About Frontiers

Frontiers is more than just an open access publisher of scholarly articles: it is a pioneering approach to the world of academia, radically improving the way scholarly research is managed. The grand vision of Frontiers is a world where all people have an equal opportunity to seek, share and generate knowledge. Frontiers provides immediate and permanent online open access to all its publications, but this alone is not enough to realize our grand goals.

Frontiers journal series

The Frontiers journal series is a multi-tier and interdisciplinary set of open-access, online journals, promising a paradigm shift from the current review, selection and dissemination processes in academic publishing. All Frontiers journals are driven by researchers for researchers; therefore, they constitute a service to the scholarly community. At the same time, the *Frontiers journal series* operates on a revolutionary invention, the tiered publishing system, initially addressing specific communities of scholars, and gradually climbing up to broader public understanding, thus serving the interests of the lay society, too.

Dedication to quality

Each Frontiers article is a landmark of the highest quality, thanks to genuinely collaborative interactions between authors and review editors, who include some of the world's best academicians. Research must be certified by peers before entering a stream of knowledge that may eventually reach the public - and shape society; therefore, Frontiers only applies the most rigorous and unbiased reviews. Frontiers revolutionizes research publishing by freely delivering the most outstanding research, evaluated with no bias from both the academic and social point of view. By applying the most advanced information technologies, Frontiers is catapulting scholarly publishing into a new generation.

What are Frontiers Research Topics?

Frontiers Research Topics are very popular trademarks of the *Frontiers journals series*: they are collections of at least ten articles, all centered on a particular subject. With their unique mix of varied contributions from Original Research to Review Articles, Frontiers Research Topics unify the most influential researchers, the latest key findings and historical advances in a hot research area.

Find out more on how to host your own Frontiers Research Topic or contribute to one as an author by contacting the Frontiers editorial office: frontiersin.org/about/contact

Biostimulants in agriculture II: Towards a sustainable future

Topic editors

Maurizio Ruzzi — University of Tuscia, Italy

Giuseppe Colla — University of Tuscia, Italy

Youssef Rouphael — University of Naples Federico II, Italy

Citation

Ruzzi, M., Colla, G., Rouphael, Y., eds. (2024). *Biostimulants in agriculture II: Towards a sustainable future*. Lausanne: Frontiers Media SA. doi: 10.3389/978-2-8325-5017-5

Table of contents

- 12 **Editorial: Biostimulants in agriculture II: towards a sustainable future**
Maurizio Ruzzi, Giuseppe Colla and Youssef Rouphael
- 19 **Evaluation of the Potential Use of a Collagen-Based Protein Hydrolysate as a Plant Multi-Stress Protectant**
Stefano Ambrosini, Davide Segal, Chiara Santi, Anita Zamboni, Zeno Varanini and Tiziana Pandolfini
- 33 **Silicon-Mediated Priming Induces Acclimation to Mild Water-Deficit Stress by Altering Physio-Biochemical Attributes in Wheat Plants**
Arruje Hameed, Tahir Farooq, Amjad Hameed and Munir Ahmad Sheikh
- 46 ***Ascophyllum nodosum* Extract (Sealicit™) Boosts Soybean Yield Through Reduction of Pod Shattering-Related Seed Loss and Enhanced Seed Production**
Łukasz Łangowski, Oscar Goñi, Fabio Serafim Marques, Osvaldo Toshiyuki Hamawaki, Carolina Oliveira da Silva, Ana Paula Oliveira Nogueira, Morgana Aparecida Justino Teixeira, Jacqueline Siqueira Glasenapp, Marcio Pereira and Shane O'Connell
- 57 **Seed Biopriming With *Trichoderma* Strains Isolated From Tree Bark Improves Plant Growth, Antioxidative Defense System in Rice and Enhance Straw Degradation Capacity**
Harekrushna Swain, Totan Adak, Arup K. Mukherjee, Sarmistha Sarangi, Pankajini Samal, Ansuman Khandual, Rupalin Jena, Pratap Bhattacharyya, Soumendra K. Naik, Sayaji T. Mehetre, Mathew S. Baite, Sunil Kumar M and Najam Waris Zaidi
- 72 **5-Aminolevulinic Acid Improves Morphogenesis and Na⁺ Subcellular Distribution in the Apical Cells of *Cucumis sativus* L. Under Salinity Stress**
Yue Wu, Na Liu, Linli Hu, Weibiao Liao, Zhongqi Tang, Xuemei Xiao, Jian Lyu, Jianming Xie, Alejandro Calderón-Urrea and Jihua Yu
- 84 **Potential of Algae–Bacteria Synergistic Effects on Vegetable Production**
Yeeun Kang, Minjeong Kim, Changki Shim, Suyea Bae and Seonghoe Jang
- 97 **Endophytic Bacterial Isolates From Halophytes Demonstrate Phytopathogen Biocontrol and Plant Growth Promotion Under High Salinity**
Christos A. Christakis, Georgia Daskalogiannis, Anastasia Chatzaki, Emmanouil A. Markakis, Glykeria Mermigka, Angeliki Sagia, Giulio Flavio Rizzo, Vittoria Catara, Ilias Lagkouvardos, David J. Studholme and Panagiotis F. Sarris
- 115 **Reducing Nitrogen Input in Barley Crops While Maintaining Yields Using an Engineered Biostimulant Derived From *Ascophyllum nodosum* to Enhance Nitrogen Use Efficiency**
Oscar Goñi, Łukasz Łangowski, Ewan Feeney, Patrick Quille and Shane O'Connell

- 133 **Effects of Seaweed Extracts on the Growth, Physiological Activity, Cane Yield and Sucrose Content of Sugarcane in China**
Diwen Chen, Wenling Zhou, Jin Yang, Junhua Ao, Ying Huang, Dachun Shen, Yong Jiang, Zhenrui Huang and Hong Shen
- 146 **Integration of Gas Exchange With Metabolomics: High-Throughput Phenotyping Methods for Screening Biostimulant-Elicited Beneficial Responses to Short-Term Water Deficit**
Giulia Antonucci, Michele Croci, Begoña Miras-Moreno, Alessandra Fracasso and Stefano Amaducci
- 162 **Impact of Plant Growth-Promoting Rhizobacteria Inoculation and Grafting on Tolerance of Tomato to Combined Water and Nutrient Stress Assessed via Metabolomics Analysis**
Panagiotis Kalozoumis, Dimitrios Savvas, Konstantinos Aliferis, Georgia Ntatsi, George Marakis, Evridiki Simou, Anastasia Tampakaki and Ioannis Karapanos
- 177 **AMF Inoculation Can Enhance Yield of Transgenic *Bt* Maize and Its Control Efficiency Against *Mythimna separata* Especially Under Elevated CO₂**
Long Wang, Xiaohui Wang, Fanqi Gao, Changning Lv, Likun Li, Tong Han and Fajun Chen
- 193 **Systematic Investigation of the Effects of Seven Plant Extracts on the Physiological Parameters, Yield, and Nutritional Quality of Radish (*Raphanus sativus* var. *sativus*)**
Katarzyna Godlewska, Paweł Pacyga, Izabela Michalak, Anita Biesiada, Antoni Szumny, Natalia Pachura and Urszula Piszcz
- 230 **Endophytic *Bacillus altitudinis* Strain Uses Different Novelty Molecular Pathways to Enhance Plant Growth**
Dening Zhang, Hongli Xu, Jingyao Gao, Roxana Portieles, Lihua Du, Xiangyou Gao, Carlos Borroto Nordelo and Orlando Borrás-Hidalgo
- 245 **Contribution of Arbuscular Mycorrhizal Fungi, Phosphate–Solubilizing Bacteria, and Silicon to P Uptake by Plant**
Hassan Etesami, Byoung Ryong Jeong and Bernard R. Glick
- 274 **Effect of Humic Acid Addition on Buffering Capacity and Nutrient Storage Capacity of Soilless Substrates**
Jingcheng Xu, Esraa Mohamed, Qiang Li, Tao Lu, Hongjun Yu and Weijie Jiang
- 286 **Bioformulation of Silk-Based Coating to Preserve and Deliver *Rhizobium tropici* to *Phaseolus vulgaris* Under Saline Environments**
Manal Mhada, Augustine T. Zvinavashe, Zakaria Hazzoumi, Youssef Zeroual, Benedetto Marelli and Lamfeddal Kouisni

- 297 **Comparative Transcriptomics and Metabolomics Reveal an Intricate Priming Mechanism Involved in PGPR-Mediated Salt Tolerance in Tomato**
Ifigeneia Mellidou, Aggeliki Ainalidou, Anastasia Papadopoulou, Kleopatra Leontidou, Savvas Genitsaris, Evangelos Karagiannis, Bram Van de Poel and Katerina Karamanoli
- 319 **Limiting-Stress-Elimination Hypothesis: Using Non-hormonal Biostimulant to Reduce Stress and Increase Savanna Cowpea [*Vigna unguiculata* (L.) Walp.] Productivity**
Acheampong Atta-Boateng and Graeme P. Berlyn
- 329 ***Pseudomonas palmensis* sp. nov., a Novel Bacterium Isolated From *Nicotiana glauca* Microbiome: Draft Genome Analysis and Biological Potential for Agriculture**
Enrique Gutierrez-Albanchez, Ana García-Villaraco, José A. Lucas, Ignacio Horche, Beatriz Ramos-Solano and F. J. Gutierrez-Mañero
- 344 **Can Inoculation With the Bacterial Biostimulant *Enterobacter* sp. Strain 15S Be an Approach for the Smarter P Fertilization of Maize and Cucumber Plants?**
Mónica Yorlady Alzate Zuluaga, André Luiz Martinez de Oliveira, Fabio Valentinuzzi, Raphael Tiziani, Youry Pii, Tanja Mimmo and Stefano Cesco
- 362 **Liquiritoside Alleviated Pb Induced Stress in *Brassica rapa* subsp. *Parachinensis*: Modulations in Glucosinolate Content and Some Physiochemical Attributes**
Waheed Akram, Waheed Ullah Khan, Anis Ali Shah, Nasim Ahmad Yasin and Guihua Li
- 374 **The Role of Plant Origin Preparations and Phenological Stage in Anatomy Structure Changes in the Rhizogenesis of *Rosa* “Hurdal”**
Marta Joanna Monder, Paweł Kozakiewicz and Agnieszka Jankowska
- 397 **Differential Effects of Exogenous Glomalin-Related Soil Proteins on Plant Growth of Trifoliate Orange Through Regulating Auxin Changes**
Rui-Cheng Liu, Wei-Qin Gao, Anoop Kumar Srivastava, Ying-Ning Zou, Kamil Kuča, Abeer Hashem, Elsayed Fathi Abd_Allah and Qiang-Sheng Wu
- 408 **Phosphorus-Use Efficiency Modified by Complementary Effects of P Supply Intensity With Limited Root Growth Space**
Haiqing Gong, Bilisuma Kabeto Wako, Yue Xiang and Xiaoqiang Jiao
- 418 **Adaptive Reprogramming During Early Seed Germination Requires Temporarily Enhanced Fermentation-A Critical Role for Alternative Oxidase Regulation That Concerns Also Microbiota Effectiveness**
Revuru Bharadwaj, Carlos Noceda, Gunasekharan Mohanapriya, Sarma Rajeev Kumar, Karine Leitão Lima Thiers, José Hélio Costa, Elisete Santos Macedo, Aprajita Kumari, Kapuganti Jagadis Gupta, Shivani Srivastava, Alok Adholeya, Manuela Oliveira, Isabel Velada, Debabrata Sircar, Ramalingam Sathishkumar and Birgit Arnholdt-Schmitt

- 429 **Dose-Dependent Application of Straw-Derived Fulvic Acid on Yield and Quality of Tomato Plants Grown in a Greenhouse**
Peijia Zhang, Hongjia Zhang, Guoqing Wu, Xiaoyuan Chen, Nazim Gruda, Xun Li, Jinlong Dong and Zengqiang Duan
- 441 **Isolation and Evaluation of Rhizosphere Actinomycetes With Potential Application for Biocontrolling *Fusarium* Wilt of Banana Caused by *Fusarium oxysporum* f. sp. *cubense* Tropical Race 4**
Lu Zhang, Huixi Zhang, Yating Huang, Jun Peng, Jianghui Xie and Wei Wang
- 457 **Efficiency of the Hydroponic System as an Approach to Confirm the Solubilization of CaHPO_4 by Microbial Strains Using *Glycine max* as a Model**
Mateus Neri Oliveira Reis, Layara Alexandre Bessa, Andressa Pereira de Jesus, Fabiano Guimarães Silva, Marialva Alvarenga Moreira and Luciana Cristina Vitorino
- 475 **2-Keto-L-Gulonic Acid Improved the Salt Stress Resistance of Non-heading Chinese Cabbage by Increasing L-Ascorbic Acid Accumulation**
Mingfu Gao, Hao Sun, Meijun Shi, Qiqi Wu, Dongxu Ji, Bing Wang, Lixin Zhang, Yang Liu, Litao Han, Xicheng Ruan, Hui Xu and Weichao Yang
- 487 **Co-composted Biochar Enhances Growth, Physiological, and Phytostabilization Efficiency of *Brassica napus* and Reduces Associated Health Risks Under Chromium Stress**
Muhammad Naveed, Bisma Tanvir, Wang Xiukang, Martin Brtnicky, Allah Ditta, Jiri Kucerik, Zinayyera Subhani, Muhammad Zubair Nazir, Maja Radziemska, Qudsia Saeed and Adnan Mustafa
- 502 **Biostimulant Capacity of an Enzymatic Extract From Rice Bran Against Ozone-Induced Damage in *Capsicum annum***
Sandra Macias-Benitez, Salvadora Navarro-Torre, Pablo Caballero, Luis Martín, Elisa Revilla, Angélica Castaño and Juan Parrado
- 515 **The Use of Interactions Between Microorganisms in Strawberry Cultivation (*Fragaria x ananassa* Duch.)**
Magdalena Drobek, Justyna Cybulska, Anna Gałązka, Beata Feledyn-Szewczyk, Anna Marzec-Grządziel, Lidia Sas-Paszt, Agata Gryta, Paweł Trzcinski, Artur Zdunek and Magdalena Frąc
- 531 **Sorghum-Phosphate Solubilizers Interactions: Crop Nutrition, Biotic Stress Alleviation, and Yield Optimization**
Asfa Rizvi, Bilal Ahmed, Mohammad Saghir Khan, Shahid Umar and Jintae Lee
- 550 **Melatonin Enhances Drought Tolerance by Regulating Leaf Stomatal Behavior, Carbon and Nitrogen Metabolism, and Related Gene Expression in Maize Plants**
Chengfeng Zhao, Haoxue Guo, Jiarui Wang, Yifan Wang and Renhe Zhang

- 566 **Coated Diammonium Phosphate Combined With Humic Acid Improves Soil Phosphorus Availability and Photosynthesis and the Yield of Maize**
Qi Chen, Zhaoming Qu, Zeli Li, Zixin Zhang, Guohua Ma, Zhiguang Liu, Yanfeng Wang, Liang Wu, Fuli Fang, Zhanbo Wei and Min Zhang
- 580 **Physiological Biochemistry-Combined Transcriptomic Analysis Reveals Mechanism of *Bacillus cereus* G2 Improved Salt-Stress Tolerance of *Glycyrrhiza uralensis* Fisch. Seedlings by Balancing Carbohydrate Metabolism**
Xiang Xiao, Qiuli Wang, Xin Ma, Duoyong Lang, Zhenggang Guo and Xinhui Zhang
- 601 **Effects of Preharvest Methyl Jasmonate and Salicylic Acid Treatments on Growth, Quality, Volatile Components, and Antioxidant Systems of Chinese Chives**
Cheng Wang, Jing Zhang, Jianming Xie, Jihua Yu, Jing Li, Jian Lv, Yanqiang Gao, Tianhang Niu and Bakpa Emily Patience
- 616 **Integration of Phenomics and Metabolomics Datasets Reveals Different Mode of Action of Biostimulants Based on Protein Hydrolysates in *Lactuca sativa* L. and *Solanum lycopersicum* L. Under Salinity**
Mirella Sorrentino, Klára Panzarová, Ioannis Spyroglou, Lukáš Spíchal, Valentina Buffagni, Paola Ganugi, Youssef Roupahel, Giuseppe Colla, Luigi Lucini and Nuria De Diego
- 634 **Multiple Arbuscular Mycorrhizal Fungal Consortia Enhance Yield and Fatty Acids of *Medicago sativa*: A Two-Year Field Study on Agronomic Traits and Tracing of Fungal Persistence**
Elisa Pellegrino, Marco Nuti and Laura Ercoli
- 653 **Myco-Synergism Boosts Herbivory-Induced Maize Defense by Triggering Antioxidants and Phytohormone Signaling**
Raufa Batool, Muhammad Jawad Umer, Yangzhou Wang, Kanglai He, Muhammad Zeeshan Shabbir, Tiantao Zhang, Shuxiong Bai, Jie Chen and Zhenying Wang
- 672 **A Global Network Meta-Analysis of the Promotion of Crop Growth, Yield, and Quality by Bioeffectors**
Michelle Natalie Herrmann, Yuan Wang, Jens Hartung, Tobias Hartmann, Wei Zhang, Peteh Mehdi Nkebiwe, Xinping Chen, Torsten Müller and Huaiyu Yang
- 687 **Identification and Characterization of *Bacillus tequilensis* GYUN-300: An Antagonistic Bacterium Against Red Pepper Anthracnose Caused by *Colletotrichum acutatum* in Korea**
Hyeok-Tae Kwon, Younmi Lee, Jungyeon Kim, Kotnala Balaraju, Heung Tae Kim and Yongho Jeon
- 705 **Application of a Biostimulant (Pepton) Based in Enzymatic Hydrolyzed Animal Protein Combined With Low Nitrogen Priming Boosts Fruit Production Without Negatively Affecting Quality in Greenhouse-Grown Tomatoes**
Tania Mesa, Javier Polo, Andrea Casadesús, Íñigo Gómez and Sergi Munné-Bosch

- 716 **Root Reinforcement Improved Performance, Productivity, and Grain Bioactive Quality of Field-Droughted Quinoa (*Chenopodium quinoa*)**
Salma Toubali, Mohamed Ait-El-Mokhtar, Abderrahim Boutasknit, Mohamed Anli, Youssef Ait-Rahou, Wissal Benaffari, Hela Ben-Ahmed, Toshiaki Mitsui, Marouane Baslam and Abdelilah Meddich
- 736 **Iron Oxide and Silicon Nanoparticles Modulate Mineral Nutrient Homeostasis and Metabolism in Cadmium-Stressed *Phaseolus vulgaris***
Lyubka Koleva, Aisha Umar, Nasim Ahmad Yasin, Anis Ali Shah, Manzer H. Siddiqui, Saud Alamri, Luqman Riaz, Ali Raza, Talha Javed and Zunera Shabbir
- 749 **Foliar Application of an Inositol-Based Plant Biostimulant Boosts Zinc Accumulation in Wheat Grains: A μ -X-Ray Fluorescence Case Study**
Douglas C. Amaral and Patrick H. Brown
- 758 **A Meta-Analysis of Biostimulant Yield Effectiveness in Field Trials**
Jing Li, Thijs Van Gerrewey and Danny Geelen
- 771 **Designing Synergistic Biostimulants Formulation Containing Autochthonous Phosphate-Solubilizing Bacteria for Sustainable Wheat Production**
Mahreen Yahya, Maria Rasul, Yasra Sarwar, Muhammad Suleman, Mohsin Tariq, Syed Zajif Hussain, Zahid Iqbal Sajid, Asma Imran, Imran Amin, Thomas Reitz, Mika Tapio Tarkka and Sumera Yasmin
- 787 **Photosynthetic Pigments and Biochemical Response of Zucchini (*Cucurbita pepo* L.) to Plant-Derived Extracts, Microbial, and Potassium Silicate as Biostimulants Under Greenhouse Conditions**
Doaa Y. Abd-Elkader, Abeer A. Mohamed, Mostafa N. Feleafele, Asma A. Al-Huqail, Mohamed Z. M. Salem, Hayssam M. Ali and Hanaa S. Hassan
- 801 **Humic Acid Modified by Being Incorporated Into Phosphate Fertilizer Increases Its Potency in Stimulating Maize Growth and Nutrient Absorption**
Jianyuan Jing, Shuiqin Zhang, Liang Yuan, Yanting Li, Chengrong Chen and Bingqiang Zhao

Editorial on the Research Topic

Biostimulants in agriculture II: towards a sustainable future

1 Introduction

Current socio-political scenarios are pushing the agricultural sector towards a rapid ecological transition. For this reason, modern agriculture is forced to expand its ordinary practices to achieve greater sustainability in line with the principles of economic and environmental circularity (Velasco-Muñoz et al., 2021). Nonetheless, current challenges such as the need to increase productivity and the efficiency of non-renewable resources in increasingly unfavorable contexts strain agro-ecosystems resilience. Over the last century, synthetic agrochemicals have been the only tool capable of increasing yields and ensuring satisfactory production volumes throughout the seasons (Donate and Frederico, 2019). Awareness of the weighty environmental impact associated with the disproportionate use of these chemicals has stimulated research and development of technological innovations capable of improving the sustainability of agricultural production without compromising yield and quality. In recent decades, biostimulants have represented an efficient and virtuous innovation capable of improving tolerance against a wide range of stressors, stimulating the growth and productivity of crops while efficiently utilizing nutrients (nutrient use efficiency). According to the latest European Regulation 2019/1009, plant biostimulants are defined as “a product that stimulates the nutritional processes of plants independently of the nutrients it contains, with the sole aim of improving one or more of the following characteristics of plants or their rhizosphere: (1) the efficiency of nutrient use; (2) tolerance to abiotic stress; (3) qualitative characteristics; (4) the availability of nutrients confined in the soil or rhizosphere.” Beneficial microorganisms and numerous natural substances and derivatives of natural and/or synthetic compounds are considered plant biostimulants; these include (1) humic substances, (2) protein hydrolysates and amino-acid based products, (3) macro- and micro-algae extracts, and plant extracts, (4) silicon; (5) Arbuscular Mycorrhizal Fungi (AMF); and (6) plant growth-promoting rhizobacteria (PGPR) belonging to the genera *Azotobacter*, *Azospirillum* and *Rhizobium* spp (EU, 2019). Although biostimulants were initially designed as a helpful tool mainly in organic farming, they are now used in all cropping systems (organic, conventional, and integrated) in the open field and protected cultivation.

Driven by the strong dependence on the agricultural sector for food, the economic size of the biostimulants market reached USD 3 billion in 2022 and is expected to grow at a compound annual growth rate (CAGR) of 10.5% over the next decade. Europe dominated the market with a revenue share of over 37.0% (GVR, 2023). This is partly attributed to the support regulations to stimulate organic food production, which are expected to drive the market in Europe and beyond in the future. The strong interest in the topic of biostimulants is confirmed by the data available on Scopus (www.scopus.com). Taking the last ten years (2013–2023) as a reference, searching for the term ‘plant biostimulants’ more than 2000 scientific papers were found. These numbers are not surprising since, as reported by several authors (Jindo et al., Tripathi et al., Herrmann et al., and Li et al.), the use of substances and microorganisms with biostimulant action is of interest in all productive agricultural systems (horticulture, arboriculture and viticulture, cereal cultivation and industrial crops), even if their efficacy as underlined by the same authors varies depending on the cultivation conditions and the sensitivity of the reference species. The present topic brings together 77 scientific contributions (68 research articles and 9 reviews; Supplementary Table 1) investigating both under optimal and sub-optimal conditions, the productive and/or qualitative response of crops of agronomic interest to the application of biostimulants, as well as the use of compounds with elicitor action.

2 Biostimulants improve tolerance to abiotic stress

Due to the unpredictable and damaging effects of climatic anomalies associated with climate change, crops experience many stresses that inevitably reduce yield and final product quality, thus making it difficult to achieve food security objectives (Goud et al., 2022). Using products with biostimulant action represents one of the most innovative and promising tools to counter these stressors and reduce the gap between achievable yield and potential yield (Rouphael and Colla, 2020). Considering that plants respond to environmental stresses through adaptive cellular reprogramming, the work of Bharadwaj et al. emphasizes that during the delicate phase of seed germination, cellular sucrose levels are a very important sensor of environmental stresses that can be used to improve germination and disease detection. As discussed by Atta-Boateng and Berlyn, yield reductions are not exclusively attributable to specific stress but to a co-presence of them. Choosing cowpea (*Vigna unguiculata* (L.) Walp.), adapted to nitrogen dependence, as a model crop, Atta-Boateng and Berlyn observed that the use of non-hormonal biostimulants (product based on antioxidants and amino acids prepared by the laboratory of the Yale School of the Environment) is an efficient tool to promote productivity when it is limited by osmotic stresses attributable to high temperatures, water limitations, and sub-optimal moisture conditions. Ambrosini et al. evaluated the ability of an animal-derived protein hydrolysate to mitigate the incidence of drought stress and root oxygen and iron deficiency conditions in hydroponically grown maize plants (*Zea mays* L.). The same authors also emphasized once again how the positive effects cannot be attributed to an exclusive mechanism of

action but are instead the result of the commercial formulation’s synergistic action of different components (mainly peptides). In this context, Antonucci et al., using a mixed phenotypic-omics approach, observed the mechanisms implemented following the use of a commercial glycine betaine-based biostimulant in tomato (*Solanum lycopersicum* L.) plants (during the flowering phase) subjected to water stress. The authors reported a priming effect of the biostimulant aimed at stabilizing the photosynthetic machinery, both mediated by the hyperaccumulation of carotenoids and lipids and improved water use efficiency. After foliar application of melatonin (100 μ M), Zhao et al. observed an improvement in the growth and photosynthetic capacity of maize plants grown under drought conditions attributable to increased proline levels. In addition, the application of melatonin increased enzyme activities involved in nitrogen metabolism. Hernandez et al., after optimizing the dose of putrescine (Put) and spermidine (Spd) in a growth chamber experiment, evaluated the effect of these two polyamines on maize plants grown in a protected environment under optimal irrigation and deficit irrigation conditions. Using Put and Spd with a higher meal’s mineral content (Ca, Cu, and Zn) improved the saleable yield under optimal and sub-optimal conditions. Starting from the assumption that continuous states of water stress (even mild ones) negatively affect plant germination, development, and proper growth, Hameed et al. evaluated on wheat (*Triticum aestivum* L.) the effect of sodium silicate (SS) as a priming agent to reduce the effects of water stress (50% of soil water retention capacity). At plant maturity, the authors observed, under water-limited conditions, an improvement in yield parameters induced by the positive action of Si for plants previously primed with SS. Also, on wheat, Lalarukh et al. investigated the efficacy of the single or combined use of *Pseudomonas aeruginosa* (Pa) (10^8 CFU ml^{-1}) and moringa leaf extracts at different doses (MLE 1 = 1:15 v/v and MLE 2 = 1:30 v/v) under drought and nutritional stress conditions. At the end of their field trial, the authors observed for plants treated with Pa + MLE 2 a significant improvement in yield traits in stressed wheat plants. The synergy between microbial and non-microbial biostimulants is paving the way for research into biopreparations that can further improve yield performance. Considering this, Kang et al. summarized in their review the potential synergistic effects of algae and bacteria on plant production as biostimulants and biofertilizers. In this context, a commercial biostimulant based on glycine betaine (GB), distributed at a rate of 6 kg ha^{-1} , was tested. The trials were conducted on tomato plants during the flowering phase in the greenhouse. A factorial combination of two irrigation (water stress and well-watered) and two biostimulant treatments (treated and control) was adopted, along with a mixed phenotypic-omics approach. The authors demonstrated the priming effect of the biostimulant on drought tolerance, detoxification, and stabilization of the photosynthetic machinery. The metabolic profile and photosynthetic performance results suggest increased effective water utilization through lipid hyperaccumulation and leaf thickening. Also, on tomatoes subjected to combined water and nutrient deficiency, Kalozoumis et al. evaluated the possible effects of inoculating plant growth-promoting rhizobacteria (PGPR) with the agronomic practice of grafting. At the end of the experimental study, the authors emphasized the importance of the combined

selection of PGPR strains and rootstock genotypes to achieve a substantial benefit under combined stress conditions. In a similar study, [Toubali et al.](#) evaluated the single and/or combined effects of inoculating arbuscular mycorrhizal fungi and compost on the field production of quinoa (*Chenopodium quinoa* Willd.) under water stress. Microbial biostimulation and the presence of compost ensured that plants subjected to suboptimal water levels maintained high production yields due to specific morpho-physiological adaptations. The review by [Etesami et al.](#) investigates in detail the contribution of AMF, phosphate-solubilizing bacteria (PSB), and silica in improving the availability and efficacy of phosphate, a limestone-limiting macroelement, especially in calcareous and acidic soils. [Wang et al.](#) observed a significant increase in maize Bt yield, foliar contents of salicylic acid (SA) and jasmonic acid, Bt toxin content, and gene expression after inoculation of an AMF species (*Glomus caledonium*). However, even though mutualistic relationships between mycorrhizal fungi and plants are routinely 'exploited' to improve the latter's tolerance to a multitude of abiotic and other stresses, most of the scientific literature is mainly concerned with the study of arbuscular mycorrhizae. The review proposed by [Wei et al.](#) focused on describing the positive effects (increased tolerance to drought, heavy metals, soil salinity, and pathogen infections) of ericoid mycorrhizae on plants belonging to the *Ericaceae* family. [Nazari et al.](#) evaluated the interactive effects between plant and bacteriocin molecules to reduce the negative impact of low-temperature stress (5°C) on canola. Specifically, treatment with 10^{-9} thuricin 17 (Th17) significantly improved seed vigor index, germination rate, root and shoot length, and fresh weight of seeds under optimal, and low-temperature conditions. According to the study by [Sun et al.](#), the definition and characterization of vegetative attributes through leaf spectral indices could provide useful information to better understand plant-microbe relationships by optimizing bioproducts. The research by [Melini et al.](#) emphasizes that the use of selected strains of *Pantoea agglomerans* can be a promising approach for the development of new plant biostimulants for agricultural use through the fermentative production of auxin/indole 3-acetate (IAA). Similarly, through *in vitro* phenotypic analyses, [Gutierrez-Albanchez et al.](#) demonstrated the ability of a new *Pseudomonas*, designated as strain BBB001T, to produce auxins and siderophores. Subsequently, the same authors confirmed the potential of this strain by testing on olives (*Olea europaea* L.) and tomatoes (*S. lycopersicum* L.) grown under water limitation or iron deficiency, respectively. Based on the phosphate-solubilising capacity and the production of IAA, *Pseudomonas* sp. strain 1008 (isolated from the rhizosphere of wheat plants), [Díaz et al.](#) observed an increase in grain yield after inoculation of the biostimulant bacterium on wheat seeds from 2010–2017. Further genome sequencing analyses revealed the ability of strain 1008 to efficiently utilise organic and inorganic sources of phosphorus and compete for iron scavenging as well as the production of auxins and GABA. To limit the negative effects induced by iron deficiency on *Cinnamomum camphora*, [Kong et al.](#) investigated the role of *Rahnella aquatilis* (JZ-GX1) by assessing the active iron content, chlorophyll, and effects on the microbial community. The results

showed that inoculation of JZ-GX1 increased chlorophyll content and enzyme activities (SOD, POD, CAT, and APX) on stressed plants. On the other hand, [Macias-Benitez et al.](#) investigated the biostimulating capacity of a rice bran enzyme extract (RBEE) used as a protective agent against oxidative damage from ozone exposure in the growth chamber. Pepper plants (*Capsicum annum* L.) treated with RBEE showed a reduction in photosynthetic limitation attributable to the oxidative action of ozone. Pot experiments conducted by [Raza et al.](#) showed that applying a vitamin B complex significantly improved the photosynthetic performance of radish plants, underlining the positive contribution of natural biostimulant products on crop productivity. Although most metals are essential trace elements for plants, their excess (often caused by human activities) is responsible for damaging effects that limit plant growth and metabolism. Considering this, the use of biostimulants to improve the effectiveness of ordinary remediation practices has been attracting increasing attention in recent years. Exploiting the synergistic effect between silicon nanoparticles and iron oxide nanoparticles, [Koleva et al.](#) observed on *Phaseolus vulgaris* plants grown on cadmium (Cd)-contaminated soil an improvement in growth and a significant reduction in electrolyte loss and malondialdehyde (MDA) content. Similarly, the foliar application of liquiritoside (liquiritin), a flavonoid complex isolated from *Glycyrrhizae radix*, proposed by [Akram et al.](#) on Chinese cabbage (*Brassica rapa* subsp. *parachinensis*) mitigated the phytotoxic effects induced by the presence of lead (Pb) through a reduction in the MDA, H₂O, and cysteine content of the treated plants. [Naveed et al.](#) evaluated the potential of compost, biochar, and co-composted biochar on *Brassica napus* plants grown on chromium (Cr)-contaminated soil. At the end of the experiment, [Naveed et al.](#) observed a significant improvement in biometric and physiological traits of Cr-stressed plants after using co-composted biochar. [Mustafa et al.](#), in a pot experiment, compared the effects of biochar obtained from agricultural waste (AB) and food waste (FWB) on key indicators of soil microbiological health with and without mineral fertilizer inputs. The results showed changes in the chemical properties of the soil after fertilization with AB and FWB, which stimulated the growth of lettuce in the growth chamber. Similarly, [Hammerschmidt et al.](#) studied the impact of different digestates (applied at a rate of 40 t ha⁻¹) on soil chemistry and lettuce yield. At the end of the experiments, the authors observed a positive stimulation of soil microbial activity following the use of legume digestates, which could, however, accelerate nitrogen mineralization processes.

One of the environmental factors that most reduces crop growth is undoubtedly salt stress ([Abdelhamid et al., 2020](#)). Intense evapotranspiration activity stimulated by environmental warming combined with poor irrigation (often with water of poor quality) increasingly causes secondary soil salinization problems. [Gao et al.](#) evaluated the potential beneficial effects of 2-keto-L-gulonic acid (2KGA) on Chinese cabbage (*Brassica campestris* ssp. *chinensis* L.) subjected to salt stress (100 mM NaCl). The results suggest that applying 2KGA by promoting the synthesis of L-ascorbic acid can effectively alleviate the inhibitory and phytotoxic effects of NaCl salinity. Exogenous application of 5-aminolevulinic acid significantly

reduced damage caused by moderate NaCl stress (50 mmol L⁻¹) on cucumber seedlings due to increased root cytoactivity and improved Na⁺ redistribution and compartmentalization (Wu et al.).

On the other hand, Sorrentino et al. observed after the application on tomato and lettuce (grown under fully controlled conditions) of a plant biostimulant based on plant-derived protein hydrolysate how the positive action of the tested product induced species-specific adaptive responses that helped to alleviate the harmful effects of NaCl salinity. Similarly, Zuluaga et al. evaluated the different sensitivity of lettuce and tomato plants to high salinity conditions (80 mM for lettuce and 120 mM for tomato) and the possible protective effects of 4 different plant-derived protein hydrolysates (C: *Malvaceae*-derived, P: *Poaceae*-derived, D: legume-derived commercial ‘Trainer®’ and H: legume-derived commercial ‘Vegamin®’). Although lettuce had a constitutive higher sensitivity to salinity than tomato, the efficacy of biostimulants was more evident in lettuce. Regarding the positive role played by microbial biostimulants, Mellidou et al. observed on tomato plants subjected to salt stress (200 mM NaCl) an up-regulation of secondary metabolism after inoculation with *Pseudomonas oryzae*, which enabled the salinized plants to respond more readily to salt-induced extremes. Also, on tomatoes, Becerril-Espinosa et al. observed how establishing an endophytic interaction with the actinobacterium *Salinispora arenicola* promotes germination and growth of roots and shoots under saline and non-saline conditions. An *in-vitro* study by Naamala et al. evaluated the stimulatory effect of cell-free supernatant (CFS) obtained from *Lactobacillus helveticus* EL2006H at different concentrations (0.2 and 1.0% v/v) on the germination and biometric traits of maize and soybean grown with NaCl levels of 100 and 150 mM. Although the results showed an efficacy of CFS, these were strongly influenced by the different concentrations used and the NaCl levels and plant species evaluated. In a hydroponic experiment, Tarroum et al. observed on tobacco plants an improved salt tolerance (250 mM) following the application of a nutrient solution of a cell-free supernatant obtained from a halotolerant fungal strain (A3) identified as *Penicillium olsonii*. The results obtained by Xiao et al. indicated that the application of *Bacillus cereus* G2 promoted the growth of *Glycyrrhiza uralensis* (Fisch. ex DC.) plants subjected to salt stress (75 mM NaCl) due to a significant improvement in photosynthetic efficiency and an increased in carbohydrate products from carbohydrate transformation. At different salinity levels (0, 20, 50, and 75 mM), Mhada et al. observed mitigation of the negative impact of salt stress on *Phaseolus vulgaris* plants previously primed and/or coated with a mixture of *Rhizobium tropici* and trehalose. Christakis et al. first identified endophytic bacteria of three aliphatic species: *Cakile maritima*, *Matthiola tricuspidate*, and *Crithmum maritimum*. Subsequently, they observed their ability to grow at high NaCl levels and inhibit the development of phytopathogens such as *Verticillium dahliae*, *Ralstonia solanacearum*, and *Clavibacter michiganensis*. Based on the results, the authors suggest testing halophyte endophytes as new ‘bio-inoculant’ agents to improve crop response to biotic and abiotic (salinity) stress conditions. Zhang et al., after identifying and isolating a new endophytic bacterium designated as *Bacillus altitudinis* strain using 16S rDNA

sequencing, evaluated through bioassays the positive influence of this on the growth and development of various plant species.

3 Biostimulants increase tolerance to biotic stress

The possibility of reducing agrochemicals by developing bio-control agents would help the entire agricultural sector become more free of dependence on conventional chemical inputs, offering sustainable solutions to producers and consumers (Lahlali et al., 2022). Zhang et al., after isolating 60 actinomycetes, observed significant antifungal activity on 17 of them against *Fusarium oxysporum* f. sp. cubense tropical race 4 (TR4), a pathogen that causes one of the most common soil diseases globally. Xu et al. reported that in cucumber plants, there was a strong biocontrol activity against *F. oxysporum* sp. *cucumerinum* by a newly isolated *Bacillus subtilis* strain named YB-04. This effect was attributed to the ability of this strain to secrete amylase, cellulase, and extracellular protease, as well as produce indoleacetic acid and siderophores. After evaluating *in vitro*, the antagonistic activity of *Bacillus tequilensis* GYUN-300 (GYUN-300) against the fungal pathogen *Colletotrichum acutatum*, Kwon et al. observed on red pepper plants inoculated with GYUN-300 a reduction in the incidence of *Colletotrichum acutatum* attacks compared to untreated controls. Drobek et al. confirmed the efficacy of several microbial consortia consisting of bacteria such as: AF117AB (*Paenibacillus polymyxa*), Sp115AD (*Bacillus subtilis*), AF75AB2, Sp115AD, AF75BC (*Bacillus* sp.), AF75AA, AF75AD (*Streptomyces* sp.), JAFGU (*Lysobacter* sp.) and AF70AC (*Pseudomonas* sp.), in controlling the main microbial pathogens (*Botrytis cinerea*, *Verticillium* sp., *Phytophthora* sp. and *Colletotrichum* sp.) of strawberries, also underlining the positive impact on the final fruit quality. Seeds of two different rice varieties coated with *Trichoderma* strains inhibited the incidence of pathogens. They improved the chlorophyll content and vigor of the treated plants (Swain et al.). Valverde et al. evaluated the antifungal activity of 20 commercial macroalgae products against two post-harvest pathogens (*B. cinerea* and *Penicillium digitatum*) of fruit. Following the chemical evaluation of the tested products, the results confirmed that some specific bioactive components reduced the incidence of *B. cinerea*. At the same time, the control of *P. digitatum* was attributed to the presence of carbohydrates and polysaccharides. The application of a consortium of *Trichoderma asperellum* GDFS1009 and *Beauveria bassiana* OFDH1-5 on maize plants not only increased antioxidant enzyme activities and chlorophyll content but also decreased the survival of *Ostrinia furnacalis* (Batoool et al.).

4 Biostimulants increase nutrient use efficiency

To maximize crop yields, farmers rely on large quantities of chemical fertilizers that are not always efficiently absorbed by the plant. In addition, their industrial production has an environmental

impact that is no longer sustainable. Incentivizing natural products that affect N and P utilization is necessary for present and future agriculture (Umar et al., 2020). As argued by Reis et al., among the most sustainable agricultural techniques, the use of phosphate-solubilizing microbial strains is a valuable tool. The results regarding the solubilization of calcium phosphate in a hydroponic system with *Glycine max* plants highlighted the potential of *Lysinibacillus fusiformis* (PA26), which was the most efficient due to the increased P uptake and growth promotion observed in the inoculated plants. Gong et al. point out that root space availability and P supply significantly influence phosphorus use efficiency (PUE) in maize. However, the inoculation of mycorrhizal fungi allowed plants grown in pots with small diameters (20 cm) to increase total biomass even with reduced P supply. In a similar study, Gong et al. suggest that a higher P supply could compensate for the yield loss attributable to lower density; in addition, for the same P supply, the use of single superphosphate versus mono ammonium phosphate improved the growth of maize-grown at lower planting densities. To improve PUE and growth of maize and cucumber plants grown in hydroponics, Alzate Zuluaga et al. tested the efficacy of the 15S strain of *Enterobacter* sp. Inoculation of the bacterium under P-limiting conditions induced a greater effect on cucumber plants due to an increase in P allocation in both the epigeal and hypogean parts of the plants. In connection with bacterial gene expression, Yahya et al. studied the action of phosphate solubilization by *Ochrobactrum* sp. SSR (DSM 109610). A higher P content characterized wheat plants inoculated with DSM 109610; the bacterial supplementation increased the soil availability of this macronutrient and the alkaline phosphatase activity. The review work proposed by Rizvi et al. investigates the still under-studied role of the phosphate-soluble microbiome in managing sorghum cultivation-related diseases to reduce dependence on chemical pesticides further. In line with this, Haque et al. evaluated the biofertilising action of *Enterobacter* sp. HSTU-ASh6, a rice root endophyte that mineralizes chlorpyrifos. The results of tomatoes show improved growth of treated plants after foliar application of the HSTU-ASh6 strain, even with reduced nitrogen fertilization rates. In a pot experiment on maize, Chen et al. observed an increase in PUE and yield after the combined application of humic acids (45 kg ha⁻¹) and an ammonium phosphate fertilizer compared to plants subjected to phosphorus fertilizer application alone. After extracting the humic acids (HA) in a phosphate fertilizer enhanced with HA, Jing et al. evaluated the effects on hydroponically grown maize seedlings. HA at doses of 2.5 and 5 mg C L⁻¹ enhanced the average N and P uptake rates compared to untreated controls. To further investigate the effects of HA on plant growth, Wang et al. evaluated the effects of two different HAs [Aojia humic acid (AHA) and Shandong humic acid (SHA)] on maize as a model crop. After characterizing the humic acids through an ESI-HPLC-MS technology, the authors observed a different beneficial effect of AHA and SHA on maize growth (with AHA better than SHA) attributable to the significant differences in molecular compositions. Furthermore, in connection with HA, Xu et al. evaluated the effects of a root application (at 1%) on cucumber in three different hydroponic substrates (pure sand, pure cocopeat,

and a mixture of sand and cocopeat). The results show that applying HA improved biometric parameters only in plants grown on pure cocopeat and cocopeat-sand mixture. Having identified, with mathematical models, the optimal doses of AMF and *Bacillus megaterium* (2.1 kg ha⁻¹ for both), Ganugi et al. observed in co-inoculated maize plants an increased accumulation of N in the grain and an improved nitrogen harvest index. Through non-invasive 3D imaging of root architecture and specific biochemical assays, Mohammed et al. showed that root application of phosphite improved nitrogen assimilation and root biomass of maize seedlings. Chen et al. recorded an improvement in N, P, and K efficiency in sugarcane plants grown in China in two cultivation areas (Suixi and Wengyuan) following the application of algae extracts at different phenological states (sowing, early elongation, and early maturity). To reduce N application rates, Goñi et al. evaluated this macroelement's uptake and assimilation mechanisms by plants treated with a biostimulant based on *Ascomyllum nodosum* extracts. The results on *Arabidopsis thaliana* showed a significant increase in nitrate content 6 days after application of the biostimulant. On the other hand, subsequent field trials revealed a significant increase in nitrate use efficiency on barley plants grown with 75% N supply. Similarly, Ciriello et al. demonstrated, on hydroponic basil, that applying a plant-derived protein hydrolysate (albeit dose-dependent) can compensate for the effects of a reduced nutrient solution (1 dS m⁻¹), even improving yield and quality attributes. To improve the efficacy of synthetic fertilizers, Amaral and Brown investigated the effects of a plant-based inositol bioproduct on zinc (Zn) accumulation and mobility in wheat (*Triticum aestivum* L.) plants. Foliar application of the stimulant in combination with zinc sulfate significantly increased the concentration of this trace element in both grains and shoots compared to fertilized but not stimulated plants.

5 Biostimulants increase the qualitative characteristics of the produce

Interest in agri-food products that meet the goal of a healthy lifestyle has grown enormously in recent years. Various agronomic approaches have been proposed to enhance food products' qualitative and functional attributes, including biostimulants (Ganugi et al., 2021; Melini et al., 2023). In this respect, Godlewska et al. observed after foliar application of plant extracts from common dandelion, valerian, and giant cabbage an improvement in vitamin C, macro- and micro-nutrient content, and a variable impact on the composition of fatty acids, and low molecular weight volatile compounds. Similarly, Abd-Elkader et al. evaluated the beneficial effects of *Trichoderma viride* and *Pseudomonas fluorescens* and three plant extracts of *Eucalyptus camaldulensis* (leaf extract indicated as LE), *Citrus sinensis* (leaf extract indicated as LE) and *Ficus benghalensis* fruits (fruit extract indicated as FE) with potassium silicate (K₂SiO₃) on the biochemical composition of courgette (*Cucurbita pepo* L.) fruits. Specifically, the LE combination with K₂SiO₃ increased greenhouse-

grown zucchini fruits' total phenolic content and antioxidant activity. Wang et al. evaluated the influence of five different concentrations of methyl jasmonate (MeJA) and salicylic acid (SA) on the yield and quality characteristics of Chinese chives. Applying MeJA and SA at concentrations of 500 and 150 μ M resulted in a significant increase in phenols and flavonoids, vitamin C, and volatile compounds while reducing the nitrate content. Mesa et al., to evaluate the additive and/or synergistic effects of the application of a protein hydrolysate of animal origin combined with low-N priming, observed an improvement in quality parameters (soluble sugars, acidity, and lycopene content, vitamin E and vitamin C) on greenhouse tomatoes. Also, on tomatoes, Zhang et al. studied the effects of fulvic acids (obtained from maize straw) on fruit quality. The use of fulvic acids increased the concentrations of minerals (Ca, Fe, and Zn), citric acid, malic acid, and some amino acids without affecting the concentrations of soluble sugars. A field experiment of AMF inoculation on alfalfa (*Medicago sativa* L.) intended for livestock consumption increased the yield and nutrient and fatty acid content of the forage. Pellegrino et al. observed the persistence of positive effects even two years after inoculation due to an abundance of AMF at the root level. Although AMF-released glomalin's functions are known, this molecule's exogenous application is still unknown. Liu et al. investigated the effects of easily extractable glomalin-related soil protein (EE-GRSP) and difficultly extractable glomalin (DE-GRSP) on the growth and development of orange trifoliolate (*Poncirus trifoliata* L.). The application of the two extracts resulted in contrasting effects. Specifically, the exogenous application of EE-GRSP enhanced growth, while a decrease was observed for plants treated with DE-GRSP. To improve the rooting of 'Hurda' rose cuttings, Monder et al. tested different plant origin preparations (algae extracts, organic preparation, and plant extract). The best results were obtained using algae extracts for plant cuttings at the phenological stage of closed flower buds. Finally, Langowski et al. observed on several soybean varieties cultivated in Canada and Brazil an increase in seed yield following the application of an *Ascochyllum nodosum* extract.

7 Conclusions and challenges ahead

It is an absolute prerogative that using plant biostimulants, irrespective of origin, will increasingly contribute to a mandatory transition to more economically and ecologically sustainable production systems. Agroecosystems that are more resilient and no longer threatened by uncontrolled human activities must be an integral part of future agriculture. Although the use of natural

products and/or plant biostimulants is now a complementary tool to synthetic agrochemicals, the scientific community is called upon to define the underlying genetic, molecular, and physiological mechanisms, as a better understanding of these aspects would greatly facilitate the dissemination of bio-based products in the agricultural sector. Moreover, elucidating biostimulant \times plant species \times environment interaction \times agricultural practices are crucial, in order to select optimal combinations in terms of yield, yield components and quality, and also optimizing application parameters (e.g. timing, mode, rate). Finally, it is also urgent to understand the interactions between biostimulant products, living organisms and chemical inputs (plant protection products and/or fertilizers) to develop more sustainable production systems.

Protein hydrolysates (PHs) are a class of plant biostimulants used in the agricultural practice to improve crop performance. In this study, we have assessed the capacity of a commercial PH derived from bovine collagen to mitigate drought, hypoxic, and Fe deficiency stress in *Zea mays*. As for the drought and hypoxic stresses, hydroponically grown plants treated with the PH exhibited an increased growth and absorption area of the roots compared with those treated with inorganic nitrogen. In the case of Fe deficiency, plants supplied with the PH mixed with FeCl₃ showed a faster recovery from deficiency compared to plants supplied with FeCl₃ alone or with FeEDTA, resulting in higher SPAD values, a greater concentration of Fe in the leaves and modulation in the expression of genes related to Fe. Moreover, through the analysis of circular dichroism spectra, we assessed that the PH interacts with Fe in a dose-dependent manner. Various hypothesis about the mechanisms of action of the collagen-based PH as stress protectant particularly in Fe-deficiency, are discussed.

Keywords: protein hydrolysates, biostimulants, collagen, crop performance, Fe deprivation, abiotic stress

INTRODUCTION

Ever since their appearance on land, plants had to deal with numerous abiotic stresses, including low or high temperature, deficient or excessive water, high light intensity and ultraviolet (UV) radiation, nutrient shortages or imbalances. These stresses are accountable for great crop yield loss (Wang et al., 2004; Wani et al., 2016) and are exacerbated by recent climate changes (Boyer, 1982; Rahmstorf and Coumou, 2011). The negative impact on plant growth is worsened when these stresses are combined, for instance, drought and heat stress were responsible for as much as the 40% of reduction in crops yield for maize (Daryanto et al., 2016), and up to 68% for cowpea (Farooq et al., 2017). Moreover, water shortage and soil salinity trigger oxidative, osmotic and temperature stress, representing another major challenge for productivity (Landi et al., 2017). In the future, the dramatic increase in land degradation rate is expected to result in a drastic loss of planet arable lands (Scherr, 1999). According to the data published by the European Union in the World Atlas of Desertification, the combined effects of soil degradation and climate changes will result in 10% reduction of global crop yield by 2050, with severe economic losses (Cherlet et al., 2018). The future scenarios urge scientists to search for new technologies to improve crop productivity, focusing on organic substances, which not only could replace chemical fertilizers, often responsible for environmental pollution, but could also be exploited to contrast abiotic stresses (Suhag, 2016). Nowadays, an increasingly employed resource in agriculture are plant biostimulants. This term

refers to a very broad class of substances and microorganisms that includes – as defined by the European Union – “fertilizing products the function of which is to stimulate plant nutrition processes independently of the products’ nutrient content with the sole aim of improving one or more of the following characteristics of the plant or the plant rhizosphere: (i) nutrient use efficiency, (ii) tolerance to abiotic stress, (iii) quality traits, or (iv) availability of confined nutrients in the soil or rhizosphere” (European Union, 2019). Many diverse bioactive substances are catalogued as plant biostimulants based on their agricultural function claims, including: (i) humic and fulvic acids, (ii) animal and vegetal protein hydrolysates (PHs), (iii) macroalgae seaweeds extracts, and (iv) silicon, and also some beneficial microorganisms such as (i) arbuscular mycorrhizal fungi (AMF) and (ii) nitrogen-fixing bacteria of strains belonging to the genera *Rhizobium*, *Azotobacter*, and *Azospirillum*. Among the listed categories, protein hydrolysates are particularly interesting, not only because they are effective biostimulants, but especially because they are mainly produced from organic waste, well fitting into the eco-friendly scheme of circular economy (Xu and Geelen, 2018). PHs are by-products from several industrial activities and can either have animal- or plant- origins. Some of the animal matrix from which PHs can be obtained are epithelial or connective tissues, hen feathers, and bone meal (Drobek et al., 2019), while plant-derived PHs can come from carob germ proteins, alfalfa residue, wheat-condensed distiller solubles, *Nicotiana* cell wall glycoproteins and algal proteins (Calvo et al., 2014).

Most of the studies regarding PHs highlight their capacity to improve plant growth and nutrient use efficiency, proposing some mechanisms of action which might include the hormone-like activities of bioactive peptides (Santi et al., 2017; Ertani et al., 2019), the stimulation of carbon and nitrogen metabolism, as well as the regulation of nutrient uptake (Ertani et al., 2009; Colla et al., 2014). For instance, Santi et al. proved that the treatment with a bovine collagen-derived PH remarkably enhanced maize root increasing the root accumulation of K, Zn, Cu, and Mn when compared with inorganic N and amino acids treatments (Santi et al., 2017). Moreover, in the same work, the microarray analysis suggested that the treatment with the bovine collagen-derived PH to the nutrient solution caused major changes in the transcriptional profile of the roots, altering the expression of genes involved in the cell wall organization, the transport processes, the stress responses and the hormone metabolism. Recently, Paul et al. (2019b) tested eight different plant-derived protein hydrolysates on tomato plants, reporting, for some of the treatments, an increase in relative growth rate and growth performance. Moreover, metabolomic profiles of the plants treated with PHs showed that ethylene precursor 1-aminocyclopropane-1-carboxylate (ACC) and polyamines were positively modulated, and the ROS-mediated signaling pathways were affected as well (Paul et al., 2019b).

While there is a vast literature on PHs efficacy as plant growth and nutrient use efficiency enhancer, relatively few works have tried to demonstrate that these compounds are also capable to ameliorate plant performances under abiotic stress conditions. In an interesting paper, Ertani et al. proved that a plant-derived PH

increased plant biomass in salt-stressed maize plants (Ertani et al., 2012), ascribing the beneficial effects to the triacontanol, a fatty acid known to act as plant growth regulator (Chen et al., 2002) and salt-stress mitigator (Çavuşoğlu et al., 2008), which is present in the PH in a noticeable amount. Another study from Lucini et al. (2015) demonstrated the beneficial effects of a plant-derived PH treatment on lettuce plants grown in pots under saline stress. The PH treatment helped the plants to better respond to saline environment compared to those treated with water only, showing an increased shoot fresh yield. In this case the authors suggested that the PH mitigated the stress by attenuating the oxidative stress, improving osmotic adjustment, and rewiring the hormone, sterol, terpene and glucosinolate profiles (Lucini et al., 2015). More recently, the work of Trevisan et al. (2019) investigated the activity of a collagen-derived PH as stress-mitigator, in maize seedlings subjected to hypoxic, saline and nutritional stress. The plants treated with this biostimulant produced longer roots in all the three stress conditions than those which did not receive the treatment. The transcription level of the superoxide dismutase *ZmSOD1a* gene was induced upon PH treatment in hypoxia, nutritional deficiency, and when saline and nutritional stress were combined. The authors therefore suggested that the PH might mitigate the effects of different stresses by regulating of the expression of genes involved in ROS scavenging (Trevisan et al., 2019). Another recent work, from Paul et al. (2019a), positively assessed the beneficial effect of a plant-derived PH as stress-mitigator on tomato plants grown under limited water availability. They suggested that PH-treated plants were able to better cope with oxidative stress thanks to major changes in phytohormones and lipid profiles (Paul et al., 2019a). Lastly, Casadesús et al. (2019, 2020) assessed the beneficial effects of a product derived from enzymatic hydrolysis of animal proteins in tomato plants grown under water, temperature or nutrient stress suggesting that the positive effects on root growth are due to the increased biosynthesis of specific phytohormones (Casadesús et al., 2019, 2020).

The aim of this work is to investigate the capacity of a collagen-based PH to act as multi-stress protectant when supplied to plant species of agricultural interest by setting up fast and reliable experimental laboratory tests. We carried out the experiments on hydroponically grown maize plants treated with a commercial PH (LMW10 – produced by SICIT group) derived from acid hydrolysis of bovine collagen. We demonstrated that the PH was able to protect the root apparatus from drought and hypoxic stresses. We also proved that the PH quickened the recovery of plants after iron (Fe) deficiency. Moreover, we provide evidence of the chemical interaction between the PH and Fe ions as a possible mechanism that could favor the micronutrient availability for root uptake in the nutrient solution.

MATERIALS AND METHODS

Plant Materials, Growth Conditions and Phenotypic Analyses

Maize seeds (P0943 Hybrid, Pioneer Italia S.p.A.) were soaked in water for 24 h and germinated in the dark on wet filter

paper for 72 h. Seedlings with similar size were then transferred in pots that can accommodate 6 plantlets, containing 2 L of a 0.5 mM CaSO_4 solution and grown for 24 h under a 16/8 h light/dark regime at 22–26°C, 40–50% relative humidity, 125 $\mu\text{E m}^{-2} \text{s}^{-1}$ light intensity. For the experiments under drought and hypoxic conditions, seedlings were successively grown in a diluted nutrient solution containing 100 μM MgSO_4 , 5 μM KCl , 200 μM K_2SO_4 , 175 μM KH_2PO_4 , 400 μM CaSO_4 , 25 μM $\text{NH}_4\text{H}_2\text{PO}_4$, 2.5 μM H_3BO_3 , 0.2 μM MnSO_4 , 0.2 μM ZnSO_4 , 0.05 μM CuSO_4 , 0.05 μM NaMoO_4 , 2 μM Fe-EDTA and supplemented with either protein hydrolysates (SICIT Group) or inorganic nitrogen ($\text{NH}_4\text{H}_2\text{PO}_4$) (Santi et al., 2017). The protein hydrolysate, a liquid formulation obtained from the hydrolysis of cow connective tissue, contains 32.3% (w/w) total carbon (C), 12.3% (w/w) total nitrogen (N), 10.9% (w/w) organic N of which 68.5% (w/w) total amino acids and 12.4% (w/w) free amino acids. The amino acids composition and the mineral ion concentrations are summarized in **Supplementary Tables 1, 2**. Drought stress was obtained following the method described by Han et al. (2017). The plants were grown in an aerated nutrient solution supplemented with 15% w/w of polyethylene glycol (PEG, MW6000), root growth as well as leaf fresh and dry weight (**Supplementary Figure 1**) was recorded after 9 days of treatment. To study the effects of PH under hypoxic stress, maize seedlings were grown in the above described nutrient solution interrupting air insufflation (see also Results section for detailed description of the experimental conditions). For the experiments on Fe deprivation and supply, seedlings were grown in 2 L pots in a aerated Fe-depleted nutrient solution (Sega et al., 2020) containing 2 mM $\text{Ca}(\text{NO}_3)_2$, 500 μM MgSO_4 , 100 μM KCl , 700 μM K_2SO_4 , 100 μM KH_2PO_4 , 10 μM H_3BO_3 , 0.5 μM MnSO_4 , 0.5 μM ZnSO_4 , 0.5 μM CuSO_4 , 0.01 μM $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}$ for 7 days. Afterwards, seedlings were transferred in the nutrient solution containing 20 μM Fe, as either FeEDTA (–Fe/+ FeEDTA), or FeCl_3 supplemented with 0.1 mL L^{-1} PH (–Fe/+ FeBio) or with the equivalent amount of N supplied (–Fe/+ FeCl_3) as inorganic nitrogen ($\text{NH}_4\text{H}_2\text{PO}_4$). Control plants were grown in the nutrient solution containing FeEDTA 20 μM for 14 days (+ FeEDTA) or in the nutrient solution deprived of Fe with the addition of 14.3 mg L^{-1} of N (–Fe/–Fe). Primary, seminal and lateral root total length and surface area were measured with WinRHIZOTM scanner and automated software (Arsenault et al., 1995).

Macro- and Micro-Nutrients Quantification

The Fe concentration in the leaf samples and in the PH product was quantified by ICP-MS analysis. For the analysis dried leaf samples and the PH product (about 5 mg) were weighted and digested in a TFM micro-sampling insert using 350 μL of 69% ultrapure HNO_3 . The inserts were put into a 100-ml oven vessel containing 10 ml of water (milliQ, 18.2 M Ωcm) and 1 ml of 30% H_2O_2 . As reference we digested 5 mg of NIST 1515 (apple leaves). The digestion of the samples was performed using a microwave oven (Milestone StartDR

microwave). A 20-min ramping period was used to reach a digestion temperature of 180°C. The temperature was thereupon maintained for 20 min. At the end, sample were diluted with water (milliQ, 18.2 M Ωcm) to a final concentration of 2% HNO_3 . Multi-elemental analysis was carried out using the Agilent 7500cx ICP-MS (Agilent). Each macro- and micronutrient was quantified using a multi-element standard solution. For the assessment of leaf Fe concentration, we collected three biological samples, each derived from a pool of 4 leaves, and two technical replicates for each measurement. For the analysis of PH mineral content, the mean values were calculated using three technical replicates.

SPAD Measurements

A SPAD-502 Plus Chlorophyll meter[®] (Konica Minolta) was used to acquire SPAD values of the third fully expanded leaf of each plant. The values were distinctly taken at the top or at the mid part of the leaves. Measurements were acquired immediately before Fe was supplied in the hydroponic solution, and two, four, and 7 days after that moment. Values from nine to twelve leaves per experimental condition were sampled and averaged to a single SPAD value for each treatment.

Circular Dichroism Spectral Measurement

Circular dichroism (CD) spectra were recorded with a JASCO J-1500 spectropolarimeter (Japan Spectroscopic Co., Tokyo, Japan), using a quartz cell of 1 mm path length at 25°C. CD spectra were scanned in the far-ultraviolet range from 190 to 250 nm. Values were measured at an interval of 1 nm, and the spectra obtained were the average of 5 reads. The biostimulant was diluted in distilled water to get a total amount of nitrogen of 71.5 mg L^{-1} . FeCl_3 was added to the biostimulant in aqueous solutions at different concentrations [μM] 0, 50, 100, 150, 200, 250]. Spectra of FeCl_3 dissolved in distilled water without the biostimulant, at different concentrations, were used as blank reference. Final spectra resulted from the subtraction of their respective blanks and subsequent smoothing. The CD data were expressed in terms of molar ellipticity, $[\theta]$, in $\text{deg cm}^2 \text{dmol}^{-1}$ and were calculated referring to a Mean Residual Weight (MRW) fixed at 106.5 g mol^{-1} .

Quantitative RT-PCR Analysis

Total RNA was extracted from root samples, using the SpectrumTM Plant Total RNA kit (Sigma-Aldrich, St. Louis, MO, United States) and quantified using NanoDropTM 1000 (Thermo Scientific, Waltham, MA, United States). For RNA extraction we used three biological samples, each consisting of the roots of four plants. DNase I treatment was carried out for each sample using one microgram of total RNA and the RQ1 RNase-Free DNase (Promega, Madison, WI, United States) according to the manufacturer's procedure. DNase-treated samples were then used to synthesize cDNA with the ImProm-II Reverse Transcription System (Promega, Madison, WI, United States). Real-time RT-PCR experiments

were performed with the Fast SYBR® Green Master Mix (Thermo Fisher Scientific) on the QuantStudio 3 Real Time-PCR (Thermo Fisher Scientific) according to the manufacturer's protocols. The reactions were carried out in a volume of 10 μ L with a final primer concentration equal to 350 nM and 1 μ L of a 1:3 solution of cDNA as template. The following thermal profile was set-up: 95°C for 20 s, 40 cycle of 95°C for 3 s and 60°C for 30 s. Two housekeeping transcripts were employed, one encoding an ubiquitin-conjugating enzyme (GRMZM2G027378_T01) and the other an unknown protein (GRMZM2G047204_T01), respectively. The analysis of the expression of *ZmIRT1* and *ZmYS1* was carried out with primers used by Nozoye et al. (2013) whilst for the expression of *ZmTOM1* the primers were designed accordingly to Chan-Rodriguez and Walker (2018). The sequences of all primers were reported in **Supplementary Table 3**.

The PCR reaction efficiencies were calculated with the LinRegPCR program (Ramakers et al., 2003). Mean normalized expression (MNE) (Simon, 2003) was calculated for each transcript and each sample using the two housekeeping transcripts separately. A mean MNE value was determined using a geometric mean of the two MNE values obtained for each transcript and each sample (Vandesompele et al., 2002).

Statistical Analysis

Statistical analysis was performed using GraphPad Prism version 5.03 software. Student's *t*-test for unpaired data was applied when two independent variables were compared as is the case of data shown in Figures, and a *p* value < 0.05 was accepted as statistically significant. Data are presented in the figures as mean and standard error of the mean.

RESULTS

The Stimulation of Root Growth Induced by PH Is Not Affected by Drought Conditions

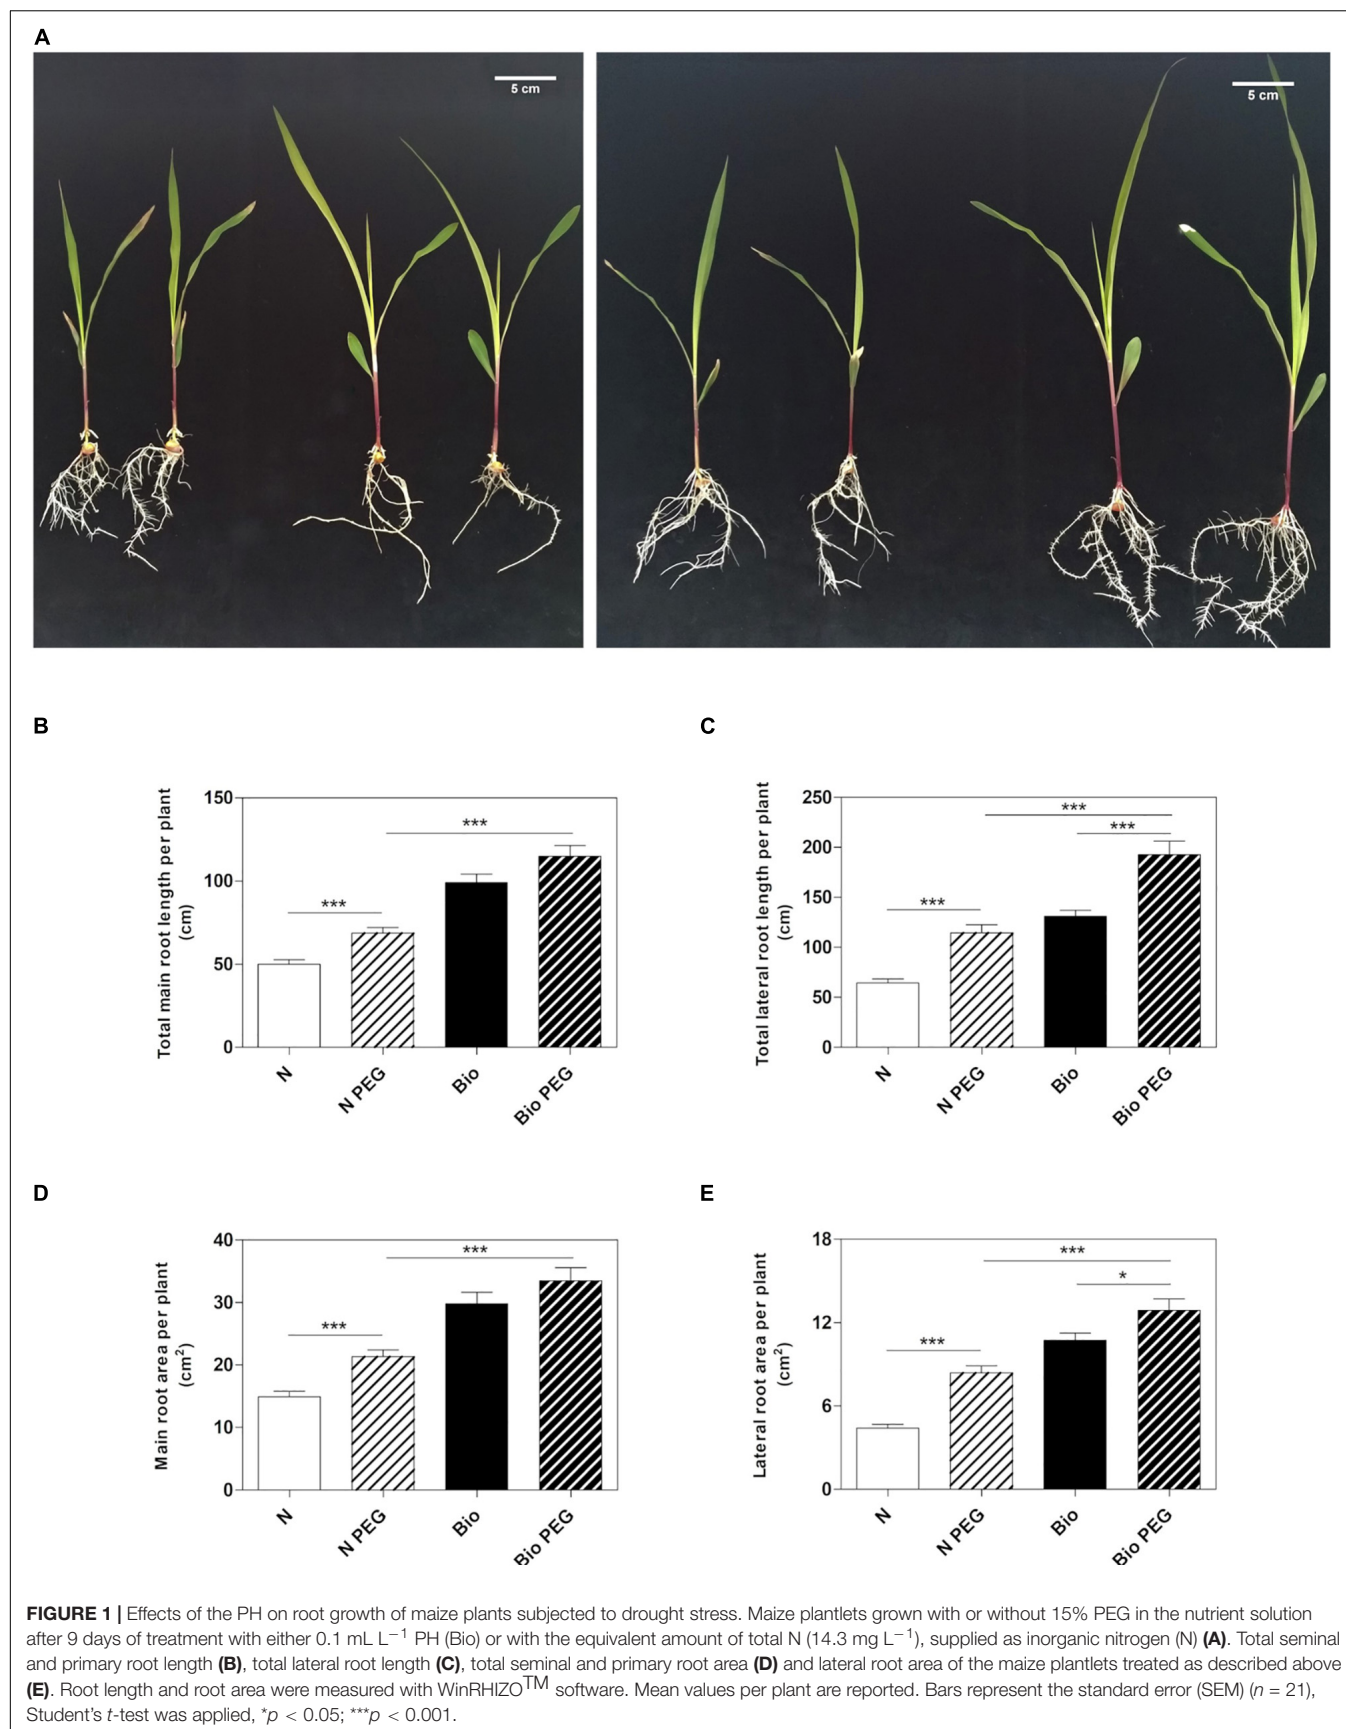

To investigate whether the PH could mitigate drought stress, we grew maize seedlings from the emergence of the primary root in a diluted nutrient solution supplemented with the PH (Bio) or inorganic nitrogen ($\text{NH}_4\text{H}_2\text{PO}_4$; N) and 15% w/w of polyethylene glycol (PEG, MW6000) (**Figure 1A**). After 9 days of treatment, we analyzed the length and surface area of the roots. Consistently with previous results (Santi et al., 2017), the plants grown in the presence of the protein hydrolysate under normal condition had longer main and lateral roots compared to inorganic N-treated plants (**Figures 1B,C**). The improved root growth confers to Bio-treated plants also an extended absorption surface (**Figures 1D,E**). Thus, we confirmed that the PH promotes the root apparatus development when water is abundantly available. Under drought conditions obtained by using 15% PEG, plants treated with N showed a significant increase in both main and lateral root length (+37.6 and +78.1%, respectively) and area (+43.1 and +90.1%, respectively) with respect to non-stressed plants. In plants treated with Bio,

drought conditions did not lead to statistically significant increase in the main root growth, while lateral roots length and area (+51.0 and +23.2%) were augmented although to a lesser extent as compared to the N-treated plants. Notably, under drought stress, plants treated with the PH maintained a significantly higher root growth compared to the plants supplied with inorganic nitrogen (main root length: +67.0%; lateral root length: +73.0%; main root area: +61.4%; lateral root area: +57.8%).

The PH Counteracts the Inhibitory Effects of Hypoxia on Root Growth

To establish whether the PH could alleviate hypoxic stress, maize seedlings were grown hydroponically in a diluted nutrient solution supplemented with the PH (Bio) or inorganic nitrogen ($\text{NH}_4\text{H}_2\text{PO}_4$; N). Control plants (N+; Bio+) were grown in pots with air insufflation, while hypoxic stress was imposed (N−; Bio−) by interrupting air flow. The plants were grown for 4 days after the emergence of the primary root, then, roots length and area were analyzed (**Figure 2A**). Under hypoxic conditions, plants treated with inorganic nitrogen (N−) showed a statistically significant reduction of main and lateral root length (−22.1 and −25.6%, respectively) (**Figures 2B,C**) and area (−24.2 and −19.5%, respectively) compared to the control (N+) (**Figures 2D,E**). The hypoxic stress in the Bio-treated plants resulted in the inhibition of lateral root growth and surface area (−35.6 and −33.7%), a bit higher than what was observed in N-treated plants. However, the PH treatment (Bio−) alleviated the effects of hypoxia on the main roots, since their length and surface area did not differ from those of Bio-treated control plants (Bio+). Overall, under hypoxic conditions, the root apparatus of Bio-treated plants (Bio−) was more developed than that of N-treated plants even when grown under sufficient oxygen supply (N+).

Further analyses were conducted to test whether the treatment with PH could favor root recovery from hypoxic stress. We therefore set up a new experiment in which plants cultivated with either the PH or inorganic nitrogen were grown hypoxically for 4 days and then supplied with air or maintained under hypoxia for further 5 days. Plants treated with inorganic nitrogen and grown for 9 days under hypoxic stress (N−−) grew stunted compared to those treated with the PH (Bio−−) (Bio−− vs. N−−: main root length: +80.1%; lateral root length: +108.1%; main root area: +65.6%; lateral root area: +136.8%; *p* < 0.001 for all the comparisons) (**Figures 3A–D**). When plants treated with inorganic nitrogen were supplied with air (N+), the root growth did not ameliorate significantly compared to that of the oxygen depleted plants (N−−). Conversely, plants treated with the PH and supplied with air (Bio+−) showed a statistically significant increase (+24.4%) in lateral root length compared to those maintained in hypoxia (Bio−−). As for the other growth parameters, the trend observed was similar (Bio+− vs. Bio−− seminal root length: +14.5%; seminal root area: +16.9%; lateral root area: +19.6%). Thus, the treatment with the PH showed beneficial effects on root growth under hypoxic stress and

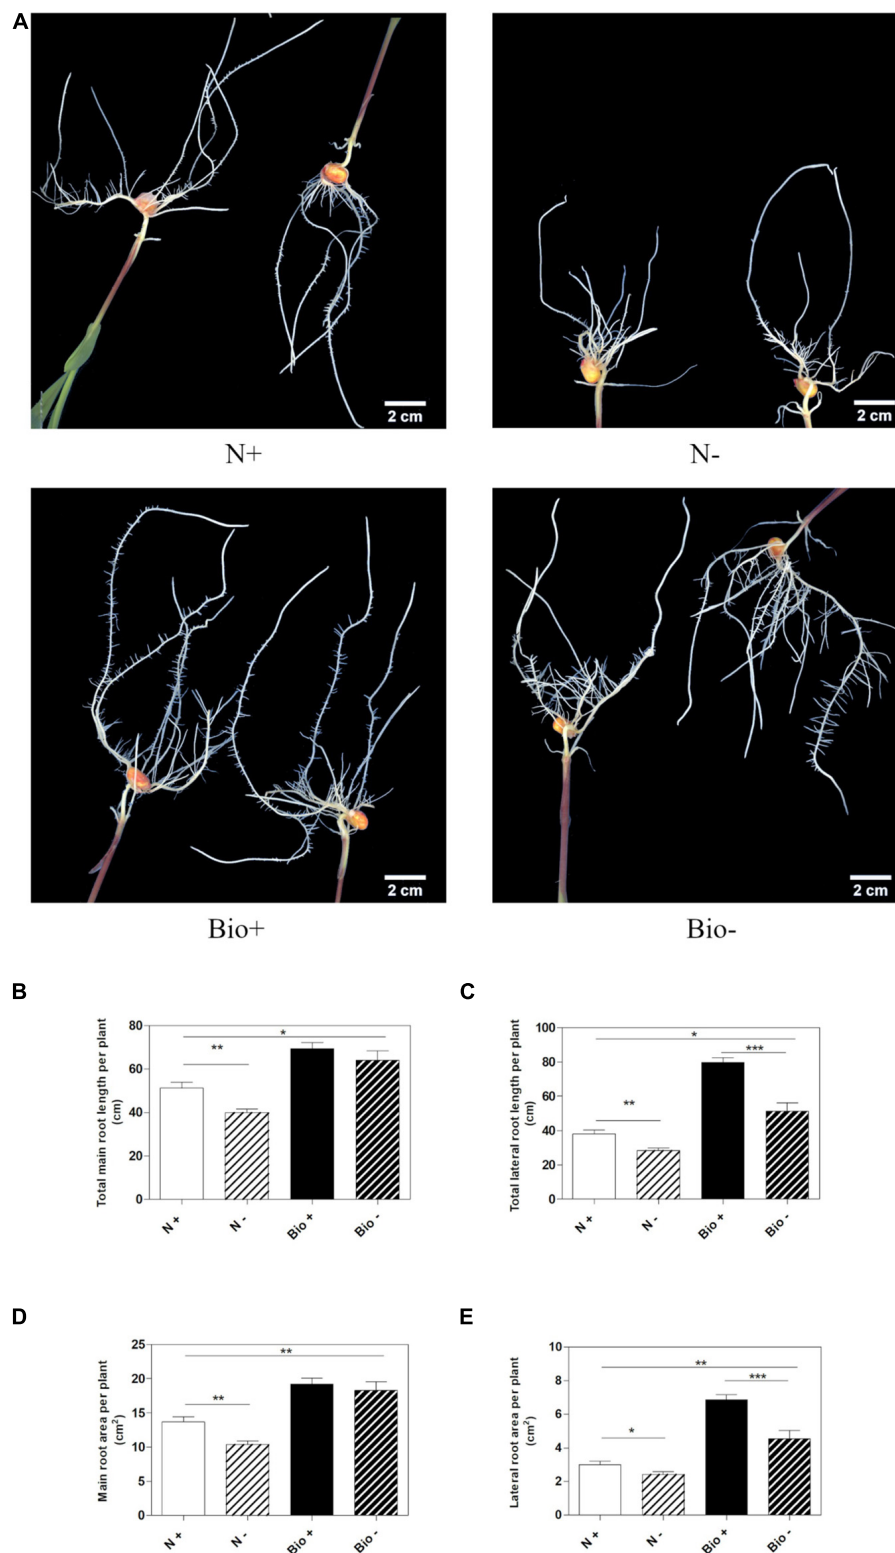

FIGURE 2 | Effects of the PH on root growth of maize plants subjected to hypoxic stress. Maize plantlets grown with (+) or without (–) air insufflation in the nutrient solution after 4 days of treatment with either 0.1 mL L^{−1} PH (Bio) or with the equivalent amount of total N (14.3 mg L^{−1}), supplied as inorganic nitrogen (N) (A). Total seminal and primary root length (B), total lateral root length (C), total seminal and primary root area (D), and lateral root area (E), of the maize plantlets treated as described above. Root length and root area were measured with WinRHIZOTM software. Mean values per plant are reported. Bars represent the standard error (SEM) ($n \geq 22$), Student's *t*-test was applied, * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$.

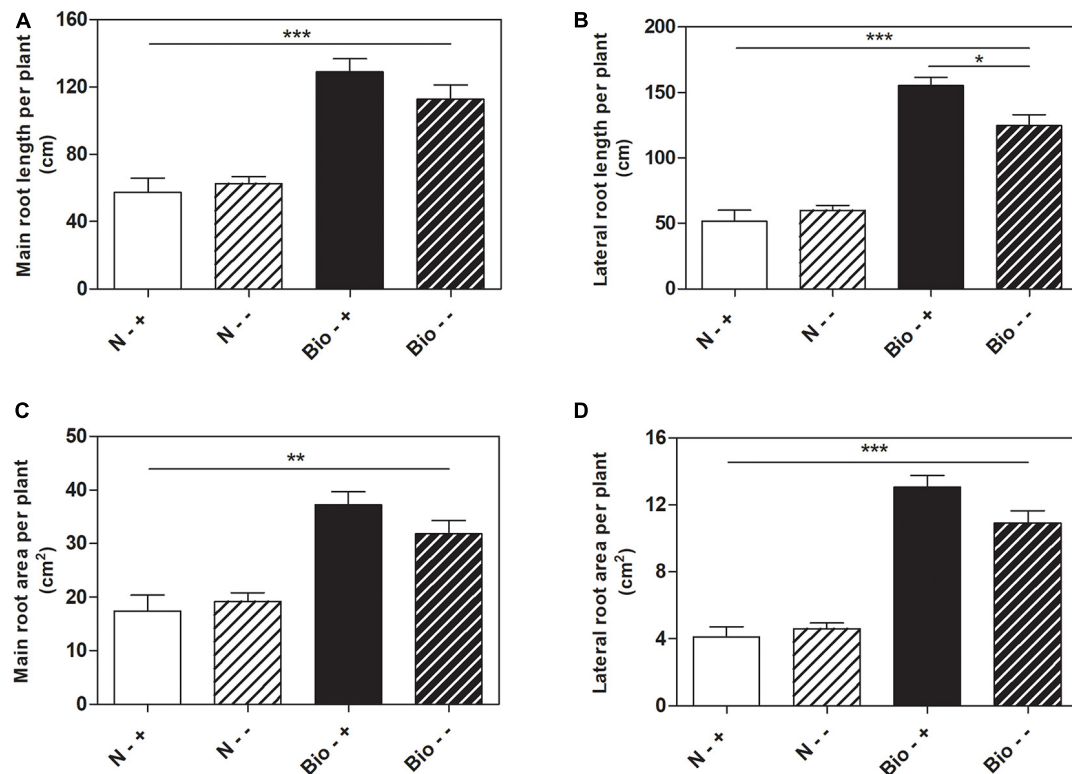

FIGURE 3 | Effects of the PH on root growth of maize plants after recovery from hypoxic stress. Total seminal and primary root length (A), lateral root length (B), total seminal and primary root area (C), lateral root area (D), of maize seedlings treated with 0.1 mL L⁻¹ PH (Bio) and seedlings treated with equivalent amounts of total N (14.3 mg L⁻¹), supplied as inorganic nitrogen (N). The seedlings were hydroponically grown under hypoxia for 5 days, and then kept under normal air flow or hypoxic stress for further 4 days. Root length and root area were measured with WinRHIZOTM software. Mean values per plant are reported. Bars represent the standard error (SEM) (n ≥ 7). Student's *t*-test was applied, **p* < 0.05; ***p* < 0.01; ****p* < 0.001.

most probably facilitate the recovery once the plants return to normal oxygen regimen.

The Presence of PH in the Growing Solution Favors the Recovery From Fe Deficiency

To investigate whether the PH can favor plant Fe uptake after starvation, maize seedlings were grown in an Fe-depleted solution for 7 days, and then Fe was supplied to a concentration of 20 μM as Fe chelated with EDTA, FeCl₃, or FeCl₃ previously mixed with the PH (Figures 4A–C). Control plants were grown in a nutrient solution containing 20 μM FeEDTA (+FeEDTA), or in the absence of Fe throughout the experiment (–Fe/–Fe). We monitored the pH of the different nutrient solutions every day during Fe supply. In all the treatments the pH was favorable for Fe uptake and showed little variation among the different solutions, ranging from 5.2 to 5.3 at first day of supply to 5.9–6.2 at the end of the experiment.

At the 2nd day after the Fe supply, plants treated with the PH performed as well as the plants treated with FeEDTA (–/+FeEDTA), and significantly better than those grown in the solution containing the Fe salt only (+56.9%) if we consider the SPAD values detected in the middle part of the leaf,

while no significant differences were observed in the top part (Figures 4B,C and Table 1). On the 4th day, SPAD values of plants supplied with Fe mixed with the PH were significantly higher than those of plants treated with FeCl₃ alone (TOP leaf: +42.0%, MID leaf: +37.5%) and similar to those of plants supplied with FeEDTA (Figures 4A–C). At the 7th day, maize grown with FeCl₃ reached mid-leaf SPAD values comparable to those of FeCl₃ plus protein PH, while the top-leaf values were still higher for those treated with the PH (+18.7%). Overall, during the supply, the plants treated with the mix of Fe and the PH were the fastest to overcome foliar chlorosis, reaching in only 4 days similar top-leaf SPAD values than those of the plants which did not undergo Fe starvation. Furthermore, these values were even increased in the mid-leaf (+32.3%). Similarly, the plants supplied with FeEDTA were able to recover from the chlorosis at the 4th day on the mid-leaf (+24.6%). However, they reached top-leaf SPAD values similar to the positive control just at the 7th day of supply. The worst performing plants were those supplied with FeCl₃: although able to reach the mid-leaf SPAD values of the positive control at the 4th day, they did not show an increase conversely to the other two theses; moreover, they could not equal the performance of the control plants at the top of the leaf (–17.5%). The analysis of the plants maintained in FeEDTA for the entire length of the experiment revealed a progressive

decrease in the mid leaf SPAD values which was probably due to the rapid growth of the plants under optimal Fe conditions.

The positive effect of PH on Fe-deprivation recovery was confirmed by the analyses of Fe concentration in maize leaves (**Figure 4D**). In fact, in plants supplied with Fe together with the PH for 7 days the concentration of Fe was higher than that of plants grown with FeEDTA or those supplied with FeCl₃. These latter plants were able to reach a concentration comparable to that of the positive control plants, but significantly lower than those grown with Fe and the PH (−25.34%).

To exclude any direct contribution of the PH on plant Fe uptake, we grew Fe-deprived plants in the nutrient solution with the addition of the PH (0.1 mL L^{−1}) alone. We have compared the SPAD values measured for seven consecutively days in the leaves of plants grown without Fe and plants grown without Fe but with the addition of PH. The values recorded were similar in both treatments (−Fe and −Fe + PH) ranging from 3.5 to 10, which are typical of chlorotic maize leaves. In addition, we assessed the concentration of Fe in the product (**Supplementary Table 2**). At our experimental condition (1:10,000 PH dilution) the Fe supplied by PH was calculated to be at a concentration of 0.032 μM, therefore irrelevant compared to that presents in the nutrient solution.

The PH Interacts With Fe Ions

To test the hypothesis that the PH under study can act as an Fe chelator, we evaluated the interaction of the PH with Fe ions by circular dichroism. We collected the CD spectrum of the PH itself dissolved in water ([N] = 71.5 mg L^{−1}), and then the spectra of the PH mixed with FeCl₃ at six different concentrations [(μM) 0, 50, 100, 150, 200, 250]. We set the PH concentration to a total amount of N of 71.75 mg L^{−1} and the FeCl₃ central concentration of the range to 100 μM, in order to obtain the same ratio between the Fe and the PH concentrations used in the hydroponic system for the Fe supply experiments. The PH CD spectrum obtained (**Figure 5**) is an intermediate between the typical soluble type II collagen spectrum, which features two characteristic peaks, a large negative one at 197 nm, and a small positive one at 220 nm, and the polyproline spectrum, which displays the large negative peak shifted at 206 nm, and the small positive one at 228 nm (Lopes et al., 2014). For instance, the CD spectrum of the PH presents two peaks one at 202 nm and the other at 221 nm, implying that for this product the chemical hydrolysis does not alter considerably the capability of the matrix to form polyproline II (PPII)-type structures. The CD spectra of the PH mixed with Fe showed a dose-dependent reduction of the peak at 202 nm compared to the reference spectrum of the PH alone (**Supplementary Table 4**), while the peak at 221 nm did not show major alterations when Fe is added (data not shown). At the lowest Fe concentration, 50 μM, a slight increase of the molar ellipticity value at 202 nm was observed; adding 100 μM Fe we found a greater increase; for concentrations higher than 150 μM, the molar ellipticity value remained almost unaltered, suggesting that the interaction between the PH and the Fe ions was saturated at 150 μM. These findings suggest that the PH PPII-type structure undergoes a slight conformational change in the secondary structure when Fe ions are present in

FIGURE 5 | Circular dichroism spectra of protein hydrolysate dissolved in aqueous solutions with FeCl₃ at different concentrations. The figure shows the CD spectra of the PH diluted in aqueous solutions ([N] = 71.5 mg L^{−1}) with different FeCl₃ concentrations [(μM) 0, 50, 100, 150, 200, 250]. Dashed lines mark 202 and 221 nm wavelengths. Molar ellipticity was calculated referring to a Mean Residual Weight (MRW) fixed at 106.5 g mol^{−1}.

the solutions. The helix is able to interact with the Fe ions, that are therefore responsible for the increase in the molar ellipticity values, although they do not destabilize the structure to the extent of denaturation (Lopes et al., 2014).

The PH Induces Transcriptional Changes in Maize Roots During Recovery From Fe Deficiency

We carried out a transcriptional analysis on the effects of the PH in maize roots during Fe supply in order to shed light on the mechanisms of action that favors recovery from Fe deficiency. We studied the expression of key genes involved in Fe uptake (*ZmTOM1*, *ZmYS1*, and *ZmIRT1*) and in peptide transport (*ZmOPT ids*. GRMZM2G152555_T01, Zm00001d031287_T001) in roots subjected for 7 days to Fe-deprivation (−Fe) and supplied for 24 h with either 20 μM FeCl₃ (−Fe/+FeCl₃) or FeCl₃ plus PH (−Fe/+FeBio) in comparison to roots of plants always grown under Fe deficiency (7 days plus 24 h; −Fe/−Fe) (**Figure 6**). *ZmTOM1* codes for an efflux transporter of mugineic acid family phytosiderophores and *ZmYS1* codes for a proton-coupled symporter of metals chelated to phytosiderophore and to nicotianamine (Schaaf et al., 2004) and both play a key role in Strategy II of Fe acquisition employed by the graminaceous species such as maize (Kobayashi and Nishizawa, 2012). On the other hand, *ZmIRT1* protein is a Fe(II) transporter involved in the Strategy I (reduction strategy). These three proteins (*ZmTOM1*, *ZmYS1*, *ZmIRT1*) have been shown to increase their expression level in maize roots under Fe deficiency (Li et al., 2013; Nozoye et al., 2013; Wairich et al., 2019). We clearly observed this effect after 24 h of FeCl₃ supply (**Figures 6A–C**). In fact, Fe supply caused a strong reduction of the transcript levels of *ZmTOM1*, *ZmYS1*, and *ZmIRT1* with respect to the roots of maize

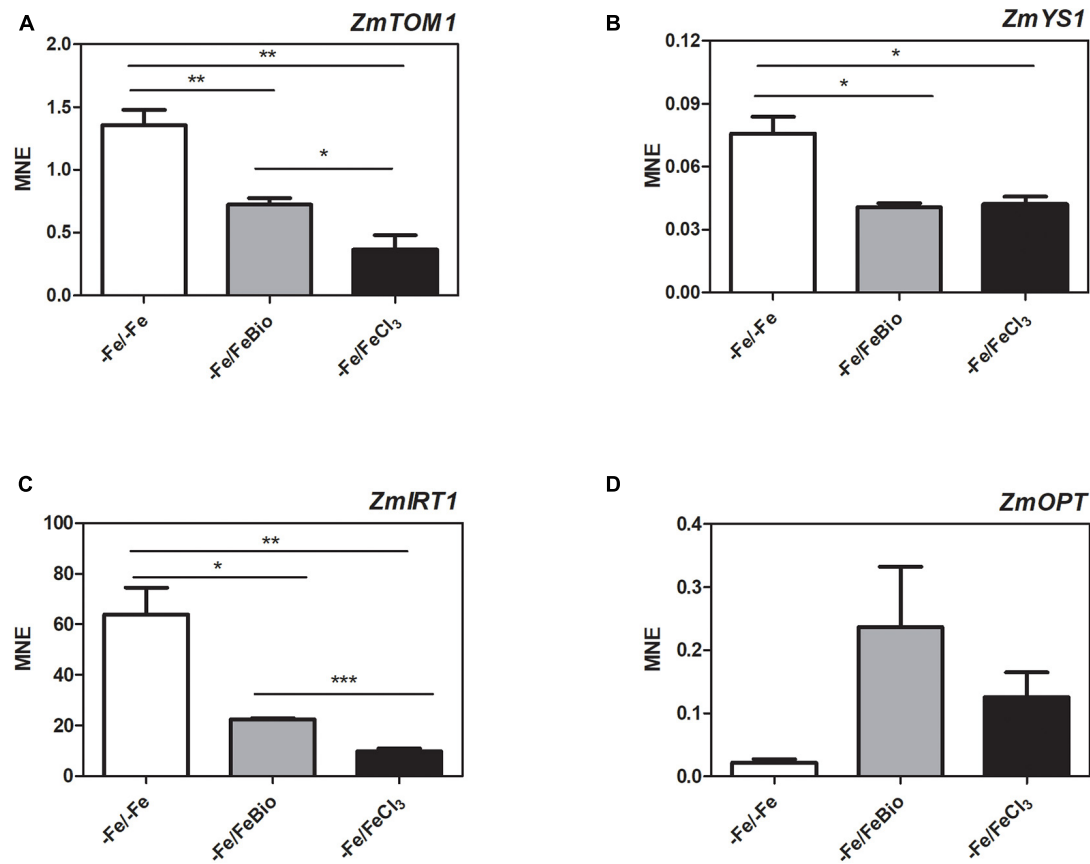

FIGURE 6 | Quantitative RT-PCR analysis of genes involved in Fe uptake in maize roots. Relative transcript level, calculated as Mean normalized expression (MNE) of *ZmTOM1* (A), *ZmYS1* (B), *ZmIRT1* (C) and *ZmOPT* (D) was assayed in roots of plants grown under Fe-deprivation conditions (-Fe/-Fe) and after 24 h Fe-resupply either as FeCl₃ (-Fe/ + FeCl₃) or FeCl₃ plus PH (-Fe/FeBio). The values are the mean of three biological replicates. Bars represent the standard error (SEM). Student's *t*-test was applied, **p* < 0.05; ***p* < 0.01; ****p* < 0.001.

plants continuously grown under Fe deficiency. In the roots supplied with FeCl₃ in the presence of the PH, the expression level of *ZmTOM1* and *ZmIRT1* was significantly higher than the expression measured with FeCl₃ alone, but still lower than the transcript levels of Fe-deprived roots (Figures 6A,C). We did not observe any significant difference in the expression level of *ZmYS1* between roots supplied with FeCl₃ in presence and absence of PH (Figure 6B).

In order to investigate the involvement of peptide transporters in the mechanisms that favors Fe recovery in plants treated with the PH, we analyzed the expression of the *ZmOPT*, a gene found to be responsive to the PH treatment (Santi et al., 2017). *ZmOPT* might be involved in mediating the uptake of Fe bound to peptides. The expression of *ZmOPT* showed an increasing tendency in both roots treated with FeCl₃ and FeCl₃ plus the PH, this trend appears more pronounced in the presence of the PH (Figure 6D).

Overall, concerning the modulation of genes involved in response to Fe deficiency, these results indicate that the roots supplied with FeCl₃ plus the PH displayed an intermediate behavior between Fe-deprived roots and roots supplied with FeCl₃ alone.

DISCUSSION

Biostimulants represent a vast category of products used in the agricultural practice to increase crop productivity, nutrient acquisition and stress resistance. They include natural products of animal and plant origin as well as microorganisms. Due to the generally complex nature of the biostimulants, often composed by a mixture of different molecules, it is very difficult to identify the active components responsible for the beneficial effects on crops (Yakhin et al., 2017). On the other hand, the presence of different active biomolecules in a single product can widen the physiological processes that can be targeted. This can explain the various beneficial effects that can be obtained by a single biostimulants.

The scientific research on biostimulants should be focused on two main targets: (i) to identify the bioactive components of a product (ii) to test the activity of the product on different physiological processes and under different environmental conditions. Concerning the first point, the possibility to find out the main active molecules can allow, on one hand to use a reductionist approach for studying the mechanism of action of the biostimulant, and, on the other hand, to optimize

the products at the industrial level. This approach appears feasible only with certain categories of biostimulants (e.g., protein hydrolysate obtained from a tissue with few abundant proteins), whereas quite difficult for biostimulants originated from complex matrix (e.g., seaweed extracts). The second goal is important for defining the product claims. The claims are usually based on the results from experiments conducted under green house or field conditions monitoring a single plant trait, principally crop growth or product quality. It is possible therefore that in many cases other beneficial effects can be disregarded. Experiments carried out under laboratory conditions can be used to easily test the effects of biostimulants on a great variety of physiological parameters and under different environmental conditions to obtain information on the potential uses of a product. The set-up of the experiments must be carefully planned to assure reproducibility, for instance the assessment of the biological variability and the choice of proper controls appear crucial. In this work, we have planned a series of laboratory experiments to test whether a collagen-based PH has the capacity to exert beneficial effects on plants subjected to different types of stress. The crop used was maize because in a previous work we demonstrated the positive effects of the collagen-based PH on maize root growth and mineral ion uptake after few days of application (Santi et al., 2017). The plants were grown hydroponically in an aerated nutrient solution supplied with the PH. The use of hydroponic culture has several advantages; for instance, it permits the precise control of the medium composition, the possibility to study the response to deprivation or excess of a single mineral nutrient and also the simulation of various stress conditions. A very critical issue in evaluating the effects of a biostimulant is also the choice of a proper control, in our case as the biostimulant object of the study was a PH, we added to the control nutrient solution NH_4^+ to reach the same amount of total N supplied with the PH. In this way we also proved that the effects of the biostimulant are not due to N fertilization. We chose to assess the potential activity of the collagen-based PH as multi-stress protectant against three different types of abiotic stresses: drought, hypoxia and Fe starvation and we analyzed the effects on growth during the first days after germination, a phase that can be critical for the plant emergence after sowing.

Our results confirmed the observations made by Trevisan et al. (2019) about the capacity of the PH to protect the root apparatus under hypoxic conditions and extended the analysis to the advantages that the presence of PH supplied in the medium can bring during the recovery from the stress (Trevisan et al., 2019). Indeed, when after 4 days of hypoxia the plants returned to the normal air insufflation, the presence of the PH in the medium rapidly stimulated the resumption of root growth whereas untreated roots did not seem to recover.

To our knowledge, the effects of collagen-derived PH on plants subjected to water stresses has not previously been investigated. To apply water stress conditions, we follow a method described by Han et al. (2017) to generate osmotic stress in maize plants under hydroponic cultivation by adding 15% PEG to the nutrient solution (Han et al., 2017). The response to osmotic stress was similar in N- and PH-treated plants. In both cases we observed a slight decrease in shoot fresh biomass (**Supplementary Figure 1**

and **Figure 1A**) and an increase in root growth – mainly in the lateral roots for what concerns the PH-treated plants- leading to a change in shoot/root ratio which is a typical response of plants to water deficit. Although the plant species and the PEG concentration used are different, our results are in accordance with those of Ji et al. (2014), who showed that one of the effects of PEG-mediated osmotic stress in wheat is the induction of lateral root development (Ji et al., 2014). Overall, we showed that the water stress did not alter the positive effects of PH on root growth most probably allowing under longer term a better acquisition of water and nutrients in the PH- treated plants compared to the control ones.

The positive effects of PH on abiotic stress resistance has often been ascribed to its capacity to counteract the oxidative stress (Lucini et al., 2015) mainly through the induction of genes involved in antioxidant defense (Caruso et al., 2019). In this regard, we previously observed that the collagen-based PH compared to other biostimulants such as free amino acids, produces only a moderate alteration of genes related to oxidative stress under normal conditions (Santi et al., 2017) suggesting that it is not itself an oxidative stress elicitor. Interestingly, the collagen-based PH acts on phytohormone homeostasis and signaling, modifying the expression of genes involved in metabolism, transport and signal transduction of gibberellin, cytokinins and auxin (Santi et al., 2017). It is presumable that the effects of the collagen-based PH on the hormone functions could be responsible for the positive effects on root growth also under stress conditions.

Concerning the experiments of recovery after Fe-starvation, we obtained several lines of evidence about the positive effects of the collagen-based PH. The SPAD measurements and Fe concentrations in the leaves clearly demonstrated that the administration of PH mixed to FeCl_3 confers a faster recovery from deprivation as compared with treatments with FeCl_3 or FeEDTA . We can hypothesize that the positive role of the PH on Fe accumulation in starved plants is linked to both biological and chemical proprieties of the PH itself. Some interesting insights concerning the structural features of the PH under study and on its interaction with Fe were discovered thanks to the CD spectra analyses. CD has been widely used as a reliable source to study the interactions among biomolecules (Greenfield, 2007), especially proteins, and some works had already highlighted the diagnostic features of collagen, collagen peptides and poly-proline type II (PPII) structures spectra (Piez, 1968; Piez and Sherman, 1970; Adzhubei et al., 2013; Lopes et al., 2014). The PH spectra obtained was extremely reproducible and had the typical shape of the collagen peptides and PPII (type II polyproline helices) reference spectra (Lopes et al., 2014). The similarities between these CD spectra were striking and we can therefore assume that the acid hydrolysis process produces a mixture of short peptides that maintains the PPII secondary structure. Furthermore, CD spectra showed that the collagen-based PH can interact with Fe in a dose-dependent manner suggesting the formation of Fe-PH complexes. Results previously reported by Santi et al. (2017) hinted that the collagen-based PH could improve Fe uptake through a transcriptional reprogramming of genes playing a role in the metal transport processes. With the exception of

ZmYS1, here we show that the molecular components involved in maize root Fe acquisition (e.g., solubilization and uptake, *ZmTOM1* and *ZmIRT1*, respectively) (Li et al., 2013, 2018; Nozoye et al., 2013; Wairich et al., 2019) are more expressed in PH-treated roots during the FeCl_3 supply (Figures 6A–C), possibly indicating that the mechanisms of Fe sensing by maize roots are, in this condition, less susceptible to the restored cellular Fe accumulation. Interestingly, a similar behavior was described in Fe-deficient tomato plants supplied with Fe chelated to fulvic acid like water-extractable humic substances, another category of plant biostimulant (Zamboni et al., 2016). Furthermore, we cannot exclude a role of *ZmOPT* in the uptake of Fe-PH complexes, since it showed the highest expression in PH-treated roots although not statistically significant (Figure 6D).

We propose that the PH role as Fe deficiency stress mitigator might be explained with a combination of possibly synergic chemical and molecular mechanisms leading to an increased uptake and distribution of Fe when Fe is supplied after shortage. In particular, these mechanisms seem to be based on: (1) an

enhanced stimulation of phytosiderophore (PS) efflux leading to a higher solubilization of Fe(III) ; (2) an increased uptake of the reduced form of Fe since the presence of *ZmFRO2* in maize genome has been ascertained (Li et al., 2018); (3) an easier uptake of Fe as a chelated complex with the PH; (4) an increased Fe solubilization due to the presence of PH and an effective ligand exchange process involving Fe-PH and PSs making more efficient the action of these chelators (Figure 7).

In conclusion, we demonstrated that the collagen-based PH under study, not only is a plant growth promoting agent, but it might also be used effectively as hypoxic, drought, and nutrient stress mitigator.

The protective effects cannot be related to a single mechanism of action, but most probably are the result of different activities of the peptides both in the external medium and inside the cells. A further characterization of this matrix could help to shed light on the role of its peptides at the cellular level, considering that many works have showed how small peptides are crucial for plant signaling (Gancheva et al., 2019). For instance, IRON MAN (IMA), CLV3/ESR-RELATE D

(CLE) and HYDROXYPROLINE-RICH GLYCOPEPTIDE SYSTEMINS (HypSys) are three important families of peptides, on the range of 5–20 amino acids, involved in very different processes. The members of the former family control iron transport in plants (Grillet et al., 2018), those of the second one are involved in the differentiation of shoot and root meristems (Leasure and He, 2012), while those of the third one are plant protective signal peptides, participating in plant defense reactions (Pearce, 2011).

doi: 10.3389/fpls.2021.625541

Water-deficit stress negatively affects seed germination, seedling development, and plant growth by disrupting cellular and metabolic functions, reducing the productivity and yield of field crops. In this study, sodium silicate (SS) has been employed as a seed priming agent for acclimation to mild water-deficit stress by invoking priming memory in wheat plants. In pot experiments, the SS-primed (20, 40, and 60 mM) and non-primed control seeds were allowed to grow under normal and mild water-deficit conditions. Subsequently, known methods were followed for physiological and biochemical studies using flag leaves of 98-day mature wheat plants. The antioxidant and hydrolytic enzymes were upregulated, while proteins, reducing sugars, total sugars, and glycine betaine increased significantly in the flag leaves of wheat plants originated from SS-treated seeds compared to the control under mild water-deficit stress. Significant decreases in the malondialdehyde (MDA) and proline contents suggested a controlled production of reactive oxygen species, which resulted in enhanced cell membrane stability. The SS priming induced a significant enhancement in yield, plant biomass, and 100-grain weight of wheat plants under water-deficit stress. The improvement in the yield parameters indicated the induction of Si-mediated stress acclimation in SS-primed seeds that elicited water-deficit tolerance until the maturity of plants, ensuring sustainable productivity of climate-smart plants.

Keywords: seed priming, sustainable productivity, water-deficit stress tolerance, wheat, silicon

INTRODUCTION

Around the world, sustainable agriculture is facing severe threats from ecotoxicological conditions, climate change, and environmental stresses that pose serious challenges to global food security. Plants growing in a dynamic environment are heavily influenced by the aforesaid stress factors and exhibit a significant reduction in growth, development, and final yield, although they try to counterbalance the negative impacts through certain adaptive mechanisms, such as changing the osmotic potential, plant structure, and growth pattern, boosting the antioxidant defense potential

and regulating physiological and biochemical processes (Teh and Koh, 2016). Over the years, drought or water deficit has been recognized as the most brutal environmental stress that retards the growth and development of plants by having negative impacts on the physiological, biochemical, and morphological traits. It hampers the normal metabolic, antioxidant, and photosynthetic activation and nutrient movement in plants. The disrupted processes at the subcellular level impair the growth-promoting parameters and lead to reduced plant growth and biomass and to yield losses (Wang et al., 2018; Easwar Rao and Viswanatha Chaitanya, 2020). Wheat is a major staple food, and its seed germination, seedling growth, and plant development also experience the drought-induced negative impacts, which ultimately result in low yield (Amirjani and Mahdijeh, 2013; Guo et al., 2017). Wheat plants experience negative changes in protein contents, antioxidant potential, and hormone composition at the vegetative and reproductive stages under drought. It also influences the chlorophyll content, cuticle thickness, and opening and closing of the stomata (Bano et al., 2012; Guan et al., 2015; Li et al., 2020). In fact, water limitations severely reduce the uptake and translocation of macro- and micronutrients, which affect leaf–water relations, photosynthesis, and chlorophyll fluorescence, resulting in reduced plant growth, early senescence, and low wheat productivity (Zlatev, 2009; Karim et al., 2012; Wang et al., 2017).

Seed germination is one of the major phases in the life of higher plants in which all well-regulated metabolic, biochemical, and physiological processes ensure the rapid and uniform emergence of seedlings and plant development. Priming is a seed pre-conditioning technique that modulates the biochemical and physiological processes for the acceleration of germination and alleviation of stress, and for higher crop yields. In fact, it programs the seeds for the tolerance of abiotic stresses by regulating metabolism, antioxidant enzymes, and protein synthesis and readjusting the underlying subcellular pathways (Wojtyla et al., 2016; Hameed et al., 2019). Over the last few decades, a range of physical, chemical, and biological treatments have been well explored for hydropriming, chemopriming, biopriming, and thermopriming for pre-germinative metabolic modulations in seeds in order to withstand abiotic and biotic stress conditions at germination, seedling growth, and plant development. Various natural and synthetic priming agents (inorganic salts, organic molecules, and natural metabolites) have been reported to boost the antioxidant potential as a stress-responsive strategy for the alleviation of drought-induced damages in germinating seeds (Aranega-Bou et al., 2014; Savvides et al., 2016; Singh et al., 2020). Various studies have reported the applications of salicylic acid, abscisic acid, jasmonic acid, hydrogen peroxide, ascorbic acid, sodium nitroprusside, sodium chloride, sodium glutamate, etc., as wheat seed priming agents to induce tolerance against drought and to mitigate the above-mentioned negative impacts (Hameed and Iqbal, 2014; Bhardwaj et al., 2017; Habib et al., 2020).

Over the last few decades, several authors have reported the ability of silicon (Si) to induce tolerance against biotic and abiotic stresses, including salinity, high temperature, chilling, drought, etc. It accelerates seed germination and enhances

plant growth and crop yield. It acts as a plant protectant and biostimulant under a range of stress conditions. It also improves the water status and water use efficiency of plants and reduces lipid peroxidation under drought stress (Hasanuzzaman et al., 2018; Liu et al., 2019). It could regulate osmolyte accumulation and readjust osmotic potential under water-deficit conditions. Si provision improved the yield of rice by increasing the mobilization of photoassimilates and amino acids from vegetative tissues to grain and nitrogen use efficiency. It redirected the primary metabolism by acting as a signaling factor under unstressed conditions (Pang et al., 2019; Mohanty et al., 2020).

Keeping the above facts in mind, this study was planned to employ Si as a wheat seed priming agent to induce acclimation to mild water-deficit stress until the maturity of plants.

MATERIALS AND METHODS

In this study, spring wheat (*Triticum aestivum* L. cv. AARI-2011) seeds (100 g for each treatment) were primed with 20, 40, and 60 mM sodium silicate (SS) solution, the Si donor, for 8 h. Then, they were washed and dried at $26 \pm 2^\circ\text{C}$ under shade. On the other hand, some wheat seeds were soaked only in water to achieve hydro-primed seeds for comparative study. Pot experiments with a completely randomized design were conducted in three replicates (five pots per replicate with five seeds per pot) to investigate the effects of silicon-induced priming on mature wheat plants produced from SS-primed seeds under normal and mild water-deficit conditions. Each pot was filled with 1.4 g cm^{-3} sandy clay loam soil containing 22% clay, 33% silt, and 45% sand. Normal growth conditions were maintained by providing water at soil water-holding capacity. On parallel, the drought stress was induced by maintaining water at 50% soil water-holding capacity. Physiological and biochemical analyses were performed using flag leaf samples collected from 98-day matured plants originated from SS-primed, hydro-primed, and non-primed control seeds grown under normal and mild drought conditions.

Physiological Analyses

A known conductometric method was employed for the measurement of cell membrane stability (CMS) (Blum and Ebercon, 1981). The samples were autoclaved for 24 h before and after conductivity reading from the control (C) and stressed (T) leaf samples.

$$\text{CMS \%} = [(1 - (T_1/T_2))/(1 - (C_1/C_2))] \times 100$$

where T_1 is the stress sample conductance before autoclaving, T_2 is the stress sample conductance after autoclaving, C_1 is the control sample conductance before autoclaving, and C_2 control sample conductance after autoclaving.

The water status parameters (turgor, osmotic, and water potential) were measured using the youngest leaf samples according to known procedures. The difference between the water potential (Ψ_w) and osmotic potential (Ψ_s) values provided the leaf turgor potential (Ψ_p).

$$(\Psi_p = \Psi_w - \Psi_s)$$

Biochemical Analyses

Biomolecules

Total soluble proteins (TSPs) were estimated by the method of Bradford using bovine serum albumin (BSA) as the standard (Bradford, 1976). Reducing sugars were determined using a well-known dinitrosalicylic acid method (Miller, 1959) and the total sugar content estimated using the phenol sulfuric acid reagent method (Dubois et al., 1951). The reducing and total sugar contents were determined from a standard curve prepared by using glucose as the standard. Non-reducing sugars were calculated by subtracting the reducing sugars from the total sugars.

Enzymatic and Non-enzymatic Antioxidants

For the different biochemical analyses, leaf samples (0.5 g) were ground in specific extraction buffer and centrifuged at $15,000 \times g$ for 20 min at 4°C for different biomolecules and enzymes. Subsequently, the separated supernatant was employed for the below given biochemical analyses according to well-established methods. Spectroscopic analyses were performed using a spectrophotometer (Hitachi, U2800).

Specific extraction buffers were used to homogenize the leaf samples (0.5 g) as in a known procedure. The activity of superoxide dismutase (SOD) was assayed by measuring its ability to inhibit the photochemical reduction of nitroblue tetrazolium (NBT) following a known method (Giannopolitis and Ries, 1977). One unit of SOD activity was defined as the amount of enzyme which caused 50% inhibition of photochemical reduction of NBT. The activities of peroxidase (POD) and catalase (CAT) were also measured using a well-established method (Chance and Maehly, 1955). For POD activity, we noted an increase in the absorbance of the reaction solution at 470 nm. In the case of CAT activity, we recorded a decrease in the absorbance of the reaction solution at 240 nm. An absorbance variation of 0.01 U/min was taken as one unit of CAT and POD activities. Further, the activities of enzymes were expressed on seed weight basis.

The level of lipid peroxidation was measured in terms of malondialdehyde (MDA, a product of lipid peroxidation) content determined by a known method which involves thiobarbituric acid (TBA) reaction (Heath and Packer, 1968). An extinction coefficient of $155 \text{ mM}^{-1} \text{ cm}^{-1}$ was used for the calculation of MDA content. The Folin-Ciocalteu reagent was employed according to a known micro-colorimetric method for the determination of the total phenolic content (TPC) (Ainsworth and Gillespie, 2007). A linear regression equation was used for the measurement of TPC after preparing the standard curve with different concentrations of gallic acid.

Hydrolytic Enzymes

Protease activity was determined by a known casein digestion assay (Drapeau, 1976). The absorbance of the filtrate was measured at 280 nm. By this method, 1 U is the amount of enzyme that releases acid-soluble fragments equivalent to 0.001 A_{280} per minute at 37°C and pH 7.8. Enzyme activity was expressed on a protein basis. The α -amylase activity was

determined by following a reported method (Varavinit et al., 2002). Accordingly, maltose was used for the construction of the standard curve to measure enzyme activity.

Osmolytes

The known acid ninhydrin method was employed for the measurement of proline content at 520 nm and expressed as micrograms proline per gram fresh weight (FW) (Bates et al., 1973). A known spectroscopic method was adopted for the determination of glycine betaine (GB) (Grieve and Grattan, 1983). Warm distilled water was used to prepare an aqueous extract of dry leaves, which was mixed with 0.2 ml of potassium triiodide solution and 0.25 ml of 2 N HCl. After keeping this solution in an ice bath for 90 min, 20 ml of dichloromethane and 2 ml of water were added for the extraction of GB. The optical density of the organic phase was determined at 365 nm, and the GB concentrations were measured on a fresh weight basis.

Pigment Contents

A known spectrophotometric-based method was followed to measure chlorophyll a (chl a), chlorophyll b (chl b), total chlorophyll (total chl), and carotenoids in leaf samples (Arnon, 1949; Peters and Noble, 2014). The pigments were extracted in 85% acetone and centrifuged at 4,000 rpm for 15 min; subsequently, the supernatant was used for the absorbance of the recorded values at 645, 663, and 480 nm. Afterward, the pigment contents were calculated as follows:

Chl a (mg/g FW)

$$= [12.7(OD_{663}) - 2.69(OD_{645}) \times V/1,000 \times W]$$

Chl b (mg/g FW)

$$= [22.9(OD_{645}) - 4.68(OD_{663}) \times V/1,000 \times W]$$

Carotenoids (mg/g FW) = $[A_{\text{car}}/EM] \times 1,000A_{\text{car}}$

$$= OD_{480} + 0.114(OD_{663}) - 0.638(OD_{645})$$

Where, OD represents optical density, V is the volume of the sample, W is the weight of fresh tissue taken for extraction, and EM is 2,500.

Yield Attributes

The mature wheat plants were used to calculate the plant biomass, 100-grain weight yield, and the grain yield per plant under stress and non-stress conditions.

Statistical Analyses

Finally, significance of the data was tested using variance and Tukey's (honestly significant difference, HSD) test at $p < 0.05$ and, where applicable, at $p < 0.01$. Thus, the mean \pm SD values are presented in graphs.

RESULTS

The SS-treated and non-treated wheat seeds were allowed to germinate in pots under normal and mild drought stress

conditions. Later, the flag leaf samples of 98-day mature plants were used for biochemical, physiological, and yield responses and compared with the control under stress and non-stress conditions.

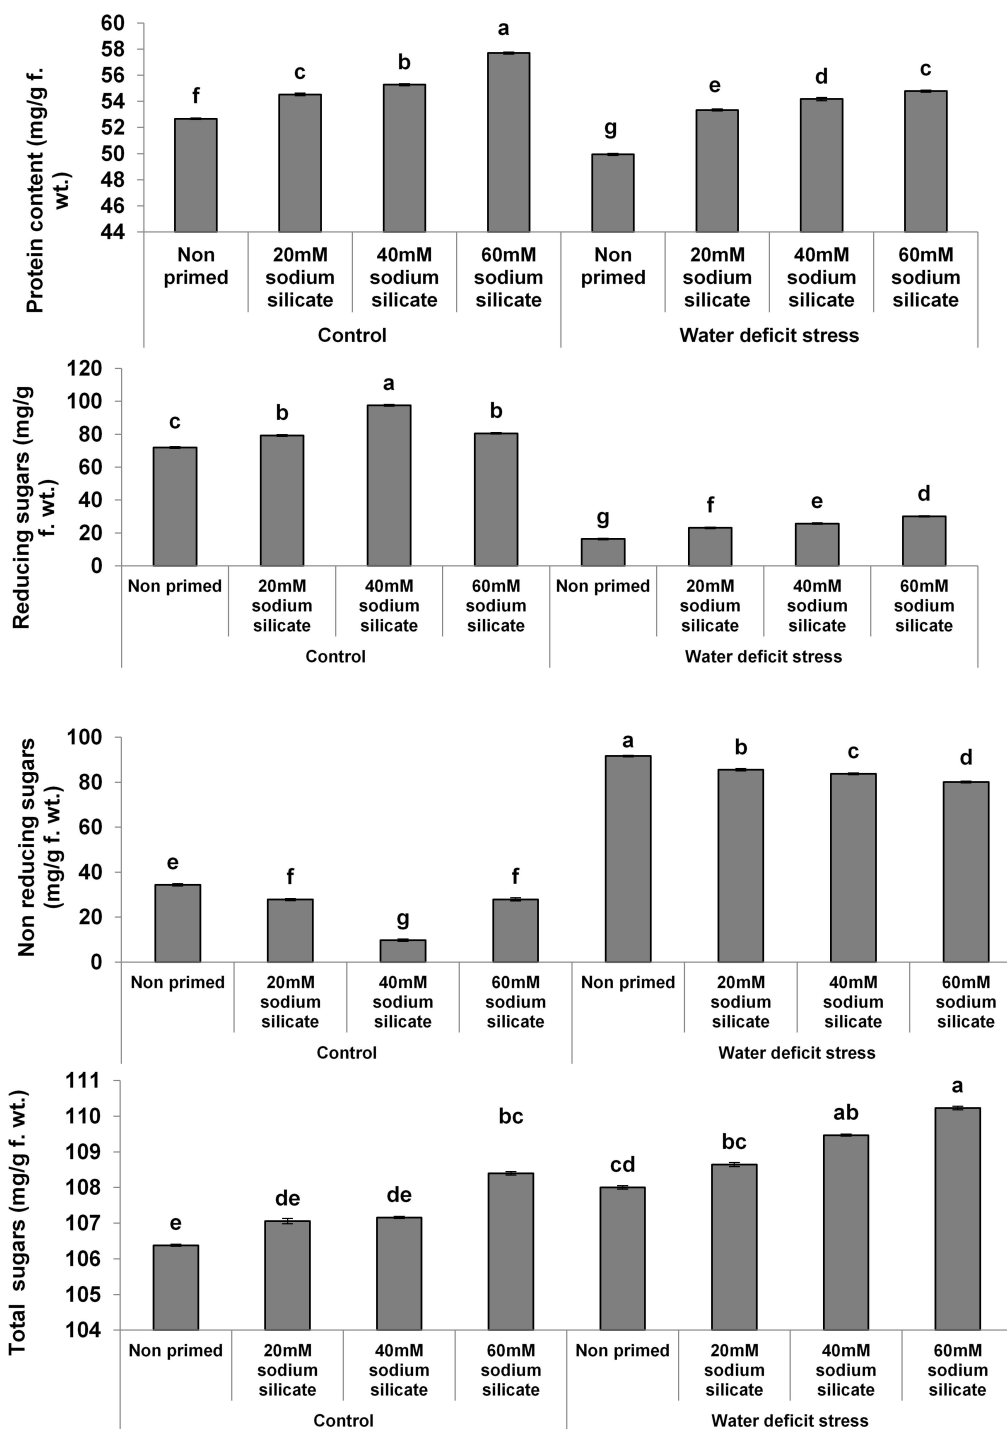

FIGURE 1 | Contents of biomolecules in the flag leaf of wheat plants grown after sodium silicate seed priming under non-stress and water-deficit stress conditions. Each data point represents the mean of three samples \pm SD. Bars with different alphabet are significantly different ($p < 0.05$ and $P > 0.01$) according to Tukey's (HSD).

Biochemical Parameters

The protein contents increased significantly with increasing concentrations of the priming agent under normal as well as stress conditions compared to the control (Figure 1). There was a significant increase in reducing sugars with increasing

concentrations of the applied sodium silicate priming solution under both conditions. However, the increasing effect was more pronounced in the flag leaves of plants originated from prime seeds under normal conditions. Interestingly, an entirely opposite effect was observed in the case of non-reducing sugars. The

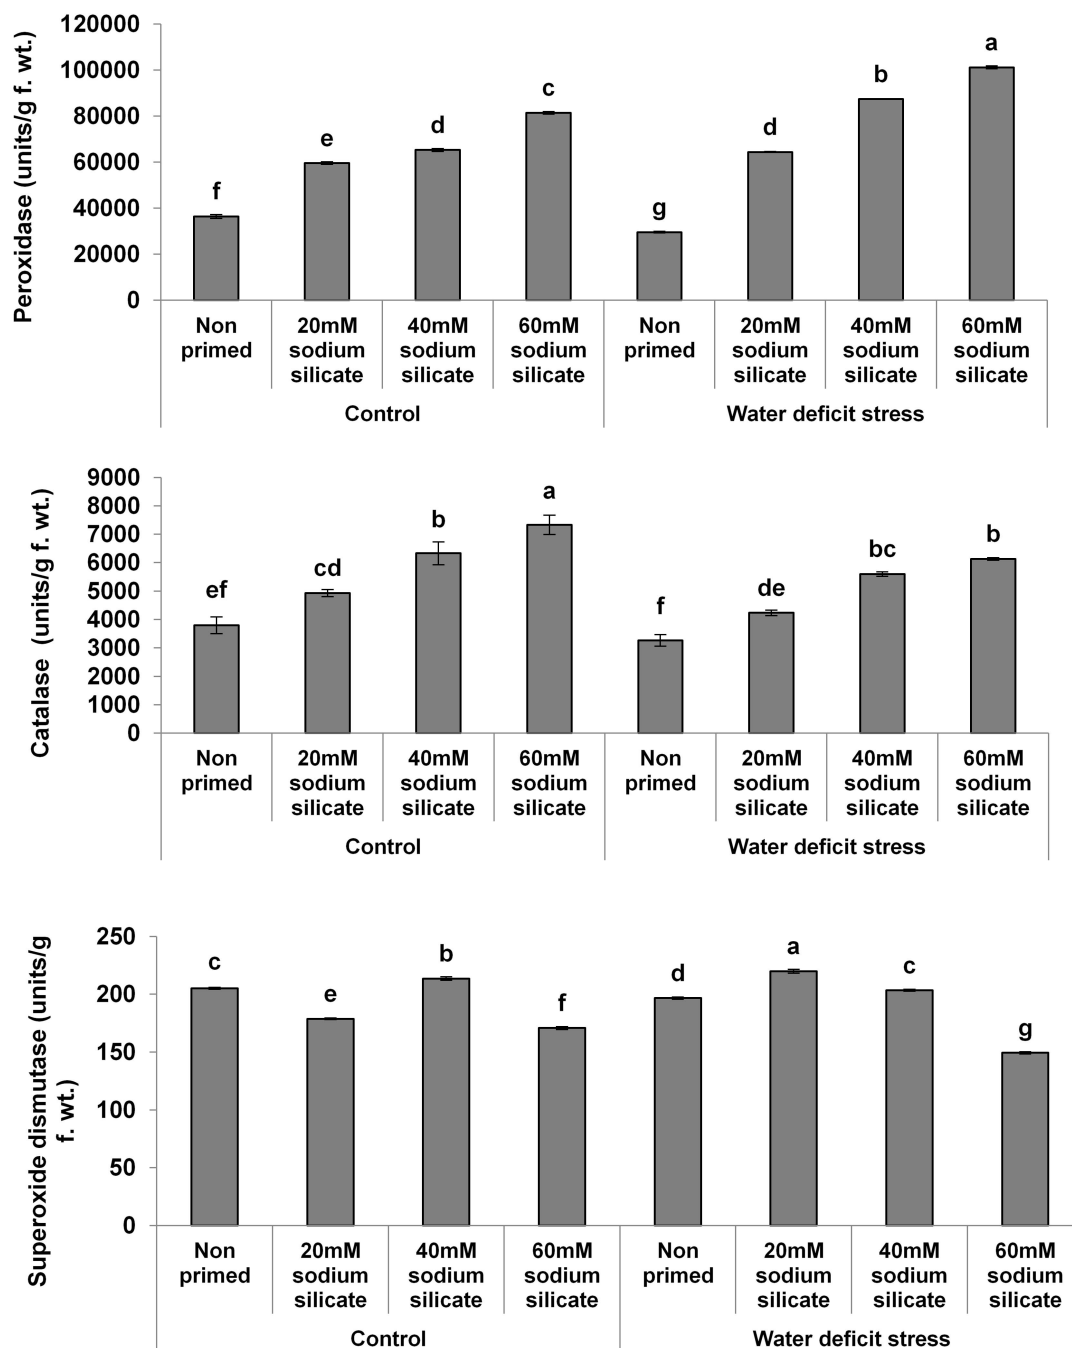

FIGURE 2 | Antioxidant enzyme activities in the flag leaf of wheat plants grown after sodium silicate seed priming under non-stress and water-deficit stress conditions. Each data point represents the mean of three samples \pm SD. Bars with different alphabet are significantly different ($p < 0.05$ and $P > 0.01$) according to Tukey's (HSD).

total sugars increased with increasing concentrations of the priming agent under drought, while under normal conditions, only priming with 60 mM SS treatment induced a significant increase in total sugars.

In the case of the antioxidant enzymes, both POD and CAT activities were upregulated significantly with increasing priming concentrations under both conditions. However, a more pronounced effect was observed in POD and CAT under the mild

drought and normal conditions, respectively. Priming with 20 and 40 mM SS induced a significant increase in SOD activity under drought. Under normal conditions, only 40 mM SS treatment caused a significant increase in SOD. The maximum upregulation of SOD was observed as a result of priming with 20 mM SS under stress (**Figure 2**).

The MDA contents exhibited a significant decreasing trend with increasing priming concentrations. The maximum MDA

FIGURE 3 | Malondialdehyde (MDA) contents and total phenolics in the flag leaf of wheat plants grown after sodium silicate seed priming under non-stress and water-deficit stress conditions. Each data point represents the mean of three samples \pm SD. Bars with different alphabet are significantly different ($p < 0.05$ and $P > 0.01$) according to Tukey's (HSD).

was observed in the flag leaves of plants originated from non-primed seeds grown under drought. Treatment with 40 mM SS induced a significant decrease, while the other treatments caused

an increment in the non-enzymatic antioxidant, the TPC, under both conditions compared to the control (**Figure 3**). In the case of the hydrolytic enzymes, the protease and α -amylase activities

FIGURE 4 | Hydrolytic enzyme activities in the flag leaf of wheat plants grown after sodium silicate seed priming under non-stress and water-deficit stress conditions. Each data point represents the mean of three samples \pm SD. Bars with different alphabet are significantly different ($p < 0.05$ and $P > 0.01$) according to Tukey's (HSD).

were significantly upregulated due to the priming treatments under normal as well as stress conditions (**Figure 4**).

The proline contents decreased significantly and linearly with increasing SS priming concentrations, while a significantly linear increase was observed in GB under both conditions (**Figure 5**).

Priming with 40 mM SS only caused a significant increase in chl a under normal conditions. The priming treatments induced a significant decrease in chl b and total chl under normal conditions. Under drought, priming with 20 and 60 mM SS caused a significant increase in chl a and chl b, respectively. Priming with 60 mM SS also increased the total chl significantly under stress. A significant increase in total carotenoids was observed as a result of priming with 20 and 40 mM SS under

normal conditions. Meanwhile, priming with 60 mM induced a significant increase in total carotenoids under stress (**Table 1**).

Physiological Parameters

There was a significant and linear decrease in the water potential of flag leaves with increasing SS priming concentrations under both conditions. The osmotic potential exhibited a similar trend under stress. However, a significant increasing effect was induced by 60 mM treatment under normal conditions. A significant increase in turgor potential was observed with increasing priming concentrations under both conditions (**Table 2**). CMS increased significantly with increasing SS priming concentrations (**Figure 6**).

FW, fresh weight. Mean values of three replicates are presented. Within a column, means sharing the same letters are non-significantly different ($p > 0.05$ and $p > 0.01$) according to Tukey's HSD test.

Yield Attributes

The yield of plants increased significantly with priming treatments under both conditions; however, the effect was more pronounced under stress-free conditions. A significant increase in 100-grain weight was observed only as a result of priming with 20 mM SS under normal and stress conditions, while the other treatments were unable to induce any perceptible change in it. The priming treatments induced a significant increase in plant biomass under both conditions (Table 2).

DISCUSSION

Applications of SS as a wheat seed priming agent induced a significant increase in TSP in the flag leaves of plants under both conditions. Proteins provide energy and amino acids to germinating seeds and developing seedlings and execute a number of physiological and biochemical processes in plants, being vital enzymes in various subcellular metabolic and signaling pathways. Drought stress induces severe negative impacts on such pathways due to their high dependence on water availability (Ali and Elozeiri, 2017). As a stress-mitigating strategy, plants produce drought-responsive proteins for biochemical readjustments to counterbalance the deleterious impacts and provision of resistance against stress (Al-Jebory, 2012). Silicon applications are known to enhance the expressions of drought-related proteins in rice plants under drought (Khatab et al., 2014). Accordingly, in our study, the Si-induced marked increment in TSP has been considered as a mechanistic response to water-deficit conditions. Hence, the significant improvement of the TSP content with increasing SS concentrations suggested the facilitating role of Si in protein synthesis under normal as well as stress conditions. The produced proteins could have assisted in the regulation of metabolic pathways and provided energy and nutrients for the induction of stress tolerance.

There were significant increases in the reducing and total sugars with increasing SS concentrations under stress and stress-free conditions. Plants increase their sugar content as a part of their stress-insulating mechanism because they could provide energy for metabolic processes and assist in the regulation of stress responses. Sugars do act as osmoprotectants and provide membrane stability, especially under water-deficit conditions (O'Hara et al., 2013; Poonam et al., 2016). Maize plants produced from Si-primed seeds were reported to show higher contents of soluble sugars under alkaline and water-deficit stress (Abdel Latif and Tran, 2016; Parveen et al., 2019). Hence, a Si-mediated increase in the reducing and total sugars has been considered as a positive factor for drought tolerance in this study. However, SS priming induced a significant decrease in non-reducing sugars, which suggested their lesser requirements in water-deficit management in this study.

In our case, the Si priming treatments significantly increased the POD and CAT activities in the flag leaves of wheat plants under normal and stress conditions. Priming with 20 and 40 mM SS caused a significant increase in SOD activity under stress and normal conditions, respectively, while all the other

Mean values of three replicates are presented. Within a column, means sharing the same letters are non-significantly different ($p > 0.05$ and $p > 0.01$) according to Tukey's HSD test.

priming treatments induced a significant decrease in SOD under both conditions. In general, plants utilize non-enzymatic and enzymatic antioxidants for real-time detoxification of stress-induced reactive oxygen species (ROS). Therefore, upregulated antioxidant enzymes have been considered as a major stress-responsive strategy for counterbalancing excessive ROS (Sofa et al., 2015). The exogenous as well as priming applications of Si have been known to boost antioxidant enzymes in late-sown wheat and maize plants under drought (Sattar et al., 2017; Parveen et al., 2019). Thus, in our case, the elevated activities of the antioxidant enzymes represented an increased antioxidant potential for the provision of water-deficit tolerance in wheat plants.

The overexpression of the antioxidant enzymes along with the readjustment of biomolecules might have mitigated the negative impacts of water-deficit and helped to detoxify the excessive generation of ROS. It has been signified by the significant reduction of MDA contents with increasing priming concentrations prominently under mild water-deficit conditions. Under both conditions, two priming treatments induced a significant increase in TPC, a non-enzymatic antioxidant. The elevated antioxidant potential with reduced MDA contents suggested acclimation to water deficit in wheat plants induced as priming memory in primed seeds.

In our study, the activities of both hydrolytic (protease and α -amylase) enzymes increased significantly and almost linearly with increasing concentrations of SS under both conditions. Usually, plants show an upregulation of hydrolytic enzymes as a mechanistic approach for the mitigation of abiotic stresses including water deficit (Wang et al., 2016). They re-mobilize stored proteins and soluble sugars for the regulation of various metabolic and physiological functions vital for seed germination, seedling development, and plant growth (Adda et al., 2014; Martinez et al., 2019). In this perspective, the upregulation of the hydrolytic enzymes has been considered as a positive factor to elicit water-deficit tolerance in wheat plants.

Proline accumulation appears as one of the major stress-combating strategies in plants against a number of abiotic stresses, including water-deficit conditions. It helps the plants in osmotic readjustments for the development of water-deficit resistance. Further, it has been suggested as the biomarker of osmotic stress injury (Heuer, 2010; Chun et al., 2018). In our case, the proline contents were decreased significantly in the flag leaf of wheat plants with increasing priming concentrations compared to the control under both conditions. Accordingly, it represented that SS priming provided water-deficit acclimation in wheat plants, thus reducing the chances of osmotic injury and the requirement of proline. Glycine betaine is also produced in plants as an adaptive mechanism to counter abiotic stresses, including drought or water-deficit conditions. It is a known osmolyte that helps in stress-related osmotic readjustments for buffering of the redox potential, membrane stability, and higher ROS scavenging capacity. It interacts with the hydrophobic and hydrophilic domains of protein complexes and membranes, protects them from ROS, and maintains their structural and functional integrity. Thus, it offers counteracting mechanisms to settle the stress-related metabolic dysfunctions, ensuring

FIGURE 6 | Effect of sodium silicate seed priming on cell membrane stability. Each data point represents the mean of three samples \pm SD. Bars with different alphabet are significantly different ($p < 0.05$ and $P > 0.01$) according to Tukey's (HSD).

improved growth and survival of plants (Xu et al., 2018; Annunziata et al., 2019). Silicon applications have regulated the osmolytes as a mechanistic approach to induce drought tolerance in different species of plants (Yang et al., 2017; Hasanuzzaman et al., 2018). In our case, there was a significant and linear increase in GB with increasing SS priming concentrations compared to the control under water-deficit and normal conditions. Therefore, the SS-mediated increase of GB in flag leaves has been suggested as a positive factor that elicits water-deficit tolerance in wheat plants.

Water-deficit conditions generally induce negative impacts on the chlorophyll content, resulting in a reduced photosynthetic activity (Chen et al., 2016; Hussain et al., 2019). In our case, SS priming produced significant increases in chl a, chl b, and total chl in flag leaves, suggesting the stress-mitigating role of Si under mild water-deficit conditions. Further, treatment with 60 mM SS caused a significant increase in total carotenoids under stress. In general, drought caused a significant reduction in carotenoid content in plants. They have been suggested as important precursors of plant hormones and accessory pigments for photosynthesis (Mibei et al., 2017). Foliar applications of Si also increased the photosynthetic pigments, including carotenoids, in wheat under normal and drought conditions (Maghsoudi et al., 2016). In a very recent study, silicon fertilization improved chlorophyll and carotenoids in sugarcane cultivars grown under water-deficit conditions (De Camargo et al., 2019). Thus, in our study, the silicon-mediated increase in photosynthetic pigments and carotenoids has been correlated to its stress alleviatory role for sustainable productivity.

In our case, the priming treatments resisted the negative impacts of mild water-deficit conditions and exhibited a significant increase in CMS in flag leaves. The increase in CMS has also been justified by a low MDA, a higher antioxidant

potential, and higher amounts of osmolytes owing to the Si-regulated metabolic, biochemical, and signaling processes under mild water-deficit conditions. The increased CMS and the higher content of osmolytes developed osmoregulation, which significantly improved the relative water contents in flag leaves. Exogenous applications of Si have also been known to improve the CMS and water status in a variety of plants under different stress conditions (Bybordi, 2015; Maghsoudi et al., 2016; Altuntas et al., 2018).

All SS priming treatments induced biochemical alterations, consequently improving yield, plant biomass, and the 100-grain weight of wheat plants grown under mild water-deficit and normal conditions. The improvement of the yield parameters at the whole plant stage indicates the induction of priming memory in SS-primed seeds, which elicited water-deficit tolerance until the maturity of plants. Therefore, silicon-mediated priming memory in primed seeds enabled them to tolerate water deficit at the seed germination, seedling growth, and plant development stages, thus ensuring sustainable productivity with long-lasting stress acclimation.

CONCLUSION

The silicon-mediated priming effects elicited water-deficit resistance in wheat plants by upregulating the antioxidant and hydrolytic enzymes with an increased level of osmoprotectants. Further, it induced a significant reduction in proline and MDA contents, representing a lesser ROS production that resulted in enhanced cell membrane stability. The improvement in the yield parameters at the whole plant stage indicated the induction of priming-mediated biochemical alterations in SS-primed seeds that invoked water-deficit acclimation until the maturity of plants, ensuring climate-smart growth of wheat.

doi: 10.3389/fpls.2021.631768

Soybean is one of the most valuable commercial crops because of its high protein, carbohydrate, and oil content. The land area cultivated with soybean in subtropical regions, such as Brazil, is continuously expanding, in some instances at the expense of carbon storing natural habitats. Strategies to decrease yield/seed losses and increase production efficiency are urgently required to meet global demand for soybean in a sustainable manner. Here, we evaluated the effectiveness of an *Ascophyllum nodosum* extract (ANE), Sealicit™, in increasing yields of different soybean varieties, in two geographical regions (Canada and Brazil). In addition, we investigated the potential of Sealicit™ to reduce pod shattering at the trials in Brazil. Three different concentrations of Sealicit™ were applied to pod shatter-susceptible (SS) UFUS 6901 and shatter-resistant (SR) UFUS 7415 varieties to assess their impact on pod firmness. SS variety demonstrated a significant decrease in pod shattering, which coincided with deregulation of *GmPDH1.1* and *GmSHAT1–5* expression, genes that determine pod dehiscence, and higher seed weight per pod. Sealicit™ application to the SR variety did not significantly alter its inherent pod shatter resistance, but provided higher increases in seed yield at harvest. This yield increase maybe associated with to other yield components stimulated by the biostimulant. This work demonstrates that Sealicit™, which has previously been shown to improve pod firmness in *Arabidopsis* and selected commercial oilseed rape varieties through *IND* gene down-regulation, also has the potential to improve pod resistance and seed productivity in soybean, a member of the legume family sharing a similar strategy for seed dispersal.

Keywords: seaweed, *Ascophyllum nodosum* extract, pod shattering, soybean (*Glycine max*), seed loss, sustainable agriculture, plant biostimulants

INTRODUCTION

The increased food production requirement, in the context of limited availability of arable land and a climate emergency driven by greenhouse gas emissions, makes the development of more efficient agricultural production a necessity. At the same time, consumer trends for consumption of more plant protein and less meat result in surging demand for plant proteins and oils that are very efficiently produced by legumes, especially soybean. Since 1961, the world production of soybean has increased 13-fold through the rapid expansion of the production area (from 23.8 to 124.9 Mha) and a significant boost of average harvested seed yield (from 1,128 to 2,791 kg/ha). In 2018, United States (35%), Brazil (34%), and Argentina (11%) produced approximately 80% of the world's harvested soybean, which is equivalent to almost 350 Mt (FAO, 2018) and steadily growing.

Soybean (*Glycine max*) is a relatively young crop; it is estimated that it was domesticated only 3,000–5,000 years ago in China (Prince et al., 2020), with subsequent cultivation spreading to other Asian regions. It is believed that during that time soybean acquired a number of shatter-resistant genes to impair an evolutionary-conserved seed dispersal mechanism (Dong et al., 2014). Current crops have been optimized for desired traits, starting from the selection by first farmers (Meng et al., 2013), through genome-wide association analysis (GWAS) combined with bioinformatics (Moreira et al., 2019). Independently of the method, the decrease of seed loss by dispersal and maximization of seed production was always the main goal. The major discoveries revealing the mechanism of seed dispersal are mostly attributed to the acquisition of *Arabidopsis thaliana* as a model plant system for fundamental research. *Arabidopsis*, a member of the Brassicaceae, develops a characteristic dry dehiscent fruit composed of two fused carpels that shatter the seeds through breaking of the dehiscence zones, along the silique, after maturity (Ferrándiz, 2002; Łangowski et al., 2016). Apart from *Arabidopsis*, several important genes involved in pod shattering, namely, *IND*, *ALC*, *SHP1*, *SHP2*, and *FUL*, and their complex regulatory network involved in pod dehiscence, were identified in a number of other members of the brassicas (Liljegren et al., 2000, 2004; Rajani and Sundaresan, 2001; Lewis et al., 2006; Girin et al., 2011; Pabón-Mora et al., 2014; Balanzà et al., 2016) such as *Capsella rubella* (Eldridge et al., 2016; Dong et al., 2019) and *Brassica juncea* (Østergaard et al., 2006), *rapa* (Mongkolporn et al., 2003), or *napus* (Raman et al., 2014), as well as in rice and soybean (Konishi et al., 2006; Li et al., 2006; Suzuki et al., 2010; Funatsuki et al., 2014; Yoon et al., 2014; Dong and Wang, 2015). In contrast to the bicarpellate silique of crucifers, legumes (including soybean) develop a fruit consisting of a single carpel fused on both sides. The pod walls, composed of several layers and cell types, are connected along the ventral and dorsal sutures. The opening of the soybean pod is triggered by the tension built inside the senescing pod and starts on the dorsal side (Tiwari and Bhatia, 1995; Zhang et al., 2018). Dong et al. (2014) found that excessive lignification of fiber cap cells (FCC) conferred the shatter-resistant phenotype. This process is controlled by SHATTERING1–5 (SHAT1–5), homologs to AtNST1/2, which is known to promote secondary wall biosynthesis. The same

study compared gene expression between the wild allele and domesticated soybean, revealing that *SHAT1–5* was 15-fold higher expressed than its wild counterpart. In parallel, Funatsuki et al. (2014) reported another major QTL (quantitative trait locus) involved in soybean pod shattering. Complementation assays showed that *POD DEHISCENCE1* (*GmPDH1.1*) was found to be highly expressed in inner sclerenchyma, which correlated with lignin deposition. *GmPDH1.1* encodes a dirigent-like protein involved in lignin biosynthesis (Suzuki et al., 2010) and pod dehiscence by increasing the twisting force in the pod wall (Dong and Wang, 2015). Therefore, the loss-of-function of *Gmpdh1* has been widely used as a shattering-resistant gene in soybean breeding (Funatsuki et al., 2014). Additionally, more than half of Chinese landraces and most of South Asian landraces were shown to possess *PDH1* and its shatter-resistant *pdh1* allele, which suggested that *pdh1* was indispensable to effectively grow soybean in a dry climate (Kaga et al., 2012; Funatsuki et al., 2014). The soybean pod is designed to withstand the natural fluctuations of humidity and temperature; however, the longer it stays in the field and the more cycles of wetting/drying occur, the higher the chance the pods will burst open with loss of the seeds to the soil. Unfortunately, because of rapidly changing weather conditions, with unexpectedly long periods of drought or rainfall and therefore delayed harvest, soybean shattering in the field, or during harvest, are becoming more frequent. These factors have been directly correlated to higher losses (Menezes et al., 2018; Zhang et al., 2018; Silveira et al., 2019), averaging 120 kg/ha in Brazil (Schanoski et al., 2011), or up to 319 kg/ha in the Southeastern United States (Philbrook and Oplinger, 1989).

