few studies exist at the field scale and any practical yield benefit from these microorganisms has yet to be quantified (Bashan et al., 2014). Other optimizations must be performed before any selected consortia can be developed into commercial products. The survivability and persistence of the applied strains must be quantified not only in the soil along with any competitive/negative effects from the native rhizosphere microbiome but also in stable storage conditions. European legislation restricting the application of chemical substances to crops has been passed relatively recently (Regulation EC 1107 (2009)). It is therefore alarming that only a single reviewed study concerned the development of commercial bioinoculants; İşçi et al. (2009) applied consortium EM-A (comprised of lactic acid, phototropic bacteria, and yeasts; EM AGRITON Ltd., Belgium) to *V. champini*, and recorded improved rooting.

Mycorrhizae

More than 400 MYA, the presence of mycorrhiza in soil was essential for the colonization of terrestrial environments by plants due to their ability to provide stress tolerance and soil resources via symbiosis (Heckman et al., 2001). This adaptation continues in the majority of plants on Earth, including grapevines (Trouvelot et al., 2015). Roots of grapevines form a particular type of mycorrhizal symbiosis called arbuscular mycorrhizae, characterized by the penetration and internal colonization of plant root cells by fungal hyphae (Trouvelot et al., 2015).

Arbuscules form within the plant roots and serve as the exchange site for various metabolites (Trouvelot et al., 2015). Arbuscular mycorrhizal fungi (AMF) are widely known for being able to enhance the uptake of P in the host roots, a nutrient that is typically limiting in cropping systems like vineyards (Smith et al., 2011; Van Geel et al., 2017). However, they also provide increased plant uptake of N and other limiting elements including trace metals Fe, Mn, Cu, and Zn (Clark and Zeto, 2000), which are also critical to plant health (Figure 1). This is accomplished by greatly extending the root system's exploration and exploitation area (Smith and Read, 2008; Trouvelot et al., 2015), simultaneously increasing plant access to water sources that would be otherwise inaccessible (Al-Karaki and Clark, 1998). This feature may be particularly advantageous in rain-fed vineyards growing in nutrient-poor soils, which are widespread in most traditionally wine-producing regions such as the Mediterranean, Middle East, and Caucasian regions (Table 6).

In addition to their role in plant water and nutrient uptake, AMF contributes to the biosynthesis of a wide range of molecules such as vitamins and hormones needed to support the metabolism and health of plants (Strzelczyk et al., 1991), although this is poorly investigated in the context of vineyards. Arbuscular mycorrhizal fungi can also protect grapevines against harmful pathogens and pests, including the root-knot forming nematode *Meloidogyne incognita*, through the induction of a defense response involving enzymes like chitinases (Li et al., 2006). Moreover, AMF contributes to the development of a healthy rhizosphere community (i.e., a microbially diverse community that is functionally linked to the plant), which in turn may confer tolerance/resistance against a range of biotic and abiotic stresses (reviewed above), including heat, drought, salinity, pathogenic infection, and pests (Fitter

TABLE 6 An overview of the main effects of mycorrhizal inoculants applied in viticulture.

Crop variety	Applied material and properties	Dosage, the form of application, and stage of plant development	Experimental condition	Effects	Reference
<i>Vitis vinifera</i> cv. Pinot noir.	Mixed inoculum of 3 AMF isolated from a vineyard and recultured with <i>Sorghum bicolor</i> : <i>Scutellospora calospora</i> INVAM# OR219, <i>G. mosseae</i> INVAM# OR218, and <i>Glomus</i> sp. INVAM#215.	A mixture of soil with AM fungal spores, hyphae, and colonized root fragments. 20 g of inoculum plant ⁻¹ .	Potted plants in a greenhouse.	Vine growth was dependent on AMF in one soil, but inoculated and non-inoculated vines grew equally well in another soil. Increase in plant dry mass with AMF due to enhanced P uptake (833% increase). The uptake of most other nutrients was also enhanced by AMF in the first soil.	Schreiner (2007).
<i>Vitis vinifera</i> cv. Pusa Navrang.	Six single strains and a mixture of AMF (<i>G. manihotis</i> , <i>Glomus mosseae</i> , and <i>G. gigantean</i>) recultured with <i>Chloris guyana</i> : <i>Acaulospora laevis</i> , <i>A. scrobiculata</i> , <i>Entrophospora colombiana</i> , <i>Gigaspora gigantea</i> , <i>Glomus manihotis</i> , and <i>Scutellospora heterogama</i> .	A mixture of soil with AM fungal spores, hyphae, and colonized root fragments. 20 g of inoculum plant ⁻¹ .	Micropropagated plantlets in a greenhouse.	Enhanced survival and improved tolerance against stresses. Improved physiological and nutritional status and higher relative water content and photosynthetic rate. Higher concentrations of N, P, Mg, and Fe. Better hardening.	Krishna et al. (2005).
<i>Vitis vinifera</i> cv. Tempranillo.	GLOMYGEL Vid, Olivo, Frutales (Mycovitro S.L., Pinos Puente, Spain): Culture of AMF <i>Rhizophagus intraradices</i> .	8 mL of diluted mycorrhizal inoculum plant ⁻¹ (equivalent to 2000 propagules).	Cuttings are planted in 6.5-L plastic pots.	AMF inoculation improved parameters linked to phenolic maturity such as anthocyanin content and increased antioxidant activity under elevated temperature.	Torres et al. (2016).
<i>Vitis vinifera</i> cv. Sangiovese.	<i>Funneliformis mosseae</i> IMA1.	A mixture of soil with AM fungal spores, hyphae, and colonized root fragments and autoclaved peat in a proportion of 1:4 v/v + 2 mL of <i>F. mosseae</i> IMA1 inoculum filtrate.	Explants were cultivated in 150 mL sanitized pots.	Greater emission of volatiles related to plant defense and water stress.	Velásquez et al. (2020b).
<i>Vitis vinifera</i> cv. Viosinho.	<i>Funneliformis mosseae</i> inoculum (isolate BEG95, Symbiom [®] , Czech Republic).	10 g of inoculum plant ⁻¹ buried in ditches and mixed with soil and rye seeds.	Field experiment.	Greater establishment of new mycorrhizal taxa in vine roots. Greater photosynthetic efficiency after a heat wave. Compensation for water competition with cover crops.	Nogales et al. (2021).
<i>Vitis vinifera</i> cv. Cabernet Sauvignon.	Commercial inoculum Mykoflor (Mykoflor, Polland).	20 mL of suspension under the vine roots (~2000 propagules).	Field experiment.	Improved leaf gas exchange. Higher yield and number of clusters. Greater polyphenols and anthocyanins.	Karoglan et al. (2021).

and Garbaye, 1994; Gryndler, 2000; Jeffries et al., 2003; Gupta et al., 2018). Given their importance in vine nutrition and pathogen response, AMF are a critical pillar of healthy, functioning vineyards (Trouvelot et al., 2015), especially in the current context of widespread environmental degradation and climate change. In addition to direct benefits to plant health, mycorrhizae may also provide important ecosystem services, including increasing potential carbon sequestration of vineyard soils and reducing erosion (Trouvelot et al., 2015).

Despite these benefits, mycorrhizal symbiosis is frequently disrupted in croplands due to intensive management, including excessive tilling, which breaks the orderly structure of soil aggregates and fungal networks (Gosling et al., 2006; Bowles et al., 2017; Porter and Sachs, 2020), although this has been poorly investigated in vineyards (Winter et al., 2018). Biocides can also negatively affect mycorrhizal fungi, with deleterious consequences on the establishment of symbiosis (Gosling et al., 2006; Zaller et al., 2018), while synthetic fertilizers disrupt the mycorrhizal association due to the ablation of nutritional constraints, such as N and P (Gosling et al., 2006; Van Geel

et al., 2017). Regenerating proper vine-mycorrhizal balance and function in degraded vineyards is thus a priority, which may yield many benefits to both growers and the wider society.

Regeneration of the vine-AMF interaction can take place through various means, which should be considered holistically in terms of impact on total vineyard management. One such strategy is the inoculation of grapevines with one or more strains of mycorrhizal fungi previously selected for their ability to colonize vine roots (Linderman and Davis, 2001; Trouvelot et al., 2015). One aspect in which inoculation with mycorrhizal biostimulants might be particularly important is to minimize the growing threat of trunk diseases (Petit and Gubler, 2006; Holland et al., 2019), which may be linked to widespread alteration of plant-microbial associations. It has been recently suggested that declines observed in woody plants are related to microbiome modifications or imbalances (i.e., dysbiosis) (Porter and Sachs, 2020). Arbuscular mycorrhizal fungi known to help re-establish symbiosis include various strains of *Glomus intraradices*, such as *G. intraradices* BEG72 (Nogales et al., 2008) and INVAM CA501 (Petit and Gubler, 2006).

Proper timing may be critical when inoculating plants with mycorrhizal biostimulants (Sohn et al., 2003), but there is little information for vineyards. It is suggested that rootstocks be submerged in an AMF spore solution before planting, but variable success is reported. For example, a study was carried out on *Vitis rupestris* cv. St. George using *G. intraradices* and reported that pre-inoculated plants were less susceptible to black foot disease (Petit and Gubler, 2006), while (Holland et al., 2019) observed no difference between inoculated and uninoculated plants. Some studies have also reported clear effects in the greenhouse, but not under realistic field conditions (Rosa et al., 2020). Other ways to add AMF to vineyards include the direct spraying of commercial biofertilizers on adult plants, through the addition of granules containing spores, and potentially also the translocation of whole soil inoculants from previously selected locations particularly diverse in terms of AMF such as forests. This latter approach is underexplored in vineyards. Perhaps contributing to variability in inoculation success is the difficulty in altering the pre-established microbiome of adult plants. Moreover, the mixed positive and neutral effects of inoculating vines with AMF, together with the fact that some (but not all) mycorrhizal fungi show a certain degree of host specificity (Campos et al., 2018), suggest the importance of screening AMF strains against potential compatible host vine cultivars/rootstocks prior to inoculum development (Schreiner, 2007). Finally, the vine-AMF symbiosis is context dependent and may be linked to factors critical for productive vineyards including soil fertility and other properties (e.g., soil organic matter content, pH, and texture) (Trouvelot et al., 2015). For example, the presence of a well-developed community of cover crops in vineyard inter-rows may favor inoculated AMF establishment, by providing an additional host crop and continuous reservoir for supplying adjacent grapevines (Winter et al., 2018).

Biological control agents

Climate change simulations predict that the fitness of crop insect pests will increase beyond 30° latitude North and South of the equator (Santos et al., 2020). Indeed, a three-decade study observed shifts in the phenology of grape berry moths (*Eupoecilia ambiguella*, *E. viteana*, and *Lobesia botrana*), distribution ranges of leafhoppers (*Scaphoideus titanus* Ball, a common vector of grapevine diseases), and range expansion of grapevine mealybugs (*Planococcus ficus*) (Reineke and Thiéry, 2016).

The effective control of crop pests is a continuous process. For native and newly introduced pests, the adoption of novel biological control agents (BCAs) is needed for sustainable alternative pest management (Figure 1). BCAs are living organisms antagonistic against pests. By definition, biological control must involve: 1) a biocontrol agent, 2) a pest to be

controlled, and 3) a farmer or a stakeholder benefitting from the pest control (Stenberg et al., 2021). Organisms such as insects or mites, bacteria, fungi, and nematodes are used to control weeds or pests and diseases of cultivated plants (Ehlers, 2011). Viruses are not living entities, but contain structural biological components such as nucleic acids and proteins and are therefore also considered BCAs (Stenberg et al., 2021). Semiochemicals (chemical molecules produced by organisms that modify the behavior of other living beings, i.e., bio-communication) and plant extracts that can act directly on a pathogen or pest are other options for BCAs (Ehlers, 2011). Biological control is an interaction between at least two organisms, and success is therefore influenced by many factors including climate, reproduction mode and rate, food availability, and others. Holistically considering the total impact of all dynamic factors together when designing a balanced pest management plan is referred to as integrated pest management (IPM). BCAs are a main component of IPM, and together, are becoming increasingly utilized in agriculture.

Biocontrol agents may be naturally present in the agroecosystem (e.g. a native population of soil microbes antagonistic to plant-parasitic nematodes), or first grown *in vitro* and then released (Sharma et al., 2009; Stenberg et al., 2021). Grapevine is a perennial crop and harbors a large microbiome in both the rhizosphere and stem tissues. Additional microorganisms which act to balance the microbiota are also found in the phyllosphere and fructosphere (Ranade et al., 2021). Many of these microorganisms act as BCAs and are a promising ecological strategy for disease control (Carro-Huerga et al., 2021).

The cropping system (e.g. conventional vs. organic farming) also influences the potential number of biocontrol agents which may be isolated for application. Cordero-Bueso et al. (2017) evaluated the biocontrol potential of 230 grape yeast isolates from different cultivation systems. The fractions with the most candidates were isolated from wild vines (62.7%) and biodynamic vineyards (17.7%). The least number of candidates were isolated from organic (6.2%) and conventional systems (7.2%). Wild vine species may therefore serve as a valuable resource for bioprospecting future BCAs. Additional potential sources of candidates include other plants, insects, animal intestinal tracts, soils, and marine and freshwater environments (Kurtzman et al., 2011).

BCAs can have several mechanisms of action against pathogens. During resource limitation, BCAs may outcompete detrimental microbes in terms of space (niches), nutrients, water, and/or light (Wang et al., 2018; Almeida et al., 2020). Other mechanisms include iron depletion (Sipiczki, 2006; Cordero-Bueso et al., 2017); production of lytic enzymes (Cordero-Bueso et al., 2017; Cabañas et al., 2020); production of volatile organic and semio-compounds antagonistic against pests (Cabañas et al., 2020; Don et al., 2021); resistance induction of the host plant (Arras, 1996; Jeandet et al., 2002; Maachia et al.,

2015; Haidar et al., 2016); direct parasitism; tolerance of reactive oxygen species (ROS) (Aziz et al., 2003; Jamalizadeh et al., 2011); biofilm formation (Cabañas et al., 2020); synthesis of pathogenesis-related proteins (Chan and Tian, 2006); and antibiotic production (Maachia et al., 2015; Cordero-Bueso et al., 2017).

Production of extracellular mucilage produced by microbial antagonists throughout host cells may be linked to cell adhesion, and contain biochemical elicitors to signal defense responses (El-Ghaouth et al., 1998). Fragments of yeast cell wall oligosaccharides have also been noted to possess elicitor potential.

In viticulture, most BCAs are applied to control fungal diseases and pests associated with insect and mite vectors. However, other biological controls have also been researched and suggested for other pests. For example, harmful mollusks (snails) in vineyards in cool and wet climates may be effectively controlled by the nematode *Phasmarhabditis hermaphrodite* (Schneider), as there are restrictions on the use of synthetic molluscicides (Eggleton et al., 2021). BCAs are also being developed for the control of weed species prevalent in vineyards (Samad et al., 2017).

In a grapevine host, antibiosis and resistance induction were observed, attributed to the antagonism of *Bacillus subtilis* B29 against *Uncinula necator* (powdery mildew) and *Botrytis cinerea* (grey mold) (Maachia et al., 2015). An n-hexane extraction of the cell-free supernatant of *B. subtilis* B29 revealed the presence of 17 fractions through HPLC. Two fractions were considered antibiotics against *M. ramannianus* and *M. luteus*, based on their antimicrobial activity (Sihem et al., 2011). *B. subtilis* B29 and B27 have also been described as inducing host resistance through the high production of phenolic compounds, with a significant increase in hydroxycinnamic acid (Maachia et al., 2015).

Antagonism against pests alone does not necessarily make an organism a BCA. The applied fungi, yeasts, and bacteria must possess other characteristics to allow for practical use in the field. For example, a BCA with greater adaptability than the pest may allow for widespread niche colonization and higher competitive potential (El-Ghaouth et al., 2004). Additionally, prior to application, the BCA candidate should be extensively screened for the production of metabolites harmful to non-pest organisms, especially humans. In the specific case of biological control of molds on grapes following harvest, the BCA should not leave residue on the berries. After identifying the mechanism of antagonism, and confirming BCA adaptability and safety, appropriate tests following the guidelines of national regulatory bodies must be conducted before registration as a commercial inoculant.

The use of BCAs in agriculture began in the second half of the 20th century, and several candidates have been identified. Although many researchers have since evaluated their pest control potential, few inoculants reach commercialization.

Bacillus subtilis is one of the most widely applied fungicidal BCAs (Garrido and Botton, 2020). During the 2020/2021 harvest in Brazil, 182 commercial brands of synthetic fungicides were available for application to vineyards, compared to 28 biological fungicides (Table 7). Only two genera were represented, *Bacillus* and *Paecilomyces*, with a predominance of *Bacillus* (mostly *B. subtilis*). Other species of *Bacillus* were *B. amyloliquefaciens*; *B. licheniformis*; *B. methylotrophicus*; and *B. pumilus*. *Paecilomyces lilacinus* has been cited as an active ingredient in seven commercial brands. Most are composed of a single species and strain.

Esca is caused by the association of the fungi *Phaeoacremonium minimum* and *Phaeomoniella chlamydospora* and is one of the main Grapevine trunk diseases (GTDs). Control of Esca is achieved mainly through BCAs, in which common biological agents are *Trichoderma* fungi (Chervin et al., 2022). *Trichoderma* atroviride-based products (CS1 by Vintec® - Belchim Crop Production and I-1237 by Esquive® - Agrauxine by Lesaffre) are often effective because they have multiple mechanisms of action: substrate competition, antibiosis, and mycoparasitism (Pertot et al., 2015; Belchim, 2022). For the control of powdery mildew (*Uncinula necator*), AQ10® (*Ampelomyces quisqualis*) is used commercially (Benuzzi and Baldoni, 2000). Another biologically-controlled disease is downy mildew (*Plasmopara viticola*). *Trichoderma harzianum* (known as Trichodex®), acts against the oomycete by increasing lignin, callose, and hydrogen peroxide, in addition to upregulating the defense enzymes phenylalanine ammonia-lyase, peroxidase, and 1,3-glucanase (Kamble et al., 2021).

The choice of BCA is of paramount importance. Simultaneous with disease control, some BCAs can influence grape productivity and quality with variable effects on acidity, soluble solids content, and berry size. Malviya et al. (2022) cite significant differences in the acidity of vine fruits treated with three BCAs ranging from 3.7 to 4.2 and 4° Brix in the SST. Production per plant doubled when treated with BCAs and almost tripled when combined with BCA + sulfur.

As for insecticides and acaricides, 55 synthetic products and 38 biological commercial products have been authorized for grapevines. Twenty-six contain *Beauveria bassiana* as an active ingredient and three with *B. thuringiensis*. For the control of insects and mites, recommendations for predatory insects (one *Orius insidiosus* and one sterile male pupal of *Ceratitis capitata*), predatory mites (four *Neoseiulus californicus* and two *Phytoseiulus macropilis* with AcMNPV virus), and one viral compound (AcMNPV virus, ChinNPV Virus, HearNPV Virus, SfMNPV Virus) are available.

Many antagonists with BCA potential are studied with increasingly efficient and cost-effective techniques. In addition to bioprospecting for biopesticides, valuable antibiotics may also be obtained from these organisms. Decreased BCA production costs and improved management techniques that increase and prolong BCA effects will allow for scaling their use in viticulture. Thus, biological products with multiple benefits (controlling

TABLE 7 Principal biological control agents (BCAs) applied in viticulture in Brazil.

Trade (and company) names	BCA	Concentration	Dosage	Target pathogens	Application
NO-NEMA® (Biovalens Biotecnologia)	<i>Bacillus amyloliquefaciens</i>	42 (3 x10 ⁹ UFC mL ⁻¹)	0.5 - 4.0 L ha ⁻¹	Nematodes (several species)	Soil/Seed
DURÁVEL® (BASF)	<i>Bacillus amyloliquefaciens</i> MBI600	110 (5.5 x 10 ¹⁰ UFC g ⁻¹)	0.5 - 1.0 kg ha ⁻¹	<i>Botrytis cinerea</i>	Soil/Aerial
ECO-SHOT® (IHARA)	<i>Bacillus amyloliquefaciens</i> cepa D-747	250 (5 x 10 ¹⁰ UFC g ⁻¹)	1.0 - 4.0 kg ha ⁻¹	<i>Sclerotinia sclerotiorum</i> , <i>Colletotrichum gloeosporioides</i>	Foliar/fruit immersion
NEMA III	<i>Bacillus amyloliquefaciens</i>	42 (3 x10 ⁹ UFC mL ⁻¹)	0.5 - 4.0 L ha ⁻¹	Nematodes (several species)	Soil
NEMACONTROL® (Simbiose®)	<i>Bacillus amyloliquefaciens</i>	30 (5 x 10 ⁹ UFC mL ⁻¹)	0.5 - 1.0 L ha ⁻¹	<i>Pratylenchus brachyurus</i>	Seed
PFC-CONTROL	<i>Bacillus amyloliquefaciens</i>	30 (5 x 10 ⁹ UFC mL ⁻¹)	0.5 - 1.0 L ha ⁻¹	<i>Pratylenchus brachyurus</i>	Seed
QUARTZ SC	<i>Bacillus amyloliquefaciens</i>	1,5 (3 x 10 ⁹ UFC mL ⁻¹)	1.0 - 2.0 L ha ⁻¹	<i>Botrytis cinerea</i>	Soil
PROFIX® (Bula)	<i>Bacillus licheniformis</i> , <i>B. subtilis</i> , <i>Paecilomyces lilacinus</i>	200 + 200 + 200 (10 ¹⁰ UFC g ⁻¹)	50 - 70 g ha ⁻¹	<i>Meloidogyne incognita</i> , <i>Pratylenchus brachyurus</i>	Soil/Seed

SONATA® (Bayer CropScience)	<i>Bacillus pumilus</i> QST 2808	14.35 (10 ⁹ UFC g ⁻¹)	2.0 - 4.0 L ha ⁻¹	<i>Uncinula necator</i> , <i>Botrytis cinerea</i>	Aerial
BIO-IMUNE® (Vittia Grupo)	<i>Bacillus subtilis</i> BV02	42 (3 x10 ⁹ UFC mL ⁻¹)	2.0 - 8.0 L ha ⁻¹	<i>Uncinula necator</i>	Foliar
BIOBACI/BIOBACI III® (Biovalens Biotecnologia)	<i>Bacillus subtilis</i> BV09	7 (10 ⁸ UFC g ⁻¹)	1.5 - 6.0 L ha ⁻¹	<i>Meloidogyne</i> spp. <i>Fusarium oxysporum</i>	Soil
PRESENCE	<i>Bacillus subtilis</i> FMCH002, <i>Bacillus licheniformis</i> FMCH001	200 + 200 (10 ¹¹ UFC g ⁻¹)	100 - 150 g 100 kg ⁻¹	<i>Meloidogyne javanica</i> , <i>Pratylenchus brachyurus</i>	Seed
SERENADE® (Bayer CropScience)	<i>Bacillus subtilis</i> QST 713	13.68 (10 ⁹ UFC g ⁻¹)	2.0 - 4.0 L ha ⁻¹	<i>Botrytis cinerea</i> , <i>Colletotrichum gloeosporioides</i>	Soil/Aerial
RIZOS OG® (Lallemand Soluções Agrobiológicas Ltda)	<i>Bacillus subtilis</i> UFPDA 764	3 (3x10 ⁹ UFC mL ⁻¹)	4.0 - 8.0 L ha ⁻¹	<i>Meloidogyne javanica</i> , <i>Pratylenchus brachyurus</i>	Seed
BIOBAC® (Vital Brasil Chemical Indústria e Comércio de Produtos Químicos Ltda – ME)	<i>Bacillus subtilis</i> Y1336	500 (10 ⁹ UFC g ⁻¹)	0.8 - 1.0 kg 100 L ⁻¹	<i>Botrytis cinerea</i>	Aerial
QUATZO® (FMC Química do Brasil Ltda)	<i>Bacillus subtilis</i> , <i>Bacillus licheniformis</i>	200 + 200 (10 ¹¹ UFC g ⁻¹)	130 - 300 g ha ⁻¹	Nematodes (several species)	Soil
BN 40.001/19 (Ballagro)	<i>Paecilomyces lilacinus</i>	300 (7.5 x 10 ⁹ UFC g ⁻¹)	1.92 kg ha ⁻¹	<i>Meloidogyne incognita</i>	Soil
MNG-02/14 (Agrobiológica Sustentabilidade)	<i>Paecilomyces lilacinus</i>	7 (10 ⁵ UFC g ⁻¹)	1.0 - 4.0 kg ha ⁻¹	<i>Meloidogyne incognita</i>	Soil
NEMAKILL® (Grupo Clínica Agrícola)	<i>Paecilomyces lilacinus</i>	7 (10 ⁵ UFC g ⁻¹)	1.0 - 4.0 kg ha ⁻¹	<i>Meloidogyne incognita</i>	Soil

(Continued)

TABLE 7 Continued

Trade (and company) names	BCA	Concentration	Dosage	Target pathogens	Application
NEMAT® (Agroindustrial Limsa)	<i>Paecilomyces lilacinus</i>	300 (7.5 x 10 ⁹ UFC g ⁻¹)	0.1 - 0.25 kg ha ⁻¹	<i>Meloidogyne incognita</i> , <i>Pratylenchus brachyurus</i>	Soil/Seed
NETTUS® (Ballagro Agro Tecnologia Ltda)	<i>Paecilomyces lilacinus</i>	300 (7.5 x 10 ⁹ UFC g ⁻¹)	1.28 - 1.92 kg ha ⁻¹	<i>Meloidogyne incognita</i>	Soil
Purpureonyd Fr25 (TZ Biotec)	<i>Paecilomyces lilacinus</i>	200(6.5 x 10 ⁷ UFC g ⁻¹)	1 kg 15 ha ⁻¹	<i>Meloidogyne incognita</i>	Soil/Aerial
VINTEC (Belchim Crop Production)	<i>Trichoderma atroviride</i>	1 x 10 ¹³ UFC g ⁻¹	200 g. ha ⁻¹	<i>Esca</i> , <i>Phaeomoniella chlamydospora</i> , <i>Togninia minima</i> (<i>Phaeoacremonium aleophilum</i>), <i>Eutypa lata</i> , <i>Botrytis fuckeliana</i> , <i>B. cinerea</i> <i>Fomitiporia mediterranea</i> , <i>Podosphaera xanthii</i> , <i>Armillaria mellea</i> , and <i>A. gallica</i>	Aerial (pulverization) or scion wood immersion

disease(s), promoting plant growth, and increasing grape quality) are compliant with the sustainable development objectives of the 2030 agenda of the United Nations (UN). The reduction of synthetic chemical inputs in this manner can simultaneously reduce contamination throughout the production chain and ecosystem.

Future studies should investigate other applications of BCAs, such as the use of parasitic nematodes (*Phasmarhabditis hermaphrodita*) or earthworms (*Lumbricidae*) for pest control against snails and slugs in vineyards.

Conclusions and future prospects for investigation

The application of biostimulants and BCAs may allow for improved sustainable viticulture and may serve as alternatives for chemically synthesized agronomic inputs, thereby reducing the negative environmental impact of pesticides and fungicides. The positive effects on plant growth are summarized in Figure 1 and vary widely depending on the type of biostimulant applied to the crop. The optimization of these materials is necessary for a successful application, by considering biostimulant concentration and dosage effects, plant developmental stage, climatic/environmental conditions, and experimental setup.

Therefore, the main limitations and areas for further investigation for future biostimulant and BCA optimization in sustainable viticulture are listed below:

A) Manufacturing and commercialization

- Harmonization of legislation and lack of regulations on product quality
- Competitive commercialization costs
- Availability of raw materials used for their manufacturing, especially the lack of quality material (i.e. heterogeneous composition)

- Storage and effectivity duration (especially for biological products)

B) Application

- Lack of information at field-scale, and very few reports on the application in uncontrolled realistic conditions with positive results
- Effect variability on the unknown plant microbiome
- Effect variability on plant growth, depending on product dosage (concentration and number of applications)
- Effect variability depending on the mode of product application (foliar spraying, or *via* soil irrigation/fertigation)
- Effect variability depending on the stage of crop development
- Speculation remains as to underlying mechanisms associated with the biostimulant
- Comparative studies with agrochemicals as control
- Synergetic effects with other products and potential negative effects
- Lack of standard protocols depending on grape cultivar

C) Environmental and practical issues

- Soil management
- Environmental and practical issues
- Soil management for effect optimization
- Integration with agronomical management (e.g. avoiding tillage for AMF)
- Short and long-term environmental impact (e.g. contamination of soil and watersheds)

Author contributions

KJ: Conceptualization, Methodology, Writing - Original Draft; TLG: Writing - Review and Editing; PP-T, MS-M, YA, AD-A, AW, MG, MS, CP, JB, RO-H, MN, JR, and RA: Writing - Original Draft; SM and MD: Funding acquisition; GT: Writing -

The hydroponic farming significantly enhances the yield and enables multiple cropping per year. These advantages can be improved by using plant growth-promoting fungi (PGPF) either under normal or stress conditions. In this study, the fungal strain (A3) isolated from the rhizosphere of the halophyte plant *Aeluropus littoralis* was identified as *Penicillium olsonii* based on sequence homology of its ITS region. The A3 fungus was shown to be halotolerant (up to 1M NaCl) and its optimal growth was at 27°C, but inhibited at 40°C. In liquid culture medium, the A3 produced indole acetic acid (IAA) especially in the presence of L-tryptophan. Tobacco plants grown under hydroponic farming system were used to evaluate the promoting activity of the direct effect of A3 mycelium (DE) and the indirect effect (IDE) of its cell-free culture filtrate (A3CFF). The results showed that for the two conditions (DE or IDE) the tobacco seedlings exhibited significant increase in their height, leaf area, dry weight, and total chlorophyll content. Interestingly, the A3CFF (added to the MS liquid medium or to nutrient solution (NS), prepared from commercial fertilizers) induced significantly the growth parameters, the proline concentration, the catalase (CAT) and the superoxide dismutase (SOD) activities of tobacco plants. The A3CFF maintained its activity even after extended storage at 4°C for 1 year. Since the A3 is a halotolerant fungus, we tested its ability to alleviate salt stress effects. Indeed, when added at 1:50 dilution factor to NS in the presence of 250mM NaCl, the A3CFF enhanced the plant salt tolerance by increasing the levels of total chlorophyll, proline, CAT, and SOD activities. In addition, the treated plants accumulated less Na⁺ in their roots but more K⁺ in their leaves. The A3CFF was also found to induce the expression of five salt stress related genes (NtSOS1, NtNHX1, NtHKT1, NtSOD, and NtCAT1).

Finally, we proved that the A3CFF can reduce by half the chemical fertilizers inputs. Indeed, the tobacco plants grown in a hydroponic system using 0.5xNS supplemented with A3CFF (1:50) exhibited significantly higher growth than those grown in 0.5xNS or 1xNS. In an attempt to explain this mechanism, the expression profile of some growth related genes (nitrogen metabolism (NR1, NRT1), auxin (TRYP1, YUCCA6-like), and brassinosteroid (DET2, DWF4) biosynthesis) was performed. The results showed that all these genes were up-regulated following plant treatment with A3CFF. In summary the results revealed that the halotolerant fungus *P. olsonii* can stimulates tobacco plant growth, enhances its salt tolerance, and reduces by half the required chemical fertilizer inputs in a hydroponic farming system.

KEYWORDS

Penicillium olsonii, halophilic PGPF, cell-free culture filtrate, salt stress, plant growth promotion, sustainable agriculture

Introduction

Plants live in unstable environments that often inhibit growth and development. Unfavorable environmental conditions include biotic and abiotic stresses, such as drought, salt, and low or high temperatures, which greatly reduce plant productivity and threaten food security (Jamil et al., 2011; Zhu, 2016). Improving agricultural sustainability requires efficient management of soil fertility, fertilizer input, water use, and crop rotations, which help maintain proper soil equilibrium and high crop productivity. Biological processes in the soil play important roles in the cycling of essential elements for plant growth, including carbon, nitrogen, phosphorus, and sulfur (Drobek et al., 2019). In 2012, more than 6.2 million hectares in European countries were treated with biostimulants (Calvo et al., 2014; Colla and Rouphael, 2015). The use of microorganisms in improving nutrient availability for plants is an important strategy to protect biodiversity, and meet the increasing food demands of the global population (Vimal et al., 2017). It is well known that plant growth and health benefit from the presence of certain bacteria and fungi that live both within and around their tissues. In particular, soil fungi have long been known as a key element of soil fertility, plant nutrient turnover, and plant growth promotion (Haro and Benito, 2019). The plant growth-promoting fungi (PGPFs) can influence germination, seedling vigor, shoot growth, root growth, photosynthetic efficiency, flowering, and yield (López-Bucio et al., 2015; Hossain and Sultana, 2020b). Moreover, previous studies have revealed that PGPFs also improve systemic tolerance of abiotic stress in various crop plants (Khan et al., 2011; Zhang et al., 2016; Chandra and Singh, 2020). PGPFs include species of the genera *Aspergillus*, *Fusarium*, *Trichoderma*, *Penicillium*, *Piriformospora*, *Phoma*, and *Rhizoctonia* (Hossain et al., 2007, 2014, 2017; Shores et al., 2010). *Aspergillus*, *Fusarium*, *Penicillium*, *Piriformospora*, *Phoma*, and *Trichoderma* are specifically involved in abiotic stress tolerance (Chandra and

Singh, 2020). The specific selection of halotolerant fungi that promote salt tolerance and plant growth could thus significantly enhance plant productivity either under normal or salt stress conditions, representing a promising approach for increasing nutrient bioavailability and helping advance saline soil-based agriculture.

The soil microorganisms play a fundamental role in regulating organic matter decomposition and the mobilization of nutrients for plants, thus promoting their growth and productivity (Yarzabal and Chica, 2017). PGPFs represent roughly 44.2% of rhizosphere fungal isolates (Hossain and Sultana, 2020a). However, their frequency of occurrence in the rhizosphere varies with host plant species (Schmid et al., 2018; Hakim et al., 2021). These beneficial fungi have a crucial role in physiological processes such as photosynthesis, phytohormone biosynthesis, and responses to salinity, drought, heat, cold and heavy metal stresses (Ansari et al., 2013). *Trichoderma virens* has been used to enhance biomass production and stimulate lateral root development in Arabidopsis seedlings (Contreras-Cornejo et al., 2009). A bushy root phenotype and strong stimulation of root hair development were observed in Chinese cabbage (*Brassica rapa*) seedlings treated with *Piriformospora indica* (Lee et al., 2011). Similarly, multiple species of PGPFs have been described that enhance cucumber (*Cucumis sativus*) plant growth via different mechanisms (Chandanie et al., 2009; Saldajeno and Hyakumachi, 2011; Hossain et al., 2014; Islam et al., 2014; Babu et al., 2015). Spinach (*Basella alba*) seedlings inoculated with the rhizosphere fungus *Fusarium* spp. showed more vegetative growth and both higher germination percentages and vigor indices compared to non-treated plants (Islam et al., 2014). Auxin and cytokinin phytohormones are involved in interactions between plant roots and soil microorganisms like bacteria and fungi (Boivin et al., 2016). The effectiveness of *Penicillium menonorum* on cucumber (*C. sativus*) growth is attributed to the secretion of indole acetic

acid (IAA), which potentially represents the main mechanism for plant growth stimulation (Babu et al., 2015). Additionally, *Arabidopsis* seedlings showed characteristic auxin-related phenotypes, including lateral root development and biomass increases, when inoculated with *Trichoderma virens* (Contreras-Cornejo et al., 2009). Salas-Marina et al. (2011) also noted that the *Aspergillus ustus* promotes growth in *Arabidopsis thaliana* through auxin synthesis in liquid cultures.

Besides observing the direct effects on plant growth from mycelium, potential effects of fungal culture filtrates have also been studied. Treatments with *Fusarium tricinctum* RSF-41 and *Alternaria alternata* RSF-61 culture filtrates have been found to improve growth of rice (*Oryza sativa*) seedlings via IAA secreted into culture media (Khan et al., 2015). Autoclaved and filter-sterilized culture filtrates of *P. indica* enhance hairy root growth and lignin production of *Linum album* (Kumar et al., 2012). Furthermore, *in vitro* co-cultivation with *P. indica* culture filtrate alters callus production, organogenesis, and photosynthetic pigment content in *Artemisia annua* (Baishya et al., 2015). Khan et al. (2015) suggested that fungi secrete plant hormone-like compounds into culture media that help re-program and regulate endogenous phytohormone levels of the host plant. The *Penicillium* genus, which is widely distributed in soil habitats of cultivated, forest, desert, beach, and marine regions, has several species that are known PGPFs that can produce phytohormones and enhance mineral solubilization (Babu et al., 2015). Results from previous studies conducted with *Penicillium* sp. showed effective enhancement of plant growth and improvement of biotic and abiotic stress tolerance in multiple plant species (Hossain et al., 2007; Khan et al., 2008; Khan and Lee, 2013; Hossain et al., 2014; Radhakrishnan et al., 2014; Khan et al., 2015), and in one such study it was demonstrated that isolated *Penicillium* sp. cultures promote growth of rice seedlings and *Suada japonica* (You et al., 2012).

Hydroponics systems usually require lower nutrients and water use and, thus promote environmental protection and agricultural sustainability, especially when combined with plant growth promoting microorganisms (PGPMs) (Bartelme et al., 2018). In the current study, our main objective was to mine the rhizosphere of the halophyte plants for the presence of beneficial microorganisms that can help plants to grow under normal as well as under stress conditions. For this, a fungus (A3) belonging to the *Penicillium* genus was isolated from the rhizosphere of the halophyte plant *A. littoralis* as first step of this work. We secondly tested the effect of A3 mycelium on plant growth in either solid or liquid media. Next, the ability of A3 cell-free culture filtrate (A3CFF) to promote the growth and to alleviate salinity stress in tobacco plants grown in a hydroponic system was evaluated. We then determined the potential of A3CFF to decrease the quantity of chemical fertilizers required in nutrient solution (NS) in a hydroponic growing system. Finally, in order to understand the possible mechanisms by which A3CFF can promote plant growth and enhance salinity stress tolerance, the expression

profiles of certain growth- and salt stress-related genes were monitored using semi-quantitative and quantitative RT-PCR.

Materials and methods

Fungi isolation and qualitative evaluation of growth-promoting activity

Following the method described by Tarroum et al. (2021), the fungi were isolated from the soil surrounding the roots of *A. littoralis*, plants that dominate the salty soil at a location called “Salboukh” (north of Riyadh, Saudi Arabia: 25°04′48.6″ N 46°20′27.7″ E). Following repeated sub-culturings on PDA plates of isolated mycelia, pure colonies were obtained and stored in 30% glycerol at −80°C for further study.

To evaluate the growth-promoting activity of the isolated fungus (referred as A3), tobacco seeds were soaked in 10% (v/v) bleach for 15 min, then rinsed with sterilized water four times and finally they were germinated on solid Murashige and Skoog medium (MS). The square petri plates (17 × 17 cm) containing seeds were incubated vertically in the growth chamber for 10 days at 25°C ± 2°C. Then, the isolated fungus (5 µl of a liquid culture) was inoculated at the bottom of treated petri dishes and for control ones 5 µl of sterilized water were added. One month after sowing, the plates were photographed and growth stimulation was evaluated qualitatively basing on root length and leaf surface.

Microscopic observation and fungal identification

Microscopic observation of A3 was performed as described by Tarroum et al. (2021). In brief, solid PDA medium was cut into small squares, and then transferred to new petri plates containing a wet filter paper. Using sterile needles, the four edges of each PDA block were then inoculated with isolated A3 fungus. Following incubation of plates for 72 h at 27°C, the coverslips were gently removed and transferred to microscope slides with a drop of lactophenol cotton blue stain. The slides were examined and photographed using a Nikon microscope.

Five-day-old mycelium was collected from PDA plate and ground in liquid nitrogen to a fine powder using a mortar and pestle. Genomic DNA was then extracted using a DNeasy Plant Mini Kit (Qiagen) according to the manufacturer's instructions. The isolated DNA was used for PCR amplification of a nuclear ribosomal internal transcribed spacer (ITS) region which was amplified by universal primers ITS1 (forward) and ITS4 (reverse) as listed in (White et al., 1990). PCR amplification was carried out in a 30 µl reaction volume as described by Tarroum et al. (2021). After running the amplified fragments on 1.5% agarose gels, they were purified and cloned into pGEM®-T Easy vectors (Promega) then sequenced by MacroGen Inc., (Seoul Korea). The resulting

sequences were used in BLAST searched using NCBI databases to identify the isolated fungus.

Temperature and salinity effects on A3 growth

To assess the effect of temperature on A3 growth, the mycelium was inoculated on PDA and incubated at 27°C or 40°C (three replicates each). The effect of salinity on fungal growth was tested on MS medium at five NaCl concentrations (100, 200, 400, 800, and 1,000 mM NaCl) with three replicates each. The isolated fungus was sub cultured at the center of 9 cm petri dishes each containing 20 ml medium and incubated at 27°C. The diameter of mycelium growth was measured every 2 days during 15 days.

Quantification of IAA in A3 filtrate

IAA production was measured according to [Gordon and Weber \(1951\)](#). In brief, the fungus was inoculated in liquid MS medium with or without L-tryptophan (1 mg/ml) and incubated at 27°C for 7, 14, 21, or 28 days. After incubation, each culture was centrifuged at 10,000 rpm during 15 min. The supernatant (1 ml) was mixed with 1 ml of Salkowski reagent (1 ml 0.5 M FeCl₃, 30 ml concentrated H₂SO₄, and 50 ml distilled H₂O) and incubated in the dark at room temperature during 20 min. The optical density at 530 nm was measured and the amount of IAA produced was calculated using a standard curve.

Quantitative evaluation of growth-promoting activity by A3 fungus

To quantitatively evaluate the effects of A3 fungus on plant growth, two vertical plastic boxes were assembled, with the top box containing 15 holes and filled with sterilized vermiculite and fixed to a lower box containing sterilized MS liquid medium. Five sterilized tobacco seeds as described above were germinated into the vermiculite-containing box. Ten days later, five microliters of liquid culture containing isolated A3 fungus added to the MS medium. After three additional weeks of inoculation, plants were harvested and plant height, leaf area, dry weight, and total chlorophyll content were recorded.

Growth-promoting activity evaluation of A3 cell-free filtrate (CFF)

In MS liquid medium

To prepare A3CFF, a mycelium disc of 5 mm in diameter was picked from a 7-day-old culture grown on solid PDA medium then inoculated into a 250 ml Erlenmeyer flask containing 100 ml of MS medium. Cultures were then incubated at 27°C with

shaking at 150 rpm for 30 days, vacuum filtered (0.22 µm), and the resulting A3CFF stored at 4°C for further use.

Growth containers were made consisting of two assembled and autoclaved boxes, with the top box containing nine holes into which plants can be inserted and the bottom box filled with 1.5 l of MS liquid media and covered with aluminum foil to avoid algal contamination. Sterilized tobacco seeds were sown in sterile 1.5 ml Eppendorf tubes that were perforated at the bottom and filled with vermiculite. One week after germination, seedlings of similar sizes were selected and transferred to growth containers containing one of three different dilutions of A3CFF (1:500, 1:1000, and 1:2000). Growth containers were then kept in a temperature and humidity-controlled growth chamber. Plants were harvested 1 month later and shoot length, root length; fresh and dry shoot weights, leaf number, and leaf area were recorded. The total chlorophyll and proline content as well as catalase (CAT) and superoxide dismutase (SOD) activity levels were also quantified.

The stability of A3CFF stored for 1 year at 4°C, was evaluated in liquid MS media using the growth containers described above. One week old seedlings were transferred to growth containers supplemented with 1:500 dilutions of fresh or stored A3CFF. The two parts of the growth container were carefully sealed and placed in growth chamber with controlled conditions. One month later, the shoot and root length, dry and fresh weight, leaf number, and leaf area was recorded.

In NS

In order to examine the potential use of A3CFF in hydroponic growing systems, its ability to promote plant growth when added to a NS in place of chemical fertilizers was evaluated. Full-strength NS was prepared by mixing the following in a total of 1 l water then adjusting the pH to 6.2: 600 mg Chem-Gro™ fertilizer 8-15-36, 600 mg CaNO₃, 373 mg MgSO₄. Following procedures described above, germinated tobacco seeds were transferred to growth containers in which the bottom part was filled with NS and supplemented with a 1:50 or 1:500 dilution of A3CFF. One month later, morphological parameters such as shoot and root length, fresh/dry weight, leaf number, and leaf area were measured.

Evaluation of salt stress alleviation of A3CFF

Tobacco seeds were sterilized (as described above) then placed in sterile 1.5 ml Eppendorf tubes (perforated from the bottom) containing vermiculite. The tubes were fixed in a small plastic cups with a hole in the bottom and then kept in a sterile box for germination. Germinated seeds were then transferred to a hydroponic system consisting of two autoclaved boxes, with the top box containing nine holes for plant placement and the bottom box filled with 1.5 l of NS and covered with aluminum

foil to avoid algal contamination. After 2 weeks of growth, plants were subjected to one of four treatments: (1) growth in a hydroponic system containing only NS (control), (2) growth in NS supplemented with A3CFF at 1:50 dilution, (3) growth in NS and 250 mM NaCl, (4) growth in NS with 250 mM NaCl and a 1:50 dilution of A3CFF. The boxes containing the plants were kept for 6 weeks in a growth chamber (16 h light, 8 h dark, $25^{\circ}\text{C} \pm 2$, relative humidity 60–70%). Plants were then harvested, growth parameters listed above recorded, and the samples immediately frozen in liquid nitrogen and kept at -80°C until further use.

Evaluation of fertilizer input substitution by A3CFF

Sterilized tobacco seeds were placed in sterile 1.5 ml Eppendorf tubes (perforated from the bottom) containing vermiculite. Following 10 days of germination, seedlings were transplanted to a hydroponic growing system (as described above) containing either full (NS) or half (0.5NS) NS. For the treated plants, 1 week after transplantation, the 0.5NS was supplemented with A3CFF at a dilution of 1:50. Plants were grown in a growth chamber (16 h light, 8 h dark, $25^{\circ}\text{C} \pm 2$, relative humidity 60–70%) and plant growth parameters were measured after 1 month.

Estimation of physiological and biochemical parameters

Chlorophyll

Total chlorophyll was extracted in 80% acetone for 24 h at 4°C in the dark. Absorbance at 645 nm and 663 nm was determined with an Amersham spectrophotometer and used to calculate total leaf chlorophyll content according to the following equation: Total chlorophyll ($\mu\text{g/ml}$) = $20.2 (A_{645}) + 8.02 (A_{663})$ (Liang et al., 2017).

Proline

Proline was extracted following the protocol described by [Ábrahám et al. \(2010\)](#). Liquid nitrogen was used to grind 0.5 g of fresh leaf tissue and the resulting powder incubated in 10 ml of 3% aqueous sulfosalicylic acid. The mixture was centrifuged at 10,000 rpm and 2 ml of supernatant added to 2 ml ninhydrin plus 2 ml glacial acetic acid. The mixture was then boiled at 100°C for 1 h and the reaction stopped by transferring the tubes to an ice bath for 5 min. Next, 6 ml of toluene was added, mixed vigorously for 15 s, and the absorbance of the upper phase read at 520 nm. The proline content was expressed in $\mu\text{g/g}$ fresh weight.

CAT and SOD activity

Enzymes were isolated as described by [Jogeswar et al. \(2006\)](#). Fresh tissue (100 mg) was ground in liquid nitrogen then

incubated in 0.1 M of phosphate buffer (pH 7.4) containing 0.1 mM EDTA, 1% (w/v) PVP, and 0.5% (v/v) Triton-X 100. The homogenate was centrifuged at 14,000 rpm for 20 min at 4°C , and the supernatant was used to estimate CAT and SOD activities.

CAT activity was measured following the method described by [Claiborne \(1985\)](#) and modified by [Jogeswar et al. \(2006\)](#). The reaction mixture consisted of 1 ml 0.06 M H_2O_2 , 0.1 M sodium phosphate buffer (pH 7.4), 1.9 ml distilled water, and 100 μl enzyme extract. Catalytic activity was recorded by spectrophotometer using the decline in absorbance at 240 nm owing to degradation of H_2O_2 and was expressed as units/g protein.

SOD activity was measured following the method described by [Chandrakar et al. \(2016\)](#) with minor modifications. The reaction mixture (3 ml) contained 50 mM of Tris-HCl buffer (pH 8.2), 1 mM EDTA, 100 μl enzyme extract, 0.4 mM pyrogallol, and H_2O up to 3 ml. SOD activity (U/g protein) was defined as the amount of enzyme required to inhibit 50% of pyrogallol oxidation based on absorbance at 420 nm.

Determination of K^+ and Na^+ content

The concentrations of Na^+ and K^+ were estimated in root and leaf. Dried tissues were incubated in 0.5% HNO_3 for 7 days ([Ben-Romdhane et al., 2018](#)). The supernatant was filtered and the concentration of Na^+ and K^+ was then estimated using an atomic absorption spectrometer (Thermo Scientific™, United Kingdom) and reported as mg/g dry weight.

RNA extraction and genes expression profiling

Total RNA was extracted following plant treatment with A3CFF at three times (0, 24, and 72 h) using the Qiagen RNeasy Plant Mini Kit following the manufacturer's instructions. After quantification, total RNA was treated with DNaseI (RQ1, Promega, United States). The cDNAs were synthesized as follow: 5 μg of total RNA was reverse transcribed with random hexamer and oligo-(dT18) primers using SuperScript™ III reverse transcriptase (Invitrogen), as described in the manufacturer's instructions. The cDNA was used for RT-qPCR reactions, which were carried out using 480 SYBER Green I Master Mix (Roche, Switzerland) as described in the manufacturer's manual. The PCR cycling conditions were as follow: 95°C for 3 min, followed by 40 cycles of 95°C for 20 s, 60°C for 30 s, and 72°C for 1 min. To create a melting curve and check primer specificity, the extension temperature was increased from 72°C to 95°C after 40 cycles of amplification. Actin (380 bp, ACT-F and ACT-R) was selected as a reference gene. Primers targeting salt stress-related genes (NtSOS1, NtNHX1, NtHKT1, NtSOD, and NtCAT1) or those implicated in nitrogen metabolism (NR1, NRT1), auxin biosynthesis (TRY1, YUCCA6-like), and brassinosteroid biosynthesis (DET2, DWF4) selected for this study ([Supplementary Table S1](#)) were designed *via* primer 3

software.¹ Target gene expression was quantified and expressed relative to actin expression using either the $\Delta\Delta C_T$ comparative method (Ben-Romdhane et al., 2018), $\Delta\Delta C_T = (C_t \text{ target gene} - C_t \text{ actin}) \text{ treated plant} - (C_t \text{ target gene} - C_t \text{ actin}) \text{ control}$ or by the semi-quantitative PCR products analyzed using a 1.5% agarose gel. To ensure reproducibility, two biological and three technical replicates were performed for this experiment.

Statistical analysis

Data were analyzed using one-way ANOVA followed by Duncan's test via SPSS software version 25. Each value presented is the mean of five replicates for all growth parameters and three replicates for qPCR. Different letters on bar charts are used to indicate means that differ significantly at $p \leq 0.05$.

The identification of isolated fungus was performed by the use of NCBI-BLAST search and the phylogenetic tree was constructed using neighbor-joining method by bootstrapping 1000 times in MEGA X software.

Results

Isolation, identification, and qualitative evaluation of fungi growth-promoting activity

As a first step, 20 soil samples were collected from the rhizosphere of the halophyte grass *A. littoralis* growing in the sebkha of Salboukh. From these samples, 18 fungi (designed A1 to A18) were identified based on visual differences in their morphology when grown on PDA medium. The 18 isolated fungi were evaluated qualitatively for their ability to promote growth of tobacco seedlings cultivated on MS medium. The results showed that out of 18 tested fungi, only seven strains were able to clearly stimulate root and leaf growth of tobacco seedlings (data not shown). For further detailed investigations, the A3 fungus was chosen as it had the greatest effect on plant growth (Figure 1). Morphologically, on PDA media after 1 week of incubation at 27°C, the A3 colonies had moderate growth, with a green color on one side and pale yellow on the reverse side. Microscopic analysis revealed that the A3 strain has a septate hypha terminating in a complex conidiophore. Moreover, *chlamydospore* was clearly visible at 40x magnification (Supplementary Figure S1a). The growth of A3 showed maximum growth after 12 days of incubation at 27°C. However, at 40°C, total inhibition of A3 growth was observed (Supplementary Figure S1b). Since A3 was isolated from the rhizosphere of the halophyte grass *A. littoralis* its tolerance to NaCl in the culture media was also investigated.

FIGURE 1
Evaluation of the qualitative growth promoting activity effect of tobacco seedlings cultivated on MS solid medium in the presence of the isolated A3 fungus.

Based on mycelial growth levels, the A3 fungus was able to grow in up to 1 M NaCl. Interestingly, the A3 fungus showed the largest colony diameter at 200 mM NaCl, while the growth rate of A3 mycelia was inhibited at NaCl concentrations above 200 mM (Supplementary Figure S1c). Finally, using Salkowski's reagent, IAA was detected in growth medium containing L-tryptophan at 0.93 ppm after 28 days of incubation. In a medium without L-tryptophan IAA was detected at 0.20, 0.22, 0.24, and 0.26 ppm after 7, 14, 20, and 28 days of incubation, respectively. This confirmed that the addition of L-tryptophan to growth media and extended incubation times are required for maximum auxin production by the A3 fungus (Supplementary Figure S2).

The ITS region was chosen as it is the barcode with the highest probability of correct identifying a huge number of sampled fungi (Raja et al., 2017). The isolated ITS sequence fragment was BLAST searched against the NCBI GenBank and showed 93.4% identity to the one of *Penicillium olsonii* (Supplementary Figure S3). Based on these results the A3 is likely *P. olsonii*.

Quantitative evaluation of the A3 growth promoting activity

The direct effect of A3 mycelium (DE) on plant growth promotion in liquid MS medium was quantitatively evaluated using plastic boxes as described in Materials and Methods (Figure 2A). When compared to control plants, A3 fungus-treated plants showed significantly higher shoot length, leaf area, dry weight, and total chlorophyll content (2, 3, 5, and 1.5 times higher, respectively (Figures 2B–E). These results confirm that the A3 fungus positively enhances growth of tobacco seedlings cultivated in hydroponic systems when added to liquid MS medium and thus A3 is potentially a PGPE.

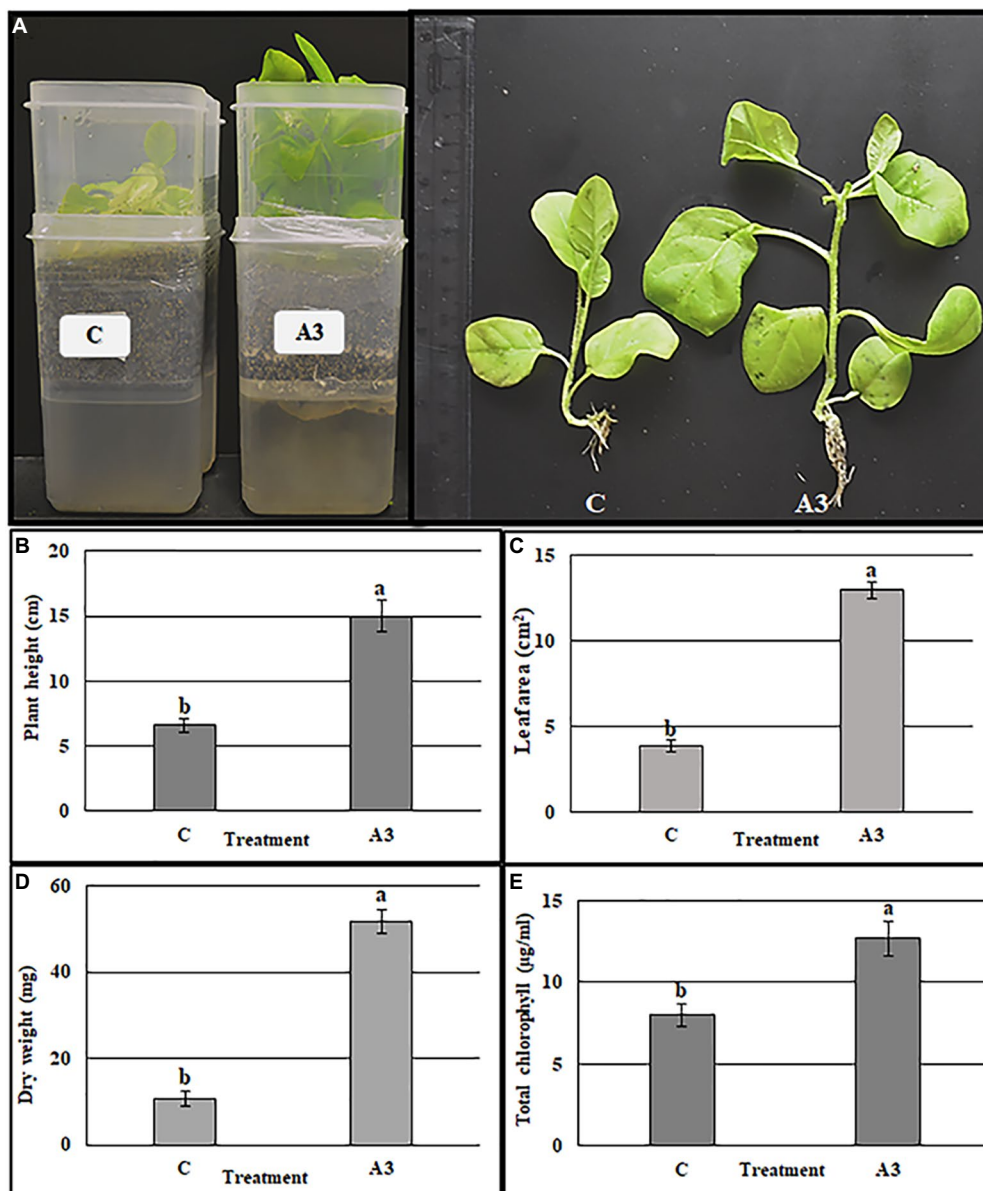

FIGURE 2
Quantification of A3 growth stimulation activity on tobacco seedling grown in MS liquid medium. Seeds of tobacco were cultivated in the two boxes hydroponic system, vermiculite in the top and MS liquid medium in the bottom. The treatment was performed by adding 5 μ l of A3 liquid culture in MS medium after 10 days of sowing seeds. Plant morphology (A), plant height (B), leaf area (C), plant dry weight (D), and total chlorophyll (E): Data are the means of five replicates \pm standard deviation; different letters on bars represent the significant values according to Duncan's test ($p < 0.05$).

Quantitative evaluation of the A3CFF growth promoting activity

In MS liquid medium

The ability of cell-free culture filtrate from A3 culture (A3CFF) to stimulate growth of tobacco plants in a hydroponic system was determined. MS liquid medium was used as the growing media and was supplemented with one of three dilutions of A3CFF (1:500, 1:1000, or 1:2000). After 1 month of treatment with A3CFF, net improvements in growth

(Figure 3A), physiological (Figures 3B–G), and biochemical (Figure 4) parameters were observed for all three tested dilutions. Each dilution significantly promoted shoot/root length, fresh/dry shoot weight, and leaf area (Figures 3B–G). In addition, the highest values of total chlorophyll (27.7 μ g/ml), proline accumulation (159 μ g/g FW), as well as CAT (8.1 U/g proteins), and SOD (19.8 U/mg proteins) activities were detected in plants treated with an A3CFF dilution of 1:500 (Figure 4). These increases in proline synthesis and CAT/SOD activities in A3CFF-treated plants suggest that A3 fungus can

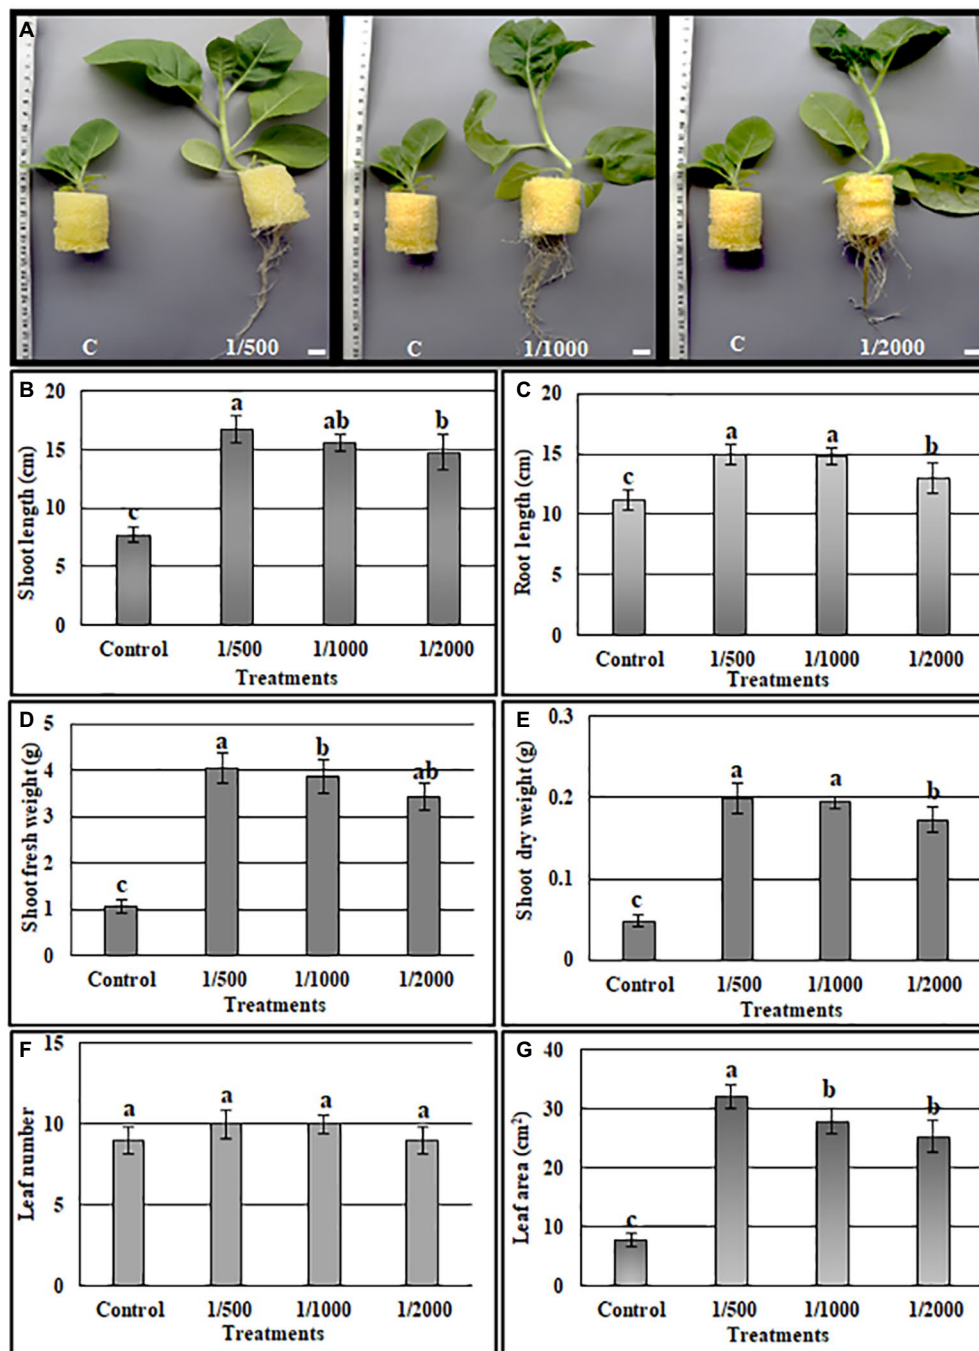

FIGURE 3

Quantification of A3 cell-free filtrate culture (CFF) growth stimulation activity on tobacco seedling grown in MS liquid medium. The MS liquid medium was supplemented with 1:500, 1:1000 and 1:2000 CFF dilutions. (A) Phenotype of plants after 1 month, the shoot length (B), root length (C), shoot fresh weight (D), shoot dry weight (E), leaf number (F), leaf area (G). Data are the means of five replicates \pm standard deviation; different letters on bars represent the significant values according to Duncan's test ($p < 0.05$).

alleviate salt stress. Finally, we tested the stability of A3CFF by growing tobacco seedlings in liquid MS medium containing a 1:500 dilution of fresh A3CFF or A3CFF stored at 4°C for 1 year (Supplementary Figure S4a). The results demonstrated that the positive effects on plant growth of A3CFF were preserved after 1 year of storage at 4°C (Supplementary Figures S4b–g).

In nutritive solution (NS)

The above results show that A3CFF stimulated plant growth when added to liquid MS medium in the absence of fungal mycelia. One of our goals from this work was to investigate the effects of PGPF application on hydroponically grown vegetable plants in conditions of reduced fertilization. We thus evaluated the

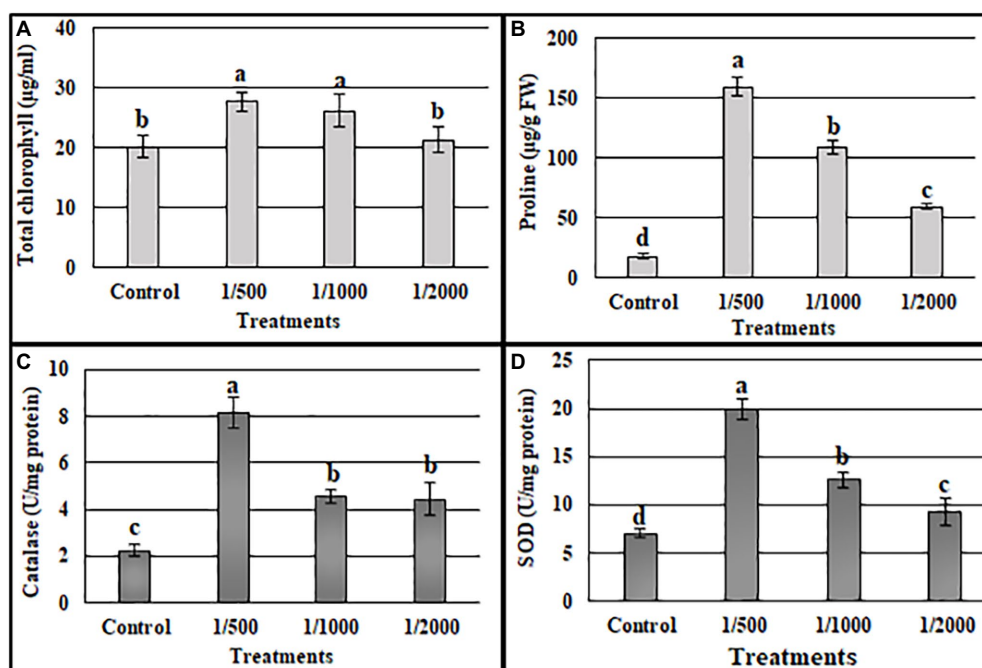

FIGURE 4
Effects of A3 CFFs at different dilutions (1:500, 1:1000 and 1:2000) on total chlorophyll (A), proline (B), catalase (C), and SOD (D) activities in tobacco plants: Data are the means of five replicates \pm standard deviation. Different letters on bars represent the significant values according to Duncan's test ($p < 0.05$).

effectiveness of A3CFF in stimulating plant growth when mixed with commercial fertilizers in NS and used in hydroponic system. The two A3CFF dilutions, 1:500 or 1:50, when applied to tobacco seedlings grown in NS significantly stimulated growth (Figure 5A). Interestingly, the A3CFF dilution of 1:50 promoted the highest growth by increasing the shoot/root length, the shoot/root dry weight, and the leaf area by factors of 198, 174, 211, 319, and 200%, respectively (Figures 5B–F).

In The presence of salt stress

Tobacco plants treated with an A3CFF dilution of 1:500 and grown in MS liquid medium produced both higher CAT and SOD activities and proline levels compared to untreated plants (Figure 4). In addition, A3CFF in NS at a dilution factor of 1:50 induced more plant growth. Based on these results, we investigated the ability of A3CFF to alleviate salt stress. The addition of A3CFF to NS at a dilution of 1:50 in the presence or absence of 250 mM NaCl enhanced tobacco plant growth compared to control plants (Figure 6A). The presence of 250 mM NaCl in NS significantly reduced the biomass production shoot/root length, weight, and leaf area of tobacco plants compared to those in NS alone. This growth inhibition due to salt stress was decreased following the addition of A3CFF (1:50) to NS containing 250 mM NaCl and (Figures 6B–F). Additionally, the root lengths of the co-treated plants were significantly larger than that of control plants grown in NS only (Figures 6A,C). Moreover, after 1 month without NaCl, A3CFF

increased shoot and root length by factors of 1.4 and 1.5, respectively, compared to control plants.

We also measured additional parameters to further assess the effects of A3CFF on salinity stress responses. Levels of total chlorophyll under salt stress were significantly lower than in control conditions. However, the application of the A3CFF in conjunction with salt stress restored total chlorophyll content to levels comparable to those of control plants under normal conditions (Figure 7A). In addition, the highest value of total chlorophyll, 14.05 µg/ml, was observed in plants grown with A3CFF without NaCl stress (Figure 7A). For proline accumulation, a significant difference was noted between inoculated and non-inoculated plants under salinity stress (Figure 7B). SOD and CAT activities during salt stress were also significantly higher in A3CFF-treated plants compared to non-treated plants (Figures 7C,D).

One of the most important mechanisms for coping with saline toxicity is the reduction of Na⁺ uptake, which is accompanied by the increased K⁺ retention in order to counter balance the Na⁺ entry. Plants treated with 250 mM NaCl showed a significant increase in Na⁺ levels in both roots and shoots compared to the control plants (Figure 7E). The addition of A3CFF to salt-stressed plants decreased Na⁺ accumulation by 14.8% in roots and 6% in shoots compared to control ones. In contrast, in the absence of NaCl, no significant difference in the Na⁺ levels in tissues was detected between inoculated and non-inoculated plants (Figure 7E). Unlike for the Na⁺ levels, salt treatment inhibited the

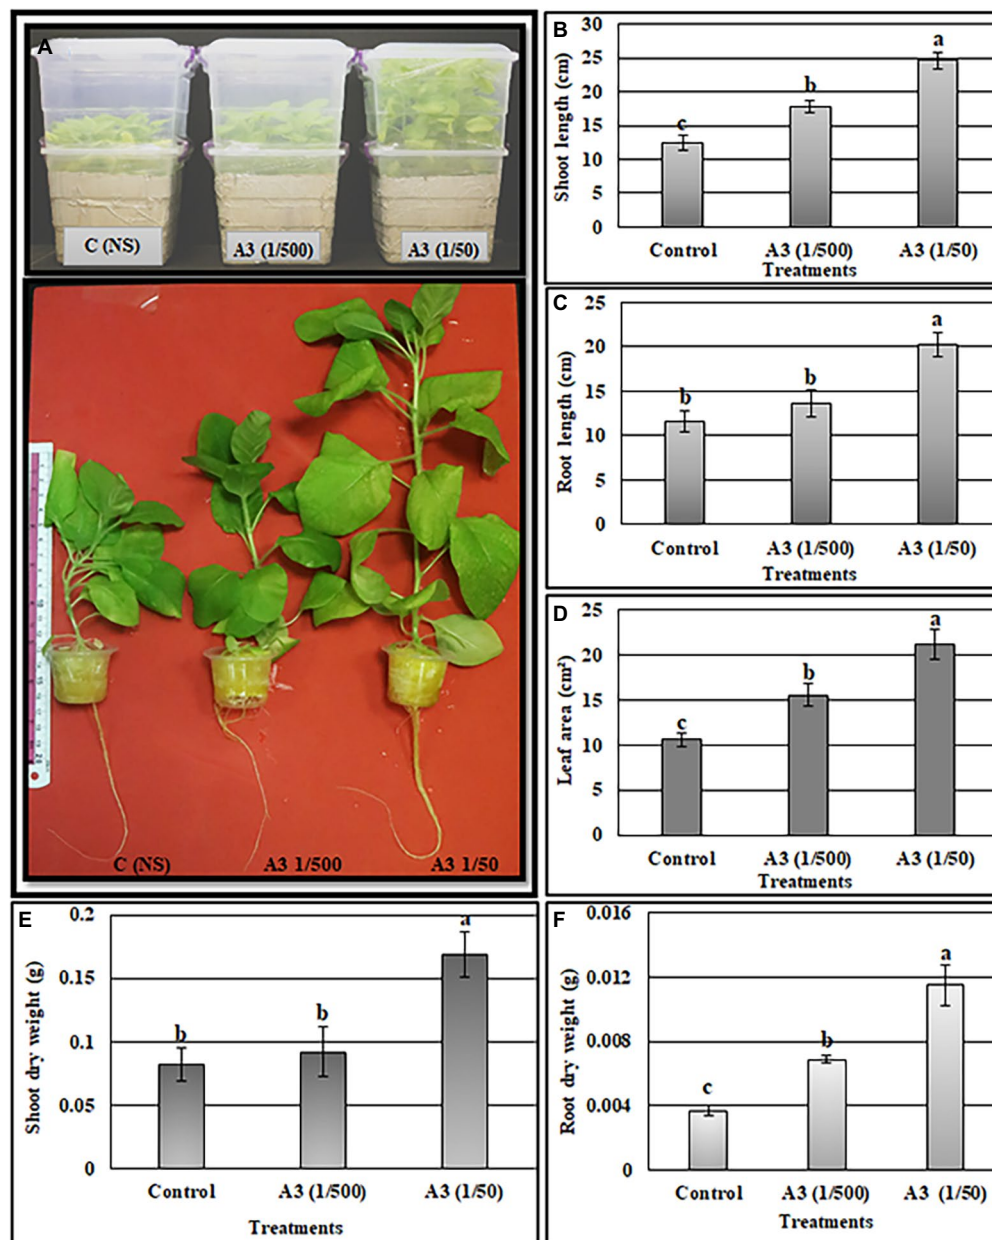

FIGURE 5

Effects of A3 CFF when added at dilutions of 1/50 and 1/500 to nutrient solution (NS) on promoting tobacco seedlings growth cultivated in hydroponics system. Plant morphology (A), shoot length (B), root length (C), leaf area (D), shoot dry weight (E), root dry weight (F). Different letters on bars represent the significant values according to Duncan's test ($p < 0.05$).

K^+ uptake in shoots and roots (Figure 7F). Nevertheless, plants inoculated with A3CFF contained significantly more K^+ compared to non-inoculated plants under both control and salt stress conditions (Figure 7F). Thus these results demonstrated that the A3CFF treatments of plants cultivated in NS with 250 mM NaCl had no effect on Na^+ and K^+ concentrations in shoots and roots, respectively. On the other hand, it decreased Na^+ in roots but increased K^+ in shoots (Figures 7E,F).

In an attempt to understand the mechanisms by which A3CFF helps plants to cope with high salinity, the expression profiles of

multiple salt stress genes (NtHKT1, NtNHX1, NtSOS1, NtSOD, and NtCAT1) were investigated in plants treated with A3CFF and 250 mM NaCl. Adding A3CFF to NS with or without 250 mM NaCl resulted in clear and significant upregulation in both roots and leaves of NtSOD and NtCAT1, which are implicated in the antioxidative mechanisms (Figures 8D,E). The highest expression levels of these two genes were recorded in the leaves and roots 72h after the addition of A3CFF to NS with 250 mM NaCl. The other three salt stress-associated genes examined, NtHKT1, NtNHX1, and NtSOS1, are the key determinants of Na^+ and K^+ homeostasis in plant cells

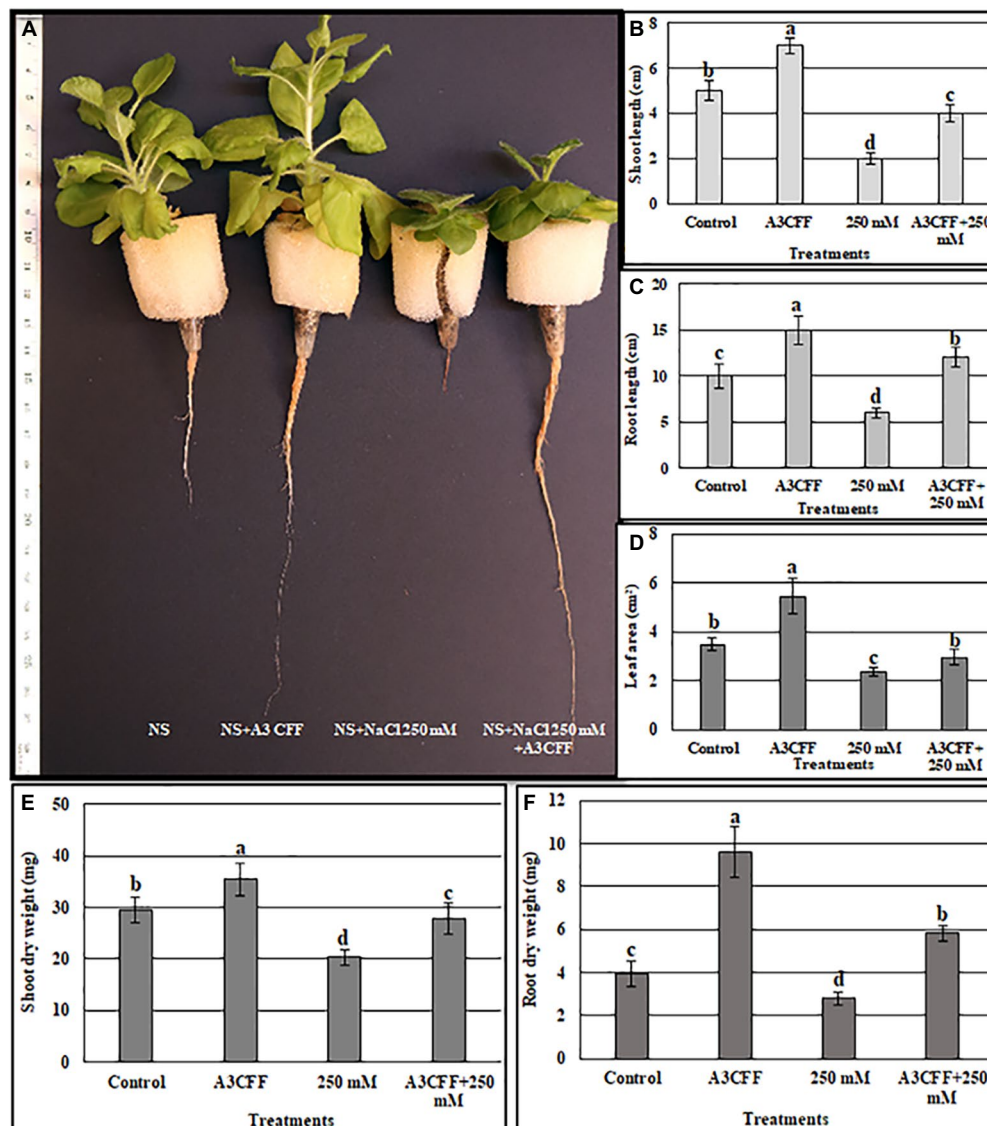

FIGURE 6
Evaluation the ability of A3 CFF to alleviate salt stress when added at 1:50 dilution to NS. (A) plant morphology photographed after 1 month of treatment, Shoot length (B), Root length (C), Leaf area (D), Shoot dry weight (E), and Root dry weight (F) of tobacco seedlings grown in NS (control), in NS with CFF (A3CFF), with NaCl (250mM), with 250mM NaCl and CFF (A3CFF+250mM). Different letters on bars represent the significant values according to Duncan's test ($p < 0.05$).

and were upregulated following A3CFF treatment (Figures 8A–C). The Na^+/H^+ antiporters (NtNHX1 and NtSOS1), which help plants to avoid Na^+ build-up in shoots were significantly upregulated in A3CFF-treated plants grown in NS with 250 mM NaCl compared to those cultivated only in the presence of salt stress. Moreover, this accumulation was higher in roots compared to leaves (Figures 8B,C).