In the last decade, a class of crop inputs known as plant biostimulants has gained significant attention for improving plant productivity. Plant biostimulants, especially those extracted from the brown alga *Ascophyllum nodosum*, have been reported to deliver a number of benefits to plants/crops (Craigie, 2011; Vera et al., 2011; Sharma et al., 2013; Ali et al., 2016; Goñi et al., 2016, 2018; Shukla et al., 2018, 2019; Carmody et al., 2020). Previously, we reported the efficacy of a specialty *A. nodosum* extract (ANE) biostimulant, namely, Sealicit™, and explored the mode of action (MOA) in reducing pod dehiscence in *A. thaliana* and winter oilseed rape (WOSR) (Łangowski et al., 2019). Sealicit™ is a novel ANE containing PSI-759 biomolecule complex, produced using a targeted plant signal induction (PSI) approach to formulation development. In this study, the goal was to test the efficacy of Sealicit™ in increasing yield and conferring pod shattering resistance in another major podded crop, soybean. The impact of Sealicit™ on soybean yield was assessed using a randomized block field trial design at two distinct geographical locations (Canada and Brazil) with four different varieties. Employing multiple experimental approaches, the impact of Sealicit™ on plant and pod phenotypic traits and pod firmness were assessed for two Brazilian soybean varieties UFUS 6901 [shattering-susceptible (SS)] and UFUS 7415 [shattering-resistant (SR)] (Bicalho et al., 2019). In order to decipher the MOA at the molecular level, the expression of soybean pod shattering genes, *GmPDH1.1* and *GmSHAT1–5* were also evaluated. Overall, the current studies aimed to further support the efficacy of a specialty biostimulant from

A. nodosum, with a defined composition, to reduce seed loss and increase yields in crops producing dry pods, bringing exciting opportunities for sustainable agriculture.

MATERIALS AND METHODS

Study Site, Experimental Conditions, and Treatment Application

The field trials in Canada were conducted in 2017 on two commercial glyphosate herbicide-resistant varieties (McLeod R2 referred to as V1 and NSC Austin RR2Y referred to as V2 throughout the manuscript). V1 and V2 varieties were evaluated in Minto midwestern Ontario (located at 49°24'26" N, 100°01'26" W and 474-m altitude) and Elm Creek, Manitoba (located at 49°40'34" N, 97°59'32" W and 252-m altitude), respectively. V1 was seeded on May 17, 2017, and harvested on September 28, 2017. V2 variety was seeded on May 11, 2017, and harvested on September 29, 2017. The climate for both locations is classified as humid continental climate (Dfa) according to the Köppen climate classification. A mean temperature of 15.8°C, ranging from 4.6 to 25.8°C, and a mean accumulated precipitation of 262.8 mm was recorded during the trial with V1 in Minto. The V2 trial was characterized by a mean temperature of 22.5°C, ranging from 5.2 to 27.5°C, and a mean accumulated precipitation of 284.5 mm. The soil type for clay loam and loamy sand for V1 and V2 field trials, respectively, and the previous crop in both sites was flax. V1 variety has an early cycle (124 days until harvest) with average *Sclerotinia* resistance and high seed yield potential (3.3 Mt/ha). V2 has an early cycle (124 days until harvest), superior white mold resistance, and high seed yield potential (3.2 Mt/ha). Soybeans were sown by mechanical drilling with a row space of 20 cm, at a seed rate of 140 and 100 kg/ha for V1 and V2, respectively. The pest management program consisted of the application of the herbicide Round-up (900 g/ha, Bayer) and the insecticide Matador (83 mL/ha; Syngenta).

Sealicit™ is a proprietary PSI-759 ANE produced under high temperatures and alkaline conditions through a targeted PSI approach to formulation development and was provided by Brandon Bioscience (Tralee, Ireland). Sealicit™ was applied at 1.5 L/ha by single foliar spray at vegetative stage V2–V3, which corresponds to the stage 14–16 according to the soybean BBCH scale (SoyBase, 2020). This system is used for uniform coding for phenologically similar growth stages of all monocotyledonous and dicotyledonous plant species (Hack et al., 1992). A portable CO₂ spraying system at a constant pressure of 2.76 bars was used to apply an equivalent volume of 100 L/ha. Control plants were sprayed with an equal volume of water. The experimental design was a randomized block design with four replicates per condition and each plot was 9 m².

The field experiments in Brazil were conducted at the FAFRAM experimental station located in the city of Ituverava-SP (20°00'00" S, 47°47'20" W and 631-m altitude) between December 2, 2019, and March 25, 2020. The climate is classified as a tropical wet and dry climate (Aw) according to the Köppen climate classification. A mean temperature of 25.2°C, ranging from 13.6°C to 34.9°C, and a mean accumulated precipitation

of 250.7 mm were recorded during the field trial period in the weather observing station INM759 of Ituverava [20°36'00" S, 47°77'00" W and 613-m altitude (Agritempo, 2020)]. The soil type was red clay latosol, and the previous crop grown in the field trial site was soybean. Both tested commercial soybean varieties were provided by the Soybean Improvement Program of the Federal University of Uberlândia (UFU, 2020). SS variety (UFUS 6901) has a very early cycle (108 days until harvest) with resistance to the nematode *Pratylenchus brachyurus* and high seed potential yield (3.9 Mt/ha). SR variety (UFUS 7415) has an early cycle (110 days until harvest) and is highly resistant to Asian soybean rust (*Phakopsora pachyrhizi*) with tolerance to drought stress and high seed potential yield (4.3 Mt/ha) (Hamawaki et al., 2018). Soybeans were sown by mechanical drilling with a row space of 50 cm, at a seed rate of 65.3 kg/ha, on December 2, 2019, with the fertilizer application of 340 kg/ha of formulated 04-14-08 (NPK). The pest management program consisted of the application of the broad-spectrum insecticide Kaiso (100 mL/ha; Nufarm), the post emergent herbicide Dribble (400 mL/ha; Sumitomo), and the systemic fungicide Fox (500 mL/ha; Bayer). Sealicit™ was applied by single foliar spray at vegetative stage V5–V7, before the emergence of the inflorescence, which corresponds to stages 16–18 according to the soybean BBCH scale. Dosage rates were 0.75, 1.5, and 3.0 L/ha of Sealicit™. A portable CO₂ spraying system at a constant pressure of 2.1 bars was used to apply an equivalent volume of 200 L/ha. Control plants were sprayed with an equal volume of water. The distance between the spray lance and the plants was 50 cm, promoting a better cover of the sprayed biostimulant on the leaf tissue. The experimental design was a randomized block design in a 4 × 2 factorial design (number of treatments × number of varieties) with 13 replicates per condition (156 plots per field trial). The plots measured 2 m wide by 5 m long (10 m²) and had four rows. These rows were spaced 0.5 m; 0.5-m buffer zones were established for each plot, and only a central 4 m² was used for phenotypic determinations or sampling purposes. The final plant stand per plot averaged 43 for both soybean varieties.

Plant and Yield Measurements

In the Canadian trials, harvesting was performed using a calibrated plot combine, and final harvested plot yields were recorded for at least four independent biological replicates per variety and treatment with soybean seed yield extrapolated to kg/ha. In Brazil, plant and yield measurements were taken in at least eight independent biological replicates per variety and treatment. Three independent biological pod samples were collected per variety and treatment and pooled for further analysis. Plant height was measured from the surface of the soil to the end of the main stem (hypocotyl) at the stages of early flowering (R1; BBCH60) and full maturity (R8; BBCH89). Plant lodging was assessed visually according to the following scale (1–5); 1: almost all plants standing, 2: less than 25% plants show stem lodging, 3: 25–50% of plants show stem lodging, 4: 50–80% of plants show stem lodging, 5: 100% plants show stem lodging. The presence of Asian soybean rust disease pressure caused by the fungus *P. pachyrhizi* was assessed visually according to a scale of one to five (1: no disease symptoms; 2: 25% plants

with disease symptoms; 3: 50% plants with disease symptoms; 4: 75% plants with disease symptoms; 5: 100% plants with disease symptoms). Soybean plants at stage R8 were harvested manually and processed by a soybean threshing machine. The seed yield was determined from the central 4-m² area of each plot. After weighing, the seed weight per plot was extrapolated to kg/ha.

Evaluation of Pod Shattering Resistance and Pod Phenotypic Traits

Soybean plants from the trials in Brazil were used for determination of pod firmness and evaluation of phenotypic traits. Before harvesting (114 days after sowing), five plants at full maturity (R8 stage or BBCH89 when the fruit ripening is complete) were picked randomly from each plot. Pods were collected randomly from these plants. In contrast to *Arabidopsis* and oilseed rape, where a mechanical test is the most common technique to measure pod firmness (Morgan et al., 2001), the oven drying method is the most convenient and widely accepted assessment of pod shattering resistance in soybean. The test implemented during the course of these field trials was based on peer-reviewed published methods with minor modifications (Funatsuki et al., 2014; Krisnawati and Adie, 2017; Krisnawati et al., 2020). First, harvested pod samples were allowed to equilibrate their moisture levels at room temperature. After this acclimatization period, pod length was measured using ImageJ software (available at¹) with a minimum of 60 biological replicates (pods) per variety and treatment. Evaluation of pod shattering resistance and seed weight per pod was performed on five biological replicates with 20 pods per replicate. Pod shattering resistance was analyzed after incubating pod samples at 65°C for the time required to open \geq 50% of the control pods (Figure 2). This time period was calibrated for both SS and SR varieties. Pod shattering was calculated as the percentage of open pods versus total number of pods. After completing the pod shattering resistance test, the same dried soybean pods were used to determine the average seed weight per pod.

RNA Isolation and qRT-PCR

RNA was obtained from soybean pods at stage R5 (BBCH 75–79), which corresponds to the stage 17b according to fruit developmental scale for the model plant *A. thaliana* (Smyth et al., 1990; Roeder and Yanofsky, 2006). Four green fruits per plant were collected from at least five plants per plot and immediately frozen in liquid nitrogen, ground, and stored in -80°C to prevent RNA degradation. All pods collected per plot were considered a single biological replicate. All samples were collected within 2 h of midday. For quantitative reverse transcriptase-polymerase chain reaction (qRT-PCR) analysis, at least three biological replicates of each treatment and variety were analyzed. Three technical replicates per biological replicate were analyzed. Expression analyses were performed by real-time PCR using a Roche LightCycler 96 System (Roche, United Kingdom). Quantitative PCR was performed using the LightCycler RNA Master SYBR Green I one-step kit (Roche, United Kingdom) according to the manufacturer's instructions.

¹<https://imagej.net/Welcome>

The expression level of genes of interest was expressed in n-fold change and calculated according to $2^{-\Delta\Delta\text{CT}}$ (Livak and Schmittgen, 2001). Primers used for qRT-PCR reactions are as follows: *GmPDH1* FW: 5'-GAGGGAGGCGTTTTACGAC-3'; REV: 5'-GACGTGGCAACCATGACTC-3' (Funatsuki et al., 2014); *GmSHAT1-5* FW: 5'-GGAGAACCACCACAACACCA-3'; REV: 5'-GTCCGTGCCCATCTCTACTG-3' (AHJ81058.1); *GmCYP2* FW: 5'-CGGGACCAGTGTGCTTCTTCA-3'; REV: 5'-CCCCTCCACTACAAAGGCTCG-3' (Jian et al., 2008). *GmCYP2* was used as the reference gene for normalization.

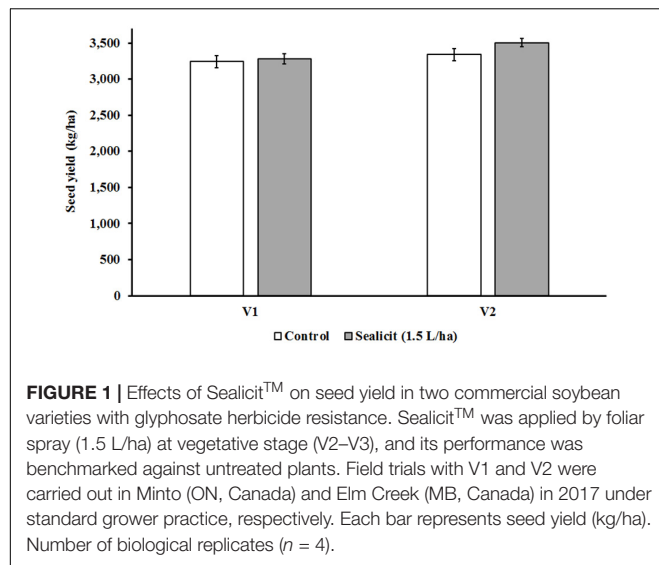

Statistical Analysis

Statistics were evaluated with Sigma Plot 12 and Statgraphics Centurion XVI software. The seed yield differences between control and SealcitTM treatment for V1 and V2 were analyzed using *t* test at $p \leq 0.05$. The effects of SealcitTM on pod shattering, *GmPDH1* and *GmSHAT1-5* gene expression was analyzed with one-way analysis of variance (ANOVA) by Tukey honestly significant difference (HSD) test at $p \leq 0.05$. The rest of plant data were compared by using two-way ANOVA, with Tukey's HSD test at $p \leq 0.05$. Where the interaction between the two factors, variety (SS and SR) and SealcitTM treatment (0, 0.75, 1.5, and 3 L/ha) ($V \times S$), was significant, data were subjected to one-way ANOVA, comparing all SealcitTM treatments with each other within the same soybean variety. Where $V \times S$ interaction was not significant, the effects of variety and SealcitTM treatments were evaluated separately, comparing the respective means through *t* test (variety) or one-way ANOVA Tukey's HSD test (SealcitTM treatment) at $p \leq 0.05$. The application of all parametric tests was performed after checking the normality of the data (Shapiro–Wilk test) and equal variance assumptions. Unless stated otherwise, all data are expressed as average \pm standard error (SE). Details of the individual sample size for each analysis are mentioned in the tables and figure legends.

RESULTS

Effects of SealcitTM on Soybean Seed Yield

The Canadian trial seed yields for control plots of both tested varieties (V1: 3,241 kg/ha; V2: 3,388 kg/ha) were similar to average values obtained by Canadian growers in the same growing season (V1: 3,256 kg/ha; V2: 3,188 kg/ha) (Manitoba Pulse Soybean Growers, 2017). The application of SealcitTM in V1 at vegetative stage did produce a small statistically nonsignificant yield increase (+1.08%; $p = 0.796$). However, the V2 variety had a larger increase in yield of 4.91% ($p = 0.207$), producing 164 kg/ha more than control plots (Figure 1). The impact of SealcitTM on yield in the Brazilian trials was also evaluated. A two-way ANOVA analysis demonstrated that SealcitTM treatment had a statistically significant effect on seed yield ($p = 0.026$). This parameter was also highly affected by the interaction variety \times SealcitTM ($p = 0.047$) (Table 1). The SS variety had increased seed yield of 6.6% ($p = 0.078$) and

6.2% ($p = 0.154$) at low (0.75 L/ha) and high (3 L/ha) doses, respectively. Only a minor increase of 2.2% ($p = 0.555$) was recorded at the 1.5 L/ha rate for the SS variety. Sealicit™ provided a more pronounced positive yield effect on the SR variety when it was applied at low (13.1%; $p = 0.047$) and medium (17.9%, $p = 0.016$) doses, respectively. However, only a small increase was recorded for the high Sealicit™ dose (1.9%; $p = 0.774$).

The Effects of Sealicit™ Treatment on Soybean Plant Development

The impact of soybean variety and Sealicit™ treatment on a number of plant phenotypic parameters including height, degree of lodging, and the prevalence of Asian soybean rust was assessed in both Brazilian varieties. A two-way ANOVA test revealed that in conjunction both parameters (variety \times Sealicit™) had no significant effect on height or lodging parameters (Table 2). The SS plants showed an overall statistically significant increase of plant height at flowering (+9.2%; $p = 0.006$) and full maturity (+9.8%; $p \leq 0.001$) stage compared to SR plants. SS plants had increased their lodging degree 1.6 times compared to SR plants ($p \leq 0.001$); however, the absolute values of this parameter confirmed that less than 25% of the soybean plants were not erect. The effect of Sealicit™ on plant height and the degree of lodging were not statistically significant with respect to the control. Finally, soybean plants did not show any symptoms of Asian rust disease indicating the quality of the field trial (Table 2).

Effects of Sealicit™ on Pod Morphology

In order to assess whether Sealicit™ had any impacts on soybean pod growth and development, as reported previously for *Arabidopsis* and WOSR (Łangowski et al., 2019), the average fresh seed weight per pod and pod length were measured in SS and SR varieties. A two-way ANOVA revealed that Sealicit™ had a significant effect on the average fresh seed weight per pod ($p = 0.024$) (Table 1). In comparison to the control, the average

NS, *, and ***, nonsignificant or significant at $p \leq 0.05$, and $p \leq 0.001$, respectively. Different letters indicate statistical differences for $p \leq 0.05$ based on *t* test (V) or one-way ANOVA Tukey's HSD test (S or V \times S). Number of biological replicates (seed weight, $n = 5$; pod length, $n \geq 60$; seed yield, $n \geq 8$). \pm represents standard error (SE).

fresh seed weight was the highest at 0.75 L/ha with the 3 L/ha application rate (7.1 and 9.5%), followed by a lower yet significant increase at the 1.5-L/ha application rate (2.4%). The two-way ANOVA test did not show any significant interactions across varieties and Sealicit™ treatments on pod length ($p = 0.060$). However, there was a significant increase in pod length in the SR, when compared to the SS variety ($p \leq 0.001$). When these differences were examined in detail, there were also significant differences between the treated and untreated plants ($p \leq 0.001$). Similarly, to seed weight per pod, the low and higher application rates, for both tested varieties, positively affected the pod length, which was longer by 2.5 and 3.4% as compared to control, respectively (Table 1).

Effects of Sealicit™ on Pod Shattering Resistance

The effect of Sealicit™ and control treatments on the shatter resistance of harvested pods from the Brazilian field trial was assessed. As expected, the SS variety required a shorter calibration time (4 h) compared to the SR variety (48 h), demonstrating the sensitivity of the method used. Interestingly, when applying the same incubation times for the treated samples, we observed a strong effect of Sealicit™ on SS with very few pods bursting compared to the controls across all treatments ($p \leq 0.001$). This suggested that the lowest dose (0.75 L/ha) was sufficient to confer

shattering resistance to the susceptible variety by decreasing pod opening by nearly fivefold. The SR samples showed minor decreases in shatter at low and high doses, but a slight increase at 1.5 L/ha dose; however, these fluctuations were not statistically significant (Figure 2).

Sealicit™ Affects the Development of Dehiscence Zone

To further assess the impact of Sealicit™ on pod shatter, the expression level of two major genes regulating pod dehiscence,

GmPDH1.1 (active in inner sclerenchyma) and *GmSHAT1-5* (active in FCCs), was examined (Funatsuki et al., 2014). The relative gene expression change was measured in reference to the housekeeping gene *CYCLOPHILIN2* (*CYP2*) (Jian et al., 2008). Funatsuki et al. (2014) showed that the transcript level of *GmPDH1.1*, which is involved in secondary wall biosynthesis and lignin deposition, decreased due to an early stop codon mutation, which is characteristic for pod-shatter resistant varieties. In our current studies, we observed that Sealicit™ significantly and gradually decreased *GmPDH1.1* expression in a concentration-dependent manner, in the variety SS (Figure 3). However, the expression analysis performed in the SR variety showed the opposite trend, which supports a variety-dependent effect. Next, the expression level of *GmSHAT1-5*, which similarly to *GmPDH1* is involved in secondary wall biosynthesis, was examined. Interestingly, the transcript level in pods collected from treated plants was increased in both varieties (Figure 4). The SR variety had a small increase that was statistically significant at the highest dose. On the other hand, a significant increase (1.6-fold) was observed for the SS variety, which is in agreement with *GmPDH1* expression level and the pod firmness test (Figure 3).

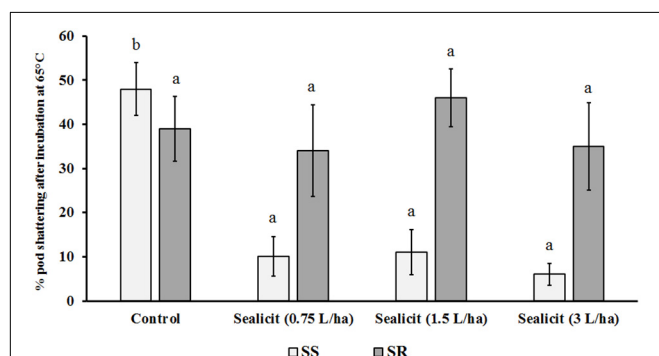

FIGURE 2 | Effects of Sealicit™ rate on soybean pod shattering. Each bar represents the percentage of open pods versus total number of pods. Different letters within the same soybean variety indicate statistically significant differences between the treatments based on one-way ANOVA Tukey's HSD test at $p \leq 0.05$. Number of biological replicates ($n = 5$).

DISCUSSION

Soybean (*G. max*) is one of the most important global crops because of its high protein and fat content. Its broad use for the production of food, oil, and fodder creates a continuously growing demand, having serious implications for the natural environment (Kocira et al., 2019). In order to reduce the

impact of agricultural-related deforestation and pollution, new solutions for more efficient and sustainable soybean production are urgently needed. In our previous work, we have shown that ANE biostimulant Sealicit™ is capable of reducing pod shattering, influencing fruit development and yield in the model plant system *Arabidopsis*, as well as selected varieties of WOSR (Łangowski et al., 2019). Following on from the previous detailed analysis of Sealicit™ action, we have tested whether similar effects can be observed in soybean grown in field conditions. In this study, the impact of Sealicit™ on soybean productivity and pod shattering, as assessed by (i) testing pod-shatter in low humidity conditions and (ii) analyzing the expression level of major genes determining pod shattering, was determined. Productivity parameters were complemented with morphological analysis of plant height, seed weight per pod, pod length, and finally seed yield assessment. Here, we demonstrated that the same biostimulant can be successfully utilized not only in the Brassicaceae family species but also legumes, providing a new solution for a pressing problem.

Soybean Yield Evaluation

Sealicit™ field testing in Canada and Brazil using a randomized block field trial design showed consistent and agronomically

sound yield results (Table 1 and Figure 1). V1 and V2 seed yield values in control plots were very similar to average values obtained by Canadian growers in the same growing season (V1: 3,256 kg/ha; V2: 3,188 kg/ha, respectively) (Manitoba Pulse Soybean Growers, 2017). The effect of Sealicit™ appears to be variety specific, which is similar to that previously observed for WOSR. The yield increase for V2 was 4.91% with a $p = 0.207$. Although the p value did not meet the typical 0.05 scientific threshold, the magnitude of the yield increase was agronomically interesting, and it provided a basis for running additional trials with a larger number of replicates to reduce the p value. It should be noted that little information is available on the susceptibility of these short-cycle Canadian varieties to pod shatter, so additional trials were performed with soybean varieties with known shatter susceptibility to investigate the potential of Sealicit™ in this crop. The harvested seed yields at full maturity for the Brazilian varieties SS and SR were in the range expected in previous field trials developed in four consecutive sowing seasons in Uberlândia-MG (Bicalho et al., 2019). All treated soybean varieties with Sealicit™ produced increased yield with respect to their untreated counterparts. Yield increases were statistically significant with $p \leq 0.05$ for treatments, likely due to the higher replicate numbers versus the Canadian trials. It is evident that there was a significant interaction between the dose (0.75 and 1.5 L/ha) and the yield for the SR variety, which was not the case for the SS variety. Therefore, dose optimization on specific varieties may be important to gain maximum benefit from Sealicit™ in soybean crops.

Impact of Sealicit™ Treatments on Soybean Architecture and Pod Phenotype

While the SS variety was significantly taller than the SR variety, Sealicit™ did not demonstrate an ability to influence plant height. From published work on ANEs in soybean and tomato plants, we have learned that this class of plant biostimulants did not have a statistically significant effect on plant height despite yield increase (Guerreiro et al., 2017; Carmody et al., 2020). It indicates that this phenotypic trait may not be sufficient to predict yield benefits provided by ANE biostimulants. We have previously reported that Sealicit™ is able to increase the pod weight in *Arabidopsis* and seed weight of some WOSR varieties (Łangowski et al., 2019). Here we observed a substantial seed weight increase in both soybean varieties tested. This result is contrary to data published by Kocira et al. (2019), which presents a 1,000-soybean-seed weight decrease after foliar spray with a nonspecialty seaweed extract from *Ecklonia maxima*. This finding highlights the importance of the seaweed specie and the process used for extraction on bioactivity-related parameters of seaweed extract biostimulants (Goñi et al., 2016, 2018; Shukla et al., 2019; Carmody et al., 2020). Moreover, both soybean varieties showed an increased pod length, which is in agreement with Sealicit™ ability to dysregulate *FUL*, *RPL*, and *IND* expression and pod length in *Arabidopsis* and some WOSR varieties (Łangowski et al., 2019), suggesting that this specialized ANE biostimulant may also modulate soybean

pod auxin homeostasis and signaling, crucial for fruit growth and development (Liljegren et al., 2004; Sorefan et al., 2009; Dong et al., 2019).

Sealicit™ Impact on Pod Shattering Resistance and Pod Dehiscence Genes

Data derived from multiple trials in commercial WOSR varieties demonstrated a positive association between pod firmness and yield (Łangowski et al., 2019). Soybean pod architecture and dehiscence mechanism show significant differences in relation to Brassicaceae fruits, yet the principle of seed dispersal is still relying on lignin deposition that determines physical resistance (Dong et al., 2014; Funatsuki et al., 2014). Pod shattering resistance tests performed on soybean control pods showed variability in treated varieties, ranging from 4 h for SS to 48 h for SR, proving the robustness and sensitivity of the method. The difference in calibration time was to be expected as both varieties are genetically diverse (Bicalho et al., 2019). On the other hand, the SR variety, classified as resistant to shatter, showed no statistically significant improvement after Sealicit™ treatments, whereas the SS variety, classified as susceptible to pod shattering, showed a very significant fruit firmness increase across all the doses applied. In addition, Sealicit™ decreased *GmPDH1.1* and increased *GmSHAT1-5* expression in the SS variety, which is consistent with a reduction in shatter. Moreover, *GmPDH1.1* transcript levels were decreasing with increasing Sealicit™ concentration in SS variety, yet increasing in SR, indicating that the effect is dose and genome/variety dependent. It is important to note that the SR variety, despite showing insignificant increase in *GmPDH1.1* transcript level, also showed slight increase in *GmSHAT1-5*. Taking into account that the transcript levels of both might be extremely different, a small increase in SR *GmSHAT1-5* transcript could not only counteract the insignificant increase of *GmPDH1*, but also account for a small increase of SR in pod firmness test (Figure 2). Therefore, it is tempting to speculate that pod firmness in soybean fruit is a balance between the amount of the lignin deposited in the FCCs and inner sclerenchyma, which may be determined by multiple genes that ultimately regulate the dorsoventral tension. In order to gain an in-depth understanding of the mechanism and critical signaling pathways, transcriptome and proteome analysis of multiple genes involved in fruit development (i.e., *FUL*, *RPL*, *IND*, *SHP*, and *ALC*) (Ferrándiz, 2002), their mutants, and complementation lines are necessary (Dong and Wang, 2015). Most importantly, the enhanced productivity of SS was positively associated with *GmPDH1.1* and *GmSHAT1-5* gene expression, increased pod shattering resistance, and higher seed weight per pod. However, the seed yield increase in treated SR soybean plants was not clearly associated with any of the parameters evaluated in this study, being likely due to additional effects promoted by Sealicit™ that have not been the subject of investigation. As observed previously by Guerreiro et al. (2017), foliar applications of ANE biostimulant can stimulate additional yield-related parameters in soybean such as increased number of pods per plant, which could be one of the contributing factors. Briglia et al. (2019) also showed an

improvement in soybean biovolume and green area after foliar spray treatment with different combinations of seaweed and plant extracts. Those additional benefits of ANE application could potentially account for increased seed weight and fresh seed yield in the SR variety.

Agronomical and Environmental Implications

The gradually increasing soybean production (by 4–5% annually) in Brazil means it will become the biggest world producer with an estimated 129 Mt in season 2020/2021. The harvested area is forecasted at a record 36.8 Mha, up by 1.7 Mha from last season's record (USDA, 2020). While soybean production in Brazil is growing, losses due to adverse weather conditions become more frequent (Rowntree et al., 2013; Van Roekel et al., 2015; Zhang et al., 2018). The Brazilian Agricultural Research Corporation (EMBRAPA) has established that one 60-kilo bag per hectare is an acceptable loss threshold value (Silveira et al., 2019). However, in the last 30 years, a wide range of yield losses (54–561 kg/ha) has been recorded in different regions of Brazil due to adverse weather events and delayed and/or inadequate mechanical harvesting (Chioderoli et al., 2012; Barbosa and Schmitz, 2015; Bandeira, 2017), averaging 120 kg/ha loss at a national level (Schanoski et al., 2011). In this study, we have demonstrated that this lost yield can be recovered and safeguarded using the ANE biostimulant Sealicit™ at a low dose rate (0.75 L/ha), increasing seed yield by an average of 9.8% in two commercial soybean varieties (+344.9 kg/ha). The use of the biostimulant would allow production output to grow in a sustainable manner contrary to expanding crop area. It is important to note that the yield uplift that can be obtained with Sealicit™ application provides a compelling return on investment for the grower (> 3:1). According to the current average market price of soybean, growers will be able to obtain added revenues of \$135/ha by applying Sealicit™ in the Brazilian market, which creates a strong financial incentive for the growers to switch to a more environment-friendly and sustainable agriculture.

Conclusions and Future Perspectives

ANE-based biostimulants are a rapidly growing crop input, because of their efficacy in a number of applications in modern agriculture. The investigations reported were undertaken to determine if Sealicit™ has an impact on pod development in soybean. The data generated suggest that Sealicit™ has a strong antishattering effect in a non-shatter-resistant soybean variety. It is also increasingly evident that Sealicit™ treatments, despite impacting on pod dehiscence, may have in some species and varieties accompanying effects stimulating average seed weight per pod and pod length, which ultimately reflects on yield. In order to gain a better understanding of Sealicit™'s MOA in soybean, lignin staining and transversal sections presenting fruit morphology and lignin deposition could be further analyzed. Pod shattering is determined by multiple contributing genes, which makes their identification challenging even by GWAS. Therefore, a lack of sufficient understanding of physiological and genetic mechanisms hinders improvements of such traits by intensive

breeding or genome editing (Verdugo et al., 2010; Korte and Farlow, 2013). SealicitTM appears to provide a solution for a yield reducing concealed developmental trait that is pod shattering, not only in oilseed rape but also in soybean and possibly other species relying on similar, conserved, seed dispersal mechanisms. Biostimulants that mobilize genetic plant potential to achieve high-quality crop with maximum yield represent an attractive tool to currently applied methods for efficient food production.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article.

AUTHOR CONTRIBUTIONS

ŁŁ, OG, JG, OH, and SO'C conceived and designed the experiments. ŁŁ, FM, MT, MP, CS, and AN performed the

experiments. ŁŁ, OG, OH, FM, and SO'C analyzed the data. ŁŁ, OG, and SO'C wrote the article. All authors contributed to the article and approved the submitted version.

FUNDING

This research has been conducted with the assistance of funding from the INNOWIDE call of the EU-Horizon 2020 Program under grant agreement No. 2019-1591 (SUSBEAN project).

ACKNOWLEDGMENTS

The authors would like to acknowledge the support of Luiz Ricardo Goulart's research group in the Nanobiotechnology Laboratory of the Federal University of Uberlândia-UFU for providing the equipment necessary for isolating RNA. The authors would also like to thank Brandon Bioscience for the gift of the ANE-based biostimulant SealicitTM used in this study.

This study is a unique report of the utilization of *Trichoderma* strains collected from even tree barks for rice plant growth, its health management, and paddy straw degradation. Seven different spp. of *Trichoderma* were characterized according to morphological and molecular tools. Two of the isolated strains, namely *Trichoderma hebeiensis* and *Trichoderma erinaceum*, outperformed the other strains. Both of the strains controlled four important rice pathogens, i.e., *Rhizoctonia solani* (100%), *Sclerotium oryzae* (84.17%), *Sclerotium rolfsii* (66.67%), and *Sclerotium delphinii* (76.25%). Seed bio-priming with respective *Trichoderma* strains reduced the mean germination time, enhanced the seedling vigor and total chlorophyll content which could be related to the higher yield observed in two rice varieties; Annapurna and Satabdi. All the seven strains accelerated the decomposition of rice straw by producing higher straw degrading enzymes like total cellulase (0.97–2.59 IU/mL), endoglucanase (0.53–0.75 IU/mL), xylanase (145.35–201.35 nkat/mL), and laccase (2.48–12.60 IU/mL). They also produced higher quantities of indole acetic acid (19.19–46.28 µg/mL), soluble phosphate (297.49–435.42 µg/mL), and prussic acid (0.01–0.37 µg/mL) which are responsible for plant growth promotion and the inhibition of rice pathogen populations. Higher expression of defense enzymes like catalase ($\geq 250\%$ both in shoot and root), peroxidase ($\geq 150\%$ in root and $\geq 100\%$ in shoot), superoxide dismutase ($\geq 150\%$ in root and $\geq 100\%$ in shoot), polyphenol oxidase ($\geq 160\%$ in shoot and $\geq 120\%$ in shoot), and total phenolics ($\geq 200\%$ in root and $\geq 250\%$ in shoot) as compared to the control indicates stress tolerance ability to rice crop. The expression of the aforementioned enzymes were confirmed by the expression of corresponding defense genes like PAL

(>3-fold), DEFENSIN (>1-fold), POX (>1.5-fold), LOX (>1-fold), and PR-3 (>2-fold) as compared to the non-treated control plants. This investigation demonstrates that *Trichoderma* strains obtained from tree bark could be considered to be utilized for the sustainable health management of rice crop.

Keywords: *Trichoderma hebeiensis*, indole acetic acid, prussic acid, straw degrading enzyme, vigor index, stress responsive enzyme, antioxidant genes, biofertilizer

INTRODUCTION

The population of the world is increasing rapidly and it is expected that the world population will be around 9.6 billion in 2050. To attain food security for all, the production of food must be increased to 70% by 2050. Crops should be protected from biotic stresses in order to achieve this goal. This should be done in a more eco-friendly and sustainable way, potentially by using certain biocontrol agents (BCA).

Different BCA like bacteria, fungi, and viruses are being used frequently for the management of diseases in different crops (Abraham et al., 2013). Fungal biocontrol agents are popular as they may be reproduced easily in an artificial nutrient media and are suitable for commercial multiplication (Singh et al., 2013). Genus *Trichoderma* is compelling as a biocontrol operator against various pathogens (Parmar et al., 2015). The primary natural habitat of *Trichoderma* is traditionally seen as soil or plant rhizosphere, even though maximum diversity of these species happens over-the-ground (Druzhinina et al., 2011). With the expanding dangers to nature and to our food security, determination of *Trichoderma* spp. as a BCA has been expecting centrality in giving security for plant protection and development (Swain and Mukherjee, 2020). *Trichoderma* spp. also induces plant growth by the creation of various phytohormones and activates plant supplements for better boost. *Trichoderma* spp. is not only marketed as a biopesticide, biofertilizer, and growth promoter, but also used as a nutrient solubilizer and organic matter decomposer (Woo et al., 2014). There are just a couple of reports on the assessment of *Trichoderma* as a biocontrol specialist obtained from above the ground territories (Jahagirdar et al., 2019). As per Whipps and Lumsden (2001), almost 60% of fungal BCA market is shared by *Trichoderma* spp. and there are significant challenges to investigate. The activity or mode of action of *Trichoderma* spp. is as per the following:

1. Generation of trichodermin, trichothecenes, trichorzianins, or gliotoxins (Mukherjee et al., 2013).
2. Seeking sustenance and space (Celar, 2003).
3. Antibiosis (Swain and Mukherjee, 2020).
4. Mycoparasitic capacities—a relationship in which one living fungus goes about as a supplement hotspot for another (Punja and Utkhede, 2003).

Trichoderma spp. produces auxins that are chargeable for plant bloom and root improvement in each symbiotic and pathogenic communication with plants (Swain et al., 2018). An amazing effect on plant improvement has been demonstrated for several *Trichoderma* secondary metabolites. Koninginins,

6-pentyl- α -pyrone, trichocaranes A–D, harzianopyridone, cyclonerodiol, harzianolide, and harzianic acid are instances of exacerbates that affect plant development in a considerably subordinate way (Swain and Mukherjee, 2020). To understand the plant growth promotion activity, rice seeds were bioprimed with the *Trichoderma* strains. Biopriming will help in increase in colonization, proliferation, and establishment of BCA on the seed surface. Consequently, it will boost seedling vigor and will be able to induce systemic resistance to biotic and abiotic stresses (Singh D. P. et al., 2020). Plant-microbe interactions setup by distant, distinct, and assorted microbial associations tend to instigate various common beneficial systemic changes in the expression level of plant genes that encode for proteins to detoxify reactive oxygen species (ROS). The beneficial microorganisms because of their presence in the plant rhizosphere help plants in easing biotic and abiotic stresses (Singh P. et al., 2020).

Faster decomposition of rice straw can be achieved by inoculating microorganisms, like ligno-cellulolytic microbes. *Trichoderma* produces high levels of several biomass degrading enzymes like cellulase and xylanase (Juturu and Wu, 2014). These enzymes degrade cellulose and hemicellulose, respectively. Lignin was degraded by ligninolytic enzymes into simpler phenyl rings (Sancez, 2009). In this investigation, we analyzed seven distinctive spp. of *Trichoderma* segregated from the bark of various trees in the Odisha province of India to consider biocontrol properties and rice straw decomposition capacity alongside their growth promotion activity in rice by the production of various enzymes and the expression of genes related to this.

MATERIALS AND METHODS

Isolation, Characterization, Growth Condition and Biocontrol Potential of *Trichoderma* spp.

Seven *Trichoderma* strains were collected from the bark of various trees. The isolation and purification of all the strains were made according to standard techniques described by Mukherjee et al. (2014). *Trichoderma* species were identified by using the typical conidiophores structure (Gams and Bissett, 1998) and according to ISTH guidelines. Molecular characterization, identification, and construction of the phylogenetic tree of all the fungal isolates were done according to Swain et al. (2018). Total genomic DNA from the young mycelia was secluded by utilizing standard SDS (sodium dodecyl sulfate) technique

(Mukherjee et al., 2014). The molecular characterization of all the fungal segregates were based on the sequences of Internal Transcribed Spacer (ITS) regions, Translation Elongation Factor 1 (TEF1) regions and RNA Polymerase B-larger subunit-II (RPB-II) regions according to standard strategies¹. The species were recognized by BLASTN search on the NCBI site and the character was affirmed by contrasting the sequences and with authentic sequences from GenBank, and a phylogenetic tree constructed on <http://www.phylogeny.fr>. Biocontrol potential of isolated *Trichoderma* strains was evaluated against above *Rhizoctonia solani* CRRI-RS-8 (MTCC-12232) causing sheath blight of rice, *Sclerotium oryzae* CRRI-S.O (MTCC-12230) causing seedling blight of rice, *Sclerotium rolfsii* causing foot rot of rice and *Sclerotium delphinii* (MTCC11568) causing seedling rot of rice.

The confrontation assay was carried out by concurrent inoculation of both *Trichoderma* and the pathogen close to the edge of the plate, put opposite to one another. Plates inoculated with pathogens only were utilized as control. The percentage of mycelial growth inhibition was determined by Swain et al. (2018)

$$\text{Percentage of inhibition} = [(R1 - R2) / R1] \times 100$$

where, R1, radial growth of the pathogen in control plate; R2, radial growth of the pathogen in test plate.

Quantification of Production of Indole Acetic Acid, Prussic Acid, and Solubilization of Inorganic Phosphate by *Trichoderma* spp.

The indole acetic acid (IAA) produced by different strains of *Trichoderma* was quantified as per Suresh Rao et al. (2016). For the quantitative estimation of IAA, agar plugs (5 mm) from the edge of actively growing colonies of *Trichoderma* were inoculated to 20 ml DF (Dworkin and Foster) salts minimal media and incubated for 3 days at 28°C. The medium was supplemented with L-tryptophan at a concentration of 1.02 g l⁻¹. After incubation for 72 h, the mycelia were removed from the culture medium by centrifugation at 5,000 rpm for 5 min. One ml aliquot of the supernatant was mixed vigorously with 4 ml of Salkowski's reagent and allowed to stand at room temperature for 20 min. The absorbance at 535 nm was measured. The concentration of IAA in each culture supernatant was determined by using an IAA (Himedia) as standard curve.

For prussic acid production, *Trichoderma* spp. was grown on Tryptic Soya Agar (TSA) supplemented with 4.4 g l⁻¹ of glycine for 2 days. White filter paper discs were cut in the same size and soaked in picric acid solution. The sheets of filter papers were placed on the upper lid of each plate. The plates were sealed with Parafilm and incubated for 7 days at 28°C. After incubation, prussic acid production was observed by the color changes of the filter paper from yellow to light brown or reddish brown (Meera and Balabaskar, 2012). The colored filter paper was then eluted by placing the filter paper in a clean test tube containing 10 mL distilled water

and the absorbance was measured at 625 nm by using a spectrophotometer (Manwar et al., 2011).

Quantitative estimation of phosphate solubilization was performed in Pikovskaya broth (Himedia) containing tricalcium phosphate as a phosphate source. Freshly grown *Trichoderma* isolates were inoculated to 50 ml of Pikovskaya's broth and incubated at 28°C and allowed to shake at 100 rpm. After 5 days the broth culture was centrifuged at 10,000 rpm for 10 min. To the 0.5 ml of the culture supernatant, 5 ml of chloromolybdic acid was added and mixed thoroughly. Volume was made up to 10 ml with distilled water and 125 µl chlorostannous acid was added to it. Immediately, the final volume was made-up to 25 ml with distilled water and mixed thoroughly. The absorbance was measured at 610 nm by using a spectrophotometer. The corresponding amount of soluble phosphorous was calculated from a standard curve of potassium dihydrogen phosphate (KH₂PO₄). Phosphate solubilizing activity was expressed in terms of tricalcium phosphate solubilization which in turn was measured by µg ml⁻¹ of available orthophosphate as calibrated from the standard curve of KH₂PO₄ (Jackson, 1973).

Qualitative and Quantitative Screening of Straw Degrading Enzymes Produced by *Trichoderma* spp.

Seven *Trichoderma* strains were screened for cellulase activity on carboxy-methyl cellulose (CMC) (Analytical Reagent grade, Himedia, India) and xylanase activity on xylan agar medium containing 1% beech wood xylan (Molecular biology grade, Himedia, India) as the substrate (Teather and Wood, 1982). The *Trichoderma* isolates were cultured on petriplates (90 mm × 15 mm, Himedia, India) containing 1% CMC agar media or 1% beech wood xylan media at 26°C. After 5 days' incubation, plates were stained with 1% solution of Congo red and followed by destained with 1N NaOH solution on a Gyrotory Shaker (Model G2, New Brunswick Scientific Co., Inc., Edison, NJ, United States) at 50 rpm for 15 min to detect clear distinct zone (Saczzi et al., 1986). The Enzymatic Index (EI) was calculated for the above two enzymes by measuring the clearance zone as per Florencio et al. (2012).

The qualitative screening for laccase activity of the *Trichoderma* strains were examined by culturing the respective isolates on PDA media supplemented with 0.04% guaiacol (Extra Pure, Himedia, India) and 0.01% (w/v) chloramphenicol with pH 5.5. They were examined for the development of a mixture of red-brown colored zone around the fungal colonies after incubation at 28°C for 72 h (Kalra et al., 2013). Here; three independent experiments were performed with three imitates per isolate. For each isolate the average EI of the three analyses was determined alongside the standard deviation.

The quantitative enzymatic screening of seven *Trichoderma* strains was carried out. Assay of four major enzymes, i.e., total cellulase, endoglucanase, xylanase, and laccase were carried out. The extraction of the crude enzyme was done using rice straw (Variety, Swarna sub-1, *Indica* type) as the base material as per Pathak et al. (2014) with minor modifications. *Trichoderma*

¹<http://www.isth.info/tools/blast/markers.php>

grown on PDA plates (2 days' culture) were sub-cultured and grown on rice bran (4%) agar media for a period of 5 days at 27°C. After completion of the incubated period, 10 mL of sterile double distilled water having 0.1% polyoxyethylene (20) sorbitan monooleate was added to the plates to collect the fungal spores. Fungal spores (2×10^6 CFU/mL) were inoculated in 250 mL flask containing grinded sterilized rice straw of 5 g and 15 mL of Mandel and Reese nutrient salt solution (NSS). After 5 days of incubation, crude enzyme extraction was done by using citrate buffer (pH 4.8) in NSS: extraction buffer (1:2: V/V). The fermented matter was shaken for 15 min at room temperature. Multilayered cheese cloth was used for the filtration of the fermented product and the centrifugation of the filtrate was done at 10,000 rpm for 15 min at 4°C (Hermel, Labortechnik GmbH, Type-Z36HK, Nr-580901000). The clear supernatant was used as a crude enzyme sample.

The total cellulase activity and endo- β -1,4-glucanase of the above *Trichoderma* strains was determined as units per milliliter (IU/mL) by Dinitro Salicylic Acid (DNS) method using Whatman No.1 filter paper and 2% CMC as substrates, respectively (Ghosh, 1987). The activity of xylanase and laccase enzyme produced by the *Trichoderma* isolates were measured by using 1% xylan (Bailey et al., 1992) and guaiacol (Monsef et al., 2016) as substrates, respectively. The activity of xylanase and laccase was expressed in nkat/mL and IU/mL, respectively.

In vitro Preparation of Rice Straw Compost by *Trichoderma* spp.

The *in vitro* preparation of rice straw compost was carried out by all the strains of *Trichoderma*. The moisture content in rice straw was measured. Inoculums of seven different isolates (10^7 cfu mL⁻¹) were poured into different conical flasks (250 mL) containing 25 gm of straw (Variety, Swarna sub-1, *Indica* type) and kept at ambient temperature. The weight of the flask was measured at regular intervals along with control until 60 days after inoculation. The C/N ration of the decomposed rice straw was determined. Total carbon and nitrogen content was measured according to the methods given by Walkley and Black (1934) and Keeney and Bremner (1965), respectively.

Measurement of Plant Growth Promoting Parameters, Vigor Index, and Chlorophyll Content Under Greenhouse Conditions

Biocontrol potential and growth promotion property of *Trichoderma* strains were confirmed under controlled conditions. Rice seeds (Annapurna, *Indica* type and Satabdi, *Indica* type) were bio-primed with respective *Trichoderma* formulations (1×10^7 cfu g⁻¹) and set in soils (double autoclaved) filled in 30 cm \times 30 cm pots. Soapstone (a mix of Talcum powder, hydrous magnesium silicate, and Talc) was used to prepare the respective *Trichoderma* formulation as per Indian Patent File no. 1240/KOL/2015. Seeds not primed with *Trichoderma* formulation were treated as control. Germination capacity and vigor index of the seeds sown in the pot were examined as per Abdul-Baki and Anderson (1973) and Swain et al. (2018). For

the assessment of vigor index germination percentage, seedling length and dry weight of seedling was taken into consideration. The effect of *Trichoderma* on the plant chlorophyll content of the leaf was evaluated as per Porra (2002).

Measurement of Plant Growth Promoting Parameters Under Field Conditions

For the assessment of growth promotion under *in vivo* conditions two direct seeded rice varieties ("Annapurna" and "Satabdi") were used. Seeds dressed with respective *Trichoderma* formulations were treated as treatments. The experiment was conducted in completely randomized design with four replications. The agronomical parameters (root length, shoot length, dry root weight, dry shoot weight, no of tiller/hill, and yield/hill) were recorded. Expression of plant stress responsive enzymes like peroxidase (PER), catalase (CAT), superoxide dismutase (SOD), polyphenol oxidase (PPO), and total phenolics (TP) conveyed by the plants treated with *Trichoderma* were investigated at active tillering stage (Arnon, 1949; Sadasivam and Manickum, 2011; Swain et al., 2018).

Extraction of RNA, cDNA Synthesis and Examination of Gene Articulation by Real-Time-PCR

Total RNA was extracted from the fresh plant leaves by utilizing RNeasy Plant Mini Kit (Qiagen, Germany). RNA concentration was quantified by using Nano Drop 2000 (Thermo Fisher Scientific). cDNA synthesis was carried out by using Maxima H minus first strand cDNA synthesis Kit with dsDNase (Thermo Fisher Scientific) as per the manufacturer's guidelines. Quantitative real-time (RT-PCR) reaction was performed in the Insta-Q96 RT-PCR system (Himedia Laboratories, Mumbai, India) using Maxima SYBRGreen/ROX qPCR master mix (Thermo Fisher Scientific) for five growth promotion and antioxidant genes, i.e., POX (peroxidase), LOX (lipoxigenase), PAL (phenylalanine ammonia lyase), DEFENSIN, PR-3 (PR protein). Act (actin) was utilized as housekeeping genes for normalization of relative gene articulation level. All primers were designed by IDT programming. All the treatments were in sets of three for each primer pair in a similar plate. The PCR reactions were set by convention formulated by Singh P. et al. (2020) with minor adjustments.

Statistical Analysis

Statistical analysis was performed by utilizing the Statistical Analysis Software (SAS) of ICAR-IASRI, New Delhi² was used for statistical analysis. All the investigations were replicated three times. Seed germination rate was ARCSINE transformed. The other seed quality boundaries were examined with no change. All the information was exposed to single way characterized analysis of variance (ANOVA) and means of treatments were compared based on Tukey's honestly significant difference test (HSD) at 0.05 probability level using SAS.

RESULTS AND DISCUSSION

Identification of *Trichoderma* Strains

Based on morphological characteristics and molecular identification, the isolates were identified as *Trichoderma harzianum* (CRRIT-1), *Trichoderma erinaceum* (CRRIT-2), *Trichoderma atroviride* (CRRIT-3), *Trichoderma hebeiensis* (CRRIT-15), *Trichoderma parareesei* (CRRIT-16), *Trichoderma longibrachiatum* (CRRIT-22), and *Trichoderma reesei* (CRRIT-27) (Figure 1 and Supplementary Figure 1). The ITS sequence data from CRRIT-1, CRRIT-2, CRRIT-3, CRRIT-22, CRRIT-27, and TEF sequence data from CRRIT-15, CRRIT-16 have been deposited with NCBI (Table 1). Out of these 7 isolates 4 are rarely found in India (i.e., *T. erinaceum*, *T. hebeiensis*, *T. parareesei*, and *T. reesei*). This provides the evidence for the maximum diversity of this genus occurring above ground. This may be the first time in India, we are reporting *T. hebeiensis*, *T. parareesei*, and *T. reesei* from the above ground. *T. reesei* reported earlier were isolated from soil and obtained from the mutation of other species of *Trichoderma* (Kar et al., 2006; Saravanan et al., 2008).

Biocontrol Capability of *Trichoderma* Strains and Its Mechanism

Mycelial growth of *R. solani*, *S. oryzae*, *S. rolfsii*, and *S. delphini* were inhibited by 98.33–100.00, 18.75–84.17, 14.17–66.67, and 56.67–76.25%, respectively. CRRIT-2, CRRIT-3, CRRIT-15, CRRIT-16 overgrew *R. solani* within 3 days. Similarly, these isolates grew quicker in dual culture against *S. oryzae* and covered minimum of 70% of the medium surface within 3 days (Table 1). In case of *S. delphini*, CRRIT-15, CRRIT-2

exhibited more than 70% inhibitory effect whereas all other strains were able to colonize in between 58 and 63% of the medium surface. Among the seven strains, *T. hebeiensis* (CRRIT-15) and *T. erinaceum* (CRRIT-2) was superior antagonist against four rice pathogens (Supplementary Figure 2). Biocontrol potential of these isolates can be correlated with prussic acid (HCN) production. The highest quantity of HCN was produced by CRRIT-15 (0.37 $\mu\text{g/mL}$) which was significantly higher as compared to other isolates. Other isolates such as CRRIT-1, CRRIT-2, CRRIT-3, CRRIT-16, and CRRIT-27 produced 0.03, 0.02, 0.05, 0.02, and 0.03 $\mu\text{g/mL}$ HCN (Table 2).

Many species of *Trichoderma* were accounted for as biocontrol specialists for a wide range of plant pathogens (Abdollahi et al., 2012; Kumar et al., 2012; Swain et al., 2018). Mycoparasitism is clearly one of the mechanisms for biocontrol action of *Trichoderma* (Mukherjee et al., 2013). Besides mycoparasitism, release of prussic acid has been proposed as a significant antifungal component. Cyanide produced by microbes may act as an inhibitor to soil borne pathogens without any harm to the host plant (Noori and Saud, 2012). Hence, for the management of soil borne pathogens, the prussic acid produced by *Trichoderma* spp. played a vital role. Biocontrol potential of *Trichoderma* spp. mainly depends on the host plant, agro climatic conditions and nutrient availability (Mukherjee et al., 2013). To the best of our knowledge, *T. hebeiensis* and *T. parareesei* from the above ground part have been explored as potential biocontrol for the first time.

Trichoderma as a Decomposer

Cellulase activity of fungal isolates with EI values of more than 1.5 were considered to be potential cellulase producers (Flores et al., 2012; Saroj et al., 2018). All the seven strains were potential

**FIGURE 2** | Enzymatic Index of cellulase and xylanase activity of *Trichoderma* isolates used in the present study.

cellulase producers as the EI value was more than 1.5. Earlier Saroj et al. (2018) reported thermophilic fungi isolated from soil, i.e., *Aspergillus fumigatus* JCM 10253 and *Aspergillus terreus* with highest EI values of 1.50 and 1.24 for cellulase activity, respectively. Florencio et al. (2012) reported *T. harzianum* CEN 139, *T. sp.* 104 NH and *T. harzianum* CEN 155 exhibited 1.74, 1.72, and 1.61 EI value for cellulase activity, respectively. Similarly, EI values of xylanase activity of *Trichoderma* isolates ranged from 0.50 to 1.33. CRRIT-15 exhibited the highest xylanase activity, i.e., 1.68 EI value followed by CRRIT-27 and CRRIT-2. The strains reported by Saroj et al. (2018) exhibited range 1.01–1.13 of EI value for xylanase activity. However, CRRIT-26, CRRIT-2, and CRRIT-27 had better cellulase and xylanase activities in comparison to others as reported earlier. All the strains exhibited positive reddish-brown zones around the fungal colonies indicating laccase activity. Monssef et al. (2016) examined 24 fungal isolates for the production laccase enzyme and found only *T. harzianum* could produce the enzyme. These

results are in line with Gochev and Krastanov (2007) who found that many of *Trichoderma* spp. with cellulase activity could also be a good source of laccase (Figure 2).

All the isolates were examined for endoglucanase, total cellulase, xylanase, and laccase activity. CRRIT-15 showed maximum endoglucanase activities, i.e., 0.75 IU/mL whereas CRRIT-22 isolate showed lowest endoglucanase activities (i.e., 0.53 IU/mL). Similarly, CRRIT-15 and CRRIT-3 showed maximum total cellulase activities, i.e., 2.59 and 2.13 IU/mL, respectively. Similarly, CRRIT-15 released maximum xylanase activity of 201.35 nkat/mL followed by CRRIT-2 195.89 nkat/mL. Among four isolates, CRRIT-15 showed 12.60 IU/mL of laccase activity followed by CRRIT-3 9.85 IU/mL of activity (Table 2).

Earlier Druzhinina et al. (2011) reported that *T. reesei* is a major source of hydrolytic enzymes like cellulase and hemicellulase. *T. harzianum* CEN 139, *T. sp.* 104 NH, and *T. harzianum* CEN 155 exhibited 1.74, 1.72, and 1.61 EI value and 0.27, 0.23, and 0.22 IU/mL of endoglucanase activity, respectively

(Flores et al., 2012). Lee et al. (2011) reported *T. harzianum* isolated from post-harvest rice straw possesses 0.095 IU/mL of endoglucanase activity and 0.222 IU/mL of total cellulase activity. Similarly, Pathak et al. (2014) reported *T. harzianum* isolated from soil, rotting wood, and manure from different locales of northern India possesses 1.28 IU/mL endoglucanase and 0.37 IU/mL of total cellulase activity. So, both the isolates NRRIT-26 and NRRIT-27 seem to be a very good potential cellulase and xylanase producer and they may be used as a better option for the preparation of rice straw compost as compared to the previous reports. According to Pathak et al. (2014) 100.2 IU/mL of xylanase activity was observed in the case of *T. harzianum* collected from various location of northern India. NRRIT-26, i.e., *T. reesei* showed highest xylanase activity as compared to the other three isolates that can be considered as the best candidate for rice straw compost. The other three strains, i.e., NRRIT-27, CRRIT-13, and CRRIT-5 also showed higher xylanase activity in comparison to isolates reported by Lee et al. (2011) and Pathak et al. (2014).

Moreover, *T. harzianum* and *T. longibrachiatum* are the wellsprings of laccase production as portrayed by Holker et al. (2002) and Velazquez-Cedeno et al. (2004), respectively. We reported here the creation of laccase enzyme in all the *Trichoderma* isolates isolated from tree bark. *Trichoderma* are adapted well to rice straw and they could be utilized to degrade straw as reported by previous researchers (Kang et al., 2004). Overall, the isolate, CRRIT-15 released the highest number of enzymes as compared to other isolates. Hence, it may be used as a candidate for the preparation of rice straw compost in an economically way.

The *Trichoderma* inoculated straw was decomposed at a faster rate as compared to the non-inoculated one. Among the seven *Trichoderma* strains, NRRIT-15, CRRIT-2, and NRRIT-27 could be able to produce compost from rice straw at a faster rate. There was 18.60, 17.46, and 16.81% of weight loss of the rice straw with NRRIT-15, CRRIT-2, and NRRIT-27 treatments, respectively, after 30 days (Table 3). The loss of weight of the rice straw was 20.95, 18.27, and 18.57%, respectively, after 60 days when treated with NRRIT-15, CRRIT-2, and NRRIT-27. The above mentioned three isolates had also secreted higher

quantities of ligno-cellulolytic enzymes as stated above. These enzymes decomposed the rice straw at a faster rate. There were insignificant changes in weight loss after 60 days of incubation as compared to 30 days of incubation. Similarly, the C/N ratio did not vary between 30 and 60 days. So based on these data, we can conclude the compost is generally stable after 30 days of incubation. As *Trichoderma* mediated rice straw compost has a low C/N ratio in *in vitro* condition, the technique can be extended to field conditions which will improve organic matter along with fertility of the soil.

Trichoderma as a Plant Growth Promoter

Auxins play a critical role for both the plant growth and root development. The quantity of IAA synthesized by various *Trichoderma* strains in the broth was ranged from 19.19 to 46.28 $\mu\text{g/mL}$ (Table 4). The highest IAA was produced by CRRIT-15 (46.28 $\mu\text{g/mL}$) which was significantly higher followed by CRRIT-2 (42.38 $\mu\text{g/mL}$).

Quantitative assessment of soluble phosphate concentrations in Pikovskaya's broth was varied from 297.49 to 435.42 $\mu\text{g/mL}$ (Table 2). CRRIT-15 may be treated as the best inducer of phosphate mobilization as it exhibited higher phosphate solubilization capacity in Pikovskaya's broth. The amount of inorganic phosphate solubilized was 435.42 $\mu\text{g/mL}$. Other *Trichoderma* strains, i.e., CRRIT-1, CRRIT-2, CRRIT-3, CRRIT-16, CRRIT-22, and CRRIT-27 were also good phosphate solubilizers.

Parameters related to seed vigor and seed germination of different *Trichoderma* dressed seeds varied from 2.13–4.13 days (Mean germination time), 2166.67–3413.33 (Vigor index-I) and 11.00–18.33 (Vigor index-II), respectively in variety Satabdi (Figure 3). A similar trend was also found in the case of the Annapurna rice variety. Physiological parameters among the treatments were significantly varied in both the varieties. Absolute chlorophyll content went from 4.61 to 18.78 mg/g in the Annapurna rice variety. Seeds inoculated with *T. hebeiensis* (CRRIT-15), *T. parareesei* (CRRIT-16), *T. erinaceum* (CRRIT-2), and *T. longibrachiatum* (CRRIT-22) had significantly higher chlorophyll parameters when contrasted with other isolates depicted in the current examination (Table 5). Seed biopriming

with beneficial microbes have been reported by several workers for their ability to mitigate biotic stress in an efficient way (Singh P. et al., 2020). During biopriming, antagonistic PGPR increases on the seed surface, thereby defending the plant from pathogen attack and enabling it to be sustained under various stress conditions (Rajput et al., 2019).

In the field study, all the strains of *Trichoderma* controlled the plant growth along with various agronomical parameters. The highest yield (31.14 g/hill) was recorded from CRRIT-15 followed by CRRIT-16 and CRRIT-13. Similar trends were observed in the case of the Satabdi rice variety (Table 6). As an overall study, all the isolates performed better than the control one (Supplementary Figures 3, 4). Previously Swain et al. (2018) reported higher total chlorophyll content, plant vigor in direct seeded rice treated with *Trichoderma*. Previously Mukherjee et al. (2013) and Mukherjee et al. (2018) explained the role of *Trichoderma* as a plant growth promoter. The enhancement of seed vigor parameters may be due to the production of phenolic compounds and secondary metabolite namely harzianolide by *Trichoderma* spp. (Cai et al., 2013). This result was also found in case of chickpea and wheat (Zhang et al., 2019). All these positive impacts of vigor property helped the plant in uptake and mobilization of nutrients for a longer time, which leads to a better yield.

Among the secondary metabolites, IAA (auxin) helps in plant growth and potentially increases the root length as well. Laboratory studies have emphasized the role of plant growth promoting fungi as auxin producers and biocontrol operators (Hossain et al., 2007; Contreras-Cornejo et al., 2009) in plant development. This key hormone was synthesized by the fungus *Trichoderma* in symbiotic as well as in pathogenic interactions (Gravel et al., 2007). Similarly, plants can only uptake and mobilize essential micronutrients if they are solubilized by microbes (Rudresh et al., 2005). As indicated by Dunaitsev et al. (2008) *Trichoderma* spp. can deliver phosphate from mineral crude materials as plant accessible structures. It was seen that *Trichoderma* isolates demonstrated higher capacity to solubilize the phosphate as they additionally displayed great reactions to plant growth promotion action after direct seed treatments. *Trichoderma* as plant symbionts for updated supplement take-up, extended root and shoot advancement, improved plant influence and biotic/abiotic stress flexibility have been widely discussed (Harman, 2011).

Improvement of Plant Resistance by the Articulation of Stress Responsive Enzymes

Inside and out higher verbalization of the enzymes related to stress was seen in *Trichoderma* seed treated plants when appeared differently in relation to untreated plants against both the rice assortments. Correspondingly, CRRIT-15, and CRRIT-2 treated root and shoots of rice assortment Annapurna and Satabdi had exceptionally higher PER, SOD, PPO, and TP activity contrasted with other treatment. Also, catalase action was higher in CRRIT-15 and CRRIT-2 treatment in both root and shoot. Comparative

examples were found in peroxidase action in root and shoot of both the rice assortments (Table 7).

In blend with their immediate impact on the pathogen structure and action, *Trichoderma* spp. has additionally been found to invigorate plant resistance mechanisms (Yedidia et al., 2001). Successful *Trichoderma* strains can instigate a more grounded reaction in the plant contrasted with pathogen-triggered immunity by creating an assortment of microorganisms related molecular patterns (MAMPs), for example, hydrophobins, expansin-like proteins, metabolites, and catalysts like catalase, peroxidase, and superoxide dismutase, having a direct antimicrobial movement (Vargas et al., 2008). *Trichoderma* can likewise improve ETI by causing a quicker reaction (preparing), or initiate it by discharging exacerbates that, similarly as with some pathogen molecules, are explicitly perceived by plant cell receptors (Bailey et al., 1993). In the present exploration, the stress enzymes expressed in a higher amount in *Trichoderma* treatments rather than the control group. Mohapatra and Mittra (2017) and Swain et al. (2018) documented that *Trichoderma* spp. triggered the fabrication of antioxidant enzymes in wheat and rice seedlings, respectively. *Trichoderma* isolates were accounted to help fundamental defense reactions through different catalysts (Małolepsza et al., 2017). PPO is engaged with the plant guard system against pathogens by catalyzing the oxidation of phenols to quinines in an oxygen-subordinate way (Daw et al., 2008). An increase in defense enzymes activity (Mandal et al., 2013) and TP content (Mandal et al., 2013) in plants with a reaction to pathogen assault has also been previously reported.

Trichoderma Seed Biopriming Induces Antioxidant Gene Expression in Rice Plants

Plants have created solid cell antioxidant molecular systems because of the utilization of biocontrol specialists like *Trichoderma* (Rejeb et al., 2014; Swain et al., 2018), however the initiation and articulation of these genes change under plant organism communication conditions (Singh D. P. et al., 2020). Albeit, both organism-treated and non-treated plants were developed under typical development conditions. We investigated the plant molecular reactions as far as the outflow of prominent defense (PAL and DEFENSIN) and antioxidant (POX, LOX, and PR-3) genes following microbial inoculation (Table 8). We observe multifold over expression of genes in both the strains. However, *Trichoderma* seed biopriming caused >2-fold up regulation of every gene in both the rice varieties. Besides, CRRIT-15 exhibited the highest level of fold expression (i.e., >3) of all the genes as compared to control one. CRRIT-16 and CRRIT-2 treatment performed the second highest level of fold expression (i.e., >2.5) by following CRRIT-15 (Figures 4, 5).

Seed biopriming with beneficial microbes have been accounted for their capacity to relieve biotic stress in an effective way. During the process of seed biopriming, antagonistic plant growth promotive activity increases on the seed surface, hence not only defending the plant from pathogen attack but also promoting the plant growth (Swain et al., 2018;

TABLE 8 | Details of primers used in antioxidant and defense related gene expression study.

Serial No.	Primer name	Gene name	Primer sequence 5'-3'
1	Rice (Actin)F	Actin	CTGCTGGAATGTGCTGAGAGAT
	Rice (Actin)R		CGTCTGCGATAATGGAAGTGG
2	Rice (POX)F	Peroxidase	CATGCTACTGCTCACCTTTGA
	Rice (POX)R		TCACTCTAGGTGGGATATACT
3	Rice (LOX)F	Lipoxygenase	AGATGAGGCGCGTGATGAC
	Rice (LOX)R		CATGGAAGTCGAGCATGAACA
4	Rice (PAL)F	Phenylalanine ammonia lyase	GGTGTTCGCGAGGTGATGA
	Rice (PAL)R		AGGGTGGTGCTTCAGCTTGT
5	Rice (Defensin)F	Defense Enzyme	CCGGCGAACTGCGTGTAC
	Rice (Defensin)R		GGCGTCGAGCAGAATTGG
6	Rice (PR-3)F	PR Protein	TACTGTGTCCAGAGCTCGCAGTGG
	Rice (PR-3)R		TCTGGTTGTAGCAGTCCAAGTTGG

**FIGURE 4 |** Expression of antioxidant and defense related genes in rice variety (Annapurna). Results are expressed as means of three replicates and vertical bars indicate the standard deviation of the means.

Rajput et al., 2019). Co-vaccination of *Paenibacillus polymyxa* and *Rhizobium tropici* mitigated drought in common bean (*Phaseolus vulgaris* L.) (Figueiredo et al., 2008). In the present study it was found that *Trichoderma* treated plants exhibited an increase in total phenol content catalase content, peroxidase content superoxide dismutase content and expression of defense gene (POX, LOX, PAL, DFENSIN, and PR-3) as compared to control one. This further authenticates the induction of growth responses and defense response in rice up on application of *Trichoderma* in rice seeds. Plant phenolics are normally framed in light of both biotic and abiotic stress through enactment of phenyl propanoid pathway and include in cellulase, lignin,

xylanase, and biosynthesis. Thus, PPO catalyzes phenolics, exacerbating the production of quinines through a secondary reaction, which further prompts the arrangement of an earthy colored complex polymer, melanin; a physical hindrance to microbe ingress (Taranto et al., 2017). In this study all the *Trichoderma* strains exhibited higher total phenol content, PPO activity as compared to the control one. Besides, CRRIT-15, CRIT-16, and CRRIT-2 out-perform the others. This suggests a synergistic effect of *Trichoderma* in induction of plant growth and defense in rice varieties. Notwithstanding these, acceptance of different development promotive genes and antioxidant agent responsive genes mitigates oxidative stress in plant

cells. Our outcomes are validated with Singh et al. (2013) in which they revealed improved movement of PAL, PPO, PO, and SOD content in chickpea treated with *Pseudomonas*, *Trichoderma*, and *Rhizobium*. Contrasting these discoveries and our outcomes prompts the presumption that stronghold of rice with microbial inoculants characteristically balanced molecular components to give resilience against ROS scavenging in a manner to making plants fortified against stress difficulties. Rice seed biopriming of *Trichoderma* could, accordingly, become a proficient methodology for raising yield for better profitability and resistance against stress conditions.

CONCLUSION

In India alone, an excess of 250 commercial formulations are available, however, a large portion of them are from a solitary strain, i.e., *Trichoderma viride* (presently renamed as *Trichoderma asperelloides*). Most of the *Trichoderma* strains defined in literature were isolated from the soil or rhizosphere, but very few are isolated from the above ground aerial parts. In the present study we evaluated both the biocontrol and growth promotion activity of seven different *Trichoderma* strains isolated from above ground parts. The rice seed treatment with *Trichoderma* strains not only promoted germination, seedling

vigor, and growth of the plant, but also increase the level of gene expression related to plant defense. Apart from growth promotion these strains imparted intrinsic stress tolerance to rice by producing a higher amount of defense enzymes like catalase, peroxidase, superoxide dismutase, polyphenol oxidase, and total phenolics content as evidenced by the expression of their respective genes. Our recent investigation tries to fill the gap by isolating and identifying above ground *Trichoderma* strains for rice health management. Two strains, namely *T. hebeiensis* and *T. erinaceum* may be promoted in sustainable crop management for their beneficial role.

Soil salinity causes damage to plants and a reduction in output. A natural plant growth regulator, 5-aminolevulinic acid (ALA), has been shown to promote plant growth under abiotic stress conditions. In the present study, we assessed the effects of exogenously applied ALA (25 mg L⁻¹) on the root architecture and Na⁺ distribution of cucumber (*Cucumis sativus* L.) seedlings under moderate NaCl stress (50 mmol L⁻¹). The results showed that exogenous ALA improved root length, root volume, root surface area, and cell activity in the root tips, which were inhibited under salt stress. In addition, although salinity stress increased the subcellular Na⁺ contents, such as those of the cell wall, nucleus, plastid, and mitochondria, ALA treatment reduced these Na⁺ contents, except the soluble fraction. Molecular biological analysis revealed that ALA application upregulated both the SOS1 and HA3 transcriptional and translational levels, which suggested that the excretion of Na⁺ into the cytoplasm cloud was promoted by exogenous ALA. Meanwhile, exogenously applied ALA also upregulated the gene and protein expression of NHX1 and VHA-A under salinity stress, which suggested that the compartmentalization of Na⁺ to the vacuole was enhanced. Overall, exogenous ALA mitigated the damage caused by NaCl in cucumber by enhancing Na⁺ redistribution and increasing the cytoactivity of root cells.

Keywords: salinity, 5-aminolevulinic acid, Na⁺ distribution, proton pump, Na⁺/H⁺ antiporter, root architecture

INTRODUCTION

High salinity levels in cultivated fields are caused by a combination of factors, such as excessive chemical fertilizer application, prolonged cultivation, or the effects of global climate change. Globally, almost 30 plant species provide 90% of the food consumed by the human population (Zörb et al., 2019). However, most of these species are salt-sensitive, and more than 20% of crops are affected by soil salinity (Negrão et al., 2016). Therefore, ways to improve the salt tolerance of crops has received a recent increase in research attention among agricultural scientists.

The imbalance of the K^+/Na^+ ratio under salt stress conditions adversely affects plant growth (Shah et al., 2021). Specifically, the harmful effects of high Na^+ concentration in the cytoplasm leads to ion toxicity, which can be observed at the whole-plant level, as lower growth rates and leaf and root damage. Under saline conditions, extracellular Na^+ competes with the K^+ transport in cells because Na^+ and K^+ have a similar hydrated radius (Gong et al., 2010). The flow of Na^+ into cells is a passive process, which requires a negative electric potential difference across the plasma membrane. However, the displacement of Na^+ is an active process that involves Na^+/H^+ antiporters located on the plasma membrane and tonoplast, which regulate the compartmentation and efflux of Na^+ (Yamaguchi et al., 2013). The Na^+/H^+ antiporters on the plasma membrane and tonoplast are encoded by *salt overly sensitive 1* (*SOS1*) and Na^+/H^+ exchanger (*NHX1*), respectively (Zhang et al., 2017; Tanveer, 2020). The cytoplasmic enzymes of halophytes are as sensitive to salinity levels as the enzymes of glycophytes (Wakeel et al., 2011). Therefore, to alleviate the ion toxicity, Na^+ can be compartmentalized into vacuole or excreted out of protoplast. The adaption of halophilous plants in saline conditions is due to their active and efficient reduction of cytoplasmic Na^+ levels, and their ability to maintain relatively lower Na^+ concentrations and higher K^+/Na^+ ratios in the cytoplasm (Cuin et al., 2011).

Ion imbalance induced by salinity directly affects plant growth in the rhizosphere environment. Under saline conditions, the Na^+ and K^+ contents have been shown to sharply increase and decrease in root cells, respectively (Zhang et al., 2018; Huo et al., 2020). Additionally, salt stress negatively affects the lateral root number and total root length, which leads to an incomplete root system architecture (Julkowska et al., 2017). Meanwhile, H^+ -pumps and Na^+/K^+ transporters, which contribute to cell ion exchange and homeostasis, respond (i.e., are up- or downregulated) to high Na^+ conditions as physiological adaptations (Zhao et al., 2016; Yan et al., 2020). In addition, lipid peroxidation occurs in root cells; thus causing increases in reactive oxygen species (Nath et al., 2019) and a reduction in root cell activity (Wang et al., 2020).

5-Aminolevulinic acid (ALA) is a metabolic intermediate in plants, animals, and bacteria. The downstream metabolic pathway of ALA provides chlorophyll, heme, siroheme, vitamin B_{12} , and phytychromobilin in higher plants (Wu et al., 2019b). ALA has been considered to play a promotive role in plants under abiotic stress and normal conditions (Ali et al., 2013a,b). Under saline conditions, the gene expression levels of proline synthesis can be upregulated by ALA in *Brassica napus* L. seedlings (Xiong et al., 2018). Moreover, exogenous ALA was shown to regulate the accumulation of H_2O_2 in roots to activate the relative gene expression of Na^+ transporters, which mitigated the harmful effect of salt on the shoots (Wu et al., 2019a). Our previous study showed that exogenous ALA enhanced the photosynthesis of cucumber leaves under NaCl stress by upregulating chlorophyll biosynthesis (Wu et al., 2018). In this study, we conducted physiological and molecular level investigations to explore the promotive role of ALA on cucumber roots under saline (NaCl) rhizospheric conditions.

Further, we also investigated the root architecture, ultrastructure of apical cells, and Na^+ distribution of cucumber root cells, and the mechanism by which ALA application impacted these factors.

MATERIALS AND METHODS

Plant Material and Growth Conditions

Cucumber (*Cucumis sativus* L. 'Xinchun No. 4') seedlings were used as the plant material. Healthy plump seeds were selected and sterilized with 0.03% potassium permanganate solution for 10 min. After soaking for 6 h in distilled water, seeds were placed on wet filter paper under dark conditions ($28 \pm 1^\circ\text{C}$). After germination, seedlings were grown in a climatic cabinet for 5 days, with a light intensity of $350\text{--}450 \mu\text{mol m}^{-2} \text{s}^{-1}$, photoperiod 12/12 h, temperature of $28/18^\circ\text{C}$ (day/night), and relative humidity of 50–60%. Seedlings with fully spread cotyledons, of uniform size, and with healthy roots were selected and transferred to opaque plastic containers for hydroponic culturing. Each container contained four cucumber seedlings. During plant cultivation, the half-strength Yamasaki cucumber nutrient solution was used [$\text{Ca}(\text{NO}_3)_2$ 1.75 mmol L^{-1} , KNO_3 3 mmol L^{-1} , $\text{NH}_4\text{H}_2\text{PO}_4$ 0.5 mmol L^{-1} , and $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ 1 mmol L^{-1}]. The nutrient solution was changed at 2-day intervals. The experimental treatments were executed using seedlings that had been grown for 30 days.

Experimental Design

Cucumber seedlings with three fully expanded true leaves, uniform size, and healthy roots were selected for the treatments. Four treatments were used in this study: (1) Control: normal nutrient solution; (2) NaCl: 50 mmol L^{-1} NaCl in nutrient solution; (3) NaCl + ALA: 50 mmol L^{-1} NaCl in nutrient solution + 25 mg L^{-1} foliar sprayed ALA, and (4) ALA: normal nutrient solution + 25 mg L^{-1} foliar sprayed ALA. The concentrations of moderate NaCl stress and optimal ALA application were selected based on the findings of our previous study (Wu et al., 2018). ALA (Sigma Aldrich, United States) applications were applied by thoroughly spraying the prepared solution on both the upper and lower surfaces of leaves with a hand sprayer (200 ml per treatment). Moreover, ALA applications involved two treatments, i.e., at 0 and 24 h. In the treatments that did not receive ALA applications, distilled water was sprayed in the same manner. Each replication comprised 10 containers, and each treatment was replicated three times. Experimental treatments were arranged in a completely randomized design. The nutrient solution was changed at 2-day intervals and aerated continuously with an air pump. All indexes were measured at 10 days after treatment application.

Root Morphology Indexes

The roots were removed from the seedlings and rinsed with distilled water. The root architecture was photographed using a root scanner (STD 4800, Canada), and the root morphology indexes (including total root length, root volume, root surface

area, and number of root tips) were analyzed using Win RHIZO 5.0 (Regent Instruments, Inc., Canada).

Root Activity and Cell Viability Staining

For fluorescence microscopy, fluorescein diacetate (FDA; 5 mg; Sigma Aldrich, United States) was dissolved in 1 ml acetone. The FDA solution (0.4 ml) was then made up to volume (5 ml) with 0.65 mmol L⁻¹ mannitol. Propidium iodide (PI; 2 mg; Sigma Aldrich, United States) was dissolved in 0.65 mmol L⁻¹ mannitol, and made up to volume of 5 ml. The FDA and PI solutions were mixed in equal volumes, and the root tips were soaked in the mixed solution for 40 min in the dark, and then washed three times with deionized water for 5 min each. Red and green fluorescence and concurrent images were obtained with a fluorescent microscope (Leica DM600 400×, Germany) at 485 and 530 nm, excitation and emission, respectively. The fluorescence densities of the FDA and PI solutions were analyzed using ImageJ software.

Root activity was determined according to the method of Zhang et al. (2013). Root tip samples (0.5 g) were soaked in a solution containing 5 ml 0.4% (w/v) triphenyl tetrazolium chloride (TTC) and 5 ml PBS (pH 7.0) under dark conditions for 1 h at 37°C. Sulfuric acid (2 ml, 1 mol L⁻¹) was then added to end the reduction of TTC. Root samples were ground with 5 ml of acetic ether and quartz sand. The extracted solution from the root was fixed to 10 ml with acetic ether. Absorbance was measured at 485 nm, and the root activity was calculated according to the standard curve.

Contents of Na⁺, K⁺ in Root Subcellular Fraction

The subcellular fractions of cucumber roots were separated according to the method described by Jabeen et al. (2014). Root samples were fully homogenized with 5 ml extracting solution (0.25 mol L⁻¹ sucrose, 50 mmol L⁻¹, pH 7.5 Tris-HCl, and 1 mmol L⁻¹ dithioerythritol), and then filtered through a filter cloth (80 μm). The filter residue was the cell wall fraction. The filtrate was made up to volume (40 ml) with the extraction solution mentioned previously. The solution was centrifuged at 1,500 × *g* for 10 min to obtain the sediment (the plastid fraction). The supernatant was then centrifuged at 5,000 × *g* for 20 min to obtain the nucleus fraction, and again at 15,000 × *g* for 30 min to obtain the mitochondrial fraction. The final supernatant represented the soluble fraction of the root cell. Every subcellular fraction was dried in an oven, and the Na⁺ and K⁺ contents were determined using an atomic absorption spectrometer (ZEEnit 700P, Analytik Jena, Germany).

Fluorescence Microscopy of Na⁺ on Root Tip and Hypocotyl

The fluorescence of Na⁺ was observed according to the method of Bonales-Alatorre et al. (2013). Coro-Na⁺-Green AM (Invitrogen, Thermo Fisher Scientific, United States) was assisting dissolved by 0.2 ml dimethyl sulfoxide. Samples with four repetitions in each treatment were stained with 15 μmol L⁻¹ CoroNa⁺-Green AM, which was dissolved by Ca²⁺-MES (pH 6.1). Root tip and

hypocotyl of seedlings were length cut and stained in dark condition for 1 h and then washed three times with deionized water for 5 min each. The green fluorescence of Na⁺ and images were obtained with a fluorescent microscope (Leica DM600 400×, Germany) at 488 and 525 nm, excitation and emission, respectively. The relative green fluorescence intensity of Na⁺ revealed in root or hypocotyl was analyzed using ImageJ software, which indicated the light intensity of in unit area of each sample.

Western Blot Analysis

The protein expression levels of Na⁺/H⁺ antiporter in plasma membrane (SOS1), Na⁺/H⁺ antiporter in tonoplast (NHX1), H⁺-ATPase in plasma membrane (HA3), and H⁺-ATPase in tonoplast were analyzed by Western blotting. The membrane protein of cucumber plants was extracted using the TCA/acetone method. The concentration of protein samples was measured using the bicinchoninic acid (BCA) method and a BCA Protein Assay Kit (Beyotime Biotechnology, P.R. China). Membrane protein samples were separated by SDS-PAGE. The separated proteins were transferred onto a polyvinylidene difluoride (PVDF) membrane, and the nonspecific binding of antibodies was blocked with 5% non-fat dried milk in PBS for 1 h at 25 ± 1°C. Membranes were then incubated overnight at 4°C with polyclonal antibodies at the appropriate dilution against SOS1 (1:2500; Agrisera, Vännäs, Sweden), NHX1 (1:2500; Agrisera, Vännäs, Sweden), HA3 (1:2500; Agrisera, Vännäs, Sweden), and VHA-A (1:5000; Abcam, Shanghai, China). The PVDF membrane was then incubated with goat anti-rabbit IgG (H&L) and HRP-conjugated secondary antibody (diluted 1:3000) for 1 h at room temperature. The color was developed using an electrochemiluminescence (ECL) substrate (BioRad, United States). Finally, the developed films were scanned and precisely quantified using Amersham Imager 600 (General Electric, United States).

Real-Time qPCR Analysis

The gene transcriptional levels of *SOS1*, *NHX1*, *HA3*, and *VHA-A* were determined by q-PCR. The cucumber *U6* gene was used as an internal control. The gene bank accession numbers of the sequences used to design the primers are shown in Table 1. Treatment samples were randomly obtained from three roots, and each treatment was replicated three times. The TaKaRa MiniBEST Plant RNA Extraction Kit (TaKaRa Biomedicals, Japan) was used to extract the total RNA from cucumber roots. The cDNA was synthesized using the Revert Aid First Strand cDNA Synthesis Kit (Thermo Scientific, United States). The reaction system of the PCR test consisted of 2 μl cDNA, 0.8 μl forward primer, 0.8 μl reverse primer, 10 μl 2 × Tli RNaseH Plus, and 6.4 μl RNase Free dH₂O. The PCR procedure was executed for three technical replications per biological sample. The PCR reaction conditions were as follows: first, 95°C for 30 s for the initial denaturation, and then 95°C for 5 s, 60°C for 30 s for the cycle steps (40 cycles), 95°C for 5 s, 60°C for 60 s for the melting curve, and, finally, 50°C for 30 s for the cooling step. Quantification analyses were conducted using the comparative CT value method, following Livak and Schmittgen (2001).

Ultrastructure Observation

Fresh root tip samples (0.5 cm) were fixed in 3% glutaraldehyde in 0.1 mol L⁻¹ phosphate buffer (pH 7.4) for 48 h at 4°C, and then fixed in 1% H₂O₄ solution for 5 h. Samples were then dehydrated using a graded ethanol series (70, 80, 90, and 100%) and then embedded in Epon812 epoxy resin. Ultrathin slices were cut using a microtome (Leica EM UC6 ultra-microtome, Japan), and the tissue slices were stained with uranyl acetate and lead citrate for 15 min. Ultrathin tissue slices of cucumber roots were observed and photographed using a transmission electron microscope (TEM, Joel JEM-1230, Japan).

Statistical Analysis

Analyses of variance were performed using SPSS 22.0 (SPSS Institute Inc., United States) software, and the treatment means were compared using Tukey's test, at a 0.05 level of probability. The results are expressed as means ± SEs. All figures were prepared using OriginPro2017 (OriginLab Institute Inc., United States) software.

RESULTS

ALA Treatment Restored Root Morphology Changes Associated With Salt Stress

Under salt stress, the total root length, number of root tips, root volume, and root surface area decreased by 33.96, 46.13, 58.17, and 47.46%, respectively (Table 2 and Figure 1). However, exogenous application of ALA restored root growth to the level observed in the control group. Furthermore, the total root length was significantly improved by ALA under conditions without salt stress.

ALA Treatment Abrogated Root Cell Activity Changes Associated With Salt Stress

The results of the living-dead fluorescence analysis of root cells are shown in Figures 2A–D. The control group root cells showed relatively higher green fluorescence. Red fluorescence was enhanced on the root tip under NaCl stress, especially in the apical elongation zone, which was wilted. The root

tips of seedlings treated with ALA under salt stress showed normal apical morphology; however, the green fluorescence was enhanced. NaCl stress significantly decreased the intensities of FDA and PI. However, application of ALA markedly increased the fluorescence of living cells (Figure 2E). The root cell activity was suppressed under saline conditions; however, the application of ALA reversed the inhibitory effect of NaCl and significantly enhanced the root tip activity (Figure 2F).

ALA Treatment Ameliorated Root Subcellular Na^+ , K^+ Changes Associated With Salt Stress

After treatment with NaCl, the Na^+ contents in the root cells increased significantly (Figure 3). The Na^+ concentrations in the cell wall, nucleus, plastid, mitochondria, and soluble fractions of roots were 1.6-, 2.1-, 8.4-, 13.0-, and 3.3-fold higher than those of control group. Moreover, the K^+ concentration was significantly decreased in the mitochondrial and soluble fractions. After the foliar spray of ALA, the Na^+ contents in each of the root cell fractions were reduced significantly, except for the cell wall. Meanwhile, the K^+ contents of the soluble fractions were markedly increased by exogenous ALA application under salt stress. Under normal growth conditions, the application of ALA increased the K^+ content in the nucleus, but decreased its content in mitochondria, compared with the control.

ALA Treatment Suppressed Na^+ Fluorescence Changes Associated With Salt Stress

The Na^+ absorption of cucumber root tips and hypocotyls were determined by staining with CoroNaTM-Green AM (Figure 4). Under NaCl stress, the Na^+ intensity in the root tips and hypocotyls increased by 102.39 and 62.41%, respectively, compared with the control (Figures 4A,B). The Na^+ fluorescence in the root tissue was obviously enhanced, especially in the epidermis and stele. However, the fluorescence intensity in both the roots and hypocotyls decreased to the level of the control after exogenous application of ALA on the leaves. At the same time, the green fluorescence in the stele of the roots and hypocotyls was weakened (Figures 4C–J).

ALA Treatment Upregulated Ion Transporters Levels Associated With Salt Stress

The expression of SOS1 protein was downregulated under saline conditions but was significantly enhanced by exogenous ALA (Figure 5A). Meanwhile, the protein expression of SOS1 was also upregulated by ALA alone. Under salt stress, the relative expression level of SOS1 was downregulated, but not significantly, compared to the control. The application of ALA significantly upregulated the transcriptional level of SOS1 under salt stress conditions, i.e., to 7.8 times that of the control. The protein expression level of the tonoplast Na^+/H^+ transporter, NHX1,

remained stable under NaCl conditions; however, exogenous ALA stimulated its expression to increase by 3-fold, compared to the control (**Figure 5B**). Moreover, the expression of *NHX1* was upregulated by ALA under normal conditions and under NaCl stress conditions (i.e., by 4.5-fold compared to the control). However, the results of the other treatments did not differ significantly from those of the control. The investigation of the proton pump in cucumber root cells revealed that the protein expression levels of HA3 and VHA-A remained stable under salt stress. However, exogenous ALA significantly upregulated their expression under stressful and non-stressful conditions (**Figures 5C,D**). Similar to *SOS1*, exogenous ALA enhanced the *HA3* gene expression level to 15 times under NaCl conditions when compared with the control (**Figure 5C**). However, the relative expression of the *VHA-A* gene was significantly upregulated by exogenous ALA under both salt stress and non-stress conditions; i.e., were 13 and 17 times that of the control, respectively (**Figure 5D**).

ALA Treatment Improved Apical Cells Ultrastructure Changes Associated With Salt Stress

The ultrastructure of the apical cell was observed by transmission electron microscopy. In the control group, the apical cells showed a regular morphology, with a clear central vacuole, a

normal number of plastids, and sufficient starch granules. The mitochondrial morphology was regular, with a clear intimal structure and they gathered near the plastids (**Figures 6A–D**). However, under NaCl stress the cell morphology of root cells was obviously altered (**Figures 6E–H**). The cell wall became thicker and had a wave shape, and the number of plastids and starch decreased; however, the number of mitochondria increased. In addition, dark ion deposition increased in the cytoplasm. Exogenous application of ALA under salt stress reduced the ion deposition in the cytoplasm of apical cells, and the central vacuole was clearly visible (**Figures 6I–L**). However, the cell morphology was not obviously improved, the intercellular space was enlarged, the plastids and starch granules were rare, and the number of mitochondria increased. Moreover, when ALA was applied under control conditions, the cell morphology was regular; the mitochondria gathered near the plastids, and clear rough endoplasmic reticuli were visible (**Figures 6M–P**).

DISCUSSION

Physiological damage occurs when plants suffer under saline conditions in the rhizosphere environment. Salt stress inhibits

many physiological and biochemical responses, including the anatomical morphology of leaves, physiological function of cells, photosynthesis reactions, water transport, protein synthesis, and energy production (Khan et al., 2020). In recent years, a natural plant growth regulator, ALA, has frequently been reported to improve plant resistance to environmental stress (see Akram and Ashraf, 2013 for a review). In the present study, NaCl stress inhibited the growth of cucumber roots. Moreover, all root morphological parameters showed significant decreases, the lateral roots were sparse, and the length of the roots decreased significantly. Moreover, NaCl caused apoptosis and wilting and a significant reduction in the living cells of roots, especially in the apical elongation area of seedlings under salt stress. These findings are consistent with those of a study on *Arabidopsis thaliana* L., in which the activity of *Arabidopsis* apical cells decreased gradually after exposure to low pH conditions, and the area of dead cells expanded gradually. The apical elongation region of *A. thaliana* was completely apoptotic after 2 h of low pH stress (Koyama et al., 2001).

However, exogenous ALA has been shown to positively affect the root inhibition caused by various abiotic stresses. For example, medium Cd stress was previously shown to inhibit the root growth of *B. napus*, but 25 mg L⁻¹ exogenous ALA application significantly improved the root average diameter, total volume, and total superficial area (Ali et al., 2013b). Additionally, in the present study, ALA application significantly increased root cell activity and the number of living cells in the apical elongation zone. Similarly, in alfalfa (*Medicago sativa* L.) plants, hydrogen-rich water (10%, v/v) was shown to relieve the harmful effects of Cd stress and decrease the number of dead root cells (Cui et al., 2013).

A relatively higher rhizospheric salt condition can cause osmotic stress in plants. In the present study, Na⁺ was mainly enriched in the cell wall under normal growth conditions, while high K⁺ and low Na⁺ environments were found in plastids, mitochondria, and the soluble fractions of root cells. In contrast, a reduction in K⁺ has been observed in the plastids, mitochondria, and the soluble fractions of root cells under

saline conditions. Moreover, in the present study, Na^+ increased significantly in each fraction of the root cells under salt stress. Similarly, the Na^+ concentration reportedly increased and the K^+ concentration decreased in barley (*Hordeum vulgare* L.)

under 300 mmol L^{-1} NaCl (Jabeen et al., 2014). Rhizospheric salt stress is considered to affect the ion balance in root cells and increase the Na^+/K^+ ratio. This imbalance occurs because Na^+ and K^+ have similar ionic radius, and excessive Na^+ in

the apoplast competes with the potassium channel. Furthermore, Na⁺ in trophoplasts disturbs the function of K⁺ and destroys the stability of the cell wall and cell membrane structure (Yamaguchi et al., 2013). In addition, excessive Na⁺ can cause damage to cell microtubules and ribosomes, and accelerate cell senescence (Munns, 1993). Therefore, maintaining the intracellular K⁺ content above a certain threshold and maintaining a high ratio of cell fluid K⁺/Na⁺ (i.e., retaining a higher K⁺ content, or preventing the accumulation of Na⁺ in leaves) is the key to normal growth and salt tolerance in plants under salt stress. Moreover, in this study, exogenous ALA reduced the accumulation of Na⁺ in cucumber root cells under salt stress and significantly lowered the Na⁺ level in organelles.

5-Aminolevulinic acid application was also shown to upregulate the transcriptional level under salt stress and the protein expression level of the Na⁺/H⁺ antiporter (SOS1) as

well as the proton pump (HA3) on the plasma membrane. On the plasma membrane, the proton-motive force is mainly formed by a proton pump, and the proton-motive force is the major driving force for the transmembrane active transport of mineral elements in plant cells. The plasma membrane Na⁺/H⁺ antiporter is an electrically neutral Na⁺/H⁺ (1:1) transmembrane transporter that is dependent on the transmembrane H⁺ concentration gradient. Generally, the potential difference in the plasma membrane could be enhanced by increasing the salt concentration in the extracellular environment. At this time, the H⁺-ATPase on the plasma membrane could utilize the energy generated by the hydrolyzed ATP to pump H⁺ out of the cells to produce an electrochemical potential gradient. This force has the ability to activate the Na⁺/H⁺ antiporter, which can transport Na⁺ out of the cell against the electrochemical potential gradient (Allakhverdiev et al., 1999). The gene encoding the Na⁺/H⁺

antiporter was first investigated and cloned in *A. thaliana* and has been shown to be associated with the salt tolerance of plants (Shi et al., 2000). Compared with wild type plants, *Arabidopsis* plants with an overexpression of *SOS1* showed significantly decreased Na^+ contents in the transpirational flow of xylem under saline conditions. Moreover, the calluses regenerated from transgenic plants also showed a strong tolerance to salt, and the concentration of Na^+ in the cells was lower than that in wild type plants (Shi et al., 2002). In addition, transgenic *Arabidopsis* plants with the soybean *GmsSOS1* gene showed improved salt tolerance and reduced reactive oxygen species contents under salt stress, and the yeast cells expressing *GmsSOS1* showed a decrease in Na^+ accumulation under NaCl conditions (Zhao et al., 2016). These research results suggest that the enhancement of the plasma membrane Na^+/H^+ antiporter and H^+ -ATPase to exude Na^+ out of the cell are prerequisites for improving plant salt tolerance. Moreover, the Na^+/H^+ antiporter and H^+ -ATPase were enhanced by exogenous ALA in cucumber root cells under NaCl stress. In fact, the *SOS1* protein functions through the SOS signal pathway, which is involved with two other proteins: *SOS2* and *SOS3*, i.e., a protein kinase and a Ca^{2+} -binding protein, respectively. Reportedly, Ca^{2+} can rapidly accumulate in the cytoplasm under high Na^+ conditions, and a higher concentration of Ca^{2+} will activate *SOS3*. The activated *SOS3* then binds *SOS2* to form a *SOS2*-*SOS3* calcium-dependent protein kinase complex, which can deactivate the self-inhibitory sites at the C terminal of the *SOS1* protein by phosphorylation, and finally increase the activity of *SOS1* (Liu and Zhu, 1998; Quintero et al., 2011).

Under saline conditions, Na^+ is usually excreted out of the cells of glycophytes, but accumulates in the vacuoles of halophytes (Blumwald, 2000). Mineral ions in the cytoplasm, such as Na^+ , can be compartmentalized into vacuoles by ion transporters located on the tonoplast. There are two kinds of tonoplast proton pumps in plants: V-H^+ -ATPase and V-H^+ -PPase. These pumps hydrolyze ATP and PPi to pump H^+ into the vacuole and develop proton-motive force across the vacuolar membrane, which stimulates the Na^+/H^+ antiporter on the tonoplast. For example, salt stress was shown to upregulate the proton pump and Na^+/H^+ antiporter on the tonoplast of *Suaeda salsa* L. leaves at the transcriptional level and transferred more Na^+ into vacuoles (Qiu et al., 2007). Previously, transgenic *Arabidopsis* plants with the gene encoding the subunit B of the tonoplast H^+ -ATPase (*HcVHA-B*) of *Halostachys caspica* had significantly higher Na^+ contents but an improved morphology and salt tolerance compared to the wild type plants, because of a substantial Na^+ enrichment of the vacuoles (Hu et al., 2012). In the present study, the transcriptional and translational levels of the subunit A of V-H^+ -ATPase under NaCl stress did not show any significant difference compared to the control; however, exogenous ALA upregulated the gene and protein expression levels of *VHA-A*. This indicated that ALA application can improve the compartmentation of Na^+ into vacuoles and enhance the salt resistance of cucumber seedlings. In fact, the tonoplast H^+ -ATPase is a multisubunit complex. Similarly, it was found that the subunit E of V-H^+ -ATPase, in *Broussonetia papyrifera* L., responded to relatively high salt conditions, and its mRNA

and protein levels were upregulated under 150 mmol L^{-1} NaCl stress (Zhang et al., 2012). Overexpression of the subunits of V-H^+ -ATPase of salt-resistant wheat in *Arabidopsis* plants, including a, A, c, C, d, D, E, I, G, and H, was found to enhance the salt tolerance of transgenic plants. Among them, the most salt-tolerant was the transgenic *A. thaliana* with the c subunit (He et al., 2014).

The tonoplast Na^+/H^+ antiporter is a structural or constitutive protein whose activity is regulated by the Na^+ content in halophytes (Apse and Blumwald, 2007). The activity of the tonoplast Na^+/H^+ antiporter can be affected rapidly by NaCl stress. In the presence of an NHX protein synthesis inhibitor, its activity can still be rapidly stimulated by NaCl, which might be due to the presence of NHX proteins rather than resynthesized proteins (Blumwald, 2000). Moreover, when salt-treated plants were transferred to Na-deficient conditions, the Na^+/H^+ antiporter was inactivated (Garbarino and DuPont, 1989). Interestingly, in *Plantago* species, the activity of the tonoplast Na^+/H^+ antiporter was only found in salt-tolerant *Plantago maritima* L., but not in salt-sensitive *Plantago media* L. (Staal et al., 1991). In this study, the seedlings treated with exogenous ALA showed higher mRNA and protein levels of NHX1, indicating that the capacity of Na^+ compartments in cells can be improved with ALA application. The Na^+ , compared to the tonoplast Na^+/H^+ antiporter from the cytoplasm to the vacuole, can be used as an osmotic agent to maintain the cell osmotic potential and contribute to water absorption. In addition, in transgenic tomato plants expressing *SbNHX* of *Sorghum bicolor*, the tonoplast Na^+/H^+ antiporter was found to have an interactive relationship with the gene family of the cation/proton antiporter (*CPA*), such as *SOS*. This suggests that NHX proteins might assist the cation antiporters on the plasma membrane to excrete Na^+ from cells and, thus, enhance the salt resistance of plants; however, the mechanism of their interaction remains unclear (Palavalasa et al., 2017). Besides, decrease of Na^+ in cytoplasm could lead to cut down of ROS and alleviate of stress damages. For example, overexpressing transcriptional activator *NAC1* could significantly reduce Na^+ content in shoot and root of *Panicum virgatum* L., and enhance the enzymatic activities of SOD, POD, and CAT (Wang et al., 2019). Inhibiting ascorbic acid synthesis regulation gene *VTC1-3* by RNA interfering technology could increase ROS production and aggravate salt damages in rice roots (Wang et al., 2018).

In the present study, rhizosphere salt stress caused root cell damage and irregular cell morphology at the subcellular level. Exogenous ALA application via leaf spraying repaired the cell wall and alleviated the degree of its thickening. These results are consistent with those of a study on *B. napus* L., where ALA application repaired the morphological disorders of root cells caused by Cd stress (Ali et al., 2013a). In addition, the number of mitochondria in apical cells under salt stress can be increased by exogenous ALA. On the other hand, the number of mitochondria in the root tip cells increased under excessive KNO_3 stress (Čiamporová and Mistrík, 1993). Mitochondria are the energy-producing organs in plant cells. The increase in mitochondria can reveal a “mitochondrial pump” function, and develop the intracellular energy regulating

mechanism, which ensures energy supply during the adaptation to salt stress. Therefore, the increase in the mitochondrial number is an adaptation mechanism of root cells to stress conditions. Exogenous ALA promotes an increase in the mitochondrial number and function in apical cells to produce more energy to and thus further adapt to salt stress. In addition, the ion concentration in the cytoplasm increased under salt stress, which led to deposition; however, exogenous ALA reduced the cytosolic concentration. Furthermore, after ALA treatment, the ion deposition in vacuoles was more obvious under NaCl, which verified that exogenous ALA application enhanced the ion compartmentalization capacity of root tip cells in cucumber seedlings.

CONCLUSION

Salt stress significantly inhibited the root architecture and activity of cucumber seedlings. However, the adverse effects caused by NaCl were shown to be abrogated by exogenous ALA application. On the one hand, the application of ALA improved the excretion of Na^+ from the cytoplasm by upregulating the H^+ -ATPase and Na^+/H^+ antiporter on the plasma membrane. On the other hand, the H^+ -ATPase and Na^+/H^+ antiporter on the tonoplast could also be enhanced at both the transcriptional and translational levels to compartmentalize Na^+ into the vacuoles. Therefore, the ultrastructure of apical cells and the biochemical reactions in the cytoplasm could be ameliorated by exogenous ALA, to effectively alleviate the effects and damage caused by salt stress in cucumber roots and shoots.

Modern agriculture has become heavily dependent on chemical fertilizers, which have caused environmental pollution and the loss of soil fertility and sustainability. Microalgae and plant growth-promoting bacteria (PGPB) have been identified as alternatives to chemical fertilizers for improving soil fertility. This is because of their biofertilizing properties, through the production of bioactive compounds (e.g., phytohormones, amino acids, and carotenoids) and their ability to inhibit plant pathogens. Although treatment based on a single species of microalgae or bacteria is commonly used in agriculture, there is growing experimental evidence suggesting that a symbiotic relationship between microalgae and bacteria synergistically affects each other's physiological and metabolomic processes. Moreover, the co-culture/combination treatment of microalgae and bacteria is considered a promising approach in biotechnology for wastewater treatment and efficient biomass production, based on the advantage of the resulting synergistic effects. However, much remains unexplored regarding the microalgal–bacterial interactions for agricultural applications. In this review, we summarize the effects of microalgae and PGPB as biofertilizing agents on vegetable cultivation. Furthermore, we present the potential of the microalgae–PGPB co-culture/combination system for the environmentally compatible production of vegetables with improved quality.

Keywords: biofertilizers, combinational application, microalgae, mixed cultures, plant growth-promoting bacteria, vegetables

INTRODUCTION

Ecological Problems Caused by Chemical Fertilizers in Agriculture

High amounts of chemical fertilizers have been used to obtain high product yields with increased cultivation efficiency in agriculture. However, the excessive use of chemical fertilizers frequently causes severe environmental damage, such as water, soil, and air pollution (Savci, 2012). Moreover, the excessive use of chemical fertilizers leads to soil acidification and hardening, which decrease root vigor with reduced respiration. The population of beneficial microorganisms is also reduced by this practice, resulting in a loss of soil fertility and a high incidence of root diseases (Chandini et al., 2019). In particular, nitrogen (N) fertilizers are absorbed by crops in reactive forms

such as nitrate (NO₃), ammonia (NH₃), and nitrogen oxides (NO_x). These reactive forms can be sustainably produced by soil microbes, but with chemical fertilizers, excessive amounts remain in the soil, flow to the groundwater, and even contribute to the production of greenhouse gases such as nitrous oxide (N₂O) (Choudhury and Kennedy, 2005; Giles, 2005).

The Advantage of Biofertilizers in Agriculture

Biofertilizers have been recommended as an alternative to chemical fertilizers in order to avoid the problems caused by chemical fertilizers in agriculture (Mahanty et al., 2017). Biofertilizers are preparations containing living or dormant cells, which have the advantage of growth-promoting functions in crops. This is performed through the production of phytohormones and/or useful substances/biochemicals, thereby enabling the development of ecofriendly and sustainable agriculture (Kumar, 2018). In general, biofertilizers play a significant role in the decomposition of organic matter, which aids mineralization within the soil, consequently increasing the availability of nutrients for plants and improving crop yield (Rodriguez and Fraga, 1999).

Moreover, the application of biofertilizers can increase the quantity and biodiversity of useful bacteria, such as plant growth-promoting rhizobacteria (PGPR) belonging to *Azotobacter*, *Bacillus*, *Burkholderia*, *Pantoea*, *Pseudomonas*, *Serratia*, and *Streptomyces* (Verma et al., 2019; Gou et al., 2020). Currently, it is believed that the co-evolution of plant–microbe interactions has allowed some of the bacteria to be facultative intracellular endophytes (Bulgarelli et al., 2013), among which are PGPR that have beneficial effects on plants through direct or indirect pathways. For example, some PGPR strains affect plant growth by synthesizing phytohormones, metabolizing them, and/or acting on hormone biosynthesis in plants, while others produce substances that work against soil-borne pathogens (Beneduzi et al., 2012). In the last few decades, as the interest of consumers toward safe agricultural products grew, it became important to exploit beneficial microbes as biofertilizers for use in food safety practices and sustainable crop production (Shi et al., 2011).

The Role of Microorganisms in Plant Growth

Different microbial species coexist in the soil and have a variety of beneficial effects on plant growth promotion and biological control. These microbes usually improve soil fertility by providing nutrients, such as carbon, nitrogen, phosphorus, potassium, trace elements, vitamins, and amino acids, and making them accessible for plants. In doing so, they promote growth by mediating various activities, such as nitrogen fixation and phosphate and potassium solubilization (Güneş et al., 2014; Bagyalakshmi et al., 2017). These microbes are able to release plant growth-regulating substances, such as phytohormones, and also have a suppressive effect on plant diseases by producing/secreting antibiotics and/or secondary metabolites that work against pathogens (Yoshihisa

et al., 1989; Sessitsch et al., 2004; Jung et al., 2006). These microorganisms are known as plant growth-promoting bacteria (PGPB), which generally belong to *Pseudomonas*, *Azospirillum*, *Rhizobium*, and *Bacillus* (Walsh et al., 2001; Esitken et al., 2010; Ahemad and Kibret, 2014).

Characteristics of Microalgae

In addition to PGPB, some microalgae species have also been used to promote plant growth, yield, and fruit quality (Guo et al., 2020). Microalgae are typically microscopic algae, which range in sizes between micrometers and tens of micrometers, depending on the species. It has been estimated that 200,000–800,000 species exist (Ebenezer et al., 2011), but only around 40,000–50,000 species have been described thus far (Suganya et al., 2016). They are photosynthetic eukaryotes, which do not have roots, stems, or leaves, unlike higher plants, and range from unicellular to multicellular species (Singh and Saxena, 2015). Many species of microalgae have been utilized for the removal of contaminants from wastewater or sewage, as well as the conversion of said sewage into an effluent that can be reused for various purposes. This is because of their ability to absorb and metabolize nutrients and heavy metals in the water such as cadmium, lead, zinc, and copper (Rajamani et al., 2007). Under certain growth conditions, microalgae produce and accumulate large amounts of lipids, proteins, and carbohydrates in the cell. The lipid content of microalgae is higher than that of other biofuels, usually between 20% and 50% of the cell's dry weight but can reach up to 70% (Duan et al., 2012; Sun et al., 2018). Because of this, they have also been regarded as a suitable candidate for third-generation biofuel feedstock. A variety of studies have been conducted to maximize the potential of microalgae as biofuels, including the applications of genetically modified microalgae; high-density mass culturing; and efficient processes for cultivation, harvest, and extraction (Ghasemi et al., 2012).

In recent years, an increasing amount of research has been conducted to study the effects of microalgal–bacterial co-culture/combination systems for wastewater treatment and biomass production (Ramanan et al., 2016; Qi et al., 2018). However, investigations into microalgal–bacterial co-culture/combination systems for crop production remain largely unexplored. Hence, the current review describes the effects of microalgae and bacteria as biofertilizer agents in vegetable cultivation. Furthermore, it aims to propose the potential of the microalgae–PGPB co-culture/combination system to improve the production and the quality of vegetables.

EVALUATION OF MICROALGAE AS BIOFERTILIZERS FOR VEGETABLE PRODUCTION

Effect of Microalgae as Biofertilizers on Crop Cultivation

Many studies have indicated that microalgae are increasingly being employed, not only in bioremediation and biofuel

production but also in agriculture. This is because a wide range of bioactive compounds, including plant growth-promoting substances (such as phytohormones), amino acids, carotenoids, and phycobilins, can be produced from microalgae. These compounds contribute to high productivity in agricultural crops by promoting plant growth and conferring resistance against pathogens with minimal environmental costs (Stirk et al., 2013b; Michalak and Chojnacka, 2014).

Microalgal extracts contain phytohormones such as auxin, cytokinin, abscisic acid, ethylene, and gibberellin, which play key roles in the regulation of growth and development. Accordingly, microalgal extracts can be used as renewable sources of plant biostimulation (Stirk et al., 2013a; Romanenko et al., 2015). Auxin is an essential regulator of various plant developmental processes, such as cell division and elongation. Indole-3-acetic acid (IAA) and indole-3-butyric acid (IBA), the two dominant types of auxins in microalgae, can both stimulate and inhibit the growth and metabolism of higher plants (Hashtroudi et al., 2013). Cytokinins are involved in many physiological processes in plants, including root and shoot development, leaf senescence, nutrient mobilization, and seed germination (Ha et al., 2012), while gibberellins are able to promote cell division, trigger the accumulation of pigments and proteins, and stimulate cell elongation and expansion (Sponsel and Hedden, 2010). Ethylene is a gaseous plant hormone that renders tolerance to abiotic stresses such as drought, low temperatures, and high salinity, as well as biotic stresses such as the penetration of pathogens (Pierik et al., 2006). Thus, phytohormones not only affect plant growth and development but also activate plant defense systems against plant pathogens via interacting/cross-talking networks among them (Checker et al., 2018).

Various Microalgae Species Used for Important Vegetable Cultivation

Based on the increasing number of studies demonstrating that microalgae have the ability to promote plant growth and defend against plant pathogens, several microalgae species are being used in the cultivation of important vegetables (Table 1). In general, *Chlorella vulgaris*, *Chlorella fusca*, and *Spirulina platensis* have been used for tomato, cucumber, onion, lettuce, and pepper cultivation with a view to promote their production with marketable quality (Kim et al., 2018; Bumandalai, 2019; Rachidi et al., 2020).

Tomato (*Solanum lycopersicum* L.)

Tomato is the most popular home garden vegetable. It is a rich source of vitamins, minerals, and flavonoids such as quercetin (Nicola et al., 2009). Strategies for improving the productivity and nutritional quality of tomatoes are of great interest to producers (Dorais et al., 2008). In tomato fruits, treatment with *Nannochloropsis oculata* has been found to induce 33% and 36% higher levels of sugar and carotenoid content, respectively, compared to those treated with inorganic fertilizer under greenhouse conditions (Coppens et al., 2016). It was also found that among young tomato plants grown in phytotrons, the number of nodes, dry weight, and length of shoots had significantly increased from treatment with polysaccharide extracts from *Arthrospira platensis*, *Dunaliella salina*, and *Porphyridium* sp. when compared to the untreated control. Tomato plants treated with polysaccharide extracts also showed an increase in the activities of nitrate reductase (NR) and NAD-glutamate dehydrogenase (NAD-GDH), key enzymes for nitrogen assimilation and amino acid synthesis, as well as

TABLE 1 | Typical cases of microalgal effects on vegetable production.

Vegetable	Microalgae species	Application	References
Tomato	<i>Nannochloropsis oculata</i>	Increased contents of sugar and carotenoid in fruits	Coppens et al. (2016)
	<i>Chlorella vulgaris</i>	Improved growth of shoot and root	Bumandalai (2019)
	<i>Arthrospira platensis</i> , <i>Dunaliella salina</i> , and <i>Porphyridium</i> sp.	Improved activities of nitrate reductase (NR) and NAD-glutamate dehydrogenase (NAD-GDH) related to nitrogen assimilation and amino acid synthesis in leaves	Rachidi et al. (2020)
	<i>Chlorella vulgaris</i> and <i>Chlorella sorokiniana</i>	Increased activities of β -1,3-glucanase and phenylalanine ammonia lyase (PAL) linked to defense mechanisms in leaves	Farid et al. (2019)
	<i>Acutodesmus dimorphus</i>	Increased number of branches and flowers in plants	Garcia-Gonzalez and Sommerfeld (2016)
Onion	<i>Spirulina platensis</i> + cow dung	Improved growth, yield, and content of pigments in leaves and elevated levels of biochemicals and minerals	Dineshkumar et al. (2020)
	<i>Scenedesmus subspicatus</i> + humic acid	Promoted root growth at the early developmental stages and increased contents of sugars and proteins in bulbs	Gemin et al. (2019)
Cucumber	<i>Chlorella vulgaris</i>	Promoted root growth	Bumandalai (2019)
	<i>Anabaena vaginicola</i> and <i>Nostoc calcicola</i>	Improved rooting abilities likely affected by indole-3-butyric acid (IBA) and indole-3-acetic acid (IAA)	Shariatmadari et al. (2013)
Eggplant	<i>Spirulina platensis</i>	Increased fruit production without significant alterations in the levels of N, P, K, and Na in the leaves, when treated with low concentrations	Dias et al. (2016)
Pepper	<i>Dunaliella salina</i> and <i>Phaeodactylum tricornutum</i>	Improved salt tolerance during germination by reducing superoxide radicals and lipid peroxidation	Guzmán-Murillo et al. (2013)
Lettuce	<i>Chlorella vulgaris</i>	Reduced mineral fertilizer consumption up to 60% by adding living <i>Chlorella vulgaris</i> in the nutrient solution	Ergun et al. (2020)
	<i>Scenedesmus quadricauda</i>	Increased plant growth and protein content in leaves by activating key enzymes related to N, C, and secondary metabolisms (i.e., phenylalanine ammonia lyase; PAL)	Puglisi et al. (2020)

phenylalanine ammonia lyase (PAL) and β -1,3-glucanase, which activate plant defenses against pathogens (Kobayashi et al., 1995; Vera et al., 2011; Chen et al., 2017; Farid et al., 2019; Rachidi et al., 2020). Microalgal polysaccharides can elevate the activity of NADPH-synthesizing enzymes, shifting conditions to be more conducive to reduction in the intracellular redox state, which may favor photosynthesis and cell division. In addition, the levels of ascorbate (AsA) content and ascorbate peroxidase (APX) activity, which play central roles in photosynthesis and abiotic stress tolerance, have been shown to increase in polysaccharide-treated plants (Castro et al., 2012; Smirnov, 2018; Chanda et al., 2019; **Figure 1**). Moreover, Garcia-Gonzalez and Sommerfeld (2016) assessed the properties of the microalgae *Acutodesmus dimorphus* as a biofertilizer and/or biostimulant. Under greenhouse conditions, foliar application of the algal extract at a concentration of 3.75 g ml^{-1} on tomato plants caused an increase in the number of branches and flowers per plant (Garcia-Gonzalez and Sommerfeld, 2016).

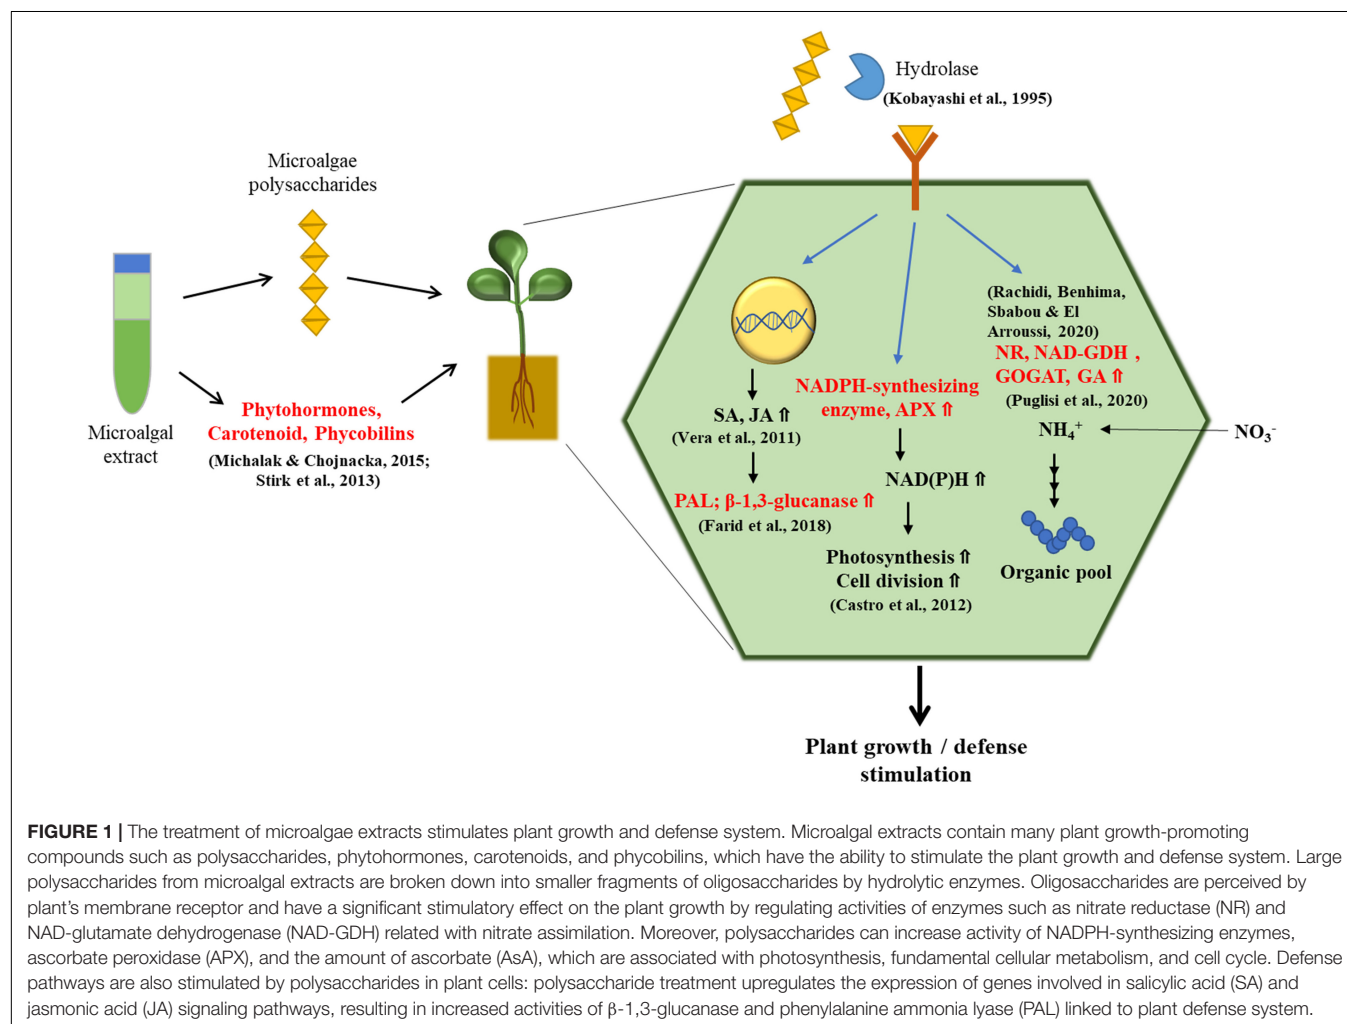

Onion (*Allium cepa* L.)

Onion is one of the most economically important vegetable crops consumed primarily because of its ability to enhance the flavor

of other foods (Kandoliya et al., 2015). Field experiments were performed at the experimental farm of Annamalai University, India, in 2016–2017 to determine the efficacy of microalgae, such as *C. vulgaris* and *S. platensis*, as biofertilizers on onion plants. Treatment comprising of cow dung with *S. platensis* on onion plants resulted in higher amounts of micro- and macronutrients available in the soil, including nitrogen, phosphate, potassium, zinc, and manganese. There was also an increase in the levels of biochemicals in the onion, such as total soluble sugars, total phenols, and free amino acids, along with improved growth parameters, when compared to the untreated control. In addition to this, higher amounts of minerals were observed in onion plants treated with “cow dung + *S. platensis*” and “cow dung + *C. vulgaris*” (Dineshkumar et al., 2020). Furthermore, compared to the untreated control, treatment with a mixture of *Scenedesmus subspicatus* and humic acid synergistically increased the onion root length by 39% and the concentration of soluble proteins by 37% (Gemin et al., 2019).

Cucumber (*Cucumis sativus* L.)

Cucumber is also an important vegetable crop (Huang et al., 2009) that is cultivated in many countries within both temperate

and tropical zones (Tatlioglu, 1993). When vegetable crops such as cucumber, tomato, and squash were treated with *Anabaena vaginicola* and *Nostoc calcicola*, they showed increased growth factors when compared to the untreated control. These growth factors included root length, fresh and dry weight of roots, and plant height. Auxins such as IBA, which are involved in root development in plants, were also shown to be available with this treatment in the range of 1.275–2.958 $\mu\text{g g}^{-1}$ dry weight with a trace amount of IAA in microalgal cells (Shariatmadari et al., 2013).

Eggplant (*Solanum melongena* L.)

Eggplant is ranked among the top 10 vegetables in terms of oxygen radical absorbance capacity due to its high content of total phenolics (Cao et al., 1996). Dias et al. (2016) conducted field and laboratory experiments to evaluate the growth, yield, and postharvest quality of eggplants with different concentrations of *S. platensis* solutions for foliar application at the Centro de Ciências e Tecnologia de Alimentos (CCTA), Brazil. This experiment was performed between October 2014 and January 2015. The results revealed that the number of fruits significantly increased in plants treated with low concentrations of this treatment (10, 15, 25, and 35 g l^{-1}). This is likely due to the greater abundance of polypeptides, amino acids, and hormones in the microalgal species acting as plant growth promoters when compared to the levels in the untreated control (Dias et al., 2016).

Pepper (*Capsicum annuum* L.)

Pepper is a popular commercial vegetable and spice crop that is valued for its fruit color, flavor, pungency, and nutrient content (Kumar et al., 2006). Treatment with extracts of *D. salina* increased the germination rate by 69% and the root length of bell peppers by 24% in 25 mM NaCl. Meanwhile, *Phaeodactylum tricornutum* treatment was found to reduce the production of superoxide radicals and lipid peroxidation triggered by salt stress, when compared to the untreated control (Guzmán-Murillo et al., 2013).

Lettuce (*Lactuca sativa* L.)

Treatment of lettuce seedlings with *Scenedesmus quadricauda* extract promoted plant growth and induced the accumulation of chlorophyll, carotenoids, and total protein content in the plant cell. In addition, the leaf dry weights were positively affected by the treatment with *S. quadricauda* extract, reaching an increase of approximately 26% when compared to the untreated control. From a metabolic point of view, the treated leaves revealed increased enzyme activity levels of glutamate synthase (GOGAT), glutamine synthase (GS), citrate synthase (CS), malate dehydrogenase (MDH), and PAL, which are key enzymes associated with nitrogen (Gupta et al., 2012), carbon (Schiavon et al., 2008), and phenylpropanoid metabolism (Hyun et al., 2011). This suggested that the positive effect on the growth of lettuce most likely occurs through the stimulation of the metabolic pathways of carbon, nitrogen, and phenylpropanoid (Puglisi et al., 2020).

EVALUATION OF BACTERIA AS BIOFERTILIZERS FOR VEGETABLE PRODUCTION

The Effect of Bacteria as Biofertilizers on Crop Cultivation

Bacteria are a major class of microorganisms that function as decomposers and recyclers in the soil. In doing so, these microbes contribute to the processes of nutrient cycling, energy flow, and bioconversion in the ecosystem. Most agricultural production systems are dependent on soil bacterial biomass pools, which facilitate quick responses to diverse environmental changes (Pankhurst et al., 1996). Microbial inoculums called effective microorganisms (EM), containing mixed cultures of beneficial and naturally occurring microorganisms, can increase the microbial diversity of the soil ecosystem. They consist mainly of lactic acid bacteria, photosynthetic bacteria, yeast, *Actinomyces*, and fermenting fungi (Balogun et al., 2016). Among these effective microorganisms, PGPB form specific symbiotic relationships with plants and directly promote plant growth by facilitating resource acquisition and/or modulating plant hormone levels (Glick, 1995). The application of PGPB to vegetable cultivations can prevent the excessive use of chemical fertilizers by up to 30%, thereby reducing production costs and pollution (Gerjes and Elsadany, 2021). PGPB treatments also have the ability to improve host plant defenses against soil-borne pathogens by producing antibiotics such as 2,4-diacetylphloroglucinol (2,4-DAPG), pyoluteorin (PLT), pyrrolnitrin, and phenazine-1-carboxylate (Banger and Thomashow, 1999; Duffy and Défago, 1999).

Various Bacterial Species Used for Vegetable Cultivation

It has been adequately demonstrated that many species of bacteria are able to promote the growth and development of vegetables and control pathogens through various mechanisms, one of which include the production/release of inhibitory substances, allowing target crops to be disease resistant (Table 2). Representative commercially available bacterial strains are of the genus *Bacillus* spp.; these include *B. amyloliquefaciens*, *B. subtilis*, *B. cereus*, *B. licheniformis*, and *B. pumilus*, which produce various compounds for the biocontrol of plant pathogens and the growth promotion of vegetables such as tomato, cucumber, onion, lettuce, and pepper (Gutiérrez-Mañero et al., 2001; Compant et al., 2005; Cawoy et al., 2011; Yuan et al., 2012; Nie et al., 2017). Silo-Suh et al. (1994) reported that *B. cereus* UW85 suppresses the damping-off disease caused by *Phytophthora medicaginis* in alfalfa through the production of two fungistatic antibiotics, zwittermicin A and kanosamine (Silo-Suh et al., 1994).

In addition, *Serratia liquefaciens* and *Pseudomonas putida* are known to generate *N*-acyl-L-homoserine lactone (AHL) signaling molecules, which enhance the systemic resistance of tomato plants against the leaf fungal pathogen, *Alternaria alternata* (Schuhegger et al., 2006). Recently, it was shown that two

TABLE 2 | Typical cases of bacterial effects on vegetable production.

Vegetable	Bacteria species	Application	References
Tomato	<i>Serratia liquefaciens</i> and <i>Pseudomonas putida</i>	Induced systemic resistance against the fungal leaf pathogen <i>Alternaria alternata</i> in tomato by producing <i>N</i> -acetyl-L-homoserine (AHL) lactone	Schuhegger et al. (2006)
	<i>Pantoea agglomerans</i> and <i>Burkholderia anthina</i>	Increased plant height, root length, shoot and root dry weight, phosphorous uptake level, and the available phosphorus content of soil	Walpolo and Yoon (2013)
	<i>Bacillus amyloliquefaciens</i>	Suppressed bacterial wilt disease by reducing the population of <i>Ralstonia solanacearum</i>	Huang et al. (2014)
	<i>Bacillus circulans</i>	Stimulated seedling growth by increasing nutrient uptake parameters	Mehta et al. (2015)
Onion	<i>Azotobacter chroococcum</i> , <i>Bacillus subtilis</i> , and <i>Pseudomonas fluorescens</i>	Produced indole-3-acetic acid (IAA) and siderophores and improved growth and yield with higher solubilization of tricalcium phosphate (TCP)	Čolo et al. (2014)
	<i>Bacillus subtilis</i>	Inhibited the growth of <i>Setophoma terrestris</i> , a causal agent of pink root disease	Albarracín Orio et al. (2016)
Cucumber	<i>Pseudomonas corrugate</i> and <i>Pseudomonas aureofaciens</i>	Inhibited root and crown rot caused by <i>Pythium aphanidermatum</i> by stimulating the activities of defense enzymes in the root tissue	Chen et al. (2000)
	<i>Bacillus subtilis</i>	Improved growth and yield by reducing losses caused by <i>Pythium</i> root rot	Utkhede and Koch (1999)
Lettuce	<i>Bacillus amyloliquefaciens</i>	Alleviated the disease severity of bottom rot caused by <i>Rhizoctonia solani</i> .	Chowdhury et al. (2013)
Pepper	<i>Bacillus licheniformis</i> and <i>Bacillus subtilis</i>	Produced auxins, antifungal β -glucanases, and siderophores; stimulated seed germination; and promoted the growth of vegetative organs such as root, stem, and leaf	Lim and Kim (2009)

phosphate-solubilizing bacteria (PSB), *Pantoea agglomerans* and *Burkholderia anthina*, contributed to improved growth traits of tomato plants with a higher level of phosphorous content in the soil, when compared to the untreated control, under greenhouse conditions (Walpolo and Yoon, 2013). The ability of *Azotobacter chroococcum* and *Pseudomonas fluorescens* to improve vegetative growth and yield in onion production through the production of IAA, siderophores, and the solubilization of tricalcium phosphate (TCP) has also been demonstrated (Tarakhovskaya et al., 2007; Čolo et al., 2014).

RELATIONSHIP BETWEEN MICROALGAE AND BACTERIA

Microalgae–Bacteria Interactions

In natural environments, microalgae and bacteria coexist and interact with each other. As a result, they demonstrate both beneficial (Unnithan et al., 2014) and harmful/toxic relationships (Doucette, 1995). The relationship between microalgae and bacteria is greatly dependent on the species and the environmental conditions (Doucette, 1995; Croft et al., 2005; Mujtaba and Lee, 2016). In actuality, both microalgae and bacteria can produce growth factors, and/or exotoxins, that promote and/or inhibit growth and development. In the beneficial relationship, microalgae enhance bacterial growth by providing photosynthetic oxygen and dissolved organic matter such as organic carbon, calcium carbonate, and 2,3-dihydroxypropane-1-sulfonate (DHPS) (Wolfaardt et al., 1994; Borde et al., 2003; Cooper and Smith, 2015). Generally speaking, the photosynthetic oxygen produced by microalgae or cyanobacteria (blue-green algae) is used as an electron acceptor in the bacterial degradation of organic matter. In turn, bacteria support photoautotrophic growth of their partners by providing carbon dioxide and other stimulatory means

(Subashchandrabose et al., 2011). In a similar way, bacteria are also able to offer a selective advantage to microalgae for enhanced growth by providing micronutrients such as B-vitamins. These vitamins act as co-factors that are required for enzyme activity in the central cellular metabolism (Croft et al., 2005). Moreover, microalgae can acquire nutrients such as inorganic carbon, nitrogen, phosphorus, and sulfate generated from organic matter, through the activities of extracellular bacterial enzymes. However, in harmful/toxic relationships, microalgae can inhibit bacterial activity by releasing antibacterial metabolites and increasing the pH, the dissolved oxygen concentration, and the temperature of the culture medium (Naviner et al., 1999; Schumacher et al., 2003; Ribalet et al., 2008).

Both microalgae and PGPB have the ability to promote plant growth by producing polysaccharides and phytohormones, such as auxin and cytokinin. Furthermore, they can prevent plant diseases by stimulating defense systems and secreting antifungal enzymes and antibiotics (Figure 2; Najdenski et al., 2013; Stirk et al., 2013b; Walpolo and Yoon, 2013; Michalak and Chojnacka, 2014; Cordero et al., 2016).

Reciprocal Influence During the Co-culture/Combination of Microalgae and Bacteria

As microalgae have been widely used in various industries, extensive studies have shown that when microalgae and bacteria are co-cultured, there is an increase in microalgal productivity in the production of useful substances such as total lipids, carbohydrates, and chlorophylls (Table 3).

Amavizca et al. (2017) demonstrated that two PGPB strains, *Azospirillum brasilense* Cd and *B. pumilus* ES4, have similar effects on the growth of the green microalga *Chlorella sorokiniana* UTEX 2714, without any form of physical contact between them. The two PGPB remotely enhanced the growth rate of microalgae up to six-fold and induced an increase in the total

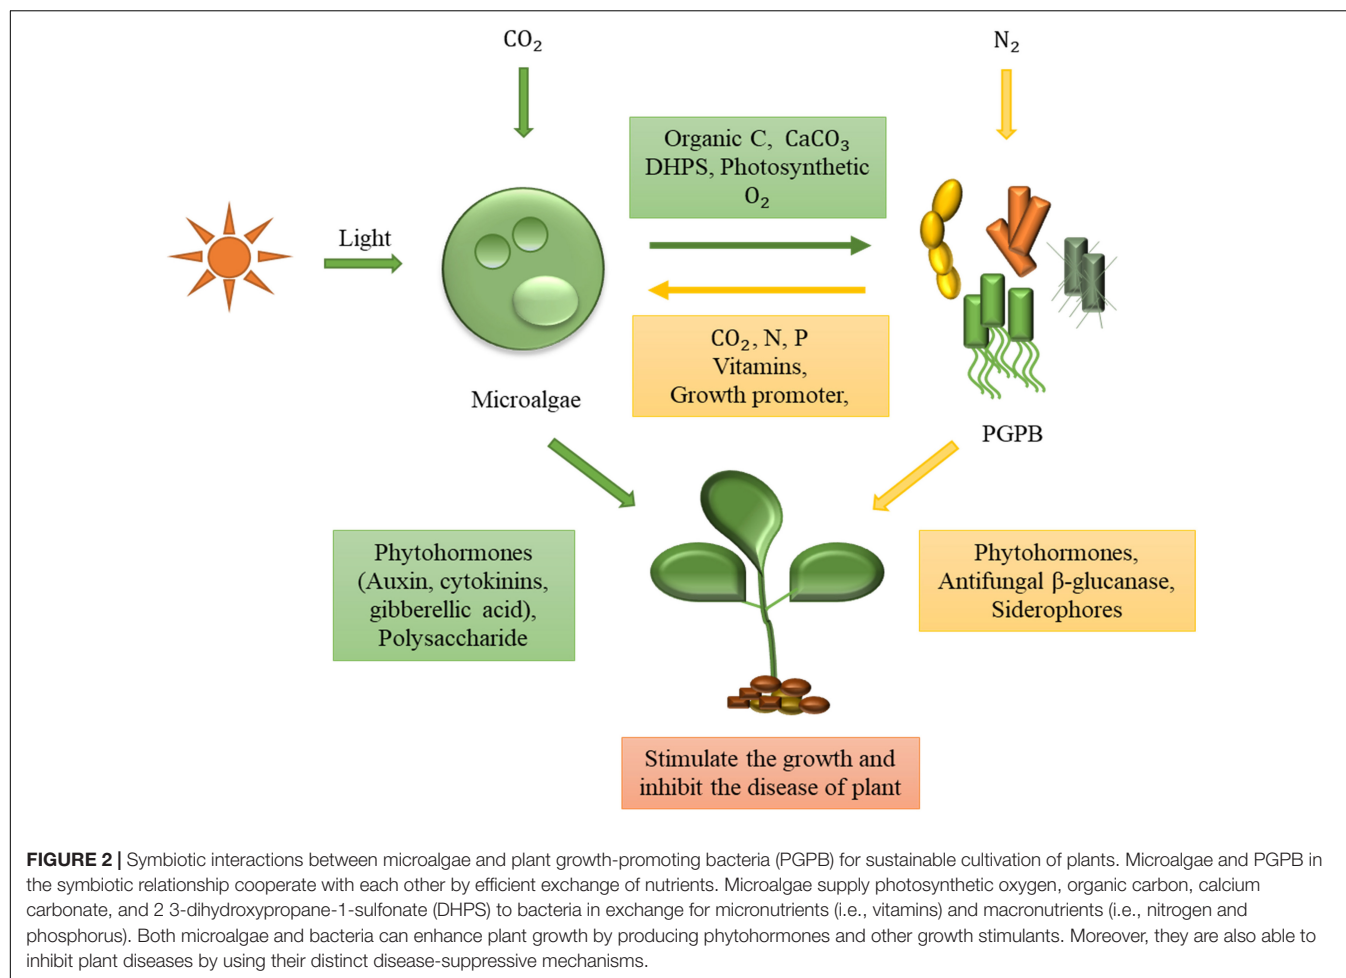

TABLE 3 | Examples of microalgae–bacteria interactions in co-culture/combination.

Microalgae	Bacteria	Comments	References
<i>Chlorella sorokiniana</i>	<i>Azospirillum brasilense</i> and <i>Bacillus pumilus</i>	Two plant growth-promoting bacteria (PGPB) remotely enhanced the growth of the microalgae with elevated amounts of total lipids, carbohydrates, and chlorophyll <i>a</i> in the microalgal cells	Amavizca et al. (2017)
	Bacterial strain CSSB-3 (98.6% identical to the 16S rDNA gene sequence of <i>Microbacterium trichotecenolyticum</i>)	Promoted the growth of <i>C. sorokiniana</i> in the mixed culture with CSSB-3 under a photoautotrophic condition	Watanabe et al. (2005)
	<i>Azospirillum brasilense</i>	<i>Azospirillum brasilense</i> increased <i>C. sorokiniana</i> growth through a variety of mechanisms, including the production of IAA	Peng et al. (2020)
<i>Chlorella vulgaris</i>	<i>Azospirillum brasilense</i>	Increased pigment and lipid contents, lipid variety, and cell and population size of the microalgae <i>Chlorella</i> spp.	de-Bashan et al. (2002)
<i>Amphidinium operculatum</i>	<i>Halomonas</i> sp.	<i>Amphidinium</i> acquires vitamin B ₁₂ through a direct interaction with <i>Halomonas</i> sp.	Croft et al. (2005)
<i>Tetraselmis chuii</i>	<i>Muricauda</i> sp.	<i>Muricauda</i> significantly promoted the growth of <i>T. chuii</i> and <i>C. fusiformis</i> , but drastically inhibited the growth of <i>N. gaditana</i> .	Han et al. (2016)
<i>Cylindrotheca fusiformis</i>			
<i>Nannochloropsis gaditana</i>			

amounts of lipids, carbohydrates, and chlorophyll *a* in the microalgal cells. These beneficial effects have been ascribed to the volatile compounds produced by the bacteria, which include CO₂ (Amavizca et al., 2017). In addition, plant growth-promoting

bacteria, such as *A. brasilense*, have the potential to significantly increase *C. sorokiniana* growth rates through a variety of mechanisms, including the production of IAA (Peng et al., 2020). Croft et al. (2005) reported that bacterial strains of

Halomonas sp. have a growth-enhancing effect on the microalga *Amphidinium operculatum* through the provision of vitamin B₁₂. In addition to this, the presence of algal extracts also leads to the promotion of bacterial growth with upregulated vitamin B₁₂ biosynthesis, displaying positive reciprocity (Croft et al., 2005). Sometimes, a single bacterial strain can induce different effects on the growth and proliferation of distinct microalgae. For example, *Muricauda* sp. was found to promote the growth of *Tetraselmis chuii* and *Cylindrotheca fusiformis*, but drastically inhibited the growth of *Nannochloropsis gaditana* (Han et al., 2016).

CO-CULTURING/COMBINATION OF MICROALGAE–BACTERIA

Microalgae–Bacteria Co-culture for Wastewater Treatment and Biomass Production

The co-culture system of bacteria and microalgae has been mainly used for wastewater treatment and biomass production. Mujtaba et al. (2017) investigated the efficiency of nutrient removal (i.e., ammonium, phosphate, etc.) and the reduction of chemical oxygen demand (COD) from wastewater, using the symbiotic co-culture of *P. putida* and immobilized *C. vulgaris*. In general, symbiotic co-culture systems facilitate the simultaneous removal of a greater variety of nutrients from wastewater compared to monocultures (Mujtaba et al., 2017). Ogbonna et al. (2000) found that it is impossible to remove all nutrients such as acetate, propionate, ammonia, nitrate, and phosphorus from wastewater at once using monocultures of *Rhodobacter sphaeroides*, *C. sorokiniana*, and *S. platensis*, whereas these nutrients can all be removed simultaneously by using the co-culture system (Ogbonna et al., 2000). Moreover, the symbiotic co-culture of *A. brasilense* and *Scenedesmus* sp. has been successfully applied to biofuel production with higher biomass volume. This indicates that the symbiotic co-culture has the potential to increase microalgal colony size, and the fatty acid content inside biofuels, in nitrogen-deficient media (Contreras et al., 2019). The combination of cyanobacteria/microalgae and bacteria can more efficiently detoxify organic and inorganic pollutants and remove nutrients from wastewater compared to using either of them alone.

Soils and aquatic systems contaminated by heavy metals have also become a serious issue in crop production because of the risks associated with food contamination. Microalgae have the ability to detoxify and volatilize heavy metals via microalgal metabolism and high levels of metal binding (Yu et al., 1999). Microalgae form metal-binding peptides (organometallic complexes) such as class III metallothionein (MtIII) (Perales-Vela et al., 2006), which facilitate appropriate control of the cytoplasmic concentration of heavy metals, thereby preventing or neutralizing the potential toxicity caused by heavy metals (Kaplan, 2013; Priya et al., 2014). The application of microalgae, which can bioabsorb and biotransform arsenate (As) in rice fields, reduces the availability of As to plants, thereby rendering the

food grains safe for human consumption (Debnath and Bhadury, 2016). In the case of the algal–bacterial synergistic interactions, a higher removal efficiency of heavy metals was achieved with the addition of bacterial inoculum, which enhanced algal growth with additional CO₂ and organic compounds provided by the bacteria (Unnithan et al., 2014; Mubashar et al., 2020). Furthermore, algae can also be recycled as biofertilizing agents (Guo et al., 2020).

Potential of Microalgae–Bacteria Co-cultures/Combination for Vegetable Cultivation

There are two distinct application methods for the simultaneous use of microalgae and bacteria, one is co-culturing the microbes from the beginning and the other is preparing a mixture containing microalgae/microalgal extract and bacteria gained from each pure culture (combination).

The combined application of specific bacteria, which are growth promoters in plants and/or biocontrol agents against plant pathogens, can lead to the synergy necessary for ideal vegetable cultivation. When *Pantoea ananatis* and *P. fluorescens* (CPP-2) were co-cultured, IAA production and phosphate solubilization were higher than those from either strain alone. Additionally, the co-culture of CPP-2 showed promotion effects on root and shoot elongation of pea (*Pisum sativum*) plants when compared to the culture of an individual strain (Anwar et al., 2019). Moreover, the combination of *P. putida* WCS358 and RE8 was shown to enhance the suppression of *Fusarium* wilt in radish by approximately 50%, when compared to the untreated control, while that of the single-strain treatments was reduced by 30%. Even when one strain failed to suppress disease with a single application, the combination treatment still exhibited a suppressive effect against the disease. This implies that the reinforced resistance, brought on the combination application, is likely due to the additive/combinational effect of different disease-suppressive mechanisms (Boer et al., 2003).

Even though the application of microorganisms, via co-culture/combination treatment, is more effective for vegetable production (Minuto et al., 1993; Raupach and Kloepper, 1998), the use of a single microbial species for vegetable cultivation is commonly observed in practical situations. Although the activity of one microbial species is relatively narrow in scope from a practical point of view, it is easier to obtain related patents and/or safety certificates for the use of a single microbial species in agricultural and commercial sectors with obvious effects in a short period of time. In addition to this, the application of a single microbial species makes the processes of cultivation, harvesting, and extraction simpler and easier (Sylvia et al., 2005). However, in the case of co-culture/combination, the ability to suppress plant pathogens and promote plant growth is much more effective than that of the monoculture system because the microbes in the co-culture/combination system promote the growth of plants and/or prevent pathogens by different mechanisms (Spadaro and Gullino, 2005).

Several important practical examples of mixed treatments of cyanobacteria/microalgae–bacteria have been reported for crop cultivation (Table 4).

TABLE 4 | Examples of co-inoculation of microalgae–bacteria in agriculture.

Crop	Microalgae/cyanobacteria	Bacteria	Application	References
Rice	<i>Anabaena laxa</i> , <i>Anabaena</i> sp., and <i>Anabaena oscillarioides</i>	<i>Providencia</i> sp., <i>Brevundimonas</i> sp., and <i>Ochrobactrum</i> sp.	Enhanced carbon sequestration and plant growth in treatments involving a combination of bacterial and microalgal strains	Prasanna et al. (2012)
Lettuce	<i>Chlorella vulgaris</i>	<i>Bacillus licheniformis</i> , <i>Bacillus</i> <i>megatherium</i> , <i>Azotobacter</i> sp., <i>Azospirillum</i> sp., and <i>Herbaspirillum</i> sp.	Increased the plant weight and total carotenoid content especially under stress conditions during summer	Kopta et al. (2018)
Common bean	<i>Anabaena cylindrica</i>	<i>Rhizobium tropici</i> , <i>Rhizobium freirei</i> , and <i>Azospirillum brasilense</i>	Promoted plant growth parameters and grain production by 84% in plants inoculated with <i>Rhizobium</i> + <i>Azospirillum</i> + <i>Anabaena</i>	Horácio et al. (2020)
Maize	<i>Anabaena cylindrica</i>	<i>Azospirillum brasilense</i>	Increased yield performance of maize hybrid in Londrina and Faxinal	Gavilanes et al. (2020)
Onion	<i>Spirulina platensis</i>	<i>Pseudomonas stutzeri</i>	Enhanced plant growth, productivity, and bulb quality and reduced the production cost in treatments involving the combined treatment of <i>S. platensis</i> extract and nitrogen-fixing <i>P. stutzeri</i>	Geries and Elsadany (2021)

In 2012, the effects of combined treatments of cyanobacterial strains—CR1, CR2, and CR3 (*Anabaena laxa*, *Anabaena* sp., and *Anabaena oscillarioides*)—and bacterial strains—PR3, PR7, and PR10 (*Providencia* sp., *Brevundimonas* sp., and *Ochrobactrum* sp.)—on rice crop yield and C-N sequestration in soil were first reported in a pot experiment (Prasanna et al., 2012).

The synergistic efficacy of the combination of freshwater algae (*C. vulgaris*) and plant growth-promoting bacteria (*B. licheniformis*, *Bacillus megatherium*, *Azotobacter* sp., *Azospirillum* sp., and *Herbaspirillum* sp.) on yields and nutritional values of leaf and romaine lettuces has also been observed. The combined application of microalgal–bacterial preparation led to a significant increase of the romaine and leaf lettuce weight by 12.9% and 22.7%, respectively. Of note, total carotenoids in amounts 26.7% higher than in the controls were detected in the treated romaine lettuce under stress conditions during summer (Kopta et al., 2018).

Recently, Horácio et al. (2020) evaluated the effects of co-inoculation with a diazotrophic cyanobacterium (*Anabaena cylindrica*, Ana), *Rhizobium* (*R. tropici* + *R. freirei*, Riz), and *A. brasilense* (Azo) on the development of the common bean under greenhouse conditions. Grain production in the plants co-inoculated with Ana + Riz + Azo and fertilized with N (100 kg N ha^{−1}) was 84.4% and 86.3% higher than that of untreated controls, respectively. This indicates that N fertilization can be replaced by co-inoculation with selected cyanobacterial–bacterial strains (Horácio et al., 2020). In addition, Gavilanes et al. (2020) conducted two field experiments to assess the efficacy of co-inoculation of *A. cylindrica* with *A. brasilense* on the yield performance of four maize cultivars in two locations (Londrina and Faxinal in Paraná, Brazil). They found that the co-inoculation of *A. cylindrica* and *A. brasilense* resulted in a yield that increased by 9% (967 kg ha^{−1}) in Londrina and 23% (1,744 kg ha^{−1}) in Faxinal, compared to the uninoculated control (Gavilanes et al., 2020).

It was also found that the growth and productivity of onion plants with the combination treatment were promoted when compared to those with either single-agent treatment.

This supports the result of biochemical analyses that state that extracts of both *S. platensis* and *Pseudomonas stutzeri* possess bioactive compounds such as HCN, NH₃, IAA, and amino acids that have stimulatory effects on plant growth and quality (Geries and Elsadany, 2021).

Additionally, after culturing *C. fusca* and *B. amyloliquefaciens* cc178 separately, they were combined in a ratio of 2:1 and used to irrigate tomato roots. It was found that rooting of fine roots was promoted and the plant growth, yield, and soluble liquid sugar content in fruits had significantly increased with the combination treatment when compared to each single treatment (unpublished data). Therefore, the combined application of microalgae and PGPB can exert beneficial effects on the yield and quality of vegetable crops.

CONCLUSION AND FUTURE DIRECTIONS

Microalgae and bacteria have received great interest as biofertilizers in ecofriendly vegetable production. Until now, monoculture systems using certain agricultural microorganisms have been highlighted to improve the yield and quality of agricultural products. However, co-culture/combination systems of microorganisms can be more effective in enhancing microbial diversity in the soil, resistance to plant diseases, and productivity of vegetable crops. Therefore, further investigations to uncover the molecular mechanisms underlying the effect of microalgae–bacteria co-culture/combination on vegetable growth, and/or plant disease suppression, will be necessary for the extension of sustainable agriculture.

AUTHOR CONTRIBUTIONS

All authors listed have made a substantial, direct and intellectual contribution to the work, and approved the final version of the manuscript for publication.

FUNDING

This research was financially supported in part by the World Vegetable Center Korea Office budget (WKO #10000379) and the long-term strategic donors to the World Vegetable Center: Republic of China (Taiwan), UK aid from the United Kingdom Government, United States Agency for International Development (USAID), Australian Centre for

International Agricultural Research (ACIAR), Germany, Thailand, Philippines, South Korea, and Japan.

ACKNOWLEDGMENTS

The authors are grateful to Dr. Srinivasan Ramasamy for careful reading of the manuscript.

Halophytic endophytes potentially contribute to the host's adaptation to adverse environments, improving its tolerance against various biotic and abiotic stresses. Here, we identified the culturable endophytic bacteria of three crop wild relative (CWR) halophytes: *Cakile maritima*, *Matthiola tricuspidata*, and *Crithmum maritimum*. In the present study, the potential of these isolates to improve crop adaptations to various stresses was investigated, using both *in vitro* and *in-planta* approaches. Endophytic isolates were identified by their 16S rRNA gene sequence and evaluated for their ability to: grow *in vitro* in high levels of NaCl; inhibit the growth of the economically important phytopathogens *Verticillium dahliae*, *Ralstonia solanacearum*, and *Clavibacter michiganensis* and the human pathogen *Aspergillus fumigatus*; provide salt tolerance *in-planta*; and provide growth promoting effect *in-planta*. Genomes of selected isolates were sequenced. In total, 115 endophytic isolates were identified. At least 16 isolates demonstrated growth under increased salinity, plant growth promotion and phytopathogen antagonistic activity. Three showed *in-planta* suppression of *Verticillium* growth. Furthermore, representatives of three novel species were identified: two *Pseudomonas* species and one *Arthrobacter*. This study provides proof-of-concept that the endophytes from CWR halophytes can be used as “bio-inoculants,” for the enhancement of growth and stress tolerance in crops, including the high-salinity stress.

Keywords: halophytes, endophytes, stress tolerance, salinity tolerance, biofertilizers, biocontrol, bio-inoculants, growth-promotion

INTRODUCTION

Bacterial endophytes are widespread among plants and colonize intercellular and intracellular spaces of all host compartments. Each individual plant is a host to bacterial and fungal endophytes that colonize its tissues for all or part of its life cycle without causing any apparent pathogenesis (Ryan et al., 2008). Various studies have shown how microbial communities contribute to plant defense and the substantial beneficial effects they have on host plants, including improved nutrient acquisition, accelerated growth, resilience against pathogens and improved resistance against abiotic stress such as heat, drought, and salinity (Rodríguez et al., 2019).

The diversity and structure of endophytic microbiomes are dynamic and directly affected by ecological characteristics of the host plant and soil such as geographic location, environmental factors and interactions within the host plant (Edwards et al., 2015). Most characterized members of bacterial endophytic communities belong to the *Actinobacteria*, *Bacteroidetes*, *Firmicutes*, and *Proteobacteria* (Bulgarelli et al., 2013, 2015; Edwards et al., 2015). However, endophytic microbiome structure can be affected by the host-plant species' genotype, plant organ or tissue type, developmental stage, growing season, geographic, and field conditions, soil type, nutrient status of the host species and cultivation practices (Rodríguez-Blanco et al., 2015; Liu et al., 2017; Rodríguez et al., 2019).

Endophytic microbes hold enormous potential to increase plant health. Interestingly, endophytic bacteria can be used to overcome the effect of salinity stress, promote plant growth and nutrient uptake; these approaches can provide beneficial and environmentally friendly solutions for a sustainable global food security (Glick, 2014; Tkacz and Poole, 2015; Vaishnav et al., 2019). For successful exploitation of endophytes, we need a deeper understanding of endophytic community composition and the mechanisms that underlie their plant growth promotion, in order to successfully select the most efficient bacterial isolates.

Members of endophytic bacterial communities influence each other with antagonistic, competitive, and mutualistic interactions (Toju et al., 2018). This results from nutritional competition, exchange and even metabolic interdependence. This, in turn can influence microbiome composition and its effect on the host-plant (Rodríguez et al., 2019). Host-plant genotype can also have a dramatic impact on microbial members; individual cultivars can influence the microbial community structure and the beneficial effects of endophytic bacteria (Haney et al., 2015; Marques et al., 2015; Pérez-Jaramillo et al., 2016; Rodríguez et al., 2019). Thus, for the utilization of endophytic bacterial isolates, an optimum approach is to isolate key bacterial strains from crop wild relatives (CWRs) (Mendes et al., 2013).

Halophytes could be valuable sources of novel endophytic isolates that can be used to overcome various biotic and abiotic stresses (Ruppel et al., 2013; Shabala, 2013; Yuan et al., 2016; Etesami and Beattie, 2018). High salinity in plants results in ionic and osmotic stress due increased extracellular

hypertonic conditions and accumulation of Na^+ and Cl^- intracellularly (Vaishnav et al., 2019). The resulting stress affects intracellular water balance, rate of cell division, hormonal imbalance, changes in photosynthesis, nutrient translocation, processes that decrease plant growth (Munns, 2002). Plant-associated microorganism can contribute to plant health impeded by salinity stress, by influencing phytohormonal levels and signaling, contributing to homeostasis maintenance of toxic ions under salinity stress, enhancing photosynthesis, and contributing to biomass production and allocation (Dodd and Pérez-Alfocea, 2012). Since soil salinity disrupts the physiological and morphological plant processes and increases pathogen susceptibility (Etesami and Beattie, 2018), the use of plant growth promoting endophytes in crops can be a more eco-friendly approach than agricultural chemicals.

Here, we tested the hypothesis that cultivated endophytic bacteria isolated from three CWR halophytic plant species have properties of salinity stress tolerance, plant growth promotion and phytopathogen growth inhibition. These species included two members of the *Brassicaceae* family (*Matthiola tricuspidata* and *Cakile maritima*), and one of the *Apiaceae* family (*Crithmum maritimum*). To test this hypothesis, we cultured and identified 115 different bacterial isolates and functionally characterized them in *in vitro* and *in-planta* assays. The bacterial isolates were tested *in vitro* for their ability to grow on salinity levels up to 17.5%, their biocontrol of the economically important plant phytopathogens *Verticillium dahliae*, *Ralstonia solanacearum*, and *Clavibacter michiganensis* ssp. *michiganensis*. Subsequently, isolates with demonstrated *in vitro* salt tolerance, were tested *in-planta* to demonstrate whether they promoted plant growth under no stress conditions and under high salinity. Furthermore, bacterial isolates were tested *in-planta* to check their biocontrol properties against *Verticillium dahliae*. This is the first study of bacterial endophytes obtained from *M. tricuspidata*, *Cr. maritimum*, and *Ca. maritima*, and identifies their potential as bacterial bio-inoculants in commercial crops to overcome salinity stress and plant diseases caused by the economically important pathogens.

MATERIALS AND METHODS

Site Description and Plant Sample Collection

Samples were collected during summer 2018 in three distinct sites in Crete, Greece: site 1 (S1: N35°25'. E24°41'), site 2 (S2: N35°06, E25°48), and site 3 (S3: N35°00, E25°44) (Supplementary Figure 1). At S1, a natural beach area favoring salt-marsh vegetation, three *Matthiola tricuspidata* individuals were collected. At S2, a beach area close to Pachia Ammos village, three *Crithmum maritimum* individuals were collected. At S3, a popular beach area located in the town of Ierapetra, three individuals of *Cakile maritima* were collected. Each sample was collected with sterile gloves, forceps and gloves, placed in separate plastic bags to avoid cross contamination and immediately transported to the laboratory for processing.

Plant Surface Sterilization and Endophytic Cell Isolation

Leaf and root materials from each species were cut and processed individually. Plant material was gently washed with sterile distilled water repeatedly to remove soil and dust particles. For surface sterilization, plant roots and leaves were placed into sterile Erlenmeyer flasks containing ethanol 75% v/v for 60 s with shaking and then in sterile Erlenmeyer flasks containing sodium hypochlorite solution 3% w/v⁻¹ (NaClO) for 10 min. The plant materials were then placed again in ethanol 75% v/v for 60 s. To remove any remaining NaClO, plant materials were rinsed 10 times with sterile distilled water (dH₂O). The sterilization and transfer procedures were carried out in a type II laminar flow hood. About 100 µL of the last rinse (for each analyzed sample) was plated on Nutrient Agar (NA) medium and monitored for microbial growth to evaluate surface sterilization efficiency. Only successfully sterilized root material was used further. Approximately 500 mg of leaves and roots per each species were weighed and slashed to small parts for further processing using a sterile scalpel and further grounded into a slurry with an autoclaved pestle and mortar. The slurry was transferred into sterile petri dishes and 30 mL of autoclaved dH₂O was added. The petri dishes were sealed and placed onto a rotary shaker (150 rpm) at 25°C for 2 h. After shaking, 100 µL of the material in triplicate were inoculated on NA plates and incubated at 28°C. Colony forming units (cfu) were chosen from each plate based on their color, texture and morphology. Pure bacterial colonies were grown in Nutrient Broth (NB) and cells stocks were stored in 50% v/v glycerol at -80°C. A total of 115 isolates were identified.

Bacterial Isolation and Identification of Isolates

To identify the 115 bacterial isolates, 16S rRNA gene Sanger sequencing method was employed. To extract crude genomic DNA, 1 mL of liquid bacterial culture in NB was placed in liquid nitrogen for 15 s. After room temperature incubation, the lysate was centrifuged at 10,000 × g for 1 min. Two microliter of the lysate were used to amplify the 16S rRNA gene using primers 27F: 5'-AGAGTTTGATCCTGGCTCAG-3' (White et al., 1990) and 1492R: 5'-GTTTACCTTGTACGACTT-3' (Lane, 1991). PCR reactions of 20 µL were amplified in a BioRad T-100 Thermocycler with initial denaturation at 94°C for 2 min, followed by 35 cycles of 5 s at 94°C, 30 s annealing at 47°C, 2 min primer extension at 72°C, and a final extension at 72°C for 5 min. Apart from the lysate, each tube contained, Bac-Free PCR Buffer, 250 nM of each primer, 0.2 mM of each deoxy- ribonucleotide triphosphate and 0.1 U BAC-Free HotStart Taq polymerase (Nippon Genetics, Europe). PCR products were purified using Nucleo Spin Gel and PCR Clean up (Macherey-Nagel, Germany). Cleaned-up PCR products were sent to Macrogen (Europe) for sequencing with primer 27F.

The resulting chromatograms were quality inspected using MEGA 5 (Kumar et al., 2018) and the start/end regions of low quality were manually trimmed off. Cleaned-up fasta files were aligned in SILVA (Quast et al., 2013). The resulting sequences of

the 16S rRNA gene were queried against ezBioCloud (Yoon et al., 2017) reference database for identification and documentation of the described bacterial isolate with the closest sequence similarity.

Bacterial Salt Tolerance Assay

The salt tolerance of all bacterial isolates was estimated on the basis of the population density of these isolates at different concentrations of NaCl (ranging from 0.5, 5, 10, 15, and 17.5% (w/v) in NA. Ten microliter drops of freshly prepared NB cultures of each isolate were inoculated on sterilized petri plates, containing 25 mL NA with increasing NaCl concentrations and incubated at 28°C. For each NaCl concentration, an *Escherichia coli* laboratory isolate was inoculated as a negative control. After 24 h of incubation, the growth of each isolate was estimated compared to *E. coli* growth.

In vitro Growth Inhibition of Phytopathogens

Antibacterial activity of the bacterial isolates against the phytopathogenic bacteria *Ralstonia solanacearum*, and *Clavibacter michiganensis* was evaluated by co-culturing each of the bacterial isolates on NA lawn covered by *R. solanacearum* or *C. michiganensis*. The inhibition zone indicating inhibition by bacterial growth was recorded as the antibacterial effect. Antifungal activity of the isolates against *Verticillium dahliae* was investigated. Potato dextrose agar (PDA) was inoculated with each bacterial isolate for 24 h at 28°C and then *V. dahliae* was inoculated at room temperature for 3–4 weeks. Fungal growth inhibition was determined by measuring the inhibition zone of *V. dahliae* hyphae on the media.

In vitro Hemolysis Screening Assay

In order to assay the bacterial isolates for hemolytic activity, each isolate was grown on blood agar plates. The bacterial isolates were inoculated with the spot test method and were incubated at room temperature for 48 h. The known non-mammalian-pathogenic species *Ensifer meliloti* was employed as a negative control (Supplementary Figure 2B).

In vitro Growth Inhibition of Fungal Human Pathogen

Antifungal activity of specific isolates against anthropopathogenic fungus *Aspergillus fumigatus* was evaluated by co-culturing 11 bacterial isolates on NA plate lawn covered by *A. fumigatus* for 72 h at room temperature under absence of light. The following isolates were tested: CML04, CMR11, CMR22, CMR25, CrR12, CrR25, MTR12, MTR17a, MTR17b, MTR17c, MTR17d. Fungal growth inhibition was determined by the growth inhibition zone of the *A. fumigatus* hyphae on the media.

In-planta Salt Tolerance Assays

Twelve of the bacterial isolates were selected, according to their ability to grow in high salinity conditions (up to 17.5% w/v NaCl), in order to test their plant growth promotion capacity of the model plant *Arabidopsis thaliana*. Firstly, the experiment was performed with no abiotic stress conditions. Bacterial isolates

were cultured in NB for 46 h at 25°C with stirring. NB cultures were centrifuged at $224 \times g$ for 15 min, the supernatant was discarded and the cells were resuspended in 50 mL sterilized dH₂O. Seeds of *A. thaliana* ecotype Columbia (Col-0) were grown in plastic pots (6 × 6 × 7 cm) filled with vermiculite: soil (1:1), at 25°C (16 h light/8 h dark). For each isolate and the corresponding control, 5 individual plants were grown in each pot. *A. thaliana* plants were watered with dH₂O for 10 days. Then, plants were watered with 10 mL suspensions of the 12 bacterial isolate liquid cultures, and were left for 7 days to let the bacterial isolates adapt. Subsequently, for a 30 day span, plants were watered every 2–3 days with dH₂O. At the end of the experiment, the fresh weight of the leaves from each plant was measured. The leaves were then dried at 65–70°C for 2 days and their dry weight was measured.

The same experiment was performed under salt treatment. Specifically, after the 7 day period of bacterial isolate inoculation, instead of dH₂O, the plants were watered with 10 mL of 250 mM NaCl. Fresh and dry weight of the leaves was measured.

For both experiments, mock samples were employed where no bacterial isolates were inoculated and control plants were inoculated with the isolate *Escherichia coli* (Control-*E. coli*), to check that the plants would not use the bacteria as a fertilizer.

Confrontation and Volatile Tests of Selected Bacterial Isolates Against *Verticillium dahliae*

A total of 16 isolates were selected for direct *in vitro* antagonism of *V. dahliae*. Fourteen of these isolates were selected due to their strong inhibition of *V. dahliae* in initial tests (**Supplementary Table 1**; CrR14, CrR18, MTR18, CMR01, CMR03, CML04, CMR25, MTR17a, MTR17d, MTR17f, MTR17g, MTR17h, and MTR17b, MTR17c). Two additional isolates were selected (CrR04 and MTR12) with medium inhibition in initial tests (**Supplementary Table 1**) for comparison. Direct *in vitro* antagonism of *V. dahliae* was evaluated by dual-culture assays (confrontation test) on PDA (Lahlali et al., 2007). In particular, a 6 mm diameter mycelial disc taken from the periphery of a 2 week-old PDA fungal culture was placed on a new PDA plate (90 mm in diameter) at approximately 25 mm-distance from the center of the plate. Then, a 30 mm-long line from each bacterial isolate (taken from a 48 h-old trypticase soy broth (TSB) liquid culture with an inoculation loop) was streaked on the opposite site of the plate at equal distance from the center (one isolate per plate). Moreover, *Trichoderma harzianum* strain T22 was isolated from the commercial biofungicide TRIANUM-P (Koppert B.V. Hellas) and included in *in vitro* bioassays for comparison. Plates inoculated only with *V. dahliae* agar discs were served as controls. Plates (three per bacterial isolate plus controls) were incubated at 24°C in the dark. The radius of fungal colonies toward the direction of the test isolate and that of controls was measured 5, 7, 9, and 12 days post inoculation (d.p.i.) and radial growth rates were expressed in mm/day. At the end of the bioassays (12 d.p.i.) the underside of the plates was scanned using a Samsung Xpress SL-M2875ND Laser Multifunction Printer at 1200 dpi and microsclerotial (black)

area on each plate image was determined manually using the image processing software ImageJ 1.46r (National Institutes of Health, United States). Then, the number of spores was estimated by transferring a 6 mm-diameter disc taken from the periphery of each culture into a 1.5 mL Eppendorf tube with 1 mL of water, and vortexed for 30 s. The number of spores was measured using a haematocytometer under a light microscope. Moreover, actively growing mycelia from cultures' periphery (located closer to test isolate) were prepared and microscopic observations (30 readings per culture) were carried out to estimate hyphae width.

To evaluate the capacity of bacterial isolates to affect *V. dahliae* growth via the production of volatile compounds, dual-plate assays (Chaurasia et al., 2005) were conducted (volatile test). In brief, one 6 mm-diameter agar disc of actively growing mycelium of the fungus was placed in the center of a new PDA plate (90 mm in diameter), whilst each bacterial isolate (taken from a 48 h-old TSB liquid culture) was streaked on another PDA plate. The covers of the two plates were removed and resultant plates were adjusted together (bacterial culture was upturned) and sealed with cellophane membrane so the two microbes would share the same headspace without coming in contact with each other. Dual plates (upright and upturned) inoculated only with *V. dahliae* served as controls. Similarly, in dual-culture assays, dual-plates (three per bacterial isolate) were incubated at 24°C in the dark and the growth, microclerotial area, sporulation and hyphae width of fungal colonies were measured as described above.

Radial growth inhibition (RGI), microsclerotia formation inhibition (MFI), sporulation inhibition (SI) and hyphae thinning (HT) were calculated according to the formula: $[(V_c - V_t)/V_c] \times 100$ where V_c = the microscopic value of *V. dahliae* in control plates and V_t = the respective value of *V. dahliae* against the antagonistic isolate in dual-culture or dual-plate assays.

Bacterial Isolates and Fungal Inoculum Preparation for *in-planta* Bioassays

The 16 selected (see above) bacterial isolates (CrR14, CrR18, CrR04, MTR12, MTR18, CMR01, CMR03, CML04, CMR25, MTR17a, MTR17d, MTR17f, MTR17g, MTR17h, and MTR17b, MTR17c) were used in *in-planta* bioassays. The isolates were grown in Erlenmeyer flasks with 200 mL liquid TSB, in an orbital incubator at 180 rpm and 28°C for 48 h in the dark. Bacterial suspensions were centrifuged at $3,000 \times g$ for 10 min and cells were re-suspended in water reaching a final concentration of 10^8 cfu mL⁻¹ (measured by dilution plating).

The highly virulent *V. dahliae* isolate 999-1 (Markakis et al., 2016), which originated from symptomatic eggplants (*Solanum melongena* L.), was used. *V. dahliae* conidial suspension for eggplant-*V. dahliae* bioassays was prepared as previously described (Markakis et al., 2016). In brief, conidia were produced by growing each *V. dahliae* strain in potato dextrose broth (PDB) at 160 rpm and 25°C in the dark for 5 days. Then, conidia were harvested by filtrating through three layers of cheesecloth and the suspensions centrifuged at $3,000 \times g$ for 10 min. Spores were re-suspended in sterilized dH₂O and their concentration was adjusted to 5×10^6 conidia mL⁻¹.

In-planta Verticillium Wilt Suppression Bioassays

Eggplant seedlings (cv. Black Beauty) were used in the *in-planta* bioassays. Plants at the one-true-leaf stage, grown in 100 mL-capacity pots containing soil substrate (HuminSubstrat, Klasmann-3 Deilmann GmbH, Germany) were root-drenched with bacterial suspension (20 mL of 10^8 cfu mL⁻¹ of each isolate per plant), whereas plants that served as controls (negative = no bacterium/no fungus assigned as “C–” and positive = no bacterium/plus pathogen assigned as “V.D.”) were treated with 20 mL of water. One week later, eggplants (at the second-true-leaf stage) were inoculated with *V. dahliae* by drenching the soil substrate in each pot with conidial suspension (20 mL of 5×10^6 conidia mL⁻¹ per pot). Negative control plants (C–) were treated with 20 mL of water. Eggplants were maintained under controlled conditions at $23 \pm 2^\circ\text{C}$ with a 12 h light and dark cycle.

Two independent experiments (experiments I and II) were conducted to evaluate the suppressive effect of the aforementioned bacterial isolates against *V. dahliae*. In experiment I, 11 treatments (C–, V.d., V.d. + CrR14, V.d. + CrR18, V.d. + CrR04, V.d. + MTR12, V.d. + MTR18, V.d. + CMR01, V.d. + CMR03, V.d. + CML04 and V.d. + CMR25) were applied; whereas in experiment II, 10 treatments were conducted (C–, V.d., V.d. + MTR17a, V.d. + MTR17d, V.d. + BMTR17f, V.d. + MTR17g, V.d. + MTR17h, V.d. + MTR17b, V.d. + MTR17c, and V.d. + TRIANUM-P). The commercial biofungicide TRIANUM-P was included in experiment II (assigned as V.d. + TRIANUM-P) and applied according to manufacturer's instruction (20 mL of 3×10^7 cfu mL⁻¹ per plant). TRIANUM-P was served as a *V. dahliae*-suppressive reference treatment. Within each experiment, each treatment consisted of seven plants and experiments were replicated three times.

Disease Assessment

Verticillium wilt symptoms on eggplant were recorded at 2-, 3-, and 4- day intervals from 12 to 30 d.p.i with *V. dahliae*. Bioassays were evaluated by estimating disease severity, disease incidence, mortality and relative area under disease progress curve (RAUDPC). Disease parameters were recorded as previously described (Markakis et al., 2016). Briefly, disease severity at each observation was calculated from the number of wilting leaves, as a percentage of total number of leaves per each plant. Disease ratings were plotted over time to generate disease progress curves. Subsequently the area under disease progress curve (AUDPC) was calculated by the trapezoidal integration method (Campbell and Madden, 1990). Disease was expressed as a percentage of the maximum possible area with reference to the maximum value potential reached over the whole period of each experiment and is referred to as RAUDPC. Disease incidence was estimated as the percentage of infected plants. Only plants with a final disease severity of $\geq 20\%$ were considered infected, to discriminate between *V. dahliae*-associated disease symptoms and other weak symptoms occasionally observed (Supplementary Table 2). Mortality was estimated as the percentage of dead plants.

Plant Growth

Growth parameters were evaluated at the end of bioassays (at 24 and 30 d.p.i. for experiments I and II, respectively). To estimate the effect of the aforementioned treatments on plant growth, all plants were clipped off at the soil surface level and their height, fresh weight and leaf number were measured.

Fungal Pathogen Re-isolation

To verify the presence of the applied *V. dahliae* strain in plant tissues, five plants per treatment in each experiment were randomly selected. Eggplant leaves which had been cut above soil level previously were removed and their stems were surface-disinfected by spraying with 95% ethyl alcohol and by quickly passing them through flame three times. For each plant, 3 xylem chips taken from different sites along the stem (base, middle and upper part of the stem) and aseptically placed onto acidified PDA after removing the phloem. Plates were then incubated at 24°C in the dark for 14 days. The emerging fungi that grew out of tissue excisions were examined visually and under a light microscope and identified according to their morphological characteristics (Pegg and Brady, 2002). Pathogen isolation ratio was expressed as the frequency of positive *V. dahliae* isolations of each plant.

Statistics

Analysis of variance (ANOVA) was employed to determine the effects of replication (1, 2, or 3), treatment (C–, V.d., V.d. + CrR14, V.d. + CrR18, V.d. + CrR04, V.d. + MTR12, V.d. + MTR18, V.d. + CMR01, V.d. + CMR03, V.d. + CML04, V.d. + CMR25 in Experiment I and C–, V.d., V.d. + MTR17a, V.d. + MTR17d, V.d. + BMTR17f, V.d. + MTR17g, V.d. + MTR17h, V.d. + MTR17b, V.d. + MTR17c, V.d. + TRIANUM-P in experiment II) and their interaction on disease incidence (DI), final disease severity (FDS), mortality (M), RAUDPC and isolation ratio (IR), and on plant height, fresh weight and total number of leaves (Supplementary Tables 2, 3). Prior to ANOVA, normality of data and homogeneity of variance across treatments was evaluated and an arcsine transformation was applied to normalize variance. When a significant *F* test was obtained for treatments ($P \leq 0.05$), the data were subjected to means separation by Tukey's honestly significant difference test. Morphological and physiological characteristics of *V. dahliae* in dual-culture and dual-plate assays were also analyzed by Tukey's test ($P \leq 0.05$). Moreover, standard errors of means were calculated.

Bacterial Genome Sequencing and Annotation

Twelve bacterial isolates were selected for whole genome sequencing (CrR16, CMR16, CrR07, CMR13, CrR06, CrR18, CrR14, CMR27, CMR25, CML04, CMR29, CrR25). The isolates were selected when they met more than two of the following criteria: (a) the 16S rRNA gene sequence of the isolates being 99.6% similar to their closest relative or lower, (b) exhibiting salt tolerance higher than the 5% threshold, (c) exhibiting medium or strong inhibition against the growth of at least 2 of the 3 tested phytopathogens *Verticillium dahliae*, *Ralstonia*

solanacearum, and *Clavibacter michiganensis* ssp. *michiganensis* (Supplementary Table 1). For each isolate a 250 bp paired-end library was produced for use with the Illumina MiSeq sequencing system (University of Exeter Sequencing Service, Exeter, United Kingdom). Reads were assembled using SPAdes 3.12.0 (Bankevich et al., 2012) and the assembled sequence was annotated using the NCBI Prokaryotic Genome Annotation Pipeline (PGAP). Raw sequence reads and assembled genomes were uploaded to the Sequence Read Archive (Leinonen et al., 2011) and GenBank (Dennis Benson et al., 2017) and are available under BioProject accession number PRJNA634334. RAST (Rapid Annotation using Subsystem Technology) (Overbeek et al., 2014) was employed for genome analysis and annotation.

Sequence Alignment and Phylogenetic Tree Construction

Selected gene sequences were aligned with ClustalX v2.0 (Larkin et al., 2007) and subsequently manually corrected. Sequence relationships were inferred using the maximum-likelihood (ML) method. ML phylogenies were constructed using MEGA 5.2 (Tamura et al., 2011). Phylogenetic trees were constructed using the concatenated *recA* and *gyrB* genes and assuming the bootstrap value derived from 1,500 replicates to represent the evolutionary history of the included taxa.

The evolutionary history of *Arthrobacter recA-gyrB* genes were inferred by using the Maximum Likelihood method based on the Tamura-Nei model (Tamura and Nei, 1993). The bootstrap consensus tree inferred from 500 replicates (Felsenstein, 1985) was taken to represent the evolutionary history of the taxa analyzed (Felsenstein, 1985). Branches corresponding to partitions reproduced in less than 50% bootstrap replicates are collapsed. Initial tree(s) for the heuristic search were obtained automatically as follows. When the number of common sites was <100 or less than one fourth of the total number of sites, the maximum parsimony method was used; otherwise BIONJ method with MCL distance matrix was used. Trees were drawn to scale, with branch lengths measured in the number of substitutions per site. The analysis involved 25 nucleotide sequences. Codon positions included were 1st + 2nd + 3rd + Non-coding. All positions with less than 95% site coverage were eliminated. That is, fewer than 5% alignment gaps, missing data, and ambiguous bases were allowed at any position. Evolutionary analyses were conducted in MEGA5 (Tamura et al., 2011).

The evolutionary history *Arthrobacter recA-gyrB* genes was inferred with the Maximum Likelihood method as above. The tree with the highest log likelihood (−7831.6808) was selected. Initial tree(s) for the heuristic search were obtained automatically as follows. When the number of common sites was <100 or less than one fourth of the total number of sites,

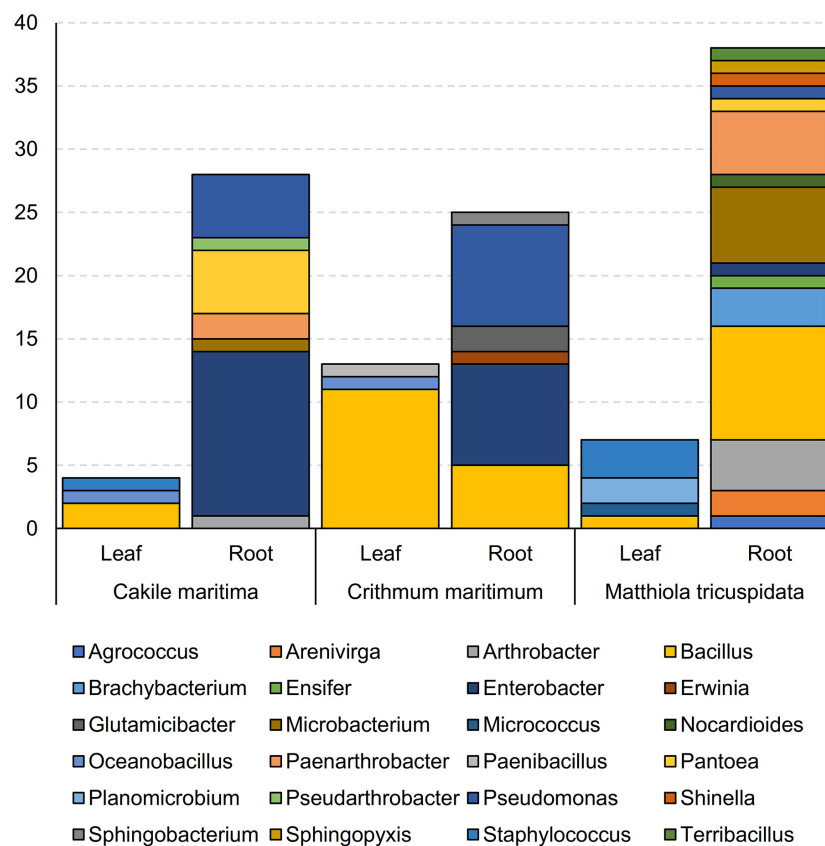

FIGURE 1 | Abundance of genera of bacterial isolates obtained from leaves and roots of *Matthiola tricuspidata*, *Crithmum maritimum*, and *Cakile maritima* plants.

the maximum parsimony method was used; otherwise BIONJ method with MCL distance matrix was used. The bootstrap consensus tree inferred from 500 replicates (Felsenstein, 1985) is taken to represent the evolutionary history of the taxa analyzed (Felsenstein, 1985). The tree was drawn to scale, with branch lengths measured in the number of substitutions per site. The analysis involved 22 nucleotide sequences. Codon positions included were 1st + 2nd + 3rd + Non-coding. All positions with less than 95% site coverage were eliminated as described above. Evolutionary analyses conducted in MEGA5 as described above.

RESULTS

Identification and Abundance of Culturable Endophytic Bacteria

Endophytic bacteria were cultivated from different surface-sterilized tissue samples from all three halophytes. A total of

115 pure bacterial cultures showing different colony morphology (from root or leaf) were obtained; 91 were retrieved from roots and 24 from leaves. In detail, 45, 31, and 39 isolates were obtained from *M. tricuspidata*, *Ca. maritima*, and *Cr. Maritimum*, respectively (Supplementary Table 1).

For all 115 isolates, total 16S rRNA gene sequencing allowed for taxonomic analysis (Figure 1 and Supplementary Table 1). Bacterial isolates were assigned to 5 different classes (Supplementary Table 1) and 24 genera (Figure 1 and Supplementary Table 1). The most prevalent genus was *Bacillus*, accounting for 24% of the isolates, followed by *Enterobacter* (19%) and *Pseudomonas* (12%). The highest number of bacteria were isolated from roots of *M. tricuspidata* (38), followed by *Ca. maritima* roots (28) and *Cr. maritimum* roots (25), in contrast to the number of bacteria isolated from leaf samples (*M. tricuspidata*: 7, *Ca. maritima*: 4 and *Cr. maritimum*: 13). Isolates of genus *Bacillus* were isolated from all plants and tissues except the roots of *Cr. maritimum*, while *Pseudomonas* isolates were only isolated from root samples.

FIGURE 2 | *In vitro* growth inhibition experiments: against phytopathogenic bacteria *Ralstonia solanacearum* or *Clavibacter michiganensis* (A), against phytopathogenic fungus *Verticillium dahliae* (B) and against human pathogenic fungus *Aspergillus fumigatus* (C). Representative experiments are shown to display their “weak” (A1–C1), “medium” (A2–C2), or “strong” (A3–C3) inhibitory activity.

TABLE 1 | *In-planta* plant growth promotion and salt tolerance assays in *Arabidopsis thaliana* plants. For the salt tolerance assays plants were watered with and without NaCl solution every 2-3 days and fresh and dry plant weight was measured.

Apart from *Bacillus*, which was isolated from both roots and leaves, the rest of the genera were isolated only from roots or leaves (**Supplementary Table 1**). Similarly, all isolates from the genera *Enterobacter*, *Pseudomonas*, *Microbacterium*, *Paenarthrobacter*, *Pantoea*, *Arthrobacter*, *Brachyбактерium*, *Arenivirga*, and *Glutamicibacter* were isolated from root samples, whereas the isolates *Oceanobacillus*, *Planomicrobium*, and *Staphylococcus* were isolated only from leaf samples (**Supplementary Table 1**).

The most frequently isolated genera were hosted in at least two of the three halophyte species. *M. tricuspidata* hosted the largest number of genera (18). *Ca. maritima* hosted the largest number of *Enterobacter* (13 out of 22) and the smallest number of *Bacillus* (2 out of 28). Members of the genera *Brachyбактерium* and *Arenivirga* were isolated only from *M. tricuspidata* plants, whilst *Glutamicibacter* were isolated only from *Cr. maritimum* and the *Planomicrobium* from *Ca. maritima*.

Bacterial Growth Under Salinity Stress

Bacterial isolates were tested for their ability to grow in elevated NaCl concentrations (5, 7.5, 10, 15, and 17.5%) (**Supplementary Figure 2A**). Most isolates showed growth at 5% NaCl (96 isolates). From the 28 isolates from *Ca. maritima* roots, 26 isolates (92.9% of the total) showed ability to grow at 5% salinity,

and 14 of these (50%) showed growth at 7.5% salinity; all four isolates from the leaves of the same plant showed growth at 10% salinity and two of these could grow at 17.5%. 21 out of 25 isolates (84%) of the roots of *Cr. maritimum* could grow at 5% salt and 16 (64%) could grow at 10% salinity. 12 out of 13 (92.3%) isolates from the leaves of *Cr. maritimum* could grow at the 5% level and eight (61.5%) could grow at 10% salt. From the 38 isolates obtained from the root of *M. tricuspidata*, 27 (71%) could grow at the 5% salt threshold and three could grow in 10% salt.

Of the six isolates that managed to grow at 17.5% salinity, four were isolated from leaf tissues (**Supplementary Table 1**): *Staphylococcus saprophyticus* (CML12) and *Oceanobacillus picturae* (CML15) isolated from *Ca. maritima* leaves, *Oceanobacillus picturae* (CrL11) from *Cr. maritimum* leaves, and *Micrococcus aloeverae* (MTL04) from *M. tricuspidata* leaves (**Supplementary Table 1** and **Supplementary Figure 2A**). The two isolates from root tissues that could grow on 17.5% are *Enterobacter hormaechei* subsp. *hoffmannii* (CMR13) isolated from *Ca. maritima* and *Bacillus hwajinpoensis* (CrR23) isolated from *Cr. maritimum* (**Supplementary Table 1** and **Supplementary Figure 2A**). Another three *Bacilli* isolates (CrR16: *Bacillus haikouensis*, CrR22: *Bacillus haikouensis*, MTR05: *Terribacillus saccharophilus*) showed

TABLE 2 | Values of fungal parameters of *Verticillium dahliae* treated with 16 different bacterial isolates (CrR14, CrR18, CrR04, MTR12, MTR18, CM0R1, CMR03, CML04, CMR25, MTR17a, MTR17d, MTR17f, MTR17g, MTR17h, MTR17b, MTR17c) and *Trichoderma harzianum* strain T22 in dual-culture and dual-plate assays. Values were estimated as the percentage of inhibition compared to control (V.d.).

^aFungal parameters were calculated according to the formula: $[(Vc-Vt)/Vc] \times 100$ where Vc = the microscopic value of *V. dahliae* in control and Vt = the respective value of *V. dahliae* toward the antagonistic isolate in dual-culture or dual-plate assays. Each value represents the mean of 3 replicates. RGI, (radial growth inhibition; SI, (sporulation (spore production) inhibition; HWT, (hyphae width thinning; MFI, (microsclerotia formation inhibition). Within columns, values followed by the same letter are not significantly different according to Tukey's HSD test at $P \leq 0.05$.

^b"nm" indicates that HWT values were not measured since *T. harzianum* overgrown *V. dahliae* in dual-culture assays and pathogen hyphae could not be identified.

^{c, d, e, f}"ne" indicates that RGI, SI, HWT and MFI were not estimated since *T. harzianum* could reach directly *V. dahliae* even in dual-plate assays.

growth on 15% salinity (Supplementary Table 1 and Supplementary Figure 2A).

Phytopathogens Growth Inhibition Ability

All bacterial isolates were subjected to *in vitro* inhibition assays against three known phytopathogens: the bacteria *Ralstonia solanacearum* and *Clavibacter michiganensis* subsp. *michiganensis* and the fungus *Verticillium dahliae*. In the assays against the phytopathogenic bacteria, the bacterial isolates that showed any kind of inhibition were characterized as having “weak,” “medium” or “strong” inhibitory activity based on the size of the inhibition zone around the bacterial colony (Figure 2). In the *in vitro* assay against *Verticillium* the inhibitory activity was similarly judged as “weak,” “medium” or “strong” based on the linear distance between the bacterial and the fungal colonies (Figure 2).

Twenty-five (21.7%) out of 115 bacterial isolates demonstrated inhibition of the *Ralstonia solanacearum* growth (Supplementary Table 1). These 25 isolates belong to six genera: *Bacillus*, *Enterobacter*, *Erwinia*, *Glutamicibacter*, *Paenarthrobacter*, and *Pseudomonas*. Isolate CML04 (*Bacillus altitudinis*), obtained from leaf tissues of *Ca. maritima*, was the only leaf-derived isolate that showed antagonistic activity against all 3 tested phytopathogens (Supplementary Table 1). Of the 45 isolates isolated from *M. triscupidata*, three isolates showed a weak inhibitory zone against *Ralstonia*. A total of 10 isolates belonging to the genera *Enterobacter*

and *Pseudomonas* (Supplementary Table 1) showed a strong inhibition (Figure 2).

A lower number of isolates showed any kind of inhibition against the phytopathogenic *Clavibacter michiganensis* subsp. *michiganensis*: 17 isolates out of 115 (14.8%). All 9 isolates from *M. triscupidata* (*Bacillus licheniformis* or *Bacillus sonorensis* isolates) demonstrated a strong inhibition zone (Figure 2). Similarly, two isolates from *Cr. maritimum* roots (both *Pseudomonas glareae*, CrR12 and CrR13) showed a strong inhibition zone (Supplementary Table 1). An additional two and four isolates showed weak and medium inhibition zone against *Clavibacter*, respectively (Supplementary Table 1).

The majority (76.5%) of the bacterial isolates demonstrated inhibition of the phytopathogenic fungus *Verticillium dahliae* (Supplementary Table 1). These isolates originate from both leaf and root tissues from all three halophytes. A strong inhibition zone was demonstrated by 34 of these 88 isolates, all of which except one, were isolated from halophytic plant roots (Supplementary Table 1). From these 34, 11 isolates belong to the genus *Bacillus*, another 11 to *Pseudomonas* and five to *Enterobacter* (Supplementary Table 1).

Eleven isolates were tested for inhibition against the human pathogenic fungus *Aspergillus fumigatus*. Interestingly, five isolates were able to inhibit the growth of *A. fumigatus* (Figure 2). Isolate CML04 (*Bacillus altitudinis*) isolated from *Ca. maritima* was the only isolate from leaf tissues able to show inhibitory effect,

FIGURE 3 | Verticillium wilt disease severity index on eggplant treated with various bacterial isolates at 12, 14, 18, 21, and 24 days post inoculation with *Verticillium dahliae* conidial suspension (20 mL of 5×10^6 conidia mL⁻¹). Each column represents the mean of 21 plants after combining the results of 3 replicated experiments (experiment I). Columns at each observation time point followed by the same letter are not significantly different according to Tukey's HSD test at $P \leq 0.05$. Vertical bars indicate standard errors.

FIGURE 4 | Verticillium wilt disease severity index on eggplant treated with various bacterial isolates and the commercial biofungicide TRIANUM-P (Koppert B.V. Hellas) at 12, 14, 16, 19, 23, 26, 28, and 30 days post inoculation with *Verticillium dahliae* conidial suspension (20 mL of 5×10^6 conidia mL⁻¹). Each column represents the mean of 21 plants after combining the results of 3 replicated experiments (experiment II). Columns at each observation time point followed by the same letter are not significantly different according to Tukey's HSD test at $P \leq 0.05$. Vertical bars indicate standard errors.

while the remaining isolates were isolated from *M. triscupidata* roots (**Supplementary Table 1**). Two isolates MTR17d (*Bacillus sonorensis*) and MTR17b (*Bacillus licheniformis*) showed a strong inhibition zone (**Figure 2** and **Supplementary Table 1**).

In-planta Assay for Plant Growth Promotion and Salt Tolerance

Bacterial isolates with *in vitro* 10% and 17.5% NaCl salt tolerance were selected for the *in-planta* assays to demonstrate potential plant growth promotion under “no stress.” *Arabidopsis thaliana* plants were imbued with bacterial cultures and left for 7 days for the bacteria to adapt. Then, after watering the plants for a month, fresh and dry leaf weight were calculated (**Table 1**). The same experiment was repeated where after the 7 day mark, the plants were watered with 10 mL of 250 mM NaCl solution every 2–3 days for 30 days.

Under no stress conditions, plants inoculated with isolates CML12, CML15, CrL01, CrL11, CrR16, CrR23, MTR05 showed an increase in fresh leaf weight between 1.1 and 2.6 times to the non-inoculated plants and between 1.0 and 2.3 times increase in dry leaf weight (**Table 1**). Under salt stress, the growth promotion effect was less accentuated, since plants imbued with isolates CML15, CrR22, MTR05 had less increased fresh and dry leaf (**Table 1**).

Isolates CML15 and MTR05 conferred an increase in fresh and dry leaf weight both under no stress and under salt stress

whereas isolate CrR22 had a positive affect only under salt stress condition (**Table 1**). On the other hand, isolates CML12, CrL01, CrL11, CrR16, and CrR23 had a positive effect on fresh and dry weight under no stress condition (**Table 1**).

Direct and Indirect *in vitro* Effects of *Verticillium dahliae* Growth

The selected 16 bacterial isolates with the exception of MTR17h inhibited significantly *V. dahliae* growth rate in dual-culture assays. However, only MTR17h, MTR17b, and MTR17c could suppress fungal growth by means of volatile compounds (**Table 2**). Likewise, nearly all isolates were capable of inhibiting fungal sporulation (except of MTR17g) in dual-culture assays. Most isolates significantly inhibited spore production in dual-plate assays. Interestingly, three isolates caused a significant induction of *V. dahliae* sporulation in such assays (MTR17h, MTR17b, and MTR17c), indicating that fungal growth suppression induces fungal sporulation (**Table 2**). Moreover, six out of 16 isolates could significantly reduce hyphae width in direct culture conditions, whereas seven out of 16 were capable of hyphae width reduction by the mean of volatiles. Additionally, nine isolates significantly inhibited microsclerotia formation in dual-culture assays; however, only three isolates significantly reduced microsclerotia formation in dual-plate assays (**Table 2**). MTR17h caused significant induction in

microsclerotia formation both in dual-culture and in dual-plate assays.

Suppression of *Verticillium* Wilt Symptoms *in-planta*

For the suppression of *Verticillium dahliae* wilt symptoms *in-planta* we used a well-established fungus/plant system, the *Verticillium*/eggplant system. We selected 16 bacterial isolates that showed promising *in vitro* growth inhibition effect to *Verticillium*.

Two distinct assays were performed (hereafter known as “experiment I” and “experiment II”). *V. dahliae* wilt symptoms on eggplant started 12 days after inoculation (d.p.i.), with *V. dahliae* conidial suspension and were recorded periodically for another 12 days in experiment I. Isolates CrR4, MTR12, MTR18, and CMR01 suppressed significantly disease severity at 18 and 21 d.p.i. whereas MTR18 and CM1 treatments caused significant reduction of disease severity at most observation time points (Table 2 and Figures 3, 4). Considering all disease parameters, CMR01 was the most effective isolate in terms of disease suppression (Table 2,

Figure 3, and Supplementary Tables 2, 3). First disease symptoms in experiment II were also observed on 12 d.p.i. and recorded until 30 d.p.i. Disease severity progressed rapidly in the control (*V.d.*) and the non-suppressive treatments (MTR17d, MTR17f, and MTR17g), whereas MTR17a-, MTR17h-, MTR17b-, and MTR17c-treated plants showed less prominent symptoms and slower disease development (Table 2 and Supplementary Figure 3). Disease parameters indicated that isolate MTR17h, is comparable to the positive control (fungus *Trichoderma harzianum* isolate + TRIANUM-P), as the most effective in symptom suppression (Table 2 and Figure 4). While observed decrease in symptom severity in MTR17h-treated plants was associated with significantly lower *V. dahliae* re-isolation ratio compared to positive control (*V.d.*) plants, MTR17h isolate did not show strong growth inhibition effect on *V. dahliae* in *in vitro* assays (Figure 4), indicating less active growth of the pathogen into the xylem vessels. This finding could suggest that the plant innate immunity activation/reinforcement effect by MTR17h, needs to be further investigated in the future. Neither symptoms nor positive isolations were observed in negative control plants.

TABLE 3 | Values (\pm standard errors) of disease parameters for eggplants inoculated with *V. dahliae* and treated with different bacterial isolates and TRIANUM-P (CrR14, CrR18, CrR04, MTR12, MTR18, CMR01, CMR03, CML04, CMR25 in experiment I, and MTR17a, MTR17d, MTR17f, MTR17g, MTR17h, MTR17b, MTR17c, TRIANUM-P in experiment II) or not (C–, *V.d.*).

^aDisease parameters were evaluated periodically on the basis of external symptoms during a period of 24 days (in Experiment I) and 30 days (in Experiment II) after root drenching with *Verticillium dahliae* conidial suspension (20 mL of 5×10^6 conidia mL⁻¹ per plant). One week prior to inoculation with *V. dahliae*, plants were root-drenched with bacterial suspension (20 mL of 10^8 cfu mL⁻¹ of each isolate per plant); whereas TRIANUM-P was also included in experiment II and applied by root drenching (20 mL of 3×10^7 cfu mL⁻¹ per plant). DI, (final disease incidence; FDS, (final disease severity; M, (mortality; RAUDPC, (relative area under the disease progress curve with reference to the maximum value potentially reached over each assessment period; IR, (isolation ratio. Each value represents the mean of 21 plants after combining the results of 3 replicated experiments (except from IR that represents the mean of 5 plants in total). Within experiments, values in columns followed by the same letter are not significantly different according to Tukey's HSD test at $P \leq 0.05$.

Effects of Treatments in Plant Growth

Growth parameters of eggplant inoculated with *V. dahliae* and treated with the 16 isolates and the *T. harzianum* isolate TRIANUM-P or not (C—), are shown on **Table 3**. *V. dahliae*-inoculated plants treated with MTR17c and *T. harzianum* TRIANUM-P developed significantly higher fresh weight compared with the *V. dahliae*-inoculated controls, whereas most of the plant growth parameters in non-inoculated plants were significantly higher than the inoculated ones.

Whole-Genome Sequencing and Analysis of Selected Endophytic Bacterial Isolates

Whole-genome sequencing (WGS) was performed on 12 selected isolates. Genomes were annotated using RAST (**Supplementary Figure 5**). All genes related to the virulence, disease and defense that were predicted are presented in **Table 4** and **Supplementary Table 2**.

Genome-wide average nucleotide identity (ANI) calculations against all bacterial genome assemblies in GenBank pointed

to the existence of three previously unknown bacterial species; their genomes showed less than 95% ANI with any previously sequenced genomes. Phylogenetic analysis of the *recA* and *gyrB* gene sequences extracted from the genomes (**Figures 5, 6**) had indicated that two isolates belong to *Pseudomonadaceae*, while the third was a member of *Arthrobacter* genus. Isolates CMR25 and CMR27 belonged to an unidentified species of the *P. putida* group (**Figure 6**) and isolate CrR25 was an undefined species of the *P. mendocina* group (**Figure 6**). Consistent with these results, 16S rRNA gene sequences of CMR25 and CMR27 were 99.8% identical to that of *Pseudomonas plecoglossicida* and CrR25 was 98.75% identical to that of *Pseudomonas benzenivorans*. WGS analysis places CMR16 as an unidentified *Arthrobacter* species (**Figure 5**), while its 16S rRNA gene sequence assigns the isolate to *Paenarthrobacter nitroguajacolicus* (Kotoučková et al., 2004) with 98.78% identity. This species has been previously isolated from leaves of maize (Pisarska and Pietr, 2012) and promoted growth of wheat under salt stress (Safdarian et al., 2019). Unfortunately, no genome sequence is available for the type strain of this species; however, the ANI between CMR16

TABLE 4 | Number of genes related to Virulence, Disease and Defense features of the three new bacterial species identified in this study. The genome analysis and the annotation was performed using the RAST genome annotation software.

genome and previously sequenced genomes (Yao et al., 2015) of *Paenarthrobacter nitroguajacolicus* (Kotoučková et al., 2004) range between 86.08 and 86.76%, well below the widely used threshold of 96% for species membership.

DISCUSSION

Utilization of endophytic microorganisms for the control of biotic/abiotic stresses is a relatively unexplored area of research. Endophytes have been studied for over two decades (Saikkonen et al., 1998; Hasegawa et al., 2006; Kaul et al., 2016), however, our understanding about their role in plant defense against biotic/abiotic stresses is still limited (Liu et al., 2020; Pascale et al., 2020). Isolation, identification

and the study of endophytes from plants that undergo continued abiotic stress could be essential for the development of proper biocontrol strategy for sustainable agriculture and food security.

Here, we investigated the abundance of taxa of the culturable bacterial endophytes of three halophytic plants, endemic in Crete island, Greece, using culture-dependent techniques (Figure 7). We also investigated the proof-of-concept of using the halophytes as a valuable source of beneficial microbes that can potentially be used in agriculture, by testing our initial hypothesis that these endophytes have plant growth promotion and biocontrol properties.

Taxonomically, 24 different genera were identified, the three most abundant ones were *Bacillus*, *Enterobacter*, and *Pseudomonas*, all of which have been previously observed in

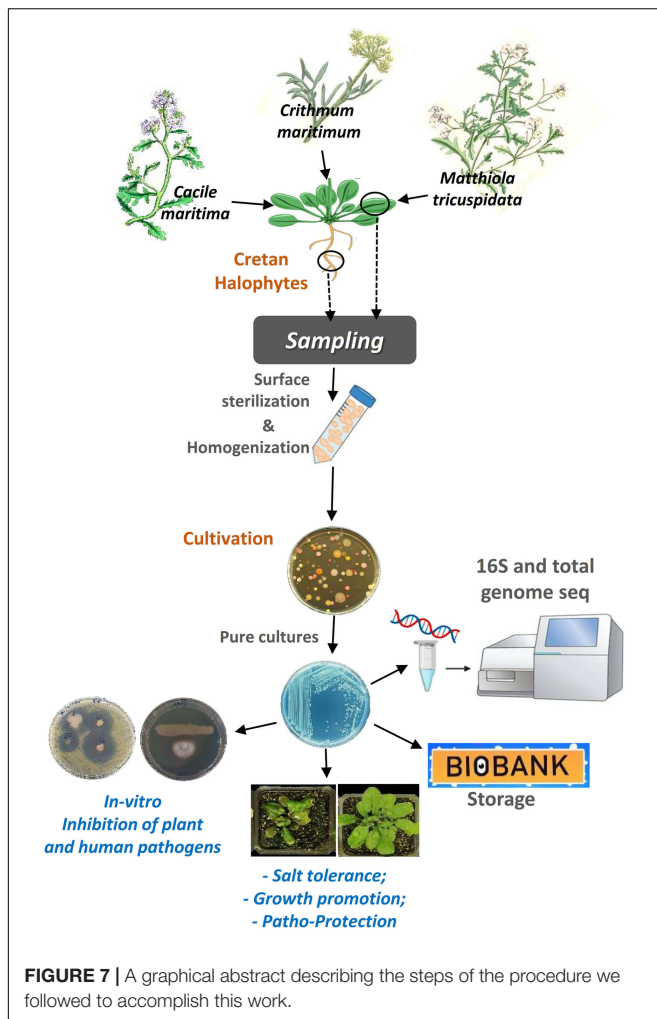

FIGURE 6 | Molecular Phylogenetic analysis of the *recA-gyrB* genes from Pseudomonads belonging to *P. putida* and *P. mendocina* groups by Maximum Likelihood method. The tree with the highest log likelihood (−7831.6808) is shown. The tree is drawn to scale, with branch lengths measured in the number of substitutions per site.

studies of the endophytic microbiome of halophytes (Shabala, 2013; Qin et al., 2014; Mora-Ruiz et al., 2016; Yuan et al., 2016).

In-planta testing of *Oceanobacillus picturae* (CML15), *Terribacillus saccharophilus* (MTR05), and *Bacillus haikouensis* (CrR22) demonstrated an increase in both dry and fresh leaf weight in *Arabidopsis thaliana* plant under salinity stress. These isolates are promising biofertilizers, since other isolates of the same species have also been shown to have plant growth promotion properties; *Terribacillus saccharophilus*, firstly reported at 2007, is a known halophilic bacterium able to grow on 0–16% NaCl (An et al., 2007; Liu et al., 2010). This species is a known endophytic bacterium (Han et al., 2011), shown to trigger an increase on monoterpenes, sesquiterpenes, tocopherols, and membrane sterols, compounds engaged in antioxidant capacity in leaf tissues of grape resulting in stress tolerance (Salomon et al., 2016). *Bacillus haikouensis* is halotolerant bacterium isolated from paddy soil, able to grow on up to 17% NaCl (Li et al., 2014).

Oceanobacillus picturae is a halophilic phosphate-solubilizing species with demonstrated siderophore production potential, isolated from saline environments and shown to promote plant growth in mangroves and confer salinity stress tolerance in barley (El-Tarabily and Youssef, 2010; Mapelli et al., 2013; Orhan and Demirci, 2020). Many of our isolates were able to grow at high concentrations of salt (5–17% NaCl).

Isolates belonging to the species *Bacillus licheniformis*, *Bacillus sonorensis*, *Pseudomonas glareae*, *Enterobacter hormaechei*, *Pseudomonas benzenivorans*, *Pseudomonas monteilii*, *Pseudomonas plecoglossicida* were shown to have strong antagonistic activity against the phytopathogenic bacteria *Ralstonia solanacearum* and *Clavibacter michiganensis* subsp. *michiganensis*, two very important plant pathogens with high economic impact on agriculture (Gartemann et al., 2003; Peeters et al., 2013). Both are very important phytopathogens, since *Ralstonia* has a large host range able to infect more than 200 plant

species easily adaptable in varying environmental conditions whereas *C. michiganensis* subsp. *michiganensis* is able to infect wheat, maize, potatoes, and red and green peppers, despite its main host being tomatoes (Eichenlaub and Gartemann, 2011; Peeters et al., 2013; Hwang et al., 2018). Moreover, specific isolates with *in vitro* growth inhibition effect against *V. dahliae*, were tested for their ability to inhibit *V. dahliae* *in-planta*. Several isolates demonstrated an *in-planta* suppression effect of the polyphagous pathogen *V. dahliae*. Interestingly, isolates with strong *in vitro* effect did not manage to inhibit *V. dahliae* *in-planta*, but other isolates with medium or low *in vitro* effect inhibited *in-planta* *V. dahliae* growth strongly. These data provide the proof of concept for our study but also indicate that in future studies all resulting isolates need to be investigated for their *in-planta* antifungal and/or antibacterial growth inhibition capacity.

Furthermore, the whole-genome sequencing (WGS) of selected isolates revealed three new previously unidentified bacterial species. The identification of three new species in a very small number isolates indicates the high potential of the wild halophytic endophytome in terms of identifying new

microbial species with novel capabilities, that could be beneficial for both agriculture (stress tolerance, growth promotion, etc.) and potentially in clinical practice (identification of new antibiotics, antifungal compounds, etc.).

The results from the study of the microbial collection we generated, could be the basis for the future development of various synthetic “bio-inoculants,” as the isolates possess all of the following attributes for such usage: (a) they are not pathogenic and do not induce plant disease; (b) are able to colonize plants, and (c) are culturable, so they can be used in modern agriculture. Furthermore, these isolates can be the basis for future studies, including the investigation of the colonization strategies that these microbes use, as well as, the elucidation of the molecular dialogs that take place during host-root colonization; the growth promotion; the salt tolerance and the immunity activation, by unique beneficial endophytes or artificial endophytic communities.

DATA AVAILABILITY STATEMENT

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article/Supplementary Material.

AUTHOR CONTRIBUTIONS

PS designed the research. CC, GD, AC, EM, AS, GM, and GR performed the research. CC, IL, DS, VC, EM, and PS analyzed the data. CC, EM, DS, VC, and PS wrote the manuscript. All authors have read and approved the manuscript.

FUNDING

This project utilized equipment funded by the Wellcome Trust Institutional Strategic Support Fund (WT097835MF), the Wellcome Trust Multi-User Equipment Award (WT101650MA) and BBSRC LOLA award (BB/K003240/1). This work benefitted from the support of the University of Exeter’s High-Performance Computing (HPC) facility. The project was partially supported by the Emblematic Action of the Greek General Secretariat for Research and Technology, “Agro4Crete,” Protocol Number: SAE 013, Operational Program: SAE 013.

ACKNOWLEDGMENTS

We acknowledge Dr. Karen Moore, Audrey Farbos, Georgina Morris of the Exeter Sequencing Service at University of Exeter, for DNA library preparation and genome sequencing.

Intensive agricultural production utilizes large amounts of nitrogen (N) mineral fertilizers that are applied to the soil to secure high crop yields. Unfortunately, up to 65% of this N fertilizer is not taken up by crops and is lost to the environment. To compensate these issues, growers usually apply more fertilizer than crops actually need, contributing significantly to N pollution and to GHG emissions. In order to combat the need for such large N inputs, a better understanding of nitrogen use efficiency (NUE) and agronomic solutions that increase NUE within crops is required. The application of biostimulants derived from extracts of the brown seaweed *Ascophyllum nodosum* has long been accepted by growers as a sustainable crop production input. However, little is known on how *Ascophyllum nodosum* extracts (ANEs) can influence mechanisms of N uptake and assimilation in crops to allow reduced N application. In this work, a significant increase in nitrate accumulation in *Arabidopsis thaliana* 6 days after applying the novel proprietary biostimulant PSI-362 was observed. Follow-up studies in barley crops revealed that PSI-362 increases NUE by 29.85–60.26% under 75% N input in multi-year field trials. When PSI-362 was incorporated as a coating to the granular N fertilizer calcium ammonium nitrate and applied to barley crop, a coordinated stimulation of N uptake and assimilation markers was observed. A key indicator of biostimulant performance was increased nitrate content in barley shoot tissue 22 days after N fertilizer application (+17.9–72.2%), that was associated with gene upregulation of root nitrate transporters (*NRT1.1*, *NRT2.1*, and *NRT1.5*). Simultaneously, PSI-362 coated fertilizer enhanced nitrate reductase and glutamine synthase activities, while higher content of free amino acids, soluble protein and photosynthetic pigments was measured. These biological changes at stem elongation stage were later translated into enhanced NUE traits in harvested grain. Overall, our results support the agronomic use of this engineered ANE

that allowed a reduction in N fertilizer usage while maintaining or increasing crop yield. The data suggests that it can be part of the solution for the successful implementation of mitigation policies for water quality and GHG emissions from N fertilizer usage.

Keywords: biostimulant, *Ascophyllum nodosum* extract, nitrogen use efficiency, barley, yield, sustainability, GHG emissions

INTRODUCTION

Nitrogen (N) is a critical nutrient to provide optimal growth and yield of all agricultural crops. The invention of the Haber–Bosch process for the production of N and its role in the green revolution during the nineteen sixties led to transformative improvements in crop yields, allowing sustained population growth worldwide. Large amounts of N fertilizer are currently intensively supplemented by growers every season in the form of nitrate (NO_3^-), ammonium (NH_4^+) or urea. The annual global demand for N chemical fertilizers is continuously increasing and is driven by population growth and a global shift toward a more protein-rich diet in developing countries (Lassaletta et al., 2016). Estimated global N containing fertilizer use in 2020 was 110 Mt (IFA, 2019). However, it is also estimated that the energy demanding Haber–Bosch process for the production of N chemical fertilizers consumes 2% of the world's energy supply as fossil fuels, making N fertilizer expensive to produce and representing a relevant cost source for growers (Pfromm, 2017).

Nitrate is the predominant form of N taken up by plants from the soil due to its negative charge and high soil mobility, however most plants also benefit from inclusion of N in the form of ammonium in order to boost their N content (Hachiya and Sakakibara, 2017; Vidal et al., 2020). Crop plants are intrinsically inefficient at accessing applied N. Depending on the crop, agronomy practices and soil type, more than half of the supplemented N fertilizer can be lost to the environment (Raun and Johnson, 1999; White and Brown, 2010; Gutiérrez, 2012; Yan et al., 2020). These losses are not only increasing the cost of production but most importantly are increasing environmental pollution. Nitrogen fertilizers that are not retained in the soil, are washed out and leached to waterways and into groundwater. Nitrogen is an important contributor to eutrophication and water quality (Ascott et al., 2017; Wang et al., 2019). Furthermore, high amounts of greenhouse gas (GHG) emissions are associated with N use, either directly through N fertilizer production (mainly CO_2 and N_2O) or indirectly via emission of nitrous oxide gas (N_2O) by denitrification processes in the soil (Schaufli et al., 2010). Therefore, maintaining high crop yields while decreasing N fertilizer requirements by improving N use efficiency (NUE) in crops is essential to produce sustainable and environment friendly food. The potential economic benefits to growers of using N more efficiently is compelling, an improvement of NUE in crops by 1% could save approximately \$1.1 billion annually (Kant et al., 2011; Kanter et al., 2015).

As a phenotypic trait, NUE is frequently defined by crop breeders/plant scientists as the rate of conversion of N input (e.g., N-fertilizer applied and/or soil N) into total plant biomass or specific plant organ biomass (e.g., grain yield). NUE is an

inherently complex trait because it involves interaction between genetic, environmental and agronomy factors. NUE can be broken down into two different components for a crop: N uptake efficiency (Nupeff) and N utilization efficiency (Nuteff) (Moll et al., 1982; Anbessa and Juskiw, 2012; Hawkesford and Riche, 2020). Nupeff is the ratio of N taken up by the crop compared to what N is available from the soil and/or applied as fertilizer. Nuteff can be calculated as the amount of crop produced per unit of N taken up by the crop. The plant biological processes responsible for NUE include: N uptake, N transport, N assimilation, N translocation and recycling when the plant or its organs are aging. Each step is tightly controlled at gene transcriptional, translational, and post-translational level and includes low and high-affinity N transporters (Noguero and Lacombe, 2016; Hachiya and Sakakibara, 2017; Wang et al., 2018; Vidal et al., 2020) along with enzymes related to N assimilation pathways such as nitrate reductase (NR), glutamate synthase (GOGAT), and glutamine synthetase (GS) (Tischner, 2000; Masclaux-Daubresse et al., 2010; Pratelli and Pilot, 2014; Hirel and Krapp, 2020).

Approaches for increasing NUE for crops includes selective plant breeding, genetic modification, soil management and fertilizer technologies/management. Breeding programs to obtain high grain yielding varieties growing under contrasting/reduced N regimes have focused on traits such as bigger root length or surface area, larger above-ground biomass, higher grain harvest index or enhanced photosynthetic capacity (Anbessa and Juskiw, 2012; Prey et al., 2019; Vicente et al., 2019; Voss-Fels et al., 2019). Genetic modification techniques have produced new varieties of some crops able to increase biomass and seed yield under reduced N inputs through manipulation of genes for N uptake and transport (Fang et al., 2013; Han et al., 2016; Wang et al., 2018; Li et al., 2020), N assimilation (Perchlik and Tegeder, 2017; James et al., 2018; Gao et al., 2019) and N remobilization (Chen et al., 2020). However, it is important to note that these new varieties have been mainly developed in pot or hydroponic systems and have not been validated in field conditions (Masclaux-Daubresse et al., 2010; Wang et al., 2018). The potential impact of novel fertilizer technologies such as urease and nitrification inhibitors or slow-release fertilizer coatings to enhance NUE and/or mitigate GHG emissions have been intensively studied over the last years, showing promising results. However, specific NUE data is limited and should be interpreted cautiously as only a few studies included reduced N rates in the trial designs (Snyder, 2017; Rose et al., 2018; Dimkpa et al., 2020).

The new EU Fertilising Products Regulation, which entered into force on 15 July 2019, establishes plant biostimulants as a separate category of fertilizers that are defined by their ability to

improve nutrient use efficiency, tolerance to abiotic stress and/or quality traits regardless of their nutrient content (EU Regulation 2019/1009, 2019). Plant biostimulants have gained significant attention from scientists, the agroindustry, and growers over recent years as more sustainable solutions for crop production are sought (Du Jardin, 2015; Rouphael and Colla, 2020). Globally, the biostimulant market accounted for \$3.19 billion in 2019 and is expected to reach \$9.22 billion by 2027, growing at a CAGR of 14.2% during the forecast period (Research and Markets, 2020). Biostimulants made using extracts from the brown seaweed *Ascophyllum nodosum* (ANE) are accepted as effective and robust products (Yakhin et al., 2017; Shukla et al., 2019). A number of publications have demonstrated that ANE biostimulants improve fruit quality (Frioni et al., 2018), reduce pod shattering (Łangowski et al., 2019), enhance tolerance to abiotic stresses (Goñi et al., 2018; Carmody et al., 2020) and improve nutrient uptake in diverse crops (Turan and Köse, 2004; Jannin et al., 2013; Billard et al., 2014; Sabir, 2014; Stamatiadis et al., 2015; Frioni et al., 2018; Laurent et al., 2020). However, little is known on how ANEs can influence mechanisms of N uptake and assimilation in crops under reduced N conditions. The integration of biostimulants with current crop husbandry practices to enhance NUE may present challenges (i.e., method of application, timing, rates, etc.) in some production systems. These challenges can be overcome with a consistent and positive yield response trend in field conditions, economic/environmental justification for their use and acceptance by relevant stakeholders of the supporting scientific evidence on the effectiveness of the technology.

In this study, we investigated the potential of an ANE based biostimulant, PSI-362, to increase NUE in barley crops under reduced N input in multi year field trials. The method of application of the biostimulant as a foliar spray or top dressing was also investigated. In order to assess the impact on NUE, well-established N uptake and assimilation plant parameters at phenotypical, metabolic, enzymatic, and molecular level were evaluated in the model plant *Arabidopsis thaliana* and barley crop. Overall, the results support the agronomic use of this engineered ANE that allowed a 25% reduction in N fertilizer usage while maintaining or increasing crop yield.

MATERIALS AND METHODS

Materials

ANE biostimulant containing the PSI-362 biomolecule complex was provided by Brandon Bioscience (Tralee, Ireland). The compositional characterization of PSI-362 was performed according to Carmody et al. (2020) and consisted of ash (43.7% w/w dry), carbohydrates (26.0% w/w dry), polyphenols (12.3% w/w dry) and other organic components (18% w/w dry). The N:P:K macronutrient content of PSI-362 was 0.4:0.1:8.0% w/v. Commercially available granular CAN + S (27% w/w N; 4% w/w S) was kindly provided by Target Fertilisers (Enniscorthy, Ireland). CAN + S was coated with PSI-362 biomolecule complex using standard fertilizer coating technology. All chemical reagents used for the biochemical assays were purchased from Sigma-Aldrich (Arklow, Ireland) and Bio-Rad (Watford,

United Kingdom). Phytostrip tubes were purchased from 4titude Ltd. (Wotton, United Kingdom). The primers were purchased from Eurofins Genomics (Ebersberg, Germany).

Evaluation of PSI-362 in *Arabidopsis thaliana* Seedlings

An initial evaluation of the ability of PSI-362 to improve NUE and nitrate content was carried out using *Arabidopsis thaliana* (Col-0) seedlings. This experiment was based on a high throughput root microphenotyping platform published previously (Vasilieva et al., 2021). *Arabidopsis* seeds were sterilized and grown on Phytostrip tubes filled with a sterile solid medium and inserted into 96-well plates (six seeds per tube). This medium contained Phytigel, sucrose, ammonium nitrate as N source, magnesium chloride and calcium chloride. Once *Arabidopsis* seeds germinated, a liquid nutrient medium based on Gamborg's B-5 (B5) medium was added to the wells. Seedlings were subjected to two different N conditions by the selective addition of ammonium nitrate to this liquid medium (2.66 and 13.33 mM, respectively). PSI-362 was applied as biostimulant treatment to the same liquid medium under low and high N conditions at 0.04% w/v per well. Distilled water was applied as an untreated control. *Arabidopsis* seedlings grew for 6 days at a temperature of 22/21°C (day/night; 16/8 h) and 70% relative humidity (RH) under a light intensity of 100 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$. After this time period, *Arabidopsis* seedling tissue was collected to determine nitrate content as described in Section "Measurement of N Metabolites, Free Amino Acids, and Soluble Protein."

Experimental Design of Barley Pot Trial

The pot experiments were performed in a cultivation room under controlled conditions (19/14°C with 16 h of light and 8 h of darkness and $80 \pm 5\%$ RH under a light intensity of 120 $\mu\text{mol}\cdot\text{m}^{-2}\cdot\text{s}^{-1}$). Winter barley plants (cv. Towers; **Supplementary Table 1**) were grown in pots with a capacity of 2 L filled with a model soil prepared by mixing one part of sand and two parts of coarse loamy soil from field trials area described in Section "Experimental Design of Field Trials With PSI-362 Applied as Foliar Spray" (bulk density 1.41 $\text{g}\cdot\text{cm}^{-3}$, pH 6.1, 33.60 $\text{g}\cdot\text{kg}^{-1}$ DW organic matter, 2.50 $\text{g}\cdot\text{kg}^{-1}$ DW total N, 230.77 $\text{g}\cdot\text{kg}^{-1}$ amino sugar-N, 2.59 $\text{mg}\cdot\text{kg}^{-1}$ DW available P, and 63.36 $\text{mg}\cdot\text{kg}^{-1}$ DW available K). Soil N, P, and K index was defined as 1, 1, and 2, respectively (Teagasc, 2015). Experiments were performed in three independent pots per treatment, with 20 plants per pot. Barley seeds were sown at a depth of 3 cm and plants were irrigated with 1 liter of water per pot every 3 days in order to create equal soil moisture conditions in all pots. Temperature and relative moisture content were recorded regularly with a portable USB data logger (EBI300 TH, Ebro Electronic). The experiment was completed for three different treatments: (1) untreated control fertilized with CAN + S; (2) treated with PSI-362 foliar spray and fertilized with CAN + S; (3) treated with CAN coated with PSI-362. Granular N fertilizer addition (CAN or coated CAN with PSI-362) was added to 7-day-old plants (growth stage GS12-14) on the soil surface at a rate

of 67 kg N·ha⁻¹ (75% of recommended N at this growth stage). Treated plants with foliar spray received the same amount of PSI-362 as those that were treated with the coated fertilizer. The barley plants were harvested 14 days after receiving treatments (growth stage GS22-23). The root and the above ground parts of the plants were washed and dried at 100°C for 24 h to determine both fresh weight (FW) and dry weight (DW). The efficiency of the conversion of added inorganic N into total plant dry matter (DM) was calculated per independent pot:

$$NUE_{plant} = DM_{plant}/N_{fertilized}$$

Experimental Design of Field Trials With PSI-362 Applied as Foliar Spray

We initially investigated the effect of PSI-362 applied by foliar spray on grain yield and NUE in recommended spring and winter barley varieties (**Supplementary Table 1**) growing under reduced N fertilizer rate (75%) and compared to standard grower practice (100% N). These open-field experiments were conducted in Tralee, Co. Kerry, Ireland (52° 16' N, 9° 41' W and 16 m altitude) during the 2016, 2017, and 2018 growing seasons. The climate is classified as temperate oceanic (Cfb) according the Köppen climate classification. The average minimum, maximum and mean temperatures of 9.9°C, 18.2°C, and 14.1°C, and a mean monthly accumulated precipitation of 63.0 mm was recorded during the field trial period. The soil type was coarse loamy, and the previous crop grown in the field trial site was grass. Soil characteristics were evaluated every season and representative samples were collected in a W shaped pattern across the sampling area. Soil bulk density was measured with a volumetric cylinder, soil pH was measured in buffer pH 4–10 to also estimate the lime requirements, organic matter content was determined gravimetrically after burning the sample at 440°C for 12 h, total N evaluation was carried out using the Kjeldahl method, amino sugar quantification was performed using the Illinois test, and available K and P were extracted through the Morgan method and quantified by ICP-MS and spectrophotometry, respectively. The obtained values for these trials were: bulk density 1.22 g·cm⁻³, pH 5.6–6.1, 43.10–49.50 g·kg⁻¹ DW organic matter, 3.40–4.10 g·kg⁻¹ DW total N, 305–388 g·kg⁻¹ amino sugar-N, 2.98–3.92 mg·kg⁻¹ DW available P, and 78.20–92.50 mg·kg⁻¹ DW available K. Soil N, P, and K index was defined as 1, 2, and 2, respectively (Teagasc, 2015). Every year, the field trials area was rotated to overcome any carryover effects from the previous year.

Two spring and one winter barley varieties (cv. KWS Irina, cv. Mickle, and cv. KWS Towers; **Supplementary Table 1**) were sown by mechanic drilling at a seed rate of 180–190 and 150–160 kg·ha⁻¹ between March–April and October, respectively. The experimental design was the same for all field trials sites: a randomized complete block with five replicates and experimental units (plots) measuring 3 m × 5 m (15 m²). N fertilization was designed to follow conventional farming practices in Ireland according to the Agriculture and Food Development Authority (Teagasc) recommendations (Teagasc, 2015). A quantity of 155 and 117 kg N·ha⁻¹ was supplied in two applications for spring barley growing under 100% N rate and 75% N rate, respectively.

200 and 150 kg N·ha⁻¹ was supplied in four applications for winter barley growing under 100% and 75% N rate, respectively. Barley crops were treated three times by foliar spray with PSI-362 (1 L·ha⁻¹) at mid tillering stage (GS22-27), at early stem elongation stage (GS30-31), and at the start of the booting stage (GS41-43). Water was sprayed as a control in the untreated plants. A central 1 m² area from the plots was harvested manually at barley maturity (GS92) and processed by a cereal threshing machine. Grain yield was measured for each plot and corrected to a standard moisture of 20%. Additional information of the grower program for spring and winter barley trials can be found in **Supplementary Tables 2, 3**, respectively.

Experimental Design of Field Trials With PSI-362 Coated Fertilizer

In the 2019 growing season, the effect of PSI-362 coated CAN + S fertilizer on spring barley (cv. Gangway) was evaluated in two independent open-field trials under different reduced N fertilizer rates (73% and 88%) and compared to standard grower practice (100% N). Field 1 was laid out in Ardfert, Co. Kerry, Ireland (52° 22' N, 9° 45' W and 16 m altitude) from April 2 to August 28, 2019. Field 2 was conducted in Courtnacuddy, Co. Wexford, Ireland (52° 28' N, 6° 42' W and 82 m altitude) from April 1 to August 19, 2019. The climate for both locations is classified as temperate oceanic (Cfb) according the Köppen climate classification. The average minimum, maximum, and mean temperatures of 7.9°C, 15.4°C, and 11.7°C, and a mean monthly accumulated precipitation of 78.21 mm was recorded during the field 1 trial period. The field 2 trial period was characterized by an average minimum, maximum and mean temperatures of 6.7°C, 14.6°C, and 10.8°C, and a mean monthly accumulated precipitation of 90.73 mm. The field 1 soil type was coarse loamy, and the previous crop rotation was potato. The field 2 soil type was clay loam, and spring barley was grown in the previous rotation. Soil chemical characteristics for both fields were evaluated before sowing and after harvesting according to the same methodology described in Section “Experimental Design of Barley Pot Trial” (**Supplementary Tables 4, 5**). For both fields, soil N, P, and K index was defined as 1, 4, and 4, respectively (Teagasc, 2015).

Barley was sown at the beginning of April by mechanical drilling at a seed rate of 190 and 140 kg·ha⁻¹ for field 1 and 2, respectively. Split plot design was used for both field trials and the average area of each condition (control 100% N or PSI-362 treated reduced N fertilizer) was 1.25 and 6.10 ha for field 1 and field 2, respectively. A quantity of 140.6 and 102.8 kg N·ha⁻¹ was supplied in two applications for field 1 under untreated 100% N rate and PSI-362 treated 73% N rate, respectively. A common first application of NPK 10-10-20 (380 kg·ha⁻¹) was added first to both conditions on sowing. A second application with CAN + S (380 kg·ha⁻¹) and PSI-362 coated CAN + S (240 kg·ha⁻¹) was applied on untreated and treated plants at mid tillering stage (GS22-27), respectively. Regarding field 2, 158.1 and 140.5 kg N·ha⁻¹ was supplied in two applications for untreated 100% N rate and PSI-362 treated 88% N rate, respectively. An

initial application of NPK 22-8-0 (375 kg·ha⁻¹) added in the seedbed to both conditions was followed by a second application with CAN + S (280 kg·ha⁻¹) and PSI-362 coated CAN + S (215 kg·ha⁻¹) to untreated and treated plants at mid tillering stage (GS22-27), respectively. Additional information of the grower program for both trials can be found in **Supplementary Table 6**.

Shoot and root tissue from untreated and treated fields were sampled and phenotypically evaluated 22 days after the second fertilizer application in plants at early stem elongation stage (GS30-31). The samples were snap-frozen in liquid nitrogen, ground and kept in -80°C until further biochemical, enzymatic and gene expression analysis. Field 1 was manually harvested at growth stage GS92 using at least six independent 1 m² plots and grain was processed through a cereal trashing machine. Field 2 was harvested at the same maturity stage using a combine harvester. Before grain harvest from each plot, whole plant samples were collected for further phenotypical determination.

Plant and Grain Measurements of Field Trials With PSI-362 Coated Fertilizer

Barley plants were harvested at 22 days after second fertilizer application (stage GS30-31) and at grain maturity (GS92). The number of plant tillers was also counted. Plants at early stem elongation stage (GS30-31) were divided into roots and shoots and FW was measured. Plant DW was determined by drying these fresh samples in a convection oven for 24 h at 100°C. Plants harvested at maturity stage (GS92) were divided into roots, grains, remaining ears (glumes and beards), and remaining shoots (stems and leaves) and dried for 72 h at 50°C before biomass determination. Obtained values were expressed at 20% moisture. The harvest index was calculated as the grain biomass divided by the above-ground plant biomass. Grain yield was determined from the harvested and trashed plots, corrected to a standard moisture of 20%, and extrapolated t·ha⁻¹. A random grain subsample from each plot was used to determine the thousand-grain weight (TGW). N content was determined in grain samples at 20% moisture through the Kjeldahl method and grain protein content was calculated by multiplying the N content by the barley-specific protein factor of 5.83 (Mariotti et al., 2008). Total P content was determined from the same grain digest samples of the Kjeldahl method through the molybdo vanadate method. Total K content was determined in grain after nitric acid extraction and further evaluation by atomic emission spectroscopy.

Calculation of NUE and Its Components for Field Trials

NUE_{grain} was calculated as the yield of grain produced per unit of N fertilizer and expressed as kg grain per kg N fertilizer:

$$NUE_{grain} = \text{Grain yield} / N_{fertilized}$$

Grain N uptake efficiency (Nu_{eff}^{grain}) was calculated as the grain N uptake (Nu_{p}^{grain}) in relation to the quantity of fertilizer and expressed as kg N available in grain per kg N fertilizer.

Nu_{p}^{grain} was calculated by multiplying its nitrogen content (N%) by grain yield at 20% moisture:

$$Nu_{eff}^{grain} = Nu_{p}^{grain} / N_{fertilized} = (\text{Grain yield} \times (N\%)_{grain}) / N_{fertilized}$$

Grain N utilization efficiency (Nu_{eff}^{grain}) was calculated as the amount of grain produced per Nu_{p}^{grain} and expressed as kg grain per kg N available in grain:

$$Nu_{eff}^{grain} = \text{Grain yield} / Nu_{p}^{grain} = \text{Grain yield} / (\text{Grain yield} \times (N\%)_{grain})$$

The soil N component was not considered for the calculation of NUE traits as per the methodology suggested by Prey et al. (2019).

Greenhouse gas emissions from field trials with PSI-362 coated fertilizer were estimated using a carbon footprint decision support tool for spring barley (AHDB, 2012) and expressed as kilograms of carbon dioxide equivalent (kgCO₂e) per hectare. The information required to calculate this carbon footprint was taken from field trial records (crop and soil type, grain yield and moisture, fertilizer rate, crop protection inputs, crop residue management, field energy use, and grain drying). PSI-362 manufacture carbon footprint was also included in the estimation for treated crops.

Measurement of N Metabolites, Free Amino Acids, and Soluble Protein

Nitrate content was determined in Arabidopsis seedlings and barley shoot tissue according to nitration of salicylic acid under acidic conditions as described by Hachiya and Okamoto (2017) and quantified as mg·g⁻¹ DW. Free amino acids and ammonium extraction was performed by mixing 40 mg of barley shoot tissue with 800 µl of ethanol 70% (v/v), kept overnight at 4°C under dark and centrifuged at 20,000 × g for 10 min at 4°C. These supernatants were first used for the estimation of total free amino acids content using ninhydrin reagent. 100 µl of supernatant was mixed with 75 µl of reaction mixture [8% (w/v) ninhydrin in acetone] and incubated for 30 min at 80°C. After cooling at room temperature, 100 µl of ethanol 50% (v/v) was added and the absorbance was measured at 570 nm. After preparing a calibration standard curve with glutamic acid, total free amino acids content was expressed as mg·g⁻¹ DW. Individual free amino acids and ammonium content was evaluated in the same extracts through a reversed phase high performance liquid chromatography (RP-HPLC) and UV detection at 280 and 300 nm of the aminoenones formed by the reaction of amino acids and ammonia with the derivatization reagent diethyl ethoxymethylenemalonate (DEEMM) (Gómez-Alonso et al., 2007). Compounds were identified by comparison of retention time to that of commercial standards, quantified by peak integration and expressed as mg·g⁻¹ DW. Soluble protein content was measured from the extracts used for the NR and GS enzymatic assays (see section “NR and GS Activity Assays”) through the modified version of the Bradford method in a 96

well plate using a protein-dye reagent (Bio-Rad) and expressed as $\text{mg} \cdot \text{g}^{-1} \text{ DW}$.

Measurement of Photosynthetic Pigments

Photosynthetic pigments from collected barley shoot tissue (chlorophyll a, chlorophyll b and carotenoids) were extracted by homogenizing 40 mg of shoot tissue with 1 ml of acetone 80% (v/v). After incubation for 5 h at 4°C, samples were centrifuged at $20,000 \times g$ for 10 min at 4°C. The supernatants were collected and diluted with acetone 80% (v/v) before measuring the absorbance at 470, 647 and 663 nm. Empirical equations described by Lichtenthaler and Buschmann (2001) for total chlorophylls (chlorophyll a + chlorophyll b) and carotenoids concentrations were used and results were expressed as $\text{mg} \cdot \text{g}^{-1} \text{ DW}$.

NR and GS Activity Assays

For the extraction of NR and GS, frozen ground barley shoot tissue was homogenized in the extraction buffer [50 mM HEPES-KOH (pH 7.5), 10% glycerol (v/v), 2% (w/v) PVPP, 2 mM DTT, 1/300 dilution protease inhibitor cocktail P9599 (Sigma-Aldrich)] for 2 h at 4°C, followed by centrifugation at $20,000 \times g$ for 20 min at 4°C. NR activity was measured in the obtained protein extracts in the absence of MgCl_2 (total activity) and in the presence of MgCl_2 (actual activity). The reaction was incubated for 45 min at 30°C after the addition of 60 μl of protein extract to 340 μl of reaction buffer containing 50 mM HEPES-KOH (pH 7.5), 10 mM KNO_3 , 5 mM EDTA (total activity) or 5 mM MgCl_2 (actual activity), 10 mM FAD, 1 mM DTT, and 0.2 mM NADH. The reaction was stopped by adding 120 μl of 0.6 M zinc acetate and the samples were centrifuged at $25,000 \times g$ for 5 min. The amount of produced nitrite was determined spectrophotometrically at 540 nm according Hachiya and Okamoto (2017) and NR activity was expressed as $\text{nmol NO}_2^- \cdot \text{h}^{-1} \cdot \text{mg}^{-1} \text{ protein}$. The activation state of NR was defined as the activity measured in the presence of 5 mM MgCl_2 divided by the activity measured in the presence of 5 mM EDTA (expressed as a percentage). GS was determined by incubating 60 μl of protein extract with 120 μl of reaction buffer (50 mM Tris-HCl (pH 7.5), 20 mM MgSO_4 , 4 mM EDTA, 80 mM sodium glutamate, 6 mM hydroxylamine, and 8 mM ATP) for 60 min at 30°C. The reaction was stopped by adding 180 μl of 0.122 M FeCl_3 , 0.5 M TCA, and 2 M HCl and the samples were centrifuged at $16,000 \times g$ for 10 min at 4°C. The absorbance of γ -glutamylmonohydroxamate (γ -GHM) in the supernatant was measured at 560 nm, with γ -GHM used as the standard for the calibration curve. GS activity was expressed as $\mu\text{mol } \gamma\text{-GHM} \cdot \text{h}^{-1} \cdot \text{mg}^{-1} \text{ protein}$.

RNA Extraction and RT-qPCR

Total RNA was isolated from frozen ground barley root tissue harvested in field 1 by Plant/Fungi Total RNA Purification Kit (Norgen Biotek, Canada) following the manufacturer's instructions. RNA was treated with RNase-Free DNase I Kit (Norgen Biotek, Canada) in order to remove efficiently

genomic DNA contamination. RNA concentration and purity was measured using Qubit (Thermo Fisher Scientific). Expression analysis of *HvNRT1.1* (*HORVU7Hr1G071600*), *HvNRT2.1* (*HORVU6Hr1G005590.1*), and *HvNRT1.5* (*HORVU6Hr1G070450.3*) genes was performed by RT-qPCR using a Roche LightCycler® 96 System (Roche, United Kingdom) and a LightCycler® RNA Master SYBR Green I one-step kit (Roche, United Kingdom) according to the manufacturer's instructions. The expression level of the barley *HvUBC9* (*HORVU5Hr1G088270*) gene was used as the reference. The $2^{-\Delta\Delta CT}$ method was used to quantify relative normalized gene expression levels. The primers sequences used are shown in **Supplementary Table 7**.

Statistical Analysis

Nitrate assessment in Arabidopsis seedlings was performed in at least four independent biological replicates per treatment and N condition (12 technical replicates per biological replicate). Phenotypic and NUE assessment of the barley pot trial was done in three independent pots, with 20 plants per pot. Grain yield, TGW, grain N content measurement, calculation of NUE derived traits, and GHG emissions was done in at least four independent biological replicates per treatment and variety. Soil characterization was performed in three independent replicates. Phenotype assessment in barley plants from field trials was carried out in at least 60 independent biological replicates. Shoot samples collected from barley plants at stage GS30-32 were pooled for further analysis. For biochemical and enzymatic analysis, at least four biological replicates of each treatment were performed, using three technical replicates per biological replicate. For gene expression analysis, at least three biological replicates of each treatment were performed, using three technical replicates per biological replicate. Statistics were evaluated with Sigma Plot 12 and Statgraphics Centurion XVI software. The differences between control and PSI-362 treatment for every field trial were analyzed using *t*-test at $p \leq 0.05$. The effect of different treatments on the barley pot trial was analyzed with the one-way analysis of variance (ANOVA) by Tukey's HSD test at $p \leq 0.05$. Arabidopsis nitrate data were compared by using two-way ANOVA, with Tukey's HSD test at $p \leq 0.05$. The application of all parametric tests was performed after checking the data normality (Shapiro-Wilk's test) and equal variance assumptions. Unless stated otherwise, all data are expressed as average \pm standard error (SE). Details of the individual sample size for each analysis and statistical test used is mentioned in the tables and figure legends.

RESULTS

Effect of PSI-362 in Nitrate Content of Arabidopsis Seedlings Under Different N Levels

The effect of PSI-362 was first evaluated in seedlings of the model plant *Arabidopsis thaliana* using a high throughput root microphenotyping platform. When a two-way ANOVA test was

run, it was found that all three parameters (N level, PSI-362 treatment and N level \times PSI-362 treatment) were statistically significant for nitrate content (**Figure 1**). Therefore, all data were subjected to *t*-test, comparing PSI-362 versus control effect under low and high N levels (2.66 and 13.33 mM of ammonium nitrate, respectively). While the different N amount added to untreated seedlings had a remarkable effect on nitrate content (low N: 2.69 mg·g⁻¹ DW vs. high N: 26.46 mg·g⁻¹ DW), our results also showed that PSI-362 applied through the root significantly increased this parameter by 11.92% ($p = 0.049$) and 6.85% ($p = 0.420$) compared to the low and high N control, respectively (**Figure 1**). It would suggest that PSI-362 can improve capacity for nitrate uptake in *Arabidopsis* under controlled conditions in the N range tested, but with the best performance at the lowest N rate.

Effect of PSI-362 Mode of Application on Pot Experiments in Barley

Granular CAN + S fertilizer was coated with PSI-362 and its biostimulant effect on plant biomass and NUE_{plant} was compared with the same amount of PSI-362 applied by a single foliar spray in a winter barley pot trial. As can be observed in **Figure 2**, regardless of the method of application, both PSI-362 treatments significantly increased plant biomass between 13.88 and 16.67% compared to untreated plants fertilized with the same amount of N ($p \leq 0.05$). The measured phenotypic change also demonstrated a superior NUE_{plant} for barley plants treated with either PSI-362 coated fertilizer (+15.03%) or foliar PSI-362 (+17.19%), indicating that bioactive molecules from PSI-362 can be easily released from CAN + S granules and stimulate the plants through their root system to utilize N fertilizer more efficiently.

Effect of PSI-362 Applied by Foliar Spray on Barley Yield and NUE

Three 1L/Ha foliar applications of PSI-362 (at tillering, stem elongation and booting stage) on recommended spring and winter barley varieties growing under reduced N fertilizer rate (75%) resulted in no difference or significantly higher grain yield for 5 out of 5 field trials performed during 2016 to 2018 compared to plants growing under the recommended rate in standard agricultural practice ($p \leq 0.05$) (**Figure 3**). Overall, PSI-362 treated barley varieties showed a statistically significant 3-year average yield increase of 5.57% ($p = 0.011$) using 25% less N. Similarly, the NUE_{grain} of the PSI-362 treatments was 29.85–60.26% higher than those of the control conditions ($p \leq 0.05$) (**Supplementary Table 8**). The data demonstrates the ability of PSI-362 to deliver yield with a 25% reduction of N mineral fertilizer, significantly enhancing the amount of barley grain per unit of N supplied under field conditions.

Effect of PSI-362 Coated Fertilizer on Vegetative Parameters at Early Stem Elongation Stage

In order to explore the effect of PSI-362 coated fertilizer on vegetative traits in spring barley, a comparative phenotypical analysis was performed on plants harvested at 22 days after the second fertilizer application (stage GS30-31). This analysis was

performed on two independent field trials characterized by a different reduction of N fertilizer rate. Barley plants treated with PSI-362 coated fertilizer from field 1 (73% N) increased their shoot FW, root FW, root DW and number of tillers per plant by 6.91, 10.79, 21.05% and 9.45% compared to 100% N control, but these changes were not statistically significant ($p > 0.05$). While the effect of PSI-362 coated fertilizer in field 2 (88% N) was not statistically significant either, the mean values of shoot DW, root FW and root DW showed a similar increasing trend compared to the untreated plants (+14.11, +6.56, and +16.43%, respectively) (**Table 1**).

Effect of PSI-362 Coated Fertilizer on N Uptake, Metabolic and Molecular Parameters

The PSI-362 coated fertilizer was applied at mid tillering stage (GS22-27), just before the stem elongation phase (GS30-39), which is the most important timing on spring barley for N uptake (Teagasc, 2015). In order to assess the long term impact of the biostimulant on N uptake and assimilation parameters, a metabolic analysis of shoot samples collected 22 days after application was performed. N uptake in control and treated plants at stage GS30-31 was evaluated through the measurement of shoot nitrate content. Plants treated with PSI-362 coated fertilizer significantly increased this parameter in field 1 (+17.87%, $p = 0.046$) and field 2 (+72.23%, $p \leq 0.001$) compared to control plants growing under 100% N rate (**Table 2**). To provide some insights on the effect of PSI-362 coated fertilizer on N uptake mechanisms, the relative gene expression levels of three major nitrate transporters, namely *NRT1.1* and *NRT2.1*, both expressed in epidermal and cortical cells, and *NRT1.5*, expressed in root pericycle cells were measured (Vidal et al., 2020). The root tissue of barley plants at stage GS30-31 was collected from plants of field 1, which had a similar N fertilizer program as the field trials performed between 2016 and 2018. The application of PSI-362 coated fertilizer caused a significant upregulation within *NRT1.1*, *NRT2.1*, and *NRT1.5* expression levels by 1.77-, 1.72-, and 1.21-fold with respect to the 100% N control ($p \leq 0.001$), suggesting increased root capacity for nitrate uptake and transport in barley crop under field conditions (**Figure 4**).

Effect of PSI-362 Coated Fertilizer on N Assimilation Metabolic Parameters

In order to assess the impact of PSI-362 coated fertilizer 22 days after application on well-known N assimilation parameters, a metabolic analysis of shoot samples from control and treated plants at early stem elongation stage (GS31-32) was performed. While reduced N fertilizer levels decreased shoot ammonium content in treated plants from field 1 (−15.56%, $p = 0.044$) and field 2 (−20.89%, $p = 0.015$), an opposite trend was observed in the content of total free amino acids. The effect of PSI-362 coated fertilizer on this N-assimilation parameter was consistent. Treated plants from field 1 and field 2 growing under 73 and 88% N fertilization levels, respectively, had significantly increased total free amino acid content in shoot tissue by 23.25% ($p = 0.021$)

FIGURE 1 | Nitrate content in Arabidopsis seedlings. The effect of PSI-362 added by root application to Arabidopsis seedlings growing under low and high N levels (2.66 and 13.33 mM ammonium nitrate, respectively) was evaluated 6 days after application. Since interaction AxB was significant ($***p \leq 0.001$), data were subjected to *t*-test, comparing PSI-362 treatment versus control within the same N level. In this case, means followed by asterisk indicate statistically significant differences between control and PSI-362 treatment within the same N level ($*p \leq 0.05$). Number of biological replicates ($n \geq 4$).

	Control	PSI-362 foliar	PSI-362 coated CAN+S
Biomass (g FW·plant ⁻¹)	0.72 ± 0.02 a	0.84 ± 0.02 b	0.82 ± 0.02 b
NUE _{plant} (g DW·g ⁻¹ N)	12.04 ± 0.42 a	14.11 ± 0.57 b	13.85 ± 0.48 b

FIGURE 2 | Effect of PSI-362 treatment applied by foliar spray or coated with CAN + S fertilizer on plant biomass and NUE of winter barley (cv. Towers). A pot trial was performed to evaluate if the application mode of PSI-362 (foliar spray or coated with N mineral fertilizer) affected differently to barley growth and compared with an untreated control. Fertilizer (CAN + S) and PSI-362 biostimulant were added to plants at 2–3 leaf stage (GS12–13) at the same time. The dose of PSI-362 applied by foliar spray or coating was exactly the same and control plants were sprayed with distilled water. The phenotypical assessment was performed 14 days after fertilizer/PSI-362 treatment application. Means followed by different small letter within the same row indicate significant differences between treatments based on one-way ANOVA Tukey's HSD test at $p \leq 0.05$. Number of biological replicates (plant biomass, $n = 60$; NUE, $n = 3$).

and 22.71% ($p = 0.050$) compared to the untreated shoots (Table 2). Glutamate was the major component of the free amino acids pool, together with glutamine, aspartate, asparagine, alanine, and serine. PSI-362 coated fertilizer strongly affected glutamate, increasing it to 18.95% ($p = 0.006$) and 46.84% ($p \leq 0.001$) of the control values in shoot tissue of field 1 and field 2, respectively. This biostimulant treatment had a similar effect on glutamine, another key N metabolite that has an important role as amino group donor to form other amino acids, with a

significant increase of 29.33 and 153.30% ($p \leq 0.001$) in PSI-362 treated plants. Aspartate increased by 28.04% ($p = 0.005$) and 112.87% ($p \leq 0.001$) in treated shoots from field 1 and field 2, respectively; while asparagine only showed a significant 4.3-fold increase ($p \leq 0.001$) in treated plants from field 2. The results in Table 2 also demonstrated that in barley plants treated with PSI-362 coated fertilizer the endogenous proline content increased significantly in both fields compared to 100% N control (+16.41–20.16%; $p \leq 0.05$). This same stimulating

FIGURE 3 | Effect of foliar PSI-362 treatment on grain yield of spring and winter barley varieties growing under 75% N fertilizer rate in 3 consecutive seasons (2016–2018). PSI-362 was applied three times by foliar spray at mid tillering stage (GS22–27), early stem elongation stage (GS30–31), and at the start of the booting stage (GS41–43), and its performance was benchmarked against untreated plants growing under 100% N fertilizer rate. SB1, spring barley cv. KWS Irina; WB1, winter barley cv. KWS Towers; SB2, spring barley cv. Mickle. Chart represents grain yield ($\text{t}\cdot\text{ha}^{-1}$) expressed at 20% moisture. Means followed by asterisk indicate statistically significant differences between control and PSI-362 treatment within the same field trial based on t -test at $p \leq 0.05$. The horizontal dashed lines represent the average yield value for untreated 100% N ($6.24 \text{ t}\cdot\text{ha}^{-1}$) and foliar PSI-362 75% N ($6.57 \text{ t}\cdot\text{ha}^{-1}$). Number of plots harvested per field trial ($n \geq 5$).

TABLE 1 | Effect of PSI-362 coated CAN + S fertilizer on phenotypic parameters in barley crop (cv. Gangway) 22 days after application.

Parameter ¹	Field 1		Field 2	
	Control 100% N	PSI-362 coated 73% N	Control 100% N	PSI-362 coated 88% N
Shoot FW (g plant^{-1})	5.26 ± 0.26	5.62 ± 0.76	5.74 ± 0.32	6.55 ± 0.08
Shoot DW (g plant^{-1})	0.57 ± 0.03	0.54 ± 0.07	0.54 ± 0.02	0.57 ± 0.01
Root FW (g plant^{-1})	0.64 ± 0.06	0.71 ± 0.10	0.41 ± 0.02	0.43 ± 0.02
Root DW (g plant^{-1})	0.13 ± 0.01	0.16 ± 0.02	0.08 ± 0.01	0.10 ± 0.01
Number tillers per plant	4.23 ± 0.47	4.63 ± 0.68	4.83 ± 0.16	4.84 ± 0.24

¹Data are the means \pm SE. Number of biological replicates ($n = 30$). No statistically significant differences between control and treated sample at $p \leq 0.05$ were observed (t -test).

effect by coated PSI-362 fertilizer under reduced N rate was also observed for alanine (+12.83–14.61%), serine (+2.94–18.12%), glycine (+7.70–55.15%), and essential amino acids such as methionine (+8.07–37.90%), lysine (+12.19–19.20%), and threonine (+14.27–80.48%) content.

The ability of PSI-362 coated fertilizer to influence N assimilation early in the stem elongation stage was also evaluated through the measurement of soluble protein and photosynthetic pigments content in shoot tissue (Table 2). Higher protein content in shoot tissue relative to 100% N control were observed for barley plants fertilized with PSI-362 coated CAN + S at 73% N (+24.86, $p \leq 0.001$) and 88% N (+21.84, $p \leq 0.001$) rate. Accumulation of both chlorophylls (a + b) was similarly affected in treated plants, increasing by 36.24% ($p = 0.003$) and 30.28% ($p = 0.050$) in field 1 and field 2, respectively. Finally, this ANE biostimulant also induced a statistically significant accumulation of carotenoids in the shoots of barley plants growing with reduced N (+40.50–60.92%).

Effect of PSI-362 Coated Fertilizer on NR and GS Activity

Total NR activity in barley shoots of control plants growing under 100% N rate was very similar for both field 1 and field 2 (15.69 and $17.94 \text{ nmol NO}_2^- \cdot \text{h}^{-1} \cdot \text{mg}^{-1}$ protein, respectively) (Figure 5). As expected, actual NR activity in presence of MgCl_2 was lower and the calculated activation state for untreated plants ranged between 60.91% (field 1) and 50.92% (field 2). While the application of PSI-362 coated fertilizer led to a significant increase in NR activity in shoot tissue of plants at stage GS31–32, the magnitude of this variation differed between field 1 and field 2, being directly correlated to nitrate content measured in the same tissue (Table 2). Treated plants growing under 73% N increased their total NR activity in shoot tissue by 24.82% ($p = 0.019$) compared to control (Figure 5A). However, this activity was 4.7-fold higher in shoots of treated plants growing in field 2 (Figure 5B). Interestingly, the NR activation state also increased

Difference between control and treated sample within the same field was significant at * $p \leq 0.05$, ** $p \leq 0.01$, and *** $p \leq 0.001$, respectively (t-test).

significantly with PSI-362 coated fertilizer treatment ($p \leq 0.001$), reaching values of 70.53 and 65.63% for plants from field 1 and field 2, respectively.

GS activity was also assayed in shoots of barley plants 22 days after the second N fertilizer application. Similarly to NR activity, control plants growing under 100% N rate showed comparable GS activity values in field 1 and field 2 (3.22 and 3.80 $\mu\text{mol } \gamma\text{-GHM} \cdot \text{h}^{-1} \cdot \text{mg}^{-1}$ protein, respectively). GS activity was also

significantly stimulated by PSI-362 coated fertilizer, increasing its γ -glutamyl transferase activity in plants from field 1 (+30.63%, $p = 0.014$) and field 2 (+7.39%, $p = 0.035$) (Figure 6).

Effect of PSI-362 Coated Fertilizer on Plant and Grain Parameters at Harvest

The results presented in Table 3 indicate that the application of PSI-362 coated fertilizer in barley grown under reduced N fertilizer rate did not have a statistically significant effect on total plant biomass at harvest compared to control crop fertilized at 100% N rate. While a reduction of 27% N in field 1 was translated in a higher biomass in treated plants (+8.14%, $p = 0.319$), no significant difference was recorded in field 2 (−0.94%, $p = 0.957$). Barley plants from field 1 fertilized with PSI-362 coated CAN + S were characterized as having a significantly higher number of tillers at maturity stage (+23.30%, $p = 0.030$), but this effect was not observed in field 2 (Table 3). Interestingly, the application of PSI-362 coated fertilizer was characterized by a higher harvest index in both fields (11.31–18.37%), and this increase in dry matter partitioned to the grain was statistically significant for treated barley plants growing with 88% N ($p = 0.044$).

Harvested grain yield differences between control plants grown under 100% N and those treated with PSI-362 coated fertilizer at reduced N rate showed a similar trend to that observed in barley trials developed from 2016 to 2018: either these differences were significantly higher in treated plants growing under 73% N rate (+3.70%, $p = 0.042$) or PSI-362 coated fertilizer led to no statistically significant difference in grain yield compared to control in field 2 ($p = 0.780$). An opposite trend was observed for the thousand grain weight (TGW) and protein

FIGURE 4 | Relative expression of major nitrate transporter genes in spring barley root tissue (cv. Gangway). Means followed by asterisk within the same NR activity type and field indicate significant differences between control and the PSI-362 treatment based on *t*-test at $p \leq 0.05$. Number of biological replicates ($n \geq 4$).

content in both fields. While there were minimal differences in both parameters between treated and control crop in field 1, a significant increase of grain protein content (+12.50%, $p \leq 0.001$) and higher TGW (3.68%, $p = 0.095$) was observed in barley treated with PSI-362 fertilizer at 88% N rate compared to untreated crop grown under 100% N rate. Concerning other macronutrients such as P and K, there were no statistically significant differences in their content between grain harvested from treated and untreated plants (Table 3).

Effect of PSI-362 Coated Fertilizer on NUE and Environmental Parameters

The process of conversion of N fertilizer into grain biomass was evaluated through the amount of grain yield harvested

per amount of N supplied to plants (NUE_{grain}). There was a consistent increase of this parameter for treated crop in field 1 (+41.83%, $p \leq 0.001$) and field 2 (+9.13%, $p = 0.225$), which agrees with the observed results in previous trials with PSI-362 applied as foliar spray (Supplementary Table 7). Because NUE_{grain} is mathematically the product of $Nu_{eff_{grain}} \times Nute_{eff_{grain}}$, both second level traits were also calculated. The plant capacity to take up soil available N by the plant and allocate it to the grain was measured through $Nu_{eff_{grain}}$ trait. Overall, barley crop treated with PSI-362 coated fertilizer significantly enhanced this parameter in both field 1 (+40.95%, $p \leq 0.001$) and field 2 (+21.92%, $p = 0.011$), being the main contribution to the observed variation between treated and control NUE_{grain} and confirming the ability of PSI-362 to recover N more efficiently (Table 4). However, we did not observe statistically significant differences between treated and untreated plants in the $Nute_{eff_{grain}}$, remaining similar in field 1 (+0.36%, $p = 0.942$) or decreasing in field 2 (−10.49%, $p = 0.355$). Therefore, it indicates that this trait was not substantially impacting on NUE_{grain} variation (Table 4).

Despite these differences on N uptake efficiency, there were no statistically significant differences in the soil total N between control and treated plots after harvesting the crop (Supplementary Tables 4, 5). In addition, there were also no statistically significant differences in the content of available P and K before sowing and after harvesting in either field 1 or field 2. A higher content of amino sugar determined through the Illinois test in the organic fraction of soils treated with PSI-362 coated fertilizer after harvesting in field 1 (+30.21%, $p = 0.085$) and field 2 (+20.83%, $p = 0.096$) was recorded.

Estimated GHG emission calculations show that the application of PSI-362 led to a reduction in GHG emissions per hectare of cultivated area. The carbon equivalent emission estimate decreased nearly 22% for the treated crop growing under 73% N in field 1 (−483.52 kgCO₂e·ha^{−1}), whereas this reduction was closer to 9% (−224.49 kgCO₂e·ha^{−1}) with the application of PSI-362 coated fertilizer at 88% N rate in field 2 (Table 4).

DISCUSSION

Nitrogen fertilizer application rates are currently unsustainable, both environmentally (e.g., N pollution of soil, water and GHG emissions) and economically (e.g., reduced grower margins). A recent data compilation from 230 studies has reported that cereal crops only take up between 36% and 42% of applied N fertilizer (Yan et al., 2020), confirming previous low NUE estimations for cereal production (Raun and Johnson, 1999; Omara et al., 2019). Therefore, enhancing NUE is a necessity for developing sustainable agricultural production to feed a growing world population. The ability of ANE biostimulants to influence N uptake and assimilation mechanisms have been previously investigated in controlled conditions in the model plant *A. thaliana* (Durand et al., 2003), and crop plants such as oilseed rape (Jannin et al., 2013; Billard et al., 2014) and durum wheat (Laurent et al., 2020). In this study, it has been demonstrated under field conditions that an engineered biostimulant derived from *Ascochyta nodosum*, PSI-362, is capable of increasing NUE_{grain} in barley by 29.85–60.26% when compared to current standard grower practices without compromising yields. Two methods of application of the biostimulant to barley were evaluated; foliar spray and top dressing via biostimulant coated granular fertilizer, with the effectiveness of the biostimulant evident for both methods in pot and field trials. Along with several enhanced N assimilation markers, a key indicator of biostimulant performance was increased nitrate content in barley

shoot tissue 22 days after N fertilizer application. Additional plant phenotype, metabolic, enzymatic, and genetic analysis was performed on top dressed PSI-362 coated CAN + S barley crops to further support its role in enhancing NUE.

Impact of PSI-362 on Phenotypic and Yield Markers

Current knowledge shows that NUE is a highly complex trait derived from diverse molecular, metabolic, physiological, developmental, and environmental interactions over the entire life cycle of the crop. Field experiments using a randomized block trial design for the ANE PSI-362 applied by foliar spray at three critical growth stages of barley provided agronomically relevant results during three consecutive growing seasons. While tested varieties showed fluctuations on harvested grain yield on their response to PSI-362, the measured values were in the range expected for spring (5.6–7.3 t.ha⁻¹) and winter (8.6–9.1 t.ha⁻¹) barley in Ireland between 2016 and 2018 (CSO, 2019). Most importantly, the field experiments demonstrated that the foliar application of an engineered ANE biostimulant was able to maintain or increase grain yield in barley grown with 25% less N fertilizer.

In order to expand the applicability and facilitate the implementation of PSI-362 in standard grower programs, PSI-362 was co-formulated with a N mineral granular fertilizer (CAN + S). Granular CAN based fertilizer is an efficient source

of N with both nitrate and ammonium forms to maximize plant growth (Hachiya and Sakakibara, 2017). This N fertilizer is widely used by growers in Western Europe ($2.16 \text{ Mt N-year}^{-1}$), representing 51% of total worldwide consumption in 2019 (IFASTAT, 2019). Synchronizing N fertilizer application with the crop demand is critical for increasing NUE and reducing fertilizer losses. The co-formulation of CAN + S and PSI-362 is in-keeping with the 4R nutrient framework for increasing crop NUE: right rate, right source, right timing, and right placement. Previous research has shown that the critical period to positively influence spring barley yield and grain quality is the tillering and early stem elongation growth stages (Křen et al., 2015). These growth stages are characterized by a significant increase of N uptake, dry matter accumulation and responsiveness to N fertilization in terms of further grain yield (Baethgen et al., 1995; McTaggart and Smith, 1995; Hauggaard-Nielsen et al., 1998; Chatskikh and Olesen, 2007). Therefore, increasing uptake with PSI-362 at this growth stage was targeted based on the observed benefits of foliar applied PSI-362 enhancing NUE. Application of PSI-362 directly to the soil at the same time as the main N fertilizer application at the mid tillering stage was anticipated to provide similar benefits by stimulating N uptake, transport and assimilation mechanisms from root and shoot tissues before the stem elongation growth stage, compensating for the decreased N rate. The pot experiments revealed that the same dose of PSI-362 delivered by either foliar spray or coating of CAN + S granules enhanced plant biomass and NUE in an equivalent way.

Environmental conditions during the trials in field 1 and field 2 were favorable for spring barley production. The average Irish grain yield from the 2019 season was 8.0 t-ha^{-1} (CSO, 2020), which was 11% higher than the average yield recorded for the period 2014–2018 (Teagasc, 2018). While variations below and above this average grain yield value from field 1 and field 2 were likely related to differences in the grower program, soil chemical characteristics or crops grown in the previous season, our current results demonstrated that a moderate (i.e., 11–27%) reduction in N rate, combined with a single application of PSI-362 coated fertilizer, can maintain or increase grain yield, confirming the previous trend observed with three foliar applications of this biostimulant. Previous research about the effects of breeding on west European and Argentinean spring barley varieties from 1931 have demonstrated that overall improvements in grain yield can be achieved via different phenotypic routes (Abeledo et al., 2008; Bingham et al., 2012). Interestingly, this biostimulant treatment was able to improve important yield components such as plant biomass and harvest index, with no effect on grain size.

PSI-362 Coated Fertilizer and N Uptake Mechanisms

The ability to take up and transport more nitrate from roots to shoots under reduced N fertilizer conditions has been observed as an adaptive response in wild barley genotypes to cope with low N field conditions (Quan et al., 2016). The top-dressing application of PSI-362 coated CAN + S to barley plants at mid-tillering stage (GS22–27) was also translated into a substantial stimulation of nitrate uptake and transport processes 22 days after

application despite the reduction of N fertilizer rate, providing a significantly higher nitrate content in shoot tissue at stage GS30–31. These results were consistent with the proof of concept nitrate accumulation results in the model plant *Arabidopsis thaliana* 6 days after applying PSI-362 through the root under two different N levels. Although previous studies have highlighted the positive impact of ANEs on N uptake of oilseed rape and durum wheat growing under optimum nutrient conditions (Jannin et al., 2013; Billard et al., 2014; Laurent et al., 2020), no research to date has demonstrated the effect of ANEs on nitrate accumulation under reduced N fertilizer rate in real field conditions. PSI-362 ANE biostimulant did not possess any relevant N content to explain this nitrate accumulation effect in barley. The ability of specific biomolecules within commercial ANEs to induce plant growth and abiotic stress defense responses has been recently reviewed (Shukla et al., 2019; Goñi et al., 2020), with some of these studies reporting that ANEs can significantly dysregulate relevant genetic markers (Gonñi et al., 2016; Goñi et al., 2018; Shukla et al., 2018; Łangowski et al., 2019; Carmody et al., 2020). To elucidate PSI-362 mode of action at the molecular level, the expression of three nitrate plasma membrane carriers (NRT1.1, NRT1.5, and NRT2.1) was tested. A strong increase of expression of these genetic markers in roots of treated barley plants growing under 73% N rate was found, indicating that they could have a prominent role in facilitating N accumulation in shoot tissue. *NRT1.1* is an extensively studied gene that codes a dual affinity nitrate transporter and can also act as a nitrate transceptor. *NRT1.1* expression is known to be highly responsive to the amount of nitrate available in the environment as well as phosphorylation events under hormonal control (Lay-Pruitt and Takahashi, 2020). *NRT2.1* is another crucial component controlling high affinity nitrate transport and predominantly localizes to the plasma membrane of root cells (Vidal et al., 2020). The long-distance nitrate transport between root and shoot is regulated by the gene *NRT1.5*, coding a low-affinity bidirectional nitrate transporter (Lin et al., 2008). Enhanced expression of *NRT1.5* gene in root tissue and increased nitrate transport from root to shoot through the xylem vascular tissues has been observed previously in a high NUE oilseed rape genotype (Han et al., 2016). Increased *NRT1.1* transceptor expression along with high-affinity transporter *NRT2.1* and long-distance transporter *NRT1.5* have implications for auxin biosynthesis and root architecture. Analysis of auxin signaling reporter lines combined with analysis of auxin biosynthesis and transport would be necessary to fully understand PSI-362 effect on plant development and physiology and what is the role of *NRT1.1* as integrator. The observed nitrate accumulation in shoot tissue suggests that this biostimulant application could also increase the nitrate transport capacity in multiple ways. For example, through phosphorylation/dephosphorylation events controlled by CIPK23 kinase (Vidal et al., 2020), which can switch NRT transporters to high-affinity mode and facilitate the nutrients flow. Although it is tempting to speculate, nitrate uptake is a complex process, therefore detailed analysis of short- and long-term effects on root and shoot transcriptome need to be performed to fully comprehend the intricacy of this ANE biostimulant effect on NUE.

PSI-362 Coated Fertilizer and Enzymes Involved in N Assimilation Mechanisms

Nitrate assimilation occurs first via NR enzyme to nitrite and then via nitrite reductase (NiR) to ammonium (Tischner, 2000; Masclaux-Daubresse et al., 2010). PSI-362 coated fertilizer did enhance nitrate assimilation at stage GS30-31 through a direct effect on increased NR enzymatic activity in shoot tissue, this change being positively correlated to nitrate accumulation. Gene expression, protein translation and enzymatic activity of NR is positively regulated by nitrate, light, and carbohydrates (Kaiser et al., 2002; Lillo, 2008; Yanagisawa, 2014; Huaranca Reyes et al., 2018). However, this regulation does not necessarily happen simultaneously at these three levels (Carillo et al., 2005). NR enzyme from PSI-362 treated plants was also found to be in a higher constitutively active state compared to untreated plants, regardless of N reduction rate in field 1 and field 2. This enhancement of the NR activation state indicates that PSI-362 may modulate the phosphorylation state of this enzyme 22 days after application, improving shoot nitrate reducing capacities under more adverse growth conditions. At the post-translational level, NR undergoes a partial kinase-dependent reversible inhibition, due to a phosphorylation of a serine residue in hinge 1 followed by a binding to 14-3-3 proteins in presence of divalent cations or polyamines. Therefore, NR activity in the presence of $MgCl_2$ usually reflects the activity of dephosphorylated NR forms versus the activity of all NR forms in presence of EDTA (Athwal and Huber, 2002; Yanagisawa, 2014).

PSI-362 Coated Fertilizer and N Assimilation to Amino Acids

The ammonium produced from reduced nitrate is fixed into the amino acid glutamine through the enzyme GS, constituting the first step in the biosynthesis of organic N compounds and serving as the cornerstone of N assimilation along with GOGAT enzyme (Hirel and Krapp, 2020). The current results showed that GS activity was significantly higher in plants treated with PSI-362 coated fertilizer, enhancing the nitrate assimilation pathway under reduced N rate, which in turn was associated to a lower content of ammonium and an accumulation of glutamine, both substrate and end-product of this enzyme. While GS has been proposed as an interesting target for genetic modification for NUE, attempts to overexpress GS have yielded inconsistent results (James et al., 2018). A recent cisgenic strategy to increase expression of native cytosolic GS1 in barley provided an enhanced enzymatic activity and did increase grain yield and NUE (Gao et al., 2019). Moreover, correlation studies performed in several wheat varieties suggested the presence of a strong relationship between GS activity and different N metabolic markers such as amino acids, soluble protein, and chlorophyll (Kichey et al., 2006, 2007). The increased glutamine assimilation occurred in a coordinated manner with the accumulation of asparagine, glutamate and other amino acids derived from glutamate through transamination reactions such as alanine, aspartate or proline, or essential amino acids derived from aspartate (e.g., methionine, lysine, and threonine) (Pratelli and Pilot, 2014). Therefore, it seems that

PSI-362 coated fertilizer had a positive influence on stimulating barley shoots ability to acquire inorganic N and assimilate it into glutamine, favoring other amino acid biosynthetic processes simultaneously.

PSI-362 Coated Fertilizer and Additional Plant Metabolic Parameters

As recently reviewed by Fernie et al. (2020), any attempt to improve crop production and plant NUE through modification of N transport and metabolism pathways will only be effective if all processes are synchronized because unbalanced changes in internal N metabolite pools can generate end-product inhibition or substrate limitations of the respective amino acid synthesis pathways. Thus, the significant accumulation of total free amino acids in barley plants treated with PSI-362 coated fertilizer was also linked to a higher content of macromolecules derived from them such as soluble proteins or chlorophylls. An increased soluble protein content in barley shoot may be associated to a stimulated carbon fixation capacity because the majority of leaf soluble protein content in leaves of C3 plants is present as ribulose-1-5 bis-phosphate carboxylase-oxygenase (Rubisco), the key enzyme of the Calvin cycle (Feller et al., 2008). Together with this factor, the higher photosynthetic pigments content observed in shoot tissue could support this improvement of canopy photosynthesis at stage GS30-31 according to the model established by Cabrera-Bosquet et al. (2009). Overall, stimulating N uptake and assimilation mechanisms before the reproductive stage could facilitate subsequent N absorption during the grain filling process thereby compensating any detrimental effect associated with lower N fertilizer rate. Previous studies in winter wheat and barley have demonstrated that grain filling is mainly fueled with N remobilized from pre-anthesis biomass accumulation (Egle et al., 2008; Zhou et al., 2018).

Impact of PSI-362 Coated Fertilizer on NUE, Soil, and Environmentally Derived Parameters

This research demonstrates that the intrinsically low barley NUE_{grain} can be enhanced consistently through the application of PSI-362, with this improvement being achieved through better $Nu_{eff_{grain}}$. Increasing $Nu_{eff_{grain}}$ trait as a way to further improve NUE has been suggested in previous breeding studies that evaluate barley and wheat varieties (Bingham et al., 2012; Thorwarth et al., 2018). However, unlike breeding programs that can take several years (Garnett et al., 2015), the application of PSI-362 coated fertilizer represents a more convenient, quicker, and profitable solution for growers to recover more N provided by reduced rates of N mineral fertilizer. The soil nitrogen analysis post-harvest suggests that soil N depletion is not occurring in the field trials performed with PSI-362. This finding is in agreement with previous observations over a wide range of N application, with similar amounts of residual N remaining in the soil after harvesting treated and untreated crops (Makowski et al., 1999; Bingham et al., 2012; Venterea et al., 2016). GHG

emissions from the use of N mineral fertilizers are usually split into two parts: emissions from the energy-intensive manufacture process (mainly CO₂ and N₂O) and the emission of N₂O from the fertilized soil (AHDB, 2012). The estimated results determined through the inputs and outputs recorded in the trials developed with PSI-362 coated fertilizer revealed a significant reduction of carbon footprint compared with current practice. Assuming savings of 483 kgCO₂e·ha⁻¹ as obtained with PSI-362 coated fertilizer under 73% N rate, a reduction of 27.5 MtCO₂e can be expected per season if this agronomic input is implemented in the whole EU cereal production area (56.9 MHa; FAOSTAT, 2019).

Summary and Perspectives

The data presented demonstrates that an engineered biostimulant, PSI-362, derived from *Ascophyllum nodosum*, is capable of increasing NUE in barley under field conditions. The targeted application of PSI-362 as a coating on a granular N mineral fertilizer enhanced N uptake, transport and assimilation markers at phenotypic, metabolic, enzymatic and genetic levels in a coordinated manner. The efficient uptake of more nitrate by the crop when it needs it, results in enhanced NUE derived traits in harvested grain. These results support the agronomic use of this biostimulant with its effect delivered through a defined physiological mode of action that allows up to 27% reduction in N fertilizer usage while maintaining or increasing crop yield. The magnitude of the nitrogen reduction achieved with PSI-362 without compromising yield suggests it can have a role in delivering the European Union (EU) target of a 20% reduction in nitrogen use in agriculture. However, in order to expand the applicability and impact of PSI-362 within agriculture, additional data supporting its efficacy in other important crops (e.g., grass, wheat, maize, etc.) may be beneficial. Further investigation of the mode of action at a basic plant science level to understand the optimal conditions for efficacy will be important to facilitate adoption of this NUE biostimulant technology. The availability of biostimulant innovations in the market to enhanced NUE are going to be critical for achieving more profitable, sustainable and environmentally acceptable agricultural practices.

Chen D, Zhou W, Yang J, Ao J, Huang Y, Shen D, Jiang Y, Huang Z and Shen H (2021) Effects of Seaweed Extracts on the Growth, Physiological Activity, Cane Yield and Sucrose Content of Sugarcane in China. *Front. Plant Sci.* 12:659130. doi: 10.3389/fpls.2021.659130

Seaweed extracts (SEs) have been widely used as biostimulants in crop management due to their growth-promoting and stress-resistant effects. To date, there are few reports of the effect of SEs on sucrose content and cane yield. Here, we conducted field experiments for three consecutive growth seasons (2017~2019) in two areas (Suixi and Wengyuan) of China, to investigate the yield and sugar content of sugarcane in response to SE treatment at different growth stages. The results showed that spraying SEs once at seedling (S), early elongation (E), and early mature (M) stages, respectively, once at S and E stages, respectively, or once at the S stage increased the cane yield by 9.23, 9.01, and 3.33%, respectively, implying that SEs application at the early elongation stage played a vital role in promoting sugarcane growth. Photosynthetic parameters and nutrient efficiency analysis showed that spraying SEs at S and E stages enhanced the net photosynthetic rate, transpiration rate, and water use efficiency, and increased N, P, or K utilization efficiency, compared with those of the control. Notably, cane yield increasing rate of SEs in 2017 and 2018 were higher than those in 2019 in Wengyuan but lower than those in 2019 in Suixi. Interestingly, the total rainfall and monthly average rainfall in 2017 and 2018 were lower than those in 2019 in Wengyuan but higher than those in 2019 in Suixi. The results suggested that the yield increasing rate of SEs on sugarcane was better in less rainfall years. The sucrose content of sugarcane showed no difference between spraying SEs at the M stage alone or at the three growth stages but was higher than those of SE treatments at S and/or E stages. Enzyme activity analysis showed that spraying SEs at the M stage increased the activity of sucrose phosphate synthase activity by 9.14% in leaves and 15.16% in stems, and decreased soluble acid invertase activity in stems by 16.52%, which contributed to the sucrose increase of 5.00%. The above results suggested that SEs could increase cane yield and promote sucrose accumulation in sugarcane. The yield increasing effect was more obvious under conditions of drought stress.

Keywords: seaweed extracts, foliar application, sugarcane (*Saccharum officinarum* L.), photosynthesis, sucrose

INTRODUCTION

Sugarcane is the most important sugar crop and is also an important renewable energy crop (Commodity Bureau, 2015). China is the third largest sugarcane producer in the world after Brazil and India (Faostat, 2016). In recent years, periods of drought have become more frequent and serious due to global climate change (Hoover et al., 2017). Some climate models predict that the occurrence frequency of drought and extreme drought in subtropical and tropical regions will increase in the future, and the impact scope will be larger (Burke et al., 2006). Drought directly causes serious damage to various crops, such as sugarcane. Drought could lead to the reduction of sugarcane yield and have a serious impact on sugarcane agricultural production and the sugar industry (Vasantha et al., 2005). The arid slope areas of Guangxi, Guangdong, and Yunnan are the main sugarcane-growing areas in China. The water source of most sugarcane fields basically depends on rainfall, and there were almost no irrigation measures. Unfortunately, the uneven rainfall in these areas was prone to seasonal drought, which seriously affects the normal growth of sugarcane. How to effectively improve the drought resistance of sugarcane and ensure the yield of sugarcane and sugar has become an important topic in the field of sugarcane research (Kumar et al., 2014; Liu et al., 2016; Pereira et al., 2019; Singh et al., 2019). Thus far, there have been some studies to achieve high-efficiency irrigation management of sugarcane by changing the field application measures (Singh A.K. et al., 2018). Others use soil water retaining agents to improve the soil water holding capacity, promote root water absorption, and improve sugarcane drought resistance to ensure sugarcane yield and sugar content (Marcos et al., 2018; Singh et al., 2018a; Silveira et al., 2019). Nowadays, more and more scholars are interested in improving the stress ability of sugarcane under biological and abiotic stress, by applying exogenous growth stimulating substances (Pereira et al., 2019; Watanabe et al., 2019).

Seaweed extracts (SEs) are a kind of biostimulant extracted from seaweed (especially brown algae) that can promote crop growth, improve crop quality, and enhance crop stress resistance. SE mainly contain natural hormones, such as auxin, cytokinin, gibberellin, abscisic acid, and other active substances such as seaweed polysaccharide, sugar alcohol, betaine, and phenolic compounds (Crouch and van Staden, 1993; Jardin, 2012; Battacharyya et al., 2015), which have been used in agriculture for many years (Friedlander and Ben-Amotz, 1990; Mukherjee and Patel, 2020). The studies have shown that SEs were beneficial to soil improvement and crop growth. The colony counts in the soil and metabolic activities of soil microbes were found to increase following SEs applications, which contributed to increase plant root and shoot growth (Alam et al., 2013). SEs increased the absorption of soil nutrients by plants, stimulated the growth of crops, increased yield (Renaut et al., 2019; Boukhari et al., 2020), and enhanced plant resistance to biotic (Machado et al., 2014; Ben Salah et al., 2018) and abiotic stress (Bradáčová et al., 2016; Cabo et al., 2019; Khompatara et al., 2019). For example, SEs sprayed on onion grown under water stress significantly increased N, P, and K uptake by 116, 113, and 93% compared to the unsprayed plants (Almaroai and Eissa, 2020). Another study found that

SEs increased chlorophyll content by increasing the biogenesis of chloroplasts and reducing chlorophyll degradation, which was due to the up-regulated genes associated with photosynthesis, cell metabolism, stress response and S and N metabolism in *Brassica napus* L. (Jannin et al., 2013). Researchers postulated that the stimulatory effect of seaweed extracts on plant growth was due to the complex of active substance, which act directly or by influencing gene regulation in the plant (Arioli et al., 2015). There was a significantly higher expression levels of the PinII and ETR-1 marker genes with SEs application than controls. This was coupled with a marked increase in gene transcripts involved in auxin (IAA), gibberellin (Ga2Ox) and cytokinin (IPT) biosynthesis, which provides possible evidence for induced growth in plants treated with SEs (Ali et al., 2019).

Seaweed extracts have been shown to be effective in improving stress resistance in many other crops, such as spinach (Xu and Leskovar, 2015), maize (Trivedi et al., 2018a,b), sweet orange (Spann and Little, 2011), zucchini squash (Rouphael et al., 2016), and cucumber (Spann and Little, 2011). There are almost no reports on the application of SEs in sugarcane, especially in arid areas without irrigation. Indian researchers have conducted field experiments in western and southern India, which showed that the application of SEs could improve the yield and sugar content of sugarcane (Deshmaukh and Phonde, 2013; Karthikeyan and Shanmugam, 2017). In addition, other reports in India showed that the application of SEs could reduce fertilizer input and increase sugar yield (Deshmaukh and Phonde, 2013; Karthikeyan and Shanmugam, 2017). Meanwhile, it is believed that the application of SEs in sugarcane could reduce carbon dioxide emission and encourage the use of biostimulants, such as SE, under the background of adverse effects of global climate change (Singh et al., 2018b). However, the soil, climate, and cultivation measures between China and India are different. It is necessary to carry out tests to investigate the application effects of SEs on sugarcane in China. Specifically, in conditions without irrigation, the effects of SEs on sugarcane growth, yield, and sucrose content are not clear. We, therefore, conducted a series of field experiments for three consecutive years (1-year planting and 2-year ratoons) in the main sugarcane producing areas of China to investigate the effects of SEs on sugarcane growth, yield, and sugar content in terms of yield components, photosynthetic parameters, nutrient utilization rate, sucrose content, and sugar-related enzyme activities.

MATERIALS AND METHODS

Trial Sites and Weather Data

Wengyuan (113.94E, 24.27N) and Suixi counties (110.28E, 21.35N), which both have subtropical climates, were selected as the trial sites. **Figure 1** shows the monthly precipitation and monthly average temperature of the two sites from 2017 to 2019. In winter, the temperature in Wengyuan was 3–6°C lower than that of Suixi. The 3-year average temperature in Wengyuan was 22.3°C and that in Suixi was 24.4°C. The rainfall in Wengyuan from 2017 to 2019 was 1,498, 1,674, and 2,183 mm, respectively, and the rainfall in Suixi from 2017 to 2019 was 1,805, 2,098, and

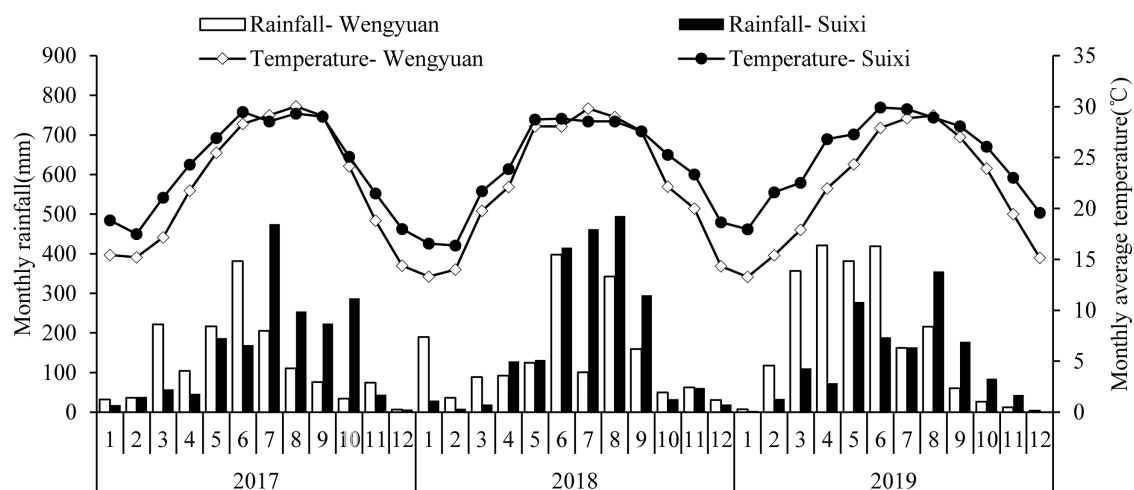

FIGURE 1 | Monthly total rainfall and average temperature during experimental year (2017–2019) in two sites. Numbers in the X axis represent the months in 3 years.

1,514 mm, respectively. The soil in the sugarcane field was latosol at Suixi and red soil at Wengyuan. Soil properties are listed in Table 1.

Plant Materials and SE

The sugarcane variety used in Suixi was “ROC22” and in Wengyuan, it was “Yuetang60.” These two varieties were the main local cultivated varieties.

The raw material of SEs was obtained from cultured kelp in the coastal waters of southeast China. The SEs was a kind of liquid product obtained by complex enzymatic hydrolysis. The content of the main nutrients and active substances in the SE were pH 6.85, EC value 14.35 mS/cm, N 0.56 g/L, P₂O₅ 0.28 g/L, K₂O 12.06 g/L, Ca 3.32 g/L, Mg 2.65 g/L, S 1.68 g/L, organic matter 25.10 g/L, alginic acid 20.16 g/L, seaweed polyphenol 205.56 mg/L, effective seaweed oligosaccharide 4.00 g/L, total sugar 13.00 g/L, mannitol 12.10 g/L, and free amino acid 5.00 g/L.

Treatments and Cultural Practices

A total of five treatments were set up in the field experiments, and each treatment was repeated four times. Treatments were randomly distributed including: (1) spraying water without SE as a control (CK); (2) spraying SEs once at the seedling stage (SE1); (3) spraying SEs both at seedling and early elongation stages (SE2); (4) spraying SEs at seedling, early elongation, and early mature stages (SE3); and (5) spraying SEs once at the early mature stage (SE4). The purpose of SE5 was only

to study the effect of SE on the sugar content of sugarcane. The application amount of SE remained constant at 3 L/ha, which was diluted 100 times with clear water and sprayed by an unmanned aerial vehicle. The application time at the seedling, early elongation, and early mature stages were in late March, mid-June, and early November every year, respectively. There was a slight difference in dates between different years (within 10 days).

Both sites were newly planted in 2017 and ratoons in 2018–2019. The former crops planted at these sites were sugarcane. The planting time of Suixi and Wengyuan was December 27, 2016 and December 10, 2016, respectively. Plot sizes were 168 m² (7 rows × 20 m) and 126 m² (7 rows × 15 m) at Suixi and Wengyuan, respectively. Both sites had a row-spacing of 1.2 m. All experiments had 3–5 guard rows to minimize cross influence. Total fertilization amounts were 483 kg N, 240 kg P₂O₅, and 450 kg K₂O, and the fertilization amount in ratoon (2018/2019) was 432 kg N, 225 kg P₂O₅, and 405 kg K₂O. Cane in all of the experiments was planted and cultivated following local cultivation practices and was harvested after approximately 12 months of growth.

Measurements

Cane Yield and Its Components

On the 15th day after the second spraying treatment in 2017–2018, plant height was measured with a special ruler for measuring the plant height of sugarcane, and 30 plants were randomly measured in each plot to take the average of a sample. Every year (2017–2019) from December 15–20, the diameter of the central stem of sugarcane was measured with a vernier caliper, and 30 plants were randomly measured in each plot to take the average of a sample. The millable cane numbers in the area of 36 m² (3 rows in the middle × 10 m length) were counted in each plot and converted into the millable cane number per hectare. The cane yield (fresh cane weight) was converted into yield per hectare by weighing an area of 36 m² in each plot.

TABLE 1 | Physical and chemical properties of experimental soils.

Trial site	pH	Organic matter (g·kg ⁻¹)	Total-N (g·kg ⁻¹)	Available P (mg·kg ⁻¹)	Available K (mg·kg ⁻¹)
Suixi	4.80	14.97	0.92	65.35	140.13
Wengyuan	4.73	20.83	1.17	21.93	66.83

SPAD (Soil and Plant Analyzer Development) Value and Photosynthetic Parameters of Leaves

In 2017 and 2018, SPAD value measurements of sugarcane leaves were taken 3 times at 2 weeks after each SE application. A chlorophyll meter (SPAD-502) was used to measure the middle part of the fully expanded leaves at the top of the sugarcane plant, and the average value of 10 plants was taken as a measured value.

In sunny weather, from 9:00 a.m. to 11:00 a.m., using a LI-6400 portable photosynthetic system, the photosynthetic parameters of the middle part of the leaves of sugarcane with red and blue light sources were measured, and 10 plants were measured repeatedly to obtain the average value. The following measurements were recorded: CO₂ concentration 390.5 μmol/mol, light intensity 800 μmol/(m²s), net photosynthetic rate (*P_n*), and transpiration rate (*Tr*). The ratio of *P_n*/*Tr* was calculated as instant water use efficiency (WUEI).

Nutrient Utilization Efficiency (NUE) and Partial Factor Productivity (PFP)

When sugarcane was harvested, 10 sugarcane plants were randomly selected from each plot, and the sugarcane stems and leaves were collected, and fresh weight were weighed, then killed at 105 °C for 30 min and dried to constant weight at 70 °C, and dry weight were weighed, and water contents of stems and leaves were calculated. The drying sample was crushed through a 0.15-mm sieve, treated with H₂SO₄-H₂O₂ followed by wet digestion (Bao, 2000), and the nutrient content of nitrogen (N) and phosphorus (P) contents were analyzed by an Automatic Flow Injection Analyzer (Proxima, Alliance, France), and potassium (K) content was measured with a Flame Emission Spectrophotometer (M425, Sherwood, United Kingdom). The Nutrient content per plant was the sum of the nutrient content of stem and leaf. The nutrient utilization efficiency (NUE) of N, P, and K were calculated as follows:

$$\text{NUE}_{N/P/K} = \text{Nutrient content per plant (N/P/K)} \times \text{millable cane number per hectare} / \text{the amount of N/P/K fertilizer applied (F}_{N/P/K}) \text{ per hectare}$$

$$\text{PFP}_{N/P/K} = \text{Cane yield} / \text{F}_{N/P/K}$$

Contents of Sucrose and Reducing Sugar in Sugarcane, and Theoretical Sugar Yield

The sugar parameters of cane were sampled and tested at each harvest time in 2017–2019. The content of sucrose, glucose, and fructose were determined by HPLC. A total of 10 canes were randomly selected from each plot, and the tenth node (counting from bottom to top) was peeled and cut into small pieces, which were ground into a uniform powder with liquid nitrogen. The powder (2.5 g) was weighed and placed in a 50 mL centrifuge tube, and 10 mL ethanol with a volume fraction of 80% was added. For extraction, the samples were incubated in an 80 °C water bath for 30 min, shaken once every 5 min, and centrifuged at 12,000 r·min⁻¹ for 15 min to collect the supernatant. The extraction was repeated twice with 80% ethanol, and the supernatants of the three extractions were combined in a 50 mL centrifuge tube, which were soaked in a water bath at 90 °C for about 3 h, volatilized to about 2 mL, and the supernatant was fixed to 10 mL.

The supernatant was filtered with a 0.22 μm microporous membrane to remove impurities and obtain the sugar extract. Chromatographic conditions were as follows: YMC-Pack NH₂ carbohydrate column (250 mm × 4.6 mm, 5 μm), column temperature 40 °C, flow rate 1 mL·min⁻¹, injection volume 20 μL, and time 20 min. According to the peak area and concentration of the standard sample, the sugar content in the sample was calculated by using the formula: standard sample peak area/standard sample concentration = sample peak area/sample concentration. The content of reducing sugar was the sum of the glucose and fructose content. Theoretical sugar yield was calculated by cane yield per unit area multiplied by sucrose content. Sucrose content, reducing sugar content, and theoretical sugar yield were all based on fresh weight of cane.

SAI and SPS Enzyme Activities

In 2018, 10–12 days after spraying SEs at the mature stage, the leaves (completely unfolded at the top of sugarcane) and stems (peeled from the tenth node, counting from bottom to top, and cut into small pieces) were sampled. After picking, they were put into liquid nitrogen until analysis and detection in the laboratory. The sample powder (2 g) was ground with liquid nitrogen, weighed, and put into a 10 mL centrifuge tube, and 8 mL of enzyme extract (50 mM Hepes (pH 7.5), 12 mM MgCl₂, 1 mM EDTA, 1 mM EGTA, 10 mM DTT, 2 mM benzamidine, 2 mM N-aminocaproate, and 10 mM diethyldithiocarbamate) was added and extracted by shaking on ice for 30 min. Samples were centrifuged at 4 °C at 15,000 rpm for 10 min. The supernatant (4 mL) was placed into a 2 mL centrifuge tube. The extraction and enzyme activity of SAI and SPS were determined according to the methods of Zhu et al. (1997) and Gutiérrez-Miceli et al. (2002).