Evaluation of A3CFF on chemical fertilizer inputs

The effectiveness of A3CFF in decreasing chemical fertilizer inputs without affecting plant growth was

investigated by growing plants in 0.5NS supplemented with 1:50 dilution of A3CFF, 0.5NS alone, or full-strength NS (Figure 9A). Plants cultivated in 0.5NS and 1:50 A3CFF showed significantly enhanced growth parameters compared to plants cultivated only in NS or 0.5NS. Specifically, shoot/root length, dry weight, leaf number, and leaf area of plants grown in 0.5NS with 1:50 A3CFF were 160, 225, 209, 123, 142, and 180%, respectively, of those values for plants grown in full NS (Figures 9B–G). These results revealed that A3CFF was able to compensate for the decrease in NS to half strength, suggesting that A3CFF can minimize the chemical fertilizers required for hydroponic systems without harming plant growth.

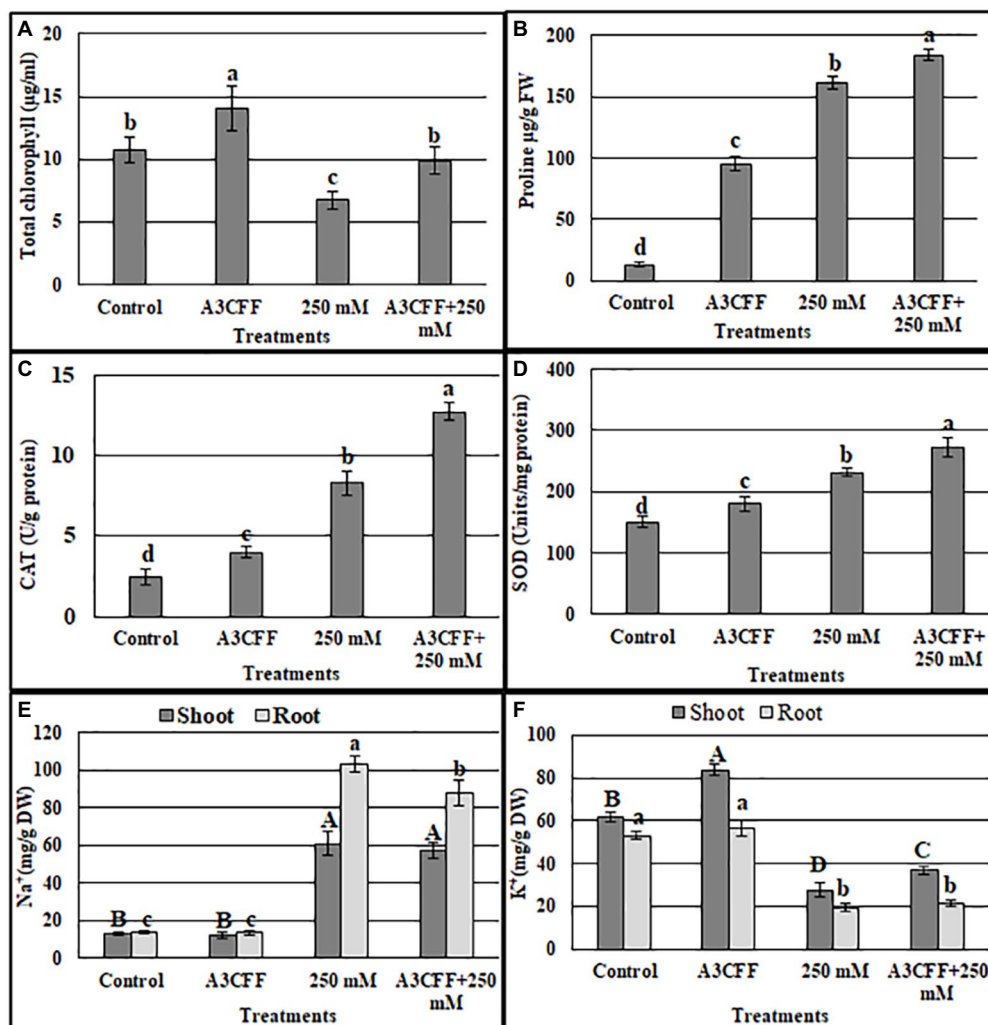

FIGURE 7

Estimation of total chlorophyll content (A), proline accumulation (B), catalase (C), and SOD (D) activities, sodium (E) and potassium (F) contents in the tobacco seedlings grown in: NS (control), NS with A3 CFF, NS with 250mM NaCl (250mM), NS with 250mM NaCl and A3 CFF (A3CFF+250mM). Values are the mean of five replicates \pm SD. Different letters on bars represent the significant values according to Duncan's test ($p < 0.05$).

The effects of the A3CFF on expression levels of several genes involved in plant growth, including DET, DWF4 (brassinosteroid biosynthesis), YUCCA6-like, TRYP1 (auxin biosynthesis), and NR1 and NRT1 (nitrogen-use efficiency) were examined in tobacco leaves and roots. Transcripts of all six genes were upregulated in both leaves and roots after A3CFF application (Supplementary Figure S5). The greatest transcript accumulation was observed for the YUCCA6-like and NR1 genes, which were most upregulated after 48 h and 72 h of treatment. Based on our results, we propose that A3CFF can induce the expression of growth-regulating DET2, DWF4, YUCCA6-like, and TRYP1 genes, likely explaining the observed plant growth stimulation. Moreover, accumulation of transcripts for the nitrogen-use efficiency-related genes NR1 and NRT may explain the compensation of A3CFF for decreased fertilizer levels in 0.5NS media.

Discussion

The main goals of smart agriculture are to assure both the quality and quantity of crops 'yield by developing organic and sustainable production systems. For this, the development of hydroponic systems ensures the reduction of fertilizer inputs and water consumption. Also, biostimulants are used in combination with conventional fertilizers to improve nutrient use efficiency and/or quality of crops (Halpern et al., 2015). The plant rhizosphere constitutes a valuable source of beneficial microorganisms that play important roles in shoot and root growth enhancement. PGPFs directly and indirectly influence both growth and productivity of a wide range of host plants with one study estimating that approximately 44% of rhizosphere fungal isolates are PGPFs (Hossain et al., 2017). In our study, a fungus designated *P. olsonii* was isolated from the

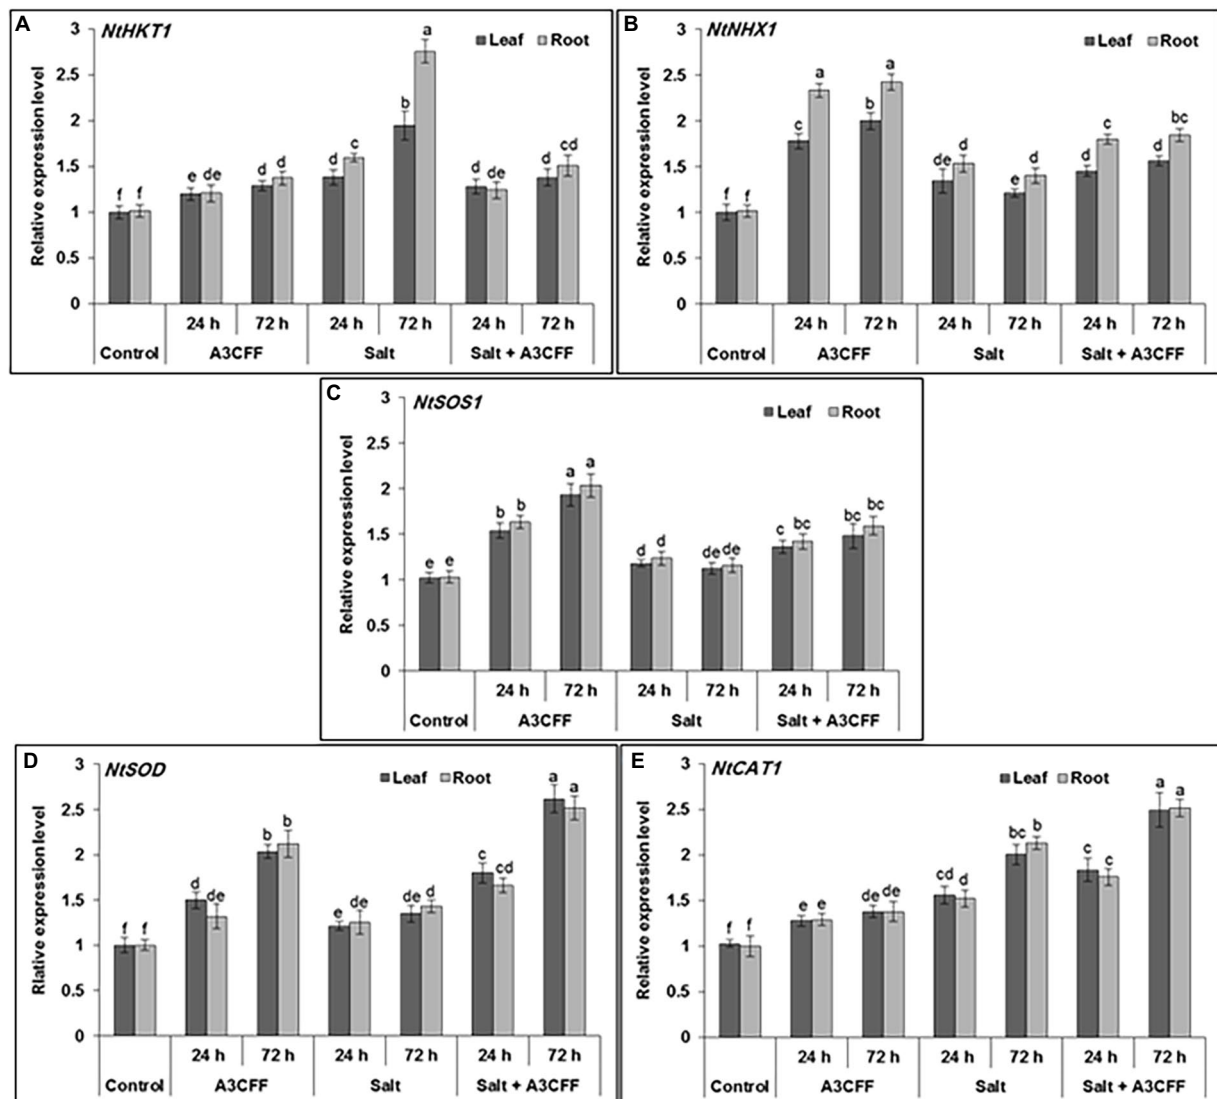

FIGURE 8

Quantitative RT-PCR analysis showing the effect of A3 CFF on gene expression levels of ROS-related and stress-responsive: HKT1 (XM_015785756), NHX1 (XM_015206776), SOS1 (KY752550), SOD (XM_019401370) and CAT (XM_009795943). The qRT-PCR was performed using RNA extracted from leaf and root at 0, 24, and 72h of salt (250mM of NaCl) application. Actin gene was used as reference.

rhizosphere of the extremophile plant *A. littoralis*. This fungus was found to significantly promote plant growth in solid or liquid culture media. Based on morphological and microscopic observations, the A3 fungus was identified as a *Penicillium* species, the morphological characteristics were in agreement with *Penicillium* description reported by Frisvad and Samson (2004). The ITS region has previously been shown to be an efficient tool for identifying huge numbers of fungal species and can help accommodate barcode gaps between inter and intra specific variation (Schoch et al., 2012). Furthermore, within the genus *Penicillium*, ITS marker has been noted to work well for providing species information (Visagie et al., 2014). Basing on the ITS sequences, the A3 fungus was identified as *P. olsonii*.

Our results showed that the optimum growth of A3 fungus is at 27°C but completely inhibited at 40°C. This finding is consistent with Diaz et al. (2002), who reported that *P. olsonii* grows at temperatures between 10°C and 25°C. In addition, the growth of *Penicillium marneffei* is dramatically inhibited at 40°C (Cao et al., 2007). As the A3 was isolated from salty soil we investigated its tolerance to the presence of NaCl in growth media. The results showed that A3 fungus tolerated up to 1,000 mM NaCl and it is an obligate halophile strain since its greatest growth was observed in the presence of 200 mM NaCl. This result is consistent with previous reports, as the growth of *P. olsonii* isolated from a sausage was enhanced by adding 3% NaCl to the media (Diaz et al., 2002). Moreover, previous research demonstrated that *P. spathulatum* grows in medium containing 5% NaCl (Frisvad et al., 2013).

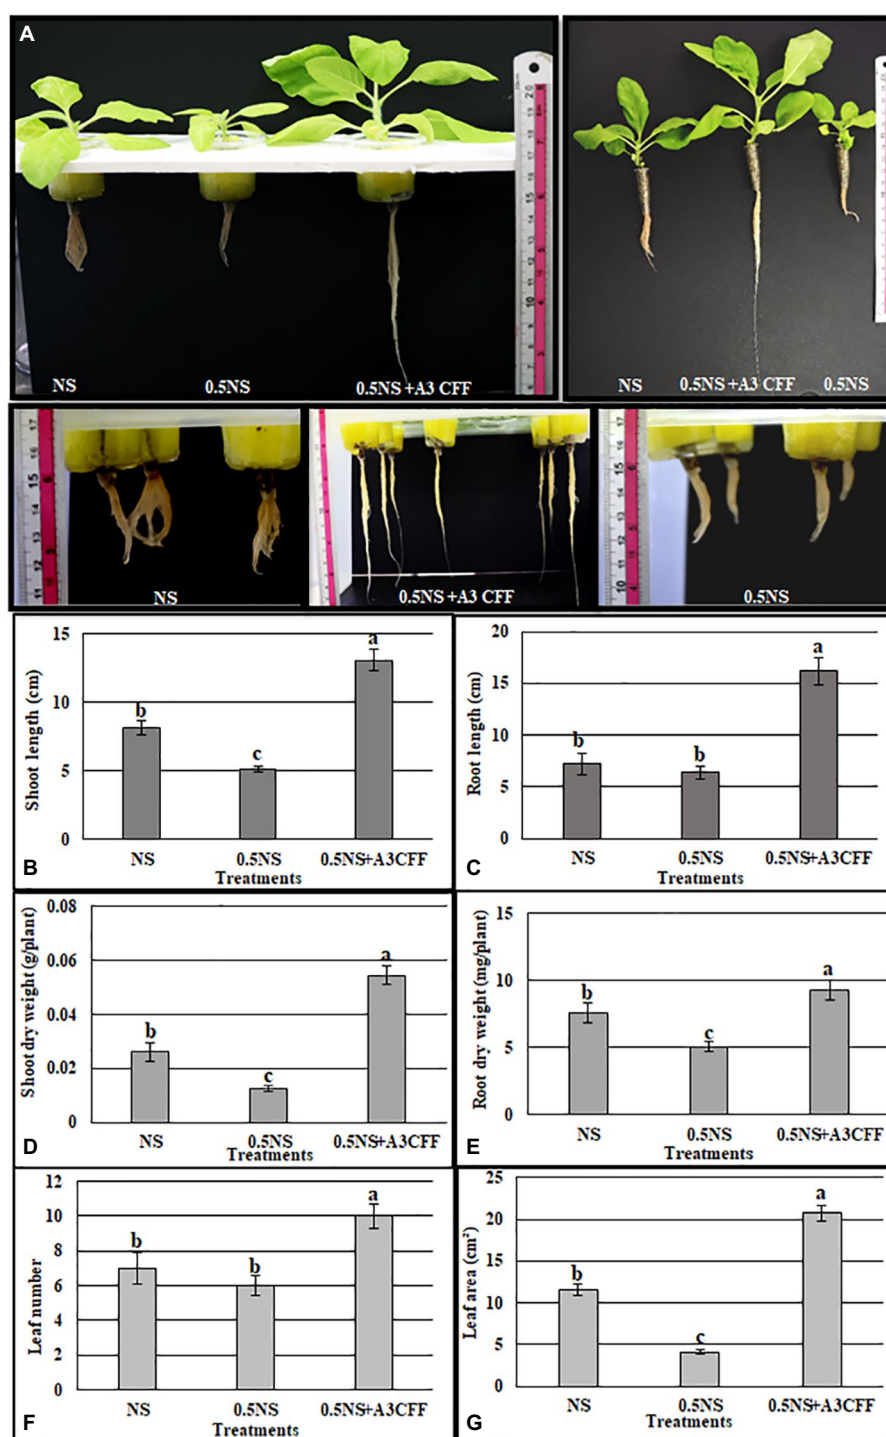

FIGURE 9

Effect of A3 CFF on tobacco plant growth cultivated in hydroponic system and in the presence of half strength NS (0.5NS). (A) Phenotypes of tobacco seedlings grown hydroponically in full NS, in 0.5 NS, in half NS supplemented with 1:50 dilution of A3 CFF (0.5NS+1:50CFF). The photos were taken after 1month following treatments. Shoot length (B), root length (C), shoot dry weight (D), root dry weight (E), leaf number (F), and leaf area (G) in tobacco seedlings grown in 0.5 NS. Values are the mean of five replicates ± SD. Different letters on bars represent the significant values according to Duncan's test ($p < 0.05$).

Fungal culture filtrates can contain metabolites, which are chemicals produced by fungi *via* multi-step enzymatic pathways. These metabolites include amino acids, mycotoxins,

cyclic aromatic peptides, phenols, terpenoids, and plant growth regulators (Ogórek, 2016). In this study, we demonstrated that the A3 fungus secreted auxin, especially when the culture media

was enriched with L-tryptophan. Several fungal species that interact with plants have been revealed to produce and secrete auxin (Chanclud and Morel, 2016). The endophyte *Penicillium* sp. isolated from the Halophyte plants was reported to produce IAA (Kondrasheva et al., 2022). Similarly, *Phoma glomerata* and *Penicillium menonorum* can synthesize IAA, which may cause the significant growth increases detected in cucumber plants cultivated with both species (Babu et al., 2015; Waqas et al., 2015).

The quantitative evaluation of plant growth promotion by the A3 fungus was initially performed by directly applying A3 mycelia to liquid MS culture media. The most important value reflecting the growth-promoting activity of A3 fungus is the dry biomass production, which is 4.8 times higher compared to control plants. Similarly, *Penicillium menonorum*, *Penicillium citrinum*, and *Penicillium simplicissimum* were reported to increase the growth of cucumber, sunflower, and *A. thaliana* plants, respectively (Hossain et al., 2007; Babu et al., 2015; Waqas et al., 2015).

Cell-free culture filtrates produced by PGPFs have been found to effectively stimulate plant growth (Hossain et al., 2017), therefore we examined effects of A3CFF from cultures on plant growth. All tested dilutions (1:500, 1:1000, 1:2000) in MS liquid medium, resulted in significant increases of tobacco seedling growth parameters. Moreover, biochemical analyses of plants grown in all A3CFF dilutions revealed high levels of chlorophyll, proline, high SOD and CAT activities. The highest growth effects were observed by using a dilution factor of 1:500 of A3CFF. Moreover, it was demonstrated that the A3CFF activity was conserved even following storage at 4°C for 1 year. To our knowledge, this represents a novel investigation of CFF characteristics. This is very important result for applied practices to integrate the A3CFF into nutritive solutions for hydroponics system. Based on these results, the effects of two concentrations of A3CFF (1:50, 1:500) on plant growth in NS were examined. Only the 1:50 dilution of A3CFF significantly enhanced all growth parameters of tobacco seedlings. Similarly, the CFF from *Penicillium citrinum* cultures induces growth stimulation when applied to *Atriplex gemelinii* seedlings cultivated in solid agar medium, this was attributed to the secondary metabolites secreted by this fungus (Khan et al., 2008). In addition, the application of filtrate from *Penicillium simplicissimum* GP17-2 cultures was as effective as living *Penicillium* in promoting the growth of *Arabidopsis*. In contrast, while direct application of *Penicillium* sp. GP16-2 promoted plant growth, CFFs from *Penicillium* sp. GP16-2 cultures failed to enhance growth (Hossain et al., 2007, 2008). Besides improving plant growth, it was found that the cell-free culture filtrate from the PGPF *P. indica* cultures increased callus growth and induced lignin production (Kumar et al., 2012; Baishya et al., 2015).

As described above, A3CFF diluted in NS enhanced proline synthesis as well as SOD and CAT activities in tobacco

seedlings grown in MS liquid medium. Several studies have demonstrated that proline is involved in osmotic homeostasis adjustments and that antioxidant enzymes such as SOD and CAT are important components of salt tolerance mechanisms in plant (Kumar et al., 2018; Ghosh et al., 2022). Basing on these findings, we tested the ability of A3CFF to alleviate salt stress in tobacco seedlings. Effects of salt stress were evident for tobacco plants grown in NS containing 250 mM NaCl, however, the addition of a 1:50 dilution of A3CFF increased all growth parameters relative to control plants. These results could be explained by the presence of IAA in the A3CFF and the significant increases in activities of SOD, CAT and levels of proline biosynthesis in treated plants. To develop sustainable approaches for salt stress alleviation, many beneficial microorganisms have been used that are efficient, low-cost, and readily adaptable (Fan et al., 2016). The harmful effects of excess salt not only disturbs ionic homeostasis and water uptake, but also causes inadequate oxidative stress responses and imbalances of growth-regulating hormones (Khalid and Aftab, 2020). The auxin secreted by cultured fungi may thus play a major role in adjusting the hormonal balance of stressed plants, contributing to stress alleviation. The application of *Phoma glomerata* and *Penicillium* sp. cultures containing IAA to cucumber plants significantly increased biomass and related growth parameters during NaCl and polyethylene glycol stresses (Waqas et al., 2012). On a related note, the IAA-producing fungus *Aspergillus aculeatus* accelerates the growth of bermudagrass under salt stress (Xie et al., 2017). It has also been reported that the endophytic fungus *Yarrowia lipolytica* promotes the growth of salt-stressed maize plants by controlling plant metabolism and hormonal (IAA and ABA) secretions (Jan et al., 2019). Likewise, application of the PGPFs *Trichoderma longibrachiatum*, *Trichoderma harzianum*, and *Paecilomyces formosus* promoted the growth of wheat, *Suaeda salsa* L, and cucumber plants, respectively, under high salinity conditions (Khan et al., 2012; Chen et al., 2016; Zhang et al., 2016).

Environmental stresses often reduce the chlorophyll content of plants, while chlorophyll accumulation is considered a potential indicator of salinity tolerance (Shah et al., 2017). In the present study, it was determined that the A3CFF significantly increased the chlorophyll content of tobacco seedlings under both normal and salinity stress conditions. Under salt stress conditions, Khan et al. (2011) observed that the growth, chlorophyll content, and photosynthesis rates were significantly higher in plants treated with *Penicillium funiculosum* LHL06 than in untreated plants. In the same way, the chlorophyll content was found to be higher in salt-stressed maize seedlings that had been inoculated with *Yarrowia lipolytica* than in uninoculated plants (Jan et al., 2019). Proline is a low molecular weight amino acid that is a well-known as osmoregulator and ROS scavenger for the salt stressed plants (Bhuyan et al., 2019; Tisarum et al., 2020). Treatment with *Trichoderma*

longibrachiatum and *Trichoderma harzianum* has been found to significantly increase the proline levels in salt-stressed wheat and *Brassica juncea* L plants, respectively (Ahmad et al., 2015; Zhang et al., 2016). In our study, under control conditions, the A3CFF was observed to exert no effect on the Na⁺ accumulation in plants (shoots and roots), although it significantly increased the K⁺ content of leaves. However, under salinity stress conditions, the A3CFF significantly decreased the Na⁺ content of roots and increased the K⁺ accumulation in leaves. It has previously shown that endophytic symbiotic fungi can both improve nutrient assimilation and assist in ionic homeostasis maintenance in saline-stressed plants (Gupta et al., 2020). For instance, the colonization of *A. thaliana* with *P. indica* under salt stress has been found to lower the Na⁺/K⁺ ratio (Abdelaziz et al., 2017). Similarly, the saline stress of *Suaeda salsa* L was determined to be counteracted by *Trichoderma harzianum* T83 colonization, thereby resulting in a higher K⁺ uptake (Chen et al., 2016).

In the experiments conducted in this study, it was demonstrated that the A3CFF induced the growth of roots under salt stress, a finding that may be explained by the low Na⁺/K⁺ ratio observed in such plants. The analysis of the expression profiles of NtCAT1 and NtSOD confirmed the biochemical experimental results describing the CAT and SOD activity levels. Indeed, the A3CFF induced the upregulation of NtCAT1 and NtSOD in both the presence and absence of NaCl. Moreover, the genes encoding the key Na⁺ transporters (NtSOS1, NtNHX1, and NtHKT1) involved in salt tolerance were also shown to be upregulated by the A3CFF treatment. Based on these results, it is likely that the enhanced salt tolerance observed in the presence of A3CFF at 250 mM NaCl occurred *via* the regulation of Na⁺ homeostasis by the Na⁺ transport system control at the whole-plant level. In addition, the enhancement of the antioxidant activities (CAT and SOD) may also have helped the plants to endure salinity stress.

It has been reported that plant growth-promoting microorganisms are able to increase the nutrient use efficiency of plants. This effect allows for crop production without yield loss in NS with 50% lower fertilizer inputs compared to in full NS (Da Costa et al., 2013). Our work revealed that reducing NS strength by 50% did not decrease plant growth when the NS was supplemented with a 1:50 dilution of A3CFF. Compared to plants grown in full NS, plants grown in 0.5NS showed significantly reduced shoot length, shoot dry weight, and root dry weight, and leaf area, while the addition of A3CFF significantly increased these parameters. In order to ultimately develop sustainable agricultural practices, several studies have been performed that use PGPFs to decrease the chemical inputs required for maximal yield (Xia et al., 2019). In one such study, tomatoes cultivated in pots or in field trials that were treated with 25% of typical commercial

fertilizer levels plus *Trichoderma*-enriched bioorganic fertilizer produced yields equivalent to tomato plants treated with normal amounts of chemical fertilizer (Ye et al., 2020).

In an attempt to explain the mechanisms underlying the promotion of plant growth by A3CFF, the effects of the A3CFF treatment on the accumulation of transcripts for six genes related to growth, brassinosteroid biosynthesis (DET2, DWF4), auxin biosynthesis (YUCCA6-like, TRYPI), and nitrogen-use efficiency (NR, NRT1) were examined. All six genes were found to be upregulated in both roots and leaves following the addition of the A3CFF to the growth media. To our knowledge, there have been no previous reports showing a role for *P. olsonii* activation of genes related to plant growth. However, other species of PGPFs have been shown to influence growth-related gene expression, as *P. indica* was able to stimulate the expression of auxin-responsive genes and nitrate reductase-encoding genes in Arabidopsis and tobacco seedlings (Sherameti et al., 2005; Meents et al., 2019). Similarly, inoculation with *Trichoderma* increased accumulation of auxin-regulated gene transcripts in Arabidopsis and triggered ethylene/indole-3-acetic acid signaling in tomato plants (Contreras-Cornejo et al., 2009; De Palma et al., 2019). However, our study is the first report demonstrating the effect of A3CFF on genes involved in brassinosteroid biosynthesis.

Conclusion

In conclusion, this study isolated a fungus (A3) from the rhizosphere of the halophyte grass *A. littoralis*, identified as *P. olsonii*, and for the first time, described its role as a PGPF. This strain was determined to significantly promote tobacco plant growth in MS and NS, both directly *via* the application of A3 mycelium and through the application of its CFF. In addition, the A3CFF appeared stable following storage at 4°C for 1 year. The application of the A3CFF decreased the chemical fertilizer levels in NS by 50% and also significantly increased plant growth when compared with the control conditions. Finally, the A3CFF was found to mitigate salinity stress by inducing morphological, biochemical, and molecular changes in salt-stressed plants. Thus, the A3CFF could be used in hydroponics as a promising biotechnological tool for enabling the reduction of expensive chemical fertilizer inputs without compromising the yield, thereby improving agriculture and sustainability.

Phosphite represents a reduced form of phosphate that belongs to a class of crop growth-promoting chemicals termed biostimulants. Previous research has shown that phosphite application can enhance root growth, but its underlying mechanism, especially during environmental stresses, remains elusive. To uncover this, we undertook a series of morphological and physiological analyses under nutrient, water and heat stresses following a foliar application in wheat. Non-invasive 3D imaging of root system architecture directly in soil using X-ray Computed Tomography revealed that phosphite treatment improves root architectural traits and increased root biomass. Biochemical and physiological assays identified that phosphite treatment significantly increases Nitrate Reductase (NR) activity, leaf photosynthesis and stomatal conductance, suggesting improved Nitrogen and Carbon assimilation, respectively. These differences were more pronounced under heat or drought treatment (photosynthesis and photosystem II stability) and nutrient deficiency (root traits and NR). Overall our results suggest that phosphite treatment improves the ability of plants to tolerate abiotic stresses through improved Nitrogen and Carbon assimilation, combined with improved root growth which may improve biomass and yield.

KEYWORDS

phosphite, biostimulants, wheat, oilseed rape, resource use efficiency, nutrition use efficiency, nitrate reductase

Introduction

Global food security is a key challenge facing world agriculture (IAASTD report, 2009; Royal Society, 2009; Godfray et al., 2010; Wheeler and von Braun, 2013; Myers et al., 2017). The world population is estimated to reach ~8.3 Bn by 2030 with the majority of that increase occurring in the developing world (IAASTD report, 2009; Royal

Society, 2009). The need to feed this growing population sustainably and against the significant threats to food crop harvests arising from climate change could not be more pressing (Hirabayashi et al., 2013; Ray et al., 2013; Ray et al., 2015). With no more agricultural land available, increases in food production of between 40–50% must be achieved through a sustainable intensification of agriculture to meet the future food demand (Wheeler and von Braun, 2013). This includes both improving and developing more diverse agricultural systems for low input agriculture against a backdrop of increasing climate unpredictability that can severely affect crop production (Wheeler and von Braun, 2013). There have been several studies and reports that suggest that improvement in root architecture can have profound impact in improving crop productivity and resource use efficiency (Lynch, 2011; Lynch, 2013; Lynch et al., 2014; Lynch, 2015; Lagunas et al., 2019; York et al., 2013).

Biostimulants are a class of biologically active chemicals that are added to plants during growth or to seeds before sowing that have been shown to have beneficial effects on growth and development (Brown and Saa, 2015; Yakhin et al., 2017; Xu and Geelen, 2018). Widely used biostimulants are typically derived from seaweed extracts and both crude extracts and more refined components rich in amino acids and peptides and polysaccharides are used. Seaweed based biostimulants have been shown to improve plant tolerance to abiotic stresses and have also been implicated in improving nutrient uptake (Khan et al., 2009; Conrath, 2011; Nair et al., 2012; Savvides et al., 2016; Rouphael and Colla, 2020). Similarly, protein hydrolysate based biostimulants have been reported to improve germination rate, plant growth and productivity in a range of crops (Colla et al., 2017). The biostimulant market is a multi-billion-dollar industry (Sible et al., 2021): based on Market date forecast, Market and Markets and Dunham Trimmer European Biostimulants Industry Council (EBIC) estimate biostimulants market in EU alone to be in the range of 1.5–2 billion USD in 2022 with a compound annual growth rate (CAGR) of 10–12% emphasizing its major importance in agriculture (EBIC, 2022).

Biostimulants are not nutrients, nor fertilizers, or pesticides and can affect plant growth and development in a variety of ways throughout the life cycle of the crop, from seed germination to plant maturity (Yakhin et al., 2017; Fleming et al., 2019). They have been shown to improve crop quality, yield and tolerance to abiotic influences (Conrath, 2011; Savvides et al., 2016) and therefore can become a key component in integrated sustainable crop production playing an important role in securing yields and increasing efficiency (Brown and Saa, 2015; Yakhin et al., 2017; Xu and Geelen, 2018). If we understood how they function we may be able to develop new traits and mechanisms to enhance yield, however this information is lacking.

Here, we focused our attention on phosphite based biostimulants. Phosphite (Phi) is a reduced form of phosphate (Pi) and has been shown to have growth promoting properties in

nutrient-replete conditions in oranges, celery, satsuma, wheat, oilseed rape and several other plants (Albrigo, 1999; Lovatt and Mikkelsen, 2006; Thao and Yamakawa, 2009; Rossall et al., 2016) but not in all cases (Carswell et al., 1996; Carswell et al., 1997; Forster et al., 1998; Ticconi et al., 2001; Varadarajan et al., 2002; Thao and Yamakawa, 2009). Phosphites cannot be used as a sole source of phosphorous as phosphites cannot replace phosphate in biological reactions (Thao and Yamakawa, 2009). There is no evidence that phosphite can replace phosphate whereas phosphite to phosphate conversion by the soil micro bacteria is too slow to provide any growth benefits (Thao and Yamakawa, 2009).

The mode of action of phosphite is still unclear, however, there is some evidence that it is root-specific, and not related to any role as pesticide or fertilizer. In a glasshouse study, carried out in axenic culture, using wheat, oilseed rape, sugar beet and ryegrass Rossall et al. (2016) showed that phosphites improved root biomass by about 30% and seemed to be acting as a specific biostimulant of root growth. Roots provide the means of capturing nutrients and water required to generate a productive photosynthetic canopy. Root anatomical properties such as root length, density, depth, root front velocity and angle could also be utilized to improve resilience in resource-poor conditions to enhance capture of water and mineral elements (Ahmadi et al., 2014). Therefore, phosphites provide scope to increase arable resilience and sustainability by potentially reducing the dependence on expensive nutrient inputs (Panda et al., 2012).

Bread wheat (*Triticum aestivum* L.) provides 20% of the calorific and protein intake in the human diet (Shiferaw et al., 2013). In the UK, grain yields typically reach between 40–95% of their yield potentials (Gobbett et al., 2017) causing large yield-gaps. Here we provide a substantial understanding of physiological mechanisms by which phosphite improves root growth in the UK winter wheat. We also show that improvement of root traits correlates with improvement in both nitrogen (N) and shoot carbon assimilation. We show that phosphite treatment increases the activity of Nitrate Reductase, which is a key enzyme in N assimilation. We propose that phosphite treatment improves plant tolerance of abiotic stresses through improved N and C assimilation which is in turn associated with improved root growth.

Materials and methods

Plant materials and growing conditions

KWS Siskin was used for most experiments including nutrient strength, water and heat temperature and X-ray micro CT imaging experiments to its versatility allowing it to grow in a diversity of sites in the UK. It is a high yield cultivar with a disease resistance rating of 6.5 for *Septoria tritici* and a

high rating for mildew and yellow rust resistance on the UK recommended list (AHDB, 2019). In addition, seven elite UK winter wheat varieties; Evolution, Diego, Leeds, Revolution, Solstice, Siskin and Skyfall were used for initial 2D root phenotyping studies.

Seeds were sieved through a calibrated graduated sieve (Scientific Laboratory Supplies Ltd. Hessle, UK) and a fraction of 2.8–3.35 mm was selected for experiments. Selected seeds were surfaced sterilized using 75% ethanol (1 min) and 30% sodium hypochlorite (10 min) and washed thoroughly using sterile water.

Germination paper assays

Sterilized seeds were germinated on a moist filter paper (Whatman) for 5–7 days at 4°C and 2 days in a controlled environment room set at 16/8h photoperiod (20/15°C). The uniformly germinated seeds (~0.5 cm radicle root) were transferred on to the blue paper germination pouches soaked in 1/6th strength Hoagland's 2.0 (Sigma) (Hoagland and Arnon, 1950) hydroponic media (pH 6.0).

4–5 days old seedlings were treated with a potassium phosphite based formulation (1 L ha⁻¹ + 0.1% NA 13 wetting agent) as a foliar spray, using a calibrated, hand-held spray gun in a volume of water equivalent to 200 L ha⁻¹. Control plants were sprayed with 0.1% NA13 wetting agent only. The root impression underneath the black sheet revealed the position of each seminal root and was marked using a blue permanent marker to indicate the position of the root at the time of the foliar application.

A randomized block design was used with a minimum of 24 replicates per treatment. After 9 days (two-leaf stage), another mark was made on the new position of the roots as well as marking the newly developed roots based on the impression. The pouches were imaged on both the black sheet and the blue paper using a Nikon D600 DSLR camera as described by Atkinson et al. (2015).

Root images were processed using RootNav software as described in Pound et al. (2013) and ImageJ software (NeuronJ) for analyzing the changes in the root development after phosphite application.

X-ray micro CT imaging experiment

Seeds were surfaced sterilized (above) and stratified at 4°C in a square petri-dish containing moist filter paper for 3 days with each seed facing down. After 3 days, they were moved to a 22°C growth chamber and the petri-dish was wrapped in aluminum foil and placed at a 65° angle to allow the root radicle to grow towards gravity.

Soil (sandy loam) was collected from a field under winter wheat at the University of Nottingham experimental farm, Sutton Bonington campus. The soil was air-dried and sieved to <2 mm before being uniformly packed into columns (7.5 cm diameter and 17 cm height). A small yellow pipette tip was placed in the middle top of the soil to 0.5 cm depth before the soil was soaked. This prevents compaction during seed transplanting. The soil moisture was saturated at field capacity 24 hr before the wheat was transplanted. Once the root radicle emerged and was 0.2 cm long, the yellow tip in the middle of the column was removed and the germinating seed was replaced in the soil with roots directly facing downward. Soil of ~1 cm thick was placed over the top to bury the seeds. A completely randomized design was used with a minimum of 10 replicates per treatment. At 4 days after transplanting, the emerging leaves were treated with a potassium phosphite based formulation (1 L ha⁻¹ + 0.1% NA 13 wetting agent) as a foliar spray, using a calibrated, hand-held spray gun in a volume of water equivalent to 200 L ha⁻¹. Control plants were sprayed with 0.1% NA13 wetting agent only. Ten biological replicates were made each and the columns were X-ray scanned at day 0, 6 and 12 after phosphite treatment using a Phoenix Nanotom (GE Measurement and Control Solutions, Wunstorf, Germany) micro CT scanner.

Image processing and analysis of the root system were segmented from the grey-scale micro CT images using the Volume Graphic Studio Max (VG StudioMax) software described by Tracy et al. (2013). The root volume and surface area were all extracted from the VG StudioMax while the root branching and root count were analyzed using semi-automated ROOTh imaging software.

Growth and phosphite application experiments in controlled conditions

For all phosphite treatments hereon, a potassium phosphite based formulation 0-28-19 (O-Phyte) (Omex Ltd.) containing 31.15% PO₃ was used. The 0-28-19 was diluted with water (5mL/L and mixed with 0.1% solution of the wetting agent NA13 (Omex Ltd). This solution containing 0.15% PO₃ was used as foliar spray at the rate of 1L per m². Control plants were sprayed with 0.1% NA13 wetting agent only.

The sterilized seeds were pre-germinated on a moist filter paper in Petri-dishes in the dark at 21°C for 3 days. Uniform-sized seeds with a root radicle of ~0.5 cm were sown in germinating plugs containing compost (John Inness, Norwich UK) and were grown in a glasshouse for 7–10 days until GS12 (Zadoks et al., 1974). Plants were then vernalized at 6°C for 4–5 weeks with a 16/8h photoperiod. Plants were then transferred into a glasshouse with 21°C/15°C day and night temperature and 16/8 h photoperiod for 7 days.

At 7 days post vernalization, plants were transplanted into deep, plastic pots filled with ~0.6–10 mm washed expanded clay pellets (Hydroleca) and maintained in this semi-hydroponic system by daily irrigation as described previously (Rossall et al., 2016). After a week in this semi-hydroponic system, phosphite and control treatments were applied as mentioned above. Root and shoots were harvested at different time points after treatment and dried at 70°C for three days before dry weight calculations.

Nutrient strength experiment

Three different hydroponic media were used in the semi-hydroponic system described above. Two were commercially available media from Omex and Hortimix with a composition of NPK: 20-8-20 + Mg and S with trace elements and NPK: 15-7-30 with trace elements respectively. While the third hydroponic media was a modified laboratory formulated Hoagland's solution with EDTA as the iron chelator. The composition (g/L) of nitrate and phosphate was reduced by half; $(\text{NH}_4)_3\text{PO}_4$, 0.058g; $\text{Ca}(\text{NO}_3)_2$, 0.66g; MgSO_4 , 1.01g; KNO_3 , 0.304g; H_3BO_3 , 0.114g; Cu_2SO_4 , 0.3g; $\text{MnCl}_2(\text{H}_2\text{O})_4$, 0.04g; MoO_3 , 0.0008g; ZnSO_4 , 0.0092g; FeHEDTA, 0.11g. The solution was adjusted to pH 6.0.

For the nutrient strength response experiment, the required amount of the two commercial hydroponic media was diluted with water to make up either $\frac{3}{4}$ or $\frac{1}{2}$ or $\frac{1}{4}$ strength.

Mild drought experiment

At 7 days post vernalisation, plants were transplanted into a 1 m PVC constructed column containing ~0.6 – 10 mm hydroleca and irrigated with the full complement of nutrients using automated irrigation drips. 10 days after transplanting into the 1 m column, the plants were treated with a potassium phosphite based formulation as a foliar spray. The plants were set to a randomized complete block design. A week after the phosphite treatment, the irrigation was restricted and as the hydroleca is inert and does not hold water, the automated irrigator supplied 75 ml of water every 6 h to achieve a moderate drought. The plants were allowed to grow in this condition until they reached Growth Stage 65–69 i.e., mid to late anthesis before the plants were harvested for the shoot and root sampling.

Heat stress experiment

At 7 days post vernalisation, the wheat seedlings were transferred into a pot containing a mixture of soil and

compost (John Innes No.3). All other environmental conditions are the same as above with the exception of the heat treatment. After 14 days at 21°C, they were sprayed with phosphite and were immediately subjected to heat stress of 35°C for 30 days in a controlled environment chamber (Conviron, Winnipeg) followed by an increased temperature of 38°C for 5 days before reducing the temperature back to 22°C for the remainder of the experiment.

Leaf gas exchange measurements and chlorophyll fluorescence

All leaf gas exchange measurements were taken on the uppermost, fully expanded leaf using an infra-red gas analyser (IRGA), Licor 6400XT or 6800 (Licor inc, Illinois, Nebraska). The same IRGA model was used within each experiment. Three types of measurements were made: single time point measurements of photosynthesis at light-saturation (A_{max}), Photosynthesis versus intercellular CO_2 concentration (C_i , A/C_i) analysis and light response curves as described previously by Webster et al. (2016). The photosynthetic model of Farquhar et al. (1980) was fitted using the bilinear method of the 'fitacis' function from the R package PLANTECOPHYS (Duursma, 2015). Except where noted, measurements were made under light-saturated conditions ($1500 \mu\text{mol m}^{-2} \text{s}^{-1}$). The block temperature was maintained at 22°C, the flow rate 500 ml min^{-1} and 60–65% humidity. The CO_2 concentration used was $400 \mu\text{mol mol}^{-1}$ (except where noted). All measurements took between 2 and 3 minutes to achieve stability. The leaf water instantaneous water use efficiency (IWUE) and intrinsic water use efficiency values (iWUE) were obtained from the ratio of photosynthetic CO_2 assimilation (A) to stomatal conductance (g_s), and A_n to leaf transpiration (E) respectively.

Chlorophyll fluorescence

From 5 days after phosphite application, between 11:00 am and 12:00 pm; the top and fully developed leaf was wrapped with a ~3 cm x 3 cm aluminium foil around the upper middle part of the leaf. The leaf was left to dark adapt for 30 mins and the light of the growth chamber was turned off before the measurement started. Handheld FluorPen FP 100 (Photon Systems Instruments, Brno) was used to measure the maximum quantum yield (F_v/F_m) of the dark-adapted leaf from ten biological replicates.

For disruptive analysis, the F_v/F_m was measured from excised leaf segment of 10 biological replicates of phosphite treated and untreated under two contrasting temperatures (Ferguson et al., 2020). The leaf segments were placed on a damp filter paper and the paper was encased between glass

plates. The plates were placed inside a closed 800C FluorCam chlorophyll fluorescence imager (Photon Systems Instrument, Brno) to dark adapt for 1 h before the standard F_v/F_m protocol was run as described by Mcausland et al. (2019).

Spectroradiometer

Hyperspectral reflectance was measured between 11:00 am and 2:00 pm using the ASD Field Spec 4 (ASD Field Spec[®] 4, Boulder, CO, USA) with a spectral range from 350 – 2500 nm. The reflectance measurement was made using the leaf clip in two different leaves of the top fully expanded leaf as described by Robles-Zazueta et al. (2021). The measurements were taken in ten biological replicates. Chlorophyll content was measured on the two top fully expanded leaves using the SPAD meter (SPAD-502 meter, Konika Minolta, Japan).

Nitrate reductase assay

Nitrate reductase assay was done as described previously (Kim and Seo, 2018). A root or shoot tissue (500 mg) was ground using liquid nitrogen and suspended in 750 μ l of chilled extraction buffer (250 mM Tris-HCl, pH8, 1 mM EDTA, 1 μ M Na₂MoO₄, 5 μ M FAD, 3 mM DTT, 1% BSA, 12 mM 2-mercaptoethanol, 250 μ M PMSF) and centrifuged at 17,000 g for 5 min. 150 μ l of supernatant was added to 850 μ l of reaction buffer (40 mM NaNO₃, 80 mM Na₂HPO₄, 20 mM NaH₂PO₄, 0.2 mM NADH) and incubated for 2 h at room temperature. 200 μ l of 1% sulfanilamide and 200 μ l of 0.05% N-(1-naphthyl) ethylenediamine were added to each reaction and incubated at room temperature for another 15 mins and absorbance measured at 540 nm. Protein contents were measured using the Bradford assay (Bradford, 1976) and NR activity was expressed as specific activity (units/mg protein).

Statistical analysis

Statistical analysis was performed within the R software environment (R Core Team, 2014) and GraphPad Prism 9.01 for Windows (La Jolla, CA, USA) for figures. Student T-tests were used in comparisons between two samples. Analysis of variance (ANOVA, one-way and two-way) with posthoc Tukey's multiple comparison procedure was used except where indicated otherwise. Pearson's product-moment correlation coefficient was performed for all pairwise traits interactions using the 'rcorr' correlation analysis from the R package Hmisc, using the 'corrplot' function (Mckenna et al, 2015).

Results

Phosphite treatment improves root growth in wheat

Initially we tested the effect of phosphite on young seedlings in six commercial winter wheat varieties Diego, Evolution, Leeds, Revolution, Siskin and Skyfall. Early seedling stage root phenotyping was done using 2D high throughput root phenotyping system (Atkinson et al., 2015). Four out of six commercial winter wheat varieties; Diego, Leeds, Siskin and Skyfall showed a significant increase (Tukey's HSD $P < 0.05$ and lower) in the seminal root length (Supplementary Figure 1A. The mean of the seminal root count in Diego was significantly ($P < 0.05$) increased by 18% while its lateral root counts significantly ($P < 0.05$) increased by 38% and Leeds by 58%. Interestingly, Evolution and Revelation did not respond to phosphite treatment indicating a varietal difference in their response to phosphite treatment.

In addition to its response to phosphite, winter wheat cultivar Siskin is more resistant to powdery mildew infection and hence was sub-selected for further experiments under reduced nutrient strength. Using the early-stage root phenotyping set up described above, Siskin plants were grown under reduced nutrient strength with and without phosphite treatment. Figure 1A shows superimposed 2D images of young Siskin seedlings showing improvement in seminal and nodal root length at 7 days post phosphite treatment and reveals an increase in the length and number of the nodal and seminal roots (Figure 1B).

X-ray CT imaging reveals that phosphite treatment improves root architectural traits

To test the impact of phosphite on root growth in soil, pre-germinated wheat (variety Siskin) seeds (~1cm radicle roots) were sown into sandy loam soil in small columns (7.5 x 17cm). 4d old seedlings were treated with a potassium phosphite based formulation through the foliar spray and X-RAY CT imaging was performed at 0, 6 and 12 d post-application (Figure 2)

The result was computed based on the changes between time points. The differences between day 6 and day 0 of treatment are referred to as $\Delta(D6-D0)$, similarly between day 12 and 6 and between day 12 and 0 as $\Delta(D12-D6)$ and $\Delta(D12-D0)$, respectively. The CT results revealed that at 6 d post-application $\Delta(D6-D0)$ there was a significant increase in the root volume ($P = 0.027$) and the surface area of the root ($P = 0.036$) by 28% and 27%, respectively. The increase in both the

root volume and the surface area in response to the phosphite application can also be seen at the later time points but the increase was not significant (Figures 2G, H). There was also a significant increase in seminal and nodal root length ($P=0.042$) by 22% and lateral root count ($P=0.002$) by 39% (Figures 2I, K) 6 days after the phosphite treatment. We also found a significant positive correlation between the root biomass and lateral root count at 12 days post treatment; root surface area and root volume after 6 days post treatment ($r=0.42$, $r=0.43$ and $r=0.60$ respectively; Supplementary Figure 2). The shoot biomass also showed positive correlation with the root volume ($r=0.55$).

Phosphite treatment improves root biomass under nutrient deficiency

Roots are crucial for nutrient and water uptake from the soil. To test if improved root growth can lead to improvement in nutrient uptake, the plants were grown under three different nutrient strength solutions: full strength (100%), $\frac{3}{4}$ strength (75%) or $\frac{1}{2}$ strength (50%). 10-day post transfer to the hydroponic set up, plants were subjected to foliar phosphite application. The growth was monitored through detailed physiological measurements and destructive root and shoot biomass analysis (30- and 45-days post treatment).

As shown in Figure 3A, phosphite treated plants showed a significant increase in root biomass at all three nutrient strengths compared to the control treatment. Phosphite treated plants at 75% nutrient strength solution showed the highest increase in root dry weight (51%) compared to control ($P=0.0258$); whereas there was a 34% increase in root dry weight at 100% strength nutrient solution ($p=0.0476$); and 40% increase at 50% strength

nutrient solution ($p=0.0128$) compared to control treatments. Moreover, phosphite treated plants grown in reduced nutrient strength solutions (75% and 50%) outperformed the full strength non-treated plants. All three nutrient concentrations also showed an increasing trend (17%, 22% and 25% respectively) in shoot biomass in phosphite treated plants compared to control treated plants.

To further validate these findings, we designed another experiment where plants were grown under formulated Hoaglands solution with half strength N and P and growth measurements were done at 2, 4 and 8 weeks post treatment. At all the three time points, phosphite treated plants had significantly longer (27, 20 and 39%, respectively) roots compared to the untreated control (Supplementary Figure 3). Results also show a significant increase in root dry weight by 28% ($P=.045$) in phosphite treated plants 2 weeks post application further confirming the observation (Figure 2) that phosphite treatment improves root growth and may help promote seedling establishment. In addition, a significant positive correlation was also seen in the root dry weight and maximum root length in both week 2 and 4 after treatment ($r=0.6$ and $r=0.53$, respectively).

Despite improvement in root growth and root dry weight, we did not detect any differences in the shoot dry weight between treated and untreated plants (Supplementary Figure 3Biii).

Phosphite treatment improves root length under limited water condition

Roots can establish at depths much greater than the pots commonly used in controlled environments. To measure root

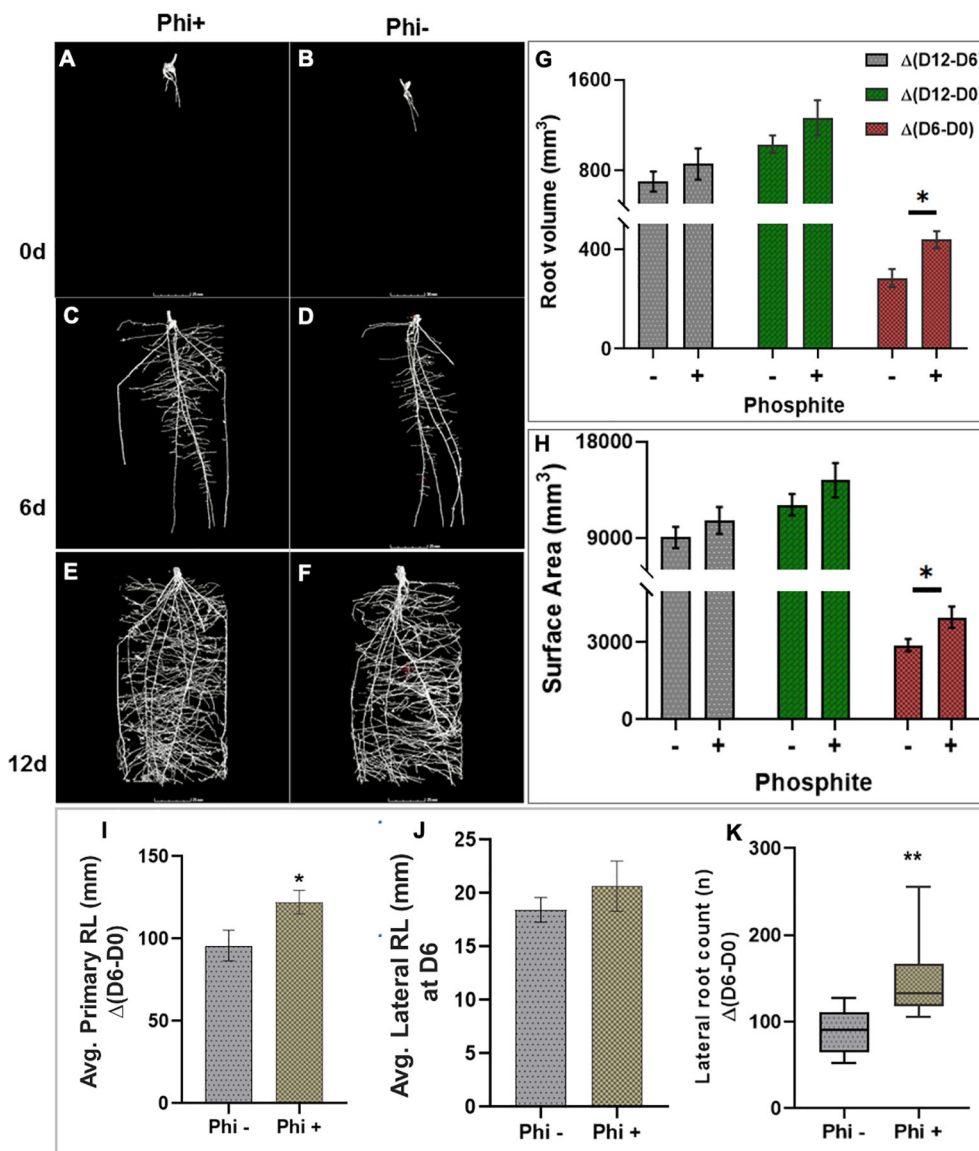

FIGURE 2

X-ray CT imaging in wheat revealed that phosphite improves root architectural traits. (A–H). Time course X-ray CT imaging at 0, 6 and 12 d post treatment (A–F) reveals that phosphite treatment results in increase in root volume (G) and root surface area (H). (I–K). Average primary root length (I) average lateral root length (J) and lateral root count (K). Wheat seedlings grown in sandy loam soil in small columns (7.5 x 17cm). 4 day old seedlings were treated with a potassium phosphite based formulation and X-RAY CT imaging performed at 0, 6 and 12 d post application. Student t test was used to compare between treatment and untreated control (*indicates significant difference * $P \leq 0.05$ and ** $P \leq 0.01$). All values are means \pm SE (n = 10).

depth in a restricted water experiment, seedlings were transferred to 1 m long columns containing expanded clay beads fitted with an automated drip irrigation system. Foliar phosphite treatment was done 5 days post transfer of the seedlings to these columns and water restriction was imposed a week later. Root growth assessment at 45 days after the treatment showed that phosphite treated plants have longer roots under restricted water regime (Figure 3B).

Phosphite treatment improves carbon assimilation under mild water and nutrient stress conditions

The observed alterations in root traits may have consequences for the plant capacity to supply the shoot with nutrients for synthesis of photosynthetic components and water for leaf gas exchange. To investigate this, we utilised infra-red

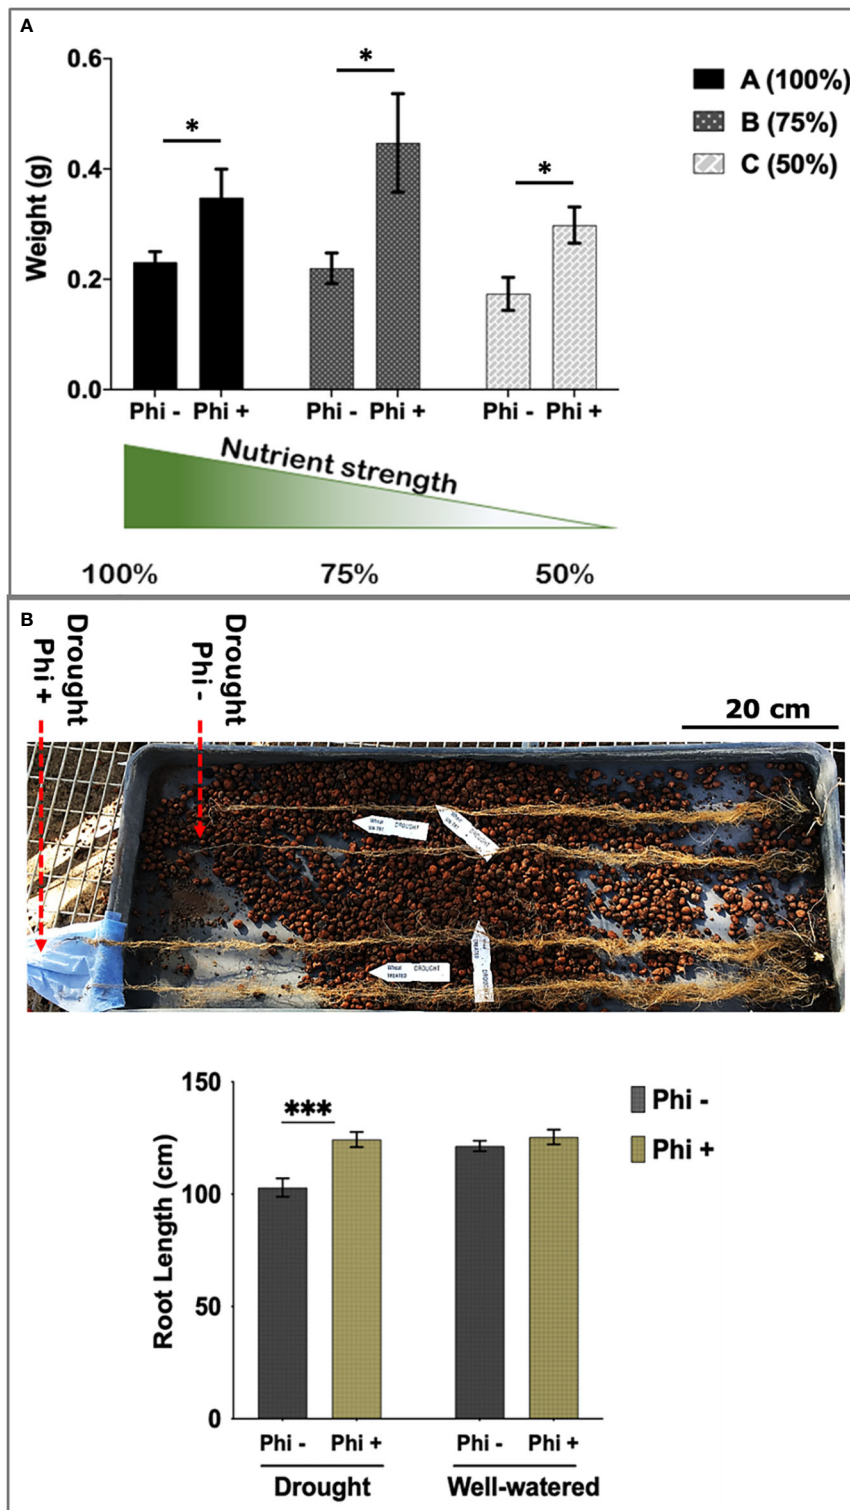

FIGURE 3

gas analysis. We observed enhanced photosynthesis as a common trend in phosphite treated plants. At both high (100%) and moderate (50%) nutrient strength, photosynthetic capacity (A_{\max}) increased significantly by 12 and 21% respectively, after 28 days of phosphite treatment ($P=0.027$ and 0.001) (Figure 4A). Stomatal conductance (g_s) and the transpiration rate at moderate nutrient strength (50%) were higher in the phosphite treated plants compared to untreated control plants ($P=0.045$ and 0.015 respectively; student's t test) (Figures 4B, C). Intrinsic leaf water use efficiency WUE (calculated as A/g_s) of phosphite treated plants in full nutrient complement also improved significantly ($P=0.0004$; Figure 4D).

Carbon assimilation and gas exchange rates were measured at 4 different time points within the first 15 days of mild water restriction (Supplementary Figure 4). Although not significant, the A_{\max} , the stomatal conductance (g_s) and the transpiration rate (E) of phosphite treated were all numerically higher at all the 4-time points compared to non-treated under mild water stress with no alteration in WUE.

A-Ci analysis was used to separate biochemical components of photosynthesis such as the maximum rate of carboxylation by Rubisco (V_{\max}) and the maximum rate of electron transport for ribulose-1-5-bisphosphonate (RuBP) regeneration (J_{\max}) at 10 days of water restriction. For both the V_{\max} and J_{\max} effects were

not significant comparing phosphite treatment under mild water stress to the untreated control (Supplementary Figure 4D).

Phosphite treatment improves responses to heat stress

During the heat stress period, the response of the maximum quantum efficiency of photosystem II (F_v/F_m) was measured every day in the first 5 days, followed by measurements at 5 days intervals. At 24 h after heat stress, F_v/F_m of the untreated plants was significantly lower than treated ($P<0.05$) (Figure 5D). When the temperature was again increased at day 30 to 38°C , there was a trend for a sharp and substantial decline in F_v/F_m for the untreated plants but not treated ($P=0.081$). This suggests that phosphite treatment plays a role in helping to prevent photoinhibition, likely caused by damage to the PSII complex during heat stress.

To investigate this further, ACi analysis was performed during the heat stress treatment at 5-day intervals. On day 1 and 4 of the heat treatment, there was a substantial reduction in V_{\max} ($P=0.0169$, Figures 5A, B) in untreated plants which mirrored the reduction in F_v/F_m but J_{\max} was not significant (Figure 5C). Additionally, to determine if phosphite treatment

has any role to play in leaf senescence under heat stress, we measured the whole plant senescence: Structural Insensitive Pigment Index (SIPI; Figure 5E) using the vegetative index calculated from hyperspectral reflectance at day 0 and 5 of heat stress.

Phosphite treatment increases nitrate reductase activity

It has recently been reported that phosphite application results in an increase in nitrate reductase activity.

To test the effect of phosphite treatment on nitrate reductase, nitrate reductase enzyme activity (NRA) was measured in

phosphite treated and untreated plants grown in different growth mediums (soil columns; field condition and hydroponics) and different growth conditions (varying nutrients and water levels).

The nitrate reductase activity was measured on wheat shoots grown in $\frac{1}{2}$ strength hydroponic media (Figure 6A). There was a significant increase in nitrate reductase activity 6 and 9d post application.

We next tested the nitrate reductase activity in field grown wheat plants. Plants were treated with phosphite in autumn, spring or both in autumn and spring. We detected a significant increase (51%) in nitrate reductase activity in dual phosphite application (autumn and spring; Figure 6B).

To test if the phosphite-influenced increase in nitrate reductase is only common to wheat, we measured the nitrate reductase

activity of winter brassica (dicot crop) using the same cultivation methodologies. In line with wheat experiments we used $\frac{1}{2}$ strength of commercial NPK 20-8-20 hydroponic media as described in the methods. Our results show that 9 days after phosphite application, there was a significant increase (44%) in the nitrate reductase activity (Supplementary Figure 5A). We also tested the nitrate reductase activity of seedlings growing in soil column under restricted water conditions. *Brassica napus* (var Anastasia) and *B. rapa* (var Skye) seedlings were treated with phosphite and 5 days after phosphite application, water was restricted and nitrate reductase activity was measured 12-day post treatment. Our results show both varieties (Skye and Anastasia) have a significant increase in the nitrate reductase activity by 67% and 60% respectively (Supplementary Figure 5A).

Discussion

Biostimulants are emerging as a class of chemicals that promote crop growth. They also have been reported to improve plant fitness and performance under stress conditions (Ziosi et al, 2013; Brown and Saa, 2015; Bulgari et al, 2015; Bulgari et al, 2019). With increasing incidents of adverse growing conditions, the use of biostimulants to enhance crop establishment and growth is becoming more important and could be crucial for meeting future food demands.

Phosphite represents a reduced form of phosphate that has been shown to act as a biostimulant (Albrigo, 1999; Lovatt and Mikkelsen, 2006). Previous studies in wheat have shown that foliar application of phosphite enhances root growth and

development in a range of plant species, typically increasing biomass by around 30% (Rossall et al., 2016) but mechanisms of action are unclear.

Here we have carried out more detailed studies on the effect of phosphite on root growth and its impact on nutrient use efficiency and above ground physiology. In early seedling stage root studies, we tested the impact of phosphite in six commercial winter wheat varieties. Four of these varieties (Diego, Leeds, Siskin and Skyfall) responded to phosphite treatment and resulted in increase in the length and number of the nodal and seminal roots (Figure 1). Interestingly, Evolution and Revelation did not respond to phosphite treatment indicating a varietal difference in their response to phosphite treatment. Currently it is not clear why some varieties respond to phosphite treatment and others don't. Phosphite cannot be used as a source of P nutrition (Carswell et al., 1996; Forster et al., 1998; Schroetter et al., 2006). Phosphite can be taken up by the phosphate transporters but cannot replace Pi in most biological reactions but suppress the Pi starvation response (McDonald et al., 2001; Varadarajan et al., 2002). There is not much evidence either to suggest that phosphite can be converted to phosphate *in planta* (Thao and Yamakawa, 2009). However, there are some reports that suggest that phosphite can be converted to Pi by soil microbacteria but the conversion is very slow to account for any nutritional benefits (McDonald et al., 2001). Besides, the doses used here are very small and typically one application of phosphite is needed to promote root growth. Therefore, we rule out the possibility of phosphite as a source of P nutrition. However, it is possible that the varieties like Evolution and Revelation that do not respond to phosphite treatment, may lack components in phosphite perception and/or signal transmission.

We also tested the impact of phosphite on root growth in soil by X-ray CT imaging. X-ray CT is a non-invasive method that generates a sequence of images through a soil column and allows the root architecture of plants to be visualised in 3D in their natural environment. We find that at 6 d post-application (Δ (D6-D0)) there was a significant increase in the root volume and the surface area of the root. There was also a significant increase in seminal and nodal root length and lateral root count six days post phosphite treatment. These results indicate a clear impact of phosphite treatment on early root growth that is likely to improve seedling establishment.

Root system architecture (RSA) determines the distribution of root surface area within the soil profile and so the plant's capacity to capture nutrients and water (Ho et al., 2004; Hochholdinger & Tuberosa, 2009; Coudert et al., 2010; Gewin, 2010; Bhosale et al., 2018; Giri et al., 2018; Meng et al., 2019). These traits therefore have a direct bearing on crop productivity, particularly under conditions of low resource availability (Lynch, 2011; Lynch, 2013; Lynch et al., 2014; Lynch, 2015). Our nutrition use efficiency experiment further supports this view

where we show that phosphite treated plants show a significant increase in root biomass compared to untreated plants when grown under reduced nutrient strength solutions and phosphite treated plants grown in 75% strength nutrient solution outperformed the full strength untreated plants (Figure 3).

Improved root traits may also have consequences for synthesis of photosynthesis components and water for leaf gas exchange and thus can explain an increase in photosynthetic capacity, transpiration rate, stomatal conductance and intrinsic leaf water use efficiency WUE of phosphite treated plants (Figure 4).

Effects of enhanced photosynthesis can be difficult to interpret due to interactions between enhancement of development in terms of plant size and increased photosynthesis per unit leaf area. We hypothesize that enhanced root morphology can provide greater opportunity to extract water for transpiration, lowering leaf resistance to CO₂ diffusion and to take up more nutrients to construct greater amounts of photosynthetic components per unit leaf area. Under conditions where resources are restricted these effects could amplify and we see some evidence of this. The difference shown in Figure 3A (moderate nutrient depletion) between control and Phi treated plants could be attributed to an increased ability to extract nutrients from the soil. However, the results we saw are not consistent: we would also expect the 25% treatment to also show a difference in A_{max} . Similarly, we would anticipate an improvement in iWUE would be expected under all treatments.

Our heat stress experiments showed improvements in F_v/F_m (an indicator of photoinactivated photosystem II (PSII)) and V_{cmax} (the maximum carboxylation rate of the enzyme Rubisco at key points following the heat treatment in phosphite treated plants. These are important findings because both of these processes are heat sensitive and represent a loss of activity in these two key photosynthetic components, PSII and Rubisco. An increased transpiration capacity that could form as a result of an enhanced root system might provide extra leaf cooling and reduce the impact of higher leaf temperatures in the initial phase of the heat treatment. To support this, we observed a significantly higher G_s in the phosphite treated plants compared to untreated at the first time point after the heat was applied. In addition, SIPI measurements revealed reduced senescence in phosphite treated plants (Figure 5E). Chlorophyll degradation can occur in cereals under high temperature stress and it is likely that phosphite treatment inhibits high temperature mediated chlorophyll degradation. However, we also cannot rule out an as yet unknown effect of phosphite on stress signalling pathways in the plant.

We find that phosphites regulate the activity of Nitrate reductase which is a key enzyme in N metabolism and catalyses nitrate to nitrite conversion (Figure 7) (Campbell,

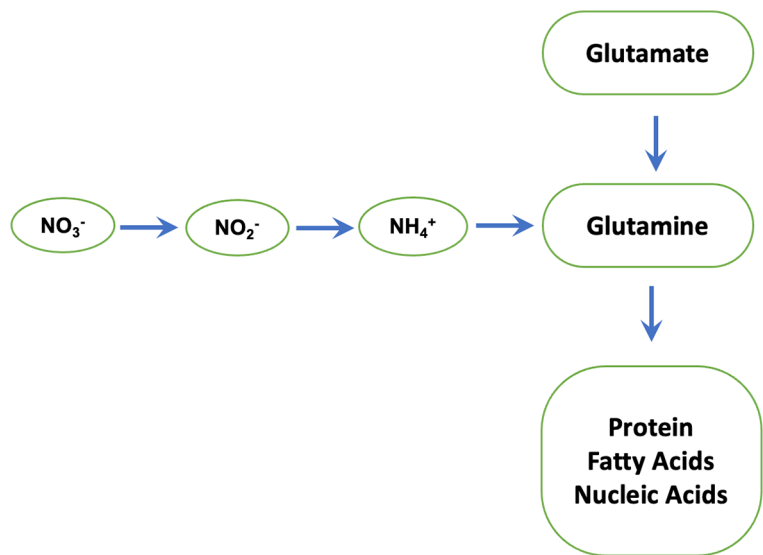

FIGURE 7
Nitrate reductase: a key enzyme in N metabolism. Nitrate reductase catalyses nitrate to nitrite conversion. The nitrite formed is reduced by the enzyme nitrite reductase to ammonium, which then reacts with glutamate to form glutamine by glutamine synthetase. The latter serves as the amino group donor for the synthesis of amino acids, proteins and Nucleic acids.

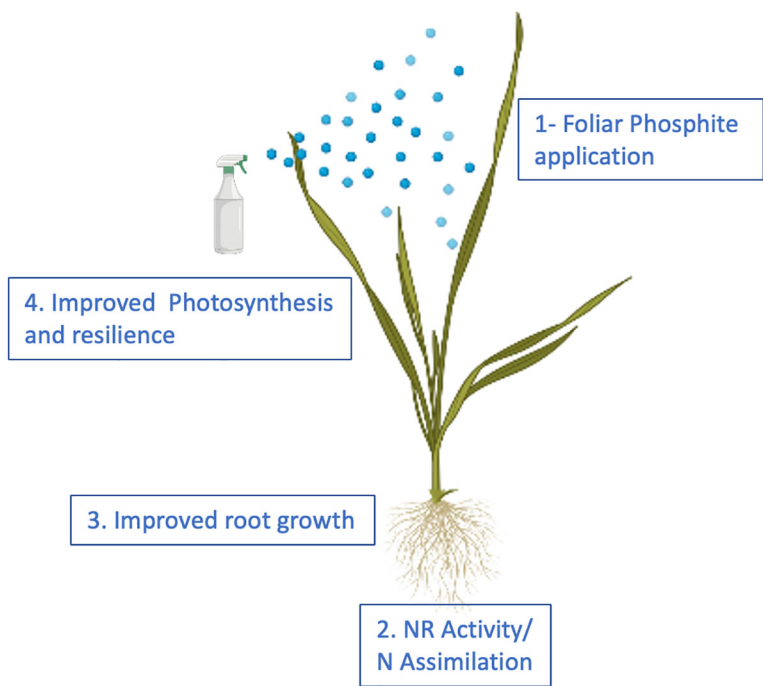

FIGURE 8
Proposed model for phosphite action. The model provides a temporal framework for impact of phosphite on root growth. Phosphite treatment results in the induction of NAS gene expression and Fe homeostasis to regulate NR activity and root growth.

1996). The nitrite formed is reduced by the enzyme nitrite reductase to ammonium, which then reacts with glutamate to form glutamine. The latter serves as the amino group donor for the synthesis of amino acids. The total nitrogen flux from nitrate to the amino acids is limited by the activity of the first enzyme nitrate reductase. In plants, the enzyme nitrate reductase therefore has an essential role in providing reduced, metabolizable nitrogen for growth and development and a decisive influence on the increased availability of nitrogen compounds in the plant. Accordingly, an increased nitrate reductase activity leads to increased assimilation of inorganic N to build up plant organs (root, stalk/stem, leaf, and grain/seed) and activity levels have been used as an indicator of plant N content.

Though currently it is not clear how phosphites regulate Nitrate reductase activity. There is some suggestion in the literature between possible link between ion homeostasis and Nitrogen metabolism (Zhao et al., 2019). It was shown that two of wheat Nicotianamine Synthase genes *TaNAS1* and *TaNAS2* are up regulated by increased N application (Zhao et al., 2019). Nicotianamine Synthases are key genes involved in the synthesis of non-proteinogenic amino acid Nicotianamine (Nozoye, 2018; Li et al., 2020). Nicotianamine is known to chelate many metal ions including Iron, Zinc, Copper and Manganese and is involved in internal metal transport (Nozoye, 2018). Crucially, Nicotianamine is involved in acquisition, transport and homeostasis (van Wieren et al., 1999; Pich et al., 2001) of iron, which is required for many of the enzymes involved in Nitrogen assimilation including Nitrate- and Nitrite-reductases (Wang et al., 2003). It has been reported that rice *NAS3* knock outs have reduced shoot and root growth further supporting a link between Nicotianamine Synthases and growth (Aung et al., 2019). In addition, over expression of *NAS* genes has been shown to increase Nicotianamine Synthase levels in several crop plants and confers tolerance to iron deficiency stress (Aung et al., 2019; Nozoye, 2018). Thus, it is possible that phosphite treatment increases Nitrate reductase activity through improved iron homeostasis.

Conclusions

Our results show that phosphite promotes root growth and improves nutrition use efficiency (root biomass per unit nutrient supply). We also present evidence for improved gas exchange capabilities under conditions of nutrient and water limitation and for enhanced abiotic stress tolerance.

We propose that phosphite treatment improves plant growth and the ability to survive abiotic stresses through improved Nitrogen and Carbon assimilation thus facilitating improved root growth that in turn improves root biomass, nutrition and water use efficiency (Figure 8).

In recent years, there has been a focus towards improving root architecture to enhance crop resource use efficiency. World food production has to increase to meet the demands of growing population and further understanding of the phosphite mediated growth promotion could provide a promising addition to agriculture management practices.

Data availability statement

The original contributions presented in the study are included in the article/Supplementary Material, further inquiries can be directed to the corresponding author/s.

Author contributions

UM, JD, SR, KS, NC, RB and RS performed experiments and contributed experimental data. UM, JD, JF, EM and RS designed experiments and analysed data. UM, JD, JF, EM, RB and RS wrote the manuscript. All authors contributed to the article and approved the submitted version.

Acknowledgments

This work was supported by the awards from the Biotechnology and Biological Sciences Research Council [grant number BB/P010520/1]. This work was also supported by funds from Industrial Partners- Biolchim S.p.A.; Brian Lewis AgricultureT/a Intracrop; Headland Amenity; OMEX Agriculture Ltd; Trade Corporation International SAU; Verdesian Life Sciences Europe Ltd. RB thanks Future Food Beacon Nottingham Research and BBSRC Discovery Fellowship (BB/S011102/1). We also thank Xin for helping in one of the experiments.

Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be constructed as a potential conflict of interest.

This study received funding from Biolchim S.p.A., Brian Lewis Agriculture/Intracrop, Headland Amenity, OMEX Agriculture Ltd, Trade Corporation International SAU and Verdesian Life Sciences Europe Ltd. Except OMEX Agriculture Ltd, no other funders were involved in the study design, collection, analysis, interpretation of data, the writing of this article or the decision to submit it for publication. OMEX Agriculture Ltd. had only the following involvement with the study: They provided plots for field trials, but they were not involved in sample collection, enzyme assays and

data analysis presented in Figure 6B and this was all done by Nottingham.

The mutualistic relationship between mycorrhizal fungi and plant roots is a widespread terrestrial symbiosis. The symbiosis enables plants to better adapt to adverse soil conditions, enhances plant tolerance to abiotic and biotic stresses, and improves plant establishment and growth. Thus, mycorrhizal fungi are considered biostimulants. Among the four most common types of mycorrhizae, arbuscular mycorrhiza (AM) and ectomycorrhiza (EcM) have been more intensively studied than ericoid mycorrhiza (ErM) and orchidaceous mycorrhiza (OrM). ErM fungi can form symbiotic relationships with plants in the family Ericaceae. Economically important plants in this family include blueberry, bilberry, cranberry, and rhododendron. ErM fungi are versatile as they are both saprotrophic and biotrophic. Increasing reports have shown that they can degrade soil organic matter, resulting in the bioavailability of nutrients for plants and microbes. ErM fungi can synthesize hormones to improve fungal establishment and plant root initiation and growth. ErM colonization enables plants to effective acquisition of mineral nutrients. Colonized plants are able to tolerate different abiotic stresses, including drought, heavy metals, and soil salinity as well as biotic stresses, such as pathogen infections. This article is intended to briefly introduce ErM fungi and document their beneficial effects on ericaceous plants. It is anticipated that the exploration of this special group of fungi will further improve our understanding of their value of symbiosis to ericaceous plants and ultimately result in the application of valuable species or strains for improving the establishment and growth of ericaceous plants.

KEYWORDS

biostimulants, blueberry, ericaceous plants, ericoid mycorrhiza, *Oidiodendron maius*, rhododendron

Introduction

Plant biostimulants are referred to as natural-occurring or synthetic substances, which when applied to soil, seeds, and/or plants, can promote plant growth. There are several definitions for plant biostimulants. [du Jardin \(2015\)](#) defined “a plant biostimulant is any substance or microorganism applied to plants with the aim to enhance nutrition efficiency, abiotic stress tolerance and/or crop quality traits, regardless of its nutrient content”. [Yakhin et al. \(2017\)](#) proposed that a biostimulant is “a formulated product of biological origin that improves plant productivity as a consequence of the novel or emergent properties of the complex of constituents, and not as a sole consequence of the presence of known essential plant nutrients, plant growth regulators, or plant protective compounds.” Under the new regulation of the European Union (EU, 2019), “a plant biostimulant shall be an EU fertilizing product, the function of which is to stimulate plant nutrition processes independently of the product’s nutrient content with the sole aim of improving one or more of the following characteristics of the plant or the plant rhizosphere: (1) nutrient use efficiency, (2) tolerance to abiotic stress, (3) quality traits, or (4) availability of confined nutrients in the soil or rhizosphere”. To be more explicit, plant biostimulants are products that can improve plant growth.