Statistical Analyses

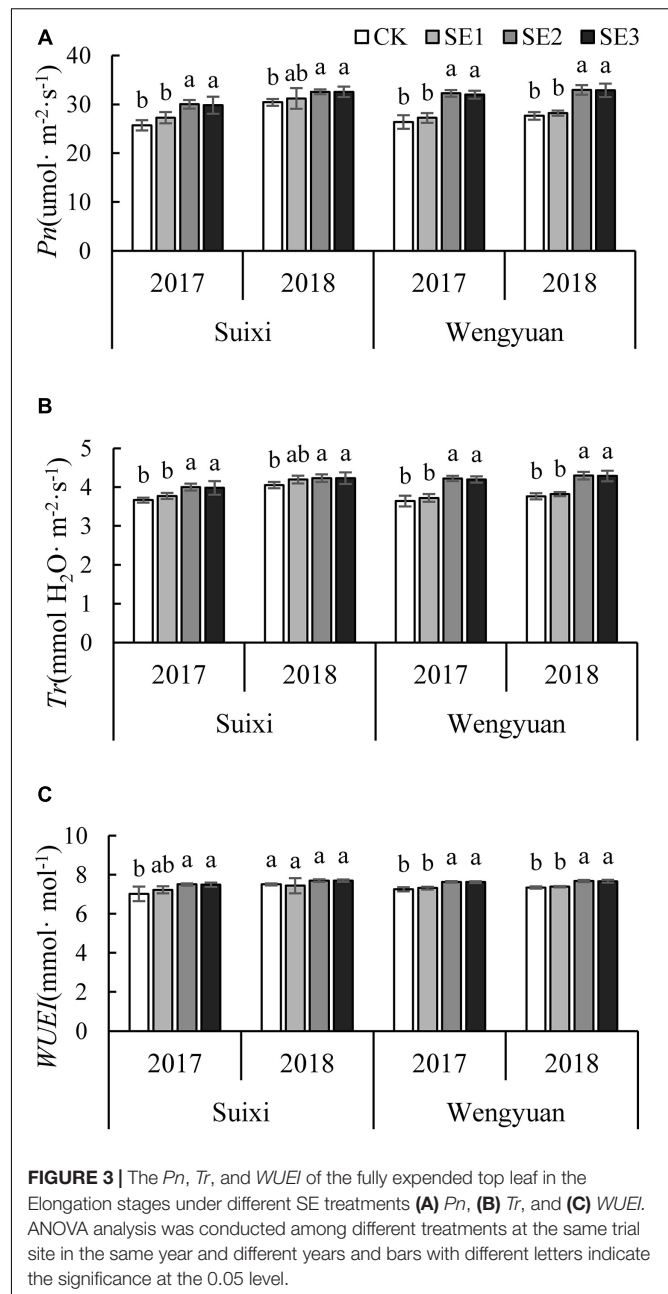

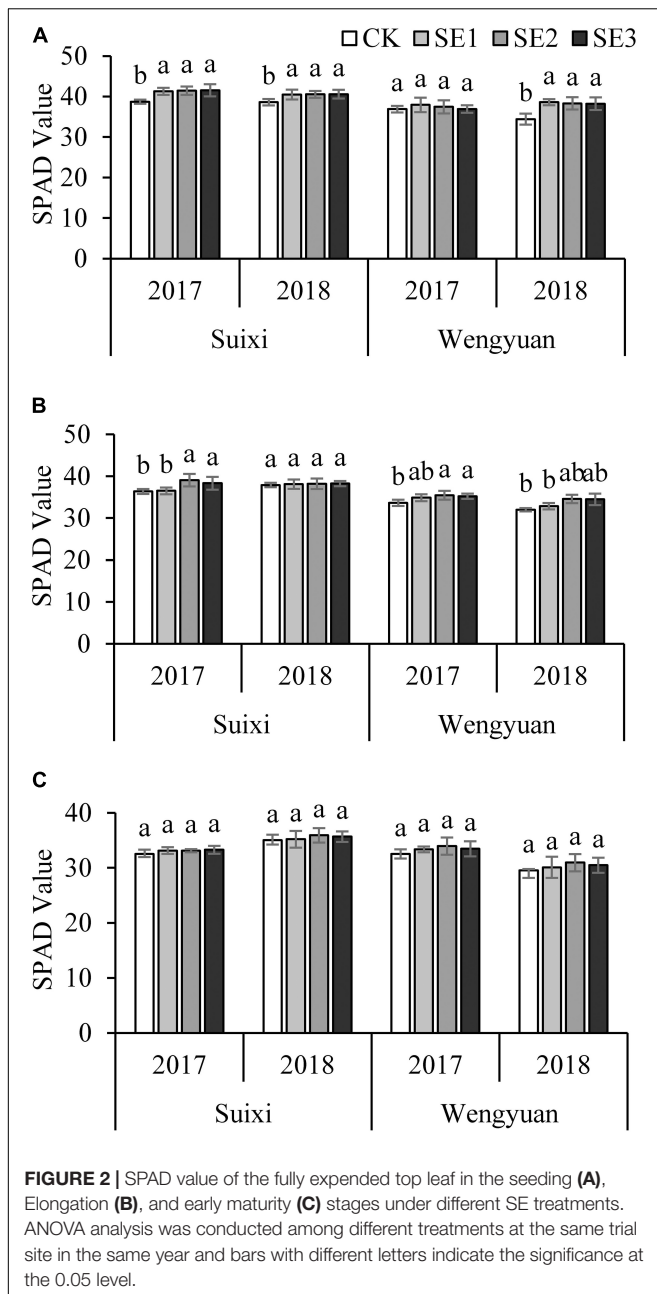

We used Microsoft Excel 2013 and SPSS 19.0 to analyze the data. The results were expressed as the mean value and standard error. Analysis of variance and average comparison were based on the least significant difference (LSD) test of 5% probability level in the same place and year.

RESULTS

Effects of SEs on Photosynthetic Physiology of Leaves

SPAD

The SPAD value of leaves increased significantly after spraying SEs at the seedling stage (Figure 2A). Similarly, after the second spraying (SE2/SE3) in the elongation period, SPAD values in plants treated with SEs were significantly higher than that without SE application (Figure 2B), but there was no significant difference between the treatment sprayed with SE only once at the seedling stage and the control treatment. Spraying for the third time at the early mature stage did not affect the SPAD value of leaves (Figure 2C). However, there were differences between different years at the same test site.

P_n , T_r , and $WUEI$

SE application at the early elongation period (SE2 and SE3) made P_n significantly higher than that of the no SE treatment, with an average increase of 14.52%. All four experiments had the same performance (Figure 3A). However, treatment of SE application only once at the seedling stage (SE1) did not have the same effect. Furthermore, the P_n of SE2 and SE3 treatments were significantly higher than that of SE1 in three trials (Suixi in 2017, Wengyuan in 2017 and 2018).

The results of T_r were similar to P_n . The T_r of sugarcane sprayed with SEs during the elongation period was significantly higher than that of the control, with an average increase of

10.62%. All experimental results were consistent (Figure 3B). In addition, T_r of SE2 and SE3 were significantly higher than that of SE1 in 3 trials (Suixi in 2017, Wengyuan in 2017 and 2018).

The $WUEI$ of SE2 and SE3 was significantly higher than that of the control in the elongation period, with an average increase of 4.70% (Figure 3C). Furthermore, $WUEI$ in SE2 and SE3 was significantly higher than that of SE1 in Wengyuan.

Effects of SEs on Nutrient Utilization Efficiency (NUE) of N, P, and K

The data shown in Table 2 comprise the NUE of N, P, and K of sugarcane, which are the average of six experimental results in

TABLE 2 | N, P, K utilization efficiency and partial productivity of sugarcane under different treatments.

Treatment	Utilization efficiency (%)			Partial productivity (kg/kg)		
	N	P	K	N	P	K
CK	32.87 ± 2.23ab	7.96 ± 0.62c	42.75 ± 2.86b	216.08 ± 18.06a	421.32 ± 33.32a	230.95 ± 19.08a
SE1	36.12 ± 4.00ab	8.22 ± 0.91bc	45.09 ± 4.67ab	223.36 ± 20.89a	435.46 ± 37.87a	238.73 ± 22.04a
SE2	38.67 ± 2.43a	9.02 ± 0.87ab	48.61 ± 4.09a	235.55 ± 22.08a	459.28 ± 40.85a	251.76 ± 23.35a
SE3	39.03 ± 5.01a	9.1 ± 0.5a	48.95 ± 3.95a	236.01 ± 20.72a	460.2 ± 38.52a	252.25 ± 21.91a

^aData presented as mean ± SE, *n* = 4. Different letters in each column show significant difference at *p* < 0.05, according to LSD.

two sites for 3 years. The results showed that the NUE of N, P, and K sprayed with SEs were all improved to a certain extent compared with the control. In SE1, SE2, and SE3, the NUE of N increased by 9.88, 17.64, and 18.74%, respectively, of P by 3.26, 13.31, and 14.31%, respectively, and of K by 5.48, 13.70, and 14.49%, respectively. In addition, the N, P, and K PFP of the two treatments (average of SE2 and SE3) were increased by 19.71, 38.42, and 21.06 kg/kg, respectively, compared with the control but the differences were not significant.

Effects of SEs on Yield Components of Sugarcane

The plant height of sugarcane sprayed with SEs in April was significantly higher than that of CK, and there were significant differences in 4 of 6 experiments (Table 3). After spraying SEs for the second time in the elongation period (SE2/SE3), the plant height of sugarcane in August was significantly higher than that of the control, and this effect was also shown in four experiments. However, spraying SEs for the third time had no significant effect on plant height. According to the results of 3 years of experiments at two sites, compared with the non-SE application, SE3, SE2, and SE1 increased the height of sugarcane by 4.81, 4.66, and 2.04%, respectively. In addition, SE application had no significant effect on the millable cane per unit area (Table 3). Therefore, the promotion effect of SEs on sugarcane growth was mainly reflected in the increase of sugarcane plant height.

Effects of Different Treatments on Sugarcane Yield

Spraying SEs both at seedling and elongation stages improved sugarcane yield significantly, and the yields of SE2 and SE3 were increased by 9.01 and 9.23%, respectively, compared with those of sugarcane without SE, while the yield of sugarcane sprayed with SEs once at the seedling stage was not significantly different from the control (with a 3.33% yield increase).

The effect of SEs on yield varied with different years and sites. SE treatment (SE3, SE2, and SE1) increased the yield by 6.17, 6.96, and 7.80%, respectively, in Suixi and by 7.59, 9.71, and 4.69%, respectively, in Wengyuan from 2017 to 2019 compared with the control. The 3-year average yield of SE2 and SE3 treatments significantly increased 9.17 and 8.95%, respectively, in Suixi and by 8.83 and 9.53%, respectively, in Wengyuan. However, the yields showed no significant difference between SE2 and SE3 treatments. Similarly, there was no difference in yield between

SE4 treatment and CK, which indicated that spraying SEs at the mature stage had no significant effect on yield.

Sucrose Content, Reducing Sugar Content, and Sugar Yield of Sugarcane in Harvest Period

Sucrose Content

Regardless of whether SEs were sprayed in both seedling and elongation stages, the sucrose content of cane with SE application in the mature stage (SE3/SE4) was significantly higher than that of cane without SE application, and the sucrose content of SE3 and SE4 in Suixi in 3 years was 5.71 and 5.49% higher, respectively, than that of the control (Table 8). Furthermore, the increase in Wengyuan was 4.72 and 4.11%, respectively. The average in 3 years at the two sites of SE3 and SE4 treatments significantly increased by 5.21 and 4.79%, respectively (total average 5.00%), compared with those of the control (*P* < 0.05). Notably, SE3 and SE4 treatments were also significantly higher than SE1 and SE2 treatments.

Reducing Sugar

Spraying SEs at the mature stage significantly decreased the reducing sugar content of sugarcane by 32.56 and 34.32% (average 33.44%) than that of SE1 and SE2, respectively (Table 4). However, there was no significant difference in reducing sugar content between SE1 and SE2 treatments and those without SE treatment.

Theoretical Sugar Yield

The 3-year average of sugar content per unit area in Suixi and Wengyuan was significantly higher than that in non-SE treatments, and SE3 was the highest in every year and each place, which was significantly higher than all other treatments. Compared with the control, the sugar content per unit area of SE3 treatment in Suixi and Wengyuan was significantly increased by 15.31 and 16.56%, respectively (*P* < 0.05) and the comprehensive average was increased by 15.92%. In addition, SE1, SE2, and SE4 treatments increased by 5.43, 12.60, and 7.83%, respectively, compared with those of the control (Table 5).

Effects of SEs on the Activity of Sucrose Phosphate Synthase (SPS) and Soluble Acid Invertase (SAI)

Compared with the treatment without SE, the activity of SPS in leaves of SE3 and SE4 treatments increased by 9.34 and

8.95% (average 9.14%), respectively, and the SPS enzyme activity in stalks increased significantly by 15.56 and 14.76% (average 15.16%), respectively ($P < 0.05$). However, the activities of SPS in leaves and stems of sugarcane treated with SE1 and SE2 did not change significantly. The SAI enzyme activity in stalks of SE3 and SE4 treatments significantly decreased by 15.20 and 17.84%, respectively (average 16.52%, $p < 0.05$), and was also significantly lower than that of the SE1 treatment (Table 6).

Correlation Analysis Between Annual Rainfall and Plant Height, Sucrose Content, Cane Yield and Cane Yield Increase

We used the data of SE2 and SE3 treatments in which SEs had the best effects on sugarcane yield to analyze the correlation of plant height, sucrose content, cane yield and cane yield increase (relative to the treatment without SEs) with annual rainfall. The results showed that plant height, sucrose content and cane yield had no significant correlations with annual rainfall, but the increase of cane yield had a significant negative correlation with rainfall (Figure 4), that means the lower the annual rainfall, the greater the increase in sugarcane yield from SEs application.

DISCUSSION

Effects of SEs on Sugarcane Growth and Cane Yield

Biostimulatory activities of SEs were evident throughout the experiments, shown by significant increases in plant height and cane yield. The results of this study are also in agreement with reports on other crops, including strawberry, maize, and tomato (Alam et al., 2013; Ali et al., 2016; Trivedi et al., 2018a,b). The yields of the treatments with SE application (SE1, SE2, and SE3) were higher than those without SE application, with the average increase range of 2.67–9.17% in Suixi and 4.04–9.53% in Wengyuan (Table 7). It has been reported that

the application of SE had a better effect on the increase of cane yield. One study showed that SE application both in the soil and on the leaves increased the yield of sugarcane by 14.1% (Deshmaukh and Phonde, 2013), and another experiment showed that spraying SEs on sugarcane three times could achieve a yield increase of 20.47–28.79% (Karthikeyan and Shanmugam, 2017). In terms of yield components, seaweed extract had the greatest effect on plant height, but had no significant effect on stem diameter and millable cane number. The growth promoting properties observed may be a result of the effects of growth regulatory substances present in SE, including low molecular weight biostimulants (seaweed oligosaccharides) that can promote crop growth and high molecular weight biostimulants (algal polysaccharides) that can improve crop stress resistance. These substances induced the biosynthesis of hormones such as phytohormones abscisic acid, cytokinin, and auxin in treated plants (Khan et al., 2009; Aremu et al., 2016; Patel et al., 2018; Ali et al., 2019; Renaut et al., 2019; Mukherjee and Patel, 2020). It has been reported that the yield increasing with SEs applications was associated with improved chlorophyll biosynthesis (higher SPAD index) (Youssef et al., 2018). Our results determined at seedling and elongation stages showed that spraying SEs could significantly increase the SPAD value of sugarcane leaves, which indicated that the application of SEs increased chlorophyll content in leaves (Figure 2), which is also supported by other reports (Lingakumar et al., 2004; Ali et al., 2016, 2019). This might be due to the existence of betaine, amino acids, and other active substances in SEs that inhibit the degradation of chlorophyll (Blunden et al., 1996). Seaweed extracts also contain magnesium, which is necessary for chlorophyll synthesis (Almaroai and Eissa, 2020). Our results showed that spraying SEs had a significant effect on the photosynthetic rate of sugarcane leaves which were consistent with those of SPAD, and these resulted in a stronger ability of plants to maintain a better photosynthetic performance (Santaniello et al., 2017).

Nutrient absorption is an important factor for high yield of crops, and more nutrient absorption leads to higher cane

yields (Rhodes et al., 2018). The results showed that the utilization efficiency of nitrogen, phosphorus and potassium in sugarcane sprayed with SEs was significantly higher than that in the treatment without SEs. Previous studies have shown that the application of SEs can promote the growth of crop roots, improve the ability of roots to absorb macroelement nutrients and transfer them to the aboveground (Crouch

et al., 1990), which is related to the hormones substances in SE (Finnie and van Staden, 1985; Jeannin et al., 1991), and the hormones substances may promote up-regulated expression of nutrient transport genes, thus improving root uptake and transport of nutrients (Krouk et al., 2010; Rathore et al., 2009). Further studies in the promotion mechanism for SEs regulating plant root growth confirmed

that SEs could up-regulated the gene expression and enzyme activity of nitrate reductase at the post-transcriptional level (Zhang et al., 2013).

Effects of SEs on Sugar Accumulation of Sugarcane

Sucrose content is the most important quality index of sugarcane. All over the world, the sugarcane industry has tried to find ways to improve the sucrose content of sugarcane or accelerate the ripening of sugarcane, among which growth regulator substances are the most frequently used (Rossetto et al., 2003; Li, 2004; Van Heerden et al., 2015; Cunha et al., 2017). In the management of sugarcane, sugar increasers or ripening agents can be applied at the early mature period to advance the harvest period or increase the sucrose content. SEs are a kind of biostimulant that contains a variety of plant hormones, which could regulate the growth and development of plants (Khan et al., 2009; Craigie, 2011; Ali et al., 2016). Therefore, our experiment also set the third application time at the early mature period (from the end of October to November) to evaluate its effects on the sucrose content of sugarcane. Furthermore, we set the treatment of spraying SEs alone in the early mature period (SE4) and compared it with SE3. The results showed that the sucrose content of canes with SE treatment (SE3 and SE4) were significantly increased in comparison with that of non-SE and the SE1 treatment at the early stage of maturity. It was even higher than that of the SE2 treatment in some experiments, and there was no significant difference between SE3 and SE4. These results indicated that the increase of sucrose was mainly due to the SE application at the mature stage, rather than at the seedling and elongation stages.

Sugar conversion and accumulation in sugarcane is regulated by many enzymes, including sucrose synthase (SS), sucrose phosphate synthase (SPS), and invertase (INV) (Sturm, 1999; Winter and Huber, 2000). SPS is a key regulatory enzyme in the distribution of photosynthetic products to sucrose and starch in plants and is positively correlated with sucrose accumulation (Grof et al., 2007). INV is one of the key enzymes controlling sucrose metabolism in plants, which irreversibly catalyzes the conversion of sucrose + H₂O into fructose + glucose. SAI is a kind of INV, which mainly exists in vacuoles and plays a role in regulating sucrose and hexose levels (Tian et al., 2009), and cane sugar is negatively correlated with SAI activity. In this study, SPS in the direction of sucrose synthesis and SAI in the direction of decomposition and transformation were selected as

representatives for analysis. The results showed that spraying SEs at the early stage of maturity significantly increased the activity of SPS enzymes in leaves and stems, which was beneficial to the synthesis and accumulation of sucrose. For stems, SE application significantly reduced the activity of the SAI enzyme, which reduced the decomposition of sucrose in sugarcane stems. Therefore, it could be speculated that SEs regulated related enzymes in sugarcane, promoted the synthesis and accumulation of sucrose, and reduced the transformation to reducing sugar, thus, improving the sucrose content of sugarcane. Reports have shown the elicitation of various plant enzymes and the increasing in the activity of these enzymes by SEs (El Modafar et al., 2012; Ali et al., 2019). The regulation of enzymes activity observed may be as a result of the effects of phytohormones and growth regulatory substances present in the SEs and induced the biosynthesis of hormones by treated plants (Kang et al., 2014; Ramkissoon et al., 2017).

Sucrose accumulation related to biosynthesis of plant hormone signal transduction, which are consistent with the physiological effects elicited by exogenous hormone substances application on sugarcane. While the hormone in signal transduction at the maturation stage are great different from other stage in sugarcane (Cunha et al., 2017). Therefore, the ideal effect can be obtained only when it is applied at mature stage.

Importance of Applying Seaweed Fertilizer in Rain-Fed Agricultural Areas

Cane yield is closely related to climate factors (Inman-Bamber and Smith, 2005; Liu et al., 2016). In this study, the cane yield of the two experimental sites were different in different years, and the effect of seaweed extract on the yield was also different in different years. In this study, the annual rainfall of the two sites were different (Figure 1 and Table 1). Sugarcane has a great demand for water during the period of rapid growth (May to August every year) in China. The growth of sugarcane is severely inhibited if there was no rainfall and irrigation, resulting in a decline in yield. The uneven seasonal rainfall was also different in the two places. Specifically, the rainfall at Wengyuan in 2017 and 2019 was mainly distributed in March to July and less in the later months, while in June to September 2018, it was less distributed in the early months (Figure 1). In Wengyuan, the highest yield of the 3 years was in 2018 (Table 7), which might be related to the high coincidence between the rainy season and rapid growth of sugarcane in that year. However, the yield in 2019 was lowest,

and there were two reasons for this. First, the rainfall decreased significantly after July in that year compared with previous years, which affected sugarcane growth; second, as the second year of ratoon, the emergence of sugarcane generally decreased with the increase of ratoon years, which led to the decrease of millable cane number per unit area (one of the yield components) (Table 3). The rainfall in Suixi from 2017 to 2019 was less in January to May, and more in June to September, especially in 2019. There was no significant difference in sugarcane production between 2017 and 2018 because the rainy season in these 2 years basically coincided with the rapid growth stage of sugarcane. The lowest output in 2019 was due to similar reasons as that of Wengyuan. The effects of SE application on yield also had year-to-year differences. SE treatments had different improvement on sugarcane yield in different years and places, among which Suixi had the largest improvement (>9%) in 2019, which had the least annual total rainfall (1513.72 mm) and monthly average rainfall (126.14 mm). The increase of yield at Wengyuan in 2017 and 2018 was > 10% and < 6% in 2019. Correspondingly, the total rainfall (1498.66 mm/1674.83 mm) and monthly rainfall average (124.89 mm/139.57 mm) in 2017 and 2018 were lower than those in 2019 (rainfall values were not shown in Figure 1). The yield increase rates of SE1, SE2, and SE3 treatments in Suixi were 2.67, 9.17, and 8.95%, respectively, and those of Wengyuan were 4.04, 8.83, and 9.53%, respectively. These results indicated that spraying SEs only once at the seedling stage was not enough to improve yield but spraying SEs two or three times at different growth stages was better.

In addition, the WUEI analysis could also well correspond with this result. The results showed that the WUEI of plants sprayed with SEs in the early elongation stage was significantly higher than that without SEs application, which indicated that SEs could improve the water use efficiency and drought resistance of crops (Neily et al., 2010; Trivedi et al., 2018a,b). Research showed that SEs induced a partial stomatal closure, associated with changes in the expression levels of genes involved in ABA-responsive and antioxidant system pathways under drought stress conditions (Santaniello et al., 2017), and SEs was able to mitigate the drought stress by regulating the expression of genes involved in ABA biosynthesis and ROS detoxification (Shukla et al., 2018).

Based on the above analysis, the effect of SEs on sugarcane yield was more obvious under drought conditions, which could be due to the fact that the SEs contained many active substances which were conducive to improving the drought tolerance of sugarcane (Spann and Little, 2011; Martynenko et al., 2016; Shukla et al., 2018). Therefore, it is suggested that SEs should be sprayed once both at seedling and early elongation stages in sugarcane management in rain-fed agricultural areas.

CONCLUSION

In this study, spraying SEs on sugarcane leaves at seedling and early elongation stages promoted sugarcane growth in rainfed areas without irrigation. SE application promoted photosynthesis and transpiration, improved WUEI and utilization efficiency of nitrogen, phosphorus, and potassium, and increased the height

of sugarcane, thus, increasing the yield and economic benefits. Moreover, in drought years, SEs had more significant effects on alleviating sugarcane yield decline caused by drought.

Furthermore, we found that spraying SEs at the early mature stage of sugarcane could regulate the activities of enzymes related to sugar accumulation in sugarcane leaves and stems, increase the activities of sucrose phosphate synthase in leaves and stems, and reduce the activities of soluble acid invertase in stems, which was conducive to promoting sucrose accumulation in sugarcane stems.

Due to the improvement effect of SEs on sugarcane yield and sucrose content in this research, we suggest that SEs should be sprayed at different growth stages in sugarcane production. It is better to spray three times at seedling, elongation, and early mature stages. These provide a theoretical basis for the application of SE in agricultural areas.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/supplementary material, further inquiries can be directed to the corresponding author/s.

AUTHOR CONTRIBUTIONS

DC conceived and designed the experiments with the help of HS. DC, WZ, JA, DS, and YJ performed the field trials and agronomy study. DC analyzed the data and wrote many parts of the manuscript. YH performed the enzyme study and analyzed the data. WZ and JY performed and wrote the statistical analyses. DS, YH, and YJ performed sucrose and nutrient analysis. ZH prepared the figures. DC wrote the first draft of the manuscript with the help of JY, WZ, and HS. ZH and DC prepared the final manuscript with the help of HS. All authors contributed to the article and approved the submitted version.

FUNDING

This study was financed by the China Agricultural Research System (CARS-170203), Guangdong Provincial Science and Technology Plan (2019B030301007), the National Key Research and Development Program of China (2017YFD0200208 and 2016YFD0200405-5), and Central Public-interest Scientific Institution Basal Research Fund for Chinese Academy of Tropical Agricultural Sciences (1630052019001).

ACKNOWLEDGMENTS

We would like to thank Mingfu Wen, Qingwen Luo, Junxian Yang, and Zhonghua Chen very much for helping us to manage sugarcane cultivation for the 3 years. We would also like to thank the LetPub (www.letpub.com) for its linguistic assistance during the preparation of this manuscript and reviewers for their valuable comments.

Biostimulants are emerging as a feasible tool for counteracting reduction in climate change-related yield and quality under water scarcity. As they are gaining attention, the necessity for accurately assessing phenotypic variables in their evaluation is emerging as a critical issue. In light of this, high-throughput phenotyping techniques have been more widely adopted. The main bottleneck of these techniques is represented by data management, which needs to be tailored to the complex, often multifactorial, data. This calls for the adoption of non-linear regression models capable of capturing dynamic data and also the interaction and effects between multiple factors. In this framework, a commercial glycinebetaine- (GB-) based biostimulant (Vegetal B60, ED&F Man) was tested and distributed at a rate of 6 kg/ha. Exogenous application of GB, a widely accumulated and documented stress adaptor molecule in plants, has been demonstrated to enhance the plant abiotic stress tolerance, including drought. Trials were conducted on tomato plants during the flowering stage in a greenhouse. The experiment was designed as a factorial combination of irrigation (water-stressed and well-watered) and biostimulant treatment (treated and control) and adopted a mixed phenotyping-omics approach. The efficacy of a continuous whole-canopy multichamber system coupled with generalized additive mixed modeling (GAMM) was evaluated to discriminate between water-stressed plants under the biostimulant treatment. Photosynthetic performance was evaluated by using GAMM, and was then correlated to metabolic profile. The results confirmed a higher photosynthetic efficiency of the treated plants, which is correlated to biostimulant-mediated drought tolerance. Furthermore, metabolomic analyses demonstrated the priming effect of the biostimulant for stress tolerance and detoxification and stabilization of photosynthetic machinery. In support of this, the overaccumulation of carotenoids was particularly relevant, given their photoprotective role in preventing the overexcitation of photosystem II. Metabolic profile

and photosynthetic performance findings suggest an increased effective use of water (EUW) through the overaccumulation of lipids and leaf thickening. The positive effect of GB on water stress resistance could be attributed to both the delayed onset of stress and the elicitation of stress priming through the induction of H₂O₂-mediated antioxidant mechanisms. Overall, the mixed approach supported by a GAMM analysis could prove a valuable contribution to high-throughput biostimulant testing.

Keywords: water stress, biostimulant, GAMM, metabolomics, tomato, gas exchange, glycinebetaine, climate change

INTRODUCTION

Adaptation to climate change is becoming central to the conversation about water management for agriculture (Iglesias and Garrote, 2015). Among the suggestions to improve resiliency and adaptive capacity, the most cited approach is the introduction of drought-resistant crops. While this can be achieved through classical breeding and biotechnology, such efforts have so far produced little results (Nuccio et al., 2018). Moreover, in the second case, even when plants are successfully genetically modified (GM), resistant plants typically represent a restricted number of crops. In this sense, a technology applicable to multiple crops in multiple locations would represent a desirable alternative: as pointed out by Del Buono (2020), biostimulants could represent a sustainable measure to foster the resilience of cropping systems under limited water conditions. The earliest response of plants to drought is represented by stomatal closure, which results in the inhibition of photosynthesis (Michaletti et al., 2018), and therefore leads to CO₂ uptake and concentration reduction (Medrano et al., 2002). Multiple osmolytes can be found among biostimulant constituents targeting water stress resistance in plants, such as glycinebetaine (GB). GB not only acts as an osmoregulator but also stabilizes the structures and activities of enzymes and protein complexes *via* detoxification of reactive oxygen species (Papageorgiou et al., 1991; Papageorgiou and Murata, 1995), while maintaining the integrity of membranes against the damaging effects of excessive salt (Tang et al., 2014; Tian et al., 2017; Yang and Lu, 2005; Mbarki et al., 2018), cold (Quan et al., 2004), heat (Yang et al., 2006; Allakhverdiev et al., 2007), freezing (Razavi et al., 2018; Wang et al., 2019), and also drought (Ma et al., 2006). The role of GB in plant resistance to abiotic stress has been widely investigated and documented (Gorham, 1995; Sakamoto and Murata, 2002; Ashraf and Foolad, 2007; Chen and Murata, 2010; Huang et al., 2020), ranging from exogenous application to genetic engineering (Fariduddin et al., 2013), to its biosynthesis and the underlying molecular mechanisms behind in planta accumulation under stress (Annunziata et al., 2019). While it has been argued that the osmolyte accumulation does not entail positive effects on yield under drought conditions (Serraj and Sinclair, 2002), many reports demonstrate the positive effect of osmolyte accumulation generally (notably Blum, 2016) and GB specifically on plant growth and final yield. Among drought resistance mechanisms activated by GB, osmotic adjustment has been observed to enhance soil moisture extraction and,

therefore, transpiration (Blum, 2016). At the same time, higher yielding plants are characterized by high stomatal conductance over time and higher transpiration (Blum, 2009). Indeed, Mäkelä et al. (1999) found that GB could enhance photosynthetic efficiency by reducing photorespiration and enhancing stomatal conductance in tomato plants grown under drought and salinity. This resulted in increased net photosynthesis of stressed plants. This is of particular relevance since tomato plants (*Solanum lycopersicum* L.) do not naturally accumulate GB (Wyn Jones and Storey, 1981). GB foliar application was also found to increase the yield of tomato plants under saline or heat stress (Mäkelä et al., 1998). Likewise, Agboma et al. (1997a,b) found that exogenous application of GB was indeed involved in the maintenance of a higher yield in maize and sorghum grains and tobacco leaves and resulted in improved water-use efficiency. GB was found to have a positive effect on yield also on soybean (Agboma et al., 1997b), common beans (Xing and Rajashekar, 1999), wheat (Agboma et al., 1997a), sunflower (Hussain et al., 2008), and cotton (Ahmad et al., 2014). Moreover, Park et al. found that genetically engineered GB (2004) and exogenously applied GB (2006) increased the tolerance of tomato plants to chilling stress. Interestingly, they suggest that, in addition to its macromolecule and membrane protecting action, GB-enhanced chilling tolerance might imply stress priming through the induction of H₂O₂-mediated antioxidant mechanisms.

According to Fleming et al. (2019), scientific recognition of the potential of biostimulants has not grown as fast as the interest from industry. This has been due to limited fundamental research of their modes of action and the speed at which new multi-compound products have entered the market. In the investigation of biostimulant activity, the necessity of accurate assessment of phenotypic variables is emerging as a critical issue (Rouphael et al., 2018) while at the same time the combined phenotypic-omic approach is gaining momentum. In recent years, emerging digital technologies such as sensors, automatic image acquisition, and the connected algorithms and models have seen an increasing adoption, resulting in increasing volumes and complexity of data. Large-scale acquisition of data has allowed data interpretation to shift from a model-based to a data-based paradigm, by improving the possibility to generalize the data acquired and consequently allowing for an increase in model accuracy. On the flip side of the coin, the main challenge lies in data management: the huge amount of data generated needs to be handled both at the acquisition and analysis stage through proper, often custom, tools (Coppens et al., 2017). In this context,

non-destructive phenotyping techniques characterized by high accuracy (high-throughput techniques) have gained popularity in the scientific community and have been successfully employed in plant breeding (Araus and Cairns, 2014; Halperin et al., 2017; Tardieu et al., 2017; Campbell et al., 2018; Mir et al., 2019), precision agriculture (Chawade et al., 2019), and biostimulant activity testing (Petrozza et al., 2014; Rouphael et al., 2018; Paul et al., 2019a,b). High-throughput phenotyping technologies have attracted attention for their potential in: (1) screening and monitoring multiple morpho-physiological traits; (2) time-series measurements, crucial in the acquisition and interpretation of high spatial and temporal resolution data; and (3) labor automation, time, and cost efficiency (Rouphael et al., 2018). Halperin et al. (2017) have proposed a platform, which uses a custom algorithm to select genotypes based on their abiotic stress resistance characteristics. The system coupled with single-leaf gas exchange acquisition provides high-resolution whole plant transpiration, biomass gain, stomatal conductance, and root flux. As pointed out by Teklić et al. (2020), in addition to the investigation of the effect of biostimulants on plant stress response, there is a growing necessity to elucidate stress and interactions of biostimulants in terms of metabolic changes. To further explore the variation in physiological traits, the integration of phenotyping data and omics data represents the next frontier and a promising tool to bridge the phenotype-genotype gap (Coppens et al., 2017) and to understand dynamic plant stress responses in a changing environment (Gosa et al., 2019). Specifically, high-throughput phenotyping data in combination with metabolomics have already been successfully applied to biostimulant testing (Lucini et al., 2015; Paul et al., 2019a,b; Rouphael et al., 2020). In metabolomics, two commonly used analytical strategies can be distinguished: untargeted and targeted strategies. Untargeted metabolomics, by aiming to detect as many metabolites as possible in a biological sample, is particularly suited to identifying metabolite abundance variations connected to either environmental stimuli or genetic variations (Cheng et al., 2018). Metabolomics has a recognized potential to provide significant insights into the mechanisms of the stress response (Shulaev et al., 2008; Arbona et al., 2013) by identifying different compounds, such as the molecules involved in stress acclimation (e.g., secondary metabolites) and by-products of stress metabolism, and has been successfully applied to the investigation of biostimulant action in general (Lucini et al., 2015, 2018; Paul et al., 2019a,b) and especially under abiotic stresses (Nephali et al., 2020). Lastly, responding to the necessity to analyze the volumes and complexity of data produced through high-throughput phenotyping, non-linear regression models are emerging. These models need to be capable of capturing dynamic data, often time series, as well as the interaction and effects between multiple factors (Ohana-Levi et al., 2020). Among these, generalized additive mixed models (GAMMs) have been successfully featured in several applied science fields (Murase et al., 2009; Zuur et al., 2009; Pedersen et al., 2019; Boswijk et al., 2020; Ohana-Levi et al., 2020) including ecology at large and plant ecophysiology. In particular, Ohana-Levi et al. (2020) highlighted the potential of GAMs to model non-linear relationships between

evapotranspiration (ETc) drivers and evaluating their impacts on grapevine transpiration.

In light of this, GB is particularly fit to test the suitability and accuracy of GAMMs in modeling dynamic plant response to drought: widely investigated, its protective action on the photosystem is documented for several abiotic stresses (Huang et al., 2020). At the same time, while available research concentrates mostly on the effect of GB application on yield traits and cell-level effects (Annunziata et al., 2019), a correlation between GB treatment and modifications in photosynthetic rates has received little attention: published research mainly concerns enhanced photosynthetic performance under salt stress (Yang and Lu, 2015; Hamani et al., 2020) and drought (Nawaz and Wang, 2020). Likewise, the effects of GB on water-use efficiency (WUE) have been scarcely investigated (Ahmed et al., 2019) and although both of its abundance (natural or GM) in plant tissues and its exogenous application have been widely linked to stress response, the effects of exogenous application of GB on the metabolomic profile of leaves are yet to be investigated.

Based on the current literature, the hypothesis tested here was whether a biostimulant (GB-based) treatment can be efficiently modeled through GAMM and whether the treatment would result in tangibly different metabolite expression profiles, thereby completing the information derived from GAMM. In order to achieve this, the duration and dynamics of the effect on photosynthesis, transpiration, and WUE were investigated, jointly with a snapshot analysis of metabolic profile.

MATERIALS AND METHODS

Plant Material and Growing Conditions

The experiments were conducted in a greenhouse and the metabolomics analysis in the laboratory of the Department of Sustainable Crop Production of the Università Cattolica del Sacro Cuore, Piacenza. Tomato seeds (H1281 variety, Heinz) were directly sown in a greenhouse at 20°C at 2 cm in a seeding tray (35-ml cell plug) containing a commercial complete mixture of sand—blonde peat—humus. Seeds were kept in dark conditions for 5 days until germination, thereafter they were provided with a PPFD of 800 $\mu\text{mol m}^{-2} \text{s}^{-1}$ through light-emitting diode (LED) lighting. Seven days after emergence (DAE), 50 uniformly developed seedlings, at second true leaf unfolded (BBCH 12), were transplanted in 2.3-L pots filled with a commercial complete mixture of sand—blonde peat—humus (1,000 \pm 1 g). Plants were fertilized at a transplant with 40 ml of a complete commercial solution (COMPO, Concime Liquido Universale, Bologna, Italy) at 1.05% w/v (7% N; 5% P; 6% K; 0.01% B; 0.004% Cu; 0.04% Fe; 0.02% Mn; 0.001% Mo; and 0.002% Zn). Fertilization was provided every 2 weeks. The pots were placed under LED lamps to provide a PPFD of 800 $\mu\text{mol m}^{-2} \text{s}^{-1}$ to the top canopy with a photoperiod of 16 h light and 8 h dark. Pots were watered to field capacity (FC) every second day. The temperature was not controlled and in the range between 35°C during the day and 8°C during the night (19.5°C average). Of the 50 plants, 32 homogeneously developed plants were selected, of which 12 plants were destined for gas exchange analysis and 20 for metabolomics analysis, while the rest was discarded.

The experiment was designed as a factorial combination of irrigation (water-stressed and well-watered) and biostimulant treatment (treated and control). The water-stressed plants were allowed to dry down for three consecutive days by the withdrawal of irrigation. Thereafter, all plants were irrigated. Gas exchange analysis was carried out on three replicates for each treatment, for a total of 12 plants while metabolomics analyses were carried out on five replicates per each treatment, totaling 20 plants. Plants dedicated to gas exchange analyses were kept in the gas exchange acquisition system for 9 days until the end of the experiment (3 initial days to adapt to the ventilation and lighting, followed by dry down) while plants dedicated to metabolomics analysis were kept in the greenhouse under a tunnel replicating the conditions of the gas exchange acquisition system (same air inlet and LED lighting).

Biostimulant Characteristics and Treatment

The day before the beginning of the gas exchange analysis, the pots were irrigated to saturation and allowed to drain overnight. The treatment with the biostimulant was carried out on 36 DAE on one half of the plant while the other half was sprayed with distilled water. Biostimulant was sprayed at a rate of 6 kg/ha, with a dilution of 300 L/ha to a total of 10 g/plant. Dose and dilution were chosen based on commercial use of the product (Vegetal B60[®], ED&F MAN Liquid Products Italia, Bologna, Italy). Vegetal B60[®] is an organic product extracted exclusively from sugar beet without any added chemical additives. It contains 30% of GB and 5% of L-amino acids, 5% of total organic nitrogen, and 12% of organic carbon.

All pots were sealed in plastic bags fitted around the base of each plant stem to prevent soil evaporation. Well-watered plants were kept at 80% FC throughout the experiment, while for water-stressed plants irrigation was interrupted 3 days after the treatment (on 39 DAE). About 200 g of water were reintegrated to WS plants on 41 DAE, 2 days after irrigation was stopped, to contrast the high rate of soil drying and allow for a longer dry-down period and a more gradual onset of drought stress (a transpiration exceeding 200 g d⁻¹ would have brought the plant at wilting point on DAE 41). Leaf area (LA) of each plant was calculated every 3 days from the start of stress imposition (39 DAE). Leaves were placed on squared paper (square of side 0.5 cm, used as the reference of known size) reinforced with a rigid base and photographed with a phone camera, taking care that no leaves overlapped. Images were then processed by using ImageJ (Schneider et al., 2012) to extract LA and compute the total LA of each plant.

Gas Exchange Analysis

Gas exchange was evaluated through a semiautomated multichamber whole-canopy system [slightly modified from the system previously described in Fracasso et al. (2017)]. In particular, the system computes net photosynthetic rate (P_n), transpiration rate (E), and WUE. Every pot was measured every 12 min for a total of 120 measurements per day. P_n ($\mu\text{mol s}^{-1} \text{m}^{-2}$) and E ($\text{mmol s}^{-1} \text{m}^{-2}$) were calculated based on flow rates and CO_2 and water vapor differentials by using the formula

provided in Long and Hallgren (1985). Data were acquired 24 h per day at intervals of 1 min. The semiautomated multichamber system is composed of 12 adjustable open chambers connected to a CIRAS-DC double channel absolute $\text{CO}_2/\text{H}_2\text{O}$ IR gas analyser (PP-System, Amesbury, MA, USA). Air drawn at 3 m above ground from outside the greenhouse is collected in a buffer tank (0.44 m³ capacity) to ensure the stability of inlet CO_2 concentration and then, forced by one centrifugal blower (Vorticent C25/2M Vortice, Milan, Italy), to distribute air to the chambers through 50-mm-diameter rigid plastic pipes. The air flow rate of each chamber is controlled by a baffle and is constantly measured at least 50 cm downstream of the baffle itself with digital flowmeters (50 Pa D6F-PH0026AD1, OMRON, Kyoto, Japan) according to a flow-restriction method (Osborne, 1977). Each chamber is connected to a set of 12 solenoid valves in series (model 177 B04/Z610, Sirai, Bussero, Italy) through a sampling tube (\varnothing 10 mm). Air sampling is switched from one chamber to another at programmed time intervals (Raspberry Pi B+, Raspberry Pi Foundation, Northants, UK). In order to ensure air flushing inside the sampling tubes and the complete air exchange inside CIRAS-DC, rotary vane pumps (model G 6/01-K-LCL; Gardner, Denver Thomas, Puchheim, Germany) with 33.3 cm³ s⁻¹ of flow rate were added before CIRAS-DC. Both the inlet air temperature and the air temperature of each chamber (outlet) were measured by using digital temperature sensors (Dallas DS18B20, Dallas Semiconductor Corp., Dallas, TX, USA).

On 36 DAE, 12 plants were transferred under the gas exchange acquisition system and were kept in the system for 9 days until the end of the experiment (as mentioned above) while 20 plants were kept under a tunnel replicating the conditions of the gas exchange acquisition system and were sampled for metabolomics analyses. Both the tunnel and the gas acquisition system were provided with the same air inlet, namely forced air collected from outside (as described above), and the same LED lighting, namely 800 $\mu\text{mol m}^{-2} \text{s}^{-1}$ PPFD.

Sample Harvest and Metabolomic Analysis

Gas exchange was measured throughout the duration of the stress: as soon as the P_n of stressed plants started decreasing, plants were sampled for metabolomics. Sampling of the 20 plants kept under the tunnel replicating the conditions of the gas acquisition system was carried out on 42 DAE. The second and third fully expanded leaves from the top of each plant were excised and dipped into liquid nitrogen. Samples were kept at -20°C and subsequently analyzed. Plant samples were homogenized in pestle and mortar by using liquid nitrogen and extracted as previously reported (Paul et al., 2019b). Briefly, an aliquot (1.0 g) was extracted in 10 ml of 0.1% HCOOH in 80% aqueous methanol by using an Ultra-Turrax (Ika T-25, Staufen, Germany). The extracts were centrifuged (12,000 g) and filtered into amber vials through a 0.22- μm cellulose membrane for analysis. Thereafter, metabolomic analysis was carried out by ultra-high performance liquid chromatograph (UHPLC) coupled to a quadrupole-time-of-flight mass spectrometer (UHPLC/QTOF-MS). The metabolomic facility included a 1,290 ultra-high-performance liquid chromatograph, a G6550

iFunnel Q-TOF mass spectrometer, and a JetStream Dual Electrospray ionization source (all from Agilent Technologies, Santa Clara, CA, USA). The untargeted analysis was carried out as previously described (Rouphael et al., 2016). Briefly, reverse-phase chromatography was carried out on an Agilent PFP column (2.0 × 100 mm, 3 μm) and by using a 33-min linear elution gradient (6–94% acetonitrile water, with a flow of 200 μl min⁻¹ at 35°C). The mass spectrometric acquisition was done in SCAN (100–1,000 m/z) and positive polarity (Pretali et al., 2016). Quality controls (QCs) were analyzed in data-dependent MS/MS mode by using 12 precursors per cycle (1 Hz, 50–1,200 m/z, positive polarity, active exclusion after 2 spectra), with collision energies of 10, 20, and 40 eV for collision-induced decomposition.

Raw spectral data were processed by using Agilent Profinder B.07 software, (Santa Clara, CA, USA) as described in Miras-Moreno et al. (2020). The PlantCyc 12.6 database (Plant Metabolic Network; Release: April 2018) was used to putatively annotate compounds according to Level 2 with reference to the COSMOS Metabolomics Standards Initiative (Salek et al., 2015). QCs were analyzed by using the MS-DIAL 3.98 (RIKEN Center for Sustainable Resource Science: Metabolome Informatics Research, Yokohama, Japan) to compare the MS/MS spectra to the publicly available MS/MS experimental spectra built in the software (e.g., MoNA) (Tsugawa et al., 2015).

Data Analysis

Gas Exchange Curve Fitting Using GAM(M)

The experiment was evaluated from the day prior to stress imposition (38 DAE) for three consecutive days of water stress (DAE 39–41) until the start of stress recovery (42 DAE). Statistical analyses on gas exchange data were carried out *via* GAMMs. GAMMs are regression models, which allow for modeling non-linear regressions (Wieling, 2018). Unlike linear models (1), which feature a sum of linear terms, GAMMs (2) are characterized by a sum of smooth functions. GAMMs are used to estimate smooth functional relationships between predictor variables and the response. GAMM data fitting is characterized by a penalized fit: the fit of the data is balanced with the complexity of the model by penalizing wiggleness, namely the deviation from total smoothness, and thus avoiding overfitting (Pedersen et al., 2019).

$$Y_{ij} = \beta_0 + \sum \beta_j x_i + \epsilon_{ij} \quad (1)$$

$$Y_{ij} = \beta_0 + \sum f_j(x_i) + \epsilon_{ij} \quad (2)$$

Among the multiple advantages of this approach is the possibility to handle the complexity of the data without oversimplifying them, the determination of the relationship between the dependent variable and the predictors as a function of the algorithm, which can be linear but is not necessarily linear, the inclusion of multiple numeric predictors and the possibility to include autoregressive AR(1) error model for Gaussian models in order to handle the autocorrelation component of the error (van Rij et al., 2019). The inclusion of autocorrelation is particularly

relevant in time-series data sets, where each datapoint is clearly correlated to (and therefore dependent on) the previous and the next datapoints. Therefore, this analysis is particularly useful to data sets characterized by dynamic and time-series data (Boswijk et al., 2020).

After Wieling (2018), the analysis started from a simple generalized additive model, the sophistication of which was progressively increased and extended step-by-step. While one would normally directly choose the model reflecting the hypothesis, this approach was chosen to shed light on the process using generalized additive modeling.

Net photosynthesis (*P_n*), transpiration rate (*E*), and WUE were used as the response variable for the following series of GAM(M)s:

- Sole irrigation as a fixed factor, including a smooth for day-of-treatment and hour in the day, based on treatment.
- Irrigation treatment and biostimulant treatment as fixed factors, no interaction between the factors. Including a smooth for day-of-treatment and hour in the day, based on both treatments.
- Irrigation treatment and biostimulant treatment as fixed factors, interaction between the factors. Including a smooth for day-of-treatment and hour in the day, based on both treatments.
- Introduction of tensor product-based smooths between hour and day.
- Inclusion of a smooth for day-of-treatment and hour in the day, based on both treatments, and allowing for random effect per individual.
- Addition of non-linear random effects per individual for day-of-treatment.
- Introduction of individual-based autocorrelation.

Models d: g are nested within model c, allowing for comparison of methods using log-likelihood/F tests. This allowed us to evaluate Akaike information criterion (AIC) changes among models and, thus, to find the model with the most explanatory power given the degrees of freedom, while at the same time assessing whether better or worse models explained significantly different amounts of the deviance in the data. Statistical tests were performed by using the software R version 4.0.2 (R Core Team, 2020). GAMM models were fitted in R by using a cubic regression spline smoother, with the package *itsadug* (van Rij et al., 2020). Mixed model selection, fitting, and validation followed (Zuur et al., 2009). Biostimulant and stress treatment factors were used in mixed linear models for hypothesis testing.

Chemometric Interpretation of Metabolites

Chemometric interpretation of metabolites was performed by using Mass Profiler Professional B.12.06 from Agilent (Santa Clara, CA, USA) as previously described (Corrado et al., 2020). The unsupervised hierarchical cluster analysis (HCA—distance measure: Euclidean; clustering algorithm: Ward's) was produced based on the normalized molecular features. The supervised orthogonal partial least squares-discriminant analysis (OPLS-DA) was carried out with SIMCA 16 (Umetrics, Umeå, Sweden)

TABLE 1 | Characteristics of the nine compared models of influence on photosynthesis.

Model	Resid. Df	Resid. Dev	AIC	dAIC	Dev. Expl (%)
a	3391.454	11624.1257	13974.67	5006.285	61.5
b	3378.586	10206.6696	13552.31	4583.922	66.2

f	3182.686	3307.85823	10024.21	1055.83	89
g	3214.175	3679.9617	8968.384	0	87.8

Model names as in the text: a is the sole irrigation as a fixed factor, including a smooth for day-of-treatment and hour in the day, based on treatment. b has both irrigation and biostimulant treatment as fixed factors. c adds the interaction between the factors and includes a smooth for day-of-treatment and hour in the day, based on both treatments. d introduces tensor product-based smooths between hour and day. e includes a smooth for day-of-treatment and hour in the day, based on both treatments, and allowing for random effect per individual. f adds non-linear random effects per individual for day-of-treatment. g introduces individual-based autocorrelation. Resid.Df, residual degrees of freedom; Resid.Dev, residual deviance; dAIC, difference in AIC based on model g. Dev. Expl. (%) = deviance explained.

at default parameters. CV-ANOVA ($p < 0.01$) and permutation testing ($n = 100$) were also applied to validate and to exclude overfitting. Goodness-of-fit R²_Y and goodness-of-prediction Q²_Y were also calculated from the OPLS-DA model. Outliers were investigated according to Hotelling's T² (95 and 99% confidence limit for the suspect and strong outliers, respectively). The most discriminant compounds in separation were selected by performing the variables importance in projection (VIP) analysis.

Thereafter, differential compounds were investigated through Volcano plot analysis, combining fold-change ($FC > 2$) and ANOVA ($p < 0.01$, Bonferroni multiple testing correction) and were then uploaded into the Omic Viewer Pathway Tool of PlantCyc (Stanford, CA, USA) to identify pathways affected by the treatments as in Caspi et al. (2013).

RESULTS

Gas Exchange Analysis

On 36 DAE, 12 plants were transferred under the gas exchange acquisition system and were kept in the system for 9 days until the end of the experiment. Plants were treated with a factorial combination of irrigation (well-watered and water-stressed) and biostimulant treatment (treated and control). Water-stressed plants were allowed to dry down for three consecutive days by the withdrawal of irrigation. Gas exchange data were processed via GAMMs. GAMMs are non-linear regression models which are characterized by a sum of smooth functions. Data were analyzed by building models of growing complexity (Table 1, model a–g), as previously explained. The regression models allowed to explore the dynamics of the influence of the biostimulant and water treatments on photosynthetic performance.

Among the candidate GAMMs, the optimal model was model g, including Photosynthesis ~ irrigation treatment * biostimulant treatment and non-linear interactions between both treatments and the duration of the experiment (expressed in days) and the

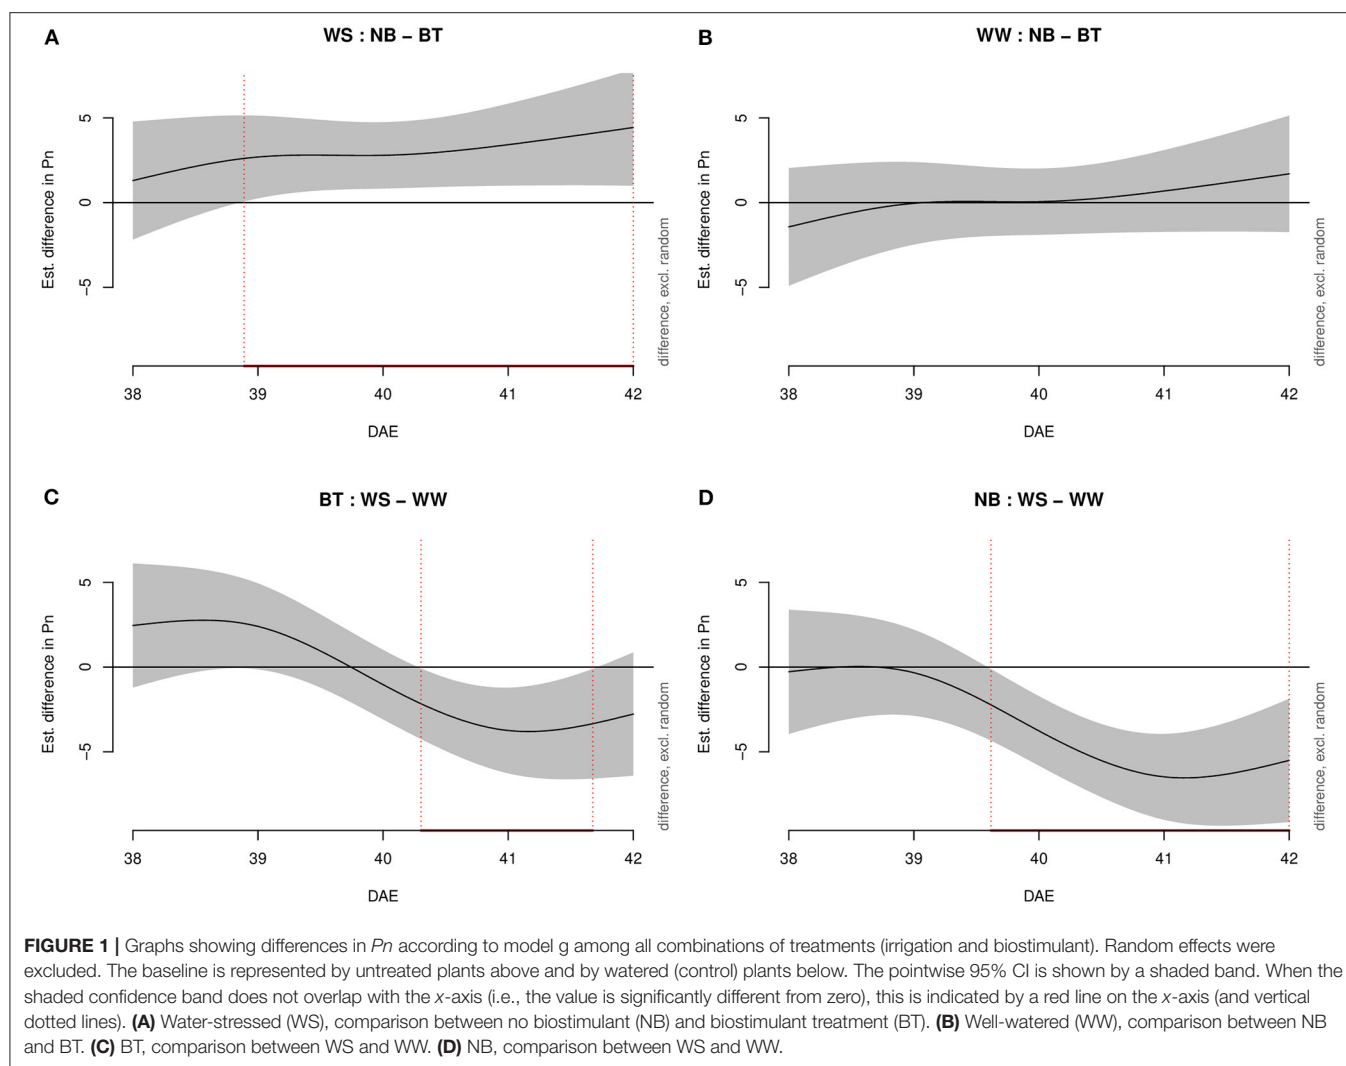

time of the day (expressed in hours), smooths for the duration of the experiment and the time of the day on both treatments and non-linear variability of the individuals over the duration of the experiment. Moreover, model g included autocorrelation for time over the individual. The model explained 87.8% of the total deviance with an Adj.R² of 0.872. While the next best model, which did not include autocorrelation (model f), explained 89% of the deviance (Adj.R² 0.883), when the models were confronted via AIC (Akaike, 1974), and model g scored consistently lower in terms of AIC score although bearing more degrees of freedom (Table 1).

The inclusion of the sole irrigation treatment factor (model a) explained 61.5% of the deviance in the data. The addition of the biostimulant treatment factor (model b) increased the deviance explained by 4.7%. The addition of further information increased the deviance explained as follows: the inclusion of the interaction between the fixed factors (model c) resulted in an additional 1.8%. The further introduction of tensor product-based smooths between hour and day (model d) added 6.7% deviance explained, while allowing for random effect per individual (model e) further added 10.5% to it. Lastly, the addition of non-linear random effects per individual for day-of-treatment (model f) resulted in 1.8% more deviance explained.

Under water-stressed conditions, model g highlighted statistically higher P_n (Figure 1) in plants treated with biostimulant compared to control plants starting shortly before 39 DAE and lasting throughout the experiment until 42 DAE. Conversely, under well-watered conditions, there was no significant difference between treatments. When considering biostimulant-treated (BT) plants, the difference between water-stressed and well-watered plants was significantly lower for water-stressed plants starting half 40 DAE to half 41 DAE. Lastly, well-watered and water-stressed untreated plants displayed a significant negative difference from mid-39 DAE to mid-42 DAE.

The influence of day-of-treatment (38–42 DAE), starting from the day prior to stress imposition, and hour was evaluated separately for each treatment (biostimulant and water treatment). Through the use of GAMMs, the significance of the effect of day and hour on biostimulant and water treatment was further investigated singularly for each dimension of both factors (biostimulant treated/control treated and water-stressed/well-watered) (Table 2). The results show that all the partial correlations were statistically significant for at least one of the two levels of the factors at the value of $p < 0.001$ level, except for the effect of hour and day of week on biostimulant treatment, which was significant at the value of $p < 0.05$. While the significance of the smooth terms does not provide information on whether the patterns are statistically significant, this suggests that each individual variable has a statistically significant influence on modeling the wiggleness of P_n , which in turn confirms the distance of P_n from a linear function.

The partial effect (referred solely to biostimulant treatment) of biostimulant treatment on P_n observed for each day-of-treatment is of particular interest (Figure 2): while no effect can be detected for the control treatment (which is represented by a linear function), the biostimulant treatment has a detectable effect on the wiggleness of the P_n curve.

Transpiration (E , $\text{mmol m}^{-2} \text{s}^{-1}$) was evaluated through increasingly complex models, as P_n . Model g was once more the best fitting model, with 88.2% of deviance explained and 0.875 Adj. R^2 . As for P_n , water-stressed BT plants performed significantly better than untreated plants (Figure 3). In particular, the performance of BT plants was significantly higher from mid-38 DAE to mid-40 DAE. Conversely, non-stressed plants (biostimulant treated/untreated) did not show any significant difference in transpiration. Water-stressed BT plants had a higher E than well-watered plants from mid-41 DAE until mid-42 DAE. Untreated plants differed from late 39 DAE throughout the end of the experiment.

As for P_n and E , WUE was evaluated through increasingly complex models (Figure 4). Model g was confirmed as the best model, with 85.3% deviance explained and 0.843 Adj. R^2 . As for P_n and E , no significant difference was highlighted among well-watered plants (both biostimulant treated and not). The difference in WUE between treated and untreated plants spanned from shortly before the day of stress imposition (39 DAE) to the third day (41 DAE). The duration of the difference among BT

plants (well-watered/water-stressed) extended from early 40 DAE to 42 DAE while the difference among untreated well-watered and water-stressed plants went from 40 DAE to 42 DAE.

Untargeted Metabolomics

In this study, the untargeted metabolomics approach was able to reveal more than 3,400 molecular features. The annotated compounds and composite mass spectra (mass and abundance combinations), together with compounds confirmed by MS/MS, are listed in **Supplementary Table 1**. The data set was first interpreted through an unsupervised hierarchical clustering. This unsupervised clustering approach enabled the description of similarities/dissimilarities among treatments, as shown in **Figure 5A**.

Two main clusters were generated—one including the BT water-stressed treatment and the other including both irrigated and stressed untreated treatments and the treated irrigated one. Two distinct subclusters, one including the untreated water stressed (WS) and the other both the treated and untreated irrigated treatments, could be identified. The

WS, BT profile differed starkly from the others: the naive (unsupervised) hierarchical clustering of metabolomic signatures revealed distinctive profiles in tomato leaves under limited water availability, which is the result of the application of the biostimulant.

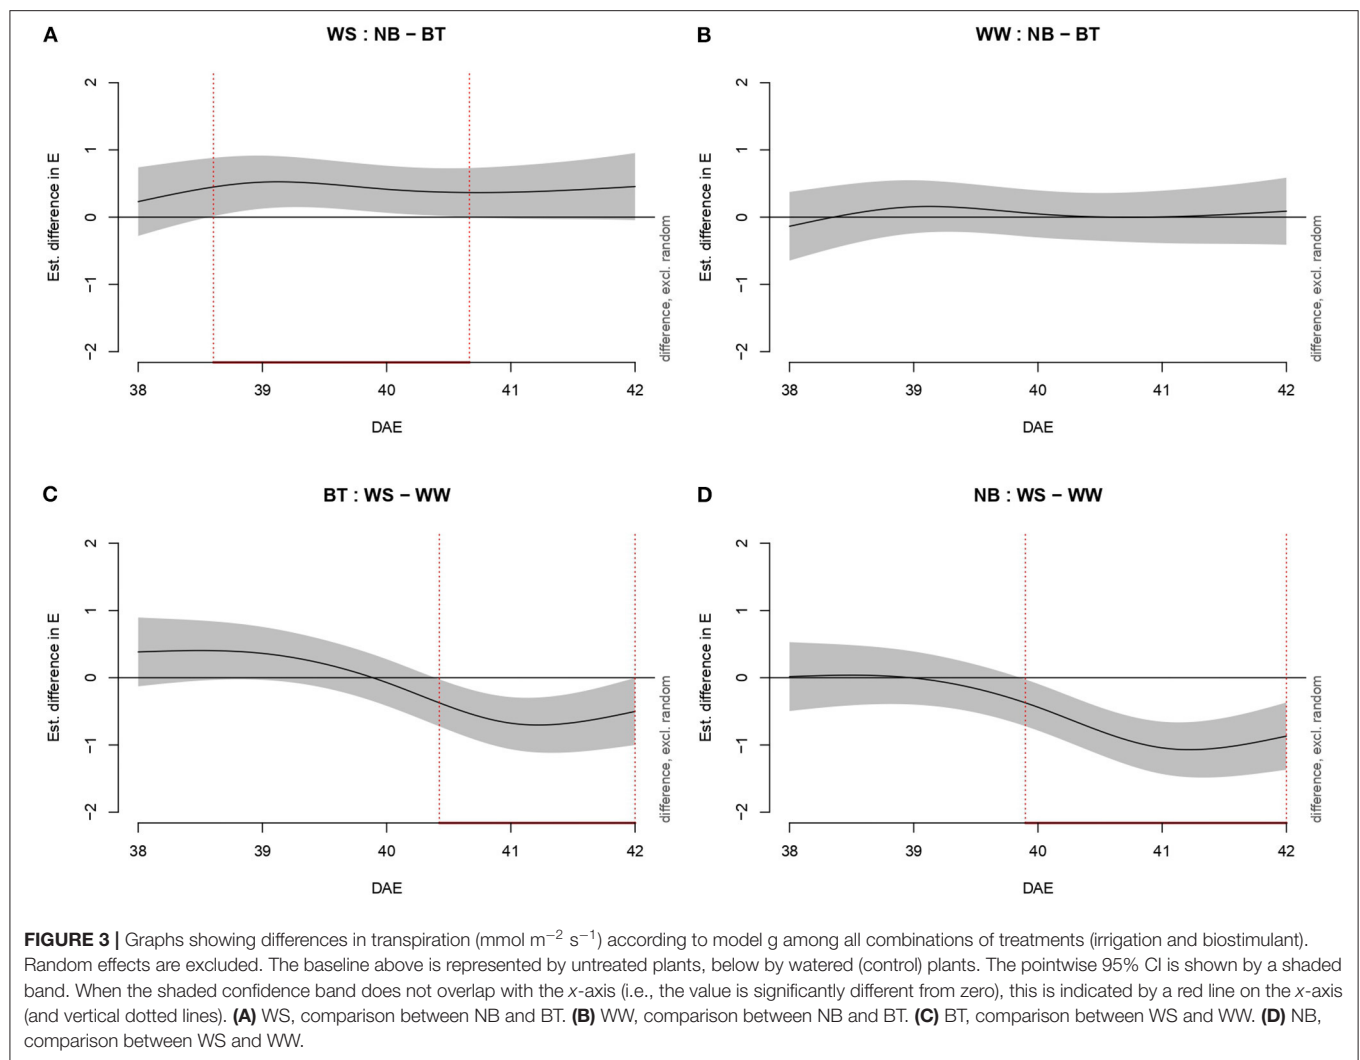

OPLS-DA analysis allowed separating predictive and orthogonal components (i.e., the components ascribable to technical and biological variation) of variance. The subsequent supervised statistics were used to discriminate the tomato samples according to the treatment. The OPLS-DA (Figure 5B) effectively separated the stressed from the non-stressed plants and pointed out irrigation as the main separation factor. Among the stressed plants, treated plants presented the most distinct profile as suggested by the HCA, and were clearly separated from the non-treated ones. Similar metabolic profiles were found for non-stressed plants regardless of the treatment. The model parameters of the OPLS-DA regression were $R^2Y = 0.89$ and $Q^2Y = 0.73$, respectively. The model was validated (CV-ANOVA $p = 1.50 \times 10^{-5}$) and overfitting was excluded through permutation testing ($N = 100$). Given the validated model outcomes, the VIP variable selection method was used to identify compounds explaining the observed differences. The discriminating compounds with a VIP score >1.3 were considered as discriminants. About 147 compounds resulted from this selection and are summarized

**FIGURE 2** | Uncoupling of the partial effects of BT/control treatment on the wigginess of P_n curve. (A) partial effects of control treatment (NB) over the day of treatment [in days after emergence (DAE)] on P_n . (B) partial effects of BT over the day-of-treatment (in DAE) on P_n .

in **Supplementary Table 2**. Thereafter, a Volcano analysis ($p < 0.01$; $FC > 2$) was performed and the significant compounds were then uploaded into the Omics Dashboard tool from PlantCyc to facilitate the discussion of results (**Supplementary Table 3**).

Notably, relatively few biochemical classes included most of the discriminant metabolites (Figure 6).

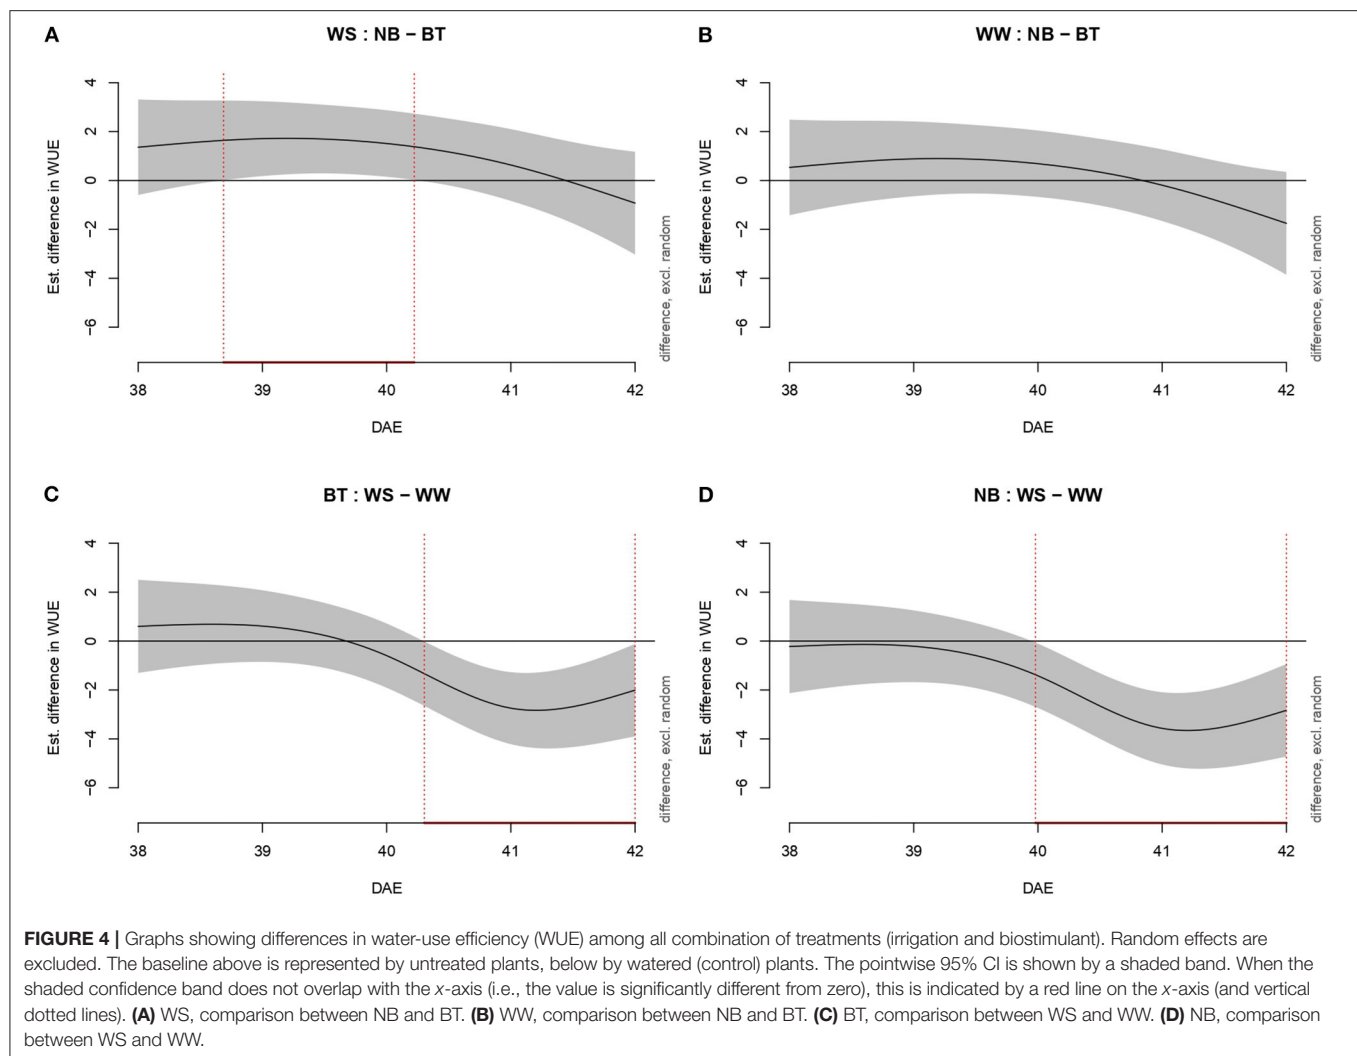

The metabolic profile of water-stressed BT plants sharply differs from the others. The most affected classes of compounds were secondary metabolites, particularly in their biosynthesis, followed by cellular structure synthase and fatty acid and lipid synthesis. Regarding secondary metabolite biosynthesis, terpenoid biosynthesis, nitrogen-containing secondary compound biosynthesis, and phenylpropanoid derivative biosynthesis were the most affected. Compounds related to terpenoid biosynthesis were strongly over-accumulated, mostly represented by triterpenoids and tetraterpenoids, with a high abundance of carotenoids: this is particularly relevant considering the role of carotenoids in photosynthetic organisms.

At the same time, compounds responsible for terpenoid degradation were significantly underaccumulated. Interestingly, phytoalexins were also found to be over-accumulated. Cell structure synthase metabolites, among which stearate and oleate, were strongly over-accumulated. Concerning vitamin biosynthesis, molecules responsible for thiamine biosynthesis were sharply over-accumulated. Among fatty acids and lipids, cutin synthase metabolites were strongly over-accumulated, together with epoxylated and hydroxylated fatty acids, stearate, and unsaturated fatty acids. Sphingolipids were also found to be over-accumulated. Concerning degradation, amino acids degrading molecules showed a generalized under-accumulation, for instance regarding glutamate, lysine, and tryptophan. Lastly, interestingly gibberellin degrading pathways were under-accumulated in BT plants, but differences could be detected among water treatments: the control group showed a sharp under-accumulation of molecules involved in epoxidation, while the stressed group showed a sharp decrease in succinate content, involved in the hydroxylation of gibberellins.

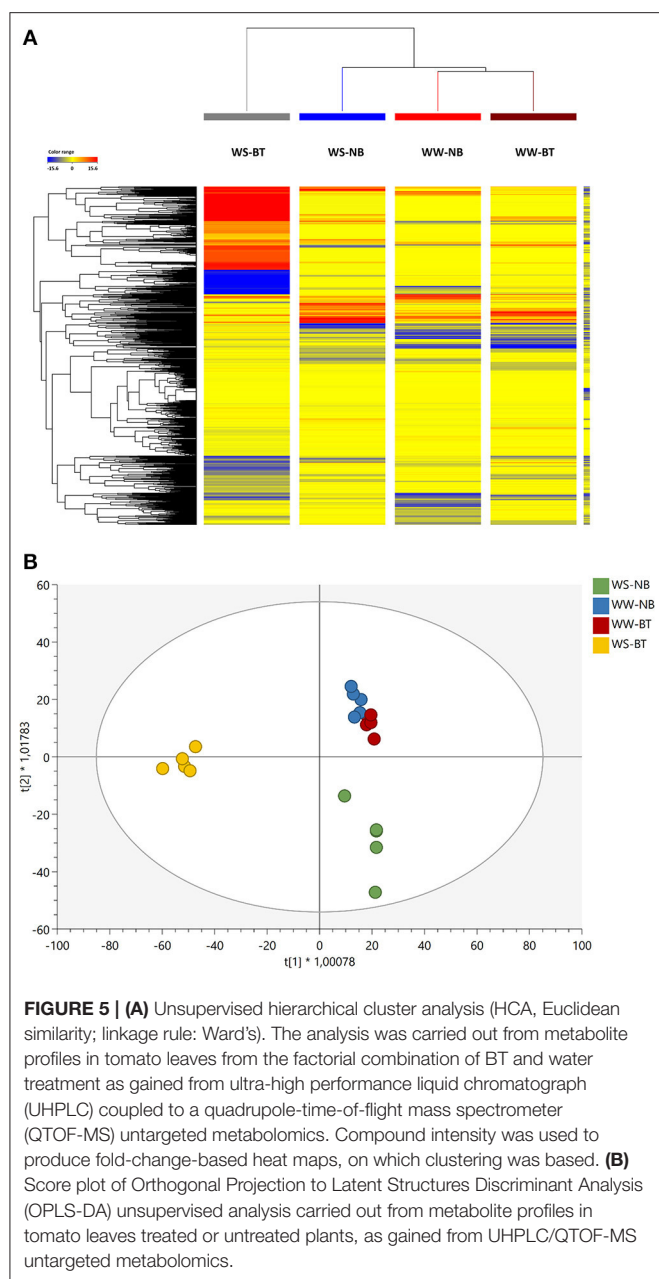

DISCUSSION

One of the primary adverse effects of water deficit stress is the inhibition of photosynthesis triggered by stomatal closure, which represents the earliest response to drought (Michaletti et al., 2018). As a result, CO₂ uptake and concentration in leaves are reduced (Medrano et al., 2002). In view of this, the results from the GAMM analysis confirmed that BT plants performed better in terms of *P_n*, *E*, and WUE compared to untreated plants under water stress. The use of generalized additive modeling enabled the analysis of the full set of dynamic data, without the need to reduce time resolution (i.e., average overtime or select specific time points). Moreover, with this analysis, the effect of treatments (i.e., drought and biostimulant application) on the patterns (i.e., wiggleness) of gas exchange data was accurately modeled and discriminated, also considering data autocorrelation. The use of GAMM allowed for the extraction of information on the effect of the biostimulant devoid of temporal correlation and random errors due to individual replicates, non-linear interactions between both treatments and the duration of the experiment

(expressed in days) and the time of the day (expressed in hours). At the same time, GAMM analysis allowed to consider different smooths for a day (duration of the experiment) and hour (time of the day) for both factors (water and biostimulant). Lastly, the use of GAMM allowed for the inclusion of non-linear variability of the individuals over the duration of the experiment. While the significance of the smooth terms does not provide information on the statistical significance between patterns, each individual variable has a statistically significant influence on modeling the wiggleness of P_n , which in turn confirms the distance of P_n from a linear function. This resulted in a model explaining 87.8% of the deviance. Further, the use of GAMMs enabled the comparison between the curves of stressed and well-watered plants, both with and without biostimulant, thereby providing both a visual screening tool and a statistical tool to further confirm or disprove the effect of biostimulant treatment. The positive effect of the biostimulant treatment observed through GAMM analysis is in line with literature findings on the potential of GB to increase photosynthetic performance under water stress (Yang and Lu, 2005; Hamani et al., 2020; Nawaz and Wang,

2020), especially in tomato (Mäkelä et al., 1999). Differences in the length of significance windows among P_n , E , and WUE were detected. While the photosynthetic rate was constantly higher for treated plants compared to the untreated ones, from stress imposition (39 DAE) to the end of stress (42 DAE), the positive effect in the BT water-stressed plants for transpiration rate, and consequently WUE, was shorter compared to P_n . Specifically, under water-stressed conditions, the positive effect of the biostimulant treatment on E was reduced in duration, indicating that higher transpiration could only be supported until late, on 40 DAE (second day of water stress) and efficacy on WUE was further reduced to early on 40 DAE. This indicates that the increased photosynthetic rate after the first day of water stress imposition is followed by increased transpiration, resulting in the reduction of the WUE advantage. WUE is a largely diffused performance indicator for crop yield and water consumption. Water-stressed plants typically exhibit a higher WUE due to a more conservative use of water, resulting in improved resource utilization efficiency under conditions of water scarcity (Zhao et al., 2020). Nevertheless, high stomatal conductance over

time is essential to high plant production, translating into maximized soil water-use for transpiration, or effective use of water (EUW) for transpiration. It is therefore evident that, under drought conditions, higher stomatal conductance over time will result in lower WUE (Blum, 2009). Indeed, drought-resistant plants display the minimization of leaf permeability, for example, by means of higher epicuticular wax deposition, in order to maximize soil water capture while diverting water to stomatal transpiration (Blum, 2009). Besides, Blum indicates the EUW as the key objective in maximizing biomass production under a limited water regime.

The increased photosynthetic rate was in line with the protective role of GB in terms of cellular osmotic adjustment,

detoxification of reactive oxygen species, and protection and stabilization of membrane integrity (Ashraf and Foolad, 2007) and is further supported by the sharp separation of the metabolic profile of the water-stressed BT thesis. At the same time, the smaller reduction in net photosynthesis in leaves subjected to water stress can be attributed to an increased stomatal conductance, as well as the maintenance of chloroplast ultrastructure (Ma et al., 2006) and Rubisco activity (Yang et al., 2005). Indeed, the overaccumulation of carotenoids is of particular interest, given their photoprotective role in preventing the overexcitation of photosystem II (Uarrotta et al., 2018), while at the same time acting as toxic oxygen species scavengers, structure stabilizers, and excess energy dissipators (Griffiths et al., 1955; Frank and Cogdell, 1996; Polívka and Sundström, 2004). GB has indeed been found to have a strong protective effect on the structure and function of the oxygen-evolving complex of PSII *in vitro* against multiple abiotic stresses (Mamedov et al., 1991, 1993; Papageorgiou et al., 1991; Papageorgiou and Murata, 1995; Allakhverdiev et al., 2003). Wang et al. (2010) found that drought stress can interfere with the state of the lipids in thylakoid membrane, which, if damaged, might cause PSII to be impaired. Concurrently, cell membrane stability depends on the absence of lipid peroxidation, caused by reactive oxygen species (ROS) accumulation. Moreover, they found that carotenoid concentrations in water stressed, GB-treated plants were consistently higher compared to untreated plants. They also demonstrated that the ability of GB to decrease ROS levels is not direct, but rather indirect. These findings imply that GB acts as an elicitor to other scavenger molecules, thereby strongly supporting our findings on carotenoid concentration. Indeed, Wang et al. (2010) correlated GB accumulation to xanthophyll cycle-dependent nonradiative energy dissipation, thereby drawing a strong connection between the protective action derived from GB overaccumulation and carotenoid synthesis. In addition, GB-synthesizing transgenic plants have been found to display higher activity of ROS-detoxifying enzymes (Yang et al., 2006; Ahmad et al., 2010). Supporting these arguments, Xu et al. (2018) hypothesized that GB may act both as an osmotic stress hardening molecule and as a signaling molecule in acclimation, rather than only *via* a direct action. Concerning energy supply, it is particularly interesting to notice the sharp accumulation of thiamine precursors, as thiamine plays a pivotal role in carbon metabolism and is essential for cell energy supply in all organisms. Moreover, it is essential in carbon fixation through the Calvin cycle and the non-mevalonate isoprenoid biosynthesis pathway, from which thousands of metabolites are derived including chlorophyll, phytols, and carotenoids, and also several phytohormones (Noordally et al., 2020). Thiamine has also been linked to plant adaptation responses to persistent abiotic stress conditions, including drought (Wong et al., 2006), and oxidative stress (Rapala-Kozik et al., 2008; Tunc-Ozdemir et al., 2009). In addition, the overaccumulation of specific secondary metabolites suggests a stress priming activity induced by the biostimulant treatment: phytoalexins have been associated with increased drought tolerance in multiple species (Kuc, 1995; Hatmi et al., 2014; Vaughan et al., 2015); phenylpropanoid biosynthetic pathway is activated under abiotic stress conditions,

resulting in stimulated biosynthesis of phenolic compounds with strong antioxidative potential (Sharma et al., 2019). Lastly, the overaccumulation of lipids and specifically cutin synthase metabolites supports the maximization of stomatal transpiration (Kerstiens, 1997, 2006). All things considered, the positive effect of GB on water stress resistance could be attributed both to the delayed onset of stress, and consequently

the enhanced natural response of tomato plants, and the elicitation of stress priming through the induction of H_2O_2 -mediated antioxidant mechanisms, as Park et al. (2004, 2006) suggested, and molecules with strong antioxidant potential (such as xanthophylls).

In conclusion, the study demonstrated the potential of the GAMM method to describe and discriminate biostimulant action

(GB, in this case) to improve photosynthetic performance under water stress conditions. In this, the GAMM method was crucial in extracting the effect of biostimulant treatment under dynamic gas exchange acquisition. GAMM analysis effectively improved the interpretation of time series data, enabling both the description of the dynamics of water stress onset and the isolation of the effect related to the biostimulant treatment. Moreover, compared to the other treatments, water-stressed BT plants displayed a starkly different and stress tolerance-related metabolic profile, in agreement with the findings on photosynthetic performance. The metabolites accumulated suggest a priming effect for stress tolerance, *via* detoxification and stabilization of the photosynthetic machinery. The duration and dynamics of the positive effect of the biostimulant treatment under water stress differed for photosynthesis, transpiration, and WUE, the last two being limited in time. This could depend on an increased transpiration efficiency, translating into maximized soil water use for transpiration, or the EUW for transpiration. At the same time, minimization of leaf permeability through increased leaf wax content is one of the main strategies that plants employ to divert water to stomatal transpiration. Indeed, the metabolic profile findings support the increased EUW through the overaccumulation of lipids and cutine synthase metabolites. The present research brought further evidence that GB protective action on photosystem II is not only direct but also strongly connected to the production of other scavenger molecules (e.g., carotenoids and phytoalexins), making the case that GB acts both as an osmotic stress hardening molecule and as a signaling molecule in acclimation. Nonetheless, further research is needed to deepen the connection between exogenous GB treatment and metabolic response.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/**Supplementary Material**, further inquiries can be directed to the corresponding author/s.

AUTHOR CONTRIBUTIONS

GA designed and performed the experiment, analyzed, and interpreted the data, created the figures for gas exchange, and wrote the manuscript. GA and MC optimized experimental techniques and analyzed gas exchange data. BM-M performed statistical analysis of the metabolome and data interpretation, created the figures for metabolomics, and participated in methods writing. AF was involved in experimental design and participated in data acquisition. SA supervised the design of the experiment, provided intellectual contributions, oversaw data analysis and interpretation, and corrected the manuscript.

ACKNOWLEDGMENTS

The authors gratefully acknowledge financial support from ED&F Man Liquid products ITALIA SRL (Bologna, Italy). One of the authors (BM-M, Grant Number: 21252/PD/19) would like to acknowledge support from the Consejería de Empleo, Universidades, Empresa y Medio Ambiente of the CARM, through the Fundación Séneca-Agencia de Ciencia y Tecnología de la Región de Murcia (Spain).

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fpls.2021.678925/full#supplementary-material>

Supplementary Table 1 | Untargeted metabolomics data set containing the annotated compounds in both ***MS-only and MS/MS following the ultra-high performance liquid chromatography coupled to a quadrupole-time-of-flight mass spectrometer (UHPLC-QTOF-MS) analysis.

Supplementary Table 2 | Discriminant metabolites identified by the variables importance in projection (VIP) analysis in leaves following biostimulant application. Compounds were selected as discriminant by possessing a VIP score > 1.3.

Supplementary Table 3 | Differential metabolites as derived from Volcano analysis [value of $p < 0.01$; field capacity (FC) > 2] and uploaded to the PlantCyc pathway Tool software for the subsequent analysis.

In the current study, inoculation with plant growth-promoting rhizobacteria (PGPR) and grafting were tested as possible cultural practices that may enhance resilience of tomato to stress induced by combined water and nutrient shortage. The roots of tomato grown on perlite were either inoculated or not with PGPR, applying four different treatments. These were PGPR-T1, a mix of two *Enterobacter* sp. strains (C1.2 and C1.5); PGPR-T2, *Paenibacillus* sp. strain DN1.2; PGPR-T3, *Enterobacter mori* strain C3.1; and PGPR-T4, *Lelliottia* sp. strain D2.4. PGPR-treated plants were either self-grafted or grafted onto *Solanum lycopersicum* cv. M82 and received either full or 50% of their standard water, nitrogen, and phosphorus needs. The vegetative biomass of plants subjected to PGPR-T1 was not reduced when plants were cultivated under combined stress, while it was reduced by stress to the rest of the PGPR treatments. However, PGPR-T3 increased considerably plant biomass of non-stressed tomato plants than did all other treatments. PGPR application had no impact on fruit biomass, while grafting onto 'M82' increased fruit production than did self-grafting. Metabolomics analysis in tomato leaves revealed that combined stress affects several metabolites, most of them already described as stress-related, including trehalose, myo-inositol, and monopalmitin. PGPR inoculation with *E. mori* strain C3.1 affected metabolites, which are important for plant/microbe symbiosis (myo-inositol and monopalmitin). The rootstock M82 did not affect many metabolites in plant leaves, but it clearly decreased the levels of malate and D-fructose and imposed an accumulation of oleic acid. In conclusion, PGPR are capable of increasing tomato tolerance to combined stress. However, further research is required to evaluate more strains and refine protocols for their application. Metabolites that were discovered as biomarkers could be used to accelerate the screening process for traits such as stress tolerance to abiotic and/or abiotic stresses. Finally, 'M82' is a suitable rootstock for tomato, as it is capable of increasing fruit biomass production.

Keywords: biostimulant, hydroponics, grafting, metabolomics, M82, PGPR, tomato, water stress

INTRODUCTION

The Mediterranean region, where tomato is widely cultivated, is expected to be strongly affected by the climate change in the following years (Giorgi, 2006; Giorgi and Lionello, 2008). One of the consequences of climate change in the Mediterranean area is the decrease of the average yearly precipitation, which leads to water scarcity, a situation already familiar to many Mediterranean countries (Saadi et al., 2015). Tomato is a water-demanding crop (Ngouajio et al., 2007), and, consequently, water deficit can result in severe yield decreases compared with cultivation under fully irrigated conditions (Kuşçu et al., 2014). Additionally, irrigation along with other parameters, including fertilization, affects the nutritional composition of tomato fruits (Smith and Hui, 2004). To cope with this situation, it is crucial to develop new cropping approaches contributing to reduced water consumption. Deficit irrigation has been postulated as an alternative irrigation strategy that might save water without or with minimal consequences on crop yield, but conclusions as to whether the concomitant yield losses are affordable do not converge (Giuliani et al., 2016).

In addition to water deficit, excessive fertilizer application in intensive agriculture and horticulture also raises environmental concerns, especially in developed countries, but also in developing countries where an increased phosphorus demand is recorded (Desmidt et al., 2015). The initial fears about the availability of P resources are currently revised, and many studies suggest that natural P reserves will not be depleted in the next 100 years (Günther, 1997; Cisse and Mrabet, 2004; Van Vuuren et al., 2010). However, if the plant-available P in the Earth's crust is depleted, access to discrete global reserves is politically sensitive, energy demanding, and economically challenging (Godfray et al., 2010; Neset and Cordell, 2012; Desmidt et al., 2015). Similarly, the use of N fertilizers is associated with increased greenhouse gas emissions, thereby contributing to climate change, firstly because their production through industrial N_2 fixation entails extensive consumption of fossil fuels (Chen et al., 2018) and secondly because part of the soil NO_3-N is converted into N_2O in the soil (Smith and Zimmerman, 1981). Thus, crop fertilization strategies associated with reduced application of N and P fertilizers are strongly supported by current European policies (EU Directive 889/2008).

Plant growth-promoting rhizobacteria (PGPR) application is considered an effective strategy to stimulate plant growth, while modulating abiotic stress responses via a multitude of mechanisms (Patakioutas et al., 2015; Ruzzi and Aroca, 2015; Backer et al., 2018; Rouphael and Colla, 2020). Plant growth promotion by PGPR is the outcome of different mechanisms, such as biological nitrogen fixation, ethylene levels reduction, siderophore production, phytohormone production, induction of pathogen resistance, nutrient solubilization, mycorrhizal functioning, and decreasing pollutant toxicity (Glick et al., 1999; Rouphael and Colla, 2020). Nutrient solubilization can lead to production of biofertilizers, particularly for solubilizing phosphorus (De Pascale et al., 2018) where resources are limited

(Bhattacharyya and Jha, 2012). Induced systemic resistance can also provide an effective pathogen protection even in organic agriculture (Ramamoorthy et al., 2001). Thus, inoculation of plant roots with a mix of different growth-promoting bacteria strains is considered a very promising technique to protect plants from diseases and simultaneously enhance plant growth (Murphy et al., 2003).

Many different PGPR strains have been already tested in tomato crops under different soil or soilless conditions (De Brito et al., 1995; Yan et al., 2003). Colonization of tomato roots with PGPR is performed by inoculating the seeds or by applying the bacteria suspension thoroughly into the soil/soilless medium with no need of sterilization (Yan et al., 2003). Many studies with tomato showed that PGPR inoculation increases yield (Gagné et al., 1993), lycopene, antioxidants, and potassium in tomato fruits (Ordookhani et al., 2010). Furthermore, PGPR increased P levels in tomato shoots (Hariprasad and Niranjana, 2009) and contributed to more efficient control of nematode and pathogen infections (Seleim et al., 2011; Shanmugam and Kanoujia, 2011; Almaghrabi et al., 2013).

Grafting is an alternative technique that can confer enhanced tolerance to tomato under both biotic and abiotic stress conditions (Lee and Oda, 2003; Rouphael et al., 2017). Amelioration of abiotic stress imposed by shortage of nutrients or water has been reported by several scientists, including Rouphael et al. (2008a,b), Savvas et al. (2010), Schwarz et al. (2010), Colla et al. (2011), and Rouphael et al. (2017). Some rootstocks proved to be capable of mitigating nutrient shortage stress by increasing the nutrient-to-water uptake ratio, thereby resulting in enhanced nutrient translocation to the shoot (Savvas et al., 2017). Nevertheless, for some other nutrients, increased nutrient-to-water uptake ratios occur merely because of their enhanced deposition to the rootstock.

Stress due to shortage of water also restricts plant growth and crop yield due to impairment of the plant metabolism. Drought stress imposes generation of reactive oxygen species during several metabolic processes (Sánchez-Rodríguez et al., 2011). Other important metabolites affected by water deficit are sugar and sugar derivatives (Dumville and Fry, 2002; Semel et al., 2007) and amino acids (Semel et al., 2007), where changes in proline and glutamate content have been recognized as responses to drought stress (Zhu, 2000; Bartels and Sunkar, 2005; Semel et al., 2007). Fatty and organic acids generally increase as a response to drought stress, especially those occurring as intermediates of the tricarboxylic acid (TCA) cycle.

Scarcity of good-quality irrigation water and high demand of energy in fertilizer production, combined with reduced availability of plant nutrient resources, impose increasing pressure to horticulture to adopt water- and nutrient-saving cultural practices with no or minimal yield losses. To address this challenge, inoculation with PGPR and grafting onto suitable rootstocks were tested in the current study as possible cultural practices that may enhance resilience of greenhouse tomato to stress induced by combined water and nutrient (N and P) shortage. To contribute to the discovery of potential biomarkers that might accelerate the progress of screening new effective biostimulants and rootstocks, the impact on plant metabolism

was studied by applying metabolomics analysis, in addition to growth and yield responses.

MATERIALS AND METHODS

Plant Material, Growth Conditions, and Treatments

The experiment was conducted during the winter of 2017 in a glasshouse at the Agricultural University of Athens (N 37°59'10", E 23°42'29", altitude 24 m). Tomato (*Solanum lycopersicum*) cv. Belladonna F1 was grown in an open hydroponic system using perlite as growing medium, placed in pots. Plants were either self-grafted (Belladonna/Belladonna) or grafted onto tomato *S. lycopersicum* Mill. cv. M82. The tomato cultivar M82, which has been previously studied under water deficit conditions (Rigano et al., 2016; Illouz-Eliaz et al., 2020), was selected because it has been used for backcrossing with *Solanum pennelli* aiming to produce water-stress-tolerant tomato rootstocks (Lippman et al., 2007; Ofner et al., 2016).

Tomato seedlings were transplanted into the greenhouse on November 23, 2018, at the stage of five true leaves. Before being transplanted, the growing medium around the roots of the seedlings was removed, and the roots were placed for 1 min into a PGPR suspension containing 10^9 CFU ml⁻¹, which was diluted 10-fold before use. The inoculation of tomato seedlings was repeated 5 days later by drenching the growing medium with the same PGPR suspension using a 5-ml pipette. Five PGPR strains were used to establish the following four PGPR treatments: PGPR-T1, a mix of two *Enterobacter* sp. strains (C1.2 and C1.5); PGPR-T2, *Paenibacillus* sp. strain DN1.2; PGPR-T3, *Enterobacter mori* strain C3.1; and PGPR-T4, *Lelliottia* sp. strain D2.4. These PGPR treatments were complemented with a control treatment in which no PGPR was applied to the tomato roots. The bacterial strains used in the present study belong to bacterial genera or species known to exhibit PGP traits according to the literature (Jha et al., 2011; Amaresan et al., 2020; Orozco-Mosqueda and Gustavo, 2020). Moreover, the strains showed tolerance in the presence of 8% (w/v) NaCl (Tampakaki et al., unpublished results), and for this reason, they were considered suitable for testing under drought conditions.

Plant density was 2.4 plants m⁻² at the beginning of the experiment. The experiment was set up as a three-factorial (2 rootstocks × 5 PGPR × 2 stress treatments), completely randomized block design with three replicates per treatment and three plants per replicate. A bumblebee hive was placed into the glasshouse on December 19, 2017, to secure optimal pollination. On January 8, 2018, i.e., 6 weeks after transplanting, one plant per replicate was sampled and used to estimate the root and the aboveground biomass production. After removal of these plants, the plant density decreased to 1.6 plants m⁻². Harvest commenced on February 9, 2018; and the experiment was terminated on March 30, 2018. Air temperature was always maintained to levels above 13°C during the night and above 18°C during the day.

Combined stress was applied by reducing water and nutrient (N and P) supply to 50% of the standard supply in the non-stress treatment. The daily amount of supplied nutrient solution (NS) differed among stressed and non-stressed treatments. Non-stressed treatments were fertigated using a solar meter to control irrigation frequency aiming to obtain a drainage fraction of 20% of the total NS amount supplied to plants. The irrigation frequency in the stressed plants was similar with that applied to the non-stress plants, but the amount of NS provided at each irrigation event was half as much as that provided to the non-stressed plants. Additionally, concentrations of nitrogen and phosphorus in the NS supplied to the stressed plants were half as high as in the standard NS for tomato (Savvas et al., 2013) provided to the non-stressed plants. Nutrient concentrations in the NS are provided in **Supplementary Table 1**.

Biomass and Total Yield Determination

Aboveground biomass samples were obtained 6 weeks after transplanting and at the end of the cultivation, by harvesting the entire shoot. Root fresh biomass was also measured at the first sampling. After the tomato shoot was harvested, fresh weight was recorded, and samples were oven-dried at 65°C for at least 72 h, until constant weight was achieved, and used to determine their dry weight and mineral composition. The impact of the experimental treatments on fruit yield was assessed by manually harvesting three times a week all commercially ripe fruits commencing on February 9, 2018, and terminating on March 30, 2018. Fruits were also classified into four classes (Extra Class, Class I, Class II, and non-marketable) as described in the Eu Regulation (543/2011).

Mineral Analysis

The dried samples of tomato leaves were powdered using a blade mill and passed through a 40-mesh sieve. Plant tissue samples were used for chemical analysis to determine total N, P, and K concentrations. Total N was determined applying the Kjeldahl method. To estimate P and K, leaf samples were milled and dry ashed at 550°C for 5 h, and the ash was dissolved in 1 M of HCl. Phosphorus was measured photometrically as phosphomolybdate blue complex at 880 nm using a 96-position microplate spectrophotometer (Anthos Zenyth 200; Biochrom, United States). Potassium was determined using a flame photometer (Sherwood Model 410, Cambridge, United Kingdom).

Gas Chromatography/Electron Impact/Mass Spectrometry Metabolomics Analysis of Tomato Leaves

Chemicals and Reagents

For the derivatization of samples for gas chromatography/electron impact/mass spectrometry (GC/EI/MS) analysis, the reagents ribitol, methoxylamine hydrochloride, *N*-methyl-*N*-(trimethyl-silyl)trifluoroacetamide (MSTFA), and pyridine were used (Sigma-Aldrich Ltd., Steinheim, Germany). The organic

solvents methanol and ethyl acetate (Carlo Erba Reagents, Val de Reuil, France) were used for the extraction of leaf tissues.

Plant Material and Sample Preparation

Entire young, fully expanded, and healthy tomato leaves were collected and placed directly in liquid nitrogen for quenching and then were stored at -80°C until further processing. Samples were collected from plants 55 days following transplantation. Metabolomics was applied to non-stressed and stressed plants and to self-grafted and grafted M82 plants. Furthermore, based on the results of early plant biomass measurements, only samples of plants from the PGPR-T3 and non-inoculated plants were subjected to metabolomics.

Metabolite Extraction for Gas Chromatography/Electron Impact/Mass Spectrometry Analysis

Tomato leaves were pulverized using pestle and mortar in liquid nitrogen, and the pulverized tissues were placed in Eppendorf tubes (2 ml) and stored in -80°C . For metabolomics, 50 mg was transferred into Eppendorf tubes (2 ml); and 1 ml of a solution of methanol:ethyl acetate (50:50 v/v) and 20 μl of ribitol (0.2 mg ml^{-1} methanol), serving as internal standard, were added. A previously described protocol was used (Kostopoulou et al., 2020), with minor modifications. Samples that were obtained by pooling portions of the biological replications of each treatment served as the quality-control samples. The resulting suspensions were sonicated for 20 min in an ultrasonic bath (Branson 1210, Danbury, United States) and then agitated using a horizontal rotary shaker (GFL 3006, Gesellschaft für Labortechnik mbH, Burfwedel, Germany) at 150 rpm for 2 h. The suspensions were filtered using PSTFA filters (0.2- μm pore diameter, Macherey-Nagel, Duren, Germany). Derivatization of samples for GC/EI/MS analysis was performed in a two-step process using methoxylamine hydrochloride in pyridine (20 mg ml^{-1}) for methoxymation and MSTFA for silylation. The derivatized samples were finally transferred to microinserters (180 μl , Macherey-Nagel).

Gas Chromatography–Mass Spectrometry Analyses

The derivatized samples were analyzed by GC/EI/MS (GC/EI/MS Agilent 6890n, Agilent Technologies Inc.) equipped with an inert mass-selective detector 5973 (MSD) and a 7683 autosampler. The electron ionization was set to 70 eV, and full scan mass spectra were acquired at 50–800 Da in a rate of 4 scans per second with a 10-min solvent delay. The temperature for the ion source was set to 150°C and for the transfer line to 230°C . An HP-5MS capillary column (30 m, i.d. 0.25 mm, and film thickness 0.25 μm ; Agilent Technologies Inc.) was used, and helium (He 6.0) was the carrier gas. Samples were injected in completely randomized order on column, and the injector split ratio was set to 5:1. The initial temperature of the oven was 70°C , stable for 5 min, followed by an increase of 5°C per min to 295°C .

Statistical Analysis

The experiment was set as a complete randomized block design with three factors ($2 \times 5 \times 2$) and three replications per

treatment. Data were analyzed by applying three-way analysis of variance (ANOVA) to assess main effects [rootstocks (R), PGPR, and stress conditions (S)], three first-order interactions ($R \times \text{PGPR}$, $R \times S$, and $\text{PRPR} \times S$), and one second-order interaction ($R \times \text{PGPR} \times S$). Multiple comparisons of means were performed by applying the Duncan multiple range test ($p < 0.05$) after performing three-way ANOVA. The data were statistically analyzed using STATISTICA, version 8.0 (StatSoft, Inc., Tulsa, OK, United States).

For the metabolomics analyses, all experimental events were controlled using the software MSD Chemstation (Agilent). The deconvolution of the acquired total ion chromatograms was performed using the software AMDIS v.2.66 [National Institute of Standards and Technology (NIST); Gaithersburg, MD, United States], and the MS database of the NIST '08 (NIST; Gaithersburg, MD, United States). The absolute identification for selected metabolites was performed by matching their retention times and mass fragmentation patterns to those of analytical standards, which had been analyzed employing the same method and analyzer, as recommended by the Metabolomics Standards Initiative (MSI) (Sansone et al., 2007). The tentative annotation of features was performed based on the similarities of their fragmentation patterns to those of entries of the NIST library ($>90\%$). Based on the deconvolution of the data, features present also in the experimental blank samples or features that correspond to column artifacts were excluded from analyses. The data pre-processing, including feature alignment and gap filling, was performed using the software MS-Dial v.3.70, applying the recommended settings for GC/EI/MS (Tsugawa et al., 2015). The discovery of trends and biomarkers was based on the values of scaled and centered orthogonal partial least square (OPLS) regression coefficients (CoeffCS) ($p < 0.05$). OPLS-discriminant analysis (OPLS-DA) was applied, since it provides optimal model interpretability and transparency (Aliferis and Chrysai-Tokousbalides, 2011), using the software SIMCA-P v.13.0.3 (Umetrics, Sartorius Stedim Data Analytics AB, Umeå, Sweden), as previously described (Chatzigianni et al., 2020; Karamanou and Aliferis, 2020; Kostopoulou et al., 2020). The hierarchical cluster analysis (HCA) of the data was performed by the Ward linkage method.

RESULTS

Biomass Production

Six weeks after transplanting, the exposure of tomato to combined nutrient (N and P) and water stress reduced significantly the aboveground fresh biomass compared with non-stressed plants (Figure 1i). Inoculation of tomato with PGPR exerted a positive influence on plant biomass than did non-inoculated plants regardless of the applied PGPR treatment. Among the different PGPR treatments, PGPR-T3 had the highest biomass under both non-stress and combined stress conditions. Plants inoculated with PGPR-T3 exhibited also significantly higher root biomass than did the rest of the PGPR treatments and the non-inoculated plants under both no stress and combined stress conditions (Figure 1ii). Grafting 'Belladonna' onto 'M82'

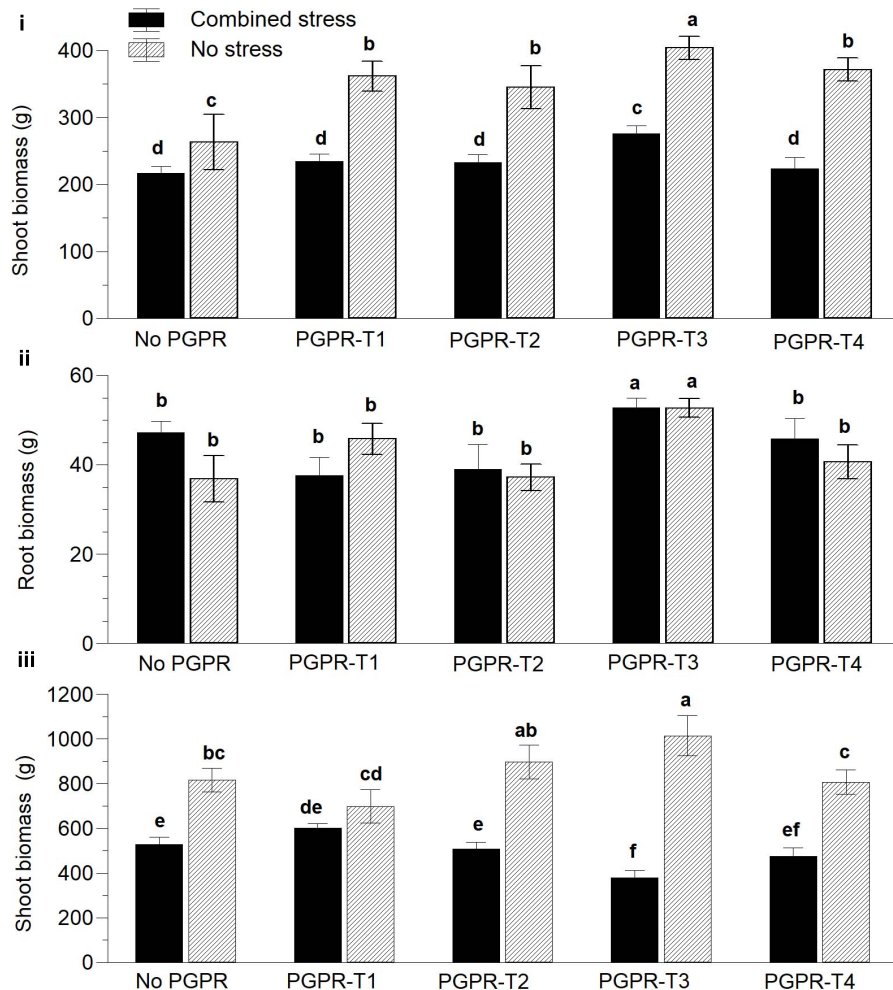

FIGURE 1 | Effects of combined water and nutrient stress (restriction of water, N, and P supply by 50%), and plant growth-promoting rhizobacteria (PGPR) inoculation on aboveground vegetative biomass (i) and root biomass (ii) 45 days after transplanting and aboveground biomass at the end of the cultivation period (iii). PGPR-T1, a mix of *Enterobacter* sp. strains C1.2 and C1.5; PGPR-T2, *Paenibacillus* sp. strain DN1.2; PGPR-T3, *Enterobacter mori* strain C3.1; and PGPR-T4, *Lelliottia* sp. strain D2.4. Data are means of three replications. Means followed by different letters indicate significant differences according to the Duncan multiple range test ($p < 0.05$).

had no impact on the fresh plant biomass 6 weeks after transplanting (data not presented).

At the end of the experiment, clear differences were again observed between non-stressed plants and plants exposed to combined water and N/P stress, regarding the aboveground fresh biomass. More specifically, non-stressed plants resulted in higher aboveground biomass than did stressed plants (Figure 1iii). The PGPR application also affected the aboveground vegetative biomass, but its impact interacted with the combined water and nutrient stress. Under non-stress conditions, PGPR-T3 resulted in the highest aboveground vegetative biomass, and the difference was significant in comparison not only with the treatment without PGPR application but also with PGPR-T1 and PGPR-T4. However, under combined water and nutrient stress conditions, PGPR-T3 resulted in the lowest aboveground vegetative biomass. Furthermore, the aboveground vegetative biomass was not reduced by combined water and nutrient stress

in plants of the PGPR-T1, while it was reduced in all other PGPR treatments.

Plants grafted onto the rootstock M82 exhibited 30% higher aboveground fresh biomass than did self-grafted plants under non-stress conditions. However, under stress conditions imposed by combined nutrient and water shortage, grafting had no impact on the aboveground vegetative biomass (data not presented).

Tomato Yield

Plants cultivated under combined water and N–P deficit produced fewer fresh fruits by 34.8% than did plants with optimal fertigation (Table 1). The reduction of yield by combined water and nutrient stress originated from decreases in both the mean fruit weight by 15.7% and the number of fruits per plant by 22.7%. Moreover, combined stress restricted also the total weight of fruit graded Extra Class and Class I by 37.9%. Inoculation of tomato roots with PGPR had no impact on total fruit yield and

yield components, as well as quality grading. Grafting onto the rootstock M82 did not affect fruit mean weight but significantly increased the number of fruits per plant resulting in 11.6% more total fruit production and a significant increase in Extra Class fruits compared with self-grafting. The effect of grafting on total fruit yield and number of fruits per plant did not interact with the combined water and nutrient stress, while the production of Extra and Class I fruits was enhanced by grafting only under non-stress conditions.

Leaf Nutrient Concentrations

Combined reduction of water, N, and P supply by 50% decreased significantly the total N concentrations in leaves when the roots were not inoculated, or inoculated with PGPR-T1 or PGPR-T3, but had no impact on leaf total-N when inoculated with PGPR-T2 and PGPR-T4 (Table 2). Grafting had no significant impact on the leaf total N concentration. Under non-stress conditions, PGPR inoculation did not affect the leaf total N level, while under combined water and nutrient stress conditions, PGPR-T2

PGPR, plant growth-promoting rhizobacteria.

and PGPR-T4 resulted in significantly higher leaf total N levels compared with PGPR-T1.

The leaf P concentration was significantly reduced by combined water and nutrient stress conditions regardless of grafting and PGPR application (Table 2). Grafting onto M82 reduced slightly but significantly the leaf P concentration from 5.3 to 4.6 mg g⁻¹. The leaf K concentration was significantly reduced from 51.4 to 45.2 mg g⁻¹ when plants were exposed to combined water and nutrient stress, while grafting and PGPR application had no significant impact on the leaf K (data not presented).

Metabolomics Analysis

Fluctuations in tomato leaf metabolome in response to combined water and nutrient stress, PGPR inoculation, and grafting were recorded using bioinformatics software and metabolite species-specific databases. A representative raw GC/EI/MS data set

[*S. lycopersicum* L. (Tomato) (PMG-01-21)] can be found at the repository of the Pesticide Metabolomics Group of the Agricultural University of Athens¹. In total, 167 metabolite features were discovered, and the annotated ones belonging to various chemical groups are presented in **Supplementary Data Set 1**. The application of OPLS-DA revealed tight groups with no outliers at $p < 0.05$ (**Figure 2**). The leaf metabolome of tomato plants treated with *E. mori* strain C3.1 (PGPR-T3) was clearly discriminated from that of non-inoculated plants, except for plants grafted onto M82 under combined stress conditions. Non-stressed plants were also clearly discriminated from plants exposed to combined water and nutrient stress, except for stressed plants, which were self-grafted and inoculated with *E. mori* strain C3.1 (**Figure 3**). The examination of the hierarchical manner of the treatments metabolism generally revealed that PGPR inoculation had the greatest cluster distance from the non-inoculated treatment except of plants inoculated with PGPR-T3, grafted onto 'M82' and cultivated under combined stress, which was discriminated from the rest of the PGPR treatments.

Based on the values of the corresponding CoeffCS, the metabolites exhibiting the most marked accumulation, which exceeded a 10-fold increase in plants exposed to combined water, N, and P stress, were ethylene glycol, L-lactic acid, ethyl phosphoric acid, phosphoric acid, glycine, malate, pyroglutamic acid, oleic acid, and α - α -trehalose, while succinic acid, glyceric acid, citric acid, D-fructose, myo-inositol, stearic acid, and 1-monopalmitin were reduced 10-fold (**Figure 4**). The PGPR inoculation with PGPR-T3 increased over 10-fold D-fructose and α - α -trehalose levels but decreased ethanolamine, glycerol, malate, myo-inositol, oleic acid, 2-O-glycerol- α -D-galactopyranoside, and 1-monopalmitin in tomato leaves

(**Figure 5**). Finally, grafting 'Belladonna' onto the rootstock 'M82' resulted in a more than 10-fold higher relative abundance of stearic acid, oleic acid, 2-O-glycerol- α -D-galactopyranoside, and 1-monopalmitin but lower than 10-fold relative abundance of malate, D-fructose, and myo-inositol than in self-grafted 'Belladonna' (**Figure 6**).

DISCUSSION

Biomass Production

Plant growth-promoting rhizobacteria can stimulate plant growth through a range of mechanisms, including excretion of substances acting as plant growth regulators or stimulation of their biosynthesis by plants, improved nutrient acquisition, and inhibition of fungal plant pathogens (Raaijmakers et al., 2009; Choudhary et al., 2011). Furthermore, PGPR can induce systemic tolerance to abiotic stress (Yang et al., 2009). In a study with tomato and pepper cultivated under optimal or water stress conditions, inoculation of the roots with PGPR increased biomass production compared with no application of PGPR under both optimal and water stress conditions (Mayak et al., 2004). On the other hand, in an experiment with tomato inoculated with different PGPR strains, Shen et al. (2012) found that PGPR-induced growth promotion occurred only under stress conditions imposed by simulated seawater irrigation. These contradictory results indicate that the impact of PGPR application on cultivated plants is species- and strain-specific, as different bacteria possess different growth stimulation mechanisms, as also suggested by Dey et al. (2004).

Although the use of PGPR on tomato cultivation has been already addressed in several studies, the PGPR strains applied in the current study have never been tested in the past as PGPR. All PGPR treatments applied in the current study enhanced the root

The ellipse represents the Hotelling T^2 with 95% confidence interval.

Despite the protective role of PGPR-T3 on tomato growth during the early cultivation stage, PGPR-T3 resulted in the lowest shoot biomass under combined nutrient and water stress conditions at crop termination. These results indicate that the

protective effect of *E. mori* strain C3.1 was attenuated during the cropping period. Since PGPR was applied only once at crop establishment, a possible explanation for the different responses of stressed tomato to PGPR-T3 at the early growth stage and at crop termination is that the stress conditions might have decreased the population density of PGPR in the long term. In agreement with this consideration, Patakioutas et al. (2015) reported an appreciable reduction in the population density of *Bacillus amyloliquefaciens* in a hydroponic greenhouse tomato crop after about 30 weeks of cultivation. This finding indicates that inoculation with some PGPR strains may need repetition one or more times in long-term greenhouse crops exposed to stress conditions to maintain an effective density of PGPR population in the root zone. However, this has to be confirmed experimentally. On the other hand, PGPR-T1 had no protective effect against combined nutrient/water stress during the early vegetative period of growth but maintained shoot growth to similar levels with non-inoculated non-stressed plants at crop termination. This response indicates that the mix of the *Enterobacter* sp. strains C1.2 and C1.5 deploys a different protective mechanism against stress than the rest of the PGPR treatments tested in the current study, which is adaptive and operates only under long-term stress conditions.

Grafting onto 'M82' did not protect plants against combined nutrient and water stress, in agreement with Rigano et al. (2016), who found that this rootstock is not tolerant to water deficit, although it is a vigorous rootstock. However, under non-stress conditions, grafting onto 'M82' boosted shoot growth, in agreement with Ntatsi et al. (2014) and Rouphael et al. (2017), who stated that grafting tomato onto vigorous rootstocks increases tomato growth.

Tomato Yield

Several studies have shown that PGPR can increase tomato fruit production, an effect that in most cases is ascribed to enhanced protection against plant diseases. For instance, Gravel et al. (2007) reported yield increases in hydroponic tomato inoculated with *Pseudomonas brevicompactum*, *Pseudomonas marginalis*, *Pseudomonas putida*, and *Trichoderma atroviride*. In other studies, PGPR enhanced tomato fruit yield only under stress conditions. Thus, Gagné et al. (1993) reported yield increases in an autumn crop of tomato inoculated with a *Pseudomonas* fluorescence strain under suboptimal natural light conditions. However, in spring, under more favorable light conditions, the tomato fruit biomass was not influenced by inoculation with *Pseudomonas*. In the current study, combined water and nutrient stress decreased significantly tomato fruit biomass, whereas PGPR inoculation under the conditions of the current experiment was incapable of eliminating or mitigating the stress effects on fruit production. The lack of any benefit from PGPR application concerning fruit yield supports the previously stated notion that the population density of PGPR in the roots decays with time under real growing conditions, and re-inoculation during a long-term cropping period is required. This suggestion is in line with a previous report of Yan et al. (2003), who found that the population density of *Pseudomonas*

strains used as PGPR in the roots followed a decreasing pattern with time.

Grafting onto M82 increased total fruit yield, regardless of stress conditions, whereas the Extra Class and Class I fruit yield was increased by grafting only under non-stress conditions. These results show that the fruit biomass production in tomato grafted onto 'M82' is less susceptible to combined nutrient/water stress than the vegetative growth. However, these results also corroborate previous results of Rigano et al. (2016), suggesting that 'M82' is not tolerant to water stress.

Leaf Nutrient Status

The reduction of the total N concentration in leaves of tomato exposed to combined nutrient and water stress is fully anticipated since one of the stress factors was the reduction of the N supply by 50%. However, under combined stress conditions, PGPR-T2, PGPR-T3, and PGPR-T4 managed to sustain the leaf N concentrations to similar levels with those measured in non-stressed plants. These results show that the PGPR strains DN1.2 of *Paenibacillus* sp., C3.1 of *E. mori*, and D2.4 of *Lelliottia* sp. are capable of maintaining normal nitrogen uptake under conditions of restricted N supply up to 50% of the standard levels. In a previous study, Adesemoye et al. (2010) found that enhanced N uptake by plants was due to increased plant uptake of N originating from fertilizer and not from enhanced mobilization of organic N reserves in the soil. The current results are in line with those findings, since in the current study the plants were cultivated on an inert medium in which only inorganic N was supplied. Cordero et al. (2018) also reported increased N concentration in tomato leaves following root inoculation with PGPR. According to these researchers, increased N acquisition by plants treated with PGPR results from increased root surface, stimulation of metabolic processes contributing to nutrient mobilization, and utilization of N reserves from the microbial biomass turnover. Nevertheless, the maintenance of normal leaf N in tomato plants inoculated with PGPR-T2, PGPR-T3, and PGPR-T4 under combined stress conditions did not prevent stress-induced fruit yield restrictions in these treatments. These results indicate that the yield reduction in tomato exposed to combined nutrient and water stress was not due to shortage of N.

Unlike the leaf N, the leaf P concentrations were not affected by PGPR, presumably because, in the current study, tomato was cultivated hydroponically on an inert medium and not in the soil. The P concentrations in NSs supplied to hydroponic crops (usually 1–1.5 mmol L⁻¹, Savvas and Gruda, 2018) may be 100-fold higher than the Pi concentrations encountered by plants in the soil solution (Schachtman et al., 1998), while the inert porous media used in hydroponics do not contain any P reserves. Thus, PGPR could not provide a benefit by mobilizing P reserves under conditions of limited P availability in the root environment. In agreement with this consideration, Gravel et al. (2007) reported that inoculation of tomato roots with PGPR had no impact on the leaf nutrient status in tomato plants grown on rockwool, whereas the same microorganisms increased the available P in plants cultivated on an organic medium. Furthermore, the same

researchers did not find any beneficial effect of PGPR on plant K status, in agreement with the current study.

Metabolomics Analysis

The metabolomics analysis in tomato leaves revealed a clear discrimination between the different treatments, which indicates that they all had an impact on leaf metabolism. PGPR-T3 exerted the strongest impact on leaf metabolism, as all PGPR-T3 treatments, irrespective of grafting and stress exposure, were clearly discriminated from the treatments without PGPR inoculation (**Figures 2, 3**). The only exception was the treatment combining PGPR-T3 inoculation with grafting onto ‘M82’ under water/nutrient stress, which exhibited a similar metabolic profile with that of the non-inoculated treatments, thus questioning the successful symbiosis of PGPR-T3 with the roots of M82.

Plants are complex organisms, and it is difficult to study and understand the exact role of each of the identified metabolites. In general, the metabolic roles of most sugars, proline, α - α -trehalose, monopalmitin, and GABA have been extensively studied. Other metabolites, for example, those participating in the TCA cycle, have also been studied extensively, but the exact function of most of them is poorly understood (Semel et al., 2007). Although many studies corroborate previous findings concerning metabolic pathways, the role of many metabolites remains contentious among researchers (Van Der Merwe et al., 2009).

The metabolic responses of plants differ when they are exposed only to water, N, or P shortage, compared with cultivation under stress caused by combined shortage. In the present study, glycine, for example, increased in plants exposed to combined water, N, and P shortage. Sung et al. (2015), who studied the impact of N, P, and K deficiencies on leaf and root metabolism in tomato, found that glycine decreases in tomato leaves exposed to partial N starvation but increases in plants exposed to P deficiency. Combined consideration of the current results and those of Sung et al. (2015) leads to the conclusion that, in the current study, the impact of P stress on glycine overwhelmed that of N stress. In contrast, citrate decreased in the present study under combined N and P stress, similarly to what Sung et al. (2015) reported under N stress, but diverged from the results under P shortage, indicating that the dominant factor for citrate in the current study was the N availability. Glycerate and fructose were reduced by combined stress in the present study, similarly to the reduction found by the same authors under only N or P stress. The observed accumulation of malate and trehalose under combined stress could be ascribed to their well-documented protective role under osmotic and oxidative stress (Cortina and Culiáñez-Macià, 2005; Semel et al., 2007). Finally, myo-inositol can be a protective compound under salt stress conditions, with a dual role. On the one hand, it can affect metabolism as a signal or a key metabolite (Hu et al., 2018). On the other hand, according to previous studies, under salinity stress, myo-inositol can balance osmotically the cytosol (Zhang et al., 2001), while its derivatives participate in plant stress responses such as programmed cell death (Kaur et al., 2013). However, in the present study, the levels of myo-inositol decreased in plants exposed to combined water, N, and P stress.

compared with non-stress conditions. This response may indicate that myo-inositol has a protective role only against salt stress, while the genes regulating its biosynthesis are downregulated under nutrient or water shortage conditions.

The phosphoric acid determined as a metabolite represents all forms of phosphates participating in cell metabolism. As reported by Wasaki et al. (2003), P deficiency imposes upregulation of many genes related to P metabolism and concomitantly enhances the biosynthesis of metabolites involved in P metabolism, such as pyruvate kinase and the accompanying phosphoenolpyruvate phosphatase, glucose-6-phosphate isomerase, inorganic pyrophosphatase, purple acid phosphatase, and inorganic phosphate transporters. Nevertheless, P deficiency also downregulates genes related to P metabolism, such as acid phosphatase (Wasaki et al., 2003). Under stress conditions, the needs for energy transport aiming to mobilize defense mechanisms entail increased biosynthesis of phosphorylated intermediates (Latz et al., 2013). As a result, upregulation of genes involved in the biosynthesis of phosphate containing metabolites exceeds downregulation, and concomitantly, the level of metabolically related phosphates increases, although the total P concentration in plant tissues may decrease, as was the case in the current study (**Table 2**). In agreement with this consideration, Wasaki et al. (2003) stated that P deficiency stress stimulates upregulation of genes that control the biosynthesis of metabolites substituting phospholipids in cell membrane, thereby increasing the levels of phosphates available for metabolic functions that contribute to energy transport. Phospholipids count for 17% of P in leaves (Lambers et al., 2012). Thus, their substitution with non-phosphorus lipids in cell membranes in response to stress conditions (Tawarayama et al., 2018) could maintain the levels of P-containing metabolites.

Colonization of tomato roots by PGPR clearly affected tomato metabolism, but only few metabolites exhibited a substantial fluctuation. The strongest impact of PGPR was on trehalose biosynthesis. Trehalose, which serves primarily as a storehouse of glucose for energy and/or for synthesis of cellular components, is also involved in functions protecting membranes and proteins against stress (Elbein et al., 2003). Furthermore, trehalose is involved in interactions between plants and microorganisms, including both symbiosis (Müller et al., 1994) and pathogenesis (Brodmann et al., 2002). More specifically, trehalose is present at relatively high concentrations in nodules, indicating a positive relationship between trehalose and nodulation (Streeter and Gomez, 2006), while the suppression of trehalose metabolism is associated with reduced pathogenicity (Tournu et al., 2013). These results indicate that trehalose promotes colonization of plants by bacterial microorganisms through alteration of the carbohydrate metabolism to their favor, regardless of whether the plant-microbe relationship is beneficial or destructive to plants. Hence, the accumulation of trehalose in plants treated with PGPR-T3 in the current study, compared with non-treated plants, is presumably part of a mechanism contributing to successful establishment of a plant/PGPR symbiosis.

Rudrappa et al. (2008) have reported that malic acid/malate is a metabolite-promoting plant-PGPR communication in roots. Rudrappa et al. (2008) performed experiments with knockout

Arabidopsis mutants for malic acid transporter and observed that the plants were unable to recruit PGPR for symbiosis. The recorded downregulation of malate in leaves of tomato inoculated with PGPR may be a result of malate translocation from leaves to roots aiming to facilitate colonization by PGPR. However, the metabolic profile of roots was not determined in the current study, and thus this hypothesis, although reasonable, is not adequately supported by the current experimental data.

Monopalmitin is a carbon source for plants, plant-related microbiome, and legume plants to sustain symbiosis with arbuscular mycorrhizal fungi, which is found in root exudates of several plant species (Feng et al., 2019). In sugarcane leaves, 2-monopalmitin content increased when inoculation with PGPR (*Gluconacetobacter diazotrophicus* and *Herbaspirillum seropedicae*) was combined with humic acid addition, whereas PGPR inoculation itself had no effect on monopalmitin accumulation (Aguilar et al., 2018). However, little is known on the exact role of monopalmitin, and although it was reduced in the leaves of plants colonized by PGPR, this metabolite in roots might be involved in plant/PGPR symbiosis.

Grafting onto the rootstock 'M82' had either a very weak or no impact on most metabolites. However, the levels of three metabolites were clearly reduced by grafting onto 'M82' (malate, D-fructose, and myo-inositol), while one metabolite (oleic acid) accumulated. According to Van Der Merwe et al. (2009), transgenic tomato exhibiting decreased expression of the mitochondrial malate dehydrogenase, and concomitantly increased malate levels, imposed a clear reduction in root biomass. In the current study, the increased root biomass of grafted plants was associated with reduced malate levels, corroborating an inverse relationship between malate levels and root biomass. The reduction of the D-fructose levels in leaves of tomato grafted onto 'M82' compared with self-grafted plants may point to an increased sink activity in roots, as many tomato rootstocks form a more vigorous root system than self-rooted plants (Rouphael et al., 2017). Oleic acid is one of the three fatty acids (along with palmitic and linoleic acid) present, as free fatty acids in tomato fruits, melons, and cucumbers and are strongly responsible for the flavor of many vegetables, as they act as precursors in the biosynthesis of most straight-chain esters in aromatic volatile compounds (Hao et al., 2018). Having a profile different than that of fruits, tomato leaf fatty acids are responsible for leaf flavor, producing aroma volatiles through the lipoxygenase/hydroperoxide lyase enzyme pathway. Thus, changes in fatty acid composition in tomato leaves can lead to altered composition of lipid-derived flavor compounds (Wang et al., 2001). The results obtained from the current study do not reveal how the genotypic difference between root and leaves in grafted plants mediates a change in the level of oleic acid in tomato leaves. Furthermore, the current study does not show if the levels of fatty acids associated with flavor were influenced also in fruit of grafted tomato. However, Hao et al. (2018) reported that the levels of free fatty acids in fruit of grafted melons were lower than in fruits from non-grafted plants, and this was associated with reduced fruit aroma. Further research is required to test the fatty acid profile in fruit of grafted tomato and relate it

to possible changes in volatile compounds and concomitantly in fruit flavor.

CONCLUSION

The improved vegetative growth of plants inoculated with all PGPR strains tested in this study, but especially with *E. mori* strain C3.1, corroborates previous studies, which showed that application of appropriate PGPR strains may improve tomato growth. On the other hand, the lack of any beneficial effect of PGPR on fruit yield, but also on the vegetative growth at the end of the crop under combined stress conditions, indicate that a single PGPR inoculation at crop establishment may be not sufficient, especially under stress conditions. Selection of appropriate PGPR strains, tolerant to multiple stress, and repetition of PGPR application during the cropping period, are key factors to obtain benefits from PGPR application, especially under stress conditions.

The improved growth and yield of non-stressed tomato plants grafted onto 'M82,' compared with non-grafted plants and the absence of any yield benefit from grafting onto this rootstock under stress conditions, corroborate previous reports suggesting that grafting onto suitable rootstocks enhances tomato fruit yield. However, on the other hand, the results of the current study show that 'M82' is not a suitable rootstock for plants grown under conditions of restricted water supply and points to the need to screen for tolerant rootstock genotypes to water and nutrient limitations.

The metabolomics analysis showed that water/nutrient stress and PGPR inoculation have a strong impact of the leaf metabolism, whereas grafting has a weaker but non-negligible impact. Combined nutrient and water stress enhanced by 10% or more the biosynthesis of L-lactic acid, ethyl phosphoric acid, phosphoric acid, glycine, malate, oleic acid, and α - α -trehalose, while it reduced by 10% or more the levels of succinic acid, glyceric acid, citric acid, D-fructose, myo-inositol, stearic acid, and 1-monopalmitin. Similarly, the application of PGPR enhanced by 10% or more D-fructose and α - α -trehalose, while it reduced by 10% or more the biosynthesis of ethanolamine, glycerol, L-serine, malate, myo-inositol, and 1-monopalmitin. Finally, grafting onto M82 enhanced by 10% or more the biosynthesis of oleic acid, while reducing by 10% or more the biosynthesis of malate, D-fructose, and myo-inositol compared with self-grafting.

As a general conclusion, this study showed that both PGPR and grafting are promising tools for improvement of tomato performance. However, to obtain a benefit under combined stress conditions, selection of appropriate PGPR strains and rootstock genotypes, and establishment of suitable protocols regarding method, time, and number of PGPR applications are crucial factors for success. The current study contributes to a better understanding of changes imposed to plant metabolism by combined water/nutrient stress, PGPR, and grafting. This new insight concerning metabolites influenced by stress, PGPR, and grafting can be useful in rapid screening of PGPR strains and rootstock genotypes with resilience to multiple stress conditions,

which may increasingly appear in commercial tomato crops in view of the climate change.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

AUTHOR CONTRIBUTIONS

DS and PK conceived and designed the experiments. PK, GN, GM, ES, and IK performed the experiments and the mineral analyses. KA and PK performed the metabolomics analysis. AT provided the PGPR strains and performed the inoculation. PK, DS, and KA analyzed the data and wrote the manuscript. DS, KA, GN, AT, and IK reviewed the manuscript. All authors have read and approved the manuscript.

FUNDING

This research was funded by the European Commission within the HORIZON2020 project “TOMRES – A novel and integrated

approach to increase multiple combined stress tolerance in plants using tomato as a model” (Grant Agreement 727929).

ACKNOWLEDGMENTS

We thank Danny Zamir from the Hebrew University of Jerusalem for providing the seeds of M82.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fpls.2021.670236/full#supplementary-material>

Supplementary Figure 1 | Orthogonal partial least squares-discriminant analysis (OPLS-DA) PC1/PC2 score plot of metabolomic profiles of non-stressed and exposed to combined stress tomato plants (i), non-inoculated plants (No PGPR) and plants inoculated with PGPR-T3 (ii), and self-grafted tomato plants ('Belladonna' F1) and plants grafted onto 'M82' (iii). The ellipse represents the Hotelling T2 with 95% confidence interval.

Supplementary Data set 1 | Annotated metabolite features in the GC/EC/MS profiles of *Solanum lycopersicum* L. leaves.

Inoculation Can Enhance Yield of
Transgenic *Bt* Maize and Its Control
Efficiency Against *Mythimna separata*
Especially Under Elevated CO₂.
Front. Plant Sci. 12:655060.
doi: 10.3389/fpls.2021.655060

The promotion and application of transgenic *Bt* crops provides an approach for the prevention and control of target lepidopteran pests and effectively relieves the environmental pressure caused by the massive usage of chemical pesticides in fields. However, studies have shown that *Bt* crops will face a new risk due to a decrease in exogenous toxin content under elevated carbon dioxide (CO₂) concentration, thus negatively affecting the ecological sustainability of *Bt* crops. Arbuscular mycorrhizal fungi (AMF) are important beneficial microorganisms that can effectively improve the nutrient status of host plants and are expected to relieve the ecological risk of *Bt* crops under increasing CO₂ due to global climate change. In this study, the *Bt* maize and its parental line of non-transgenic *Bt* maize were selected and inoculated with a species of AMF (*Funneliformis caledonium*, synonyms: *Glomus caledonium*), in order to study the secondary defensive chemicals and yield of maize, and to explore the effects of *F. caledonium* inoculation on the growth, development, and reproduction of the pest *Mythimna separata* fed on *Bt* maize and non-*Bt* maize under ambient carbon dioxide concentration (aCO₂) and elevated carbon dioxide concentration (eCO₂). The results showed that eCO₂ increased the AM fungal colonization, maize yield, and foliar contents of jasmonic acid (JA) and salicylic acid (SA), but decreased foliar *Bt* toxin content and *Bt* gene expression in *Bt* maize leaves. *F. caledonium* inoculation increased maize yield, foliar JA, SA contents, *Bt* toxin contents, and *Bt* gene expression in *Bt* maize leaves, and positively improved the growth, development, reproduction, and food utilization of the *M. separata* fed on non-*Bt* maize. However, *F. caledonium* inoculation was unfavorable for the fitness of *M. separata* fed on *Bt* maize, and the effect was intensified when combined with eCO₂. It is indicated that *F. caledonium* inoculation had adverse effects on the production of non-*Bt* maize due to the high potential risk of population occurrence of *M. separata*, while it was just the opposite for *Bt* maize. Therefore, this study confirms that the AMF can increase the yield and promote the expression levels of its endogenous (JA,

SA) and exogenous (Bt toxin) secondary defense substances of *Bt* maize under $e\text{CO}_2$, and finally can enhance the insect resistance capacity of *Bt* crops, which will help ensure the sustainable utilization and safety of *Bt* crops under climate change.

Keywords: elevated CO_2 , transgenic *Bt* maize, arbuscular mycorrhizal fungi, *Mythimna separata*, control efficiency, yield

INTRODUCTION

In recent years, many transgenic *Bt* crops, such as *Bt* maize and *Bt* cotton, have been grown around the world and have shown high resistance to specific target pests, mainly Lepidoptera insects (Wu et al., 2008; Liu et al., 2016). As a result, *Bt* crops have been used to control a wider range of pests, such as *Helicoverpa armigera* (Hübner), *Heliothis virescens*, and *Mythimna separata* (Riddick et al., 1998; Chen F. J. et al., 2011; Chang et al., 2013). Meanwhile, human activities, specifically fossil fuel burning and land-use change, are rapidly increasing the level of carbon dioxide (CO_2) in the atmosphere (Yu and Chen, 2019; Yao et al., 2020). Specifically, it has been reported that the atmospheric CO_2 concentration increased from 288 to 405 ppm from 1800 to 2018 (www.esrl.noaa.gov/gmd/ccgg/trends/). With the acceleration of industrialization, it is estimated that the concentration of CO_2 in the atmosphere will increase from 800 to 1,000 ppm by the end of the twenty-first century (Pachauri and Reisinger, 2014).

Plant productivity is fundamentally tied to atmospheric CO_2 by photosynthesis, and the increase in atmospheric CO_2 concentration can improve the photosynthetic capacity of plants and undoubtedly affect the plant physiology with profound impacts on all aspects, including the increase in photosynthetic rate, biomass, and seed production (Dietterich et al., 2015; Johnson and Hartley, 2018; Zhu et al., 2018). Most studies reported that elevated CO_2 ($e\text{CO}_2$) increased the C/N ratio in plant tissues; thus, the content of carbohydrates in plant tissues increased and the content of N-containing compounds decreased (Chen et al., 2005a; Xu et al., 2015; Dai et al., 2018). All these changes in turn affect the production of plant secondary metabolites (Stiling and Cornelissen, 2007). Elevated CO_2 may enhance or weaken plant defense against herbivorous insects, at least partly due to the changes in C- and N-based defensive metabolites, as well as plant nutrients, especially protein content (Kretschmar et al., 2009). Some studies have shown that jasmonic acid (JA), ethylene (ET), and salicylic acid (SA) are secondary defense substances of plants against aphids under $e\text{CO}_2$ (Sun et al., 2013; Guo et al., 2014), and reported that $e\text{CO}_2$ caused a significant reduction of N-based compounds (i.e., *Bt* toxin proteins) in *Bt* crops (Chen et al., 2005b; Wu et al., 2011a; Liu et al., 2019). Hence, it is speculated that under the condition of climate change, transgenic *Bt* crops will face a new risk that the effective control of the target pests will be reduced.

Arbuscular mycorrhizal fungi (AMF) can form associations with the roots of about 80% of terrestrial plant species (Smith and Read, 2008) and exchange soil-derived nutrients (Marschner and Dell, 1994) for plant-derived hexoses and lipids (Helber et al., 2011; Keymer and Lankau, 2017). AMF improve the supply of inorganic nutrients, especially phosphate (Rillig and Mummey,

2006). However, since AMF can also enhance the nitrogen uptake and utilization of plants (Hawkins et al., 2000) and improve their resistance to external biotic and abiotic stresses (Jung et al., 2012; Frew and Price, 2019), we hypothesize that they can be used to alleviate the problems of *Bt* toxin protein decline under $e\text{CO}_2$, and reduce the risk of *Bt* crops under future climate change. In order to test this hypothesis, we inoculated *Bt* maize with AMF (*Funneliformis caledonium*) under elevated CO_2 concentration to explore the interaction between $e\text{CO}_2$ and AM fungal inoculation on plant growth and secondary defense metabolites of *Bt* maize, and the effects on the growth and development and food utilization of the main maize pest armyworm from 2017 to 2018. We further hypothesize that *F. caledonium* inoculation under $e\text{CO}_2$ could (a) increase the biomass and yield of maize; (b) promote the expression of endogenous (JA, SA) and exogenous (Bt toxin) secondary defense substances in *Bt* maize leaves; and (c) decrease indices of growth, development, and reproduction of *M. separata*.

MATERIALS AND METHODS

CO_2 Setting

A 2-year experiment (2017–2018) was conducted in six open-top chambers (OTCs) in Ningjin County, Shandong Province of China (37.64° N, 116.8° E). OTCs are 2.5 m in height \times 3.2 m in diameter. Two concentration levels of CO_2 are applied successively, namely, the ambient level ($a\text{CO}_2$, 375 $\mu\text{l/l}$) and the elevated level ($e\text{CO}_2$, 750 $\mu\text{l/l}$). Each CO_2 treatment uses three OTCs. During the experiment, OTCs were continuously filled with CO_2 . The average CO_2 concentration is shown in **Supplementary Table 1**.

Arbuscular Mycorrhizal Fungi and *Bt* Maize

Funneliformis caledonium (strain number 90036, referred to as FC, synonyms: *Glomus caledonium*) was provided by the State Key Laboratory of Soil & Sustainable Agriculture, Institute of Soil Science, the Chinese Academy of Sciences. The inoculum consisted of spores, mycelium, maize root fragments, and soil (storage: under normal temperature, keep in dry, cool place). The *Bt* maize cultivar (line IE09S034 with *Cry1Ie*, namely, *Bt*) and the parental line of non-transgenic *Bt* maize (cv. Xianyu 335, namely, Xy) were provided by The Institute of Crop Sciences of the Chinese Academy of Agricultural Science. *Bt* maize and non-*Bt* maize were planted in plastic barrels (the height of 45 cm and the diameter of 30 cm) filled with 20 kg soils and 10 g compound fertilizer (N: P: K = 18: 15: 12), respectively. Soil pH was 7.2, organic carbon 11.7 g/kg, total nitrogen 2.27 g/kg, and total phosphorus 0.56 g/kg. On June 10 of each sampling year, 100 g inoculum of *F. caledonium* (namely, FC in figure) and 100 g

sterilized strain (namely, CK in figure) were evenly spread at 4 cm under maize seed as control; three maize seeds were sown in each barrel with a sowing depth of 2 cm, and two maize were reserved after emergence. Maize were irrigated every two to three days to ensure the water demand for maize growth.

There were eight treatments [two CO₂ concentration (aCO₂ and eCO₂), two maize treatments (*Bt* and *Xy*), and two AMF inoculations (*F. caledonium* and CK)]. Each treatment included three OTCs; each OTC included four planting patterns (*Bt* + AMF, *Bt* + CK, *Xy* + AMF, and *Xy* + CK); each planting pattern included five repeats; that is, each treatment contained a total of 15 repeats.

Arbuscular Mycorrhizal Fungi Colonization and AMF Phospholipid Fatty Acid (PLFA) Content

In two sampling years, AMF colonization was determined on heading stage (BBCH-59), and it was determined by the method of trypan blue staining and grid counting (Phillips and Hayman, 1970). The fresh plant roots were washed with distilled water and then blotted dry with absorbent paper. One hundred one centimeter roots were randomly cut and placed in a 10% KOH solution at 30°C for 30 min, and then, the KOH was discarded and rinsed with distilled water. After acidification in 2% HCl for 60 min, the HCl was discarded, rinsed with distilled water, and stained in 5% trypan blue dye solution (w/v, lactic acid: glycerol: water = 1: 1: 1). Then, the dye solution was discarded, and the roots were rinsed with distilled water and transferred to a square with a grid at the bottom. We observed the number of infected and uninfected root segments under the microscope. Colonization (%) = number of infected root segments/total root segments (Mcgonigle et al., 1990). The improved Bligh-Dyer method was used to extract microbial PLFA from soil (Bossio and Scow, 1998; Ruess and Chamberlain, 2010). About 8.0 g of the freeze-dried soil sample was weighed into a Teflon tube, and the lipids from soil were extracted by multiple oscillation centrifugation with a Bligh-Dyer mixed extract prepared in a ratio of 1: 2: 0.8 with chloroform: methanol: citrate buffer. The aqueous phase and the organic phase were separated by keeping away from light overnight, and the lower organic-phase supernatant containing the phospholipid was taken up and then dried with nitrogen in a water bath. The sample was dissolved and dried with a small amount of chloroform and acetone several times and passed through a SPE silica gel column to remove neutral lipids and glycolipids from the sample, followed by separation and purification with methanol to collect PLFA, and dried with nitrogen again. The separated PLFA is methylated by a liquid (methanol: toluene 1:1 mixture) and a liquid of KOH-methanol solution, and then the reaction was terminated with acetic acid. Finally, it was extracted with n-hexane and dried with nitrogen to obtain PLFA methyl ester. With C19: 0 as the internal standard, the content of methyl ester of characteristic fatty acids was analyzed by MIDI identification system, and the soil PLFA content was expressed in nmol/g through peak area and internal standard curve.

Foliar Bt Toxin Content and *Bt* Gene Expression in the Leaves of *Bt* Maize

During the heading stage (BBCH-59) of maize, the foliar content of Bt toxin protein was measured by using plant *Bt-CryIIe* protein ELISA Kit (mlbio, China). Moreover, the real-time quantitative reverse transcription PCR was performed on a 7500 real-time PCR system (Applied Biosystems Inc.) for *Bt* gene expression analysis. Total RNA was extracted from the leaf tissues by using TRIzol[®] reagent (Invitrogen). The concentration and quality of samples were determined by NanoDrop[™] spectrophotometer (Thermo Scientific) and 1.5% agarose gel electrophoresis. The cDNA synthesis was carried out with 100 ng of total RNA by using PrimeScript[™] RT reagent Kit with gDNA Eraser (Takara, Japan). Reverse transcriptase reactions were performed in a reaction volume of 20 µl. Quantitative real-time PCR was performed with a 7500 real-time PCR detection system (Applied Biosystems) using 1 × SYBR[®] Premix Ex Taq[™] (TaKaRa, Japan), 2 µl cDNA products (diluted from 20 to 200 µl with RNase-free water), and 0.2 µM primers in a final volume of 20 µl. Reaction conditions are 95°C, 30 s pre-denaturation; 95°C, 5 s, 60°C, 34 s, 40 cycles. The cDNA was amplified by PCR using the primers shown in **Supplementary Table 2**. Quantification of the transcript levels of target genes was conducted by following the 2^{-ΔΔCt} normalization method. The relative expression level was represented as the fold change by comparing three treatments (aCO₂ + AMF, aCO₂ + CK, and eCO₂ + AMF) and the treatment of eCO₂ + CK, respectively. Three technical replicates were performed on each sample of cDNA.

Jasmonic Acid and Salicylic Acid Contents in Maize Leaves

During the heading stage (BBCH-59) of maize, the foliar contents of JA and SA were measured in our laboratory by using plant JA ELISA Kit (YaJi Biological, China) and plant SA ELISA Kit (YaJi Biological, China).

Insect Development and Food Utilization

The colony of armyworm, *M. separata*, was collected in maize fields in Kangbao County, Hebei (China), and continuously reared on artificial diet for more than 15 generations in growth chamber (GDN-400D-4; Ningbo Southeast Instrument CO., LTD, Ningbo, China) (Song et al., 2020). The third-instar larvae with uniform size were randomly selected and were individually fed on fresh maize leaves, which were selected from each treatment at the heading stage (BBCH-59). The feeding trials were conducted in a plastic dish (6 cm in diameter) in 2017 and 2018. Each treatment consisted of five replicates (a total of 20 larvae per replicate).

The initial weights of third-instar larvae were individually measured with an electronic balance (AL104; METTLER-TOLEDO, Greifensee). Larvae feces, pupal weight, and the remaining parts of leaves were also carefully weighed. At the same time, dry weight of larvae and maize leaves was calculated during the experiment. Moreover, the food utilization indices, including relative consumption rate (RCR), relative growth rate (RGR), efficiency of conversion of digested food (ECD), and efficiency

of conversion of ingested food (ECI), were measured (Chen et al., 2005b).

$$RCR = I/(B \cdot T); RGR = G/(B \cdot T);$$

$$ECD (\%) = G/(I - F) \cdot 100\%; ECI (\%) = G/I \cdot 100\%$$

where *I* is the feeding amount (the weight of maize leaves before feeding minus the weight of maize leaves before feeding and after feeding); *B* is the average larval weight during the experiment (the average larval weight before feeding and after feeding); *T* is the experiment time (d); *G* is the added larval weight (the larval weight after feeding minus the larval weight before feeding); and *F* is the weight of total feces.

The larval lifespan, pupation rate/duration, and emergence of *M. separata* fed on leaves of *Bt* and non-*Bt* maize inoculated with and without *F. caledonium* were recorded every 12 h. Pairs of novel moths, including female: male ratio of 1: 1, were transferred to metal screen cages for oviposition and fed on 10% honey. The survivorship and fecundity of *M. separata* were observed every day until death.

Data Analysis

Data were analyzed using IBM-SPSS v.20.0 software (IBM, Armonk, NY). Three-way ANOVAs were used to test the effects of sampling years (2017 vs. 2018), CO₂ levels (elevated vs. ambient), AMF inoculation (*F. caledonium* vs. CK), transgenic treatment (*Bt* maize vs. non-*Bt* maize), and their interactions on the indices of *Bt* toxin and *Bt* gene expression in the leaves of *Bt* maize. Four-way ANOVAs were used to test the effects of sampling years (2017 vs. 2018), CO₂ levels (elevated vs. ambient), AMF inoculation (*F. caledonium* vs. CK), transgenic treatment (*Bt* maize vs. non-*Bt* maize), and their interactions on the indices of AMF colonization and AMF-PLFA content, foliar contents of JA and SA, and growth, development, and reproduction of *M. separata*. Significant differences between or among treatments were analyzed by Tukey's test at *P* < 0.05.

RESULTS

Arbuscular Mycorrhizal Fungi Colonization and AMF-PLFA Content of *Bt* and Non-*Bt* Maize Influenced by CO₂ Levels and *F. caledonium* Inoculation

Four-way ANOVAs showed that AMF inoculation, CO₂ level, and sampling years, and the interactions between AMF inoculation and CO₂ level (*F* ≥ 4.47, *P* ≤ 0.042 < 0.05) significantly affected the AMF colonization on *Bt* and non-*Bt* maize (Supplementary Table 3). Compared with control, AMF inoculation significantly increased the AMF colonization of *Bt* and non-*Bt* maize in two sample years no matter under *a*CO₂ or *e*CO₂ (Figures 1A,C). Compared with *a*CO₂, *e*CO₂ significantly increased the AMF colonization of non-*Bt* maize inoculated with *F. caledonium* in 2017 and 2018, that of *Bt* maize inoculated with *F. caledonium* in 2017, and that of *Bt* maize not inoculated in 2018 (*P* < 0.05; Figures 1A,C).

Moreover, four-way ANOVAs also showed that AMF inoculation (*F* = 3385.14, *P* < 0.001), CO₂ level (*F* = 52.68, *P* < 0.001), and sampling years (*F* = 17.27, *P* < 0.001) significantly affected the AMF-PLFA content of *Bt* and non-*Bt* maize (Supplementary Table 3). Compared with control, AMF inoculation significantly increased the AMF-PLFA content of *Bt* and non-*Bt* maize in two sample years no matter under *a*CO₂ or *e*CO₂ (Figures 1B,D). Compared with *a*CO₂, *e*CO₂ significantly increased the AMF-PLFA content of *Bt* maize inoculated with *F. caledonium* in 2017 and 2018, and also significantly increased the AMF-PLFA content of non-*Bt* maize inoculated with *F. caledonium* in 2018 and non-*Bt* maize not inoculated in 2017 (*P* < 0.05; Figures 1B,D).

Foliar *Bt* Protein Content and *Bt* Gene Relative Expression Level in Leaves of *Bt* Maize Influenced by CO₂ Levels and *F. caledonium* Inoculation

Three-way ANOVAs showed that AMF inoculation (*F* ≥ 275.07, *P* < 0.001), CO₂ level (*F* ≥ 5.89, *P* ≤ 0.027), and their interaction (*F* ≥ 18.88, *P* < 0.001) significantly affected the foliar *Bt* protein content and *Bt* gene relative expression level in the leaves of *Bt* maize (Supplementary Table 4).

For the foliar *Bt* protein content, compared with *a*CO₂, *e*CO₂ significantly decreased the foliar *Bt* protein content of *Bt* maize without *F. caledonium* inoculation, but significantly increased the foliar *Bt* protein content of *Bt* maize inoculated with *F. caledonium* (Figures 2A,C). Compared with control, AMF inoculation significantly increased the foliar *Bt* protein content of *Bt* maize under *a*CO₂ and *e*CO₂ (*P* < 0.05; Figures 2A,C).

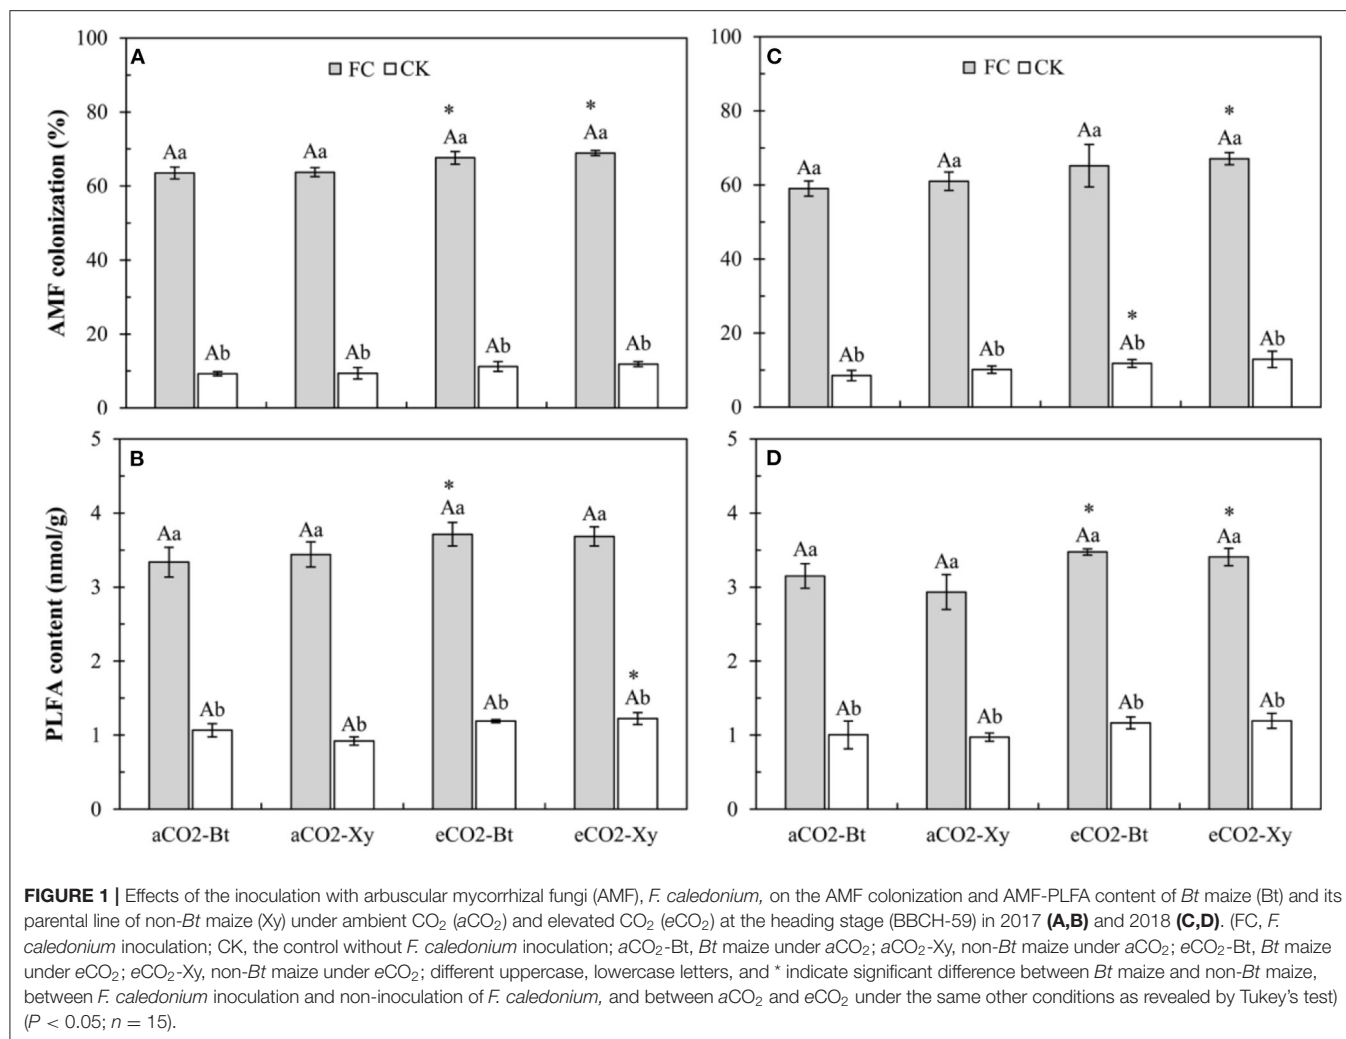

For the *Bt* gene relative expression level, compared with *a*CO₂, *e*CO₂ significantly decreased the *Bt* gene relative expression level in the leaves of *Bt* maize without *F. caledonium* inoculation (Figures 2B,D). Compared with control, AMF inoculation significantly increased the *Bt* gene relative expression level of *Bt* maize under *a*CO₂ and *e*CO₂ (*P* < 0.05; Figures 2B,D).

Foliar JA and SA Contents in Leaves of *Bt* and Non-*Bt* Maize Influenced by CO₂ Levels and *F. caledonium* Inoculation

Four-way ANOVAs showed that AMF inoculation (*F* ≥ 216.16, *P* < 0.001) and CO₂ level (*F* ≥ 99.02, *P* < 0.001) significantly affected the foliar JA and SA contents of *Bt* and non-*Bt* maize (Supplementary Table 4).

For the foliar JA content, compared with control, AMF inoculation significantly increased the foliar JA content of *Bt* and non-*Bt* maize in two sample years no matter under *a*CO₂ or *e*CO₂ (Figures 3A,C). Compared with *a*CO₂, *e*CO₂ significantly increased the foliar JA content of *Bt* and non-*Bt* maize without *F. caledonium* inoculation in 2017 and 2018, and *Bt* maize inoculated with *F. caledonium* in 2017 and non-*Bt* maize inoculated with *F. caledonium* in 2018 (*P* < 0.05; Figures 3A,C).

For the foliar SA content, compared with control, AMF inoculation significantly increased the foliar SA content of *Bt* and non-*Bt* maize in two sample years no matter under *a*CO₂ or *e*CO₂ (Figures 3B,D). Compared with *a*CO₂, *e*CO₂ significantly

increased the foliar SA content of *Bt* and non-*Bt* maize in two sample years regardless of *F. caledonium* inoculation or not (Figures 3B,D).

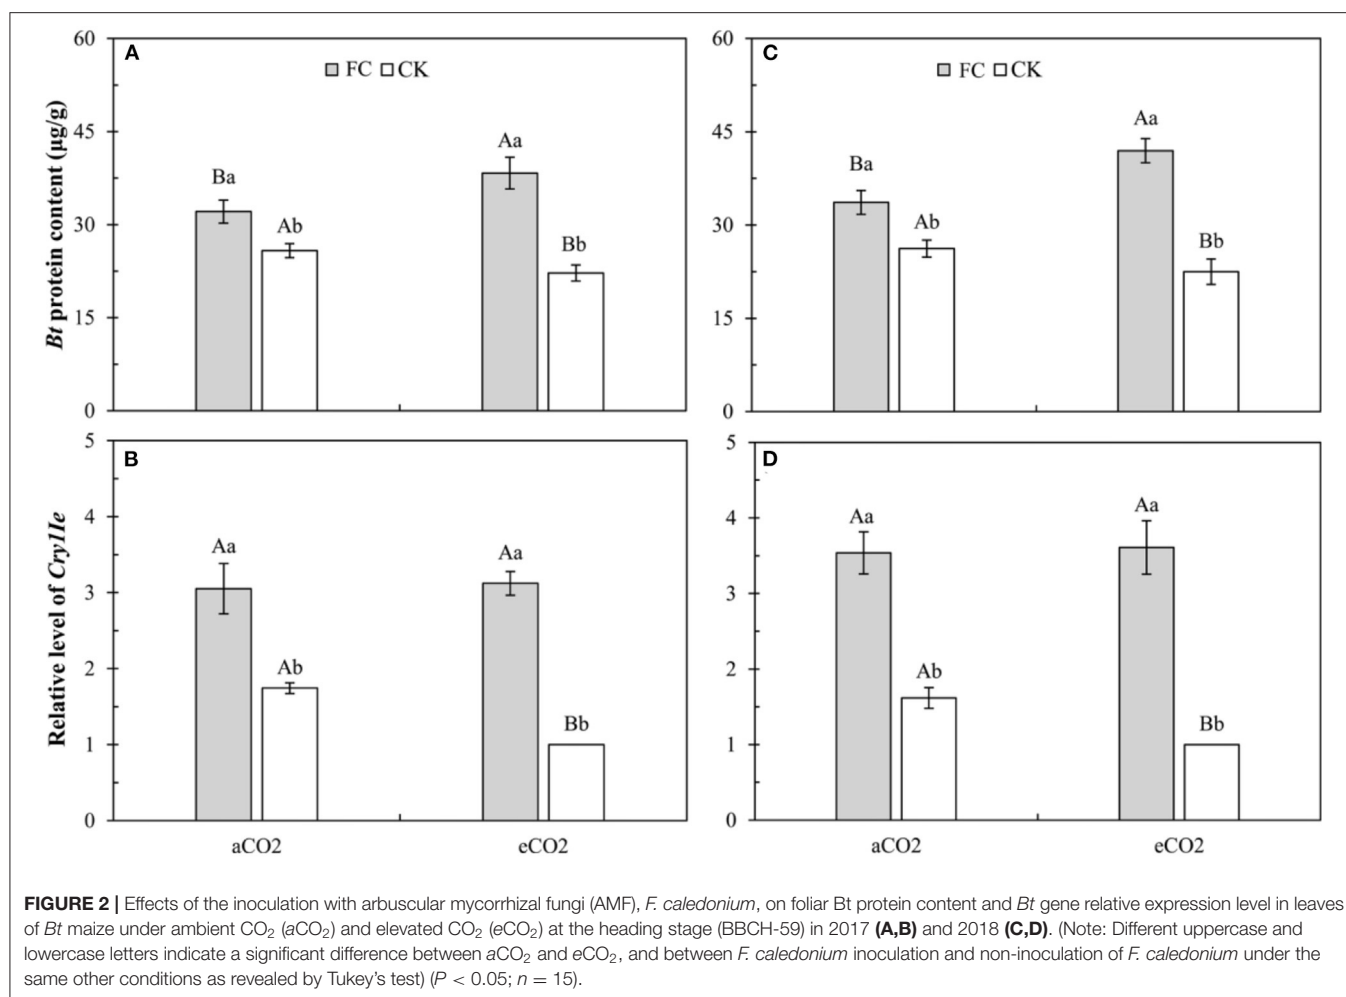

Food Utilization of *M. separata* Larvae Fed on *Bt* and Non-*Bt* Maize Influenced by CO₂ Levels and *F. caledonium* Inoculation

Four-way ANOVAs showed that AMF inoculation ($F \geq 4.20$, $P \leq 0.048$), CO₂ level ($F \geq 4.24$, $P \leq 0.047$), transgenic treatment ($F \geq 36.98$, $P < 0.001$), and their interactions ($F \geq 12.19$, $P < 0.0014$) significantly affected all the food utilization indices of *M. separata* larvae, except for the interaction between CO₂ level and AMF inoculation on RGR ($F = 0.72$, $P = 0.40 > 0.05$; Supplementary Table 5). Moreover, the interaction between CO₂ level, AMF inoculation, and transgenic treatment also significantly affected the ECD ($F = 32.63$, $P < 0.001$) and ECI ($F = 9.78$, $P = 0.004 < 0.01$) of *M. separata* larvae (Supplementary Table 5).

Compared with non-*Bt* maize, the ECD of *M. separata* larvae fed on *Bt* maize inoculated with and without *F. caledonium*

was significantly decreased in two sample years no matter under aCO₂ or eCO₂. Compared with control, AMF inoculation significantly increased the ECD of *M. separata* larvae fed on non-*Bt* maize under eCO₂ in 2017 and 2018. Compared with aCO₂, eCO₂ significantly decreased the ECD of *M. separata* larvae fed on *Bt* maize inoculated with and without *F. caledonium* in two sample years, while significantly increased the ECD of *M. separata* larvae fed on non-*Bt* maize inoculated with *F. caledonium* in 2017 and 2018, and significantly decreased the ECD of *M. separata* larvae fed on non-*Bt* maize without *F. caledonium* inoculation in 2018 ($P < 0.05$; Figures 4A,E).

Compared with non-*Bt* maize, the ECI of *M. separata* larvae fed on *Bt* maize inoculated with and without *F. caledonium* was significantly decreased in two sample years no matter under aCO₂ or eCO₂. Compared with control, AMF inoculation significantly increased the ECI of *M. separata* larvae fed on non-*Bt* maize under aCO₂ and eCO₂ in two sample years, while significantly decreased the ECI of *M. separata* larvae fed on *Bt* maize under aCO₂ in 2017 and 2018. Compared with aCO₂, eCO₂ significantly decreased the ECI of *M. separata* larvae fed on *Bt* and non-*Bt* maize without *F. caledonium* inoculation in 2017

and 2018, while significantly increased the ECI of *M. separata* larvae fed on non-Bt maize with *F. caledonium* inoculation in 2017 and significantly decreased the ECI of *M. separata* larvae fed on Bt maize with *F. caledonium* inoculation in 2018 ($P < 0.05$; Figures 4B,F).

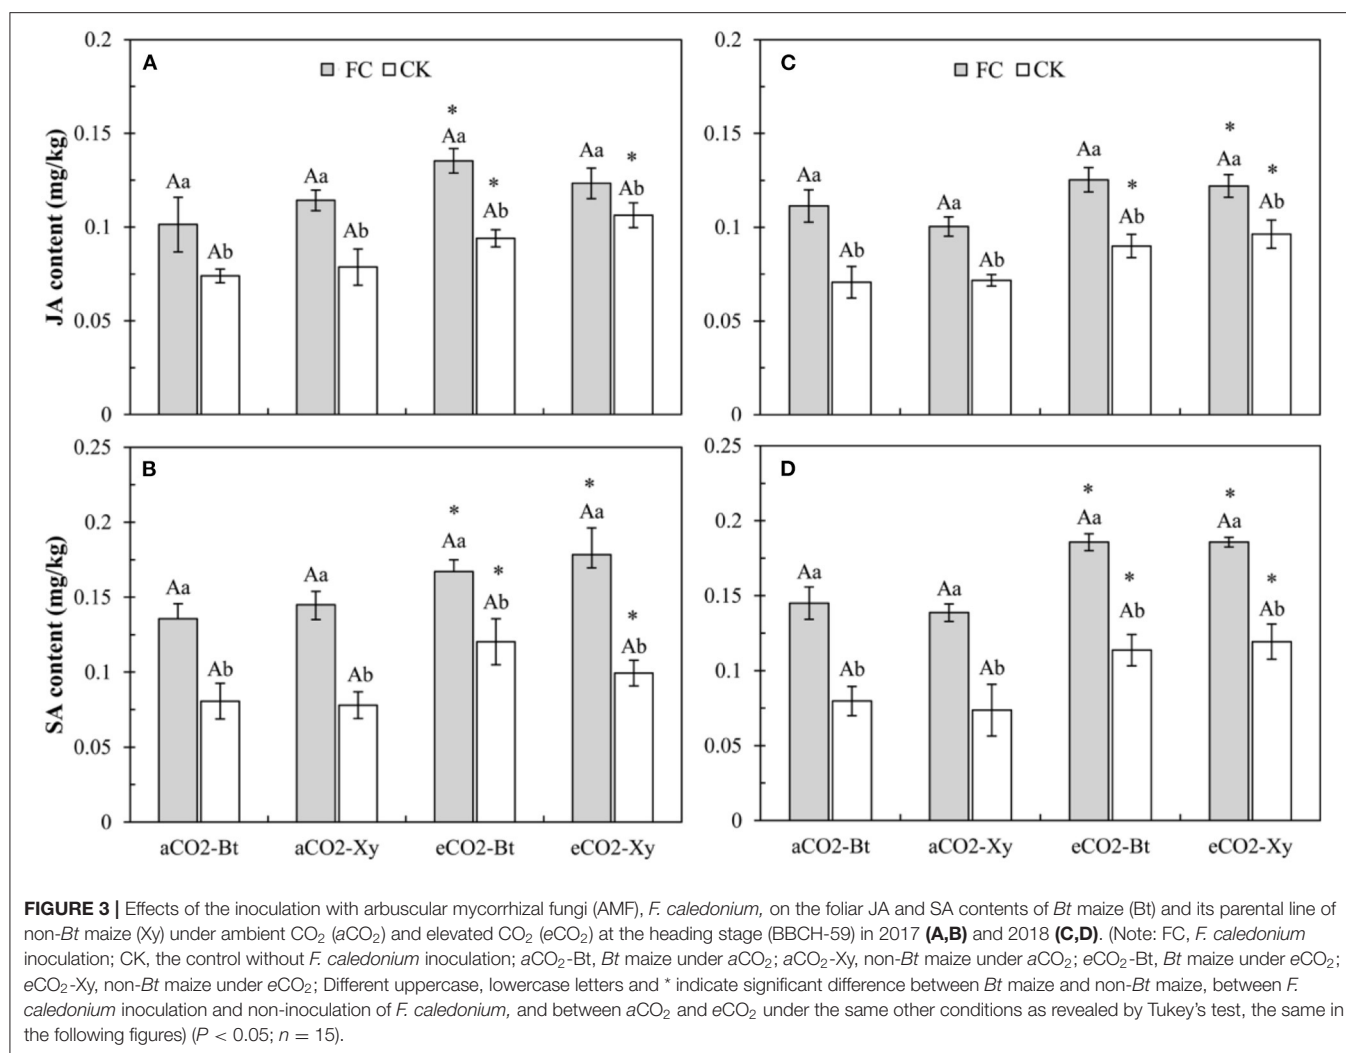

Compared with non-Bt maize, the RGR of *M. separata* larvae fed on Bt maize inoculated with and without *F. caledonium* was significantly decreased in two sample years no matter under aCO₂ or eCO₂. Compared with control, AMF inoculation significantly increased the RGR of *M. separata* larvae fed on non-Bt maize under aCO₂ and eCO₂ in 2017 and 2018, while significantly decreased the RGR of *M. separata* larvae fed on Bt maize under aCO₂ and eCO₂ in two sample years. Compared with aCO₂, eCO₂ significantly decreased the RGR of *M. separata* larvae fed on non-Bt maize without *F. caledonium* inoculation in 2017 and 2018, and that of *M. separata* larvae fed on non-Bt maize with *F. caledonium* inoculation in 2017 ($P < 0.05$; Figures 4C,G).

Compared with non-Bt maize, the RCR of *M. separata* larvae fed on Bt maize inoculated with and without *F. caledonium* was significantly decreased under aCO₂ in 2017 and 2018, while the RCR of *M. separata* larvae fed on Bt maize without *F. caledonium*

inoculation significantly increased under eCO₂ in two sample years. Compared with control, AMF inoculation significantly decreased the RCR of *M. separata* larvae fed on Bt maize in two sample years no matter under aCO₂ or eCO₂, while significantly increased the RCR of *M. separata* larvae fed on non-Bt maize under aCO₂ in 2017 and 2018. Compared with aCO₂, eCO₂ significantly decreased the RCR of *M. separata* larvae fed on non-Bt maize inoculated with *F. caledonium* in 2017 and 2018, while significantly increased the RCR of *M. separata* larvae fed on Bt maize without *F. caledonium* inoculation in two sample years ($P < 0.05$; Figures 4D,H).

Growth, Development, and Reproduction of *M. separata* Fed on Bt and Non-Bt Maize Influenced by CO₂ Levels and *F. caledonium* Inoculation

Four-way ANOVAs showed that sampling year ($F \geq 7.97$, $P \leq 0.008$), CO₂ level ($F \geq 24.20$, $P < 0.001$), transgenic treatment ($F \geq 164.88$, $P < 0.001$), and the interaction between transgenic treatment and AMF inoculation ($F \geq 4.23$, $P \leq 0.047$) significantly affected all measured indices of *M. separata*,

except the interaction between transgenic treatment and AMF inoculation on pupation rate of *M. separata* ($F = 0.23$, $P = 0.63$; **Supplementary Table 6**). Moreover, AMF inoculation significantly affected pupal weight and pupal duration of *M. separata* ($F \geq 15.07$, $P < 0.001$), the interaction between CO₂ level and transgenic treatment significantly affected larval lifespan of *M. separata* ($F = 89.64$, $P < 0.001$), and the interactions between CO₂ level and AMF inoculation affected fecundity of *M. separata* ($F = 12.65$, $P = 0.001$) (**Supplementary Table 6**).

Compared with non-Bt maize, the larval lifespan of *M. separata* larvae fed on Bt maize inoculated with and without *F. caledonium* was significantly extended in two sample years no matter under aCO₂ or eCO₂. Compared with control, AMF inoculation significantly shortened the larval lifespan of *M. separata* fed on non-Bt maize under aCO₂ and eCO₂ in 2017 and 2018, while significantly prolonged the larval lifespan of *M. separata* fed on Bt maize under aCO₂ and eCO₂ in 2017 and 2018. Compared with aCO₂, eCO₂ significantly extended the larval lifespan of *M. separata* larvae fed on Bt maize

inoculated with and without *F. caledonium* in two sample years ($P < 0.05$; **Figures 5A,E**).

Compared with non-Bt maize, the pupation rate of *M. separata* fed on Bt maize inoculated with and without *F. caledonium* was significantly decreased under aCO₂ in two sample years no matter under aCO₂ or eCO₂ ($P < 0.05$; **Figures 5B,F**).

Compared with non-Bt maize, the pupal weight of *M. separata* fed on Bt maize inoculated with and without *F. caledonium* was significantly decreased in two sample years no matter under aCO₂ or eCO₂. Compared with control, AMF inoculation significantly increased the pupal weight of *M. separata* fed on non-Bt maize under aCO₂ and eCO₂ in 2017 and 2018, while significantly decreased the pupal weight of *M. separata* fed on Bt maize under aCO₂ and eCO₂ in two sample years. Compared with aCO₂, eCO₂ significantly decreased the pupal weight of *M. separata* fed on Bt and non-Bt maize in two sample years regardless of *F. caledonium* inoculation or not ($P < 0.05$; **Figures 5C,G**), respectively.

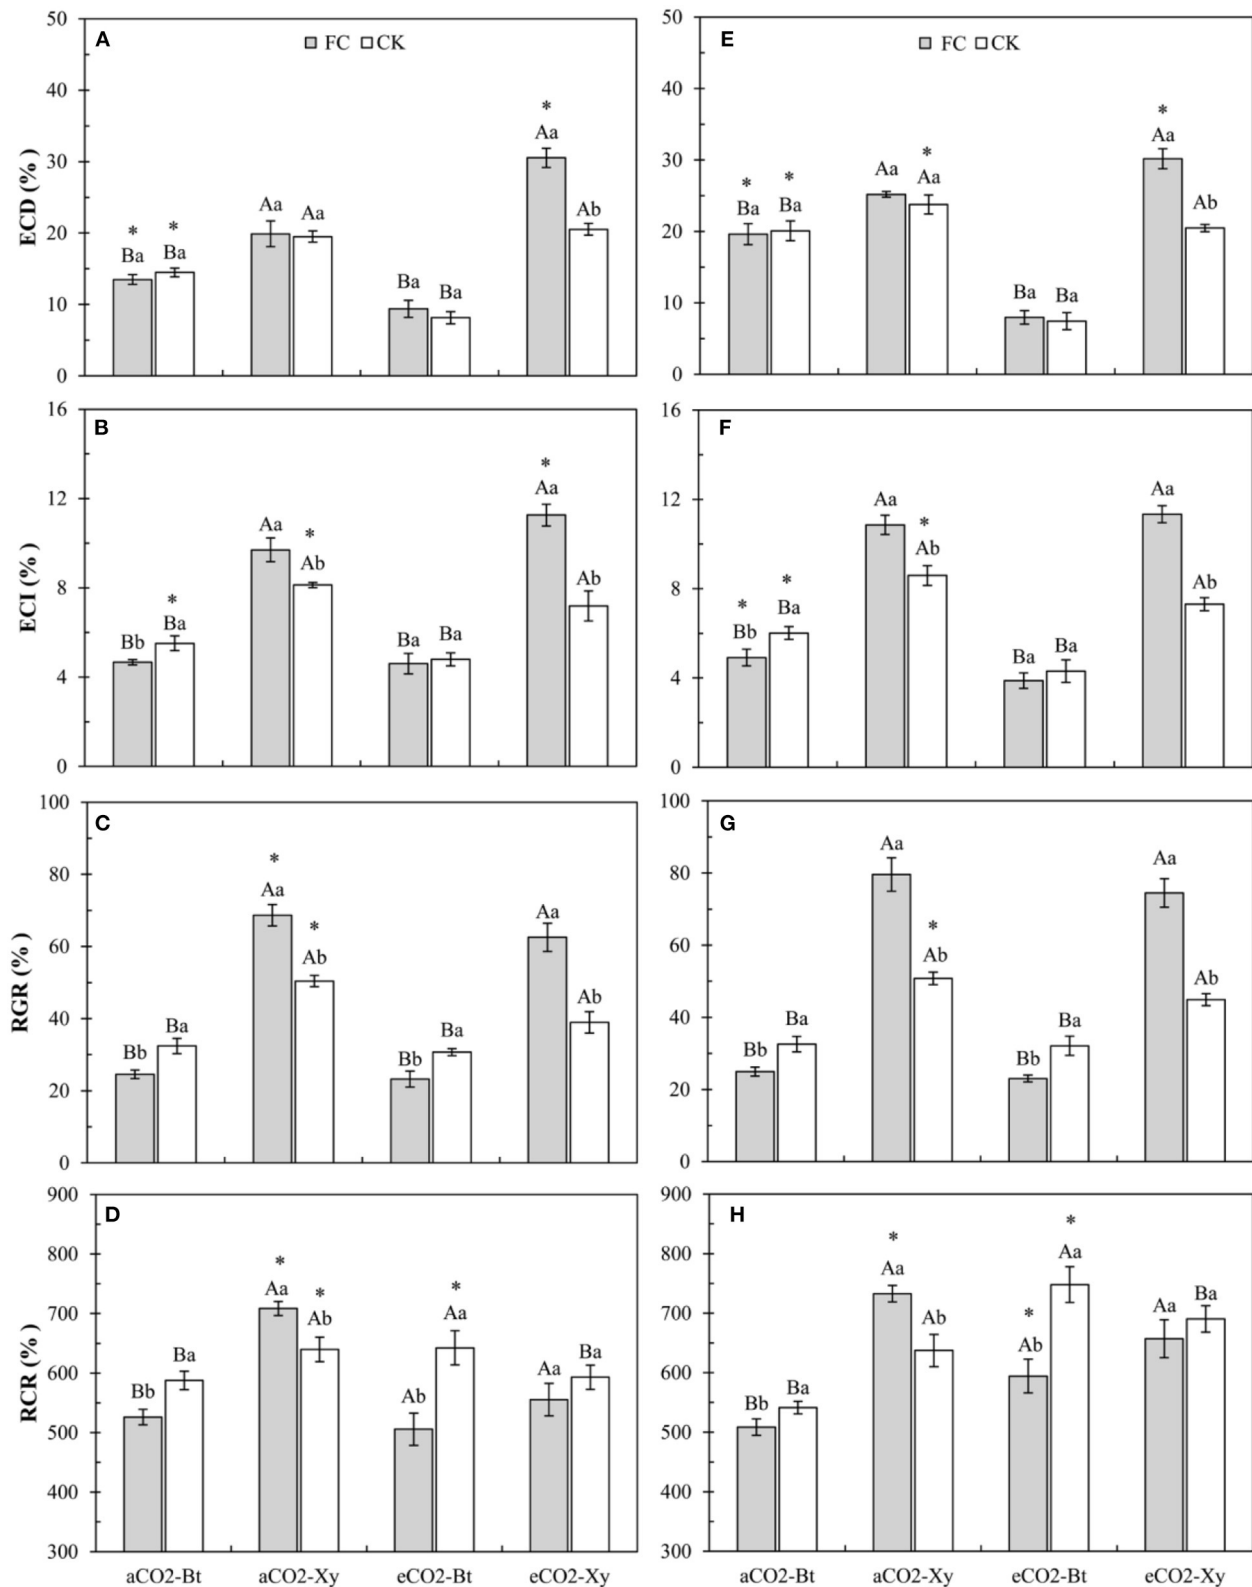

FIGURE 4 | Effects of the inoculation with arbuscular mycorrhizal fungi (AMF), *F. caledonium*, on the food utilization of *M. separata* larvae fed on *Bt* maize (Bt) and its parental line of non-*Bt* maize (Xy) under ambient CO₂ (aCO₂) and elevated CO₂ (eCO₂) at the heading stage (BBCH-59) in 2017 (A–D) and 2018 (E–H). (Note: the same as Figure 3) ($P < 0.05$; $n = 5$).

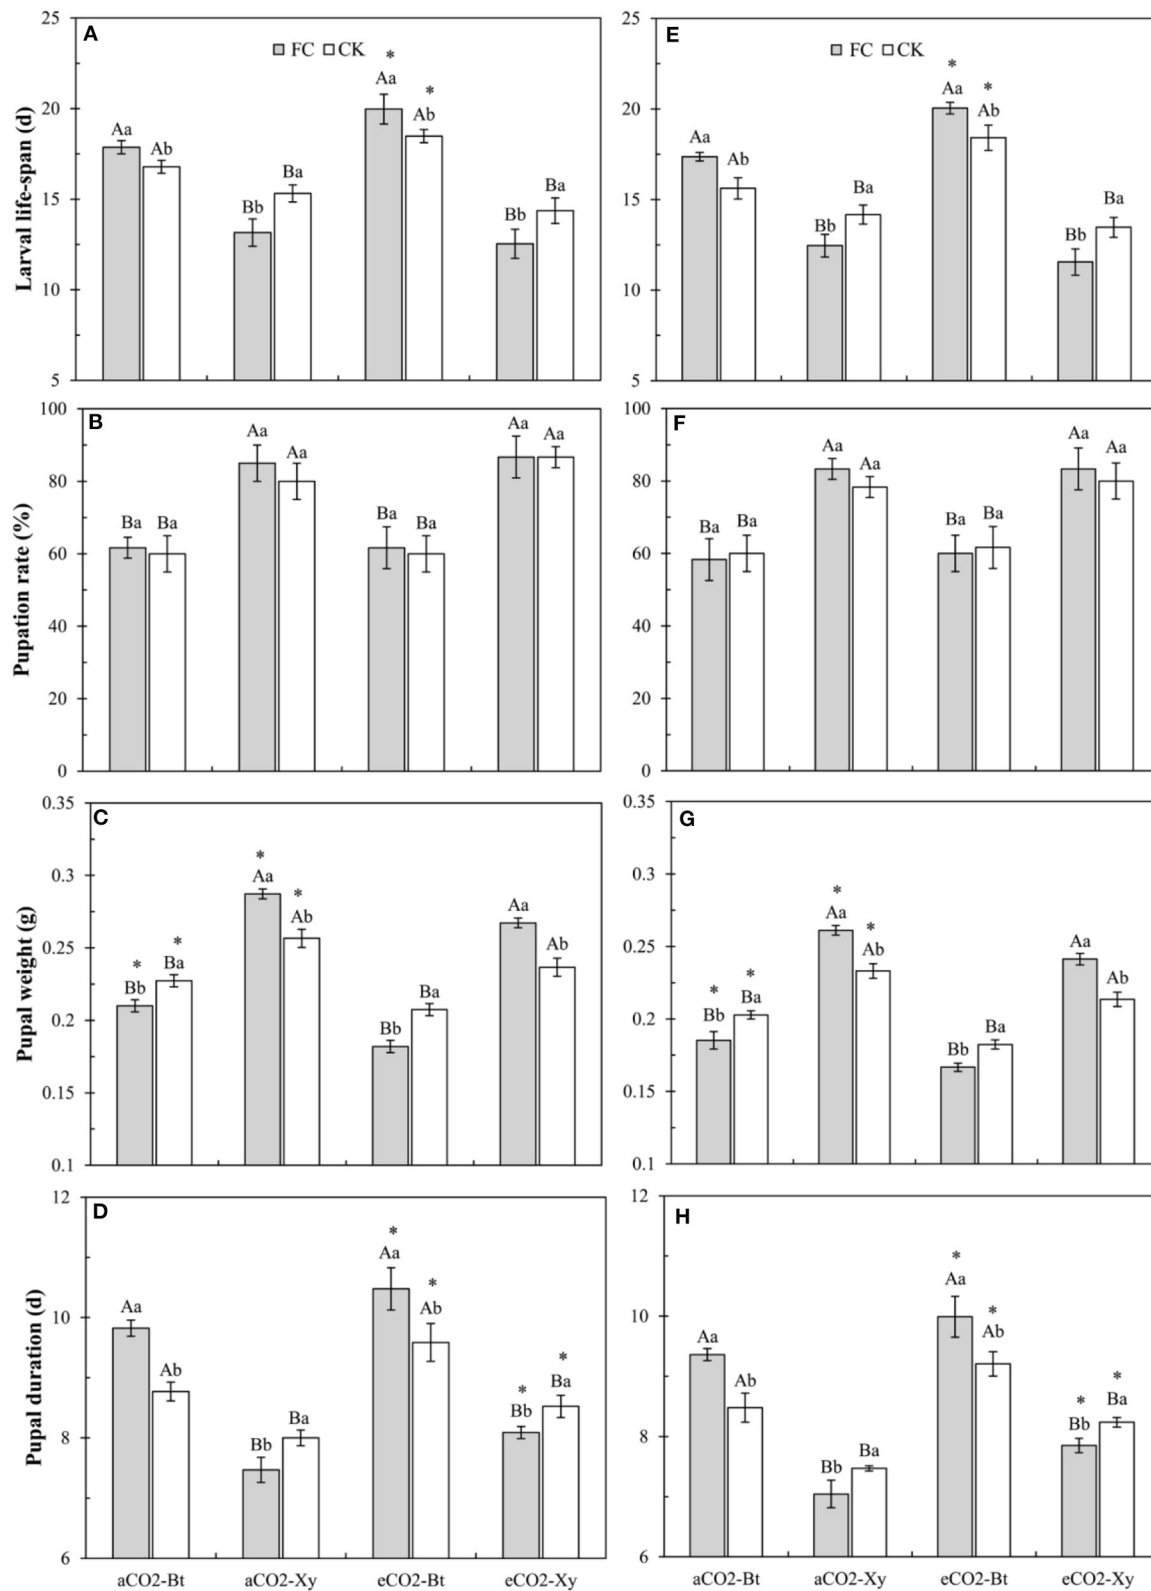

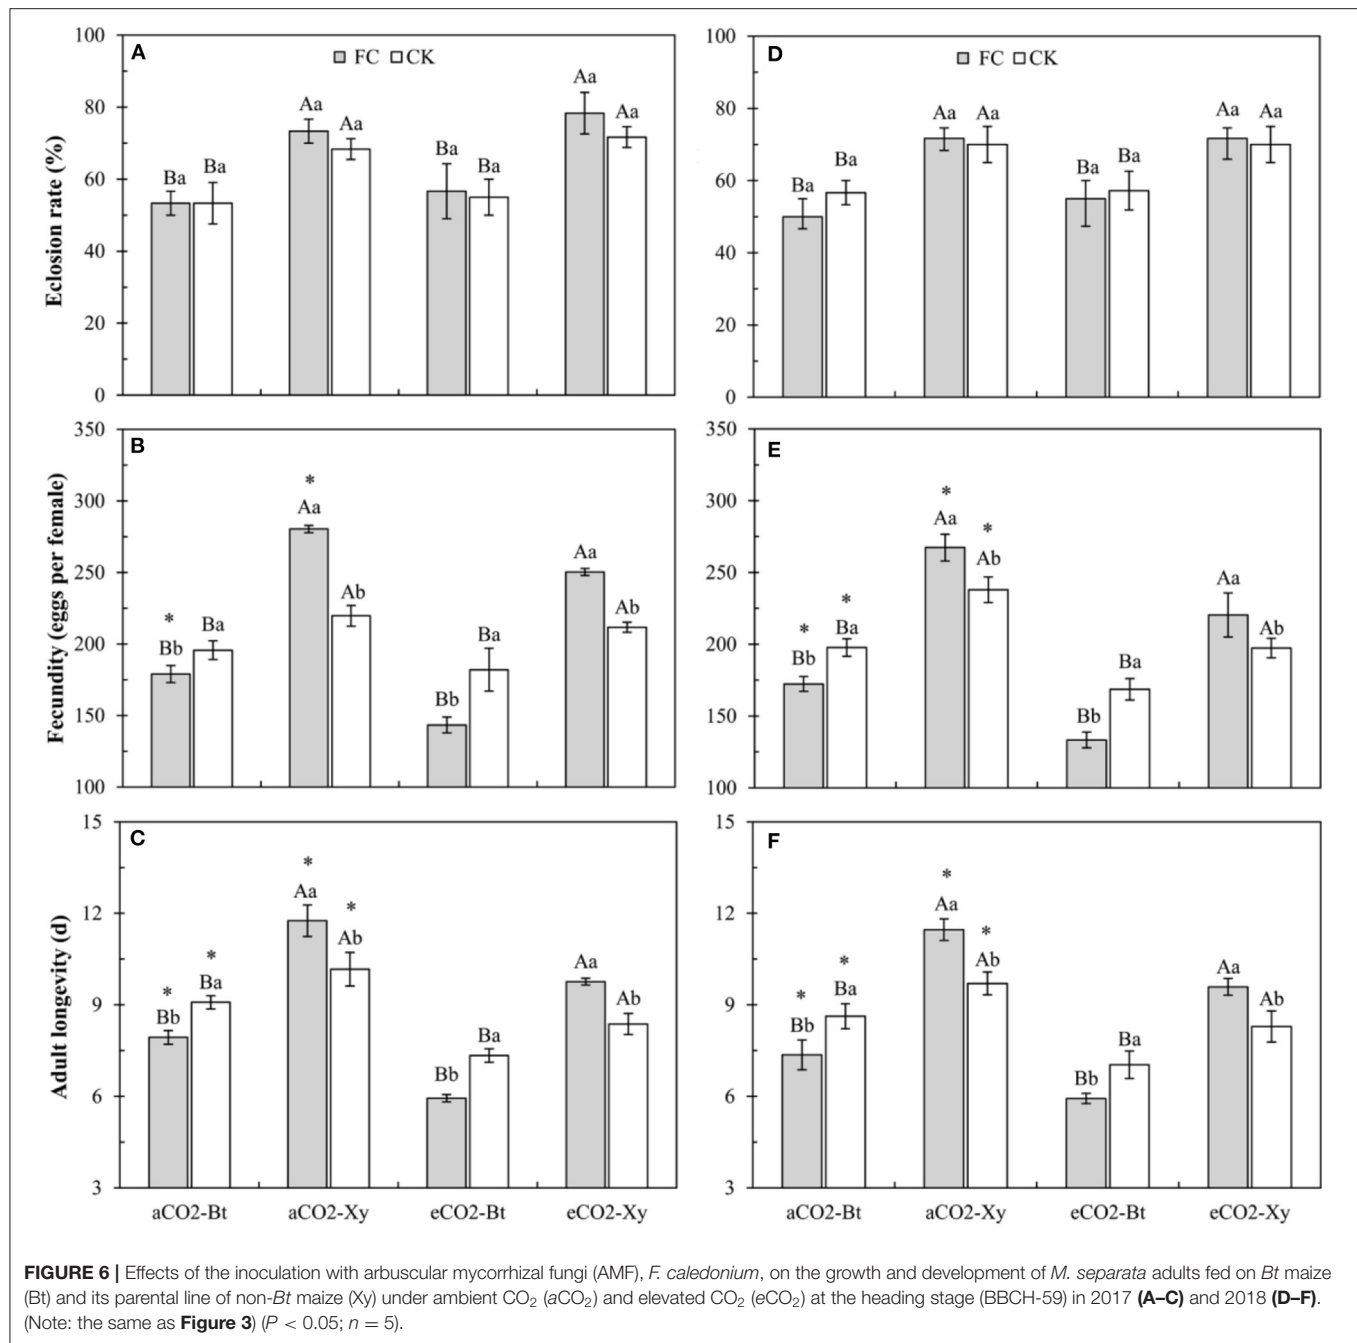

FIGURE 5 | Effects of the inoculation with arbuscular mycorrhizal fungi (AMF), *F. caledonium*, on the growth and development of *M. separata* larvae fed on *Bt* maize (Bt) and its parental line of non-*Bt* maize (Xy) under ambient CO₂ (aCO₂) and elevated CO₂ (eCO₂) at the heading stage (BBCH-59) in 2017 (A–D) and 2018 (E–H). (Note: the same as **Figure 3**) ($P < 0.05$; $n = 5$).

Compared with non-*Bt* maize, the pupal duration of *M. separata* fed on *Bt* maize inoculated with and without *F. caledonium* was significantly extended in two sample years no matter under aCO₂ or eCO₂. Compared with control, AMF inoculation significantly shortened the pupal duration of *M. separata* fed on non-*Bt* maize under aCO₂ and eCO₂ in 2017 and 2018, while significantly extended the pupal duration of *M. separata* fed on *Bt* maize under aCO₂ and eCO₂ in two sample years. Compared with aCO₂, eCO₂ significantly extended the pupal duration of *M. separata* fed on *Bt* and non-*Bt* maize in two

sample years regardless of *F. caledonium* inoculation or not ($P < 0.05$; **Figures 5D,H**).

Compared with non-*Bt* maize, the eclosion rate of *M. separata* fed on *Bt* maize inoculated with and without *F. caledonium* was significantly decreased in two sample years no matter under aCO₂ or eCO₂ ($P < 0.05$; **Figures 6A,D**).

Compared with non-*Bt* maize, the fecundity of *M. separata* fed on *Bt* maize inoculated with and without *F. caledonium* was significantly decreased in two sample years no matter under aCO₂ or eCO₂. Compared with control, AMF inoculation

significantly increased the fecundity of *M. separata* fed on non-*Bt* maize under *aCO*₂ and *eCO*₂ in 2017 and 2018, while significantly decreased the fecundity of *M. separata* fed on *Bt* maize under *aCO*₂ and *eCO*₂ in two sample years. Compared with *aCO*₂, *eCO*₂ significantly decreased the fecundity of *M. separata* fed on *Bt* and non-*Bt* maize in two sample years regardless of *F. caledonium* inoculation or not ($P < 0.05$; **Figures 6B,E**).

Compared with non-*Bt* maize, the adult longevity of *M. separata* fed on *Bt* maize inoculated with and without *F. caledonium* was significantly shortened in two sample years no matter under *aCO*₂ or *eCO*₂. Compared with control, AMF inoculation significantly extended the adult longevity of *M. separata* fed on non-*Bt* maize under *aCO*₂ and *eCO*₂ in 2017 and 2018, while significantly shortened the adult longevity of *M. separata* fed on *Bt* maize under *aCO*₂ and *eCO*₂ in two sample years. Compared with *aCO*₂, *eCO*₂ significantly shortened the adult longevity of *M. separata* fed on *Bt* and non-*Bt* maize in two sample years regardless of *F. caledonium* inoculation or not ($P < 0.05$; **Figures 6C,F**).

Yield of *Bt* and Non-*Bt* Maize Influenced by CO₂ Levels and *F. caledonium* Inoculation

Four-way ANOVAs showed that AMF inoculation significantly affected all indices of maize yield ($F \geq 10.23$, $P \leq 0.003$), CO₂ level significantly affected ear weight per plant and grain weight per ear (CO₂ level: $F \geq 45.24$, $P < 0.001$), transgenic treatment significantly affected ear weight per plant ($F = 10.89$, $P = 0.002$), and the interaction between CO₂ level and AMF inoculation significantly affected the grain weight per ear ($F = 4.48$, $P = 0.042 < 0.05$) (**Supplementary Table 3**).

Compared with non-*Bt* maize, the dry ear weight per plant of *Bt* maize without *F. caledonium* inoculation was significantly enhanced under *eCO*₂ in 2017, and that with *F. caledonium* inoculation was significantly increased under *aCO*₂ in 2018. Compared with control, AMF inoculation significantly increased the dry ear weight per plant of *Bt* and non-*Bt* maize in two sample years no matter under *aCO*₂ or *eCO*₂. Compared with *aCO*₂, *eCO*₂ significantly increased the dry ear weight per plant of *Bt* and non-*Bt* maize in two sample years regardless of *F. caledonium* inoculation or not ($P < 0.05$; **Figures 7A,D**).

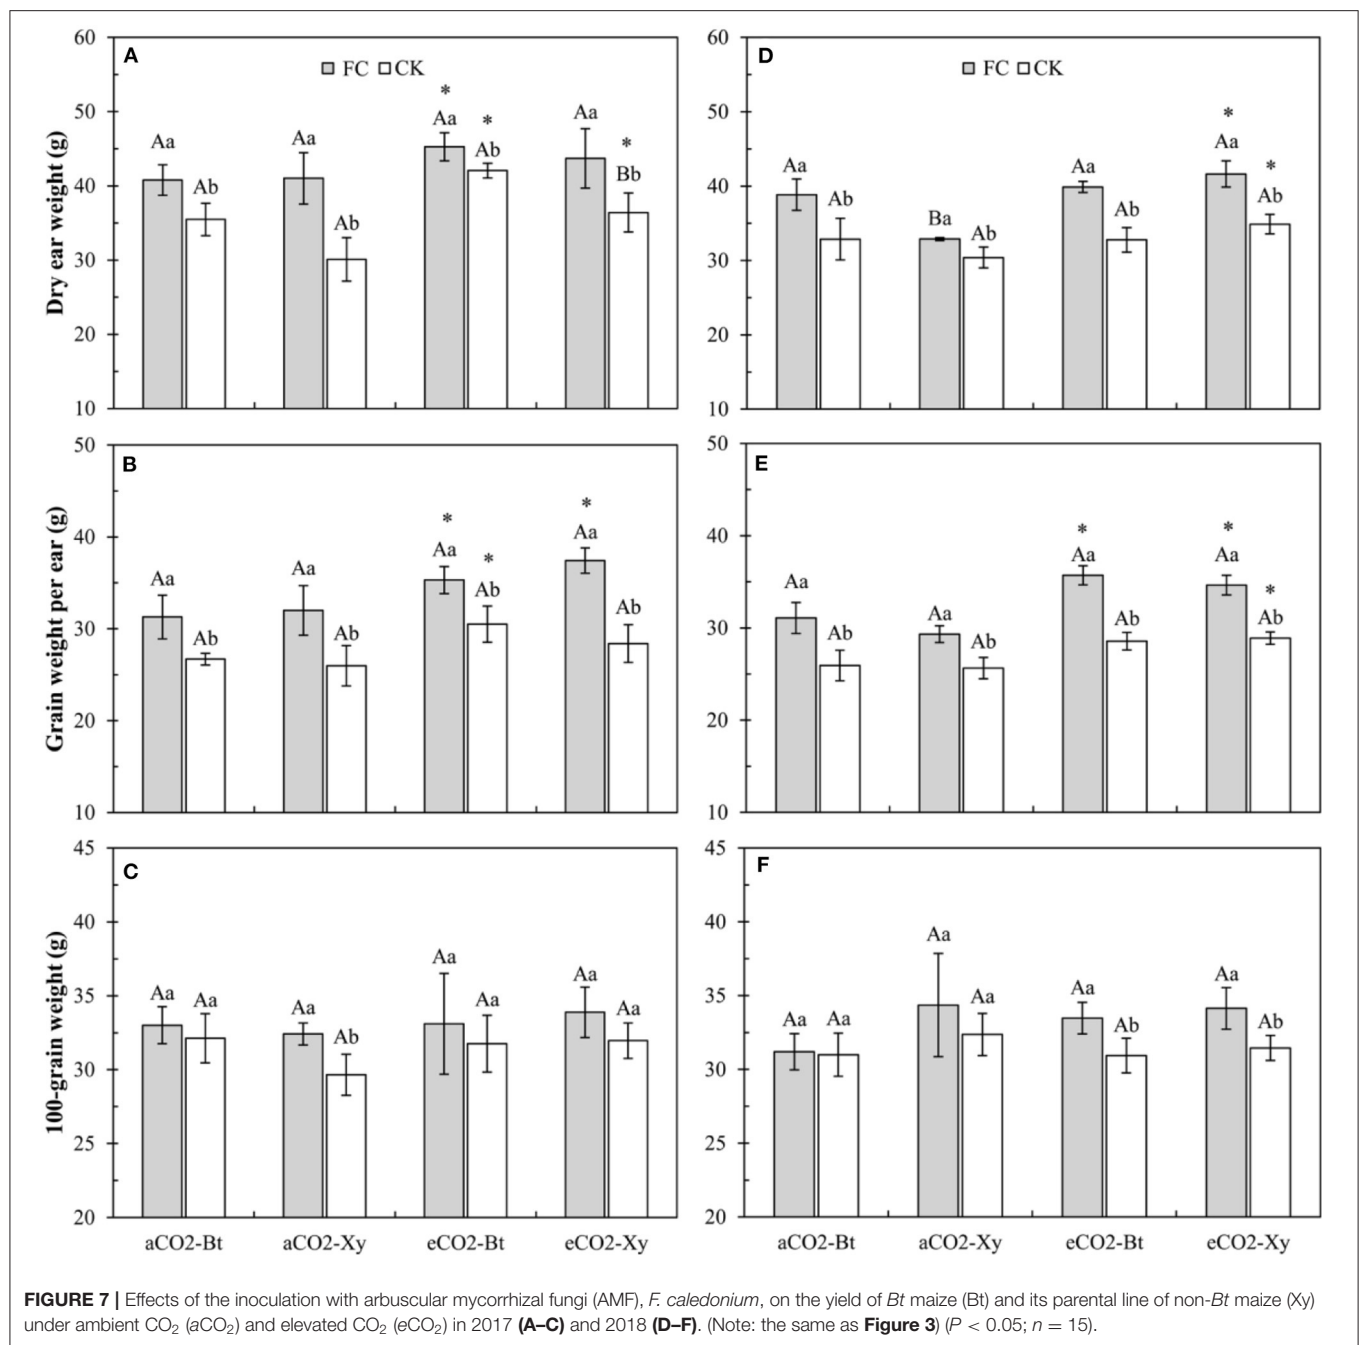

Compared with control, AMF inoculation significantly increased the grain weight per ear of *Bt* and non-*Bt* maize in two sample years no matter under *aCO*₂ or *eCO*₂. Compared with *aCO*₂, *eCO*₂ significantly increased the grain weight per ear of *Bt* and non-*Bt* maize inoculated with *F. caledonium* in two sample years, and significantly increased that of *Bt* maize without *F. caledonium* inoculation in 2017 and that of non-*Bt* maize without *F. caledonium* inoculation in 2018 ($P < 0.05$; **Figures 7B,E**). Compared with control, AMF inoculation significantly increased the 100-grain weight of non-*Bt* maize under *aCO*₂ in 2017, and that of *Bt* and non-*Bt* maize under *eCO*₂ in 2018 ($P < 0.05$; **Figures 7C,F**).

DISCUSSION

The values of AMF colonization and AMF-PLFA content indicate the colonization efficiency of AMF on maize. In this experiment, *F. caledonium* inoculation significantly increased the AMF colonization and AMF-PLFA content no matter what maize variety or CO₂ level, and this ensured the validity of the following research work. Meanwhile, elevated CO₂ can increase photosynthesis of plants, improve plant growth, and promote the transfer of carbon source substances from host plants to the root-symbiotic AMF, which is beneficial for AMF colonization and growth (Diaz et al., 1993; Cheng et al., 2012). The colonization was increased by ~10% in *Medicago truncatula* and by as much as 50% in *Brachypodium distachyon* (Jakobsen et al., 2016). Treseder (2004) also reported that the AMF colonization reflected an increased colonization speed under *eCO*₂. Alberton et al. (2005) found that mycorrhizal fungi and mycorrhizal plants to elevated CO₂ were significantly positive, and the response ratio for AM fungi was 1.21 (an increase of 21%), indicating a significantly different response, and AM colonization percentage also had a certain degree of improvement. In this study, the AMF colonization and the AMF-PLFA content of *Bt* and non-*Bt* maize under *eCO*₂ were generally higher than those under *aCO*₂; therefore, it is presumed that elevated CO₂ did have a positive facilitation on the colonization of *F. caledonium* on maize (Diaz et al., 1993; Drigo et al., 2013; Becklin et al., 2016). Besides, there were no differences in the AMF colonization and AMF-PLFA content between *Bt* maize and its parental line of non-*Bt* maize; the results showed that the presence of the cry1Ie protein in maize did not affect the colonization of the AMF community, and it is consistent with the research report of Cheeke et al.; Cheeke et al. (2014; 2015; Zeng et al., 2018).

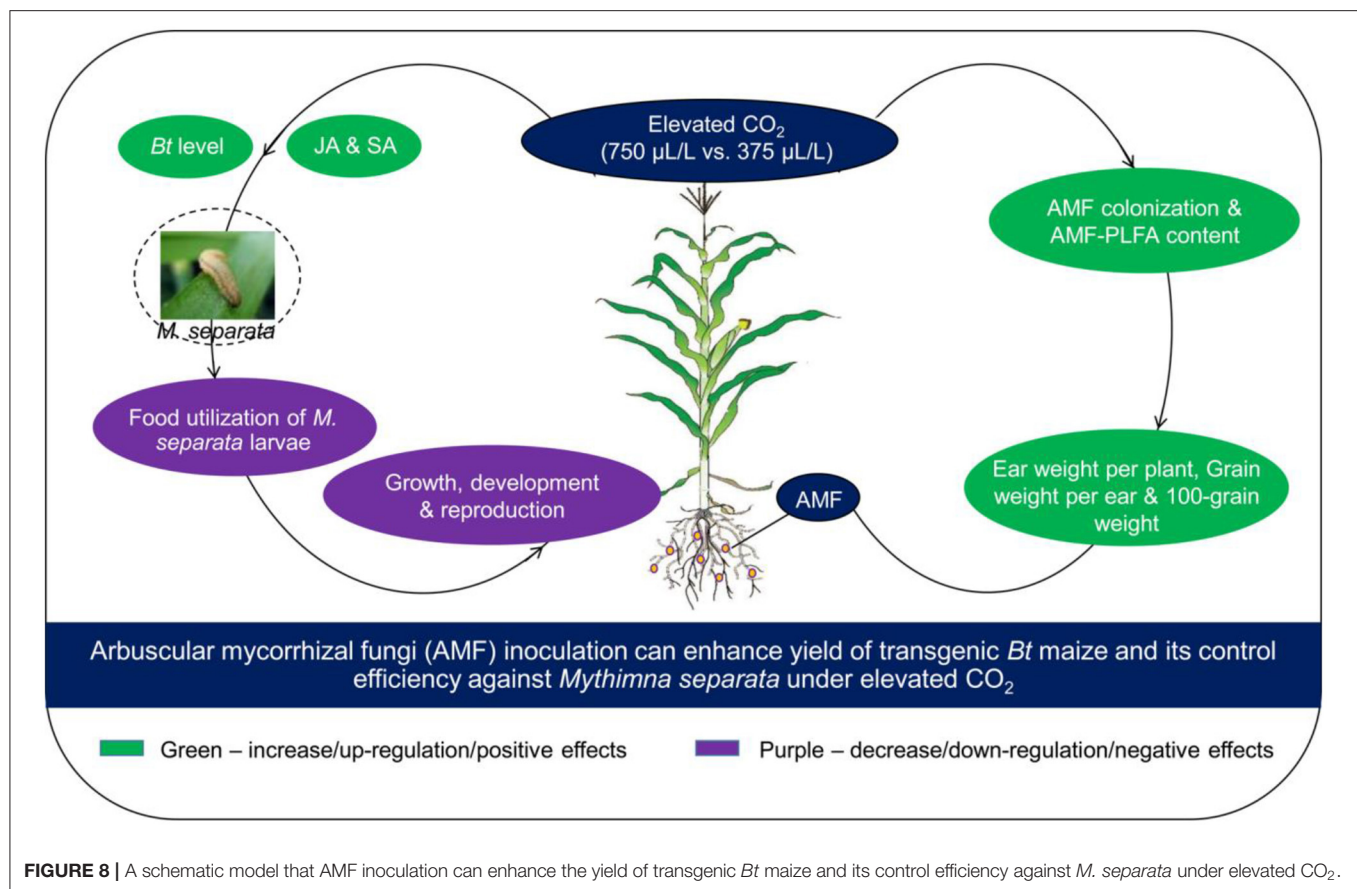

Overall, the plant biomass and grain yield increased with the increasing level (200–400 ppm) of atmospheric CO₂ for most crops (Chen M. et al., 2011; Wang et al., 2018). In this study, the results showed that *eCO*₂ significantly increased maize ear weight per plant and grain weight per ear, while it did not significantly affect the 100-grain weight. It is mainly because *eCO*₂ can enhance photosynthesis and in turn, has a positive effect on crop biomass and production (Guo et al., 2016; Liu et al., 2019). Although the maize yield was improved, the comprehensive nutritional quality of maize grain (100-grain weight) could not be improved; it may be due to the decreased nitrogen content at high CO₂ levels. Moreover, *F. caledonium* inoculation significantly increased all the yield indices (ear weight per plant, grain weight per ear, and 100-grain weight). The main function of AMF is to enhance the uptake of nutrient elements (e.g., N, P, K, Ca, Mg, Zn, and Fe) by host plants, improve the nutrient metabolism capacity and nutrient level of plant tissues, and then promote the growth and fruiting of plants (Sharifi et al., 2007; Terrer et al., 2016; Turrini et al., 2017). In addition, under the combined effects of *eCO*₂ and *F. caledonium* inoculation, the ear weight per plant and grain weight per ear of *Bt* and non-*Bt* maize showed a further significant increase, which benefit from the improvement of AMF colonization under *eCO*₂.

Insects are sensitive to environmental variations, and environmental stresses can cause changes in their growth,

development, fecundity, food utilization, and the occurrence and distribution of populations as a result of metabolic rate fluctuation (Bloom et al., 2010). Usually, endogenously secondary defensive chemicals (e.g., JA and SA) and nutrient components (e.g., C, N, P, and K) are the two main factors that affect the population fitness of pests; the balance between secondary defensive chemicals and nutrient components determines the development trend of pests after feeding. If the pests feed on transgenic *Bt* plants, in addition to the above-mentioned two influencing factors, the *Bt* toxin protein will also have a significant adverse effect on the growth and food utilization

of pests and occupy the dominant position among the three. Prutz and Dettner (2005) reported that the transgenic *Bt* maize decreased the growth rate and increased the mortality of *Chilo partellus*, which might be attributed to the termination of larval metamorphosis fed on *Bt* maize. Most studies showed adverse effects of *Cry* proteins on lifetable parameters of different herbivores (Lawo et al., 2010), which might be due to the interaction of feeding inhibitors and growth inhibitors. In this study, we found that *Bt* maize obviously decreased almost all measured indices of food utilization (ECD, ECI, and RGR), and it showed that the ability of food digestion and absorption

of pests has caused serious damage by Bt toxin. Meanwhile, life table parameters (growth, development, and reproduction of *M. separata* larvae; pupation rate, pupal weight, eclosion rate, and fecundity of *M. separata* adult) markedly decreased feeding on Bt maize, and Bt toxin also prolonged the larval lifespan and shortened the adult longevity of *M. separata* regardless of the CO_2 level and *F. caledonium* inoculation or not in 2017 and 2018. These results showed that Bt maize obviously retarded the growth and development of *M. separata* and were similar to those of previous studies.

Previous studies have examined that in most plants, elevated CO_2 tends to promote plant photosynthesis and also leads to a decrease in foliar nitrogen content and an increase in C: N ratio (Johns et al., 2003; Li et al., 2018). Meanwhile, nitrogen is the main component of exogenous Bt protein in Bt crops. Plant nitrogen uptake, nitrogen-level status, and C: N ratio could affect the production of exogenous Bt toxins for Bt crops (Gao et al., 2009; Jiang et al., 2013). Numerous studies have shown that $e\text{CO}_2$ can significantly reduce the exogenous Bt protein content of Bt cotton and Bt rice, while increasing their yield (Coviella et al., 2000, 2002; Chen et al., 2005b; Wu et al., 2011a,b), and also found the “dilution effect” on exogenous Bt protein or inhibition on Bt-transgene expression (Chen F. J. et al., 2011; Jiang et al., 2017; Liu et al., 2019). Moreover, elevated CO_2 also affected the production of primary and secondary

metabolites, and the defense mechanisms of crop plants (e.g., JA and SA) (Stiling and Cornelissen, 2007; Sun et al., 2016). In this study, $e\text{CO}_2$ significantly decreased the ECI and RGR of *M. separata* larvae fed on non-Bt maize without *F. caledonium* inoculation, and was almost adverse to all the measured indices of growth and development of *M. separata*; it is mainly due to the increased secondary defense substances (i.e., JA and SA) in plants and the declined food nutrient level (e.g., fewer N) under elevated CO_2 (Armstrong et al., 1995; Coviella et al., 2002; Liu et al., 2019). Many studies found that elevated CO_2 had adverse effects on the developmental duration, pupation, and eclosion of cotton bollworm, *H. armigera* (Akbar et al., 2016), and reduced the oviposition number of borers and semilooper (Stange, 1997; Rao et al., 2013). On the other hand, elevated CO_2 decreased the RGR of the *Spodoptera litura* and *H. armigera* (Hattenschwiler and Schafellner, 2004), and also significantly reduced the ECD and ECI of *H. armigera* (Yin et al., 2010). Meanwhile, $e\text{CO}_2$ also significantly reduced the ECD, ECI, pupal weight, fecundity, and adult longevity, and significantly extended the development duration of *M. separata* fed on Bt maize with and without *F. caledonium* inoculation. This shows that despite the decrease in exogenous Bt toxin content, the increase in secondary defense substances and the decline in nutrient quality can also make a relatively adverse effect on *M. separata*.

The effect of *F. caledonium* inoculation on *M. separata* fed on *Bt* maize and non-*Bt* maize was just the opposite; that is, *F. caledonium* inoculation significantly reduced the ECI, RGR, and RCR of *M. separata* larvae fed on *Bt* maize under *a*CO₂ and *e*CO₂, while significantly increased the ECI and RGR of *M. separata* larvae fed non-*Bt* maize under *a*CO₂ and *e*CO₂, and RCR of *M. separata* larvae fed on non-*Bt* maize under *a*CO₂, and ECD of *M. separata* larvae fed on non-*Bt* maize under *e*CO₂. In addition, *F. caledonium* inoculation and transgenic treatment had a significant interaction on the growth, development, and reproduction of *M. separata*. Specifically, as fed on *Bt* maize, *F. caledonium* inoculation significantly extended the developmental duration of larvae and pupae of *M. separata* under *a*CO₂ and *e*CO₂, significantly reduced the pupal weight and fecundity, and significantly shortened the adult longevity of *M. separata*. On the contrary, as fed on non-*Bt* maize, *F. caledonium* inoculation significantly shortened the developmental duration of larvae and pupae of *M. separata* under *a*CO₂ and *e*CO₂, and significantly increased the pupal weight of *M. separata* under *a*CO₂ and *e*CO₂. Thus, it was observed that *F. caledonium* inoculation had diametrically opposite effects on the growth, development, and food utilization of *M. separata* fed on *Bt* maize and non-*Bt* maize; that is, *F. caledonium* inoculation reduced the food utilization efficiency and had adverse effects on the growth, development, and reproduction of *M. separata* fed on *Bt* maize, while it improved the food utilization efficiency and had positive effects on the growth, development, and reproduction of *M. separata* fed on non-*Bt* maize. This is mainly due to the promotion of the absorption and utilization of soil nutrients in maize plants by *F. caledonium* inoculation, thus improving the nutrient level of maize plant tissues (Sharifi et al., 2007; Rodriguez and Sanders, 2015). So it is concluded that *M. separata* larvae can get more plant nutrition when fed on non-*Bt* maize inoculated with *F. caledonium*. When fed on *Bt* maize inoculated with *F. caledonium*, *M. separata* larvae not only obtained more plant nutrients, but also ingested more doses of exogenous *Bt* toxin, which improved the target resistance ability of *Bt* crops based on the exogenous *Bt* toxin, and further reduced the food utilization efficiency, growth, development, and reproduction of *M. separata*, and at the same time, the promotion of AMF colonization by *e*CO₂ further enhanced the target resistance level of *Bt* maize to *M. separata*.

Overall, our research showed that *e*CO₂ was beneficial for AMF colonization on roots, and maize yield, but it had negative effects on the growth, development, reproduction, and food utilization of *M. separata*. *F. caledonium* inoculation was positive for maize yield and nutrient quality, and in favor of the growth, development, reproduction, and food utilization of the *M. separata* fed on non-*Bt* maize. However, *F. caledonium*

inoculation was unfavorable for the population fitness of *M. separata* fed on *Bt* maize. Namely, regardless of the CO₂ level, inoculation of *F. caledonium* had a detrimental effect on the production of non-*Bt* maize as the result of a high potential risk of *M. separata* production hazard, while its effects on *Bt* maize were just the opposite; that is, *F. caledonium* inoculation had positive effects on the production of *Bt* maize especially under *e*CO₂ due to the lower potential risk of population occurrence of *M. separata*. Ultimately, the results proved that all of our hypotheses were confirmed: It showed that the AMF inoculation of *F. caledonium* under *e*CO₂ was more effective in improving the control efficiency of *Bt* maize on the target insect pest, *M. separata*, promoted the expression of endogenous (JA, SA) and exogenous (*Bt* toxin) secondary defense substances in *Bt* maize leaves, and also increased the biomass and yield of maize (Figure 8). We have reason to expect this friendly and effective biological way serving for mitigating the ecological risk of *Bt* maize and improving its ecological sustainable utilization capacity under global climate change.

The modern agricultural sector faces the challenge of addressing the needs of the fast-growing global population. This process should be both high-yielding and sustainable, without creating risks for the environment and human health. Therefore, natural products are gaining attention in the production of safe and nutritious food. In a systematic effort to develop affordable and effective biostimulants, we examined the impact of botanical extracts on the growth and physiological parameters of radish plants under field conditions. Ultrasound-assisted extraction, mechanical homogenization, and water were used for the production of potential plant-based biostimulants. Foliar applications of the bio-products, developed and used in our study, have led to an increase in the examined parameters (total yield, dry weight, photosynthetic pigments, vitamin C, nitrates, and micro- and macroelements). A decrease in the total phenolic compounds content was also noted, as well as a varied impact on the steam volatile compounds, fatty acids, sterol, and glucosinolates composition. The most beneficial effects on radish, in terms of physiological and biochemical properties, were found in groups treated with extracts based on the common dandelion, valerian, and giant goldenrod. This innovative approach presented in our study could provide a valuable tool for sustainable horticultural production.

Keywords: higher plants, extraction, bioactive compounds, radish, yield, nutritional quality, sustainable food production

INTRODUCTION

Globally, agriculture and horticulture constitute a multitrillion dollar industry. This sector provides a wide variety of crops for food, feed, and ornamental purposes (Zulfiqar et al., 2019). Due to the exponentially growing population, limited available farmland, genetic potential of crops, depletion of natural resources, and climate change, agribusiness is facing the challenge of devising more

effective and sustainable solutions to facilitate the reduction of malnutrition, poverty, starvation, and energy and water usage while concurrently increasing the yield and the quality of crops (Campos et al., 2019; Pereira et al., 2019; Szparaga et al., 2019; Zulfiqar et al., 2019; Kamble et al., 2020). The Green Revolution implemented in the 1960s was characterized by large increases in crop yields due to the extensive use of pesticides and fertilizers (Pereira et al., 2019; Rose et al., 2019). The long-standing excess usage of these products has led to serious threats to human health and the environment worldwide (e.g., ground water and air pollution, water eutrophication, and soil quality degradation) (Ertani et al., 2014; Vejan et al., 2016; Campos et al., 2019; Costa et al., 2019; Ekin, 2019; Pereira et al., 2019; Shang et al., 2019; Shukla et al., 2019; Zulfiqar et al., 2019). On the other hand, these products have been necessary to satisfy the growing human demand for food. Furthermore, the overuse of fertilizers has increased the cost of production and reduced the profit margins for farmers (Zulfiqar et al., 2019). Climate change and unfavorable growing conditions can increase plant susceptibility to pathogens (Shukla et al., 2019). Consequently, the establishment of sustainable principles, strategies, technological advancements, and innovations (Pereira et al., 2019; Shang et al., 2019) is crucial to enhance the effectiveness of fertilizers, to meet the requirements of environmentally friendly crop management practices, and to cope with high productivity demands (Bulgari et al., 2015; Paradiković et al., 2018; Ekin, 2019; Shang et al., 2019; Shukla et al., 2019). Crop resistance to diseases, soil salinity, drought, heavy metals, as well as their increased nutritional value are getting highly desirable (Vejan et al., 2016; Bulgari et al., 2019).

Bio-based products (including crop residues, plants, and seaweed), applied at low doses, may be a promising solution to diminish fertilizer rates and simultaneously exert beneficial effects on plant growth (Ertani et al., 2014). Biostimulants have become more popular in sustainable agriculture in recent years because of their beneficial properties. They stimulate various physiological processes that promote nutrient acquisition and utilization by plants; enhance the root development (the length and number of root hairs), shoot development, yield, and nutritional quality of plants; counteract the effects of biotic and abiotic stresses; improve the activity of soil microbiota; and reduce the use of fertilizers and the content of undesirable compounds (e.g., nitrates and heavy metals) in cultivated plants (Ertani et al., 2014; Bulgari et al., 2015; Paradiković et al., 2018; Rouphael et al., 2018; Szparaga et al., 2018; Carillo et al., 2019a,b; Ekin, 2019; Shukla et al., 2019; Cozzolino et al., 2020). The effects of biostimulants may differ, depending on the plant species (e.g., different leaf permeability levels), cultivar, physiological stages, type of product, dose, concentration, time, and application method (e.g., foliar, soil drench, or seed treatment), as well as environmental conditions (Ertani et al., 2014; Bulgari et al., 2015; Paradiković et al., 2018; Szparaga et al., 2018). In the European Union, the countries of France, Italy, and Spain are the primary producers of biostimulants. As reported by Grand View Research, Inc., the market size of these products is projected to be worth approximately USD 4.14 billion by 2025 (Bulgari et al., 2019). According to the new European

Union Regulation, 2019/1009, plant biostimulants are defined on the basis of their agricultural impacts on crops. They may contain protein hydrolysates, humic substances, algal and botanical extracts, inorganic compounds (e.g., Si), growth-promoting bacteria, mycorrhizal fungi (D'Addabbo et al., 2019; Cozzolino et al., 2020), amino acids, chitin, chitosan, vitamins, and poly- and oligosaccharides (Bulgari et al., 2015). The beneficial effects of biostimulants are not associated with their macro- and micronutrient composition but rather with their content of activating compounds, like endogenous hormones, small peptides, free amino acids, phenolics, and triacontanol (Ertani et al., 2014; Yakhin et al., 2017), which may affect plant metabolisms by triggering glycolysis enzyme activities, the Krebs cycle, and nitrate assimilation (Ertani et al., 2009; Colla et al., 2015, 2017; Yakhin et al., 2017; Palumbo et al., 2018; Sandhu et al., 2018; Alfosea-Simón et al., 2020; Cozzolino et al., 2020; Francesca et al., 2020). On the other hand, if their biological activity depends on the presence of natural plant hormones, they ought to be classified as plant growth regulators (Bulgari et al., 2015). The hormonal activity of plants can alter the electrochemical gradient of protons formed across the cell membrane through proton pump modulation (Paradiković et al., 2018). By virtue of the complexity of biostimulants' composition, it is difficult to assign their beneficial effects on plants to a particular compound, especially when that compound may interact with other molecules in a synergistic way (Bulgari et al., 2015, 2019). Hence, their mechanism of action is still not well-understood, and these types of products should be categorized based on the physiological responses of plants (Bulgari et al., 2015).

In recent years, numerous reports have highlighted the beneficial effects of biostimulants applications in the worldwide cultivation of various crops, especially for achieving higher yields. New research should focus not only on short-term studies of young seedlings but also on real field conditions with mature plants (Ertani et al., 2014). Nevertheless, the impact of the application of bio-products on the nutritional value and health-promoting potential of plants is not well-documented but has been observed in several crops (Kocira, 2019; Cocetta and Ferrante, 2020). Many of these compounds exhibit a favorable impact on the health-related characteristics of vegetables and fruits (Cocetta and Ferrante, 2020)—for example, the presence of antioxidants imparts nutraceutical properties to plant products (Kocira, 2019). Presently, fruits, vegetables, and edible flowers rich in phytonutrients (plant-derived substances; neither vitamins nor minerals) are gaining more attention both among scientists and consumers. These are usually plant secondary metabolites (synthesized from primary metabolites) and are involved in various mechanisms, e.g., in plant interaction with the environment, defense responses to stresses (by serving as phytoalexins, antioxidants, and signal molecules), as well as to deter animals or, conversely, to attract them to spread seeds or pollinate flowers (due to their anthocyanin content). These compounds often function as antioxidants; they increase the antioxidant potential of fruits, vegetables, and flowers, and they obstruct oxidative reactions under stress conditions (Bulgari et al., 2015). A diet low in fruits and vegetables is associated with an increased risk of various debilitating nutritional diseases. As

reported by the Global Burden of Disease Study, a low intake of fruits can be attributed to 3.4 million deaths, while low vegetable consumption was estimated to cause 1.8 million demises globally (Bulgari et al., 2019). Presently, healthy lifestyles and high-quality foods are piquing a growing interest among consumers. Therefore, there is a need to develop new, cheaper products for use in organic agriculture to enable greater access to more affordable and eco-friendly food (Kowalski and Kaniszewski, 2017).

Radish (*Raphanus sativus* var. *sativus*) was chosen as a model plant in the present study. There are numerous radish cultivars differing in shape (round, oval, icicle, half long, long, conical, cylindrical, spindle), color (white, pink, red, purple, black), flavor, and growing conditions (Paul et al., 2016; Dhaliwal, 2017). Radish is widely cultivated due to its taste and low content of calories but high nutrients (e.g., K, Fe, Ca, Na, Zn, Mn, P, vitamins C and B, folic acid, fiber) (Paul et al., 2016; Banihani, 2017; Dhaliwal, 2017; Kowalski and Kaniszewski, 2017). This root vegetable is valued for the presence of phytochemicals, especially glucosinolates, which are hydrolyzed into bioactive compounds (e.g., isothiocyanates, nitriles, thiocyanates, epithionitriles, and oxazolidinethiones) that are of use to plants (e.g., for defense) and human health. The consumption of radish has been shown to lower the risk of different types of cancers (e.g., breast, colon, lung, stomach, prostate, pancreas, and rectal cancer), as well as supports the prevention of constipation, stone formation, and jaundice (Paul et al., 2016; Banihani, 2017; Dhaliwal, 2017; Manivannan et al., 2019). Radish also exhibits antimicrobial, anticancer, antioxidant, and anxiety-reducing properties (Manivannan et al., 2019). In Poland, the cultivation area of radish is estimated at 700 ha and field cultivation accounts for one-third of the whole area (Chohura and Kołota, 2011). Due to the low light in the autumn–spring period, the overaccumulation of nitrates in plant tissues may sometimes be a problem (Kowalski and Kaniszewski, 2017).

Hence, our current study aimed to determine the possibility of transforming higher plants that are widely found in Europe (herbs of St. John's wort, leaves of giant goldenrod, flowers and leaves of common dandelion, flowers of red clover, leaves of nettle, and roots of valerian) into low-cost products that are rich in bioactive compounds for use in modern horticulture to achieve higher yield, quality, and profitability. Ultrasound-assisted extraction (UAE) and mechanical homogenization (MH) were used for the production of potential water-based biostimulants. The selected raw materials were not previously used for these purposes.

MATERIALS AND METHODS

All analyses were carried out according to the methodology provided by Godlewska et al. (2020b). Brief descriptions of our methodology are presented below.

Raw Materials for the Botanical Extract Production

This study assessed the potential of using higher plants for the production of plant-based extracts. The raw materials collection

date depended on the plant part used for the extraction and the plant developmental stage. They were collected/purchased once in 2017 in the amount needed to carry out all planned research. The extraction of biologically active compounds from St. John's wort (*Hypericum perforatum* L.; herb) (marked as: Hp H), giant goldenrod (*Solidago gigantea* Ait.; leaf) (Sg L), common dandelion (*Taraxacum officinale* (L.) Weber ex F.H. Wigg; flower, leaf) (To F, To L), red clover (*Trifolium pretense* L.; flower) (Tp F), nettle (*Urtica dioica* L.; leaf) (Ur L), and valerian (*Valeriana officinalis* L.; root) (Vo R) was performed using ultrasound-assisted extraction (UAE) and mechanical shearing combined with sonic energy (MH). For the first method, the dried and ground biomass was mixed with deionized water (1:20 w/v), soaked (30 min), subsequently sonicated (30 min), and then centrifuged (10 min, 4,500 rpm). For the second method (MH), the mixture was homogenized (1 min, 28,000 rpm) and centrifuged (10 min, 4,500 rpm). The final bioactive formulations were composed of an active ingredient (extract, 0.5% w/v), an antioxidant agent (L-ascorbic acid, 0.15% w/v), an adjuvant (Protector, 0.02% w/v), a preservative (potassium sorbate, 0.1% w/v), and water (up to 100%).

The Field Trials

The radish (*Raphanus sativus* var. *sativus*) was grown in the field under a temperate climate in Poland (**Supplementary Figure 1**). Hydrocomplex Yara Mila (250 kg·ha⁻¹) and ammonium saltpetre (330 kg·ha⁻¹) were used for the fertilization of the fine clay soil (pH 7.05, EC 144.3 μS·cm⁻¹, 1.8% humus, 35.1 mg P, 89.5 mg K, and 44 mg Mg in 1 dm³). The experiments were performed in randomized complete blocks. Seeds (cultivar “Carmen,” PlantiCo) were sown on August 20, 2018, with spacing of 20 cm × 4 cm (plot size: 1 m²; 125 plants per plot; 3 plots per treatment). The spraying, at a dose of 300 L·ha⁻¹, was performed three times in the morning on sunny and windless days (September 5, September 12, and September 19, 2018). Plants were harvested on September 24, 2018. During the growing season, regular mechanical weeding and irrigation were conducted. Moreover, the insecticide (Karate Zeon 050 CS) was applied in accordance with the manufacturer's recommendations. Plant samples were collected twice: 7 days after the second spraying (the first term of leaves of rosette collection) and after harvesting (the second term of leaves of rosette and root collection) to perform chemical analyses. As the control groups, we used plants sprayed with water (C), a formulation with water without an active ingredient (CF), and a commercial biostimulant (CB).

Chemicals

Acetone, calcium carbonate, ethanol, potassium persulphate, sodium acetate, and sodium carbonate were purchased from IDALIA (Radom, Poland); azino-bis-3-ethylbenzthiazoline-6-sulphonic acid (ABTS), diphenyl-2-picrylhydrazyl (DPPH), ferric-reducing antioxidant power (FRAP), Folin–Ciocalteu's phenol reagent, gallic acid, tripyridyl-S-triazine (TPTZ), and Trolox were purchased from Archem (Łany, Poland); acetic acid, activated carbon, ammonium metavanadate, ammonium molybdate tetrahydrate, ascorbic acid, barium chloride dihydrate, cyclohexane, magnesium nitrate, 65% nitric

acid, oxalic acid, sodium bicarbonate, and sodium sulfate were purchased from CHEMPUR (Piekary Śląskie, Poland); 2,6-dichlorophenolindophenol sodium salt hydrate was purchased from ACROS ORGANICS (ARGENTA; Poznań, Poland); chloroform, hydrochloric acid (38%), and methanol were purchased from STANLAB (Lublin, Poland); standard solutions and Tween TM 80 were purchased from Merck (Darmstadt, Germany); 2-undecanone and BF_3/MeOH were purchased from Sigma-Aldrich (Saint Louis, MO, USA); hexane and sodium bicarbonate were purchased from UQF (Wrocław, Poland); n-hexane (99%) was purchased from POCH Basic (Gliwice, Poland); helium was purchased from Air Products (Warsaw, Poland); and potassium hydroxide was purchased from Avantor (Gliwice, Poland).

The Photosynthetic Pigments, Greenness Index of the Leaves, and Leaf Color

The contents of chlorophyll *a* + *b* and carotenoids were determined in fresh leaves. Samples (0.4 g) were disintegrated, using a mortar and a pestle with the addition of a few drops of acetone (80%), a pinch of sand, and calcium carbonate. The obtained mixture was filtered, transferred to a volumetric flask (50 ml) and filled with acetone. The absorbances were measured in four replicates at 663, 645, and 470 nm with the use of a spectrophotometer (HACH DR1900, Berlin, Germany). The greenness indexes of the leaves were evaluated, using an SPAD 502 Plus Chlorophyll Meter (Konica Minolta, Osaka, Japan), and the colors of the leaves were measured, using MiniScan (Hunter Lab EZ, Reston, Virginia, USA) (in 10 replicates).

Vitamin C

For determination of the vitamin C content, the fresh leaves (~10 g) and roots (~15 g) were homogenized in oxalic acid (200 ml, 2%) and filtrated. Solutions (10 ml) were titrated (in four replicates) with Tillmans' reagent as long as a light pinkish color appeared and was maintained for at least 30 s.

Total Phenolic Compounds

The total phenolic compound (TPC) content was evaluated in fresh, comminuted shoots and roots (~2 g). The biomasses were placed in tubes, mixed with aqueous methanol (20 ml, 80%), sonicated (15 min), and centrifuged (10 min, 4,500 rpm). To the obtained supernatants (0.1 ml), the Folin–Ciocalteu's phenol reagent (0.2 ml) and distilled water (2 ml) were added, and the mixtures were kept in the dark (3 min). Next, sodium carbonate (1 ml, 20%) was added to the reaction mixtures and left in the dark for 1 h. The absorbance (765 nm) was then assessed (in four replicates).

The Antioxidant Activity (DPPH, ABTS, and FRAP Assays)

The antioxidant activities were assessed in ten-fold diluted supernatants prepared for TPC analyses. The absorbance measurements were made in four replicates.

For the DPPH assay, supernatants (0.5 ml), ethanol (1.5 ml), and DPPH solution (0.5 ml) were mixed and incubated at room

temperature without access to light (10 min). The radical stock solution of DPPH was freshly prepared by dissolving in ethanol.

For the ABTS assay, a diluted ABTS solution (3 ml) was added to the supernatants (30 μl) and kept in the dark (6 min). The $\text{ABTS}^{\bullet+}$ solution was prepared by the reaction of aqueous ABTS solution (5 ml, 7 mM) with potassium persulfate solution (88 μl , 140 mM). The mixture was incubated in the dark at 29°C for more than 14 h.

For the FRAP assay, supernatants (1 ml) and FRAP reagent (3 ml) were left to react (10 min). The FRAP reagent was prepared by mixing the acetate buffer (300 mM), TPTZ (10 ml in 40 mM HCl) and $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ (20 mM) in a ratio of 10:1:1.

For the DPPH assay, the absorbance was measured at 517 nm; for the ABTS assay, the absorbance was measured at 734 nm; and for the FRAP assay, the absorbance was measured at 593 nm.

Nitrates

For the assessment of nitrates, the dried and ground samples (0.4 g) were mixed with acetic acid (100 ml, 2%) and activated carbon (0.5–1 g), shaken (30 min, 150 rpm), and filtrated (the first drops were not collected). An ionometer (Thermo 5 Star Orion, Beverly, MA, USA) with an ion-selective electrode was used for the measurements.

Macroelements, Microelements, and Heavy Metals

For the macroelement (Ca, K, Mg, P), microelement (Cu, Fe, Mn, Zn), and heavy metal (Ni, Cd, Pb) content evaluations, the dried and ground samples were mineralized (450°C, 8 h) in the oven (CZYŁOK, Jastrzębie-Zdrój, Poland); then, the ash was digested (65% HNO_3) and evaporated on a heating plate (110°C, 6 h), dissolved (1 M HNO_3), and transferred to a flask. The phosphorus content of P was determined colorimetrically at 400 nm after a reaction with molybdate and ammonium metavanadate (Cecil CE 2011 photometer; Cambridge, UK). Atomic absorption spectrophotometry (ASA) (Varian Spectra AA 220/FS, Mulgrave, Australia) was used for the determination of the K, Ca, Mg, Mn, Fe, Cu, Zn, Cd, Pb, and Ni content. The S content was examined according to the oxidation of sulfur-based on the turbidity of the solution of sulfate content precipitating as barium sulfate (Cecil CE 2011 photometer; Cambridge, UK). The N content was examined by the Kjeldahl method. The samples were mineralized in concentrated H_2SO_4 with the addition of Se and H_2O_2 . The cooled solution was mixed with a strong base solution, and the emitted ammonia was distilled into a saturated boric acids solution with the addition of a mixed indicator (methyl red and bromocresol green). The solution of ammonia in boric acid was determined by titration with a standard hydrochloric acid solution (0.01 M) until an initial color was obtained.

Steam Volatile Compounds

For the steam volatile compounds analyses (the amount of a single component calculated as a percentage (%) of the whole GC-MS chromatogram area), the frozen leaves (30 g) were placed in flasks and boiled with distilled water (100 ml) in a

heating mantle. The cyclohexane (1 ml), containing 1 mg of 2-undecanone, was used as an internal standard. A distillation process (50 min) was performed, using a Deryng apparatus (Szczepanik et al., 2018). The chromatographic analyses (GCMS QP 2020, Shimadzu, Kyoto, Japan) were carried out in three replicates.

Fatty Acids

For the preparation of the lipid fraction (the amount of a single component calculated as a percentage (%) of the whole GC-MS chromatogram area), the dried roots (350 mg) were macerated with chloroform (5 ml), filtered, and evaporated. The extracted non-polar lipid fraction (25 mg) was saponified (5 min at 65°C) with 0.5 M KOH/MeOH solution (2 ml), and subjected to methylation (10 min at 65°C) by adding 14% (v/v) BF₃/MeOH (2 ml). In the next step, distilled water (5 ml) was added, and the methyl esters of fatty acids were extracted with hexane (10 ml). The mixture was then washed with 10% sodium bicarbonate (10 ml) and dried over anhydrous sodium sulfate. The organic phase was evaporated under reduced pressure and dissolved in hexane (200 µl). The gas chromatograph coupled with a mass spectrometer (Shimadzu GCMS QP 2020) was used to analyze the profiles of fatty acid methyl esters (in three replicates).

Sterols

A dried radish root (300 mg) was macerated with chloroform (5 ml). The sterol profile was evaluated, using the method of derivatization with N, O-Bis(trimethylsilyl)trifluoroacetamide (BSTFA) silylation via GC-MS (Shimadzu QP 2020, Shimadzu, Kyoto, Japan). The solution was filtered and then evaporated on a vacuum evaporator under reduced pressure. Next, pyridine (500 µl) and BSTFA (50 µl) were added to the sample. The mixture was then transferred to a vial and heated for 15 min at 70°C. Separation was achieved using a Zebron ZB-5 capillary column (30 m, 0.25 mm, 0.25 µm; Phenomenex, Torrance, CA, USA). The parameters of the GC-MS analysis were as follows: a scan mode with a mass range from 40 to 1,050 *m/z* in the electronic impact (EI) mode at 70 eV with the 10 scan s⁻¹ mode. Helium was used as a carrier gas at a flow rate of 1 ml·min⁻¹ in a split ratio of 1:20, along with the following program: (a) 100°C for 1 min; (b) a rate of 2°C min⁻¹ from 100 to 190°C; and (c) a rate of 5°C min⁻¹ from 190 to 300°C. The injector was maintained at 280°C. Identification of the compounds was performed, using two different analytical methods to compare the retention times with those of authentic chemicals (Supelco C7–C40 Saturated Alkanes Standard), and the mass spectra were obtained with the available library data (Wiley NIST 17, match index > 90%).

Glucosinolates

Freeze-dried samples of radish roots (0.5 g) were extracted with 90% methanol (10 ml, 30 min, 70°C, shaken every 5 min). After this process, the samples were filtered and centrifuged (10 min, 15,000 rpm). The supernatants were separated; methanol was evaporated from the mixtures. Then, the samples were dissolved in water (1 ml), and the LC-MS analyses were carried out by means of reversed-phase high-performance liquid chromatography (HPLC Shimadzu Prominence-i LC-2030C,

Kyoto, Japan), equipped with a PDA detector coupled to a triple quadrupole mass spectrometer (Shimadzu LCMS-8045). Glucosinolates present in the radish roots were semi-quantified, using the LC-MS-tq apparatus in the MRMs mode (Table 1). The separation of the desired compounds was performed, using the following mobile phase: water with 0.1% TFA (eluent A) and acetonitrile with 0.1% TFA (eluent B). The flow rate was set at 0.25 ml·min⁻¹, and the gradient was as follows: starting at 1% solvent B for 3 min, then reaching 20% up to 20 min, 30% up to 23 min, and 0.1% B at 35 min. The Kinetex C18 100A column (100 × 3 mm, 2.6 µm particle size, Phenomenex, Germany) was used. Singrin was used as an external standard (Ciska et al., 2000; Ediage et al., 2011; Maldini et al., 2017).

Statistical Analyses

The STATISTICA program ver. 13.3 (TIBCO Software Inc., Tulsa, OK, USA) was used for the statistical analyses of the results. The normality of the distribution was assessed, using the Shapiro–Wilk test and homogeneity of variances by the Brown–Forsythe test. For the normal distribution and homogeneity of variances, differences were evaluated, using the Tukey's Honest Significant Difference (HSD) test. The data were significantly different for *p* < 0.05. For distributions other than normal, the Kruskal–Wallis test was used. An “a” was used to indicate statistically significant differences between the botanical extracts and water (C), “b” indicates a significant difference between the botanical extracts and the formulation (CF), and “c” indicates a significant difference between the botanical extracts and the commercial biostimulant (CB).

RESULTS

Total Yield, Fresh, and Dry Weight of Leaves of Rosette and Roots

In our experimental design, the first control group contained plants that were sprayed with water (C), the second one included plants sprayed with the formulation in water (without an active ingredient—extract) (CF), and the third one included plants sprayed with the commercial biostimulant (CB).

The application of all botanical extracts significantly increased the total yield of radish (Table 2). The highest root yield was achieved in the groups treated with To L MH and Sg L MH (81.2 and 80.6% more than in C and 24.9 and 24.5% more than in CB, respectively), while the lowest yield was found with Ur L MH and Ur L UAE (44 and 44.2% more than in C; 0.7 and 0.6% less than in CB). The largest yield of leaves of rosette was observed after the application of Sg L MH and Hp H MH (31.3 and 27.6% more than in C; 15.4 and 12.2% more than in CB), and the smallest was found for To F UAE and Ur L MH (2.7 and 7.2% more than in C; 9.7 and 5.4% less than in CB). Bio-products also promoted the growth of radish roots with diameters >4 cm (e.g., Tp F UAE: 10.2% more than in CB), as well as the aboveground parts (e.g., Hp H MH and Sg L UAE: 32.8 and 34% more than in CB). There were no plants of the aforementioned size in the control group (C). The least stimulating activity in this root range was noted after the use of Hp H UAE for roots (35.7% less than in CB) and Vo R UAE for leaves of rosette (8.2% less than in CB). The

RT, retention time; Q1, parent ion; Q3, fragment ion; CE, collision energy.

heaviest average root weight with a diameter between 2 and 4 cm was found in the groups treated with To L MH (50.7 and 24.4% more than in C and CB) and Sg L MH (42.7 and 17.9% more than in C and CB), and the heaviest leaves were found for Hp H MH (35 and 14.9% more than in C and CB), Sg L MH (34.6 and 14.5% more than in C and CB), and Vo R MH (31.4 and 11.8% more than in C and CB). Decreased fresh weight was observed only in the leaves of rosette after the application of To F UAE (4.3 and 18.5% less than in C and CB). The highest average weight of the root with a diameter smaller than 2 cm was observed after spraying radish with Vo R MH (4.8% less than in C and 67% more than in CB) and Sg L MH (8.8% less than in C and 60% more than in CB), while the lowest was found with Ur L UAE (40.5% less than in C and 4.4% more than in CB). The heaviest weight of the aboveground parts within this root diameter was achieved after radish treatment with To F UAE (2.4% less than in C and 20.4% more than in CB) and Vo R MH (3.9% less than in C and 18.5% more than in CB), and the lowest was found with To L MH (30.4 and 14.1% less than in C and CB) and Ur L UAE (29.4 and 13% less than in C and CB). The application of Ur L UAE increased the dry weight of leaves of rosette (**Table 2**) in both the first and the second terms of the plant collection (7.5 and 8.3% more than

in C; 17.2 and 10.9% more than in CB), while To L MH decreased the examined parameter (12.7 and 13.9% less than in C; 4.8 and 11.9% less than in CB). In the case of roots (**Table 2**), Ur L UAE increased the dry weight the most (37.9 and 51.8% more than in C and CB), and Sg L MH increased dry weight the least (7.3% less than in C and 2.1% more than in CB).

Photosynthetic Pigments, Greenness Index of the Leaves, and Leaf Color

An increase in the content of photosynthetic pigments in the cultivated plants treated with botanical extracts was observed in the first term of the sample collection but showed varying impacts in the second term. In the first term, the bio-product Vo R UAE particularly increased the chlorophyll content (**Table 3**) (31.5 and 26.3% more than in C and CB), whereas To L MH decreased its content (16.4 and 19.7% less than in C and CB). In the second term (**Table 3**), the application of Vo R UAE, Sg L MH, and Ur L MH resulted in a slightly higher amount of a green pigment in leaves (4.5, 4.5, and 3% more than in C; 16.7, 16.7, and 15% more than in CB). The use of To L UAE, To F MH, and Sg L UAE caused a significant reduction in its content (19.4, 19.4, and 17.9% less than in C; 10, 10, and 8.3% less than in CB). In the first

TABLE 2 | Effect of the foliar application of the botanical extracts on the fresh weight of leaves of rosette and root (after harvest), the total yield of radish ($N = 3^*$, mean \pm SD), and dry weight of radish leaves of rosette (after second spraying and after harvest) and root (after harvest) ($N = 3$, mean \pm SD).

(a) Statistically significant differences ($p < 0.05$) between the control group (C) and the botanical extracts. (b) Statistically significant differences ($p < 0.05$) between the formulation (CF) and the botanical extracts. (c) Statistically significant differences ($p < 0.05$) between commercial biostimulant (CB) and the botanical extracts. UAE, ultrasound-assisted extraction; MH, mechanical homogenization; Hp H, *Hypericum perforatum* L. (St. John's wort, herb); Sg L, *Solidago gigantea* Ait. (giant goldenrod, leaf); To F, To L, *Taraxacum officinale* (L.) Weber ex F.H. Wigg (common dandelion, flower, leaf); Tp F, *Trifolium pratense* L. (red clover, flower); Ur L, *Urtica dioica* L. (nettle, leaf); Vo R, *Valeriana officinalis* L. (valerian, root). * Three replications (plots)—each consisted of 125 plants.

term, the highest content of carotenoids (**Table 3**) was observed after the application of Vo R UAE (31.3 and 19.9% more than in C and CB), like in the case of chlorophyll content. In the second term, this extract showed the most stimulating activity, but the difference was nonsignificant in comparison to the control group (1.2 and 14.4% more than in C and CB). The lowest carotenoid content was observed for To L MH (in the first term: 28.7 and 34.9% less than in C and CB) and for To F MH (in the second term: 19.7 and 9.3% less than in C and CB).

Most bio-products did not significantly increase the leaf color, expressed as the *L*, *a*, *b* values presented in **Table 3**. The level of light or dark is described by the *L* value, redness or greenness is indicated by the *a* value, and yellowness or blueness is represented by the *b* value. These values are necessary to depict the leaf color.

The SPAD measurements demonstrated that all obtained bio-products increased the greenness index of the leaves (**Table 3**). In the first term, the greatest enhancement of the SPAD index was noted in the group treated with Hp H MH (24.5 and 27.8% more than in C and CB), while the smallest was found for Tp F MH (5 and 7.7% more than in C and CB). In the second term, the highest stimulating activity was observed for Vo R UAE (28.1 and 21.4% more than in C and CB), which corresponds to the results obtained for chlorophyll, with the lowest observed for To L UAE (11.9 and 6.1% more than in C and CB).

Vitamin C

In the majority of cases, the novel extracts raised the level of vitamin C in the leaves of rosette and in the roots (**Table 4**). For instance, in both terms of the samples collection, Vo R MH increased its content (in the first term: 29.9 and 10.5% more than in C and CB; in the second term: 116 and 44.4% more than in C and CB), while To L MH decreased its content (in the first term: 6.9 and 20.7% less than in C and CB; in the second term: 25.8% more than in C and 15.7% less than in CB). However, for the roots, Tp F MH increased the content of vitamin C (46.3 and 33.8% more than in C and CB), while Vo R MH reduced it (10.5 and 18.2% less than in C and CB).

Total Phenolic Compounds and Antioxidant Activity (DPPH, ABTS, and FRAP Assays)

In general, the content of total phenolic compounds (TPC) in radish (**Table 4**) was not intensified by the application of botanical extracts in relation to the control groups. The largest amount of TPC in the leaves of rosette, in both terms, was observed in the groups treated with Sg L MH (in the first term: 1.1% less than in C but 23.8% more than in CB; in the second term: 10.7 and 2.9% more than in C and CB) and To F UAE (in the first term: 0.1 and 25.3% more than in C and CB; in the second term: 7.2% more than in C and 0.4% less than in CB). In the roots (**Table 4**), the most elevated amount of TPC was noted after the application of To F MH (13.2 and 50.5% more than in C and CB), and the lowest was observed for Tp F UAE (37.2 and 16.5% less than in C and CB).

The DPPH assay revealed that the bio-products mainly lowered the antioxidant activity in the leaves but increased it in the roots (**Table 5**). The natural preparations based on To F

(UAE) and Vo R (MH) increased the activity by 76.5 and 79.8% in comparison to C and by 147 and 152% in comparison to CB in the leaves collected during the first term. The lowest activity was caused by the application of To L MH and Tp F MH (35.3 and 33.6% less than in C and 9.4 and 7.1% less than in CB). In the leaves from the second term of the plant collection, the extract Sg L UAE enhanced the activity by 28.6 and 51.8% in comparison to C and CB, while To F MH and Ur L MH diminished this activity by 40.8 and 39.8% when compared with C and by 30.1 and 28.9% when compared with CB. The antioxidant activity assessed in the roots was mostly increased after the foliar spraying with To F MH (158 and 170% more than in C and CB) but decreased with Sg L UAE (26.7 and 23.3% less than in C and CB) and To L UAE (33.3 and 30.2% less than in C and CB).

The antioxidant activity measured with the ABTS assay in the aboveground parts (in both terms) was not increased after the application of all examined bio-products, whereas, in the roots, in all cases, the activity was significantly higher with reference to the control group (**Table 5**). In the leaves collected in the first term, the most elevated activity was found after the use of Vo R MH (25% less than in C and 104% more than in CB), and the least was found for To F MH (65.9 and 7% less than in C and CB) and Sg L UAE (65.7 and 6.5% less than in C and CB). In the second term of the samples collection, the highest level was noted for Tp F UAE (21.8% less than in C and 228% more than in CB), and the lowest was found for Ur L UAE (73.4% less than in C and 11.5% more than in CB). The foliar spraying with To L UAE increased the antioxidant activity the most (178 and 10.7% more than in C and CB), while Tp F MH showed the least impact (24.1% more than in C and 36.8% less than in CB).

The opposite trend was observed in the case of antioxidant activity measured with the FRAP assay. In general, this activity was increased in leaves of rosette but decreased in the roots (**Table 5**). For example, the highest activity was noted in the group treated with Sg L MH (53.4 and 20.2% more than in C and CB), and the lowest was observed for Hp H UAE (5.7 and 26.1% less than in C and CB) and Vo R UAE (6.1 and 26.4% less than in C and CB) in the leaves from the first collection, whereas for the aboveground parts from the second term, Sg L UAE enhanced the activity (73.8 and 76.8% more than in C and CB), while Sg L MH reduced it (18.9 and 17.5% less than in C and CB). In the roots, the formulation based on Sg L (UAE) increased the activity (4.2 and 16.2% more than in C and CB), while the one based on Hp H (MH) decreased it (43.6 and 37.2% less than in C and CB).

Nitrates

In most instances, the application of the obtained bio-products resulted in a higher content of nitrates in all parts of the model plant (**Table 6**). The foliar spraying with Vo R MH increased the amount of examined ions in the leaves of rosette collected in the first term (57.5 and 39% more than in C and CB), while Vo R UAE and Ur L UAE (21.9 and 31.1% less than in C and CB for both extracts) decreased its content. In the harvested leaves of rosette and roots, the highest amount was observed in the groups treated with Ur L UAE (in leaves: 52.7 and 51.1% more than in C and CB; in the roots: 73.7 and 125% more than in C and CB), and the lowest was found for Vo R UAE and To F UAE

TABLE 4 | The effect of the foliar application of the botanical extracts on the vitamin C content ($N = 4$, mean \pm SD) and the total phenolic compounds content ($N = 4$, mean \pm SD) of radish leaves (after second spraying and after harvest) and roots (after harvest).

Group	Vitamin C			Total phenolic compounds

(a) Statistically significant differences ($p < 0.05$) between the control group (C) and the botanical extracts. (b) Statistically significant differences ($p < 0.05$) between the formulation (CF) and the botanical extracts. (c) Statistically significant differences ($p < 0.05$) between commercial biostimulant (CB) and the botanical extracts. UAE, ultrasound-assisted extraction; MH, mechanical homogenization; Hp H, *Hypericum perforatum* L. (St. John's wort, herb); Sg L, *Solidago gigantea* Ait. (giant goldenrod, leaf); To F, To L, *Taraxacum officinale* (L.) Weber ex F.H. Wigg (common dandelion, flower, leaf); Tp F, *Trifolium pratense* L. (red clover, flower); Ur L, *Urtica dioica* L. (nettle, leaf); Vo R, *Valeriana officinalis* L. (valerian, root).

in both leaves (20.3 and 21.1% less than in C and CB for both extracts) and roots (20.2% less than in C and 3.2% more than in CB; 17.5% less than in C and 6.8% more than in CB). Notably, the amount of nitrates in radish was lower than the maximum allowable levels established for vegetables, e.g., fresh spinach (3,500 mg·kg⁻¹), lettuce (3,000–5,000 mg·kg⁻¹), iceberg lettuce (2,000–2,500 mg·kg⁻¹), and wild rocket (6,000–7,000 mg·kg⁻¹) (European Communities, 2006).

Macroelements, Microelements, and Heavy Metals

In the case of radish leaves, generally, P, K, Mg, and S were increased in the biomass, and N and Ca decreased. The highest content of P was observed in the group treated with To F MH and Vo R MH (higher by 25.8% than in the control group–C), and the highest content of K was observed in the groups treated with Ur L UAE (higher by 29.7% than in C), Vo R MH (higher by 27.2% than in C), and Hp H UAE (higher by 24.5% than in C). The greatest amount of Mg was found in the group treated with Sg L UAE (higher by only 3.1% than in C), and Vo R MH (higher by only 1.5% than in C), and the highest content of S was found in the groups treated with To L MH (higher by 18.4% than in C), Vo R UAE (higher by 13.2% than in C), and Ur L UAE (higher by 11.4% than in C). The extracts produced from nettle (*Urtica dioica* L.) and valerian (*Valeriana officinalis* L.) ensured an increase in the content of macronutrients. The amount of

nitrogen was comparable in all tested groups, but, for botanical extracts, it was slightly lower than in the control group (C), from 2.7% for Ur L UAE to 8.1% for Sg L UAE. The same was observed for the content of Ca in the leaves. In all experimental groups, this content was lower than in the control group (from 18.5% for Tp F UAE to 2.5% for To L MH) (Table 7A).

The results showed that the tested macroelements were better accumulated in the roots, as more statistically significant differences were demonstrated (Table 7A). The content of N was highest in the groups treated with Hp H UAE (by 5.7% higher than in C), P for Ur L UAE (by 20.4% higher), K for Vo R MH (by 6.8% higher), Ca for Vo R MH (by 25.4% higher), and Mg for Vo R MH (by 75.1% higher). The content of S was comparable in all experimental groups but was slightly lower than that in the control group. This analysis showed that the extract from valerian (*Valeriana officinalis* L.) was the most effective in increasing the macronutrient content in the roots. In most cases, the production method did not affect the macronutrient content in the tested biomass.

The examined botanical extracts, applied foliarly, increased the level of some microelements (Table 7B), especially Zn in the leaves (in all experimental groups). In other cases, the micronutrient composition of the leaves was comparable to that in the control group. Higher contents of the examined elements were reported for Fe (for To L UAE, higher by 24.3% than in the control group) and Zn (for Sg L UAE, higher by 24.8% than in

TABLE 5 | The effect of the foliar application of the botanical extracts on the antioxidant activities (DPPH assay, ABTS assay, FRAP assay) ($N = 4$, mean \pm SD) of radish leaves (after second spraying and after harvest) and roots (after harvest).

(giant goldenrod, leaf); To F, To L, *Taraxacum officinale* (L.) Weber ex F.H. Wigg (common dandelion, flower, leaf); Tp F, *Trifolium pratense* L. (red clover, flower); Ur L, *Urtica dioica* L. (nettle, leaf); Vo R, *Valeriana officinalis* L. (valerian, root).

the control group). As with macronutrients, the micronutrients (Fe, Cu, Zn, Mn) were more strongly accumulated in the roots (Table 7B). Again, the most significant results were obtained for the extract from valerian, whose Fe, Cu, and Mn contents were, respectively, 27.9, 45.5, and 29.3% higher than those in the control group.

The content of heavy metals (Ni, Cd, and Pb) was generally lower in the leaves and roots of radish in the experimental groups compared with the control, with the exception of the Ni content in the roots, which was higher than in the control group (Table 7B). The obtained levels of Cd and Pb were comparable with the results presented in other studies, where the content of Cd was at a level between 1 and 2.8 mg·kg⁻¹, and Pb was found at 6.4–10.98 mg·kg⁻¹ (Varalakshmi and Ganeshamurthy, 2008; Veissi et al., 2015; Rolli et al., 2016). The tolerable levels in agricultural crops are 3 mg·kg⁻¹ for Cd and 10 mg·kg⁻¹ for Pb (Rolli et al., 2016), whereas, according to the EC Commission Regulations, the threshold content is 0.05–0.2 and 0.1–0.3 mg·kg⁻¹, respectively [(EC) Commission Regulation No. 2006.364.5 of 19 December 2006, setting maximum levels for certain contaminants in foodstuffs].

Steam Volatile Compounds

GC–MS analyses of the distilled essential oil from the radish leaves revealed 38 peaks, which were found to represent steam volatile compounds (SVCs) (Supplementary Table 1). The following components constituted the main parts of the SVCs:

limonene, myrcene, phytol, and cis- β -ocimene. However, p-Cymene, β -pinene, ionone epoxide, nonanal, hexahydrofarnesyl acetone, and hex-(2E)-enal were present in smaller quantities. In most cases, the examined extracts did not increase the content of limonene, except for Vo R UAE (11.3 and 9.5% more than in C and CB), To L UAE (4.8 and 3.1% more than in C and CB), and Hp H UAE (3.2 and 1.5% more than in C and CB). The lowest increment was observed after treatment with Tp F MH (25.4 and 26.6% less than in C and CB). The amount of myrcene was mostly lower than that in the control group (C), but an increase was noted after the application of the aforementioned bio-products, Vo R UAE (7.4 and 25.9% more than in C and CB), To L UAE (2.3 and 19.9% more than in C and CB), and Hp H UAE (1.1 and 18.5% more than in C and CB). The foliar spraying with Tp F MH decreased the content of myrcene (33.4 and 21.9% less than in C and CB). A great diversity was observed among the examined groups in terms of phytol content. Extracts based on e.g., Tp F MH significantly increased the phytol amount (329 and 468% more than in C and CB), along with Sg L UAE (175 and 234% more than in C and CB), To L MH (132 and 207% more than in C and CB), Sg L MH (120 and 192% more than in C and CB), and To F UAE (110 and 178% more than in C and CB). On the other hand, extracts obtained from Vo R UAE (64.4 and 52.9% less than in C and CB) and To L UAE (56.9 and 42.9% less than in C and CB) significantly reduced the phytol amount. In most cases, the content of cis- β -ocimene was also decreased compared with the control group (C). The highest increment was noted in the groups sprayed with Hp H UAE (7.3 and 21% more than in

TABLE 7A | The effect of the foliar application of the botanical extracts on the content of macroelements ($N = 3$, mean \pm SD) in radish leaves of rosette and roots (after harvest).

(a) Statistically significant differences ($p < 0.05$) between the control group (C) and the botanical extracts. (b) Statistically significant differences ($p < 0.05$) between the formulation (CF) and the botanical extracts. (c) Statistically significant differences ($p < 0.05$) between commercial biostimulant (CB) and the botanical extracts. UAE, ultrasound-assisted extraction; MH, mechanical homogenization; Hp H, *Hypericum perforatum* L. (St. John's wort, herb); Sg L, *Solidago gigantea* Ait. (giant goldenrod, leaf); To F, To L, *Taraxacum officinale* (L.) Weber ex F.H. Wigg (common dandelion, flower, leaf); Tp F, *Trifolium pratense* L. (red clover, flower); Ur L, *Urtica dioica* L. (nettle, leaf); Vo R, *Valeriana officinalis* L. (valerian, root).

C and CB) and Vo R UAE (3.4 and 16.6% more than in C and CB), and the lowest was found with Tp F MH (31.4 and 22.6% less than in C and CB).

Fatty Acids

The largest percentage share of fatty acids (Supplementary Table 2) accounted for linolenic acid (methyl ester) and hexadecanoic acid (methyl ester), followed by 9,12-hexadecadienoic acid (methyl ester), 9Z-9-octadecenoic acid (ethyl ester), 11-octadecenoic acid (methyl ester), and octadecanoic acid (methyl ester). The content of linolenic acid was the highest in the groups treated with Ur L UAE (14.7 and 19.3% more than in C and CB) and Sg L MH (14.3 and 18.8% more than in C and CB) and the lowest after the application of Ur L MH (27.2 and 24.3% less than in C and CB) and Tp F MH (24.8 and 21.8% less than in C and CB). The tested botanical extracts did not increase the amount of the second acid in comparison with the control group. The highest value was achieved for Sg L MH (13.2% less than in C and 9% more than in CB), and the lowest was achieved for To F MH (34.7 and 18% less than in C and CB). The application of Sg L MH resulted in the highest amount of 9,12-hexadecadienoic acid (6.4 and 23.7% more than in C and CB) and 11-octadecenoic acid (1% less than in C and 19.3% more than in CB) in comparison to the other examined extracts, while the lowest was observed in groups treated with Ur L MH: 38.7 and 28.7% less than in C and CB for 9,12-hexadecadienoic acid and 35.1 and 21.8% less than in C and CB for 11-octadecenoic acid, respectively. On the other hand, the largest percentage share of 9Z-9-octadecenoic acid was noted after the foliar spraying with Ur L UAE (29.5 and 16% less than in C and CB). The greatest stimulation of octadecanoic acid content was observed in the group treated with To F UAE (39.3% less than in C and 10% more than in CB). The application of To F MH caused the smallest increase in 9Z-9-octadecenoic acid (53 and 43.9% less than in C and CB) and octadecanoic acid (53.3 and 15.4% less than in C and CB) content. It can be seen that, of all used extracts, To F UAE increased to the greatest extent the content of tetradecanoic acid (ethyl ester) (no change in the control group and 225% more than in CB), tetradecanoic acid (12-methyl-, methyl ester) (8.4 and 177% more than in C and CB), and pentadecanoic acid (14-methyl-, methyl ester) (4.1 and 181% more than in C and CB), while Tp F UAE had the greatest content of Z-9-Hexadecenoic acid (methyl ester) (3.4 and 29.5% more than in C and CB). The treatment with Tp F MH decreased the amount of tetradecanoic acid (ethyl ester) (65% less than in C and 13.7% more than in CB) and pentadecanoic acid (14-methyl-, methyl ester) (63.2 and 0.8% less than in C and CB). The lowest content of tetradecanoic acid (12-methyl-, methyl ester) was observed for Hp H MH (59% less than in C and 4.6% more than in CB), while the lowest content of Z-9-hexadecenoic acid (methyl ester) was observed for To L UAE (62.1 and 52.6% less than in C and CB).

Sterols

Only two sterols were observed in the dried radish roots (Table 8). It can be seen that the botanical extracts mostly lowered the content of β -sitosterol (TMS derivative), for instance, after treatment with To L MH (8.9 and 8.4% less than in C and

TABLE 8 | The effect of the foliar application of the botanical extracts on the sterols composition [the amount of a single component calculated as a percentage (%) of the whole GC-MS chromatogram area] ($N = 3$, mean \pm SD) of radish roots (after harvest).

(a) Statistically significant differences ($p < 0.05$) between the control group (C) and the botanical extracts. (b) Statistically significant differences ($p < 0.05$) between the formulation (CF) and the botanical extracts. (c) Statistically significant differences ($p < 0.05$) between commercial biostimulant (CB) and the botanical extracts. RT, retention time; RI, retention indices; RI_lit, retention indices according to NIST (The NIST Mass Spectral Search Program for the NIST/EPA/NIH EI and NIST Tandem Spectral Library, 2017); RI_exp, retention indices based on experiments; UAE, ultrasound-assisted extraction; MH, mechanical homogenization; Hp H, *Hypericum perforatum* L. (St. John's wort, herb); Sg L, *Solidago gigantea* Ait. (giant goldenrod, leaf); To F, To L, *Taraxacum officinale* (L.) Weber ex F.H. Wigg (common dandelion, flower, leaf); Tp F, *Trifolium pratense* L. (red clover, flower); Ur L, *Urtica dioica* L. (nettle, leaf); Vo R, *Valeriana officinalis* L. (valerian, root).

CB). Only the foliar application of Tp F UAE (1.9 and 2.5% more than in C and CB) and Sg L UAE (0.1 and 0.7% more than in C and CB) led to an increase of the previously mentioned content. The opposite trend was observed in the amount of campesterol (TMS derivative); in most of the cases, this content was enhanced, e.g., in the group sprayed with To L MH (15.7 and 14.5% more than in C and CB), while only two bio-products diminished it: Tp F UAE (3.3 and 4.3% less than in C and CB) and Sg L UAE (0.2 and 1.3% less than in C and CB).

Glucosinolates

The detected glucosinolates in the radish roots are presented in Table 9. It can be noted that the foliar treatment with the botanical extracts had a statistically significant impact on the glucosinolates composition. The chromatographic analyses revealed that the roots consisted mostly of glucoerucin and glucobrassicinapin, followed by gluconasturtiin, and then gluconapin. The content of glucoerucin was the most increased in the groups treated with Sg L UAE (9.8 and 8.5% more than in

C and CB), Hp H UAE (7.2 and 5.9% more than in C and CB), Hp H MH (6.6 and 5.3% more than in C and CB), and the least with Vo R MH (8.6 and 9.8% less than in C and CB), To F UAE (8.3 and 9.4% less than in C and CB), and Ur L UAE (8.2 and 9.3% less than in C and CB). In the case of glucobrassicinapin, the highest amounts were observed in the groups treated with To L UAE (7 and 8.5% more than in C and CB) and Ur L MH (5.9 and 7.4% more than in C and CB), while the lowest with Hp H MH (1% less than in C and 0.3% more than in CB), Sg L MH (0.5% less than in C and 0.8% more than in CB), and Hp H UAE (0.5% less than in C and 0.9% more than in CB). The concentration of gluconasturtiin was the most increased after the treatment with Sg L MH (2.9 and 10.6% more than in C and CB), Vo R MH (2.2 and 9.8% more than in C and CB), and Tp F UAE (1.1 and 8.7% more than in C and CB), while the most decreased with To L UAE (10.6 and 4% less than in C and CB), Ur L MH (10.1 and 3.4% less than in C and CB), and Sg L UAE (9.8 and 3.1% less than in C and CB). The content of gluconapin was the most elevated in the groups sprayed with Sg L MH (39.2 and 18.7% more than in C and CB) and Vo R MH (38.4 and 18% more than in C and CB), whereas the utilization of To F MH (0.4 and 15.1% less than in C and CB) and Tp F MH (2.3% more than in C and 12.8% less than in CB) led to the lowest values this parameter.

DISCUSSION

About 33% of global organic farming is located in Europe, and 6.4% of this farming is situated in Poland, where the interest in sustainable agricultural techniques and technologies is constantly growing and has been especially strong in the recent years of 1999–2013. During this period, the number of Polish producers of organic food increased from 27 to 26,499, and the crop area increased from 300 to 674,694 ha (Pylak et al., 2019). Thus, there is clearly a need to develop new, sustainable products to provide high-quality yields and support the future of organic farming (Röös et al., 2018). The lower yield (by 5–32%) in organic horticulture, in relation to conventional farming, is mostly caused by nutrient availability (mainly N and P) but is also linked to fungal or bacteria pathogens (Fess and Benedito, 2018; Pylak et al., 2019). Therefore, the application of biostimulants to increase crop productivity, soil nutrient availability, water use efficiency, plant nutrient uptake, and assimilation has emerged as a promising eco-friendly approach. These factors could contribute to a decrease in the use of fertilizers (in particular, rich in nitrogen) and an increase in crop tolerance to abiotic and biotic stresses (Bulgari et al., 2015, 2019; Paradiković et al., 2018; Drobek et al., 2019; Pylak et al., 2019; Roupheal and Colla, 2020). The broad modes of action of biostimulants range from triggering N metabolism or P release from soil to stimulating root growth and improving plant establishment (Madende and Hayes, 2020), which are advantageous activities from both an economic and environmental perspective (Roupheal and Colla, 2020). Furthermore, these products have not shown negative or harmful impacts on people and animals. The positive effects resulting from their use are influenced by many factors, including the type of bio-product, the dose, the application method, and the plant cultivar (Drobek et al., 2019).

The types of raw materials, solvents, and extraction methods have a significant influence on the final composition of biostimulants of plant growth (Pylak et al., 2019; Madende and Hayes, 2020). For biostimulant production, fresh (when unstable compounds are present) or dry materials, grounded into small particles, can be used. Water is the most popular solvent, but the use of organic ones (e.g., ethanol, methanol) allows to extract more substances (aromatic or saturated organic compounds), exhibiting better activity (e.g., antimicrobial) (Pylak et al., 2019). Biostimulants consist of various bioactive compounds, such as amino acids, peptides, proteins, nucleotides, nucleosides, lipids, phenols, phenolic acids, quinones, flavones, flavonoids, flavonols, tannins and coumarins, terpenoids/isoprenoids, alkaloids, glucosinolates, plant hormones (abscisic acid, auxins, cytokinins, gibberellins, ethylene), plant growth regulators (brassinosteroids), betaines, sugars (carbohydrates, oligo-, and polysaccharides), aminopolysaccharides, vitamins, humic substances, beneficial elements, furostanol glycosides, and sterols (Baghel et al., 2019; Pylak et al., 2019; Madende and Hayes, 2020). Because these chemical substances exhibit diverse effects, the modes of their action remain mostly unidentified (Paradiković et al., 2018; Bulgari et al., 2019; Caradonia et al., 2019; Drobek et al., 2019; Kim et al., 2019; Madende and Hayes, 2020). Furthermore, the composition of various biostimulants has still not been fully characterized (Pylak et al., 2019; Madende and Hayes, 2020), and biostimulants usually consist of complex multicomponents whose activities depend on the synergistic action of different bioactive molecules rather than individual compounds (Bulgari et al., 2019; Caradonia et al., 2019). Transcriptome analyses will allow us to scrutinize gene expression and thus provide greater knowledge of the biostimulant targets in plants, the affected physiological pathways, and the activated receptors. This information will improve our understanding of the effects and functions of their components (identified and unidentified) and may be used in the classification of new products and assessment of their effectiveness (Bulgari et al., 2015).

The current state of knowledge shows that different mechanisms may participate in the stimulating properties of biostimulants. Their positive effects on the yield and the quality of crops may result from the use of a single bio-product, as well as a combination of several products, allowing them to provide even better results. It is still necessary to undertake detailed wide-scale research on the impact of specific biostimulants on various species, treatments (e.g., doses and application methods), growth stages, etc. (Paradiković et al., 2018). We have conducted a series of experiments on various plant species, including radish (present study, field conditions), celeriac (field conditions) (Godlewska et al., 2020b), cabbage seedlings (laboratory tests) (Godlewska et al., 2019, 2020a), and white head cabbage (field conditions) (Godlewska et al., 2021), using botanical extracts (produced from St. John's wort, giant goldenrod, common dandelion, red clover, nettle, and valerian). Significant differences were observed in the plant responses to these bioproducts. The plant-based extracts that exerted the highest (↑) and lowest (↓) biostimulating activity of the examined parameters are summarized in **Tables 10A,B**. This comparison indicates the importance of precise planning

TABLE 9 | The effect of the foliar application of the botanical extracts on the glucosinolates content ($\mu\text{g}\cdot\text{g}^{-1}$) ($N = 3$, mean \pm SD) of radish roots (after harvest).

of research, as well as studying the impact of the obtained products on various plant species. In general, extracts based on the common dandelion, valerian, nettle, and giant goldenrod could be considered in the cultivation of cabbage; those based on St. John's wort, common dandelion, and giant goldenrod could be used to cultivate celeriac; and those based on the common dandelion, valerian, giant goldenrod could be used for growing radish.

The application of plant-derived biostimulants has continued to rise by virtue of their favorable impact on the growth, yield, vigor, quality, and shelf life of some horticultural plants (e.g., due to the content of bioactive peptides that activate signaling pathways involving phytohormone biosynthesis) (Baghel et al., 2019; Caradonia et al., 2019; Jindo et al., 2020; Roupheal and Colla, 2020; Zulfiqar et al., 2020). Peptides are also engaged in the cell differentiation, induction of protease inhibitors, cell division, and pollen self-incompatibility responses (Kim et al., 2019). A higher content of proteins may be associated with an increase in the carbohydrate content in leaves. In turn, a greater amount of sugars generally accelerates nitrogen inclusions through the nitrate assimilation pathway. This increased growth can be also ascribed to sugars that serve as an energy source and stimulate nitrogen uptake. Carbohydrates provide the skeleton for the incorporation of reduced nitrate (ammonia) in amino acids and increased protein biosynthesis. The enhancement of sugar biosynthesis in plants is also linked to the higher content of chlorophyll, net photosynthesis, and quantum efficiency of photosystem II (Bulgari et al., 2015). Polysaccharides and a combination of diverse amino acids and short peptides (protein hydrolysates) exhibit a beneficial impact on plant growth and protection against abiotic and/or biotic stresses (Bulgari et al., 2019).

Biostimulants act in numerous stages of plant growth, from increasing the accessibility of nutrients in the soil to improving the postharvest quality of crops (even during stress conditions) (Zulfiqar et al., 2020). Their mechanisms, founded upon enhanced physiological, biochemical, and molecular processes, can be attributed to (a) the stimulation of essential enzymatic activities that correlate with the metabolism of nitrogen and the elicitation of target hormone-like activity (auxin and gibberellin; direct mechanism) and (b) the increase in the nutritional status of crops through the alteration of root development (biomass, density, and lateral root branching), which increases the absorption and translocation of macro and micro-nutrients (Caruso et al., 2019; Pylak et al., 2019; Zulfiqar et al., 2020). Higher nutrient availability can be affected by several factors, such as the presence of compounds in biostimulants (e.g., nutrients, amino acids, peptides, peptones, or proteins), improved microbial activity, or the content of chelating agents, thereby increasing nutrient solubility in soil. Biostimulants can also enhance nutrient uptake by upregulating the genes involved in their transport (Pylak et al., 2019), ameliorate the microbial and enzymatic activity of the soil, modify the solubility and transportability of micronutrients, increase soil cation exchange via nitrogen provision, and create more available complexes with insoluble elements (e.g., Fe) (Bulgari et al., 2019; Madende and Hayes, 2020). An improved photosynthesis process and carbon metabolism may also be observed (Zulfiqar et al., 2020). Studies

showed that improved root growth is not necessarily associated with the presence of auxins due to their low concentrations but, instead, with organic compounds (e.g., amino acids, linear carboxylic acids, and aromatic carboxylic acids) that show auxin-like activity (Pylak et al., 2019).

The use of biostimulants can be particularly advantageous in poor soil conditions and in horticultural crops with low inputs (Bulgari et al., 2019). The inhibition of pathogen growth, antimicrobial activity, and defense mechanisms can be triggered by the presence of compounds that have phenolic structures, e.g., carvacrol, eugenol, or thymol (Pylak et al., 2019). Various antioxidants and elicitors, due to their synthesis in plants, can help deal with adverse growth conditions (e.g., temperature extremes, drought, and reduced nutrient absorption) (Paradiković et al., 2018). Biostimulants can alter the activity of enzymes and influence the antioxidant properties of compounds, such as lycopene, ascorbic acid, and phenolic compounds (Drobek et al., 2019).

The present study showed that extracts based on higher plants had a significant impact on the growth and physiological parameters of radish. The foliar application of the obtained formulations increased the yield of leaves of rosette (e.g., Sg L MH, Hp H MH), as well as the roots (e.g., To L MH, Sg L MH), dry weight (e.g., Ur L UAE), the content of photosynthetic pigments (e.g., Vo R UAE) and vitamin C (e.g., Vo R MH, Tp F MH). In the majority of cases, the tested extracts did not enhance the amount of total phenolic compounds (excluding, e.g., To F MH). The antioxidant activity (measured using the DPPH and ABTS assays) was mainly decreased in the leaves and increased in the roots after the application of the botanical extracts. The opposite trend was observed in the antioxidant activity measured using the FRAP assay. We also observed macronutrient enrichment in the leaves of rosette (e.g., Ur L UAE, Vo R MH, To L MH) and the roots (e.g., Hp H UAE, Vo R MH, Sg L UAE, To L UAE), alongside enrichment of micronutrients in the leaves of rosette (e.g., To L UAE, Hp H UAE, Vo R UAE, Sg L UAE) and the roots (e.g., Vo R MH, To F UAE). In most cases, the obtained bio-products lowered the content of heavy metals in the radish leaves and roots. The foliar application of the extracts exerted a varied impact on the composition of steam volatile compounds, fatty acids, sterols, and glucosinolates. The application of the bio-products resulted in higher content of nitrates in all parts of the model plant (e.g., Vo R MH, Ur L UAE).

The tested plant-based extracts are products that can be used in agriculture as potential biostimulants to reduce the cost of food production and achieve better quality yields. The raw materials (plants commonly found in the natural environment) constitute a rich source of biologically active compounds that exhibit a beneficial effect on the growth and chemical composition of crop plants. The final effect of their action depends on numerous factors (e.g., the raw material type, the extraction method, the application method, the plant variety, and the growth conditions). It is still necessary to conduct further research to gain a better understanding of their mechanisms. To understand the multiple effects of biostimulants, the development of appropriately designed experiments is crucial. Considering their positive effects on plants and various novel research possibilities, these biostimulants are attracting

TABLE 10A | Effect of the foliar application of the examined botanical extracts on the growth and development of different model plants under controlled conditions (laboratory tests) and real environmental conditions (field trials).

increasing attention every year among scientists, producers, and possible consumers. Appropriately prepared, characterized, and tested bio-products could be an integral component of sustainable agriculture in the foreseeable future.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/Supplementary Material, further inquiries can be directed to the corresponding author.

AUTHOR CONTRIBUTIONS

KG designed and conducted all the research, analyzed the obtained data, and wrote the paper. PP participated in the field experiments, reviewed, and edited the paper. IM analyzed the obtained data and reviewed and edited the paper. AB supervised the work and reviewed and edited the paper. AS participated in the analyses of essential oils and fatty acids. NP participated in the analyses of essential oils and fatty acids. UP conducted the analyses of elements. All authors have read and agreed to the published version of the manuscript.

FUNDING

This work was supported by The Wrocław University of Environmental and Life Sciences (Poland) as the Ph.D., research program Innowacyjny Doktorat, Grant No. D220/0008/18 and financed in the framework of the grant entitled Mechanism of Action of Novel Plant-Derived Extracts and Their Impact on Stress Resilience of *Arabidopsis thaliana* (2018/29/N/NZ9/02430) attributed by The National Science Center in Poland.

(2021) Endophytic *Bacillus altitudinis*
Strain Uses Different Novelty
Molecular Pathways to Enhance Plant
Growth. *Front. Microbiol.* 12:692313.
doi: 10.3389/fmicb.2021.692313

The identification and use of endophytic bacteria capable of triggering plant growth is an important aim in sustainable agriculture. In nature, plants live in alliance with multiple plant growth-promoting endophytic microorganisms. In the current study, we isolated and identified a new endophytic bacterium from a wild plant species *Glyceria chinensis* (Keng). The bacterium was designated as a *Bacillus altitudinis* strain using 16S rDNA sequencing. The endophytic *B. altitudinis* had a notable influence on plant growth. The results of our assays revealed that the endophytic *B. altitudinis* raised the growth of different plant species. Remarkably, we found transcriptional changes in plants treated with the bacterium. Genes such as maturase K, tetratricopeptide repeat-like superfamily protein, LOB domain-containing protein, and BTB/POZ/TAZ domain-containing protein were highly expressed. In addition, we identified for the first time an induction in the endophytic bacterium of the major facilitator superfamily transporter and DNA gyrase subunit B genes during interaction with the plant. These new findings show that endophytic *B. altitudinis* could be used as a favourable candidate source to enhance plant growth in sustainable agriculture.

Keywords: endophytic bacteria, *Bacillus altitudinis*, plant growth, transcriptome, *Glyceria chinensis*

INTRODUCTION

The use of fertilisers in agricultural practice to increase yields has had harmful effects on the environment and quality of the soil for a long time (Worlanyo and Jiangfeng, 2021). To minimise these negative impacts, the use of microorganisms located in the rhizosphere and in endophytic environments, such as bio-fertilisers, has received increased attention (Atieno et al., 2020). Beneficial plant–bacteria communities have been studied for many years (Pieterse et al., 2012; Zipfel and Oldroyd, 2017; Afzal et al., 2019; Ke et al., 2021; Song et al., 2021; Zhang et al., 2021). There are different bacteria in a direct interconnection with the plant cells; therefore, they might produce a direct beneficial effect (Hallmann et al., 1997). Different plant species are colonised by a great diversity of endophytic bacteria, such as *Pseudomonas*, *Bacillus*, *Enterobacter*, *Burkholderia*, and *Azospirillum* (Lodewyckx et al., 2002; Weyens et al., 2009).

The range of endophytic bacteria depends on the plant species and crop conditions (Zinniel et al., 2002; Ulrich et al., 2008). Endophytic bacteria colonise the intracellular and intercellular

spaces of plant tissues and promote plant growth (Ulrich et al., 2008; Lugtenberg and Kamilova, 2009; Vacheron et al., 2013; Hardoim et al., 2015; Santoyo et al., 2016; Gouda et al., 2018). The procedures used by endophytic bacteria to boost plant growth constitute an essential step in the endophytic bacteria applications (Wani et al., 2015). However, the process by which endophytic bacteria enhance plant growth are not well understood (Hardoim et al., 2008; Marasco et al., 2012; Rashid et al., 2012; Bruto et al., 2014). Important evidence suggests that there is a relationship between genes involved in beneficial features (Bruto et al., 2014). The useful functions comprise the bacterial ability to enhance nutrient acquisition, fix nitrogen, acquire iron, and produce siderophores in plant species (Zhang et al., 2009; Hardoim et al., 2015; Zhou et al., 2016).

Furthermore, endophytic bacteria enhance plant growth through the production of different phytohormones. Phytohormones produced during endophytic colonisation process improved plant nutrient absorption and biomass (Gravel et al., 2007; Phetcharat and Duangpaeng, 2012; Shi et al., 2014). Plant growth regulators such as cytokines, ethylene, abscisic acid (ABA), gibberellins, and indole-3-acetic acid (IAA) are produced by endophytic bacteria during interactions with plants (Vacheron et al., 2013). Interestingly, IAA showed a crucial effect on plant growth and development processes. Modulating IAA is a notable hallmark through which the endophytic bacteria might strengthen plant growth. In addition, ethylene constitutes an essential plant hormone involved in different developmental and physiological processes (Sun et al., 2016). The enzyme 1-aminocyclopropane-1-carboxylate (ACC) deaminase precursor of ethylene is produced by endophytic bacteria (Sun et al., 2009). The hydrolysis of ACC improved plant growth under stress conditions (Santoyo et al., 2016). Plant growth-promoting endophytic bacteria displayed ACC deaminase activity (Nikolic et al., 2011; Zhang et al., 2011; Rashid et al., 2012). These bacteria can produce ACC deaminase to enhance plant growth. Mutation of the ACC deaminase gene compromised the canola growth (Sun et al., 2009). Moreover, diverse endophytic bacterial strains have the ability to release volatile organic compounds such as acetoin, pentadecane, 2,3-butanediol, 1 hexanol, and indole, which enhance plant growth (Ryu et al., 2003; Gutiérrez-Luna et al., 2010; Blom et al., 2011; Hernández-Calderón et al., 2018).

Plant endophytic bacteria have great potential to be used as bio-fertilisers. Although different types of bacterial species were identified from a broad plant species range, the action of these bacteria is commonly unstable under field conditions (Afzal et al., 2019). The poor understanding of the tricky events that control this alliance at the molecular level might be the reason. However, it is possible to obtain a better understanding through the evaluation of the both bacterial and plant genes expressed during the interaction (Afzal et al., 2019). The development of RNA-sequencing techniques has allowed the identification of transcripts involved in plant growth. However, few studies have investigated the endophytic bacterial diversity in unexplored wild plant species. Wild plant species survive in different environments and under diverse stress conditions. Identification of endophytic bacteria isolated from these species might allow the use of diverse mechanisms in these bacteria to promote plant

growth (Afzal et al., 2019). The present study aimed to isolate, identify, and characterise endophytic bacteria from wild plant species and characterise their plant growth-promoting properties and the main molecular events involved in endophytic bacteria–plant interactions.

MATERIALS AND METHODS

Isolation of Endophytic Bacterium

The samples were collected from wild plant species *Glyceria chinensis* (Keng) localised along the margin of the Fu Tuan River (35°20'17"N, 119°26'8"E) within 5 km¹ of the coastal region of Rizhao City in Shandong Province (People's Republic of China). The wild plant species was classified according to data on morphological traits from the Flora of China.² This experimental study complies with Chinese national and local laws, and sample collection has been permitted by the Rizhao administration and Municipal Sciences and Technology Department [Collection information: South China Botanical Garden (IBSC) of the Chinese Academy of Sciences. Source: China Digital Plant Specimens Museum. Identifier: 0114164. Collector: Zhang Zhisong Acquisition number: 401467]. A total of 100 samples were collected randomly during the spring season. Firstly, the plant material (stems and roots) was rinsed with water. The samples were cut into small pieces under aseptic conditions. Each sample was surface sterilised with 70% ethanol for 1 min and immersed in a sodium hypochlorite solution (5%) during 1 min. Subsequently, the samples were washed in sterile distilled water during 1 min and dried on filter paper. After proper drying, pieces of plant parts were physically treated in a TissueLyser (Qiagen, Hilden, Germany) during 5 min in 1 ml of sterile water. The debris was decanted and 100 µl of the remaining water was incubated in Luria–Bertani (LB) agar medium (yeast extract, 5 g/L; peptone, 10 g/L; sodium chloride, 5 g/L; agar, 12 g/L; pH 7) at 37°C for 3 days. Parallel to the samples, the final wash solution of the surface sterilisation procedure was also spread plated onto the MS medium plate which served as a control. The bacteria were only isolated from processed samples internally. This was the criteria to classify as endophytes and not the surface contaminants. Bacterial colonies were selected based on growth rate, colony morphology, and pigmentation. Bacterial isolates were selected and purified by streaking procedure. These were incubated at 37°C. Pure cultures of the bacterial strains were maintained in 30% glycerol at –80°C.

Plant Materials and Growth Conditions

Arabidopsis thaliana ecotype Columbia plants were used in the experiments. First, surface-sterilised seeds were plated on Murashige and Skoog (0.5 × MS) basal media (Sigma Aldrich, St. Louis, MO, United States) supplemented with 1% w/v sucrose. The seeds were stored at 4°C in the dark for 2 days and transferred to a controlled growth room under a 16-h light/8-h dark photoperiod at 22°C. Small plants were transplanted to a

¹<https://www.ezbiocloud.net>

²<http://www.iplant.cn/foc/>

mixture of soil composed of peat plugs and vermiculite in a 1:1 ratio during 14 days. In addition, *Nicotiana tabacum*, corn, and soybean seeds were germinated and the plants grown in pots (6") containing sterilised black turf and rice husk (4:1) substrate and maintained in a controlled growth room at 23°C.

Identification of Endophytic Bacterium

The DNA from endophytic bacterium was extracted according to Sambrook et al. (1989). The 16S rRNA gene was used for molecular identification. A fragment of 16S rRNA gene was amplified by polymerase chain reaction (PCR) using the forward primer 27F 5'-AGAGTTTGATCCTGGCTCAG-3' and reverse primer 1492R 5'-GGTACCTGTTACGACTT-3'. The amplification process was conducted in a Thermal Cycler T100 machine (Bio-Rad Life Science Research, Shanghai, People's Republic of China) using a Taq PCR Master Mix Kit (Qiagen, Hilden, Germany). The PCR reaction was as follows: 95°C for 10 min; 35 cycles of 95°C for 30 s, 55°C for 1 min, and 72°C for 1.5 min; and final extension at 72°C for 10 min. The purified PCR fragment was sequenced using an ABI 3730 DNA sequencer (Applied Biosystems, ThermoFisher Scientific, Chino, CA, United States). The 16S rRNA gene fragment sequence (1,147 bp) was identified using BLASTN homology searches (Altschul et al., 1997). The National Center for Biotechnology Information (NCBI) GenBank, European Molecular Biology Laboratory–European Bioinformatics Institute (EMBL–EBI), and taxonomically united database of 16S rRNA EzBioCloud² were used as databases (Yoon et al., 2017; De Los Santos Villalobos et al., 2019; Ha et al., 2019). Additionally, the full 16S rRNA gene (1,544 bp), glycosyl hydrolase lipoprotein, and SDR family oxidoreductase genes sequenced through RNA sequencing were used to an accurate identification. The phylogenetic tree was done using the neighbour-joining method and the full 16S rRNA (Saitou and Nei, 1987).

Greenhouse Experiments

Seeds pre-germinated from *A. thaliana*, *N. tabacum*, corn, and soybean were treated with endophytic bacterial fermentation twice weekly for 1 month. The selected bacterial strain was incubated in 100 ml of LB broth medium in a 250-ml Erlenmeyer flask with shaking (200 rpm) for 1 day at 37°C in the dark. The optical density (OD) from endophytic bacterial fermentation was adjusted to 1.0 (4.77×10^9 CFU/ml), and 30 ml of the fermentation was applied per pot. Each plastic pot received three pre-germinated seeds, and the plants were grown in a controlled growth room at 25°C and irrigated with water without any fertilisers. A completely randomised pot experiment with five replicates for each treatment was done to analyse the influence of the endophytic bacterium on the growing of different plant species. The substrate contained black turf and rice husks (4:1). The substrate was sterilised at 120°C during 20 min. Additionally, the roots of the plants inoculated with the endophytic bacterium used in the experiments were processed, and the bacterium was again isolated and classified as the original strain using the same protocol mentioned above. In *Arabidopsis* plants, the rosette diameter, leaf size, root size, and fresh weight parameters were evaluated after 1 month of treatment with endophytic bacterial

fermentation. In addition, colony-forming units from endophytic bacteria were determined after 1 month of treatment. Plant size and fresh weight were evaluated in *N. tabacum*, corn, and soybean plants after 1 month of treatment. Data were analysed using GraphPad Prism software (La Jolla, CA, United States). Significant differences among the mean values were determined using *t*-test at $p < 0.05$. Five replicates were used for each treatment. The experiments were replicated twice.