Biostimulants are derived from a wide range of biological and inorganic materials ([Calvo et al., 2014](#)) and have been classified into seven categories ([du Jardin, 2015](#)): (1) humic and fulvic acids or humic substances, which are a group of heterogeneous, highly acidic compounds resulting from the decomposition of soil animal, microbial, and plant residues; (2) protein hydrolysate and other nitrogen (N)-containing compounds, referring to a mixture of amino acids and peptides obtained through enzymatic and chemical hydrolyses of animal wastes and plant residues; (3) seaweed extracts and botanicals, which are derived from seaweed or plants with biostimulant activities; (4) chitosan and other biopolymers, this includes biodegradable and biocompatible poly- and oligomers produced from natural produces; (5) inorganic compounds, mainly referring to beneficial elements, such as silicon, titanium, sodium, selenium, iodine, and aluminum (Al); (6) beneficial fungi, which include those either associated, endophytic or symbiotic with plants that possess biostimulant activities; and (7) beneficial bacteria, also referring to associated, endophytic, or symbiotic bacteria promoting plant growth. Based on the above classifications, biostimulants could be broadly divided into non-microbial and microbial plant biostimulants ([Rouphael and Colla, 2020](#)). It was estimated that biostimulant products could grow to \$2 billion in sales in 2018 ([Calvo et al., 2014](#)). More than 700 scientific papers on biostimulants had been published from 2009 to 2019 ([Rouphael and Colla, 2020](#)), indicating an increasing awareness of their importance to crop production.

Beneficial fungi include *Trichoderma* species, mycorrhizal fungi, yeasts, endophytes, and avirulent/hypovirulent strains of some pathogens ([Ghorbanpour et al., 2018](#)). Mycorrhizal fungi are a heterogeneous group of taxa that can establish symbiotic relationships with roots of most terrestrial plants, promoting plant acquisition of nutrients in exchange for carbon sources derived from photosynthesis ([Addy et al., 2005](#); [Bonfante and Genre, 2010](#); [Leopold, 2016](#)). Mycorrhizas are traditionally grouped into arbuscular mycorrhiza (AM), ericoid mycorrhiza (ErM), ectomycorrhiza (EcM), and orchidaceous mycorrhiza (OrM) ([Pandey et al., 2019](#); [Miyachi et al., 2020](#)). AMs are considered the most widespread symbiotic association as 80–90% of terrestrial plants can be colonized by this group of fungi ([Gianinazzi et al., 2010](#)). The beneficial effects of AMs on plants are known to be most noticeable when symbiotic relationships are established at the earliest stage of plant growth ([Niemi et al., 2004](#)). AM fungi have been reported as biostimulants ([Xavier and Boyetchko, 2002](#); [Rouphael et al., 2015](#)), natural biofertilizers ([Berruti et al., 2016](#)), and plant growth regulators ([Begum et al., 2019](#)). However, ErM fungi as biostimulants have not been reported. An ErM is referred to as a symbiotic complex of plant roots and fungal components. ErM fungi represent a unique group of fungi that can symbolize with plants in the family Ericaceae or heather family and play vital roles for plants in adapting harsh growing environments ([Read, 1996](#)); however, ErM has been the least studied, and the least understood mycorrhizal symbiosis ([Vohník, 2020](#)).

This article is intended to briefly introduce ErM fungi and review available literature related to ErM fungi in biosynthesizing bioactive compounds, promoting plant growth, and improving plant tolerance and resilience to abiotic and biotic stresses. Our review indicates that ErM fungi are valuable biostimulants that can synthesize bioactive compounds, including plant growth regulators, promote seed germination and rooting of cuttings, improve plant tolerance to heavy metals, drought, and soil salinity, and resistance to plant diseases, and enhance the growth of ericaceous plants ([Figure 1](#)).

Ericoid mycorrhizal fungi

Ericoid mycorrhizal fungi largely belong to Ascomycota and Basidiomycota ([Perotto et al., 2018](#); [Fehrer et al., 2019](#); [Vohník, 2020](#)). The most important ErM fungi in Ascomycota include the *Hyaloscypha hepaticicola* aggregate, formerly known as the *Rhizoscyphus ericae* aggregate or *Hymenoscyphus ericae* aggregate ([Fehrer et al., 2019](#)), which include *H. hepaticicola*, possibly *Hyaloscypha variabilis* (syn. *Meliniomyces variabilis*) as well as *Oidiodendron maius* and *Leohumicola* spp ([Vohník, 2020](#)). *H. hepaticicola* was actually the first experimentally confirmed ErM species ([Pearson and Read, 1973](#)). *O. maius* was initially isolated by [Barron \(1962\)](#) from peat soils collected in Canada and subsequently from ericaceous plant roots in

FIGURE 1

A schematic illustration of ericoid mycorrhizal fungi in establishment of the symbiotic relationship with an ericaceous plant (blueberry) and production bioactive compounds, which result in the improved seed germination and rooting of cuttings, and the symbiosis also enhances plant tolerance to different abiotic stresses and resistance to pathogen infections and promotes plant growth.

Japan (Tokumasu, 1973). Later, *O. maius* was identified from other plant roots and decayed organic materials, peat, and acidic soils (Rice and Currah, 2005; Rice and Currah, 2006). *Leohumicola* species are another group of ErM fungi, which have a remarkable tolerance to high temperatures (Adeoyo et al., 2018; Adeoyo et al., 2019).

The basidiomycetous ErM fungi are composed of sebacinoid fungi from Serendipitaceae (Vohník et al., 2016) and non-sebacinoid fungi (Kolařík and Vohník, 2018) as well as those from the *Kurtia argillacea* species complex (syn. *Hyphodontia argillaceum*, *Hyphoderma argillaceum*) (Vohník, 2020). With increasing exploitation of ErM fungi worldwide, more ericoid mycorrhizal fungi have been reported. For instance, two ascomycetous genera: *Cairneyella* (Midgley et al., 2016) and *Gamarada* (Midgley et al., 2018) were found to be ErM fungi in Australia.

Ericoid mycorrhizal fungi are able to colonize roots of ericaceous plants. The fungi initially grow on the surface of hair roots, establishing loose hyphal networks. Hyphae then penetrate cortical cell walls to form intracellular densely packed individual cells, which is known as coils (Vohník et al., 2012). Thus, ericoid mycorrhiza has structurally well-defined

endomycorrhiza that are distinctly different from the other mycorrhizae due to the formation of fine compact intracellular hyphal coils in the rhizodermal cells of hair roots. The coil is the site for transferring nutrients absorbed by ErM fungi from the soil to root cells and carbohydrates fixed by plant photosynthesis to fungi. The hyphal sheaths or mantles around healthy hair roots are somewhat similar to those occurring in some EcM (Vohník, 2020). It was observed that both cell-to-cell (between neighboring rhizodermal cells) and single cell (from soil to individual rhizodermal cells) hyphal colonization happened in the rhizodermis of ErM-colonized hair roots (Massicotte et al., 2005; Vohník, 2020).

Interestingly, a recent study showed that ErM fungi, specifically those in the genus *Hyaloscypha* can colonize not only roots, but also stems, leaves, and flowers of *Vaccinium myrtillus* (Daghino et al., 2022). The colonization of the above-ground organs is explained by the evolutionary closeness between the genus *Hyaloscypha* and non-mycorrhizal fungal endophytes based on the genomic similarity. However, it is unknown at present what role *Hyaloscypha* plays in the aerial plant organs of ericaceous plants.

Ericaceous plants and their growing conditions

The family Ericaceae has about 4,500 species across 125 genera, which are either herbs, dwarf shrubs, shrubs, or trees that are distributed in tundra, heathland, and understory of boreal forests in the Northern Hemisphere (Luteyn, 2002; Grelet et al., 2009). Economically important ericaceous plants include *Rhododendron* L., blueberry (*Vaccinium* sect. *Cyanococcus* Rydb. spp.), bilberry (*Vaccinium myrtillus* L.), cranberry (*Vaccinium* subg. *Oxycoccus* (Hill) A. Gray spp.), and huckleberry (*Vaccinium parvifolium* sm.). Plants in the genus *Rhododendron* are popular ornamental plants. There are more than 28,000 cultivars of *Rhododendron* (12,989 azaleas, 14,298 rhododendron, and 108 azaleodendrons hybrids) in the International Rhododendron Registry held by the Royal Horticultural Society (Leslie, 2002). Additionally, rhododendron plants are important ethnopharmacological and toxicological plants (Popescu and Kopp, 2013; Wei et al., 2018). On the other hand, the berries, such as blueberry and cranberry have high nutraceutical and pharmaceutical value and are considered super fruit (Whyte and Williams, 2015; Vendrame et al., 2016). Blueberry varieties include lowbush, southern highbush, northern highbush, half-high, and rabbiteye. Among them, the production of highbush varieties increased substantially from 58,400 ha in 2007 to 110,800 ha in 2014. North America accounted for more than 50% of the production area, representing about 60% of highbush blueberry production in the world in 2014 (Qiu et al., 2018).

Ericaceous plants have some unique characteristics: (1) Roots are fibrous, very fine multicellular roots ranging from 100 to 750 μm in diameter, and cortical cells never form root hairs. Instead, roots of ericaceous plants are known as hair roots (Watkinson, 2016). Roots are mainly distributed in the upper 5 cm of soil depth, representing more than 50% of new roots

produced during a growing season (Atucha et al., 2020). Root growth of cranberry exhibited a unimodal curve with one significant flush at bloom and a peak at the end of fruit maturation. (2) They are able to grow in soils low in pH (4 to 5) and poor in nutrient availability. Under such a pH range, nitrification could be largely negligible due to its detrimental effect on the nitrifying bacteria (Paul and Clark, 1989). It was proposed that ericaceous plants grown in the low pH soil might lose their ability to take up nitrate (NO_3^-). (3) Roots are colonized by mycorrhizal fungi, mainly ErM fungi (Xiao and Berch, 1992; Usuki et al., 2003; Vohník et al., 2007; Tian et al., 2011). Root cortex and epidermis could be fully filled with mycorrhizal hyphal coils (Atucha et al., 2020). The colonization plays a critical role for ericaceous plants to absorb nutrients including NO_3^- . Cranberry roots inoculated with *R. ericae* were able to absorb NO_3^- under a low pH regime (Kosola et al., 2007). Accumulating evidence has indicated that the symbiosis established between roots and ErM fungi is essential for ericaceous plants to absorb nutrients and to survive and grow in the harsh environment (Read, 1996; Cairney and Meharg, 2003; Zhang et al., 2009; Perotto et al., 2012).

Ericoid mycorrhizal fungi promote seed germination and rooting of cuttings

Ericoid mycorrhizal fungi have been shown to improve seed germination and rooting of microcuttings or stem cuttings of ericaceous plants (Table 1). Seeds of ericaceous plants are small with an average length of 1.5 mm and a mean width of 0.5 mm, and they generally have a poor germination rate due to the limited supply of nutrition from the endosperm. In a mesocosm study conducted for determining if novel ErM communities could assist or hamper the shift of northward species of

TABLE 1 Ericoid mycorrhizal fungi improve seed germination and rooting of cuttings.

Unspecified ericoid mycorrhizal fungi	<i>Rhododendron catawbiense</i> and <i>R. maximum</i>	Increased seed germination rates	Mueller et al., 2022

Rhododendron, Mueller et al. (2022) reported that germination rates of *R. catawbiense* and *R. maximum* after inoculation with novel soils containing ErM fungi were significantly greater than those of controls (without mycorrhizal fungi) or inoculated with conspecific soils, 75.2% vs. 54.5% for *R. catawbiense* and 65.7% vs. 54.4% for *R. maximum*. The increased germination rates were attributed to the occurrence in ErM fungi, but the authors did not provide the underlying mechanisms. In addition to seed germination, ErM has been documented to promote seedling growth of *Rhododendron*. An ErM fungus known as *O. maius* Om19 inoculated in a peat-based substrate substantially enhanced seedling growth of *R. fortunei* Lindl. because root growth including root length, root numbers, root fresh weight as well as shoot growth, including shoot overall height and shoot fresh weight of Om19 colonized seedlings were doubled compared to the uninoculated control seedlings (Wei et al., 2016a). Additionally, overall fresh and dry weights of *R. fortunei* seedlings inoculated with Om19 were 81% and 84% higher than those of the control, respectively. Furthermore, genes related to N uptake and metabolism were analyzed by qRT-PCR, and results showed that the expression of an ammonium transporter (*AMT*), two nitrate transporters (*NRT1-1* and *NRT1-2*), glutamate synthase (*GOGAT*), and glutamine synthetase (*GS*) were highly upregulated in plants inoculated with Om19, ranging from 2 to 9 folds greater than the uninoculated plants (Wei et al., 2016a).

Ericoid mycorrhizal fungi can substantially improve rooting of stem cuttings as well as microcuttings derived from tissue culture (Eccher et al., 2010; Wei et al., 2020). Stem cuttings of blueberry plants inoculated with ErM fungi rooted more successfully and were followed by enhanced plant growth (Scagel et al., 2005a; Scagel et al., 2005b). Root initiation and root growth of dog hobble (*Leucothoe fontanesiana*) (Scagel, 2005b) and *Vaccinium meridionale*, a Colombian blueberry (Ávila Díaz-Granados et al., 2009) also increased with the inoculation of ErM fungi. Recently, micropropagation, shoot culture in particular, has been increasingly used for propagation of important ericaceous plants, such as rhododendron, cranberry, and blueberry (Fan et al., 2017; Wei et al., 2018). An interesting phenomenon observed during the rooting of microcuttings is that *in vitro* rooting is more difficult than *ex vitro* rooting (Gorecka, 1979; Fan et al., 2017; Qiu et al., 2018; Wei et al., 2018). To explore the underlying mechanisms behind this phenomenon, Wei et al. (2020) developed an *in vitro* culture system for *R. fortunei* and investigated the adventitious root (AR) formation in microcuttings inoculated with or without *O. maius* Om19. Key phytohormones and precursors involved in the pathway of indole-3-acetic acid (IAA) biosynthesis were analyzed in Om19 mycelium. Om19 was able to synthesize tryptophan (Trp), indole-3-pyruvate (IPA), and IAA, of which Trp concentration was greater than 4,000 mg/kg. The occurrence in Trp, IPA, and IAA indicated that Om19 biosynthesis of IAA is through the Trp-dependent pathway

(Mano and Nemoto, 2012). Other hormones synthesized by Om19 include brassinolides (BRs), jasmonic acid (JA), and salicylic acid (SA). BRs were reported to positively impact the symbiosis of either tomato or tobacco roots with an AM fungus (von Sivers et al., 2019). JAs are known as a wound signal in AR formation because wounding quickly induces JA accumulation in plant tissues (Zhang et al., 2019). Increased JA concentrations have been shown to promote AR formation in cuttings by IAA accumulation in the base of stem cuttings towards AR source cells (Druege and Franken, 2019). SA is known for triggering systemic-acquired resistance (SAR) in plants (Chen et al., 1996). Low concentrations of SA was reported to promote AR formation and change the root apical meristem architecture, but high SA concentrations suppressed the root growth process (Pasternak et al., 2019). After Om19 inoculation, ARs rapidly appeared from microcuttings. Meanwhile, genes related the symbiosis including *SymRK* and *DMI* were activated in ARs, resulting in Om19 colonization of the roots. Furthermore, *YUC3*, a key gene controlling IAA biosynthesis in plants (Cheng et al., 2007; Won et al., 2011), genes encoding N absorption (*AMT* and *NRT*) and N metabolism (*GOGAT* and *GS*) as well as phosphate transporter (*PHT*) in Om19-inoculated plants were upregulated by 3 to 7 folds compared to control plants without Om19 inoculation. As a result, inoculated plants were able to take up significantly higher quantities of nutrients including N, P, K, Ca, Mg, and S, and plant growth substantially increased compared to the control plants. A working model for the Om19-mediated AR formation was proposed. The rapid AR formation on the one hand was induced by IAA produced by Om19 and on the other hand by IAA biosynthesized by plants. The high concentration of Trp synthesized by Om19 could be readily used by plant as the precursor to synthesis of IAA. The formation ARs, in turn, provided Om19 with host for colonization. This study for the first time documented the ability of Om19 to biosynthesize several hormones, of which IAA plays an important role in inducing AR formation.

This model also provides explanations as to why *ex vitro* rooting of microcuttings is more effective than *in vitro* rooting. A major component of commercial substrates is peat moss, ranging from 30% to 75% based on volume (Chen et al., 2005). As mentioned before, *O. maius* was initially isolated from peat soils by Barron (1962). Commercial substrates rich in peat moss might have ErM mycorrhizal fungi. Gorman and Starrett (2003) screened ErM occurrence in commercial substrates and found that the majority of the peat and peat-based substrates used in the U.S. and Canada contained ErM fungi. ErM fungi were reported to naturally colonize roots of blueberry plants during nursery production (Scagel, 2005a). Thus, the ErM fungi in the substrates could act similar to Om19 in biosynthesis of phytohormones including IAA for inducing AR formation of ericaceous plant cuttings. Those ErM may also synthesize a large amount of Trp for plants to produce endogenous IAA. In general, endogenous hormones are

more effective than exogenous application. [Ismail et al. \(2021\)](#) reported that bacterial and fungal endophytic metabolites significantly enhanced plant growth compared to exogenous applied hormones. IAA biosynthesized inside plants by either plants or ErM could be considered endogenous and thus could be more effective for inducing AR formation than exogenous applied auxin during *in vitro* rooting.

Ericoid mycorrhizal fungi also produce other bioactive compounds ([Table 2](#)). Some can increase bioavailability of soil mineral elements, such as siderophore for chelating soil Fe ([Ahmed and Holmström, 2014](#)). Some are enzymes, including cell-wall-degrading enzymes (PCWDEs) that can degrade soil organic matter (SOM) ([Kohler et al., 2015](#); [Martino et al., 2018](#)). Others have antimicrobial activities ([Hosoe et al., 1999](#); [Ouyang, 2021](#)), and still others are antioxidants, such as rutin ([Lin et al., 2021](#)).

Ericoid mycorrhizal fungi enhance plant growth

Ericoid mycorrhizal fungi have been well documented for promoting the growth of ericaceous crops. ErM fungi are able to establish symbiotic relationships with plant roots. The

established symbiosis enables plants to better adapt to acidic soils with low pH values and low nutrient status and improve root acquisition of nutrients, thus, enhancing plant growth. The growth enhancement is attributed to several factors: (1) The ability of ErM to biodegrade SOM resulting in the bioavailability of nutrients for plants; (2) the symbiosis-resultant expansion of nutrient acquisition surface area for capturing more mineral elements; and (3) the upregulation of gene expression, such as those associated with symbiosis and N and P uptake and metabolism, leading to the increased N and P absorption and metabolism and enhanced plant growth.

ErM fungi mediated degradation of soil organic matter

A unique characteristic of ErM fungi is their capability to biodegrade SOM ([Martino et al., 2018](#)). SOM is the organic fraction of the soil consisting of animal and plant residues and microorganisms at different stages of decomposition and contributes significantly to soil fertility and productivity ([Myers and Leake, 1996](#); [Biswas and Kole, 2017](#)). Ericaceous plants are native to acidic soils, low in nutrients but high in recalcitrant organic materials, which results in a low bioavailability of mineral

TABLE 2 Bioactive compounds released by ericoid mycorrhizal fungi.

<i>Oidiodendron maius</i>	Tryptophan, indole-3-pyruvate, indole-3-acetic acid (IAA), brassinolides (BRs), jasmonic acid (JA), and salicylic acid (SA)	Precursor for IAA biosynthesis. IAA, BRs, JA, and SA are plant growth regulators	Wei et al., 2020
<i>Oidiodendron flavum</i>	Harzianic acid	Antimicrobial activity	Ouyang, 2021
<i>Oidiodendron truncatum</i>	Fourteen norditerpene and three anthraquinone metabolites.	Antifungal activity	Rusman et al., 2020
Ericoid mycorrhizal fungi	Indole-3-acetic acid (IAA), hydrogen cyanide (HCN), siderophores, and phosphatase	IAA is plant growth regulator; HCN is a co-product of ethylene biosynthesis; siderophores improve nutrient bioavailability; and phosphatase solubilizes insoluble forms of phosphorus	Hamim et al., 2019

elements, particularly N and P (Cairney and Meharg, 2003). ErM fungi can degrade SOM, leading to the release of nutrients for host plants. Among the ErMs, *R. ericae* and *O. maius* were found to degrade cellulose, tannic acid, pectin, and chitin (Rice and Currah, 2001; Thormann et al., 2002; Rice and Currah, 2005). A wide range of enzymes were released from the two ErM fungi for degrading fungal and plant cell wall polymers, complex aliphatic compounds, and organic phosphorus (Smith and Read, 2008). Kohler et al. (2015) sequenced 13 EcM, ErM, and OrM species as well as five saprotrophs and found that EcM fungi have reduced numbers of genes for PCWDEs compared to their ancestral wood decayers. Later, Martino et al. (2018) sequenced genomes of ErM fungi *R. ericae*, *Meliniomyces bicolor*, *M. variabilis*, and *O. maius* and compared their gene repertoires with EcM, OrM, and six pathogenic or saprotrophic Leotimycetes and 50 other Basidiomycetes and Ascomycetes. The authors found that ErM fungi possessed lipases, polysaccharide-degrading enzymes, proteases, and enzymes in secondary metabolism that were comparable to those of pathogens and saprotrophs but higher than those of EcM fungi, suggesting the ErM fungi are unique due to their dual saprotrophic and biotrophic lifestyle. Additionally, RNA-Seq analysis showed that highly upregulated genes in ErM fungi were those involved in lipases, cell wall-degrading enzymes (CWDEs), transporters, proteases, and mycorrhizal-induced small-secreted proteins (MiSSPs). Thus, ErM fungi represent a unique group of fungi in degradation of SOM, which explains in part as to why ericaceous plants can survive and grow in the acidic and low nutrient soils.

Soil organic nitrogen (ON) is a fraction of SOM, including intracellular and cell-wall bound proteins and nucleic acids of plant and microbial origin (Nemeth et al., 1987; Abuarqhub and Read, 1988). The main groups of soil ON compounds are aliphatic-N, including polysaccharide N and amino-N as well as aromatic N, such as those present in soil humus (Chen and Xu, 2006; Talbot and Treseder, 2010). These large molecules can be degraded by enzymes of ErM fungi into monomers, such as oligomer, small peptides, and amino acids (Talbot and Treseder, 2010) which are small enough for soil microbes and plants to take up or further mineralize and incorporate as ammonium and nitrate (Séneca et al., 2021). Studies have shown that mycorrhizal fungi and plant roots can take up amino acids. ErM fungi *R. ericae* were able to use all 20 common amino acids except glycine (Leake and Read, 1990; Cairney et al., 2000; Midgley et al., 2006), while *O. spp.* can use alanine, glutamic acid, arginine, lysine, proline, asparagine, glutamine, histidine, and cysteine (Whittaker and Cairney, 2001). Furthermore, ErM fungi have the capacity to use proteins, peptides or even chitin as a sole N source (Leake and Read, 1990; Read, 1996). Lin et al. (2011) evaluated three ErM isolates, Rf9 and Rf32 belonging to the genus *Cryptosporiopsis* and Rf28, a member of *Phialocephala* in decomposition SOM. Both Rf28 and Rf32 possessed the highest decomposition rates, up to 10.4% in 70 days, but Rf9 had a decomposition rate of 6.8%. Enzymatic assay showed that

Rf28 and Rf 32 secreted cellulase, laccase, peroxidase, and tyrosinase, but Rf9 mainly released peroxidase and tyrosinase. Seedlings of *R. formosanum* Hemsl. grown in substrate without ErM inoculation showed chlorotic symptoms and limited root growth, while those inoculated with ErM exhibited much stronger growth vigor than those of the control. This study implies that ErM-mediated decomposition of soil ON provides seedlings with nutrients, particularly N.

Enhanced growth of plants through symbiosis

Inoculation of ErM fungi can substantially enhance the growth of ericaceous plants. In general, ericaceous plants can be naturally colonized by ErM fungi (Hambleton and Currah, 1997; Gorman and Starrett, 2003), but the colonization rates are low, less than 15%. Inoculation of ErM fungi can increase colonization rates, up to 30% (Scagel, 2005a), and the colonization promoted growth in blueberry cultivars. Table 3 lists growth enhancement of ErM fungi on ericaceous plants. Inoculation of ErM fungi affected acclimatization and growth of microcuttings of *Pieris floribunda* (Starrett et al., 2001). Container-grown *R. indica* inoculated with *O. maius* Om19 had more abundant roots and a larger above ground canopy than those uninoculated (Wei et al., 2016a). Plant height, root, shoot, and total fresh weights of seedlings of *R. kanehirae* inoculated with two ErM strains significantly increased when ammonium was used as a N source (Lin et al., 2021). ErM fungi in nature Finnish peat moss promoted rooting of rabbiteye blueberry (*V. virgatum* Ait.) and vegetative growth (Li et al., 2021). Dry weights of shoots, leaves, and roots of rooted cuttings were 2.37, 4.51, and 4.34 g, respectively compared to 0.47, 0.90, and 0.67 g of those grown in sterilized peat moss. Furthermore, root P and Mg concentrations and shoot K content increased in plants grown in unsterilized peat moss. A recent study also showed that single inoculation of *V. corymbosum* with *O. maius* or *Phialocephala fortinii* significantly increased plant dry weight (Wazny et al., 2022).

The increased growth of plants is largely attributed to the following factors: (1) The bioavailability of small ON compounds degraded by ErM fungi mentioned above. (2) The symbiosis results in the establishment of root and hyphal networks that greatly expand root surface areas for capturing more mineral nutrients. Atucha et al. (2020) studied the phenology of roots, root anatomy and morphology in terms of root orders in cranberry (*V. macrocarpon* Ait). More than 50% of new roots produced during the growing season were vertically distributed in the upper 5 cm of soil depth, and mycorrhizal fungi were able to colonize the intact cortex and epidermis of the first three root orders. It is known that large root systems generally have a larger root surface areas and concomitantly shorter average half distance between root axes in the soil or

substrate for more effectively capturing nutrient elements (Chen and Gabelman, 2000). Thus, absorption of N, P, and other mineral nutrients was markedly increased in ErM colonized plants. (3) ErM fungi are able to biosynthesize and release hormones for stimulating root growth, such as IAA, BR, JA, and SA, which can stimulate plant growth and improve plant stress tolerance. (4) ErM-colonization results in the increased expression of a large number of genes. To gain insight into the intimate relationships of ErM fungi with ericaceous plants and the mechanism underlying growth stimulation, Wei et al. (2016b) analyzed transcripts induced by the symbiosis between ErM Om19 and *R. fortunei* using RNA-Seq. The symbiosis induced 16,892 upregulated genes in Om19-colonized roots. Homologous to symbiosis related genes, such as *SymRK*, *CCaMK*, *DMI1*, *NORK*, genes involved in N uptake including *AMT3*, *NRT1-1*, *NRT1-2*, as well as N metabolism, such as *GS-1* and *GS-2* and *GOGAT-1* and *GOGAT-2* were highly upregulated in roots inoculated with Om19, suggesting that ErM fungi might share the same strategy as AM fungi in the establishment of symbiotic relationships with ericaceous plants. The increased expression of the genes in N uptake and metabolism corresponded to the increased N absorption and metabolism as well as plant growth. Thus, the ability of ericaceous plants to survive and grow in acidic and low nutrient soils is largely

associated with their symbiotic relationship with ErM fungi (Cairney and Meharg, 2003).

It is worthy of note that different strains within an ErM species may perform differently in regulation of N uptake in ericaceous plants. Five strains isolated from *Calluna vulgaris* had different capacities to use organic and mineral N sources (Grelet et al., 2005). Different isolates of epacrid root endophytes differed in the use of amino acids (Whittaker and Cairney, 2001). Using ^{15}N tracing, Grelet et al. (2009) found that the rates of appearance of ^{15}N in shoots of cranberry after roots were inoculated with three strains of Helotiales were low and not different from the control (no ErM inoculation) when nitrate was used as a N source. However, differences occurred among strains when glutamine was used as a N source. When NH_4 was used as a N source, two strains had the highest rates compared to the other strains. Thus, for practical application of ErM fungi as biostimulants, appropriate species or strains should be chosen.

Improve plant tolerance to abiotic and biotic stresses

Plants as sessile organisms and permanently stay in their established sites. In addition to harsh environmental conditions,

ericaceous plants often encounter other stressful factors, such as salt, drought, heavy metals as well as plant pathogens. Evidence has shown that in addition to growth promotion, symbiotic ErM fungi can substantially improve plant tolerance to abiotic and biotic stresses (Table 4). The enhanced stress tolerance in turn can improve plant productivity compared to those without symbiotic establishment.

Resistance to heavy metals

Another distinct characteristic of ErM fungi is their adaptability to heavy metal stress (Meharg and Cairney, 2000). *C. vulgaris* is a dominant plant in mine spoil sites as it can tolerate Cu^{2+} and Zn^{2+} . Such a tolerance is attributed to its symbiotic relationship with ErM fungi. In the early 1980s, Bradley et al. (1981) reported that resistance of *C. vulgaris* to Cu^{2+} and Zn^{2+} was constitutive even in those mycorrhizal endophyte plants collected from sites without metal contamination (Bradley et al., 1981; Bradley et al., 1982). Martino et al. (2000b) reported that two isolates of *O. maius* from metal contaminated soils showed enhanced tolerance to Zn^{2+} *in vitro*, and later they reported that the mechanism behind the tolerance was due to the production of extracellular compounds, such as malate and citrate either to solubilize or chelate heavy metal ions (Martino et al., 2003). Subsequently, the ErM metal tolerant isolate known as *Oidiodendron maius* Zn has

been used as model for studying the molecular basis underlying ErM-mediated metal tolerance (Daghino et al., 2016). Its genome was sequenced (Kohler et al., 2015). A recent report showed that a homeostatic mechanism at the cellular level mediated by transport proteins may play an important role (Ruytinx et al., 2020). Blueberry plants colonized by ErM fungi were also found to be able to tolerate high concentrations of Fe and Mn (Hashem, 1995a; Hashem, 1995b) as well as Al (Yang and Goulart, 2000). In addition to tolerance to Cu^{2+} , Cd^{2+} , and Zn^{2+} , ErM fungi are particularly resistant to arsenate (AsO_4^{3-}). Sharples et al. (2001) compared As resistance between isolates of *Hymenoscyphus ericae* derived from *C. vulgaris* in soils contaminated with AsO_4^{3-} and natural heathland soils and found that *H. ericae* isolated from the mine sites sustained significant growth at AsO_4^{3-} concentration up to 4.67 mol m^{-3} ; however, the growth of the isolates from the heathland soils were almost completely inhibited. All isolates regardless of their origins had an identical response to Cu^{2+} . These results suggest that *H. ericae* response to As is adaptive but their response to Cu^{2+} is constitutive.

Although some progress on the tolerance of ErM fungi to heavy metals has been made, our understanding on how ErM colonization can improve plant tolerance to heavy metal stress remains incomplete. Sharples et al. (2001) reported that *C. vulgaris* tolerance to As in the mine sites was due to the colonization of *H. ericae*, which allows the host to maintain an adequate supply of PO_3^{3-} to limit the level of AsO_4^{3-} in the

cytosol, i.e., an ErM-mediated avoidance mechanism in *C. vulgaris*. To address ErM fungal colonization modulated plant tolerance to heavy metals, Casarrubia et al. (2020) studied *O. maius* mediated Cd tolerance in *V. myrtillus* and found that ErM colonized roots exposed to Cd had a reduced level of Cd compared to those uninoculated. Transcriptomic analysis showed that GSH metabolism was involved in the Cd tolerance as phytochelatins are biosynthesized from GSH, which can bind Cd to reduce toxicity (Chen and Goldsbrough, 1994; Chen et al., 1997). Some plant metal transporters were also regulated during the symbiosis and may be responsible for the reduced Cd content observed in mycorrhizal roots exposed to this metal.

Tolerance to salt and drought stress

Several recent studies showed that ErM fungi can effectively improve ericaceous plant tolerance to salt stress. A recent study showed that velvetleaf blueberry (*V. myrtilloides*), labrador tea (*R. groenlandicum*), and lingonberry (*V. vitisidaea*) plants inoculated with *M. variabilis* had increased dry weights of roots when imposed on NaCl-treatment. Inoculation of *O. maius* increased root dry weight accumulation in lingonberry plants treated with NaCl at 30 mM (Fadaei et al., 2020). Salt stress generally disrupts plant water relations by adversely affecting water uptake and osmotic balance as well as root hydraulic conductivity in plants (Sutka et al., 2011), which then lead to the decrease in cell turgor and stomatal opening and the inhibition of cell elongation. As a result, transpiration rates and net photosynthetic rates decreased, and plant growth was suppressed (Vaziriyaneganeh et al., 2018). In the report of Fadaei et al. (2020), transpiration and net photosynthetic rates of three ericaceous plant species treated with 30 mM NaCl were drastically reduced when grown in a substrate without ErM inoculation, but such detrimental effects were either completely or partially reversed by the inoculation of *O. maius* and *M. variabilis*. It was reported that EcM and AM colonization of roots increased the expression level of root aquaporins, resulting in the substantial improvement of root hydraulic conductivity (Xu et al., 2015). The authors believed that ErM fungi may act similar to AM in the alleviation of plant salt stress.

The ErM colonization also enhances drought tolerance of ericaceous plants. Mu et al. (2021) studied responses of lowland and upland blueberry seedlings to drought stress. Seedlings were grown in sterilized soil under controlled environmental conditions and inoculated with *M. variabilis*, *O. maius*, *P. ericae*, and *Pezoloma ericae*. All plants were imposed on three cycles of drought stress through withdrawing watering. Uninoculated, well-watered upland plants after three weeks of drought treatments produced higher dry weights compared to the uninoculated lowland plants. This difference, however, was offset after the plants were inoculated with ErM fungi, indicating that ErM addition significantly

improved drought tolerance of the lowland and upland plants. Among the four ErM species, *Pezizula ericae* was found to be the most effective in enhancing drought resistance in lowland and upland seedlings as its inoculation maintained a higher water potential in plant shoots and higher net photosynthetic and transpiration rates, thus increased dry weight production.

Responses to biotic stress

Information regarding ErM fungi improving ericaceous plant resistance to pathogens is rather limited. In a study conducted to test if ErM fungi could suppress the infection of soil-borne pathogens on mycorrhizal roots of *C. vulgaris* and *R. hirsutum*, Grunewaldt-Stöcker et al. (2013) inoculated *Pythium* spp. and *Phytophthora cinnamomica*, respectively to roots. The establishment of mycorrhizae, pathogen infections, and disease development in plants were examined microscopically. Results showed that ErM fungi suppressed the growth of external pathogenic mycelium and reduced pathogen infections. A complete reduction was observed at higher ErM colonization levels. However, pathogen infection occurred in those with low ErM colonization. These results showed that ErM colonization played a role in the direct suppression of oomycete pathogens from infection of ericaceous plants.

Systemic acquired resistance (SAR) is an immune response of plants against pathogen infection. It has been reported that some mycorrhizal fungi and plant growth promoting bacteria can induce SAR against a wide range of plant pathogens (Pieterse et al., 2014; Backer et al., 2018). However, SAR induction by ErM fungi has not been reported in ericaceous crops. Considering the fact that SA can effectively induce SAR in plants (Chen et al., 1996; Metraux, 2001) and *O. maius* can biosynthesize SA (Wei et al., 2020), it is likely that ErM fungi, *O. maius* in particular, should be able to induce SAR in plants, providing plants with long-lasting resistance to some plant pathogens. Further studies are warranted to test this hypothesis.

Conclusion and future perspectives

Ericoid mycorrhizal fungi have saprotrophic and biotrophic lifestyles and are able to biodegrade SOM and establish symbiotic relationships with plants in the family Ericaceae. The degradation of SOM results in the bioavailability of nutrients to themselves and plants. The symbiosis extends their life cycle and also enhances seed germination, rooting of cuttings, plant growth as well as tolerance to abiotic and biotic stresses. This review documents that the improved plant growth is related to hormones produced by ErM fungi and also colonization-resultant expression of genes in N and P absorption and metabolisms. Thus, ErM fungi is considered biostimulants for promoting the establishment and growth of

ericaceous plants. Considering some species in the family Ericaceae are economically important crops, it is expected that some ErM fungi could be developed as biofertilizers for improve plant propagation and production.

Our understanding of the ErM-mediated biostimulating effects on ericaceous plants, however, is largely incomplete. Further research is warranted to (1) identify and isolate key genes from ErM fungi in biodegradation of SOM, particularly ON and explore the genes for improving soil fertility, (2) evaluate important ErM species or strains in biosynthesis of hormones and isolate those for increased production of hormones through bioreactor and utilize the isolates for improving plant propagation and production, (3) analyze heavy metal tolerant species or strains of ErM through omics to identify the mechanism underlying metal tolerance and use the isolates for phytoremediation of metal-contaminated soils, and (4) develop ErM biofertilizers by combining different species or strains, each with specific biostimulating effects on propagation, growth promotion, and/or stress tolerance for improving the productivity of ericaceous plants.

Author contributions

JC, XW, CZ, and FZ conceived the idea, WZ conducted literature search and prepared the tables and figures. JC and XW wrote the initial draft. All authors edited, refined the manuscript, and approved for its submission.

The chlorpyrifos-mineralizing rice root endophyte *Enterobacter* sp. HSTU-ASh6 strain was identified, which enormously enhanced the growth of tomato plant under epiphytic conditions. The strain solubilizes phosphate and grew in nitrogen-free Jensen's medium. It secreted indole acetic acid (IAA; 4.8 mg/mL) and ACC deaminase (0.0076 μ g/mL/h) and hydrolyzed chlorpyrifos phosphodiester bonds into 3,5,6-trichloro-2-pyridinol and diethyl methyl-monophosphate, which was confirmed by Gas Chromatography – Tandem Mass Spectrometry (GC–MS/MS) analysis. *In vitro* and *in silico* (ANI, DDH, housekeeping genes and whole genome phylogenetic tree, and genome comparison) analyses confirmed that the strain belonged to a new species of *Enterobacter*. The annotated genome of strain HSTU-ASh6 revealed a sets of nitrogen-fixing, siderophore, *acdS*, and IAA producing, stress tolerance, phosphate metabolizing, and pesticide-degrading genes. The 3D structure of 28 potential model proteins that can degrade pesticides was validated, and virtual screening using 105 different pesticides revealed that the proteins exhibit strong catalytic interaction with organophosphorus pesticides. Selected docked complexes such as α/β hydrolase–crotoxyphos, carboxylesterase–coumaphos, α/β hydrolase–cypermethrin, α/β hydrolase–diazinon, and amidohydrolase–chlorpyrifos meet their catalytic triads in visualization, which showed stability in molecular dynamics simulation up to

100 ns. The foliar application of *Enterobacter* sp. strain HSTU-ASh6 on tomato plants significantly improved their growth and development at vegetative and reproductive stages in fields, resulting in fresh weight and dry weight was 1.8–2.0-fold and 1.3–1.6-fold higher in where urea application was cut by 70%, respectively. Therefore, the newly discovered chlorpyrifos-degrading species *Enterobacter* sp. HSTU-ASh6 could be used as a smart biofertilizer component for sustainable tomato cultivation.

KEYWORDS

chlorpyrifos mineralization, *Enterobacter* sp., tomato growth and yield, GC–MS/MS, MD simulation, *in silico* analysis, organophosphate pesticides (OPPs)

Introduction

Several strategies have been implemented in the agricultural sector to increase the production of crops/foods, such as the application of biofertilizers, chemical fertilizers, and pesticides, among which synthetic pesticides effectively improve the productivity of food and other agricultural commodities (Popp et al., 2013). Organophosphate (OP) pesticides are highly toxic chemicals that demonstrate extensive activity against pests and comprise approximately 38% of the all pesticides used on crops globally (Zhang et al., 2009). Excessive and inappropriate use of agrochemicals such as pesticides, herbicides, and fertilizers causes severe environmental and health issues (Dar et al., 2019).

To maintain sustainable food production, environmentally protected approaches, biofertilizers are urgently needed to improve crop growth, nitrogen fixation, and decrease yield loss under diverse stress conditions. The utilization of plant growth-promoting (PGP) endophytic bacteria is an efficient approach for stabilizing and improving crop yield. Due to their direct contact to plants, endophytic bacteria may exhibit greater ecological advantages than rhizospheric and epiphytic bacteria (James, 2000). The growth promotion of crop plants is regulated by endophytes by providing plant growth regulators, N fixation, phosphate solubilization, and ACC deaminase activity and improving tolerance against plant biotic and abiotic stresses (Carvalho et al., 2014). The application of PGP rhizobacteria (PPGPR) with plant growth-promoting traits is wanted due to its pragmatic, sustainable, and ecofriendly characteristics (Ali et al., 2022; Moon and Ali, 2022). In fact, a lot of ACC deaminase enzyme secreting PGPR was reported to improve crop plants' growth and development under various abiotic stress conditions (Moon and Ali, 2022). The PGPR can provide nutrients to non-leguminous plants even though they lack nodules, a process known as "associative nitrogen fixation" (Carvalho et al., 2014).

Furthermore, microorganisms play an important role in the detoxification of synthetic chemicals in soil (Bhatt et al., 2020; Rojas-Sánchez et al., 2022) and in the adaptation and defense of host plants by secreting bioactive compounds

(Narayanan and Glick, 2022). They consume almost all-natural and synthetic compounds as their source of carbon and energy. Moreover, a significant number of genes such as *opd* (organophosphate degrading), carboxylesterase, *mpd* (methyl parathion degrading), and amidohydrolase, α/β hydrolase and several enzymes are known to be involved in degrading certain organophosphate pesticides (Yang et al., 2006; Parakhia et al., 2014; Lee et al., 2021; Das et al., 2022).

The endophyte *Enterobacter cloacae* have been reported to promote the growth of crop plants, such as rice, groundnut, black gram, and *Brassica napus* (Panigrahi et al., 2020). It has also been shown to establish nutrient transfer symbiosis with banana plants and protect them against the black sigatoka pathogen (Macedo-Raygoza et al., 2019) and exhibit antagonistic activity against *Pythium* damping-off of cucumber (Kazerooni et al., 2020). However, the effects of *E. cloacae* on tomato plants under epiphytic conditions have not been reported. Tomato plants are susceptible to diseases such as *Fusarium* and *Verticillium* wilt, early and late blight, bacterial speck, and anthracnose. Therefore, several agrochemicals and pesticides are being applied in tropical countries such as Bangladesh to prevent the frequent attacks of pests, insects, and pathogens, which has resulted in the contamination of tomato fruit bodies with excessive pesticide residues that can be ingested through diet and cause health hazards.

Endophytic effects on tomato plant growth and development with *Enterobacter* sp. were not thoroughly investigated. Endophytic effects on tomato plant growth and development with *Enterobacter* sp. were not thoroughly investigated yet. However, several studies have been conducted with other endophytes, such as indole acetic acid (IAA)-secreting *Bacillus subtilis* (Khan et al., 2016), ACC (1-aminocyclopropane-1-carboxylate) deaminase producing *Burkholderia* species (Onofre-Lemus et al., 2009), as well as *Ampelomyces* sp. and *Penicillium* sp. (Morsy et al., 2020), which improved tomato plant growth and promotion. Because tomato plants are non-leguminous, nitrogen fixation is not possible as it is in other leguminous plants. We chose an endophytic

bacterium from a non-leguminous rice plant for this purpose. A selective powerful strain namely *Enterobacter* sp. HSTU-ASH6 expressing higher plant growth promoting (PGP) traits such as germination induction, root and shoot development, IAA, ACC-deaminase producing activity, and chlorpyrifos pesticide degrading capability was assessed as biofertilizer components in fields at epiphytic conditions. With the application of this strain in fields, tomato plants demonstrated its resistance against pathogens and pests. Therefore, no additional agrochemicals were used in the fields, resulting in survival of the plants against biotic stress and saving the tomato plant from being impregnated with pesticides. The results of this study will be highly significant for the production of agrochemical-free edible crops with higher yields at a lower cost.

Materials and methods

Isolation and biochemical characterization of endophytic strain

The endophytic strain HSTU-ASH6 was isolated from healthy fresh rice plant roots. Two months old rice plants were collected from farmers' fields near Basherhat (25° 37' 59.88" N; 88° 39' 0.00" E), Sadar, Dinajpur, Bangladesh. The roots of rice plants were separated from whole plants. To get rid of soil and dust, the root samples were gently washed in distilled water. Following this, twenty root samples were then surface sterilized with 75% ethanol for 3 min and shaken in a 2.5% (w/v) NaOCl solution for 10 min at 120 rpm, which was adopted from Khan et al. (2016) and Das et al. (2022). The root samples underwent additional washings with autoclaved distilled water while they were agitated for 20 min. The roots were rolled on nutrient agar plates, and a 0.1 mL aliquot from the final wash was inoculated into 10 mL of nutrient broth for sterility testing. Samples were discarded if any growth of bacteria was detected in the sterility check (Das et al., 2022). Finally, sterilized rice plant roots were ground using a mortar and pestle and placed in a sterilized test tube (Haque et al., 2015). The squeezed roots were cultured in chlorpyrifos-enriched minimal nutrient media to isolate the chlorpyrifos mineralizing endophytic bacteria, as described (Das et al., 2022). Selected bacteria with prompt growth potentialities were sub-cultured in the same medium to obtain pure colonies, as described previously (Das et al., 2022). The isolate was preserved in 80% (v/v) glycerol at -20°C for further analysis. Biochemical tests, including methyl red, Voges-Proskauer, catalase, KOH string, oxidase, triple sugar iron, citrate utilization, motility indole urease, and urease, and individual sugar fermentation tests such as dextrose, lactose, maltose, and sucrose utilization (Adedayo et al., 2004; Das et al., 2022), were performed to facilitate the identification of the bacterium. In addition, the activities of extracellular cellulase,

amylase, protease, and xylanase were determined as described elsewhere (Abdullah-Al-Mamun et al., 2022; Das et al., 2022).

Plant growth promoting activity tests

Indole acetic acid test

The quantification method for IAA of *Enterobacter* sp. HSTU-ASH6 was adopted as previous described (Ullah et al., 2013). Briefly, the bacterial suspension was cultured in 7 mL of modified Luria Bertani broth containing 0.01% tryptophan (L-Trp) separately and combined at 37°C for 7 days in a shaking incubator at 120 rpm. Then, 1 mL of each culture was transferred to 1.5-mL Eppendorf tubes and centrifuged at 10,000 rpm. The supernatant was transferred to glass test tubes to which 2 mL of Salkowski reagent (1 mL of 0.5 mL FeCl₃ to 50 mL of 35% HClO₄) was added. Then, the mixture was placed in the dark for 120 min. The resultant reddish-colored spectrum was read using spectrophotometer (UV-VIS spectrophotometer) at 530 nm. Finally, the strain HSTU-ASH6 secreted quantity of IAA was calculated using the standard calibration curve equation of pure IAA (Sigma-Aldrich Ltd, St. Louis, MO, USA) prepared separately.

1-Aminocyclopropane-1-carboxylate deaminase activity assay

The ACC deaminase activity of the bacterium was determined according to the modified methods of Shaharoon et al. (2006) and Belimov et al. (2015), which measures the amount of α -ketobutyrate produced upon the hydrolysis of ACC. The endophytic bacterium strain *Enterobacter* sp. strain HSTU-ASH6 was grown in Tryptic Soy Broth medium (TSB) for 18 h at 28°C to determine ACC deaminase activity. The cells were then harvested by centrifugation, washed with 0.1 M Tris-HCl (pH 7.5), and incubated for another 18 h in minimal medium containing 3 mM ACC as the sole source of nitrogen. The bacterial cells were collected by centrifugation and suspended in 5 mL of 0.1 mol L⁻¹ of Tris-HCl, pH 7.6, and transferred to microcentrifuge tube. The contents of the tubes were centrifuged at 16,000 rpm for 5 min, and supernatant was removed. The pellets were suspended in 2 mL of 0.1 mol L⁻¹ Tris HCl, pH 8.5. Next, 30 μ L of toluene was added to the cell suspension and vortexed for 30 s. After 200 μ L of the toluenized cells were placed in a fresh microcentrifuge tube, 20 μ L of 0.5 mol L⁻¹ ACC was added to the suspension, vortexed, and then incubated at 30°C for 15 min. Following the addition of 1 mL of 0.56 mol L⁻¹ HCl, the mixture was vortexed and centrifuged for 5 min at 13,000 rpm at room temperature. Two mL of the supernatant was vortexed together with 1 mL of 0.56 mol

L^{-1} HCl. Thereupon, 2 mL of the 2, 4-dinitrophenylhydrazine reagent (0.2% 2, 4-dinitrophenylhydrazine in 2 mol L^{-1} HCl) was added to the glass tube, and the contents were vortexed and then incubated at 30°C for 30 min. Following the addition and mixing of 2 mL of 2 mol L^{-1} of NaOH, the absorbance of the mixture was measured by using a spectrophotometer at 540 nm. The cell suspension without ACC was used as a negative control and with $(NH_4)_2SO_4$ (0.2% w/v) as the positive control. The number of μ mol of α -ketobutyrate produced by this reaction was determined by comparing the absorbance at 540 nm of a sample to a standard curve of α -ketobutyrate ranging between 10 and 200 μ mol (Honma and Shimomura, 1978; Shaharoona et al., 2006; Belimov et al., 2015).

Phosphate solubilization test

The phosphate solubilization ability of the isolate was determined qualitatively by streaking a strain on PVK agar media in a Petri plate. The plate was placed at 30°C for 72 h under aerobic conditions. The colonies that could grow and create a zone on the insoluble phosphate media were selected as the phosphate-solubilizing bacteria (Madhusmita et al., 2017).

Nitrogen fixation test

The nitrogen fixation capability of the endophytic strain HSTU-ASH6 was determined by streaking the strain on completely nitrogen-free Jensen's media (Sulistiyani and Meliah, 2017). The strain was grown for 5–7 days at 37°C in an incubator under aerobic conditions.

DNA extraction, amplification, sequencing, and analysis

The genomic content of the isolate was extracted using a commercial Quick-DNATM Miniprep Kit specific for bacteria (Zymo Research, Irvine, CA, USA), according to the manufacturer's specification. The 16S rRNA gene was amplified from the extracted DNA by polymerase chain reaction. The bacterial-specific universal forward primer 27F 5'-AGAGTTTGATCCTGGCTCAG-3' and reverse primer 1492R 5'-TACGGTTACCTGTTCGACTT-3' were used in the PCR mixture. The master mix was prepared by adding Taq buffer, dNTPs, $MgCl_2$, and nuclease-free water in a PCR tube. The forward and reverse primers, $MgCl_2$, template DNA, and Taq DNA polymerase enzyme were added just before loading the sample in the PCR system (Haque et al., 2020; Das et al., 2022). After 36 cycles of PCR steps, the amplicon was stored at –20°C for further analysis. The amplified PCR products were visualized by agarose gel electrophoresis. DNA purification,

cycle sequencing, and DNA sequencing of PCR amplicons were performed using a BDT v3 Cycle sequencing kit in a genetic analyzer 3130 (Haque et al., 2015, 2020). Finally, the 16S rRNA sequence was submitted to GenBank on the NCBI online server.

Effect of *Enterobacter* sp. strain HSTU-ASH6 on tomato plant growth promotion

The *Enterobacter* sp. HSTU-ASH6 effect on tomato plant growth promotion was assessed in two different ways. Firstly, its effect at seed germination stage was performed in laboratory conditions. Secondly, its effect on tomato plant seedlings development to vegetative and reproductive stages was investigated in fields at epiphytic conditions.

Effect of strain HSTU-ASH6 on tomato seeds germination

Seed sterilization and preparation

The tomato seeds were collected from Bangladesh Agricultural Development Corporation nursery. Firstly, the seeds were allowed to sundry. Then seeds were sterilized with 70% ethanol for 1 min and washed several times with sterilized water.

Seed bacterization

The sterilized seeds were placed in two sets of sterilized Eppendorf tubes. The first set of tubes contained seeds in 1 mL of bacterial suspension, and the second set contained seeds in 1 mL of distilled water without the strain (control). All tubes were placed in a dark environment for 8 h. After that the seeds were ready for germination.

Seed inoculation onto petri dishes

The seeds were sown for germination on Whatman filter paper in Petri dishes. The petri dishes were arranged in a Completely Randomized Design (CRD) with three replications. After 7 days of seed germination, 0.25 mL of bacterial suspension was applied in each petri dish. After 15 days of seed plantation, the following parameters of tomato plants with and without the strain were recorded.

Germination percentage

Germination percentage was calculated using the formula $GP = \text{Total germinated seeds} / \text{Total number of seeds} \times 100$ (Ashraf and Foolad, 2005).

Root length and shoot length

Root length and shoot length were measured using a graduated ruler.

Vigor index

The vigor index was calculated using the formula Seedling length \times germination percentage.

Effect of HSTU-ASH6 strain on tomato seedlings in field conditions

Tomato seedlings aged 32 days were collected from a local nursery and planted in the research field using a randomized complete block design method. The experiment was divided into the following five treatments to observe the effect of using different concentrations (30–100%) of urea doses and bacterial strains: T1 (30% urea with bacterium), T2 (70% urea with bacterium), T3 (100% urea with bacterium), Tc (100% urea without bacterium), and T0 (no urea and no bacterium/control). The experimental unit area (plot) was 1.80 m² and consisted of four rows measuring 1.32 m in width and 1.37 m in length, and the seedlings were planted using a hand drill method, maintaining a row-to-row distance of 40 cm and a plant-to-plant distance of 10 cm in a line. The plants were irrigated regularly according to requirement. The treatments were applied to the plants after 10, 20, 30, and 40 days of plantation. The root length, shoot length, leaf size, fresh weight, and dry weight were measured two times after 30 and 45 days of plantation.

Pesticide degradation analysis using GC–MS/MS

Firstly, the growth of the strain was checked in chlorpyrifos-enriched minimal salt broth media, in which chlorpyrifos (1 g/L) was the sole source of carbon (Lee et al., 2021; Das et al., 2022). Next, 5 μ L of the stock bacterium was inoculated into the medium and kept for 14 days, after which 5 mL of chlorpyrifos-containing MSM was transferred into a separating funnel. Secondly, 25 mL of distilled water and 5 mL of *n*-hexane were added to the funnel and shaken vigorously for 5–10 min. The desired solvents in the *n*-hexane layer appeared on the top layer, whereas the unwanted layer remained on the bottom layer. The bottom layer was separated and kept in a bottle. Finally, to examine the biodegradation of chlorpyrifos, the *n*-hexane with appropriate solvent-containing layer solution was run on Gas Chromatography – Tandem Mass Spectrometry (GC–MS/MS) (Shimadzu QP2010, Japan). The GC–MS/MS instrumentation was set up according to Al Mansur et al. (2018), and following examination of each compound's mass spectrum were determined using the NIST11 library (Zaman et al., 2021).

Genomic DNA extraction, library preparation, whole genome sequencing

The preparation of the genomic library of *Enterobacter* sp. HSTU-ASH6 and the sequencing of the complete genome were performed using the Illumina MiniSeq System (Illumina, Inc., San Diego, CA, USA), as described previously (Abdullah-Al-Mamun et al., 2022; Das et al., 2022). After complete genome sequencing, the quality test was conducted using the fast QC analysis and Illumina Base Space sequence analysis Hub. SPAdes assembler version 3.5 was used to assemble the complete genome of *Enterobacter* sp. HSTU-ASH6, and the resulting assembled genome was annotated and analyzed using NCBI Prokaryotic Genome Annotation Pipeline (PGAP) version 4.5, Prokka. The circular genome map of *Enterobacter* sp. HSTU-ASH6 was prepared using CGView Comparison Tool. Next, different types of genes, e.g., those responsible for plant growth promotion (nitrogen fixation, phosphate solubilization, IAA production, ACC deaminase production, and sulfur assimilation), biofilm formation, root colonization (chemotaxis and mortality), pesticide degradation, and stress tolerance (heat shock and cold shock), were predicted from the PGAP file.

Strain classification

Phylogenetic tree construction

A comparative phylogenetic analysis of housekeeping genes, e.g., 16S rRNA, *gyrB*, *recA*, *rpoB*, and *tonB* of different closely related *Enterobacter* sp. sequences, was performed using the NCBI database. The phylogenetic tree of HSTU-ASH6 whole genome sequence was constructed along with 29 nearest homologs genebank files accumulated from the NCBI database. The REALPHY 1.12 online server was used to construct the complete genome phylogenetic tree, which was modified using the MEGA-X.0 program. Finally, the phylogenetic trees of the housekeeping genes were constructed by the neighbor-joining method using Molecular Evolutionary Genetics Analysis (MEGA-X).

Average nucleotide identity and DNA–DNA hybridization

Average nucleotide identity (ANI) and digital DNA–DNA hybridization (DDH) analyses were performed using the JSpecies WS, Type Strain Genome Server (TYGS) and GGDC web server, respectively (Abdullah-Al-Mamun et al., 2022). A total of 15 types of nearest homolog complete genome sequences were utilized for the ANI analysis. For the DDH analysis, 15 different types of genomes were aligned with the HSTU-ASH6 genome.

Genome comparison

Multiple genome sequence alignment and pangenomic analysis

To determine the genetic diversity and similarities of *Enterobacter* sp. HSTU-ASh6, its genome sequence was compared with the genome sequences of six most closely related species, viz., *E. asburiae* (CP007546), *E. bugandensis* 220 (CP039453), *E. chengduensis* (CP043318), *E. cloacae* A1137 (CP021851), *E. roggenkampii* RHBSTW 00695 (CP056168), and *E. sichuanensis* SGAir0282 (CP027986), by pangenomic analysis using GView Server. The genome of *Enterobacter* sp. HSTU-ASh6 was further compared with four recently published nearest homologs, viz., *E. cloacae* A1137 (NZ_CP021851), *E. sichuanensis* SGAir0282 (NZ_CP027986), *E. roggenkampii* Ecl 20 981 (CP048650), and *E. asburiae* ATCC 35953 (CP011863), by multiple genomic analysis using the progressive Mauve software¹.

Insecticide degradation demonstrated by enzyme catalytic reaction

Homology modeling, protein preparation, and validation

The homology modeling of the protein was performed using the Iterative Threading ASSEmbly Refinement (I-TASSER) Server. Next, the model was subjected to energy minimization using the steepest descent and conjugate gradient techniques to eliminate lower quality contacts among protein atoms. Computations were performed *in vacuo* with GROMOS 96 43B1 parameters set using the Swiss-PDB Viewer. The 3D structures of the protein were saved in .pdb format. The SAVES v6.0 online server was used to check the validation and evaluate the quality of the minimized protein².

Small molecule/ligand collection and optimization

A total of 105 various types of organophosphorus pesticides, weed killers, and nerve agent small molecules were collected from the PubChem database³. After ordering, the ligands were optimized and minimized using the mmff94 force field and the steepest descent algorithm in the PyRx software environment. The 3D structures of small molecules were stored in a file in .sdf format.

Virtual screening, molecular docking, and visualization

A total of 105 pesticides (small molecules) with 28 valid protein structures were used individually and screened with 105 ligands for virtual screening. Virtual screening and molecular docking were performed using the PyRx software (Dallakyan and Olson, 2015). Protein–ligand complexes were constructed using the Chimera software, and 2D and 3D structure visualization was performed using Discover Studio 2021 Client. The results of virtual screening were displayed by boxplot analysis performed using the Origin Pro 8.0 software. Furthermore, protein and ligand non-bonded interactions were recognized using Discovery Studio 2021 Client. At the time of virtual screening, the grid box sizes were fixed at 61.6411, 61.6072, and 61.8787, which was the maximum size of the grid box, respectively for X, Y, and Z. However, in the case of molecular docking, the grid box sizes were not fixed, and they were dissimilar as for (i) α/β fold hydrolase (GM298_18675) with crotoxyphos, (ii) carboxylesterase with coumaphos, (iii) α/β fold hydrolase (GM298_08590) with cypermethrin, (iv) α/β fold hydrolase (GM298_00815) protein with diazinon, (v) amidohydrolase family protein (GM298_20245) with chlorpyrifos, and the X, Y, and Z sizes were 61.6411, 61.6072, and 61.8787, respectively. The binding affinity of protein with ligands was calculated in kcal/mole for a negative score.

Molecular dynamics simulation

To determine the potential pesticide-degrading stability of proteins with pesticides, a molecular dynamics simulation was run using the Desmond program (Schrodinger) that has an explicit solvent MD package linked to the OPLS 2005 force field. The protein preparation wizard was used to create the protein–ligand complexes, and the system builder panel was solvated them using the orthorhombic simple point-charge water model. The counter ions Na⁺ or Cl[−] were added as necessary to charge and neutralize the solvated system. In order to relax the system to the lowest local energy, minimization tasks were carried out. Next, this model system was run to MD simulation steps using the OPLS 2005 force field parameter (Lee et al., 2021; Patel et al., 2021). The MD simulation was performed up to 100 ns using the NPT ensemble (isothermal-isobaric ensemble, constant temperature, constant pressure, and constant number of particles) at 300 K temperature and 1.013 bar pressure (Jorgensen et al., 1996; Lee et al., 2021). For controlling temperature and pressure, the Noose-Hover chain thermostat algorithm and the Martyna-Tobias-Klein barostat algorithm were employed, respectively. The particle mesh Ewald method was used to measure long-range electrostatic interactions, while

¹ <http://darlinglab.org/mauve/mauve.html>

² <https://saves.mbi.ucla.edu/>

³ <https://pubchem.ncbi.nlm.nih.gov/>

the other parameters were left at their default values (Patel et al., 2021). The behavior and interactions between the ligands and protein were examined using the Simulation Interaction Diagram tool. The output.cms file was imported, and root mean square deviation (RMSD) and root mean square fluctuation (RMSF) was chosen to produce the revealed plots.

Results

Isolation and biochemical characterization

The biochemical characterization of HSTU-ASh6 is summarized in [Supplementary Figure 1](#). The strain was gram-negative; KOH dissolves the thin peptidoglycan layer of the cell wall of gram-negative bacteria, and they showed viscously and stuck in the loop within 30 s after the addition of KOH to the bacteria cultured for 24 h. Conversely, the isolate demonstrated positive results in the Voges-Proskauer, catalase, triple sugar iron, citrate utilization, motility indole urease, urease, dextrose, lactose, maltose, and sucrose utilization tests. However, the strain showed negative results in the indole, MR, and oxidase tests. It also exhibited mild activities of cellulase, amylase, and xylanase but a vigorous protease activity in the plate assay.

P solubilization, N fixation, indole acetic acid production, 1-aminocyclopropane-1-carboxylate deaminase activity

The results of phosphate solubilization, nitrogen fixation, and IAA production are summarized in [Supplementary Figure 2](#). The phosphate solubilization test was positive because growth was detected and a hollow zone appeared in the PVK plate. The nitrogen fixation test was also positive based on the detection of the growth of HSTU-ASh6 in Jensen's medium. Moreover, the strain was capable of producing IAA as demonstrated by the reddish pink color, which amounted to 4.8 mg/mL compared to that in the control. In addition, the ACC deaminase activity of the strain was 0.0076 μ g/mL/h.

Growth promotion

Seed germination effect on tomato seeds

The HSTU-ASh6 suspension was applied three times to the tomato seeds sown on a filter paper in a Petri dish. After 9 days, the germination percentage, root length, shoot length, seedling length, and vigor index were recorded as 92%, 6.09, 5.39, 12.02 cm, and 1109.57 in the treated plants, respectively.

In the control (seeds not treated with the bacterial strain), the respective values were 69%, 3.50, 5.34, 8.84 cm, and 611.99 ([Table 1](#)).

Tomato plant growth at vegetative and reproductive stages

The root length, shoot length, leaf length, fresh weight, and dry weight of tomato plants measured after 30 and 45 days of plantation are shown in [Table 2](#). The highest root length, shoot length, leaf length, fresh weight, and dry weight were observed in T3 treatment. In particular, the fresh and dry weights of tomato plants were significantly higher in T3 treatment than in T2 and other treatments. The fresh and dry weights were 1.33–2.93-fold and 1.8–2.43-fold higher in T3 treatment, 1.95–2.3-fold and 1.41–2.17-fold higher in T2 treatment, 1.8–2.0-fold and 1.3–1.6-fold higher in T1 treatment, respectively, than in Tc treatment after 30–45 days of plantation. These results suggest that the inoculation of *Enterobacter* sp. strain HSTU-ASh6 significantly improved tomato plants' growth and development in fields at epiphytic conditions where the amount of urea fertilizer application was cut by 30–70% ([Table 2](#) and [Supplementary Figure 3](#)).

Chlorpyrifos biodegradation analysis using GC–MS

The GC–MS/MS analysis spectra revealed the presence of phorate sulfoxide, phorate sulfone, chlorpyrifos methyl, carbophenothion sulfoxide, oxydisulfoton, carbonochloridic acid, 2,4,5-trichlorophenyl ester, thionodemeton sulfone, 3-(2-thienyl)-DL-alanine, chlorpyrifos oxon, diethyl methanephosphonate (DEMP), and 3,5,6-trichloro-2-pyridinol (TCP), etc. ([Table 3](#)). On the basis of GC–MS/MS results, a pathway of chlorpyrifos biodegradation by HSTU-ASh6 was proposed as illustrated in [Figure 1](#). Chlorpyrifos was initially degraded by hydrolysis to generate chlorpyrifos oxon that was further broken down to generate TCP and DEMP (spectrum = 8). Subsequently, TCP was again degraded by ring breakage, resulting in its complete detoxification.

Genomic features of *Enterobacter* sp. HSTU-ASh6

The genome size of *Enterobacter* sp. HSTU-ASh6 was 4,857,424 bp with 55.1% GC, 4478 protein-coding sequences (CDS), and 72 tRNAs. The subsystem of the RAST annotation is shown in [Supplementary Figure 4](#). All proteins of *Enterobacter* sp. HSTU-ASh6 were revealed by CGview analysis in a proper genomic map ([Figure 2](#)).

TABLE 1 Germination percentage, root length, shoot length, seedling length, and vigor index of tomato plant with the strain at 9 days of seed plantation.

Name of isolate	Germination percentage	Root length (cm)	Shoot length (cm)	Seedling length (cm)	Vigor index
Control	69.23 ± 0.0 ^b	3.50 ± 0.58 ^b	5.34 ± 0.11 ^{ab}	8.84 ± 0.53 ^b	611.99 ± 36.71 ^b
HSTU-ASH6 (P7)	92.31 ± 0.0 ^a	6.09 ± 0.26 ^a	5.39 ± 0.13 ^a	12.02 ± 0.28 ^a	1109.57 ± 25.58 ^a

Different lowercase letters indicate significant difference at the 5% level.

TABLE 2 Effect of bacterium and fertilizer in different time period among different treatment group.

Data collection time	Treatments	Root length (cm)	Shoot length (cm)	Leaf length (cm)	Fresh weight (gm)	Dry weight (gm)
After 30 days of plantation	T1	22.33 ± 1.86 ^{ab}	32.67 ± 2.84 ^a	20.33 ± 0.88 ^{ab}	150 ± 1.16 ^c	78 ± 1.16 ^c
	T2	24.33 ± 0.33 ^a	34 ± 0.58 ^a	21 ± 0.58 ^a	162.67 ± 1.45 ^b	85.33 ± 0.88 ^b
	T3	25.33 ± 0.67 ^a	35 ± 0.58 ^a	21.33 ± 0.67 ^a	180 ± 1.15 ^a	90.33 ± 1.20 ^a

	T3	29 ± 3.06 ^a	40.33 ± 0.88 ^a	23.67 ± 0.33 ^a	278.33 ± 2.12 ^a	187.33 ± 1.45 ^a
	Tc	17.67 ± 0.67 ^b	30.67 ± 2.12 ^b	20.67 ± 1.45 ^c	95 ± 1.16 ^d	77.33 ± 1.45 ^d
	To	12 ± 0.58 ^c	25 ± 1.15 ^c	17.33 ± 0.33 ^d	83.67 ± 0.88 ^e	56.67 ± 1.20 ^e

T1, 30% urea treatment + strain HSTU-ASH6 treatment; T2, 70% urea treatment + HSTU-ASH6 treatment; T3, 100% urea treatment + HSTU-ASH6 treatment; T0, 0% urea treatment; Tc, 100% urea treatment. Different lowercase letters indicate significant difference at the 5% level.

The genomic map of proteins from *Enterobacter* sp. HSTU-ASH6 was created successfully, where GC-skew positivity indicates the presence of CDS downstream and GC-skew negativity shows the presence of CDS upstream. Although GC-skew is predominantly introduced by RNA synthesis in local genomic areas, it was first used to estimate the *ori* and *ter* positions computationally by looking at known genome sequences.

Taxonomic classification

Phylogenetic tree

Phylogenetic tree of housekeeping genes

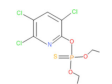

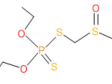

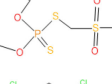

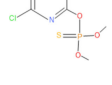

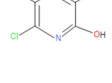

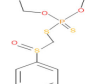

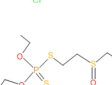

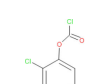

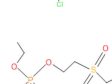

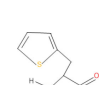

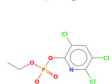

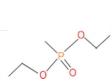

The 16S rRNA phylogenetic tree demonstrated that HSTU-ASH6 positioned in the same sister taxa (with 45% similarity) with *E. sichuanensis* WCHECL1597 (Figure 3A). According to *gyrB* (Figure 3B) and *rpoB* (Figure 3C) alignment tree, HSTU-ASH6 was located in the same sister taxa with *E. cloacae* A1137 with 62% and 35% similarities, respectively. Moreover, *recA* (Figure 3D) tree showed that HSTU-ASH6 was located in a different clade with *E. cloacae* A1137 and *E. sichuanensis* WCHECL1597. Moreover, *tonB* (Figure 3E) phylogenetic tree showed that HSTU-ASH6 was placed with *E. cloacae* A1137 and *E. sichuanensis* WCHECL1597 in the different taxa of the same node. In particular, HSTU-ASH6 was placed in the same node and was more close to *E. cloacae* A1137 in the whole genome sequence phylogenetic tree (Figure 3F).

Genome comparison

The pairwise ANI blast (ANIb) value observed between HSTU-ASH6 and *E. cloacae* A1137 was 98.89%. In fact, *E. sichuanensis* SGAir0282, *E. roggenkampii* RHBSTW, *E. asburiae* RHBSTW-01009, and *E. roggenkampii* Ecl 20 981 showed 98.12, 91.12, 91.02, and 91.06% ANIb values, respectively, where other *Enterobacter* species showed ANIb values < 91% (Supplementary Table 1). The DNA–DNA hybridization analysis of HSTU-ASH6 with its nearest homolog *E. cloacae* A1137 showed 92.6% DDH, whereas all other *Enterobacter* strains showed 38.9–45.6% DDH, except *E. sichuanensis* SGAir0282 that showed 85.6% DDH (Table 4).

The locally collinear block (LCB) of HSTU-ASH6 genome did not completely match with the LCBs of genomes included for genomic comparison. Therefore, there was a rearrangement of genomic regions between the two genomes in terms of collinearity. As shown in Figure 4A, HSTU-ASH6 shared the highest homologous region with A1137. It also shared almost similar LCBs as those of A1137 strain with SGAir0282. We performed a pangenomic analysis of HSTU-ASH6 with six nearest homologs to further investigate the genomic variance. In the circular plot, the pink color slot is identified as the pangenome, and the white space indicates a region missing in the specified genome (Figure 4B). The circular plot clearly indicates that several portions of the genome sequence of HSTU-ASH6 were not similar compared with the other six closest strains.

TABLE 3 Spectrum, molecular form and chemical structure of chlorpyrifos (1 gm/100 mL) biodegradation observed using GC–MS/MS analysis.

Similarity of hit	Search Spectrum	Soft ionization (SI)	Spectrum	Molecular weight (Da)	Molecular form	Chemical structure
1	77	2921	88	2	Chlorpyrifos	
7	60	2588	3	6	Phorate sulfoxide

24	51	683	8	9	Diethyl methanephosphonate	

Plant growth-promoting and stress-tolerating genes

The genome of *Enterobacter* sp. HSTU-ASh6 harbors various types of PGP genes, namely those encoding nitrogen fixation (*iscU*, *nifJ*, *iscA*, *iscR*, *iscS*, *iscX*, *sufABCDE*, and *fdx*), nitrosative stress (*ntrB*, *norR*, *norV*, *nsrR*, and *glnK*), nitrogen metabolism regulation (*glnD*, *glnB*, and *ptsN*), ammonia assimilation (*gltB*), ACC deaminase

(*dcyD* and *rimM*), siderophore enterobactin (*fes*, *entFSD*, *fhuABCD*, and *tonB*), IAA production (*trpCFBDS* and *ipdC*), phosphate metabolism (*pitA*, *pstABCS*, *phoU*, *ugpABE*, *phoABERHQ*, and *pntAB*), biofilm formation (*tomB*, *luxS*, *efp*, *flgABCDGHIJKLMN*, *motAB*, and *hfg*), sulfur assimilation (*cysACHIJKMNTWZ*), sulfur metabolism (*fdxH* and *cysACDEHIJKMNQSWZ*), root colonization (*cheZYBRWA*, *malE*, *rbsB*, *fliZDSTFZGHIJKMPQR*, *hofC*, *pgaABCD*, *motAB*, and *murJ*), superoxide dismutase

(*sodABC*), and trehalose metabolism (*treBCR*, *otsAB*, and *lamb*) (Table 5). Furthermore, numerous types of genes associated with stress tolerance e.g., heat shock (*smpB*, *ibpAB*, *hspQ*, *dnaJK*, *rpoH*, *lepA*, and *grpE*), cold shock (*cspADE*), and drought resistance (*nhaA*, *chaAB*, *proABQVWXPS*, *betABT*, *trkAH*, and *kdpABCF*) were detected in the HSTU-ASH6 genome (Table 5). These genes are essential for the plant to survive and grow in a harsh environment.

Pesticide-degrading protein model validation and evaluation

A significant number of genes whose products were responsible for pesticide degradation (*ampD*, *glpABQ*, *pdeHR*, *pepABDQ*, *phnFDGHJKLMOP*, *paaC*, *hpxKW*, amidohydrolase, and alpha/beta fold hydrolase) were identified in the genome of HSTU-ASH6 (Supplementary Table 2).

For model validation, 39 modeled proteins were analyzed using the SAVESv6.0-structure validation server, among which 28 were validated according to VERIFY (3D-1D score), with their score recorded as 80.05–97.97%. Among these, alpha/beta fold hydrolase family protein (GM298_09990) had the maximum ERRAT quality score of 97.35 (Table 6). The individual protein average TM score, RMSD, IDEN, and Cov were 0.95, 0.75, 0.51, and 0.97, respectively, based on the I-TASSER result (Table 6). Moreover, the Ramachandran plot regions, including the most favored regions (A, B, L), additional allowed regions (a, b, l, p), generously allowed regions (~, ~b, ~l, ~p), and disallowed regions of the model proteins, are presented in Table 6. Consequently, the 28 validated model proteins were selected for virtual screening with 105 small molecules.

A total of 105 different pesticides, including weed killers and organophosphorus nerve agents, were screened with the 28 validated model proteins of *Enterobacter* sp. HSTU-ASH6 (Figure 5). The score ranged from −8.8 to −3.1 (kcal/mol). The highest negative score was recorded for cypermethrin with *phnL* (−8.8 kcal/mol), and the lowest negative score was found for demephion-O with amidohydrolase (GM298_10355) (−3.1 kcal/mol). The box plot analysis revealed that each box with the bold line represents median values, and the square sign indicates mean values. Moreover, the upper and lower lines in the box plots represent minimum and maximum values, respectively. Interestingly, most values were found between the 25th and 75th percentile. The 25th and 75th percentile quartile differences indicated the interquartile range. Surprisingly, in this dataset, some outlier data were observed, indicating the presence of some small molecules possessing an excellent binding affinity with respective proteins. It was also observed that the nine proteins' outlier binding affinities values were outside of IQR1.5.

Catalytic interactions of model proteins with selective pesticides

As shown in Figure 6, the alpha/beta fold hydrolase (GM298_18675) of *Enterobacter* sp. HSTU-ASH6 anchored with crotoxyphos and formed a potential catalytic triad in the binding pocket region with residues Ser153-His277-Asp152. Ser153 and Gly81 specifically mediated the attractive charge connection with the +P-atom of crotoxyphos and the typical H-bond contact with the O atom (Figure 6A). Besides other interactions, Val201 and Phe14 directly interacted with the phosphodiester bond of crotoxyphos via π -sigma and π - π stacked interaction. The interaction distances among the residues of the catalytic site were recorded within < 3 Å, except for Asp152, which was 5.36 Å.

Surprisingly, the residues Ser195, His400, and Glu194 constituted a putative catalytic triad in the binding pocket region of the *Enterobacter* sp. HSTU-ASH6 carboxylesterase. Ser195 and Arg199 interacted with the O atom to form the traditional H-bond, and Glu194 interacted with the +P atom to form phosphodiester bonds and the H atom to interact with the carbon-hydrogen bond of coumaphos (Figure 6B). Moreover, the π - π stacked bond was formed by the His400 residue of carboxylesterase with coumaphos ligand, and it directly interacted with the phosphodiester bond of ligand. The interaction distances among the residues of the catalytic site were recorded within <4 Å.

The alpha/beta fold hydrolase (GM298_08590) formed a potential catalytic triad Ser157-His279-Asp156 in the binding pocket region with cypermethrin (Figure 6C). The interaction distances among the catalytic site residues were recorded within <5.25 Å. Furthermore, the alpha/beta fold hydrolase (GM298_00815) protein–diazinon docked complex demonstrated interaction with multiple residues (Figure 6D). In particular, conventional H-bonds were made by Ser99, His231 with the O atom of the diazinon compound. In addition, the amidohydrolase family protein (GM298_20245) anchored with chlorpyrifos and showed a significant interaction (Figure 6E). For instance, Arg408 interacted with the O atom of chlorpyrifos by a conventional hydrogen bond. Moreover, alkyl and pi-alkyl bonds were made by Val547, Arg408, Ala550, Lys549, His250, His467, and Tyr545 with chlorpyrifos, respectively. Interestingly, all of them were observed with two bonds, except His467 and Tyr545. Only one amino acid made the attractive charge and was interconnected with +P-atom. His250 made pi-sulfur and pi-alkyl bond at a time.

Molecular dynamics simulation

The RMSD plot of the α/β hydrolase (GM298_18675)–crotoxyphos complex was sharply increased from 0 to 4 ns (Figure 7Aa), and it continued up to 30 ns with an

RMSD ranging from 2.6 to 3.45 Å. After a slight decrease in the RMSD of the protein, at 35 ns, an increasing parallel trend continued up to 100 ns, with an RMSD ranging from 2.5 to 3.35 Å, except a slight decrease at 83–86 ns of the ligand. In the RMSF plot of the alpha/beta hydrolase (GM298_18675)–crotoxyphos complex (Figure 7Ab), the favorable residues of alpha/beta hydrolase (GM298_18675) with crotoxyphos were observed at Leu10 (0.93 Å), Phe14 (1.161 Å), Lys19 (2.806 Å), Ser21 (3.243 Å), Ser22 (3.639 Å), Arg30 (0.798 Å), Gly33 (0.714 Å), Thr34 (0.636 Å), Ser37 (0.842 Å), Leu40 (0.975 Å), Gly81 (0.43 Å), Cys82 (0.416 Å), Ser85 (0.449 Å), Asp152 (0.378 Å), Tyr181 (0.425 Å), Val201 (0.70 Å), Ile202 (0.659 Å), Thr206 (0.644 Å), Leu207 (0.51 Å), Ile276 (0.542 Å), His277 (0.493 Å), Gly278

(0.456 Å), Gln281 (0.452 Å), Leu282 (0.539 Å), and Ile285 (1.005 Å). The Rg of the α/β hydrolase (GM298_18675)–crotoxyphos complex fluctuated throughout the simulation, with an average value of 3.960 Å. The MolSA, solvent-accessible surface area (SASA), and PSA of the alpha/beta hydrolase (GM298_18675)–crotoxyphos complex insignificantly varied throughout the simulation period. The average MolSA, SASA, and PSA were 310.304, 56.5454, and 81.3709 Å², respectively (Figure 7Ac).