Identification of New Genes Using RNA Sequencing

The *Arabidopsis* plants were treated with aliquots of 30 ml (4.77×10^9 CFU/ml) of endophytic bacterium. The bacterium was inoculated in the sterilised substrate around the plants (5-day-old). The colonisation of bacterium in the roots was verified using the same protocol used in the isolation of this strain from wild plant species on LB plates at different time points. The endophytic bacterium was well established 72 h post-inoculation. Leaves, stems, and roots from five plants were collected 72 h post-inoculation. Plants treated with water were used as control. Treatments and controls were repeated three times per group. The total RNA was extracted using the Qiagen RNeasy Midi Kit (Hilden, Germany), and the concentration of the total RNA was determined using spectrometry. The treatment and control samples were repeated three times per group. After extracting the total RNA, eukaryotic mRNA was enriched using oligo(dT) beads. The samples were sequenced using Illumina HiSeqTM 2000 (Personalbio Co., Shanghai, People's Republic of China). High-quality reads were processed using the Perl script, and the differentially expressed genes were identified using the edgeR package.³ Genes with a fold change ≥ 2 were considered significant differentially expressed genes. Gene ontology (GO) and the Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment analysis were used to characterise the differentially expressed genes. GO functional annotations were obtained from the non-redundant annotation results. In addition, the GO annotations were analysed using the Blast2GO software⁴ (Conesa et al., 2005). The RNA sequencing was done following these steps: (1) total RNA extraction; (2) total RNA quality test; (3) rRNA removal; (4) RNA fragmentation between 200 and 300 bp by ion disruption; (5) PCR: the first chain of cDNA was synthesised by random primers and reverse transcriptase; when the second chain of cDNA was synthesised, the library of chain-specific components was constructed, and dTTP was replaced by dUTP, which greatly improved the accuracy of the results. (6) PCR enrichment of library fragments: the size of the library ranged from 300 to 400 bp. (7) Library quality inspection: the size of the library was detected by Agilent 2100 Bioanalyzer, and the total concentration of the library was detected by fluorescence quantitative analysis. (8) Illumina sequencing: the best amount of sample was selected for PCR amplification. (9) Annealing of sequencing at the same time of synthesis: the prokaryote genetic analysis process firstly filtered the raw off-machine data to obtain a high-quality sequence, comparing the

filtered sequence with the species reference genome. Based on the results of the comparison, the amount of expression of each gene was calculated. On this basis, the expression difference analysis, enrichment analysis, and cluster analysis of the sample were further carried out. The transcription structure of the sample was analysed and the manipulative substructure of the sample gene obtained. UTR, SNP, and InDel were obtained. HTSeq 0.6.1p2⁵ was used to compare the read count values from each gene as the original expression of the gene. To make gene expression levels comparable between different genes and samples, we normalised the sequencing depth and gene length using fragments per kilobase of transcript per million (FPKM). FPKM calculates the number of fragments that two reads can compare to the same transcript. In the reference transcription group, we generally took into account the FPKM > 1 when the gene was expressed. Pearson correlation coefficients were used to indicate the level of expression correlation between genes in the sample to test the reliability of the experiments and whether sample selection was reasonable. The level correlation of gene expression between samples was an important index to test the reliability of the experiments and whether sample selection was reasonable. The log2 fold change was calculated by dividing the FPKM values from the bacterium during interaction with *Arabidopsis* (SB001) and the bacterium without interaction with *Arabidopsis* (B001).

RESULTS

Isolation and Identification of the Endophytic Bacterium *Bacillus altitudinis*

Six endophytic bacteria strains were isolated from wild plant species. The ability of the six isolated endophytic bacteria to colonise and persist in wild plant species was tested. Of these six, only one isolate (SB001) colonised this plant species at levels ranging from 9.40×10^2 CFU/cm fresh root compared with the other five strains, where the level was lower (Table 1). Based on the levels of colonisation, the isolated endophytic strain SB001 was selected for further assays.

The isolate SB001 showed a small rod-shaped structure and Gram-positive spore-forming bacterium distinctive of the genus *Bacillus*. The bacterium strain was identified using the partial (1,147 bp) and full (1,544 bp) 16S rRNA gene. Using the taxonomically united database of 16S rRNA in

EzBioCloud, the full 16S rRNA was definitively identified as a top hit with *Bacillus altitudinis* with 100% similarity. Partial 16S rRNA sequences had an ambiguous 96.94% of similarity with *B. altitudinis*. Additionally, glycosyl hydrolase lipoprotein and SDR family oxidoreductase genes confirmed the identification of *B. altitudinis* (Supplementary Table 1). Considering the identification, the phylogenetic tree was constructed by comparing the full 16S rRNA gene sequences of the isolate SB001 with the reference strain sequences from the NCBI GenBank public database. Molecular analysis indicated that the isolated strain SB001 belongs to the genus *Bacillus* showing an identity percentage of 100% and *E*-value of 0.0 with *B. altitudinis* strain W3 (Figure 1).

Bacillus altitudinis Strain Promotes the Growth of Different Plant Species

The endophytic strain was also evaluated for plant growth promotion in different plant species. There was significant growth in *Arabidopsis* plants treated with the endophytic bacterium *B. altitudinis* (Figure 2A). The rosette diameter (Figure 2B), leaf size (Figure 2C), and fresh weight (Figure 2E) were considerably increased by inoculation with the *B. altitudinis* strain compared with the control in *Arabidopsis* plants at 20 days. However, endophytic bacteria did not influence root size (Figure 2D). Nevertheless, endophytic bacteria were suitably established in *Arabidopsis* roots (Figure 2F).

The *B. altitudinis* strain significantly stimulated the growth of *N. tabacum* plants (Figure 3A) and showed a substantial influence on plant size (Figure 3B) and fresh weight (Figure 3C) in *N. tabacum* plants. Inoculation with the *B. altitudinis* strain considerably enhanced the growth of maize plants with respect to non-inoculated plants (Figure 4A). Compared with the non-inoculated plants, the endophytic strain increased the plant size (Figure 4B) and fresh weight (Figure 4C) in inoculated plants. However, the endophytic strain had no significant influence on soybean plant growth (Figure 5). Overall, these results revealed that *B. altitudinis* improved the vegetative growth of different plant species following inoculation.

Bacillus altitudinis Induces Transcriptional Changes in Genes Involved in Plant Growth

RNA-seq was used to evaluate the interactions between *B. altitudinis* and *Arabidopsis*. To generate RNA-seq data sets, we prepared cDNA libraries from mock-inoculated and inoculated with the endophytic bacterium *B. altitudinis* from *Arabidopsis* plant RNA and sequenced them on two separate flow cells. The range of gene expression during the *B. altitudinis*-*Arabidopsis* interaction was determined. During the interaction, 27,628 transcripts were identified and annotated (Supplementary Table 2). From this, 7,379 new transcripts were annotated (Supplementary Table 3). The highest number of transcripts (33.57%) showed an expression level change of between 1- and 10-fold. The lowest number of transcripts was distributed at the highest expression level

between >100-fold change (Figure 6). Analysis of RNA-seq data during the interaction revealed 368 differentially expressed transcripts, which included 256 upregulated and 112 downregulated transcripts (Figure 7). Among them, maturase K, tetratricopeptide repeat (TPR)-like superfamily protein, LOB domain-containing protein, and BTB/POZ and TAZ domain-containing proteins showed the highest gene differential expression during *B. altitudinis*-*Arabidopsis* interaction.

Trihelix transcription factor (TF) ASR3, TF MYB90, and O-methyltransferase family proteins were significantly repressed during the interaction (Table 2 and Supplementary Table 4).

Differentially expressed transcripts were subjected to functional analyses. GO enrichment analysis was performed using the annotated difference gene to calculate the list

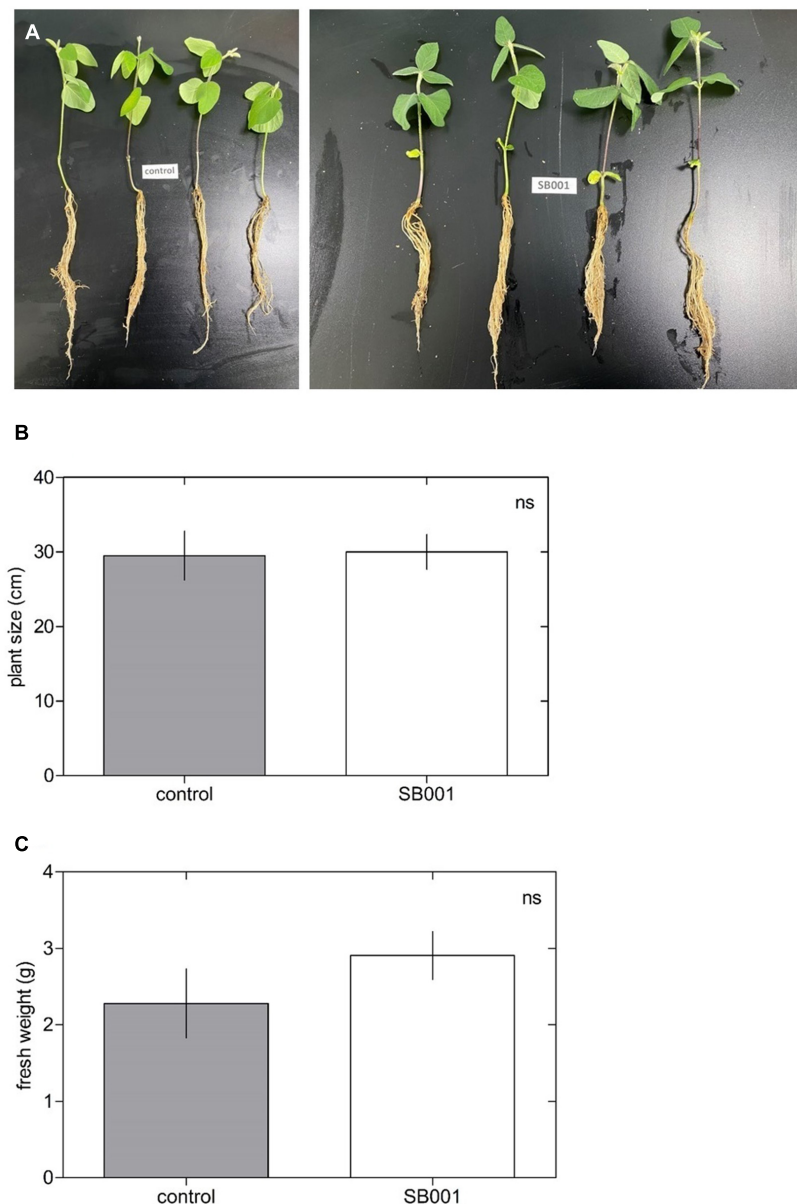

FIGURE 5 | Endophytic bacterium *B. altitudinis* does not induce soybean plant growth. Plants (5-day-old) were mock-treated (control) or inoculated with 30 ml of *B. altitudinis* at 4.77×10^9 CFU/ml. **(A)** Phenotype of soybean plants mock-treated (control) and treated with *B. altitudinis* fermentations (SB001) at 20 days post-inoculation. Each bar represents mean values with standard errors of two independent experiments ($n = 10$).

of genes and the number of genes for each term. The transcripts with the largest increases in expression were NADH dehydrogenase (quinone), NADH dehydrogenase (ubiquinone) activity, NADH dehydrogenase, and oxidoreductase (Figure 8A). Based on the KEGG pathway, we categorised the most significant transcripts into nitrogen metabolism and oxidative phosphorylation pathways (Figure 8B and Supplementary Table 5). The expression profile of TF genes displays the upcoming transcription actions regulated by these genes. To determine their important roles, the TFs involved

in the *B. altitudinis*–*Arabidopsis* interaction were analysed. The largest TF families detected in our study were basic helix-loop-helix (bHLH) DNA-binding superfamily protein, TF MYB13 (MYB), ethylene responsive factor (ERF), NAC domain-containing protein 1 (NAC), and zinc finger protein ZAT1 (C2H2), respectively (Figure 9).

During the interaction, a total of 3,413 genes were annotated from *B. altitudinis*. From these, genes with a log2 fold change between -1.2 and 5.3 were analysed. Twenty-two and 8 *B. altitudinis* genes were up- and down-regulated

FIGURE 6 | Statistics showing the range of plant gene expressions during the *B. altitudinis*–*Arabidopsis* interaction. Horizontal coordinates represent the range of expression measures, and ordinates represent the number of genes in each expression interval.

FIGURE 7 | Volcanic diagrams of differential expression genes. The horizontal coordinates are \log_2 (fold change) and the ordinates are $-\log_{10}$ (p -value). The two vertical dashed lines are 2 times the difference threshold, and the horizontal dashed lines are p -value 0.05 thresholds. A red dot indicates the upregulated genes group, a blue dot indicates the downregulated genes group, and a grey dot represents a non-significant difference in the expression of the genes group. The scale was fixed considering the minimum and maximum \log_2 values (between -7.60 and 15.70) included in the **Supplementary Table 4**.

during the interaction with *Arabidopsis* plants, respectively. The rest of these genes were undefined, repeated, low significant fold change, or involved in the primary metabolism of the bacterium. The major facilitator superfamily (MFS) transporter, sucrose-6-phosphate hydrolase, phosphate ABC transporter, DNA gyrase subunit B, polysaccharide biosynthesis protein, serine phosphatase, and flagellar biosynthesis protein had the highest expression levels in *B. altitudinis* during the interaction with *Arabidopsis* plants. Moreover, elongation factors G, 2,3-butanediol dehydrogenase, dihydrolipoamide succinyltransferase, and proline dehydrogenase were highly downregulated in bacteria (**Table 3** and **Supplementary Table 6**).

DISCUSSION

Different classes of microorganism have the potential to promote plant growth. The favourable effects of endophytic bacteria derived from the roots have been demonstrated. The significant reaction of these endophytic bacteria on plant growth has been achieved by both direct and indirect processes. Direct effects comprise the production of molecules that encourage plant growth (Goswami et al., 2016). In the current study, different endophytic bacteria strains were isolated from wild plant species. The SB001 strain was the most abundant in the inner tissues of the wild plant species. The strain was identified as *B. altitudinis* through morphological and molecular analyses.

Several plant growth promotion assays were conducted to determine whether SB001 could promote plant growth in different plant species under greenhouse conditions. Inoculated *A. thaliana*, *N. tabacum*, and maize plants exhibited growth improvement, and significant increases were observed for several growth variables, such as fresh weight and plant size, between the inoculated and non-inoculated control plants. However, this strain did not influence soybean growth. It is likely that the internal tissue environment of soybean roots is not suitable for the correct setting of the bacterium. Interestingly, *B. altitudinis* strain was well established in *Arabidopsis* roots,

which constitutes important evidence of the ability of this strain to colonise internal tissues. Remarkably, this endophytic strain displayed vigorous plant growth-promoting effects in non-host plants. This result proposes that SB001 has the ability to efficiently enhance the growth of a broad range of plant species, and consequently, this might be used in applications under field conditions.

Earlier studies showed that several *Bacillus* species isolated from various hosts promote plant growth (Ashraf et al., 2004; Xie et al., 2014; Kuan et al., 2016; Pourbabaee et al., 2016; Radhakrishnan and Lee, 2016; Fouda et al., 2021). For example, *B. insolitus*, *B. subtilis*, and *B. methylotrophicus* increased the size and weight of shoots, leaves, and roots from diverse plant species (Ashraf et al., 2004; Radhakrishnan and Lee, 2016).

Gene3183	-1.4	Crp/Fnr family transcriptional regulator
Gene3475	-1.2	Flotillin

Furthermore, *B. subtilis* and *B. methylotrophicus* induced the production of hormones such as IAA, cytokinins, gibberellic acid (GA), and spermidines to stimulate plant growth (Xie et al., 2014; Radhakrishnan and Lee, 2016; Fouda et al., 2021), whereas *B. megaterium* and *B. methylotrophicus* boosted endogenous proteins, amino acids, and minerals in plants (Kang et al., 2014; Radhakrishnan and Lee, 2016). Strain SB001 exhibited different plant growth-promoting properties, which were reflected in the enhanced vegetative growth of different plant species, although these properties under soil conditions need to be investigated. Due to its beneficial plant growth-promoting activities, the *B. altitudinis* strain may be used as a source of bio-fertiliser in sustainable agriculture.

Plant-harmless bacteria interactions have been studied for many years. However, the molecular events used and involved during the interaction are not well understood, which makes it difficult to use the advantages of these complex interactions under natural conditions. Endophytic bacteria positively impact plant growth and select beneficial bacterial colonisers (Hardoim et al., 2008; Marasco et al., 2012; Rashid et al., 2012). In this study, we conducted transcriptome sequencing of *Arabidopsis*–*B. altitudinis* interactions to identify and quantify the expression grades of transcripts. A large number of novel candidate genes related with primary and secondary metabolite biosynthesis were identified in our expressed sequence tag (EST) data set. The results show new understandings in the expression data of this endophytic bacterium, as well as a first insight into the gene expression patterns during *Arabidopsis*–*B. altitudinis* interaction. Moreover, the transcriptome information obtained in this study provides a significant contribution to gaining a suitable understanding of the molecular events implicated in the interaction.

Remarkably, GO and KEGG analyses showed significant changes, suggesting that the *B. altitudinis* strain had a considerable effect on the plant. Our data indicated that SB001 induces important pathways involved in plant growth. All the information about the molecular interactions in known metabolic and regulatory pathways are contained in the KEGG pathway database (Kanehisa and Goto, 2000). Interestingly, the maturase K (chloroplast-encoded splicing factor), TPR-like superfamily protein, LOB domain-containing protein, and BTB/POZ and TAZ domain-containing protein genes were highly induced for the first time during the *Arabidopsis*–*B. altitudinis* interaction.

Previously, maturase K gene expression was associated with developmental stage, etiolation, and regulation processes related with development and photosynthesis (Barthet and Hilu, 2007). Maturase K has influence in gene expression in plants and interferes with the proper expression of the photosynthetic mechanism (Qu et al., 2018). Indeed, the induction of the maturase K gene might have an effect on plant growth during the interaction, through an enhancing photosynthetic process. TPR proteins are important in plant hormone signalling, such as GA, cytokinin, and ethylene (Jacobsen et al., 1996; Wang et al., 2004; Greenboim-Wainberg et al., 2005; Yoshida et al., 2005). In addition, the TPR gene was a key positive regulator of ABA during *Arabidopsis* seedling development (Rosado et al., 2006).

Conversely, LOB domain-containing protein genes constitute a gene family that encodes plant-specific TFs that play key functions during plant growth (Zhang et al., 2020). These proteins are essential TFs that regulate plant organ development, photomorphogenesis (Mangeon et al., 2011), petiole development (Ge et al., 2014), hormone response (Zentella et al., 2007), and metabolism regulation (Rubin et al., 2009). Additionally, BTB/POZ and TAZ domain-containing protein genes are required during gametophyte development (Robert et al., 2009). This is an essential element of a signalling network that recognises and responds to diverse stimuli (Mandadi et al., 2009). Furthermore, the TF MYB90 is repressed during the interaction. Previously, it was found

that heterologous expression of the TF AtMYB90 increased the anthocyanin production and inhibited the tomato plant growth (Li et al., 2018). The endophytic bacterium SB001 was capable of promoting growth through activation of important pathways implicated in plant growth, including the synthesis of phytohormones and TFs.

The TFs constitute crucial functional factors involved in the regulation of gene expression (Jiao et al., 2003). Numerous processes such as brassinosteroid signalling, ABA signalling, and axillary meristem formation are regulated by bHLH family members during seedling development (Zhao et al., 2012). A total of 153 transcripts were identified as bHLH TF proteins, and these constituted the largest TF family during the interaction. In addition, the bHLH proteins are a phytochrome interacting factor (Toledo-Ortiz et al., 2003).

The MYB proteins were involved in regulatory networks controlling development and metabolism of a diversity of plant species (Dubos et al., 2010). MYB115 and MYB118 had a key part in embryogenesis in *Arabidopsis* plants (Wang et al., 2009). Also, MYB38 and MYB18 regulate hypocotyl elongation in response to blue (Hong et al., 2008) and far-red light, respectively (Yang et al., 2009). Other MYB proteins, such as MYB58, MYB63, MYB85, MYB68, and MYB46, were related in the regulation of cell wall biosynthesis (Zhou et al., 2009). In this study, 144 putative MYB genes were detected during *Arabidopsis* seedling development.

The large NAC TF family was involved in a diversity of developmental events in *Arabidopsis* and soybean (Shamimuzzaman and Vodkin, 2013). This NAC TF family has the capacity to permit crosstalk between different pathways (Olsen et al., 2005). Furthermore, C2H2 zinc finger protein genes play a significant part in the development and differentiation (Razin et al., 2012). During the interaction, 100 putative C2H2 zinc finger genes were identified. In addition, ethylene responsive factor (ERF) TFs belong to the Apetala2/ERF TF family involved in plant growth.

Interestingly, the MFS transporter and DNA gyrase subunit B protein genes were highly expressed in *B. altitudinis* during the interaction with the plant, which constitutes the first evidence of the expression of these types of genes in this species. The MFS transporter facilitates the transport of diverse molecules such as sugars, vitamins, amino acids, and hormones across cell membranes. These proteins are in different prokaryote and eukaryote organisms (Pao et al., 1998). It is likely that the high expression of this gene allows the transport of important hormones involved in plant growth. Silencing of the *A. thaliana* gyrase-A gene was embryo-lethal, whereas silencing of gyrase-B genes led to severely affected growth and development (Wall et al., 2004). We speculate that the overexpression of the gyrase gene in *B. altitudinis* might enhance plant growth.

CONCLUSION

Here, we report a new *B. altitudinis* endophytic strain isolated from wild plant species. Our finding revealed that the endophytic

bacterium induced a key group of genes associated with plant growth-promoting traits. We demonstrated that this strain has a favourable reaction on plant growth. Remarkably, our results suggest that maturase K, TPR-like superfamily protein, LOB domain-containing protein, and BTB/POZ/TAZ domain-containing protein might be involved for the first time in this process. Furthermore, the MFS transporter and DNA gyrase subunit B genes expressed in *B. altitudinis* may be implicated in the observed effects. Future studies should evaluate the direct functions of these genes in plant growth during interactions. In addition, the potential beneficial effects of *B. altitudinis* strain under natural conditions need to be further investigated. In the long term, the new finding would allow the development of suitable and effective strategies in sustainable agriculture.

DATA AVAILABILITY STATEMENT

The data presented in the study are deposited in the (SRX11022601) repository, accession number (PRJNA733570).

AUTHOR CONTRIBUTIONS

OB-H, HX, and XG conceived the study. OB-H and DZ designed the experiments. DZ, HX, JG, RP, LD, XG, CB, and OB-H did the experiments. DZ and OB-H assisted in the data analysis. OB-H wrote the manuscript. All authors contributed to the article and approved the submitted version.

FUNDING

This study was supported by the Special Funds for Guiding Local Science and Technology Development of Central Government of Shandong Province (No. YDZX20193700004362).

Phosphorus (P) availability is usually low in soils around the globe. Most soils have a deficiency of available P; if they are not fertilized, they will not be able to satisfy the P requirement of plants. P fertilization is generally recommended to manage soil P deficiency; however, the low efficacy of P fertilizers in acidic and in calcareous soils restricts P availability. Moreover, the overuse of P fertilizers is a cause of significant environmental concerns. However, the use of arbuscular mycorrhizal fungi (AMF), phosphate–solubilizing bacteria (PSB), and the addition of silicon (Si) are effective and economical ways to improve the availability and efficacy of P. In this review the contributions of Si, PSB, and AMF in improving the P availability is discussed. Based on what is known about them, the combined strategy of using Si along with AMF and PSB may be highly useful in improving the P availability and as a result, its uptake by plants compared to using either of them alone. A better understanding how the two microorganism groups and Si interact is crucial to preserving soil fertility and improving the economic and environmental sustainability of crop production in P deficient soils. This review summarizes and discusses the current knowledge concerning the interactions among AMF, PSB, and Si in enhancing P availability and its uptake by plants in sustainable agriculture.

Keywords: phosphorus availability, silicon fertilizer, silicate solubilization, silicate-solubilizing bacteria, synergistic interactions

INTRODUCTION

There is a growing need to improve food production to meet the requirements of the increasing world population. This may be done in either of two ways: increasing the area under cultivation or enhancing the yield per unit area. The former is not possible in many countries of the world due to a number of restrictions including the availability of water or soil resources, climate change, drought, and soil salinization (Etesami and Noori, 2019). On the other hand, one of the ways to increase the yield per unit area is to improve the nutritional properties of the soil. As an essential plant nutrient, P is required for carbon metabolism, energy generation, energy transfer, enzyme

activation, membrane formation, and nitrogen (N_2) fixation (Schachtman et al., 1998). P also forms key biological molecules like ATP, nucleic acids, and phospholipids (Marschner, 1995). P deficiency is a significant limiting factor for the growth and yield of crops that affects approximately 50% of all agricultural ecosystems around the world (Lynch, 2011; Ringeval et al., 2017; Etesami, 2020). To address this issue, there has been an enormous worldwide increase in the use of P fertilizers. The high agricultural P demand has put the sustainability of P mining for fertilizer production into question (Elser, 2012). P fertilizers often lead to the addition of a large excess of P in agricultural soils. Unfortunately, >80% of the P fertilizers applied to the soil is lost due to adsorption and fixation processes (de La Vega et al., 2000; Vance et al., 2003) or it is transformed into organic forms (Holford, 1997), which represent 40–80% of total soil P (Bünemann et al., 2010), with phytates as the most common form (Menezes-Blackburn et al., 2014). Therefore, the availability of this added P to plants is limited (about 0.1% of the total P).

P is usually absorbed by the plant in a limited range of soil conditions, i.e., pH 6.5–7 as $H_2PO_4^-$ and HPO_4^{2-} . When the soil pH exceeds 7.0, inorganic phosphate (Pi) is predominantly mineralized and immobilized as calcium phosphates. At lower soil pH levels, P is usually bound/adsorbed by soluble aluminum (Al), iron (Fe), manganese (Mn), or the associated hydrous oxides (Brady and Weil, 1999). At neutral pH, Pi adsorbs to weathered silicates such as clay minerals (Rajan, 1975). Thus, the P concentration in soils with pH < 6.5 or pH > 7 is suboptimal, and is generally about 1–10 μM (Schachtman et al., 1998), which can result in crop yield depressions of 5–15% (Shenoy and Kalagudi, 2005).

The theoretical increase in plant growth efficiency from adding chemical P fertilizers has peaked so that additional chemical P fertilization cannot be expected to significantly increase plant yield (Etesami, 2020). Twenty-two million tons of P (3–4% of the total P demand) are annually extracted from natural sources (i.e., non-renewable phosphate rocks), according to the US geological survey (Gaxiola et al., 2011), which puts the natural P sources in risk of depletion (Cordell et al., 2009). Therefore, a more efficient use of P is needed, including maximizing P acquisition and utilization efficiencies (Veneklaas et al., 2012).

Some plants can efficiently acquire and/or use P to maintain metabolism and growth (Lambers et al., 2010; Aziz et al., 2014). Some plant mechanisms for improving P acquisition efficiency include (Ramaekers et al., 2010; Johri et al., 2015): (i) increased expression of high affinity P transporters; (ii) soil exploration at a minimal metabolic cost; (iii) topsoil foraging; (iv) stimulation of root hair growth; (v) redistribution of growth among root types; (vi) increase of the root-to-shoot ratio; (vii) the secretion of organic acids (e.g., citrate, malate, or oxalate) from roots to the soil; (viii) the activation of an advanced bio-molecular system; and (xi) enhanced acid phosphatase (rAPase) or phytase secretion.

Plants have also developed some biotic interactions with diverse soil microorganisms that promote plant growth. Arbuscular mycorrhizal fungi (AMF) and plant growth-promoting bacteria (PGPB) are the most common such

microorganisms. AMF and PGPB, and especially the phosphate-solubilizing bacteria subgroup (PSB), are known to help overcome P deficiency in plants. PSB and AMF are a part of the key biogeochemical cycling processes (Sharma et al., 2013; Etesami, 2020).

Phosphate-solubilizing bacteria exist in most soils (Rodríguez and Fraga, 1999). In *in vitro* conditions, they can improve P bioavailability by lowering the soil pH, solubilizing Pi, activating synthesized phosphatases, mineralizing organic P, and/or chelating P from Al^{3+} , Ca^{2+} , and Fe^{3+} (Rodríguez and Fraga, 1999; Browne et al., 2009; Sharma et al., 2013; Etesami, 2020). Nearly all soils also contain AMF, which associate with approximately 80% of all plant roots (Smith and Read, 2008; Brundrett and Tedersoo, 2018). The ability of AMF to promote plant growth and yield and enhance P uptake has been well documented (Miransari, 2010; Jansa et al., 2011; Smith et al., 2011; Smith and Smith, 2011; Nadeem et al., 2014; Brundrett and Tedersoo, 2018; Etesami, 2020).

As a consequence of variable soil conditions, microorganisms may change crop productivity. Climate change also has a substantial impact on the effectiveness of microorganisms. One way to increase the efficiency of microorganisms under adverse environmental conditions is the co-inoculation of microorganisms (Nadeem et al., 2014; Etesami et al., 2015b; Etesami and Maheshwari, 2018; Ghorchiani et al., 2018) that stimulates plant growth through various mechanisms (Bashan et al., 2004). AMF and PGPB can work together to yield sustainable plant growth in malnourished environments (Zarei et al., 2006; Mohamed et al., 2014; Nadeem et al., 2014; Lee et al., 2015; Xun et al., 2015). Combinations of AMF and PGPB are commonly used to increase crop yields (Mäder et al., 2011; Ghorchiani et al., 2018), improve fruit quality (Ordookhani et al., 2010; Bona et al., 2016), boost phytoremediation, enhance the fertilizer nutrient use efficiency (Xun et al., 2015), lower chemical fertilization application requirements (Adesemoye et al., 2009), and increase salinity tolerance (Gamalero et al., 2009).

The use of silicon (Si) fertilizer has also been proposed as an environmentally friendly, ecologically compatible method of improving plant growth and the resistance to multiple environmental stresses including nutritional imbalances (Etesami and Jeong, 2018, 2020; Etesami et al., 2020). Previous studies have reported that Si increases plant uptake of P (Kostic et al., 2017; Neu et al., 2017; Reza khani et al., 2019a,b; Schaller et al., 2019). Combining Si and microorganism applications has been proposed to effectively induce improved plant growth and nutrition (Etesami, 2018; Etesami and Adl, 2020). Previous studies have observed that AMF and Si work together to improve plant growth regardless of the stress conditions (Hajiboland et al., 2018; Morad talab et al., 2019), and that PSB and Si synergistically help plants better uptake P (Reza khani et al., 2019a,b). However, how AMF, PSB and Si interact to affect P availability for plants is poorly understood. Thus, a better understanding of the interactions of AMF, PSB and Si would allow growers to rely less on chemical P fertilizers and instead utilize biological processes to maintain fertility and enhance plant growth. Hence, this review discusses the mechanisms which AMF, PSB, and Si, individually and together, use to

increase plant uptake of P in agricultural systems where proper nutrition might otherwise suggest heavy use of P fertilizers. This review also highlights future research needs regarding how to improve plant uptake of P using AMF, PSB, and Si. In addition, the role of silicate-solubilizing bacteria (SSB), which convert insoluble silicate forms to available forms for the plant, in increasing P and Si availability and their uptake by plants is discussed.

PLANT RESPONSES TO P SCARCITY

Plants exhibit a complex array of biochemical, morphological, and physiological adaptations to deal with P deficiency, which are generally known as “P starvation responses” (Plaxton, 2004) and endeavor to increase P acquisition capacity and to preserve plant vitality (Pang et al., 2015). Some P deficiency responses are as follows. A preferential carbohydrate allocation toward the roots, higher density of root hairs, greater root surface area and length, as well as root cluster formations alter the root structure and lead to reduced plant growth and increased root-to-shoot ratio (Gilroy and Jones, 2000; Liao et al., 2001; Sánchez-Calderón et al., 2006; Lynch, 2007; Niu et al., 2013; Aziz et al., 2014; Lambers and Plaxton, 2015). The greater surface area provided by the larger root system allows for better absorption of nutrients, including P, through increased contact with the soil (Römer and Schenk, 1998; López-Bucio et al., 2003; Lynch, 2007). Another important response to P deficiency is an increase in the root organic acid exudations, i.e., carboxylates (mainly citrate and malate) to the rhizosphere to increase the rhizospheric inorganic P availability (Neumann and Römheld, 1999; Vance et al., 2003; Raghothama and Karthikeyan, 2005; Johnson and Loeppert, 2006; Pang et al., 2015). Plants also exhibit an increased efficiency of cellular P uptake. Inorganic P in soils is generally very immobile, so that the uptake of rhizospheric P_i is affected by the high-affinity P_i/H^+ symporters associated to the plasma membranes that belong to the *PHT1* gene family (Gu et al., 2016). Previous studies observed that P deficiency induced the expression of P_i transporters in wheat (Gilroy and Jones, 2000; Tittarelli et al., 2007; Miao et al., 2009; Jia et al., 2011; Kostic et al., 2015; Kostic et al., 2017). Plants also induce enzymes that scavenge and recycle P_i , such as acid phosphatase, which catalyzes P_i hydrolysis from P_i -monoesters; nuclease, which degrades extracellular DNA and RNA; and phosphodiesterase, which liberates P_i from nucleic acids (Duff et al., 1994; Plaxton and Carswell, 1999; Gaume et al., 2001; Plaxton, 2004). Plants may also induce alternate cytosolic glycolysis pathways (Plaxton and Carswell, 1999), tonoplast pyrophosphatase that pumps H^+ , and different respiratory electron transport pathways (González-Meler et al., 2001; Plaxton, 2004). Plants also remobilize the internal P from one plant part to another (Gill and Ahmad, 2003). Plants modify the carbohydrate partitioning between source and sink, photosynthesis, sugar metabolism in response to P deficiency (Sánchez-Calderón et al., 2006), the cations in carbon metabolism and alternate respiratory pathways (Uhde-Stone et al., 2003), and/or membrane biosynthesis to require lower amounts of P

(Uhde-Stone et al., 2003; Lambers et al., 2006). Moreover, plants establish mycorrhizal symbioses, beneficial associations between soil fungi and plant roots (Smith and Read, 2008).

AMF AND THEIR MECHANISMS OF P UPTAKE/MOBILIZATION

Arbuscular mycorrhizae are endomycorrhiza where the fungal hyphae penetrate the root cell walls and get in touch with the plasmalemma. AMF are commonly found in all of earth's ecosystems with plants (Redecker et al., 2013). The formation of arbuscular mycorrhiza has allowed plants to survive and grow in natural habitats for millions of years without fertilizers, pesticides and irrigation. AMF belong to the subphylum Glomeromycotina (Bruns et al., 2018), encompassing 340 described species¹.

Having evolved 400–450 million years ago, this symbiosis is likely the oldest type of mycorrhiza, and it involves a wide variety of plants (Smith and Read, 2008). AMF are obligate symbionts and acquire all of their organic carbon requirements from their plant partners. The symbiosis is often mutualistic based largely on carbon exchange from the plant (4–20% of photosynthetically fixed carbon) and P delivered by the fungi (Wright et al., 1998; Smith and Smith, 2011). More than 80% of earth's plant species are estimated to be able to form this mycorrhizal symbiosis (Wang and Qiu, 2006). The benefits of the arbuscular mycorrhizae in various plants (mostly in crops) have been proven (Smith and Read, 2008). AMF increase plant resistance to abiotic stresses, improve mineral uptake (particularly of P), enhance water relations, and provide protection against soil-borne pathogens to promote plant growth (Smith and Read, 2008). On top of significantly aiding the P supply to plants, AMF can help plants acquire macronutrients and micronutrients like Cu, K, Mg, N, and Zn, especially when they're present in less soluble forms in soils (Meding and Zasoski, 2008; Smith and Read, 2008). These fungi penetrate the root cortical cell walls and establish arbuscules, which are haustoria-like structures, that mediate the metabolite exchanges between the host cell and the fungi (Oueslati, 2003). AMF enhance the root zone absorption area by 10–100% and improve the plant ability to utilize more soil resources. Mycorrhizal roots are able to reach a greater soil volume than non-mycorrhizal ones, thanks to the extraradical hyphae that facilitate the nutrient absorption and translocation (Smith and Read, 2008). AMF increase the nutrient absorption by increasing the absorption area of the roots, and also release chemicals such as glomalin, a glycoprotein secreted by hyphae and spores of AMF. Glomalin in the soil aids the uptake of nutrients such as Fe and P that are difficult to dissolve (Smith and Read, 2008; Miransari, 2010; Emran et al., 2017; Begum et al., 2019). P is easily absorbed from soil particles and therefore P_i -free zones are readily formed around the roots. Extraradical hyphae of the mycorrhizal roots extend beyond these P-depleted zones, taking up the bio-available P_i that is otherwise inaccessible to plants.

¹<http://www.amf-phylogeny.com>

The roots of arbuscular mycorrhizal plants have two pathways to absorb P. The first pathway is common to both arbuscular mycorrhizal plants and non-arbuscular mycorrhizal plants, where P is directly absorbed from the root epidermis and hairs. The second pathway involves P entering the root cortical cells (intraradical mycelium) (Smith and Smith, 2011), where symbiotic interfaces are provided by arbuscules or hyphal coils, through the fungal hyphae (P uptake from the interfacial apoplast by cell-specific Pi transporter gene expression in the mycorrhizal roots) (Benedetto et al., 2005; Balestrini et al., 2007; Gomez-Ariza et al., 2009; Tisserant et al., 2012; Fiorilli et al., 2013). This is a rapid P translocation over many centimeters. New physiological and molecular evidence suggests that for P, regardless of plant growth responses, the mycorrhizal pathway is operational (Smith and Smith, 2011). The function of the transporters and the translocation of Pi in the fungi and the transfer of Pi to the host plants have been well reviewed (Johri et al., 2015; Ezawa and Saito, 2018).

As mentioned above, the low solubility of P in acidic and alkaline soils (e.g., lower than 10 μM) results in a very low mobility (Schachtman et al., 1998). Therefore, when P is absorbed by the roots, its replacement from bulk soil is very slow, which leads to the establishment of P-depletion zones, where all the available P has been utilized quickly from around the roots, thereby reducing P uptake by the root epidermis hairs (the first pathway of P absorption) (Schachtman et al., 1998; Smith and Smith, 2011). Therefore, for improved P acquisition, plants must overcome these depletion areas and display root activities in other parts of the soil. The result of this effort for P (and other relatively immobile soil resources) acquisition is determined by the root system surface area. The most important role of the hyphae in mycorrhizal fungi is the increase of the root surface area (depletion is lower around small-diameter arbuscular mycorrhizal fungal hyphae) (Smith and Smith, 2011). In addition, mycorrhizal plants are able to exude organic acids such as citrate and malate that chelate Al^{3+} (Klugh and Cumming, 2007; Klugh-Stewart and Cumming, 2009) and Ca^{2+} and dissolve aluminum and calcium phosphates. By enhancing the soil contact area through AMF hyphae, plants are granted improved access to Pi and orthophosphates in the soil solution (Bouhraoua et al., 2015), as the roots are able to directly take up the released Pi with the help of arbuscular mycorrhizal fungal hyphae. Arbuscular mycorrhizal roots do not establish a fungal sheath, and theoretically are able to use both of the nutrient uptake pathways. It has been proposed that the two nutrient uptake pathways act additively in the arbuscular mycorrhizal symbiosis (Bücking et al., 2012). However, approximately 80% of P uptake in a mycorrhizal plant is estimated to be supplied by the fungi (Marschner and Dell, 1994). AMF also increase the ability of legumes to fix N_2 and reduce the amount of inorganic N that leaches (Veresoglou et al., 2012). Nitrogen is a component of chlorophyll and thus is important for photosynthesis. The transfer of photosynthetic materials to the roots results, in turn, in increased activity of soil microorganisms including AMF and PSB.

In general, AMF can increase P uptake in P-deficient soils by (i) increasing the P uptake rate (P influx) per unit of arbuscular

mycorrhizal root. This increased P uptake rate with AMF is due to the high effectiveness with which hyphal surfaces absorb P from the soil, compared to the cylindrical root surfaces (Sharif and Claassen, 2011); (ii) expanding the mycorrhizal hyphal network to reach beyond the rhizosphere, absorbing Pi by AMF hyphae via fungal Pi transporters up to 25 cm around the roots, translocating the Pi to intracellular fungal structures in the root cortical cells (Smith et al., 2011; Garg and Pandey, 2015); (iii) storing P in the form of polyphosphates, such that the fungi can keep the internal Pi levels relatively low, effectively transferring P from soil to plant-based hyphae through appressoria and from the extraradical mycelium to the intraradical mycelium (Pepe et al., 2020); (iv) having hyphae with a small diameter (2–20 μm) that allow the fungi to access small soil cores for P, and achieve greater P influx rates for a given surface area (Jakobsen et al., 1992; Jakobsen et al., 2001); and (v) decreasing the depletion zone around the roots or hyphae (decreasing the impact of rhizospheric Pi depletion) (Smith et al., 2011; Garg and Pandey, 2015). In one study, P depletion around the roots of *Capsicum annuum* L. plants or the hyphae of *Glomus mossea* only extended to about 0.06 cm and thus only ~7% of the soil P was positionally available to the roots. But for the hyphae it was ~100%, of the soil was positionally available because the half distance between neighboring hyphae was only 0.01 cm (Sharif and Claassen, 2011). As a general conclusion, the high effectiveness of hyphal surfaces to absorb P from soils may be enough in most cases to explain how AMF improve the uptake of available P from the soil.

PSB AND THEIR MECHANISMS OF P UPTAKE/MOBILIZATION

Rhizospheric P mineralization and solubilization are important mechanisms by which PSB increase the nutrient availability for plants (Glick, 2012). PSB play a major role in all three main parts of the soil P cycle (dissolution–precipitation, mineralization–immobilization, and sorption–desorption). There are various mechanisms by which PSB can change the insoluble phosphates into available forms (Gyaneshwar et al., 2002; Khan et al., 2007; Sharma et al., 2013; Etesami and Maheshwari, 2018; Etesami, 2020). PSB strains belong to various genera (e.g., *Achromobacter*, *Actinomadura*, *Aerobacter*, *Agrobacterium*, *Alcaligenes*, *Arthrobacter*, *Azotobacter*, *Azospirillum*, *Bacillus*, *Chryseobacterium*, *Delftia*, *Enterobacter*, *Gordonia*, *Klebsiella*, *Pantoea*, *Phyllobacterium*, *Pseudomonas*, *Rhizobium*, *Rhodococcus*, *Serratia*, *Streptomyces*, *Thiobacillus*, *Xanthobacter*, *Xanthomonas*) (Sharma et al., 2013; Etesami, 2020) and can solubilize insoluble Pi compounds including dicalcium phosphate, hydroxyapatite, tricalcium phosphate, and rock phosphate, and mineralize organic phosphate compounds to forms that can be absorbed by plants (i.e., H_2PO_4^- and HPO_4^{2-}) (Khan et al., 2009; Ramaekers et al., 2010; Alori et al., 2017; Etesami, 2020). Each phosphate-solubilizing bacterium may employ multiple mechanisms to solubilize insoluble P. Some of the most significant bacterial mechanisms that increases P availability for plants are briefly discussed in the following sections.

Production of Organic Acids

Most P uptake occurs in the pH range 6.5–7. However, because of equilibrium reactions such as sorption/desorption and the dissolution of P-bearing minerals are pH-dependent, PSB solubilize Pi in neutral to alkaline soils by excreting protons and producing organic and inorganic acids (Farhat et al., 2009; Jones and Oburger, 2011). NH_4^+ assimilation by plants and PSB leads to hydrogen ion (H^+) excretion to maintain electroneutrality (Parks et al., 1990; Wu et al., 2008). Organic acids (e.g., 2-ketogluconic, aspartic, citric, gluconic, lactic, malic, malonic, oxalic, succinic, and tartaric acid) are produced by bacterial metabolism, mainly due to oxidative respiration or carbon source fermentations, such as periplasmic glucose oxidizing into gluconic acid and being released into the soil solution, or the oxidation of organic matter or animal fertilizers added to the soil (Gyaneshwar et al., 2002; Trolove et al., 2003; Goldstein, 2007; Jones and Oburger, 2011). Organic acids can solubilize P from mineral surfaces via ligand-promoted dissolution or ligand exchange (Jones and Oburger, 2011; Oburger et al., 2011). In addition, PSB can indirectly reduce the pH of the rhizosphere and increase P levels by affecting the root system and, consequently, increasing the root exudates. Since root exudates contain different chelating agents and organic acids, they can increase the rhizospheric P availability. Organic acids (or organic anions) can enhance the rhizospheric P levels by lowering the pH, as PSB generally release the dissociated organic acids with protons, which allows them to preserve electroneutrality (Whitelaw et al., 1999; Castagno et al., 2011; Jones and Oburger, 2011). Organic acids compete with phosphates for fixation sites, or even replace the adsorbed phosphates on the soil clays surfaces, such as amorphous aluminum oxides, goethite, kaolinite, and montmorillonite. Chelating agents present in the root exudates (e.g., siderophores) can improve P availability to plants by promoting the chelation of P-bound Al^{3+} , Ca^{2+} , and Fe^{3+} , or establishing soluble complexes with metal ions associated with insoluble P, which circumvents Pi precipitation (Figure 1) (Whitelaw, 1999; Rashid et al., 2004; Osorio Vega, 2007). On the other hand, root exudates come from different carbon sources (e.g., amino acids, mucilage, nucleotides, organic acids, phyto-siderophores, sugars, and vitamins) and have different signals, which lead to the attraction of microbial flora at the root level, including PSB. Increases in the microbial population result in the production of more rhizospheric organic acid production and subsequently decreases the rhizospheric pH (Khan et al., 2007; Pothier et al., 2007; Badri and Vivanco, 2009; Drogue et al., 2013; Sharma et al., 2013; Etesami et al., 2015b; Etesami, 2020; Figure 1).

Production of Inorganic Acids

Mineral acids like carbonic acid (H_2CO_3), hydrochloric acid (HCl), nitric acid (HNO_3), and sulfuric acid (H_2SO_4), in addition to organic acids, have been reported to contribute to solubilizing insoluble Pi (Sharma et al., 2013). Sulfur-oxidizing bacteria (SOB) such as those belonging to the genus *Thiobacillus* and nitrifying bacteria (NB) like those belonging to the genera *Nitrosomonas* and *Nitrobacter*, oxidize sulfur and ammonia and

lead to the formation of inorganic acids and, consequently, reduce the pH, which ultimately increases the rhizospheric P availability (Stamford et al., 2003). SOB oxidize reduced sulfur compounds to produce sulfuric acid in the presence of oxygen to obtain energy while NB get their energy by oxidizing inorganic nitrogen compounds. Carbon dioxide (CO_2) resulting from microbial respiration and organic matter decomposition, after combining with water, becomes carbonic acid which can also reduce the rhizospheric pH and lead to increased P availability (Figure 1). In general, the role of inorganic acids in the solubilization of P is lower than that of organic acids and is less frequently reported. Since the ability of PSB to lower the pH in certain instances is not always associated with Pi solubilization ability, acidification cannot be the only mechanism for dissolving insoluble Pi (Bashan et al., 2013).

Siderophore Production

Plants and microorganisms in low-iron conditions produce siderophores which are low molecular weight (200–2000 Da) organic compounds with an iron-chelating ability (Ahmed and Holmström, 2014). The primary role of siderophores is to chelate Fe(III) under various environmental conditions making the element available to plants and microorganisms. Siderophores can bind to a variety of metals besides Fe(III) including Al, Ca, Cd, Co, Cu, Mn, Mo, Ni, Pb, and Zn, albeit with a lower affinity (Ahmed and Holmström, 2014). PSB have also been shown to be capable of producing siderophores (Vassilev et al., 2006; Caballero-Mellado et al., 2007; Hamdali et al., 2008; Karimzadeh et al., 2020) which can promote the dissolution of insoluble mineral P (Sharma et al., 2013). Siderophores can improve P availability for plants by ligand exchange and chelating the elements (e.g., Al^{3+} , Ca^{2+} , and Fe^{3+}) that form a complex with P (Figure 1).

Indole-3-Acetic Acid (IAA) and ACC-Deaminase Production

One mechanism that plants employ to deal with P deficiency is to allocate a large portion of the photosynthetic substrates to root growth, to develop fine roots with small diameters with greater surface area. Fine roots, especially root hairs, are associated with scavenging soil P with their high surface area (Rengel and Marschner, 2005). PGPB, including PSB, can improve a plant's P capturing capacity by promoting root growth through branching, hormonal stimulation, or root hair development (phytostimulation; e.g., production of IAA or enzymes that modify plant ethylene precursors, like 1-aminocyclopropane 1-carboxylic acid (ACC) deaminase) (Richardson et al., 2009; Hayat et al., 2010; Emami et al., 2019). A plant's response to P starvation stress can result in a decrease in the number of root hairs (Borch et al., 1999). The ACC deaminase enzyme can degrade the precursor for the ethylene production and influences how P affects the root growth; ethylene can adjust the root architectural response to soil P availability (Etesami and Maheshwari, 2018).

The abundance and length of the root hairs are positively correlated with the immobile element uptake. Modified root

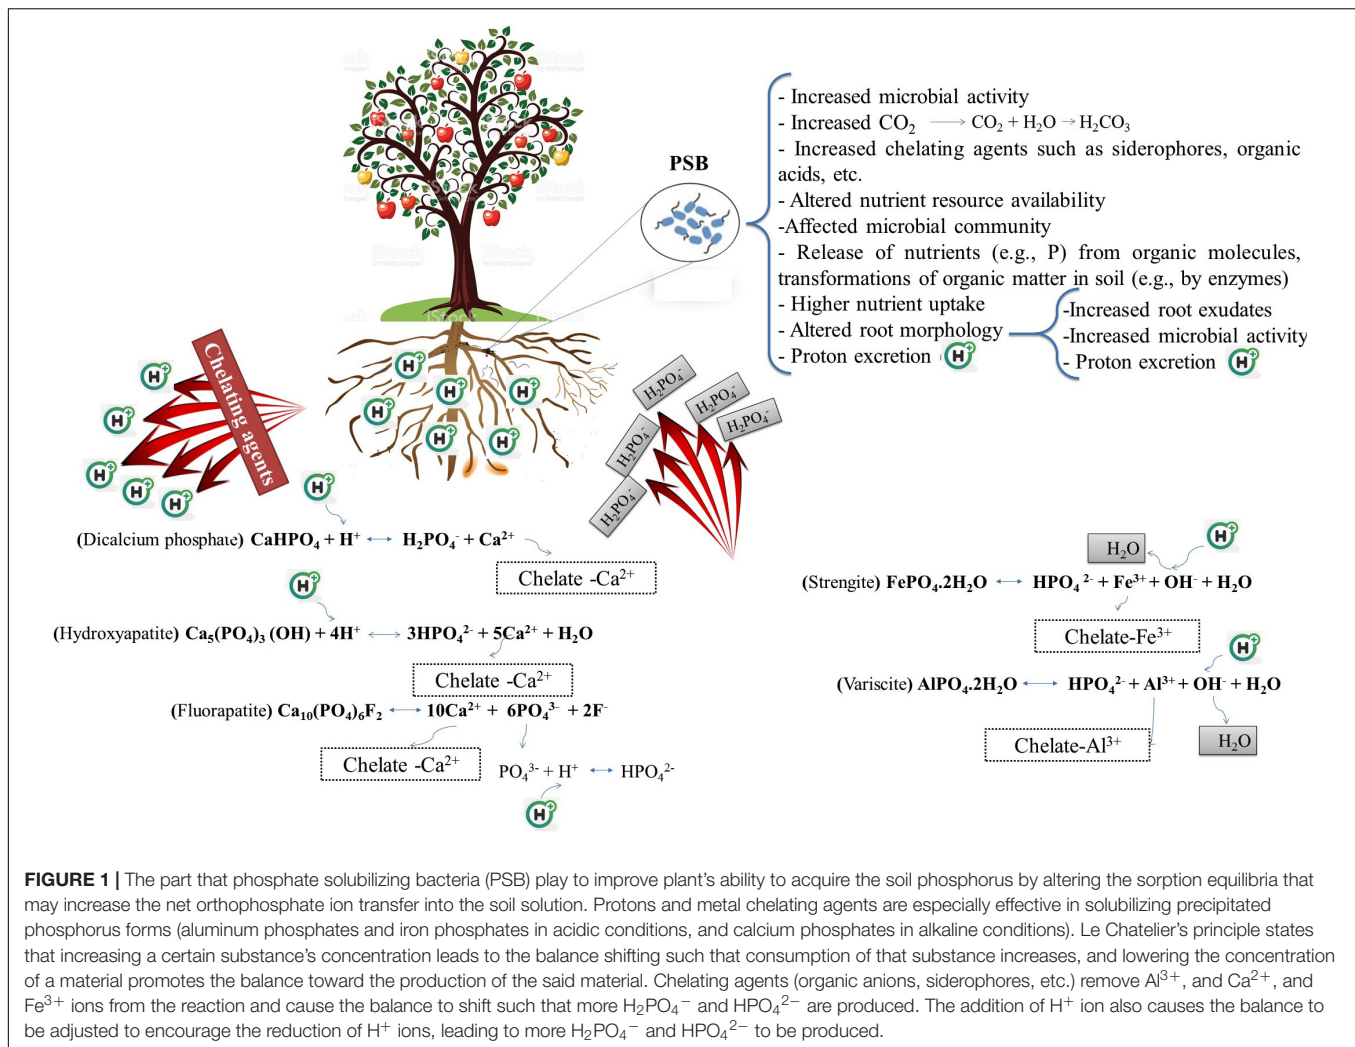

FIGURE 1 | The part that phosphate solubilizing bacteria (PSB) play to improve plant's ability to acquire the soil phosphorus by altering the sorption equilibria that may increase the net orthophosphate ion transfer into the soil solution. Protons and metal chelating agents are especially effective in solubilizing precipitated phosphorus forms (aluminum phosphates and iron phosphates in acidic conditions, and calcium phosphates in alkaline conditions). Le Chatelier's principle states that increasing a certain substance's concentration leads to the balance shifting such that consumption of that substance increases, and lowering the concentration of a material promotes the balance toward the production of the said material. Chelating agents (organic anions, siderophores, etc.) remove Al^{3+} , and Ca^{2+} , and Fe^{3+} ions from the reaction and cause the balance to shift such that more H_2PO_4^- and HPO_4^{2-} are produced. The addition of H^+ ion also causes the balance to be adjusted to encourage the reduction of H^+ ions, leading to more H_2PO_4^- and HPO_4^{2-} to be produced.

morphology of inoculated plants may enhance P uptake (Rengel and Marschner, 2005). Many PSB genera in soils are known to secrete IAA (Ahemad and Khan, 2010; He et al., 2010; Ahemad, 2012; Misra et al., 2012; Oves et al., 2013; Etesami and Alikhani, 2016a,b; Etesami and Maheshwari, 2018; Emami et al., 2019; Karimzadeh et al., 2020) that plant roots absorb, leading to increased endogenous pool of IAA in plants (Glick et al., 2007). In addition, many PSB are also reported to produce ACC deaminase (Iqbal et al., 2012; Sarathambal and Ilamurugu, 2013; Etesami et al., 2014; Shahzad et al., 2014; Etesami and Alikhani, 2016a; Karimzadeh et al., 2020).

Bacterial IAA can promote the development (architecture, branching, etc.) of the root system and increase root exudation. Organic acids in root exudates lead to rhizosphere acidification (Dakora and Phillips, 2002; Amir and Pineau, 2003; Jones et al., 2003) and also play an important part in forming and increasing the mobility of complexes with essential ions for plant uptake (Figure 1; Etesami et al., 2015a). For example, Hinsinger (2001) reported the role of exuded carboxylates in solubilizing various P complexes. Exuded organic acid anions may also be the growth substrates for microorganisms. Root exudates are

a more effective nutrient source than soil organic matter that are easily degradable for microorganisms in the rhizosphere (Rengel and Marschner, 2005).

The increase in CO_2 production from respiration of the rhizosphere microbial population leads to acidification of the rhizospheric environment. This can also lead to enhanced P availability, by increasing the release of new root extracts. Rhizospheric acidification also results from the H^+ pump from plant and microbe nutrient uptake, N_2 fixation by the symbiosis between *Rhizobium* and legume, and organic matter decomposition (Marschner and Rimmington, 1988). Certain microorganisms may indirectly enhance P nutrition for plants by enhancing root growth or root hair elongation, which allows for a greater degree of soil exploration instead of directly increasing soil P availability. IAA-producing PSB can also solubilize insoluble Pi in a manner similar to PSB by increasing the root surface area and subsequently increasing the root exudates (Dobbelaere et al., 1999; Lambrecht et al., 2000; Steenhoudt and Vanderleyden, 2000; Etesami and Maheshwari, 2018; Emami et al., 2019). In general, plant growth regulators influence root architecture and can increase P acquisition efficiency, especially

from unavailable forms, and for this purpose root traits are a key factor (Campos et al., 2018).

Organic P Mineralization

Organic P forms a significant part (40–80%) of the total soil P. Plants encountering P deficiency increase the exudation of P-hydrolyzing enzymes. In addition to dissolving phosphates affected by organic acids, the reactions of the phosphatase group of enzymes in the soil are also important. Phosphatases play a significant part in the organic P mineralization in soils. PSB can mineralize organic P by secreting phosphatases (Khan et al., 2009; Sharma et al., 2013; Etesami, 2020). Microbial-derived phosphatases are more likely to be combined with phosphate compounds than plant phosphatases are, and they help release orthophosphates from soil organic P (Tarafdar et al., 2001). Phytate (inositol hexaphosphate) is one of main soil organic P forms, accounting for over 50% of the total soil P (Osborne and Rengel, 2002). Phosphatases are not effective in mineralizing phytate. Phytase secreted by microorganisms converts phytate into P esters that can be broken down into Pi by phosphatases (Rengel and Marschner, 2005). Inorganic P immobilization by PSB can indirectly help P solubilization. PSB remove and assimilate P from the liquid culture medium according to the sink theory, activating the indirect dissolution of apatite or $\text{Ca}_3(\text{PO}_4)_2$ (Illmer et al., 1995; Guidry and Mackenzie, 2003). This can be explained according to Le Chatelier's principle, which states that lowering the concentration of Pi in soil solution promotes the balance toward the production of the Pi (e.g., release of Pi from calcium phosphates). Over a long period of time, all of the microbial P can potentially become available to plants. P immobilization in the biomass has been suggested to be an important mechanism for regulating P supply in a soil solution (Seeling and Zasoski, 1993), and for keeping labile P forms protected from reactions with the soil (Olander and Vitousek, 2004).

Si AND ITS ROLE IN P UPTAKE/MOBILIZATION

Elemental Si is the second most abundant element in the lithosphere (approximately 28%). Si dioxide (SiO_2) is the most common form of Si in soils. The main Si components in most soils includes amorphous silica, feldspars, kaolin, orthoclase, plagioclase, quartz, smectite, and vermiculite (Sahebi et al., 2015). Most Si contained in silicate minerals, and only a very small portion of the Si found in nature is available for use by plants (Struyf et al., 2010). The soluble Si is dependent on the pH and redox potential of the soil (Ma and Takahashi, 2002). In soils, Si is found as amorphous Si (minerogenic silica nodules, biogenic phytoliths, etc.), dissolved Si (adsorbed to aluminum or iron oxides/hydroxides or free in the soil solution), crystalline Si (primary silicates like feldspars, mica, quartz and secondary silicates like clay minerals), and poorly crystalline Si (e.g., secondary quartz) (Sauer et al., 2006). The soil soluble Si levels in ecosystems can differ up to two orders of magnitude (0.01–2.0 mM) (Haynes, 2014), and is mainly dependent on the parent

material, soil diagenesis stage, and vegetation type (Derry et al., 2005; Struyf and Conley, 2009).

Si is not identified as an essential nutrient for plant growth and development. However, an increasing number of studies indicate that Si is a quasi-essential nutrient and is beneficial to plants, especially when under different stresses such as drought, heavy metal toxicity, nutritional imbalance, plant pathogens, and salinity; Si is also known to play an important part in plant ecology and evolution (Etesami and Jeong, 2018). Plant roots absorb the Si present as silicic acid [$\text{Si}(\text{OH})_4$] at levels of 0.1–0.6 mM in the soil solution, and pass it through the plasma membrane via two Si transporters, *Lsi1* and *Lsi2*, that respectively function as the influx and efflux transporters and have been identified in barley, pumpkin, rice, and wheat (Ma et al., 2006, 2007; Chiba et al., 2009; Mitani-Ueno et al., 2011; Montpetit et al., 2012). Si is polymerized to silica gel ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$) in plants, generally referred to as silica bodies or phytoliths, which are released back into the soil as dead plant materials that decay and then may be taken up by plants (Carey and Fulweiler, 2012). Si is customarily found as hydrogen-bound bound organic Si complexes in plant tissues (Carlisle et al., 1977) and saturates the walls of the epidermis and vessels (Kaufman et al., 1969) where it strengthens plant tissues and reduces water transpiration.

Si levels in the aboveground plant parts differ greatly depending on the plant species, accounting for 0.1–10.0% of the dry weight, and are often at concentrations similar to that of essential macronutrients such as K, N, and P (Epstein, 1999). Plants take up Si actively via metabolically-driven transporters, or passively or rejectively, with water (Mitani and Ma, 2005). The disparity in the Si accumulation of different crop species is due to the difference in the Si absorbing capacity of the roots. Generally, monocots are considered good Si accumulators, where Si concentrations are greater than 1% of the dry weight, whereas most dicots accumulate Si at levels lower than 0.1% of the total biomass and are considered excluders (Guntzer et al., 2012).

Si also influences the uptake of micronutrients and macronutrients in plants (Etesami and Jeong, 2018; Greger et al., 2018). Si fertilization increases P levels in different crops and improves plant growth by enhancing P availability for plants (Gladkova, 1982; Jianfeng and Takahashi, 1991; Singh and Sarkar, 1992; Owino-Gerroh and Gascho, 2005; Kostic et al., 2017; Neu et al., 2017; Reithmaier et al., 2017; Etesami and Jeong, 2018; Rezakhani et al., 2019a,b; Schaller et al., 2019). For example, Greger et al. (2018) found that Si increased the soil P availability by up to 50%. Kostic et al. (2017) also observed that Si supplied as Na_2SiO_3 increased P levels in the shoots of wheat grown in low P acid soil (available P < 4 mg kg⁻¹ and pH 4.0) to an adequate level (>0.3%) in the range of P-fertilized wheat under greenhouse conditions. In this study, Si application increased the root organic acid exudation, such as malate and citrate that mobilize the rhizospheric Pi and up-regulate expression of Pi transporters (*TaPHT1.1* and *TaPHT1.2*). This organic acid exudation by the wheat roots was many times higher than without Si application, and the P uptake was doubled. There is insufficient data regarding the effect of exogenous Si on organic acid production in plants. In a recent study, it was found that Si can alter organic acid production in plants by increasing carbon

fluxes into TCA cycle and the activity of TCA cycle enzymes (Das et al., 2019). However, further work is needed to elucidate how Si modulates organic acid metabolism in plants under P deficit conditions.

Much remains to be investigated on how Si interferes with soil P mobilization. Some mechanisms by which Si improves soil P availability and plant P uptake are as follows: (i) competitive exchange and sorptive interaction of P and Si (Smyth and Sanchez, 1980; Koski-Vähälä et al., 2001; Owino-Gerroh and Gascho, 2005; Konhauser et al., 2007; Planavsky et al., 2010). P binding to soil minerals was observed to be the lowest with silicate minerals (Rajan, 1975; Brady and Weil, 1999); (ii) increasing the soil pH to enhance soil P availability in acidic soils (Owino-Gerroh and Gascho, 2005); (iii) indirectly improving P utilization by plants by decreasing the uptake and availability of metals (Hingston, 1972; Sigg and Stumm, 1981; Schwertmann and Fechter, 1982; Ma and Takahashi, 1990). P availability is controlled by levels of other metals such as Fe and Mn under P deficiency. A large proportion of soil Pi is strongly bound/adsorbed to aluminum, iron and manganese hydroxides in the soil (Beauchemin et al., 2003). Si decreases the iron and manganese availability in soil by affecting the element binding to the soil particles (Schaller et al., 2019) and reducing the pool of hydroxides (Treder and Cieslinski, 2005; Meharg and Meharg, 2015) and can therefore indirectly increase P availability (Ma, 2004; Greger et al., 2018). Si may increase P availability for plants even in high P conditions by mobilizing P from such mineral surfaces (e.g., aluminum, iron and manganese hydroxides) (Cross and Schlesinger, 1995; Yang and Post, 2011); (iv) modifying the C:N:P stoichiometry and improving the nutrient use efficiency (Neu et al., 2017); (v) increasing the root organic anion efflux to mobilize the rhizospheric Pi (Kostic et al., 2017; Etesami and Jeong, 2018). Si significantly increased the exudation rates of citrate and malate to directly stimulate inorganic P acquisition by the roots (Kostic et al., 2017). Organic anions such as acetic, aconitic, citric, malic, fumaric, lactic, oxalic, and succinic acids compete with Pi to form complexes with aluminum, calcium, and iron and may hydrolyze organic P (Grierson, 1992; Gerke et al., 2000; Hinsinger, 2001; Kihara et al., 2003; Aziz et al., 2011; Etesami and Jeong, 2018). Organic acids like malic and citric acids were observed to reduce the pH and result in a substantially increased P mobilization from calcium compounds (Dinkelaker and Marschner, 1992) and effectively enhanced P uptake from sparingly soluble rock phosphates (Aziz et al., 2011); (vi) enhancing the gene expressions related to Pi uptake under P deficiency, which is key to improving the Pi absorption in different plant species (Leggiewie et al., 1997; Karthikeyan et al., 2002; Tittarelli et al., 2007; Miao et al., 2009; Kostic et al., 2017). The P use efficiency of plants under P deficiency could be improved with manipulation of gene expressions related to Pi uptake (Aziz et al., 2014). A number of genes are involved with plant adaptation to P deficiency, associated with regulating the acquisition, internal remobilization of P, and changing the metabolism as well as signaling transduction (Fang et al., 2009). Si has been observed to modulate the expression of stress-related genes and alter plant metabolism in response to various plant stresses (Pavlovic et al., 2013; Ye et al., 2013; Kim et al., 2014;

Kostic et al., 2017); and (vii) mobilizing or desorbing of organic carbon from soil particles or mineral binding sites (e.g., goethite) (Tipping, 1981; Reithmaier et al., 2017). Si has a strong bonding affinity to minerals in the soil comparable with carbon and P, and may mobilize the two elements and make them more available for microbial decomposition (Schaller et al., 2019). The released carbon can supply the microorganisms, including PSB, with energy for their growth in soils. The carbon dioxide produced by microbial respiration results in the production of carbonic acid, leading to increased P availability. Microbial respiration was observed to lower the soil pH by producing carbonic acid, and thus led to dissolution of apatite as Pi (Guidry and Mackenzie, 2003). How the Si availability in soils interacts with P availability in soils is generally poorly understood and requires further research.

SYNERGISTIC EFFECTS OF AMF, PSB, AND Si ON P AVAILABILITY

Synergistic Effects of AMF and PSB on P Availability

In mycorrhizal association, the plant and fungi interact both in the soil around the root (rhizosphere) and in soil around the fungal hyphae (mycorrhizosphere) (Johansson et al., 2004). The fungi interact with other microorganisms in the mycorrhizosphere whose synergistic effects increase plant growth and also populations of both (Artursson et al., 2006; Agnolucci et al., 2015). The presence of different bacterial taxa that colonized the surface of AM extraradical hyphae and spores that form biofilm-like structures on them has been reported in natural ecosystems (Scheublin et al., 2010; Lecomte et al., 2011; Cruz and Ishii, 2012; Agnolucci et al., 2015; Iffis et al., 2016). There may exist cooperation between AMF and the associated bacteria, such as PSB (Zhang et al., 2016). PSB may provide the hyphae with Pi and rely on the carbon released by AMF. Earlier research demonstrated that AMF and PSB may enhance P acquisition of the AM host plant through their interactions (Kim et al., 1997; Toro et al., 1997; Sharma et al., 2013; Calvo et al., 2014; **Figure 2**). However, the mechanisms by which this nutritional improvement is brought about remain unclear (Artursson et al., 2006). In the following sections, what is currently known of how AMF and PSB influence each other and, consequently, increase P availability, are discussed separately.

Effects of PSB on AMF and AMF-Mediated P Availability

Effect of PSB on solubilizing insoluble phosphates

The phosphate-solubilizing activities of AMF are still controversial although AM plants have generally been shown to increase the uptake of insoluble Pi (Yao et al., 2001; Klugh-Stewart and Cumming, 2009; Campos et al., 2018). In many studies, mycorrhizal inoculants were observed to alter the composition and/or amount of total low molecular weight organic acids (LMWOAs) exuded by AM plants (Klugh and Cumming, 2007; Klugh-Stewart and Cumming, 2009). However,

direct evidence for solubilization of P by AM fungi has not been obtained to date. Despite the fact that AM fungi might not exude LMWOAAs by themselves, they can, however, improve P solubilization and/or mineralization indirectly by stimulating the surrounding soil microbes via the exudation of labile C, thus increasing local nutrient availability in the hyphosphere and in soil patches beyond the root hairs (Hodge et al., 2009; Cheng et al., 2012; Jansa et al., 2013).

PSB solubilize phosphates and release P_i ions from the sparingly soluble organic/inorganic P compounds found in nature into a form that AMF can acquire and deliver to the plant (Toro et al., 1997, 1998; Ordoñez et al., 2016). ^{32}P -Labeling

studies have shown that mycorrhiza increase the absorptive root surface areas to facilitate P uptake, but do not help in P solubilization (Gaur, 2003). In another ^{32}P -labeling study, seven bacterial strains isolated from AMF spores facilitated P uptake by promoting the development of AM extraradical mycelium (Battini et al., 2017).

Arbuscular mycorrhizal fungi cannot extract P on their own from indigenous less-available forms of P sources, such as rock phosphates, and can only absorb P_i ions from the soil solution (Antunes et al., 2007). However, with the help of certain bacteria (Villegas and Fortin, 2001) AMF can acquire P from rock phosphates and translocate it to the host plant.

AMF were able to acquire P from sources that were otherwise inaccessible with the help of PSB (Toro et al., 1997). These interactions can also indirectly benefit plants; *Medicago sativa* shoot P concentrations were observed to be improved (Zhang et al., 2016). The interaction between the two microorganism groups may lead to synergistic effects. It has been found that the AMF-PSB interactions only benefit plants when additional P was also supplied (Zhang et al., 2016). Zhang et al. (2014a) showed that P concentrations available in the soil regulate P mobilization and immobilization to determine the bacterial P contribution to plants. In general, when the available P level is low in soils, AMF and PSB compete for the P, and this competition is not stimulated by the fungi. With additional P supply, PSB improved the AMF hyphal growth, and the PSB activities were stimulated by the fungi (Zhang et al., 2016).

Effect of PSB on mineralizing organic P

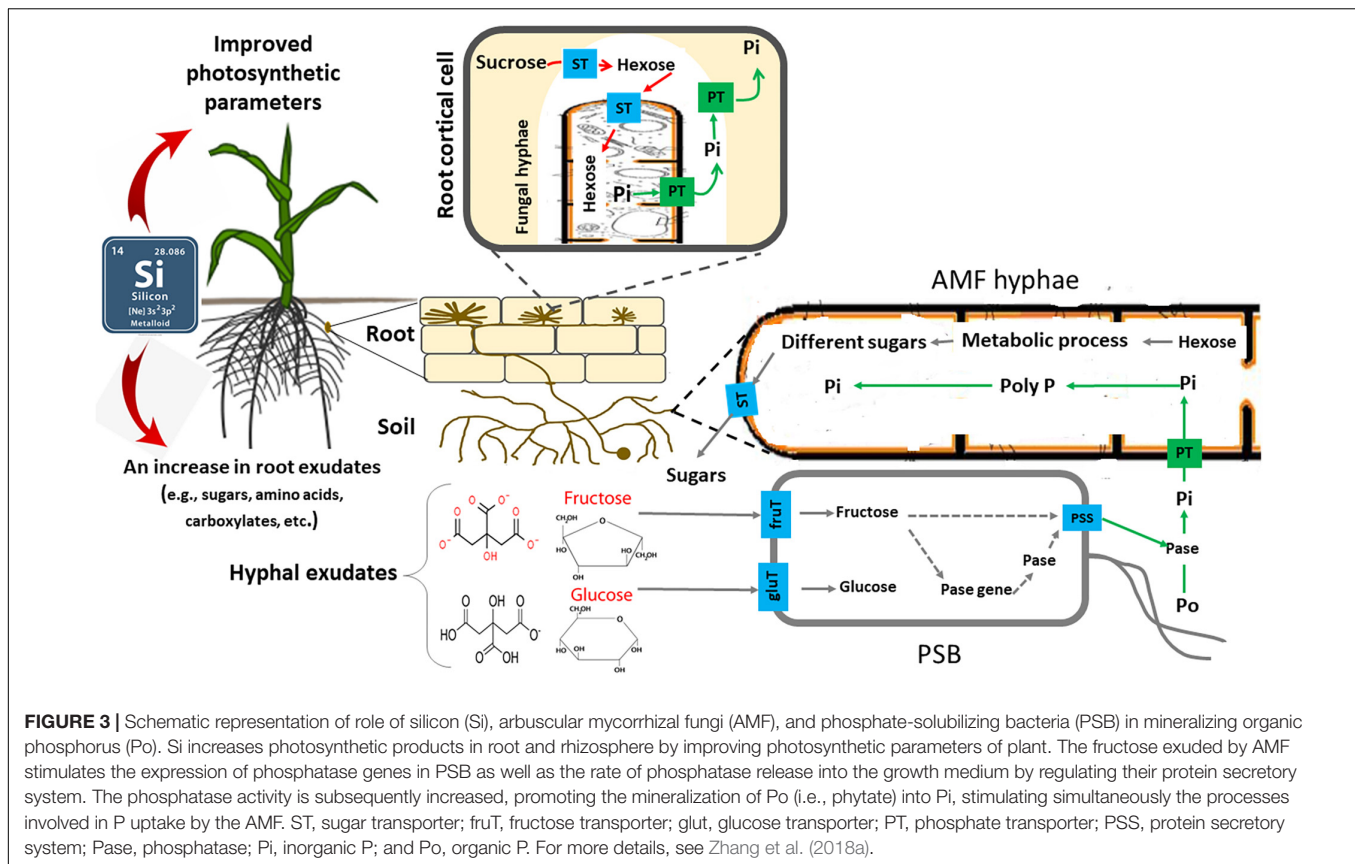

During evolution with plants, AMF have lost the genes encoding proteins involved in saprotrophic function (Tisserant et al., 2013), which means that they cannot directly breakdown soil organic matter (Leigh et al., 2011; Zhang et al., 2014b). PSB can increase the AMF hyphal growth by hydrolyzing organic P with secretion of the phosphatases and phytases and providing mineral P to the fungi (Dobbelaere et al., 2003; Wang et al., 2016; Zhang et al., 2016). It has been reported that AMF cannot secrete phosphatases (Tisserant et al., 2013) and directly decompose organic nutrients (Smith and Read, 2008; Tisserant et al., 2013). AM fungi possess many genes encoding acid phosphatases in their genomes, with at least seven genes expressed in *Rhizophagus clarus* (Sato et al., 2015). However, secretion of phosphatases is mostly associated with the cell wall (Olsson et al., 2002) and their presence in the rhizosphere has been demonstrated only in limited cases (Tarafdar and Marschner, 1994; Koide and Kabir, 2000). The magnitude of these processes is questioned as it is difficult to isolate the effects of plants, fungi and others microorganisms present in the experiments under non-sterile conditions (Joner and Jakobsen, 1995; Joner et al., 2000). In an *in vitro* monoxenic culture, Sato et al. (2015) provided evidence that the acid phosphatase activity originated from *R. clarus*. Nevertheless, the interaction of AM association with the phosphatase activity and the subsequent P acquisition by efficient genotypes is still unclear (Campos et al., 2018).

Because AMF are unable to release phosphatases outside the hyphae, AMF's organic P utilization appears to depend on the recruitment of other soil microbes (Tisserant et al., 2013; Zhang et al., 2016). The microbiome associated with the hyphae may play a key role in AMF's utilization of organic P. AMF may shift the microbiome composition to influence organic P mineralization (Zhang et al., 2016, 2018b). Importantly, AMF hyphae seem to specifically recruit bacteria that produce alkaline phosphatase which can mineralize organic P; these species are not found when AMF is excluded (Zhang et al., 2018b). Despite the fact that a major AMF function is to increase P availability to plants (Smith and Read, 2008), AMF cannot release phosphatases into the soil (Tisserant et al., 2013; Zhang et al., 2016). In a study under controlled, sterile conditions, the AMF *Rhizophagus irregularis* DAOM 197198 released carbon-rich compounds to

stimulate PSB functions, but did not directly influence the phosphatase activities (Zhang et al., 2016). Thus, AMF cannot directly utilize organic P, which limits its contribution to plant uptake of P. PSB accounts for up to 40% of all culturable bacteria (Jorquera et al., 2008) and can make up for this defect in AMF. This suggests that AMF and PSB need to interact to help plants uptake P (Zhang et al., 2018b). Recent results demonstrate that the AMF hyphal surfaces are colonized by PSB and the hyphal exudates are utilized as a carbon source (Wang et al., 2016). In other words, AMF can attract PSB and help them multiply to improve the organic P utilization by releasing hyphal exudates and providing a carbon source (Zhang et al., 2014b, 2016; Wang et al., 2016). PSB can then colonize the AMF hyphal surfaces (Wang et al., 2016). This enhances the activities of the phosphatases released by the PSB, and stimulates the organic P mineralization (Zhang et al., 2016). The extraradical AMF hyphae can then access Pi released from organic P sources (Tarafdar and Marschner, 1994; Feng et al., 2003). In addition, AMF hyphae-associated PSB in the soil play an important role in phytate P mineralization and that the AMF primes the mineralization and turnover of the organic P (organic P utilization affected by the AMF-bacteria interaction) (Zhang et al., 2014b). For example, in a recent study Zhang et al. (2018a) observed that fructose exuded by an arbuscular mycorrhizal fungus, *Rhizophagus irregularis*, stimulated the expression of phosphatase genes in a phosphate solubilizing bacterium, *Rahnella aquatilis*, as well as the rate of phosphatase release into the growth medium by regulating its protein secretory system. The phosphatase activity was also subsequently increased, promoting the mineralization of organic P (i.e., phytate) into Pi, stimulating simultaneously the processes involved in P uptake by *Rh. irregularis*. In general, PSB can increase P availability for AMF, especially from organic P sources, which may increase the expression of Pi transporter genes in the AMF hyphae (Zhang et al., 2016; **Figure 3**).

Effect of PSB on arbuscular mycorrhizal symbiosis

Bacteria are known to influence AMF fitness (Frey-Klett et al., 2007; Scheublin et al., 2010; Nuccio et al., 2013) and ecological functions (Hodge et al., 2001; Feng et al., 2003; Cheng et al., 2012; Zhang et al., 2014b). PSB can lead to increased plant growth parameters by stimulating the native AMF's establishment, growth rate, multiplication, and spore germination (Barea et al., 2002; Bianciotto and Bonfante, 2002; Artursson et al., 2006; Frey-Klett et al., 2007; Berta et al., 2014). PSB can promote AMF extraradical hyphal growth and allow PSB to explore a greater volume of the mycorrhizosphere and AMF hyphae to gain access to new solubilized P sources (Ordoñez et al., 2016). Increased mycelial growth of *Glomus mosseae* spores, for example, was reported to be caused by an unidentified PGP rhizobacterium (Azcón, 1987). These bacteria also helped mycorrhiza by promoting root colonization by indigenous and introduced AMF (Toro et al., 1997). Bacteria can promote hyphal growth and facilitate root penetration by AMF via producing compounds that increase cell penetrability and result in increased root exudation rates (Hildebrandt et al., 2002; Jeffries et al., 2003; Jäderlund et al., 2008). Following hyphal growth, the rates of root colonization and AMF development also increase

(Barea et al., 2005; Richardson et al., 2009). Bacterial IAA is known to be able to loosen plant cell walls and therefore promote root exudation which supplies additional nutrition that can support microbial growth (Chaintreuil et al., 2000; Sevilla et al., 2001; James et al., 2002; Chi et al., 2005). One of components of root exudates is enzymes such as amylase, DNase, phosphatase, polygalacturonase, protease, RNase, sucrase, urease, and xylanase that can play a role in organic P mineralization, decomposition of other organic compounds, and release of mineral elements (Ahemad and Kibret, 2014; Canarini et al., 2019), and, therefore, provide mineral P and other elements for the AMF. It is well established that bacterial IAA increases the ability of plants to convert nutrients from non-available forms to available forms by increasing the root system, root discharge and microbial flora (Etesami et al., 2015b). Bacteria IAA-mediated release of root exudates can enhance P mobility for plants and AMF by releasing protons (H^+) or by forming amino/organic acid mineral complexes (by chelation of cations accompanying P e.g., Fe^{3+} , Al^{3+} , and Ca^{2+}), and indirectly (as a source of nutrients for microorganisms) by stimulating the microbial activities in the rhizosphere (functioning, growth, propagation, survival) (Etesami et al., 2015b). The increased soil saprobic microbial populations mediated by root exudates can, in turn, improve N availability for AMF through organic matter decomposition (Leigh et al., 2011; Herman et al., 2012; Nuccio et al., 2013). Other microorganisms attracted to root exudates stimulate hyphal growth, mycorrhizal colonization, and spore

production, thereby increasing AMF fitness (Frey-Klett et al., 2007). Flavonoids are the main signaling compounds that are isolated from plant root exudates, and it's been suggested that they play a distinct role in the AM development. Different flavonoids affect the growth and differentiation of the hyphae as well as root colonization in a structure-specific manner. Flavonoids also influence presymbiotic growth differently according to the genus and species. Furthermore, it has also been proposed that some of the so-called mycorrhiza helper bacteria that promote mycorrhiza formation induce flavonoid release from plants, and facilitate root colonization by mycorrhizal plants (Schrey et al., 2014). A number of studies have demonstrated that the IAA-secretion induced stimulation of root hair growth and lateral root elongation supplies more active sites and access for symbiotic AMF and PSB associations (Aarab et al., 2015; Etesami et al., 2015b). Therefore, it seems that PSB (IAA positive) stimulate root hair elongation to improve root weight and architecture, and therefore potentially improve mycorrhizal formation. Previous studies have shown that PGPB modify hormonal signaling in plants to influence root architecture, stimulate the growth of the shoots and roots, and increase essential nutrient uptake (Appanna, 2007; Bhattacharyya and Jha, 2012). AMF-induced plant growth is in part attributed to modified plant hormone level (Bi et al., 2019; Wang et al., 2021).

The relationship between the AMF and host roots is complex and requires a continuous exchange of signals which leads to a developmental coexistence (Gianinazzi-Pearson, 1996;

Hause and Fester, 2005). Phytohormones are the signals that regulate various plant growth processes and can therefore manage colonization and AM symbiosis formation (Barker and Tagu, 2000; Ludwig-Müller and Güther, 2007; Foo et al., 2013; Gutjahr, 2014). For example, bacterial IAA may increase the number of lateral roots for fungi to colonize in early growth stages to facilitate host colonization (Kaldorf and Ludwig-Müller, 2000). Increased IAA levels and IAA-induced gene expressions have been suggested to contribute to phenotypic changes during mycorrhizal colonization (Ludwig-Müller and Güther, 2007). Fungi may use IAA and the related compounds as a colonization strategy to interact with plants, stimulating plant growth and modifying basal plant defense mechanisms (Prusty et al., 2004; Contreras-Cornejo et al., 2009). Generally, the increased levels of IAA result in more lateral roots that form the preferred penetration sites for the AM hyphae.

Abscissic acid (ABA) is a sesquiterpenoid hormone, derived from carotenoids, which functions at multiple levels to regulate AM symbiosis (Ludwig-Müller, 2010). ABA deficiency also results in the induction of ethylene production, which adversely affects mycorrhizal interaction with plants (Herrera-Medina et al., 2007; Martín-Rodríguez et al., 2011). The synthesis of ACC deaminase produced by PSB lowers the stress ethylene levels associated with stimulating AMF growth (Gamalero et al., 2008; Etesami et al., 2015b).

In addition, gibberellins (GAs), key regulators of plant growth and development, play a role during arbuscular mycorrhizal (AM) formation (Foo et al., 2013; Martín-Rodríguez et al., 2015, 2016; Foo et al., 2016; Pons et al., 2020). GAs inhibit arbuscular mycorrhizal symbioses (McGuinness et al., 2019) by altering GA response changes in the expression of genes associated with mycorrhizal colonization (Martín-Rodríguez et al., 2015), inhibiting AM hyphal entry into the host root, and suppressing the expression of reduced arbuscular mycorrhization1 (RAM1) and RAM2 homologs that function in hyphal entry and arbuscule formation (Takeda et al., 2015). The balance between ABA and GAs is also essential for AM formation in plant roots (Martín-Rodríguez et al., 2016; McGuinness et al., 2019) as the imbalance in the ABA/GAs ratio can reduce arbuscule abundance in mycorrhizal roots (Martín-Rodríguez et al., 2015). In addition, GA signaling also positively interacts with symbiotic responses and promotes AM colonization of the host root. For example, in one study (Takeda et al., 2015), low GA conditions suppressed arbuscular mycorrhiza-induced subtilisin-like serine protease1 (SbtM1) expression, which is required for AM fungal colonization and reduced hyphal branching in the host root. In this study, the reduced hyphal branching and SbtM1 expression due to the inhibition of GA biosynthesis were recovered by GA treatment, supporting the theory that insufficient GA signaling causes inhibitory effects on arbuscular mycorrhiza development. Accordingly, it seems that PSB positive for ABA and GA-producing traits can regulate the level of production of these hormones in the plant and lead to improved arbuscular mycorrhizal symbioses. The ability to produce GAs in some bacteria has been reported (Hamayun et al., 2010; Kang et al., 2012; Tatsukami and Ueda, 2016; Etesami and Glick, 2020).

However, it is not yet clear if mycorrhizal fungi produce GA. Therefore, the presence of such bacteria is necessary to improve mycorrhizal symbioses.

Effects of AMF on PSB and PSB-Mediated P Availability

Mycorrhizae affect both the composition and number of the rhizospheric and hyphospheric bacterial communities (Offre et al., 2007; Agnolucci et al., 2015; Taktek et al., 2015), as well as bacterial communities of the surface of the AMF hyphae or mycelium closely attached to the soil (Zhang et al., 2014b; Turrini et al., 2018). AMF result in the establishment of an extensive soil hyphal network, creating a dedicated niche for bacteria (Bianciotto and Bonfante, 2002; Agnolucci et al., 2015). In the cytoplasm of some AMF isolates belonging to the Gigasporaceae family endophytic bacteria are found, which is a case where bacteria coexist with fungi (Turrini et al., 2018). The bacterial colonization of the AMF hyphal and spore surfaces has been confirmed with molecular and microscopic analyses and illustrates the existence of a close relationship between the two microorganism groups (Toljander et al., 2006; Bharadwaj et al., 2008; Scheublin et al., 2010; Agnolucci et al., 2015). Similar to roots, AMF hyphae are rapid channels for photosynthates and release carbon-rich compounds into the soil (Toljander et al., 2007; Bharadwaj et al., 2012) and can stimulate microbial growth and function (Drigo et al., 2010; Leigh et al., 2011; Blagodatskaya and Kuzyakov, 2013; Kaiser et al., 2015; Zhang et al., 2016). The root exudates are a major nutrient source for the rhizospheric PSB, and its chemical composition may be influenced by the AMF (Artursson et al., 2006). Furthermore, the extensive extraradical AMF hyphae and the exudates create conditions that can influence bacterial activities and growth (Toljander et al., 2007; Bharadwaj et al., 2012; Gahan and Schmalenberger, 2015) including PSB (Taktek et al., 2015; Ordoñez et al., 2016; Wang et al., 2016; Turrini et al., 2018). The changes in the soil bacterial community composition induced by AMF are described, both under *in vivo* and controlled conditions (Marschner et al., 2001; Toljander et al., 2006, 2007).

Arbuscular mycorrhizal fungi enhance the chlorophyll content, PSII photochemical efficiency, and net photosynthetic rate of plants (Wu and Xia, 2006; Zhu et al., 2014; Augé et al., 2016; Shi-Chu et al., 2019) and also transfer plant photosynthates underground, which can stimulate PSB activity and growth (Zhang et al., 2016) as most PSB are heterotrophic and depend on nutrient substrates that can be easily decomposed. AMF hyphae are also rapid channels for the recently produced photosynthates, which can attract PSB and promote their growth (Kaiser et al., 2015). In addition, it has been found that the availability of easily decomposable organic compounds limits microbial P solubilization in soil extracts from phosphate minerals (Brucker and Spohn, 2019; Brucker et al., 2020). Saprotrophic phosphate solubilizing microorganisms in mineral soils generally lack sufficient carbon (Demoling et al., 2007; Heuck et al., 2015) because most organic carbon in soils is protected from sorptive or recalcitrant microbial decomposition or is simply spatially inaccessible (De Nobili et al., 2001; Dungait et al., 2012). Accordingly, increased microbial P solubilization rates are

reported when carbon sources become available (Hameeda et al., 2006; Patel et al., 2008).

Arbuscular mycorrhizal fungi generate a vast extraradical hyphae in the soil that microorganisms can inhabit (Gahan and Schmalenberger, 2015). PSB can grow alongside AMF hyphae in and out of the root, in sterile conditions as well as with an indigenous microbial community (Ordoñez et al., 2016), demonstrating the close relationship of AMF and PSB (Scheublin et al., 2010; Agnolucci et al., 2015). This may help PSB to use the hyphae to access areas further away in the soil to acquire insoluble P. By developing an external mycelium, AMF, upon root colonization, connect the root with the surrounding soil microhabitats and can contribute to nutrient capture and supply (Toro et al., 1997). The PSB can also use the AMF hyphae to allow growth in the direction toward the plant, colonize the rhizosphere, and use more plant exudates (Ordoñez et al., 2016).

Phosphate-solubilizing bacteria attachment to the extraradical AMF hyphae can ensure that P solubilization would occur in locations where it is the most beneficial for fungi to access the additional soluble P. The phosphate solubilized by AMF and PSB is effectively absorbed by plants through a channel formed by the mycorrhiza between plant roots and the surrounding soil (Artursson et al., 2006).

Since the mobilized orthophosphates can quickly be immobilized by microbial biomass, AMF can absorb and transfer the nutrients to the roots through their effective mycorrhizal mycelium, and reach microhabitats where orthophosphates are made available by P-mobilizing microorganisms (Richardson et al., 2009). AMF cannot directly decompose organic nutrients, as they have no known saprotrophic capabilities (Smith and Read, 2008; Tisserant et al., 2013). AMF can also increase the soil saprobic microbe activities, including those of PSB. These bacteria can decompose organic matter and in turn also improve the N and P availability for AMF and plants (Leigh et al., 2011; Herman et al., 2012; Nuccio et al., 2013). Previously, Linderman (1992) reported that AMF enhance the activity of nitrogen-fixing bacteria (NFB) and PSB and thus promote plant growth. PSB can also release different enzymes to decompose the organic matter, and can provide mineral nutrients for the AMF hyphae (Hodge and Fitter, 2010; Hodge, 2014; Zhang et al., 2014b). Therefore, in exchange for using the carbon released by the AMF, these microbes can provide additional benefits to the fungi. AMF and PSB may obtain their required nutrients from their partners and enhance their own fitness through cooperation. By increasing the root surface areas for nutrient acquisition, or through more specific mechanisms, AMF can also help plants resist abiotic and biotic stresses (Artursson et al., 2006; Miransari, 2010; Sikes, 2010; Mohammad and Mittra, 2013). PSB solubilize phosphates into forms that are usable by the AMF, and AMF can absorb the P and transport it to the plant using a range of mechanisms. AMF may also help spread PSB to neighboring rhizospheres. Therefore, AMF and PSB interact synergistically.

AMF Increase Si Uptake by Plants

The benefits of Si nutrition, although significant, are limited due to its restricted uptake by plant (Anda et al., 2016). However, AMF such as *Glomus etunicatum*, *G. versiform*, *G. coronatum*,

Rhizophagus clarus (= *Glomus clarum*), *Rhizophagus irregularis* (= *Glomus intraradices*), and *Funneliformis mosseae* (= *Glomus mosseae*) were observed to increase Si uptake in the roots and shoots of mycorrhizal plants (i.e., *Saccharum* spp., *Glycine max* L., *Zea mays* L., *Cajanus cajan* L., *Cicer arietinum* L., strawberry, and banana) compared to non-mycorrhizal plants (Yost and Fox, 1982; Kothari et al., 1990; Clark and Zeto, 1996; Clark and Zeto, 2000; Nogueira et al., 2002; Hammer et al., 2011; Garg and Singla, 2015; Anda et al., 2016; Garg and Bhandari, 2016a,b; Frew et al., 2017; Garg and Singh, 2018; Hajiboland et al., 2018; Gbongue et al., 2019; Moradtalab et al., 2019). AMF play a substantial role in Si uptake, translocation from the external solution to the intraradical mycelium, and transfer from the fungal cells to the root cells. The mechanisms remain unclear but it is not excluded that active transport is involved via transporters located within the extraradical hyphae at the soil-fungus interface for the uptake of Si and at the plant-fungal interface (i.e., arbuscule) for its transfer across the peri-arbuscular interface in the plant cells (Yost and Fox, 1982; Hammer et al., 2011; Anda et al., 2016; Garg and Bhandari, 2016b). These studies highlight the importance of AMF inoculation as tools to effectively enhance Si uptake by plants. Therefore, it would be of great interest to investigate how AM symbiosis enhances the host plant uptake of Si and how AM symbiosis and Si uptake help to improve P nutrition and plant growth.

Si Increases Mycorrhizal Effectiveness in Plants

Mycorrhizal effectiveness (or responsiveness of plants to mycorrhizae) is defined as the difference in the growth of plants with and without mycorrhizae (Janos, 2007). Mycorrhizal effectiveness is influenced by different factors like fungal species, plant species and genotype, and soil conditions (Tawaraya, 2003). Compared to the studies widely performed on the effects of P availability as a soil chemical factor on the mycorrhizal effectiveness, research on how Si affects mycorrhizal effectiveness are lacking. However, in two recent studies (Hajiboland et al., 2018; Moradtalab et al., 2019), mycorrhizal effectiveness was increased with Si treatments in strawberry plants inoculated with AMF *Rhizophagus clarus*, *Rhizophagus intraradices*, and *Glomus versiform* compared to AMF plants not treated with Si. Some known mechanisms by which Si benefits the AMF effectiveness include: (i) enhancing the uptake and transfer of nutrients for plants and stimulating the root growth in AMF plants, which can lead to promoted AMF colonization (Hajiboland et al., 2018); (ii) increasing the photosynthetic rate such that the fungal partner is able to receive a greater carbon supply, for example, by increasing the leaf chlorophyll levels, photosynthetic enzyme activities, and stomatal conductance (Guntzer et al., 2012; Hajiboland, 2012) (Figure 3) and improving the leaf stability so that leaves are oriented more horizontally (Botta et al., 2014). Since 4–20% of the fixed carbon from photosynthesis is transferred to the AMF, the mycorrhizal association relies on the organic carbon supplied from their photosynthetic partners (Smith and Read, 2008). Furthermore, the photosynthetic rate (organic carbon supply) is positively correlated with the hyphal absorption capacity and

arbuscule formation (Smith and Read, 2008; Anda et al., 2016; Moradtalab et al., 2019); (iii) modifying the phenolic metabolic pathways in AMF host plants and/or reducing polymerization and lignin synthesis (Rodrigues et al., 2004; Mandal et al., 2010; Hajiboland et al., 2018), which can affect how AMF interact with the host plant. Studies have investigated how Si affects the metabolism of phenolic compounds in plants (Dragišić Maksimović et al., 2007; Hajiboland et al., 2017). Phenolic compounds, such as flavonoids, are known to potentially help facilitate AMF to interact with their host plants (Vierheilig, 2004; Mandal et al., 2010), improve fungal growth parameters such as branching, hyphal growth, spore germination (Steinkellner et al., 2007) and secondary spore formation, and contribute to the fungal invasion and root arbuscule formation (Hassan and Mathesius, 2012); and (iv) increasing the pool of soluble sugars in the roots, which is crucial for the entry and further establishment in the roots, of AMF (Moradtalab et al., 2019). Future research should investigate the metabolic and molecular mechanisms that are associated with the synergistic relationship of Si and AMF.

PSB Increase the Availability and Uptake of Si for Plants

Phosphate-solubilizing bacteria generally have the ability to weather silicates, likely because basic metabolic activities like organic acid production and respiration can cause the weathering of minerals (Brucker et al., 2020). PSB mainly solubilize insoluble Pi by acidifying the microenvironment (Etesami, 2020). In addition to increasing P availability for plants, there are some reports that PSB are also able to increase Si availability and uptake. Lee et al. (2019) observed that the PSB strain *Enterobacter ludwigii* GAK2, isolated from paddy soils, was able to significantly increase P and Si levels in rice plant tissues grown on insoluble Pi [$\text{Ca}_3(\text{PO}_4)_2$] and insoluble silicate ($\text{Mg}_2\text{O}_8\text{Si}_3$) based soils. This bacterial strain also increased rice plant growth indices (chlorophyll content, fresh biomass, root and shoot lengths). In another study, the PSB strains *Bacillus simplex* UT1 and *Pseudomonas* sp. FA1 significantly increased the shoot Si levels in sorghum (*Sorghum bicolor* L.) (Rezakhani et al., 2019a) and wheat (*Triticum aestivum* L.) (Rezakhani et al., 2019b). Given the role of Si in increasing soil P availability, one question that arises here is whether the Si-mediated increase in soil P availability has an inhibitory effect on bacterial solubilization of P from insoluble Pi sources. It is noteworthy that microbial P solubilization is not influenced by the soil P availability. For example, in a study (Brucker et al., 2020), adding P (100 mg of ground apatite) to soil extracts from soils with various P fractions (bioavailable P between 0.6 to 38 mg kg⁻¹ and total P between 0.42 to 1.23 g kg⁻¹) and degree of weathering, which had been incubated 28 days, did not substantially reduce P solubilization rates, which indicates that the P availability does not affect the microbial soil P solubilization. It is probable that microbial P solubilization is not driven by the microbial P demand but rather is a side effect of microbial metabolism. It was also observed that P fertilization over several years did not influence PSB abundance in the grassland soils of different continents (Widdig et al., 2019). Generally, PSB can benefit plants

by accelerating the weathering of silicates and increasing the rhizospheric concentration of available Si.

Si Increases the Population of PSB

The potential effect of Si on the soil microbial community has attracted only a limited amount of attention. However, there are some reports showing that Si can significantly influences some soil microbial community components (e.g., it increased beneficial bacterial population and reduced soil fungi/bacteria ratio) (Wainwright et al., 2003; Hordiienko et al., 2010; Karunakaran et al., 2013; Wang et al., 2013; Lin et al., 2020). It is reported that bacteria use Si-based autotrophy as a source of energy to support CO₂ fixation (Das et al., 1992). It is also proposed that the first bacteria may have evolved on earth because of Si (Wainwright et al., 2003). A number of bacteria and fungi are able to grow on nutrient-free silica gel and distilled water (Wainwright et al., 1991). According to a study (Wainwright et al., 2003), silicic acid increases the number of both aerobic and facultative anaerobic bacteria in ultra-pure water incubated under strict oligotrophic conditions. In addition, organisms use silica through silicification, a process by which silica is utilized and deposited by bacteria (Perry, 2003) and also Si-based compounds stimulate the population of oligotrophic bacteria in soil (Ai-Falih, 2003). In a previous study (Karunakaran et al., 2013), it was shown that the microbial population increased with an increase in concentration of nanosilica. In addition, silica content in biomass also increased with an increase in the concentration of nanosilica. It is known that nanosilica is not toxic to the soil bacterial community (Karunakaran et al., 2013). The reason behind the interaction between nanosilica and bacteria may reflect a hydration property of the nanosilica surface, which could facilitate the attraction of silica to the microbial surface (Gordienko and Kurdish, 2007).

There are a few studies that have focused on the effect of Si application on the activity and population of PSB. In one study, the efficiency of nanosilica (0.5 g kg⁻¹ of soil) was evaluated in terms of its effects on beneficial microbial population such as PSB in the rhizosphere soil of maize (Rangaraj et al., 2014). When compared with the control (2.0 × 10⁴ CFU g⁻¹), the silica-treated rhizosphere soils revealed an increase in the PSB population (4.4 × 10⁴ CFU g⁻¹). This shows that the addition of silica may act as a substrate for P uptake systems in soil as well as in plants. An increase in the population of PSB of nanosilica-amended soil indicates enhanced soil fertility and enhanced available nutrients to the plants. The increased population of PSB in nanosilica-treated rhizosphere soil may be due to the availability of more P to plants, as the Si competes for P in a plant system. Because both P and Si influence the P content and the population of PSB, the uptake of either source increases the populations of PSB. Hence, silica may act as a substrate for PSB, which results in an increase in the population of PSB and availability of P. The changes in soil inorganic nutrients with respect to silica fertilization may also be due to the production of organic compounds by increased microbial activity and desorption of inorganic nutrients from soil mineral compounds (Karunakaran et al., 2013). It is also reported that the bacteria use silica from soil and hence, there is a decrease in the silica content in the soil (Wainwright et al., 2003). Thus,

nanosilica can be included for fertilizer formulations to make the soil more fertile and to improve soil phosphate-solubilizing bacterial community for improving plant P nutrition.

SSB INCREASE AVAILABILITY OF P AND Si AND THEIR UPTAKE BY PLANTS

Plants are not able to absorb Si until monosilicic acid (H_4SiO_4) is released into the soil solution through weathering or dissolution (Kang et al., 2017). Monosilicic acid generally originates from the weathering of soil minerals that contain Si, desorption from the soil matrix, irrigation water, and Si fertilizers (Klotzbücher et al., 2015). Si fertilizers, unlike conventional fertilizers, have a limited availability and are often not affordable for many farmers (Meena et al., 2014). Therefore, they are rarely used in many countries, especially in developing countries. Silicate fertilizers are usually composed of (i) industrial byproducts or slags rich in Si, whose application may lead to metal contamination of soils, (ii) bentonite, diatomaceous earth, feldspars, and micas, which are biologically/minerally derived Si fertilizers with low Si bioavailability and high application rates and (iii) highly soluble, but very expensive, potassium silicates (Datnoff et al., 2001). Si-rich crop residues, construction/demolition wastes that contain aluminum, calcium, and potassium silicates, mineral/metal mining wastes, and silicate rocks may be recycled to affordable silicate fertilizers. The solubility of the primary and secondary minerals in soils is the main factor that influences the soil Si concentration (Sommer et al., 2006). The primary and secondary minerals can be subjected to physico-chemical and biochemical interventions that accelerate the solubility for soil applications (Bin et al., 2008), but biochemical action via microbial activities is considered most important for this process (Vasanthi et al., 2018). Many studies have observed that microbes isolated from the surface of silicate minerals weather different silicates (Sheng et al., 2008; Lapanje et al., 2012; Wang et al., 2015).

Plants and their associated microflora are known to also influence silicate weathering (the dissolution and mobilization of silicate minerals in soil) by altering the physical soil properties, modifying the soil pH, and producing chelating ligands (Cornelis et al., 2011). It has been reported that among microorganisms, plant associated bacteria accelerate the dissolution of silicates and release Si to the plant–soil system (Savant et al., 1996; Hutchens et al., 2003; Sheng and He, 2006; Uroz et al., 2009; Chandrakala et al., 2019) through bio-weathering processes (Klotzbücher et al., 2015). With an increase in knowledge of how Si benefits plants, rhizospheric soils have been explored in search of new bacteria that solubilize silicates (Kang et al., 2017; Vasanthi et al., 2018). SSB have been gathering increasing interest, as rhizospheric silicate solubilization leads to increased potassium and Si uptake, which reduces the need for potash fertilizers.

The ability to solubilize silicates (to depolymerize crystalline silicate) has been reported in various Gram-positive and Gram-negative bacteria (*Burkholderia eburnea* CS4-2, *Bacillus* sp., *Bacillus flexus*, *Bacillus globisporus*, *B. mucilaginosus*, *B. megaterium* and *Pseudomonas fluorescens*, *Burkholderia susongensis* sp., *Rhizobium* sp., *Rhizobium yantingense*,

Rhizobium tropici, and *Pseudomonas stutzeri*) (Malinovskaya et al., 1990; Lin et al., 2002; Liu et al., 2006; Vasanthi et al., 2013, 2018; Chen et al., 2015; Gu et al., 2015; Wang et al., 2015; Umamaheswari et al., 2016; Kang et al., 2017; Chandrakala et al., 2019).

Silicate-solubilizing bacteria can potentially release soluble silica from biogenic materials such as diatomaceous earth, rice husks, rice straw, and siliceous earth, as well as from insoluble, inorganic (Al, Ca, K, and Mg) silicates and silicate minerals such as feldspar and biotite (Wang et al., 2015; Chandrakala et al., 2019). These bacteria have been isolated from different habitats, such as rice plant rhizospheres (Kang et al., 2017; Chandrakala et al., 2019), from rice field soil samples (Vasanthi et al., 2013), weathered feldspar surfaces (Sheng and He, 2006), weathered rock surfaces (Gu et al., 2015), weathered rock (purple siltstone) surfaces (Chen et al., 2015), pond sediments, river water, soils, and talc minerals (Umamaheswari et al., 2016), potassium mine tailings (Huang et al., 2013), quercus petraea oak mycorrhizal roots surroundings (Calvaruso et al., 2010), and weathered rocks (Wang et al., 2015).

Some mechanisms which SSB could utilize to release soluble silica from insoluble silicates include: (i) production of organic acids including citric, tartaric, acetic, gluconic, hexadecanoic, malic, oxalic, phthalic, oleic, heptadecanoic, and hydroxypropionic acids (Vassilev et al., 2006; Vasanthi et al., 2018), which have metal complexing properties that may bind with aluminum and iron silicates and render silicates soluble, also provide protons (H^+) for protonation for silicate hydrolysis (Duff and Webley, 1959; Avakyan et al., 1986; Drever and Stillings, 1997); (ii) inorganic acid production (i.e., oxidation of sulfur, reduction of sulfides to sulfuric acid, oxidation of ammonia to nitrates, and conversion of nitrates to nitric acid, which can act on silicates); (iii) synthesis and discharge of carbonic anhydrase that catalyzes the interconversion between carbon dioxide produced by soil microbes and water, and the dissociated ions of carbonic acid (Brucker et al., 2020), which promotes the microbial conversion of silicate minerals as observed in orthoclase degradation to kaolinite (Waksman and Starkey, 1924). In addition, CO_2 sequestration in basaltic aquifers and the associated carbonate mineralization might maintain an environment suitable for silicate mineral dissolution (Pokrovsky et al., 2011); (iv) production of siderophores, which bind and transport iron(III) which can play a part in silicate solubilization by scavenging iron from silicate minerals as observed in hornblende degradation (Kalinowski et al., 2000); (v) the reduction of sulfates and production of H_2S , which reacts with cations like Ca and Fe of silicate minerals forming sulfides and thus rendering silicate solubilization (Ehrlich et al., 2015); (vi) absorption and binding of the inorganic silicate ions on bacterial surfaces, due to having ionizable carboxylates and phosphates of lipopolysaccharides in Gram-negative bacteria and peptidoglycan, teichoic acids and teichoic acids in Gram-positive bacteria and their high reactivity to the ions, rendering dissolution (Urrutia and Beveridge, 1994); (vii) extracellular polysaccharide production (Xiao et al., 2016; Kang et al., 2017), which is implicated in weathering of rocks and breakdown of silicates due to their wetting and drying

properties and acting as a sorbent of metal ions (binding silicates and affecting the equilibrium between the fluid and mineral phases, rendering them soluble) during this vital activity. The biofilm formation also solubilizes silicates in their microenvironment (Malinovskaya et al., 1990); and (viii) alkali production (Kutuzova, 1969). It is known that SSB can solubilize silicates by shifting the pH of the environment toward alkalinity by decomposing the organic matter and fixing nitrogen, to subsequently form ammonia and amines (Vasanthi et al., 2018); and acidolysis, the most commonly found mechanism of silicate mineral weathering (Jongmans et al., 1997; Chandrakala et al., 2019). Future research should focus on the yet unknown mineral weathering mechanisms of these bacteria (Kang et al., 2017).

These bacteria, isolated from both plant roots and soil minerals, could also increase the plant Si uptake and therefore Si levels in plants (Peera et al., 2016; Kang et al., 2017; Vasanthi et al., 2018; Chandrakala et al., 2019). In one study (Kang et al., 2017), it was found that inoculation of japonica rice plants with the SSB strain *Burkholderia eburnea* CS4-2 increased the Si content in the plants grown on the plant growth substrate including insoluble silicates. In addition, the plant growth attributes (chlorophyll levels, root and shoot lengths, root and shoot fresh weights, etc.) were also improved compared to those of the control and of plants grown on insoluble silica. CS4-2, when applied together with insoluble silica, significantly promoted the growth of rice plants (Kang et al., 2017). Chandrakala et al. (2019) found that the SSB strain *Rhizobium* sp. IIRR-1 isolated from the rhizospheric soil around rice plants could colonize and grow on all insoluble silicates, which resulted in increased silica release into the culture media (12.45–60.15% over that of the control). This strain also successfully colonized the roots of rice seedlings and improved their vigor by 29.18% compared to that of the control.

In addition to providing plants with Si, SSB can also solubilize P and other nutrients like Ca, Fe, K, Mg, and Zn, bound to the silicate minerals from insoluble sources and provide plants with P (Lin et al., 2002; Liu et al., 2006; Vasanthi et al., 2018; Chandrakala et al., 2019; Lee et al., 2019). The mechanisms for P solubilization are also responsible for the biogenic silicate weathering; namely, the release of extracellular polysaccharides, organic acids, protons, and siderophores (Vassilev et al., 2006; Gorbushina and Broughton, 2009; Uroz et al., 2009; Etesami, 2020). Silicate weathering provides access to minerals that contain P, such as apatite, which are calcium phosphates, and therefore is also related to P solubilization (Gorbushina and Broughton, 2009; Uroz et al., 2009). For example, studies have reported that SSB produce organic acids such as acetic, formic, and gluconic acids during the solubilization of insoluble tri-calcium silicates and other insoluble nutrient sources (Park et al., 2009). The aforementioned studies show that SSB utilization may improve the solubilization of insoluble P and Si, which could ultimately increase the plant P and Si uptake and to substantially improve the plant growth and health. Compared to the studies performed on PSB and other PGPB, very few studies have been conducted to isolate SSB with plant growth-promoting activities from plant-associated soils (Kang et al., 2017; Vasanthi et al., 2018), likely because SSB only accounts for a low proportion

of the total bacteria that exist in soils and silicate minerals (Vasanthi et al., 2018).

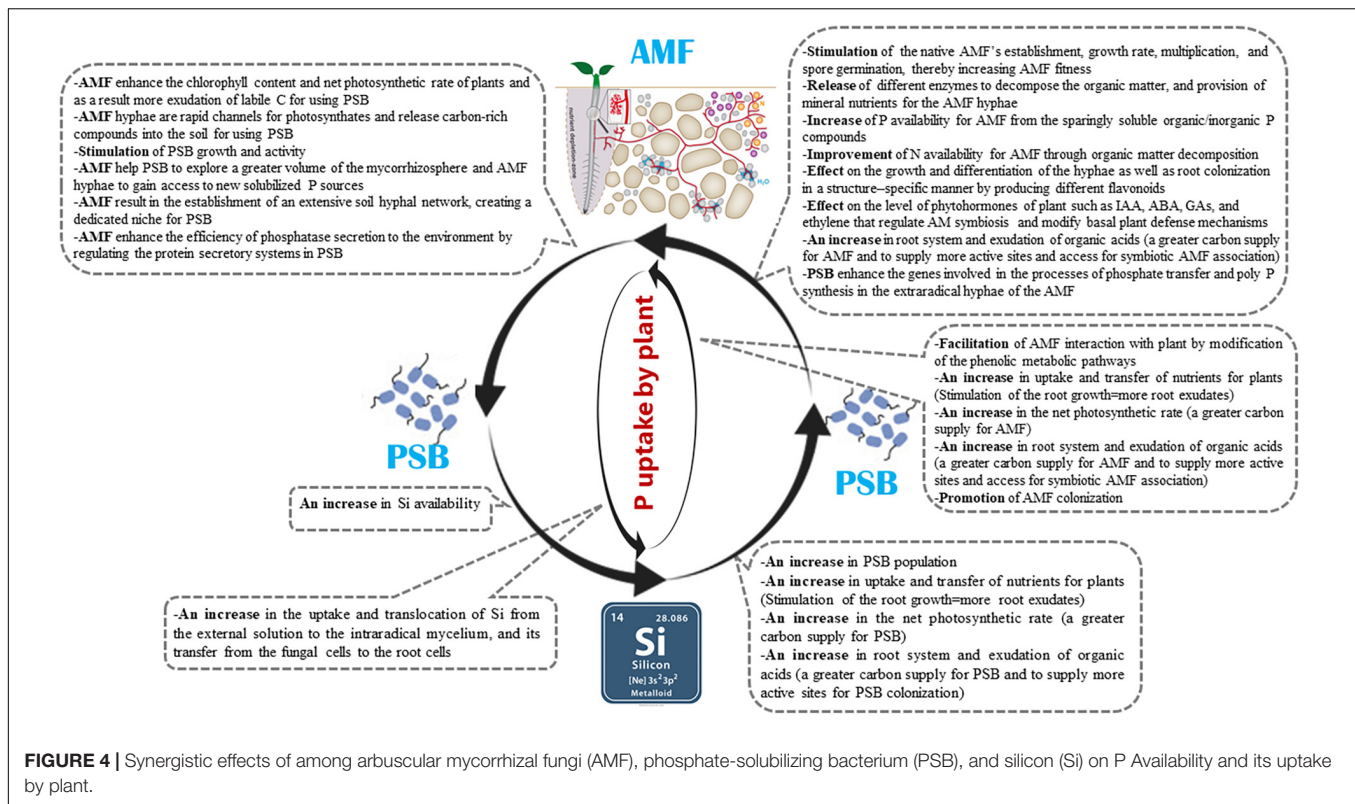

The outcome of this review paper may widen research scope for use of Si/nanosilica (or SSB) in combination with AMF and PSB in improving P use efficiency in sustainable agriculture (Figure 4).

FUTURE PROSPECTS

Arbuscular mycorrhizal fungi provide their host plants with P and other nutrients in exchange for photosynthates, by effectively increasing the volume of the soil solution that host plants can acquire minerals from via the hyphae that develop from the roots. AMF prevent the available P from re-precipitating before plants have access, and their capacity to transport P to plants can account for up to 80% of a plant's total P uptake. However, much of the soil P exists in an insoluble form, and some AMF can only exploit soluble P sources. PSB can solubilize these insoluble P forms and potentially make them available for absorption by AMF hyphae and plants. PSB also increase the AMF hyphal expression Pi transporter genes. In addition to increasing P availability in soils, Si also enhances the expression of plant genes associated with inorganic P absorption under P-deficient conditions. Previous studies, indicate that AMF and PSB, Si and AMF, and Si and PSB synergistically act to more effectively increase the plant uptake of P, improving the growth of different plants more than when each was applied on its own. Accordingly, the use of Si along with these two microbial groups may increase P availability in the rhizosphere.

Several suggestions and avenues of research would move us closer to adopting this strategy for developing environment-friendly P-biofertilizer to be used as supplements and/or alternatives to chemical P fertilizers:

- (i) It is known that AMF and PSB cooperate, in addition to having synergistic effects (Zhang et al., 2016). According to Zhang et al. (2016) AMF and free-living PSB cooperated for mutual benefit by supplying the required carbon or P for each microorganism, though these interactions were dependent on the environmental P availability. This indicates that when using co-inoculation of AMF and PSB, the amount of available P in the soil should be considered;
- (ii) AMF hyphae, by secreting certain metabolites such as carbohydrates (Hooker et al., 2007; Toljander et al., 2007) (e.g., sugars such as galactose, fructose, glucose, and trehalose) (Zhang et al., 2018a,b), carboxylates (e.g., aconitate, citrate, and succinate) (Tawarayama et al., 2006; Zhang et al., 2018b), and amino acids (Bharadwaj et al., 2012), only benefit specific microorganisms and inhibit others (Nuccio et al., 2013; Bender et al., 2014). The exact mechanisms of these interactions remains to be investigated, although previous research has made suggestions: physical interactions such as the capacity to attach to the hyphae of the AMF (Scheublin et al., 2010), niche competition for nutrients (Veresoglou et al., 2011), and AMF hyphal exudation directly and indirectly

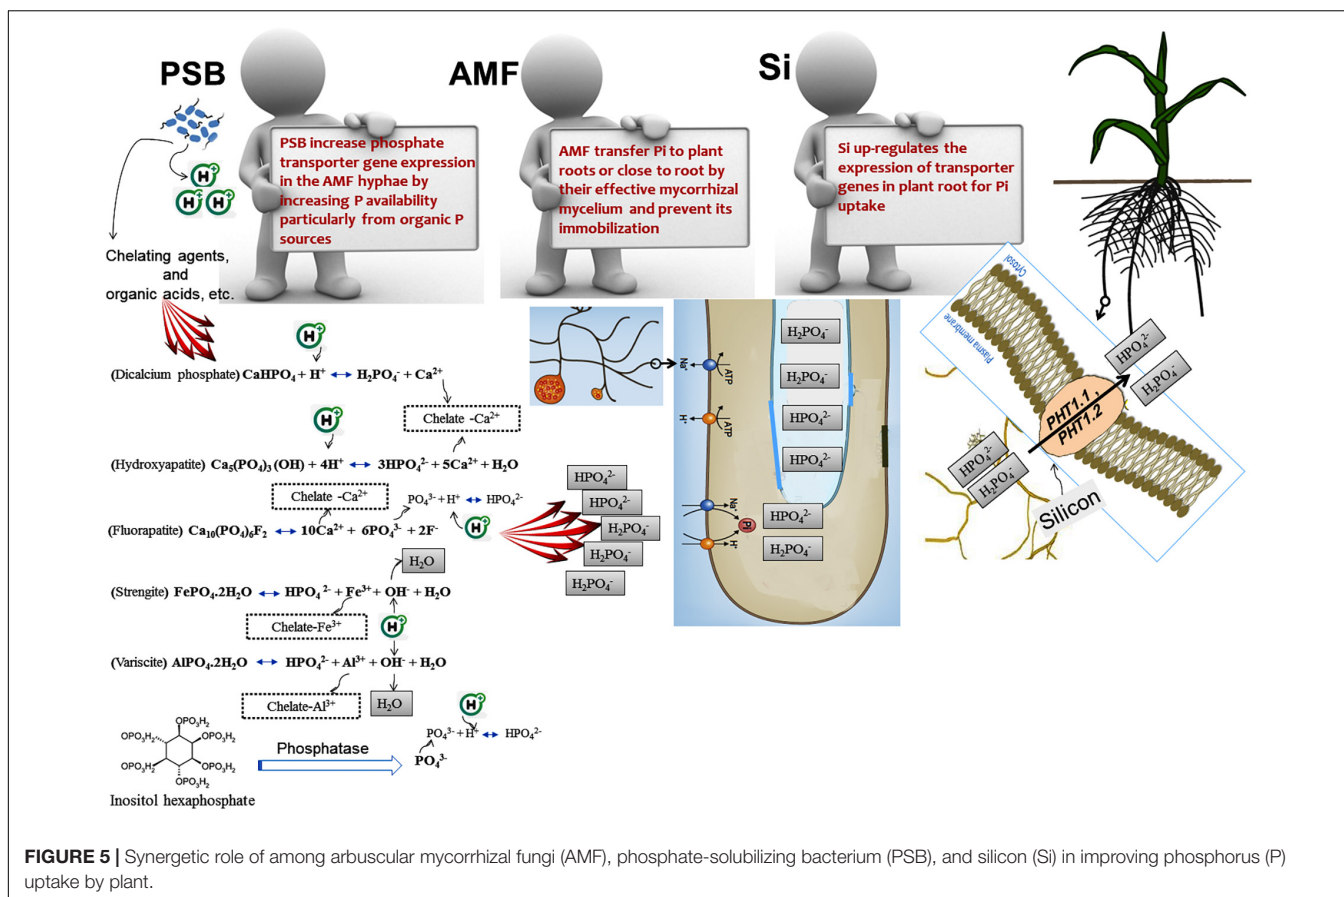

manipulating the community (Toljander et al., 2007). In addition, it is important to note that the stimulated microbes positively affect AMF fitness in general (Scheublin et al., 2010; Nuccio et al., 2013);

- (iii) It has also been found that relative to other PSB strains, the different bacteria may positively or negatively influence the AMF hyphal growth. Future research should investigate which combination and plant-growth-promoting characteristics are the most affected by fungal secretions, as the knowledge is yet unclear. Furthermore, it should be investigated which soil conditions (available P content, pH, organic matter composition, etc.) lead to the best results in plants when the co-inoculation of AMF and PSB with Si is provided;
- (iv) Further research is necessary to identify the different mechanisms with which spore- and AMF hyphae-associated PSB affect plant growth with and without AMF in non-sterile conditions in the field. Evidence to date is still inconsistent regarding significant organic P mineralization by AMF. Continuous monitoring of the characteristics of the different AMF mycelial exudates, and how they interact with the biotic and abiotic environments *in situ* will also help further the understanding AMF's ecological roles (Toljander, 2006);
- (v) The relationship between certain soil bacteria and mycorrhizal fungi provides new insights into the design of mixed inoculation, while identifying fungal strains that contain plant growth-promoting endosymbiotic bacteria and mycorrhiza helper bacteria (bacterial communities

living strictly associated with AMF spores extraradical mycelium and mycorrhizal roots, in the mycorrhizosphere) evidenced by ACC deaminase activities, IAA production, siderophore production, Pi solubilization, and N₂ fixation ability enables new strategies for AMF use (Turrini et al., 2018). A better understanding of such relationships between certain bacteria and fungi should lead to substantial ecological benefits and contribute to sustainable agriculture;

- (vi) To make optimal use of soil microorganisms to maximize the benefits for plant growth and development, future research should investigate how the soil bacteria and fungi interact. Calcareous soils with a high pH and low P availability could benefit greatly from making use of such microorganism interactions;
- (vii) Since the coexistence of AMF and PSB in the rhizosphere spans millions of years, numerous interactions should have evolved between the two microorganism groups. The exact mechanisms between AMF and PSB should be identified. It is not clear whether the phosphate-solubilizing ability of any bacteria allows them to attach to the extraradical AMF hyphae (Scheublin et al., 2010);
- (viii) Most research has been done using culturable bacteria. Since most bacteria are unculturable, more research is needed dealing with unculturable bacteria in the mycorrhizosphere, which will lead to an improved knowledge of the microbial community and the associated mycorrhizospheric interactions (Toljander, 2006);

- (ix) Further research to evaluate the application and the efficacy of AMF, PSB, and SSB (or Si fertilizers) as co-inoculants or as independent inoculants under various environmental stresses on crops fertilized with different low-solubility P sources in real world conditions is necessary, where the survival of AMF, PSB, and SSB, as well as how the mechanisms with which they promote plant growth is affected by competition with the endemic microorganisms, environmental stresses, and soil conditions;
- (x) Further research is necessary to validate the AMF and PSB performance in conjunction with SSB or suitable insoluble silicate sources, as silica itself is considered as agronomically beneficial and its mobilization is always accompanied by the release of other macronutrients and macronutrients that are bound to silicate minerals, under various field conditions and different ecosystems; and
- (xi) Because AMF are unable to release phosphatases outside the hyphae, organic P utilization by AMF seems to depend on the presence of other soil microbes. Since different bacterial genera possess different organic P mineralization abilities (Rodriguez and Fraga, 1999) and multiple plant-growth-promoting characteristics, bacteria are expected to promote plant growth more effectively in comparison to microorganisms that only possess a single plant growth-promoting trait (Shahi et al., 2011; Etesami and Maheshwari, 2018); manipulation of the

bacterial community associated with the AMF hyphae (i.e., introduction of superior PSB and SSB into the hyphae) may influence the organic P mineralization and Si uptake processes in plants.

CONCLUSION

P is a vital element in crop nutrition. Adverse environmental effects of chemical-based P fertilizers have compelled us to find a sustainable approach for efficient P availability in agriculture to meet the ever-increasing global demand of food. According to the review paper, the use of AMF, PSB, and the addition of Si can be an effective and economical way to improve the availability and efficacy of P. Based on what is known about them, the combination of AMF, PSB, and Si (or SSB) may be utilized as a strategy for improving plant growth in P-deficient soils and minimizing chemical fertilization to exercise sustainable agriculture (Figure 5). The combination can help plants effectively utilize the low-solubility P sources by solubilizing them into utilizable forms that are later absorbed by plants. This may assist in solving problems encountered with the crop production economy and food shortages, which also make the co-inoculation with Si or SSB a promising technique for use in commercial inoculant formulations.

AUTHOR CONTRIBUTIONS

HE wrote the manuscript. BJ checked and edited the sections related to silicon in this manuscript. BG revised and approved the final version to be published. All the authors contributed to the article and approved the submitted version.

Excessive application of fertilizers has become a major issue in croplands of intensive agricultural systems in China, resulting in severe non-point source pollution; thus, reduction in the use of chemical fertilizers has received significant attention. Improving the nutrient storage capacity of soils or substrates is an effective approach for solving this problem. Humic acids (HA) are excellent soil conditioners. Thus, in the present study, their ability to improve the physico-chemical properties of three substrates with different textures was evaluated. HA treatments included 1% HA root application in three different types of substrates, including pure sand, pure cocopeat, and a mixture of sand:cocopeat (1:1, v/v) and their relative controls. We examined the morphological parameters of cucumber seedlings as well as pH buffering capacity (pHBC), total organic carbon (TOC), organic matter (OM), cation exchange capacity (CEC), and nutrient storage capacity of the three substrates. The results show that HA application improved the morphological parameters of cucumber seedlings (plant height, stem diameter, and biomass) in pure cocopeat and cocopeat-sand mixture treatments. On the contrary, HA addition had harmful effects on the cucumber seedlings cultivated in sand due to the low pHBC of sand. The seedlings cultivated in pure cocopeat showed the best morphological parameter performances among the seedlings grown in the three substrates. Furthermore, pHBC, TOC, OM, and CEC were enhanced by HA application. Incorporation of HA improved ammonium (NH₄⁺) and potassium (K⁺) storage capacity while decreasing phosphorus (P) storage. Pure cocopeat had the highest pHBC, TOC, OM, CEC, and nutrient storage capacity among the three substrates. In conclusion, mixing 1% HA into substrates promoted cucumber growth, improved substrate properties, and enhanced fertilizer use efficiency. Pure cocopeat is a suitable substrate for cucumber cultivation, and mixing cocopeat with sand amends the substrate properties and consequently improves plant growth.

Keywords: humic acid, substrate properties, cucumber, pH buffering capacity, storage capacity

Abbreviations: CEC, Cation exchange capacity; HA, humic acid; OM, Organic carbon; pHBC, pH buffering capacity; TOC, Total organic carbon.

INTRODUCTION

Chemical fertilizers are one of the most important factors in the agricultural production of modern civilization, and they can dramatically enhance crop yield. In China, the unprecedented population boom is threatening food production self-sufficiency (Wei et al., 2015). In an attempt to make the most of the limited productive arable land and achieve high food production sustainably, farmers tend to cultivate high-yielding varieties which have a high demand for nutrients. Therefore, substantial quantities of synthetic fertilizers are chronically input into fields (Cai et al., 2002; Chen et al., 2004; Cui et al., 2008; He et al., 2009; Yan et al., 2012). However, irrational agricultural practices lead to low fertilizer use efficiency and severe agricultural non-point source pollution (Sun et al., 2012; Fan et al., 2014). Compared with developed countries, China lost more nutrients in agricultural production, and fertilizer use efficiency of nitrogen (N), phosphorus (P), and potassium (K) was less than 35, 20, and 50%, respectively (Li et al., 2010); thus, taking a deep look into the improvement of fertilizer use efficiency is of great significance and necessity.

In general, after fertilization, some nutrients are absorbed by the soil, and others are lost, such as leaching and volatilization loss (Ahmad et al., 1982; Dong et al., 2009). The storage capacity of nutrients (mainly N, P, and K) is considered a crucial index of soil productivity evaluation. Nutrient absorption and release play a vital role in fertilizer use efficiency as they affect soil nutrient supplies, which are important for crop nutrient uptake (Anderson and Magdoff, 2005; Simonsson et al., 2009; Nieder et al., 2011). With the current concerns regarding environmental protection and the demand for production of more food with less fertilizer application, the focus is directed toward enhancing soil nutrient storage capacity, which could be a way to improve fertilizer use efficiency to minimize fertilizer loss and leaching into the environment.

Humic acids (HA) are a new type of biostimulant that have become popular in recent years and are mainly derived from the decomposition of animal and plant remains by microbes under aerobic and anaerobic conditions and during various geochemical processes (Dogan et al., 2014). HA perform various functions in agricultural production; for instance, HA could be used as growth regulators to alter hormone levels in plants and to alleviate the deleterious effects of abiotic stress on plants (Mora et al., 2012; Bijanzadeh et al., 2019). A previous study shows that soil properties, such as aggregation, aeration, and permeability, could be greatly improved by HA application in saline-sodic soils (Nan et al., 2016). K fixation was significantly reduced by incorporation of HA in brown soils (Liang et al., 2005; Lan et al., 2016). In addition, previous studies demonstrate that the addition of HA significantly improved P availability in inceptisol (Cimrin and Yilmaz, 2005). In general, previous studies mainly focus on the effects of HA application on natural soil types with similar physico-chemical properties. For example, the bulk density of saline-sodic soils and brown soils is about $1.40 \text{ g}\cdot\text{cm}^{-3}$, and the organic matter (OM) content of saline-sodic soils, brown soils, and inceptisol is about $10 \text{ g}\cdot\text{kg}^{-1}$. Soilless substrates have proper pH value, lighter bulk density and no soil-borne disease, which

can replace soil to provide a good growth environment for plants (Vaughn et al., 2011; Banitalebi et al., 2021). Nowadays, more and more farmers are inclined to use soilless substrates for vegetable cultivation in protected fields (Gao et al., 2018). Limited studies have been carried out on the effects of HA application on soilless substrates with significantly different bulk density, porosity, OM, pH buffering capacity (pHBC), and nutrient storage capacity. Cocopeat is an organic soilless substrate made of coir, which is suitable for use as a growing substrate due to its excellent physical properties, such as high water-holding capacity and porosity (Abad et al., 2005). Cucumber is widely cultivated in China on account of its delicious taste, short nutritional cycle and high economic benefits (Zhao et al., 2019). According to the results of preliminary experiments, the addition of HA to cocopeat at a rate of 1% (HA:water, w/w) significantly improved cucumber yield under 15% fertilizer reduction (unpublished). Seedling quality has a significant effect on the yield of plants (Markovic et al., 1997). Thus, in the present study, our primary aim was to investigate the effects of 1% HA application to substrates with significantly different physico-chemical properties on cucumber seedling growth and substrate properties, especially on the pHBC and nutrient storage capacity.

MATERIALS AND METHODS

Growth Conditions and Experimental Materials

The experiment was conducted in a glasshouse at the Soilless Culture Department, Institute of Vegetables and Flowers (IVF), Chinese Academy of Agricultural Sciences (CAAS), Beijing, China, in the period from February to April 2019. Cucumber (*Cucumis sativus* L.) (cv. Zhongnong No. 26) was selected as the plant material. Cucumber seedlings were kept in a glasshouse under natural light intensity and a natural photoperiod. Cocopeat and sand were provided by the Beijing Yinong Agricultural Technology Company (Beijing, China). Characteristics of the three different substrates used in the study are shown in **Table 1**. Humic acid (pH: 5.74, fulvic acid: 43.94%, organic matter: 47.3%, total N: 5.98%, total K: 2.25%, total P: 0.04%, SiO_2 : 0.18%) was obtained from Shandong Quanlinjiayou Humic Acid Technology Company (Shandong, China) and was extracted from wheat straw, and there is no hormone in this humic acid.

Experimental Design

The trial consisted of two treatments [no HA application and 1% HA (HA:water, w/w) root application], using three types of substrates: pure sand, pure cocopeat, and a mixture of sand:cocopeat (1:1, v/v), for a total of six treatment combinations [T1: pure sand without HA, T2: pure sand with 1% HA, T3: pure cocopeat without HA, T4: pure cocopeat with 1% HA, T5: mixture of sand: cocopeat (1:1, v/v) without HA, T6: mixture of sand: cocopeat (1:1, v/v) with 1% HA]. The treatments were organized in a randomized complete block design with three replicates for each treatment, and each treatment included 18 plants. The addition rate of HA, 1% (HA:water, w/w), was determined according to previous experiments (unpublished).

TABLE 1 | Basic physico-chemical properties of three different substrates.

Substrates	pH	Total N (g kg ⁻¹)	Total P (g kg ⁻¹)	Total K (g kg ⁻¹)	Bulk density (g cm ⁻³)	Total porosity (%)	Water-holding porosity (%)	Air-filled porosity (%)
Pure sand	8.17	0.47	0.02	0.24	1.34	36.57	9.53	27.04
Pure cocopeat	6.50	6.35	0.60	8.28	0.13	76.66	57.96	18.70
Mixture of sand and cocopeat (1:1, v/v)	7.00	3.19	0.24	4.17	0.52	55.29	33.22	22.07

TABLE 2 | Composition of nutrient solution for cucumber proposed by Yamazaki.

Macronutrients	Final concentration (mg/L)	Micronutrients	Final concentration (mg/L)
KNO ₃	607	H ₃ BO ₃	2.86
Ca(NO ₃) ₂ ·4H ₂ O	826	MnSO ₄ ·4H ₂ O	2.13
NH ₄ H ₂ PO ₄	115	ZnSO ₄ ·7H ₂ O	0.22
MgSO ₄ ·7H ₂ O	483	CuSO ₄ ·5H ₂ O	0.08
		(NH ₄) ₆ Mo ₇ O ₂₄ ·4H ₂ O	0.02
		Na-Fe-EDTA	30

Cucumber seeds were germinated and sown in the trays filled with peat until the seedlings developed three true leaves. Before transplanting, HA was thoroughly mixed with different substrates [pure sand, pure cocopeat, and a mixture of sand:cocopeat (1:1, v/v)]. The seedlings were then transplanted into plastic pots containing 1.2 L of substrate [T1: pure sand without HA, T2: pure sand with 1% HA, T3: pure cocopeat without HA, T4: pure cocopeat with 1% HA, T5: mixture of sand: cocopeat (1:1, v/v) without HA, T6: mixture of sand: cocopeat (1:1, v/v) with 1% HA]. The same management practices were applied across all treatments. The nutrient solution used in the experiment was a special Yamazaki cucumber cultivation formula as shown in **Table 2**. The pots were watered with this nutrient solution once or twice a week, depending on substrate humidity, and the same quantity of nutrient solution was applied to all treatments.

Morphological Measurements

At the end of the experiment, 18 plants were randomly sampled from each treatment to measure plant height and stem diameter using a ruler and an electronic vernier caliper, respectively. Thereafter, the roots and shoots of these plants were separated. Fresh weights of shoots and roots were measured immediately after harvesting using an electronic balance. The plant materials were then dried in a ventilated oven at 70°C for 4–5 days until the dry weights were constant, and their dry weight was determined by an electronic balance.

Substrate Properties

Substrate samples were air-dried, ground, and sieved through a 2-mm sieve to attain homogeneity in their properties.

The pH buffering capacity (pHBC) was determined using acid-base titration techniques (Xu et al., 2012).

Substrate samples were analyzed for TOC using the dry combustion method. OM was calculated as OM (g/kg) = TOC (g/kg) × 1.724 (Gao et al., 2018). CEC of the substrates

was measured using the ammonium acetate compulsory displacement method (Xu et al., 2012).

The storage capacity of NH₄⁺ of different substrates was measured by a modified method (Nieder et al., 2011). In detail, 1 g of substrate was weighed into each of three 50-mL polyethylene tubes, and 30 mL of different concentration NH₄Cl solutions were added, whose concentrations were 0.001, 0.005, 0.01, 0.05, 0.1, 0.3, 0.5, and, 1 M (standardized), respectively. The suspensions were shaken for 24 h at 25°C and equilibrated for 1 day at 25°C, after that collected 10 mL of supernatant. The residual NH₄⁺ in supernatants were determined by Kjeldahl procedure. Due to the addition amount of NH₄⁺ was known, which could be calculated, combined with the data of the residual NH₄⁺ in supernatants, and the total adsorption quantity of NH₄⁺ of substrates treated by different concentration NH₄Cl solutions were calculated. According to the above-mentioned data, the curves of NH₄⁺ concentration and total adsorption quantity of NH₄⁺ of treated substrates were fitted by Excel, absorption saturation point of different substrates were known. The treated substrates corresponding to the absorption saturation point were then dried at 50°C for 72 h prior to fixed NH₄⁺ measurement. The method for the determination of fixed NH₄⁺ is that 0.5 g of dried substrate was weighed into each of three 50 mL polyethylene tubes, and 20 mL of alkaline KBr solution was added into each tube; the suspensions were shaken for 30 min and equilibrated for 2 h and then heated in a water bath and boiled for 5 min. After that, it was cooled and equilibrated the suspension overnight. The next day, the supernatants were discarded and the residues were washed by 40 mL of 0.5 M KCl three times, then 20 mL 5 N HF:1 N HCl was added into each tube and shaken for 24 h; all fixed NH₄⁺ of substrates were released into the suspensions after the above procedure. Finally, the NH₄⁺ released was determined by steam distillation of the substrate-sulfuric acid mixture after adding 1M NaOH by Kjeldahl procedure.

The storage capacity of P of different substrates was measured by a modified method (Butegwa et al., 1995). In detail, 1 g of substrate was weighed into each of three 50-mL polyethylene tubes, and 30 mL of different concentration KH₂PO₄ solutions were added, whose concentrations of P were 100, 300, 500, 1,000, 1,500, 2,000, 3,000, 4,000, 5,000, and 6,000 mg/L (standardized), respectively. The suspensions were shaken for 24 h at 25°C and equilibrated for 1 day at 25°C; after that were collected 10 mL of supernatant, the residual P in supernatants were determined by ICP-AES (ICP6300, Britain). Due to the additional amount of P being known, which could be calculated, combined with the data of residual P in supernatants, the total adsorption quantity of P of substrates treated by different

concentration KH_2PO_4 solutions were calculated. According to the above-mentioned data, the curves of P concentration and total adsorption quantity of P of treated substrates was fitted by Excel, and absorption saturation point of different substrates were known. The treated substrates corresponding to the absorption saturation point were then dried at 50°C for 72 h prior to fixed phosphorus measurement. Exchangeable P was determined by extractions in 1% NH_4HCO_3 (pH 7.0) and analysis of the extracts with ICP-AES (ICP6300, Britain) following filtration through filter paper. Fixed P was calculated by subtracting the amount of exchangeable P from the total adsorption quantity of P.

The storage capacity of K^+ of different substrates was measured by a modified method (Simonsson et al., 2009). In detail, 1 g of substrate was weighed into each of three 50 mL polyethylene tubes, and 30 mL of different concentration KCl solutions were added, whose concentrations of K^+ were 100, 200, 400, 1,000, 1,500, 2,000, 3,000, 4,000, 6,000, and 8,000 mg/L (standardized), respectively. The suspensions were shaken for 24 h at 25°C and equilibrated for 1 day at 25°C ; after that was collected 10 mL of supernatant, the residual K^+ in supernatants was determined by ICP-AES (ICP6300, Britain). Due to the additional amount of K^+ being known, which could be calculated, combined with the data of residual K^+ in supernatants, the total adsorption quantity of K^+ of substrates treated by different concentration KCl solutions was calculated. According to the above-mentioned data, the curves of K^+ concentration and total adsorption quantity of K^+ of treated substrates was fitted by Excel, and the absorption saturation point of different substrates were known. The treated substrates corresponding to the absorption saturation point underwent two additional wetting-drying cycles, which each involved shaking with 5 mL distilled water for 6 h and drying at 105°C for 16 h prior to fixed K^+ measurement. Exchangeable K^+ was determined by repeated extractions in 1 M NH_4Ac (pH 7.0) and analysis of the extracts with ICP-AES (ICP6300, Britain) following centrifugation (2,000 rpm \times 10 min) and filtration through a filter paper. Fixed K^+ was calculated by subtracting the amount of exchangeable K^+ from the total adsorption quantity of K^+ .

Statistical Analysis

All data were analyzed using Excel 2019 and SPSS 17.0 software, and the statistical significance of the differences between treatments was determined by Duncan's multiple range test (significance level $P < 0.05$).

RESULTS

Morphological Parameters

There was a difference in plant height among the six treatments (Table 3). HA application increased the height of cucumber seedlings cultivated in pure cocopeat and the mixture of sand:cocopeat (1:1, v/v) by 17.59 and 20.02%, respectively, whereas the pure sand treatments showed an opposite trend

when HA was applied, indicating that the three substrates responded differently to the application of HA. HA application to cocopeat or the mixture of sand:cocopeat (1:1, v/v) did not have effect on the stem diameter, whereas it decreased the stem diameter of cucumber seedlings grown in sand (by 16.29%) compared with that of cucumber seedlings grown in sand without HA addition. To investigate whether HA utilization affected cucumber biomass, we analyzed the fresh and dry weights of shoots and roots at the end of the trial period. Incorporation of 1% HA to the cocopeat increased the fresh and dry weight of roots by 26.37 and 17.86%, respectively, compared with that of roots of plants grown in cocopeat without HA application. HA addition to the mixture of sand:cocopeat (1:1, v/v) significantly increased the fresh and dry weight of shoots and roots compared with those of the groups without HA application. In contrast, there was a decrease in the fresh and dry weight of cucumber shoots and roots when 1% HA was applied to sand compared with that without HA addition.

pH Buffering Capacity

The pH buffering capacity (pHBC) was defined as the number of moles of H^+ or OH^- necessary to increase and decrease the pH of 1 kg of soil by 1 pH unit (Mowbray and Schlesinger, 1988). The acid and alkali buffering curves for the six treatments are presented in Figures 1, 2, respectively, and all correlation coefficients of the quadratic regression curve (R^2) were > 0.95 . The pHBC values for the six treatments were calculated using the corresponding regression equations of the buffering curves. In the case when the same amount of acid was added, the faster the pH value decreased, the lower the acid buffering capacity of the substrate, whereas in the case when the same amount of alkali was added, the faster the pH value increased, the lower the alkali buffering capacity of the substrate. The substrates with poor acid or alkali buffering capacity showed a more dramatic change in the acid or alkali buffering curve. As shown in Figures 1, 2, the pHBC of the groups without HA addition fluctuated more sharply after acid or alkali addition than that of the groups to which HA was applied. As shown in Figure 3, there was a great variation in pHBC among the different groups. The presence of HA contributed to an increase in acid and alkali pHBC compared with those in groups without HA application. In addition, among the three types of substrates, the greatest acid and alkali pHBC were observed in the cocopeat groups, whereas the groups with the mixture of sand:cocopeat (1:1, v/v) showed better performance of acid and alkali pHBC than that of the sand groups.

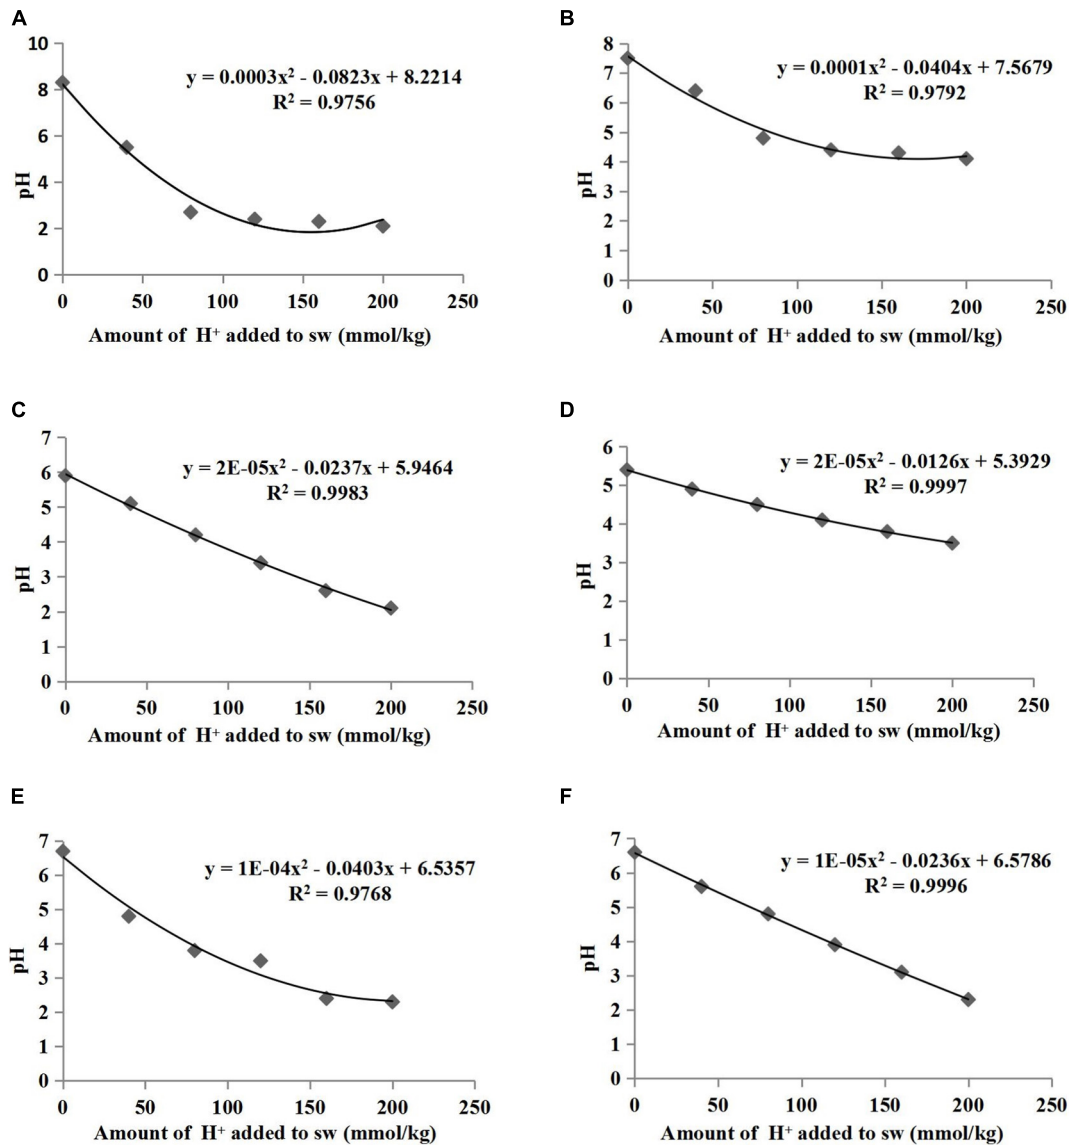

TOC, OM, and CEC

As shown in Table 4, higher TOC and OM were observed in the substrates with 1% HA application than those in the substrates without HA application, and CEC was consistently influenced by HA application. Moreover, in comparison to sand and the mixture of sand:cocopeat (1:1, v/v) treatments, the cocopeat treatment performed better with respect to TOC, OM, and CEC.

Storage Capacity of NH_4^+ in Different Substrates

As shown in **Figure 4**, it could be clearly noted that the adsorption saturation points varied among the substrates. In the case of pure sand and pure cocopeat groups, total NH_4^+ adsorption tended to be saturated when the concentration of NH_4Cl solution reached 0.3 and 0.5 M, respectively. The total NH_4^+ adsorption curves of all treatments could be divided into two distinct parts. In the first part, NH_4Cl solution concentrations were below the saturation point, and the total NH_4^+ adsorption quantity increased greatly with increasing solution concentrations. The second part of the curve was associated with the NH_4Cl solution concentrations

beyond the saturation point, at which all absorption curves became relatively flat, which indicated that they were almost saturated. Furthermore, all substrates were already saturated with 1.0 M NH_4Cl solution. In relation to the abovementioned results, we calculated the storage capacity of NH_4^+ at the complete saturation point (the corresponding concentration of NH_4Cl solution was 1.0 M). The storage capacity of NH_4^+ was related to three parameters, including total NH_4^+ , fixed NH_4^+ , and exchangeable NH_4^+ adsorption quantities. Among the three types of substrates, the storage capacity of NH_4^+ in cocopeat and in sand were the highest and the lowest, respectively. As shown in **Table 5**, HA application seemed to be an important factor that influenced the NH_4^+

adsorption of substrates due to the significantly higher total NH_4^+ , fixed NH_4^+ , and exchangeable NH_4^+ adsorption in the substrates to which 1% HA was applied. Additionally, most of the adsorbed NH_4^+ was present in the exchangeable form, which could easily be released from substrates and used by crops when needed.

Storage Capacity of P in Different Substrates

The relationships between the concentrations of KH_2PO_4 solution added and the total phosphorus adsorption quantities of different substrates are shown in Figure 5. The total P adsorption quantity increased with increasing solution concentrations until the substrates were completely saturated with P. The absorption saturation points of pure sand, pure cocopeat, and the mixture of sand:cocopeat (1:1, v/v) were approximately 2,000, 3,000, and 2,000 mg/L, respectively. To ensure that all substrates were in a state of complete saturation and to obtain accurate results, we selected the 6,000 mg/L point to calculate the storage capacity of P for different types of substrates, and the corresponding results are presented in Table 6. Cocopeat treatments absorbed the greatest amount of P, whereas sand treatments absorbed the least, which was in accordance with the results of the NH_4^+ absorption measurement. According to the analysis of the variance, no significant difference in exchangeable P was detected between HA application and no HA application treatments, whereas the treatments without HA addition were higher than those with HA addition on both total and fixed P adsorption quantity for three types of substrates.

Storage Capacity of K^+ in Different Substrates

We found that there was a difference in the K adsorption saturation point among different substrates. Pure sand, pure cocopeat, and the mixture of both were nearly saturated when the concentration of KCl solution was 2,000, 3,000, and 2,000 mg/L, respectively. The shapes of the total K adsorption curves were similar to those of the NH_4^+ adsorption curves, and the substrates were completely saturated when they were treated with the 8,000 mg/L KCl solution. Based on these results, we calculated the storage capacity of K at the saturation point (the concentration of the corresponding KCl solution was 8,000 mg/L). The storage capacity parameters of K included total K, fixed K, and exchangeable K adsorption quantities. It was apparent that the storage capacity parameters of K in cocopeat were the highest among the three substrate types (Figure 6). As shown in Table 7, for the three types of substrates, the total K, fixed K, and exchangeable K adsorption quantities were enhanced by HA addition compared with those without HA addition. Moreover, we also observed that exchangeable K played a key role

in the amount of total adsorbed K, and this was consistent with the results of NH_4^+ absorption.

DISCUSSION

Effects of HA Addition to Different Substrates on Plant Morphological Parameters

We comparatively evaluated the effects of HA addition on three differently textured substrates and found that the effects varied. The results revealed that the addition of 1% HA to the pure cocopeat substrate and to a mixture of sand:cocopeat (1:1, v/v) had a positive effect on the morphological characteristics of cucumber plants, which was consistent with previous results related to soil measurements (Dobbss et al., 2007). The reason for this may be that HA benefits various biochemical processes. Several studies indicate that HA has auxin-like activity, stimulating root development through a significant proliferation of lateral roots and activation of H^+ -ATPases and H^+ -PPase in vacuoles as well as in the plasmalemma (Zandonadi et al., 2007).

Roots are the main plant organ for the absorption of nutrients and water, and an optimal root system is one of the requirements for yield formation (Liu et al., 2015). In the present study, the root biomass of cucumber seedlings with HA addition was higher than that of cucumber seedlings without HA addition in the pure cocopeat and in the mixture of sand:cocopeat (1:1, v/v) treatments. In addition, HA can also increase the water-holding capacity of the substrate to alleviate water stress, which may explain why HA benefits plants (García et al., 2014). HA addition achieved favorable results in pure cocopeat and in the mixture of sand:cocopeat (1:1, v/v), whereas the results were completely opposite in the pure sand groups. This may be attributed to the poor acid pHBC of sand as shown in **Figure 3A**. There were differences in acid pHBC between sand and the other substrates. HA is an acidic substance, and pH is one of the most representative indicators of substrate chemical properties (Gao et al., 2018). When HA was added to sand, pH decreased dramatically, owing to the poor acidic pHBC, and improper rhizospheric pH led to physiological disorder of roots, thereby severely affecting plant uptake of water and nutrients, which consequently resulted in low plant biomass (Wang et al., 2016).

Morphological plant parameters can indirectly reflect substrate quality. In the present study, all morphological parameters of cucumber seedlings differed among the three substrates, and seedlings in the cocopeat groups showed the best performance. Previous studies demonstrate that cocopeat is suitable for use as a growing substrate because of its excellent physical properties, such as high water-holding capacity and porosity, which are beneficial to root development (Zhu et al., 2019). In addition, the root system releases some CO₂ during root respiration that must dissipate from the root environment (Li et al., 2018), and because cocopeat has high porosity, CO₂ could rapidly dissipate from the rhizosphere. Compared with cocopeat, sand was more compact and had a lower water retention capacity, which led to a severe restriction of root growth (Liu et al., 2015). Therefore, significant differences were observed in the morphological parameters of plants grown in pure cocopeat and those grown in pure sand.

Effects of HA Addition to Different Substrates on pHBC, TOC, OM, and CEC

Soil pHBC refers to the ability of soil to mitigate the change in pH after the addition of acidic or alkaline substances, and it includes acid and alkali buffering capacity (Lieb et al., 2011). In general, the application of chemical fertilizers greatly affects soil pH; for instance, NH₄⁺ application results in acidification because plants absorb more cations than anions and consequently release protons to the soil, whereas excess nitrates lead to soil alkalization (Schaller, 1987). Logically, soils with low pHBC are sensitive to acidification or alkalization, which greatly influences their nutrient availability and thereby the acquisition of nutrients by plants (Shi et al., 2017). Therefore, substrates with high pHBC are beneficial for cultivation. In the present study, the incorporation of HA resulted in stronger pH buffering behavior of the three substrates (**Figure 3**), indicating that HA addition is

beneficial for stabilizing the rhizosphere pH, and consequently promoting plant growth.

As shown in **Table 4**, compared with the treatments without HA addition, the treatments with HA addition increased TOC and OM in the three different substrates. HA is a macromolecular organic substance rich in organic carbon (Saidimoradi et al., 2019), which is why mixing HA into substrates enhanced TOC and OM in the three substrates (**Table 4**). A previous study reported that the content of OM in the soil was positively correlated with soil pHBC (Xu et al., 2012). This is because there is an ample amount of oxygen-containing functional groups, such as carboxyl and phenolic hydroxyl groups, on the surface of OM (Liang et al., 2011). These groups accept protons when pH decreases and provide protons when pH increases (Kida et al., 2005), making a great contribution to pHBC improvement. Furthermore, we found that in the HA application treatments, the alkali buffering capacity of the three substrates was greater than their acid buffering capacity. The reason for this was because HA carries abundant acidic functional groups which can effectively neutralize alkaline components.

Cation exchange capacity (CEC) is a crucial index for assessing substrate quality, and it describes the potential of a substrate to absorb and release nutrients. High CEC can reduce fluctuations in ion concentrations (Pincus et al., 2017). As shown in **Table 4**, there was a difference in CEC between the treatments with and without HA addition. Previous studies have demonstrated that there was a positive correlation between CEC and OM. The reason for this positive correlation is that OM possesses a large number of functional groups which can be hydrolyzed to produce negative charges; these negative charges are able to adsorb a high amount of exchangeable cations and consequently improve CEC (Shekofteh et al., 2017).

Our results show that the TOC and OM of cocopeat groups were higher than those of the other groups (**Table 4**). Cocopeat is an agricultural by-product manufactured after the selection of fiber from coconut husks (Hongpakdee and Ruamrungsri, 2017); thus, it is rich in OM. On the other hand, sand is an inorganic substrate; therefore, TOC and OM differed significantly among the three substrates. In addition, it could be clearly observed that pHBC of cocopeat was significantly higher than that of the other two substrates (**Figure 3**), which was consistent with the high OM content of cocopeat. Furthermore, the CEC results coincided with OM measurements as shown in **Table 4**. The CEC of the cocopeat was significantly higher than that of the other two substrates. Additionally, in the mixture of sand:cocopeat (1:1, v/v), cocopeat addition compensated for the deficiency of OM in sand and consequently improved the CEC.

Effects of HA Addition to Different Substrates on N, P, and K Storage Capacities

The results show that the presence of HA increased the NH₄⁺ storage capacity in the three different substrates (**Table 5**). CEC affects the soil storage capacity for nutrients (Wang et al., 2019); therefore, a difference in CEC between HA groups and no HA groups might lead to differences in NH₄⁺ storage capacity.

Additionally, the chemical reaction of NH_4^+ with HA is closely linked to NH_4^+ storage because these two substances frequently form NH_4^+ humate, which has higher stability than other NH_4^+ salts. NH_4^+ volatilization loss was reduced by this process, and this ultimately increased the storage capacity of NH_4^+ (Dong et al., 2009). Furthermore, NH_4^+ could be incorporated into HA through covalent bonding, and the majority of NH_4^+ appears to be in the form of indole and pyrrole N (Thorn and Mikita, 1992). This may also explain why HA addition actively modified NH_4^+ storage capacity. Moreover, a previous study showed that HA could easily bind with NH_4^+ owing to its strong complexation and absorption capabilities. In the present study, HA showed significant slow-release effects on N release and utilization, which consequently increased fertilizer use efficiency (Chen et al., 2017). Fixed NH_4^+ and exchangeable NH_4^+ are the main constituents of adsorbed NH_4^+ in the soil (Egashira et al., 1998). Exchangeable NH_4^+ can be directly used by plants (Beuters et al., 2014), and this accounted for the majority of absorbed NH_4^+ in the present study (Table 5), implying that the adsorption of NH_4^+ by the three substrates was temporary and easily taken up by plants. Compared with that in the groups without HA addition, higher exchangeable NH_4^+ was observed in the HA addition groups, indicating that HA could improve the exchangeable NH_4^+ storage capacity in the three substrates.

P is an essential nutrient for plant growth, and phosphate deficiency can disrupt plant metabolism (Yang et al., 2004); therefore, the availability of phosphates is an important agricultural issue. Once phosphate fertilizers are applied to soils, a series of complex reactions that decrease phosphate availability may gradually occur. The main reactions include phosphate adsorption into soil and precipitation in the form of calcium phosphate minerals (Parfitt et al., 2010; Perassi and Borgnino, 2014), which can adversely affect the uptake of phosphorus by plant roots. In our experiment, the results showed that HA addition decreased total P adsorption, indicating that it has a desirable impact on the improvement of phosphate availability. It is generally accepted that HA is rich in anions, such as hydroxyl and carboxyl ions (Liang et al., 2011), and that it can reduce the adsorption of soil minerals to phosphates because of the strong competition of both anions for the same adsorption sites on the surface of soil minerals. In addition, HA can bind with Ca^{2+} in the soil and interact with Ca-P to inhibit the formation of Ca-P precipitates. These effects improved the mobility of P and ultimately enhanced P availability in the soil (Cimrin and Yilmaz, 2005; Antelo et al., 2007; Perassi and Borgnino, 2014; Zhou et al., 2015). The results of our study were in accordance with those of previous studies as shown in Table 6. HA addition could suppress phosphate fixation in the three different substrates; in other words, the availability of phosphates was increased.

The release of absorbed K^+ in the soil occurred in the rhizosphere when K^+ concentration in the rhizosphere solution decreased below the threshold (Hinsinger and Jaillard, 2010). HA exerts a regulatory effect on nutrient forms in fertilizers, and it could react with K^+ in fertilizers to form K^+ humate, which is not easily lost with water, and the presence of potassium humate can provide the ability to slowly release potassium (Liu et al., 2006).

This means that HA application directly enhances the storage capacity of K^+ in the soil and modifies the potassium supply pattern. Our results are in accordance with the results of earlier research as shown in Table 7. The total K^+ adsorption of the three different substrates with HA application was significantly higher than that of the three groups without HA application. The total adsorbed K^+ comprises exchangeable K^+ and fixed K^+ (Askegaard et al., 2003). In the present study, exchangeable K^+ accounted for the majority of adsorbed K^+ . Exchangeable K^+ in the rhizosphere serves as the main source of K for plants (Madaras and Koubová, 2016). In our experiment, the amount of absorbed exchangeable K^+ in the HA addition groups was significantly higher than that in the groups without HA addition, and the difference in this indicator might explain the difference in plant growth between the treatments with and without HA addition. Furthermore, a previous study demonstrated that HA could enhance the proportion of exchangeable K^+ in adsorbed K^+ (Olk and Cassman, 1995). In the present study, the presence of HA increased the proportion of exchangeable K^+ in adsorbed K^+ .

CONCLUSION

Incorporation of HA to different texture substrates had different effects on plant growth parameters (plant height, stem diameter, and biomass). In pure cocopeat and the mixture of sand: cocopeat (1:1, v/v), HA application improved the growth of cucumber seedlings, whereas in sand, HA addition was harmful to plant growth. The comprehensive evaluation showed that pHBC, organic matter content, and CEC in the HA groups were higher than those in the groups without HA. Treatments with HA addition resulted in higher NH_4^+ and K^+ storage capacity, while decreasing P fixation, thus increasing P availability, indicating that HA application enhanced fertilizer efficiency. Among the three substrates, cocopeat was the best substrate for cultivation, and incorporating cocopeat into sand was beneficial to plant growth. Overall, cocopeat with 1% HA was the best treatment in this study.

Mhada M, Zvinavashe AT, Hazzoumi Z, Zeroual Y, Marelli B and Kouisni L (2021) Bioformulation of Silk-Based Coating to Preserve and Deliver *Rhizobium tropici* to *Phaseolus vulgaris* Under Saline Environments. *Front. Plant Sci.* 12:700273. doi: 10.3389/fpls.2021.700273

Seed priming has been for a long time an efficient application method of biofertilizers and biocontrol agents. Due to the quick degradation of the priming agents, this technique has been limited to specific immediate uses. With the increase of awareness of the importance of sustainable use of biofertilizers, seed coating has presented a competitive advantage regarding its ability to adhere easily to the seed, preserve the inoculant, and decompose in the soil. This study compared primed *Phaseolus vulgaris* seeds with *Rhizobium tropici* and trehalose with coated seeds using a silk solution mixed with *R. tropici* and trehalose. We represented the effect of priming and seed coating on seed germination and the development of seedlings by evaluating physiological and morphological parameters under different salinity levels (0, 20, 50, and 75 mM). Results showed that germination and morphological parameters have been significantly enhanced by applying *R. tropici* and trehalose. Seedlings of coated seeds show higher root density than the freshly primed seeds and the control. The physiological response has been evaluated through the stomatal conductance, the chlorophyll content, and the total phenolic compounds. The stability of these physiological traits indicated the role of trehalose in the protection of the photosystems of the plant under low and medium salinity levels. *R. tropici* and trehalose helped the plant mitigate the negative impact of salt stress on all traits. These findings represent an essential contribution to our understanding of stress responses in coated and primed seeds. This knowledge is essential to the design of coating materials optimized for stressed environments. However, further progress in this area of research must anticipate the development of coatings adapted to different stresses using micro and macro elements, bacteria, and fungi with a significant focus on biopolymers for sustainable agriculture and soil microbiome preservation.

Keywords: biomaterial in agriculture, sustainable agriculture, food security, soil salinity, seed coating

INTRODUCTION

Seed production is one of the critical agri-businesses that relies not only on exploiting potential genetic resources of the crop-seed itself but also on advances in multiple technologies that enable efficient use of different biological resources such as beneficial microorganisms.

Seed priming or pretreatment was used in agriculture a century ago. However, the use of bioagents was first reported by Callan et al. (1990). The method implies seed inoculation with beneficial microorganisms. According to Bisen et al. (2015), the biopriming with beneficial microbes offers an innovative crop protection tool by improving the seed quality, germination rate, seedling vigor and uniformity, and plant ability to withstand harsh growth conditions, thus ensuring sustainable crop production (Bisen et al., 2015). Another use of biopriming has sprung by understanding plant growth promoting bacteria functions and mechanisms. The discovery of phosphate solubilizing bacteria has led to its use in agriculture as a potential biofertilizer. For example, it has been reported that phosphate solubilizing rhizobacteria strongly influences wheat root traits and aboveground physiology (Elhaissoufi et al., 2020). Although seed priming is facing many challenges related to the conservation of bioformulation, storage, and difficulties in upscaling management. We can overcome challenges by coating seeds using biofertilizers embodied within films synthesized from biomaterials (Zvinavashe et al., 2021).

Among the most important features that a germinating seed may exhibit would be a coating agent that preserves seed health, guarantees a high germination rate, tolerates stresses, delivers beneficial microorganisms, and contributes to sustainable agriculture (Pedrini et al., 2017; Rocha et al., 2019). Thus, the importance of biopolymers designed for agriculture and inspired by nature. Silk was one of the most promising biopolymers due to its natural properties. The combination of beta-sheet structures with inter- and intra-molecular hydrogen bonds that provides high flexibility in the natural fiber also guarantees extreme conformability in regenerated film format (Marelli et al., 2016).

Many research activities are conducted to develop a good coating agent and components that could play a role in crucial stages in plant growth in stressed environments (Maity et al., 2019; Soumare et al., 2020; Meftah Kadmiri et al., 2021). To develop new strategies to enhance abiotic stress tolerance of crop plants (Iordachescu and Imai, 2008), bioinspired coating using silk was developed (Zvinavashe et al., 2019), combining trehalose and *R. tropici*. Both have been known for their effect on different stages of the crop cycle and their ability to promote growth.

Trehalose has been identified as an osmoprotectant and signaling molecule controlling various processes ranging from seed development and germination to guard cell movement and overall plant growth (Gómez et al., 2010). Trehalose is biosynthesized through different pathways in different living organisms except for mammals (Elbein et al., 2003). The catabolism enzymes are trehalase, trehalose phosphorylase, trehalose-6-phosphate phosphorylase, and trehalose-6-phosphate hydrolase which are widespread in living cells

and may be of considerable importance in regulating the level of trehalose in the cell and managing the trehalose/sugar ratio in the demanding sink (Chen and Haddad, 2004). The level of trehalose is significantly increased in various cells when exposed to various environmental stresses, reflecting that abiotic stresses differentially regulate trehalose biosynthesis genes in higher plants (Bae et al., 2005).

The second component of the newly designed coating called “Silk Coating” is *R. tropici*. Besides its ability to promote growth and increase stress tolerance in legumes, trehalose accumulation has also been described in *Rhizobium* in response to several stressful conditions such as high external osmolarity, low oxygen concentrations, or desiccation (McIntyre et al., 2007). Trehalose also acts as an osmoprotectant when exogenously supplied to *R. leguminosarum* (Gouffi et al., 1999). It is also a common disaccharide in the root nodules of legumes and is present in bacteroids serving as molecular signals during biological nitrogen fixation (Gómez et al., 2010; Zvinavashe et al., 2019), which could reflect an important role for this molecule in symbiosis. It was also demonstrated by Müller et al. (1998) that the addition of exogenous trehalose to the growth medium increased sucrose synthase and alkaline invertase activities in soybean. Besides, the inoculation of common bean (*Phaseolus vulgaris*) with the symbiotic bacterium *R. etli*, which was engineered to overexpress the *Escherichia coli* trehalose-6-phosphate synthase (*otsA*), resulted in more trehalose production and formation of more nodules with higher nitrogenase activity (Suárez et al., 2008). In agreement with this, deletion of the endogenous *otsA* gene in *R. etli* reduced the number of nodules, nitrogenase activity, and plant biomass.

Due to the well-known stress-protecting properties of trehalose in microorganisms and plants, “trehalose/bacteria” could be a valuable mixture to target to improve abiotic stress tolerance in crop plants.

The objectives of this study were (1) to investigate the effect of exogenous application of trehalose and *R. tropici* in two different methods (Priming and coating) on different parameters; (2) to compare the freshly primed *P. vulgaris* seeds with trehalose and *R. tropici* with seeds coated with trehalose and *R. tropici* using silk as a coating agent; and (3) and to explore the potential of silk as a coating agent.

MATERIALS AND METHODS

Plant Material

Seeds of common bean (*P. vulgaris*) commercial variety White Kidney, with an initial germination rate above 95% and initial seed moisture content below 10% (on a dry weight basis), were used in this study. To minimize fungal contamination during the experiment, seeds were surface sterilized with 2% NaOCl solution (household bleach diluted with sterile water) for 15 min and rinsed three times with sterile water.

Before seed preparation, the coating solution was prepared using the protocol developed by Zvinavashe et al. A 6% silk solution was prepared based on Rockwood et al. (2011) protocol to which we added trehalose at 6% and *R. tropici* grown in Lysogeny broth (LB) media at 28°C until achieving an OD₆₀₀

value of 2. The bacterial solution was centrifuged for 5 min. The pellet was rinsed two times using sterile water, as shown in **Figure 1**. Before usage, seeds were stored at cool temperature (4°C) for 70 days.

Experimental Details

In addition to seeds coated with silk, trehalose, and *R. tropici* (named: Coating) previously described, healthy seeds were primed at the laboratory using sterile water for the negative control and Trehalose 6% and *R. tropici* (cultivated at LB media and watched and centrifuged twice with distilled and sterilized water) as a positive control with constant gentle agitation for 30 min (**Figure 1**). To ensure that the priming solution covered all the seed surfaces, a volume of 1:5 is used for negative and positive control treatments. This methodology was inspired by *On-farm* seed priming described by Harris et al. (2001).

To assess the effect of each treatment on common bean germination, 15 healthy seeds from each treatment were evenly germinated on two layers of filter paper in 10 cm diameter Petri dishes. After adding 10 mL of NaCl solutions ($S_0 = 0$, $S_1 = 15$, $S_2 = 25$, and $S_3 = 50$ mM) to each replicate, Petri dishes were covered with lids and placed in the dark. An equal volume of distilled water was applied to all Petri dishes when their moisture content declined. All the treatments were laid out in a randomized complete block design, replicated three times, and kept recording physiological attributes.

To ascertain the role of seed priming in alleviating salinity, the pots experiment was conducted using large pots (20/30 cm) filled with local soil without any physical treatment. The four previous seed treatments were applied to determine the effect of salinity on the plant establishment and behavior along the growth cycle. Five salinity levels (0, 25, 50, 75, and 100 mM) were applied.

Morphological and Physiological Response of the Seed and Plant

During the experiment, different levels of analysis were conducted to dissociate the components of the combined effects of the treatment. At the seed level: (1) daily germination and (2) germination rate. At the shoot level: (1) shoot length; (2) stomatal conductance using an SC-1 Leaf Porometer (Decagon Devices, Inc., Pullman, WA); and (3) chlorophyll content using the CL-01 Chlorophyll Content System. Moreover, at the root level, (1) root density; (2) primary root length; and (3) lateral root length were measured using the root scanner WinRhizo (Regent Instruments Inc., Quebec, Canada).

Biochemical Response

Extraction of Total Phenolic Compounds (TPC)

Fragments of leaves and roots (0.5 g FM) were ground in a mortar containing a specific volume, usually 5 mL, of ethanol 50% (water-alcohol solution). The extracts were collected in tubes with lids and well-numbered, then left overnight at 4°C to let ethanol extracting the maximum amount of phenol present in the leaves extract as described by Singleton and Rossi (1965). In the tubes containing the leaf extracts, there was a risk of the existence of chlorophylls, eliminated by adding 3 mL of the extract on 0.5 mL of chloroforms.

Tubes were vortexed and centrifuged for 5 min at $5 \times 1,000$ mtp; two phases were separated, supernatant was added, and pellet.

Determination of TPC

We followed the method based on the Folin–Ciocalteu reagent, described by Singleton and Rossi (1965) and Hazzoumi et al. (2017). The following mixture was prepared in test tubes: 0.5 mL of extract, 3 mL of distilled water, 0.5 mL of Na₂CO₃ (20%), to which 0.5 mL of Folin–Ciocalteu reagent was added after 3 min. The tubes were agitated and then placed for 30 min at 40°C. After that, the absorbance was read at 760 nm. The content of phenolic compounds was calculated using gallic acid for the standard curve and expressed in milligrams per gram of fresh leaf matter.

Statistical Analysis

A two-way ANOVA was performed using the general linear model to compare seed treatments and saline levels. Descriptive statistics and ANOVA were carried out using the software R version 3.6.0 with the Agricolae, followed by Tukey's multiple comparison test ($p < 0.05$) to discriminate statistically different values. Graphs were generated using the ggplot2 in R version 4.0.5 version.

RESULTS

Germination and Seedlings Development

Seed germination is a critical phase that impacts crop establishment and yield. It is considered a bottleneck, and once surpassed, the plant can use other strategies to tolerate an excess of salt in the environment. To evaluate the effect of salinity on seed germination and seedlings, a daily record was conducted. ANOVA test (**Table 1**) shows that seed treatment and salinity significantly affect germination throughout the experiment. A highly significant interaction was observed between the treatments.

Table 2 illustrates the effect of increasing salt (0 mM to 50 mM) on the percent of germinating seeds. It was observed that the percentage of germination decreases with increasing salt concentrations for the control seeds. However, a significant increase happens when applying a seed treatment. The ANOVA (**Table 1**) showed that coated seeds behave better at a high salinity level than the freshly treated seeds because the silk preserves the bacteria and the trehalose in its fibroins.

Besides germination rate, ANOVA analysis showed that hypocotyl diameter (HD) varies significantly between seed treatments and saline levels (**Table 1**). Presented data showed that salinity stress distinctly decreases hypocotyl diameter (**Figure 2**). However, the seed treatment affects the behavior of the seedling and induces an increase in hypocotyl diameter. At a low salinity level (S_1), the Silk Coating presents the largest diameter with 0.67 cm, followed by trehalose and bacteria (0.50 and 0.46 cm, respectively). The same trend is observed at 15, 25, and 50 mM of salinity levels.

At S_2 (25 mM), the common bean is intensely influenced by salinity, and seed treatments reinforce the seedling by

increasing the hypocotyl diameter. At S3, the highest salinity level (50 mM), the inoculated seed with *R. Tropici*, presented a diameter equivalent to the control seeds. The Silk Coating and trehalose remained higher with 0.45 and 0.44 cm. Nevertheless, the control presents the lowest diameter in all salinity levels. At 15 mM, salinity concentration stimulates the growth for the control, indicating that salt at low concentration can be used as a priming agent even for glycophytes.

Physiological Activity

The ANOVA for different physiological parameters showed that the effects of seed treatments and salinity on common bean plants are significant (Table 3).

Stomatal Conductance

The effects of salinity on stomatal conductance are shown in Figure 2. Stomatal conductance always declines with increasing salinity concentration. The effect of salinity was more dramatic

in control seeds than in the other treatments. At S3 (50 mM), Silk Coating performs better than seeds treated with trehalose and the bacteria, while the control remains at the last position, indicating that plant reaction to salinity relies on the seed treatments.

Chlorophyll Content

Data for stomatal conductance as a gas exchange characteristic and a level of plant control showed that, upon exposure to saline stress, the plant significantly reduces its photosynthetic activity through the control of the stomata. Damages caused by salinity are felt at the photosynthesis machinery. Data presented in **Figure 2** shows that the application of saline stress significantly reduced the photosynthetic activity at the branching and vegetative growth stage of the common bean. This decrease

in the chlorophyll index was more intense for the control as compared with the other treatments. However, freshly treated seeds presented a high photosynthetic activity in comparison with the coated seeds.

At S0, seeds soaked in trehalose showed the highest photosynthetic activity, followed equally by the seeds soaked in the bacteria, the Silk Coating, and the control. By increasing the salinity level to 25 mM, the plant activity decreases slightly compared with 50 mM salinity level where the control reduces its photosynthetic activity to half, while the treated seeds with *R. tropici* and trehalose maintain their activity. Silk Coating and trehalose treated seeds showed a different reaction compared to the control and the bacteria in 75 mM because of the existing charge of bacteria and trehalose that could be preserved in the silk fibroins.

TPCs

Content of TPC changes with the coating application, trehalose, and salinity level. According to **Figure 2**, the quantity of phenolic compounds in the control plant increases progressively with salinity levels, reflecting a natural response of the plant against the ions of the salt in the medium. However, the seeds soaked in the trehalose reflect a significant reduction of the TPC level. The soaked seeds with bacteria presented the best response against salts in the medium. By recording the most significant decrease of TPC, the content of this latter was less than the control, which means that the plant did not need to synthesize more TPC to tolerate salt stress.

The biosynthesis of phenolic compounds is proportionally linked to salts concentration in the plant microenvironment, whatever the treatment is. About 0 mM showed one-third <75 mM; this variation keeps the same trend in *R. tropici* and Silk Coating, but the trehalose showed a different reaction for 25 mM and 50 mM salinity levels. These treatments reflect almost the same TPC content, highlighting the ability of the trehalose ability to mitigate the negative impact of salt stress on the plant up to an optimal concentration (50 mM in this case).

Using a formulation based on Silk material enriched by *R. tropici* helped the plant to tolerate salt stress, especially in the lowest and highest concentrations; however, the trehalose showed a significant effect in the medium salt stress concentration (50 mM).

Morphology of the Plant

Length of the Shoot

Application of salt stress significantly reduced the plant length for all seed treatments (**Table 4**). A similar decreasing trend was observed due to salt stress. However, this decrease was not the same in all seed treatments. The control seeds were more severely affected by salinity than were the primed and coated seeds. The trehalose and the bacteria significantly increased the length under stress and non-stress conditions (**Figure 3**).

Architecture of the Root

Density of the Root

At different salinity levels, seed treatments have increased the root density compared to the untreated control (**Figure 4**). Nevertheless, data indicate that gradually increasing salinity levels from 0 to 75 mM NaCl has decreased root density. The application of trehalose induces an additive stimulatory effect on

roots. The same growth pattern was observed for seeds freshly inoculated with *R. tropici*. However, the effect is reduced with increased salinity level testifying to the impact of salinity on the bacterial development in soil. In addition, it was noticed that the Silk Coating has a more pronounced and significant increase of roots than the control. At 75 mM of NaCl, the uncoated control and the seed treated with the bacteria did not tolerate the high salinity level and died after 35 days. In contrast, seeds treated with trehalose and coated seeds are behaving well and produce mature plants. This salt concentration is a threshold concentration for common bean; the cultivar used in this experiment does not survive beyond it. The plant viability at this salt concentration may be due to trehalose that promotes roots formation and growth at an early stage. The coated seeds with silk also showed viable plants, and this could be evidence of the role of the silk-based coating on the protection of the bacteria in a high salinity environment.

Primary and Lateral Roots

After 90 days of growth, it was observed that common bean seedlings produce a highly branched root system with abundant lateral roots and a short primary root. Changes in root parameters of common bean under three seed treatments are presented in **Figure 5**. Response to seed treatments did not differ significantly for primary root length under stress and non-stress conditions. However, they are significantly higher than the control.

Irrigation of common bean plants with saline water caused significant decreases in root development relative to control plants. On the other hand, plants from treated seeds enhanced lateral root length under unstressed and salinity-stressed environments. At a low salinity level, inoculation with *R. tropici* was more effective, followed by trehalose. Coated seeds have presented the same principal root length but less lateral root length. Even though it has better performance than the control at unstressed and salinity-stressed conditions, these results suggest that, in *P. vulgaris*, Silk Coating, trehalose, and *R. tropici* may play a crucial role in changing root architecture under saline stress.

DISCUSSION

Germination and Seedlings Development

Germination is a critical stage in the crop cycle. It has been demonstrated that this stage is susceptible to all stresses. In this study, the effect on germination rate induced by seed treatment underlines the importance of priming and biopriming in seed production to improve plant behavior under stressed environments. To alleviate saline stress, a seed coating was developed using Silk as a binding agent, trehalose for its ability to stimulate germination and growth in saline stress and *R. tropici* for its ability to colonize common bean roots and produce nodules for an efficient Nitrogen fixation (Zvinavashe et al., 2019).

Seed priming is one of the universal methods used in fertilizers application. Freshly primed seeds usually contain a high concentration of the priming agents, but it is susceptible to degradation or leaching after irrigation. Results are proof of

FIGURE 3 | Effect of different salinity levels (S0 = 0 mM, S1 = 25 mM, S2 = 50 mM, and S3 = 75 mM) on *Phaseolus vulgaris* shoot length in centimeters.

FIGURE 4 | Effect of different salinity levels (S0 = 0 mM, S1 = 25 mM, S2 = 50 mM, and S3 = 75 mM) on *Phaseolus vulgaris* root density.

the efficiency of the Silk Coating since it exceeds all the seed treatments, mainly in the high salinity levels by maintaining the trehalose and the bacteria in the seed microenvironment. It has also shown a high germination rate and high seedlings diameter at the highest salinity level, supporting the hypothesis of the conservation of the formulation elements by the Silk fibroins in saline conditions.

To further understand the priming effect on germination, independent experimentation was conducted *in vitro* using a

Petri dish to evaluate the germination rate and the seedling vigor under saline treatments. The same trend was observed, and the coated seeds performed better than the other treatments for inducing germination in saline treatments. Besides, it confers to the seedling a significant vigor, explaining the plant strength during the growth cycle. The observed effects are mainly due to the combined action of trehalose and *R. Tropici*, both of which promote growth through different mechanisms. Trehalose, a disaccharide, is an essential signal metabolite in plants

and an essential regulator of many physiological processes, including seed germination and stress response. Within the seed germination process, trehalose plays an essential role in regulating the growth of vegetative and embryogenic tissue in a mechanism involving ABA and sugar metabolism (Gómez et al., 2010). It also plays a vital role as an osmolyte, stress signaling, and stress protectant of the membrane and proteins against the adverse effects of stress (Crowe et al., 1984).

Trehalose regulates many genes, among them the transcription factor bZIP11, which affects the regulation of carbohydrate metabolism, inducing a regulation of the developmental phase transitions (like germination and flowering), carbohydrate, and amino acid metabolisms (Gazzarrini and Tsai, 2014). Accordingly, it has been reported that, in rice, the [trehalose:sucrose] ratio in germinating tissues leads to a regulation of amylase activation for increased starch mobilization and contributes through its regulators OsTPP7 to anaerobic germination tolerance (Kretzschmar et al., 2015). Trehalose hydrolysis is a major reaction during early germination. Presumably, it serves as a source of carbon for synthesis and glucose for energy, and its use in seed coating has been efficient.

R. tropici was added to the silk and trehalose to increase the efficiency of the coating formulation. This bacterium has been widely studied and has proven its ability to increase yield components during the crop cycle, even in areas with medium salinity where untreated seeds do not perform very well. However, it has been observed that it is sensitive to high salinity. Therefore, an exogenous application of trehalose may also help the bacteria tolerate abiotic stress (Cardoso et al., 2007), which supports our results showing the performance of the coated seeds with a mixture of trehalose, *R. tropici*, and silk in high salinity levels.

Physiological Response

Salt stress presents one of the most limiting abiotic factors that affect plant growth and production by altering physiological and biochemical activities (Rockwood et al., 2011; Hazzoumi et al., 2017). Protection of the photosynthetic machinery

significantly contributes to the ability of the plant to withstand stress and reactive oxygen species (ROS) produced upon exposure to saline stress. This study demonstrated that the coated and primed seeds maintained several physiological processes under saline treatments, including photosynthesis through stomatal conductance and chlorophyll content. Many studies highlighted the effect of salinity on photosynthetic activity due to the sensitivity of Photosystem II to NaCl as a non-stomatal regulation (Brugnoli and Lauteri, 1991; Taïbi et al., 2016). While there is stomatal regulation that has also been reported for several plant species, both halophytes and non-halophytes, which refers to stomatal conductance, correlated with photosynthetic capacity (Wong et al., 1979). In this study, and to attenuate the effect of salinity on photosynthetic activity, seeds were treated with trehalose and *R. tropici*. Both directly affect photosynthesis by allocating and metabolizing carbohydrates (Gazzarrini and Tsai, 2014) and contributing to a higher N₂ fixation rate (Bethlenfalvay et al., 1978), respectively.

Previous studies have shown that supplementation of trehalose in saline medium protects *Catharanthus roseus* from the inhibitory effects of salt on growth and photosynthesis (Crowe et al., 1984; Gazzarrini and Tsai, 2014; Hazzoumi et al., 2017). Trehalose accumulation was correlated with higher soluble carbohydrate levels, and a high photosynthesis capacity under stress and non-stress conditions, supporting the increase observed in non-saline treatment. In this study, variation in stomatal conductance and chlorophyll content were strongly expressed in high salinity levels, where coated seeds performed better than the treated seeds and the control, showing that combining trehalose and *R. tropici* helps to maintain a high photosynthetic activity. These increments probably may be attributed to the protective effects of trehalose on photosynthetic systems (Abdallah et al., 2016). Besides, it has been discovered that trehalose plays an important role in plant-microorganism interactions through a higher number of nodules and nitrogenase activity, greater biomass, and an increase in grain yield in inoculated plants under normal or stress conditions (Iturriaga et al., 2009). Photosynthetic and chlorophyll parameters in our

study indicated that trehalose helps the plant mitigate the adverse effects of salinity and increase *R. tropici* performance under saline stress.

To tolerate salt ions, the plant accumulates polyphenols which are involved in the defense mechanism. The role of TPCs in the stimulation of plant resistance was provided in many species and for different biotic and abiotic stress situations (Benhamou et al., 2000). Phenolic compounds are directly involved in scavenging free radicals and protect plants against the damaging effects of increased ROS levels (Petridis et al., 2012). The negative impact of salinity was mainly attributed to water deficit due to lowered water potential in the root zone, specific ion toxicity arising from a higher concentration of sodium and chloride, and the nutritional imbalance.

The osmotic adjustment is a central part of the physiological mechanisms by which plants respond to salinity stress. The salinity generates water stress by disturbance of plant water balance (caused by ions disequilibrium). The accumulation of specific osmotic adjustment solutes (e.g., proline, soluble sugars, and soluble protein) in the cytosol and organelles helps in the osmotic adjustment and improving the growth and development of plants. We note that salt stress causes an increase in TPC accumulation. Increasing polyphenols content in tissue is reported to be a plant response to salinity and indicates the induction of synthesis of secondary metabolism to defend against salt stress. This considerable accumulation is confirmed in *Anethum graveolens* L. (Mehr et al., 2012) and *Vetiveria zizanioides* L. (Manebr et al., 2011). However, the plants treated with trehalose presents better performance in stressful environments. According to Sadak et al. (2019), trehalose foliar application in different concentrations (0,1 mM and 0,5 mM) improves the antioxidant defense system of the quinoa plant against reactive oxygen species (Sadak et al., 2019). The impact of trehalose was accompanied by a significant decrease in lipid peroxidation, hydrogen peroxide contents, and LOX (Lipoxygenase) activity. These decreases were correlated with significant increases in total phenolic contents as compared with untreated plants. A similar positive impact of trehalose was recorded in maize plants exposed to salt stress by increasing the growth parameters and photosynthetic activity of the plant (Rohman et al., 2019).

The antioxidant activity of phenolic compounds was principally due to their role as electron and hydrogen donors, which stabilize the unpaired electron (Huang et al., 2005). The stimulation of TPC by trehalose might be due to the role of this latter as signaling function and their implication in different metabolic pathways in stress conditions by inducing the synthesis of TPC (Alam et al., 2014; Sadak et al., 2019).

Shoots and Root Development Under Salinity Stress

The present study includes the effect of seed treatments on photosynthetic activity through the regulation of stomata. Previous studies demonstrate that the effect of salinity on the CO₂ assimilation rate was mainly due to the reduction of stomatal conductance (Brugnoli and Lauteri, 1991). Evidence of the impact on biomass production.

Exogenous trehalose application was effective in mitigating the harmful effects of saline stress conditions on gas exchange attributes. The ameliorative effect of trehalose on photosynthesis indicates that it plays a role in protecting the photosynthetic system, as already reported, through trehalose signaling mechanisms that can enhance this capacity. Furthermore, trehalose induces an ameliorative effect in plant biomass when carbon supply is not a limiting factor (Rady et al., 2011).

Such effects of exogenously applied trehalose might have been due to its contribution to lowering the cell osmotic potential, which helps plants absorb water from the soil. Plant length is one of the biomass components in addition to the total leaf area and dry biomass. This study demonstrated that seed treatments, under saline and normal conditions, help to maintain and improve plant biomass relative to the control. Other studies emphasized the role of trehalose in the regulation of Na⁺ in plant tissues, including leaves (Garcia et al., 1997), indicating that it may play a direct or indirect role in determining ion selectivity by controlling cellular exclusion of Na⁺. A hypothesis was supported by Joshi et al. (2020), where transgenic lines had higher K⁺/Na⁺ ratios than the wild type under salinity stress.

Our studies showed that coated and primed seeds and seedlings were less affected by saline stress in comparison to the control, as evidenced by their higher germination rates and better subsequent growth under these stress conditions due to efficient sequestration of sodium that has been considered as one of the critical components differentiating between control and treated seeds. Moreover, the degree of damage increases with stress intensity.

Based on the present results, it could be concluded that salinity stress adversely affected growth and physiological parameters compared with control plants. Trehalose can neutralize the effect of salinity stress and result in a significant improvement of morphological traits, physiological parameters, and phytochemical activity (Ding et al., 2018). Trehalose pretreatment alleviated damages through efficient stimulation of the antioxidant defense. Exogenous application of trehalose enhanced the level of internal trehalose, which mainly stimulated the protective activities for the plants (Abdallah et al., 2016).

The *P. vulgaris* root system undergoes significant architectural changes in root density and lateral root length due to the exogenous seed treatments. Those modifications in the root architecture may determine the capacity of the plant to acquire available water and nutrient. Analysis of plants from treated seeds showed that trehalose and *R. tropici* increase the root density. It also promotes the principal and lateral root formation under saline treatments. The same result was observed for coated seeds, indicating the effect of trehalose and the bacteria after 3 months of conservation at 4°C. Lateral root development has been suggested to be under the control of polar auxin transport (Casimiro et al., 2001). Many studies have confirmed that trehalose is an essential signal metabolite in plants, linking growth and development to carbon metabolism (Figuerola and Lunn, 2016). A recent study suggests that auxin acts downstream of trehalose 6 Phosphate to promote seed filling, thereby providing an

outstanding example of how a metabolic signal governs the hormonal control in a critical phase transition in a crop plant (Meitzel et al., 2021).

CONCLUSION

Exogenous application of trehalose and *R. tropici*, ingredients of the seed coating, impacts plant growth under non-stressed and stressed environments. The roots readily absorb trehalose and are easily transported to the aerial parts to function as a major defensive response to several abiotic stresses. This experiment is evidence of the role of trehalose in seed priming. This sugar induces osmotic stress that stimulates the growth of shoots and roots. This study proves that fresh soaking seems to be more productive. Using silk-based coating can be more efficient for preserving the formulation in stored seeds and delivering it to seedlings. This study shines a new light on the role of trehalose in the biofertilizers preservation, plant survival under osmotic stress conditions, and the development of new functional seed coatings that integrate Rhizobium preservation with precise delivery in the soil.

AUTHOR CONTRIBUTIONS

BM and ATZ contributed to the coating design and formulation at MIT. LK managed the project at the UM6P. YZ contributed by funding and scientific follow-up from OCP. MM and ZH contributed in the physiological and agronomic evaluation of the seed coating at the UM6P. All authors contributed to the article and approved the submitted version.

FUNDING

OCP Group supported this work under the UM6P and MIT Research Program (UMRP) within the framework of Project AS12 (2017–2021) granted to Benedetto Marelli at the Massachusetts Institute of Technology (MIT).

ACKNOWLEDGMENTS

We are grateful for the support of the UM6P research facilities and experimental farm staff and the Université Mohammed VI Polytechnique–MIT Research Program (UMRP).

Plant-associated beneficial strains inhabiting plants grown under harsh ecosystems can help them cope with abiotic stress factors by positively influencing plant physiology, development, and environmental adaptation. Previously, we isolated a potential plant growth promoting strain (AXSa06) identified as *Pseudomonas oryzihabitans*, possessing 1-aminocyclopropane-1-carboxylate deaminase activity, producing indole-3-acetic acid and siderophores, as well as solubilizing inorganic phosphorus. In this study, we aimed to further evaluate the effects of AXSa06 seed inoculation on the growth of tomato seedlings under excess salt (200 mM NaCl) by deciphering their transcriptomic and metabolomic profiles. Differences in transcript levels and metabolites following AXSa06 inoculation seem likely to have contributed to the observed difference in salt adaptation of inoculated plants. In particular, inoculations exerted a positive effect on plant growth and photosynthetic parameters, imposing plants to a primed state, at which they were able to respond more robustly to salt stress probably by efficiently activating antioxidant metabolism, by dampening stress signals, by detoxifying Na⁺, as well as by effectively assimilating carbon and nitrogen. The primed state of AXSa06-inoculated plants is supported by the increased leaf lipid peroxidation, ascorbate content, as well as the enhanced activities of antioxidant enzymes, prior to stress treatment. The identified signatory molecules of AXSa06-mediated salt tolerance included the amino acids aspartate, threonine, serine, and glutamate, as well as key genes related to ethylene or abscisic acid homeostasis and perception, and ion antiporters. Our findings represent a promising sustainable solution to improve agricultural production under the forthcoming climate change conditions.

Keywords: abiotic tolerance, ACC-deaminase, antioxidant metabolism, bio-stimulants, priming state, *Pseudomonas oryzihabitans*

INTRODUCTION

In the forthcoming years, global challenges due to climate change and environmental stresses, including soil salinity, are expected to significantly alter soil properties, causing detrimental effects not only on plant growth and crop production, but also on cultivable area worldwide due to salinization (Liu et al., 2017; Kozminska et al., 2018; Corwin, 2021). Apart from disrupting ion balance and cellular homeostasis, high Na^+ concentrations in the soil trigger osmotic stress that impairs water usage, photosynthesis, and biosynthesis of proteins and lipids, as well as cell redox state by over-accumulating reactive oxygen species (ROS) (Liu et al., 2017). Excess salt may activate a wide range of physiological and biochemical adjustments to support plant growth and cellular functions. These include the effective compartmentalization of Na^+ in vacuoles by specific transporters, long-distance ion transport from roots to leaves and stems, alterations in leaf or root morpho-anatomical structures, as well as the production of osmotically active compounds and the accumulation of plant hormones and other signaling molecules (Shabala, 2013; Mellidou et al., 2016; Devkar et al., 2020).

Among the effective strategies to cope with soil salinity, the use of improved management practices in highly saline regions, as well as the implication of conventional or molecular technologies toward the development of salt tolerant crop species are of outmost importance. However, these strategies are often time consuming and cost-demanding. The application of beneficial microbes represents an alternative environmental-friendly strategy to address this issue (Chauhan et al., 2019). The plant rhizosphere represents a delicate and dynamic ecosystem that hosts a variety of microorganisms with diverse and multifaceted functions in plant growth and development, or survival under unfavorable environmental conditions (Kearl et al., 2019; Genitsaris et al., 2020). Plant Growth Promoting Rhizobacteria (PGPR) can provide cross-protection against multiple stress factors by facilitating the growth of their plant symbionts in many different ways (Bruto et al., 2014). Among others, they supply atmospheric nitrogen, synthesize siderophore and phytohormones, solubilize inorganic phosphorus (P), release volatiles, form biofilm, or produce stress alleviating enzymes, such as the 1-aminocyclopropane-1-carboxylate (ACC) deaminase, and cell-wall degrading enzymes (Mayak et al., 2004; Yang et al., 2009; Shariati et al., 2017; Leontidou et al., 2020; Jiao et al., 2021). PGPR-mediated salt tolerance may be achieved via modifications in Na^+ , K^+ , and Ca^{+2} homeostasis thereby allowing plants to sustain a higher K^+/Na^+ within cells (Bharti et al., 2016; Safdarian et al., 2019). At the molecular level, salt stress regulates the expression of several genes coding for late embryogenesis (LEA) proteins, osmoregulatory proteins, redox-regulated proteins, transcription factors (TFs) such as WRKY, transporters/antiporters, and salt overly sensitive (SOS) proteins (Safdarian et al., 2019).

In an attempt to investigate plant microbiomes and the co-evolutionary signature of host-microorganism interactions, a large number of emblematic PGPR model strains have been isolated, characterized and applied as “biostimulants” to enhance

plant abiotic stress tolerance (Liu et al., 2017; Olanrewaju et al., 2017; Leontidou et al., 2020; Yadav et al., 2020). The physiological, transcriptomic, and metabolomic profiles of PGPR-mediated salt tolerance have been explored in differed crops including *Arabidopsis* (Liu et al., 2017), rice (Chauhan et al., 2019), and wheat (Safdarian et al., 2019), suggesting intricate metabolic and hormonal signaling events implicated in plant responses against salt stress.

Plant-associated beneficial strains inhabiting arid and harsh ecosystems may help plants survive under abiotic and biotic stress factors, as these microbes have developed complex adaptive traits in co-evolution with their plant hosts, in contrast to those found in frequently cultivated areas (Fierer, 2017). Previously, we were able to isolate a potential PGPR strain (AXSa06), identified as *Pseudomonas oryzihabitans*, from the National Park of Delta Axios (Leontidou et al., 2020), a highly diverse ecosystem which includes the estuaries of four rivers and has been included in the Natura 2000 network of European ecological regions with code GR122000268 (Vokou et al., 2016). *In vitro* experiments showed that AXSa06 possessed ACC deaminase activity, produced a considerable amount of IAA and siderophores, as well as solubilized inorganic P (Leontidou et al., 2020). PGPR strains containing ACC deaminase activity may help plants ameliorate stress injury by promoting plant and root growth, through scavenging plant ACC, thereby reducing ethylene production (Orozco-Mosqueda et al., 2020). Although this strain has been isolated from a perennial *Sarcocornia* sp. grown in highly saline soils, it could efficiently colonize the rhizosphere of tomato plants (Leontidou et al., 2020).

Due to its interesting phyto-beneficial traits, we aimed to further evaluate the effects of AXSa06 seed inoculation on the growth of tomato seedlings under excess salt (200 mM NaCl). Deciphering transcriptomic and metabolomic changes of inoculated plants exposed to salt stress provided important insights into the complicated mechanism that allowed our novel strain to induce salt tolerance in plants. The proposed model suggests that AXSa06 forced plants to a “primed” state. This state is related to specific metabolite accumulation, repressed stress-inducing signals through a dampened ethylene and abscisic acid (ABA) metabolism, and eventually in effective trade-off between growth and defense responses. The identified signatory molecules including AsA, and the amino acids aspartate, threonine, serine, and glutamate, may serve as possible biomarkers for PGPR priming in tomato.

MATERIALS AND METHODS

Plant Material, Growth Conditions, and Salt Treatment

Tomato seeds of cv “ACE 55” were used to explore plant responses to salt stress upon AXSa06 inoculation. The strain has been previously isolated from an adverse—highly saline—ecosystem (National Park of Delta Axios, Greece) and genetically characterized as *Pseudomonas oryzihabitans* using a Whole Genome Sequencing approach (Leontidou et al., 2020). Seeds were surface sterilized in 70% ethanol (v/v) and subsequently in

2.4% (v/v) sodium hypochlorite. Prior sterilization, seeds were kept in the dark for 24 h at 4°C and then incubated for 72 h in PNS agar plates (1.8% agar) at 25°C to ensure synchronization in growth.

For inoculation with the selected bacteria, called AXSa06, spontaneous rifampicin-resistant mutants were prepared as described earlier (Karamanoli et al., 2005) in order to easily monitor bacterial dynamics in the rhizosphere during experimentation. Seeds were “bacterized” for 30 min in a mixture of the bacterial suspension and 2% methyl cellulose (MC) solution (w/v) (Sigma, Germany) in a 1:1 (v/v) ratio, as previously described (Leontidou et al., 2020). The control seeds were immersed in a mixture of Phosphate Buffer Saline (PBS) and MC (1:1). In turn, seeds of both treatments were placed in pots filled with sterilized peat and perlite (3:1 v/v) in a growth chamber (Snijders Microclima 1,750, Snijders Scientific BV, Netherlands) for 3 weeks at 16/8 h and 25/22°C, receiving plant nutrient medium containing 0.5% (w/v) sucrose (PNS). Salt stress was applied to 21-day old seedlings by the addition of 200 mM NaCl for 7 days based on our preliminary experiments in tobacco (Mellidou et al., 2016) and tomato (Leontidou et al., 2020). Plants received equal volume of 200 mM NaCl solution or tap water (control plants), without leaching. The concentration of NaCl in the pots was regularly monitored by measuring the Electrical Conductivity (EC) after the completion of the irrigation, and values had to be in the range of 3.0–3.5 dS m⁻¹. In total, there were four treatments, (1) non-inoculated non-stressed (0 mM NaCl), (2) non-inoculated salt-stressed (200 mM NaCl), (3) AXSa06-inoculated non-stressed, and (4) AXSa06-inoculated salt-stressed, each consisted of 20 plants (**Supplementary Figure 1**). At the end of the stress period, plant growth-related and physiological parameters were evaluated, while leaf and root tissues were frozen in liquid nitrogen and kept at –80°C until further analysis.

Plant Growth and Physiological Measurements

Shoot length and total leaf number were recorded for all plants exposed to 200 mM NaCl for 7 days, while above the ground biomass (stems and leaves), on a fresh weight basis, was evaluated for 10 plants per treatment, at the end of stress treatment. Among the physiological parameters, net photosynthetic rate (A_{net} , mmol m⁻² s⁻¹), and chlorophyll content index [$\text{CCI} = (\% \text{ transmittance at } 931 \text{ nm}) / (\% \text{ transmittance at } 653 \text{ nm})$] were assessed in 10 plants per treatment using a portable photosynthesis meter (LCPROT-001/BW, ADC Bioscientific Ltd., UK), and an Opti-Sciences CCM-200 chlorophyll content meter (OptiSciences Inc.), respectively. Measurements were taken on the second fully expanded leaf (counting from the apex) as described earlier (Mellidou et al., 2016, 2017).

Salt Stress Markers Evaluation

The accumulation of Na⁺ in tomato leaves inoculated with AXSa06 following treatments with 200 mM NaCl for 7 days was determined as previously described (Mellidou et al., 2016).

Briefly, leaf samples (0.5 g) were heated in a muffle furnace at 500°C for at least 4 h, and the residue was dissolved in a 3.6 M

HCl/1.4 M HNO₃ aqueous solution. In turn, Na⁺ content was determined in a flame photometer (Jenway PFP 7, Gransmore Green, Felsted England).

Malonyldialdehyde (MDA) content was determined in leaf samples to estimate the degree of lipid peroxidation using the thiobarbituric acid (TBA) test (Heath and Packer, 1968), with a few modifications (Mellidou et al., 2020). Briefly, frozen leaf powder (200 mg) was homogenized in 600 mL 0.1% (w/v) trichloroacetic acid (TCA) solution, and centrifuged at 14,000 rpm for 15 min at 4°C. In turn, 0.5 mL of the supernatant was added to 1.5 mL 0.5% (w/v) TBA in 20% TCA, the mixture was boiled for 25 min, and the reaction was completed by immersing the reaction tubes on ice. The MDA content was calculated by measuring the absorbance of supernatant at 532 nm, after subtracting the value for non-specific absorption at 600 nm, using an extinction coefficient of 155 mM⁻¹ cm⁻¹.

REL was determined essentially as previously described (McKay, 1998). Briefly, at the end of stress treatment, roots were thoroughly rinsed with tap water, immersed in glass tubes containing 15 ml of deionized water with known EC and vortexed vigorously. After 24 h in dark, EC was measured before and after boiling at 110°C for 20 min using the electrical conductivity meter ConductoMeter (Metrohm, Herisau, Switzerland). The injury index was estimated from the formula: REL (%) = [(EC before/EC after boiling) × 100]/initial root weight. Measurements were performed using five replicates per treatment.

Proline content was also assayed in leaf tissues according to Bates (1976). Briefly, 100 mg of leaf powder was homogenized in 5 ml of 3% (w/v) aqueous sulfosalicylic acid and then centrifuged at 14,000 rpm for 10 min at 4°C. One ml acid-nynhydrin reagent and 1 ml glacial acetic acid was added to 1 ml of supernatant, and the mixture was heated at 100°C for 1 h. After terminating the reaction in an ice bath, the reaction mixture was extracted with 2 ml toluene, vortexed vigorously, and left at room temperature for 30 min. Proline content was determined by measuring the absorbance of the fraction with toluene at 520 nm, based on a standard curve with pure proline of known concentrations.

For all measurements, five biological replications per treatment were used, corresponding to five individual plants.

Determination of Non-enzymatic and Enzymatic Antioxidants

Ascorbic acid (AsA) was determined spectrophotometrically using the ascorbate oxidase (AO) enzyme as previously described (Pateraki et al., 2004). Calculations were based upon the difference in absorbance at 265 nm before and 3 min after the addition of AO (1 U/μl) to a 200 μL aliquot of extract in 200 mM sodium phosphate buffer (pH 5.6). Total AsA (totAsA) content was determined by measuring absorbance 10 min after adding 10 mM DTT to a separate extract aliquot. Measurements were performed using five biological and two technical replicates per treatment.

For enzyme activities, total proteins were extracted from 500 mg of leaf tissues, and purified using ion-exclusion Sephadex G-25 column (PD 10, GE Healthcare) essentially as previously described (Mellidou et al., 2012). Bovine serum albumin (Sigma)

was used as standard for the quantification of protein content of the extracts according to Bradford method (Bradford, 1976). The activities of catalase (EC 1.11.1.6, CAT), superoxide dismutase (SOD; EC 1.15.1.1), pyrogallol-based peroxidase (EC 1.11.1.7, POX), and ascorbate peroxidase (EC 1.11.1.11, APX) were determined based on optimized “in-house” protocols (Mellidou et al., 2012, 2017). All technical measurements were conducted in duplicates for each of the five biological replicates per treatment.

Quantification of ACC and MACC Content in Leaves and Roots

As AXSa06 strain possesses ACC deaminase gene, as well as *in vitro* ACC activity (Leontidou et al., 2020), metabolites from the ethylene biosynthetic pathway (ACC and MACC) were quantified in leaves and roots of the plants at exposure to 200 mM NaCl, essentially as previously described (Bulens et al., 2011; Van de Poel et al., 2014). Enzyme activities of ACC synthase and ACC oxidase were below the threshold of detection limit, and thus not able to be quantified.

Ethylene Quantification in Excised Tomato Leaves

Ethylene production was quantified in excised non-inoculated and AXSa06-inoculated tomato leaves upon salt stress as previously described (Kim et al., 2013, 2016). Briefly, leaves were excised, weighted, and placed in a glass tube. After 30 min without sealing, the glass tubes were capped with a septa stopper, and incubated for an hour at room temperature. One ml gas sample was removed from the tube using a syringe and injected into a gas chromatograph (GC-2014ATF Shimadzu), equipped with a flame ionization detector (FID) and a stainless-steel column (filled with Porapak P, Q, R, S), to quantify ethylene gas levels. Measurements were performed using five individual biological replicates per treatment.

RNA Isolation, Library Construction, and Sequencing

Leaf tissues were used for total RNA extraction using RNeasy Plant Mini Kit (QIAGEN) according to the manufacturer's instructions. Three biological replicates were employed per treatment. Quantification and qualification of the extracted RNA was checked using the RNA Nano 6000 Assay Kit of the Agilent Bioanalyzer 2100 system (Agilent, CA, USA) to ensure that the RNA Integrity Number (RIN) values were above 7. In total, 12 RNA-Seq libraries were prepared and purified using QIAseq Stranded mRNA Select Kit (QIAGEN) following manufacturer's instructions. After generating the index-coded samples, each cDNA library was sequenced in a single lane of Illumina platforms (Novaseq 6000 System) with 150 bp paired-end reads, obtaining above 24 M raw reads per sample. Raw data obtained from sequencing were converted to Fastq format and deposited to the European Nucleotide Archive, under PRJEB42497.

Analysis of Sequencing Data

Raw sequences were processed with fastp (Chen et al., 2018) to remove reads containing adapter bases, poly-N sequences, and reads with low quality. After quality control, high quality

paired-end reads were aligned to the tomato reference genome (Hosmani et al., 2019) using HISAT2 (Kim et al., 2015). The Stringtie (Kovaka et al., 2019) was used to assemble the set of transcript isoforms obtained in the mapping step, and gffcompare (Pertea and Pertea, 2020) was used to compare the assemblies to reference annotation files and sort out new genes from known ones. The read counts mapped for each gene, including known and novel genes, were produced using Featurecounts (Liao et al., 2014), and fragments per kilobase for exon model (FPKM) was calculated for each gene. Differential gene expression levels between treatments (consisted of three biological replicates) were determined using DESeq2 R package. *P*-values were corrected with the Benjamini-Hochberg adjustment within the R *p.adjust* function and the FDR (False Discovery Rate) was also calculated among the genes. Genes adjusted $P \leq 0.01$ and \log_2 (fold-change) ≥ 1.5 were considered as up-regulated, and those with \log_2 (fold-change) ≤ -1.5 as down-regulated. Gene ontology (GO) and KEGG enrichment analysis of DEGs was accomplished using clusterProfiler (Yu et al., 2012).

Metabolite Extraction and Derivatization

Analysis of polar metabolites was performed as previously described (Ainalidou et al., 2016). Leaf tissues (500 mg) were homogenized in liquid nitrogen and transferred to 2 mL screw cap tubes with 1,400 μ L of 100% methanol. Adonitol (100 μ L of 0.2 mg mL⁻¹ aqueous solution) was added as internal quantitative standard and vortexed, following incubation at 70°C for 10 min. Samples were then centrifuged at 11,000 \times g (4°C) for 10 min and the supernatants were transferred to glass vials. Subsequently, 750 μ L of chloroform and 1,500 μ L of cold distilled H₂O were added. The mixtures were centrifuged at 2,200 g (4°C) for 15 min and 150 μ L from the upper phase (polar phase) were transferred into new 1.5 mL glass vials. The vials were placed in a vacuum desiccator for overnight drying. For the derivatization, dried residues were re-dissolved in 40 μ L of 20 mg mL⁻¹ methoxyamine hydrochloride in pyridine, and were shaken at 37°C for 2 h. For the completion of derivatization, samples were treating with 70 μ L of N-Methyl-N-(trimethylsilyl)-trifluoroacetamide (MSTFA) reagent and incubated at 37°C for 30 min. The aliquots were stored at -20°C, until further analysis by a GC-MS system.

Gas Chromatography–Mass Spectrometry (GC–MS)–Based Metabolite Profiling

GC–MS analysis was performed in Thermo Trace Ultra GC equipped with ISQ MS and TriPlus RSH autosampler (Switzerland). One microliter sample volumes were injected with a split ratio of 70:1. Separations were carried out on a TR-5MS capillary column 30 m \times 0.25 mm \times 0.25 μ m. Injector temperature was set at 220°C, ion source at 230°C, and the interface at 250°C, while a constant flow rate of the carrier gas (He) was set at 1 mL min⁻¹. The GC temperature program was held at 70°C for 5 min, then increased to 240°C at a rate of 8°C min⁻¹, and held at 240°C for 15 min. After 5 min solvent delay, mass range of *m/z* 50–600 was recorded. The mass spectra were acquired in electron impact ionization (EI) mode. The peak area integration and chromatogram visualization were performed

using Xcalibur processing program. For peak identification and mass spectra tick evaluation was performed and NIST11 database were used. Mass spectra were cross referenced with those of authentic standards in the GOLM metabolome database (Kopka et al., 2005; Ainalidou et al., 2016). Quantification of the detected metabolites was assessed based on the relative response compared to adonitol as the internal standard, and expressed as relative abundance.

Statistical Analysis

All data were analyzed by SPSS (Version 25. Chicago, SPSS Inc.). Duncan multiple-range tests were performed to determine significant differences between inoculated vs. non-inoculated seedlings under control or salt stress conditions.

RESULTS

AXSa06 Inoculation Improved Morpho-Physiological and Biochemical Traits in Tomato During Salt Stress

In order to easily monitor strain population throughout the experiment, rifampicin resistant mutants were employed. Under the selected experimental growth conditions, the AXSa06 strain was well-established in the rhizosphere of inoculated plants prior to stress application, while it was also able to grow at highly saline soil conditions (Leontidou et al., 2020). To confirm that AXSa06, identified as *Pseudomonas oryzae*, was able to alleviate salt stress in tomato seedlings, plant-growth, and physiological traits were recorded in treatments with or without 200 mM NaCl. At control conditions (0 mM NaCl), no particular differences related to growth or photosynthesis were recorded between non-inoculated and AXSa06-inoculated plants (Figures 1A–D). Treatments with 200 mM NaCl led to a significant decrease in both shoot length (Figure 1A) and leaf number (Figure 1B) only in non-inoculated plants compared to non-stressed plants. Inoculated plants, not only maintained their growth-related traits at non-stressed levels, but also had higher shoot length (14.2%; Figure 1A) and more leaves (8.7%; Figure 1B) compared to non-inoculated stressed plants. Salt stress caused a significant decrease in A_{net} (50.5% Figure 1C) and CCI (50.2%; Figure 1D), respectively, in non-inoculated plants compared to control conditions. By contrast, the negative effect of 200 mM NaCl in AXSa06-inoculated plants was less prominent, with a 33.9 and 3.9% reduction in A_{net} and CCI, respectively. Both A_{net} and CCI were higher in inoculated plants compared to non-inoculated ones (33.4 and 52.3%, respectively) under salt stress. These results support the positive effect of inoculation with AXSa06 on plant growth and physiological parameters of tomato seedlings exposed to 200 mM NaCl.

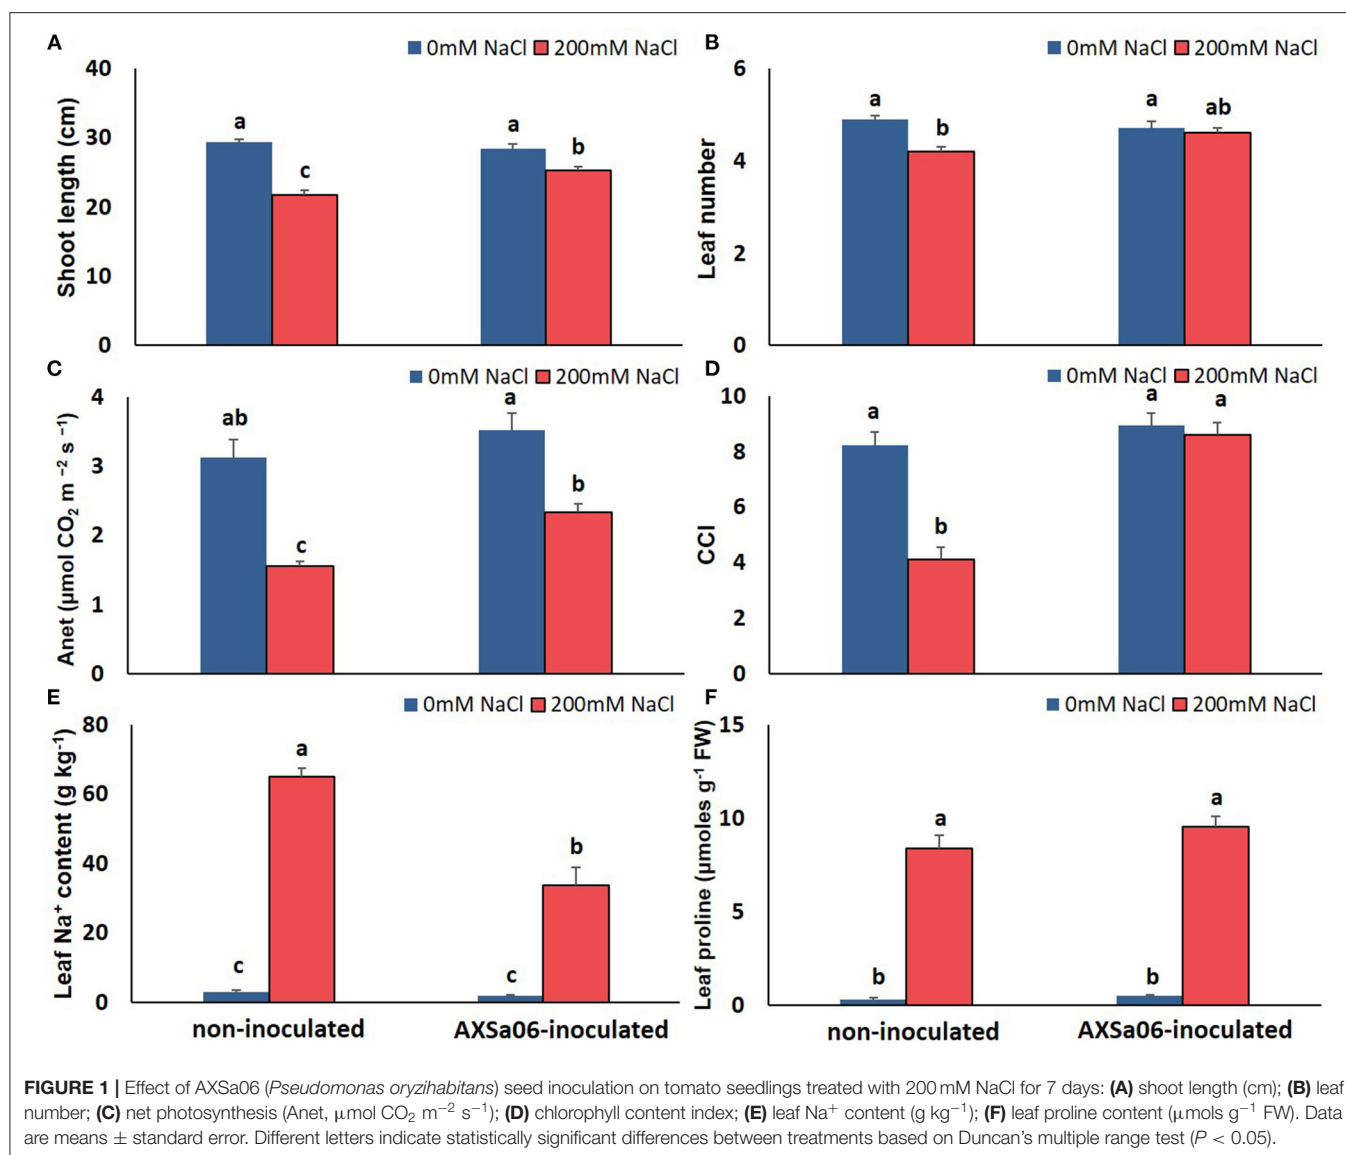

The accumulation of leaf Na^+ and proline contents was dramatically enhanced at exposure of plants to 200 mM NaCl (Figures 1E,F). Nonetheless, leaves of non-inoculated plants contained significantly higher amount (54.0%) of Na^+ compared to inoculated ones, while inoculated plants accumulated slightly more proline (12.4%) in leaves than non-inoculated ones, yet not significant. Interestingly, in the absence of NaCl, inoculation with

AXSa06 resulted in enhanced leaf MDA content (68.6% higher compared to non-inoculated plants), suggesting that inoculation with the strain probably imitated the effect of mild oxidative stress (Figure 2A). With regard to REL, it was significantly enhanced at exposure to 200 mM NaCl, regardless the presence of AXSa06 (Figure 2B). Nonetheless, REL of AXSa06-inoculated plants at exposure to salt stress was lower (80.23% on average) compared to non-inoculated plants (91.83%), although not significant due to the large scale of values, indicating that there was probably less negative impact of salt in the roots at the presence of the strain. At the same time, the fact that REL of unstressed inoculated plants was also lower (35.5%) compared to non-inoculated plants (44.6%) suggested that the potential oxidative boost at control conditions, as highlighted by the enhanced MDA content, was not harmful with regard to electrolyte leakage from roots.

This mild oxidative boost in AXSa06-inoculated plants was further supported by the increased activities of antioxidant enzymes, POX (Figure 2C) and CAT (Figure 2D), at control conditions. In particular, POX and CAT specific activities were 73.0 or 68.4% higher in inoculated plants compared to non-inoculated ones, respectively. When 200 mM NaCl was applied, no further induction in MDA content or POX activity was observed in inoculated plants, likewise in non-inoculated plants, in which both traits were remarkably enhanced. By contrast, CAT activity decreased in inoculated plants at exposure to salt stress, nearly at control levels of non-inoculated plants. Upon salt stress, SOD activity was significantly increased in inoculated plants, but remained unaltered in non-inoculated ones (Figure 2E). The activity of APX, the first enzyme in the AsA-GSH (glutathione) cycle responsible for the oxidation of AsA to monodehydroascorbate (MDHA) with the parallel detoxification of H_2O_2 , was increased in non-inoculated plants at exposure to stress. Notwithstanding, APX activity remained at low levels in inoculated plants (Figure 2F), probable due to the lower H_2O_2 accumulation within the cell owing to its better detoxification by other peroxidases (Figure 2C).

Inoculation With AXSa06 Altered Root and Leaf ACC Levels Under Salinity Stress

In this study, the application of 200 mM NaCl enhanced ACC and reduced MACC levels in the roots of non-inoculated plants (Figures 3A,B). By contrast, inoculation with the ACC-deaminase possessing strain, AXSa06, maintained root ACC content under salt stress similar to control levels, probably due to the ACC deaminase activity of the strain. Intriguingly though, a remarkable increase in root MACC content was observed after inoculation owing to salt stress, probably indicative of a AXSa06-mediated feedback regulation on redirecting plant ethylene synthesis. The opposite trend was evident in the leaves of salt-stressed plants (Figures 3C,D). In particular, at the absence of inoculum, leaf ACC content decreased, probably to support the ethylene production owing to stress, as indicated in the excised leaves of the same plants (Supplementary Figure 2). However, in inoculated plants, ACC levels remained unaltered upon salt stress (Figure 3C), whilst a significant decrease in

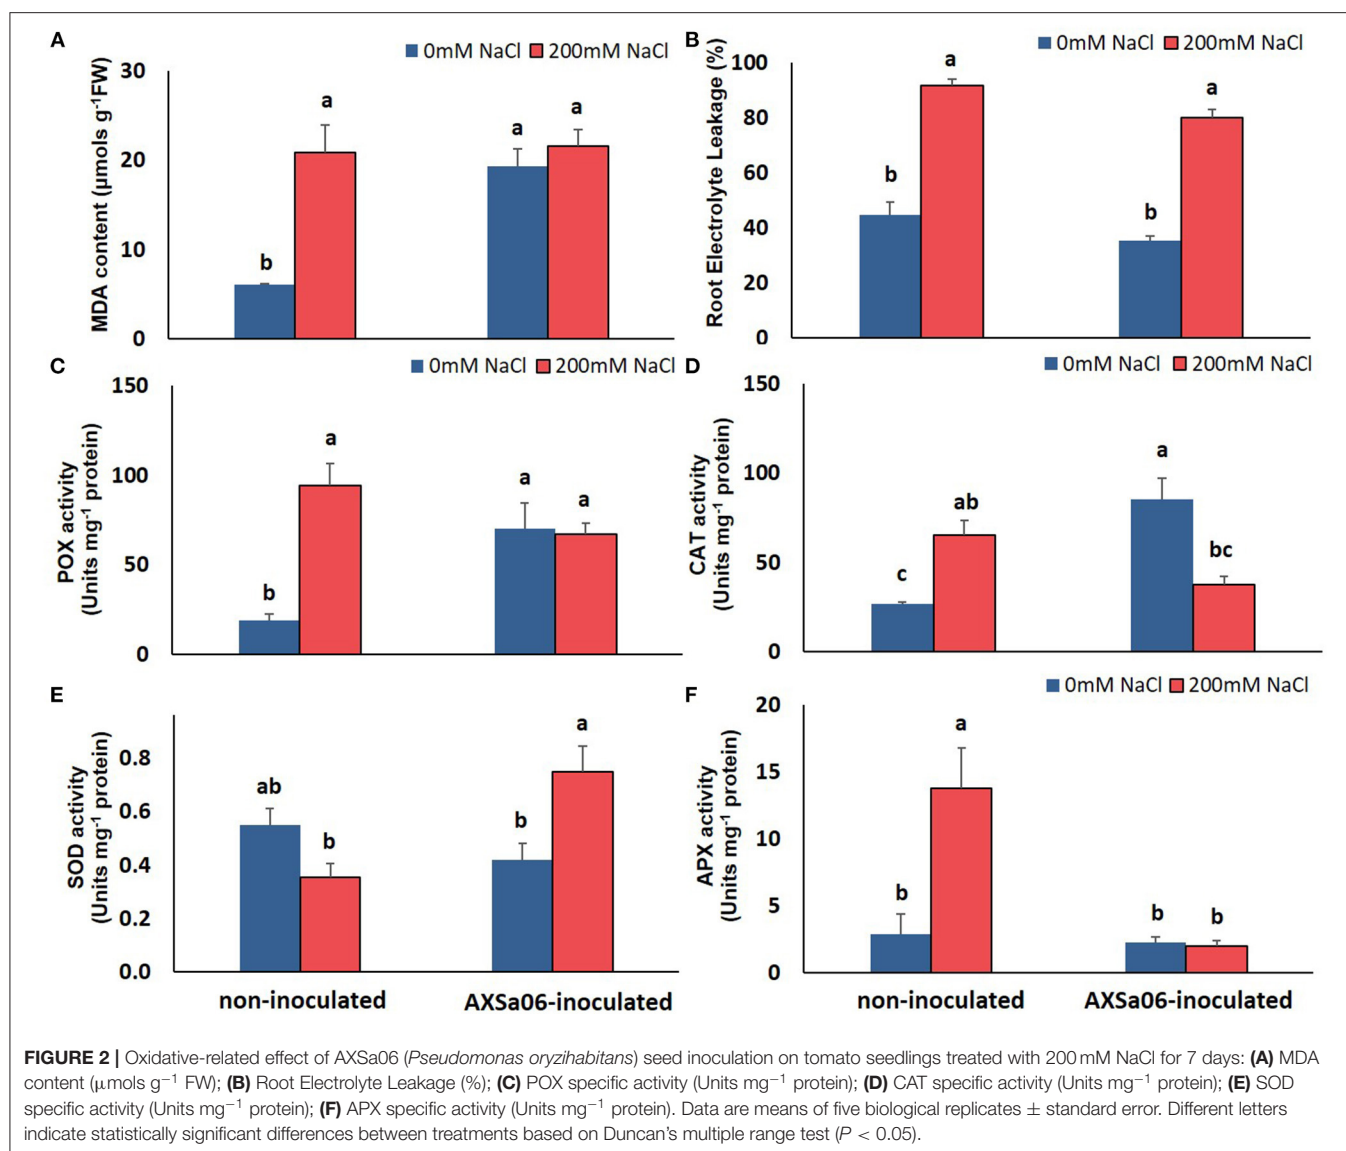

ethylene production was evident in excised leaves at exposure to 200 mM NaCl (**Supplementary Figure 2**). Although no *in vivo* ethylene measurements were performed, ethylene determination in excised leaves of plants inoculated with AXSa06 highlighted the capacity of these plants to produce ethylene upon salt stress. Leaf MACC levels remained largely unchanged by both the salinity or inoculation treatment (**Figure 3D**). These observations suggested that at the presence of AXSa06, the above-the-ground tissues may accumulate lower ACC levels, that could lead to reduced ethylene-related stress signals as a result of ACC deaminase activity below the ground, compared to non-inoculated plants.

Overview of Transcriptome Analysis and Read Assembly

To unravel the mechanism of AXSa06-mediated salt tolerance in tomato plants, transcriptome profiling was carried out using

an RNA-Seq approach. After removing adapter sequences and low-quality reads, a total of 677.6M with an average of 56.5M clean reads and a Q30 percentage $\geq 95\%$ were generated for the 12 cDNA libraries (**Supplementary Table 1**). No remarkable differences were observed in read number between inoculated vs. non-inoculated plants, or between control and salt stress conditions. The clean reads were mapped to the tomato reference genome, cv Heinz 1706 version 4.0 (Hosmani et al., 2019), with an average total mapping ratio around 97%, and uniquely mapping ratio at 94.6%. After averaging replicate values, total transcripts with FPKM > 1 for each treatment varied from 17,873 to 18,153, of which the novel transcripts ranged from 249 to 274 (**Supplementary Tables 2–5**).

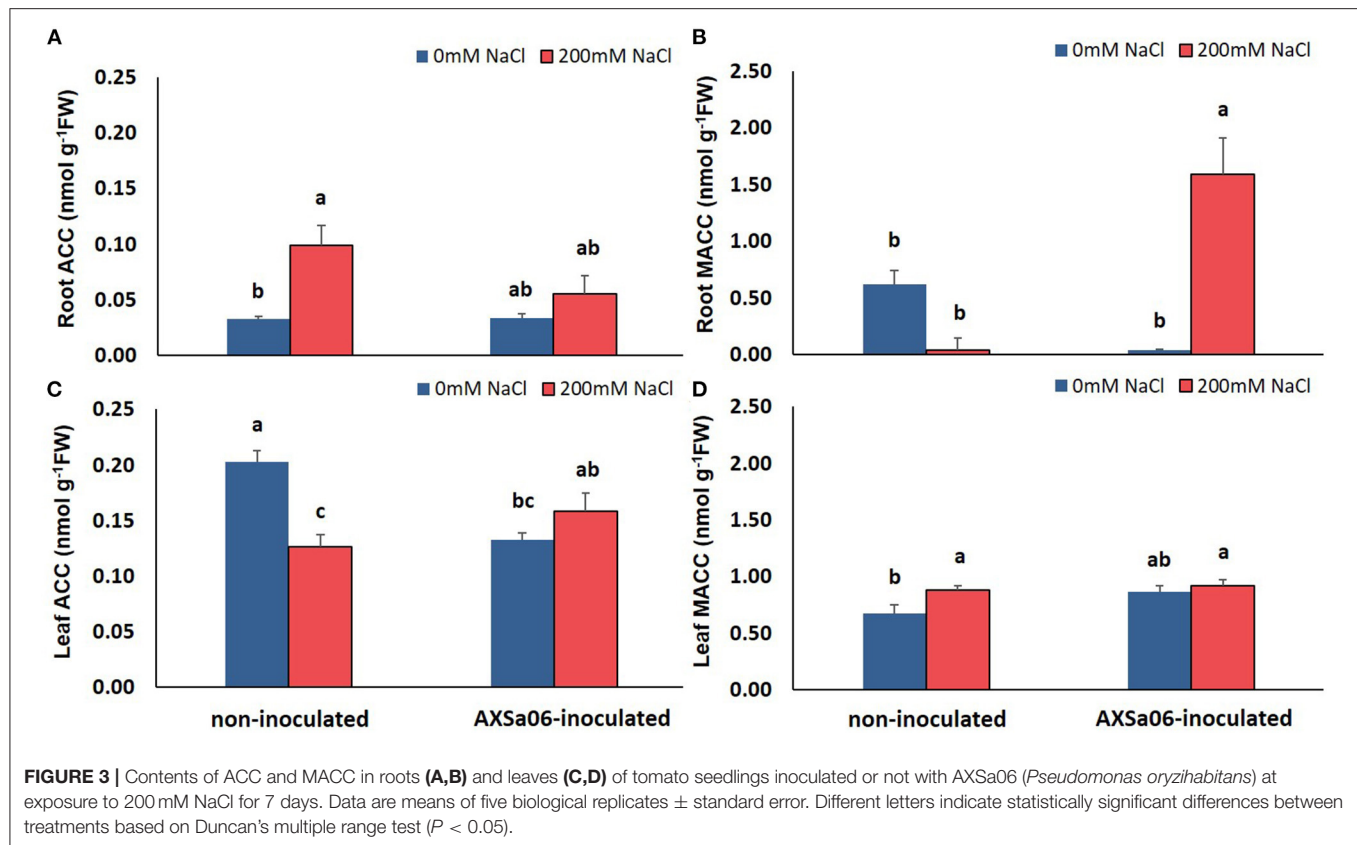

The expression of these transcripts was subjected to a Principal component analysis (PCA) (**Figure 4A**). The first two components, which explained 61% of the variation, were able to distinguish the four different groups of treatments,

with three biological replicates clustering together, and each group having certain differences in their gene expression profiles. Furthermore, at total number of 17,263 transcripts (on average 96% of total expressed genes) were expressed in all treatments, with the uniquely expressed transcripts ranging from 110 (AXSa06-inoculated at 0 mM) to 213 (non-inoculated at 200 mM) (Figure 4B). Differentially Expressed Genes (DEGs) between treatments were defined using $|\log_2(\text{fold change})| > 1.5$, and corrected ($p \leq 0.01$). In total, 264 and 108 DEGs were identified between control and salt stress, in non-inoculated or inoculated plants, respectively (Figure 4C and Supplementary Tables 6, 7). Among them, 159 and 83 genes were significantly up-regulated in salt-treated plants in non-inoculated and inoculated plants, respectively, whilst 105 and 25 were down-regulated, suggesting that transcriptomic profiles of non-inoculated plants were more disturbed by NaCl, compared to those of inoculated plants. Although gene expression profiles altered significantly as a response to salt stress

to a different extent, there were 43 overlapping DEGs that were regulated by salt stress, regardless inoculations with AXSa06. Among them, the most interesting DEGs up-regulated due to stress involved in central metabolic pathways were alcohol dehydrogenase (ID544074), chitinase (ID544149), L-ascorbate oxidase (ID101252861), and proline dehydrogenase (ID778202). In the same regard, 3-ketoacyl-CoA synthase 11 (ID101268510), indole-3-acetic acid-amino synthetase (ID101258277), inositol 2-dehydrogenase (ID101260461), and indole-3-pyruvate monooxygenase YUCCA5 (ID101267265) were significantly down-regulated in both non-inoculated and inoculated plants owing to NaCl treatment. By contrast, there were also two inositol oxygenase genes (ID 101263222 and 101254427) that were up-regulated in inoculated plants but down-regulated in non-inoculated plants.

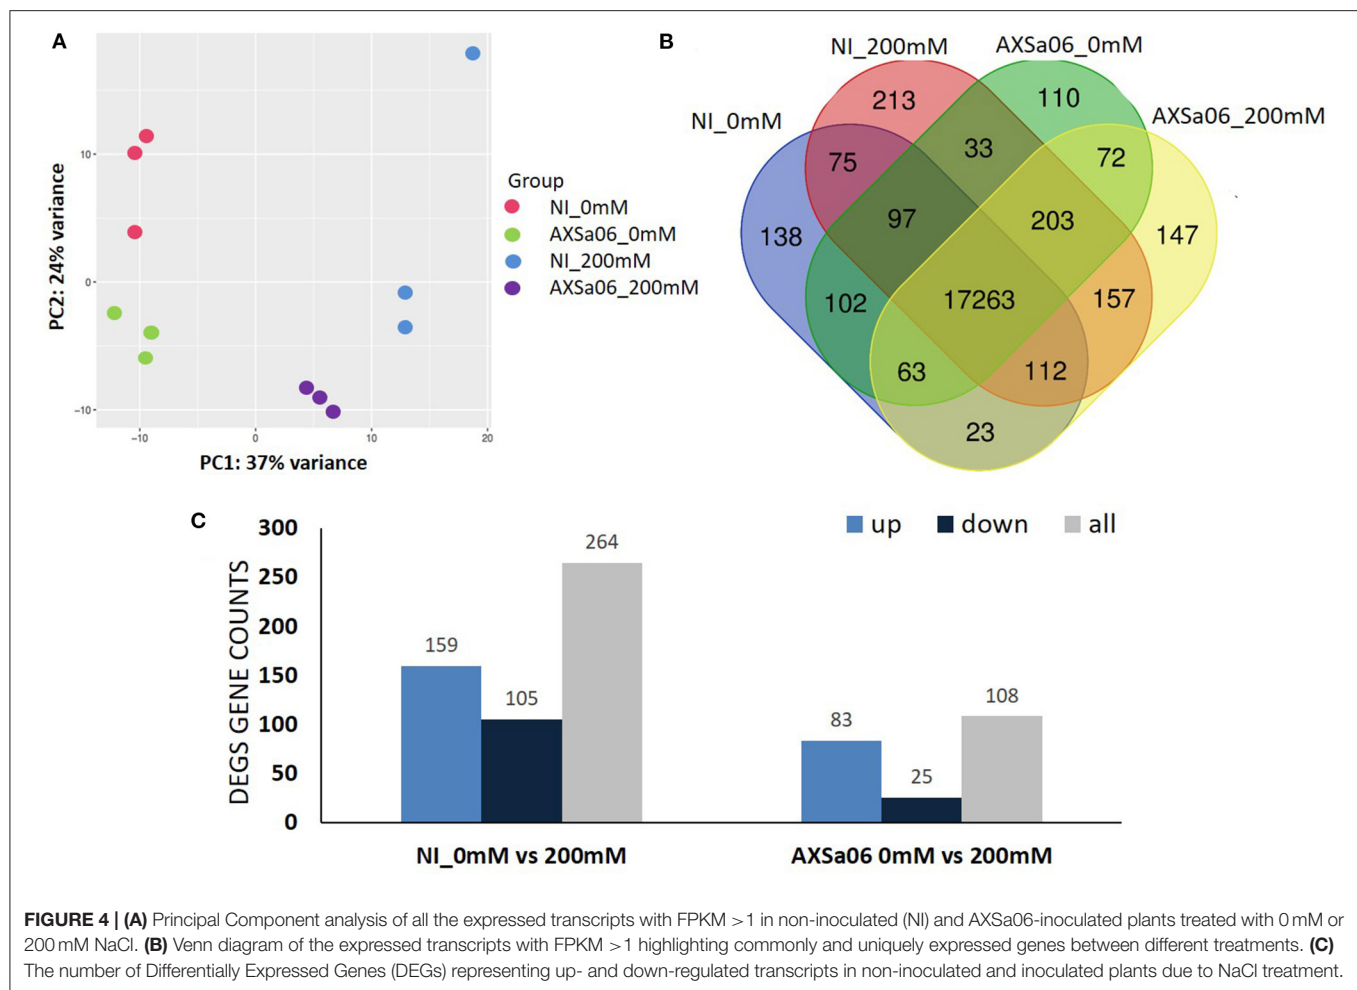

Gene ontology (GO) annotation analysis of DEGs between stressed and non-stressed plants returned 170 GO terms, classified into the two GO classes (BP, Biological Process;

ME, Molecular Function). Among them, 20 or 30 significant GO terms were enriched for non-inoculated and AXSa06-inoculated plants, respectively (Supplementary Table 8 and Supplementary Figure 3). At the absence of inoculum, the most significant (corrected $p < 0.05$) enrichment terms of up-regulated genes due to NaCl treatments in the BP category were response to wounding (GO:0009611), and amine metabolic process (GO:0009308), whilst in the ME, there were endopeptidase inhibitor (GO:0004866) and regulator (GO:0061135) activity, peptidase regulator (GO:0061134), and inhibitor (GO:0030414), as well as enzyme inhibitor (GO:0004857), and regulator (GO:0030234) activity (Supplementary Figure 3A). By contrast, at inoculations with AXSa06, GO terms of the BP category such as response to stress (GO:0006950), defense response (GO:0006952), and response to biotic stimulus (GO:0009607) were significantly enriched under salt stress (Supplementary Figure 3B). Among the most significant down-regulated GO terms at the absence of inoculum, there were small molecular metabolic process (GO:0006950), cellular carbohydrate metabolic process (GO:0044262), single organism carbohydrate metabolic (GO:0044723), and catabolic (GO:0044724) processes (Supplementary Figure 3C). Interestingly, the majority of up-regulated GO terms significantly enriched in non-inoculated plants exposed to stress, were identified as significantly down-regulated in inoculated plants (Supplementary Figures 3A,D), suggesting that *Pseudomonas oryzae* AXSa06 strain was able to

reverse—to some extent—the modifications stimulated by salt treatment.

As a further step, the DEGs were also examined against KEGG database to identify active biological pathways in tomato seedlings at exposure to salt and AXSa06 treatments (Supplementary Figure 4 and Supplementary Table 9). Assignments of significant DEGs between stressed and non-stressed plants into KEGG pathways showed that the most significant induced pathways were protein processing in endoplasmic reticulum (sly04141), phenylpropanoid biosynthesis (sly00940), plant-pathogen interaction (sly04626), and arginine-proline metabolism (sly00330) in non-inoculated plants (Supplementary Figure 4A), while in AXSa06-plants, pathways of phenylpropanoid biosynthesis (sly00940), as well as starch and sucrose metabolism (sly00500) were up-regulated (Supplementary Figure 4B). The phenylpropanoid metabolic pathway that was induced regardless the presence of the PGP strain, contributes to lignin biosynthesis, including several lignin-forming peroxidases and cell-wall related proteins that were found to be over-expressed upon salt treatment (Supplementary Tables 6, 7). Plant hormone signal transduction pathway (sly04075) was significant down-regulated as a response to stress, regardless inoculation with AXSa06 (Supplementary Figures 4C,D), but in a very different way, as it will be discussed below. By contrast, photosynthetic-related pathways (sly00195 and sly00196), as well as those related to carbon (sly00710, sly 01200), glyoxylate and dicarboxylate

(sly00630), or nitrogen metabolism (sly00910), were only repressed at the absence of inoculum in response to salt stress (**Supplementary Figure 4B**), indicating the notable salt-mediated handicap in primary metabolism. Intriguingly, amino acid biosynthesis (sly01230) was significantly down-regulated in AXSa06-inoculated plants exposed to 200 mM NaCl.

Transcript abundance of DEGs in non-inoculated and inoculated plants in response to 200 mM NaCl, is also presented using heat maps (**Supplementary Figures 5, 6**), highlighting a series of changes in gene expression profiles when plants subjected to stress, whilst the entire list of DEGs between stressed and non-stressed plants is also displayed (**Supplementary Tables 6, 7**). The highest up-regulated genes in non-inoculated plants as a response to salt stress were ferredoxin (ID101248335) and a small heat shock protein (ID544205), whilst the top down-regulated DEGs included a spermidine hydroxycinnamoyl transferase-like (ID101254821), and the MYB transcription factor RADIALIS-like 6 protein (ID101244580) (**Supplementary Table 6**). By contrast, among the highest up-regulated genes in AXSa06-inoculated plants as a response to salt stress, there were abscisic acid 8'-hydroxylase 3 (ID101254720), and a non-specific lipid-transfer protein

1-like (ID101265675), while among the highest down-regulated genes, there were the MYB transcription factor RADIALIS-like 3 (ID101246530), and gamma-glutamyl peptidase 3-like (ID101254399) (**Supplementary Table 7**). Below, we explored manually a broad number of genes of particular interest that were modulated by AXSa06-inoculation by focusing on transcripts related to photosynthesis, amino acid metabolism, plant growth and development, stress responses, hormone synthesis and signaling, transcription factors, and other salt-responsive proteins (**Figure 5**). Genes with FPKM > 1 in at least one treatment were considered as expressed (**Supplementary Table 10**).

Energy Metabolism

Some genes of the central metabolism such as phosphoenolpyruvate carboxylase (ID101245149) and O-acetyltransferase WSD1 (ID101246264) were significantly up-regulated, and some others including 3-ketoacyl-CoA synthase 11 (ID101268510) were down-regulated, in non-inoculated plants as a response to salt stress (**Supplementary Table 6**). Others related to lipid-metabolism were down-regulated when non-inoculated plants were exposed to 200 mM NaCl.

These included glycerophosphodiester phosphodiesterase (ID101261081), palmitoyl-monogalactosyldiacylglycerol delta-7 desaturase (ID101250586), GDSL esterase/lipase 1 (ID101268445), and 3-ketodihydrosphingosine reductase (ID101248253). Similarly, the expression of several genes involved in these pathways were also induced [O-acyltransferase WSD1 (ID101251623) and GDSL esterase/lipase (ID101250696)] or repressed [glycerophosphodiester phosphodiesterase (ID101261081), 3-ketoacyl-CoA synthase 11 (ID101268510)] under salt condition in AXSa06-inoculated plants (**Supplementary Table 7**).

Compared to 0 mM NaCl, a wide number of genes related to light reaction in photosynthesis and ATP synthesis were found to be down-regulated upon salt stress in the absence of inoculum (**Figure 5** and **Supplementary Table 10**), as further suggested by

KEGG enrichment (**Supplementary Table 9**). These included the ATP synthases CF1 alpha (*atpA*), beta (*atpB*), epsilon (*atpE*), and CF0 (*atpF*), chloroplastic plastocyanin (*PETE*), photosystem II 23 protein (*PSBP*), photosystem II CP47 apoprotein (*psbB*), chloroplastic oxygen-evolving enhancer protein 1 (*PSBO*), photosystem II oxygen-evolving complex protein 3 (*psbQ*), and ferredoxin-I (SEND33) (**Figure 5**). Down-regulation of the above-mentioned photosynthesis-related genes occurred to a lesser extent in AXSa06-inoculated plants upon salt stress, suggesting that the energy metabolism related to photosynthetic apparatus was less disturbed compared to non-inoculated plants. This is in line with the enhanced net photosynthesis in inoculated plants compared to non-inoculated plants at exposure to 200 mM NaCl (**Figures 1C,D**). Interestingly, transcript levels of the chloroplastic *ruBisCO* large subunit-binding protein

subunit alpha (ID101265242), subunit beta (ID101253117) and accumulation factor 1.1 (ID101251433) were also higher in inoculated plants compared to non-inoculated ones at control conditions, suggesting a probable better carbon assimilation due to the inoculum.

Amino Acid Metabolism

Several pathways related to the metabolism of amino acids were also modulated in response to salt stress regardless inoculation with AXSa06 (Figure 5 and Supplementary Table 10). Proline is an important osmoprotectant synthesized in plant cells to alleviate salt stress conditions, over-accumulated in stressed plants regardless inoculation with AXSa06 (Figure 1E). In line with this observation, the key gene in the proline biosynthesis, delta-1-pyrroline-5-carboxylate synthase (*P5CS1*; ID101244293), was significantly up-regulated in the presence of salt, probably to help plants survive unfavorable abiotic conditions. Furthermore, the negative regulation of proline dehydrogenase (*PDH*), the enzyme that converts L-proline to L-glutamate, was conducive to the accumulation of proline in both non-inoculated (ID778202, ID101268445) and inoculated (ID778202) plants in response to NaCl treatment. Intriguingly, at the absence of inoculum, threonine dehydratase (*TD*; ID543983) responsible for the synthesis of L-isoleucine from L-threonine, and tryptophan synthase beta chain (*TSB*; ID101256422), responsible for the synthesis of L-tryptophan from indole and L-serine, were significantly up-regulated in stressed plants. By contrast, isoaspartyl peptidase/L-asparaginase 2 (*ASRGL2*; ID101245157) from the asparagine catabolic pathway was down-regulated.

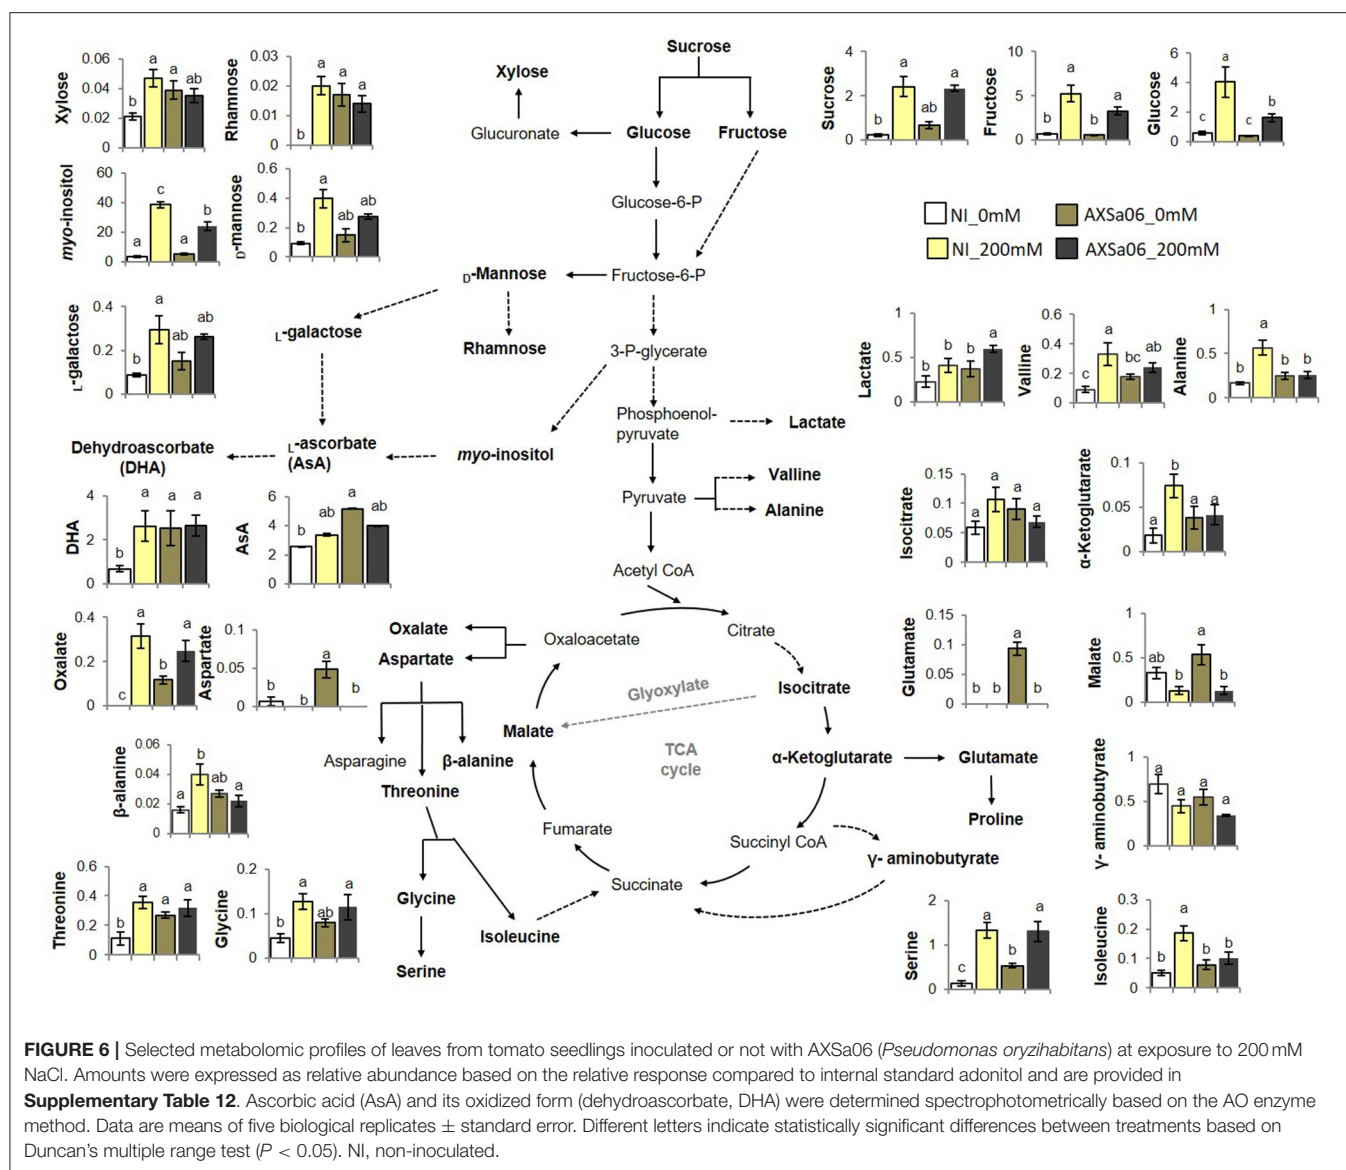

Plant Growth and Development

The transcript levels of several genes involved in plant growth-related processes were also induced at 200 mM NaCl, regardless PGPR inoculation. These included extensins (*EXT*; ID544158, ID101249726) and chitinases (*CHI*; ID544149, ID544147) (Figure 5 and Supplementary Table 10). In addition, cell-wall modification enzymes such as xyloglucan endotransglucosylase/hydrolase (*XTH*; ID101258345) that participates in cell-wall loosening and might benefit cell wall extension, or the plant cell wall protein *SITFR88* (ID778266) were upregulated by salt stress at the absence of inoculum. By contrast, a pectate lyase (*PL*; ID778293), involved in cell-wall composition, was up-regulated by AXSa06-inoculation in response to salt stress. These changes in transcript levels of genes related to cell-wall modification alterations may be necessary for plant survival under unfavorable conditions, and were probably triggered by ethylene. On the other hand, nitrate reductase (*NR*; ID100736473), encoding the enzyme catalyzing the NAD(P)H-mediated conversion of nitrate to nitrite, which is the rate-limiting step of nitrogen assimilation pathway in higher plants, was significantly down-regulated only in non-inoculated plants due to salt stress. This finding may indicate a transition of metabolism from developmental processes to defense mechanisms. Thus, the inhibition of nitrogen assimilation pathway driven via *NR* activity, and occurred at high salinity conditions, may be prevented by AXSa06-inoculation.

Antioxidant-Related Genes

Several stress-responsive transcripts were detected among DEGs between control and salt stress treatments. At the absence of inoculum, transcripts related to ROS detoxification and homeostasis including ferredoxin (ID101248335), AO (ID101252344), L-ascorbate peroxidase (*APX*; ID101258987), and lignin-forming anionic peroxidase (*LPOX*; ID101261260), showed higher expression in stressed plants compared to control ones (Figure 5 and Supplementary Tables 6, 10). By contrast, others such as myo-inositol oxygenase (*MIOX*; ID100316875 and ID101254427) and peroxidase 51 (*POX51*; ID101244162) or peroxidase 3 (*POX3*; ID101244376) exhibited lower expression. Similarly, the transcript levels of several stress-induced genes were up-regulated in AXSa06-inoculated plants at exposure to 200 mM NaCl. These included lignin-forming anionic peroxidase (*LPOX*; ID101261260), suberization-associated anionic peroxidase 2 (ID101245316), ferredoxin (ID101266472), AO (ID101252861), and inositol oxygenase 1 (ID101263222) (Figure 5 and Supplementary Tables 7, 10, 11). Heat-shock proteins (HSPs) the molecular chaperones that inhibit the stress-mediated denaturation of proteins, were also up-regulated in this study. In particular, five HSPs (ID544024, ID544205, ID101254946, ID101264936, and ID101255223) were induced after salt stress only in non-inoculated plants (Supplementary Table 6). An up-regulation of key ascorbate (AsA) biosynthetic genes including GDP-L-galactose phosphorylase (*GGP*, ID101255942), L-galactose dehydrogenase (*GalDH*; ID101254135), and L-galactono-1,4-lactone dehydrogenase (*GLDH*; ID544206), as well as monodehydroascorbate reductase (*MDHAR*; ID101264360) from the AsA recycling pathway, was also evident in AXSa06-inoculated plants at control conditions compared to non-inoculated ones, supporting an enhancement of AsA-mediated antioxidant defense mechanism in these plants (Figure 5 and Supplementary Table 10). This is also in agreement with an enhanced AsA pool due to inoculation as well be discussed below (Figure 6).

Since phenylpropanoids contribute to plant abiotic stress responses, genes encoding for key enzymes of their biosynthetic pathways were searched in a query to the KEGG database (Supplementary Tables 9, 11). Transcripts coding for 24 genes were found to be up-regulated in response to NaCl treatments in both non-inoculated and inoculated plants (Supplementary Figure 7). The identified genes have diverse functions related to phenylpropanoid-related pathways, being involved in key steps such as L-phenylalanine conversion in cinnamic acid [phenylalanine ammonia lyase (*PAL2*)], or catalysis of the final branches for lignin production (i.e., lignin-forming anionic peroxidase, ID101261260) or suberization (suberization-associated peroxidases, *TMPI*, *TAP2*, and ID101265511). Interestingly, although several β -glucosidase genes (ID101247513, ID101263519, and ID100191127) were up-regulated due to salt stress in both non-inoculated and inoculated plants, their transcript levels were higher at the absence of NaCl in inoculated compared to non-inoculated plants, suggesting

that AXSa06 inoculation has also affected and remodeled phenylpropanoid pathway.

Hormone-Related Pathways

The expression levels of hormone-related genes were also differentially regulated by both AXSa06-inoculation and treatment with 200 mM NaCl (**Figure 5** and **Supplementary Table 10**). At the absence of inoculum, salt stress enhanced ethylene biosynthesis as indicated by the significant up-regulation of ACC-synthase 1A (*ACS1A*; ID544028). At the same time S-adenosylmethionine decarboxylase (*SAMDC2*, ID101260400), a key enzyme linking ethylene metabolism and polyamine (spermine and spermidine biosynthesis), previously associated with modified salt responses in tobacco plants (Mellidou et al., 2016, 2020), was also over-expressed under salt stress. The remarkable up-regulation of ethylene biosynthesis

through transcription of *ACS1* and *ACO1* due to NaCl treatments was evident at the absence of inoculum (**Figure 5**). Notably, AXSa06-inoculated plants showed no particular alteration in the expression of ethylene biosynthetic genes upon exposure to salt stress. This is in line with results on ACC accumulation in the leaves (**Figure 3C**), supporting the impact of the ACC deaminase strain, AXSa06, in inhibiting ethylene synthesis either due to limited precursor availability or ethylene signaling.

Three ABA receptors *PYL4* (ID101250944, ID101258963, and ID101256856), required for ABA-mediated responses such as stomatal closure, were significantly down-regulated in non-inoculated plants in response to salt stress (**Supplementary Table 6**), whilst only one ABA receptor *PYL4* (ID101258963) was repressed in inoculated plants (**Supplementary Table 7**). On the other hand, although the expression levels of some ABA-signaling genes such as protein

phosphatase 2C (*PP2C*; ID101249794, ID101258071) that act as negative regulators of ABA-mediated responses, or ABA 8'-hydroxylase (*CYP707A1*; ID101254720), the key enzyme in ABA oxidation/catabolism, were induced upon salt stress regardless the presence of the inoculum (**Figure 5** and **Supplementary Table 10**), but the induction was more drastic in AXSa06-inoculated plants. In particular, these three genes were detected among the top DEGs in AXSa06-inoculated plants in response to 200 mM NaCl (**Supplementary Table 7**), suggesting a more stunning suppression of ABA signaling due to the PGP strain. Notably however, considering expression levels of these negative regulators of ABA signaling, inoculated plants showed lower expression regardless stress treatment compared to non-inoculated plants. Genes related to other hormone catabolism, such as cytokinin oxidation (cytokinin dehydrogenase; *CKX8*; ID101055579) or gibberellin oxidation (gibberellin 2-oxidase; *GA2ox3*; ID100134888) were up-regulated only in stressed non-inoculated plants, suggesting that these plants probably perceive more stress signals than inoculated ones (**Figure 5**). Another gene involved in auxin metabolism (indole-3-acetic acid-amido synthetase; *GH3.10*; ID101258277) was significantly down-regulated due to NaCl treatment regardless inoculation with AXSa06.

Transcription Factors

Several transcription factor (TFs) families such as WRKY, MYB, and bHLH exert pivotal roles in plant responses to abiotic stress factors. In non-inoculated plants, a broad number of TFs were induced by salt stress, including dehydration-responsive element-binding protein 1A (*DREB1A*; ID109119806 and ID101248897), ethylene-responsive *ERF027* (ID101246746), *WRKY* (ID101264826, ID101246812, ID101261141), *EARLY-RESPONIVE TO DEHYDRATION* protein (*ERD7*; ID101263355), *bHLH92* (ID101245202), and heat stress TF *HsfA2* (ID101255223) (**Figure 5** and **Supplementary Table 10**). A few TFs were also down-regulated in non-inoculated plants treated with NaCl. These included *ERF061* (ID10125880) and *MYB20* (ID101264349). By contrast, only one abiotic stress-responsive TF, *ERF3*-like (ID606713) was up-regulated in inoculated plants under salt stress conditions. Since TFs act downstream the hormonal signals, this finding further supports the previous hypothesis that inoculated plants may receive less stress signals than non-inoculated ones due to the suppression of ABA- and ethylene-activated responses.

Other Salt-Responsive Genes

The broad number of secondary structures enables LEA proteins to play multiple roles in abiotic stress, constituting an essential footprint of plant tolerance against irreversible damage (Artur et al., 2019). Homologs of this large protein family were found to be over-expressed at 200 mM NaCl in both non-inoculated (ID544157; **Supplementary Table 6**) and AXSa06-inoculated plants (ID100750252; **Supplementary Table 7**). Laccases are also widely present in plants, and have been related to disease resistance and lignin biosynthesis, while their involvement in abiotic stress tolerance is less clear (Liu et al., 2017). In this study, two different laccases (ID101251693 and ID101253711)

were positively regulated by salt stress, regardless the presence of inoculum (**Supplementary Tables 6, 7**). By contrast, galactinol synthase (ID101261450), the key enzyme in the biosynthesis of raffinose, was only up-regulated in AXSa06-inoculated plants exposed to 200 mM NaCl (**Supplementary Table 7**).

An interesting observation of this study is that the *SOS1* protein (ID778208), a putative plasmalemma Na^+/H^+ antiporter essential in maintaining ion homeostasis under salinity, through partitioning Na^+ between plant organs (Oliás et al., 2009), was significantly higher (1.4-fold) in AXSa06-inoculated plants compared to non-inoculated plants at control conditions (0 mM NaCl) (**Figure 5** and **Supplementary Table 10**). At salt stress, transcript levels of *SOS1* were induced in non-inoculated plants, while remained at very high levels in inoculated ones. Similarly, the Na^+ transporter *HKT1*, as well as the Na^+/H^+ antiporters (*NHX1* and *NHX2*), were up-regulated due to AXSa06 inoculation at control conditions. These findings indicated a putative improved mechanism of preventing the accumulation of excess Na^+ in photosynthetic tissues, thus supporting a role of AXSa06 as a priming agent that facilitated plants to tolerate abiotic stress factors.

Metabolome Reprogramming Under Salt Treatment

In an attempt to generate a comprehensive picture of metabolite reprogramming occurring in AXSa06-inoculated plants at exposure to 200 mM NaCl, we evaluated the abundance of 46 metabolites using GC-MS (**Figure 6** and **Supplementary Table 12**). In total, 25 metabolites showed differential accumulation at the absence of inoculum in plants exposed to salt stress compared to control, whilst at the presence of inoculum, only 14 metabolites differed significantly between stressed and un-stressed plants. Among them, 24 and seven were increased, while one and seven were decreased, in non-inoculated or inoculated plants, respectively.

Of the metabolites with differential accumulation during salt stress, most of them belonged to sugars or amino acids, indicating that their metabolic pathways were predominantly affected by NaCl treatments. In particular, accumulation of sucrose, fructose, glucose, *myo*-inositol, and xylitol, were significantly increased due to salt treatment in both non-inoculated and inoculated plants, but to a greater extent at the absence of inoculum (**Figure 6**). By contrast, xylose, rhamnose, D-mannose, L-galactose, allose, sedoheptulose, erythrose, and 2-deoxy-D-erythro-pentitol, showed higher accumulation due to salt stress only in non-inoculated plants. As for organic acids identified in this study, oxalate and 2-ketoglutarate increased in non-inoculated plants exposed to stress, whilst lactate and oxalate increased in AXSa06-inoculated ones. However, the accumulation of two other organic acids, malate, and galactarate decreased in inoculated plants. A broad number of amino acids increased as a response to salt stress at the absence of inoculum, including alanine, valine, isoleucine, glycine, serine, threonine, and cystathionine. Among them, only serine was induced in AXSa06 plants, while two other

amino acids, aspartate and glutamate decreased at exposure to 200 mM NaCl. No particular changes in AsA contents due to NaCl application were recorded, but inoculated plants had significantly higher AsA levels at control conditions (**Figure 6**). Furthermore, similar to the majority of sugars, DHA, the oxidized form of AsA representing an indicator of cellular redox homeostasis was enhanced at NaCl treatment of non-inoculated plants, but remained unaltered when the inoculum was applied.

Collectively, these metabolomic findings suggest that salt stress imposed far less metabolomic reprogramming when plants were inoculated with AXSa06. The metabolomic profile of non-inoculated compared to inoculated plants at control conditions (0 mM NaCl) revealed a vast number of metabolites over-accumulated in AXSa06 treatments (**Figure 6** and **Supplementary Table 12**). In particular, the sugars 2-deoxy-inosose, 2-deoxy ribose and the cell-wall related xylose and rhamnose, the sugar alcohols erythritol and 2-deoxy ribitol, the amino acids aspartate, threonine, serine and glutamate, as well as the acids 2-deoxy ribonate, oxalate and AsA, were all increased owing to AXSa06 inoculation, indicating a probably reprogramming of metabolism that may support plant adaptation against salt. This pattern was further supported by results concerning sucrose, mannose, valine, glycine, and malate, although differences were not statistically significant.

DISCUSSION

Plants have evolved symbiotic interactions with soil microbes that can alter plant phenotypic plasticity in a broad range of traits during plant growth or in response to changing environment (Goh et al., 2013). PGPR can enhance plant growth via direct or indirect mechanisms, including nutrient mobilization, solubilization and bio-availability, phyto-hormone biosynthesis, and induced systemic resistance (Yang et al., 2009; Pérez-Jaramillo et al., 2018; Gamez et al., 2019). Along with their plant-growth-promoting properties, and their ability to protect from phytopathogenic infections, some PGPR are also capable of enhancing tolerance to abiotic stresses such as salinity and drought (Yang et al., 2009). The exact mode of action by which PGPR affect plant growth under adverse environmental conditions may be both plant species- and strain-specific, as highlighted by the vast number of studies in different plants (Liu et al., 2017; Chauhan et al., 2019; Gamez et al., 2019; Safdarian et al., 2019). The present study demonstrated that AXSa06, a *Pseudomonas oryzae* strain previously isolated from extreme saline ecosystem, able to consume ACC, to produce IAA and siderophores, as well as to solubilize inorganic P (Leontidou et al., 2020), efficiently colonized the rhizosphere of tomato seedlings and promoted plant growth under salt stress. Inoculations with the strain seem to impose plants to a primed state, at which they are able to respond more robustly to abiotic stress owing to the earlier increased and more efficient activation of the defense response, as previously reported (Conrath, 2011). The investigation of key genes and metabolic pathways further

supported the primed state of AXSa06-inoculated plants prior to NaCl treatments that probably has led to a less disturbed metabolism after exposure to stress, by dampening stress signals, contributing to AXSa06-mediated tolerance. This is further supported by the GO enrichment analysis demonstrating that *Pseudomonas oryzae* strain was able to down-regulate transcripts related to peptidase regulator or inhibitor activity that were otherwise found to be stimulated by salt treatment in non-inoculated plants due to protein degradation and synthesis of defensive proteins.

AXSa06 Stimulated Antioxidant Mechanism

As a primary stress response to NaCl treatments, a burst in ROS production is expected, resulting in extensive cellular damage if not tightly regulated by the antioxidant scavenging systems in plants (Gemes et al., 2016; Noctor et al., 2016). Several antioxidant enzymes, including CAT, SOD, APX, and POX are known to increase in response to salt stress in order to mitigate salt-induced damage as has been reported in many plant species, including tobacco (Mellidou et al., 2016) and cotton (Hamani et al., 2020). Previous studies also reported an up-regulation of ROS scavenging activities and of antioxidant components accumulation due to bacteria inoculation under salt conditions (Bharti et al., 2016; Chen et al., 2016). Nevertheless, in this study, the prior-to-stress stimulation of antioxidant machinery (enzymatic and non-enzymatic) in AXSa06 plants may account for the improved salt adaptation, without any additional energy cost to support the protection of cellular redox homeostasis when stress is applied. In other words, strain inoculation may have imitated the effect of mild oxidative stress, similar to what is expected during salt stress. This primed state of AXSa06-inoculated plants is supported by the increased content of AsA and its oxidized form, DHA, as well as the enhanced activities of antioxidant enzymes, including POX and CAT that scavenge H₂O₂, compared to non-inoculated ones at control conditions. Within this context, the induction of antioxidant defense mechanism probably has occurred to limit down lipid peroxidation due to inoculation in non-stressed plants, which, however, did not show any visual symptom of oxidative stress. Although MDA content has been mostly considered as an oxidative stress marker triggering a wide range of other developmental signals, it can be also beneficial for plants in a number of ways participating in the induction of antioxidant defense or membrane repair (Tounekti et al., 2011; Kurutas, 2016; Morales and Munné-Bosch, 2019). Since photosynthetic process was not inhibited, plant growth was vigor, and ROS were probably efficiently removed in the inoculated plants, these plants may experience a mild oxidative boost just enough to increase their alertness, for amplified defense responses upon the onset of stress treatment. In other words, lipid peroxidation in inoculated plants may be beneficial—to a certain extent—to stimulate their alertness prior to stress. Tounekti et al. (2011) also reported that when MDA accumulation is elevated, rosemary plants can withstand salt-induced oxidative stress, by activating the xanthophyll cycle-dependent dissipation of excess excitation energy in leaves.

Due to their non-specific reactions with different ROS, POX enzymes participate in a broad number of physiological functions, including auxin catabolism, suberization, lignifications, cell wall elongation, and pathogen attack (Malviya et al., 2020). Previously, homologs of different *POX* genes have been implicated in lignin and xylan accumulation in *Arabidopsis* through ROS signaling (Cosio et al., 2017), as well as in salt tolerance in soybean (Jin et al., 2019). Herein, a lignin-related *POX* was up-regulated at exposure to 200 mM NaCl regardless inoculation, but a suberization-associated *POX* only at the presence of the PGPR strain. Although suberization primary occurs in the roots, this adaptive anatomical process is important for the prevention of apoplastic flow of toxic Na^+ under salt stress (Shabala et al., 2012).

In response to abiotic stress, plants synthesize a broad number of secondary metabolites possessing or inducing antioxidant properties to alleviate the over-accumulation of ROS and inhibit cell membrane peroxidation (Baba et al., 2017; Sharma et al., 2019). In particular, upon stress treatments, the phenylpropanoid pathways are commonly activated through the up-regulation of the transcript levels of genes encoding key biosynthetic enzymes like *PAL*, chalcone synthase and isomerase (Perin et al., 2019). In line with previous reports, several phenylpropanoid-related genes were up-regulated upon salt treatment, but this occurred regardless the presence of AXSa06. Although phenolic compounds were not determined in this study, the slightly increased transcript levels of the related genes at control conditions due to AXSa06 compared to non-inoculated plants, suggested that plants employed these metabolites as a communication tool to attract desirable symbiotic rhizobacteria, as have already been demonstrated between legumes and nitrogen fixing bacteria (Biała and Jasiński, 2018). On the other hand, β -glucosidases have an interesting role in abiotic stresses, particularly dehydration through ABA, by hydrolyzing secondary metabolites that are stored in inactive glycosylated forms (Baba et al., 2017). These enzymes have crucial functions in plants in response to altered environmental cues, including the glycosylation of secondary metabolites that are stored in inactive glycosylated forms and the activation of lignin precursors (Rouyi et al., 2014). The higher transcript levels of various β -glucosidase genes due to AXSa06 may contribute to the enhanced stress tolerance of inoculated plants, by releasing glucose which could serve as an alternative source of energy during insufficient photosynthesis.

AsA has numerous functions linked to oxidative relief under stress conditions, including the cellular scavenging of H_2O_2 via APX, or the apoplastic regulation of the AsA redox state via AO, which is important for stress perception and orchestration of defense responses (Mellidou and Kanellis, 2017). Therefore, AsA pool size and homeostasis may act as the signal of the oxidative injury occurring under stress, and play a pivotal role in controlling plant responses to environmental changes (Pignocchi et al., 2003). Transcript levels of *APX* were up-regulated at the absence of inoculum as a response to salinity, contributing to the significant increase in DHA accumulation in these plants, but no similar pattern was observed in AXSa06 treatments, indicated that these plants may sense less oxidative stress. If these

oxidized forms cannot be regenerated by monodehydroascorbate reductase (MDHAR) and dehydroascorbate reductases (DHAR) in the AsA-GSH cycle, then AsA is permanently lost (Noctor et al., 2016). The increased transcript levels of AsA biosynthetic and recycling genes, combined with the accumulation of AsA itself and its precursor, L-galactose at control conditions, indicated that inoculations with AXSa06 enhanced the AsA-mediated capacity of plants to scavenge ROS, further supporting the role of this strain as a priming agent against stress. This is in line with previous studies demonstrating that the regulation of antioxidant enzyme activities by PGPR exert a pivotal role in stimulating strain-mediated salt tolerance of plants (Safdarian et al., 2019).

AXSa06 Altered Amino Acid and Sugar Metabolism Imitating Salt Stress Responses

Although the phenomenon has been known for decades, the molecular basis of PGPR-mediated priming against abiotic stresses is far from being clearly elucidated. The over-accumulation of osmoprotectants such as proline is considered as the most usual mechanism of osmotic stress avoidance. Indeed, at exposure to salt stress, proline levels highly increased in both inoculated and non-inoculated plants, and similar to results from others (Kim et al., 2014; Liu et al., 2017), transcript levels of *P5CS1*, a key gene from proline biosynthetic pathway leading to osmoregulation, was also stimulated, independently of inoculation. These findings indicated that AXSa06-mediated stress tolerance is probably not related to a more efficient osmoregulatory activity in inoculated plants, at least due to proline.

Carbohydrates, including hexoses (fructose and glucose), disaccharides (sucrose and trehalose), and oligosaccharides (raffinose), are well-known to control ionic balance, maintaining cell turgor, while some of them are also considered as signaling molecules or even as ROS detoxification molecules in response to salt stress (Keunen et al., 2013; Patel et al., 2020). In this study, inoculated plants showed enhanced accumulation of certain sugars prior to stress application (erythrose, xylose, 2-deoxy-ribose, and 2-desoxy-inosose), or displayed no particular induction of some other sugars (sucrose and galactose) in exposure to salt stress similar to those observed in non-inoculated plants. These results support the notion that the metabolism of AXSa06-inoculated plants was less disturbed due to salt. The synthesis of other compatible solutes, such as raffinose family oligosaccharides (RFOs), represents an additional mechanism used by plants to adapt during the adverse effects of stressful conditions (Liu et al., 2021). Their mode of action involves the protection of membranes from hydroxyl radicals, as they are found between the head groups of lipids. The formation of galactinol from *myo*-inositol is catalyzed by galactinol synthase, representing the first enzyme that commits carbon toward RFO formation (Vinson et al., 2020). Transcript levels of this gene were only significantly induced in AXSa06-inoculated plants exposed to 200 mM NaCl, indicating an additional role of galactinols as osmoprotectants

and stabilizers of cellular membranes, but also as scavengers of ROS under excess salt (Nishizawa et al., 2008). Although none of these compounds were quantified in this study, the decreased levels of *myo*-inositol—the substrate of galactinol synthase—upon AXSa06 inoculation due to stress, may reflect the better adaptation of inoculated plants through this pathway.

Notably, the level of four amino acids (aspartate, threonine, serine, and glutamate) all increased owing to AXSa06 inoculation under control conditions indicating prominent changes in amino acids metabolism. Previously, the accumulation of free amino acids in combination with the higher transcript levels of related biosynthesis genes have been linked with salt tolerance, suggesting a crucial role of amino acid metabolism in stress tolerance (Zhang et al., 2017; Liu et al., 2020). Among these amino acids, the higher abundance of aspartate and glutamate mediated by AXSa06 inoculation at the absence of stress is of particular interest. Both molecules are involved in asparagine biosynthesis that is a major part of amino acid and nitrogen metabolism in plants (Curtis et al., 2018), strongly regulated by salt stress (Rashmi et al., 2019), and may operate as a pool of precursors for this metabolic branch, when plants exposed to NaCl. Asparagine has been also implicated in the early responses against salt stress in sugar beet (Liu et al., 2020), and can be further used as precursor in methionine and glutathione biosynthesis, that are able to scavenge ROS (Noctor et al., 2012). On the other hand, glutamate can be used to produce proline and gamma-aminobutyric acid (GABA) (Liu et al., 2020). In *Arabidopsis*, knockout mutants with T-DNA insertion in asparagine synthetase 2 gene exhibited limited salt tolerance and impaired nitrogen assimilation and translocation by the NaCl treatment relative to the wild-type (Maaroufi-Dguimi et al., 2011). In spite of the fact that GABA has been reported to alleviate salt stress injury in tomato seedlings by modifications in ion flux, amino acid synthesis and key enzyme expression (Wu et al., 2020), no similar relation was found in this study. Moreover, the increased levels of threonine and serine after AXSa06 inoculation revealed the modification of “glycine, serine, and threonine metabolism” pathway in response to inoculum at control conditions. Similarly, in non-inoculated plants exposed to salt stress, genes related to this pathway, such as *TD* and *TSB* were significantly up-regulated, with a concomitant increase in metabolic fluxes, whilst *ASRGL2* involved in asparagine metabolic pathway was down-regulated in non-inoculated plants, probably to support fluxes toward threonine and serine that were enhanced. These findings further support the notion that at control conditions AXSa06 exerted a similar response of primary metabolism related to amino acids as non-inoculated plants at the presence of NaCl, suggesting a kind of mild stress due to the inoculum that primed plants prior stress exposure.

No particular changes in tricarboxylic acid cycle were observed between non-inoculated and AXSa06-inoculated plants at metabolic or transcriptomic level in response to salt stress. This could be probably explained by an earlier induction of this pathway during the first days of stress application, as previously reported in sugar beet (Liu et al., 2020), that we were not able to detect at long-term (7 days) salt stress. An early down-regulation of pathways related to energy metabolism could serve as the

signal for the transition from plant growth to the enhancement of defense mechanisms to cope with the stress factor (Bandehagh and Taylor, 2020). On the basis of these considerations, future studies should focus on discriminating early and late responses to salt stress, as well as providing clues on their importance in alleviating stress injury.

AXSa06 Regulates Hormone Production and Signaling

Ethylene and ABA are considered as key phytohormones, acting in concert as double-edged swords to coordinate stress responses to various abiotic factors (Müller, 2021). Several lines of evidence over the last decades suggest that salt stress stimulates ethylene production in plants, ultimately inhibiting plant growth and development (Riyazuddin et al., 2020). In this regard, PGPR that possess ACC deaminase activity are considered to increase salt tolerance of plants through inhibiting ethylene production by consuming ACC, and thus enhancing plant growth (Liu et al., 2017; Safdarian et al., 2019), although this is not their sole mode of action accounting for salt tolerance. In this study, root ACC content decreased in inoculated plants compared to non-inoculated ones exposed to salt stress, highlighting the positive effect of inoculation with the ACC deaminase-containing strain on inhibiting the ACC flux toward ethylene biosynthesis. Nonetheless, its effect in the above-the-ground parts is less clear. Under salt stress, the reduction in ACC content at the absence of inoculum may be attributed to its consumption to produce ethylene due to NaCl treatments, whilst no particular changes were observed at the presence of inoculum, probably because the ethylene signal from the roots is inhibited due to the consumption of ACC from the strain. During salt stress, *ACS3* and *ACO4* displayed no particular up-regulation, while *ACS1A* and *ACO1* were upregulated, but to a lesser extent when plants were inoculated with ASXa06. This data suggests that ethylene production, and in turn, ethylene signaling, are probably inhibited by the AXSa06 inoculum. Although the ethylene production has not been measured *in vivo*, ethylene determination in the excised leaves of AXSa06-inoculated plants further confirmed that there was less ethylene signaling-sensitivity during salt stress, and consequently less feedback of ethylene on its own biosynthesis, as highlighted by the lack of major modifications in the expression of ethylene-biosynthetic genes. The reduced ethylene production could also account for the observed higher ACC accumulation under salt stress compared to non-inoculated plants, suggesting that ACC was not consumed for ethylene production in inoculated plants. All these findings need to be further confirmed to elucidate the exact role of ethylene in PGPR-mediating tolerance. Previously, it has been demonstrated that ethylene signaling and homeostasis is linked with certain PGPR-mediated responses in modulating plant stress tolerance (Chen et al., 2013; Poupin et al., 2016; Liu et al., 2017). The dramatic increase in root MACC content of inoculated plants exposed to 200 mM NaCl indicated that the major part of ACC was used for MACC formation rather than ethylene biosynthesis, thus evidencing that the ethylene accumulation in the roots is inhibited resulting to lower levels

of ethylene signaling in the above-the ground-parts. MACC is an end product, providing a potential mechanism to control ethylene biosynthesis (Van de Poel et al., 2014), while its exact mode of action under salt stress requires further investigation.

ABA and ethylene have antagonistic relations in the control of stomatal opening and closure (Müller, 2021). In this study, the expression of some ABA signaling components such as protein phosphatases 2C that act as negative regulators of ABA-mediated responses, or ABA 8'-hydroxylase, the key enzyme in ABA oxidation/catabolism, were more drastically induced under salt stress conditions owing to AXSa06 inoculation compared to non-inoculated plants, suggesting a more vivid suppression of ABA signaling and accumulation. The up-regulation of these genes has been previously correlated to enhanced salt tolerance, as ABA regulates the integration of stress signals, especially the ethylene-mediated ones (Campobenedetto et al., 2020). At the same time, the lower absolute expression of these ABA-related genes at both control and stress conditions in the presence of AXSa06 may be related to the lower accumulation of ABA, that could have otherwise led to stomata closure, disturbing photosynthesis (Jakab et al., 2005; Vishwakarma et al., 2017). Previously, the ABA-signaling components have been found to regulate both fast and slow ABA-mediated responses to tackle dehydration under salinity (Vishwakarma et al., 2017). Therefore, the beneficial impact of AXSa06 inoculations in plant salt tolerance could be possibly due to the more rapid and efficient suppression of both ethylene- and ABA-mediated stress signals.

Several TF families, including WRKY, bHLH, and DREB, have been previously demonstrated to orchestrate plant stress reactions against abiotic stress (Golldack et al., 2011; Liu et al., 2017). In the present study, non-inoculated plants showed an induction of these TFs when exposed to salt stress, which may be regarded as a defense reaction to ameliorate stress damage, by modulating osmotic and ROS homeostasis. In contrast to other studies on PGPR strains (Liu et al., 2017; Safdarian et al., 2019), these stress-responsive TFs, similar to ERFs that are located downstream the genes of the ethylene signaling pathway, were not upregulated in AXSa06-inoculated plants exposed to stress compared to non-stress conditions. These observations suggest that AXSa06 prevented the induction of the stress-induced ethylene biosynthesis, and further damped ABA synthesis and signaling during salt stress. In other words, AXSa06 minimizes the activity of two major abiotic stress hormones, and thus inoculated plants displayed less hormone-mediated responses due to salt stress.

As AXSa06 is able to produce IAA *in vitro* (Leontidou et al., 2020), the probable enhanced strain-mediated IAA production may serve as an important signal for plants to cope with salt stress. Although salt stress imposed IAA modifications at the transcript level regardless AXSa06 inoculation, there was no clear link between the PGP strain and IAA homeostasis. In particular, an indole-3-acetic acid-amino synthetase, responsible for the inhibition of free IAA accumulation (Ding et al., 2008), was down-regulated regardless the presence of the strain. Genes of the GH3 (Gretchen Hagen 3) family are involved in IAA homeostasis through catalysis of auxin conjugation and by binding free IAA to amino acids (Liu et al., 2016). In rice, some GH3 genes were

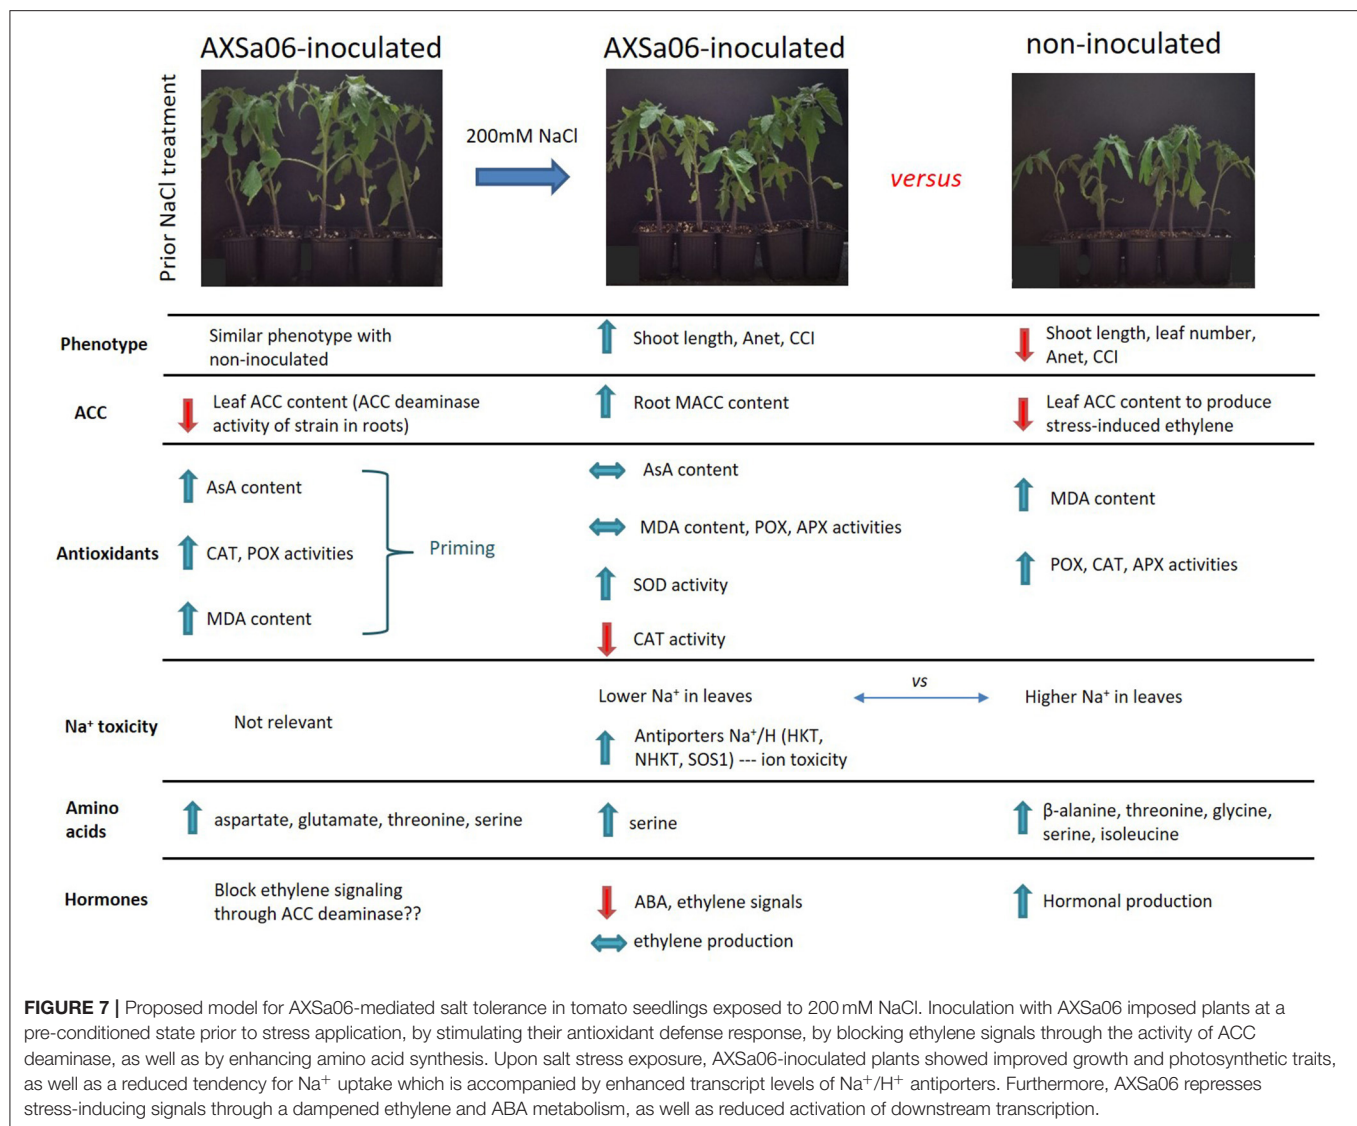

found to be related to stress responses, i.e., by decreasing the endogenous IAA content enhancing drought tolerance (Zhang et al., 2009), or through modulating ABA levels under drought and freezing stress (Du et al., 2012). One of the key genes in the tryptophan-dependent pathway of auxin biosynthesis is indole-3-pyruvate monooxygenase YUCCA, which convert indole-3-pyruvic acid to bioactive IAA (Zhao et al., 2001). Its transcript levels were also found to be down-regulated regardless the presence of the PGP strain, further supporting the disruption of IAA homeostasis predominantly due to salt stress, and not owing to AXSa06. Taken together, it is evident that AXSa06 did not have a direct impact on IAA metabolism, while the intriguing crosstalk between IAA, ethylene and ABA metabolism, as well as other signal networks, needs to be further elucidated using hormone-deficient mutants.

AXSa06 Alleviates Ion Toxicity

On the other hand, salt stress evokes ion toxicity due to the higher Na⁺ accumulation within plant tissues. Several ion transporters have been shown to regulate Na⁺ influxes into plant cells, by inducing Na⁺ circulation and sequestration (Liu et al., 2017). For instance, overexpression of *NHX* encoding a tonoplast Na⁺/H⁺ antiporter enhanced salt tolerance of *Arabidopsis* plants (Zhang and Blumwald, 2001), while its expression can be induced by inoculations with *Bacillus amyloliquefaciens* in maize (Chen et al., 2016) and *Arabidopsis* (Liu et al., 2017), but not in rice (Nautiyal et al., 2013), indicating that transcriptome responses are species-dependent. Another Na⁺ transporter with high affinity for K⁺, the sodium transporter *HKT1*, is also known to be induced in plants due to inoculations with *Bacillus* species, thereby limiting Na⁺ accumulation and toxicity in plant cells (Chen et al., 2016; Liu et al., 2017). In this study, the lower Na⁺ contents measured in leaves of AXSa06-inoculated plants may be due to the induction of *NHX1*, *NHX2*, and *HKT1* transcript levels due to bacterial inoculation prior to stress application that enabled an efficient mechanism of Na⁺ detoxification for coping with salt stress in tomato seedlings (Bharti et al., 2016; Chen et al., 2016). Furthermore, the SOS signaling pathway has been proposed to mediate cellular signaling under salt stress, in order to maintain ion homeostasis (Ji et al., 2013). The expression pattern of *SOS1* was induced both at control and NaCl treatments at inoculations with the *Pseudomonas oryzae* strain, further contributing to the observed salt tolerance of inoculated plants. Taking into consideration that the ABA signaling pathway was not enhanced in the presence of bacterium, it is evident that this SOS-mediated pathway acts independent of ABA to help plants withstand Na⁺ toxicity during salt stress through an intricate mechanism that needs to be further explored.