The RMSD plot (Figure 7Ba) of the carboxylesterase–coumaphos complex was sharply increased from 0 to 3 ns, and it continued up to 23 ns, with an RMSD ranging from 2.3 to 3.45 Å. After a slight decrease in the RMSD of the protein, at 35 ns, a parallel increasing trend continued up to

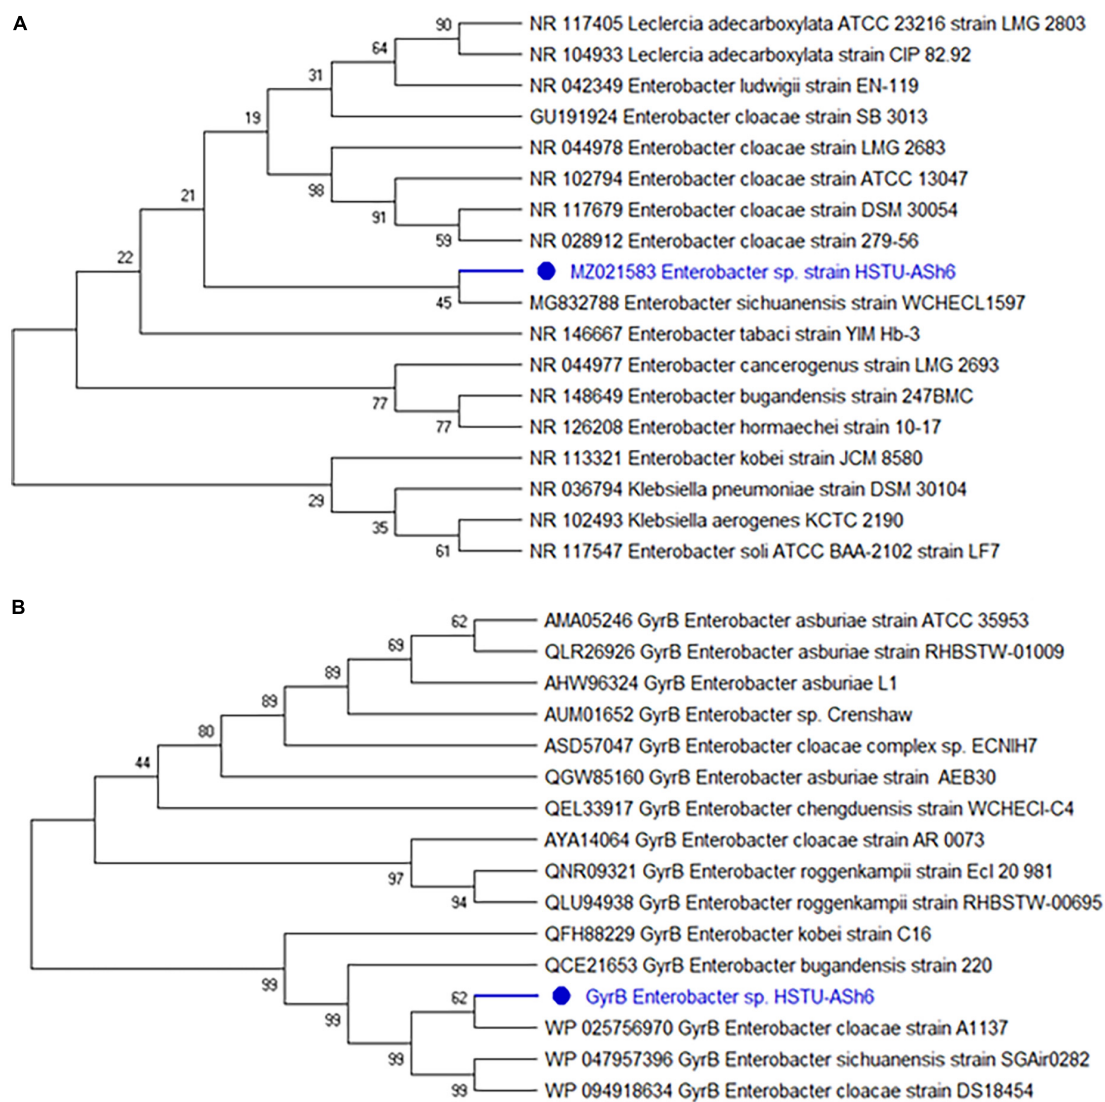

FIGURE 3
(Continued)

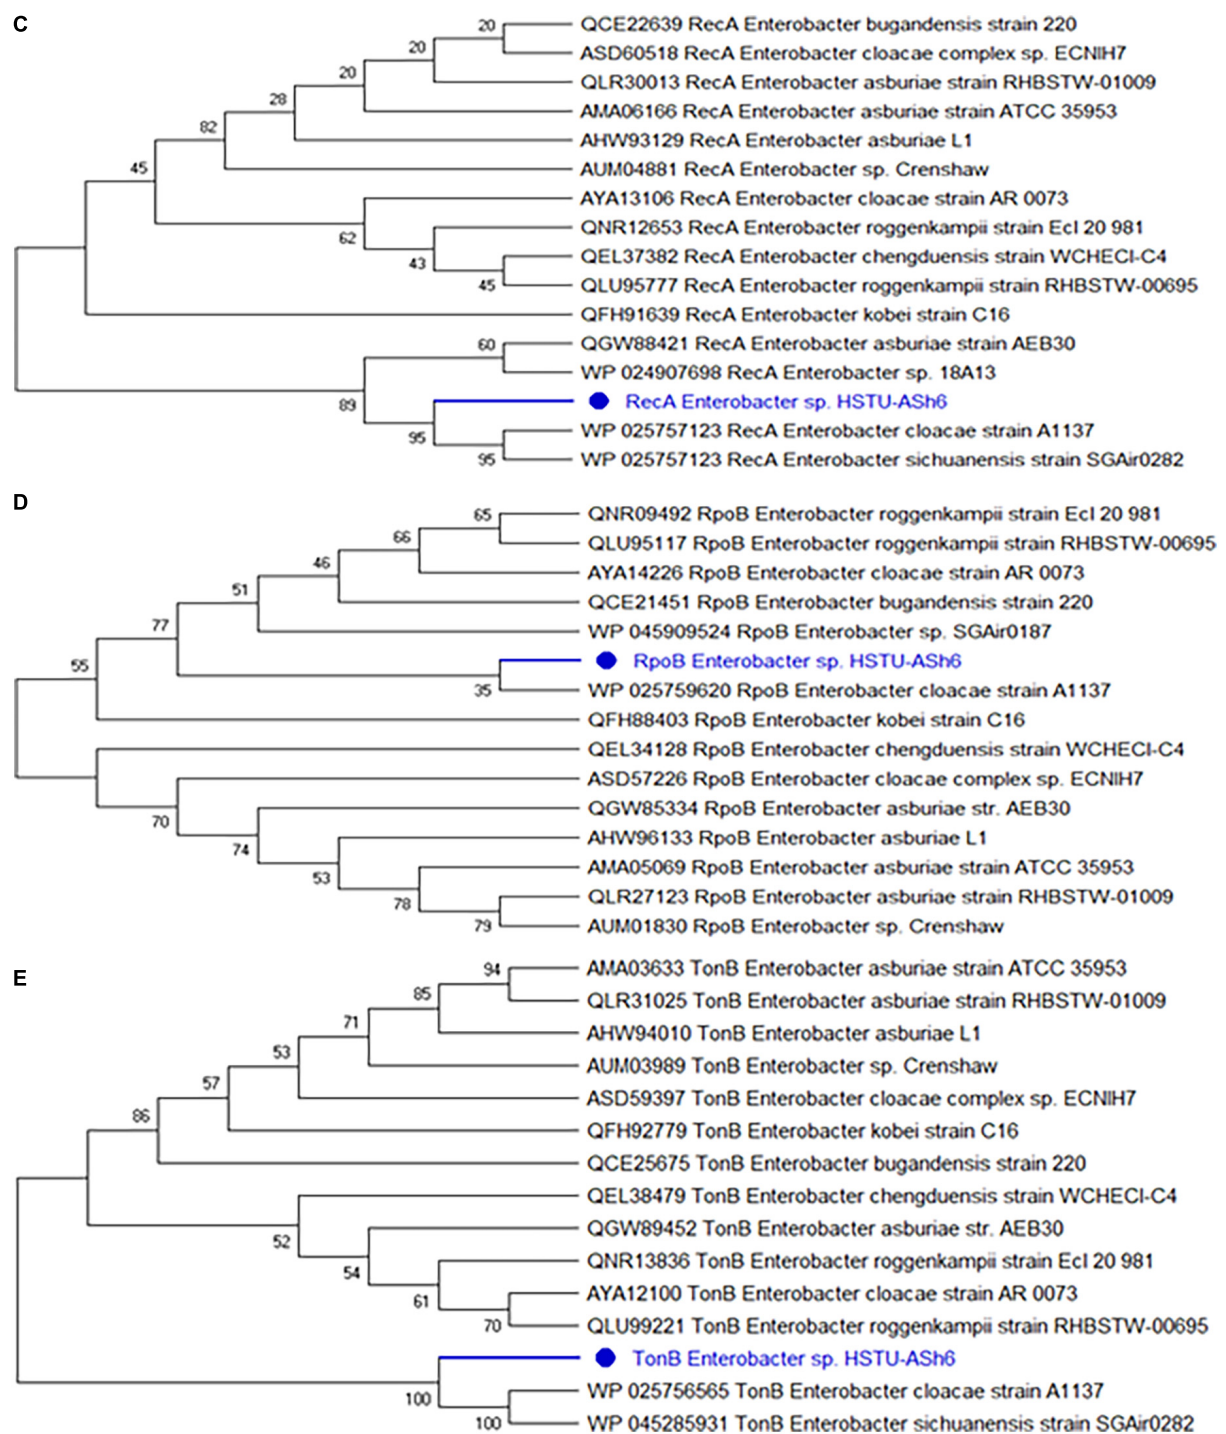

FIGURE 3
(Continued)

100 ns, with an RMSD ranging from 2.5 to 3.80 Å, except a slight decrease at 83–86 ns of the ligand. In the RMSF plot of the carboxylesterase–coumaphos complex (Figure 7Bb), the favorable residues of carboxylesterase with coumaphos were observed at Glu69 (1.491 Å), Thr73 (1.723 Å), Gly75 (1.948 Å),

Gly76 (1.807 Å), Trp106 (0.456 Å), His108 (0.787 Å), Ile114 (0.918 Å), Leu119 (0.923 Å), Pro121 (0.736 Å), Tyr122 (0.66 Å), Phe192 (0.437 Å), Ser195 (0.64 Å), Ala196 (0.829 Å), Arg199 (0.71 Å), Ser221 (0.717 Å), Thr224 (2.112 Å), Leu225 (1.79 Å), Glu308 (0.59 Å), Val311 (0.716 Å), Met312 (0.884 Å), Val314

(1.919 Å), Phe315 (1.881 Å), Ile317 (1.698 Å), Ala359 (0.803 Å), Phe360 (0.643 Å), His391 (1.243 Å), Trp399 (0.976 Å), His400 (0.734 Å), and Val404 (0.761 Å). The Rg of the carboxylesterase–coumaphos complex fluctuated throughout the simulation, with an average value of 4.147 Å. The MolSA, SASA, and PSA of the carboxylesterase–coumaphos complex insignificantly varied throughout the simulation period. The average MolSA, SASA, and PSA were 317.102, 38.885, and 82.488 Å², respectively (Figure 7Bc).

The RMSD plot of the α/β hydrolase (GM298_08590)–cypermethrin complex was sharply increased from 0 to 3 ns (Figure 7Ca), and it continued up to 100 ns with the exception of a few irregularities. The overall RMSD difference ranged from 3.5 to 4.01 Å. In the RMSF plot of the alpha/beta hydrolase (GM298_08590)–cypermethrin complex (Figure 7Cb), the favorable residues of alpha/beta hydrolase (GM298_08590) with cypermethrin were observed at Ala17 (3.112 Å), Pro18 (2.65 Å), Leu26 (0.956 Å), Ala29 (1.522 Å), Thr30 (1.435 Å), Leu34

(1.069 Å), Leu37 (1.135 Å), His83 (0.858 Å), Gly85 (1.275 Å), Gly86 (1.409 Å), Trp87 (1.15 Å), Cys88 (1.027 Å), Leu89 (0.969 Å), Asp156 (0.639 Å), Ser157 (0.688 Å), Ala158 (0.771 Å), Gly159 (0.63 Å), Tyr185 (0.628 Å), Ala187 (0.845 Å), Phe205 (0.93 Å), Leu206 (1.228 Å), Asp209 (0.995 Å), Ala210 (0.974 Å), Met211 (0.878 Å), Phe213 (0.867 Å), Cys214 (0.883 Å), Thr215 (0.929 Å), Leu251 (0.61 Å), His279 (0.561 Å), Ala280 (0.652 Å), and His283 (0.856 Å). The Rg of the alpha/beta hydrolase (GM298_08590)–cypermethrin complex fluctuated throughout the simulation, with an average value of 4.512 Å. The MolSA, SASA, and PSA of the alpha/beta hydrolase (GM298_08590)–cypermethrin complex insignificantly varied throughout the simulation period. The average MolSA, SASA, and PSA were 378.775, 26.194, and 93.0372 Å², respectively (Figure 7Cc).

The RMSD plot of the α/β hydrolase (GM298_00815)–diazinon complex was sharply increased from 0 to 17 ns (Figure 7Da), and it continued up to 75 ns. Next, a slight parallel downward trend appeared from 75 to 100 ns. The overall RMSD difference ranged from 1.2 to 1.7 Å. In the

RMSF plot of the alpha/beta fold hydrolase (GM298_00815)–diazinon complex (Figure 7Db), the favorable residues of alpha/beta fold hydrolase (GM298_00815) with diazinon were observed at Gly30 (0.689 Å), Leu31 (0.553 Å), Gly32 (0.767 Å), Cys33 (0.934 Å), Ala34 (0.947 Å), Ala35 (1.37 Å), Ser99 (0.656 Å), Met100 (0.76 Å), Ser103 (0.906 Å), Glu123 (0.66 Å), Pro124 (0.801 Å), Asn125 (1.033 Å), His127 (1.774 Å), Met132 (1.439 Å), Phe 133 (1.301 Å), Ser136 (1.316 Å), Ile137 (0.994 Å), Phe145 (1.217 Å), Gln148 (1.277 Å), Gly149 (1.105 Å), Asp151 (1.429 Å), Met153 (1.143 Å), Val181 (0.822 Å), Val184 (0.792 Å), Ser207 (1.098 Å), Leu208 (1.684 Å), and His231 (1.028 Å). The Rg of the alpha/beta fold hydrolase (GM298_00815)–diazinon complex fluctuated throughout the simulation, with an average value of 3.29 Å. The MolSA, SASA, and PSA of the alpha/beta fold hydrolase (GM298_00815)–diazinon complex insignificantly varied throughout the simulation period. The average MolSA, SASA, and PSA were 304.144, 88.6872, and 33.733 Å², respectively (Figure 7Dc).

(A) Synteny analysis of *Enterobacter* sp. HSTU-ASH6 strain with other close related strains. (B) Pangenomic comparison map of *Enterobacter* sp. HSTU-ASH6 with nearest homologs. Multiple genome sequence analysis of *Enterobacter* sp. HSTU-ASH6 with other closely related strains. The same color module represents the homologs region. Good homology of *Enterobacter* sp. HSTU-ASH6 and other *E. cloacae* strains is shown.

The RMSD plot of the amidohydrolase (GM298_20245)–chlorpyrifos complex (Figure 7Ea) showed an increasing trend for the ligand protein from 0 to 14 ns. After 17 ns, an increasing parallel trend continued up to 44 ns, with an RMSD ranging from 2.5 to 3.5 Å. Next, a steady and stable RMSD remained up to 80 ns. Then, the RMSD difference was below ~1.2 Å up to 93 ns, which indicated the stable protein–ligand

complex. In the RMSF plot of the amidohydrolase–chlorpyrifos complex (Figure 7Eb), the favorable residues of amidohydrolase with chlorpyrifos were observed at His81 (0.826 Å), Ser84 (0.99 Å), His109 (0.872 Å), Glu110 (0.888 Å), Glu174 (0.906 Å), Met176 (1.848 Å), Arg207 (1.4 Å), Asp276 (1.373 Å), Asp277 (1.118 Å), Ala407 (1.276 Å), Arg408 (1.631 Å), Tyr465 (0.683 Å), Ser466 (1.006 Å), His467 (1.215 Å), Asp468 (0.95 Å), Lys549 (1.393 Å), Ala550 (1.131 Å), Glu552

(1.336 Å), Gly553 (1.338 Å), and Leu556 (1.327 Å). The Rg of the amidohydrolase–chlorpyrifos complex fluctuated throughout the simulation, with an average value of 3.48 Å. The MolSA, SASA, and PSA of the amidohydrolase–chlorpyrifos complex insignificantly varied throughout the simulation period. The average MolSA, SASA, and PSA were 278.25, 156.69, and 37.03 Å², respectively (Figure 7Ec).

Discussion

Endophytes play an important role in the agricultural sector by enhancing crop production, pathogen resistance, and pesticide detoxification. These characteristic endophytic bacteria can be used as biofertilizers for sustainable agriculture. In the present study, we extensively investigated a newly isolated rice root endophyte strain that might have mineralized chlorpyrifos as its carbon source and demonstrated the tomato PGP activities at germination, vegetative, and reproductive stages. In particular, the strain classification revealed that it newly evolved in Bangladesh and deviated far away from its nearest homologs.

The gram-negative bacterium HSTU-ASH6 showed positive results in the VP test, indicating its capability to produce acetoin in the growth media. It also showed a positive result in the catalase test. Several studies reported that endophytic strain showed catalase positive test (Son et al., 2006; Das et al., 2022). Catalase helps bacteria avoid cellular toxicity. The positive triple sugar iron test indicated that the isolate

could ferment three sugars, including lactose, sucrose, and glucose, and iron. As the strain produced gas and exhibited motility properties, it was confirmed to be motility indole urease (MIU)–positive. The strain was also urease-positive, which is important for endophytic bacteria. Urease is an enzyme that splits urea into simple forms of nitrogen that the plants can readily absorb to promote growth. A previous study also demonstrated the occurrence and distribution of urease-positive endophytic bacteria in a legume community (Kumaresan and Suryanarayanan, 2001).

Previous reports have shown that several endophytic bacteria, including *Pseudomonas*, *Serratia*, and *Bacillus* species, can synthesize IAA that is involved in plant root regulation and growth control (Sgroy et al., 2009; Liu et al., 2010). Moreover, endophytes such as *Pantoea*, *Pseudomonas*, and *Serratia* have the ability to fix nitrogen in some plants (Loiret et al., 2004; Das et al., 2022). The present study assumed that the strain HSTU-ASH6 could fix nitrogen in Jensen's medium. Phosphate-solubilizing bacteria can dissolve insoluble phosphate and increase soil fertility and plant growth (Loiret et al., 2004; Das et al., 2022), which was also demonstrated by the strain HSTU-ASH6. Moreover, the strain enhanced the germination rate and increased tomato plant growth at vegetative and reproductive stages when using 70 and 30% reduced doses of urea. These results indicated that the strain could fix nitrogen in the tomato plant and assist its growth by providing phosphate solubilization, IAA, and ACC deaminase activities. In particular, a massive growth of tomato plants was observed in 100% urea + HSTU-ASH6 strain treatment

compared with the control. The multi-branched bushy structure of bacterium-treated tomato plants was due to the secretion of the auxin (**Supplementary Figures 3A,B**), which is agreed to the **Khan et al. (2016)**. Based on these results, it was confirmed that the bacterium exerted robust growth-promoting effects on tomato plants.

HSTU-ASh6 completely degraded 1 g L⁻¹ of chlorpyrifos within 14 days of incubation in the minimal salt medium. A previous study reported that *Enterobacter* sp. B-14 rapidly

degraded chlorpyrifos in MSM, and this strain used chlorpyrifos as the only source of carbon and phosphorus (**Singh et al., 2004**). **Das et al. (2022)** reported that HSTU strains degraded 42–100% of chlorpyrifos in broth media. **Li et al. (2007)** showed that *Sphingomonas* sp. DSP2 degraded 100% of chlorpyrifos (100 mg L⁻¹) in 24 h. It has also been shown that chlorpyrifos degradation results in the generation of several byproducts such as chlorpyrifos oxon, 3,5,6-trichloro-2-methoxypyridine, and 2-chloro-6-hydroxypyridine (**Singh et al., 2004**). A significant

FIGURE 5

Graphical representation of virtual screening results of pesticide-degrading validated model proteins with 105 different organophosphorus pesticides and other common pesticides applied in fields.

number of spinoff products were observed, for instance, chlorodihydro-2-pyridone, dihydroxy pyridine, tetrahydro-2-pyridone, maleamide semialdehyde, maleamic acid, and pyruvic acid. It was reported that chlorpyrifos and TCP can be broken down to produce 1,3-bis (1,1-dimethylethyl) and benzene (Abraham and Silambarasan, 2013). Chlorpyrifos oxon, TCP, and DEMP are the metabolic byproducts generated by the breakdown of chlorpyrifos organophosphorus insecticide (Lovecka et al., 2015). In this study, the products generated after chlorpyrifos degradation were phorate sulfoxide, phorate sulfone, chlorpyrifos methyl, TCP, carbophenothion sulfoxide, oxydisulfoton, carbonochloridic acid, 2,4,5-trichlorophenyl ester, thionodemeton sulfone, 3-(2-thienyl)-DL-alanine, chlorpyrifos oxon, diethyl methanephosphonate, which were confirmed through GC-MS/MS analysis (Table 3). To the best of our knowledge, this is the first report describing that diethyl methanephosphonate (DEMP) is a chlorpyrifos metabolic byproduct.

The quality of the genome sequence was predicted according to the GC% of strain DNA. A good-quality sequence is ensured by its GC%, and at least 40–70% of GC% is accepted in research (Abdullah-Al-Mamun et al., 2022). The strain investigated in this study exhibited 55.1% GC% after fast QC analysis, and the sequence quality was confirmed to be excellent.

According to the phylogenetic tree analysis of 16S rRNA genes, *Enterobacter* sp. HSTU-ASH6 was placed with *E. sichuanensis* WCHECL1597 (MG832788) in the sister taxa. They were 45% similar to each other and identified as *E. sichuanensis*. However, depending only on 16S rRNA and the polyphyletic nature of the genus *Enterobacter* make its identification and categorization extremely difficult. Therefore, we further confirmed our result using three housekeeping genes (*recA*, *gyrB*, and *rpoB*), and a complete genome phylogenetic tree was constructed and analyzed separately. The constructed tree revealed that HSTU-ASH6 was appeared as *E. cloacae* A1137. Based on 16S rRNA, *Enterobacter* sp. HSTU-ASH6 was specified as *E. sichuanensis*. However, after the analysis

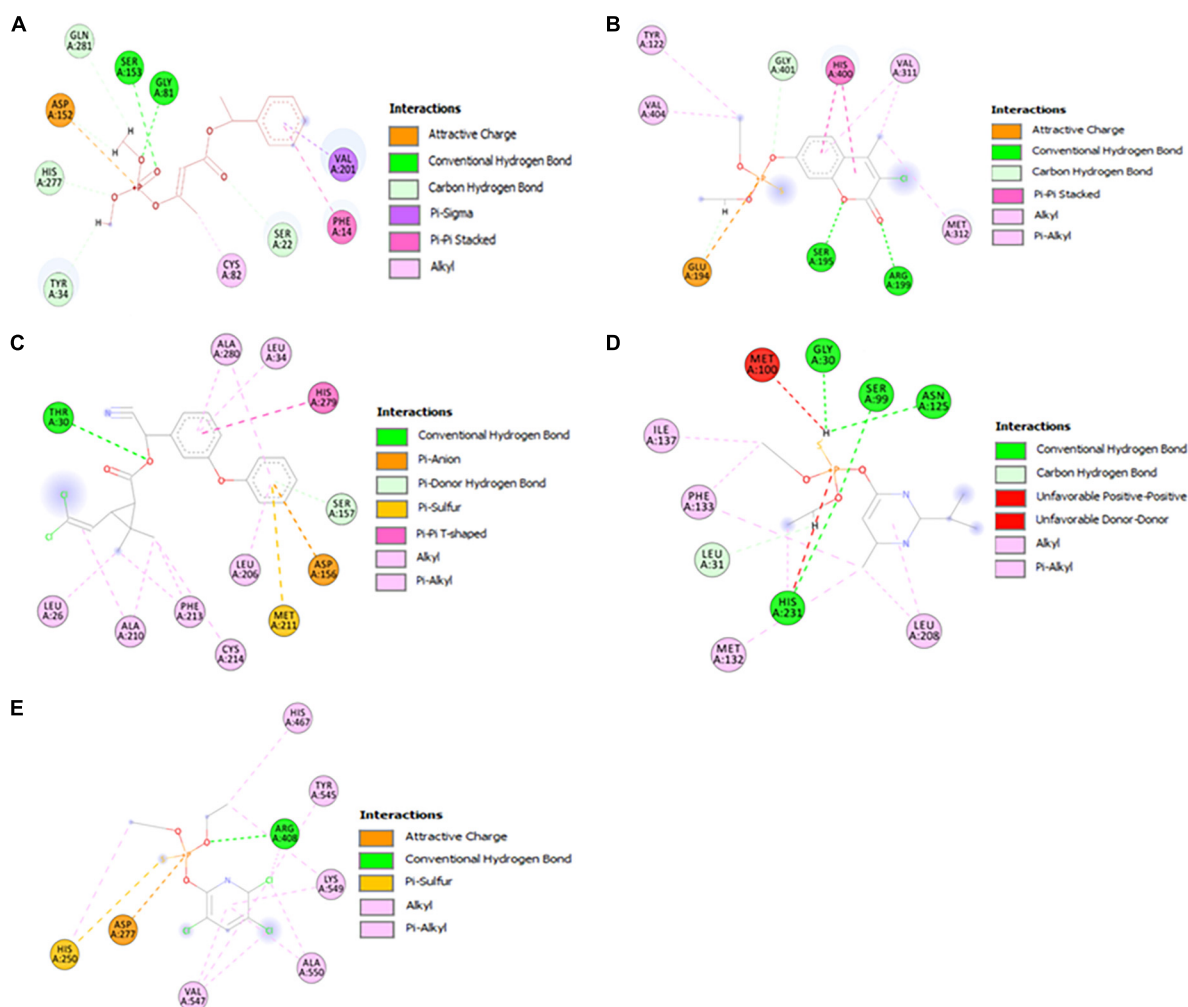

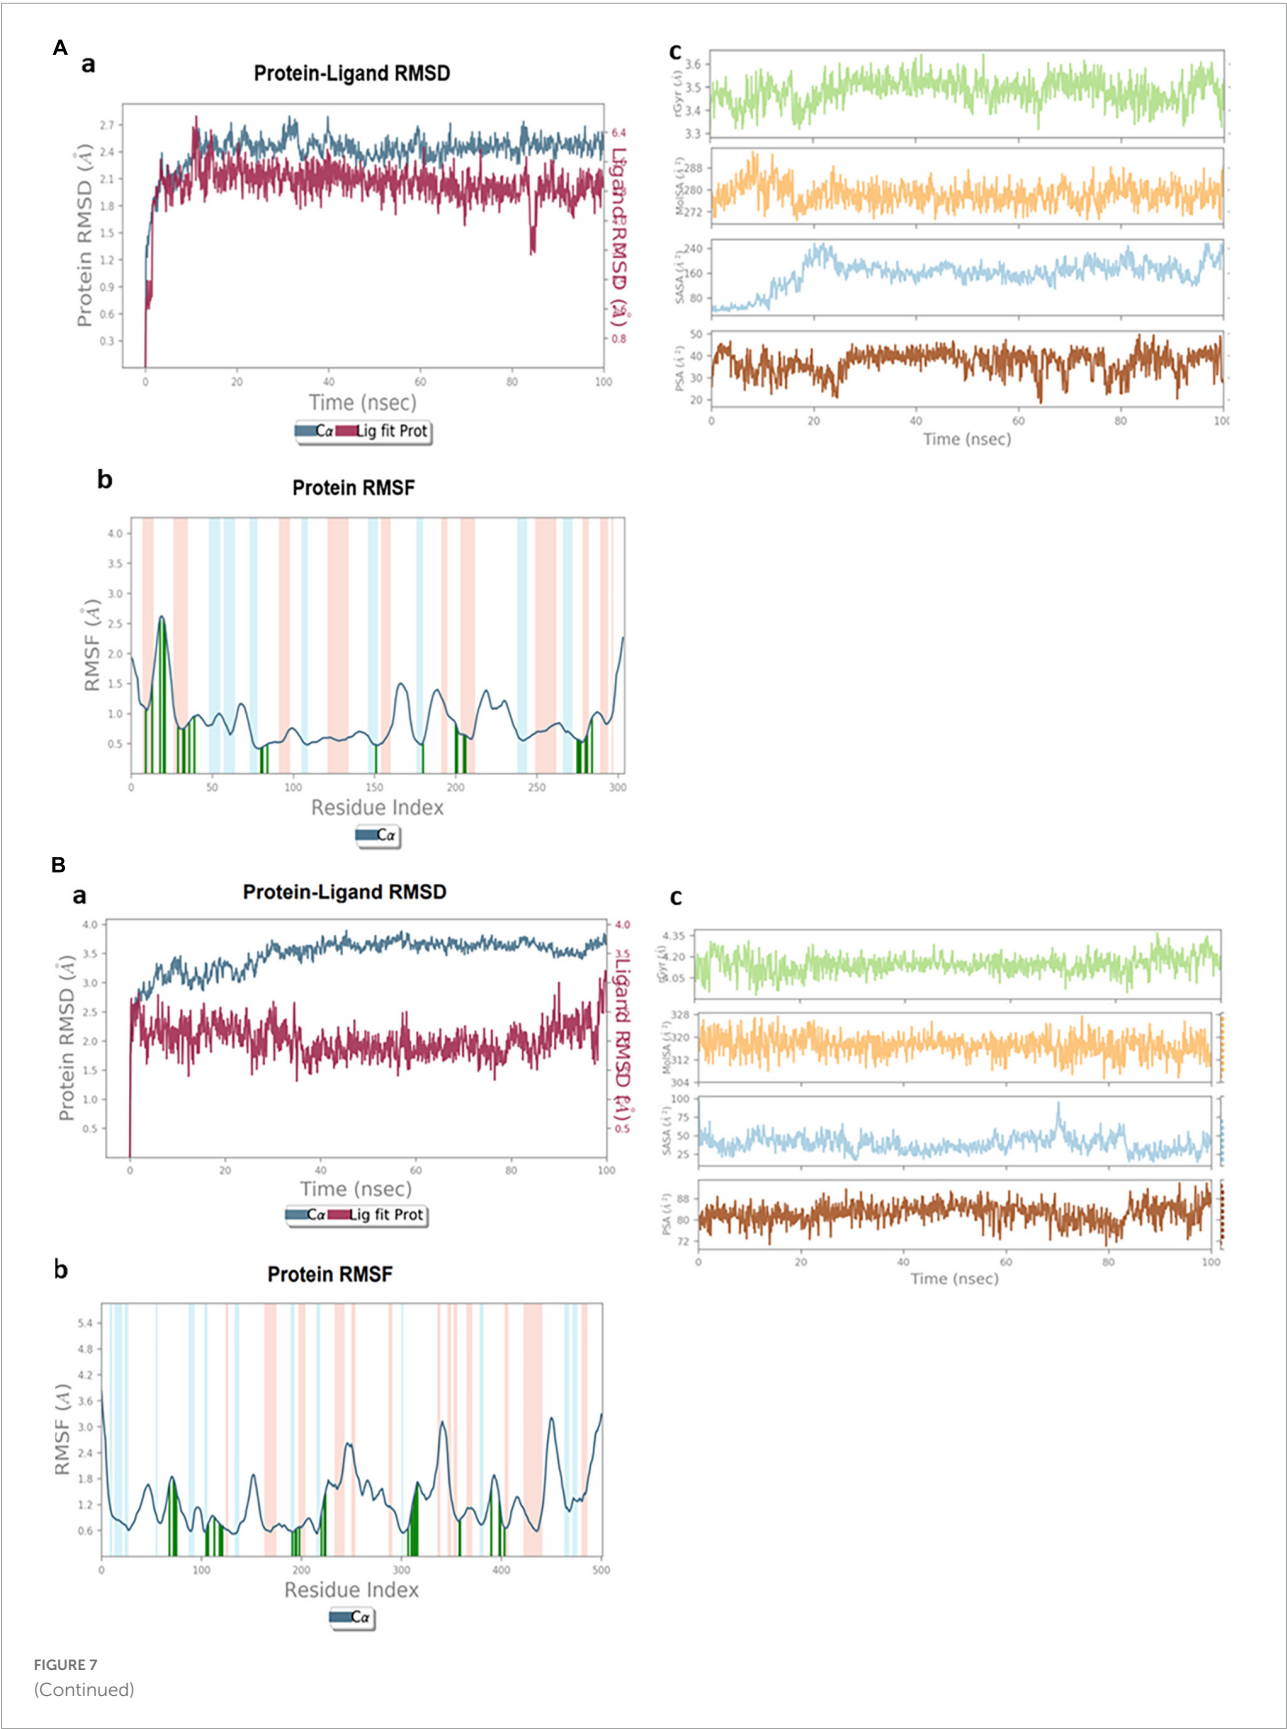

FIGURE 6

Visualization of the catalytic interactions of potential model proteins with pesticides. (A) α/β hydrolase (GM298_18675) with crotoxyphos, (B) carboxylesterase with coumaphos, (C) alpha/beta fold hydrolase (GM298_08590) with cypermethrin, (D) alpha/beta fold hydrolase (GM298_00815) protein with diazinon, (E) amidohydrolase family protein (GM298_20245) with chlorpyrifos.

of another three housekeeping genes and complete genome phylogenetic tree analyses, it was identified as *E. cloacae*. However, in the case of *recA* tree, both *E. cloacae* A1137 and *E. sichuanensis* WCHECL1597 were placed in a different clade with *Enterobacter* sp. HSTU-ASH6, where *E. cloacae* A1137 was located in the first node. According to GGDC web server, a DDH value of >70% indicates that the strain belongs to the same species and >79% based on the formula: 2 indicates that the strain belongs to the same subspecies. In another analysis, an ANI cut-off of > 96% was observed for species declaration. Consequently, our study results suggested that the strain HSTU-ASH6 belonged to *Enterobacter* species because both DDH and ANI values exceeded the cut-off. After progressive Mauve and pangenomic analysis, it was concluded that *Enterobacter* sp. HSTU-ASH6 was completely diversified from its closest strains, which indicates its evolutionary properties. Therefore,

Enterobacter sp. HSTU-ASH6 might be a new member of the *Enterobacter* species.

Escherichia coli and closely related *Enterobacteria* possess both Isc and Suf systems, encoded by the *iscRSUA-hscBA-fdx-iscX* operon and *sufABCDSE* operon, respectively (Ayala-Castro et al., 2008). In general, the endophytic bacterial genome contains *nif* and *fix* gene clusters for nitrogen fixation. However, a few endophytic bacteria contain other types of gene clusters, namely, Isc and Suf systems, which are responsible for nitrogen fixation in critical situations (Ayala-Castro et al., 2008). The present study showed that the genome of *Enterobacter* sp. HSTU-ASH6 harbors both Isc and Suf systems for biological nitrogen fixation, and the genome machinery also indicated that both Isc and Suf operons were present. To summarize, the PGP mechanism is encoded by genes that are directly linked to the generation of IAA and ACC deaminase and siderophore in

Enterobacter sp. HSTU-ASH6. In the same way, genes like *nhaA*, *chaAB*, *proABpqvwxs*, *betABT*, *trkAH*, *kdpABCEF*, and *kdbD* that help the plant deal with drought stress have been found in the genomes, indicating their involvement in drought tolerance by the plant (Das et al., 2022).

The conserved pentapeptide motif G-X-S-X-G is commonly observed in bacterial genome sequences (Schloss and Handelsman, 2003). The genome of *Enterobacter* sp. HSTU-ASH6 encodes proteins such as alpha/beta fold hydrolase (GM298_18675), alpha/beta fold hydrolase (GM298_08590), alpha/beta fold hydrolase (GM298_00815), and carboxylesterase sequences carrying the conserved pentapeptide G-X-S-X-G motif. The hydrolase-encoding genes, for instance, *opd* (McDaniel et al., 1988), *mpd* (Lu et al., 2013), and *ophc2* (Ningfeng et al., 2004; Shen et al., 2010), are also crucial for the breakdown of pesticides. Das et al. (2022) reported that carboxylesterase and phosphotriesterase are directly involved in the breakdown of organophosphorus insecticides. Haque et al. (2018, 2020) also reported that several *opd* genes (*opdA*, *opdE*, and *opdD*) can degrade a range of organophosphorus insecticides. These results suggested that the genome of *Enterobacter* sp. HSTU-ASH6 retains pesticide-mineralizing genes. In addition, several hydrolases, esterase, and some hypothetical proteins may have catalytic interactions with organophosphorus insecticides, which is beyond the scope of this study.

The molecular docking investigations of pesticide-degrading enzymes with pesticides were subjected with a validity score. The RMSD of model protein indicates its acceptance when compared to a typical protein model. Since a smaller RMSD suggests fewer errors, it is always preferred. The 28 modeled proteins' average RMSD was 1.0, indicating that the analyses were valid. According to reports, protein models with RMSDs between 0.35 and 2.36 and their nearby homologs are acceptable (Dadheech et al., 2019). Depending on the molecular docking analysis, all five proteins (alpha/beta fold hydrolase (GM298_18675), alpha/beta fold hydrolase (GM298_08590), alpha/beta fold hydrolase (GM298_00815), amidohydrolase family protein (GM298_20245), and carboxyl esterase) with important amino acid residues for catalysis were found within 1.5–5.5 Å, which suggested its involvement in the degradation of organophosphate pesticides. Haque et al. (2018) reported that carboxylesterase provides Ser-His-Glu catalytic triad. The present study indicated that carboxylesterase docked with coumaphos and provided a similar type of Ser-His-Glu catalytic triad. Consequently, the alpha/beta fold hydrolase (GM298_18675) of *Enterobacter* sp. HSTU-ASH6 originated as a potential catalytic triad Ser-His-Asp (Hosokawa, 2008). Therefore, the α/β fold hydrolase (GM298_08590) was docked with cypermethrin and provided Ser-His-Asp catalytic triad (Hosokawa, 2008). Kubiak et al. (2001) detected the Arg-Asp-His catalytic triad in the enzymatic cleavage of

the phosphodiester bond. A similar triad (Arg-Asp-His) was observed in the present study, where amidohydrolase docked with chlorpyrifos insecticide. A recent study indicated that the Ser-His-Glu catalytic triad is predominant in long PepEs, and the Ser-His-Asn “catalytic triad” is predominant in short PepEs (Yadav et al., 2019). Interestingly, alpha/beta fold hydrolase (GM298_00815) bonded with diazinon pesticide and formed a new possible catalytic triad Ser-His-Asn.

Five different proteins with five different pesticides complex were subjected to MD simulation for 100 ns. The stability of the protein-ligand complex was determined (Patel et al., 2021) by comparing the RMSD and RMSF values of the unbound protein structure. In MD simulations, the RMSD parameter is used to evaluate the coherence and flexibility of proteins as well as to keep track of the separation between their atoms and backbones (Sargsyan et al., 2017). While a greater RMSD value signifies relatively less stability of the protein-ligand complex, a lower RMSD value throughout the simulation shows higher stability of the protein-ligand complex. It was shown that the enzyme-substrate complexes are stable for the biodegradation of pesticides by a slight fluctuation with lower smaller RMSD (Lee et al., 2021). The results showed that the MD simulations were stable at 100 ns for the insecticides chlorpyrifos, diazinon, crotoxyphos, cypermethrin, and coumaphos complex with pesticides degrading potential proteins (Figures 7A–E). The RMSF number reflects how each protein's amino acid moved and changed throughout the simulation. More flexibility during the simulation is implied by higher RMSF values, whilst superior stability is indicated by lower RMSF values. In this study, the RMSF values were different for the chlorpyrifos–amidohydrolase protein family (GM298_20245), diazinon– α/β fold hydrolase (GM298_00815), crotoxyphos– α/β fold hydrolase (GM298_18675), cypermethrin–alpha/beta fold hydrolase (GM298_08590), and coumaphos–carboxylesterase complexes, suggesting that the RMSF of these complexes was stable during the catalytic reactions. Previously, researchers have used RMSF to examine enzyme-pesticide complexes (Lee et al., 2021). The microbial enzymes are responsible for the biodegradation of pollutants like pesticides and they are interconnected (Joshi et al., 2021; Bhatt and Maheshwari, 2022). The changes in compactness of an enzyme-substrate complex are described using the radius of gyration (Rg). It refers to the folding and unfolding of proteins during MD simulations. Enzyme folding indicates Rg stability, whereas fluctuations in Rg signify enzyme unfolding (Adams et al., 2008). The results of Rg and PSA revealed that every enzyme-substrate complex displayed stable compactness in five instances of protein-ligand complexes, indicating that these are superiorly superimposed on each other and perfectly overlaid. SASA stands for solvent-assisted structure-activity relationship. It foresees the structural alterations that take place during interactions. All five protein-ligand complexes' SASA values during the 100-ns MD simulations of the enzyme-substrate complexes were significantly stable, indicating that the protein structure remained unchanged.

Conclusion

The endophytic and pesticide-degrading strain *Enterobacter* sp. HSTU-ASH6 isolated from rice roots significantly affected plant growth and pesticide detoxification. Housekeeping gene and whole genome phylogenetic tree, ANI, and DDH genomic analysis confirmed that *Enterobacter* sp. HSTU-ASH6 is a new species of *Enterobacter* strain. Whole genome sequencing also confirmed the presence of genes involved in plant growth, stress tolerance, and pesticide degradation. Therefore, the utilization of this remarkably versatile PGPB may be an essential eco-friendly alternative to improve crop growth and pesticide detoxification.

Nucleotide sequence accession number

The whole Genome sequence of the *Enterobacter* sp. HSTU-ASH6 strains was deposited at NCBI GenBank under the BioProject PRJNA591446, BioSample SAMN13387920 and accession number: WSPD000000000. In addition, the 16S rRNA gene sequence of the strain was deposited in the NCBI with accession number: MZ021583.

Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: BioProject: PRJNA591446, BioSample: SAMN13387920, and accession number: WSPD000000000.

Author contributions

Comparative study of the chemical composition and antifungal activity of commercial brown seaweed extracts

Silvia Valverde *, Paul Luis Williams, Begoña Mayans,
Juan J. Lucena and Lourdes Hernández-Apaolaza

Department of Agricultural Chemistry and Food Science, Universidad Autónoma de Madrid,
Madrid, Spain

Introduction: A sustainable agriculture and the great increase in consumers of organic products in the last years make the use of natural products one of the main challenges of modern agriculture. This is the reason that the use of products based on seaweed extracts has increased exponentially, specifically brown seaweeds, including *Ascophyllum nodosum* and *Ecklonia maxima*.

Methods: In this study, the chemical composition of 20 commercial seaweed extract products used as biostimulants and their antifungal activity against two common postharvest pathogens (*Botrytis cinerea* and *Penicillium digitatum*) from fruits were evaluated. Data were processed using chemometric techniques based on linear and non-linear models.

Results and discussion: The results showed that the algae species and the percentage of seaweed had a significant effect on the final composition of the products. In addition, great disparity was observed between formulations with similar labeling and antifungal effect of most of the analyzed products against some of the tested pathogens. These findings indicate the need for further research.

KEYWORDS

brown seaweed extracts, biostimulants, chemical composition, antifungal activity, chemometrics

Abbreviations: AA, alginic acid; AN, *Ascophyllum nodosum*; EM, *Ecklonia maxima*; IAA, indole-3-acetic acid; Lam, laminarin; Man-ol, mannitol; TAC, total antioxidant capacity; TCC, total carotenoid content; TFC, total flavonoid content; TTC, total tannin condensed capacity; TPC, total phenolic content; SA, salicylic acid; SWEs, seaweed extracts.

1 Introduction

The great challenge of food production is to use sustainable practices that increase the harvestable yield and quality of crops with minimal impact on the environment. It is well-known that chemical fertilizers have led to the deterioration of agricultural systems (Biau et al., 2012). In recent years, environment-friendly and economic alternatives have been sought that can reduce the use of traditional fertilizers (Trivedi et al., 2018), such as seaweed extracts (SWEs). Recently, a growing interest has been observed for the use of this type of products because they are natural and biostimulant substances that improve the crop growth and quality of fruits (Tabbara et al., 2018). Despite the fact that SWEs are traditionally used as biostimulants, supplementary fertilizers, or soil quality improvers, their use has also been reported as animal feed supplement, human nutritional supplement, and cosmetic products (Pereira et al., 2020).

The most widely used macroalgae in agriculture are brown seaweeds, including *Ascophyllum nodosum* (AN), *Ecklonia maxima* (EM), *Fucus vesiculosus*, *Laminaria digitata*, *Sargassum* spp., and *Turbinarias* spp. (Khan et al., 2009), being the most commercialized extracts of the first two species. Their biochemical composition depends on their location and the conditions of the place where they grow. In this way, the content of active ingredients will be modified between each species and within the same species in relation to the availability of nutrients, light, salinity, depth, presence of organic contaminants, or content of heavy metals (Kumar and Sharma, 2021) with potential human risk associated, among others. *A. nodosum* grows on the coasts of the North Atlantic, mainly on the northwestern coast of Europe and North America. Unlike other species of brown algae, it supports periods of marine immersion and periods of exposure to the elements, depending on the tidal cycle. This fact of physiological adaptation provides a characteristic biochemical composition that is very useful for their use in agriculture (Hurtado et al., 2021). Meanwhile, *E. maxima*, an endemic South African seaweed, always grows submerged in water and did not emerge at times of low tide; thus, it is considered a potential source of beneficial bioactive compounds. After seaweed recollection, the active ingredients contained in algae are extracted from the cells and transferred to a liquid medium to obtain a commercial product using different extraction processes. Depending on the process used, the final composition of the product can be significantly altered (Povero et al., 2016). The most widespread extraction processes are traditional extraction based on the use of chemical agents and cold extraction. Chemical extraction uses strong acids or alkalis (KOH), and the product obtained is dark due to the high oxidation of its active components leading to denaturation of active ingredients that results in a drastic loss of properties (Calvo et al., 2014). Cold extraction has gained popularity because algae are subjected to a micronized process under high pressure without loss of active ingredients and pH is kept at its physiological level of 4.5

(Crampon et al., 2011). These products have a characteristic marine aroma and color that ranges from green to light brown.

SWEs contain a multitude of active components (Khan et al., 2009), although it is considered that the following are the main active ingredients: alginic acid, which is present in the cell walls and confers flexibility and adaptation to stress phenomena; mannitol, which blocks reactive species and prevents metabolic damage; reserve polysaccharides (laminarin and fucoidan) that are not found in terrestrial plants; polyphenols and tannins with high antioxidant power, which stabilizes and strengthens cell walls against pathogen attacks and minerals, among others. All these components have a synergistic effect in the crops, providing a strong root system, promoting plant growth, and improving leaf development and flowering (Mukherjee and Patel, 2019). In addition, the quality of the fruit and vegetables has been reported in numerous studies, not only providing physiological and nutritional benefits but also improving the organoleptic properties by the consumer (Kocira et al., 2018; Meng et al., 2022). The antifungal activity of SWE has also been studied in several research as preventive treatment to postharvest pathogens (De Corato et al., 2017; Lahbib et al., 2022). This is because marine organisms have developed an antimicrobial defense strategy based on the production of bioactive metabolites (Cortés et al., 2014) with antioxidant character.

According to the growing organic production expansion and efforts to reduce the use of chemical fungicides and fertilizers, SWEs may play a greater role in crop protection than was previously realized. In fact, many products containing SWEs are commercially available for application to various horticultural crops under different trade names. In most of the products, there is no homogeneity in the labeling, and a detailed description of the composition is not usual, making it difficult to understand its mode of action and its influence on the plant growth, fruit quality, and antifungal activity.

Hence, this study was conducted to investigate the chemical composition and *in vitro* antifungal assays against two common pathogens on four different fresh fruits of 20 representative commercial seaweed extracts and to further treat data by multivariate statistical analysis. To the authors' knowledge, this is the first time that such a detailed study of several brown seaweed extracts has been carried out. The contribution of this study is expected to provide a reference for the knowledge of these products and the ability of chemometrics multivariate methods to know the production factors that influence their composition and their relationship with antifungal activity.

2 Materials and methods

2.1 Samples

Several representative seaweed commercial products were selected in this study according to the species (*A. nodosum* and

E. maxima), method of extraction (basic media-KOH, acid media, or cold), pH (from 3.20 to 10.8), the way in which they are marketed—liquid products (LP, $n=16$) or solid products (SP, $n=4$)—and percentage of algae in the product—low (10%–30%) and high (100%). Products with high percentage (100%) are those that consist only of algae extract, while those that have low percentage are mixtures of algae extracts with other components such as amino acids or sugars, among others. The percentage indicates the amount of seaweed in the product and is usually specified on the labeling. All the samples were kindly provided by different fertilizer companies ($n=18$) and by Laboratorio Arbitral (Spain's Ministry of Agriculture, Fisheries and Food; MAPA) ($n=2$). Table 1 summarizes the main characteristics of the seaweed products selected in this study.

2.2 Sample preparation

Formulated liquid samples were previously freeze-dried and then pulverized with a mortar for all tests except for polysaccharides content (alginic acid, mannitol, and laminarin) and antifungal *in vitro* assays. Solid samples were previously homogenized with a mortar. All measurements were performed in triplicate.

2.2.1 Determination of chemical composition

2.2.1.1 Polysaccharides content

To estimate the alginic acid (AA), mannitol (Man-ol, polyol), and laminarin (Lam) content, the method of Valverde

et al. (2022) was used. Briefly, 40 mg of liquid product (LP) or 20 mg of solid product (SP) was diluted in 100 ml (LP) or 250 ml (SP) of ultrapure water. For SP, a previous step was necessary based on crushing with a grind and passing it through a 40-mesh screen to obtain a homogenous sample. Then, the mixture was shaken in a vortex for 1 min and centrifuged for 5 min at 3,000 rpm. The samples were filtered through 0.45- μ m nylon filter before analysis by high-performance liquid chromatography refractive index detector (HPLC-RID) system (1260 Infinity model Agilent Technologies, Waldbronn, Germany). A Bio-Rad Aminex HPX-87 H column (300 \times 7.8 mm, 9 μ m) was used, protected by a guard column from Phenomenex (Torrance, CA, USA). Analysis conditions were set as follows: the mobile phase was a 0.05% acetic acid, the flow rate was 0.5 ml/min, the injection volume was 50 μ l, the column temperature was set at 65°C, and the temperature of the refractive index detector was at 50°C in positive polarity mode. Quantification was achieved using glycerol as internal standard (IS) calibration, employing glycerol in order to reduce analysis error ($n=6$) and fluctuations on the signal.

2.2.1.2 Sugar content

Sugar analysis (arabinose, fucose, glucose, glucuronic acid, rhamnose, sucrose, and xylose) was carried out using the reported methods with slight modifications (Sluiter et al., 2012; Manns et al., 2014; Badmus et al., 2019): A total of 150 mg of the sample was hydrolysed with 200 μ l of sulphuric acid 72% w/w at 30°C for 1 h; the reaction mixture was then diluted

TABLE 1 Description of the seaweed products selected for this study according to criteria described in Section 2.1.

Sample code	Formulated	Species	Algae percentage (%)	Extraction method	pH \pm SD	EC (mS cm ⁻¹) \pm SD
1	Liquid	AN	Low (25)	Cold	4.59 \pm 0.01	5.34 \pm 0.07
2		AN	Low (27)	Cold	4.26 \pm 0.02	8.71 \pm 0.1
3		AN	High (100)	Acid	3.35 \pm 0.01	3.75 \pm 0.02
4		AN	High (100)	Cold	4.40 \pm 0.02	8.04 \pm 0.09
5		AN	Low (27)	Cold	5.33 \pm 0.03	20.1 \pm 0.1

with 3.6 ml of ultrapure water reacting for 40 min at 100°C. After cooling, samples were centrifuged for 10 min at 5,000 rpm; ultrapure water was added, taking the supernatant up to 5 ml, and it was filtered through a 0.45- μ m nylon filter before analysis by HPLC-RID system. A Bio-Rad Aminex HPX-87 H column (300 \times 7.8 mm, 9 μ m) was selected with 4 mM H₂SO₄ solution as the mobile phase at a flow rate of 0.6 ml/min; the injection volume was 50 μ l, and the column temperature was set at 60°C.

2.2.1.3 Mineral content

Mineral profiling was obtained through digestion of 50 mg of powdered seaweed weighed into an Erlenmeyer flask and addition of 5 ml of concentrated trace metal grade nitric acid (67% assay) and 5 ml of hydrogen peroxide (30% assay). The mixture was left to react for an hour at room temperature and then heated at 80°C for 30 min with a plate digestion. After cooling, samples were filtered and made up to 25 ml with Milli-Q water. The certified reference material (CRM) NCS DC73350 (leaves of poplar) was prepared in the same manner to validate the accuracy of the analysis. The samples were analyzed by inductively coupled plasma-optical emission spectrometry (ICP-OES) (iCAP-PRO XDuo Spectrometer, Thermo Scientific, UK). Fourteen minerals were measured: calcium (Ca), magnesium (Mg), potassium (K), aluminium (Al), phosphorous (P), iron (Fe), copper (Cu), manganese (Mn), zinc (Zn), nickel (Ni), arsenic (As), cadmium (Cd), chromium (Cr), and lead (Pb). The optimal instrumental conditions of ICP-OES, along with the selected wavelengths and IS, are presented in [Supplementary Table S1](#). In order to avoid ion signal fluctuations caused by the matrix, a diluted internal standard (IS) solution (10mg/L of ⁸⁹Y) was used. This solution was distributed in all solutions (blank, standard solutions, and unknown samples) using a second channel of the peristaltic pump.

2.2.1.4 Hormonal composition

Plant hormones (abscisic acid, indole-3-acetic acid, indole butyric acid, gibberellic acid, and salicylic acid) were analyzed using reported validated analytical methodologies ([Jiang et al., 2006](#); [Górka and Wieczorek, 2017](#)). Briefly, 50 mg of powdered samples were extracted with 0.5 ml methanol 70% (v/v) and remained overnight at 4°C. The supernatant was concentrated under N₂ stream and dissolved in 1 ml Na₂HPO₄ at pH 9.0. The solution was extracted three times with ethyl acetate and adjusted to pH=2.5. Finally, the organic phases were dried with a gentle stream of N₂, dissolved in 1 ml of methanol 70% (v/v), and filtered through 0.45- μ m nylon filter before analysis by HPLC with a diode-array detector (DAD) (HPLC-DAD) system. Chromatographic conditions were set as follows: analytical column Luna C₁₈ (2) (150 \times 4.6 mm, 3 μ m), mobile phase consisted of (A) acetonitrile (0.1% formic acid) and (B) 0.1% formic acid in gradient elution mode; 0–10 min A:B, 25:75 (v/v); 11–17 min A:B, 50:50 (v/v); and 18–30 min A:B, 25:75 (v/v).

Flow rate was 0.5 ml/min, injection volume was 10 μ l, and the temperature of the column was maintained at 25°C. Detection was carried out at a wavelength of λ =214 nm.

2.2.1.5 Total phenol content

Methanolic SWE were obtained according to [Badmus et al. \(2019\)](#). Briefly, 250 mg of SWE and 5 ml of methanol was sonicated for 30 min and shaken for 4 h in an orbital shaker. Then, extracts were centrifuged for 10 min at 2,500 rpm. To estimate the total phenolic content (TPC), the modified Folin–Ciocalteu method was used with minor modifications. A total of 20 μ l of the extract was combined with 100 μ l of Folin–Ciocalteu reagent (1:10 v/v) and 80 μ l of 7.5% sodium carbonate. The mixture was shaken for 30 s and allowed to stand for 2 h at room temperature in darkness. Standards (gallic acid) and blanks (methanol) were prepared and processed using the same method as for SWE. The absorbance was measured at 765 nm using a microtiter plate (SPECTROstar Nano, BMG Labtech Germany). Gallic acid was used as standard, and blanks (methanol) were prepared following the same method as for seaweed samples. Results were expressed as mg gallic acid equivalents/g dry extract.

2.2.1.6 Total flavonoid content

Seaweed ethanolic extracts were obtained previously as described in the previous section. Total flavonoid content was determined as described by [Chang et al. \(2002\)](#). Briefly, 15 μ l of the sample was mixed with 307 μ l of 10% aluminium chloride, 307 μ l of 1M potassium acetate, and 200 μ l of Milli-Q water. After incubation for 30 min in the dark at room temperature, the absorbance was measured at 510 nm (SPECTROstar Nano, BMG Labtech Germany), using quercetin as standard.

2.2.1.7 Total condensed tannin

The total condensed tannin content was performed by the vanillin–HCl method ([Cox et al. \(2010\)](#)). Seaweed methanol extract (25 μ l), obtained as in [Section 2.2.1.5](#), was mixed with 150 μ l of vanillin 4% and 75 μ l of HCl concentrated. The solution was shaken and left at room temperature for 20 min of protected light. The absorbance of samples, standards ((+) catechin), and blanks (methanol) were recorded using a microtiter plate (SPECTROstar Nano, BMG Labtech Germany) at 500 nm.

2.2.1.8 Total carotenoid content

Carotenoids were determined according to the methodology of [Kumar et al. \(2009\)](#), with slight modifications. Briefly, 1 g of powdered samples was incubated with 10 ml of 80% acetone for 90 min at 20°C. Then, the mixture was centrifuged for 15 min at 3,000 rpm and filtered using a filter paper (Whatman No. 1). A standard curve was prepared using β -carotene, and results were obtained by measuring the absorbance at 480 nm (SPECTROstar Nano, BMG Labtech Germany).

2.2.1.9 Total antioxidant capacity

Total antioxidant capacity (TAC) was assessed according to a previous method (Costa et al., 2011). Seaweed methanolic extract (100 µl), obtained as previously described, was mixed with 1 ml of a solution containing 0.6 M sulphuric acid, 28 mM sodium phosphate dibasic and 4 mM ammonium molybdate (4:2:4 v/v/v). The mixture was incubated for 90 min at 95°C and cooled at room temperature. Then, the absorbance of standards (ascorbic acid), blanks (methanol), and samples were measured at 695 nm (SPECTROstar Nano, BMG Labtech Germany).

2.2.1.10 DPPH radical scavenging activity

The DPPH radical scavenging activity was determined using the method of Zhang et al. (2008) and Yang et al. (2008). Seaweed methanol extract (100 µl) and 0.16 mM 2,2-diphenyl-1-picrylhydrazyl hydrate (DPPH) (100 µl) in methanol were mixed. The mixture was shaken for 30 s and left in darkness at room temperature for 30 min. The absorbance was read in a microtiter plate (SPECTROstar Nano, BMG Labtech Germany) at 517 nm. The scavenging effect was calculated as an inhibition percentage using Eq. (1) as follows:

$$\text{DPPH inhibition}(\%) = \left(\frac{A_c - A_s}{A_c} \right) \times 100$$

where A_c is the absorbance of the control (100 µl of methanol solvent with 100 µl of the DPPH solution), and A_s is the absorbance of the sample.

2.2.2 In vitro antifungal activity assays

Previously, the products under study were tested to verify that they were free of microorganisms. For that purpose, the products were prepared at recommended dose by the manufacturer, and 500 µl was incubated on Petri dishes with a general culture medium, potato dextrose agar (PDA), to check the presence of any kind of microorganism. All the samples were done in triplicate. They were incubated at 26°C in the dark in a growth chamber for a week.

Pathogen fungi were isolated from the selected rotten fruits: *Penicillium digitatum* from orange, *Botrytis cinerea* from strawberry, blueberry, and tomato in PDA. Petri dishes were incubated in a growth chamber at 26°C in the dark. Once grown, 5-mm fungal plugs were inoculated in PDA plates, and the correspondent product was poured at a recommended dose by manufacturer, all in triplicate. They were grown in the same conditions for 22 days. The growth inhibition halo was evaluated.

2.3 Statistical analysis

IBM SPSS Statistics 26.0 software (SPSS Inc., Chicago, IL, USA) was used for multivariate analysis of covariance (MANCOVA), principal component analysis (PCA),

hierarchical cluster analysis (HCA), and artificial neural network analysis (ANN).

3 Results

3.1 Chemical composition

The results of the analysis of characteristic and bioactive compounds, including the mean (and standard deviation), minimum, and maximum values of the products evaluated, are shown in Table 2. The selected products presented a wide range of pH from 3.9 to 10.7. This variety is mainly due to the extraction method used and the algae percentage in the product. The EC provides the value of the soluble salts present in the SWEs. The strong differences observed among the products can be attributed to the way in which the algae are extracted, e.g., alkaline media provide high concentrations of potassium, and/or the area where they have been collected (mainly AN grows in the Atlantic Ocean and EM in South Africa). It is recommended that a fertilizer has a low EC value to facilitate fertilization and avoid crop phytotoxicity. The variations in AA, Man-ol, and Lam were attributed to intrinsic botanical differences of the species. It was observed that AN products presented higher contents for these three components than EM. These results agreed with those reported in previous studies and can also be attributed to the different growing conditions of the source material and possible variations in the processing methods (Pereira et al., 2020; Valverde et al., 2022). Sugar profile was similar for both species, following the trend: glucose > glucuronic acid > sucrose > fucose > xylose. Although the concentration of sugars was higher for AN, all the products presented a variety of sugars that will facilitate the assimilation of nutrients and their transport by the plant, as they reduce the osmotic pressure, thus improving vegetative development. The mineral composition for AN product (Table 2) followed the trend, K > Mg > Ca > Al > P > Fe > Mn > Zn > Cu, whereas EM followed the trend, K > Mg > Ca > P > Al > Fe > Zn > Mn > Cu. Potassium, Mg, and Ca were the most abundant plant macronutrients in the studied products, highlighting that the higher concentrations of K may be due to the accumulation in the tissues of the algae and extraction methodology employed. Variations in microelements are attributed to the species of algae, the season in which they were collected, and the algae percentage of the product. Heavy metals were analyzed because seaweeds are known to accumulate pollutants. The results revealed the presence of Cr and Ni in most of the products, which can affect both the nutrition of the plants and their productive quality. *A. nodosum* products presented the higher concentrations (Ni, 0.15 ± 0.002 mg/kg; Cr, 0.19 ± 0.001 mg/kg) although within the established limits by European Commission under Regulation (UE) 2019/1009 about fertilizer products (Ni = 50 mg/kg and Cr = 2 mg/kg dry matter). These results are in relation to those previously reported, indicating that AN is used as a biomonitor of metal concentration in coastal habitats (Morrison et al., 2008). The results of the hormonal analysis

^apH dilution (1:5) for liquid products.^bpH dilution (1:25) for solid products.^cThe measurement was under the detection limit (LOD).

were conditioned by the instrumental analysis technique used (HPLC-DAD) because these analytes are expected in low concentrations. Despite this, the most remarkable results, as expected, were for indole-3-acetic acid (IAA), the major hormone. It is the main auxin in plants and controls several physiological processes such as cell elongation and division. It was detected in products of both species; however, it was not detected in the solid formulations. This fact has not been previously reported in any studies, which suggests that the type of formulation may influence in some way the final hormonal composition of the product. The analysis of bioactive compounds revealed that the

concentration of TFC (274 ± 2.0 g/kg) was higher than that of TPC (107 ± 1.9 g/kg) in all the products tested, AN being the products with the highest concentration. Notable concentrations of TCC (14.6 ± 0.87 g/kg), associated with the characteristic brownish color, were also detected with the same trend described above. Most of the samples presented tannins although at very low concentrations. It should be noted that the presence and abundance of these compounds depend on the species, the habitat, the seasonal influence, the stage of the life cycle, the environmental conditions, and the extraction method. All the products tested presented high concentrations of bioactive components as described in previous

studies (Agregán et al., 2017; Kocira et al., 2018; Habeebullah et al., 2021). The presence of these compounds will benefit the productive development of the plant and the quality of the fruit, providing them high added value. The antioxidant activity was evaluated by TAC and DPPH assays. According to the parameters studied previously, it was observed that the TAC was higher for AN (24.4 ± 0.32 g/kg) than for EM (0.84 ± 0.32 g/kg). These results are related to the presence of antioxidant compounds, which agree with the results obtained previously. DPPH assay has been used extensively as a free radical to evaluate the antioxidant potentials in plant extracts (Duan et al., 2006; Farasat et al., 2014). SWEs contain numerous antioxidant molecules that are able to reduce the DPPH free radicals by attacking the molecules to add hydrogen atom to it or donate an electron to it, providing a color change from purple to yellow in the DPPH solution (Devi et al., 2011). The average values for scavenging DPPH radical were always higher than 40% for most products, with a trend similar to that observed in TAC assay. Previous studies reported that brown seaweeds are rich in bioactive compounds compared with red and green seaweeds, so %DPPH reduction is greater (Cox et al., 2010; Leelavathi & Prasad, 2014).

3.2 Antifungal activity

All products under study were evaluated to elucidate if they could have any effect on the most common pathogen fungi of orange, strawberry, blueberry, and tomato. The presence of inhibition haloes was considered positive, as the products used in crops could inhibit the growth of these undesirable pathogens. Some of the tested products inhibited the fungal growth, as is shown in Table 3 with a (+) sign at 48 h, although the cultures were incubated for 22 days to know if the effect persisted. The initial microbiological test showed that at recommended doses, products 8 and 12 promoted in themselves the growth of some kind of microorganisms. The plates with product 8 seemed to grow fungi; meanwhile, product 12 showed a bacterial growth, but specialized research was required to properly describe them (see Supplementary Figure S1). Thus, their use might not be recommended, as the effect on soil microbiota and on fruits is not known and should be evaluated in further research. It should be noted that both products correspond to AN with low algae percentage. The results showed the products that inhibited both fungal growth at 48 h and continued with the effect for 22 days. *Botrytis cinerea* in tomato was inhibited in 65% (4,6,8–14,16–20) of the products studied, while in strawberry and blueberry, there were fewer products that presented action, 25% (6,10–13) and 35% (4,6,8–9, 16–17,20), respectively. Noteworthy, most of the products that showed inhibition in strawberry corresponded to EM. *Penicillium digitatum* was inhibited in 25% of the products studied (5,8–9,13,17). The products that inhibited the growth in more fruits were the following: product 6 against *B. cinerea* in all of the fruits studied; products 8, 9, and 17 showed a positive effect on tomato, blueberry, and orange; and product 13 against

pathogens in tomato, blueberry, and orange. In Supplementary Figure S2, the Petri dishes of tomato and strawberry with product 13 (EM, 100%) are shown; the inhibition halo can be clearly seen especially in strawberry at 48 h (Supplementary Figure S2E), and the effect remains for 22 days (Supplementary Figure S2F).

These facts indicate that products of both species (AN and EM) showed inhibition halo and products of different percentage and type of formulation. Table 4 shows the most relevant previous works where the efficacy of SWE against different pathogens was evaluated. Only one previous study was found in which the effectiveness of EM was evaluated (Righini et al., 2020). In this research, EM did not present antifungal activity; it should be noted that both the pathogen and the fruit studied were different (*P. xanthii* in cucumber). Our study showed promising results for EM extracts especially in strawberry. Furthermore, previous studies also found a positive activity of AN against the pathogen *B. cinerea* in carrot, cucumber, and pear (Jayaraj et al., 2008; Jayaraj et al., 2011; Lutz et al., 2022) and similar results in *L. digitata* (common brown seaweed used in agriculture) in strawberry (De Corato et al., 2017). The antifungal effect of those products was related to polysaccharide content, carbohydrate content, or bioactive molecules of the algae such as polyphenols or pigments like carotene (see Table 4). In these studies, the SWE used presented 12%–18% alginic acid, 5%–6% Man-ol, and 10%–15%

PS, polysaccharide content; CH, carbohydrate content; NS, not specified.

carbohydrate content, comparable to the solid products of this study (17–20), which showed activity against *B. cinerea* in different fruits. *Penicillium digitatum* was evaluated to a lesser extent; only two recent studies were found in brown algae. One of them evaluated the species *L. digitata* in citrus lemon (De Corato et al., 2017), and its positive effect was related to the content of polysaccharides (23%) and TPC (2.3%). In general, this content was higher than in the products of this study that presented positive activity against *P. digitatum*, but a relationship between two products was found: product 17 presented 19% polysaccharides content and product 5 a 2.5% TPC. Lahbib et al. (2022) related the fungicidal activity with TPC (14.26 mg/g) and TFC (9.16 mg/g). The products of this study present TPC values between 7–17 mg/g but much higher for TFC (30–240 mg/g). All these suggest that the antifungal activity may be due to the combined action of different compounds. Although it is true that previous works have evaluated other types of algae (red and green), brown algae are the ones that presented the highest fungicidal capacity (De Corato et al., 2017; Righini et al., 2020; Lahbib et al., 2022). This study evaluated for the first time the action of AN and EM against *P. digitatum*. Promising results were found for tomato (65% of the products showed positive action) and EM in strawberry. It should be noted that no previous studies on blueberries were found. In addition, 20

SWEs were evaluated compared to 5 in other studies, being the maximum number of products studied in previous research and providing a much more detailed information on the chemical composition. Moreover, this study lasted for 22 days to check the long-term fungicidal effect, while previously reported studies did not indicate this effect. However, in those pathogens, more research should be done, since the application of algae extract to fertilize the crops could have a positive effect on inhibiting pathogens, providing added value to these products. These promising results indicate that these products could be an alternative to use in to treat fruits and vegetables postharvest to minimize the damage caused by the attack of microorganisms.

These findings revealed that market SWEs have a great variety in their composition, thus justifying this study and the need to continue with this line of research carrying out tests *in vivo*.

3.3 Chemometric analysis

3.3.1 Multivariate generalized linear model

MANCOVA analysis was used to evaluate the effect of algae species and algae percentage on the final composition of the products studied. It was conducted to test the influence of several

independent variables in structural (AA, Man-ol, Lam, metal profile, IAA, SA, and sugar content) and bioactive compounds (TPC, TFC, TCC, TTC, TAC, and DPPH) of products studied. In order to make a preliminary determination of algae species, the percentage of SWE in the product and the extraction process were used as fixed factor and the formulation type as covariate. To evaluate the statistical significance of the model, Wilks's lambda, F-value, and p-values for main and interaction effects were employed. Levene's test of equality of error variances was given for all measured parameters. The level of significance was set at $p < 0.05$. The results showed that the strongest explanatory variables were the percentage of SWE in the product (Wilks's $\lambda = 0.02$, $F = 4.045$, $p = 0.028$) and algae species (Wilks's $\lambda = 0.01$, $F = 190.9$, $p = 0.047$); meanwhile, the extraction process (Wilks's $\lambda = 0.01$, $F = 3.080$, $p = 0.164$) had no significant effect, so we omitted this variable in the final MANCOVA model. The formulation type did not interact with fixed factors and had no significant effect (Wilks's $\lambda = 0.02$, $F = 81.98$, $p = 0.085$), indicating that this covariate was selected correctly. The reported tests showed that for these variables—species and SWE percentage—the null hypothesis is rejected, so they significantly influence on the final composition of the products. These findings contribute to understanding the role of variables related to the production process on the final composition of SWE.

3.3.2 Principal component analysis

PCA was made using the raw data obtained from the composition analysis of SWE. To examine the suitability of these data, the Kaiser–Meyer–Olkin (KMO) test was performed. The KMO test measures the sampling adequacy and indicates the proportion of variance. The KMO result was 0.82 (≥ 0.5), indicating that PCA could be useful in providing significant reductions in the dimensionality of the raw data. Major components were extracted with eigenvalues > 1.0 . In this model, PC1 explains 35% of the accumulative variance; PC2, 60%; PC3, 69%; PC4, 75%; PC5, 84%; PC6, 87%; PC7, 91%; PC8, 92%; and PC9, 99%. The component plot rotated space generated from the first two PCs explained the variations in the seaweed products in relation to their composition (Figure 1A). PC1 had a medium positive loading (loading values, 0.50–0.70) of Ca, Mg, Al, TCC, and TTC and strong negative loading (loading values, 0.7–1.00) for Man-ol, TAC, and pH. Most of the samples showed a positive relation with PC1. On the other hand, a high negative relationship was observed corresponding to the solid formulations (see in Figure 1B) due to their low concentration of Ca, Mg, and Al and high levels of Man-ol, pH, and TAC. PC2 showed a medium positive loading (loading value, 0.50–0.70) of TPC, Ni, glucuronic acid, SA, TFC, TCC, and TTC and a medium negative loading of rhamnose, Mn, and Zn. As can be seen in Figure 1B, the product that presented the greatest negative

relationship corresponded to sample number 13 and product 14 and showed a positive relationship with PC2. Product 13 is related to species EM and products with the highest algae percentage content. Hence, it has the lowest values for these variables and the highest value for rhamnose, which is specific for EM. Product 14 was related to AN, had 100% algae percentage, and had the highest values for these variables, especially Ni (0.15 ± 0.002 mg/kg) and no rhamnose levels. AN, hence, is found at a higher relationship with PC2 than EM. Overall, these findings are in accordance with the MANCOVA and concluded that composition profiling was influenced by species and percentage of seaweed in the formulation. In this way, it can be concluded that PCA satisfactorily highlighted the differences between the products based on the species and percentage of algae (Figure 1C).

3.3.3 Hierarchical cluster analysis

HCA allows to classify the products studied according to their similarities in chemical composition. It was performed using Ward's method with squared Euclidean distances to examine station similarities. Ward's method uses ANOVA to calculate the distance between groups to minimize the sum of squares of two possible groups at each step. Figure 2A shows the dendrogram of the products based on the analysis of polysaccharide's composition. Three well-defined main clusters were observed. Cluster 1 was clearly discernible and constituted by low algae percentage products mainly obtained through cold extraction and acid media. Clusters 2 and 3 were explained by algae percentage of products (100%) and the type of formulation; all solid products were grouped in these clusters and represented the products with the high polysaccharide content, between 8% and 12%. HCA results for the mineral profile is shown in Figure 2B. Two clusters with great similarities were observed, which is in good agreement with the previously described results. Most of the products follow the same trend in the mineral profile with the exception of products 6 and 16. These products showed large Euclidean distance, which indicated dissimilarity between the other products. Figure 2C represents the dendrogram of the sugar content. Clusters 1 and 2 are established by the products with the highest sugar content. They correspond to AN products, and most of them are in solid formulation. Clusters 3 and 4 are formed by the samples that have 3%–5% sugar content. The products with the highest sucrose content were grouped in cluster 3, while cluster 4 was formed by those with the highest glucose content. All the products of EM under the study were in cluster 4. Sample numbers 11 and 14 were the most different and had more than 15% sugar content. Figure 2D shows 3 main clusters for bioactive compounds and antioxidant activity. Cluster 1 grouped 13 products with the highest DPPH percentage (products 7, 8, 10, 11). This cluster was defined by high percentage SWE products, both AN and EM, and all solid products were in this

FIGURE 1
(A) Principal components plot in rotated space of variances of seaweed extracts based on chemical composition; (B) PCA based on algae species (*AN* and *EM*); (C) PCA based on algae percentage in products studied (low and high).

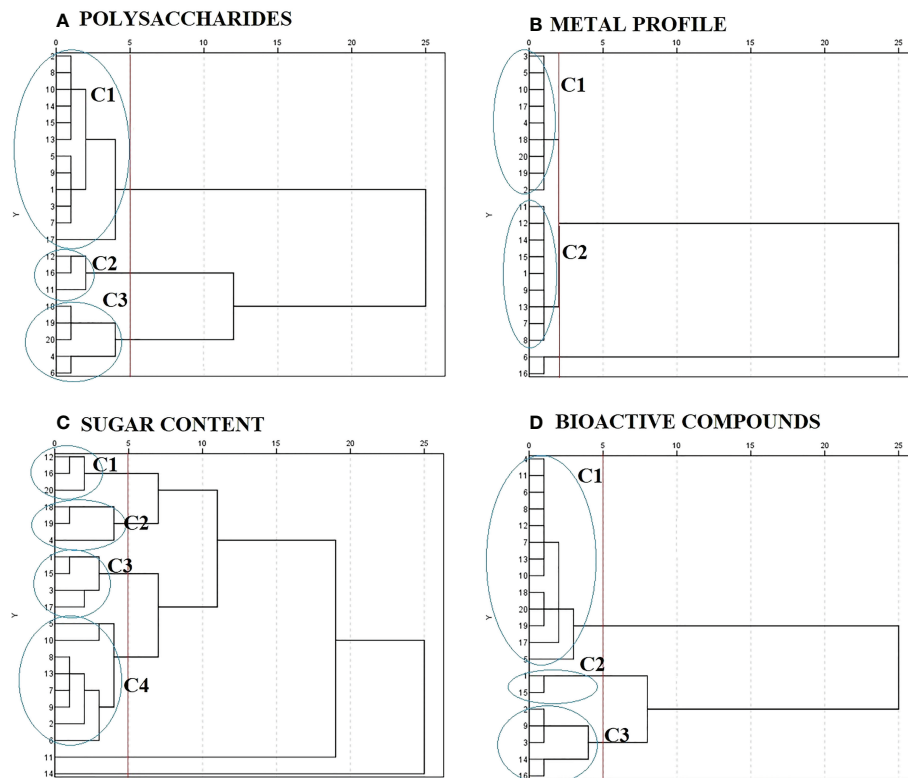

FIGURE 2

Dendrogram of hierarchical cluster analysis of seaweed extracts based on: (A) polysaccharides composition, (B) metal profile, (C) sugar content, and (D) bioactive compounds.

group. Cluster 2 was composed of the products with the highest TPC and cluster 3 with those that had the highest TFC. Both clusters presented similarities in terms of being formed by the products that correspond to mixtures (low algae percentage). This fact suggests that the products are mixed with some components that could enhance the presence of phenolic compounds. HCA has given a clear view of the composition pattern of SWE of the respective species and algae percentage. These results are in very good agreement with those observed in MANCOVA and PCA.

On the other hand, it is well-known that antifungal activity is related to the presence of multiple compounds, and HCA can be a useful tool to relate it. The products that presented action against *P. digitatum* (5, 8, 9, 13, and 17) were grouped in the same polysaccharide cluster (cluster 1), and for carbohydrates, four of them were grouped in cluster 4 and the other one in cluster 3. The characteristics of these clusters have been discussed previously; however, it should be noted that sucrose was not detected in these products. Sucrose is used by pathogens as a carbon source; possibly, its absence has inhibited their growth. In the case of tomato, the products of interest were grouped in cluster 1 (4, 6, 8, 10–13, 17–20) and cluster 3 (9, 14,

16) for bioactive components. The products that presented action on strawberry (6,10–13) were grouped in cluster 1 of bioactive components and that on blueberry were grouped in cluster 1 (4, 6, 8, 17, 20) and cluster 3 (9, 16). As can be seen, the fungicidal effect on *B. cinerea* was associated with polyphenolic compounds as described in other works (Table 4), while for *P. digitatum*, it was associated with polysaccharide and carbohydrate content.

3.3.4 Artificial neural network analysis

ANN have gained popularity in recent years for modeling methodologies for food quality and food processing (Bhagya Raj and Kshirod, 2022). This methodology has numerous advantages such as flexibility, mapping ability, and high-speed information processing ability, and the ability to solve non-linear complex analysis even if the exact nature of the non-linear relationship between the input and output neurons is unknown (Abiodun et al., 2018). A multilayer perceptron (MLP) based on back propagation (BP) was applied for modeling the composition of the seaweed products. The best model analysis conditions were as follows: the activation function and the number of hidden layers were hyperbolic tangent and four

layers, respectively. The output layer activation function was Softmax, and the training type was batch training. Under this condition, the correct rate of model training and testing was 97.3% and 91.7%, respectively. The results showed that the SWE can be distinguished according to the components analyzed. Under this model, the components that made the greatest contribution to classification and their normalized importance were Zn (100%), EC (95%), K (91%), glucuronic acid (86%), TCC (77%), and Mn (72%).

4 Conclusions

This study has contributed to the knowledge about commercial SWEs used in agriculture. The composition of 20 commercial products with relevant characteristics and their antifungal potential against the usual fungi of certain fruits were analyzed. These results revealed important information about them and can contribute to improved labeling, whose problem is latent. Chemometric techniques were applied using linear and non-linear models in order to establish how the variables related to the production of the extracts influence the chemical composition of the products. MANCOVA allowed to determine the variable species and algae percentage in products as the most influential (p-value and Wilk's lambda test). Principal component analysis and hierarchical cluster analysis discriminated the dependent variables according to species and algae percentage. PCA revealed that rhamnose was a characteristic in *E. maxima* with 100% seaweed in its composition; this parameter could be used to control fraud in these products. In addition, a characteristic composition was observed in the solid products, defined by low concentrations of Ca, Mg, and Al and high concentrations of mannitol, total antioxidant content, and high pH values. HCA showed that the highest concentration of bioactive components was grouped in the same cluster corresponding to low algae percentage. This fact suggests that some component has been added to the products. In addition, HCA was used to relate the antifungal capacity of SWE to their composition. These results revealed that the fungal capacity against *B. cinerea* was related to the bioactive components, while that against *P. digitatum* was related to the polysaccharides and carbohydrates content. Moreover, ANN allowed to establish the influence of other variables (K, glucuronic acid, laminarin, and total carotenoid content) that were not revealed by the linear methods. The overall results could help to better understand the mode of action of these products through their composition and the importance of chemometric techniques to discern the most significant variables in the production process and their relationship with their fungal capacity. Future research on other products available on the market is recommended to deepen the investigation related to postharvest treatments due to their action against common pathogens in fruits.

Data availability statement

The original contributions presented in the study are included in the article/[Supplementary Material](#). Further inquiries can be directed to the corresponding author.

Author contributions

SV, JLL and LHA designed the experiments. SV and PLW performed the analysis of chemical composition of SWEs. SV, PLW and BM performed the microbiological assays. SV and PLW acquired and analyzed of data; BM, JLL and LHA helped perform the analysis of data with constructive discussions. SV, PLW and LHA wrote the manuscript. All authors revised the manuscript and approved the submitted version.

Funding

The authors gratefully acknowledge the financial support of Spain's Ministry of Economy and Competitiveness project no. RTI2018-096268-B-I00 and the Comunidad de Madrid (Spain) and Structural Funds 2014–2020 (ERDF and ESF) project AGRISOST-CM S2018/BAA-4330.

Acknowledgments

The authors are grateful to the fertilizer companies and Laboratorio Arbitral (Spain's Ministry of Agriculture, Fisheries and Food) for kindly donating samples for this investigation.

Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Digestate prepared from anaerobic digestion can be used as a fertilizer, as it contains ample amounts of plant nutrients, mainly nitrogen, phosphorous, and potassium. In this regard, digestates produced from mixed intercropped cereal and legume biomass have the potential to enrich soil and plants with nutrients more efficiently than monoculture-based digestates. The objective of this study was to determine the impact of different types of digestates applied at a rate of 40 t ha⁻¹ of fresh matter on soil properties and crop yield in a pot experiment with lettuce (*Lactuca sativa*) as a test crop. Anaerobic digestion of silages was prepared from the following monocultures and mixed cultures: broad bean, maize, maize and broad bean, maize and white sweet clover, and white sweet clover. Anaerobic digestion was performed in an automatic custom-made system and applied to the soil. Results revealed that fresh and dry aboveground biomass as well as the amount of nitrogen in plants significantly increased in all digestate-amended variants in comparison to control. The highest content of soil total nitrogen (+11% compared to the control) and urease (+3% compared to control) were observed for maize digestate amendment. Broad bean digestate mediated the highest oxidizable carbon (+48%), basal respiration (+46%), and N-acetyl- β -D-glucosamine-, L-alanine-, and L-lysine-induced respiration (+22%, +35%, +22%) compared to control. Moreover, maize and broad bean digestate resulted in the highest values of N-acetyl- β -D-glucosaminidase and β -glucosidase (+35% and +39%), and maize and white sweet clover digestate revealed the highest value of arylsulfatase (+32%). The observed differences in results suggest different effects of applied digestates. We thus concluded that legume-containing digestates possibly stimulate microbial activity (as found in increased

respiration rates), and might lead to increased nitrogen losses if the more quickly mineralized nitrogen is not taken up by the plants.

Introduction

Anaerobic digestion (AD) is a microbially-controlled process of biomethanization. Originally it was used for processing of biodegradable waste from agriculture, industry, or households (Angelidaki et al., 2003). Due to increasing threat of climate change and limited fossil energy sources, the bioenergy obtained from biogas has become essential in climate change mitigation, energy security, resourcing, and sustainable agriculture development (Shakoor et al., 2020). Research on the processing of liquid animal manure and plant raw material by AD has been promoted and expanded across the world (Aravani et al., 2022). Especially in Europe, biogas production from energy crops has developed considerably, and maize (*Zea mays* L.) used to be the most common and preferred source crop (Weiland, 2010) until recently. The advantages of maize biomass as substrate are high yield performance and established crop management technology (Gissén et al., 2014; Purdy et al., 2017; Theuerl et al., 2019). However, scientists have recently been looking for possible new substrates (Dębowski et al., 2022), mainly because of the negative environmental impacts and economic balance associated with maize cultivation (von Cossel et al., 2021; Herman et al., 2022).

Apart from the main product's renewable energy (biogas), AD converts plant biomass to the second useful by-product—digestate. The resultant digestate has been characterized as having high amounts of plant-available nutrients and can act as a soil conditioner (Liedl et al., 2004; Arthurson, 2009; Brtnický et al., 2022) or can be used as substrate for microalgae cultivation (Bauer et al., 2021; Kisiełewska et al., 2021). Compared to the raw feedstock, the digestate obtains beneficial properties during AD, e.g., the increased availability of nitrogen mainly in NH_4^+ form (Gutser et al., 2005), potassium (Slepetiene et al., 2020) and phosphorus (Barlóg et al., 2020) for plants. The composition of digestate also depends on the raw materials being used as AD feedstock; for example, pig slurry contains more potassium (Zhan et al., 2020), whereas co-digested cattle slurry increased the content of phosphorus (Bachmann et al., 2011). Therefore, digestate (as an organo-mineral fertilizer) can provide comparably or almost as rich a nutrient supply as either mineral (Riva et al., 2016; Šimon et al., 2016) or organic

fertilizers such as manure (Albuquerque et al., 2012; Bougnom et al., 2012).

So far, only a few studies have been focused on the quality of final digestate that are further governed by the type of feedstock (Risberg et al., 2017; Ehmann et al., 2018; Szymanska et al., 2018). However, substitutional crops are promising alternatives to biogas and digestate production from maize monocultures (Lebuhn et al., 2008; Oslaj et al., 2010; Sigurnjak et al., 2017; Gissén et al., 2014). Substitutional crops can be used either as co-substrates only (Meyer et al., 2015; Nurk et al., 2016; Fahlbusch et al., 2018; von Cossel et al., 2020) or blended biomass harvested from mixed cultures, such as maize and intercropped sunflower (Karpenstein-Machan 2005; Nassab et al., 2011), sorghum (Schittenhelm 2010; Samarappuli and Berti 2018), or legume (Gatta et al., 2013; Kintl et al., 2019). Alternatively, maize could be fully replaced by another bioenergy crop of a common type (e.g. sugar beet, wheat, hemp) (Nges et al., 2012; González-García et al., 2013; Gissén et al., 2014). Moreover, the intercropping of energy crops with legumes represents a promising approach. The main advantage is the contribution of leguminous species to the nitrogen nutrition of non-leguminous species (Råberg et al., 2017). Legume biomass itself tends to have higher nitrogen content and lower C:N ratio than non-leguminous material (Peoples et al., 1995). A low C:N ratio changes the stability and consumption of available N nutrients, leading to slower nitrogen utilization, followed by higher alkalinity, *via* ammonia metabolism (Muhayodin et al., 2021). The higher content of ammonium from legumes in the intercrop biomass could inhibit the production of methane in biogas during AD (Wahid et al., 2018; Kintl et al., 2022). According to Hutnan et al. (2010), the process of anaerobic digestion is unstable at low N content in maize silage, and they recommend the addition of a substrate with higher nitrogen content for stabilization. Nevertheless, down-shifted AD performance and efficiency is compensated by higher residual nitrogen in the final digestate. The significantly negative correlation between cumulative nitrogen mineralization and the C:N ratio in digestate (Tambone and Adani 2017) is indicative of improved digestate-derived nitrogen availability for plants in the amended soil (Barlóg et al., 2020), which is expected to further increase with increasing nitrogen content in

the digestate (Andruschkewitsch et al., 2013). Another study indicated that reallocation of processed plant biomass (crop residues and cover crops) in the form of digestate can increase the crop dry matter yield, as well as nitrogen content in soil over a long term (Stinner et al., 2008). We assume that the use of digestate from cereal-legume mixed substrate as fertilizer could keep the subsequent crop biomass productivity consistently enhanced, as discussed by Råberg et al. (2017). Such an agro-system could become the future direction of sustainable agriculture and management of renewable sources (Kettl et al., 2010; Lamei Hervani 2013).

The main objective of this study was thus to determine the impact of different types of digestates on soil properties and crop yield in a pot experiment with lettuce (*Lactuca sativa*). The feedstock used for digestate preparation was the biomass of either mixed crop (cereal-legume) cultures or monocultures (legumes, maize) varying in their chemical composition. We hypothesized that the soil amended with different digestates would contrast in: (I) final nutrient content (nitrogen, organic carbon) in soil, (II) the biomass yield of tested crop, and (III) soil microbial activities in relation to nutrient content in the digestates.

Materials and methods

Experimental field, plant biomass, and preparation of silages

The plants used for preparing digestates were grown at the Experimental Station for Fodder Crops in Vatin, Czech Republic (49°31'6"N 15°58'10"E). The station is located in a moderately warm area of the Bohemian-Moravian Highlands with a long-term average annual temperature of 7°C and a year-round long-term average rainfall of 658.6 mm; the values correspond to climate standards between 1981 and 2010 (Kintl et al., 2022). The soil of this site is characterized as sandy loam cambisol. The

following variants were grown: a) monoculture of maize (*Zea mays* L.; BAYER, Ltd, Czech Republic); b) monoculture of broad bean (*Vicia faba* L. Amiga variety; Selgen a.s., Czech Republic); c) monoculture of white sweet clover (*Melilotus albus* MED., Meba variety - Research Institute for Fodder Crops, Ltd, Czech Republic); d) mixed culture of maize and broad bean; and e) mixed culture of maize and white sweet clover. The single crops as well as combination of maize and legume plants were sown by using the Kinze 3500 (Kinze Manufacturing, Williamsburg, IA, USA) "interplant system" seeding machine in a single operation (Kintl et al., 2019). Sowing was performed by alternating two rows of maize with two rows of legumes (Figure 1) to achieve a mixed culture system. The combination of maize and legume plants was sown at a rate of 150 thousand seeds per hectare, with maize and legume at the same rate of 75 thousand each. The monocultures were planted in half this sowing density at 75 thousand seeds per hectare with same row spacing (37.5 cm) as shown in Figure 1.

DASA fertilizer (300 kg·ha⁻¹; DASA® 26/13 Fertilizer CE, produced by Duslo corp., Slovakia; 18.5% w/w N-NH₄, 7.5% w/w N-NO₃, 13% w/w soluble S) was applied to all variants before sowing, in a dose that was sufficient to cover the nutritional requirements of maize and not limit the growth of legumes at the same time. The plant biomass was harvested at DM 35% (BBCH stage 77 – 83), determined on maize crop.

Sampling of plant biomass was performed manually at a height of 18 cm above the ground. Subsequently, a 15–20 mm cut was carried out using the Deutz-Fahr MH 6505 cutter (Deutz-Fahr, Lauingen, Germany). The cut was used to prepare model micro-silages in triplicate; see Table 1. The preparation of micro-silages was the same for all variants. Cut biomass (8 kg) was placed in a micro-silage container (Ø150 mm x 1000 mm) with inoculant (Silo Solve EF, Chr. Hansen, Denmark; *Lactococcus lactis*, *L. plantarum*, *Enterococcus faecium* - dose 6.25·10⁵ CFU per g of plant biomass), which equalled a dosage of 5 g·t⁻¹ (of inoculant matter) + 3.5 L·t⁻¹ H₂O. The prepared inoculated cut biomass was compacted in

FIGURE 1
Scheme of sowing mixed culture of maize and selected legumes (Kintl et al., 2022).

TABLE 1 Prepared model silages.

Abbrev.	Variant	Weight content of maize fresh matter (%)	Weight content of broad bean fresh matter (%)	Weight content of white sweet clover fresh matter (%)	Ratio
M	Maize	100	0	0	1
BB	Broad bean	0	100	0	1
WSC	White sweet clover	0	0	100	1
M+BB	M+BB	78.9	21.1	0	3.75:1
M+WSC	M+WSC	92.6	0	7.4	12.50:1

micro-silage containers using a pneumatic press with a force of 6 N·m⁻². Subsequently, the micro-silage container was sealed and placed in an incubation room without access to light at a constant temperature of 28°C ± 1°C for 90 days. At the end of the incubation period, the micro-silage containers were opened, silage was extracted and homogenized. Frozen samples of silages were transported to the laboratory to perform chemical analysis and fermentation tests.

Production of digestate

Anaerobic digestion of prepared silages was performed using fermentation batch tests in an automatic custom-made system consisting of 5 L glass fermenters placed in a heated water bath with adjustable temperature of 42°C ± 0.1°C. Each sample was fermented in triplicate. On the first day of the experiment, the fermenters were filled with 3 L of filtered (3 mm) inoculum obtained from agricultural biogas plant-processing maize silage and slurry (80/20, w/w%), operated at mesophilic conditions, with a hydraulic retention time of 80–90 days. The basic parameters of inoculum were as follows: total solids content 3.8%, volatile solids content 73%, pH 7.2, FOS 1452 mg·L⁻¹, TAC 4330 mg·L⁻¹, and FOS : TAC 0.34.

Initial organic loading rate was 5.5 g volatile solids of introduced substrate per L. The fermentation test was carried out until the daily biogas production in three consecutive days was < 1% of the total biogas production as stated in VDI 4630 (2016). This led to a retention time of 21 days. The digestate produced

was subsequently analyzed to determine the following parameters. The dry matter was determined gravimetrically by desiccation at a temperature of 105°C ± 3.5°C to constant weight according to standard CSN EN 15934. TN (total nitrogen) and TC (total carbon) were measured using the Vario Macro Cube (Elementar Analysensysteme GmbH, Langenselbold, Germany). The content of total organic (TOC) and total inorganic (TIC) carbon was measured using Soli TOC[®] Cube (Elementar Analysensysteme GmbH, Langenselbold, Germany). Basic nutrients (P, K) were extracted using the Mehlich III reagent and then analyzed using atomic emission spectroscopy (The Agilent55B AA, Agilent, CA, USA).

Pot experiment

The following pot experiment investigated the effect of prepared digestates (Table 2) amendment on the soil properties and the growth of lettuce (*Lactuca sativa*). The experimental pots of volume 1 L were filled with 1 kg of experimental soil, which was prepared from silty clay loam (Haplic Luvisol) collected from a depth of 0–10 cm, sieved through a grid size of 2.0 mm to remove all roots and coarse particles, and mixed with fine quartz sand 0.1–1.0 mm (1:1 each, w/w). The content of nutrients in the topsoil used was as follows: total carbon (TC) 7.0 g·kg⁻¹, total nitrogen (TN) 800 mg·kg⁻¹, available phosphorus (P) 485 mg·kg⁻¹, and available potassium (K) 0.115 mg·kg⁻¹. The detailed properties of the soil used can be found elsewhere (Holatko et al., 2020; Brtnický et al., 2021).

DM., dry matter; N, P, K, total nutrient (nitrogen, phosphorus, potassium) content; TOC, total organic carbon; TIC, total inorganic carbon. Different superscript letters indicate statistically significant differences between displayed values at the significance level $p \leq 0.05$.

*, that the respective variants were presented in our previous paper Brtnický et al. (2022).

The control variant was unamended, whereas digestates were applied to the other variants at a dose corresponding to 40 t·ha⁻¹; see Table 2. A total of 6 variants (control and 5 digestate variants) were made in 3 repetitions each.

Five sprouted seeds of lettuce (*Lactuca sativa*) were planted into each of the filled pots. Seedlings were reduced to one in each pot after 14 days. The pot experiment was conducted for 6 weeks under controlled conditions in a growth chamber Climacell Evo (BMT, Czech Republic) under the following conditions: 12-hour photoperiod, white illumination, light intensity 20,000 lx, day/night temperature 22/18°C, and relative atmospheric humidity 70%. Soil moisture was maintained at 65% water-holding capacity throughout the experiment. Pots were placed in the growth chamber using a randomized scheme and rotated weekly to ensure homogeneity of growing conditions.

Plant and soil measurements and data collection

At the end of the experiment, the aboveground biomass (AGB) of individual seedlings was harvested, and the weight of fresh and subsequently dry (drying at 60°C) biomass was determined. Nitrogen content in harvested lettuce (Plant N) was measured using the Vario Macro Cube (Elementar Analysensysteme GmbH, Langenselbold, Germany). Nitrogen uptake by plants (N uptake) was calculated from dry weight of the plant and the nitrogen content in biomass. After harvest, a mixed soil sample from each pot was taken, homogenized, sieved (≤ 2 mm), and air-dried for measuring pH, total nitrogen (TN), and oxidizable carbon (C_{ox}); cooled to 4°C for respiration measurement; and freeze-dried for enzyme activity estimation. The TN was determined according to ISO_13878 1998 and C_{ox} according to ISO_14235 1998. Basal respiration (BR) and substrate-induced respirations (SIRs) were measured using a MicroResp (The James Hutton Institute, Scotland) device according to the method (Campbell et al., 2003). Substrate-induced respiration was measured after adding specific energy sources to the substrate: N-acetyl- β -D-glucosamine (NAG-SIR), L-alanine (Ala-SIR), L-lysine (Lys-SIR), and L-arginine (Arg-SIR). Enzymatic activities of β -glucosidase (GLU), N-acetyl- β -D-glucosaminidase (NAG), arylsulfatase (ARS), phosphatase (Phos), and urease (Ure) were measured according to ISO_20130 2018.

Statistical analysis

Data processing and statistical analysis were carried out with the help of the statistical program R version 3.6.3. (R_CORE_TEAM 2020) together with the additional packages “ggplot2” (Wickham, 2016). Multivariate analysis of variance (MANOVA) and principal component analysis (PCA) with

dependence of different treatments were used for modelling the relation between the soil properties and selected treatments with help of the additional packages “factoextra” (Kassambara and Mundt 2017) and “FactoMineR” (Lê et al., 2008). One-way analysis of variance (ANOVA) and Tukey’s Honest Significant Difference (HSD) from package “agricolae” (Mendiburu 2020) at the significance level of 0.05 were used to detect the difference among the treatments. The factor level means calculation (with 95% confidence interval – CI) was carried out by using “treatment contrast”. Partial eta-squared (η^2) from package “BaylorEdPsych” (Beaujean, 2012) was used to measure the effect size, and the Pearson correlation coefficient was applied to determine the linear dependence among soil properties.

Results

Soil chemical properties and aboveground biomass

All the digestate-amended soils showed insignificantly different pH values compared to each other; the lowest average value of M+BB was 7.09; see Figure 2A. Also M, WSC, and M+BB digestates reduced soil pH significantly in comparison to the control. An antagonism was apparent between pH and Arg-SIR as well as NAG; see Figure 3. Further, pH was synergistic with Ure activity. The pH demonstrated significant ($p \leq 0.01$) but low negative correlation with C_{ox} ($r = -0.44$); see Figure 4A.

The highest soil TN (0.089%, in average) was detected in the M variant. On the other hand, BB variant showed the lowest TN value (0.07%). M, M+WSC, and WSC showed insignificantly different TN values (Figure 2B); all were significantly more TN abundant compared to the BB variant. TN correlated negatively and significantly ($p \leq 0.001$) with Ala-SIR ($r = -0.53$, Figure 4A) and showed an antagonism with other amino acid-induced respirations (Ala-SIR, Lys-SIR, NAG-SIR); see Figure 3.

The highest average C_{ox} was calculated in the WSC variant, but no statistical differences in values were found in any digestate-amended variants, which were significantly increased compared to the control; see Figure 2C. C_{ox} correlated positively and significantly with fresh AGB ($p \leq 0.001$, $r = 0.73$) and with dry AGB ($p \leq 0.01$, $r = 0.70$); see Figure 4A. Moreover, a significant ($p \leq 0.01$) positive correlation was found with BR ($r = 0.51$) and Arg-SIR ($r = 0.52$). C_{ox} showed synergism with all mentioned traits and Phos, and an antagonism with pH and Ure.

Both fresh and dry AGB were significantly increased in all digestate-amended variants compared to the control. However, the differences between the amended variants were insignificant; see Figures 2D, E. The highest average fresh and dry AGB were achieved by fertilization with BB digestate, despite having the lowest value of TN and only the third highest C_{ox} content in the respective soil. Concurrently with lowest TN, nitrogen uptake by plant (N uptake) was on average (insignificantly) the highest in

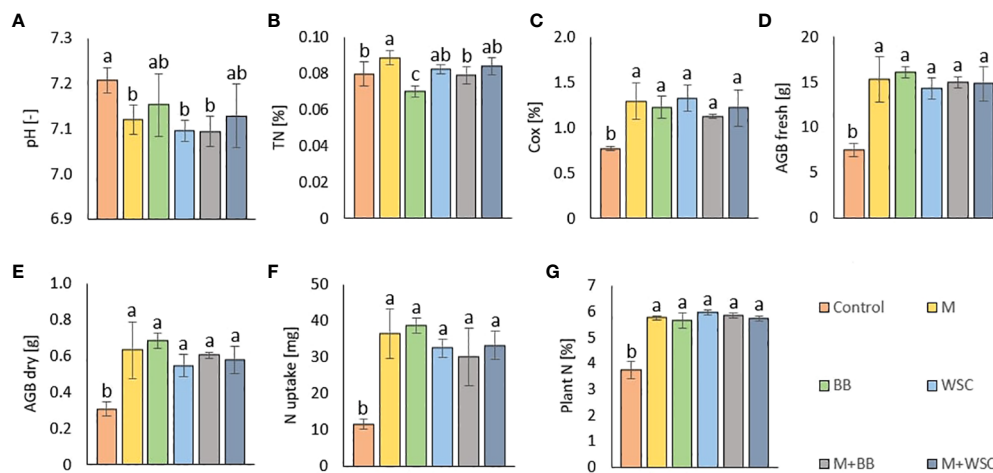

FIGURE 2

Mean \pm standard error of mean (error bars); different letters indicate statistically significant differences at the significance level $p \leq 0.05$.

the BB variant (Figure 2F). Nevertheless, neither N uptake nor nitrogen content in dry AGB (Plant N) showed any significant differences between the digestate-amended variants; only the unamended control significantly had the lowest values of both properties; see Figures 2F, G. Fresh and dry AGB correlated

significantly ($p \leq 0.001$) positively and highly (r were 0.99 and 0.98) with N uptake; see Figure 4B. Both fresh and dry AGB correlated significantly ($p \leq 0.05$) positively with enzyme activities, namely ARS (r was 0.59 and 0.58, respectively), Phos (r was 0.53 and 0.47, respectively), and GLU (r was 0.57 and 0.54,

FIGURE 3

PCA biplot of relationships between soil and plant properties of all variants. Fresh (AGB_fresh) and dry (AGB_dry) aboveground plant biomass, soil pH, total nitrogen (TN), total oxidizable carbon (Cox), basal (BR), and substrate-induced respirations - N-acetyl- β -D-glucosamine (NAG_SIR), L-alanine (Ala_SIR), L-lysine (Lys_SIR), and L-arginine (Arg_SIR); enzyme activities - urease (Ure), arylsulfatase (ARS), N-acetyl- β -D-glucosaminidase (NAG), β -glucosidase (GLU), and phosphatase (Phos).

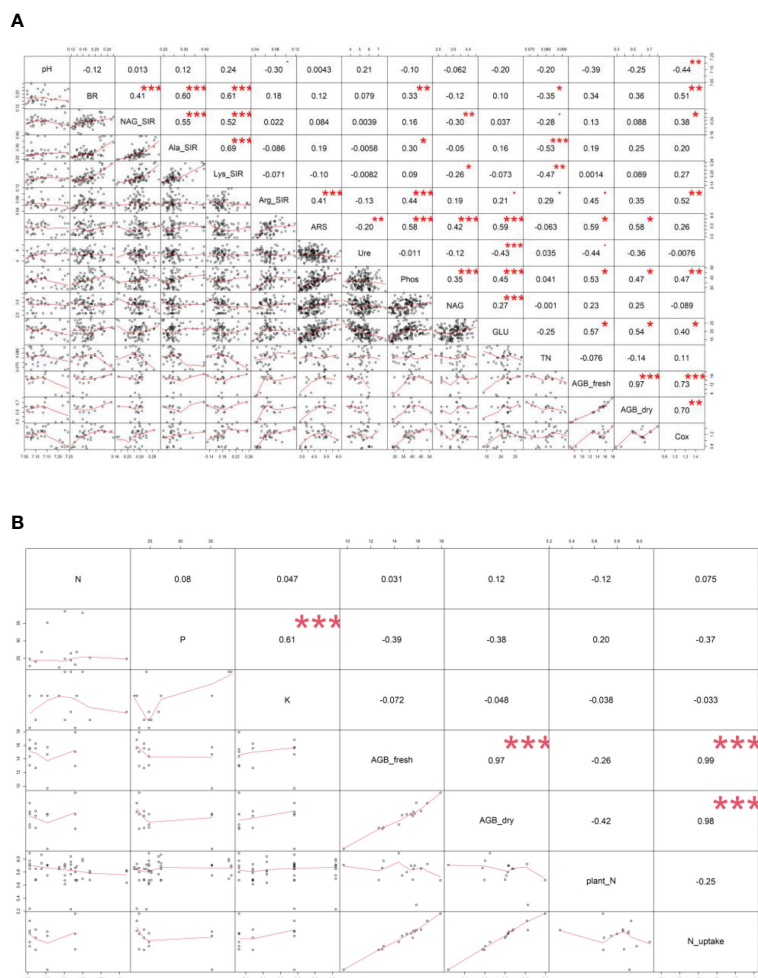

FIGURE 4

Pearson's correlation analysis – values of correlation coefficient (r) between (A) soil and plant properties, (B) digestate (N, P, K content) and plant properties of all variants. Displayed correlation coefficients (r) were calculated on the statistical level of significance: * $p \leq 0.05$, ** $p \leq 0.01$, *** $p \leq 0.001$. Fresh (AGB_fresh) and dry (AGB_dry) aboveground plant biomass, soil pH, total nitrogen (TN), total oxidizable carbon (Cox), basal (BR) and substrate-induced respirations - N-acetyl- β -D-glucosamine (NAG_SIR), L-alanine (Ala_SIR), L-lysine (Lys_SIR) and L-arginine (Arg_SIR), enzyme activities - urease (Ure), arylsulfatase (ARS), N-acetyl- β -D-glucosaminidase (NAG), β -glucosidase (GLU), phosphatase (Phos).

respectively); see Figure 3. Both fresh and dry AGB showed a strong synergism with these mentioned traits; see Figure 3.

Soil respiration and enzymatic activities

Soil BR was significantly increased (compared to the control) only in two variants: BB (the highest average value, $219 \mu\text{g CO}_2\text{-g}^{-1}\text{-h}^{-1}$) and M+WSC; see Figure 5A. On the other hand, the soil fertilized with M+BB digestate and control exerted the significantly lowest BR. BR showed significant ($p \leq 0.001$) positive correlation with NAG-SIR, Ala-SIR, and Lys-SIR (r was 0.41, 0.60, and 0.61, respectively); see Figure 4A. We revealed apparent synergism for four soil-respiration traits

(BR, NAG-SIR, Ala-SIR, Lys-SIR); see Figure 3. NAG-SIR correlated significantly ($p \leq 0.001$) and positively with Ala-SIR and Lys-SIR (r was 0.55 and 0.52, respectively); see Figure 4A.

BB was only variant which exerted significantly increased NAG-, Ala-, and Lys-SIR in comparison to the control; see Figures 5B–D. We detected comparable values of these SIR for all other variants. Mutual correlation between NAG- and Ala-SIR, NAG- and Lys-SIR, and Ala- and Lys-SIR was significant ($p \leq 0.001$) and positive (r was 0.55, 0.52, and 0.69, respectively); see Figure 4A. Contrary to the other respiration traits, Arg-SIR was increased in all digestate-amended variants compared to the control; see Figure 5E. The amendment of M+WSC digestate showed the highest Arg-SIR. Arg-SIR correlated significantly ($p \leq 0.001$) and positively with ARS ($r = 0.41$) and Phos ($r = 0.44$); see Figure 4A.

We detected the unaltered Ure activity (compared to the control) only in two variants amended with digestate: BB and M; see Figure 6A. The M variant showed significantly increased Ure activity in comparison to WSC, M+WSC, and M+BB (the lowest Ure value). A significant ($p \leq 0.001$) negative correlation was found between Ure and GLU activity ($r = -0.43$); see Figure 4A. PCA biplot showed antagonism with GLU, ARS, NAG activity, and Arg-SIR; see Figure 3.

Soil amended with M+WSC digestate exerted the significantly highest ARS activity, whereas amendment of WSC digestate resulted in comparably low ARS as detected in the control; see Figure 6B. ARS correlated highly significantly ($p \leq 0.001$) and positively with GLU, Phos, and NAG activity (r was 0.59, 0.58, and 0.42, respectively); less significant ($p \leq 0.05$) was the correlation of ARS and fresh AGB and dry AGB (r was 0.59 and 0.58, respectively); see Figure 4A. PCA biplot showed antagonism with GLU, ARS, NAG activity, and Arg-SIR; see Figure 3. The WSC variant revealed both the lowest ARS and lowest NAG from all digestate-amended variants; its NAG was significantly lower compared to the control; see Figure 6C. All other variants showed significantly increased NAG compared to the control, and M+BB variant had the significantly highest NAG.

The GLU and Phos activities of the control were significantly lowest compared to all other variants. GLU values of M and WSC variants were significantly lower in comparison to the highest M+BB variant; see Figure 6D. The highest Phos was

revealed in the BB variant, which was significantly increased compared to the M+BB and WSC variants; see Figure 6E. GLU correlated significantly positively ($p \leq 0.001$) with Phos ($r = 0.45$) and less significantly ($p \leq 0.05$) with fresh AGB, dry AGB, and C_{ox} (r was 0.57, 0.54, and 0.40, respectively). Phos correlated significantly ($p \leq 0.05$) with fresh AGB and dry AGB (r was 0.53 and 0.47, respectively) and ($p \leq 0.01$) with C_{ox} ($r = 0.47$); see Figure 4A.

Discussion

Soil chemical properties and aboveground biomass

We discovered that adjustment of all digestates prepared from M, WSC, and M+BB decreased the average values of soil pH compared to the control's unamended soil; see Figure 2. The respective digestates (M, WSC, and M+BB) exerted lower nitrogen content (on average 152.17, 146.60, and 159.86 g.kg⁻¹ d.m., respectively) and potassium content compared to other two digestate types (Table 2). These digestate properties might have contributed to the observed differences in soil pH values.

The highest TN (0.09%) content in soil was detected under treatment with M-derived digestate, which was the only significantly increased value in comparison to the control. This

Mean ± standard error of mean (error bars); different letters indicate statistically significant differences at the significance level $p \leq 0.05$.

finding did not correspond to the nitrogen doses applied to the soil with digestates. The M variant received a lower nitrogen dose compared to the nitrogen in BB and M+BB variants; see Table 2; however, these variants showed decreased TN in soil compared to the M digestate-amended soil. Because the nitrogen input did not correlate with N uptake by plants (Figure 4B), a possible explanation for this could be the lowered losses of nitrogen: lower pH putatively mediated reduction of ammonium to non-volatile cation form, and its volatilization was further mitigated due to enhanced nitrogen transformation and mineralization activities. A study done with slurry digestate showed that NH_3 emissions were lower when it was acidified (Covali et al., 2021). Decreased TN content in the M+BB variant could have been coupled with decreased nitrogen mineralization, determined by urease (Ure) activity (compared to other legume-based digestate variants); see Figure 6A. Ure was comparable to the control only in M variant, in which the Ure value was significantly increased compared to WSC, M+BB, and M+WSC. A ratio of soil C:N (C_{ox} :TN) was also slightly different from the most favorable value, 20:1, which presented an assimilation:mineralization equilibrium value as 14.6:1 in M variant, which was lower in comparison to 17.6:1 in BB and 16.2:1 in WSC variants, indicating an M digestate-mediated higher nitrogen mineralization, as discussed by Brust (2019). We ascertained from these findings a higher nitrification rate in soil

treated with M digestate, which was evidenced by high Ure value and significantly increased Arg-SIR compared to control; see Figure 5E. These assumptions were further corroborated by negative correlation between TN content and Ala-SIR ($r = -0.53$, Figure 4A) and antagonism with Ala-SIR, Lys-SIR, and NAG-SIR, as displayed in PCA biplot; see Figure 3.

N-acetyl-β-D-glucosaminidase (NAG) was significantly increased in soil treated with M+BB variant compared to all other digestate variants; see Figure 6C. High NAG together with the (average) highest β-glucosidase (GLU) activity indicated enhanced turnover of soil fungal necromass and coupled nitrogen transformation, which could be also ascertained from the second lowest C_{ox} :TN ratio (14.3:1) of M+BB variant (Hu et al., 2015). With the enhanced turnover of putatively more abundant fungal biomass in the soil amended with the most phosphorus-rich digestate M+BB ($31.63 \pm 1.21 \text{ g·kg}^{-1}$, Table 2), it was assumed that increment in fungal biomass was coupled with the respective digestate-derived improvement of phosphorus content in soil, as referred to by Du et al. (2019). On the other hand, a similar contributing effect to fungal biomass *via* higher access of phosphorus in soil could also be achieved by its mineral source, due to the fungal-derived improvement of phosphorus solubilization (Ceci et al., 2018).

All digestate-amended variants exerted significantly increased soil C_{ox} in comparison to the control variant. As C_{ox}

represents a sub-pool of labile SOC, we expected that C_{ox} could correspond to a dose of TOC applied in the digestate to the respective variants. However, disproportions between C_{ox} and the applied dose of TOC were detected; see Table 2 and Figure 2C. Although WSC showed the highest soil C_{ox} and the second highest TOC content in digestate, M+WSC reached the second lowest soil C_{ox} and concurrently the highest content of TOC in the respective digestate. The significant differences might have been caused by varied assimilation rate of carbon and nitrogen among the tested variants and could also be attributed to the digestibility of the organic carbon in the respective digestates, with higher lability of organic carbon in the fertilizer obtained from mono-substrate BB and WSC, M digestion. This assumption was based on the observed significantly longer lag in biogas production of the mixed culture feedstock compared to the monoculture corn feedstock (Kintl et al., 2022). We assumed vastly pre-digested, partially consumed (and therefore decreased to lower TOC values), and more easily available recalcitrant compounds in TOC of monoculture digestate, whereas the mixed culture digestate likely preserved a higher portion of moderately recalcitrant carbon. This might cause C_{ox} values to affect the respiratory and enzymatic activities in soil differently and incoherently with the carbon inputs derived by the various digestate variants. The efficiency of utilizing the digestate-derived external organic matter in the form of oxidizable carbon could be expressed as a ratio between TOC values of all digestate variants and C_{ox} values of respective amended variants used to treat soil. These ratios, calculated from Table 2 and the values in Figure 2C, were also the lowest for WSC (22.5:1), M (22.6:1), and BB (23.4:1), compared to values of M+WSC (24.7:1) and M+BB (26.2:1). The microbial community amended with mixed culture digestate putatively oxidized such partially digested recalcitrant carbon more slowly and likely led to the significantly lowered respiration (BR, NAG-SIR, Ala-SIR, Lys-SIR) values in M+BB compared to BB variant; see Figure 5. The observed higher soil catabolic activity (BR, SIRs, GLU, NAG) in the respective monoculture digestate variants, namely BB, corroborates this presumption of higher organic matter decomposition in the monoculture digestate-amended variants. A contradictory significant positive correlation between C_{ox} and both fresh and dry AGB (r was 0.73 and 0.70, respectively) could also be explained by this hypothesis and the mutual synergy of these properties on the PCA biplot; Figures 3, 4. An active pool of TOC could be also affected by the land use systems (Sahoo et al., 2019), but in this experiment the carbon sources in soil were much more affected by the addition of external organic matter of variable quality than by the changes in complexity of intrinsic SOM. Because C_{ox} correlated significantly and positively with BR ($r = 0.51$, $p \leq 0.01$), we presumed that higher digestibility of digestate amendment enhanced organic matter aerobic decomposition. Moreover, TN content was coupled with increased respiration, evidenced by the significant negative

correlation of TN and Ala-SIR and Lys-SIR (r were - 0.53 and - 0.47, $p \leq 0.001$ and ≤ 0.01 , respectively), and antagonism on PCA biplot; Figures 3, 4. Therefore, a strong dependence between a decrease in nitrogen content in soil and the co-decomposition of nitrogen sources together with carbon sources and their mineralization was ascertained from these relations. Nevertheless, all digestate-amended variants significantly increased fresh and dry AGB in comparison to the control, and their effects remained similar to each other (Figures 2D, E). The highest average fresh and dry AGB value was achieved in BB digestate-treated variant despite the lowest value of TN and the third highest C_{ox} content in soil. It was reported that digestates have a higher potential over a short- to mid-term use period to positively affect plant biomass yield in comparison to synthetic nitrogen fertilizer under favorable climatic conditions (Doyeni et al., 2021). However, we discovered that plant nitrogen content (%) in plant dry biomass did not correspond to the amount of nitrogen amended with the respective digestate doses to the experimental variants. Nevertheless, we found a very high significant correlation of N uptake and fresh and dry AGB (Figure 4B), despite the differences between variants not being significant. Thus, soil nitrogen losses and N uptake at the end of the experiment are balanced through nitrogen access (provided by amended digestate) and acquisition by the plant. However, we can ascribe the rate of nitrogen efflux from soil to higher incorporation of nitrogen into plant biomass, as revealed in the BB variant, which showed the lowest soil TN and the highest average N uptake by plants.

Soil respiration and enzymatic activities

Tested digestates consisting of M, M+BB, and WSC did not enhance the soil BR compared to the control; see Figure 5. Nevertheless, BR values of M, WSC, and M+WSC were comparable. We ascribed this finding to observation that the remaining organic fraction after AD was more recalcitrant than the feedstocks (Möller 2015), thus the readily available carbon for aerobic catabolism was limited. The highest BR in BB-treated soil corresponded to the significantly lower content of stable (left intact after AD decomposition) carbonaceous compounds (hemicellulose, neutral detergent fiber) in legume-based digestate than in *Poales*-based digestate (Slepetiene et al., 2016). This was putatively caused by the reported higher (by +62%) inhibition of plant cell wall digestion by lignin in grasses than in legumes (Buxton and Russell, 1988). The significantly highest NAG-SIR in the BB variant was thought to be caused by higher degradable organic matter (fungal necromass) and other labile SOM-associated organic nitrogen supplied *via* respective legume-digestate amendment. Nitrogen scarcity anticipated the level of Ure activity as well, which was significantly increased in the variant BB (with the lowest TN) compared to all other

legume-based variants (except WSC); see [Figures 2B, 6A](#). The soil treated with variants M+BB, M+WSC, and WSC with TN was comparable to the control value, and the $C_{ox} : TN$ ratio was significantly lower (from 14.5:1 to 16.2:1) compared to the BB (17.6:1) soil; significantly decreased Ure compared to the control and M was also found. Retarded organic matter deamination in M+BB variant was again putatively caused by higher recalcitrance of external organic matter of digestate and indicated by low $C_{ox} : N$ ratio. Positive correlation between Ure activity and C:N ratio value was already reported ([Gao et al., 2019](#); [Pan et al., 2021](#)).

It is generally known that fodder legumes are relatively less abundant in sulfur amino acids ([Witten et al., 2015](#)) compared to cereals such as maize. Thus, it was expected that the digestate made of single cropped BB and WSC might be deficient in sulfur. This assumption explained lower ARS (the enzyme involved in mineralization of organo-sulphates) in the WSC variant; see [Figure 6B](#). The low ARS value in the M digestate-treated variant was less expected and comparable to the effect of BB digestate.

NAG is an enzyme involved in decomposition of fungal cell wall polysaccharide (chitin). Mycorrhizal fungi in the tested soil might have significantly affected the final fungal biomass and its turnover. Increment in fungal biomass was presumably coupled with the respective digestate-derived improvement of phosphorus content in soil, as discussed [Du et al. \(2019\)](#). The study by [Yu et al. \(2020\)](#) evidenced a negative correlation between N:P ratio and arbuscular mycorrhizal abundance and vesicle formation after root infection. This means that phosphorus supplementation by M+BB digestate with significantly lower N:P ratio (5.1:1) compared to other digestates (with N:P ratios demonstrably higher - from 6.7:1 to 7.8:1) may cause an increment in NAG values; see [Figure 6C](#). On the other hand, WSC digestate dose exerted a higher N:P ratio of 6.7:1, which might partially explain the revealed lowest NAG although it was in contrast with the result of NAG-SIR determination. Our findings that NAG and ARS activity was related to the availability of nutrients in soil are further supported by the positive correlation of both enzyme activities with fresh and dry AGB.

The GLU enzyme catalyzes the hydrolysis of β -1 \rightarrow 4-bonds in the cellulose and oligosaccharide molecules of soil organic matter (SOM) or digestate, especially its organic carbon fraction. Therefore, the significantly highest level of GLU in the M+BB variant corresponded to the highest dose of TOC in the respective applied digestate (372 kg-ha⁻¹). Moreover, we assumed that digestates made of mixed cultures and monocultures of legumes contained more decomposition products of cellulose (hemicellulose) compounds due to the already mentioned digestion inhibition of cell wall compounds by lignin in grasses ([Buxton and Russell, 1988](#)) and thus induced higher GLU activity in comparison to the M digestate-amended variant.

We revealed the highest Phos activity in the BB variant, which was supplied with the lowest amount of available phosphorus (23 kg-ha⁻¹) within the amended digestate dose in comparison to all other digestate variants; see [Table 2](#). We assume that the increased demand for phosphorus of lettuce seedlings exerting the highest

fresh and dry AGB in the BB variant induced the enhanced phosphate-solubilizing activity in soil, catalyzed by the Phos enzyme. We discovered that the enhanced Phos activity was related to the increase in GLU values, and this was in the line with coupled carbon- and phosphorus-cycling enzyme activities ([Loeppmann et al., 2020](#)). On the other hand, the significantly lowest Phos in WSC was indirectly related to the highest TOC:P ratio (13.8:1) in the respective amended digestate calculated from [Table 2](#). This finding agreed with a negative correlation of C:P ratio to phosphate solubilization efficiency as reported by [Zhan et al. \(2021\)](#).

Conclusions

This study verified an apparently variable effect of digestates made from different feedstocks on soil properties. Fresh and dry aboveground biomass was significantly increased in the digestate-amended variants in comparison to the control but comparable after application of all five digestate types. The demonstrably highest content of total nitrogen and urease, and very high content of oxidizable carbon were observed for maize digestate amendment. However, the highest induction of respiration and enzyme activities occurred with the addition of digestates made of either legume monoculture or mixed cultures. We ascribe these observed differences to the effect of presumably increased soil degradability of legume-derived digestate organic matter and joint increased availability of nutrients after application, which might also lead to increased risks of nitrogen loss. Therefore, further investigation in this area could focus on the different ratios between maize and legume biomass in feedstock to achieve a better balance between the availability and recalcitrance of the digestate organic matter.

The stimulatory effect of Thuricin 17, a PGPR-produced bacteriocin, on canola (*Brassica, napus* L.) germination and vegetative growth under stressful temperatures

Mahtab Nazari, Iraj Yaghoobian and Donald L. Smith*

Department of Plant Science, McGill University, Montreal, QC, Canada

Exposure to unfavorable conditions is becoming more frequent for plants due to climate change, posing a threat to global food security. Stressful temperature, as a major environmental factor, adversely affects plant growth and development, and consequently agricultural production. Hence, development of sustainable approaches to assist plants in dealing with environmental challenges is of great importance. Compatible plant-microbe interactions and signal molecules produced within these interactions, such as bacteriocins, could be promising approaches to managing the impacts of abiotic stresses on crops. Although the use of bacteriocins in food preservation is widespread, only a small number of studies have examined their potential in agriculture. Therefore, we studied the effect of three concentrations of Thuricin17 (Th17), a plant growth-promoting rhizobacterial signal molecule produced by *Bacillus thuringiensis*, on germination and vegetative growth of canola (*Brassica napus* L.) under stressful temperatures. Canola responded positively to treatment with the bacterial signal molecule under stressful temperatures. Treatment with 10^{-9} M Th17 (Thu2) was found to significantly enhance germination rate, seed vigor index, radical and shoot length and seedling fresh weight under low temperature, and this treatment reduced germination time which would be an asset for higher latitude, short growing season climates. Likewise, Thu2 was able to alleviate the adverse effects of high temperature on germination and seed vigor. Regarding vegetative growth, interestingly, moderate high temperature with the assistance of the compound caused more growth and development than the control conditions. Conversely, low temperature negatively affected plant growth, and Th17 did not help overcome this effect. Specifically, the application of 10^{-9} (Thu2) and 10^{-11} M (Thu3) Th17 had a stimulatory effect on height, leaf area and biomass accumulation under above-optimal conditions, which could be attributed to modifications of below-ground structures, including root length, root surface, root volume and root diameter, as well as photosynthetic rate. However, no significant effects were observed under optimal conditions for almost all measured variables.

Therefore, the signal compound tends to have a stimulatory impact at stressful temperatures but not under optimal conditions. Hence, supplementation with Th17 would have the potential as a plant growth promoter under stressed circumstances.

KEYWORDS

Brassica napus, bacteriocin, stressful temperatures, germination, vegetative growth

Introduction

Germination and vegetative growth are fundamentals of crop production. Rapid, uniform germination and emergence under various climatic conditions play a pivotal role in global food security. Abiotic and biotic factors including extreme temperature, moisture, light, nutrient availability, soil-borne pests and non-pathogen organisms, influence seed germination and establishment (Wang et al., 2016; Lamichhane et al., 2017). Among these, temperature is one of the major environmental factors influencing various plant functions, including seed dormancy and germination. Previous studies have emphasized the role of temperature in the regulatory network of seed germination (Xia et al., 2018; Zhou et al., 2018; Suriyasak et al., 2020; Xue et al., 2021). Temperature controls metabolic and cellular mechanisms, including phytohormone contents, mostly gibberellins and abscisic acid, and determines germination capability and rate (Oracz and Karpiński, 2016; Urbanova and Leubner-Metzger, 2016; Wang et al., 2018b). Some plant seeds germinate across a wide range of temperatures, while others germinate only at a narrow range of temperatures. Canola (*Brassica napus* [L.]) has been widely cultivated and is one of the most important oilseeds and biodiesel fuel crops. However, cool spring temperatures slow germination and emergence of spring-sown *B. napus*, which delays flowering in mid-summer. Hence, strategies that improve early germination impact canola yield in cooler (higher latitude and altitude) climates. After seed germination, sufficient vegetative growth is required for the development of roots to uptake water and nutrients, shoots to support aboveground stems, and leaves for photosynthesis and biomass accumulation. However, climate change significantly increases the occurrence of abiotic stresses that adversely affect vegetative growth and development, and ultimately crop production. In such cases, sustainable practices and adopting environmentally friendly approaches can enhance resource efficiency and crop production under stressful conditions. Application of plant-associated microbes, or signal compounds produced by them, such as bacteriocins, can increase plant resistance through direct and indirect mechanisms, including nutrient acquisition, phytohormone production, siderophore

production, biocontrol and induced systematic resistance to biotic stressful conditions (Khan et al., 2019; Xia et al., 2020; Antar et al., 2021; Lyu et al., 2021; Shah et al., 2021). Often, plant-microbe interaction signals positively influence plant growth at nearly all stages, from germination to seedling establishment, flowering, seed development and maturity (Gautam et al., 2016; Schwinghamer et al., 2016; Arunachalam et al., 2018). One of the well-known signal molecules is lipo-chitooligosaccharide (LCO) which specifies host-symbiont crosstalk communication and mediates rhizobia-legume associations (Oldroyd et al., 2011; Zipfel and Oldroyd, 2017). In addition, bacteriocins, a specific type of signal molecule with potential positive impacts on agriculture, are yet less known. They can control microbial population dynamics by excretion of versatile compounds known as bacteriocins acting as either a “a never ending arms race” (Riley, 1998) against competitors or, in some cases, signalling compounds are involved in plant colonization and plant growth stimulation. Bacteriocins are antimicrobial peptides produced by bacterial ribosomes and secreted by the bacteria (Arnison et al., 2013). They differ from antibiotics in that they hinder organisms that are closely related to the producer strains, and are active at extremely low concentrations (Mak, 2018). Bacteriocins can sometimes be efficient biocontrol agents in the food and pharmaceutical industries while less attention has been paid to their potential in agriculture. The capacity for bacteriocin production by plant growth-promoting rhizobacteria (PGPR) has been reported in some limited studies, such as bacteriocin exertion by *Pseudomonas fluorescens* SF39a, isolated from the wheat rhizosphere, which suppresses the growth of the phytopathogenic *Pseudomonas* and *Xanthomonas* strains (Godino et al., 2016). Bacteriocins synthesized by rhizobia have been named “Rhizobiocins” (Schwinghamer, 1975). For instance bacteriocin-substances have been isolated by *Bradyrhizobium japonicum* (Gross and Vidaver, 1978; Mojgani, 2017) and *Rhizobium leguminosarum* related strains (Hirsch, 1979; Hafeez et al., 2005). Among rhizosphere microbiome, *Bacillus* species were one of the first groups studied for production of diverse bacteriocins. So far, there have been reports of the synthesis of 18 bacteriocins from *B. thuringiensis* (Mojgani, 2017). Yet, bacteriocin excretion by *Bacillus* PGPR is poorly understood,

and none have been examined as thoroughly as Th17 for plant growth promotion; Th17 was discovered in our laboratory and is produced by *B. thuringiensis* non-*Bradyrhizobium* Endophytic Bacterium 17 (BtNEB17), an endophytic bacterium isolated from soybean root nodules [patent by Smith et al. (2008)]. Th17 is highly resistant to heat, stable across a pH range of 1.0–9.25 and is a low molecular weight peptide of 3.162 kDa with anti-microbial activity and plant growth promotion ability, particularly under stressful conditions (Jung et al., 2011; Prudent et al., 2015; Schwinghamer et al., 2015; Subramanian et al., 2016; Schwinghamer et al., 2016; Nazari and Smith, 2020). Interestingly, this bacteriocin could alter physiological and biochemical attributes of plants including increases in photosynthetic rate and antioxidant enzymes contents of plants under normal and stressed conditions (He, 2009; Jung et al., 2011). We should note that more recent characterization of Th17 has shown sufficient differences from our original understanding of its composition that we are considering renaming it to Bacillin 20. Although studies on the efficacy of plant-microbe interactions are abundant, there is a lack of studies around the agricultural potential of bacteriocins. We, therefore, conducted a series of experiments to examine the stimulatory effect of Th17, a plant growth promoting rhizobacteria signal molecule, on germination and vegetative growth of canola under contrasting temperature conditions. The aim is to develop an environmentally friendly approach to stimulation of plant growth and development in a constantly changing environment.

Materials and methods

Isolation and purification of Th17

BtNEB17 was grown in King's medium B as previously described (Gray et al., 2006). Cells for the initial broth inoculum were taken from plated material and cultivated in 250 mL flasks with 50 mL medium. For 48 h, the bacterium was cultivated at 28 ± 2 °C on an orbital shaker rotating at 150 rev min⁻¹. For the initial culture, 5 mL of subculture was inoculated into 2000 mL of broth, and the culture was grown under the same conditions. Bacterial populations were assessed by an Ultrospec 4050 Pro UV/Visible Spectrophotometer at 600 nm 96 h after initiation. A cell-free supernatant (CFS) containing BtNEB17 was obtained through centrifuging the bacterial culture at 13,000 g for 10 min, followed by analytical-HPLC identification. For partial purification, 800 mL of butanol was added to 2000 mL of bacterial culture for 12 h then the collected upper layer was extracted under vacuum in rotary evaporator. The viscose extract was collected with 12 mL of 30% Acetonitrile and centrifuged at 13,000 g for 13 min, and the supernatant was collected for chromatography (Gray et al., 2006). Th17 was selected based on peaks and retention times. After being lyophilized, the samples were kept at 20 °C for dilution to the

required concentrations. For all experiments, 10^{-7} (Thu1), 10^{-9} (Thu2) and 10^{-11} (Thu3) M of Th17 were prepared based on the molecular weight of Th17.

Germination experiments

Canola seeds (cultivar L233P) were disinfected with 20% sodium hypochlorite and rinsed with distilled water before applying treatments. Twenty-five sterilized seeds were placed on petri plates (100 x 15 mm) lined with filter paper (QualitativeP8). The plates were randomly treated with 10 mL of Thu1, Thu2, Thu3 solution and distilled water. Petri dishes were then sealed with parafilm to prevent water loss and arranged in a completely randomized design, with four replications for each treatment, in growth chambers. Growth chambers were set to low (5 °C), optimal (20 °C), high (30 °C) temperatures, 70% humidity, and zero illumination. The total number of germinated seeds were counted at 24 h intervals, for 72 h at optimum and high temperature and 7 days for low temperature. Radical and shoot length were measured for all experiments after 7 days, and seedlings were weighted. Each experiment was repeated twice, and the data was pooled for analysis.

Plant growth experiments

Th17 was applied as a pre-planting seed treatment, seeds were soaked in 10 mL Thu1, Thu2, Thu3 solution and distilled water, and root irrigation after the stress induction time. Canola seeds (5 seeds per pot) were placed in 10 cm pots filled with AGRO MIX[®] G10 media, which was a mix of peat, limestone, balanced nutrient materials, with micronutrients, gypsum and wetting agent. This growth medium was chosen based on root application of Th17 and the ability of peat to gradually release water and/or the compound. The pots were placed in a growth chamber (Conviron R, Canada) at 22/18 °C day/night, with a photoperiod of 14/10 h light/darkness cycle, 60–70% relative humidity and photosynthetic irradiance of 350–400 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (Figure 1A). After a week, the seedlings were counted, and the plants were thinned to one seedling per pot. Plants were regularly watered with half strength Hoagland's solution and grown in the growth chamber until the end of the third week (Figure 1B). Then, 3-week-old seedlings (Figure 2) were randomly selected to transfer to the low (10/5 °C), optimum (22/18 °C) and high temperature (30/25 °C) chambers to determine the effect of stressful temperatures on the vegetative growth of canola. Plants were watered semi-weekly with 250 mL of either water (for controls) or Th17 (for Th17-treated plants). Following the start of the temperature treatment, the plants in each case were allowed to develop for 4 weeks before being sampled for data collection. A LI-COR 6400 portable photosynthesis metre (LI-COR Lincoln, NE), was used to measure the photosynthetic rate, transpiration rate,

FIGURE 1

(A) Canola pots after seeding in the growth chamber (22/18 °C), (B) 3-week-old canola plants grown under optimal conditions (before starting temperature stress), (C) Physiological measurements with Licor from 7-week-old canola plants, (D) 7-week-old canola roots after removing soil particles.

stomatal conductance and CO₂ concentration inside the leaves. Readings were taken on a weekly basis (4, 5, 6, 7 weeks) after the 3-week-old seedling stage. An upper-most fully expanded leaf was used for determination of physiological variables between 10:00 and 14:00 h (Figure 1C). Plants were sampled at the end of the

experiment for the following variables: plant height, leaf area, fresh weight, dry weight and root variables. After harvesting plants and measuring morphological traits, roots were coarsely shaken off to remove soil (destructive methods). Roots were then washed with water and adhering soil particles removed with

FIGURE 2

3-week-old canola plants grown under optimal conditions. Ctrl: seeds treated with distilled water, Th1: seeds treated with 10⁻⁷ M Th17, Th2: seeds treated with 10⁻⁹ M Th17, Th3: seeds treated with 10⁻¹¹ M Th17.

brushes (Figure 1D). Total roots were scanned using EPSON-Expression 11000XL then root length, root volume, total root surface and root diameter were analyzed by WinRHIZO™ Pro software. Each experiment described above was repeated twice with four replicates, and data were pooled for analysis.

Data analysis

Data from the experiments were analyzed, based on a completely randomized factorial design, using the SAS Statistical Package 9.3 (SAS Institute Inc., Cary, NC, USA). For germination data, observed values were analysed similarly to other variables and a non-linear regression model was fitted to predict the probability of germination, in Figure 3 (Piegorsch and Bailer, 2005; Schwinghamer et al., 2015). Duncan's multiple comparison test was used when there was a significant difference at the 95% confidence level.

Results

Germination

There were no significant differences in germination rate under optimal conditions (20 °C) (Figure 3B). The control had the highest germination rate, which did not differ significantly from Th17-treated seeds. The lowest germination rate under optimal conditions was for seeds treated with the lowest concentration, Thu3. With increasing temperature to 30 °C (Figure 3C), germination decreased although applying Th17 helped alleviate the negative effect of high temperature on germination; in particular Thu2 treatment increased

germination significantly. Cold stress strongly affected germination (Figure 3A); about 100 h were required to start germination, and it increased slowly after that. In marked contrast, the first germination was recorded approximately 12 h after onset of the experiment at 20 °C. Under cold stress conditions, the interaction of temperature and the compound application was significant ($p < 0.002$), and application of Th17 significantly influenced germination, mainly mid-range concentration (Thu2) maximized germination rate.

Germination time

Germination time, one of the main indicators of germination process, was altered by Th17 application and temperature (Figure 4). In general, temperature caused a decrease or increase in germination time whereas the application of different Th17 levels minimized germination time under low temperature, except for Thu1, which showed a maximum time of 7.54 days. Thu2 treatment caused the shortest germination time at 5 °C, at 7.23 days while this time was 1.84 and 1.66 days for control and Thu1 at 20 and 30 °C, respectively.

Length of radical and shoot

It is clear from data that radical and shoot length significantly responded to the interaction of Th17 and temperatures ($p < 0.001$ and $p < 0.002$, respectively) (Figure 5). The greatest radical length was for Thu1 treatment, 9.38 cm, at optimal temperature; however, it was not significantly different from the control. Although increasing the temperature reduced the radical length, using Th17 at low concentrations (Thu3) increased length and reduced the harmful effects of high temperature. Under low temperature, the longest and shortest radical were observed for Thu2 treated seedlings (7.6 cm) and the control (4.5 cm), respectively

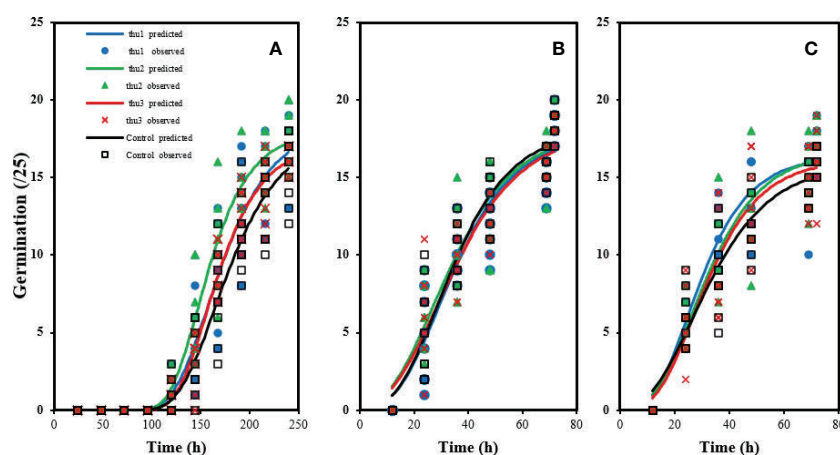

FIGURE 3

FIGURE 4
Effects of temperature and Th17 concentrations on mean germination time. Thu1: 10^{-7} M Th17, Thu2: 10^{-9} M Th17, Thu3: 10^{-11} M Th17. Each bar represents mean \pm standard error ($n=8$). Means with the same letters are not significantly different ($p < 0.05$).

(Figure 5A). For shoot length, the tallest shoots (3.6 cm) were from Thu2 treated plants at 30 °C, which were about 0.5 cm longer than the control (Figure 5B). Likewise, shoot length increased at low temperature from 1.84 for the control (the shortest across all temperatures) to 2.9 cm for Thu2 seedlings. Surprisingly, Th17

application could not significantly affect shoot length compared to untreated seeds under optimal temperature conditions.

Seedling weight and length

The interaction of temperature and Th17 concentrations on radical ($p < 0.001$), shoot ($p < 0.001$) and seedling weight ($p < 0.001$) was significant. Cold stress caused a sharp decrease in the fresh weight of radicals, shoots and seedlings; however, Th17 enhanced seedling fresh weight, from 0.54 mg for control to 0.66 mg for Thu2. Conversely, under optimal conditions, radical, shoot and seedlings of untreated seeds were heavier, 0.38, 0.64 and 1.02 g, respectively, than Th17 treatments. At high temperature, similar to the optimum temperature, the highest fresh weight of radical and shoot was for control seeds. In addition, there were no significant effects of treatment on seedling length at 20 °C; however, the greatest level was for Thu1 treated seedlings (12.58 cm); the shortest seedling was that of the control under low temperature conditions (Table 1).

Seed vigor

Data in Figure 6 reveals the adverse effects of high and low temperatures on seed vigor; Th17 application significantly mitigated detrimental impacts of stressful temperatures ($p < 0.001$) while seed vigor decreased significantly by 33.99 and 56.18% for control seeds in response to high and low temperatures, respectively.

Plant growth and development

Plant height

Treating seeds with Th17 increased plant height, specifically Thu2 (Figure 7); the compound enhanced height by 25, 22.75 and 8.25% over control, at low, optimal and high temperatures, respectively.

Thu1: 10^{-7} M Th17, Thu2: 10^{-9} M Th17, Thu3: 10^{-11} M Th17. Each value represents mean ± standard error (n=8). Means with the same letters are not significantly different ($p < 0.05$).

Leaf area

Leaf area responded strongly to Th17 at stressful temperatures (Figure 8). It decreased by 6.19 and 43.11% for the controls at high and low temperatures, respectively. Under optimal conditions, no

stimulatory effect of Th17 was observed, except for Thu3, whereas positive responses occurred at stressful temperatures, particularly for Thu2 plants where leaf area increased by 39 and 30%, at 10 and 30 °C temperatures, respectively, compared to the control.

FIGURE 8

Biomass

Plants grown at 30 °C had the highest fresh biomass accumulation (Figures 9, 10), particularly those treated with Thu2, with 38.33 g. Conversely, much less biomass accumulated under low temperature conditions although it increased by 25% when plants treated with Thu2 (Figure 9A). Our data clearly

demonstrated that dry biomass significantly declined under stressful temperatures; however, Th17 application showed positive effects, with dry biomass increasing by 20.16 and 43.49% for Thu2 compared to the control at 30 and 10 °C, respectively. Similarly, dry biomass accumulation increased from 5.24 g for control to 5.56 g for Thu3 under optimal conditions (Figure 9B).

Root variables

Table 2 presents the root dry weight, length and root surface data and shows that they were negatively affected by stressful temperatures. Root dry weight ranged from 0.31 g for the control at 10 °C to 0.74 g for Thu3 under optimal conditions. Watering plants with Thu3 enhanced root length and surface across all temperatures (Figure 11). Conversely, the highest values for root diameter and volume were detected from Thu2 and Thu3 plants, respectively, at 30 °C.

Physiological variables

Photosynthetic rate was affected by temperature and Th17 as indicated in Figure 12; changes either below or above optimal temperature led to photosynthesis decline. As we expected, plants grown in a cold growth chamber manifested a steady decrease over time, and maximum photosynthesis was observed from Thu2-treated plants in the first week of measurement. Conversely, all treatments had an upward trend under optimal conditions during measurement times, and followed the same general pattern. The trend for 30 °C was increasing until the third measurement then control and Thu1 showed a decrease whereas Thu2 and Thu3 continued to increase; photosynthesis of Thu2 plants was approximately 40% higher than the control in the final measurement.

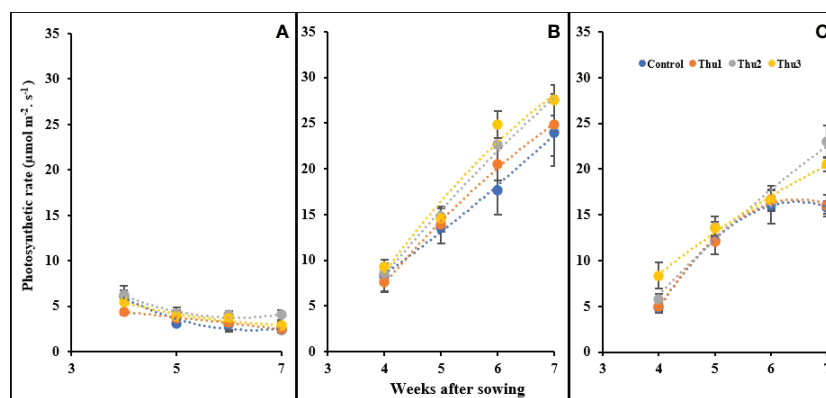

FIGURE 12

Changes in the photosynthetic rate under application of Th17 at low (A), optimum (B) and high (C) temperature at 4, 5, 6 and 7 weeks after sowing. Thu1: 10^{-7} M Th17, Thu2: 10^{-9} M Th17, Thu3: 10^{-11} M Th17. Each point represents mean \pm standard error (n=8).

Stomatal conductance

As indicated in Figure 13, stomatal conductance responded strongly to temperature and concentration of Th17. With rising temperature, conductivity increased; Thu2 treated plants indicated a sharp increase and had the highest conductivity, at $0.345 \text{ mol m}^{-2} \text{ s}^{-1}$, as opposed to control with a gradual downward trend at 30°C . Under cold temperature, conductivity drastically dropped for all plants; Thu2 plants could maintain their highest capacity for gas transport through the stomata. In clear contrast, a consistent enhancement occurred under optimal conditions, and this upward trend was similar for all treatments.

Intercellular CO_2

There were significant changes in intercellular CO_2 in response to temperature and Th17 levels (Figure 14). Our

measurements indicated that the highest levels of intercellular CO_2 occurred at 20°C , ranging from $225 \mu\text{mol mol}^{-1}$ for the control at the first measurement, to $380 \mu\text{mol mol}^{-1}$ for Thu2 at the last reading. Stressful temperatures both had a downward trend in which control plants absorbed more CO_2 than treated ones.

Transpiration

Transpiration rate was enhanced by increasing temperature; control plants grown at 10°C had the lowest transpiration ($1.21 \text{ mol m}^{-2} \text{ s}^{-1}$) whereas the highest level was for Thu2 treatment ($4.95 \text{ mol m}^{-2} \text{ s}^{-1}$) at 30°C . Interestingly, plants under high stress conditions showed an increase until 6 weeks after sowing, after which transpiration changed only slightly and/or decreased. Conversely, plants maintained a constant upward transpiration

over time at optimal temperature. Predictably, at 10 °C, the transpiration rate was very low and slightly changed; Thu2 and Thu3 caused a marginal increase while transpiration for Thu1 and the control treatments showed a negligible decrease (Figure 15).

Discussion

Germination

Seed germination is a very important stage in the life cycle of a plant and one that is very sensitive to both the intrinsic and extrinsic factors (Rifna et al., 2019). Among them, temperature is a major environmental factor determining seed germination (Finch-Savage and Leubner-Metzger, 2006). Early germination is an essential element that impacts the production of canola (*B. napus* [L.]). The optimal temperature for canola germination is 22°C (Nykiforuk and Johnson-Flanagan, 1994; Tasseva et al., 2004). Any temperature either below or above optimal induces uneven germination and, in the field, poor stand establishment, restricting the crop potential to produce yield. In this study, we found that germination and seedling growth indices were negatively affected by both low and high temperatures. Germination was delayed under low temperature conditions, which could have arisen from slowed water uptake, slower enzyme kinetics, higher levels of late embryogenesis-abundant proteins, induction of nuclear stress-responsive proteins and imbalanced amount of inhibitor and promoter phytohormones (Achard et al., 2008; Copeland and McDonald, 2012; Abdul Aziz et al., 2021). However, faster germination occurred at a higher temperature than optimal conditions, which could be due to a thermal effect, related to number of heat units required for germination. These results are consistent with previous studies that found stressfully high and low temperatures hindered final

germination percentage of five cultivars of canola between 10 to 20 percent (Schwinghamer et al., 2015). Seedling growth was also impeded by both high and low temperatures, resulting in lower fresh weight and seedling vigor indices than optimum conditions (Zhang et al., 2015). Hence, discovery of technologies that improve seed germination and seedling establishment are of importance in agriculture. Here, the application of a bacteriocin could enhance canola germination percentage, radical and shoot length, seedling fresh weight and seed vigor compared to the controls under both low and high temperature stress conditions. To be more precise, among three levels of the compound, Thu2 considerably ameliorated negative effects of stress and showed high stimulatory impacts on both seeds and seedlings. This result is in line with findings of Gautam et al. (2016), which highlighted the response of soybean to 10^{-9} M and 10^{-11} M Th17 during germination and seedling development under low temperature. A similar conclusion was reached by He (2009) for Th17 treated corn seeds under a combination of stresses, including low temperature, salinity and drought stress under both controlled environment conditions and a cool spring climate in the field. In another study, the effect of LCO, a compound produced by *B. japonicum* 532C, Th17 and chitopentaose were tested on high oil content cultivars of canola. Treatment with 10^{-6} M LCO accelerated germination at 10 °C while seeds treated with 10^{-9} M Th17 had more even and uniform germination (Schwinghamer et al., 2015). LCO has been shown to be a stimulant for seed germination and seedling establishment as illustrated in a large body of published research, whereas Th17 has not been well studied (Kidaj et al., 2012; Suganya et al., 2016; Nandhini et al., 2018). The underlying mechanism of LCO and Th17 in soybean germination under stressful conditions was studied through proteomic approaches. The results indicated that energy, carbon and nitrogen metabolic pathways were influenced by signal compounds under stressful

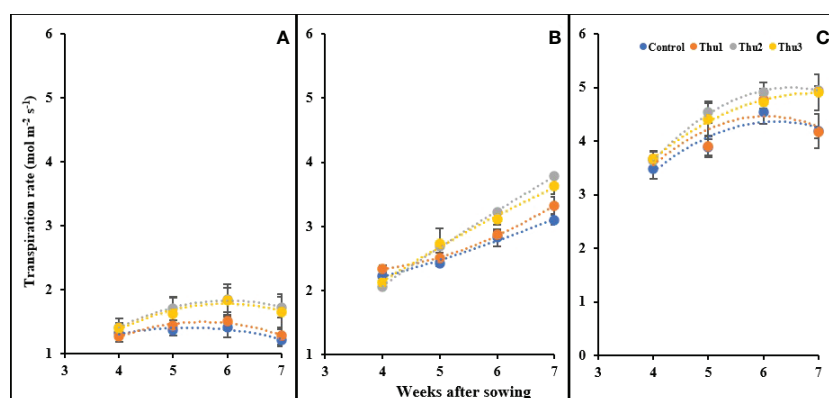

FIGURE 15

Changes in the transpiration rate under application of Th17 at low (A), optimum (B) and high (C) temperature at 4, 5, 6 and 7 weeks after sowing. Thu1: 10^{-7} M Th17, Thu2: 10^{-9} M Th17, Thu3: 10^{-11} M Th17. Each point represents mean \pm standard error (n=8).

environments. Some notable stress-related proteins, including PEP carboxylase, rubisco oxygenase large subunit, pyruvate kinase and other proteins are up regulated in response to LCO and Th17 treatments under stressful conditions (Subramanian et al., 2016). Similar results were observed where over 600 genes, mostly related to stress and defense, were up regulated in LCO treated soybean leaf tissue under stressful conditions (Wang et al., 2012). These findings highlight that signal molecules can alter metabolism and physiology to assist in alleviating sub-optimal conditions and improve germination and early growth.

Th17 effects on canola aboveground growth

Unfavourable temperature, as a major environmental factor, considerably affects plant growth and development. Some plants adapt themselves by altering their morphology, while others adjust their physiology or exhibit changes in gene expression, which modifies how they grow, survive and tolerate stresses (Raza et al., 2020; Gupta et al., 2020). However, susceptibility or tolerance is directly associated with plant lifecycle stage. We hypothesized that during vegetative growth of canola, different levels of Th17 would assist in tolerating stressful temperatures and enhance growth variables. The exposure of canola to cold conditions in northern climates like western Canada is unavoidable in early spring because early spring sowing is required to ensure that the crop matures without suffering yield losses due to summer heat stress. Canola, as a cold-acclimated crop, has the capacity to develop cold stress tolerance, known as cold acclimation, once exposed to chilling but not freezing temperature, although its growth might be slowed. Furthermore, the likelihood of high temperature occurrence during mid to end of canola vegetative growth is relatively high, as we experienced during May-June of the 2020 and 2021 canola field seasons in eastern Canada (unpublished data). In this study, plant height, leaf area and biomass accumulations were negatively altered, in contrast to optimal temperature, after 3 weeks of growing in the 10/5°C temperature range, but surprisingly application of the signal molecule efficiently acted as an alleviator and effective plant growth regulator. In contrast, canola showed positive responses to 30/25 °C temperature, suggesting acclimation ability to moderately high temperature. This could arise from thermomorphogenesis, a group of morphological and architectural alterations caused by higher ambient temperatures, below the heat-stress level (Quint et al., 2016; Casal and Balasubramanian, 2019; Ludwig et al., 2021). Based on this, canola height was significantly enhanced across all treatments at moderately high temperature, which may indicate that the plant shifted from vegetative stage to flowering by stem elongation; leaf area and fresh biomass were also increased while irrigation with Thu2 and Thu3 resulted in higher levels of these variables than the control and Thu1

treatments. In contrast to many previous studies, which indicated heat as a growth inhibitor, in our experiment canola growth and development continued well at higher temperature, implying that heat acclimation ability, with assistance of the signal compound, could be quite high. However, stress-induction stage, duration of stress and combination with other stressors play a significant role in response to heat. A body of research has taken shape around the effects of high temperature on crops, but only a few studies have examined the interaction of microbial signal molecules and high temperature on plants (Kilasi et al., 2018; Hussain et al., 2019; Anwar and Kim, 2020; Ayub et al., 2021; Lohani et al., 2021; Ahmad et al., 2021). Our findings fit well with previous studies that reported the interaction of 10^{-6} M LCO irrigation with relatively high temperature (30/30 °C), resulting in 1 more leaf per canola plant, as apposed to the 25/20 °C water-treated controls, which were unifoliolate. Similarly, Th17 treatment increased the dry biomass of canola cultivar 04C111, by approximately 70 mg under saline (0.1 M NaCl) and moderately high (30/30 °C) temperature conditions (Schwinghamer et al., 2016). In this study, we observed that two concentrations, Thu2 and Thu3, had considerable positive impacts whereas the higher concentration level, Thu1, showed no significant stimulatory effect compared to the control. It is not surprising that such results were reported because most of the microbially produced substances are signalling molecules which are similar to phytohormones in that their presence, at very low concentrations, has long been recognised to either promote or inhibit plant growth (Backer et al., 2018; Antar et al., 2021). More than this, there are some other factors that highlight the effect of concentrations, including plant species, stage of life, growth conditions, method of application and so on. While certain chemicals can significantly improve plant growth at extremely low concentrations, others must be used at relatively high levels to have a positive impact.

Effects of Th17 on root architecture

Root growth relies on cell production within the root meristem, cell expansion and differentiation in which environmental factors play a vital role as stimuli. The root system possesses spatial architecture by which it can dynamically adapt itself to changes in the environment, such as shifts in temperature (Bardgett et al., 2014; Onwuka and Mang, 2018). It is worth noting that unlike the broad optimum temperature ranges for the development of aerial parts of various species, optimum root temperature (12–20 °C) is quite similar for almost all species except for tundra plants (Bell and Bliss, 1978). When plants are exposed to low and high temperatures, changes in the root system occur (Alsajri et al., 2019; Fonseca de Lima et al., 2021). In this study, root system growth was inhibited by low temperature, which is in line with previous

studies (Rymen et al., 2007; Shibasaki et al., 2009; Zhou et al., 2021). This could be explained by the fact that low temperature hinders cell cycle progression and cell division in root meristems. In addition, lower carbohydrate assimilation under chilling conditions impedes nutrient allocation to the underground system. Interestingly, the interaction of temperature and Th17 was significant; root system architecture was positively modified by irrigation with the compound, particularly Thu3-treated roots, which produced the highest length, surface area, volume, and dry weight across all temperatures. This might be associated with the role of Th17 in phytohormones modifications. In this regard, Prudent et al. (2015) reported that abscisic acid (ABA) was the first plant hormone to be considerably increased in soybean leaves and roots after the application of Th17. This phytohormone facilitates root elongation by restricting ethylene production, suggesting that a reason for changes in root architecture could be a shift in the balance of plant hormones (originating at the roots). As such, Th17 treatment could cause plants to modify their ABA content, which may have resulted in maximal root growth. However, to ascertain the mode of action of Th17 in canola roots, precise phytohormone measurements would be required in future studies.

Th17 and physiology characteristics

Most physiological functions of plants, including photosynthesis and transpiration are impacted by temperature. Stomatal conductance controls both carbon assimilation, and transpiration, and they mutually influence one another. Hence, temperature affects stomata indirectly by alterations in plant water status and vapor pressure deficit. We determined that photosynthesis increased linearly with time and was maximum under optimal temperature conditions whereas a considerable decline was seen across all physiology variables at low temperature. In accordance with our results, many studies have demonstrated a significant reduction of carbon assimilation rate and stomatal conductance at low temperatures, which is partly explained by disruption of chloroplast structure, thylakoid membrane damage, reductions in enzyme activities, decreased chlorophyll levels, reductions in expression and resulting concentrations of photosynthesis proteins, and reduced electron transport (Liu et al., 2012; Paredes and Quiles, 2015; Li et al., 2018; Khan et al., 2019; Zhao et al., 2020). Regarding high temperature, in line with many studies, carbon assimilation rate decreased with increasing temperature although in our study, the Th17 application could mitigate the reduction. In this regard, Thu2 and Thu3 enhanced photosynthesis rate compared to the control. Increasing conductivity with time under optimal conditions, coupled with

more diffusion of CO₂, resulting in greater assimilation rates, whereas it caused higher transpiration rates which could lead to reduced leaf water potential at high temperatures. These results agree with those studies that reported stomata opening and increased transpiration at higher temperatures (Lu et al., 2000; Mott and Peak, 2010; Xu et al., 2016; Urban et al., 2017), while our findings are in contrast with some experiments that observed no significant changes of conductivity and/or closure of stomata (von Caemmerer and Evans, 2015; Abdulmajeed et al., 2017; Hlaváčová et al., 2018). It is worth noting that higher leaf temperature causes reduction in protein translation, chlorophyll breakdown, rubisco inactivation, photosystem II activity, electron transport chain activity and increased damage to photosynthetic apparatus (Kang et al., 2017; Wang et al., 2018a; Balfagón et al., 2019; Hu et al., 2020). As such, lowering leaf temperature by transpiration would be an approach to compensate for assimilation reduction which could be beneficial, even if, to some extent, water loss was not constrained. We observed greater transpiration rates in Th2 and Th3 treated plants which meant enhanced photosynthesis came at the cost of losing more water; however, it would assist in cooling leaves when water is not a limiting factor; therefore, photosynthesis systems could function more efficiently. This might be one of the explanations for continued increase of photosynthesis in Thu2 and Thu3 plants despite lower intercellular CO₂ amounts than the control. Lee et al. (2009) demonstrated that application of 10⁻⁹ and 10⁻¹¹ M Th17, either through root irrigation or leaf spray enhanced soybean photosynthetic rate and leaf greenness. Our finding partly ties with a conclusion reached by Prudent et al. (2015); they demonstrated the positive effects of Th17 treatment on improving carbon assimilation in water-stressed soybean plants, but this was associated with an increased level of ABA, resulting in stomatal closure and reduced transpiration which is opposite to our findings.

Conclusions

Our results demonstrated that the Thu2 solution interacted with stressful temperatures to affect canola germination and seedling development. Notably, germination time was significantly reduced when seeds were treated with Thu2 under low temperature conditions, which would be a solution for slow germination of spring-sown canola. The moderately high temperature along with Thu2 and Thu3 treatments could produce taller plants with more leaf area and fresh biomass accumulation than control plants grown under optimal conditions. Watering plants with the bacterial compound promoted root growth and development, including root length, root volume and root diameter, which could facilitate

the uptake of water and nutrients. Interestingly, two levels of Th17 had stimulatory effects on photosynthetic rate although the mechanism underlying this is not yet clear. Considering these findings, it seems likely that this signal molecule had stimulatory effects, particularly under stressful temperatures, but we remain inconclusive regarding its mode of action.

Data availability statement

The original contributions presented in the study are included in the article/supplementary material. Further inquiries can be directed to the corresponding author.

Author contributions

MN designed the experiment, collected data and wrote the manuscript. IY assisted in data analysis. DS advised on scientific approach and provided editorial input and intellectual context as well as funding. All authors contributed to the article and approved the submitted version.

Sowmyalakshmi Subramanian and Donald L. Smith*

Department of Plant Science, McGill University, Montreal, QC, Canada

Plant growth promoting microorganisms and their derived compounds, such as cell-free supernatant (CFS), enhance plant growth under stressed and non stressed conditions. Such technology is sustainable and environmentally friendly, which is desirable amidst the climate change threat. The current study evaluated the effect of CFS obtained from *Lactobacillus helveticus* EL2006H on its ability to enhance mean percentage germination and mean radicle length of corn and soybean, as well as growth parameters of potato, using treatment formulations that consisted of 0.2 and 1.0% [v/v] *L. helveticus* EL2006H CFS concentrations and 100mM NaCl and 150mM NaCl levels. Results show that treatment with 100mM NaCl lowered percentage germination of corn by 52.63%, at 72h, and soybean by 50%, at 48h. Treatment with 100 NaCl +0.2% EL2006H enhanced percentage germination of soybean by 44.37%, at 48h, in comparison to that of the 100mM NaCl control. One hundred mM NaCl lowered radicle length of corn and soybean by 38.58 and 36.43%, respectively. Treatment with 100Mm NaCl +1.0% EL2006H significantly increased radicle length of corn by 23.04%. Treatment with 100mM NaCl +0.2% EL2006H significantly increased photosynthetic rate, leaf greenness and fresh weight of potato. Increasing NaCl concentration to 150 NaCl lowered the effectiveness of the 0.2% EL2006H CFS on the same growth variables of potato. In general, the lower CFS concentration of 0.2% was more efficient at enhancing germination in soybean while the higher concentration of 1.0% was more efficient at enhancing radicle length of corn. There was an observed variation in the effectiveness of *L. helveticus* EL2006H CFS across the different CFS concentrations, NaCl levels and crop species studied. In conclusion, based on findings of this study, CFS obtained from *L. helveticus* can be used as a bio stimulant to enhance growth of corn, soybean and potato. However, further studies need to be conducted, for validation, especially under field conditions, for commercial application.

KEYWORDS

cell-free supernatant, *Lactobacillus helveticus*, salinity stress, germination, radicle length, plant growth

1. Introduction

Plant growth promoting microorganisms (PGPM) live in close association with their host plants, forming a holobiont (Hartmann et al., 2014; Lyu et al., 2021); these relationships have existed for at least half a billion years (Knack et al., 2015). A plant's exudates into its surroundings are a major determinant of the phytomicrobiome composition in its rhizosphere (Zhang et al., 2017). The association between PGPM and their host plants can enhance the latter's growth and development, through mechanisms such as biostimulation, mitigation of abiotic stress effects, bioremediation and biocontrol (Glick, 2012; Ahemad and Kibret, 2014; Backer et al., 2018; Naamala and Smith, 2020), in a sustainable and environmentally friendly manner (Naamala and Smith, 2021a,b). PGPM and their derived compounds can be utilised in singular or consortium forms, results varying in such a way that some strains may be more effective when applied as single cells while others, in a consortium (Giassi et al., 2016; Subramanian et al., 2016a,b; Shah et al., 2022). *Lactobacillus helveticus* is a gram positive facultative anaerobic lactic acid bacterium (LAB) that is mostly known for its role in the food processing industry. Use of *L. helveticus* in plant agriculture, especially as biostimulants is not widely documented although the use of members of the genera *Lactobacillus* in crop production, as biostimulants and biocontrol agents, among other uses, has been practiced (Hamed et al., 2011). Members of the genus *Lactobacillus* are endophytic to a variety of plants species (Baffoni et al., 2015; Minervini et al., 2015; Lamont et al., 2017) while others have been isolated from the rhizosphere of plants. Examples of LAB species that have been used in plant agriculture include *Lactobacillus acidophilus*, *Lactobacillus plantarum*, *Lactobacillus rhamnosus* and *L. helveticus* (Hamed et al., 2011; Caballero et al., 2020; Msimbira et al., 2022). LAB play an important role in fermentation of organic matter to form organic fertilisers used in crop production (Lamont et al., 2017; Caballero et al., 2020). Lactic acid, a by-product of LAB has been reported to enhance plant growth (Rodríguez-Morgado et al., 2017). LAB strains have been reported to solubilise phosphate, produce siderophores (Shrestha et al., 2014; Giassi et al., 2016), produce antimicrobial compounds (Stoyanova et al., 2012), produce phytohormones such as indole –3- acetic acid [IAA] (Shrestha et al., 2014; Giassi et al., 2016) and enhance systemic acquired resistance (Hamed et al., 2011), all of which are desirable characteristics of PGPM.

Microbes, such as bacteria and fungi, exude into their growth environment, secondary metabolites such as hormones, enzymes, organic acids, bacteriocins, oligopolysaccharides and siderophores, among others (Piechulla et al., 2017; Schulz-Bohm

et al., 2017; Lemfack et al., 2018). In laboratory-based experiments, such metabolites are exuded into the microbe's growth medium. Recent studies have focused on the possibility that such metabolite rich media, also known as cell-free supernatant (CFS) can enhance plant growth without the presence of microbial cells. Experimentation with CFSs has previously yielded interesting results, showing that such CFSs can enhance the growth of different crop species, such as corn, soybean, canola and tomato, at germination and seedling stages (Msimbira et al., 2022; Naamala et al., 2022; Shah et al., 2022). Earlier studies went further and extracted bioactive compounds from the CFS, resulting in the discovery of compounds such as lipochitooligosaccharide (LCO) from *Bradyrhizobium japonicum* CFS and thuricin17 from *Bacillus thuringiensis* NEB17 CFS (Prithiviraj et al., 2003; Gray et al., 2006a,b; Lee et al., 2009), which are already on the market as plant growth promoting biostimulants. Both compounds have shown efficacy in enhancing plant growth under growth chamber and field conditions (Subramanian et al., 2016a,b; Arunachalam et al., 2018). They were reported to enhance plant growth under normal and salt-stress conditions (Subramanian et al., 2016a,b). It has been reported that the nature of metabolites exuded vary with varying conditions of growth media in which the microbe is growing (Subramanian et al., 2021). For instance, the metabolic profile of CFS of a microbe grown under ideal conditions may significantly vary from that of the same microbe exposed to some level of stress, such as low pH or high salinity levels. Not all metabolites exuded in growth media enhance plant growth, although some are the bioactive ingredients that do so. The effectiveness of a bioactive metabolite/CFS also varies across plant species, concentration of the compound, level of stress to which a plant is exposed and growth stage of the plant (Msimbira et al., 2022; Naamala et al., 2022; Shah et al., 2022). This, in a sense, complicates the process of discovering novel microbe derived plant growth promoting compounds as it may require trials on several crop species under different growth conditions, at different concentrations, before bioactivity may be detected. The seemingly long and possibly complicated process is however potentially worth the effort since microbial derived compounds can overcome some issues associated with using microbial cells as inoculants if they are produced in fairly large quantities and are economical to isolate for application. For instance, compounds are less prone to diminished effects under harsh field conditions, are generally required in low concentrations and are easier to store compared to live microbial cells (Naamala and Smith, 2021a).

Salinity stress is a major abiotic stress of agricultural crops, resulting in decreased yield quantity and quality which subsequently causes economic losses estimated at US\$ 12 billion

per year (FAO, 2020). It affects leaf area, chlorophyll content, plant vigour, plant height, rootlength, plant dry matter, nutrient, metabolite and protein contents, can delay plant development and at severe stress levels may lead to plant death (Bistgani et al., 2019; Garcia et al., 2019). Unfortunately, with current climate change projections, reduced rainfall, excess and improper application of inorganic fertilisers and other chemicals, arable land affected by salinity stress is projected to increase by 50% by 2050 (Jamil et al., 2011). PGPM and their derived compounds can mitigate the effect of salt stress on plants, hence, allowing better growth, yield quality and yield quantity, in salt affected fields (Naamala and Smith, 2021b). The aim of this study therefore was to elucidate the ability of *L. helveticus* EL2006H CFS to enhance germination and radicle length of corn and soybean, and growth parameters of potato, under saline conditions. Results of the study will be a baseline for further studies, with a possibility of isolating and identifying bioactive compounds. This study is part of a broader study that is studying CFSs of the EVL Inc., consortium strains, which comprises *L. helveticus* EL2006H and four other microbial species, in an effort to improve the product and or come up with new product combinations.

2. Materials and methods

2.1. Obtaining microbial CFS

L. helveticus EL2006H was cultured in De man, Rogosa and Sharpe (MRS) medium at pH 7.0, and incubated for 48 h, at 120 rpm and 37°C. At 48 h, the microbial culture was centrifuged for 10 min, at 10,000 rpm and 4°C, to pellet the microbial cells and separate them from the CFS (Gray et al., 2006a,b; Subramanian et al., 2021). The CFS was further filtered using 0.22 µm nylon filters to remove any microbial cells that could have remained after centrifugation. The obtained CFS was then used in the formulation of treatments used in the study.

2.2. Formulation of treatments

Treatments were formulated by mixing known quantities of distilled water, NaCl and CFS. Two NaCl levels, (100 mM NaCl and 150 mM NaCl) and two CFS levels (1.0 and 0.20% [v/v]) were used in the mixtures to formulate treatments. The two CFS concentrations were chosen because they exhibited positive results with *Bacillus amyloliquefaciens* EB2003 CFS, in our previous study (Naamala et al., 2022). 0, 100 and 150 mM NaCl, with no addition of CFS were used as negative controls. In addition, for each microbial CFS concentration, a similar concentration of microbial growth medium (not inoculated with microbe), was used to formulate positive controls. A treatment name ending in MRS or EL2006H implies that MRS medium and *L. helveticus* EL2006H CFSs were used, respectively.

2.3. Set up of germination and radicle length experiments

The germination experiments were carried out in a phytorium located at the Macdonald Campus of McGill University, Sainte Anne de Bellevue, Quebec, Canada. Soybean (cultivar P0962X) and corn (Hybrid 25 M75) were used for the study. The two crop species were chosen because they are widely consumed in Canada and the world over. In our previous study, the two species' germination and radicle lengths were stimulated by *B. amyloliquefaciens* CFS. The following treatments were used for the study: 0 mM NaCl (control), 100 mM NaCl (control), 100 mM NaCl +0.2% MRS (control), 100 mM NaCl +0.2% EL2006H, 100 mM NaCl +1.0% MRS (control) and 100 mM NaCl +1.0% EL2006H. Treatments with 0.2% EL2006H and 1.0% EL2006H, with their corresponding controls, were studied separately. It should also be noted that each crop was studied separately. Therefore, because each treatment, within each crop species, was studied in a separate experiment and the data obtained analysed separately, a completely randomised design (CRD) was used for each experiment, to randomly apply experimental units to treatments. For each experiment, ten seeds of the crop species under study were surface sterilized using 2% sodium hypochlorite, for 2 min, rinsed with 5 changes of sterilized distilled water and placed on petri-plates (Cat. no. 431760, sterile 100 × 15 mm polystyrene Petri dish, Fisher Scientific Co., Whitby, ON, Canada), lined with filter paper (09-795D, QualitativeP8, porosity coarse, Fisher Scientific Co., Pittsburg, PA, United States). Petri plates with seeds then randomly received the treatments with ten replicates per treatment, hence, 40 samples per experiment. The Petri plates were then sealed with parafilm and incubated for 7 days in the dark, at 25°C. Total number of germinated seeds per plate was recorded at 24 h intervals, for 72 h, as a percentage of the total number of seeds in the plate. i.e., $(x/10) \times 100$, where X is the total number of germinated seeds per petri plate. After 7 days, radicle length was measured, in centimeters (cm). For each replicate, radicle length for all the germinated seeds, was summed, to obtain total radicle length of germinated seeds per plate. Each experiment was repeated twice. Percentage germination data for each time interval (24, 48, and 72 h) were analyzed separately.

2.4. Set up of greenhouse experiment

Potato cultivar goldrush was used for the study. Potato is grown and widely consumed in Canada, with a sizable fresh market area of production in Quebec. EVL Inc., the source of the bacterial strains in collaboration with SynAgri, focus on cultivation of potato cultivars. Hence this part of the study was focused on potato's response to treatment with the CFS, under greenhouse conditions. Treatments used for this experiment

were: 0 mM NaCl (control), 100 mM NaCl (control), 100 mM NaCl +0.2% MRS (control), 100 mM NaCl +0.2% EL2006H, 150 mM NaCl (control), 150 mM NaCl +0.2% MRS (control) and 150 mM NaCl +0.2% EL2006H. Twelve L pots were filled with G7 growth medium were used for plant growth. The rooting medium in each pot was fully saturated with water before sowing one potato seed per pot. At emergence, pots were allocated to treatments following a CRD, with four replicates per treatment, hence, a total of 28 samples. The experiment was repeated twice. A number of excess pots were sown with seed so that on the day of treatment application, only pots with seeds that emerged on the same day were applied to treatments, to minimize initial variation. Two L of treatment were applied twice a week, per pot, for 4 weeks after emergence, at which time harvesting was conducted. Data on variables: greenness, photosynthetic rate, leaf area, plant height and plant fresh weight were taken. Leaf greenness was measured in SPAD units, using a SPAD-502 chlorophyll meter at 3 weeks after treatment application. Greenness of ten leaves was randomly measured and average greenness recorded. Photosynthetic rate was measured in $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ using a LI-COR 6400 portable photosynthesis meter (Lincoln, NE, United States), and recorded, 3 weeks after treatment application. Plant height was measured using a meter ruler, first, at emergence, just before the first application of treatments and 3 weeks after emergence. The difference in height was then recorded. Fresh weight was measured in grams, using a weighing scale balance (ME4001E, CH), 4 weeks after emergence. Leaf area was measured in cm^2 , using a leaf area meter (LI-3100 C, Lincoln, NE, United States), 4 weeks after emergence.

2.5. Data analysis

Data obtained from all samples were analyzed using PROC GLM (SAS 9.4 software). Type III tests were used to determine effects of treatments on seed germination while differences between the treatments were assessed using a student t-test with the least square means (LSMEANS) statement, with Tukey's adjustment for multiple comparisons. Differences were considered significant at $p \leq 0.05$.

3. Results

3.1. Mean radicle length

3.1.1. Corn

3.1.1.1. 100mM NaCl +1.0% EL2006H

There was a significant effect of *L. helveticus* CFS on radicle length of corn, as shown in Figure 1. One hundred mM NaCl significantly lowered radicle length of corn by 38.58% ($p < 0.0001$) in comparison to the 0 mM NaCl control. Treatment with 100 mM NaCl +1.0% EL2006H significantly increased mean radicle length of corn by 23.04% ($p < 0.0001$). The greatest radicle length was for

the 0 mM control (55.38 cm) while the smallest was for the 100 mM NaCl control (35.205 cm), which was also not significantly different from the 100 mM NaCl +1.0% MRS control (36.735 cm).

There was no significant effect of the 0.2% *L. helveticus* CFS on radicle length of corn.

3.1.2. Soybean

There was no significant effect of *L. helveticus* CFS on radicle length of soybean at both 0.2 and 1.0% concentrations, as shown in Table 1. Figure 2 shows the effect of treatments on radicle length of corn (1) and soybean (2).

3.2. Mean percentage germination

3.2.1. Soybean

3.2.1.1. 100mM NaCl +0.2% EL2006

At 24 h, there was a significant effect of *L. helveticus* EL2006H CFS on soybean germination. At 48 h, CFS significantly

FIGURE 1
Effect of treatments on radicle length of corn at 1.0% [v/v]. Data represents the mean \pm SE ($n=80$); different letters indicate values determined by Tukey's multiple mean comparison significantly different at $p < 0.05$. Values with the same letters are not significantly different at $p < 0.05$.

TABLE 1 Effect of treatments on mean radicle length of soybean and corn.

Treatment	Mean radicle length of soybean (cm)	Mean radicle length of corn (cm)
0 mM NaCl	57.98 \pm 2.636 ^a	49.81 \pm 1.879 ^a
100 mM NaCl	37.43 \pm 1.766 ^b	35.15 \pm 1.232 ^b
100 Mm NaCl +0.2% EL2006	38.05 \pm 1.773 ^b	38.76 \pm 1.193 ^b
100 Mm NaCl +0.2% MRS	37.12 \pm 2.088 ^b	40.26 \pm 1.705 ^b
0 mM NaCl	63.355 \pm 4.230 ^a	55.38 \pm 2.084 ^a
100 mM NaCl	38.910 \pm 2.213 ^b	35.205 \pm 2.491 ^c
100 Mm NaCl +1.0% EL2006	41.195 \pm 2.393 ^b	45.745 \pm 2.233 ^b
100 Mm NaCl +1.0% MRS	44.445 \pm 3.600 ^b	36.735 \pm 2.66 ^c

Data represents the mean \pm SE ($n=80$); in a column, different letters indicate values determined by Tukey's multiple mean comparison significantly different at $p < 0.05$. Values with the same letters are not significantly different at $p < 0.05$.

FIGURE 2

Effect of treatments on germination and radicle length of corn (1) and soybean (2). From left to right: 0mM NaCl (A), 100mM NaCl (B), 100mM NaCl +0.2% EL2006H (C) and 100mM NaCl +0.2% MRS (D).

enhanced percentage germination of soybean. Treatment with 100 mM NaCl lowered percentage germination by 50% in comparison to the 0 mM NaCl control. The highest percentage germination was observed in the 0 mM NaCl control (84%) while the lowest was observed in soybean treated with 100 mM NaCl (42%). Percentage germination of soybean treated with 100 mM NaCl +0.2% EL2006H and 100 mM NaCl +0.2% MRS were 75.5 and 67.5%, respectively. The two were significantly higher than that observed for the 100 mM NaCl control ($p < 0.0001$). In fact, the percentage germination of soybean treated with 100 mM NaCl +0.2% EL2006H CFS was significantly higher than that of the 100 mM NaCl control, by 44.37% ($p < 0.0001$) when treated with CFS and not different from that of the 0 mM NaCl control.

At 72 h, treatment with microbial CFS did not result in significant differences in the germination of soybean, when compared to the 100 mM NaCl control. However, treatments 100 mM NaCl +0.2% EL2006H increased percentage germination by 16.1, to a percentage not significantly different from the 0 mM NaCl control. Table 2 show the effect of treatments on percentage germination of soybean (Figure 3).

3.2.1.2. 100mM NaCl +1.0% EL2006

At 24 h, microbial CFS has not significant effect on germination of soybean. At 48 h, soybean treated with 100 mM NaCl +1.0% EL2006H and 100 mM NaCl +1.0% MRS exhibited percentages of 70.5 and 74%, respectively; both values were not significantly different from that of the 0 mM control, and higher,

though not significantly different from the percentage germination observed for the 100 mM NaCl control. At 72 h there was no observed significant difference among the percentage germination of the different treatments.

3.2.2. Corn

There was no significant effect of *L. helveticus* CFS on germination percentage of corn at both 0.2 and 1.0% concentrations, as shown in Tables 3, 4.

3.2.3. Greenhouse experiment

While the above germination experiments were to establish the effects of *L. helveticus* CFS on seed/tuber germination as a possible positive plant growth promoter, the greenhouse experiment with potato was to add more value to the commercial application of the CFS, which is one of the goals of SynAgri/EVL's mandate and the crop of importance. Hence, experiments were carried out using potato variety goldrush (as per company's recommendation), to elucidate the effect of *L. helveticus* EL2006H CFS on the growth variables of potato. Results regarding variables varied between treatments.

3.2.3.1. Mean leaf greenness

The effect of treatments on mean leaf greenness was significantly different among treatments. Treatment with 100 mM and 150 mM NaCl resulted in 27.014 and 19.88% decreases in mean leaf greenness, respectively, in comparison to the 0 mM NaCl control, the two becoming significantly lower than the later

TABLE 2 Effect of treatments on mean percentage germination of soybean, at 72, 48 and 24h, respectively.

Treatment	Mean percentage germination at 72h	Mean percentage germination at 48h	Mean percentage germination at 24h
0 mM NaCl	89.5 ± 1.697 ^a	86.0 ± 1.835 ^a	34.5 ± 2.563 ^b
100 mM NaCl	82.5 ± 3.898 ^a	66.0 ± 4.834 ^b	1.00 ± 0.688 ^a
100 mM NaCl + 1.0% EL2006	88.5 ± 3.647 ^a	70.5 ± 5.452 ^{ab}	0.50 ± 0.500 ^a
100 mM NaCl + 1.0% MRS	85.0 ± 3.591 ^a	74 ± 4.995 ^{ab}	1.00 ± 0.688 ^a

Data represents the mean ± SE ($n=80$); in a column, different letters indicate values determined by Tukey's multiple mean comparison significantly different at $p<0.05$. Values with the same letters are not significantly different at $p<0.05$.

TABLE 3 Effect of treatments on mean percentage germination of corn at 72, 48 and 24h, respectively.

Treatment	Mean percentage germination at 72h±SEM	Mean percentage germination at 48h±SEM	Mean percentage germination at 24h±SEM
0 mM NaCl	57.0 ± 3.332 ^a	16.0 ± 2.938 ^a	0.00 ± 0.000 ^a
100 mM NaCl	27.0 ± 4.110 ^b	3.5 ± 1.817 ^b	0.00 ± 0.000 ^a
100 mM NaCl + 0.2% EL2006	28.5 ± 3.789 ^b	4.0 ± 1.338 ^b	0.00 ± 0.000 ^a
100 mM NaCl + 0.2% MRS	32.0 ± 3.742 ^b	0.00 ± 0 ^b	0.00 ± 0.000 ^a

Data represents the mean ± SE ($n=80$); in a column, different letters indicate values determined by Tukey's multiple mean comparison significantly different at $p<0.05$. Values with the same letters are not significantly different at $p<0.05$.

FIGURE 3
Effect of treatments on mean percentage germination of soybean. Data represents mean ± SE ($n=80$); different letters indicate values determined by Tukey's multiple mean comparison significantly different at $p<0.05$. Values with the same letters are not significantly different at $p<0.05$.

($p<0.0001$). Treatment with 100 mM NaCl + 0.2% EL2006 resulted in leaf greenness significantly higher than the 100 mM NaCl control by 13.56% ($p<0.0001$) and not significantly different from the 0 mM NaCl control, as shown in Figure 4. Although not significantly different, it was also higher than the 100 mM NaCl + 0.2% MRS control. There was no significant difference between treatment 150 mM NaCl + 0.2% EL2006 and its corresponding controls 150 mM NaCl and 150 mM NaCl + 0.2% MRS. *L. helveticus* EL2006H CFS enhanced leaf greenness in potato treated with 100 mM NaCl but not 150 mM NaCl.

3.2.3.2. Mean photosynthetic rate

There was a significant effect of *L. helveticus* CFS on mean photosynthetic rate, as shown in Figure 4. Treatment with 100 and

150 mM NaCl resulted in 13.76 and 26.6% decreases in photosynthetic rate, respectively, in comparison to the 0 mM NaCl control. Treatment with 100 mM NaCl + 0.2% EL2006 resulted in the highest photosynthetic rate ($21.00 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ S}^{-1}$), significantly higher than that of the 100 mM NaCl control, by 17.97% ($p<0.0001$), and higher but not significantly different from the 0 mM NaCl control, as shown in Figure 4. The lowest photosynthetic rate was observed in potato treated with 150 mM NaCl ($14.863 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ S}^{-1}$).

3.2.3.3. Mean fresh weight

There was a significant effect of *L. helveticus* CFS on fresh weight of potato. One hundred mM NaCl and 150 mM NaCl lowered fresh weight of potato by 19.62 and 23.61%, respectively, in comparison to the fresh weight observed for the 0 mM NaCl control. Treatment with 100 mM NaCl + 0.2% EL2006 resulted in potato with fresh weight higher but not significantly different from the 0 mM control. It was also significantly higher than the fresh weight of potato treated with 100 mM NaCl + 0.2% MRS control (Figure 5).

There was no significant effect of *L. helveticus* CFS on leaf area and plant height of potato, as shown in Table 5.

4. Discussion

There is a continuous need to increase food production to quantities sufficient to feed the growing human population, without compromising quality, using sustainable and environmentally friendly approaches such as plant growth promoting microorganisms (PGPM) and their derived compounds (Lyu et al., 2020; Shah et al., 2021). NaCl stress is a

TABLE 4 Effect of treatments on mean percentage germination of corn at 72, 48 and 24h, respectively.

Treatment	Mean percentage germination at 72h±SEM	Mean percentage germination at 48h±SEM	Mean percentage germination at 24h±SEM
0 mM NaCl	71.5 ± 5.144 ^a	15.5 ± 1.846 ^a	0.00 ± 0.000 ^a

major global constraint to food production (Naamala and Smith, 2021b). Plant growth promoting microorganisms (PGPM), or their derived compounds have been reported to enhance plant growth under saline conditions (Schwinghamer et al., 2016;

Subramanian et al., 2016a,b; Ilangumaran et al., 2021; Naamala et al., 2022). However, use of microbial CFS as plant growth biostimulants is less explored, with just a handful of publications available (Tewari et al., 2020; Naamala et al., 2022; Shah et al., 2022). It is possible that CFS could enhance plant growth because microbes exude metabolites into their growth media in response to various signals, such as those related to biotic or abiotic stress (Subramanian et al., 2021). Among the exuded metabolites are some that possess phyto-stimulation properties, such as IAA, LCO and thuricin17 (Prithiviraj et al., 2003; Mohite, 2013; Subramanian et al., 2016a,b; Antar et al., 2021). In the laboratory setting, such signals/metabolites are exuded into the microbe's growth medium, which when filtered of microbial cells, will still contain the metabolites that can then enhance plant growth (Gray et al., 2006a). Consequently, the possible modes of action through CFS could enhance plant growth include presence of phytohormones such as jasmonic acid; presence of enzymes such as ACC deaminase; presence of osmoprotectants such as proline and presence of volatile organic compounds and exopolysaccharides, all of which may function to mitigate osmotic, oxidative and ionic stress associated with salinity (Forni et al., 2017; Khan et al., 2019; Cappellari and Banchio, 2020; Kumar et al., 2020; Fincheira et al., 2021; Lopes et al., 2021). There is limited publication on the role of members of the genus *Lactobacillus* and/or their CFS as plant growth biostimulants (Hamed et al., 2011; Lamont et al., 2017; Msimbira et al., 2022). The modes of action through which members of the genus *Lactobacillus* and their CFSs enhance plant growth are not fully understood (Lamont et al., 2017). However, plant growth promotion by LAB species has been attributed to production of metabolites such as IAA and siderophores (Omer et al., 2010; Mohite, 2013; Shrestha et al., 2014; Limanska N.V. et al., 2015; Limanska N. et al., 2015), and solubilisation of phosphorus (Shrestha et al., 2014), among other mechanisms. In general, PGPM and or their derived compounds can mitigate salinity stress by employing one or more of the following mechanisms: Production of antioxidants, production of enzymes such as ACC deaminase, production of exopolysaccharides, inducing systemic resistance in plants (Shrivastava and Kumar, 2015; Amna et al., 2019) and production of microbe-to-plant signal compounds (Backer et al., 2018).

The current study focused on the ability of CFS obtained from *L. helveticus* EL2006H to enhance growth of three crop species: corn, soybean and potato, exposed to NaCl stress, under

FIGURE 5
Potato treated with 0mM NaCl (A), 100mM NaCl (B), 100mM NaCl +0.2% MRS (C) and 100mM NaCl +0.2% EL2006H (D).

TABLE 5 Effect of treatments on selected growth variables of potato.

Treatment	Height gain (cm)	Leaf area (cm ²)
0 mM NaCl	37.275 ± 7.531 ^a	2851.261 ± 158.736 ^a
100 mM NaCl	32.263 ± 5.739 ^a	2951.652 ± 180.931 ^a
100 mM NaCl +0.2% EL2006	34.838 ± 6.937 ^a	3358.082 ± 156.557 ^a

controlled conditions. Results of the study highlight the role CFS concentration, NaCl level, crop species and growth level play in the effectiveness and efficacy of CFS as plant growth biostimulants.

The effect of CFS on mean radicle length varied among crop species, concentration of the CFS, and level of NaCl in the treatment. For instance, treatment with 100 mM NaCl +1.0% EL2006H resulted in a significant increase in corn radicle length but not soybean, suggesting crop specific responses. Although some PGPM, such as some *Rhizobium* species, can be promiscuous, enhancing growth in a wide range of crop species, others are host specific, enhancing growth of just one or two crop species (Lyu et al., 2020). PGPM and their host plants communicate through signals, which vary depending on the host plant needs (Antar et al., 2021). Sometimes, such signals will limit the host range of a particular PGPM. However, such PGPM can produce metabolites that enhance growth in a wide range of crops. For instance, LCO, can enhance growth of non-legumes although it is produced by *B. japonicum*, and plays a major role in nodulation of soybean. It is such advantages that make CFS and plant derived compounds relevant in PGPM technology (Naamala

and Smith, 2020). Even then, there is not yet a single microbial derived compound or PGPM that enhances growth of all crop species. It is possible that the varied responses to CFS observed in corn, soybean and potato are in part due to variation in ways through which the three crops perceive and respond to the bioactive signals in the CFS. In another study, we also observed variation in soybean and corn responses to *B. amyloliquefaciens* CFS (Naamala et al., 2022). The *B. japonicum* derived LCO also exhibited variation in its effect on corn and soybean (Souleimanov et al., 2002). At a lower concentration, variations were observed in the response of canola varieties treated with LCO (Schwinghamer et al., 2015).

Lowering CFS concentration from 1.0% (v/v) to 0.2% EL2006H CFS resulted in no significant effect on both corn and soybean mean radicle length. This seems to suggest that the concentration and quantity of CFS applied to a plant is vital in determining efficacy and effectiveness of the applied CFS in enhancing plant growth. In this case, especially for corn, higher concentrations resulting in more effective results than lesser concentrations. The same cannot be said about soybean. Its possible that in soybean, perhaps minute quantities of the supernatant were enough to enhance growth. For example, Msimbira et al. (2022) observed variation in germination of corn, in response to *Bacillus subtilis* CFS, where a concentration of 0.1% (v/v) yielded better results than higher concentrations of 0.2, 0.4 and 1.0%. It should also be noted that high concentrations may sometimes inhibit growth of the crop in question (Naamala et al., 2021b), although there is no universal description of how much is sufficient and this could vary among crop species. Published studies on *L. helveticus* CFS as a plant biostimulant are currently limited to a study by Msimbira et al. (2022). In our previous study on *B. amyloliquefaciens* EB2003 CFS, we observed the effect of CFS concentration on its effectiveness in enhancing germination and radicle length of corn and soybean (Naamala et al., 2022). Studies on other members of the genus *Lactobacillus* have also

reported concentration as a major determinant of effectiveness and efficacy in plant growth promotion. For instance, radish plants responded differently to varying concentrations of *L. plantarum* (Higa and Kinjo, 1991).

Results on mean percentage germination varied between corn and soybean at the two CFS concentrations and three different time frames studied. For instance, in soybean, following treatment with 100 mM NaCl +0.2% EL2006H, greatest significance was observed at 48 h, where percentage germination of soybean was not only significantly higher than that of the 100 mM NaCl control, but was also not significantly different from that of the unstressed 0 mM NaCl control. At 24 h, there was no observed difference among the effects of treatments for percentage germination. It is however possible that the CFS was already working on the physio-chemical properties of the seed to mitigate the effect of NaCl on the plant, hence the higher percentage germination observed at 48 h. The plant also naturally attempts to put in place a defence against stress, but can be slower, which could explain why at 72 h, there was no significant difference in the percentage germination of all the treatments on soybean. Therefore, it seems likely that at 48 h, CFS mitigated delays in germination due to 100 mM stress, resulting in percentage germination levels higher than the stressed control and not significantly different from the unstressed control, which is desirable because slow germination exposes seed to attack by pathogens in the soil, among other disadvantages. Similar results were obtained by Msimbira et al. (2022) who observed variation in the effect of EL2006H CFS on germination of corn and tomato across time. Naamala et al. (2022) also observed variation in effect of *B. amyloliquefaciens* CFS among 24, 48 and 72 h sampling times. In corn however, there was no significant effect of the EL2006H CFS on mean percentage germination at all time intervals. The mean percentage germination of corn was significantly lower than the unstressed control at both 48 and 72 h. This again takes us back to the effect of crop species on effectiveness of the CFS. The effect of PGPM CFS and other PGPM derived compounds on seed germination has been reported by other researchers (Tallapragada et al., 2015; Subramanian et al., 2016a,b; Shah et al., 2022). *Devosia* sp. CFS enhanced germination of canola and soybean under NaCl stressed and optimal conditions (Shah et al., 2022).

Increasing concentration from 0.2 to 1.0% of CFS yielded less desirable results in soybean as there was no significant difference between mean percentage germination of soybean treated with 100 mM NaCl +0.2% EL2006H and 100 mM NaCl, at all measurement times, although the percentage germination of the latter was not significantly different from that observed in the 0 mM control at 48 h. Results seem to suggest that when it comes to mean percentage germination, lesser quantities of the CFS are required to mitigate the effect of NaCl stress on germination of soybean. In corn, CFS had no significant effect on mean percentage germination, with the unstressed control still significantly higher at both 48 and 72 h. Shah et al. also observed variations in the germination of canola and soybean treated with a range of concentrations of *Devosia* sp. CFS (Shah et al., 2022).

In the potato experiment, results exhibited effects of stress level on effectiveness of EL2006H CFS. The supernatant enhanced some growth variables but not all. Specifically, CFS enhanced fresh weight, photosynthetic rate and leaf greenness but not leaf area and plant height. Among the variables enhanced, levels varied across NaCl levels. Better results of the CFS were observed in potato treated with 100 mM NaCl than 150 mM NaCl. This implies that increasing NaCl level by 50 mM reduced effectiveness of the CFS. This is not surprising as it is possible that the potential bioactive substance was less effective at 150 mM NaCl so that it/they could not function as efficiently as they would at lower concentrations, or, at 150 mM NaCl, potato plant cell components could have been damaged (Ilanguvaran et al., 2021) to a point where even the CFS could not fully mitigate these effects on growth. The effect of NaCl level on the effectiveness of CFS was also observed by Naamala et al. (2022) on percentage germination and radicle length of soybean and corn treated with different concentrations of NaCl. The CFS enhanced radicle length in soybean not stressed with NaCl but not in soybean exposed to NaCl while the reverse was true for corn (Naamala et al., 2022). Subramanian et al. (2016a) also observed that LCO enhanced germination of soybean exposed to 100 mM NaCl but not higher NaCl concentrations of 150 mM NaCl and 175 mM NaCl. Shah et al. observed significant increases in germination of canola and soybean treated with *Devosia* sp. CFS (Shah et al., 2022).

The ability of PGPM, LAB included, to enhance plant growth can be affected by plant growth stage and growth variables, in which case a microbial strain or its CFS can enhance plant growth at a certain plant growth stage and not at another or enhance growth of one variable but not the other. For instance, under field conditions, Shrestha et al. (2014) observed an increase in growth of pepper plants treated with each of the three LAB they were studying, 1 week after transplanting. However, after that stage, only one strain of the three was able to enhance plant height. This, in a way, points out the complexity of depending on the plant-microbe interactions for plant growth stimulation.

Published research on *L. helveticus* as a plant growth biostimulant remains minimal. However, other members of the genus have been reported to enhance plant growth. For example, *L. plantarum* exhibited antimicrobial activity against *Fusarium* spp. in agar plate assays and a consortium consisting of the same and *B. amyloliquefaciens* reduced severity of *Fusarium* spp. in wheat (Baffoni et al., 2015). *L. plantarum* ONU 12 expressed antimicrobial properties in carrot, kalanchoe and grapes exposed to *Agrobacterium tumefaciens*, protection ranging from 72.7 to 100% of wounded kalanchoe tissues, depending on mode of application (Limanska N. et al., 2015). LAB species KLF01, KLC02 and KPD03 had antagonistic effects against *Xanthomonas campestris* pv. *vesicatoria* (Shrestha et al., 2014) while strains LB-1, LB-2 and LB-3 increased total fresh weight of tomato plants by 348, 260, and 390%, respectively (Hamed et al., 2011). LAB species identified as KLF01, KLC02 and KPD03 were reported to enhance chlorophyll content in pepper (Shrestha et al., 2014). The same strains, except KLC02, were reported to enhance shoot length in

pepper (Shrestha et al., 2014). Recently, research on PGPM has extended to their CFSs, attempting to elucidate whether it can enhance plant growth in the absence of the microbial cell. The ability of *L. helveticus* CFS at varying pH levels to enhance plant growth was recently reported (Msimbira et al., 2022). The effectiveness and efficacy of PGPM or their CFS, including LAB is dependent on several soil, plant and microbe factors, such as soil conditions and plant species. A PGPM can enhance growth of one crop species but not another or enhance growth under certain soil conditions, such as under stressed conditions but not under optimal conditions.

At this stage we do not know whether the effect of CFS on the different variables is from a single bioactive compound or more than one; both scenarios are possible. As mentioned earlier, knowledge on the mechanisms employed by members of the genus *Lactobacillus* and or their CFSs to enhance plant growth remain poorly understood.

5. Conclusion

Based on the results of this study, it seems likely that *L. helveticus* EL2006H exudes into its growth media substances which enhance radicle length in corn, mean percentage germination in soybean and photosynthetic rate, greenness and mean fresh weight in potato. However, the effect varies depending on crop species, concentration of CFS and level of NaCl stress. *L. helveticus* CFS concentration of 0.2 and 1.0% were more effective at enhancing radicle length in corn and percentage germination in soybean, respectively. One hundred and fifty mM NaCl lowered the effectiveness of the 0.2% concentration in enhancing leaf greenness, mean photosynthetic rate and mean fresh weight of potato. Findings of this study can be used as a basis to further study of *Lactobacillus* CFSs and possibly identify the bioactive substances therein. Findings of this study are promising in the field of microbial inoculants where new ways of improving efficacy and effectiveness of the technology, especially under field conditions, are constantly sought. However, further studies need to be done, especially under field conditions, with trials on different crop species and varying soil conditions.

Plants have evolved diverse plant-species specific tolerance mechanisms to cope with salt stress. However, these adaptive strategies often inefficiently mitigate the stress related to increasing salinity. In this respect, plant-based biostimulants have gained increasing popularity since they can alleviate deleterious effects of salinity. Hence, this study aimed to evaluate the sensitivity of tomato and lettuce plants grown under high salinity and the possible protective effects of four biostimulants based on vegetal protein hydrolysates. Plants were set in a 2 × 5 factorial experimental design completely randomized with two salt conditions, no salt (0 mM) and high salt (120 mM for tomato or 80 mM for lettuce), and five biostimulant treatments (C: *Malvaceae*-derived, P: *Poaceae*-derived, D: Legume-derived commercial 'Trainer®', H: Legume-derived commercial 'Vegamin®', and Control: distilled water). Our results showed that both salinity and biostimulant treatments affected the biomass accumulation in the two plant species, albeit to different extents. The salinity stress induced a higher activity of antioxidant enzymes (e.g., catalase, ascorbate peroxidase, guaiacol peroxidase and superoxide dismutase) and the overaccumulation of osmolyte proline in both lettuce and tomato plants. Interestingly, salt-stressed lettuce plants showed a higher accumulation of proline as compared to tomato plants. On the other hand, the treatment with biostimulants in salt-stressed plants caused a differential induction of enzymatic activity depending on the plant and the biostimulant considered. Overall, our results suggest that tomato plants were constitutively more tolerant to salinity than lettuce plants. As a consequence, the effectiveness of biostimulants in alleviating high salt concentrations was more evident in lettuce. Among the four biostimulants tested, P and D showed to be the most promising for the amelioration of salt stress in both the plant species, thereby suggesting their possible application in the agricultural practice.

KEYWORDS

abiotic stress, antioxidant defense system, proline, salt-tolerant crop, salt-sensitive crop

Introduction

It is well known that plants, being sessile organisms, must exhibit a certain adaptive plasticity to survive when unfavorable or stressful factors are present in their growing environment (Zhu, 2016). Therefore, to efficiently express the adaptive responses to specific abiotic stresses, the quick reaction to environmental changes appears to be crucial (Nguyen et al., 2016). Among these stresses, salinity is certainly one of the most devastating, causing severe damage to plant growth and productivity and threatening food security. Around 20% of the world's cultivable lands (about 300 Mha) are impaired by high salinity, with an estimated annual global loss of 12 billion USD (Behera et al., 2022).

Vegetable crops are particularly susceptible to salinity stress compared to other agricultural crops (Machado and Serralheiro, 2017). In fact, the majority of vegetable crops have a low salinity threshold (EC_t) that ranges from 1.0 to 2.5 dS m^{-1} in saturated soil. However, it should be noted that the severity of salinity effects is variable among different plant species (Abiala et al., 2018). For instance, onion and carrot are considered salt-sensitive vegetable crops ($EC_t < 1.2$), potato, tomato and lettuce are moderately sensitive ($1.7 < EC_t < 2.5$), while asparagus has been classified as the most salt-tolerant vegetable crop ($EC_t > 4.0$) (Machado and Serralheiro, 2017). As concerns the plant effects, salinity can negatively alter morpho-physiological and biochemical functions at extents that are plant species-specific, thus resulting in nutritional and ion imbalance, oxidative and osmotic stress, damage to the cell membranes, proteins and photosynthetic machinery, and a decrease in plant growth and yield (Hasanuzzaman and Fujita, 2022).

To face salt stress and its effects, plants have developed different adaptive mechanisms, including the production of enzymes (e.g., ascorbate peroxidase - APX, catalase - CAT, superoxide dismutase - SOD, monodehydroascorbate reductase - MDHAR) and molecules (e.g., ascorbic acid, phenolic compounds, alkaloids, α -tocopherols) with antioxidant activity, and compatible osmolytes (e.g., proline, glycine, betaine) (Ismail et al., 2014; Zaid and Wani, 2019; Behera et al., 2022). In addition, the modulation of the levels of endogenous phytohormones (e.g., auxins, abscisic acid, salicylic acid, jasmonic acid, brassinosteroids) and the downstream changes in roots, leaves and cellular structures are also important response mechanisms (Fariduddin et al., 2019; Sadiq et al., 2020; Zaid et al., 2021; Behera et al., 2022). However, these adaptive strategies might not be enough to efficiently overcome the limitations imposed by salt stress. Therefore, the acquisition of new knowledge appears crucial for the development of agronomic approaches/practices that can strengthen the adaptive response of plants to salt stress. In this respect and in a framework of increasingly sustainable agriculture, different approaches based on the use of natural products have been developed.

Among these products, the class of plant biostimulants (PBs) encompasses a wide variety of effectors, including organic or inorganic substances and/or microorganisms, and they have recently emerged as potential and eco-friendly tools to improve plant growth, productivity and alleviate the negative effects of abiotic stresses (Bulgari et al., 2019). Vegetal-derived protein hydrolysates (PHs) are a particular category of PBs, formed by a mixture of soluble peptides and free amino acids with potential

bioactive effects aimed at enhancing plant growth and nutrition as well as at improving tolerance to salt stress following leaves or roots application (Colla et al., 2017). The mechanisms underlying the protective action of PHs in the salinity stress mitigation may include: i) regulation of key enzymes involved in the TCA-cycle and N-assimilation pathway (Colla et al., 2017); ii) increased photosynthetic metabolism by the elicitation of hormone-like activities (Di Mola et al., 2021); iii) modulation of the phenylpropanoids metabolism (Bavaresco et al., 2020); iv) changes in the gene expression of certain stress-inducible proteins (Vaseva et al., 2022).

Considering the potential role of PHs in mitigating the harmful effects of abiotic stresses, their use in vegetable species, which are more prone to salinity stress, represents a feasible strategy to encounter the negative impact of high salt concentrations. Among vegetable crops, tomato constitutes one of the most important fruiting vegetable crop in the world (Behera et al., 2022), whereas lettuce is one of the most consumed leafy vegetables (Shin et al., 2020). However, for both the negative effect of salt stress on the growth, biomass accumulation and yield are well described (Rouphael et al., 2017; Alam et al., 2021).

Based on the premises previously reported, and also considering the increasing global concerns about salinity as well as the economic and nutritional importance of vegetable crops, this work aims at investigating i) the different sensitivity of tomato and lettuce plants to salinity stress, ii) the constitutive biochemical mechanisms (i.e., activation of antioxidant enzymes, osmolyte accumulation) underpinning the different plant response to salinity in the short-term and iii) the effects of four PHs, obtained from different vegetal sources, in eliciting protective mechanisms (i.e., osmolyte accumulation, antioxidant defense system, modulation of key genes and ion homeostasis) in tomato and lettuce grown under optimal and salt-stress conditions. Considering that PHs have been described as plant species-specific and origin-specific (Paradić et al., 2019), we hypothesize that the effects observed on one particular PH-plant species combination could not be directly generalized to other PHs or other vegetable crops. For these reasons, we adopted a fully randomized experimental design based on two plant species, two salinity levels and five different treatments (four biostimulants and a negative control), focusing our investigations on biochemical and molecular parameters in a short-term experiment.

Materials and methods

Vegetal-derived biostimulants

Four protein hydrolysates (PHs) plus a control (consisting only of distilled water) were used in this experiment. Two of the biostimulants were commercial products resulting from enzymatic hydrolysis of legume-derived proteins: Trainer[®] (D) and Vegamin[®] (H) commercialized by Hello Nature USA Inc. (Anderson, IN 46016, US). The other two were provided by the Department of Agriculture and Forest Sciences (University of Tuscia, Italy) which were obtained by enzymatic hydrolysis of *Malvaceae* (C) and *Poaceae* (P) biomass, as previously described (Ceccarelli et al., 2021; Sorrentino et al., 2021).

The biostimulants were prepared at a concentration of 3 mL L⁻¹ of water solution and then evaluated through foliar application. Plants were exposed to the biostimulants once a week until the harvest (Figure 1A).

Plant growth conditions and experimental design

Tomato (*Solanum. lycopersicum* L. cv MicroTom) and lettuce (*Lactuca. sativa* L. cv Aquino) plants were grown in 200 mL pots filled with 150 g of a substrate obtained by mixing sand and sieved peat (Substrate 2, Klasmann-Deilmann GmbH, Germany) in a proportion of 1:1 (w/w) ratio. Two hours before sowing, pots were irrigated with 40 mL of distilled water and afterwards two seeds were sown at a depth of 1 cm into each pot and placed into a climatic chamber (conditions: 14/10-h light/dark period, 24/19 °C, 250 μmol m⁻² s⁻¹ light intensity, and 70% relative humidity). After germination, seedlings were thinned to one plant per pot and irrigated twice a week with 40 mL of a modified Hoagland's solution (NS) composed as follows: 0.36 g L⁻¹ Ca (NO₃)₂, 0.1 g L⁻¹ KH₂PO₄, 0.80 g L⁻¹ KNO₃, 0.04 g L⁻¹ NH₄NO₃, 0.13 g L⁻¹ MgSO₄, and 0.01 mg L⁻¹ of Mikron fertilizer (Cifo Srl, Italy) (Figure 1A). At ten days after germination (DAG), when seedlings have reached the 2-true-leaf stage, salinity condition was imposed by irrigating plants with NS supplemented with NaCl at the final concentration of 120 mM for tomato plants or 80 mM for lettuce plants, as described by Sorrentino et al. (2022). Plants were subjected twice a week to salt application, resulting in a total of five applications throughout the whole experimental period (Figure 1A). Starting from 12 DAG, biostimulants were applied

through foliar spraying once a week as described by (Zuluaga et al., 2022). A total of three foliar applications of PHs were done throughout the experiment (Figure 1A). Summarizing, plants were set in a 2 × 5 factorial experimental design completely randomized with two salt conditions: no salt (0 mM) and high salt (120 mM for tomato or 80 mM for lettuce); and four biostimulant treatments with the PHs (C, D, H and P) plus a Control treatment with distilled water (Figure 1B). Three biological replicates with two plants per replicate were performed for each treatment. At 28 DAG, plants were harvested: one plant of each biological was dried to a constant weight at 65°C following the determination of root dry weight (RDW) and shoot dry weight (SDW), while leaves from the remaining plant were immediately frozen in liquid nitrogen, then stored at -80°C until use.

Sodium and potassium content

Leaf tissues dried at 65°C were ground to a fine powder using Tissue Lyser II. Approximately 0.2–0.3 g of sample was weighed and acid digested with 69% ultrapure HNO₃ (Carlo Erba, Milano, Italy) in a single reaction chamber microwave digestion system (UltraWAVE, Milestone, Shelton, CT, USA). The digested samples were diluted to 2% HNO₃ with ultrapure grade water (18.2 MΩ·cm at 25°C), and then the concentration of Na and K was determined using an inductively coupled plasma–mass spectrometer (ICP-MS, iCAPTM RQ, Thermo Scientific). Element quantification was carried out using certified multi-element standards (CPI International, <https://cpiinternational.com>). NIST standard reference materials 1573a (tomato leaves) and 1570a

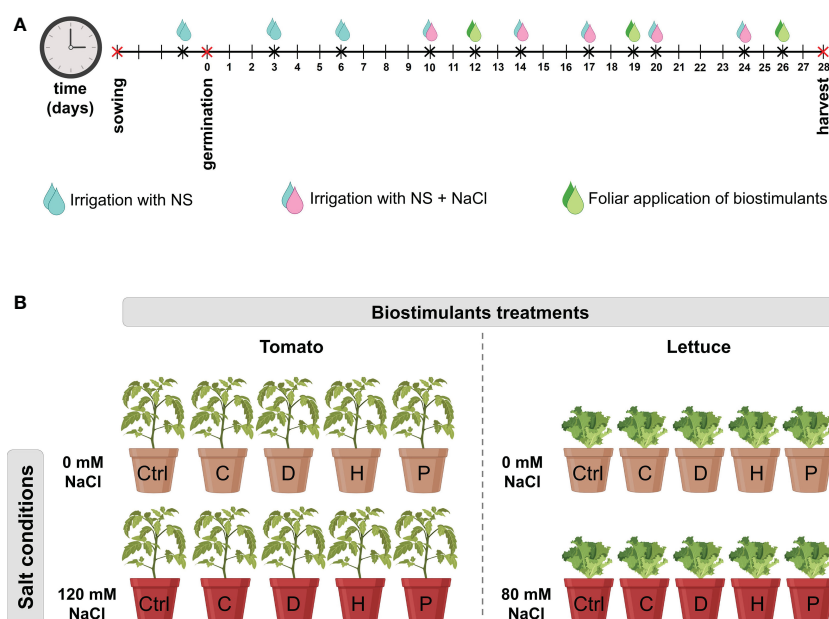

FIGURE 1

(A) Timeline of plant cultivation and treatments. Tomato and lettuce seeds were germinated for 5 days. After germination, seedlings were irrigated twice a week with 40 mL of NS. At 10 DAG, salinity condition was imposed by irrigating plants with NS supplemented with NaCl (120 mM for tomato and 80 mM for lettuce plants). Salt treatment was repeated twice a week. Starting from 12 DAG, biostimulants were foliarly applied once a week. Sampling was carried out at 28 DAG. (B) The experimental design of the present study. Plants were set in a 2 × 5 factorial experimental design completely randomized with two salt conditions: no salt (0 mM) and high salt (120 mM for tomato or 80 mM for lettuce); and four biostimulant treatments with the PHs (C, D, H and P) plus a Control (Ctrl) treatment with distilled water.

(spinach leaves) were used as external certified references, which were digested and analyzed the same way as the samples.

Proline content

Free proline content was determined *via* reaction with ninhydrin according to the method described by Bates et al. (1973). Briefly, 0.5 g of leaf samples frozen in liquid nitrogen were homogenized in 10 mL of 3% sulfosalicylic acid and centrifuged at 3000 \times g at 4°C for 10 min. Two milliliters of supernatant were reacted with 2 mL of freshly prepared acid-ninhydrin reagent for 1 h at 90°C. The reaction was then stopped by an ice bath. The chromophore was extracted using 4 mL of toluene and the absorbance at 520 nm was recorded. The proline concentration was estimated through a calibration curve and data were expressed as μ g proline per g fresh weight (μ g g⁻¹ FW).

Antioxidant enzyme activity

The enzymatic extract was prepared by grinding 0.5 g of frozen leaves in 5 mL of extraction buffer (100 mM potassium phosphate buffer, pH 7.5, containing 0.5 mM EDTA). The homogenate was centrifuged at 10,000 \times g and 4°C for 10 min. The enzymatic extract was collected and subsequently used to determine APX, GPX, CAT, SOD and the total protein content determined by the Lowry method (Lowry et al., 1951) with bovine serum albumin as a standard curve.

Ascorbate peroxidase (EC 1.11.1.11) was assessed by following the consumption of ascorbate at 290 nm (Nakano and Asada, 1981). The APX activity was estimated based on the molar extinction coefficient of 2.8 mM⁻¹ cm⁻¹ and expressed in μ mol ascorbate mg⁻¹ protein min⁻¹. Guaiacol peroxidase (GPX, EC 1.11.1.7) activity was estimated by measuring the formation of tetraguaiacol at 470 nm (Castillo et al., 1984). The activity of the enzyme was calculated using the molar extinction coefficient of 26.6 mM⁻¹ cm⁻¹ and expressed in μ mol tetraguaiacol mg⁻¹ protein min⁻¹. Catalase (CAT, EC 1.11.1.6) activity was determined by following the consumption of H₂O₂ at 240 nm (Aebi, 1984). The enzyme activity was calculated based on the molar extinction coefficient of 39.4 mM⁻¹ cm⁻¹ and expressed in μ mol H₂O₂ mg⁻¹ protein min⁻¹. Superoxide dismutase (SOD, EC 1.15.1.1) activity was measured at 560 nm using the photochemical reduction of nitroblue tetrazolium, NBT (Dhindsa et al., 1981). SOD activity was expressed on protein basis as units mg⁻¹ protein. All the determinations have been performed on three independent biological replicates, whereby each biological replicate was formed by a pool of two plants.

Gene expression analysis

Leaf tissues frozen in liquid nitrogen were ground to a fine powder. Total RNA was extracted from 100 mg of ground leaves using the Spectrum Plant Total RNA Kit (Sigma- Aldrich, St. Louis, MO, USA) according to the manufacturer's instructions. The total RNA (1 μ g) was treated with 10U of DNase RQ1 to degrade possible DNA contamination, and cDNA was synthesized using the ImProm-

II Reverse Transcription System (Promega, Madison, WI, USA) following the manufacturer's instructions. Gene-specific primers were designed for the target gene, as well as for the housekeeping gene, the elongation factor 1 α (Supplementary Table 1). Quantitative real-time reverse transcription PCR (qRT-PCR) was carried out in triplicate with the following conditions: 5 min at 95°C, followed by 40 cycles at 95°C for 30 s and 55°C for 30 s. The housekeeping transcript was used to calculate the mean normalized expression value (MNE; (Simon, 2003)) for each sample and the relative expression ratio values were calculated by the 2^{- $\Delta\Delta$ Ct} method according to Livak and Schmittgen (2001).

Statistical analysis

All the experimental data for both plant species (*S. lycopersicum* and *L. sativa*) were statistically subjected to two-way ANOVA using R software (version 4.0.3). The mean values were separated according to Tukey's HSD test with $p < 0.05$, and salinity levels effects were compared using the t-test. The following R packages were used for data visualization and statistical analyses: ggplot2, agricolae and ggpubr.

Results

Plant biomass

The biomass accumulation of both plant species was strongly influenced by salt stress. The results showed that dry matter accumulation in lettuce was more affected by salinity than in tomato plants. Moreover, the root system underwent a more pronounced decrease than the aerial parts, in both plant species. For instance, the root dry weight (RDW) of tomato under saline conditions, independently of the treatment applied, was significantly decreased by 58-65%, whilst in lettuce, the drop ranged between 47-72% compared to the no-salt condition (Table 1). On the other hand, the shoot dry weight (SDW) of tomato was reduced by about 28-42% under high salinity, whilst a decrement of 17-58% was observed in lettuce plants (Table 1). However, the application of PHs induced differential effects in each plant species, and they were dependent on the nature of the biostimulant applied and the salinity conditions. In the specific case of lettuce plants, all PHs applied stimulated the biomass accumulation in roots and shoots under high salinity compared to the saline control. Yet, biostimulant P induced the most remarkable effects enhancing RDW and SDW by more than 130%. Nonetheless, under no salt conditions, only biostimulant P induced the most significant effects in increasing lettuce biomass when compared to the untreated control (Table 1). Regarding tomato plants growing under salinity stress, only the application of PHs D and P significantly enhanced RDW (by 22% and 32%, respectively). At the same time, no significant effects were induced by the PHs on the SDW. However, under no-salt conditions, PHs D and P were also efficient in increasing RDW of tomato plants by about 20%. In contrast, C, H and P enhanced the accumulation of SDW by more than 15% compared to control plants (Table 1). In addition, as high

TABLE 1 Root dry weight (RDW), shoot dry weight (SDW) and root to shoot (R/S) ratio of tomato and lettuce grown under salinity stress and protein hydrolysates application.

Differences between biostimulant treatments were determined using Tukey's HSD test, and significant differences ($p < 0.05$) are indicated by different lowercase letters when comparing means in rows. Salt level effects were compared using Student's *t*-test, and significant differences ($p < 0.05$) are indicated by different capital letters when comparing means in columns. No significant differences are indicated by omitting notation letters.

salt concentrations inhibited root growth more than shoot growth, the expected reduction of root-to-shoot ratio (R/S) was also observed in both plant species (Table 1). Nevertheless, tomato plants treated with biostimulant D presented a higher R/S ratio under both salinity conditions, whilst biostimulant P was notably better for lettuce plants.

Ion homeostasis

To investigate whether PHs application could mitigate salt stress in both plant species, we measured leaves' Na^+ and K^+ content. The salt stress significantly increased Na^+ content (ranging from 46% to 129%) and decreased K^+ content (ranging from 16% to 26%) in tomato under all treatments (Figures 2A, B). However, when PHs H and P were applied to NaCl-stressed tomato plants, there was a significant decrease in Na^+ content (by 12% and 25%, respectively) when compared to high salt control plants (Figure 2A), yet no remarkable differences were observed for K^+ concentration (Figure 2B).

On the other hand, in control lettuce plants, salt stress induced an increase of 246% in the Na^+ concentration compared to no salt plants; when considering the application of PHs, the most remarkable effect was produced by P, which reduced Na^+ concentration by about 21% compared to P-treated non-stressed plants (Figure 2D). Considering the data obtained in lettuce plants subjected to high salt stress, differential effects were triggered by the PHs application. In fact, PHs P and D reduced Na^+ concentration by about 69%, H by 56% and C by 34% compared to salt-stressed control plants (Figure 2D). In addition, under high salt conditions, K^+ concentration decreased by 15% in untreated-control plants and by 11% in P-treated plants (Figure 2E), whilst the application of C increased K^+ concentration by 28%, and no significant differences were observed for D and H, when compared to the same treatments under no-salt conditions (Figure 2E).

As a consequence of the changes in both elements induced by the use of different PHs, the Na^+/K^+ ratio of salt-stressed tomato plants significantly decreased in tomato plants treated with PHs H and P (by 12% and 23%, respectively) (Figure 2C), whereas for salt-stressed lettuce plants all PHs decreased the Na^+/K^+ ratio by 73% (D), 65% (P and H) and 45% (C), compared to NaCl-control plants (Figure 2F).

Osmolytes and antioxidative enzyme activities in leaves

The concentration of the osmolyte proline increased in the leaf tissue of both plant species when exposed to salinity stress (Figure 3). In salt-stressed tomato plants, proline concentration increased by about 100%, compared to non-stressed plants, independently of the PH applied (Figure 3A). On the other hand, in lettuce plants, salt stress induced an increase in the accumulation of proline by about 25-fold in untreated plants. However, the highest proline concentration was detected in salt-stressed lettuce treated with PHs D and P (increased by 200-fold and 90-fold, respectively) (Figure 3B). Interestingly, under non-saline conditions, the constitutive accumulation of proline in tomato plants was notably higher than in lettuce plants (by 80-fold). Moreover, the treatment of salt-stressed tomato plants with PHs did not induce significant effects in the accumulation of proline, while under no-salt conditions PHs C, D and H significantly increased this osmolyte compared to the corresponding control plants (Figure 3A). In salt-stressed lettuce plants, all PHs induced a significant increase of this osmolyte (ranging from 19–44%) compared to NaCl-control plants, whilst under normal conditions, only PHs C and H enhanced proline content (Figure 3B).

High salinity also stimulated the activity of antioxidant enzymes (CAT, APX, GPX and SOD) in leaves of both plant species, but APX and GPX were more enhanced in tomato, whereas CAT and APX were the most induced in lettuce (Table 2). In addition, the use of biostimulants promoted differential responses that were dependent on the plant species and the nature of the PHs applied. For instance, in lettuce plants grown under salinity stress, the use of PHs P and H significantly increased the activity of most of the antioxidant enzymes compared to untreated-control plants (Table 2), whereas in stressed-tomato plants each PH was efficient in enhancing the activity of a given enzyme.

PAL gene expression in leaves

Since phenylalanine ammonia lyase (PAL; EC 4.3.1.5) is a key upstream enzyme in synthesizing the majority of polyphenolic compounds involved in plant response to stresses (Hoffmann et al.,

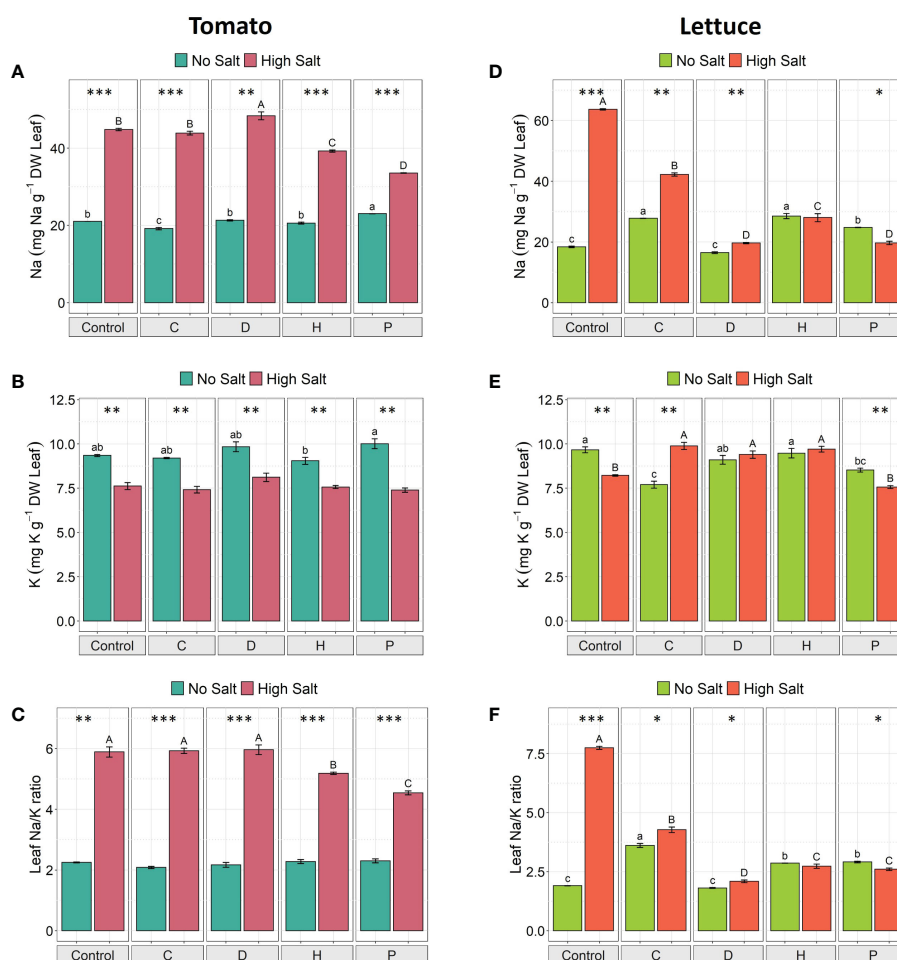

FIGURE 2

2021), its transcriptional modulation was studied in order to shed light on its role in plant tolerance to high salinity conditions. The application of PHs influenced the *PAL* gene expression in both plant species subjected to either optimal or high salt conditions (Figure 4).

In tomato plants grown under high NaCl, PHs C and D induced a slightly higher expression of the *PAL6* gene (1.3-fold) compared to control plants, albeit not significantly. However, under non-saline conditions, the biostimulant P was the only one to induce a higher

gene expression (1.4-fold) (Figure 4A). On the other hand, the application of P induced significant over-expression of *PAL2* in salt-stressed lettuce plants (1.7-fold), yet C and H also enhanced its expression (by ~1.4-fold), even though not significant when compared to the saline control. Under no salt conditions, all PHs downregulated the *PAL2* expression in lettuce leaves compared to the untreated control (Figure 4B).

PCA of plant responses to PHs application and salt stress

In order to better understand the influence of the single parameters recorded on the overall performance of plants subjected to the different treatments, a principal component analysis (PCA) considering both the agronomical and biochemical data was performed for each plant species. PCA confirmed that salt stress was the prevalent factor influencing the behavior of tomato and lettuce plants (Supplementary Figure S1). In this sense, to better

understand the possible positive effects of PHs application, separated PCA have been carried out for the two plant species, keeping high salt and no salt conditions separated (Figure 5).

In tomato plants subjected to high salinity, the scatterplot obtained by combining the two principal components (PC1 and PC2) accounted for about 61% of the total variance and clearly showed the separation of the plants treated with PHs P and D along the PC1, with respect to a cluster formed by all the other samples (Figure 5A). For biostimulant P, the main drivers of the separation were the growth parameters and the CAT activity. At the same time, proline, GPX, Na^+/K^+ ratio (PC1) and K (PC2) were important to discriminate biostimulant D. Considering tomato grown under no-salt conditions (Figure 5B), the two principal components explained together about 70% of the total variance, showing that PHs D and P presented a similar effect on tomato plants mainly discriminated by the antioxidant enzymes, RDW, R/S ratio and K^+ content along PC1 axis. On the other hand, C and H biostimulants clustered very close to control samples, suggesting a milder effect on plants compared to the other PHs (Figure 5B).

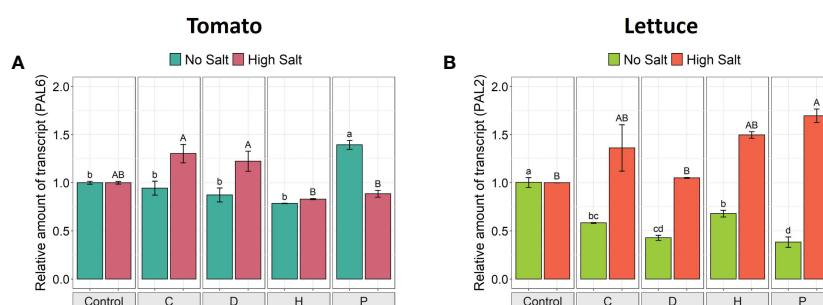

FIGURE 4

Gene expression analysis of *PAL6* in leaves of tomato (A) and *PAL2* in leaves of lettuce (B) grown under salinity stress and protein hydrolysates application. The expression levels of *PAL6* and *PAL2* genes were normalized to the expression levels of the elongation factor isoform 1- α (EF-1 α) and the adenosine phosphoribosyl transferase (APT1), respectively. The relative expression ratios were calculated using the control treatment in each salinity condition as a calibrator sample. Values are means \pm SE; $n = 3$. Lowercase letters compare treatments under no salt, and capital letters compare treatments under high salt. Equal letters correspond to average values that do not differ according to Tukey's HSD test ($p < 0.05$).

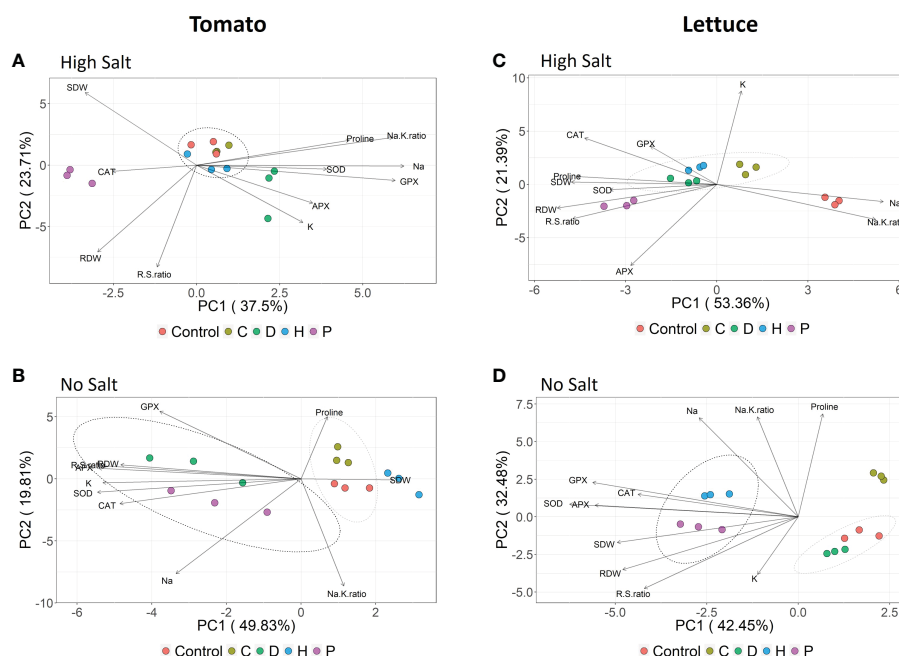

FIGURE 5

Principal component analysis (PCA) of major traits measured for tomato (A, B) and lettuce (C, D) summarizing the responses to vegetal-derived protein hydrolysates application (Control, C, D, H and P) under each salinity condition (no salt: 0 mM NaCl or high salt: 120 mM NaCl and 80 mM NaCl for tomato and lettuce, respectively).

In salt-stressed lettuce plants, the PCA produced a model in which the first two principal components, PC1 and PC2, accounted for about 53% and 21% of data variance, respectively (Figure 5C). Under this salinity condition, untreated-control plants were clearly separated along the PC1 from the PHs mainly due to Na^+ concentration and Na^+/K^+ ratio, whereas biostimulant P presented the most distinctive effect when compared to the other three PHs, mainly driven by the growth parameters and proline, as well as the antioxidant enzymes CAT and APX. Regarding the lettuce plants grown under no-salt conditions (Figure 5D), 75% of the total variance was explained by combining PC1 and PC2. The PHs P and H presented similar effects on lettuce plants under no saline conditions, strongly driven by the growth parameters and all antioxidant enzymes along the PC1 axis.

Discussion

Results here presented show that salinity stress shrank biomass accumulation of both vegetable species. However, this effect was particularly pronounced in lettuce. From a general point of view, it is well demonstrated that high salt concentrations within the plant tissues compromise the development of roots and leaves in most crops (Robin et al., 2016). Nevertheless, the severity of symptoms induced by salinity stress depends upon many factors, including species, genotype, phenological stage, salt concentration, and time span of plant exposure to the stress (Giordano et al., 2021). It is interesting to note that in this work the use of protein hydrolysates (PHs) induced a differential response in the plant growth according to the vegetable species, the salinity levels, and the origin of the PHs. In this respect, it should be noted that the bioactive potential of PHs in

relation to root growth and leaf biomass is often ascribed to the stimulation of cell proliferation associated with the amino acids and peptides composing the PHs, which work as signaling molecules involved in the N metabolism (Caruso et al., 2019). All the four PHs supplied in the present work efficiently enhanced the growth of both root and shoot of salt-stressed lettuce plants, albeit the *Poaceae*-derived PH (P) induced more remarkable effect. On the other hand, none of the four tested PHs induced significant effects on leaves of salt-stressed tomato, whilst only D (Trainer®) and P improved root growth. Under abiotic stresses, PHs have been described to trigger several physiological and metabolic mechanisms, including plant hormone regulation, chlorophyll-related metabolism and stress-related metabolism (Lucini et al., 2015; Rouphael et al., 2017; Sorrentino et al., 2022). However, due to the variable composition of PHs, many crop systems respond differently to the biostimulant applied (Paradić et al., 2019).

Previous studies have demonstrated that salt-tolerant species differ from more sensitive ones in preventing the accumulation of toxic salt levels in leaves (Munns, 2002). In the present work, both crop species showed an elevated Na^+ ion concentration in leaves, which led to ionic imbalance and decreased the concentration of K^+ ions. However, this effect was more marked in lettuce plants. Tomato and lettuce, featuring an EC_e of 2.5 and 2.0 dS m^{-1} , respectively, are considered moderately sensitive to salinity and show adaptive mechanisms to this abiotic stressor (Machado and Serralheiro, 2017). Nonetheless, variation in salt sensitivity is found between species and genotypes, mainly due to the ability to store Na^+ ions in leaves (Munns et al., 2016). Interestingly, all PHs reduced the concentration of Na^+ and Na^+/K^+ ratio in leaves of lettuce grown under high salinity, whereas only the PHs H and P produced the same effect in tomato. Indeed, maintaining the Na^+/K^+ ratio to minimal

values in leaves is an important indicator of salinity tolerance (Assaha et al., 2017), clearly suggesting active and differential roles of PHs in modulating ion homeostasis. In this sense, it has been previously reported that applying a plant-based biostimulant to chili pepper plant significantly alleviated the negative effects of salinity stress by rebalancing ions content and modulating phytohormones concentrations (Abou-Sreya et al., 2021).

Under salinity stress, plants can accumulate compatible solutes, such as proline, which play protective roles as an osmoprotectant, scavenging reactive oxygen species (ROS), stabilizing cellular structures and enzymes, and providing cellular redox balance (Meena et al., 2019). Although proline accumulation can be considered a general response to salinity in many plant species, its role in salinity tolerance can be ambiguous and strongly dependent on plant species (Arteaga et al., 2020). In this work, proline content in tomato plants grown under optimal conditions was constitutively higher than lettuce plants. However, under salinity stress, lettuce plants presented a higher accumulation, in terms of fold-change, of this osmolyte over tomato. Depending on the species involved and the severity and duration of the stress, proline content can be accumulated at significantly levels compared to non-stress conditions (Kavi Kishor and Sreenivasulu, 2014). In this context, it has been reported that salt-tolerant species are more efficient in maintaining cell osmolarity under saline conditions, whereas salt-sensitive species need to synthesize higher levels of proline to balance the intracellular osmotic potential (Chen et al., 2007; Kozminska et al., 2018). Therefore, our results suggest that lettuce is more sensitive to salt stress than tomato plants, albeit previous data consider them equally sensitive to salinity (Machado and Serralheiro, 2017). Furthermore, in salt-stressed tomato plants, the foliar application of PHs did not enhance the levels of proline, whereas in salt-stressed lettuce all PHs increased this osmolyte, indicating a correlation between salt-sensitivity and the beneficial effect of PHs. More precisely, the more salt-sensitive is a vegetable species, the higher is the ability of PHs to counteract the adverse effects of salinity.

It is well documented that, to deal with the oxidative damage induced by salinity stress, plants can activate the enzymatic antioxidant defense system represented by enzymes such as catalase (CAT), ascorbate peroxidase (APX), guaiacol peroxidase (GPX), and superoxide dismutase (SOD). In fact, they are all crucial in regulating and/or detoxifying harmful levels of reactive oxygen species (*i.e.*, H_2O_2 , $\text{O}_2^{\cdot-}$, HO_2^{\cdot} , RO^{\cdot} , $^{\cdot}\text{OH}$) (Hasanuzzaman et al., 2020) as a consequence of the stress. Results here presented show that the activities of the four enzymes were increased under high salinity and showed responses both plant species-specific and PH-related. It has been reported that an enhanced antioxidant defense system induced using biostimulants is directly involved in ROS scavenging and oxidative stress reduction in plants under salinity (Hasanuzzaman et al., 2021). Noteworthy, the specific use of PHs P (*Poaceae*-derived) and H (Vegamin[®]) showed greater potential in eliciting the antioxidant system in lettuce plants, whereas none of the tested PHs could contemporarily upregulate the activities of all the antioxidant enzymes in tomato plants. The fact that a specific PH induces a plant species-specific response in terms of enhanced activity of enzymatic antioxidants may be ascribable, at least in part, to the peptide components in the PH, acting as signal molecules in regulating physiological processes.

Overexpression of specific *PAL* gene isoforms has been reported to improve plant tolerance to several environmental stresses (Olsen et al., 2008; Kim and Hwang, 2014; Zhang et al., 2018). In the present work, when high salinity stress was imposed, some PHs up-regulated the expression of *PAL6* and *PAL2* in tomato and lettuce plants, respectively, but these responses were dependent on the vegetable species and the nature of the biostimulant applied. These results agree with other studies, which have also reported that using plant-based biostimulants can enhance the transcription of a set of stress-related genes, including *PAL* isoforms (Ertani et al., 2011; Ertani et al., 2013; Trevisan et al., 2019). Increased *PAL* activity is generally correlated with the increased production of phenylpropanoids and flavonoids (Vogt, 2010), which are believed to play a key role in plant stress protection by regulating the antioxidant system, photosynthetic system, plasma membrane integrity, and gene expression levels (Yaqoob et al., 2022).

The multivariate statistical analyses further demonstrated the variability observed in the response of the individual vegetable species to biostimulants application under a given salinity condition. All four tested PHs prompted the amelioration of NaCl-induced toxicity in lettuce plants. Yet, the *Poaceae*-derived biostimulant (P) showed the most remarkable effect associated with multiple mechanisms, including enhanced biomass accumulation, improved antioxidant defense machinery, and balanced ionic content. Under non-stress conditions, only P and H (Vegamin[®]) presented promising effects in enhancing lettuce growth and health. On the other hand, applying P and D (Trainer[®]) allowed tomato plants to cope with the adverse effects of salinity through different ways of action: while P stimulated plant growth, D activated the antioxidant system and ion homeostasis. The same two PHs also contributed to plant growth and the general fitness of tomato under no-salt conditions. Indeed, the differential effectiveness of plant-derived PHs can be ascribed to either synergistic or antagonistic effects of several bioactive molecules that are inherently present in the mixtures used (Bulgari et al., 2019). Therefore, the biostimulant properties of protein hydrolysates under normal or saline conditions seem to be strongly correlated to their origin and, thus, their composition, as reported in previous comparative studies using plant-derived biostimulants (Abdel Latef et al., 2017; Abou-Sreya et al., 2021).

Yet, it is very important to further highlight the demonstrated role of PHs in mitigating the harmful effects of abiotic stresses, which are predicted to threaten the agricultural production in the next years. Indeed, the regular application of these natural substances obtained by the valorization of waste biomass could represent on one side a virtuous example of circular economy and, on the other hand, they might constitute an innovative and sustainable agricultural approach.

Conclusions

The findings provided by this study demonstrate that foliar application of vegetal-derived protein hydrolysates to two different plant species grown under contrasting saline conditions effectively attenuated salinity stress damage to different extents. Our results demonstrated that, albeit being previously assessed as equally

sensitive, lettuce plants showed less tolerance to salt stress with respect to tomato plants. In addition, the effectiveness of PHs in counteracting the toxic effects of salinity was more evident in lettuce plants, *i.e.*, the most sensitive of the two vegetables used in this study. Nonetheless, we also demonstrated that both the botanical origin and the composition of PHs play a major role in the biostimulants effects on plant growth and stress amelioration. Yet, the *Poaceae*-derived (P) and Trainer® (D) were revealed as the most promising PHs for the amelioration of salt stress in both vegetable species. Overall, the evidence gathered strongly suggests that, to completely exploit the biostimulant potential of PHs in the context of specific abiotic stresses, the correct combination of plant species and PHs needs to be carefully considered. To this purpose, a deeper understanding of the mechanisms underlying the PHs effects on crops represents a fundamental step also for a more focused, efficient, and large-scale use of these natural products in a context of a continuously more sustainable and resilient agriculture.

Rhizosphere bacteria can have wide-ranging effects on their host plants, influencing plant biochemical and structural characteristics, and overall productivity. The implications of plant-microbe interactions provides an opportunity to interfere agriculture ecosystem with exogenous regulation of soil microbial community. Therefore, how to efficiently predict soil bacterial community at low cost is becoming a practical demand. Here, we hypothesize that foliar spectral traits can predict the diversity of bacterial community in orchard ecosystem. We tested this hypothesis by studying the ecological linkages between foliar spectral traits and soil bacterial community in a peach orchard in Yanqing, Beijing in 2020. Foliar spectral indexes were strongly correlated with alpha bacterial diversity and abundant genera that can promote soil nutrient conversion and utilization, such as *Blastococcus*, *Solirubrobacter*, and *Sphingomonas* at fruit mature stage. Certain unidentified or relative abundance <1% genera were also associated with foliar spectral traits. We selected specific indicators (photochemical reflectance index, normalized difference vegetable index, greenness index, and optimized soil-adjusted vegetation index) of foliar spectral indexes, alpha and beta diversities of bacterial community, and quantified the relations between foliar spectral traits and belowground bacterial community *via* SEM. The results of this study indicated that foliar spectral traits could powerfully predict belowground bacterial diversity. Characterizing plant attributes with easy-accessed foliar spectral indexes provides a new thinking in untangling the complex plant-microbe relationship, which could better cope with the decreased functional attributes (physiological, ecological, and productive traits) in orchard ecosystem.

KEYWORDS

foliar spectral traits, plant productivity, fruit quality, bacterial diversity, soil conditioner

1. Introduction

1.1. The interaction between plant and soil microbial community

Plants, microorganisms, and soils interact with each other and unite biotic and abiotic factors into a living complexity *via* material cycling and energy flow in the terrestrial ecosystem (Wardle et al., 2004; Bardgett et al., 2006; Bardgett and Van der Putten, 2014). The interactions between plants and soil biota exert influences on ecosystem functioning and plant community (Fierer et al., 2009; Sul et al., 2013; Tedersoo et al., 2014; Kaiser et al., 2016), in undescribed and diverse ways that were poorly understood to date (Sul et al., 2013). This has induced great

enthusiasm of researchers into interactions between aboveground plant productivity and belowground ecological functioning (Bardgett and Van der Putten, 2014; Leff et al., 2018; Cavender-Bares et al., 2022). Individual plant species can greatly impact soil microbial communities (Bardgett et al., 1999; Berg, 2009). Growing evidence showed discrepancies in soil bacterial and fungal communities that were linked to plant community composition at landscape (Grayston et al., 2001; de Vries et al., 2012) and global scales (Prober et al., 2015) in recent decades. Moreover, strong correlations between individual plant species and soil fungal (Lekberg and Waller, 2006), bacterial (Berg, 2009), and nematode (Bezemer et al., 2010) communities were observed in previous studies. However, it remains unclear that whether these correlations were driven by shared environmental preferences or by the direct influence from locally dominant plant species. Furthermore, plants affect soil microbial community in numerous ways, and it is not clear whether and what plant attributes could be used to predict soil microbial community (Leff et al., 2018; Cavender-Bares et al., 2022).

1.2. Plant traits characterize soil microbial community

The difficulty in understanding what controls co-distribution of plants and soil microbes is that plants exert influences on while subjecting to impacts from soil microbial community. The complex interactions pose an obstacle in understanding the co-distribution of plants and soil microbes. For instance, plants were reported associated with a nonrandom subset of soil microbes within distinct ecosystems (Gottel et al., 2011; Lundberg et al., 2012; Sul et al., 2013; Shi et al., 2015), while soil microbes can be differentiated within co-occurring plant species (Ishida et al., 2007; Bonito et al., 2014; Burns et al., 2015) or even different individuals within the same species (Massensini et al., 2015; Gehring et al., 2016; Wagner et al., 2016). It has been observed that soil biota was more responsive to key functional traits of plants than to plant diversity. Foliar traits, such as biochemical and structural characteristics (Violle et al., 2007), were indicative for plant strategies (Wright et al., 2004), plant responses to environmental pressures (Garnier et al., 2007), and ecosystem processes and services (Díaz and Cabido, 2001; Lavorel and Garnier, 2002; Lavorel et al., 2011). Therefore, ecosystem management and studies are increasingly using foliar traits (Kokaly et al., 2003; Douma et al., 2012). However, the conditional acquisition of essential foliar traits is costly, time-consuming, and notoriously difficult to acquire, especially in remote areas (Schweiger et al., 2017).

1.3. Foliar spectral traits and their applications

The distinct spectral responses of vegetation are determined by biochemical and structural traits of plant tissues, and the three-dimensional structure of the canopy, which could be predicted by imaging spectroscopy that captures the spectral response in narrow, spectrally contiguous bands (Schaepman, 2007; Sul et al., 2013; Asner et al., 2017). Certain spectral bands were proved sensitive to biochemical and structural traits of plant tissues (Curran, 1989). For instance, foliar trait could influence its spectral properties:

reflectance, transmittance, and absorbance of light (Ustin et al., 2009; Sul et al., 2013; Schneider et al., 2017; Schweiger et al., 2018). Hence, by measuring foliar spectral properties using, for example, spectroscopy (many adjacent spectral bands with high spectral resolution), foliar traits may be approximated easily and low-cost (Sul et al., 2013). Foliar spectral properties determined by a field spectrometer or airborne remote sensing have been widely used for individual sunlit top of canopy leaves in forest ecosystem (Asner et al., 2011; Doughty et al., 2017), and aboveground biomass of prairie ecosystems (Cavender-Bares et al., 2021). Little is known about the spectral properties in orchard ecosystem (Liu, 2022), which harbor a diverse microbial community that can be affected by tillage, microbicide application, soil fumigation, and fertilization (Peck et al., 2011; Sul et al., 2013; Wang et al., 2017; Liang et al., 2018). Monitoring plant (community) attributes has dramatically improved in recent decades with advances in fine-grain mapping of canopy structure and chemistry (Cavender-Bares et al., 2022), which could benefit the investigation of plant-microbe relationship in the orchard ecosystem.

Considering the feedback process between orchard ecosystem productivity and belowground bacterial composition and diversity, we hypothesized that plant productivity of orchard ecosystem would be detectable with field spectrometer and could be used to predict belowground bacterial diversity. To test this hypothesis, we adopted root-zone ecological restoration practices (RERP) with soil conditioner or organic fertilizer at the end of growing season to realize differentiated soil bacterial communities in a peach orchard in Beijing. Our previous results demonstrated that RERP increased bacterial diversity and altered bacterial taxonomy and metabolic functions *via* improved soil properties (balanced nutrients, decreased bulk density, and increased water holding capacity) at soil depth of 20–40 cm (Sun et al., 2022). In this study, soil bacterial diversity (0–20 cm and 20–40 cm), plant productivity, and the parallel foliar spectral profiles were obtained at fruit mature stage of the following growing season after treatment, with objectives as follows: (1) clarify which foliar spectral indexes could represent peach productivity; (2) test whether aboveground plant productivity, as detected from foliar spectral indexes, could predict soil bacterial processes and community composition; and (3) determine to what extent of belowground soil bacterial alpha and beta diversity processes could be inferred by foliar spectral indexes. Quantified linkage between foliar spectral indexes with soil bacterial diversity attributes could provide an easy access to belowground bacterial community for better coping with the decreased functional attributes (physiological, ecological, and productive traits) in degraded orchard ecosystem.

2. Materials and methods

The experimental peach orchard (20 ha) was established in 2008 on meadow cinnamon soil in Yanqing District, Beijing (115.99E, 40.53N), with a warm, temperate, continental monsoon climate. The experimental location has an average annual temperature of 8.5°C and an average annual precipitation of 443 mm. Planted on a flat terrain, the test peach trees all received the same environmental conditions, such as sunlight and precipitation. An early-maturing cultivar named Chunxue has been planted since 2012 in the orchard, with a row

spacing of 4 m and a line spacing of 3 m. See pre-treatment soil properties of the orchard in 2020 in [Supplementary Table S1](#).

2.1. Experimental treatments

A self-invented soil restoration practice-RERP (patent application No. 2021115124384) was employed in the experimental peach orchard ([Sun et al., 2022](#)). RERP can increase the productivity of the peach orchard (reflecting in fruit yield and quality) by improving soil physical, chemical, and microbial properties in the root zone. In order to implement RERP, a trench (12 m long, 0.8 m wide, and 0.6 m deep) that was 1.2 m apart from the west side of the trees were dug out in October 2020. The dug-out soil was placed in three piles and filled back to the trench according to soil depths (0–20 cm, 20–40 cm, and 40–60 cm). There were three treatments that applied on a total of 45 trees, with three replications for each treatment. Border rows were arranged around test trees. Treatment 1 (T1) was RERP with soil conditioner (3 t ha^{-1}), organic fertilizer ($15 \text{ t ha}^{-1} \text{ DW}$), and mineral fertilizer ($\text{N:P}_2\text{O}_5:\text{K}_2\text{O} = 15:5:10$, 900 kg ha^{-1}) and evenly applied at soil depths of 20, 40, and 60 cm in the trench. Treatment 2 (T2) was RERP with organic fertilizer. Application materials and methods of T2 was the same as T1, only without the application of 3 t ha^{-1} soil conditioner. Conventional practice (CK) in the orchard was considered as control, receiving 650 kg ha^{-1} of urea (46%), 600 kg ha^{-1} of calcium superphosphate, and 310 kg ha^{-1} potassium sulfate each year (applied on May and November). Pest control and regular management were conducted as required, following the local practices for all treatments.

2.2. Foliar spectral traits and fruit attributes determination

Foliar spectral traits were measured at mature fruit stage (July 19, 2021) on a sunny day during 10:00–11:00 am, with no irrigation or rainfall 1 week earlier. Normalized difference vegetation index (NDVI), greenness index (GI), optimized soil-adjusted vegetation index (OSAVI), photochemical reflectance index (PRI), normalized pigment chlorophyll index (NPCI), modified chlorophyll absorption ratio index (MCARI), and structure insensitive pigment index (SIPI) were measured on the 7th or 8th functional leaves on both south and north sides of each tree, using a portable plant reflectance spectrometer (PolyPen RP-410, Photon System Instruments, Drasov, CZ). Foliar spectral indexes were averaged over six reads from three trees (in one block) for each replication. Equations for calculation of these indexes are listed in [Supplementary Table S2](#). Computed data of these indexes were downloaded from the reflectance spectrometer via SpectraPen software 1.1.0.14 (Photon System Instruments, Drasov, CZ).

For each treatment, a total of 18 mature fruits were taken on south and north sides of three trees for the determination of fruit attributes on 19 July 2021. Fruit attributes of each replication were determined and averaged over six fruits from three trees in one block. Fruit thinning was evenly performed on all test trees, with the same level of fruit numbers on each tree. Thereby, it is assumed that single fruit weight could represent yield. Fruit transverse diameter and vertical diameter were determined by a Vernier caliper. Total soluble solid content was determined using a refractometer (RHBO-90, Link Co. Ltd., Taiwan, China). Soluble sugar content was determined with

anthrone-sulfuric colorimetric method ([Dreywood, 1946](#)). The contents of titratable acid, vitamin C, and nitrate were determined following national standards of GB 12293–90 (SBQTS 1990), GB 5009.86–2016 (NHFP 2016), and GB 5009.33–2016 (NHFP 2016), respectively.

2.3. DNA extraction, PCR amplification, and high-throughput sequencing

Soil samples (separately in two depths, 0–20 cm and 20–40 cm) were taken at six spots in root zone that were 1.5 m away from west side of three trees (in one block) and mixed together as one replication of each treatment on July 19, 2021. The collected samples were then transported to the lab in a box with ice packs, sieved (2 mm) and sent to Majorbio Bio-Pharm Technology Co. Ltd. with dry ice. Total bacterial community genomic DNA was extracted from 0.5 g fresh soil samples of surface (0–20 cm) and subsurface soils (20–40 cm). A pair of primers 338F (5'-ACTCCTACGGGAGGAGCAGCAG-3') and 806R (5'-GGACTACHVGGGTWTCTAAT-3') was used for bacterial 16S rDNA gene amplification in the hypervariable V3-V4 region. The polymerase chain reaction (PCR) was conducted with an ABI GeneAmp® 9,700 PCR thermocycler (ABI, CA, United States), with amplification conditions and PCR reaction mixture that can be found in [Sun et al. \(2022\)](#). PCR products were quantified using Quantus™ Fluorometer (Promega, United States) after purification. Purified amplicons were pooled in equimolar and paired-end sequenced on an Illumina MiSeq PE300 platform (Illumina, San Diego, United States) according to the standard protocols by Majorbio Bio-Pharm Technology Co. Ltd. (Shanghai, China). The obtained gene sequences from Illumina platform are deposited in the National Center for Biotechnology Information (NCBI) Sequence Read Archive with the accession number PRJNA835607.

The sequencing data were trimmed for barcodes and primers. Low-quality reads less than Q20 were removed ([Magoč and Salzberg, 2011](#)). The 18 test samples had a total number of 958,788 effective sequences with an average length of 417 bp. High-quality sequences were clustered into operational taxonomic units (OTUs) with a 97% similarity using UPARSE (1st version 7.1). RDP classifier (2nd version 2.2) was used for comparison of the representative sequence of each OUT to the database Silva (Release 115³) with a confidence threshold of 0.7 ([Wang et al., 2007](#)).

2.4. Data analysis

Analysis of variance (ANOVA) was conducted for foliar spectral traits (NDVI, GI, OSAVI, PRI, NPCI, MCARI, and SIPI), fruit attributes (single fruit weight, transverse diameter, vertical diameter, nitrate content, vitamin C, soluble sugar, titratable acid, and total soluble solid), and alpha diversity estimates (Sobs, Shannon, Simpson, ACE, and Chao1) as a function of three treatments at different soil depths using the PROC ANOVA procedure in the SAS statistical

1 <http://drive5.com/uparse/>

2 <http://rdp.cme.msu.edu/>

3 <http://www.arb-silva.de>

software package (SAS Institute Inc., Cary NC, United States). Shannon and Simpson estimate bacterial community diversity while ACE and Chao1 estimate bacterial community richness. Alpha-diversity metrics were assessed using Mothur (⁴version 1.31.2). Means were compared using the least significant difference test at the 5% probability level. The 30 most abundant genera at both soil depths of all treatments were compared *via* phyla stacked column diagram analysis in Origin 2021 (OriginLab Corporation, Northampton, MA, United States).

Bacterial genera in this study were firstly divided in identified or unidentified genera. The identified genera were then defined as abundant (>1%) or rare (<1%) genera. Beta-diversity of all treatments was calculated with the Bray–Curtis dissimilarity metric and visualized in a Principal Coordinates Analysis (PCoA) plot using R version 3.3.1 (Linux-GNU). Spearman correlation analysis was conducted between alpha diversity estimates (fruit attributes) and foliar spectral indexes and demonstrated in a heatmap *via* OriginLab. A redundancy analysis (RDA) was performed for relationships between foliar spectral indexes and fruit attributes in CANOCO 5.0. The manual forward-selection procedure was used to determine significance of soil characteristic variables ($p < 0.05$) using a Monte Carlo test with 499 permutations. Linear regression model was conducted to analyze the relations between foliar spectral indexes and alpha diversity estimates in OriginLab. Clustered heatmap analysis of the relations between foliar spectral indexes and the 30 most abundant genera were conducted using the pheatmap package in R (version 3.3.1, Linux-GNU).

Independent structural equation models (SEMs) were constructed at both soil depths, based on known effects and relationships among the drivers of plant productivity. Since some of the variables introduced were not normally distributed, the probability of a path coefficient differs from zero was tested using bootstrap resampling. Thus, data are randomly sampled with replacement to arrive at estimates of standard errors that are empirically associated with the distribution of the data found in the samples (Grace et al., 2010). For the structural model, we used the acceptable fit by Hair et al. (2019): Collinearity Statistics ($VIF \geq 5$, probable critical collinearity; $5 > VIF \geq 3$, possible collinearity; $VIF < 3$, ideally show). The best fit

SEM was accomplished *via* T Statistics ($T > 1.96$), p values ($p < 0.05$), root mean square error of approximation (SRMR; $SRMR < 0.08$), and Comparative fit index ($d_ULS < 0.95$ and $d_G < 0.95$) (Hair et al., 2019). All the SEM analyses were used SmartPLS (⁵ version 3.0).

3. Results and discussion

3.1. Linkage between foliar spectral traits and plant productivity characteristics

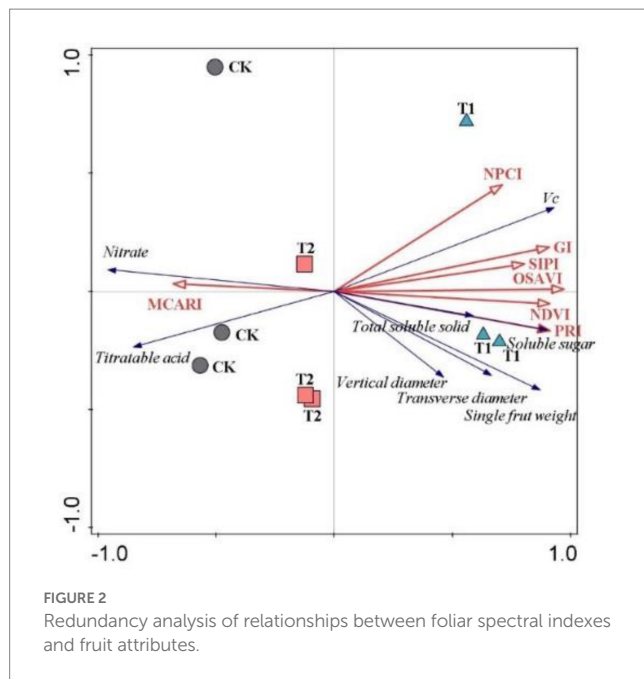

A previous study reported that spectral functional diversity of plant community explained 51% of the total variation of plant productivity ($r^2 = 0.51$, $p < 0.001$, Schweiger et al., 2018). This linkage between foliar spectral traits, functional, and evolutionary divergence provides the rationale for using spectral profiles in estimating biodiversity (Maherali and Klironomos, 2007; Cadotte et al., 2008; Hector et al., 2010). However, it is still challenging to choose spectral functional diversity indexes to capture the productivity of plant community that is location and time specific (Schweiger et al., 2018). Ultimately, the effects of biodiversity on plant community are a result of individual variation (Bolnick et al., 2011; Violle et al., 2012). Considering foliar spectral traits can be acquired relatively rapid on a regular basis than traditional protocols, we proposed to employ foliar spectral traits as indicators for plant productivity in orchard ecosystem.

In this study, RERP had positive effects on foliar spectral traits, fruit yield and quality ($p < 0.05$), with T1 a more efficient approach than T2 (Supplementary Tables S3, S4). Spearman correlation analysis revealed that selected spectral indexes of NDVI, GI, OSAVI, and PRI were significantly correlated to yield (single fruit weight) and quality (nitrate titrateable acid, Vc, soluble sugar, and total soluble solid contents) as shown in Figure 1. Previous studies reported similar results of foliar spectral traits in assessing plant attributes (productivity) in other semi-arid ecosystems. Vegetation indexes, such as NDVI, GI, and OSAVI, reflected information of leaf area index and chlorophyll content, and were often used in inversion of vegetation coverage and growth status (Li et al., 2009; Ferna et al., 2018; Yang et al., 2020). NDVI and OSAVI estimated green biomass and vegetative coverage in grass ecosystem (Ferna et al., 2018), while PRI estimates instant light use efficiency at leaf scale, which was used to track changes of photoprotective pigment pools and capture eco-hydrologic sensitivity of a mixed conifer forest (Yang et al., 2020). Daily PRI measurements could be used to track changes of photoprotective pigment pools as plants respond to seasonal environment change. OSAVI introduced the factor of bare land in the calculation, which was in accordance with the increased bare land area from agricultural practices (such as weeding and pruning) for better growing conditions and higher yield in the orchard (Shu, 2003). Meanwhile, these agricultural practices affected fruit availability of photosynthetically active radiation, and consequently fruit sensorial and nutritional quality (Gullo et al., 2014).

RDA analysis further revealed a relationship between spectral traits and plant productivity (Figure 2). T1 was distinct from CK and T2, indicating a profound effect of RERP with soil conditioner

⁴ <http://www.mothur.org/>

⁵ <http://www.smartpls.com>

(T1) on fruit yield and quality (Figure 3). The seven spectral indexes accounted for 94.3% in the first two constrained axes (axis 1 and 2 explained 83.15 and 11.15% of the variance, respectively). OSAVI was the only index that greatly contributed to the total variance (78.8%, $p = 0.002$). Spectral reflectance profiles are continuous representations of the interaction between electromagnetic radiation and matter across a range of wavelengths. In visible spectrum (400–700 nm), light is predominantly absorbed by leaf pigments (Ustin et al., 2009; Sul et al., 2013). Schweiger et al. (2018) also proved that spectral diversity (400–900 nm) was as predictive of ecosystem function as functional, phylogenetic or taxonomic diversity. Foliar spectral indexes were therefore used to assess biochemical traits that are significant in understanding plant growth and physiological status (Díaz and Cabido, 2001; Lavorel and Garnier, 2002; Wright et al., 2004; Asner et al., 2011; Lavorel et al., 2011). The results above suggested that plant productivity

embodied in fruit yield and quality in orchard ecosystem could reflect in foliar traits and be predicted by foliar spectral indexes.

3.2. Linkage between foliar spectral traits and soil bacterial alpha diversity

Individuals with distinct ecological phenotypes within a plant community may influence soil microbial community (Scheibe et al., 2015; Gehring et al., 2016). In fact, plant ecological phenotype was not only displayed as distinct physical structures (plant organ, tissue, and cell), but also reflected in the quantizable phenotypic parameters related to plant physiology and biochemistry (Ustin et al., 2009; Ustin, 2013; Scheres and Van Der Putten, 2017), such as foliar spectral traits (Schweiger et al., 2018). Although leaf and canopy optical data from imaging spectroscopy were incorporate into ecological studies (Asner et al., 2011; Doughty et al., 2017), foliar spectral traits were seldomly studied in association with belowground microbial diversity.

In the present study, RERP (T1 in particular) had positive effects on bacterial alpha diversity that were soil depth dependent (Supplementary Table S5). T1 significantly increased bacterial diversity (Shannon) and richness (ACE and Chao1) in both surface and subsurface soils, mainly due to increased nutrient availability (N, K, Ca, Mg, and Zn), soil organic matter content, water holding capacity, soil porosity, and decreased soil bulk density (Sun et al., 2022). Stronger correlations between foliar spectral indexes and bacterial alpha diversity were observed in surface soil than in subsurface soil (Figure 3). Each foliar spectral index was significantly correlated to at least one bacterial diversity and richness estimates. NDVI, GI, and OSAVI were significantly correlated to all bacterial diversity and richness estimates in surface soil, but only to ACE and Shannon in subsurface soil. OSAVI had the highest correlation coefficients with alpha diversity estimate, such as Sobs, ACE, and Chao1 in surface soil and ACE and Shannon in subsurface soil. PRI and NPCI, relevant to leaf photosynthesis were correlated to both diversity and richness estimates at both soil depths. Although MCARI and SIPI were pertinent to foliar pigments, MCARI was only significantly correlated to alpha diversity in surface soil, while SIPI was better indicative of Sobs and Chao1 in subsurface soil.

Correlation analysis revealed that bacterial alpha diversity estimates were correlated with foliar spectral indexes to different extents. It is not clear whether the relations could be quantified by reliable models for prediction of bacterial diversity. Linear regression model was then employed to quantify the association between soil bacterial diversity and foliar spectral indexes (Figures 4A,B). Regression analysis results suggested that foliar spectral indexes could be adopted to predict bacterial alpha diversity. The relationships between foliar spectral indexes and bacterial diversity estimates varied by soil depths and the specific index (estimate). OSAVI, GI, and MCARI in surface soil, and OSAVI, PRI, GI, and SIPI in subsurface soil could directly explain 53–92% variance of bacterial alpha diversity. Foliar spectral indexes were more indicative of bacterial richness estimates than diversity estimates in general. Similarly, Cavender-Bares et al. (2021) reported remotely sensed vegetation cover was positively correlated with Simpson in prairie ecosystem with high productivity in Wood River, while Aji et al. (2021) reported a weak correlation between a large scale NDVI and soil microbial biomass

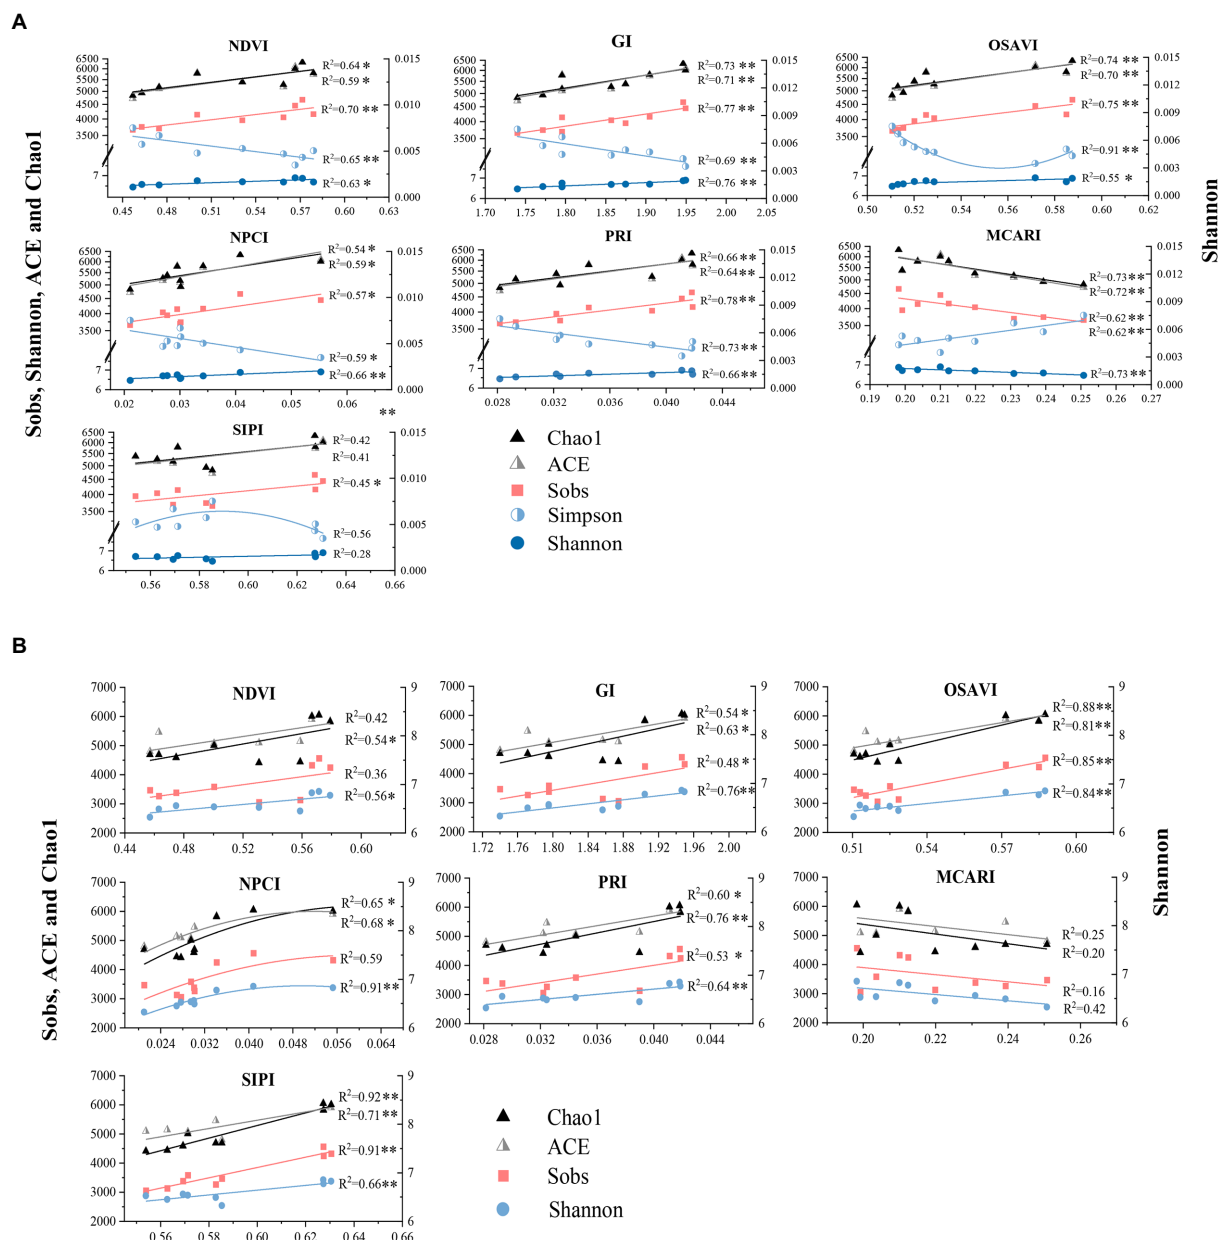

FIGURE 4

Linear regression analysis between foliar spectral indexes and alpha diversity estimates of bacterial community in surface (A) and subsurface (B) soils. * indicates significant correlation ($p < 0.05$), while ** indicates extremely significant correlation ($p < 0.01$).

in natural ecosystems (including lake area and protected forests) with minimum human disturbance. Generally, spectral indexes were more indicative of bacterial richness estimates than diversity estimates, and in subsurface soil than surface soil for all bacterial diversity estimates, except for Simpson. To date, few studies have been conducted on the association between specific spectral index and bacterial alpha diversity. In last decades, plant productivity was affected by declined microbial diversity from human activities and climate changes. This has triggered concerns of soil microbial diversity loss may impair key ecosystem functions with potential consequences on plant productivity (Cadotte, 2017; Schweiger et al., 2018; Chen et al., 2019). Therefore, avoiding or alleviating

the loss of soil microbial diversity is critical in ecosystem (Chen Q. et al., 2020).

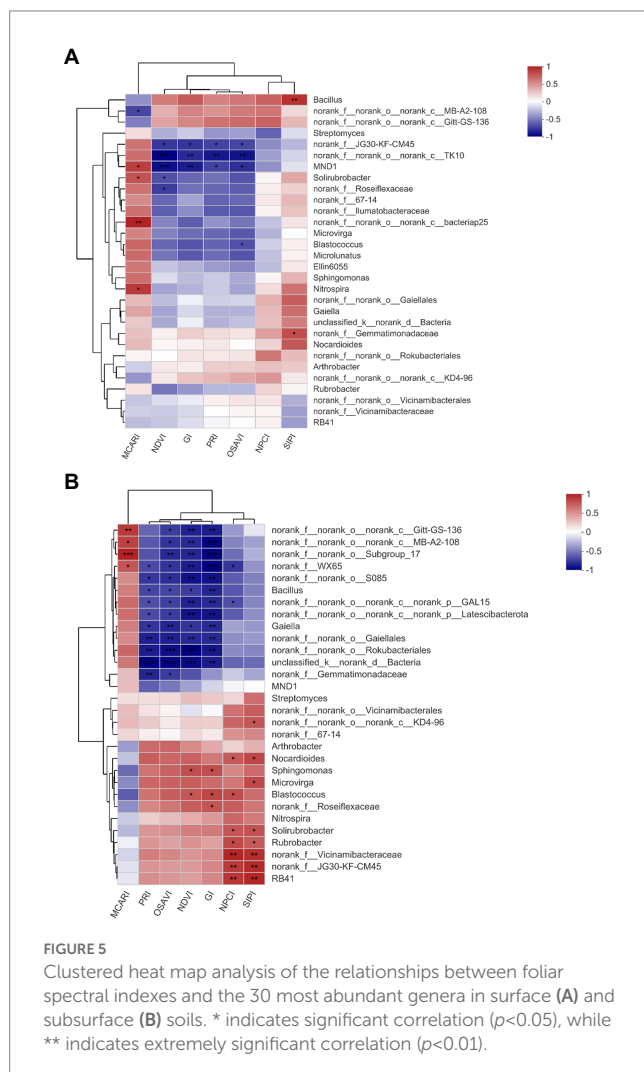

In this study, we draw the above conclusions based on the experimental orchard at the sampling time. Due to seasonal shifts in alpha diversity of soil bacterial community (Shi et al., 2015; Wagner et al., 2016), and in foliar spectral traits of deciduous trees in temperate arid and semiarid regions (Pederson et al., 2014), it is too early to decide if this quantified relations between foliar spectral traits and bacterial diversity can be applied at other growing stages of orchard ecosystem or to other ecosystems with the same spectral indexes at the same soil depths. Deeper understanding of specialized spectral indexes for further investigation of bacterial community variation is needed.

3.3. Linkage between foliar spectral traits and soil bacterial beta diversity

Soil bacterial assembly plays a more important role in driving soil bacterial and ecological functioning than bacterial alpha diversity (Bever et al., 2012; Bardgett and Van der Putten, 2014; Leff et al., 2018), which drove us into exploring whether and which foliar spectral traits could be employed as indicators of certain bacterial genera. RERP (both T1 and T2) significantly affected the bacterial composition on genus level in surface soil and subsurface soil (Supplementary Figure S1). Improved soil properties from RERP enriched certain genera (such as *Blastococcus*, *Bacillus*, *Sphingomonas*, and *Solirubrobacter*) in relation to increased soil nutrient content, organic matter, porosity, and water content (Sun et al., 2022). PCoA revealed larger discrepancy of bacterial community of three treatments in subsurface soil than in surface soil on genus level (Supplementary Figures S2A,B). In subsurface soil, 76.73% of the total variance was explained by the first two components. Samples of T1 were grouped together and distinct from samples of CK and T2. According to spearman correlation analysis (Figures 5A,B), more genera were in significant correlations with foliar spectral indexes in subsurface soil than in surface soil, possibly due to the frequent

agricultural practices that have reduced differences between treatments in the orchard, or the more bacterial functional redundancy in surface soil. *MND1* in surface soil, and nine genera in subsurface soil (*Bacillus*, *Gaiella*, *Nocardioides*, *Sphingomonas*, *Microvirga*, *Blastococcus*, *Solirubrobacter*, *Rubrobacter*, and *RB41*) were significantly correlated to at least one foliar spectral index (NDVI, GI, OSAVI, and PRI in particular). Furthermore, correlations between the same foliar spectral indexes and soil bacteria genera were interacted with soil depth. Some genera were only in significant relations with certain foliar spectral indexes in one soil layer, such as *MND1* in surface soil (absolute value of correlation coefficient: 0.72–0.90, $p < 0.05$), and *Gaiella*, *Nocardioides*, and *Rubrobacter* in subsurface soil (absolute value of correlation coefficient: 0.67–0.82, $p < 0.05$). Some genera had opposite and enhanced relations with foliar spectral indexes at these two soil layers. For instance, *Bacillus* was in positive relation with SIPI in surface soil (correlation coefficient: 0.80, $p < 0.05$), but in negative relations with NDVI, GI, PRI, and OSAVI in subsurface soil (correlation coefficient: -0.7 to -0.82 , $p < 0.05$). *Blastococcus* was in negative correlation with OSAVI (correlation coefficient: -0.67 , $p < 0.05$), but in positive relations with NDVI, GI, and NPCI (correlation coefficient: 0.68 to 0.75, $p < 0.05$). *Gaiella* (reduce nitrate to nitrite) were involved in N cycle, which could affect soil N content and plant growth that further reflect on foliar spectral characteristics (Asner et al., 2011; Sul et al., 2013; Sebin et al., 2014). *MND1* and *Nocardioides* were relevant to C and N nutrient cycling (Sul et al., 2013; Zhang et al., 2022) while *Solirubrobacter* were reported to affect sulfur availability for peach plants (Liu et al., 2022). *Microvirga* belong to α -proteobacterial that favored for nutritious soil (Sul et al., 2013). *Blastococcus* degrade organic material through proteolysis (Chen et al., 2016; Duan et al., 2019). *Sphingomonas* have been reported as plant growth promoting bacteria (Asaf et al., 2020; Chen L. et al., 2020) and was active in the biocontrol of pathogenic bacteria (Innerebner et al., 2011). According to previous studies, these bacterial genera in strong correlation with foliar spectral traits were those promoted soil nutrients (such as C, N, P, K, and S) cycling and uptake. This was supported by previous conclusion that foliar spectral profiles can reflect plant traits (including leaf structure, and the contents of pigments, nutrients and water) that were key to resource acquisition and stress tolerance (Sebin et al., 2014; Schweiger et al., 2018). Among these bacteria, genera with greater abundance discrepancy between treatments were in stronger correlations with foliar spectral indexes, indicating that leaf and canopy optical data were responsive to structural variance of bacterial community. It was speculated that these genera might have greater impact on aboveground plant.

However, we only investigated the 30 most abundant genera with relative abundances $>1\%$. Certain unidentified or abundances $<1\%$ genera may have played an over-proportional role in biological processes, and being the major drive for bacterial community multifunctionality (Chen L. et al., 2020). Incomplete knowledge of these bacteria hindered further illustration of their function and contribution to plant productivity. Functional redundancy may have covered the distinction of soil microbial community, and compensated ecological functioning and plant productivity of the orchard ecosystem, which could have interfered the investigation on the relations between bacterial components and foliar spectral traits. Under the assumption that these genera in significant correlation with foliar spectral traits were key to ecosystem functioning, further investigation is in need on if exogenous addition of these bacteria in

bio-organic fertilizer could improve plant productivity and ecological functioning in fruit orchards (Gottel et al., 2011; Lundberg et al., 2012; Wagner et al., 2016).

3.4. Structural equation models between foliar spectral traits and soil bacterial community

Structural equation modeling (SEM) analyzes the complex networks of causal relationships among multiple variables, which has been increasingly adopted in ecological sciences in the last decade (Grace et al., 2010; Eisenhauer et al., 2015). Four similar latent variables were employed in both soil layers, with three of them (bacterial diversity, abundant genera and unidentified or < 1% genera)

had soil-depth dependent indicators (Figures 6A,B). NDVI, PRI, GI, and OSAVI were best indicators of foliar spectral traits to detect bacterial diversity. Similarly, Delgado-Baquerizo et al. (2017) used NDVI as indicator of plant productivity, while Ferna et al. (2018) suggested NDVI and OSAVI as indicators of green biomass and coverage in a semi-arid rangeland. All variables were explained with different proportion of variance by the selected indicators. Generally, variables had higher R² value in surface soil than in subsurface soil. This is possible due to the interference from frequent agricultural practices which resulted in a less effective approach of RERP in topsoil. Meanwhile, correlation coefficients between indicators and variables were higher in surface soil, which was in accordance with the higher bacterial diversity in surface soil (Delgado-Baquerizo et al., 2017). Foliar spectral traits were in negative association with unidentified or < 1% genera, and in positive associations with all other

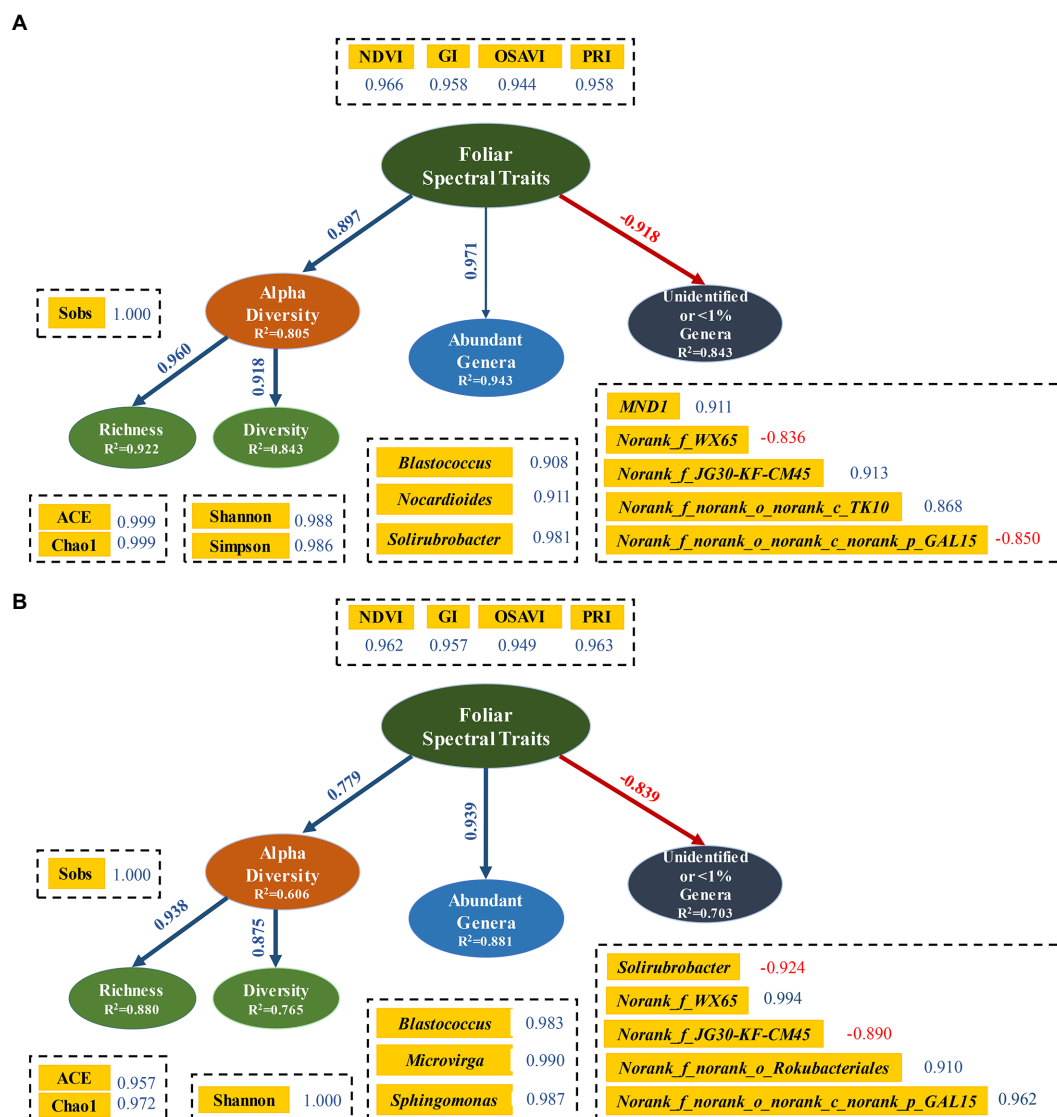

FIGURE 6

Structural equation models of relationships among foliar spectral traits, alpha diversity, abundant genera and rare genera in surface (A) and subsurface (B) soils. Blue lines indicate positive correlations. Red lines and numbers indicate negative correlations. Rare genera were with relative abundances <1%. Relationship between foliar spectral traits and abundant genera was not significant ($p=0.086$), indicating with a thin line, while all other relations were significant ($p<0.05$) with thicker lines.

variables. Furthermore, all path coefficients were extremely significant, except for association between abundant genera and foliar spectral traits in surface soil. This is likely due to the non-significant impacts of abundant genus in topsoil on plant growth, or functional redundancy from enriched abundant genera in topsoil, or the limited soil samples taken from the orchard.

Although experimental and observational databases in ecological studies are often complex, non-randomly distributed, and have spatial and temporal constraints (i.e., potential autocorrelations), SEM in this study indicated that foliar spectral traits (measured for peach productivity) were effective in predicting soil bacterial diversity and key genera. Latent variables, indicators and pathway coefficient of SEM in semi-arid peach orchard lay groundwork for further forecasting of bacterial diversity and structure in surface and subsurface soils. Environment, climate, and soil properties would all affect bacterial community and foliar spectral traits on a large scale. In this study, we focused on using foliar spectral traits to predict bacterial diversity at low cost, by using RERP to alter soil properties and obtain differentiated soil bacterial community (Sun et al., 2022). Since we conducted the field experiment in a peach orchard, the environmental and climatic factors were the same among treatments in this small scale. Although foliar spectral traits and soil microorganisms have obvious temporal dynamics, we selected the maturity period of experimental peach (July) as the critical timing for foliar spectral traits to represent productivity, since peach trees bear fruit only once a year in Beijing and the productivity of fruit trees is mainly reflected by fruit yield and quality. Spectral traits of typical leaves could then be used to characterize bacterial diversity and taxonomy. Of course, sampling on large scale with temporal dynamic are needed in order to obtain the general relationships between foliar spectra traits and soil bacteria community.

Generally, soil microbes were constrained by abiotic factors at large temporal and spatial scales, and by biotic factors at regional scale (Wang et al., 2015; Zhang et al., 2020). Ji et al. (2011) reported that cultivar, rather than tree age, played an important role in dominant bacteria community of rhizosphere soil in peach orchards in Shanghai. This has led us to the question: if the quantified linkage between foliar spectral indexes and soil bacterial community is applicable to other peach cultivar or to the same cultivar at different tree ages. Furthermore, can the quantified linkage be applied to other orchard ecosystems? Shao et al. (2020) reported eight deciduous fruit trees with different levels of metabolism and functional diversity of the soil bacterial community. Schweiger et al. (2017) also argued that spectral detectability of plant life/growth forms was dependent on the studied ecosystem and plant community. If this linkage can be extended to other fruit orchards, we could provide new insights into the mechanisms of optimizing plant productivity and maintaining plant community structure.

Hyperspectral measurements acquired from the method of airborne hyperspectral imaging in combination with high precision GNSS/IMU have improved spatial and spectral resolution to a centimeter level accuracy, which revealed messages that could not be recognized by RGB or multi-spectral imaging. Recently, plant functional diversity was reported better indicated by spectral indexes in red edge, near infrared, shortwave infrared regions and other hyperspectral images, rather than in visible region (Asner et al., 2017; Schneider et al., 2017; Schweiger et al., 2018; Ma et al., 2019; Cavender-Bares et al., 2021, 2022). In future research, foliar spectral characteristics in near and far infrared region could be further looked into for the

elucidation of broadened ecological linkages between foliar spectral characteristics and soil bacterial community in orchard ecosystem.

4. Conclusion

Foliar spectral traits are indicative of plant productivity and could be used to predict soil bacterial diversity in peach orchard. NDVI, GI, PRI, and in particularly OSAVI were selected as appropriate indicators of plant productivity. SEM revealed quantified linkages between foliar spectral indexes and bacterial richness, bacterial diversity, abundant genera, and unidentified or < 1% genera in both surface and subsurface soils. The results of this study enabled deeper understanding of the mechanisms in responses and adaptations of fruit trees to agricultural practices in the orchard ecosystem. Foliar spectral indexes could efficiently monitor soil bacterial diversity and functionality at low cost, with an ultimate goal of regulating plant physiological function by adjusting agricultural practices and the consequent microbial community accordingly.

However, additional information is in need on if the reliability of foliar spectral traits in predicting soil microbial community would be affected by plant species, environmental conditions and agricultural practices. A new concept of adopting foliar spectral traits as plant traits has simplified the research in exploring the associations between aboveground plant traits and belowground biodiversity at the scale of orchard ecosystem. With the scalability and repeatability of valid spectral indexes, this research could be scaled up to community, field, regional, and even terrestrial levels, to better realize the forecasting and regulating of aboveground and underground functionality in agricultural system, and further trade-offs of ecological and economical function in agroecological system.

Introduction: The fermentative production of auxin/indole 3-acetate (IAA) using selected *Pantoea agglomerans* strains can be a promising approach to developing novel plant biostimulants for agriculture use.

Methods: By integrating metabolomics and fermentation technologies, this study aimed to define the optimal culture conditions to obtain auxin/IAA-enriched plant postbiotics using *P. agglomerans* strain C1. Metabolomics analysis allowed us to demonstrate that the production of a selected.

Results and discussion: Array of compounds with plant growth-promoting- (IAA and hypoxanthine) and biocontrol activity (NS-5, cyclohexanone, homo-L-arginine, methyl hexadecenoic acid, and indole-3-carbinol) can be stimulated by cultivating this strain on minimal saline medium amended with sucrose as a carbon source. We applied a three-level-two-factor central composite design (CCD) based response surface methodology (RSM) to explore the impact of the independent variables (rotation speed and medium liquid-to-flask volume ratio) on the production of IAA and IAA precursors. The ANOVA component of the CCD indicated that all the process-independent variables investigated significantly impacted the auxin/IAA production by *P. agglomerans* strain C1. The optimum values of variables were a rotation speed of 180 rpm and a medium liquid-to-flask volume ratio of 1:10. Using the CCD-RSM method, we obtained a maximum indole auxin production of 208.3 ± 0.4 mg IAA_{equ}/L, which was a 40% increase compared to the growth conditions used in previous studies. Targeted metabolomics allowed us to demonstrate that the IAA product selectivity and the accumulation of the IAA precursor indole-3-pyruvic acid were significantly affected by the increase in the rotation speed and the aeration efficiency.

Pantoea agglomerans, metabolomics, response surface methodology, postbiotics, plant growth-promoting rhizobacteria, auxin

Introduction

World population growth (UN, 2017), the effect of climate change on the global food systems (Myers et al., 2017), the COVID-19 pandemic (Mardones et al., 2020), and the impact of the war in Ukraine on the global energy market, the grains supply, and the food prices (Toffelson, 2022) are critical challenges for today's agriculture. Within this framework, the use of plant biostimulants has generated significant interest, and, among biostimulants, plant growth-promoting (rhizo)bacteria (PGPR or PGPB) look very promising to develop more efficient and sustainable production methods (Calvo et al., 2014; Ruzzi and Aroca, 2015; Rouphael and Colla, 2018).

PGPB are a heterogeneous group of endophytic and epiphytic bacteria associated with plant tissues and plant surfaces which can positively affect the health and growth of plants (Glick, 2012; de Souza et al., 2015). They can increase crop tolerance against abiotic stresses and improve nutrient use efficiency, plant health, productivity, and yield at different stages (Bulgari et al., 2015; Toscano et al., 2018). They exert beneficial effects on plants through direct and indirect mechanisms, which range from changes in hormonal content to the production of volatile organic compounds, the increase in nutrient availability, or the enhancement of abiotic stress tolerance (Ruzzi and Aroca, 2015; Oleńska et al., 2020).

So far, the European Union Regulation (EU) (2019)/1009 authorizes, as "microbial biostimulants," the use of bacteria belonging to only three taxonomic groups, namely, *Azotobacter*, *Azospirillum*, and *Rhizobium* [European Union Regulation (EU), 2019/1009]. These constraints preclude and limit the development of novel biostimulants that contain PGPR belonging to different taxonomic groups. A microorganism belonging to Risk Group I, according to the European Parliament Directive 2000/54/EC, is unlikely to cause disease in humans, animals, or plants, which does not mean that its presence could not affect the microbial biodiversity or, under critical life circumstances (e.g., an impaired health status), the health of a higher organism.

In many cases, in both humans and plants, health-promoting traits are associated with the production of soluble and volatile metabolites secreted in the culture medium. Recently, in the human sector, it has been introduced a new class of dietary biotics, the postbiotics or metabiotics. In 2021, the panel of experts designated by the International Association of Probiotics and Prebiotics (ISAPP) defined these products as a "preparation of inanimate microorganisms and/or their components that confer a health benefit on the host" containing "inactivated microbial cells or cell components, with or without metabolites, that contribute to observed health benefits" (Salminen et al., 2021). Bioactive compounds generated by fermentation using PGPR can represent a valuable approach to developing a novel class of biostimulants with higher safety and a lower environmental impact and studying the host plant response to PGPR's metabolites at the molecular level.

Regarding the production and activation of phytohormones by which plant growth is prompted, indole-3-acetic acid (IAA) is the primary auxin endogenously synthesized by PGPR with an essential effect on plant growth and development processes, such as cell elongation and organogenesis, and tropic responses (Woodward and Bartel, 2005; Teale et al., 2006; Halliday et al., 2009). Auxin contributes to root initiation, helps loosen plant cell walls to release exudates,

stimulates root hair overproduction, increases lateral root formation, acts as a signaling molecule to both the plant and bacteria, aids in root elongation (Kasahara, 2016), and in the developmental response to stress (Bielach et al., 2017) and other environmental stimuli (Zwiewka et al., 2019). In plant tissues, the auxin responses are concentration-dependent, and different cells respond very differently to exogenous auxins (Paponov et al., 2008).

Indole auxin production by microbial isolates changes among different species and strains of the same species and is influenced by culture conditions, growth stage, and substrate availability (Duca et al., 2014). The presence of tryptophan, vitamins, salt, pH, temperature, carbon source, nitrogen source, and growth phase contribute to regulating auxin/IAA biosynthesis (Ryu and Patten, 2008; Swain and Ray, 2008; Apine and Jadhav, 2011; Bharucha et al., 2013; Peng et al., 2014; Luziatelli et al., 2020a). Plant exudates or specific compounds present in the rhizosphere are among the factors influencing bacterial auxin/IAA biosynthesis. Therefore, the mechanisms involved in the control of biosynthesis of IAA and indole-related compounds require a complete understanding.

Various IAA biosynthetic pathways have been proposed in plant-associated bacteria (Spaepen and Vanderleyden, 2011; McClerklin et al., 2018). Tryptophan is a major effector of IAA biosynthesis, considering most IAA biosynthesis pathways begin with tryptophan. Tryptophan-dependent pathways comprise the indole-3-acetamide (IAM), indole-3-pyruvic acid (IPyA), indole-3-acetonitrile (IAN), tryptamine (TAM), and tryptophan side-chain oxidase (TSO) pathways (Duca et al., 2014; Di et al., 2016). Organic nitrogen sources have been observed to promote auxin/IAA production more than inorganic nitrogen sources, and this may be due to the increased availability of tryptophan from proteins.

The application of the genus *Pantoea* as a biocontrol agent has been increasingly investigated, and exciting results have been obtained. Strains belonging to *Pantoea agglomerans* species are frequently found in association with plant hosts (Walterson and Stavrinides, 2015). These microorganisms are agronomically relevant for their plant-growth-promoting (PGP) features, biocontrol activity, and involvement in plant disease management (Dutkiewicz et al., 2016).

The PGP activities of *P. agglomerans* strains have been investigated through different application modes and under diverse experimental conditions (e.g., glasshouse, field, pots, greenhouse, etc.; Nunes et al., 2002; Feng et al., 2006; Venkadesaperumal et al., 2014; Moustaine et al., 2016; Paredes-Páliz et al., 2016; Kamran et al., 2017; Ozaktan et al., 2017; Xie et al., 2017; Saia et al., 2020; Luziatelli et al., 2020a,b).

Recently, we demonstrated by comparative genomic analysis high levels of conservation within genes of the IPyA pathway in this species. Independently from the natural environment from which the strain was isolated, in most of the sequenced genomes of isolates belonging to *P. agglomerans* species (45 out of 50), the genes encoding enzymes of the IPyA pathway share an identity higher than 95% over the full length of the sequence (Luziatelli et al., 2020a). This high sequence conservation has never been reported for IAA genes belonging to other species underlining that the production of auxin/IAA plays an important role in the interaction between *P. agglomerans* and host plants (Luziatelli et al., 2020a).

Optimizing the physical and chemical environmental factors that affect a fermentation process (such as temperature, pH,

aeration, and medium composition) is crucial for maximizing the yield of a specific bioproduct (Schmidt, 2005; Singh et al., 2017). Several optimization approaches can be used for this purpose, but the most common is the one-factor-at-a-time (OFAT). This approach offers the advantage of measuring whether a factor has any effect on the microbial production of the desired product and affects the metabolic traits of the producing strain (Singh et al., 2011). For the same reason, classical studies on comparative metabolomics mainly focus on the metabolic changes associated with the variation of an environmental factor only (Putri et al., 2013). The major downside of using OFAT is that it requires many experimental runs and is time-consuming and expensive, particularly in fermentation processes (Panda et al., 2007) and metabolomics analysis. Moreover, OFAT is not adequate for investigating the interaction between different variables. This limitation can be overcome using a statistical approach such as Response Surface Methodology (RSM). The latter is a useful multivariate statistical tool that allows one to design experiments, construct models, evaluate the combined effect of two or more parameters, and search for optimum conditions for desirable responses (Bezerra et al., 2008; Breig and Luti, 2021). RSM has been widely exploited to optimize fermentation processes, but surprisingly it has not been used in combination with metabolomics. This is probably because metabolomics (particularly untargeted metabolomics) is used when no *a priori* metabolic hypothesis is available (Gertsman and Barshop, 2018). At the same time, a proper selection of the factors ranges for designing the experimental matrix needs prior knowledge of the genetics and physiology of the microorganism (Breig and Luti, 2021).

Few studies are available on the process optimization of indole auxin production in *P. agglomerans* and other PGPB (Apine and Jadhav, 2011; Chaiharin and Lumyong, 2011; Balaji et al., 2012; Bharucha et al., 2013; Tallapragada et al., 2015; Bhutani et al., 2018; Myo et al., 2019; Luziatelli et al., 2021). Furthermore, there are no reports on the effect of the medium aeration on the *in vitro* production of indole auxin and, except for Luziatelli et al. (2020a), none of the above-mentioned studies has evaluated the impact of the culture conditions stimulating IAA synthesis on the production of other metabolites involved in pathways associated with PGP traits. *In vitro* studies carried out on *Pyrus communis* shoots demonstrated that *P. agglomerans* strain C1 produces metabolites that act in synergy with auxin, accelerating the adventitious roots (AR) formation when auxins are present, increasing the number and length of AR primordia that develop from stems, and modifying the response of the pear plant to exogenous auxins (Luziatelli et al., 2020c). These data suggest that in the development of an auxin-enriched plant postbiotic, the auxin/IAA concentration is not the unique parameter that should be considered.

The main goal of the present study was to optimize the auxin production in *P. agglomerans* strain C1 and evaluate the effect of the optimum conditions on the metabolites secreted in combination with auxin. To this aim, we investigated, by central composite design (CCD) combined with RSM, the effect of aeration efficiency and medium composition on auxin production. In combination with RSM-CCD, we also used a targeted and untargeted metabolomics approach to evaluate the effect of the growth conditions on the auxins profile and the production of metabolites potentially involved in the plant-microbe interaction.

Materials and methods

Bacterial strain and culture media

Pantoea agglomerans strain C1 was previously isolated from the phyllosphere of lettuce (*Lactuca sativa* L.) plants treated with vegetal-derived protein hydrolysates (Luziatelli et al., 2016, 2019a). Working cultures were routinely grown at 25°C on Lennox broth (LB; composition per liter: tryptone 10g, yeast extract 5g, NaCl 5g; Lennox, 1955); and stored at −80°C as stock cultures, using glycerol (20% w/w) as a cryoprotectant. For auxin production, the strain was cultivated in a medium amended with 4 mM tryptophan (Trp), using either LB or a saline M9-sucrose broth (YES; composition per liter: M9 minimal salts 1× yeast extract 5g, and sucrose 5g). Tryptophan was prepared as 40 mM stock solution in mildly alkaline water, filter sterilized (0.22 µm), and stored in the dark at 4°C. All culture mediums were sterilized by autoclaving at 121°C for 20 min. Tryptone and yeast extract were purchased from BD Difco (Thermo Fisher Scientific, MA, United States), and sucrose and chemicals were procured from Sigma-Aldrich (Merck KGaA, Darmstadt, Germany).

Culture conditions

Pre-cultures were prepared by inoculating 50 mL of LB with 500 µL of a frozen (−80°C) stock culture. Cells were grown at 25°C in agitation (150 rpm) until the late exponential phase of growth (10⁸ CFU/mL) using an INFORS HT Multitron incubator (Infors AG, Bottmingen, Switzerland). Aliquots of the pre-culture were transferred into 250 mL Erlenmeyer flasks containing YES medium broth amended with Trp to obtain an initial OD₆₀₀ of 0.1 and were incubated at 25°C for 24 h. The total medium volume (mL) per flask and the agitation speed (rpm) were varied according to the experimental design described below (Table 1). To avoid any interference due to the flask geometry and type of closure, all experiments were carried out using (i) 500 mL Erlenmeyer flasks for strain pre-activation experiments, (ii) certified 250 mL narrow-neck Erlenmeyer flasks corresponding to the ISO 1773:1997 specifications (external diameter of bottom and neck of 85 ± 2 and 34 ± 1.5 mm, respectively), and (iii) T-32 silicon plugs with bubble sponge, for optimization of auxin/IAA production. Culture volume and vessels affect physiological responses and genetic stability in several microorganisms, such as *Escherichia coli* (Kram and Finkel, 2014; Gross et al., 2020).

TABLE 1 Range and levels of experimental variables of the two sets of experiments.

Factor	Experimental design no. 1			Experimental design no. 2		
	Actual levels of coded factors			Actual levels of coded factors		
	−1	0	+1	−1	0	+1
Rotation speed (rpm)	100	140	180	160	180	200
Medium volume (mL)	25	62.5	100	10	25	40

Factorial design for cell growth

The experimental design was established by using the DOE software package MODDE ver. 12 (Sartorius, Göttingen, Germany) as reported elsewhere (Luziatelli et al., 2019b). The Response Surface Methodology (RSM) method was used to determine the optimum level of each variable, and the combination thereof allowed the maximum productivity of auxin. Rotation speed (rpm) and liquid medium volume (mL) were set as factors. Cell biomass (OD_{600}) and auxin production (mg/L) were set as responses. Figure 1 shows the procedure used to develop the RSM design matrix and find optimum values for the input process parameters.

In the first experimental design, two ranges of values were set for the relevant factors (i.e., rotation speed and medium volume), as shown in Table 1. Each independent variable was tested at three levels, indicated as -1 (low level), 0 (central level), and $+1$ (high level).

According to the first Central Composite Design (CCD1), 20 experimental runs were executed, with four center value replications, and the observations were fitted to the following second-order polynomial model:

$$Y = \beta_0 + \beta_1(X_1) + \beta_2(X_2) + \beta_{11}(X_1^2) + \beta_{22}(X_2^2) + \beta_{12}(X_1X_2).$$

Where: Y is the dependent variable (indole auxins production); X_1 and X_2 are the coded independent variables (rotation speed and medium volume); β_0 is the regression coefficient at the center point; β_1 and β_2 are the linear coefficients; β_{11} and β_{22} are the quadratic coefficients; β_{12} is the second-order interaction coefficient. The developed regression model was evaluated by analysis of variance (ANOVA) and p - and F -values. The quality of the fit of the polynomial model equation was expressed by the coefficient of determination, R^2 . The significance of all terms in the polynomial was judged statistically by computing the F value at a probability (p) of 0.05. The regression coefficients were used to make statistical calculations to generate response surface curves from the regression models. To test the model accuracy, R^2 and adjusted R^2 were estimated.

Based on the results of the first round of experiments, a second experimental design was set by MODDE ver. 12 by centering on the agitation speed of 180 rpm and the volume of 25 mL. The RSM-CDD (CDD2) comprised a total of 18 experimental runs. The two ranges of value for the relevant factors set in the second experimental design are shown in Table 1.

All experiments were carried out in duplicate in the standard conditions previously defined: growth in YES-Trp medium for 24 h; cultivation in a rotary shaker at 25°C using 250 mL narrow-neck Erlenmeyer flasks with T-32 silicon plugs.

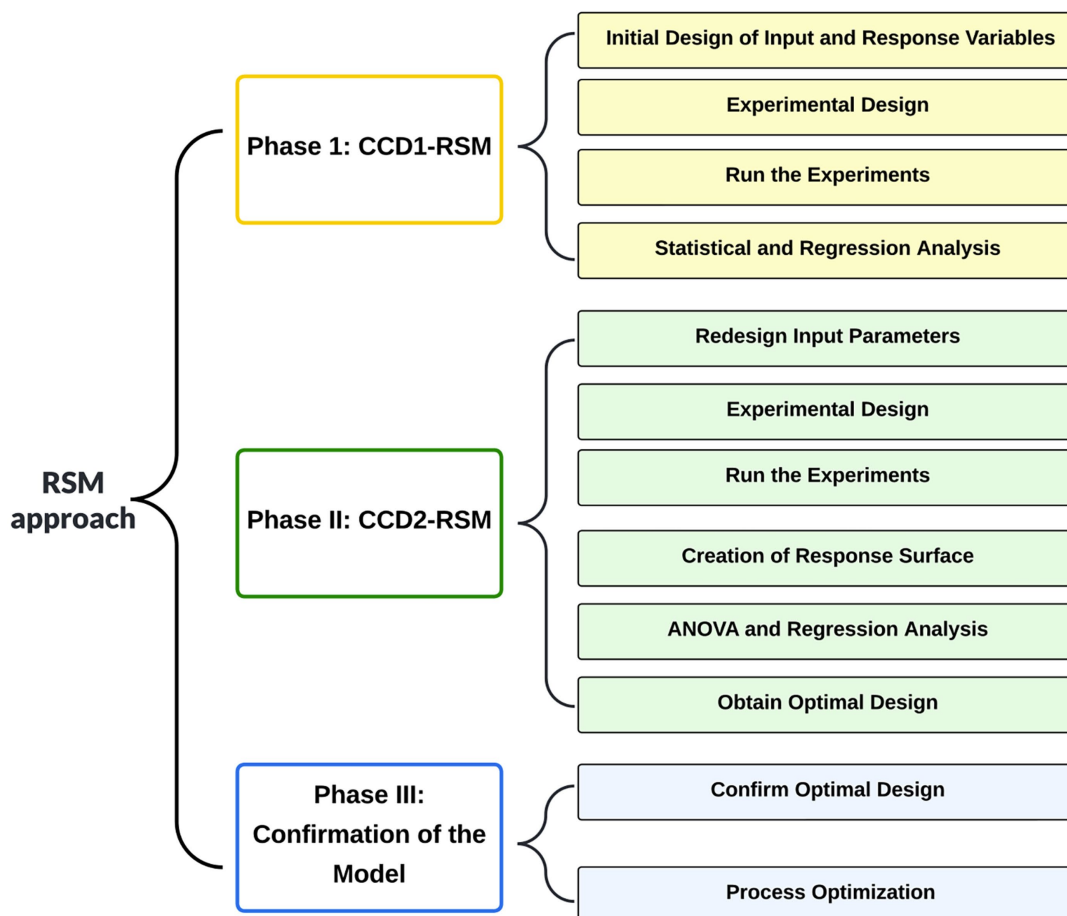

FIGURE 1
Flowchart of the Response Surface Methodology (RSM) modeling approach.

Spectrophotometric estimation of indole auxins

Auxin production was measured in the cell-free spent medium using a colorimetric assay with Salkowski's reagent (Patten and Glick, 2002). Briefly, cell culture was centrifuged at 10000 rpm for 10 min in a multispeed centrifuge (Thermo Fisher Scientific, Waltham, MA, USA), and the supernatant was recovered and filter-sterilized (0.22 µm). An aliquot (1 mL) of the supernatant, diluted as needed, was mixed vigorously with 2 mL of Salkowski's reagent (0.5 M FeCl₃, 35% v/v HClO₄), and the mixture was incubated at room temperature for 20 min in the dark. The developed pink color was read at 530 nm. Total indole auxins were quantified by using a calibration curve of pure indole-3-acetic-acid (Sigma-Aldrich, Milan, Italy) as a standard. Data were expressed as µg IAA equivalents (IAA_{equ}) per mL of liquid culture. No reaction product was determined using not inoculated medium amended with tryptophan as a control.

Footprinting of extracellular metabolites

The effect of the growth medium on the extracellular metabolites was tested by cultivating *P. agglomerans* strain C1, at optimal growth temperature (30°C), on LB and YES medium supplemented with Trp (4 mM). Exhausted liquid broth samples (1 mL) were extracted in 5 mL of cold (−20°C) acidified (0.1% HCOOH) 80:20 methanol:water using an Ultra-Turrax (Ika T-25, Staufen, Germany), centrifuged at 1,200 rpm and filtered through a 0.2 µm cellulose membrane. The analysis was carried out on an Agilent 6550 Q-TOF with ESI source (Agilent Technologies, Santa Clara, CA, United States), coupled with an Agilent 1290 UHPLC, as reported elsewhere (Luziatelli et al., 2020a). 2 µL of each sample were injected on a reversed-phase Acquity ethylene-bridged hybrid (BEH) HILIC C18 column (100 mm × 2.1 mm, 1.7 µm, Waters, Milford, MA, USA). A pooled quality control was obtained by mixing 10 µL of each sample and acquired in tandem mass spectroscopy mode using iterative function five consecutive times to increase the number of compounds with associate MS2 spectra.

The raw data were processed with the procedure described by Blaženović et al. (2019). Compounds identification was based on accurate mass and isotopic patterns and expressed as an overall identification score. Chemical Similarity Enrichment Analysis (ChemRICH) was performed, as described by Barupal and Fiehn (2017), and statistical significance *p*-values were obtained by self-contained Kolmogorov–Smirnov tests.

Auxin profiling

In targeted metabolomics, chromatographic separation, MS, and MS/MS acquisition parameters were carried out following the FiehnLab HILIC protocol, as previously described (Blaženović et al., 2018; Teleki and Takors, 2019). The injection volume was 2 µL, whereas Q-TOF was operated in positive SCAN mode (100–1,700 *m/z* + range) and extended dynamic range mode. All samples were injected in three biological replicates with three technical replicates each (total 9 injections/sample). Deconvolution, mass and retention time alignment, normalization, blank filtering, and

identification were carried out using the Agilent Mass Hunter Quantitative Analysis software for Q-TOF version B.09. Standards for quantification and identification of Trp, IAA, and IPyA were purchased from Sigma-Aldrich. Three dilutions were prepared in duplicate with a concentration of 10, 100, 500, and 1,000 ppm from each standard to calculate the calibration curve, reaching an *R*² of 0.999 in all compounds.

Statistical analysis

Differences between treatment groups were compared using the One-way analysis of variance (ANOVA) test, followed by Tukey's honestly significant difference (HSD) test with significance set at *p* < 0.05.

Results

Effect of growth medium composition on exometabolome

As demonstrated in previous work (Luziatelli et al., 2020a), the production of IAA by *P. agglomerans* strain C1 is affected by the carbon source and the incubation temperature. Higher auxin levels were obtained by growing C1 strain on an M9 saline medium with sucrose (YES) as a carbon source under suboptimal temperature conditions (25°C; Luziatelli et al., 2020a). In this work, we comprehensively characterized strain C1 exometabolome of cultures grown on a medium amended with tryptophan as an auxin/IAA precursor. UHPLC-ESI-Q-TOF-MS analysis of the exhausted growth medium revealed a total of 204 features: 16 were more than two-fold higher, and 54 were more than two-fold lower, changing the cultivation medium from LB+Trp to YES+Trp (Figure 2; Supplementary Table S1). Comparing the metabolomic datasets of cultures grown on LB and YES medium by Chemical Similarity Enrichment Analysis (ChemRICH), we observed a significant increase in IAA (5.4 folds), indole-3-carbinol (3.9 folds), quinoline (2.8 folds), cyclohexane derivatives shifting from LB to YES (Supplementary Table S1). Under the same conditions, a significant decrease of IAA precursors (i.e., indole-3-acrylic acid, indole acetaldehyde, indole-3-acetamide, and indole-3-carboxylic acid) was observed (Supplementary Table S2). Growth in the YES medium also determined a significant variation in the hypoxanthine/xanthine ratio due to a 4.8-fold increase in hypoxanthine concentration and a 105-fold decrease in xanthine. Other metabolites, whose production was stimulated on YES medium, included compounds with antimicrobial activity such as the β-lactam antibiotics NS-5 and 2-hydroxyethylclavam, the cyclohexanone, the homo-L-arginine, and the methyl hexadecanoic acid.

Effect of oxygen availability on biomass and auxin yield

The effect of oxygen availability on cell biomass and auxin production was evaluated on YES medium using a shake-flask methodology by varying medium liquid-to-flask volume ratio

FIGURE 2

ChemRich analysis of exometabolome of *Pantoea agglomerans* C1 grown on YES vs. LB medium. Red clusters are associated with higher outcomes, and the blue ones are associated with lower outcomes.

(V_m/V_f) and rotation speed (rpm). Data reported in Figure 3A indicated that an increase in the biomass yield (OD_{600}) occurred upon increasing the gas–liquid interfacial area by either changing the V_m/V_f ratio (from 1:2.5 to 1:10) or the rotation speed (from 100 to 180 rpm). OD_{600} varied between 3.4 ± 0.0 and 6.4 ± 0.1 , and the highest biomass production ($OD_{600} = 6.45$) was achieved at 180 rpm and V_m/V_f ratio of 1:10 (Table 2, run 4). At all V_m/V_f ratio values, no significant change in the OD_{600} was measured by increasing the rotation speed from 100 to 140 rpm. As expected, at 180 rpm, the increase in the biomass yield was more marked (OD_{600} from 4.2 ± 0.0 and 6.4 ± 0.1) by increasing the V_m/V_f ratio from 1:2.5 to 1:10 (Figure 3A).

Data reported in Figure 3B indicated that the aeration efficiency of the culture medium, dependent upon the rotation speed and liquid-to-flask volume ratio, also affected the extracellular concentration and specific productivity of auxin. When the oxygen availability was lower (lower rotation speed and higher medium liquid-to-flask volume ratio), a lower amount of auxin was obtained. At all agitation regimes, higher auxin values were achieved using a 1:10 medium liquid-to-flask volume ratio (Figure 3B). The highest auxin titer (208.0 ± 2.0 mg of IAA_{eq}/L) and specific productivity (32.6 ± 0.1 mg of $IAA_{eq}/L/OD_{600}$) mean values were obtained at 180 rpm with 25 mL of liquid culture in a 250 mL flask (run 4 and 20; Table 2).

Optimization of auxins production by RSM

To evaluate more precisely the effect of oxygen availability on auxin yield, a second experimental design centered on the agitation speed of 180 rpm and the liquid-to-flask volume ratio of 1:10 was performed. Predicted and observed data of CCD No. 2 for biomass (OD_{600}) and auxins production (mg/L) are reported in Table 3.

The results obtained with the experiments scheduled in the CCD2 confirmed that the highest auxin values (208.0 ± 0.2 mg of IAA_{eq}/L) were achieved when the C1 strain was grown at 180 rpm with 25 mL of liquid culture (1:10 medium liquid-to-flask volume ratio) in a 250 mL flask (run 9 and 18; Table 3).

The experimental results were fitted to a second-order polynomial quadratic equation. A multiple correlation analysis was done, and the following equation was thus obtained:

$$Y = 206.94 - 6.85 X_1 - 6.31 X_2 - 16.44 X_1^2 - 26.76 X_2^2 + 3.53 X_1 X_2$$

where Y was the predicted auxin concentration, and X_1 and X_2 were the coded values for medium volume and rotation speed, respectively.

FIGURE 3

Effect of the rotation speed on biomass (A) and auxin yield (B) by *Pantoea agglomerans* strain C1 in shake-flask cultivation experiments carried out at a liquid-to flask V_m/V_f ratio of 1:2.5 (low) and 1:10 (high).

Statistical analysis results, including the regression coefficient and p -values for linear, quadratic, and interaction effects, are shown in Table 4.

The multiple regression analysis of auxin production showed that the model was significant ($p < 0.05$) and did not present a lack of fit ($p = 0.04$). The regression-based determination of R^2 was evaluated to test the model equation's fit. The R^2 value, which always ranges between 0 and 1, provided a measure of how the experimental factors and their interactions can explain much variability in the observed response values. In this study, the multiple coefficients of determination (R^2) for auxin production were 0.974, which means that the model can account for 97.4% of the variability in the response. The adjusted R^2 of 0.964 corrects the R^2 value for the sample size and the number of terms in the model. The Q^2 value, which provides a qualitative measure of consistency between the predicted and original data, was equal to 0.943, indicating that the model has good predictive relevance.

A response surface was also produced to determine each variable's optimum level for maximum productivity response and the combined effect of rotation speed and medium-to-flask volume ratio on auxin production (Figure 4). The graphical representation was a useful method to visualize the relationship between the response and the experimental levels of each variable and the type of interaction between test variables to deduce the optimum conditions. Response surface and contour plots showed that the highest auxin production (>205 mg IAA_{equ}/L) occurred when rotation speed ranges between 165 and 186 rpm and volume ranges from 17.25 to 29.25 mL. Above and below the ranges specified for rotation speed and volume, auxin production decreased, and lower values were obtained.

The objective of the application of RSM to C1 strain growth was to determine the levels of experimental factors which would allow obtaining the highest auxin production. The model allowed the prediction of an auxin production of 207.3 mg IAA_{equ}/L when optimal growth conditions, that is, 176 rpm and 24 mL medium volume, were applied. To validate the predicted model, five experiments were thus conducted at these optimum growth conditions, and the results showed a close match (208.3 ± 0.4 mg IAA_{equ}/L).

Effect of cultivation conditions on auxin profile

Targeted metabolomics provided insights into the effect of the culture conditions on the levels of IAA and its main precursor, indole-3-pyruvic acid (IPyA; Figure 5). After 24 of growth at 180 rpm, IPyA accumulated in the culture medium at a concentration between 0.12 ± 0.0 mM (and V_m/V_f ratio of 1:2.5) and 0.5 ± 0.0 mM (V_m/V_f ratio of 1:10; Figure 5A).

At a V_m/V_f ratio of 1:10, we observed an increase in the IPyA concentration (from 0.2 ± 0.0 to 0.5 ± 0.0 mM; Figure 5B) and a decrease in the IAA/IPyA ratio (from 5.2 ± 0.1 to 1.8 ± 0.1 ; Table 5) by increasing the agitation speed from 160 to 200 rpm.

At constant agitation speed (180 rpm), we observed that the accumulation of IAA and IPyA were inversely correlated to the culture volume. The IAA/IPyA ratio increased (from 1.5 ± 0.0 to 3.0 ± 0.1) by decreasing the culture volume from 100 ($V_m/V_f = 1:2.5$) to 25 ($V_m/V_f = 1:10$; Table 5).

TABLE 2 Experimental design No. 1 and results of CCD1-RSM.

Run	Factor		Volume ratio V_m/V_f	Observed response		Predicted response		Auxin spec. productivity (mg IAA _{equ} /L/ OD ₆₀₀)
	Rotation speed (rpm)	Medium volume (mL)		Biomass (OD ₆₀₀)	Auxin (mg IAA _{equ} /L)	Biomass (OD ₆₀₀)	Auxin (mg IAA _{equ} /L)	
1	(0) 140	(−1) 25.0	1:10	6.11	163.21	5.99	158.97	26.71

Coded (in parentheses) and real values are shown.

The sum of IAA and IPyA concentrations was affected by both parameters. It was maximal (1.5 ± 0.1) at a working volume of 25 mL in a 250 mL flask ($V_m/V_f = 1:10$) and an agitation speed of 180 rpm (Figure 5).

The change in tryptophan (Trp) concentration (the precursor of IPyA and IAA; Table 5) was not consistent with the total content of IAA + IPyA (Figure 5). In almost all culture conditions, the moles of products (IAA + IPyA) obtained per moles of the substrate (Trp) were not equal to 1. Notably, at $V_m/V_f = 1:10$ (25 mL) and 160 rpm, only part of the consumed Trp was converted to IAA and IPyA (Table 5). In contrast, increasing the agitation speed up to 180 or 200 rpm, the final concentration of Trp after 24 h of growth was higher or equal to that of the not inoculated broths (Table 5), indicating that higher agitation speeds (up to 180 rpm) promote the biosynthesis of both IAA (Table 4) and Trp (Table 5).

Discussion

The production of phytohormones such as auxin is one of the central mechanisms beneficial bacteria use to enhance plant growth. Selection of the culture medium and optimization of the culture parameters that affect the biosynthesis of these compounds is thus pivotal to obtaining plant probiotics based on auxin and plant

growth-promoting molecules produced by PGPR. We previously demonstrated that selected *P. agglomerans* strains secrete a combination of metabolites that can act in synergy with auxins to induce adventitious root formation (Luziatelli et al., 2020c). Using *Pyrus communis* as a model system, we demonstrated that, in contrast to the synthetic hormone indole-3-butyric acid (IBA), the metabolites secreted by *P. agglomerans* C1 strain have an unusual auxin-like activity that could determine direct shoot regeneration without callus formation and earlier emergence of roots from stem tissues (Luziatelli et al., 2020c).

One of the major goals of this work was to analyze how to rationally develop plant biostimulants that fit within the definition of probiotics (“preparation of inanimate microorganisms and/or their components”) and make the most of the biosynthetic capabilities of a selected PGPR strain integrating metabolomics and fermentation technologies. For this purpose, we first identified, by untargeted metabolomics, the culture medium that better stimulates the production of a more comprehensive array of metabolites with plant-promoting or biocontrol activity, including auxin/IAA. We then used a three-level-two-factor response surface methodology based on the central composite design (RSM-CCD) to optimize the auxin/IAA production on the selected medium. For this purpose, we set two parameters (rotation speed and medium liquid-to-flask volume ratio) that affect the aeration efficiency in

TABLE 3 Experimental design No. 2 and results of CCD2-RSM.

Run	Factor		Liquid-to-flask volume ratio	Observed Response	Predicted Response

shake-flask conditions as response factors. Moreover, to better understand the interaction between these two parameters, we used an iterative RSM-CCD approach to define the correct ranges of the factors. Finally, by targeted metabolomics, we analyzed the effect of the aeration efficiency of the culture medium on the IAA product selectivity and the metabolic flux of Trp to IAA through IPyA.

Results reported in Figure 1 indicated that, in the production of a plant postbiotic, the culture medium has a central role in the balance between the target compound (indole auxins) and other metabolites secreted by the microorganism. A PGPR can produce and release in the culture medium a wide array of compounds that can enhance or modulate the plant's response to the exogenous auxins (Duca et al., 2014) or promote plant growth through different mechanisms

(Olanrewaju et al., 2017). In this respect, the possibility of modifying the hypoxanthine/xanthine ratio shifting from LB to YES medium can be particularly interesting since these molecules interplay with the plant's response to auxin, environmental stresses, and, in the case of hypoxanthine, purine salvage (Ashihara et al., 2018).

Untargeted metabolomics also indicated that the shift from LB to YES had a positive effect on the accumulation of some *P. agglomerans* metabolites with antimicrobial activity that can indirectly affect the promotion of plant growth, preventing the development of plant pathogens (Glick, 1995). Among these compounds, we found: NS-5, a β-lactam antibiotic active against Gram-positive and Gram-negative bacteria (Papp-Wallace et al., 2011); methyl hexadecanoic acid, a fatty acid methyl ester (FAME) with antibacterial activity against Gram-negative (Thormar, 2010); indole-3-carbinol, a compound toxic to herbivores, insects and pathogens (Kim and Jander, 2007; Figure 2; Supplementary Table S1).

In summary, the metabolomics analysis indicated that the use of plant postbiotics, in alternative to IBA or other synthetic hormones, gives the advantage of obtaining a selected array of compounds with plant-promoting or biocontrol activity whose synthesis pattern in the natural environment is unpredictable and whose importance in plant-microbe interaction could not be easily recognized using conventional systems. At the same time, the use of microbial metabolites by PGP bacteria or fungi not included in the list of microbial biostimulants approved by the EU legislation 2019/1009 can offer an interesting opportunity for scientists and entrepreneurs to develop novel bio-based biostimulants with a well-defined composition and well-characterized activities.

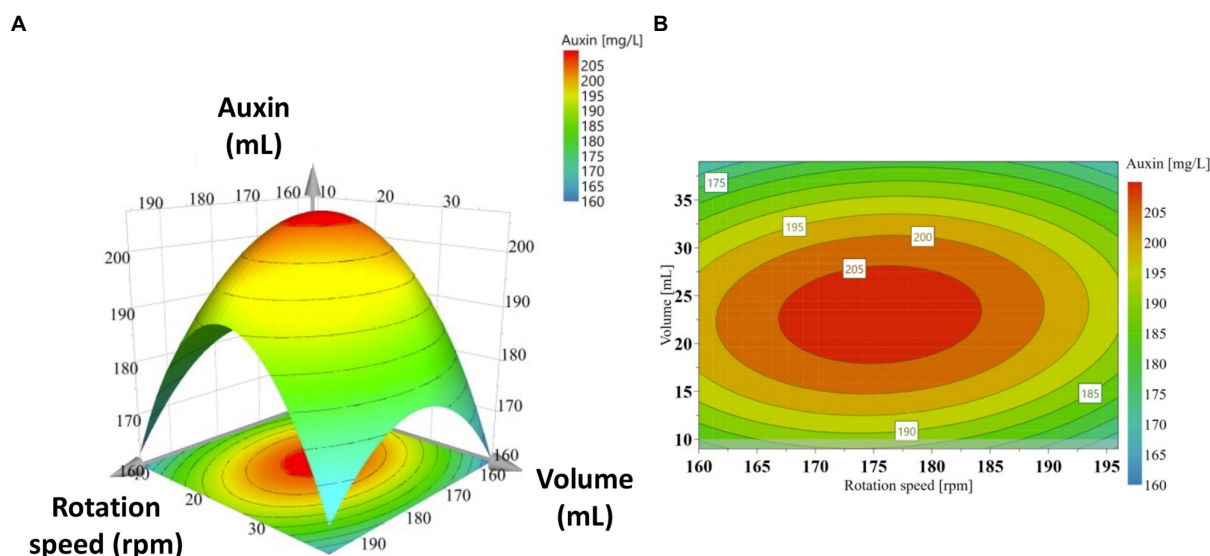

FIGURE 4

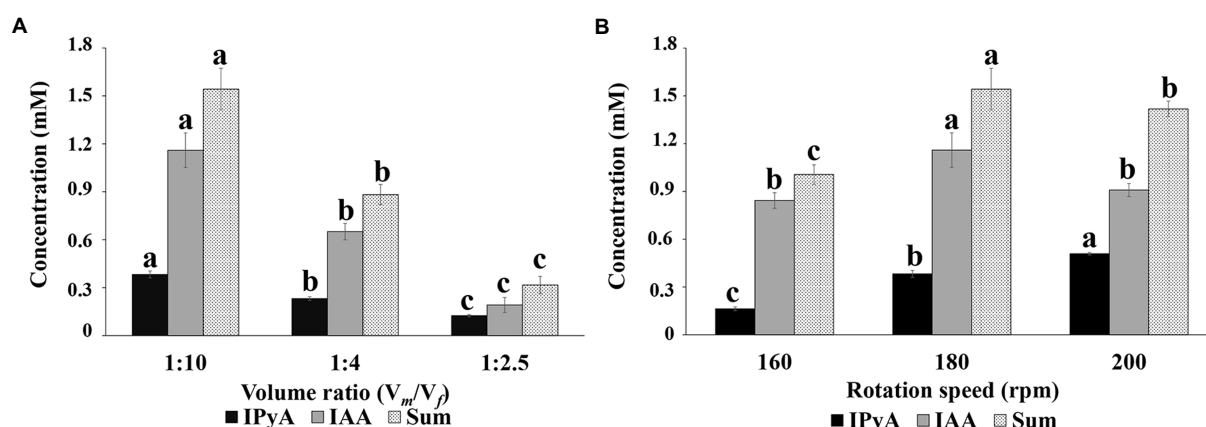

FIGURE 5

Results of the HPLC-MS analysis showing the effect of liquid-to-flask volume ratio (**A**) and rotation speed (**B**) on the conversion of tryptophan (Trp) to indole-3-acetic acid (IAA) via the indole-3-pyruvic acid (IPyA) pathway. All cultures were grown in YES + Trp medium at 25°C for 24h. Data are means \pm standard error and refer to cultures grown at 180rpm (**A**) and a medium-to-flask volume ratio (V_m/V_f) of 1:10 (**B**). The graphs show the molar concentration of the single compounds and the IAA+IPyA sum. Bars with no letter in common significantly differ at $p \leq 0.05$ (Tukey HSD test).

Results reported in Figure 1 also indicated that the shift from the rich (LB) to the saline (YES) medium determined a reduction in the formation of indolic secondary metabolites, including indole-3-acetaldehyde and indole-3-carboxylic acid (Supplementary Table S2). The latter compound can play an important role in pathogen defense (Böttcher et al., 2014) but can interfere with auxin-signaling (Kumar et al., 2021). Comparative metabolomics indicated that, if the primary goal is the production of postbiotics with higher auxin/IAA levels, the YES medium can provide better results regarding IAA titer and product selectivity. With *P. agglomerans* strain C1, shifting from LB to YES medium, most of the Trp-derived indoles, 11 out of 14 compounds belonging to the indoles and derivatives cluster, decreased, and a

5.4-fold IAA titer increase occurred (Supplementary Table S2). These differences can be dependent on differences in the composition of the growth media in terms of carbon and nitrogen source (peptides in LB and sucrose and NH_4^+ ions in YES) and Mg^{2+} ion concentration (30–40 μM in LB and 1 mM in YES; Papp-Wallace and Maguire, 2008). Magnesium ions, in combination with thiamine pyrophosphate (ThDP), are an essential cofactor of IPDC, the key enzyme involved in IAA biosynthesis via the tryptophan-dependent IPyA pathway. Koga et al. (1992) demonstrated that, in the absence of ThDP and Mg^{2+} , the active IPDC tetramers dissociate into inactive monomers and dimers. It can be postulated that the differences in the Mg^{2+} ion concentration can differentially modulate the IPDC activity and play a role in the

TABLE 5 Effect of medium-to-flask volume ratio (V_m/V_f) and rotation speed (rpm) on the product selectivity (IAA/IPyA) and substrate consumption rate (final-to-initial Trp ratio).

Factor	Condition	Relative molar ratio	
		IAA/IPyA	Trp _f /Trp _i
Volume ratio (V_m/V_f)	1:10	3.0 ± 0.1 ^a	1.1 ± 0.1 ^b
	1:4	2.8 ± 0.1 ^b	1.3 ± 0.1 ^a
	1:2.5	1.5 ± 0.0 ^c	1.2 ± 0.1 ^{ab}
Rotation speed (rpm)	160	5.2 ± 0.1 ^A	0.6 ± 0.0 ^C
	180	3.0 ± 0.1 ^B	1.1 ± 0.1 ^A
	200	1.8 ± 0.1 ^C	1.0 ± 0.1 ^B

The superscript letters indicate similarities or significant differences between the values. Values with no letter in common significantly differ at $p \leq 0.05$ (Tukey HSD test).

differential accumulation of the Trp-derived indoles. The scientific literature provides extensive evidence that the magnesium availability in the fermentation media significantly affects the growth and metabolism of microbial cells (Walker, 1994). Our results showed that a culture medium with a higher Mg^{2+} content could be valuable for the microbial production of auxin/IAA through the IPyA pathway.

Many reports indicate that, in bacteria, auxin/IAA production is affected by several parameters, including medium components, growth temperature, incubation time, and medium pH (Apine and Jadhav, 2011; Balaji et al., 2012; Peng et al., 2014; Bhutani et al., 2018; Srisuk et al., 2018; Myo et al., 2019; Baliyan et al., 2021). Notably, none of these studies reported a detailed metabolomics analysis of the effect of these parameters on the production of other auxin-related compounds. On the other hand, no information is available on the effect of aeration efficiency on the microbial production of phytohormones such as auxin, whereas oxygen plays a crucial role in the growth and metabolism of aerobic and facultative anaerobic bacteria (Garcia-Ochoa et al., 2010; Seidel et al., 2021).

In this work, we demonstrated that the statistical optimization of the growth conditions was a powerful tool to optimize the auxin production by *P. agglomerans* strain C1 (Figure 4; Tables 2, 3). To the best of our knowledge, this is the first study investigating the effect of aeration efficiency on auxin production by plant growth-promoting bacteria. The statistical optimization of aeration efficiency, performed by varying the medium liquid-to-flask volume ratio (V_m/V_f) and rotation speed (rpm; Table 1), provided valuable insights into the effect of oxygen availability on IAA production by the *P. agglomerans* strain C1 (Tables 2, 3). From an agroecological perspective, this result also highlights the importance of oxygen availability on the plant-microbe's interaction in the rhizosphere, phyllosphere, and endosphere.

Our results indicated that the parameters that directly affect aeration efficiency in shake flask conditions (rotation speed and liquid-to-flask volume ratio) play an essential role in auxin/IAA production, which was improved from 3.1 mg IAA_{equi}/L (CCD1, rotation speed 140 rpm, 1:2.5 V_m/V_f) to 208.1 mg IAA_{equi}/L (CCD2, rotation speed 180 rpm, 1:10 V_m/V_f ; Table 2; Figure 3). In agreement with this observation, higher IAA values were achieved using a 1:10 liquid-to-flask volume ratio at all agitation regimes (Table 2; Figure 3B). A higher amount of auxin/IAA was obtained when the oxygen availability was higher because of higher rotation speed and lower medium

liquid-to-flask volume ratio (Tables 2, 3). However, data showed low tolerance of strain C1 to mechanical stress: IAA concentration decreased when the rotation speed was higher than 180 rpm (Table 3).

The polynomial equation indicated that the two independent variables, rotation speed (X_1 and X_1^2) and medium volume (X_2 and X_2^2), had a negative effect on the response (Table 4). In contrast, the interactive effect of these variables (X_1X_2) positively affected the auxin production (Table 4). The equation also indicated that the coefficient of the quadratic X_2 was larger than that of X_1^2 , which means that the medium volume, and therefore the medium volume-to-flask ratio, had a greater effect on the auxin production than the rotation speed. This information was corroborated by the curvature of the 3D response surface that was more pronounced on the "Medium Volume" axis (Figure 4A). Similar evidence was also obtained by the 2D contour plot in which the contours around the stationary point were elliptical and elongated on the rotation speed axis (Figure 4B). Both plots indicated that: (1) at the extreme values of both variables, auxin/IAA concentration was low; (2) a slight change of the response value required a more significant move along the rotation speed axis than on the medium volume axis.

Validation carried out to verify the accuracy of the model showed that the predicted value (207.3 mg IAA_{equi}/L) agreed well with the experimental value (208.3 ± 0.4 mg IAA_{equi}/L). The application of the RSM through CCD allowed us to obtain the maximum auxin concentration at a medium liquid-to-flask volume ratio of 1:10 and a rotation speed of 176 rpm. The auxin concentration obtained under optimized conditions (208.3 ± 0.4 mg IAA_{equi}/L) was about 40% higher compared to the growth conditions previously described (Luziatelli et al., 2020b).

Targeted metabolomics highlighted some features of the *P. agglomerans*' IAA biosynthetic metabolism, which were not addressed by the RSM analysis underlining the importance of integrating the two methodologies. Data in Table 5 indicated that the culture conditions affected the flux of Trp to IAA through IPyA. At a rotary speed of 180 rpm, the product selectivity (IAA/IPyA molar ratio) had a 2-fold increase reducing the medium-to-flask volume ratio from 1:2.5 to 1:10 (higher aeration efficiency; Table 5). Surprisingly, at the lower medium-to-flask volume ratio (1:10), the product selectivity decreased about 2.9-fold when the rotation speed was increased from 160 to 200 rpm (Table 5). Thus, independently from the final concentration of IAA, it was evident that the mechanical and oxidative stresses associated with the increase in the rotary speed affected the conversion of Trp to IAA.

Results of targeted metabolomics indicated that an increase in the rotation speed determined an accumulation of IPyA in the culture medium (Figure 5B) and a decrease in the IAA product selectivity (Table 5, column IAA/IPyA). The increased difference between IAA and IAA + IPyA (Figure 5B) also indicated that the moles of IPyA converted to IAA decreased with the increase in the rotation speed from 180 to 200 rpm. Since no significant difference in the IAA level was observed between rotation speeds 160 and 200 rpm, the variation in the total amount of IAA + IPyA was strictly related to a difference in the accumulation of IPyA (Figure 5B). The higher flux of Trp in the IAA biosynthetic pathway and the lower conversion rate of IPyA to IAA occurring when the rotation speed was increased from 160 to 180 rpm could be due to a difference in the availability of the cofactors of the key enzyme of the IPyA pathway: pyridoxal-5-phosphate (PLP) for L-tryptophan/aromatic

amino acid aminotransferase (AAT); thiamin diphosphate for indole-3-pyruvate decarboxylase (IPDC); NAD(H)⁺ for indole-3-acetaldehyde (IAAld) dehydrogenase/oxidase (AAO). Based on the literature (Lakaye et al., 2004; Taboada et al., 2008; Tramonti et al., 2021; Yuan et al., 2021), we expected, also in *P. agglomerans*, that the levels of these cofactors could be higher when the dissolved oxygen is not a limiting factor and its replenishment satisfies metabolic oxygen demands. However, the availability of these cofactors for the enzymes involved in the IAA synthesis depends upon the number of competitive reactions that consume the same cofactors and are active under the same growth conditions. In future research, we intend to combine metabolomics and RSM analysis to explore the correlation between IAA product selectivity and cofactors availability and improve the fermentation strategies focusing on both IAA yield and product selectivity.

Whereas in all *P. agglomerans* strains described so far (including strain C1), the production of high levels of IAA is dependent upon the addition of Trp to the culture medium, our data indicated that, under our experimental conditions, strain C1 synthesized Trp and released part of it in the culture medium (Table 5, column Trp/Trp_i). Interestingly, the highest IAA product selectivity was obtained when the residual Trp level was lower (Table 5, rotation speed of 160 rpm). Considering that the first step of the major pathways of Trp degradation involves PLP-dependent enzymes (Cellini et al., 2020), it can be postulated that the flux of Trp versus IPyA is modulated by the affinity of the AAT versus the substrate (Trp) and the cofactor (PLP) and the intracellular concentration of both. The highest IAA product selectivity obtained when the Trp biosynthesis is limited (Table 5, rotation speed of 160 rpm) can indicate that redirecting the Trp metabolic flux is pivotal, either in laboratory conditions or in natural environments, to modulate the IAA production by PGPRs.

The levels of auxin/IAA obtained in this study are lower than those reported for *P. agglomerans* PVM (Apine and Jadhav, 2011), *Klebsiella* SN 1.1 (Chaiharu and Lumyong, 2011), *Enterobacter* sp. DMKU-rp206 strain (Srisuk et al., 2018) and *Enterobacter* sp. P-36 (Luziatelli et al., 2021), but are indeed higher than those obtained upon optimization of IAA production by *Bacillus* strains isolated from *Vigna radiata* (Bhutani et al., 2018), *Streptomyces* sp. VSMGT1014 (Harikrishnan et al., 2014), *Burkholderia seminalis* S52 (Tallapragada et al., 2015), or *Pseudomonas putida* sp. Rs-198 strain (Peng et al., 2014). For *P. agglomerans* strain PVM (Apine and Jadhav, 2011), the higher levels of IAA were produced on a medium containing animal-derived ingredients (meat), which are not compliant with EU rules on fertilizing products.

Conclusion

Integration of RSM with metabolomics, which provides comprehensive information on the cellular response to external stimuli, can be valuable for optimizing various microbial products. In this study, we provided evidence that, in developing auxin-enriched plant postbiotics, the combined use of RSM and untargeted and targeted metabolomics can help discover new properties of PGPRs and take advantage of their metabolic capabilities. Postbiotics allow the rational design of cocktails of metabolites associated with PGP traits. The separate production of

metabolites can be a valuable strategy in synthesizing molecules whose biosynthetic pathways compete in the cell for ATP, cofactors (auxins and gibberellins), or precursors (auxins and phenylpropanoids). Metabolites synthesized under different growing conditions or from different PGPRs can be produced separately and appropriately mixed to obtain tailor-made products for different crops and growing conditions. This study provides guidance for the sustainable development and optimization of postbiotics for agriculture.

Data availability statement

The original contributions presented in the study are included in the article/Supplementary material, further inquiries can be directed to the corresponding authors.

Author contributions

FM, FL, and MR contributed to the conception and design of the study, wrote the first draft of the manuscript, and wrote and edited the final version of the manuscript. FM, FL, PB, AF, VM, and MR contributed to defining the methodology and investigation. FM, FL, PB, and MR contributed to software analysis and data validation. All authors contributed to the article and approved the submitted version.

Funding

This study was carried out within the Agritech National Research Center and received funding from the European Union Next-GenerationEU [Piano Nazionale di Ripresa e Resilienza (PNRR)—Missione 4 Componente 2, Investimento 1.4—D.D. 1032 17/06/2022 and CN000000022].

Acknowledgments

We are grateful to the NGA Laboratory (Spain) for helping us with the metabolomics analysis and metabolite annotation.

Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Introduction: Humic substances (HSs), components of plant biostimulants, are known to influence plant physiological processes, nutrient uptake and plant growth, thereby increasing crop yield. However, few studies have focused on the impact of HS on overall plant metabolism, and there is still debate over the connection between HS' structural characteristics and their stimulatory actions.

Methods: In this study, two different HSs (AHA, Aojia humic acid and SHA, Shandong humic acid) screened in a previous experiment were chosen for foliar spraying, and plant samples were collected on the tenth day after spraying (62 days after germination) to investigate the effects of different HSs on photosynthesis, dry matter accumulation, carbon and nitrogen metabolism and overall metabolism in maize leaf.

Results and discussion: The results showed different molecular compositions for AHA and SHA and a total of 510 small molecules with significant differences were screened using an ESI-OPLC-MS techno. AHA and SHA exerted different effects on maize growth, with the AHA inducing more effective stimulation than the SHA doing. Untargeted metabolomic analysis revealed that the phospholipid components of maize leaves treated by SHA generally increased significantly than that in the AHA and control treatments. Additionally, both HS-treated maize leaves exhibited different levels of accumulation of trans-zeatin, but SHA treatment significantly decreased the accumulation of zeatin riboside. Compared to CK treatment, AHA treatment resulted in the reorganization of four metabolic pathways: starch and sucrose metabolism, TCA cycle, stilbenes, diarylheptanes, and curcumin biosynthesis, and ABC transport, SHA treatment modified starch and sucrose metabolism and unsaturated fatty acid biosynthesis. These results demonstrate that HSs exert their function through a multifaceted mechanism of action, partially connected to their hormone-like activity but also involving hormoneindependent signaling pathways.

KEYWORDS

humic substances, metabolomics, hormone-like activity, starch and sucrose metabolism, chemical structures

1 Introduction

An inventive approach to the problems facing sustainable agriculture is the use of natural plant biostimulants. Humic substances (HSs), one type of plant biostimulants, has received increasing attention from researchers and farmers. Numerous studies have shown that plants grown in soils with sufficient HSs or exposed to foliar sprays composed of HSs are healthier because these plants are well adapted to and resistant to stressful conditions and show increased yield through increasing nutrient uptake (Quaggiotti et al., 2004; Mora et al., 2010).

For many years, soil scientists have been working to determine the chemical characteristics and molecular structure of HSs and to study how they regulate plant growth and development. Several studies have proposed the hypothesis that HSs may act on plants through two different mechanisms: (1) indirectly, by enhancing the chemical, physical and biological qualities of the soil; and (2) directly, by regulating growth processes, nutrient transport systems and primary and secondary metabolism through HSs active components (Canellas and Olivares, 2014; Nardi et al., 2016; Nunes et al., 2019; Pizzeghello et al., 2020). For example, HSs stimulate the synthesis of plasma membrane H^+ -ATPase. Through the combination of ATP hydrolysis and H^+ transfer across the cell membrane, this enzyme promotes root growth by acidifying the plasma outer body, loosening the cell wall, and lengthening the cell (Zandonadi et al., 2007; Canellas and Olivares, 2014; De Azevedo et al., 2019). Activation of plasma membrane H^+ -ATPase also improves plant nutrition by increasing the electrochemical proton gradient that drives ion transport across the cell membrane (Canellas et al., 2002). Earthworm-like HSs induce changes in the metabolism of reactive oxygen species (ROS) in plants after root application (García et al., 2012; García et al., 2014). ROS have been categorized as signal transduction molecules that participate in transduction mechanisms regulating metabolic activities, including plant growth and development, although they are mainly considered as hazardous compounds resulting from aerobic metabolism (Mittler et al., 2011; Mittler, 2017). In this context, ROS has been proposed as a possible target for the action of HSs in plants (García et al., 2016; Roomi et al., 2018). Additionally, Zandonadi et al. (2010) showed that HSs induce nitric oxide (NO) production at the site of lateral root emergence. Both primary and secondary metabolism have been documented to be altered by HSs. For example, Nardi et al. (2007) observed the upregulation of glycolysis and the tricarboxylic acid cycle (TCA) enzymes in maize plants treated with 1 mg C L^{-1} HS, which also increased nitrogen uptake/assimilation and nitrogen metabolism. Furthermore, HS treatment was able to lower the pH of the root surface, promote H^+/NO_3^- symport and stimulate nitrate uptake, transport and nitrogen metabolism enzyme activity. In addition, HS treatment exerted a positive effect on phenylpropane metabolism and enzymes associated with cytoprotection (García et al., 2016). Taken together, these findings illustrate the complexity of the relationship between HSs and plant physiology and emphasize the value of molecular approaches in understanding the nature of this interaction.

In the last decade, new molecular “omics” techniques (genomics, transcriptomics, proteomics and metabolism) have been applied to evaluate the effects of HSs on plant metabolism (Carletti et al., 2008; Nephali et al., 2020). Recent studies have described the impeccable ability and potential of omics techniques to reveal the mechanisms describing the interaction of biostimulants with plants. Trevisan et al. (2011) performed a transcriptomic analysis and Gene Ontology classification on *Arabidopsis* after three days of treatment and observed a widespread but slight modulation of the transcriptional activity involving the plant’s main metabolic functions: respiration and photosynthesis, general cellular metabolism, fatty acids, nitrogen/sulfur, plant hormones, plant development, senescence, stress response, ion and water transport. Nunes et al. (2019) used a label-free quantitative proteomic approach to analyze the effect of humic acid on the soluble protein fraction of maize seedling roots, and differences were detected in root proteins relation to energy metabolism, the cytoskeleton, cellular trafficking, protein conformation and degradation, and DNA replication. However, few studies have investigated the effects of HSs on plant metabolism via metabolomics analysis. Metabolomics is a multidisciplinary omics science that provides unique opportunities to predict the mode of action of biostimulants on crops and to identify markers of biostimulatory effects (Nephali et al., 2020). In one of the very few cases when metabolomics techniques were utilized in HS response research, Marino et al. (2013) showed that HS-treated pears and papaya calli produced more asparagine than controls using 1H HR-MAS NMR analysis.

Numerous studies have highlighted how HSs might improve plant responses and growth metrics, but the new challenge is to determine which parts or specific components of HSs are most likely to induce a positive response. For this analysis, the structure and composition of humic substances must be examined and characterized. In general, the characterization of HSs is divided into elemental, functional group and molecular weight categories, but these characterizations do not provide information at the molecular level. In 2001, Piccolo (2001) redefined fulvic acid (FA) as a hydrophilic small molecule conjugate with sufficient acid functional groups to allow its dispersion in solution at any pH. At neutral or alkaline pH, HSs are not stable polymers but supramolecular associations of relatively small heterogeneous molecules (polymethylenic chains, fatty acids and steroid compounds) held together by weak dispersion forces, such as van der Waals, π - π , CH- π , and interactions. As intermolecular hydrogen bonds are gradually formed at lower pH values, their conformation gradually increases until flocculation, and the concept of “humeomics” was thus introduced (Piccolo, 2001; Nebbioso and Piccolo, 2011). Furthermore, researchers have speculated that the progressive breakdown of the intra- and intermolecular interactions that support complex superstructures may reduce the complexity of humic supramolecules, releasing individual humic substances molecules that enter the plant or engage with receptors that interact with plant cells. These molecules are separated and identified by combining advanced analytical techniques (Nebbioso and Piccolo, 2011; Drosos et al., 2017). Further studies have noted that the main molecular components of HSs are fatty acids, ethers,

esters, alcohols, aromatic lignified fragments, polysaccharides and peptides (Scaglia et al., 2016; Drosos et al., 2017).

The complexity of the HS structure and its associated biological activity in plants has been extensively described. Despite the fact that several approaches have been employed in research on this topic, the direct relationship between the chemical structures of HSs and their effects on plant metabolism has not yet been fully elucidated so far. Initially, the molecule size, hydrophilicity, and particular functional groups of HSs were proposed to be closely associated with their activity. According to Nardi et al. (2007), the size exclusion chromatography fraction of HSs with the lowest molecular weight is the most effective in promoting plant metabolism, the most hydrophilic, and contains more sugars and less lignin-derived materials. Similarly, the effects of different molecular size fractions of HSs on root growth have been explored (Dobbss et al., 2010; Canellas et al., 2012). While all HS induced root growth in *Arabidopsis* and maize seedlings, the intensity of their effects varied depending on HS molecular size and plant species. Further analysis revealed that the hydrophobicity index (HB/HI) of HSs obtained using NMR parameters correlates with the appearance of lateral root hairs, but that the hydrophobic carbon content correlates negatively with the induction of lateral roots (Canellas et al., 2012). Other studies have also discovered a connection between hydrophobicity and plant responses, whereby more hydrophobic humic acids showed the greatest activity in stimulating plant responses, with certain HSs lengthening roots and others increasing root density. According to Scaglia et al. (2016), the hormone-like activity of HSs extracted from compost prepared from cow manure and leather waste varies depending on the maturity stage, and the molecules correlating with growth hormone-like activity were identified as carboxylic acids and amino acids.

The combination of a fine chemical analysis of HS molecules and overall metabolic studies of their effects on plants provides a new opportunity to expand knowledge of both the detailed chemistry and use management aspects of HSs. Based on this hypothesis, we sought to analyze the molecular composition of HSs through UHPLC-QTOF-MS technology, we employed a method based on UHPLC-QTOF-MS non-target metabolome to study the overall effect on HSs on maize metabolism. The main aim of this study were as follows: i) assaying differences in chemical composition and biological activity from two different reservoirs; ii) appraising differential effects of these HSs on altering maize growth and metabolism over a long period; iii) attempt to analyze the molecular compositions of HSs, and explore the mechanism of promoting growth from the perspective of metabolomics in maize.

2 Materials and methods

2.1 Materials

The two HSs selected for this investigation were those that had been screened in earlier corn field trials and displayed the greatest variation in effects (data not shown). One of the humic substances (AHA, Aojia humic acid) was supplied by Beijing Aojia Fertilizer

Co., Ltd. (Beijing, China), using Heilongjiang lignite as the raw material, and the other (SHA, Shangdong humic acid) was supplied by Shandong Nongda Fertilizer Technology Co., Ltd. (Jinan, China), also using Inner Mongolia lignite as the raw material.

The experiment was conducted in a glass greenhouse of the Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences. Both plant groups were grown in pots containing a mixture of perlite/vermiculite (1:1, v/v) in glass house. The composition of the Hoagland nutrient solution is as follows: 2 mM MgSO_4 , 1 mM NH_4NO_3 , 5 mM KNO_3 , 1 mM KH_2PO_4 , 0.005 mM KI, 5.76 mM $\text{Ca}(\text{NO}_3)_2$, 0.1 mM H_3BO_3 , 0.15 mM MnSO_4 , 0.05 mM ZnSO_4 , 0.00016 mM CuSO_4 , 0.0019 mM CoCl_2 , 0.1 mM NaFe-EDTA. The initial pH was adjusted to 5.8 ± 0.1 .

Maize seeds (*Zea mays* L., hybrid Zhengdan 958) were soaked in 0.5% NaClO for 30 min, then rinsed and soaked in water for 12 h for surface sterilization. Afterward, the seeds were sown in vermiculite-filled seedling trays and allowed to germinate in an incubator with 14 h of light at 28°C and 10 h of darkness at 20°C. The seedlings with the same growth vigor were selected and placed in pots after 7 days. During the rejuvenation period, Hoagland nutrient solution with a half-ionic strength was used. After 7 days, it was replaced with complete nutrient solution, and 1L of nutrient solution was applied every week.

2.2 Determination of molecular composition of HSs

HS molecular composition was determined using UHPLC-QTOF-MS as described below.

2.2.1 Sample preparation

The metabolites were extracted by adding 1 mL of pre-chilled extraction solution (2:2:1, (v/v/v) methanol: acetonitrile: water solvent mixture) to 80 mg of the samples. The sample was vortexed and mixed, sonicated at low temperature for 30 min, and then centrifuged at 14000×g for 20 min at 4°C. The supernatant was dried in a vacuum centrifuge, 100 µL of aqueous acetonitrile (1:1, (v/v) acetonitrile: water) was added before the LC-MS analysis, vortexed and centrifuged at 14000×g for 15 min at 4°C, and the supernatant was collected as the sample for analysis. In addition, pooled quality control (QC) samples were prepared by combining of equal amounts of the samples.

2.2.2 Liquid phase parameters

All samples were analyzed using the UHPLC (1290 Infinity LC, Agilent Technologies) system. An ACQUITY UPLC BEH HILIC column (100 mm × 2.1 mm, 1.7 µm, Waters, Ireland) was used for separation at a column oven temperature maintained at 25°C. The flow rate was set to 0.5 mL/min, while the mobile phase comprised solvent A (water, 25 mM ammonium acetate and 25 mM ammonium hydroxide) and solvent B (Acetonitrile). Gradient elution conditions were set as follows: 0–0.5 min, 95% B; 0.5–7 min, 95–65% B; 7–8 min, 65–40% B; 8–9 min, 40% B; 9–9.1 min, 40–95% B; and 9.1–12 min, 95% B. The injection volume for each

sample was 42 μL . A random order was used for continuous analysis of the samples to avoid fluctuations detection signal in the instrument. QC samples were inserted in the sample queue for monitoring and evaluating the stability of the system and the reliability of the experimental data.

2.2.3 Mass spectrometry parameters

Samples eluted from the column were detected using a TripleTOF6600 high-resolution tandem mass spectrometer with Q-TOF operated in both positive and negative ion modes. The Ion spray voltage floating was set to 5500 and -5500 V for the positive and negative ion modes, respectively. Mass spectrometry data were acquired on the information dependent acquisition (IDA) mode, with a TOF mass range set from 25 to 1000 Da, and the accumulation time for product ion scan was set to 0.05 s/spectra.

2.2.4 Data processing

The raw MS data were converted to MzXML files by ProteoWizard MSConvert, and then peak alignment and integration were conducted using XCMS software. The parameters of XCMS were as follows: mass range 25–1000 m/z, mass tolerance 10 ppm, retention time (RT) range 0.5–12.0 min, and RT width threshold 0.2 min. In the extracted ion features, only the variables with more than 50% of the nonzero measurement values in at least one group were retained. Compound identification of metabolites was performed by comparing of accuracy m/z value (<10 ppm), and MS/MS spectra with an in-house database established with available authentic standards.

After data normalization, the processed data matrix was submitted to R package (ropls) for multivariate statistical analysis. Principal component analysis (PCA) was conducted to observe the clustering pattern of all samples and the repeatability of the intra-group samples. Orthogonal partial least squares discriminant analysis (OPLS-DA) was further applied to filter out the noise irrelevant to the classification information and improve the parsing ability and effectiveness of the model. Variables with variable importance for the projection (VIP) values from the OPLS-DA analysis larger than 1.0 were considered as potential biomarkers since they can discriminate between two compared groups.

2.3 Experimental design

The experiment was arranged in randomized blocks using three treatments and ten replicates. The treatments were as follows: 1) foliar application of pure water, (CK), 2) foliar application of AHA (AHA), 3) foliar application of SHA (SHA). HSs was sprayed at a concentration of 0.5%, which was selected based on supplier recommendations and preliminary experiments assessing the effects of HS spraying on maize growth. Plants underwent foliar spraying around 16:00 using a portable sprayer, with which the upper and the lower surface of leaves were treated. The first spraying was conducted at 14 days after transplantation, and the remaining foliar sprays were applied at 10-day intervals for 5 total applications. The sampling point for plant samples was 10 days after the last spraying. For non-target metabolome analysis, the tip,

middle, and base of the latest fully expanded leaves of six plants were collected and mixed, and immediately frozen in liquid nitrogen and stored at -80°C for subsequent analysis. For the biochemical analysis and to measure the fresh and dry weight of each plant's leaf, stem, and root, four samples were collected. Then, the different parts of the maize plant were oven-dried at 105°C for 30 min and maintained at 75°C for 48 h to obtain a stable dry weight. Dry matter was analyzed for total nitrogen, phosphorus and potassium percentages. Total nutrition absorption per plant was calculated based on the tissue nutrition content and dry weight.

2.4 Phenotypic analysis

A ruler was used to measure plant height from the stem base to the tip of the latest fully expanded leaf. Plant stem diameter was measured with caliper. Expanded leaves area was estimated non-destructively using the Yanxin-1242 portable leaf area meter of each leaf with ligule emergence. Vegetative developmental stage was based on the number of leaves with an emerged ligule and the number of visible leaves at harvest.

2.5 Parameters for measuring photosynthesis

The photosynthetic rates were measured between 9:00 and 11:00 using a portable photosynthesis system (Li-6400, LICOR Biosciences, Lincoln, USA). The air temperature, CO_2 concentration and photosynthetic photon flux density in the leaf chamber were set to 28°C , $500 \mu\text{mol}\cdot\text{mol}^{-1}$, $1500 \mu\text{mol m}^{-2} \text{s}^{-1}$, respectively. Three biological repeats were included per data point. The instantaneous WUE was calculated as $\text{WUE} = \text{Pn}/\text{Tr}$ (Chen et al., 2018).

Relative chlorophyll concentration in leaves was recorded using a portable SPAD meter (SPAD-502 Plus, KONICA MINOLTA, Japan) with 10 reading data. Both of these values were detected using the youngest leaf with ligule emergence.

2.6 Measurement of physiological parameters

Fresh leaf samples, which were previously stored at -80°C , were ground to a homogenous powder with liquid nitrogen. The protein concentration was determined using the Bradford method and a UV/Vis spectrophotometer at 595 nm wavelength. The protein concentration was reported as mg of protein per g of fresh leaf. The soluble sugar concentration was calculated using the sulfuric acid-anthrone colorimetric method. The free amino acid content was determined using the ninhydrin method with leucine as the standard.

Phenylalanine ammonia-lyase (PAL) was extracted by homogenizing frozen tissue into pre-cooled sodium borate buffer (100 mM, pH 8.7) at a ratio of 1:9 (w/v). After centrifugation at 10,000 rpm/min for 10 min at 4°C , the supernatant was collected for the enzyme assay using a previously described method (Assis et al., 2001). One unit

(U) of PAL activity was defined as the amount of enzyme extract producing an increase in the optical density of 0.1 per min, which was measured at 290 nm by using UV/Vis spectrophotometer. Sucrose synthase (SS) and nitrate reductase (NR) activities were measured using the corresponding assay kits according to the manufacturer's instructions (Beijing Solarbio Technology Co., Ltd., Beijing, China). Briefly, 0.1 g leaf sample was added to 1 mL extraction solution, followed by the ice bath homogenization, and the mixture was centrifuged at 8000 g for 10 min at 4°C, supernatant was collected for further analysis. The absorbance at 480 nm was used for the calculation of SS activity and one unit of SS activity was defined as 1 µg of sucrose per g of tissue catalyzed per minute. For NR activity, 0.1 g leaf samples were extracted in 1 mL extraction solution and the mixture was centrifuged at 4000 g for 10 min. The resulting supernatant was collected for further analysis. The absorbance at 340 nm was used for the calculation of NR activity, one unit (U) of NR activity was defined as the amount of 1 µmol NADH consumed per hour per g of sample.

2.7 Metabolomics analysis of maize leaf

2.7.1 Sample preparation

The maize leaf samples were quickly frozen in liquid nitrogen and grounded with a homogenizer. The metabolites were extracted by adding 1 mL of pre-chilled extraction solution (2:2:1, (v/v/v) methanol: acetonitrile: water-water solvent mixture) to 80 mg (fresh weight) of the samples. The sample was vortexed and mixed, sonicated at low temperature for 30 min, and then centrifuged at 14000×g for 20 min at 4°C. The supernatant was dried in vacuum centrifuge, and 100 µL of aqueous acetonitrile (1:1, (v/v) acetonitrile: water) were added before the LC-MS analysis. The samples were vortexed and centrifuged at 14000×g for 15 min at 4°C, and the supernatant was collected as the sample for analysis.

2.7.2 Liquid phase parameters

The samples were separated using a UHPLC (1290 Infinity LC, Agilent Technologies) system with a C-18 column. The column temperature was 40°C. The flow rate was set to 0.4 mL/min; and the injection volume was 2 µL. The mobile phase A consisted of 25 mM ammonium acetate and 0.5% formic acid in water, mobile phase B was methanol. Gradient elution conditions were set as follows: 0–0.5 min, 5% B; 0.5–10 min, 5–100% B; 10–12 min, 100% B; 12–12.1 min, 100–5% B; 12.1–16 min, 5% B. During the whole analysis, the sample was placed in an automatic sampler at 4°C.

The mass spectrometry parameters and data processing were the same as the determination of the HS molecular composition described in Section 2.2.

2.8 Data analysis

Analysis of variance (one-way ANOVA) was performed using the SPSS 23 (IBM Corp) software with type of treatment as factor followed by a pairwise *post hoc* analyses (Duncan test) to determine which means differed significantly at $p < 0.05$.

3 Results

3.1 The molecular composition of HSs

An untargeted metabolomics approach based on UHPLC-QTOF-MS was used to obtain the molecular composition profiles of these two HSs, and 1320 small molecules were detected, of which 754 were detected in positive ion mode and 566 were detected in negative ion mode. The principal component analysis (PCA) explained 59.43%, 69.55% of the overall variance in molecules detected in positive and negative ion mode, respectively (Figure 1). The PCA score plots (Figure 1) showed two main clusters accounting for the AHA and SHA, respectively. Within each cluster, the molecular composition profiles did not overlap, thus indicating distinct molecular signatures.

The 1320 small molecules classified into eighteen categories according to their chemical properties (Figure 2). The six categories that accounted for a higher percentage were benzenes, organic heterocyclic compounds, organic acids and derivatives, lipids and lipid-like molecules, organic oxygen compounds, phenylpropanoids and polyketides.

As PCA is an unsupervised data analysis method, orthogonal partial least squares discriminant analysis (OPLS-DA) was further employed to filter out the noise unrelated to the classification information and improve the parsing ability and effectiveness of the model. The OPLS-DA plot (Figure S1) of the two samples showed a clear separation. The OPLS-DA model was also used to obtain the variable weight values (VIP) and measure the intensity and explanatory power of the effect of each small-molecule substance on the classification discrimination of the AHA and SHA groups. Thereafter, multivariate analysis of OPLS-DA and univariate analysis of *t*-test were used to identify differential accumulated component ions. The use of $VIP \geq 1$ and $p \leq 0.05$ as cutoff thresholds revealed 357 differentially expressed positive ions, of which 234 and 123 shown FC (fold change, AHA/SHA) >1 and $FC < 1$, respectively (Support Material 1, Figure S2).

Among the 510 small molecules with significant differences, 17 were attributed to hormones and their derivatives (Table 1). With exception of Trans-zeatin and Forchlorfenuron, two plant and hormone-like substances with an ionic strength $FC < 1$, the remaining 15 bioactive substances showed $FC > 1$, especially 5-methoxytryptophan, Gibberellin a4 and gamma-hydroxybutyric acid, whose FC were 486.10, 263.50 and 109.57, respectively. Notably, we also found that AHA and SHA contain a variety of substances with bacteriostatic and anthelmintic effects, such as fludioxonil, vanillic acid, triadimefon, Penthiopyrad, dinex, dichlormid, etc (Support Material 1).

3.2 Phenotype changes in maize

Foliar applications of AHA and SHA exerted differing effects on maize growth. In plant treated with AHA, a greater number of expanded leaves, plant height, leaf area and leaf dry weight was observed (+4.72%, 6.12%, 12.87% and 13.29%, respectively) compared to CK treatment ($p < 0.05$), but root growth was not

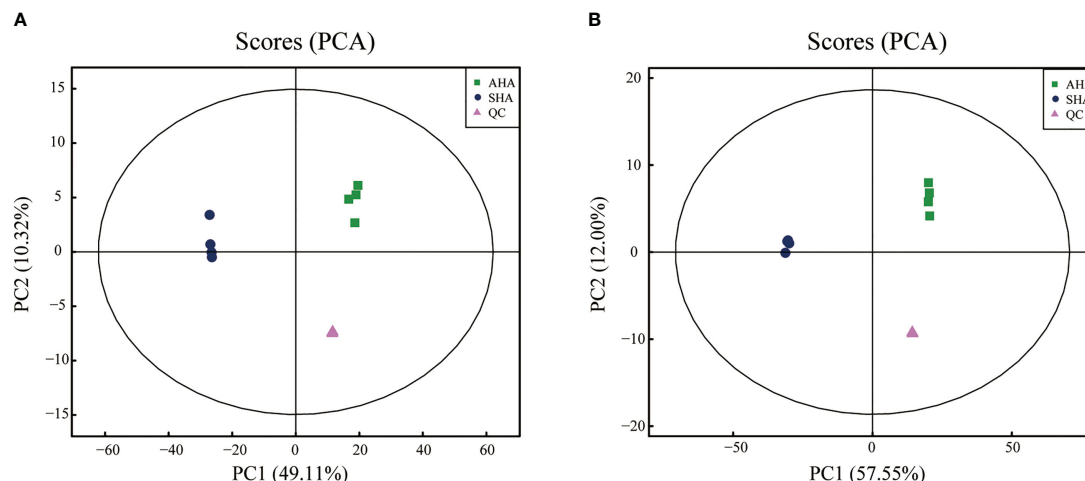

FIGURE 1
PCA score plots of the molecules profiles in positive ions mode (A) and negative ions mode (B).

modified (Table 2). Meanwhile, SHA treatment did not induce any significant changes in these parameters (except for the number of expanded leaves) compared to CK treatment. The increment in shoot leaf area after treatment with AHA was due to a small increment in total leaf number per shoot and a significant increment in average leaf size compared to SHA and CK treatments. In particular, compared with SHA and CK, the leaf area of AHA treatment group increased by 12.87% and 18.91%, respectively, and the leaf dry weight increased by 13.29% and 11.69%, respectively. Based on these results, AHA inducing more effective stimulation than the SHA.

3.3 Nutrient absorption

Both foliar spray treatments increased the P concentration in the leaves, stems and roots of maize plants (Figure 3A). The AHA and SHA treatments increased the stem N concentration by 6.4% and 13.04%, respectively, compared with the control treatment, but only the SHA group was declared to be significantly different from

control plants ($p < 0.05$). The K concentrations in maize were not affected by the tested biostimulants (Figure 3A). In contrast to stem N concentration, the N content in the plant following the AHA treatment increased by 43.52%, 20.62% compared with that observed after SHA and control treatments, respectively, due to the higher stem dry weight (Figure 3B). Similarly, the AHA treatment significantly increased the N, P and K content of the whole plant than that in SHA treatment plant ($p < 0.05$, Figure 3B).

3.4 Photosynthetic parameters

A positive effect of HSs was also been observed on the photosynthesis in maize leaves (Figure 4). Compared to the control treatment, plants subjected to the AHA foliar spraying treatment exhibited a significantly increased relative chlorophyll content (SPAD value) and C and subsequently displayed an increase in net photosynthesis; whereas there was a slight increase in SPAD values of SHA-treated leaves, their C and Pn were similarly significantly increased. There was no statistical

FIGURE 2
The classification of small molecules of AHA and SHA. The numbers in parentheses represent the amount of small molecule in each category and their proportion to the total number small molecules identified.

3.5 Carbon and nitrogen metabolism-related enzymes and substances

Compared to the control group, plants subjected to the AHA foliar spraying treatment presented higher levels of soluble carbohydrates and free amino acid content, but did not exhibit a change in the leaf protein concentration (Figure 5). SHA treatment did not exert any significant effect on leaf soluble carbohydrate concentrations but induced a slight reduction in free amino acid concentration when compared to CK treatment. SS, NR and PAL activities in maize leaves were significantly increased by AHA

3.6 Metabolomic profile

3.6.1 Effects of different treatments on overall metabolic profile

An untargeted metabolomics approach based on UPLC-QTOF-MS was used to obtain the metabolite profiles of maize leaves. Notably, 1373 characteristic peaks were detected and 1272 metabolites were identified. The PCA score plot (Figure 6) showed that the positive and negative ion modes explained 45.09% and 43.15% of the total variance, respectively. All groups in the positive ion mode were separated along PC2, and in the

negative ion mode the treatment groups and CK were separated along PC2 and between treatment groups along PC1, reflecting the differences in their metabolic profiles. Metabolomics data were compared between the three treatment groups using OPLS-DA for a two-by-two comparison to maximize intragroup separation. The OPLS-DA scores for metabolomic profiles of the various treatment groups indicated a definite distinction between the groups (Figure 7).

3.6.2 Identification of the discriminatory metabolites

Based on the VIP threshold ($VIP > 1$) in OPLS-DA combined with $p < 0.05$ from the univariate statistical analysis, 145 differentially abundant metabolites were screened. The identification of metabolites associated with the effects of humic acid spraying contributes to the understanding of the mechanism of action of HS. A Venn diagram (Figure 8A) was constructed to depict the differences and shared differentially abundant metabolites between the AHA treatment and CK groups, between the SHA treatment and CK groups, and between the AHA treatment and SHA treatment. Six shared differentially abundant metabolites were identified in all pairwise comparisons (trehalose, palatinose, diadinoxanthin A, fecosterol murrayone and 5-O-feruloylquinic

acid). Compared to the CK treatment, there were 15 specific differentially abundant metabolites observed in the AHA treatment group (including HDMBOA-Glc and Hirsuteine) and 42 specific differentially abundant metabolites were observed in the SHA treatment (such as jasmonic acid, linolenic acid and diosmin).

The 145 differentially abundant metabolites were classified into six categories according to their chemical properties (Figure 8B). Among which 80 metabolites (55.17% of the differentially abundant metabolites) were classified as lipids and lipid-like molecules, which are integral cellular components of the organism and play a key role in regulating normal cellular physiology and function, indicating that the different treatments significantly interfered with lipid metabolism in maize leaves. Phospholipids are a large class of lipids and lipid-like molecules and essential components of plant cell membranes and cellular signal transduction cascade reactions. In this study, 13 classes of phospholipid molecules and 53 species were identified. Eleven differentially abundant phospholipid molecules were screened in the comparison of SHA and CK treated maize leaves, of which 10 differentially abundant phospholipid molecules had an $FC > 1$ (Table S1). Ten differentially abundant phospholipid molecules were screened in the comparison of AHA and SHA treated maize leaves, of which

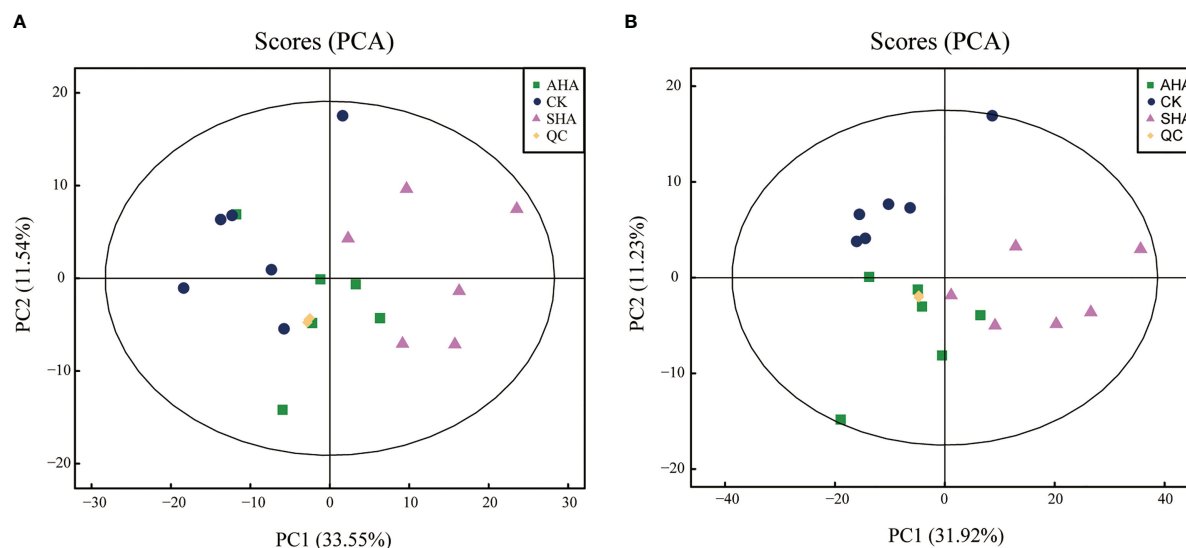

FIGURE 6

PCA score plots of metabolite profiles data obtained for maize leaf in positive ions mode (A) and negative ions mode (B) (n=6).

9 differentially abundant phospholipid molecules had an FC>1 (Table S1). In summary, a generally significant increase in phospholipid composition was observed in SHA treated maize leaves, suggesting a disorder of lipid metabolism.

Nine of the nineteen organic oxygen compounds were carbohydrates and carbohydrate conjugates (Figures 8B, 9A),

which are the energy carriers and the building blocks of primary and secondary metabolism in plants and play an important role in plant growth. Therefore, changes in carbohydrate response suggest that carbon redistribution and mobilization are important features of maize leaves subjected to different treatments.

FIGURE 8

(A) Venn diagram of differentially abundant metabolites in maize leaves from different treatment groups. (B) the classification of differentially abundant metabolites in maize leaf.

Among other metabolites, the response of benzoxazinone-glucoside (Bxs-Glc) differed among the different treatment (Figure 9B), and the relative abundance values of DIMBOA-Glc and HMBOA-Glc were significantly lower in the leaves of both groups subjected to humic acid spray treatments than in the CK treated leaves, while HDMBOA-Glc was a specific differentially abundant metabolite detected in the AHA treated leaves.

3.6.3 Alterations in metabolic pathways in maize leaves in response to different treatments

Changes in the abundance of metabolites reflect the inhibition or activation of specific metabolic pathways, which also represent the regulation of metabolism. Annotation of the identified metabolites yielded 19 metabolic pathways, including starch and sucrose metabolism; the citrate cycle (TCA cycle); stilbenoid, diarylheptanoid and gingerol biosynthesis; ABC transporters; biosynthesis of unsaturated fatty acids; alpha-linolenic acid

metabolism; tryptophan metabolism and carotenoid biosynthesis, among others (Table S1). The present study identified 21 differentially abundant metabolites produced by various metabolic pathways, including trehalose, sucrose, phenmetrazine, trimethoprim, meperidine, nandrolone, 2,5-Dihydroxybenzoic acid, 3-p-coumaroylquinic acid, stearic acid, trimethoprim, nostoxanthin, antheraxanthin, 9s,13r-12-oxophytodienoic acid, jasmonic acid, linolenic acid, safranal, cyromazine, cinobufagin, cholestenone, tryptophol, peonidin-3,5-O-di-beta-glucopyranoside, phenmetrazine, pergolide.

An enrichment analysis of metabolic pathways was subsequently performed to identify significantly affected metabolic and signal transduction pathways (Figure 10). Compared to the CK treatment, AHA treatment resulted in the reorganization of four metabolic pathways: starch and sucrose metabolism, TCA cycle, stilbenes, diarylheptanes, and curcumin biosynthesis, and ABC transport (Figure 10A). Of these, starch and sucrose metabolism,

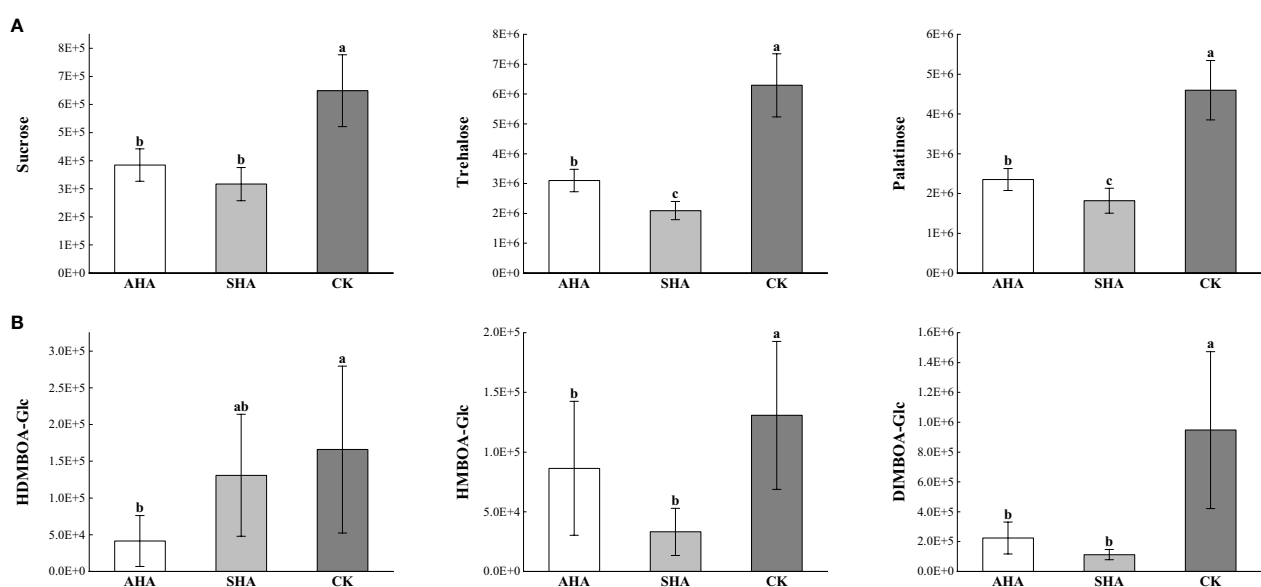

FIGURE 9

Relative abundance of differential metabolites in Maize leaf in different treatments. (A) relative abundance of carbohydrates; (B) relative abundance of Benzoxazinones (Bxs).

the TCA cycle is central to carbohydrate metabolism. Two metabolic pathways—starch and sucrose metabolism and unsaturated fatty acid biosynthesis—were modified by SHA therapy (Figure 10B). Only one metabolic pathway, starch and sucrose metabolism, was enriched when comparing the metabolic enrichment status of leaves treated with AHA and SHA (Figure 10C). One biological pathway, starch and sucrose metabolism, was altered in the comparisons of all treatment groups when they were compared, indicating that this pathway is sensitive in leaf tissue.

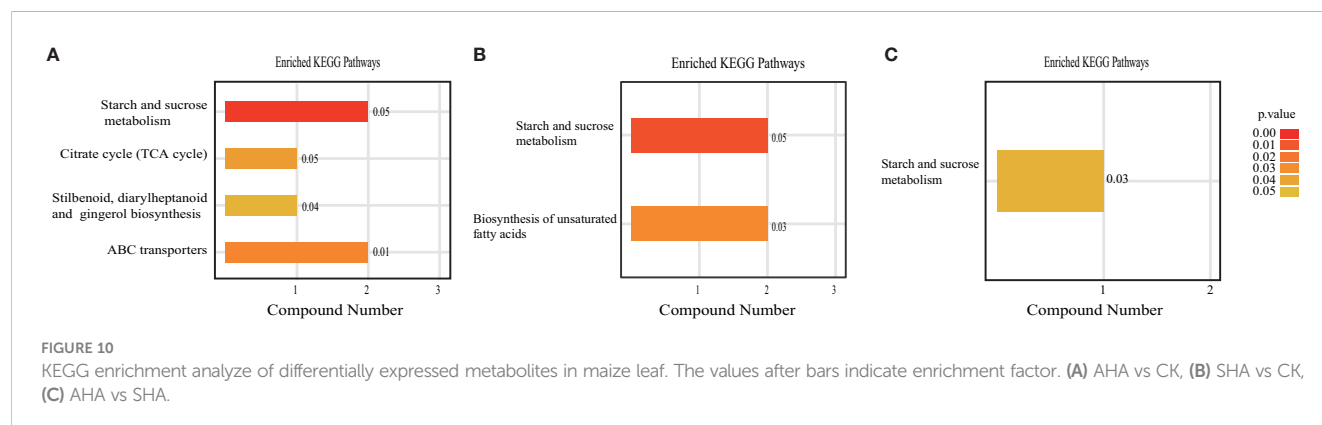

However, considering the effects of interconnected networks of metabolic pathways leads to a more thorough understanding. A more detailed sketch map of the metabolite network modifications in the main metabolic biosynthetic pathway which includes glycolysis, the TCA cycle, abscisic acid biosynthesis, and jasmonic acid biosynthesis, was shown in Figure 11. Regarding phytohormones, nostoxanthin and antheraxanthin, which are intermediates in the abscisic acid biosynthesis pathway, were down-regulated by both humic acid spray treatments when compared to CK treatment (Figure 11; Table S1), which may have led to a reduction in abscisic acid synthesis. Compared to the CK treatment, the accumulation of linolenic acid, jasmonic acid, and methyl jasmonate was decreased by SHA treatment in terms of the biosynthesis of jasmonic acid; AHA treatment only reduced the accumulation of methyl jasmonate, it had no effect on the accumulation of α -linolenic acid, 12-OPDA, or jasmonic acid (Figure 11; Table S1). Additionally, different treatments exerted distinct effects on the cytokinin production pathway. Compared to the CK treatment, SHA treatment increased trans-zeatin accumulation (VIP=0.18, $p<0.05$), while AHA treatment increased trans-zeatin accumulation (VIP=0.20, $p<0.05$), but substantially decreased zeatin nucleoside accumulation (VIP=0.44, $p<0.05$).

4 Discussion

HSs increase plant growth, root system development (Canellas et al., 2002; Zandonadi et al., 2007; Trevisan et al., 2010), and several physiological processes (Mora et al., 2010; Conselvan et al., 2017). HSs may be applied directly to the soil or sprayed over leaves. Both applications are commonly utilized in agricultural practices, the majority of the documented effects of HSs on plant growth are

derived from studies of short-term HSs application to roots in the greenhouse, whether in hydroponics or soil. However, other studies have highlighted the ability of HSs to promote plant growth when applied as a foliar spray. The effects of root-applied HSs are typically distinguished by two different mechanisms: one is indirect and involves enhancing the chemical, physical, and biological qualities of soil; the other is a direct result of the effects of the active ingredients on the controlling of growth processes, nutrient transport mechanisms, and primary and secondary metabolism. HSs applied to the leaves have little impact on the soil or rhizosphere, but there are major responses and interactions that take place between the soil and the roots that boost nutrient absorption. In this case, the mode of action of HSs seems to involve unique plant nutritional, metabolic and physiological responses.

De Hita et al. (2020) designed experiments to distinguish the mechanisms of action of foliar treatment of sedimentary humic acid on plant development compared with root application. Both application strategies promoted the growth of aboveground parts and roots. The potential of sedimentary humic acid to increase cytokinin concentration in aboveground tissues and indole-3-acetic acid concentrations in roots was shared by its foliar and root applications. Although foliar-applied sedimentary humic acid significantly increased shoot and root growth, it had no effect on the levels of nutrients in the leaves. Kishor et al. (2021) and Hernandez et al. (2014) found that foliar application of humic acid improved significantly the plant growth, yield and physiological processes in coffee and lettuce. The results presented here reveal various effects of two HSs from distinct origins on plant growth and highlight the challenge of research involving complex mixtures of poorly characterized components. Previous studies have observed the full range of plant responses to HSs, ranging from an inhibitory effect to a stimulatory effect (Rose et al., 2014; Canellas et al., 2015). In this study, foliar-applied AHA produced a larger biomass, plant height, leaf area, relative chlorophyll content and net photosynthesis, all of which indicated rapid resource utilization and subsequent rapid growth. However, AHA treatment did not cause any change in plant nutrient concentrations (except for the leaf P concentration, Figure 3). In combination with the findings of De Hita et al. (2020), this result may be attributed to the lack of an increase in H^+ -ATPase activity in the root plasma membrane following foliar spraying. The diluting effect may also account for the comparability of N and

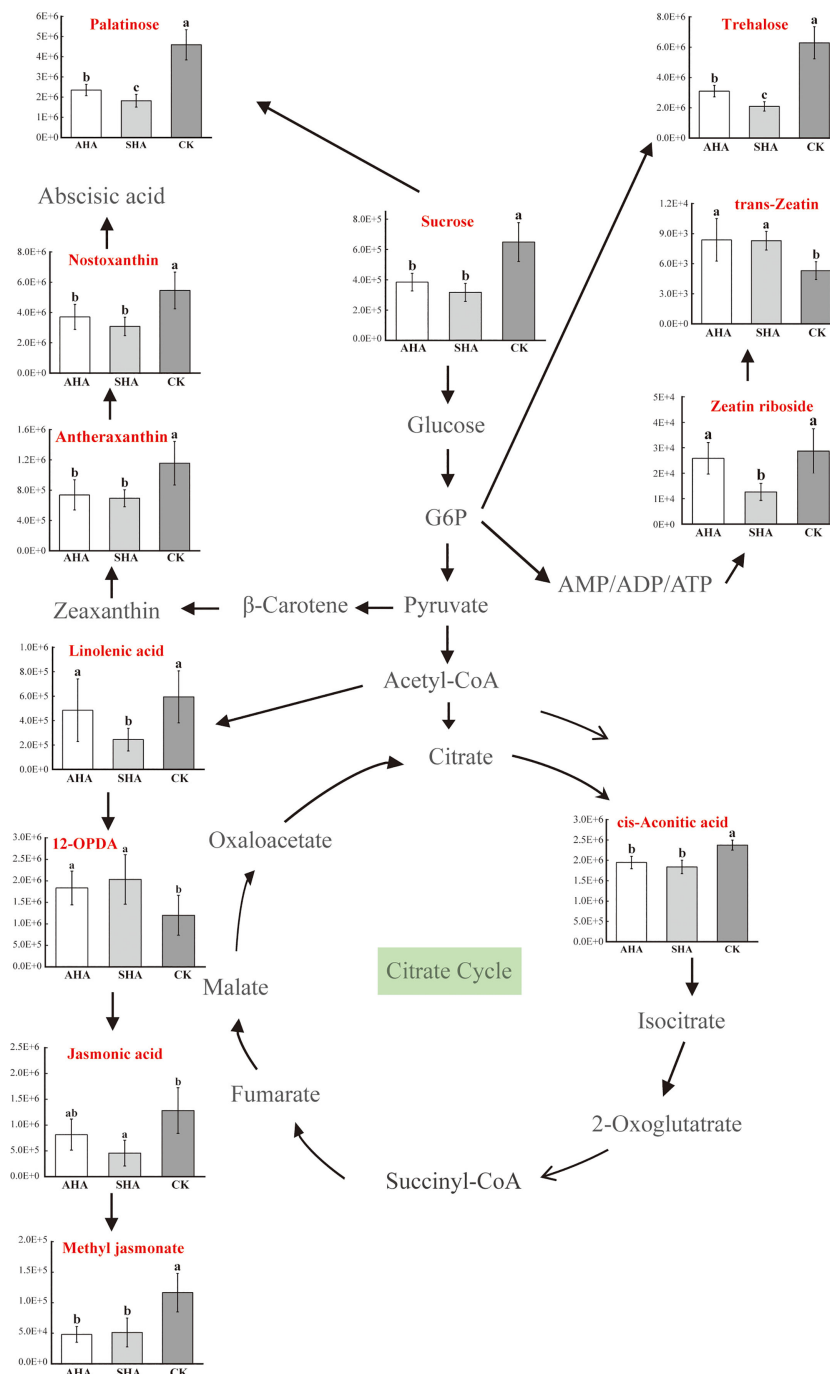

FIGURE 11

Simplified metabolic pathways of maize leaves exposed to different treatments. G6P, glucose-6-phosphate; AMP/ADP/ATP, adenosine monophosphate/adenosine diphosphate/adenosine triphosphate.

K concentrations in the AHA-treated plants to the control plants due to the relatively large plant size (Figure 3; Table 2). Furthermore, the AHA treatment significantly increased leaf dry matter while having no effect on plant root growth (Table 2). A possible explanation for this phenomenon is that AHA treatment reduces root redundancy in maize plants, which is highly energy intensive and has significant constraints on the formation of economic yield. It has long been accepted wisdom that the larger the root system, the more water and nutrients the plant

obtains, and the greater the output. However, excessive root growth will unavoidably result in redundancy, which will have an effect on aboveground growth (Hu et al., 2011). In addition, the application of AHA to maize leaves significantly enhanced photosynthesis, which in turn increased the amount of soluble sugar in the leaves. Meanwhile, AHA treatment also raised sucrose synthase activity, therefore, promoting the conversion and utilization of sugars in leaves, leading to an increase in the aboveground biomass.

Despite the considerable amount of data concerning the physiological and biochemical effects of these compounds on specific metabolic pathways, little information is available on the global effects exerted by HS on metabolism. As stated above, HSs appears to influence plant physiology through a cascade mechanism targeting multiple metabolic steps. Their hormone-like activity may have a role in this process, but other unidentified signaling networks may also contribute. A comprehensive study of the plant response to these substances might significantly contribute to improving our understanding of the molecular mode of action of these substances. Thus, we employed metabolomics to perform a large-scale investigation into the overall metabolic effects of HSs on maize. In this study, an untargeted metabolomics approach based on UPLC-QTOF-MS was used to obtain metabolite profiles of maize leaves, and PCA revealed differences in the metabolic profiles between the two humic acid treatment groups and CK group, as well as between the two humic acid treatment groups, which verified the different effects of these two humic acids on maize growth. Integration of KEGG enrichment analysis of differential metabolites revealed that compared to the CK group, AHA treatment reshaped four metabolic pathways: starch and sucrose metabolism, the TCA cycle, stilbenes, diarylheptanes and curcumin biosynthesis and ABC transport, of which starch and sucrose metabolism and the TCA cycle are the core of carbohydrate and energy metabolism.

Sugar is an energy source for plants and can act as a signaling molecule during plant growth. Previous studies have shown that changes in the amount of free sugars in maize modulate the expression of growth regulatory genes (Gibson, 2005). In this study, the relative sucrose content in maize leaves treated with CK was higher than that in AHA treatment group, and the stomatal conductance of leaves was also observed to be lower than that in AHA treatment group, resulting in a significant reduction in leaf photosynthesis. Several research papers have documented an effect of HSs on carbohydrate metabolism, modifying the level and distribution of sugars in treated plants. As an illustration, Conselvan et al. (2018) suggested that the lower sucrose concentration in HS-treated *Arabidopsis* roots and leaves may be responsible for higher glycolytic activity to support HS-stimulated metabolic activities and hence boost plant growth. This result is supported by the discovery of increased sucrose synthase activity in the AHA-treated leaves in the current study (Figure 5). A logical assumption is that rapidly growing plants have an increased demand for source leaf (fully expanded leaves) photoassimilates after spraying with AHA. Therefore, the sucrose export rate from the source leaf should be higher, with less sucrose accumulated during the daytime. As anticipated, the sucrose concentration was lower than that in parallel control leaves, but the photosynthesis and soluble sugar contents of the AHA-treated source leaves were higher than those of parallel control leaves (Figures 4, 5). Furthermore, excess sucrose may act as a signaling molecule to induce stomatal closure and reduce CO₂ uptake in guard cell. The surplus sucrose is delivered toward the stomata by the transpiration stream and triggers stomatal closure via hexokinase when the rate of sucrose production exceeds the rate at which sucrose is loaded into the phloem (Kelly et al., 2013). Regarding trehalose, which is a

typical stress metabolite, the larger amount of trehalose in CK treatment leaves may suggest the onset of a state of stress in plants. Indeed, plants typically contain little trehalose, as environmental stress increases, trehalose production starts to increase (Iordachescu and Imai, 2008; Wang et al., 2020).

Membrane lipids are also involved in the HS-induced modulation of plant signaling molecules. Phospholipids, which are plasma membrane component, are crucial for cell signaling, membrane trafficking, and apoptosis (Xue et al., 2009). The HS-based biostimulant treatment changed the phospholipids profile. The SHA treatment altered the levels of 11 foliar metabolites compared to CK, and 10 foliar metabolites compared to the AHA treatment. Therefore, maize leaves exposed to SHA may exhibit abnormalities in lipid metabolism, which exert a negative effect on the fluidity and integrity of cell membranes, thereby inhibiting maize growth and development.

Furthermore, we particularly noted that the content of benzoxazinones (BXs, such as BIMBOA-Glc, HDMBOA-Glc and HMBOA-Glc) was significantly lower in the leaves of maize sprayed with HSs than that in CK treatment. Benzoxazinoids (BXs) are regarded as a class of secondary metabolites involved in general defense in gramineae. Generally, BXs exist stably in plants in the form of glucosides, which are degraded into the corresponding glycosides and sugars to play a defensive role when the plant is attacked (Du Fall and Solomon, 2011). A general threshold for the induction of BXs production exists in plants upon pest and disease infestation and insect feeding, indicating that the plant mobilizes BXs for defense only after a certain level of damage by pathogens and insects occurs, which reduces the metabolic burden (Gianoli and Niemeyer, 1997). Furthermore, fulvic acid fractions have been shown to be effective in controlling several plant diseases, which were characterized by their capacity to induce host resistance towards a wide range of diseases or by directly acting as an antibacterial agent (Abdel-Monaim et al., 2011; Kamel et al., 2014). This also explained that the relative abundance of HDMBOA-Glc, HMBOA-Glc and DIMBOA-Glc in maize leaves sprayed with AHA and SHA in this study was generally lower than that in CK group, which may imply that maize leaves in the CK treatment group may consume more energy for defense.

The modulation of the phytohormone network contributed to the responses of plants to HS spray treatment. Nostoxanthin and antheraxanthin are two important intermediates in the synthetic pathway of the phytohormone abscisic acid (ABA). ABA is generally considered as the main phytohormone for plant resistance to abiotic stress, and ABA levels in plants increase when they are exposed to drought, salt, low temperature, high temperature, and injury. Therefore, ABA is also known as the adversity hormone (Klingler et al., 2010). Both HSs spray treatments significantly decreased the accumulation of these two metabolites, which may inhibit ABA synthesis. In addition, in this experiment, we observed that the stomatal conductance of CK-treated maize leaves was significantly lower than that of the humic acid spray treatment (Figure 4), which may also imply that the ABA content of humic acid-treated maize leaves was lower than that of the CK treatment, considering the relationship between stomatal conductance and ABA (Wang et al., 1994).

In the present study, SHA treatment decreased the accumulation of linolenic acid, a precursor in the jasmonic acid biosynthetic pathway, and the accumulation of jasmonic acid (JA) and methyl jasmonate (MeJA). Similarly, AHA treatment also decreased linolenic acid, JA and MeJA levels, but only the accumulation of MeJA was significantly different (Figure 10; Table S1). Since plant defense is an energy-intensive operation, JA is a stress hormone that controls how plants adapt to biotic and abiotic stress, forcing plants to stop active development (Ghorbel et al., 2021). In respect to cytokinins (CTK), both HSs treated maize leaves exhibited different levels of accumulation of *trans*-zeatin (tZ), but SHA treatment significantly decreased the accumulation of zeatin riboside when compared to CK treatment (Figure 11). The decreased accumulation of zeatin riboside, the main transport form of CTK, indicated that the CTK reserve in leaves treated with SHA was lower than that in leaves treated with CK and AHA (Figure 11). CTK negatively regulates the expression of chlorophyll-degrading enzyme-related genes, and induces the degradation of chlorophyll-degrading enzymes, resulting in an increase in the chlorophyll content, maintaining the normal photosynthetic capacity of leaves and the structure and function of the photosynthetic system, and extending the valid period of photosynthesis and the supply of photosynthetic compounds, it is the only known plant hormone that can delay leaf senescence (Talla et al., 2016). In the present study, the order of SPAD of maize leaves was AHA>SHA>CK, and the order of net photosynthesis was AHA, SHA>CK (Figure 4), consistent with the trend for tZ accumulation in leaves. In combination with the above discussion, the application of humic acid AHA increased the accumulation of tZ and down-regulated the relative levels of JA, MeJA and BXs in maize compared to CK, suggesting that there is a trade-off between growth and defense in plants sprayed with AHA and that this trade-off results in stimulation of plant growth.

Overall, although attributing the stimulation of the plant to few/some specific compounds is difficult, we speculate that the altered balance of phytohormones may have played a pivotal role in plant growth. Indeed, plant growth and development have consistently been shown to be tightly connected to hormone profile. Comparatively, much less is understood about the signaling pathways related to membrane lipids and the elicitation of secondary metabolism by HSs in terms of biotic stress induced systemic response to data, and further studies on this topic are advised.

For many years, soil scientists have endeavored to define the chemical characteristics and molecular structure of HSs and clarify how they can affect the growth and development of plants. Previous studies have observed that the complexity, chemical structure characteristics and biological activity of HSs determine their roles as plant growth biostimulators. Nardi et al. (2007) reported that low molecular weight HSs with high content of hydrophilic compounds significantly increased nitrogen uptake, the glycolytic pathway and the Krebs cycle in maize seedlings. The experimental results reported by Conselvan et al. (2018) revealed different response between plants treated with IAA and HS, emphasizing that responses evidenced by changes carbohydrate and amino acid concentrations were only partially attributed to

the effects of IAA on HS substrates. The presence of other molecules present in the HS matrix can be used to determine their biostimulatory effect.

Most commercial products currently available for agronomic purposes are obtained from nonrenewable coal substrates such as peat, weathered coal coals and lignite, which raises the question of whether key structural aspects related to plant stimulation are also present in coal-related HSs. The opposite consequences of coal-derived HS on crop productivity (i.e., promoted or diminished effects) may be reinterpreted in light of the different structures of these materials. In the present study, the differences in plant growth and nutrient content between the AHA and SHA treatment groups (Table 2; Figure 3) suggested that the response of maize plant to HSs depends on its molecular composition. The positive effects of AHA on maize growth, even under well-watered and fertilized conditions, suggest a direct effect of compounds present in AHA on the plant. These two HSs have different elemental and molecular structural compositions (Table 2; Figure 1; Support Material 1). Combining the molecular structural features of the two HSs, we deduced that growth-promoting effect observed following AHA application was mainly attributed to GA4, JA, dopamine, and cross talk with the other hormones present at lower concentrations. Gibberellin plays an important role in regulating the growth and size of various organs during the period of plant nutritional growth, including hypocotyl growth, leaf extension, plant height regulation and root development. Its regulation of plant nutritional organ growth and development is mainly reflected in the promotion of cell elongation and promotion of cell division.

3,5-dichlorosalicylic acid is a chemical inducer of systemic acquired resistance of plants to a wide range of pathogens (Basson and Dubery, 2007) with an FC value of 404.91 in both HS-treated groups (Support Material 1). In addition, we found that the two HSs contained different levels of small molecules with fungicidal and insecticidal properties, including methamidophos, dichlorimid, drazoxolon, triadimefon, penthiopyrad, pyrimethanil, perillaldehyde isocarbamid, mepanipyrim, moxamide, diethofencarb, triflumuron, bixafen, flusilazole, omethoate, spirodiclofen, fludioxonil, vanillic acid chlorogenic acid, quinolin-2-ol. These molecules may partly be responsible for the decreased activity of pathways regulating the biosynthesis of JA and ABA were in the HS-sprayed maize plants.

5 Conclusions

In this study, the molecular structures of two humic acids were characterized by ESI-UPLC-MS technique, and it was discovered that the molecular compositions of different sources of humic acids were similar with different relative abundances, and a total of 510 small molecules with significant differences were screened by combining multivariate statistical analysis. Pot spraying trials showed different effects of the two humic acids on maize growth and development: higher biomass, plant height, leaf area, chlorophyll content, and net photosynthesis were all observed in maize plants treated with AHA; the SHA treatment did not induce any significant changes in maize growth. Metabolomics revealed

that a total of 145 metabolites were significantly altered between the different spray treatments. Further analysis revealed that leaf lipid metabolism, starch and sucrose metabolism and some phytohormone-related biological pathways were regulated by the humic acid spray treatments. Among them, there was a generally significant increase in phospholipid composition of SHA treated maize leaves compared to CK and AHA treatments. Regarding phytohormones, nostoxanthin and antheraxanthin, which are intermediates in the abscisic acid biosynthesis pathway, were down-regulated by both spray treatments. In addition, both humic acid treatments stimulated the accumulation of tZ, SHA treatment significantly down-regulated the accumulation of zeatin nucleosides when compared to CK treatment.

Data availability statement

The original contributions presented in the study are publicly available. This data can be found here: MetaboLights, accession MTBLS7849.