AXSa06 Mitigates the Negative Effect of Salt Stress on Photosynthesis

The increased net photosynthetic rate and chlorophyll content of the AXSa06-inoculated plants compared to non-inoculated plants under salt stress can be attributed to the ACC-deaminase activity due to the presence of inoculum in the rhizosphere that can mitigate the effect of salt on photosynthesis, as previously reported (Chauhan et al., 2019). In tomato, ethylene levels can

have a negative impact on plant photosynthesis (Ceusters and Van de Poel, 2018), which is probably ameliorated by the ASXa06 inoculum. Furthermore, the enhanced net photosynthesis upon salt stress in the presence of the PGP strain may be related to the suppression of ABA signals that would otherwise had led to stomatal closure and photosynthesis suppression (Yu et al., 2020). This is in accordance with the down-regulation of the photosynthetic KEGG pathway, as well as the transcript levels of *NR*, at the absence of inoculum under salt stress. *NR* is the key enzyme for the reduction of NO_3^- to NO_2^- in nitrogen assimilation in plants cells, which coordinates with the rate of photosynthesis and the availability of C skeletons. It can also function as a key enzymatic source of nitric oxide, which then regulates plant growth and resistance to abiotic stresses (Fu et al., 2018). Thus, a better assimilation of both N and C may be evident at the presence of AXSa06, as further illustrated by the more active ruBisCO.

CONCLUSION

Collectively, our results reinforce the hypothesis that inoculations with the *Pseudomonas oryzae* strain (AXSa06) significantly increased the alertness of inoculated plants, imposing them on a pre-conditioned state prior to stress application that render them primed for amplified defense responses. The primed state resulted from an enhancement of antioxidant adaptive mechanism, accompanied by a reduced tendency for Na⁺ uptake (Figure 7). Furthermore, AXSa06 represses stress-inducing signals through a dampened ethylene and ABA metabolism and a reduced activation of downstream transcription factors when stress is applied. The differential modulation of the identified metabolites and transcripts is dependent on the perceived stimuli originated from AXSa06 inoculation that enables plants to fine-tune their defense responses. The identified signatory molecules including AsA,

and the amino acids aspartate, threonine, serine, and glutamate, may serve as possible biomarkers for PGPR priming in tomato. Furthermore, inoculations with AXSa06 alleviate the negative impact of salinity on photosynthetic machinery and carbon assimilation, through a more active *ruBisCO* and *NR*, involving an efficient mechanism of Na^+ detoxification. The molecular mechanism that links microbial signals with plant phenotypic plasticity and fitness merits further investigation to identify possible links between PGPR-priming and epigenetic memory to enhance plant tolerance under diverse environmental cues.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are publicly available. This data can be found here: NCBI repository, accession number: PRJEB42497.

AUTHOR CONTRIBUTIONS

This study was designed and conceived by IM and KK. Stress experiments, plant growth, physiological, and biochemical evaluation was conducted by IM and AP. Determination of Na^+ was conducted by AP. Ethylene-metabolite related work was carried out by BVP, while ethylene determination by EK. Transcriptomic analyses were performed by IM, KL, and SG.

An alternative decision axiom to guide in determining the optimal intervention strategy to maximize cowpea production is proposed. According to the decrement from the maximum concept of Mitscherlich, the decrement from the maximum for each stressor must be minimized to produce the absolute maximum production. In crop production, this means all deficient nutrients must be supplemented to ensure maximum yield and laid the foundation in fertilizer formulation. However, its implementation is not economically feasible in many situations, particularly where multiple environmental factors impact crop productivity as in the case of low resource conditions. We propose and test the hypothesis that yield allocation will increase when the most limiting stressor among prevailing stressors is eliminated at least until the next limiting stressor impacts productivity. We selected drought limiting savanna conditions and cowpea (*Vigna unguiculata*), adapted to nitrogen dependence. To determine the limiting condition, we measured the response of cowpea to D-sorbitol, nitrogen, and non-hormonal biostimulant (nhB) treatments. The nhB treatment increased total biomass by 45% compared to nitrogen, 13%, and D-sorbitol, 17%, suggesting osmotic stress is more limiting in the observed savanna conditions. The effect of the biostimulant is due to antioxidants and key amino acids that stimulate metabolism and stress resistance. Where nitrogen becomes the next constraining factor, biostimulants can contribute organic nitrogen. The study supports the use of biostimulants as candidate intervention under conditions where crop productivity is limited by multiple or alternating constraints during crop growth.

Keywords: biostimulant, cowpea, osmotic stress, nitrogen, fertilizer, sprengel-liebig law, sustainable agriculture

INTRODUCTION

The plant stress–response–feedback continuum is an important physiological process that shapes plant plasticity. Factors that account for stress in plants are broadly categorized into abiotic and biotic stressors. Biotic stressors, such as herbivory, pest attack, and disease-causing pathogens, and abiotic stressors, such as drought, salinity, heavy metals, floods, and extreme temperatures, account for major crop losses globally (Gull et al., 2019). To understand how plants respond and cope

with stress, a stressor, such as heat or drought, is introduced to the living plant specimen under controlled conditions to observe the response (Arbona et al., 2016; Atta-Boateng et al., 2019). However, under field conditions, crops are exposed to multiple environmental factors (Chapin et al., 1987). In addition, the relative impact of all the possible prevailing stressors on yield is difficult to detect. Furthermore, the intensity of the stress effect does not stay constant throughout the growing season. The centralized system of stress response concept suggests that all plants respond to different stress types in the same basic way, particularly those adapted to low-resourced environments or adjusted to low resource supply (Chapin, 1991). This framework has implications on the implementation of agricultural advances and oversimplifies interventions, especially under marginal conditions where crops, such as legumes, are adopted to low soil nutrients or drought.

Cowpea is the most cultivated legume in West Africa, and its production benefits human and livestock nutrition in addition to long-term soil amendment that sustains cropping systems on marginal lands in low-income economies (Dakora and Keya, 1997; Duranti and Gius, 1997; FAO, 2004; IITA, 2010; Foyer et al., 2016). Cowpea is suggested to originate from West and Central Africa, which currently has most of the germplasm (Boukar et al., 2019b). The biotic constraints of cowpea include parasitic weeds, insect pests particularly aphids, fungal, viral, and bacterial diseases, whereas high temperature, drought, and erratic rainfalls during the growing season constitute major abiotic constraints (Boukar et al., 2019a,b; Horn and Shimelis, 2020). Biotic and abiotic interventions in the past few decades include the introduction of drought-resistant and disease-tolerance cowpea varieties and supporting genetic breeding research programs across Sub-Saharan Africa (SSA) (Boukar et al., 2019a,b). These are essential for managing long-term biotic and abiotic growth conditions. However, major gaps exist for inputs required to manage short-term in-season growth conditions.

Early work by Carl Sprengel and Justus von Liebig's Law of the Minimum revolutionized plant mineral nutrition, where the scarcest nutrient was found to govern growth (Liebig, 1840; van der Ploeg et al., 1999). Later, Mitscherlich (1909), based on Liebig's Law further showed that marginal productivity decreased as levels of limiting growth factor increased. Meaning, when all other factors of growth are kept constant at optimum levels, increase in the levels of the limiting factor increases yield until no further increment affects yield. As all other growth factors cannot be optimal and constant under field conditions, this implies in practice that all stress factors must be eliminated to attain maximum yield. Harmsen (2000) acknowledged the limitations of the Mitscherlich equation in rainfed semi-arid conditions and proposed a modified theory (Equation 1):

$$Y = Y_{\theta} - Y_{\theta} e^{-\epsilon_{nt} N_t Y_{\theta}^{n-1}} \quad (1)$$

where Y is the total dry matter, Y_{θ} , potential yield as a function of available moisture (θ), ϵ_{nt} , activity coefficient, N_t , total nutrient content, and n is a constant. The model (Equation 1) describes crop response to nutrient availability under rainfed semi-arid conditions and can predict the nutrient requirement for a

specified yield level. Nonetheless, the model assumptions restrict practical interventions to mineral nutrient input, given seasonal rainfall availability. The yield impact of limiting factors that alternates during the growing season and the difficulty of its prediction require alternatives frameworks that allow the design of inputs that are pliable to manage dynamic field conditions.

Although SSA contributes more than 70% of global cowpea output, cowpea cultivation is under-produced and concentrated in low-productive regions, which are particularly vulnerable to climate risks (Timko et al., 2008; IITA, 2010; Muñoz-Amatriáin et al., 2017). In the Guinea savanna ecological biome, high temperature, low soil nitrogen, and soil structure exacerbate threats the peak rainy and the dry season conditions cause to agricultural production (Runge-Metzger and Diehl, 1993; Gyasi, 1995). Interventions that can address specific production constraint is currently lacking.

Policy directives on interventions, especially for smallholder farmers in savanna regions continue to focus narrowly on increasing fertilizer inputs (FAO, 2005, 2011; Martey et al., 2014). However, it is unclear whether N fertilizer for instance is the ideal intervention for increasing legume production in the savanna. N fertilization has been shown to decrease N-fixing rates in legumes (McAuliffe et al., 1958; Salvagiotti et al., 2008). Although the application of inoculants in combination with fertilizers on cowpea showed a promising yield effect (Kyei-Boahen et al., 2017), the treatment was beneficial only at specific nutrient deficiency levels. Meanwhile, besides the complexity of the socioeconomic factors that limit fertilizer access in the least productive regions (Erisman et al., 2008; Brown, 2014), the negative environmental impact of misapplied fertilizers is overlooked (Ann and Socolow, 1994; Vitousek et al., 1997). The Ceres2030 report investigated the impact of scientific productivity toward eradicating global hunger (Laborde et al., 2020). The study found that more than 95% of global research interventions toward food security was less relevant toward addressing key need gaps (Laborde et al., 2020). Others have highlighted the need for strategic interventions through sustainable crop production to overcome food insecurity amid climate threats and the rising global population (Tilman et al., 2002; Bitá and Gerats, 2013).

In our study, we propose and report a preliminary test of an alternative approach to increase cowpea production under savanna conditions. We hypothesize that productivity, such as growth (total biomass allocation) increases when a relatively more limiting constraint among existing growth constraints is relieved until the next limiting constraint impacts productivity. We formulate a non-hormonal biostimulant (nhB) that treats multiple stressors and tests its effect on nodulation, biomass, and leaf physiological responses in cowpea in comparison with inorganic N fertilizer and exogenous compatible osmolyte.

MATERIALS AND METHODS

Study Area

The study site was located in the Northern region and covers 40% of (92,456 mile⁻²; latitudes 4°-12°N) land cover by area of Ghana. Two major ecological zones characterize the region:

the sub-humid to semi-arid Guinea savanna and the arid Sudan savanna zones (Gyasi, 1995). The Inter-Tropical Convergence Zone controls rainfall seasons in Ghana, with one wet season in the north and two wet seasons in the south. Low, erratic rainfall ranging between 150 and 250 mm/month in a single dry season to 1,100–1,200 mm month⁻¹ in a single wet season characterizes the study area. Mean monthly temperature during the growing season ranges between 26 and 30°C (Buah and Mwinkaara, 2009). During the study period, the total rainfall (daily mean) recorded was 203.8 (6.6 mm day⁻¹); average sunshine was 5.8 h; the mean temperature was 26.7°C (ranging from 29.7°C_{max} to 23.6°C_{min}); and the mean relative humidity recorded was 84% (ranging from 93 to 75% min). The soil at the study site constituted 55.8% sand, 41.96% silt, and 2.2% loam. Weather and soil analysis data were obtained from the Savanna Agriculture Research Institute, Council for Scientific and Industrial Research, Ghana.

Plant Preparation and Treatments

Three experimental blocks, each containing four distinct raised soil beds of dimension 2 × 8 m each and interspaced by a meter gap, were prepared across a slope in a series-like fashion. Each bed in a block represented a treatment group based on a Randomized Complete Block Design. Each soil bed was seeded with cowpea, the common African cultivar Songotra-IT97K-499-35, which is *Striga gesnerioides* resistant (Asare et al., 2011; Muñoz-Amatriaín et al., 2017).

Germinated seedlings were thinned at 10 cm height to 40 plants for each growing bed of size 80 × 40 cm. Treatments were assigned randomly within and between blocks.

Given the conditions of Guinea savanna, we will use the term osmotic stress to represent the likelihood of both drought and heat stress incidence as they occur in tandem (Dwivedi et al., 2018) or specifically to represent conditions, such as low soil moisture, atmospheric vapor pressure deficit, and salinity, for their similarity in physiological responses (Munns, 2002; Chaves et al., 2009). Three treatments were prepared to treat osmotic stress. First, 0.25 g L⁻¹ (coded *sorbl*), and second, 0.5 g L⁻¹ (coded *sorbH*) compatible osmolyte, D-Sorbitol (Hexane 1, 2, 3, 4, 5, 6-Hexol) of molecular weight 182.17 g mol⁻¹ obtained from Sigma-Aldrich, USA. The third osmotic treatment was an antioxidant and amino acid-based nhB (coded *nhB*), prepared from the laboratory at the Yale School of the Environment. The active components of nhB include 2-amino-5-guanidinopentanoic acid, L-ascorbic acid, thiamine mononitrate, and *cis*-1, 2, 3, 5-*trans*-4, 6-cyclohexanhexol. To arrive at the final treatment formulation, different iterations of nhB beta were evaluated in root-shoot allocation experimental trials in a glasshouse using *Raphanus sativus* (cherry belle variety) as a model plant. The satisfactory formulation was attained when *R. sativus* maintained a fresh root: shoot biomass ratio of ~1:1 and yields over 100%. By this approach, we assumed that the overall yield output of nhB treatment will vary by species type and allocation cost to stress response depending on field conditions.

Furthermore, 5 g L⁻¹ nitrogen was prepared from 98% ammonium nitrate (NH₄NO₃) as inorganic nitrogen treatment (coded *Nfert*). All control groups were treated with equal volumes

of distilled water, which was used to prepare treatment solutions. Each plant replicate received 50 ml of treatment dose biweekly until the onset of pod formation. Nitrogen was applied directly to the soil around the stem of plants while *sorbl*, *sorbH*, *nhB*, and controls were applied to both foliage and soil.

Plant Sampling and Measurement

Out of 40 plant without growth defects, 15 plants were tagged for repeated measurements throughout the growth stages. Leaf measurements were conducted during the active photosynthetic period in the morning (PPDF ranged from 900 to 1,200 mmol m⁻²s⁻¹). Leaf temperature, chlorophyll fluorescence, and chlorophyll content of the youngest fully expanded leaf of each tagged plant were measured 2 weeks after each treatment time during the vegetative, flowering, and pod growth stages of cowpea. We used common plant biophysical markers (Ernst, 1999) and traits in our assessment to allow reliable reproducibility and convenience in the study sites.

Biomass and Nitrogen-Fixing Traits

The root zones were softened by inundating with water to allow the whole plant to be removed from the soil bed with intact roots. The soil debris was brushed off, and the root nodules per plant were carefully removed, counted, weighed, and re-weighed after oven drying to a constant weight at 60°C to obtain the total weight of nodule per plant and the total number of nodules formed per plant. Furthermore, whole plants with intact pods were oven-dried to constant weight to obtain total biomass, then followed by separate measurements of pods.

Leaf Physiological Measurement

Leaf temperature, T_l was measured as an indicator of plant stress (Udompetaikul et al., 2011; Rodríguez et al., 2015; Carroll et al., 2017). Variations in moisture stresses are known to significantly alter leaf temperature, causing it to deviate from ambient temperature (Wiegand and Namken, 1966). T_l was measured by a laser-guided infrared thermometer (ST60 ProPlus™ Raytec, Santa Cruz, CA, USA). The laser was pointed to the adaxial surface of the leaf, where the device collects optically emitted, reflected, and transmitted energy by the leaf surface on a detector as an ambient temperature reading in °C (±0.07°C).

The stress manifested in plants can be determined by observing the leaf photosystem II (PSII), which is a protein complex in the light-dependent reactions of plant photosynthesis. PSII damage is the first manifestation of stress in plant leaves (Maxwell and Johnson, 2000), and the efficiency of this state is referred to as photochemical efficiency. Maximum quantum yield at PSII is determined based on the chlorophyll fluorescence ratio, F_v/F_m^{-1} , a well-studied phenomenon in the plant physiology (Rodríguez et al., 2015) and a well-established physiological indicator of plant tolerance to the environmental stress, including drought and heat (Méthy et al., 1994; Maxwell and Johnson, 2000; Dwivedi et al., 2018). Plant stress that affects the PSII is determined based on a calculated variable fluorescence (F_v) to maximal fluorescence (F_m) ratio using a chlorophyll fluorescence device (model OS-30p, Opti-Sciences,

Inc. Hudson, New Hampshire, USA). To measure $F_v F_m^{-1}$, leaf samples were dark-adapted by placing leaves inside plastic cuvettes to block the incident light on the selected portion of the leaf blade for 30 min. Then a weak modulated light is immediately irradiated from a fluorometer on dark-adapted leaf blade to excite a pre-photosynthetic antenna. Upon light saturation at maximum light exposure, the maximum fluorescence, F_m , is determined and $F_v F_m^{-1}$ computed and recorded by the fluorometer. Chlorophyll fluorescence is one of the most frequently used plant measurement techniques (Schreiber and Bilger, 1993) and has been used extensively in stress studies in several legumes (Georgieva and Yordanov, 1993; Stoddard et al., 2006). The leaf chlorophyll content is a physiological trait associated with drought and heat stress (Dwivedi et al., 2018). A handheld chlorophyll-detecting device, SPAD-502 (Minolta Camera Co., Osaka, Japan), was used to measure the leaf chlorophyll content. The sample leaf was placed in between a receptor window and a measuring head. By pressing the measuring head, the chlorophyll content was determined at 650 and 940 nm in SPAD units at ± 1.0 accuracy (see Richardson et al., 2002).

Statistical Analysis

The Lme4 package in R (Bates et al., 2015) was used to perform mixed-effect modeling (MEM) by restricted maximum likelihood t -tests. MEM performs ANOVA on repeatedly measured variables and estimates fixed and random sources of variation. To know where significant differences occurred, we tested general linear hypotheses by multiple pairwise comparisons of means based on Tukey's honestly significant difference (HSD) tests on normally distributed data. All statistical analyses were conducted using the R programming language and environment (R Core Team). The null hypothesis (H_0) assume no differences in population means such that: T_1 (control), $= T_2 = T_3 = \dots T_x$; where $\alpha \leq 0.05$ and T_x indicates x treatment type. Furthermore, the alternative hypothesis (H_a) assumes differences in population means such that: $T_1 \neq T_2$, or $T_3, = \dots T_x$; at least at a significance level of $p < 0.05$.

RESULTS

Effect of Treatments on Biomass, Pod Capacity, and Root Nodulation

The mean biomass of cowpea was significantly different between nhB and all other treatments ($p < 0.001$, Table 1). nhB had the highest biomass output, 45% followed by sorbL (17%), sorbH (13.3%), Nfert (13.1%), and controls. Nodulation capacity determined by the means of the total number of nodules formed per cowpea was significantly different ($p < 0.01$) among treatment groups.

N-treated cowpea relatively formed the highest number of nodules per root and nodule weight (Figures 1C,D). Thus, we refuse to accept the null hypothesis that there is no difference in the mean effect of treatment interventions on cowpea growth with respect to biomass and nodulation capacity. The effect of blocking was significant on biomass response ($p < 0.01$), number of pods ($p < 0.05$), and mean number and oven-dry weight of

TABLE 1 | Summary ANOVA of mean response of treatment groups.

Parameter variables		DF	F-Value	(Pr > F)
Biomass	Treatment	4	6.1889	<0.0001***
	Blocks	2	4.907	0.0082**
No. of pods	Treatment	4	1.598	0.1759 ^{ns}
	Blocks	2	4.207	0.016*
Nodule mass	Treatment	4	0.414	0.798 ^{ns}
	Blocks	2	83.59	<0.0001***
No. of nodules	Treatment	4	3.413	0.009**
	Blocks	2	55.2	<0.0001***

Superscript stars indicate the levels of significance, where * (0.05), ** (0.01), *** (0.001), and ^{ns} (not significant).

nodules ($p < 0.0001$). This indicates that measured responses to treatments are independent of the significant variations in site conditions. This is of statistical importance to emphasize the reliability of the study outcome.

The treatment effects on both the mean number of pods formed per cowpea and the mean nodule mass per cowpea root were not significant (Table 1). Nevertheless, pod yield per plant was relatively highest in nhB-treated cowpea (Figure 1B).

Effect of Treatments on Leaf Physiological Responses

The mean effect of treatments on leaf chlorophyll content in cowpea did not differ significantly; however, the difference ($p = 0.05$) in leaf chlorophyll responses to sorbL and sorbH (which vary by D-sorbitol concentration) indicates that the concentration of exogenous D-sorbitol application on cowpea leaves might be important to chlorophyll response under savanna conditions. Leaf fluorescence in nitrogen-fertilized cowpea differed significantly from cowpeas treated with nhB, sorbL, and sorbH (Table 2).

Treatment effect on leaf temperature, T_l response was significantly different in fertilizer-treated cowpea and the rest of treatment groups (Table 2). Although stress variables are weakly correlated (Supplementary Figure 1), the correlation plot shows the general relation of leaf physiological indicators to aid in the interpretation of leaf treatment responses. Higher leaf temperature does not necessarily indicate a healthy status as in controls. A relatively higher T_l , lower leaf chlorophyll content, and fluorescence should indicate a relatively stressful condition.

DISCUSSION

Biomass and Physiological Responses of Cowpea to Osmotic and N Treatments

Low soil fertility and drought constitute abiotic factors that constrain cowpea production (Roberts, 2013). Although legumes are adapted to low nitrogen conditions, N-fixation may come at a cost. Nodulation has been used to evaluate stress in legumes (Rai and Singh, 1999). Under savanna conditions, other competing abiotic factors further constrain the biological N-fixing capacity of nodulating legumes and consequently may limit

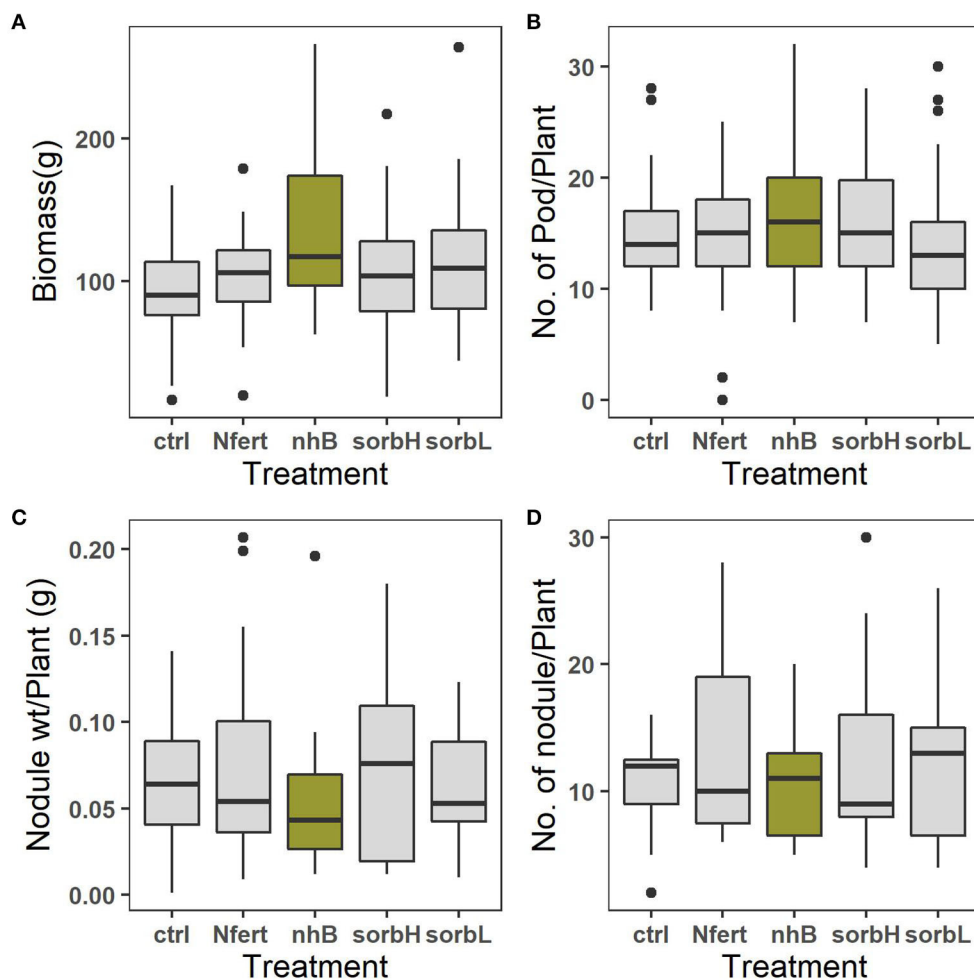

FIGURE 1 | Means of total biomass, grams per plant (A), mean number of pods per plant (B), mean weight of root nodule per plant (C), and mean number of root nodules formed by roots per plant (D) in response to cowpea treatments; control, N fertilizer (Nfert), sorbitol (sorbL and sorbH), and non-hormonal biostimulant (nhB).

nitrogen contribution to productivity. We hypothesized that where cowpea is constrained by multiple factors, an intervention that alleviates the relatively more limiting factor may lower the physiological cost of mitigating the constraining factor, allowing allocation toward yield. Total biomass and pod yield are used in the study as proxies for productivity or yield allocation. Biomass is a common measure of plant productivity in ecological studies (Roberts et al., 1993; Tilman et al., 1997; Klironomos et al., 2000; van Grunsven et al., 2007; TerHorst and Munguia, 2008; Fraser et al., 2015), and stress evaluation in legume crops (Ashraf and Chishti, 1993; Ashraf and Zafar, 1997; O'Toole et al., 2001). Based on the relatively higher biomass, pod yield, and lower investment in the root nodules in nhB, sorbL, and sorbH cowpea treatments (Figures 1A–D), we conjecture that osmotic stress is more limiting than soil nitrogen need in cowpea in the study area. The additional higher yield in nhB may be due to the combined effect of antioxidants and amino acids used in the formulation. More nodules were formed in untreated controls than biostimulant, nitrogen, and sorbitol treatments and may indicate the reduced need for nitrogen.

TABLE 2 | Significant pairs from multiple mean comparisons based on Tukey's honestly significant difference (HSD) test from a linear mixed-effect model fit.

Parameter variables	Treatments	Estimate (error)	Z-value	(Pr > z)
Chlorophyll fluorescence, $F_vF_m^{-1}$	Nfert-nhB	0.0368 (0.0128)	2.859	0.033*
	Nfert-sorbL	−0.0333 (0.0113)	−2.926	0.028*
	Nfert-sorbH	−0.0399 (0.0113)	−3.506	0.004**
Chlorophyll content	sorbL-sorbH	−2.5979 (1.0300)	−2.522	0.05
Leaf temperature, T_l	Nfert-nhB	−1.1436 (0.2867)	−3.989	<0.001***
	Nfert-cntl	−1.3616 (0.2554)	−5.345	<0.001***
	Nfert-sorbL	0.7694 (0.2548)	3.020	0.021*
	Nfert-sorbH	0.9004 (0.2548)	3.534	0.003***

Except reported, all other possible mean pairs were not significant. Superscript stars indicate the levels of significance, where * (0.05), ** (0.01), and *** (0.001).

Nitrogen, biostimulant, and sorbitol treatments reduced cowpea stress in contrast with controls (Figure 2). While we expected higher N-fixing capacity and $F_vF_m^{-1}$ to increase

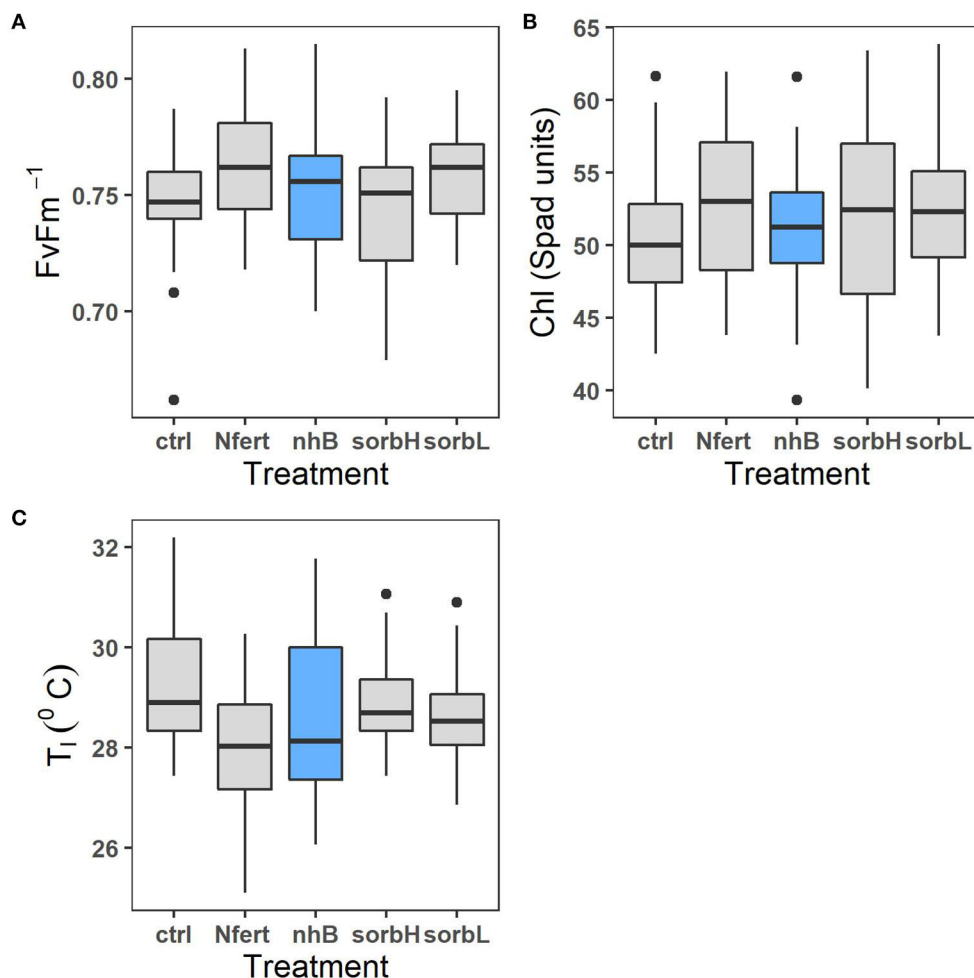

FIGURE 2 | Leaf physiological response of cowpea to osmotic treatments (sorbL, sorbH, and nhB) and N fertilizer treatment (Nfert). Plots represent chlorophyll fluorescence ratio (A), leaf chlorophyll content (B), and leaf temperature (C).

productivity, the response was relatively lower in N treatment than in biostimulant and sorbitol treatments. Maintaining leaf moisture while fixing carbon may be the more efficient strategic role of the osmoprotection compared to N-fertilized cowpea, which showed higher proxy-photosynthetic activity (Figures 2A,B), yet seemingly more leaf water loss, resulting from a cooling effect and lower leaf temperature. The relatively lower biomass and increased nodulation response to N treatment suggest a plausible trade-off to increased investment toward a need for physiological response and N-fixation (Figures 1C,D). Contrary, higher biomass and leaf stress responses to osmotic treatments support the conjecture that exogenous osmolytes alleviate the need and the cost of metabolic response, thereby directing more allocation toward whole-plant biomass output.

Effect of Non-hormonal Biostimulant and D-Sorbitol on Cowpea

Biostimulants, since their origination, definition, and development over the past four decades, have been shown to improve stress resistance and promote plant development

(Russo and Berlyn, 1991). Although drought avoidance by hydraulic controls (Hall and Schulze, 1980; Turk and Hall, 1980) and leaf paraheliotropism (Schakel and Hall, 1979) (also observed in this study) persists in cowpea, osmoadaptation through metabolite accumulation is reported as a more conservative strategy in cowpea (Goufo et al., 2017). The relative increase in biomass, following sorbitol and biostimulant treatments supports osmoadaptation as an important drought response strategy in cowpea. From our results, we conjecture that external application of osmolyte-containing compounds may prevent the inherent metabolic need and cost for cowpeas to initiate osmoadaptation, thereby making readily available more resources for biomass allocation.

In a study of 88 cowpea metabolites, *myoinositol* and *arginine* were reported to have no beneficial effect on cowpea yield (Goufo et al., 2017). Contrary to our findings, *myoinositol* and *arginine*, both active constituents of the nhB formulation improved biomass allocation in cowpea. The contrasting findings may result from differences between the metabolite concentration in naturally occurring cowpea leaves and the concentrations used

in the nhB formula. Further, our study reports the first yield effects of exogenous D-sorbitol on savanna cowpea. Although D-sorbitol does not constitute the reported metabolites expressed in drought-stressed cowpea, its effect on yield in our study suggests that metabolite–yield relations may be non-species specific. In that, the metabolites expressed by plants under stressful conditions may not represent the only possible strategy but a choice, perhaps governed by adoptive mechanisms peculiar to the species or based on inherent biochemical resources available to initiate the metabolic response process.

Implication of the Limiting-Stress-Elimination Hypothesis in Savanna Legume Production

According to the proposed limiting-stress-elimination hypothesis (LSEH), when the limiting stress is eliminated, stress impact is relieved (Figures 3A,B), until the next available stress becomes most limiting. The scope of this study here is not to establish the most limiting stressor in cowpea.

Instead, we have demonstrated which, among identifiable constraints relatively limits cowpea productivity most by showing whose “elimination” (by treatment) relatively increased cowpea biomass. This makes the study application relevant to ongoing field situations where stressors may be short-lived yet damaging to yield. Contrary to the law of minimum and diminishing soil productivity (Mitscherlich, 1909) whereby maximum productivity requires relieving all decrements from the optimal level for each nutrient, intervention by the LSEH focuses on the predominant limiting stressor given prevailing conditions and not a host of stressors. In the Guinea savanna of West Africa, where leguminous crops are predominantly constrained by limited soil nitrogen and osmotic stress, the simultaneous treatment to eliminate multiple abiotic stressors may increase farming costs beyond economic practicality.

Increasing legume production constitutes a long-term food security initiative and ecological restoration strategy whereby legumes improve soil N, increase the availability of percent arable lands, and the possible recruitment or cultivation of less competitive but essential non-legume plants or crop species in the savanna. In our study, we measured N-fixation indirectly by the number of nodules formed per plant and dry mass. While N treatment relatively increased nodulation capacity significantly, the effect of inorganic N, the biostimulant, and sorbitol on mean nodule dry mass did not vary significantly. Thus, exogenous osmotic stress treatment constitutes a promising alternative for increasing cowpea production without impairing their biological N-fixing capacity. N-fixation may be an important agroecological tool for improving long-term savanna ecosystem productivity. Where necessary, the use of N fertilizers to maximize legume yield should depend on whether additional inorganic N supplement addresses the yield gap in the specific growing area. Evidence exists to question the relevance of N fertilization in cowpea. For instance, in a study by Martins et al. (2003), bacteria inoculated cowpea improved grain productivity more than N-fertilized cowpea through increased biological N-fixation. In this instance, regardless

of N supplement, increased biological N-fixation through bacterial inoculation accounted for higher yield. Essentially, the metabolic cost of microbial-aided N-fixation may be lower than the metabolic cost of converting inorganic N fertilizers to readily available forms to impact yield. Similarly, in our study, minimizing the cost of stress allocation may have enhanced yield in which amino acid in nhB contributes organic nitrogen. Besides direct plant growth, biostimulants can be designed to supplement the resource needs of N-fixing bacteria to indirectly improve yield.

It can be inferred from biomass responses that a less productive outcome may ensue when an intervention targets a lesser limiting factor, while the relatively more limiting factor persists, as in the common practice of fertilizer use in crop production in arid landscapes. Hence, it becomes imperative for the agronomist to determine what constitutes the measurable limiting factor for a crop, given its growth conditions. When that is determined, management techniques and tools that improve resource use efficiency become the next relevant agronomic asset (Chaves et al., 2009). The LSEH utilizes a cost-benefit utility that should inform decisions and potential innovations entrenched in the principle of efficiency and sustainability in agricultural practices, particularly in regions challenged by both limited economic and environmental constraints. In the search for sustainable agroecological solutions, LSEH can assist agronomists to decipher appropriate interventions optimal for improving productivity.

The yield effect of biostimulant on N-fixing crops and trees and as a low input for sustainable agriculture has been discussed (Berlyn and Russo, 1990; Russo and Berlyn, 1991, 1992). The goal of this study was to demonstrate the potential of nhB as an input specifically in conditions where fluctuating diurnal or within-season temporal biophysical stressors can impact yield. Although the study satisfies statistical assumptions, it is a test of hypothesis limited to a single species as such, further inquiry can be useful to expand the scope and limitations of the hypothesis. However, from years of experience in biostimulant formulation, there is a remarkable advantage, especially when adopting core formula to other crops and often require small adjustment in the constituent compounds and or their concentrations. Further, our study does not report on the potential implementation cost. Earlier developments, including ROOT 1TM and ROOT 2TM that constituted mycorrhiza were successfully commercialized and available at low cost, and we assume that recent developments based on more available resources will likewise make nhB accessible at low cost.

CONCLUSIONS

Crops growing in the Guinea savanna sub-biome are constrained by a myriad of factors including low soil N, high temperature, and drought. Eliminating each constraint as proposed by the decrement from the maximum concept can be impractical, especially in low-income economies that depend on rainfed

FIGURE 3 | A schematic of the limiting-stress-elimination hypothesis (LSEH). Circles represent whole-plant organisms. Balanced plane implies a notion of significance or pedigree of stress impact. Vertical arrows indicate stressors (osmotic and nitrogen limitation), downward arrow implies stress impact, and upward arrow implies relieved stress. Curved arrows indicate applied intervention (exogenous biostimulant and nitrogen deposition). At equilibrium (**A**), the stressor impact on productivity is assumed similar. Without any intervention, the impact of multiple stressors can be assumed to be synergetic and difficult to detect. However, when defined interventions are simultaneously applied, a shift in slope or tilt (**B**) distinguishes the relative magnitude of the impact of a conjectured stressor and how much it limits plant productivity. The favored intervention (**B**) in the red circle shows sensitivity to stress response by plant and eliminates or alleviates the impact of the stressor. This results in increased productivity indicated by an upward tilt (analogous to a "lighter weighing effect").

agriculture. Although fertilizer input remains the predominant approach to crop nutrient enrichment, it is beneficial where soil nutrient deficit mostly limits crop productivity. The study hypothesized that productivity is relatively maximized when a relatively more limiting stress factor to growth is relieved among other possible stressors. In a case study with cowpea growing in the savanna conditions, osmotic stress treatment increased yield more than N treatment. However, non-hormonal biostimulant treatment, which constitutes both osmolyte and organic nitrogen sources impacted yield most. We conjecture that biostimulants can better manage crop production where productivity may be limited by alternating factors across the growing cycle or by multiple constraints.

doi: 10.3389/fmicb.2021.672751

A novel *Pseudomonas*, designated strain BBB001^T, an aerobic, rod-shaped bacterium, was isolated from the rhizosphere of *Nicotiana glauca* in Las Palmas Gran Canaria, Spain. Genomic analysis revealed that it could not be assigned to any known species of *Pseudomonas*, so the name *Pseudomonas palmensis* sp. nov. was proposed. A 16S rRNA gene phylogenetic analysis suggested affiliation to the *Pseudomonas brassicae* group, being *P. brassicae* MAFF212427^T the closest related type strain. Upon genomic comparisons of both strains, all values were below thresholds established for differentiation: average nucleotide identity (ANI, 88.29%), average amino acid identity (AAI, 84.53%), digital DNA-DNA hybridization (dDDH, 35.4%), and TETRA values (0.98). When comparing complete genomes, a total of 96 genes present exclusively in BBB001^T were identified, 80 of which appear associated with specific subsystems. Phenotypic analysis has shown its ability to assimilate glucose, potassium gluconate, capric acid malate, trisodium citrate, and phenylacetic acid; it was oxidase positive. It is able to produce auxins and siderophores *in vitro*; its metabolic profile based on BIOLOG Eco has shown a high catabolic capacity. The major fatty acids accounting for 81.17% of the total fatty acids were as follows: C_{16:0} (33.29%), summed feature 3 (22.80%) comprising C_{16:1} ω7c and C_{16:1} ω6c, summed feature 8 (13.66%) comprising C_{18:1} ω7c, and C_{18:1} ω6c and C_{17:0} cyclo (11.42%). The ability of this strain to improve plant fitness was tested on tomato and olive trees, demonstrating a great potential for agriculture as it is able to trigger herbaceous and woody species. First, it was able to improve iron nutrition and growth on iron-starved tomatoes, demonstrating its nutrient mobilization capacity; this effect is related to its unique genes related to iron metabolism. Second, it increased olive and oil yield up to 30% on intensive olive orchards under water-limiting conditions, demonstrating its capacity to improve adaptation to adverse conditions. Results from genomic analysis together with differences in phenotypic features and chemotaxonomic analysis support the proposal of strain BBB001^T (=LMG 31775^T = NCTC 14418^T) as the type strain of a novel species for which the name *P. palmensis* sp. nov. is proposed.

Keywords: *Pseudomonas palmensis*, rhizobacteria, *Nicotiana glauca*, PGPB, iron mobilization, plant adaptation, drought, biostimulant

INTRODUCTION

Plant growth-promoting bacteria (PGPBs) are bacteria that colonize plant roots and promote plant growth. These bacteria live in the rhizosphere and play a very important role in plant fitness; in some species, they live in symbiosis with the plant, whereas in most of them, they establish a loose relationship colonizing the root surface. Plants often depend on these PGPBs to acquire nutrients, whereas in other cases, PGPB provides protection against certain pathogens, produces phytohormones such as auxins improving plant development, or helps the plant to get adapted to biotic and abiotic stresses such as herbivores, pathogenic microorganisms, or salinity (Barriuso et al., 2005; Delfin et al., 2015; Bano and Muqarab, 2017).

Nicotiana glauca is a plant species from the *Solanaceae* family, native from South America and naturalized in the Mediterranean area and in the Canary Islands. Able to colonize poor soils, *N. glauca* contains anabasine, an alkaloid that confers some toxicity, and indicates the existence of a complex secondary metabolism, inducible and probably related to defense and plant adaptation (Sinclair et al., 2004; DeBoer et al., 2009). Therefore, wild populations of *N. glauca* colonizing harsh environments will select the best candidates for adaptation and would be a good source for putative PGPBs (Ramos-Solano et al., 2010). Many different bacterial genera have been reported to be PGPBs, and among them, *Pseudomonas* strains are very abundant. They are Gram-negative flagellated bacteria, often known because of the pigment production; they play crucial roles in soil health and plant development (Kloepper, 1992) and affect plant growth (Van Loon, 2007). Among the mechanisms frequently used by *Pseudomonas* species to benefit plant growth are siderophore production (Mavrodi et al., 2001; Rasouli-Sadaghiani et al., 2014), phosphate solubilization (Anzuay et al., 2013), or stimulation of plant protection triggering induced systemic resistance (Bakker et al., 2007; Fatima and Anjum, 2017).

As part of an ongoing research, bacteria from the rhizosphere of *N. glauca* were isolated, and strain BBB001^T was characterized. In this study, a full genetic analysis was conducted to investigate the phylogenetic relationship of strain BBB001^T within the *Pseudomonas* genus by sequencing the whole genome and comparing with those of the most similar genomes within this genus. A polyphasic characterization was also carried out. In addition, two biological assays were performed to support its potential for agriculture, one to demonstrate its ability to improve iron nutrition in tomato and another one to increase olive production under water-limiting conditions.

RESULTS

Phenotypic Characterization

Strain BBB001^T isolated from the rhizosphere of *N. glauca* was classed as a Gram-negative, non-endospore-forming rod. Strain BBB001^T grows on plate count agar (PCA) at 28°C forming circular colonies < 1 mm Ø, with smooth borders, opaque, yellowish, and creamy texture. In liquid culture (nutrient broth),

color changes from pale yellow in the exponential growth phase to intense yellow on the stationary phase after 24 h at 28°C.

Temperature growth test shows that the strain BBB001^T grows in 24 h from 4 to 40°C, although at low temperatures (4°C) it takes up to 72 h. As regards pH, strain BBB001^T grows in a pH range from 6 to 10 and with a salt concentration from 2 to 6%. The optimal temperature, pH, and salinity of growth for strain BBB001^T are as follows: 28°C, pH 8, and 0% salinity.

The API20 NE reveals its ability to assimilate several substrates, namely, glucose, potassium gluconate, capric acid, malate, trisodium citrate, and phenylacetic acid; it is oxidase positive (Table 1). Compared to *Pseudomonas brassicae* MAFF212427^T and *Pseudomonas laurentiana* GSL-010^T, strain BBB001^T is able to degrade CAP, whereas *P. brassicae*^T cannot, and it is oxidase positive, whereas *P. laurentiana*^T is not, sharing all other metabolic capabilities with the two type strains.

According to BIOLOG ECO, strain BBB001^T is able to degrade several carboxylic acids, among which it is worth noting malic acid, hydroxybutyric acid and glucosaminic acid, the latter can also be consumed as a source of nitrogen. Among sugars, glucose-1-phosphate, cellobiose, lactose, and *N*-acetyl glucosamine stand out. As a nitrogen source, strain BBB001^T catabolizes the two amines (putrescine and phenyl ethylamine), although the consumption of some amino acids, such as serine and glycol-L-glutamic acid, is also remarkable (Supplementary Table 2).

The major fatty acids (>81.17% of the total fatty acids) are C_{16:0} (33.29%), summed feature 3 (22.80%) comprising C_{16:1} ω7c and C_{16:1} ω6c, summed feature 8 (13.66%) comprising C_{18:1} ω7c, and C_{18:1} ω6c and C_{17:0} cyclo (11.42%).

In addition, this strain resulted positive for auxins as for siderophores synthesis and negative for chitinases production.

In addition to API20 information, Table 1 summarizes available information from the most closely related *Pseudomonas* species, confirming differences for strain BBB001^T. Interestingly, and different from BBB001^T, “*Pseudomonas qingdaonensis*” strain JJ3^T was not able to degrade D-galacturonic acid, and its temperature range runs from 4 to 37°C, whereas BBB001^T runs from 4 to 40°C (Sawada et al., 2020).

Phylogenetic Analysis

The genome of the BBB001^T strain was analyzed with the tools available at EzBioCloud. First, EzBioCloud's identification service provides proven similarity-based searches against quality-controlled databases of 16S rRNA sequences. After that, the ANI (average nucleotide identity), AAI (average amino acid identity), dDDH, and TETRA analysis were performed. Type (Strain) Genome Server (TYGS) was used to analyze the complete genome.

Estimates of the Degree of Similarity Between Genomes

(a) Phylogenetic analysis and delimitation of species based on the analysis of 16S. The size of 16S rRNA gene was 1,541 bp (MW009702). The analysis based on 16S rRNA gene indicated that the strain BBB001^T shared the highest similarity with *P. qingdaonensis* JJ3^T (100%, non-validated taxon), *P. brassicae* MAFF212427^T (99.85%), and *Pseudomonas*

TABLE 1 | Characteristics that differentiate *Pseudomonas palmensis* sp. nov. from the type strains of the most closely related *Pseudomonas* species: *Pseudomonas brassicae* MAFF212427^T (Sawada et al., 2020) and *Pseudomonas laurentiana* GSL-010^T (Wright et al., 2018).

For API20 NE results obtained in this study, all three strains were negative for NO₃, TRP, GLU, ADH, URE, ESC, GEL, PNPG, GLU, ARA, MNE, MAN, NAG, MAL, GNT, and ADI and positive for GNT, GLU, MLT, CIT, and PAC. Characteristics for API20 NE and biolog plates are scored as follows: – negative reaction; + positive reaction. Fatty acid profile expressed as% (FAME): – indicates absence of the fatty acid. Summed feature* represents two or three fatty acids that cannot be separated using the MIDI system. Summed feature 3 comprises C_{16:1} ω 7c/C_{16:1} ω 6c; summed feature 8 comprises C_{18:1} ω 7c/C_{18:1} ω 6c.

defluvii WCHP16^T (99.31%), whereas *P. laurentiana* GSL-010^T, *Pseudomonas japonica* NBRC 103040^T, and *Pseudomonas huaxiensis* WCHPS060044^T were between 99.00 and 99.1% (Table 2). A phylogenetic tree was constructed based on comparison of the most similar 16S rRNA gene sequences available in the TYGS database (Figure 1). Three different groups appeared in the tree: group 1 in which *Pseudomonas japonica* NBRC 103040^T, *Pseudomonas sinwaenensis* WCHPS060039^T, and *Pseudomonas ineficax* JV551A3^T were located; group

2, represented by *Pseudomonas alkylphenolica* KL28^T, *Pseudomonas huaxiensis* WCHPS060044^T, *Pseudomonas vranoviensis* CCM 7279^T, *Pseudomonas donghuensis* HYS^T, *Pseudomonas wandersilveriensis* CCOS 864^T, and *Pseudomonas tructae* SNU WT1^T; finally group 3, involving *P. qingdaonensis* JJ3(T), strain BBB001, *P. brassicae* MAFF212427^T, *P. laurentiana* GSL-010^T, and *Pseudomonas akapagensis* PS24^T. In the third group, *P. laurentiana* GSL-010^T and *P. akapagensis* PS24^T separated from the other three, showing that

In column 1, accession number is indicated after the species name.

P. qingdaonensis JJ3(T) and strain BBB001 grouped together, separate from *P. brassicae* MAFF212427^T, which is the closest phylogenetically related strain.

(b) The highest values of ANI and AAI (88.29 and 84.83%, respectively) were obtained with the genome of the species *P. brassicae* MAFF212427^T. The highest value of dDDH (35.4%) and the lower intergenomic distance (0.11) was obtained when comparing strain BBB001^T and *P. brassicae* MAFF212427^T (Table 1). G + C content shows a difference of 0.65% between genomes of these two strains. TETRA values were between 0.86 and 0.988, not showing a significant resemblance between the genome of strain BBB001^T and the other 24 genomes (Table 3). Comparison with the genome of *P. qingdaonensis* JJ3(T) (non-validated taxon) showed the highest values (Table 3).

Phylogenetic Analyses Based on Complete Genome Sequences

The genome of strain BBB001^T ¹ (WGS: JAFKEC000000000) was compared against all type strain genomes available in the TYGS database via the MASH algorithm, a fast approximation

of intergenomic relatedness (Ondov et al., 2016), and the 10 type strains with the smallest MASH distances chosen per user genome resulting in a phylogenetic tree (Figure 2).

The comparative analysis of the complete genomes identified a total of 79 genes present exclusively in strain BBB001^T (Supplementary Table 2). Among these genes (Figure 3), transcription-related genes were the most abundant (18) representing 23% or these unique genes; 16 genes were not associated with specific subsystems (20%); 6 were associated with cell wall, membrane, and envelope synthesis (8%); and 6 (8%) were related to inorganic transport and metabolism (eggNOG-emapper). Further analysis was carried out on genes related to inorganic transport and metabolism, and two genes related to the uptake and iron metabolism were identified by blast in antiSMASH 5.0² secondary metabolism database; this is consistent with data from phenotypic characterization.

Biological Assays

The biological assay on iron-starved tomato was conducted to proof the biological effect associated with iron absorption

¹<https://www.ncbi.nlm.nih.gov/bioproject/PRJNA705568>

²<https://antismash.secondarymetabolites.org/#!/start>

(Fe³⁺) and metabolism unique genes of this strain (**Figure 3**). Data showed that both strain BBB001^T and its culture media free of bacteria (chelate) supplemented with non-soluble iron were able to revert chlorosis due to iron deficiency, according to visual evaluation (data not shown). Strain BBB001^T significantly increased dry weight (**Figure 4A**), Fe concentration (**Figure 4B**), and photosynthetic pigments (chlorophylls and carotenes, **Figure 4C**), against the positive control (Fe-EDTA) and the negative control. The chelate produced by the bacteria significantly increased all parameters, except the increase in dry weight, which was non-significant; increases were not as marked as with the bacteria (**Figure 4**).

The biological assay in the intensive olive orchard was conducted aiming to demonstrate the ability of the strain to improve plant adaptation to stress situations, decreasing water input by 25% of regular watering. Results showed a statistically significant increase in olive yield up to 30% (kg/ha), as well as in oil production (**Figure 5**). Interestingly, the production achieved with strain BBB001^T under water-limiting conditions (12,000 kg/ha) reached similar values to controls under regular water regime (data not shown).

DISCUSSION

Strain BBB001^T isolated from the rhizosphere of *N. glauca* is able to improve plant yield in olive trees under water-limiting conditions and to efficiently supply iron to tomato

under iron-limiting conditions, demonstrating its good potential for agriculture. Although the beneficial effects in plants have been described before for other *Pseudomonas* (Kloepper, 1992; Mavrodi et al., 2001; Bakker et al., 2007; Van Loon, 2007; Anzuay et al., 2013; Rasouli-Sadaghiani et al., 2014; Fatima and Anjum, 2017), the multiphasic genomic analysis has evidenced that this is a new strain with beneficial properties for agriculture, for which the name *Pseudomonas palmensis* sp. nov. has been proposed.

The ability of *N. glauca* to select the best strains to improve adaptation to harsh environments has been evidenced consistent with previous studies (Ramos-Solano et al., 2010). Its complex secondary metabolism, inducible and probably related to defense and plant adaptation (Sinclair et al., 2004; DeBoer et al., 2009), together with scarcity of nutrients, is key to select strains that play crucial roles in soil health and plant development. In line with this statement, strain BBB001^T was positive for auxins and for siderophore production. The ability to produce auxins is very common and is related to increases in root surface, which provide plants with an enhanced capacity to absorb water and nutrients and therefore increased growth potential (Gutierrez Mañero et al., 1996).

The carbon source utilization fingerprint characteristic of strain BBB001^T indicates a great adaptive capacity to survive in the rhizosphere of plants, quickly metabolizing organic acids and carbohydrates released by roots, which makes this strain a good root colonizer, one of the traits necessary for effective PGPBs (Posada et al., 2018). This is consistent with bioassay results, as

For each genome, its length [in base pairs (bp)], number of annotated genes, and the values of ANI, AAI, dDDH, intergenomic distance, G + C difference, and TETRA index estimated in the comparison with the genome of *Pseudomonas* BBB001^T. In column 1, the genome accession number is indicated after the species name in RefSeq.

field-grown olives evidence an increase in yield due to bacterial effects, probably due to an efficient colonization.

As there is an increasing number of PGPBs being described, many of which belong to *Pseudomonas*, a multiphasic approach to study its genome was taken to unravel the hidden information of this strain with such a good performance. First, analysis of the 16S rRNA revealed a high similarity (>99%) to five species with validated names. Sequencing of the 16S ribosomal gene (16S rRNA) is the basic tool in the current system classification of bacterial species. Generally, similarity values for the 16S rRNA gene less than 98.65 to 99% are accepted for different species (Kim et al., 2014). However, the 16S rRNA gene may offer limited resolution power as it shows a low capacity for discrimination between closely related species. Furthermore, some species may show very similar sequences of 16S rRNA (>99%), despite being clearly different according to DDH values (Ash et al., 1991; Rosselló-Móra and Amann, 2001). Consistently, ANI and AAI values confirmed differences to existing validated genomes. The values of ANI and AAI represent a robust measure of the evolutionary distance between genomes, as it has been empirically verified that ANI and AAI values of 95 to 96% equals a DDH value (DNA–DNA hybridization) of 70%, commonly used to delimit prokaryotic species (Konstantinidis and Tiedje, 2005; Richter and Rosselló-Móra, 2009; Kim et al., 2014). The closer related strain genomes will show similar frequencies of tetranucleotide use, with correlation indexes

(TETRA) equal to or greater than 0.99 (Teeling et al., 2004; Richter and Rosselló-Móra, 2009). The highest values of ANI and AAI obtained in the comparison with the genome of the species *P. brassicae* were well below the 95% threshold established for considering that both genomes belong to the same species. The highest value of dDDH and the lower intergenomic distance were obtained when comparing strain BBB001^T and *P. brassicae* MAFF212427^T (Table 3), being the value of dDDH much lower than the 70% necessary to be able to assign strain BBB001^T to this species. This result is also corroborated by TETRA values, which did not show a significant resemblance between the genome of strain BBB001^T and the other genomes with values less than 0.99%. In the phylogenetic tree constructed in TYGS with complete genome data (Figure 2), strain BBB001^T is closely related with *P. brassicae* MAFF212427^T and *P. qingdaonensis* JJ3^T. In this case, the analysis establishes a closer relationship between strain BBB001^T and *P. qingdaonensis* JJ3^T, which taxonomic name is not validated yet³. It is likely therefore that the repertoire of accessory genes of strain BBB001^T is more like that of *P. qingdaonensis* JJ3^T than that of *P. brassicae* MAFF212427^T.

Comparison of the most similar complete genomes at Pan-seq revealed novel regions of this strain, a total of 96 genes were present exclusively in strain BBB001^T, and 80 of these genes appear associated with specific subsystems. Among these genes

³<https://lpsn.dsmz.de/species/pseudomonas-qingdaonensis>

FIGURE 2 | Phylogenetic tree constructed in TYGS. Tree inferred with FastME 2.1.6.1 (Lefort et al., 2015) from GBDP distances calculated from genome sequences. The branch lengths are scaled in terms of GBDP distance formula d5. The numbers above the branches are GBDP pseudo-bootstrap support values > 60% from 100 replications, with an average branch support of 94.3%. The branch length values represent the evolutionary time between two nodes. Unit: substitutions per sequence site. The tree was rooted at the midpoint (Farris, 1972).

FIGURE 3 | Representation of functional categories of novel regions of strain BBB001^T.

Different letters denote statistically significant differences according to LSD test ($p < 0.05$) for chlorophyll a (a, b, and c), chlorophyll b (x, y, and z), and carotenes (m, n, and p).

FIGURE 5 | Olive and olive oil production of *Olea europaea* trees (kg/ha). Different letters denote statistically significant differences according to LSD test ($p < 0.05$) for olive yield (a, b), oil yield (x, y).

(Figure 3), those related to the uptake and iron metabolism were found (Coulton et al., 1983; Braun, 2003; Miethke and Marahiel, 2007) and correlate with data from phenotypic characterization.

Biological assays were designed to evidence the potential of the strain for agriculture based on its unique genes related to

iron metabolism on the one hand and of its general performance. The biological assay on iron-starved tomato was conducted based on information about unique genes of this strain related to iron absorption (Fe^{3+}) and metabolism (Figure 3). Data showed that both BBB001^T and its culture media free of bacteria

(chelate) supplemented with non-soluble iron were able to revert chlorosis due to iron deficiency, according to visual evaluation, significantly increasing dry weight, iron concentration and photosynthetic pigments in iron-starved tomatoes, being the bacteria much more efficient than the chelate (Figure 4).

The differences between the bacteria and the culture media suggest that the increased iron mobilization is strongly improved when the bacteria are present, consistent with the multitarget response proposed for beneficial bacteria (Ilangumaran and Smith, 2017). In this type of response, bacteria improve iron mobilization probably supported by an increased root development that allows an increase in absorption surface (Gutierrez Mañero et al., 1996), a response attributed to auxin concentration, also present in the unique gene set of the strain. The beneficial effect on iron nutrition also shows an increase of photosynthetic pigments on the shoot, being especially striking the increase on chlorophyll a, the key player on light reactions as it is mainly located on photosystems. The increase in photosynthetic potential is evidenced on growth (dry weight), with the highest increase in dry weight on the bacteria treated plants, confirming that not only iron limits plant growth and supporting the better performance of bacteria in agriculture, where many environmental factors change along plant growth cycle.

The biological assay in the intensive olive orchard was conducted aiming to demonstrate the ability of the strain to improve plant adaptation to stress situations, especially the lack of water, as this situation becomes more and more frequent nowadays. The mechanisms involved in plant adaptation to stress are common to many other stressful situations such as salinity or biotic stress, through common signaling pathways (Martin-Rivilla et al., 2020). Plant adaptive mechanisms involve ionic homeostasis and modulation of redox balance among others (Kangasjärvi et al., 2014; Kollist et al., 2019). Olive yield (kg/ha) and oil production increased significantly (up to 30%) despite the 25% decrease of water input (Figure 4). The registered increase in oil was due to two factors: the increment in olive production and the increase in fat yield, reaching similar values to controls under regular water regimen (data not shown).

These results support the suitability of this strain to activate adaptive mechanisms in different plant species, from herbaceous to woody plant species, as well as its versatility to different environmental stress factors, evidencing its multitarget power (Ilangumaran and Smith, 2017).

Genomic analysis on strain BBB001 revealed that it could not be assigned to any known species of *Pseudomonas*, so the name *P. palmensis* sp. nov. was proposed for strain BBB001^T. A 16S rRNA gene sequence-based phylogenetic analysis suggested that the strain BBB001^T was affiliated with the *P. brassicae* group with *P. brassicae* MAFF212427^T as the most closely related type strain (99.85% similarity). Genomic comparisons of strain BBB001^T with the type strain species *P. brassicae* MAFF212427^T were all below thresholds established for differentiation. In the comparative analysis of complete genomes, a total of 96 genes present exclusively in strain BBB001^T were identified, 80 of which appear associated with specific subsystems.

Also, the novel taxon possesses several phenotypic traits related to beneficial plant traits, like auxin production or iron mobilization. Results obtained in iron-starved tomato and water-limited olive orchards confirm the potential of this strain for agriculture. On the one hand, it is efficient for iron mobilization under nutrient stress and adverse conditions, consistent with the specific and unique set of genes associated with iron metabolism, so it can be used to develop organic Fe supplies for sustainable agriculture, both the strain and its metabolites. On the other hand, it can improve adaptation to water-limiting conditions while keeping high productivity, so it is an excellent candidate to develop biotechnological products for agriculture under harsh conditions. Finally, the effects recorded in herbaceous species such as tomato, as well as in a woody species such as olive, confirm its wide scope capability to succeed in most agronomic crops, as this strain can trigger plant metabolism in different species.

In summary, all phenotypic and genomic characterization of the novel strain BBB001^T reveals a distinct and well-differentiated species from all *Pseudomonas* species with validated reference taxons and, more precisely, different from *P. brassicae* MAFF212427^T.

Thus, based on the polyphasic approach, we describe a novel *Pseudomonas* species, for which the name *P. palmensis* sp. nov. is proposed, based on the geographical origin of isolation, Las Palmas de Gran Canarias (Islas Canarias, Spain). The type strain is strain BBB001^T (= LMG 31775 = NCTC 14418).

Description of *Pseudomonas palmensis* sp. nov

Pseudomonas palmensis (palm.en'sis), N.L. masc./fem. adj. palmensis, belonging to Las Palmas de Gran Canaria, Spain, from which the type strain was isolated.

Cells are Gram-reaction negative, aerobic, rod-shaped bacteria ranging between 0.5 and 0.8 μm \times 1.5–3.8 μm long, non-endospore-forming rods. Colonies grow on PCA at 28°C forming circular colonies < 1 mm \varnothing , with smooth borders, opaque, yellowish, and creamy texture. In liquid culture (nutrient broth), color changes from pale yellow in the exponential growth phase to intense yellow on the stationary phase after 24 h at 28°C. Growth occurs at 4 to 40°C in 24 h but not at 42°C. As regards pH, strain BBB001^T grows in a pH range from 6 to 10 and with a salt concentration from 2 to 6%. The optimal temperature, pH, and salinity of growth for BBB001^T are 28°C, pH 8, and 0% salinity. It is able to assimilate glucose, potassium gluconate, capric acid malate, trisodium citrate, and phenylacetic acid; it is oxidase positive. Its metabolic profile based on BIOLOG Eco shows a high catabolic capacity. It is able to produce auxins and siderophores, but not chitinases. The major fatty acids (> 81.17% of the total fatty acids) are C_{16:0} > summed feature 3 (C_{16:1} ω 7c/C_{16:1} ω 6c), > summed feature 8 (C_{18:1} ω 7c/C_{18:1} ω 6c) > C_{17:0} cyclo.

The strain BBB001^T was isolated from the rhizosphere of *N. glauca* L. in Las Palmas de Gran Canaria Spain, in 2017. The genomic DNA G + C content of the type strain is 64.05%. The draft genome and 16S rRNA gene

sequences of the strain BBB001^T have been deposited at the NCBI GenBank under accession numbers MW009702 and JAFKEC000000000, respectively. The type strain is BBB001^T (= LMG 31775 = NCTC 14418).

MATERIALS AND METHODS

Origin of Bacteria

The bacterial screening was carried out over the rhizosphere of wild populations of *N. glauca* in Las Palmas de Gran Canaria (Islas Canarias, Spain; Coordinates UTM: 28°01'36.8" N 15°23'19.7W) in December 2017. The soil intimately adhered to roots, and the thinner roots (diameter 1–2 mm) of four plants were pooled at random and constituted a replicate; four replicates were sampled. All materials were brought to the laboratory in plastic bags at 4°C. One gram of rhizosphere soil and thinner roots were suspended in 10 mL sterile distilled water and homogenized for 1 min in an Omni Mixer. One hundred microliters of the soil suspension was used to prepare serial 10-fold dilutions in a final volume of 1 mL; 100 µL was plated on Standard Methods Agar (Pronadisa Spain) and incubated for 4 days at 28°C. Individual colonies were selected after 36 h. To avoid duplication, isolated colonies were marked on the plate after selection. Eighty colony-forming units (cfu) were selected from each serial-dilution series, that is, from each replicate (four), constituting 320 cfu. All were isolated and grouped according to Gram staining, morphological characteristics, and sporulating capacity into four parataxonomic groups: Gram-positive endospore-forming bacilli, Gram-positive non-endospore-forming bacilli, Gram-negative bacilli, and other morphologies were grouped under "Others." All isolates were kept at –20°C on glycerol: water (1:4) (Ramos-Solano et al., 2010). Our bacterium was isolated from these dilutions and was kept at –20°C on glycerol: water (1:4).

Phenotypic Characterization

Our bacterium was tested for *in vitro* production of auxins, (Benizri et al., 1998), siderophores (Alexander and Zuberer, 1991), and chitinases (Rodríguez-Kábana et al., 1983; Frändberg and Schnürer, 1998) using specific culture media in which a color change reveals the biochemical trait.

To test pH and salt tolerance rates of BBB001^T, the following procedure was followed. Growth was tested in presence of 0 to 8% (wt/vol) NaCl (at intervals of 1%) and at pH 4 to 10 (at intervals of 0.5 pH units) by supplementing TSB with appropriate buffer systems (pH 4–5.5, 0.1 M citric acid/0.1 M sodium citrate; pH 6–9, 0.1 M KH₂PO₄/0.1 M NaOH; pH 8.5–10, 0.1 M NaHCO₃/0.1 M Na₂CO₃ (Xu et al., 2005). After autoclaving, pH medium was adjusted by the addition of NaOH/HCl 1 M before sterile filtration (pore size 0.22 µm). Analyses were carried out at 28°C for 48 h by shaking at 140 revolutions/min (rpm) in an orbital shaker and measuring OD₆₀₀ nm every 2 h. Each well contained 200 µL of the selected medium and was inoculated at a dilution of 1:1,000 with an overnight culture of cells grown in unmodified TSB at 28°C for 24 h. Periphery pH and NaCl growth conditions previously obtained were also

studied, using 5-mL tubes at 28°C for 1 week. Growth at 4 to 42°C was tested in tubes containing 7 mL TSB with shaking at 140 rpm for 8 days. All strains were precultured overnight at 28°C with TSB before suspending one loop of cells in 1 mL TSB as inoculation culture. The 7-mL test tubes were inoculated with 10 µL of the inoculation culture. The optimal growth temperature was determined using the SPECTROstar nano (BMG Labtech) and TSB under the same conditions as used for testing growth at different NaCl concentrations and pH. The range for optimal growth was determined by the length of the lag phase until the cultures achieved an increase in OD₆₀₀ of 0.2.

The metabolic capabilities were evaluated by API 20NE and BIOLOG ECO according to manufacturer instructions. The bacterial suspension was prepared from bacterial biomass grown for 24 h in PCA resuspended in MgSO₄ 10 mM to achieve 95% of transmittance at 620 nm. Biolog ECO plates were then inoculated with 150 µL per well. Plates were incubated at 25°C in darkness. Each well contained a substrate and tetrazolium salts, which turn violet when reduced by the activity of microorganisms. Three replicates per treatment and sampling time were performed. Kinetics of average well color development (AWCD) were used to perform a curve and to determine bacterial speed using the 31 provided substrates. From this curve, 7-day incubation time was chosen to represent the catabolic profile of the strain.

Fatty acid composition was determined according to MIDI microbial identification system (Sasser, 1990) on an Agilent 6850 gas chromatograph, provided with the MIDI microbial identification system with method TSBA6 (MIDI, 2008). This fatty acid profile was obtained from strain BBB001 grown in nutrient agar, at 28°C, for 24 h.

Phylogenetic Analysis

To investigate the phylogenetic relationship of strain BBB001^T with other species of *Pseudomonas* genus and define the taxonomic allocation, three main strategies were used:

- Estimate the similarity between genomes: (a) phylogenetic analysis and delimitation of species based on the analysis of 16S rRNA and (b) ANI, AAI, hybridization DNA–DNA *in silico* or dDDH (digital DNA–DNA hybridization), difference in the content of guanine-cytosine (G + C), and frequency of tetranucleotide use.
- Phylogenetic analysis at complete genome level.
- Characterization of novel regions.

Libraries Preparation

The DNA extraction from the lyophilized culture was performed with the REAL MicroSpin DNA Isolation kit (Durviz), strictly following the manufacturer's instructions. A sample that did not contain a bacterial culture was processed in parallel with the other samples to verify the absence of cross contamination during DNA extraction. DNA was quantified using fluorometric methods (Qubit, Thermo Fisher Scientific).

Nextera XT Library Prep kit (Illumina) was used to prepare the library, following the manufacturer's instructions. The fragment size distribution was then checked on an Agilent 2100

Bioanalyzer, using the Agilent DNA 1000 kit. Qubit dsDNA HS kit was used to check library concentration.

Based on these concentration data, the library was equimolarly mixed and loaded in a fraction of a MiSeq Paired-End 300 (Illumina) run.

Quality Analysis and Sequencing Data

The FastQC 0.11.3 program was used to analyze the quality of the sequencing. Trimmomatic 0.36 (Bolger et al., 2014) was used to remove the adapters (ILLUMINACLIP option) and poor-quality regions (SLIDINGWINDOW: 5: 30). All sequences smaller than 80 base pairs were also discarded.

De novo Assembly and Quality Analysis

Short sequences were assembled *de novo* using SPAdes 3.10 (Bankevich et al., 2012). SPAdes is based on the creation of graphs using the algorithm known as de Bruijn using different kmers. As recommended in the manual, kmers 21, 33, 55, 77, 99, and 127 were used; the *-cov-cutoff* option was set to auto and the *-careful* option was enabled. SPAdes use the information from the two pairs of files generated in the sequencing to transform contigs into scaffolds by introducing Ns between the contigs that can be joined.

The quality of the assemblies was analyzed using the QUAST 4.4 program (Gurevich et al., 2013).

The sequences of each sample were mapped in the assembly generated by SPAdes, to determine the coverage of each genomic region using BWA 0.7.12 (Li and Durbin, 2010). SAMtools 0.1.19 (Li et al., 2009) was used to determine the depth of sequencing and eliminate secondary or poor-quality mappings.

Qualimap 2.2.1 (Okonechnikov et al., 2015) was used to observe how the coverage is distributed throughout the genome and, in addition, to extract the specific coverage of each scaffold. To avoid possible inconsistencies or the presence of contaminating sequences, those scaffolds with less than 10 X coverage were discarded from the successive analyses. In addition, those scaffolds with a length less than 1,000 base pairs were also eliminated.

The sequencing of the complete genome on the Illumina platform MiSeq PE300 generated 986,724 sequences and a total of 290 megabases (Mb). The sequences obtained after applying the quality filters were assembled *de novo* to create larger sequences (scaffolds). Strain BBB001^T genome assembly generated 128 scaffolds with a total length of 5.91 Mb. The mapping of the sequences against the assembled genome confirmed that 99.94% of the sequences obtained for strain BBB001^T could be used for the generation of the assembly.

Estimates of the Degree of Similarity Between Genomes

Phylogenetic Analysis and Delimitation of Species Based on the Analysis of 16S

16S rRNA sequences were BLAST-queried against all strains with a validated name in the reference database at the Ezbiocloud website.

ANI and AAI

The first stage of this analysis consists in the comparison at the nucleotide (ANI) and amino acid (AAI) level of strain BBB001^T genome with all complete genomes available in the EzBiocloud database for similar genomes according to the 16S analysis previously performed. The estimates of the nucleotide identity index (ANI) were calculated using⁴. The amino acid content (AAI) was calculated at <http://enve-omics.ce.gatech.edu/aai/>. Values below 95% indicate a new species (Richter and Rosselló-Móra, 2009; Kim et al., 2014).

dDDH and Content in G + C

Based on the results of the previous section, the 26 genomes located in the fourth quartile of the distribution of the ANI values were selected (i.e., predictably, the most closely related to strain BBB001^T), to calculate the intergenomic distances and the dDDH indexes, using the GGDC web server (Genome-to-Genome Distance Calculator). This server also calculates the difference in G + C content of genomes analyzed. Values less than 70% are indicative of significant differences (Richter and Rosselló-Móra, 2009; Kim et al., 2014).

Frequencies of Use of Tetranucleotides

The JSpecies software (Richter and Rosselló-Móra, 2009) was used to calculate the differences in tetranucleotide usage profiles between the genome of strain BBB001^T and the 26 most related genomes. Values greater than 99% are indicative of significant differences (Teeling et al., 2004; Richter and Rosselló-Móra, 2009).

Phylogenetic Analyses Based on Complete Genome Sequences

The genome sequence of BB001 was uploaded to the TYGS, a free bioinformatics platform available under <https://tygs.dsmz.de>, for a whole genome-based taxonomic analysis (Meier Kolthoff and Göker, 2019).

First, BB001 genome was compared against all type strain genomes available in the TYGS database *via* the MASH algorithm, a fast approximation of intergenomic relatedness (Ondov et al., 2016), and the 10 type strains with the smallest MASH distances chosen per user genome. This was used as a proxy to find the best 50 matching type strains (according to the bitscore) for each user genome and to subsequently calculate precise distances using the Genome BLAST Distance Phylogeny (GBDP) approach under the algorithm “coverage” and distance formula d5 (Meier-Kolthoff et al., 2013). These distances were finally used to determine the 10 closest type strain genomes for each of the user genomes.

For the phylogenomic inference, all pairwise comparisons among the set of genomes were conducted using GBDP and accurate intergenomic distances inferred under the algorithm “trimming” and distance formula d5 (Meier-Kolthoff et al., 2013). One hundred distance replicates were calculated each. Digital DDH values and confidence intervals were calculated using the recommended settings of the GGDC 2.1 (Meier-Kolthoff et al., 2013).

⁴<https://www.ezbiocloud.net/tools/ani>

The resulting intergenomic distances were used to infer a balanced minimum evolution tree with branch support *via* FASTME 2.1.6.1 including SPR postprocessing (Lefort et al., 2015). Branch support was inferred from 100 pseudo-bootstrap replicates each. The trees were rooted at the midpoint (Farris, 1972) and visualized with PhyD3 (Kreft et al., 2017).

Characterization of *Pseudomonas* BBB001^T Novel Regions

The novel regions were determined using the web server Panseq⁵. The Novel Region Finder of this software currently identifies any genomic regions present in any of the “Selected Query” sequences (genomes of the 26 species closer in EzBiocloud) that are not present in any of the “Selected Reference” sequences (genome of BBB001) and returns these regions in multi-fasta format. These comparisons are done using the nucmer program from MUMmer v3. Annotations of novel sequences were computed using eggNOG-mapper (Huerta-Cepas et al., 2017) based on eggNOG 4.5 orthology data (Huerta-Cepas et al., 2018).

Biological Assays Experimental Set Up Iron Mobilization on Tomato

Tomato (*Solanum lycopersicum* L.) seeds were germinated in cocopeat with 24°C/19°C (day/night), and 15-h/9-h light-dark and kept in the greenhouse under controlled conditions throughout the 12 weeks of the experiment. Four treatments were used in this experiment: (1) control + (Fe-EDTA), (2) control– (no iron, no bacterial treatment), (3) strain BBB001^T, and (4) the culture media free of bacteria [chelate (Q) produced by BBB001^T]; to obtain treatments 3 and 4, strain was inoculated on nutrient broth and was grown for 24 h at 28°C under shaking, and then the culture media was centrifuged at 4,000 rpm, and the supernatant was treatment 4 (chelate), and treatment 3 was made by resuspending cells in the same volume of MgSO₄ 10 mM solution. A total of 96 plants arranged in three replicates with eight plants each per treatment. Plants were grown under iron deficiency conditions achieved by washing substrate with bicarbonate buffer pH 8.5 to bring substrate to basic pH preventing iron absorption. After sowing, plants were watered twice a week with bicarbonate buffer pH 8.5 to maintain a high pH and with Hoagland without iron once a week. When chlorosis appeared (6 weeks after sowing), bacteria were delivered to plant roots by soil drench supplemented with iron (FeCl₃). Three doses were delivered every 2 weeks; each dose consisted of 10 mL of strain BBB001^T (or chelate), at 1×10^8 cfu/mL per plant supplemented with FeCl₃ in an equivalent concentration of iron per plant to even that of Fe-EDTA. Two days after the last inoculation, plants were harvested to analyze dry weight, iron content, and photosynthetic pigments.

After 12 weeks of experiment, plants were harvested and dried, and plant weight was recorded. Leaves from plants in a replicate were pooled, and chlorophylls and carotenes were analyzed according to Lichtenthaler and Hartmut (1987), and iron was determined by atomic absorption spectrometry (method PNT.08.01).

Olea europaea Production in Intensive Orchards Under Water Limitation

A 12-year-old intensive orchard of *O. europaea* var. Arbequina in Toledo (Spain) (Coordinates UTM 393782–4343510) was used for this experiment. Two lines of 100 m each were selected, and treatments were marked within the two lines on a random block design. Treatments consisted in three replicates of seven trees; BBB001^T treatment was root inoculated (500 mL per tree with a bacterial concentration 1×10^8 cfu/mL) every 2 weeks from April to October, and controls were mock inoculated with water. Regular watering consists of four times a week, each 2 L/h for 3 h; in experimental trees, one time was skipped to decrease water input by 25%. Olives were harvested at the end of October, collecting all olives from the seven trees in the replicate, which were weighed, and fat content determined with Soxhlet. Production (kg/ha) was estimated calculating production per plant and considering orchard's plant density (1,600/ha).

Statistical Analysis

To evaluate treatment effects on all variables, one-way analysis of variance was performed. When significant differences appeared ($p < 0.05$), LSD test (least significant difference) Fisher was used. Statgraphics Plus for Windows was the program used.

DATA AVAILABILITY STATEMENT

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: <https://www.ncbi.nlm.nih.gov/bioproject/PRJNA705568>.

AUTHOR CONTRIBUTIONS

FJGM conceptualized the manuscript. EG-A and IH carried on the bacterial isolation. EG-A analyzed the genomic data. JL, AG-V, and EG-A developed tomato bioassay and drafted the manuscript. EG-A, BR-S, and FJGM developed olive assay. FJGM and BR-S wrote and supervised the final version. All authors contributed to the article and approved the submitted version.

ACKNOWLEDGMENTS

The authors would like to thank Antonio Marin for providing olive orchards and manipulation.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fmicb.2021.672751/full#supplementary-material>

Strain 15S Be an Approach for the Smarter P Fertilization of Maize and Cucumber Plants? Front. Plant Sci. 12:719873. doi: 10.3389/fpls.2021.719873

Phosphorus (P) is an essential nutrient for plants. The use of plant growth-promoting bacteria (PGPB) may also improve plant development and enhance nutrient availability, thus providing a promising alternative or supplement to chemical fertilizers. This study aimed to evaluate the effectiveness of *Enterobacter* sp. strain 15S in improving the growth and P acquisition of maize (monocot) and cucumber (dicot) plants under P-deficient hydroponic conditions, either by itself or by solubilizing an external source of inorganic phosphate (Pi) [Ca₃(PO₄)₂]. The inoculation with *Enterobacter* 15S elicited different effects on the root architecture and biomass of cucumber and maize depending on the P supply. Under sufficient P, the bacterium induced a positive effect on the whole root system architecture of both plants. However, under P deficiency, the bacterium in combination with Ca₃(PO₄)₂ induced a more remarkable effect on cucumber, while the bacterium alone was better in improving the root system of maize compared to non-inoculated plants. In P-deficient plants, bacterial inoculation also led to a chlorophyll content [soil-plant analysis development (SPAD) index] like that in P-sufficient plants ($p < 0.05$). Regarding P nutrition, the ionomic analysis indicated that inoculation with *Enterobacter* 15S increased the allocation of P in roots (+31%) and shoots (+53%) of cucumber plants grown in a P-free nutrient solution (NS) supplemented with the external insoluble phosphate, whereas maize plants inoculated with the bacterium alone showed a higher content of P only in roots (36%) but not in shoots. Furthermore, in P-deficient cucumber plants, all Pi transporter genes (*CsPT1.3*, *CsPT1.4*, *CsPT1.9*, and *Cucs383630.1*) were upregulated by the bacterium inoculation, whereas, in P-deficient maize plants, the expression of *ZmPT1* and *ZmPT5* was downregulated by the bacterial inoculation. Taken together, these results suggest that, in its interaction with P-deficient cucumber plants, *Enterobacter* strain 15S might have solubilized the Ca₃(PO₄)₂ to help the plants overcome P deficiency, while the association of maize plants with the bacterium might have triggered a different mechanism affecting plant metabolism. Thus, the mechanisms by which *Enterobacter* 15S improves plant growth and P nutrition are dependent on crop and nutrient status.

INTRODUCTION

Crops cultivated around the world, belonging to both monocot and dicot clades, can be very diverse; nevertheless, their growth and development are strongly influenced by the state and the availability of nutrients in the soil. Consequently, the yield levels and the overall performance of a crop can considerably vary both spatially and temporally, depending on both soil characteristics and agricultural practices. In this context, phosphorus (P) is known to play a crucial role in plant nutrition; thus helping to achieve optimal growth and productivity. Plants take up P as inorganic phosphate (Pi); however, due to its low solubility and mobility, P is sparingly available in the soil solution, as its concentration is often rather limited ($<10\ \mu\text{M}$) (Wang et al., 2017). To cope with this issue, plants have evolved morphological, biochemical, and metabolic strategies, which include: (i) the enhancement of root density and length, (ii) the release of organic acids and phosphatases, (iii) an increase in the expression of high-affinity Pi transporters, and (iv) the establishment of a symbiotic association with mycorrhizal fungi (López-Arredondo et al., 2014).

In addition to the genetic improvement of crops achieved through breeding programs, the exogenous root-inoculation with plant growth-promoting bacteria (PGPB) could prove itself to be an interesting and promising agricultural approach to the amelioration of the mineral nutrition of plants (Ramaekers et al., 2010). Indeed, beneficial bacteria colonize the root surface in the rhizosphere, where they can exert positive effects on a wide range of plant species *via* direct and indirect mechanisms (Dakora et al., 2015; Backer et al., 2018). The direct effects of PGPB inoculation can be related to either activity aimed at ameliorating the mineral nutrition of plants [e.g., nitrogen (N) fixation, P solubilization, the release of siderophores, and the enhancement of mineral nutrients uptake] (Pii et al., 2015b) or the release of hormone-like compounds that can modulate the growth of plants (Glick, 2012; Goswami et al., 2016). On the other hand, indirect effects are related to the ability of PGPB to protect plants from both abiotic (e.g., drought and salinity) and biotic (e.g., pathogens) stresses (Glick, 2012; Goswami et al., 2016).

Focusing on the biogeochemical cycle of P in soil, it has been well-demonstrated that PGPB can enhance the available fraction of this nutrient *via* an augmented secretion in the rhizosphere of organic acids and phosphatases (Billah et al., 2019). Although examples of improved plant acquisition of P have been well-described as a consequence of root inoculation with different PGPB strains, the mechanisms underlying the phenomenon remain unknown. The understanding of these interactions can be further complicated by the co-occurrence of processes underpinning P acquisition by plants; for instance, the increased nutrient bioavailability at the root-soil interface on the one hand, and the enhanced capacity of plants to transport Pi across the plasma membrane on the other hand (Pii et al., 2015b). Moreover, the ability of the roots to reacquire a wide range of small organic molecules belonging to root exudates, recently demonstrated in P-deficient tomato plants, further complicates the biochemical P cycle in the rhizosphere (Tiziani et al., 2020). Collectively, deeper comprehension of all these processes

through the application of multidisciplinary approaches appears to be crucial to better exploit the properties of the PGPB strains at the field scale for the more efficient use of the endogenous P sources in soil within the context of more sustainable agriculture.

With respect to Pi-uptake mechanisms in roots, there are diverse experiences in literature aimed at the identification of the genes encoding the specific transporters and the characterization of the regulation of the entire Pi-uptake process in the roots (López-Arredondo et al., 2014). Considering the first aspect, among the genes identified, the *PHT1* gene family has the largest number of members expressed in roots, is well-recognized as mediators of Pi uptake from the external medium, and is predominantly overexpressed under P starvation (Wang et al., 2018). Considering crops and in particular monocots, 13 *PHT1* members have been identified in rice (*Oryza sativa*) (Paszkowski et al., 2002) and maize (*Zea mays*) (Liu et al., 2016), 16 in wheat (*Triticum aestivum*) (Grün et al., 2018), and nine in sorghum (*Sorghum bicolor*) (Tavares de Oliveira Melo, 2016). On the other hand, in dicots, 15 genes have been identified in the soybean (*Glycine max*) genome (Fan et al., 2013), eight in tomato (*Solanum lycopersicum*) (Chen et al., 2014) and potato (*Solanum tuberosum*) (Liu et al., 2017), and five in tobacco (*Nicotiana tabacum*) and pepper (*Capsicum frutescens*) (Chen et al., 2007). In this respect, it is interesting to note that studies aimed at characterizing the expression levels of these genes in inoculated plants (and, thence, the functionality of the Pi transporters) have been mainly conducted in plants colonized with arbuscular mycorrhizal fungi (AMF), while only a few of them considered inoculation with PGPB (Duan et al., 2015; Liu et al., 2018; Zhang et al., 2019). Therefore, the regulatory effects of PGPB on these transporters are still quite unknown. Additionally, considering that the effects of PGPB on plants significantly depend on specific interactions between plant genotypes and bacterial strains (Pii et al., 2015b; Crecchio et al., 2018), deeper knowledge about the PGPB strains (already isolated and belonging to the microbial collection banks in several research centers but not yet thoroughly investigated and characterized) appears to be fundamental.

Considering the possibility of improving P nutrition in crops using PGPB, it is worth mentioning that, in the context of previous research, the bacterium *Enterobacter* sp. strain 15S has been isolated and characterized for its particular ability to solubilize P *in vitro*, thus making it a promising tool for sustainable fertilization strategies (Zuluaga et al., 2020). Nevertheless, considering the abovementioned specificity in the PGPB-host interplay, it is mandatory to characterize the interaction of *Enterobacter* sp. strain 15S with model crops belonging to both monocots and dicots to unravel whether this bacterial strain might find a useful application at the field scale.

Based on these observations, the present research aimed to investigate the effect of *Enterobacter* sp. strain 15S inoculation on the development and P nutrition of cucumber and maize plants, which were chosen as representatives of the clades dicots and monocots, respectively. Considering the strong ability of P solubilization featured by *Enterobacter* sp. strain 15S, the bacterium effects on root P uptake of plants fed with an inorganic Pi source [$\text{Ca}_3(\text{PO}_4)_2$] were also monitored. Plants were grown

in hydroponic conditions, either in the presence (P+) or in the absence (P-) of the macronutrient P; plants were also either inoculated or not inoculated with *Enterobacter* sp. strain 15S. In addition, considering the strong P solubilization ability featured by *Enterobacter* sp. strain 15S, a set of plants were also fed an insoluble inorganic Pi source [$\text{Ca}_3(\text{PO}_4)_2$] and monitored for their growth and mineral nutrient accumulation. After a cultivation period of 21 days, the plants were sampled and assessed for their growth, the concentration of mineral elements in their tissues, biological activities of their roots (i.e., release of exudates), and the molecular modulation of Pi transporters at the root level.

MATERIALS AND METHODS

Experimental Design and Plant Growth Conditions

Cucumber (*Cucumis sativus* L. cv. Chinese Long) and maize (*Z. mays* L. – hybrid P0423, Pioneer Hi-Bred Italia S.r.l) plants were hydroponically grown under controlled environmental conditions in a climatic chamber with a 14/10-h light/dark period, 24/19°C, 250 $\mu\text{mol m}^{-2} \text{s}^{-1}$ light intensity, and 70% relative humidity. Seeds were germinated for 5 days in the dark at 22°C on filter paper moistened with 0.5 mM CaSO_4 . Five-day-old seedlings were then transferred into 2-L plastic pots filled with 1.5 L of a full-strength nutrient solution (NS), either not supplemented (P-) or P-supplemented (P+) using the soluble phosphate 0.1 mM KH_2PO_4 . The NS had the following composition: 2 mM Ca (NO_3)₂, 0.5 mM MgSO_4 , 0.7 mM K_2SO_4 , 0.1 mM KCl, 10 μM H_3BO_3 , 0.5 μM MnSO_4 , 0.2 μM CuSO_4 , 0.5 μM ZnSO_4 , 0.01 μM $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}$, and 80 μM Fe-EDTA. The solution was continuously aerated and changed two times per week. After 7 days of hydroponic culture, plants were set in a 2 × 4 factorial experimental design completely randomized with two P conditions (P+ and P-) and two biostimulant treatments with the PGPB *Enterobacter* 15S, with or without insoluble $\text{Ca}_3(\text{PO}_4)_2$, provided with a dialysis tube (named 15S and 15SIP, respectively), plus two inoculated controls (named C and CIP, respectively) (Figure 1). Three biological replicates, with 10 (cucumber) or eight (maize) seedlings per replicate, were performed for each treatment. After 21 days of cultivation, the plants were harvested and assessed as described below.

Bacterial Biostimulant

Enterobacter sp. 15S strain (KX884932.1) was originally isolated from bulk soil under conventional horticultural management in the Laboratory of Molecular Biochemistry of the State University of Londrina (Paraná, Brazil) (Zuluaga et al., 2020). The bacterial strain was grown in Luria-Bertani (LB) medium (10 g L⁻¹ tryptone, 5 g L⁻¹ yeast extract, and 10 g L⁻¹ NaCl) under orbital shaking at 180 rpm, 28°C, for 24 h. After that period, the cells were harvested, washed three times, and resuspended in a sterile saline solution (0.85% w/v NaCl). Bacterial biostimulant suspension was used to inoculate the hydroponic NS to a final concentration of 10⁶ cell ml⁻¹ (Figure 1). Control treatments were treated with the same amount of sterile saline solution.

Plant Analysis

Morpho-Physiological Parameters

SPAD Values

After 15 days of hydroponic culture, the plants were harvested and the changes in chlorophyll concentration of the youngest fully expanded leaves were determined using a portable chlorophyll meter (SPAD-502, Minolta, Osaka, Japan) and presented as soil-plant analysis development (SPAD) units. Measurements were performed on three plants per pot of each of the three biological replicates and at least two readings per plant were taken and averaged.

Plant Biomass

At harvest, three biological replicates of the shoots and roots were separated and dried at 65°C until constant weight. The dry weight (DW) of the roots and shoots was recorded.

Root Morphological Characteristics

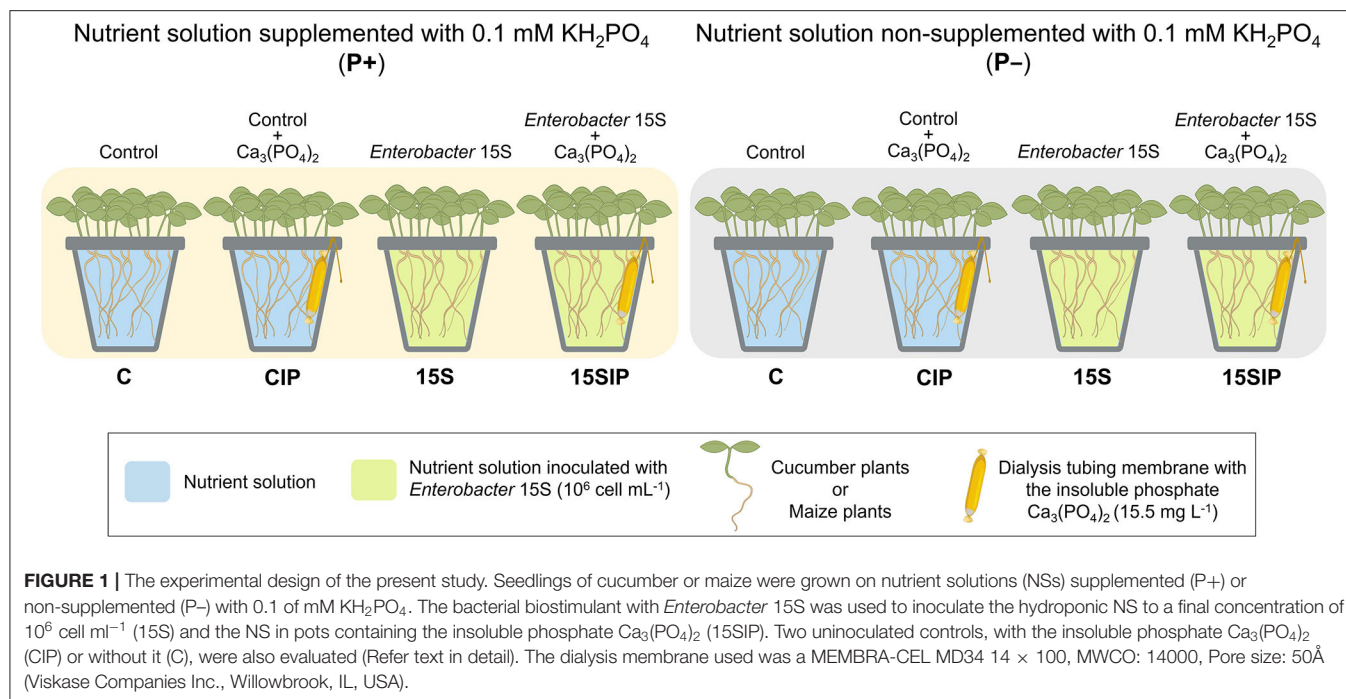

For the analysis of root morphology, fresh roots were scanned using a root scanner system (EPSON Perfection V800, Regent Instruments Inc., Quebec, Canada) and data were then analyzed with the WinRHIZO software (EPSON 1680, WinRHIZO Pro2003b) to determine the root characteristics, including length, surface area, diameter, volume, and the number of tips. All determinations were made in triplicates.

Element Analysis

The plant tissue of the shoots and roots were dried at 65°C and acid digested with 68% ultrapure HNO_3 (Carlo Erba, Milano, Italy) in a single reaction chamber microwave digestion system (UltraWAVE, Milestone, Shelton, CT, USA). Concentrations of macro and micronutrients were determined using an inductively coupled plasma–optical emission spectrometer (ICP-OES Spectro CirosCCD, Spectro, Germany). Element quantification was carried out using certified multi-element standards (CPI International, <https://cpiinternational.com>). Tomato leaves (SRM 1573a) and spinach leaves (SRM 1547) were used as the external certified reference materials. Determinations were carried out in triplicates.

Root Exudation of Phenolics and Flavonoids

Root exudates were collected at the end of the hydroponic cultivation period. One plant of each biological replicate was removed from the NS and their roots were washed with distilled water. Plants were then transferred separately into smaller pots containing 20 ml of H_2O MQ (18.2 M Ω cm³) as a trap solution. Pots were covered with aluminum foil to keep the roots in the dark, with the trap solution being continuously aerated. Root exudates were collected after 24 h, filtered at 0.45 μm , frozen at –80°C, freeze-dried, and resuspended in methanol 60%. The total phenolic content in the root exudates was determined using the Folin-Ciocalteu method (Folin and Ciocalteu, 1927) and was expressed as the nmol equivalent of gallic acid per gram of root fresh weight (RFW). Total flavonoid content was measured with the aluminum chloride colorimetric method (Miliauskas

et al., 2004) and expressed as the nmol equivalent of rutin per gram of root fresh weight.

Gene Expression Analysis

Root tissues from two plants of each biological replicate were collected. The harvested roots were frozen in liquid N and stored at -80°C until use. Total RNA was extracted from frozen roots using the Spectrum Plant Total RNA Kit (Sigma-Aldrich, St. Louis, MO, USA) according to the instructions of the manufacturer. The total RNA ($1 \mu\text{g}$) was treated with 10 U of DNase RQ1 and used for cDNA synthesis using the ImProm-II Reverse Transcription System (Promega, Madison, WI, USA) and oligo (dT)₁₅ primer as per the recommendations of the manufacturer. The cDNA obtained was used as a template for the quantitative real-time reverse transcription PCR (qRT-PCR) performed using the SsoFast EvaGreen Supermix (Bio-Rad, Hercules, CA, USA) and the Bio-Rad iCycler MyiQ real-time PCR system (Bio-Rad). Gene-specific primers were designed for the target genes and the housekeeping gene, the elongation factor 1 α (Supplementary Table 1). Experiments were carried out in triplicates with the following conditions: 5 min at 95°C , followed by 40 cycles at 95°C for 30 s, and 55°C for 30 s, as described previously (Pii et al., 2016, 2019). The amplification efficiency was calculated from raw data using the LinRegPCR software (Ramakers et al., 2003). For each transcript, the mean normalized expression value (MNE; Simon, 2003) was calculated using the housekeeping transcript and the relative expression ratio values were calculated by the $2^{-\Delta\Delta\text{Ct}}$ method according to Livak and Schmittgen (2001).

Data Analysis

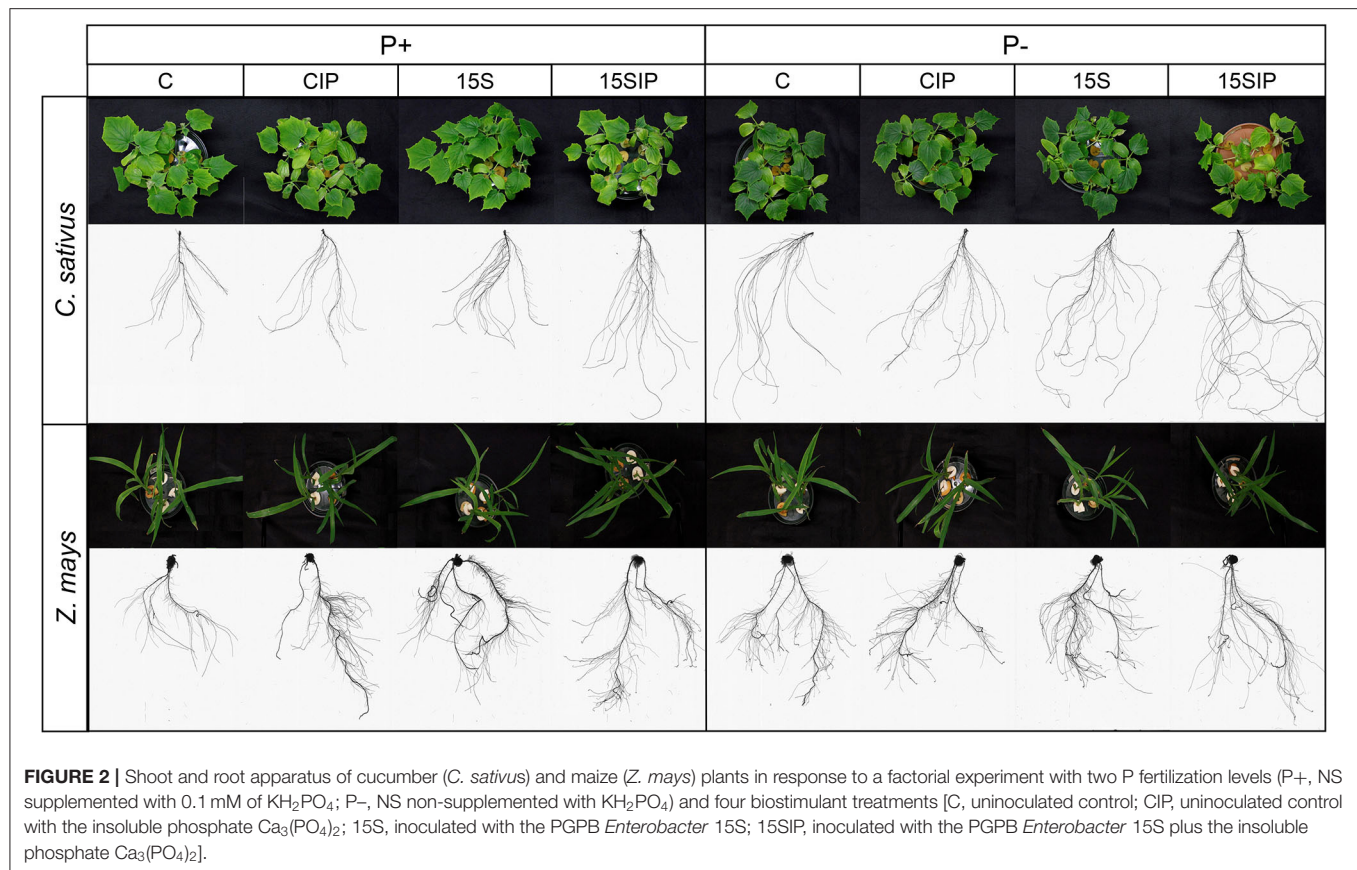

All experimental data for both plant species (*C. sativus* and *Z. mays*) were statistically subjected to two-way ANOVA using

the software IBM SPSS Statistics 20. The mean values were separated according to Tukey's HSD test with $p < 0.05$ and P levels effects were compared using the *t*-test. A heatmap summarizing the morpho-physiological parameters, ionomic analysis, and root exudation responses of both plant species to the biostimulant treatments and P fertilization levels were also generated using the R software (<https://www.r-project.org>, performing "pheatmap," "ggplot2," and "RColorBrewer" packages). Hierarchical clustering based on standardized data was performed with Complete linkage and Manhattan distance was used as the similarity measure.

RESULTS

Plant Growth and Morpho-Physiological Parameters

At the end of the growing period, P deficiency in plants was visually and more identified in cucumber plants when compared with maize plants, since they showed typical symptoms like the dark green color of the leaves and higher expansion of the root system (Figure 2). However, for both plant species, the ANOVA results showed that most of the measured morpho-physiological parameters were significantly affected by P fertilization levels (P) and biostimulant treatments (I), except for the root diameter, which was not affected by the biostimulant treatments (Supplementary Table 2). The $P \times I$ interaction effects were also significant for both plant species, influencing most of the parameters (Supplementary Table 2). This interaction was better noted when comparing the mean values, as shown in Table 1. For instance, in cucumber plants, the SPAD index values were significantly higher in P-deficient plants (P-) when compared with P-fed plants (P+). As expected, P-deficient cucumber plants appeared darker in color (Figure 2) with the

exception of the 15SIP treatment. In the latter, the plants did not exhibit darker green leaves with average values not different from those measured in plants grown in P-full condition (P+: 15SIP) (Table 1). Similarly, in maize plants, the highest SPAD index values were recorded under P deficiency with no visible symptoms of pigmentation on the leaves. However, in both inoculation treatments, maize plants presented lower SPAD values, which were no different from those recorded in plants grown under full P (Table 1). It is interesting to note that, for P-fed maize plants, the effect of the bacterial inoculation on the levels of chlorophyll contents was not significant when compared to the control. Nevertheless, a more evident effect was noted in P-deficient maize plants, suggesting the involvement of the bacteria in the amelioration of photosynthetic rates during P starvation.

In both plant species, the biomass and the architecture of the root systems were also affected by both P levels and inoculation treatments. For instance, in cucumber, the mean values recorded for root DW, total root length, surface area, volume, tips, and the root/shoot (R/S) ratio were significantly higher under P deficiency when compared with plants grown with full P; on the contrary, the shoot DW was higher under complete P (Table 1). Furthermore, when inoculated with *Enterobacter* 15S, P-deficient cucumber plants showed a significant decrease in the root length and surface area with respect to the uninoculated control, whereas supplementation with the insoluble $\text{Ca}_3(\text{PO}_4)_2$

(treatment P-: 15SIP) produced a significant increase in these parameters, albeit not significant when compared to the control. Additionally, root and shoot biomass were unaffected by the inoculation, whereas the R/S ratio was highly increased in both inoculant treatments (Table 1). A different response to the inoculation was observed in P+ cucumber plants. In particular, the length, surface area, and volume of roots were significantly increased with the use of *Enterobacter* 15S alone or in combination with the insoluble phosphate (P+: 15S and 15SIP). However, the root and shoot biomass of the cucumber plants inoculated with *Enterobacter* alone were not significantly different from control plants; instead, its combination with $\text{Ca}_3(\text{PO}_4)_2$ produced a reduction in plant biomass accumulation, while the R/S ratio was not affected.

In contrast with cucumber, P fertilization levels did not affect the root architecture of maize plants. Nonetheless, the root and shoot biomass were significantly higher under the P-full condition, while the R/S ratio increased in P-deficient plants (Table 1). Moreover, P- maize plants inoculated with *Enterobacter* 15S did not show significant changes in length, diameter, volume, and root biomass as compared to control plants. On the other hand, the surface area and root tips were significantly increased in plants treated with the bacteria alone (P-: 15S), albeit a reduction of 37% in the shoot biomass was observed. In P+ maize plants, the inoculation

Phosphorus level effects were compared using *t*-tests. Differences between means were determined using Tukey's HSD test. Significant differences ($p < 0.05$) according to Tukey's test are indicated by different capital letters when comparing contrasts in columns and different lowercase letters when comparing contrasts in rows. No significant differences are indicated by omitting notation letters.

with the *Enterobacter* alone (P+: 15S) significantly increased the architecture of the root system as compared to control plants, albeit the root biomass was not affected; on the other hand, a decrease in the shoot biomass was recorded.

Evaluation of Element Composition in the Roots and Shoots of Cucumber and Maize

A suite of 10 mineral elements, among which were macronutrients (P, calcium - Ca, magnesium - Mg, and sulfur - S), micronutrients (iron - Fe, zinc - Zn, manganese - Mn, and copper - Cu), and beneficial nonessential elements (barium - Ba and sodium - Na), were analyzed in the roots and shoots of both plant species (**Figure 3** and **Supplementary Table 3**). In cucumber, regardless of P fertilization and PGPB inoculation, foliar concentrations of P, Ca, Mg, and Mn exceeded those in the roots, while Fe and Cu concentrations were higher in the roots. On the other hand, the concentrations of Ba, Zn, S, and Na were dependent on both P fertilization and PGPB inoculation. For instance, the elements mentioned were higher in roots of P+ cucumber plants as compared to shoots but displayed higher concentrations in the shoots of P- plants (**Figure 3**). In maize, the concentration of all the mineral elements was higher in roots, regardless of the P levels and inoculant treatments, except for P concentration, which was higher in aboveground tissues.

Nevertheless, P fertilization level and biostimulant treatments caused the imbalanced nutrient distribution in the roots and shoots of both plant species. As expected, P deficiency led to a decreased P concentration in the roots and shoots of both plants (**Figure 3A**). However, in cucumber, the inoculation with *Enterobacter* 15S in combination with $\text{Ca}_3(\text{PO}_4)_2$ (treatment P-: 15SIP) significantly increased the content of P in the roots and shoots by about 31 and 53%, respectively, as compared to the P- uninoculated samples (P-: C). In contrast, in maize, P-deficient plants inoculated with the bacteria alone (P-: 15S) led to the enhancement of P concentration in the roots (+36%) as compared to uninoculated plants (P-: C); however, P concentration in the shoots was not affected (**Supplementary Table 3**). In the P+ condition, the P concentration values in the roots of the cucumber plants were unaffected by the treatments imposed, whereas inoculation with PGPB induced a slight decrease of this mineral in the shoots. On the contrary, in maize plants, inoculation with *Enterobacter* caused a higher accumulation of P in both the roots and shoots (**Figure 3A**).

The accumulation of Ca and Mg in the roots and shoots of both cucumber and maize grown in P deficiency was decreased when compared to plants grown in P+ conditions (**Figures 3B,C**). An exception to this trend is represented by maize roots, in which the inoculation with *Enterobacter* 15S (treatment P-: 15S) induced a higher accumulation of Mg compared to P+ plants. On the contrary, in P+ cucumber plants, treatments with the inoculants caused a significant decrease in Mg concentration (**Supplementary Table 3**). Calcium concentration was, in both P+ and P- plants, significantly increased in the roots of both 15SIP cucumber and maize, although the same treatment induced the opposite effect in cucumber shoots and no effects in maize shoot when compared

to the control. Additionally, the treatment with the bacterium (i.e., 15S) resulted in the highest content of Ca in the shoots of all the maize plants.

Under P deficiency, S concentration in the roots of cucumber was increased by the 15SIP treatment as compared to P+ conditions, whereas, in the case of maize, only inoculated P-deficient plants (i.e., P-: 15S and 15SIP) showed higher S content in the roots with respect to the plants grown under P+ conditions (**Figure 3D**). The inoculation with *Enterobacter* significantly increased the concentration of S by more than 45% in the roots of both P-full and P-deficient cucumber plants compared to the control alone, while the highest content in shoots was observed in control plants combined with $\text{Ca}_3(\text{PO}_4)_2$ (treatment CIP). In contrast, the different treatments did not affect the accumulation of S in maize shoots.

Concerning the micronutrients (**Figures 3E-H**) and non-essential elements (**Figures 3I,J**), the P deprivation in the NS led to a decreasing trend in all the elements in the roots of cucumber plants, except for Mn, but caused an increase in the concentration of Fe, Mn, and Ba in the aboveground tissues. In maize plants, P deficiency induced the increase in Fe and Ba concentration at the shoot level, as well Zn and Mn in the roots. Furthermore, under P deficiency conditions, the inoculation of cucumber with *Enterobacter* 15S in combination with the insoluble phosphate (P-: 15SIP) had a significant promoting effect on the accumulation of all micronutrients in the roots when compared to the uninoculated control, whereas the same treatment had no significant effects on Fe and Mn concentration in the shoots. However, under P-sufficient conditions, a decrease in the content of all micronutrients in the shoots of cucumber was associated with *Enterobacter* 15S inoculation. Besides, the supplementation with $\text{Ca}_3(\text{PO}_4)_2$ (treatment P+: CIP) induced the highest Fe, Zn, and Ba concentrations in cucumber roots (**Figure 3** and **Supplementary Table 3**). On the other hand, P-deficient maize plants treated with the bacterium plus $\text{Ca}_3(\text{PO}_4)_2$ (treatment P-: 15SIP) showed a significant increase in the concentration of Mn and Zn in the roots and a decrease in that of Na; no changes were observed for Fe and Cu. When the bacterial inoculant was used alone, the highest concentrations of Zn, Mn, and Cu were detected in the leaves of maize as compared with uninoculated plants. In contrast, the inoculation treatments did not induce remarkable changes in the accumulation of micronutrients in the roots and shoots of maize plants grown under the full-P NS (**Figures 3E,J**). Additionally, under P+ conditions, the inoculated maize and cucumber plants showed a decreased content of Na in the roots when compared to the uninoculated plants (**Figure 3J**, treatments P+: 15S and 15SIP).

Release of Phenolics and Flavonoids

The root exudate concentration released by both plant species was determined spectrophotometrically in terms of phenolic compounds and flavonoids. **Figure 4A** shows the total content of phenolic compounds released by the cucumber and maize plants in the different conditions considered in the study. In cucumber, the amount of phenolics was higher in P-deficient conditions (ranging from 5 to 7 nmol g⁻¹ RFW) compared to P+ plants (ranging from 2 to 4 nmol g⁻¹ RFW). Any

(A) Phosphorus, P; (B) Calcium, Ca; (C) Magnesium, Mg; (D) Sulfur, S; (E) Iron, Fe; (F) Zinc, Zn; (G) Manganese, Mn; (H) Copper, Cu; (I) Barium, Ba; (J) Sodium, Na concentrations in roots and shoots of cucumber and maize grown hydroponically under different P-fertilization levels (P+ and P-) and different biostimulant treatments with *Enterobacter* 15S (C, CIP, 15S, 15SIP). Values are means \pm SE; $n = 3$. Uppercase letters compare treatments under P+, and lowercase letters compare treatments under P-. An asterisk is present when there is a difference in the same treatment between P+ and P-. Equal letters correspond to average values that do not differ according to Tukey's test ($p < 0.05$).

statistically significant difference was recorded between the different treatments. Under the P+ conditions, the content of phenolics was significantly higher in the control treatment, while inoculation with *Enterobacter* 15S induced a smaller release

of phenolic compounds (Figure 4A). In maize plants, the root exudation of phenolics was higher as compared to cucumber. In the P+ condition, inoculation with the bacterium (P+: 15S and 15SIP treatments) induced a higher exudation of phenolics

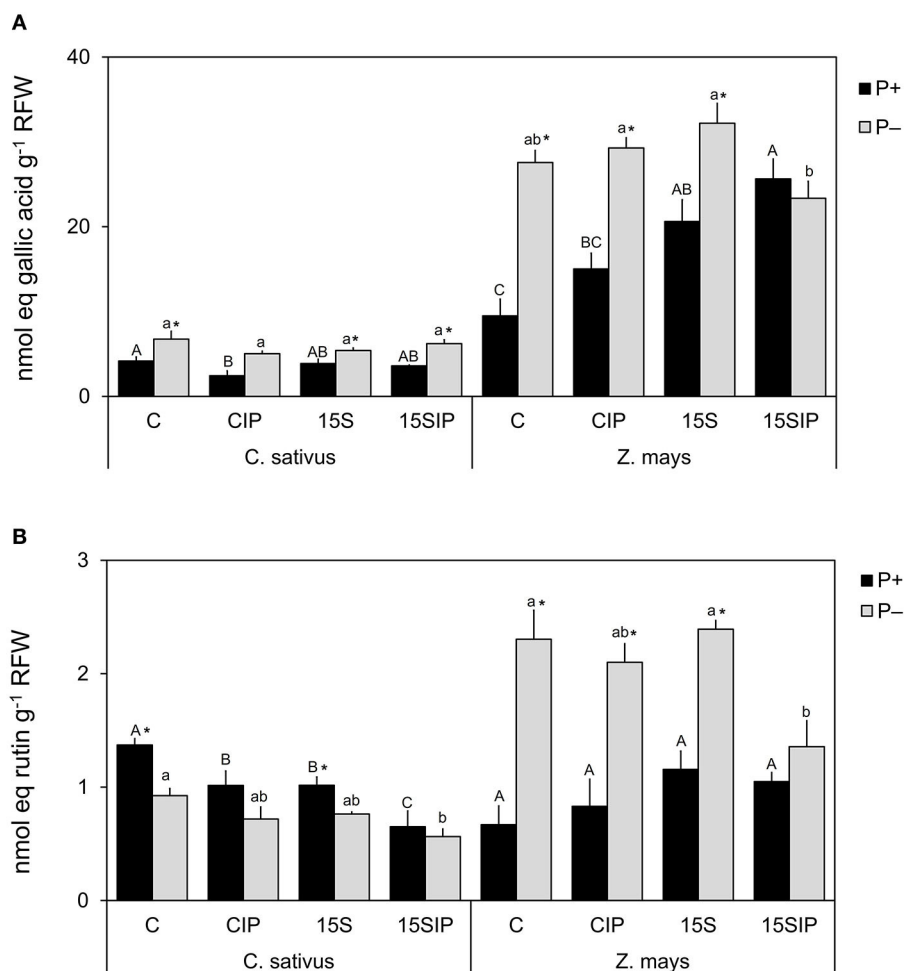

FIGURE 4 | Total phenolic compounds content **(A)** and total flavonoid content **(B)** determined in the root exudates of cucumber and maize collected at the end of the cultivation period. Values are means \pm SE; $n = 3$. Capital letters compare treatments under P+, and lowercase letters compare treatments under P-. An asterisk is present when there is a difference in the same treatment between P+ and P-. Equal letters correspond to average values that do not differ according to Tukey's test ($p < 0.05$). Two-way ANOVA results: Phenolic compounds: cucumber, P ($p < 0.001$), I ($p < 0.01$), P \times I (NS); maize, P ($p < 0.001$), I ($p < 0.001$), P \times I ($p < 0.001$). Flavonoids: cucumber, P ($p < 0.001$), I ($p < 0.001$), P \times I (NS); maize, P ($p < 0.01$), I (NS), P \times I ($p < 0.01$).

compared to the uninoculated controls. On the other hand, the release of phenolics by maize plants grown in P deficiency was significantly higher (23–32 nmol g⁻¹ RFW) than that observed in P+ conditions (9–26 nmol g⁻¹ RFW), except for the treatment P-: 15SIP. In the latter, the bacterial inoculation and supplementation with Ca₃(PO₄)₂ induced a decrease in the exuded phenolics, presenting levels significantly lower than that measured in control plants (**Figure 4A**).

The root exudation of flavonoids by both plant species is shown in **Figure 4B**. In cucumber, the total flavonoid content was significantly reduced by the bacterial inoculation in both P fertilization levels. However, in P+ conditions, a significantly higher production was observed for C and 15S treatments (1 and 1.4 nmol g⁻¹ RFW, respectively), compared with the same treatments under P deficiency (0.8 and 0.9 nmol g⁻¹ RFW, respectively); any remarkable effects were observed for CIP and 15SIP in both P+ and P- conditions (**Figure 4B**). On the other

hand, P deficiency induced a higher exudation of flavonoids in maize (ranging from 2.1 to 2.4 nmol g⁻¹ RFW) with respect to P+ plants (ranging from 0.7 to 1.2 nmol g⁻¹ RFW), except for the 15SIP treatment. No significant effects were observed within P+ plants subjected to different treatments.

Phosphate Transporters Gene Expression Analysis

In plants, Pi transporter genes belonging to the *Pht1* family are strongly expressed in roots and play important roles in the transmembrane transport of Pi for its acquisition and allocation within the plants and the single cell. Most of these genes have been reported to be highly induced by P deficiency (Wang et al., 2018). In cucumber, six genes involved in the phosphate uptake have been identified, namely, *CsPT1.3*, *CsPT1.4*, *CsPT1.7*, *CsPT1.9*, *CsPT1.11*, and *Cucs383630.1* (Naureen et al., 2018; Feil et al., 2020). However, under the conditions, the expression of

CsPT1.7 and *CsPT1.11* was not detectable under P starvation (data not shown). In maize, 13 *PhT1s* genes have been identified (Liu et al., 2016), but in this work, six of these genes were reported by Nagy et al. (2006), namely, *ZmPT1*, *ZmPT2*, *ZmPT3*, *ZmPT4*, *ZmPT5*, and *ZmPT6* were analyzed. Nonetheless, four genes (*ZmPT2*, *ZmPT3*, *ZmPT4*, and *ZmPT6*) were poorly induced by P deficiency in our experimental conditions (data not shown).

Figure 5 shows the relative expression levels of the *CsPTs* and *ZmPTs* genes under P deficiency. Results indicate that, in both plants, all the analyzed genes were expressed under the P+ condition but were highly upregulated in P-deficiency. For instance, in cucumber, *CsPT1.4* was highly induced in P- (>160-fold up to 270-fold), followed by *CsPT1.9* (>50-fold up to 150-fold) and *Cucsa383630.1* (>4-fold up to 15-fold), while *CsPT1.3* was less expressed (>2-fold) when compared to control plants under complete P fertilization. Additionally, in cucumber plants grown under a P-full NS, the expression of all *CsPTs* genes was not significantly affected by the treatments (**Figure 5**). On the other hand, inoculation with *Enterobacter* 15S induced transcriptional changes for all *CsPTs* genes under P starvation. For instance, *CsPT1.3* and *CsPT1.4* were induced by both inoculant treatments (P-: 15S and 15SIP) in comparison to uninoculated plants (P-: C and CIP). On the contrary, inoculation with the bacterium (P-: 15S) induced a significantly higher expression of the *CsPT1.9* and *Cucsa383630.1* genes as compared with the other three treatments.

In maize plants grown under P deficiency, *ZmPT5* was expressed more (>14-fold up to 127-fold) than *ZmPT1* (>2-fold up to 7-fold), compared with P-sufficient control plants. However, the inoculation induced different relative transcript levels in both genes. For instance, in maize plants grown in either P-full or P-deprived NSs, inoculation with *Enterobacter* 15S downregulated the expression of *ZmPT5* in roots when compared to uninoculated control plants under the same conditions (**Figure 5**). Nonetheless, the relative transcript levels of *ZmPT1* were significantly lower in P-deficient plants inoculated with the bacterium alone (P-: 15S), while the inoculant treatment supplemented with the insoluble phosphate (P-: 15SIP) induced the expression of a higher amount of transcript, yet not much higher than the uninoculated controls (**Figure 5**). No significant differences were observed in the expression of *ZmPT1* in maize plants under P-full conditions.

DISCUSSION

Plant Growth and Morpho-Physiological Responses to Bacterial Biostimulant Inoculation and/or P Supply

The inoculation with PGPB has been shown to improve plant growth in both favorable and unfavorable conditions, including low-nutrient availability (Oleńska et al., 2020). In the specific case of P) shortage, it has been broadly described that physiological, morphological, and molecular changes are induced in plants as a specific response to this nutritional stress (López-Arredondo et al., 2014; Elanchezhian et al., 2015). Results reported in this study show that both P availability in the NS and the

bacterial biostimulant *Enterobacter* 15S were able to influence the plant biomass accumulation and the development of morpho-physiological traits in cucumber and maize plants, although to a different extent. The cucumber plants exhibited a more remarkable response to P starvation, in particular, showing a more developed root system with respect to the maize plants. Indeed, the root system is very responsive to low-P availability in the growth medium; thus, in the majority of plant species, increasing root length root surface area, and enhancing the growth of root hairs are described as common strategies to explore larger soil surfaces and intercept nutrients (Ramaekers et al., 2010). Despite the root system architecture being different between monocots and dicots, the signaling pathways underpinning P-acquisition mechanisms are conserved (Shahzad and Amtmann, 2017). The low-P availability induces an increase in the R/S ratio that is generally ascribable to a limitation in shoot biomass accumulation, an increase in root production, or both (Campos et al., 2019). However, in our experimental conditions, the biomass allocations among the two plant species resulted quite differently. While the root biomass in maize plants was reduced under P starvation, it was significantly increased in the cucumbers. In this regard, it is worth mentioning that, from a nutrient availability perspective, plants have to balance the biomass allocation to leaves and/or roots to an extent that matches the physiological activities and functions performed by these organs (Poorter et al., 2012), including those related to plant responses to nutritional disorders.

The inoculation with the bacterial biostimulant *Enterobacter* 15S affected the root architecture and biomass of both plants differently depending on P supply. Overall, the data suggest that *Enterobacter* 15S led to the improved growth of the root system in both plant species grown in P-sufficient conditions. Under P deficiency, the bacterium in combination with $\text{Ca}_3(\text{PO}_4)_2$ (P-: 15SIP) induced a remarkable effect on the whole cucumber plant, whilst the bacterium alone (P-: 15S) was more effective in improving the root system of maize plants. *Enterobacter* strains have been described to enhance the plant growth of different plant species, including monocot and dicot types (Naveed et al., 2013; Gupta et al., 2020; Ji et al., 2020). The biostimulant strain 15S used in this work was previously reported by Zuluaga et al. (2020) to have the ability to produce auxins and solubilize Pi. Bacteria-derived auxins are well-known for promoting morphological and physiological processes in plants, leading to increased growth of the root system in terms of root length and surface area; thus enhancing nutrient and water uptake (Hakim et al., 2021). Under stressful conditions (e.g., P deficiency), plants can stimulate bacteria to produce auxins (Kudoyarova et al., 2019). However, when produced in high concentrations, bacteria-derived auxins can inhibit root elongation in dicots, whereas monocots resulted in less sensitivity to such inhibition (Kudoyarova et al., 2019). In this context, it is also worth mentioning that a particular plant nutritional state (e.g., P sufficiency or P deficiency) may influence the interaction mechanisms between PGPB and host plants (Pii et al., 2016), thus explaining the contrasting results observed in this study for cucumber and maize plants. Moreover, it is important to highlight that, in a specific edaphic condition, PGPB may also

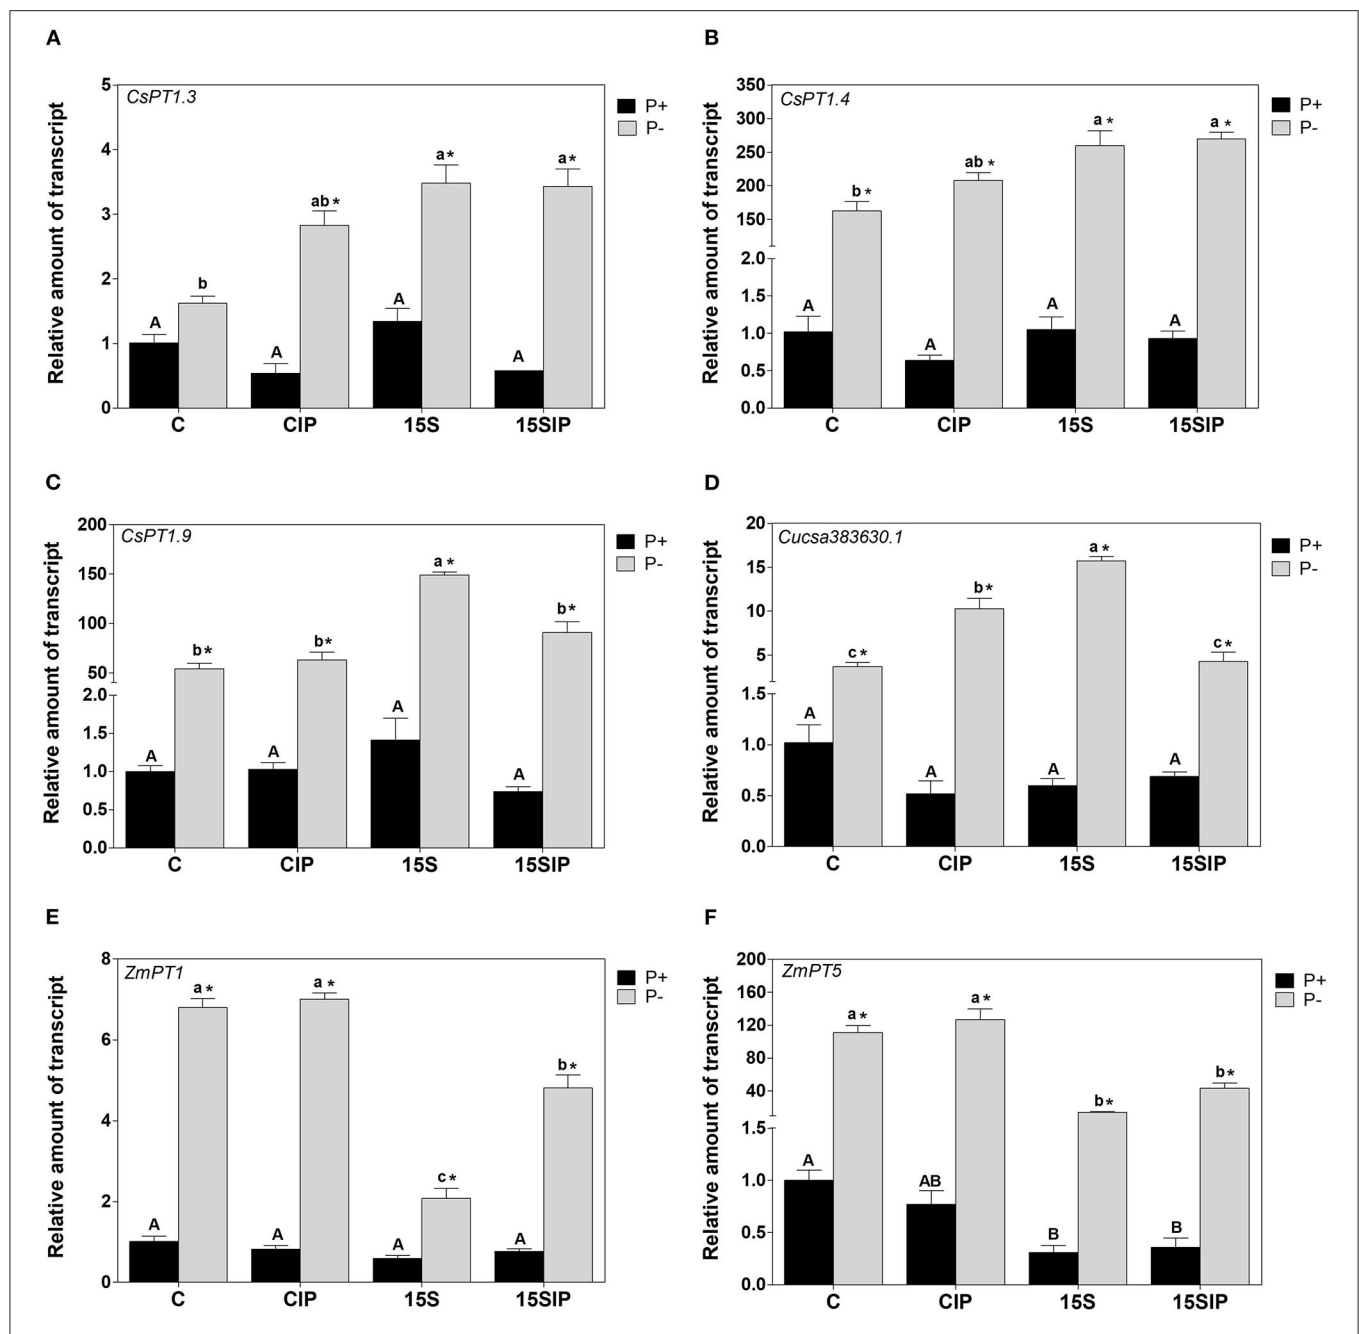

FIGURE 5 | Gene expression analysis of (A) *CsPT1.3*, (B) *CsPT1.4*, (C) *CsPT1.9*, and (D) *Cucsa383630.1* in the roots of the cucumbers, and (E) *ZmPT1* and (F) *ZmPT5* in the roots of maize grown hydroponically under different P-fertilization levels (P+ and P-) and different biostimulant treatments with *Enterobacter* 15S (C, CIP, 15S, 15SIP). The expression level of each gene was normalized to the expression level of the elongation factor isoform 1- α (EF-1 α). The relative expression ratios were calculated using the uninoculated control under complete P (P+: C) as a calibrator sample. Values are means \pm SE; $n = 3$. Uppercase letters compare treatments under P+ and lowercase letters compare treatments under P-. An asterisk is present when there is a difference in the same treatment between P+ and P-. Equal letters correspond to average values that do not differ according to Tukey's test ($p < 0.05$).

display a differential preference for one particular plant species over another (Glick, 2005). The effects of this interaction rely on a set of adaptation mechanisms by both the inoculated bacteria and the host plant (Droge et al., 2012).

Concerning chlorophyll content, a significant increase in both plant species grown under P starvation has been recorded,

is particularly pronounced in cucumber leaves manifesting a particular dark green color. A similar trend has also been described in strawberry and apple plants (Valentinuzzi et al., 2015, 2019; Delaporte-Quintana et al., 2017). Moreover, a more severe or prolonged P deficiency may result in the accumulation of anthocyanins, consequently increasing the pigmentation

of the newest leaves and chlorophyll concentrations (Veazie et al., 2020). However, the inoculation of P-deficient maize plants with *Enterobacter* 15S (i.e., 15S and 15SIP) reduced the levels of chlorophyll content to the same values of the inoculated P-sufficient plants. In contrast, in cucumber plants, only the treatment with the bacterium in combination with the insoluble phosphate (15SIP) was able to induce chlorophyll contents similar to those measured in P-sufficient plants. In this respect, Delaporte-Quintana et al. (2017) already reported that the SPAD values of P-deficient strawberry plants inoculated with *Gluconacetobacter diazotrophicus* PAL5 were similar to those obtained in plants grown under sufficient P, indicating the contribution of this strain to plant P nutrition and photosynthesis.

Effects of Bacterial Biostimulant and P Supply on Mineral Nutrient Content

Several agronomic conditions such as physical-chemical properties of the growth substrate, fertilization regimes, and inoculation with PGPB have been described to induce changes in the elemental composition of crops, regardless of the clade considered (Pii et al., 2015a,b). In the present study, P deficiency led to a reduction of P content in the roots and shoots of both plants, while inoculation with the bacterial biostimulant with *Enterobacter* 15S induced a differential allocation of this element. For instance, in P-deficient cucumber plants, the inoculation in combination with $\text{Ca}_3(\text{PO}_4)_2$ (P-: 15SIP) induced a higher allocation of P in roots and shoots, whereas maize plants inoculated with the bacterial biostimulant alone showed a higher content of P only in roots. Recent study showed that the inoculation of tomato plants grown under P-deficiency and salt stress conditions with different strains of *Arthrobacter* and *Bacillus* induced an increased P concentration in roots and shoots (Tchakounté et al., 2020) and the shoots of *Brachypodium* plants (Schillaci et al., 2021). On the contrary, the inoculation of wheat plants with beneficial bacteria led to a reduced P content in roots (Talboys et al., 2014). Interestingly, under P-sufficient conditions, *Enterobacter* 15S induced opposite effects on the P concentration in the shoots of the two plant species, showing a decrease in cucumber and an increase in maize plants. The results suggest that the mechanisms by which *Enterobacter* 15S improves P acquisition and its translocation within the plant can be dependent on both plant species and nutritional status. It was observed in cultivated monocots grown at different P levels that the inoculation with PGPB can increase the adaptation of these grasses to the low-P availability through an improvement in P-use efficiency, with the functionality of the P-uptake mechanism still not being affected (Pereira et al., 2020; Schillaci et al., 2021). Moreover, in dicots grown under different P states, it has been described that plant development stimulation *via* PGPB inoculation was not accompanied by an increase in nutrient uptake by the roots and the P content in shoots that, on the contrary, appeared to be rather decreased (Belimov et al., 2002).

Regarding micronutrients (i.e., Fe, Zn, Mn, and Cu) and non-essential beneficial elements (i.e., Ba and Na), inoculation with *Enterobacter* 15S promoted their accumulation at the

root level only in cucumber plants supplemented with the insoluble phosphate grown under P-deficient conditions. The same trend was also observed at the shoot level, except for Fe and Mn. In maize plants, under the same condition described for cucumber, only Mn and Zn were increased in roots, while inoculation with the bacterium alone improved the allocation of Zn, Mn, and Cu to shoots. The biochemical mechanisms underlying the nutritional processes in plants and nutrient availability can be altered by PGPB as a strategy to improve plant nutrient uptake, which, in turn, is influenced by microbial strains and plant species (Pii et al., 2015b). Additionally, under equilibrate P availability, bacterial inoculation induced a decrease in the concentrations of all micronutrients in the subaerial part of cucumber plants, whilst no significant changes were induced in maize plants. Under a specific nutritional shortage, plants can also trigger physiological modulations to maintain the ionic equilibrium of the tissues (Marschner, 1995). Thus, changes in the concentration of a mineral element might induce modulations (positive or negative) of the concentration levels of one (or more than a single) essential or non-essential nutrient. It is worth noting that, under sufficient P conditions, the accumulation of Na in the roots of both plants was reduced by inoculation with *Enterobacter* 15S. Decreased concentrations of Na have been reported in plants inoculated with PGPB and AMF as a mechanism to protect plant cells against oxidative stress by maintaining intracellular ionic homeostasis (Giri and Mukerji, 2004; Panwar et al., 2016).

A Differential Root Exudation Pattern Was Induced by P Deficiency and Bacterial Biostimulant

In specific nutritional conditions, plants can change their qualitative and quantitative composition of root exudates to increase the availability of nutrients (Badri and Vivanco, 2009) and/or to influence the microbial populations colonizing the roots (Cesco et al., 2012). Phenolic acids and flavonoids have been reported as the major secondary metabolites exuded by plant roots and are significant in diverse biological processes (Mandal et al., 2010; Cesco et al., 2012). Root exudation and regulation of these compounds seems to be an important strategy for plants to overcome P deficiency (Malus et al., 2006). Regardless of P supply, the total content of phenolic acids exuded by roots was plant species-dependent, whereas the release of flavonoids was similar in both plants hereby evaluated. In general terms, the amount and diversity of secondary metabolites released by roots are highly species-specific (Zwetsloot et al., 2018). P deficiency induced an increase in the content of phenolic acids exuded by the roots of both plants, which is in accordance with other works. For instance, under P deficiency, the amount of exuded phenolics from bean roots was five times higher (Juszczuk et al., 2004) and *Stylosanthes* roots had more than 10-fold in exudates (Luo et al., 2020), as compared to their respective controls. However, both the accumulation and exudation of phenolic compounds can also be modified in response to microbial inoculation (Vacheron et al., 2013). The inoculation of P-sufficient maize plants with *Enterobacter* 15S (treatment P+: 15SIP) induced a higher

production of phenolic compounds, while the same treatment under P deficiency elicited a lower release. No effects were induced by the inoculation in cucumber plants. These results suggest that plants interacted with the bacterial biostimulant in different ways. The exudation of phenolic compounds is induced by PGPB inoculation also in plants subjected to other nutrients deficiencies. For instance, under N scarcity, peanut plants inoculated with *Stenotrophomonas maltophilia* modified their metabolism in response to the inoculum by producing a higher amount of total phenolic compounds, thus resulting in increased antioxidants and free radical scavenging activities (Alexander et al., 2019).

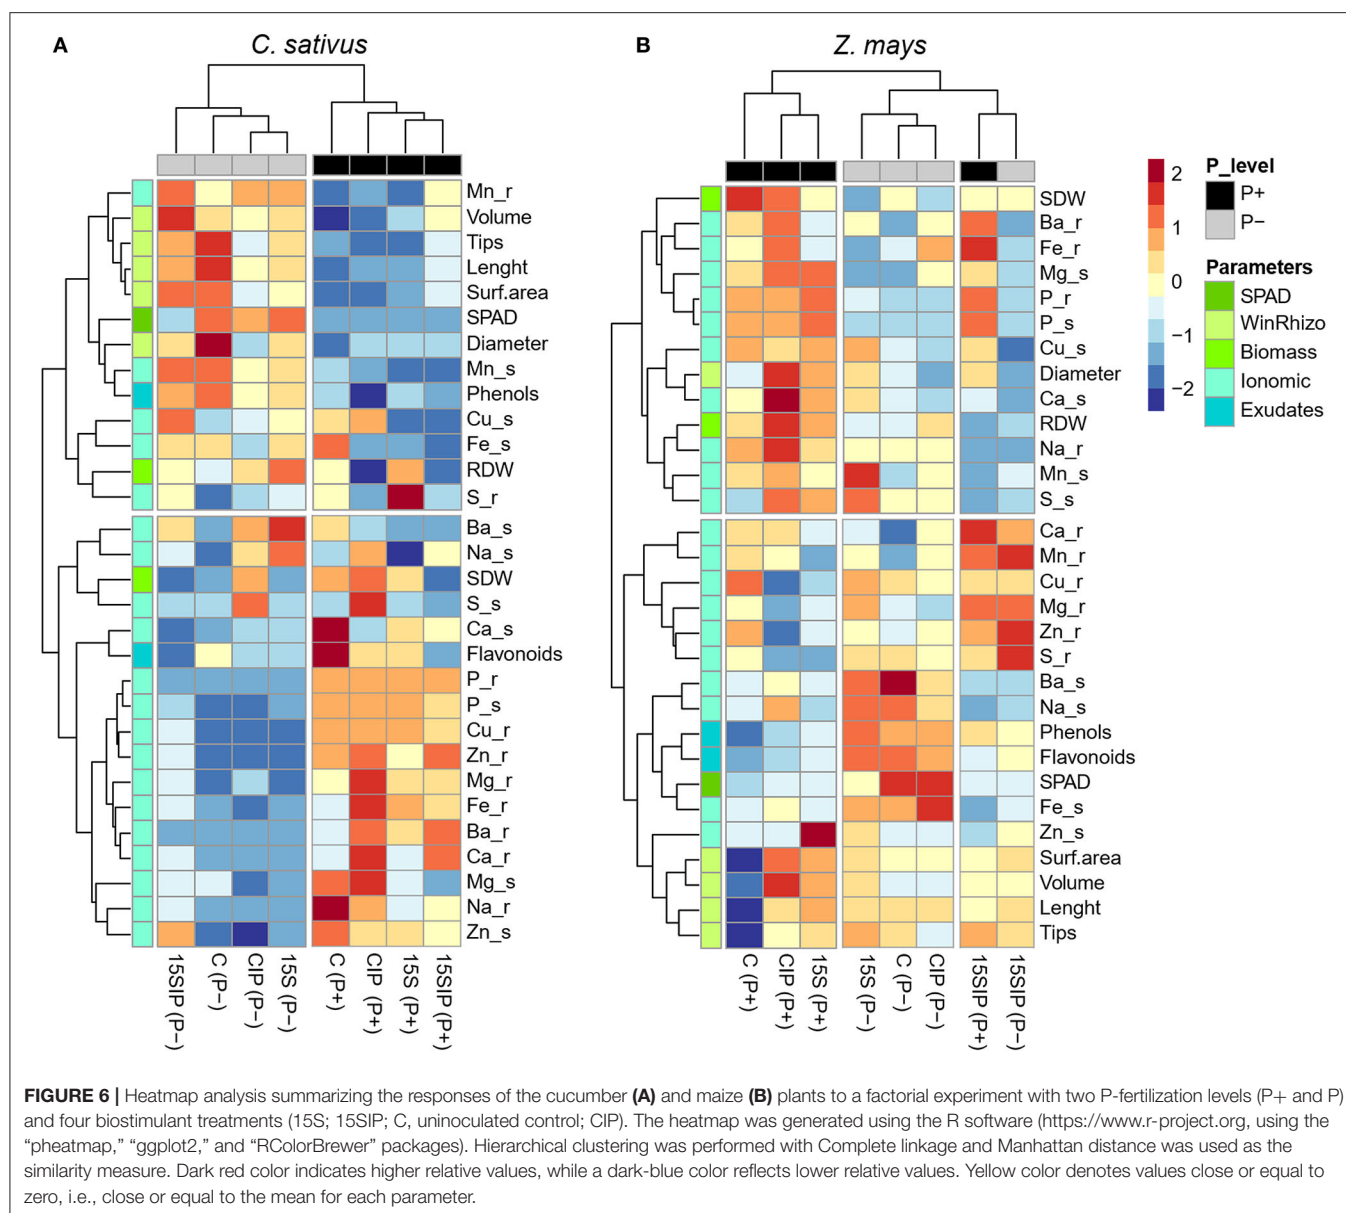

In the present study, we observed that the root exudation of flavonoids was lower in both plant species when compared with the total release of phenolics. P deficiency induced an increase in the flavonoids released by maize plants, while a decreased exudation of these compounds was observed in cucumber plants. Flavonoids are known for assisting plants in tolerating and overcoming biotic and abiotic stresses generated by the external environment (Shah and Smith, 2020). It has been suggested that flavonoids released from the roots of P-deficient plants can facilitate the mobilization of P-insoluble complexes (e.g., Fe-P) and also reduce the microbial degradation of organic acids (Tomasi et al., 2008). Furthermore, inoculation with PGPB can alter not only the content but also the profile of flavonoids in root exudates (Garcia-Seco et al., 2015). In this study, regardless of P supply, the inoculation with the bacterial biostimulant significantly reduced flavonoid content in the root exudates of cucumber plants, while their concentration in maize exudates was not affected, except for the treatment 15SIP (P-); in this case, a reduction of flavonoids was induced as also observed for phenolic compounds. A differential accumulation of flavonoids was described by Zuluaga et al. (2021) in root exudates of tomato plants inoculated with the same *Enterobacter* 15S strain used in the present study. In some cases, the down-accumulation of flavonoids in PGPB-inoculated plants may indicate its consumption as a C source or a blocking in their biosynthesis (Dardanelli et al., 2010; Wu et al., 2018). In this respect, it is interesting to note that the reacquisition of a fair range of exudates by roots of intact plants as recently demonstrated by Tiziani et al. (2020) makes this assessment rather complicated.

Differential Regulation of Phosphate Transporters Was Elicited by P Starvation and the Inoculation With *Enterobacter* 15S

Members of the *PHT1* family are the most intensively studied Pi transporters genes in plants. They are known for exhibiting strong expression in the roots of both monocots and dicots (Nussaume et al., 2011). Most of these genes are strongly induced under P-limiting conditions and have been reported to be involved in the root uptake of Pi from soil solutions and then its translocation within the plant (Wang et al., 2018). Consistently, all the Pi transporters genes herein evaluated were greatly expressed in the roots of both P-starved plant species compared to P-sufficient ones. Since bacterial

inoculation in P-deficient cucumber plants supplemented with $\text{Ca}_3(\text{PO}_4)_2$ increased the P accumulation in roots and shoots, a reduction in the expression of the *CsPTs* genes compared to uninoculated controls can reasonably be expected. However, in P deficiency, all Pi transporter genes were over-expressed in cucumber plants inoculated with *Enterobacter* 15S. Moreover, *CsPT1.3* and *CsPT1.4* were also upregulated in the inoculation treatment combined with the insoluble phosphate. Indeed, the downregulation of Pi transporters by microbial inoculants has not been observed for all *PHT1* Pi transporters (Duan et al., 2015). Accordingly, the results might suggest that *Enterobacter* 15S in association with cucumber plants supplemented with $\text{Ca}_3(\text{PO}_4)_2$ would have induced a greater P-uptake capacity. Similar behavior was also reported by Cataldi et al. (2020) in the expression levels of *TaPHT6* during the interaction of wheat plants with *Bacillus* strain 12A under P starvation. Concerning the inoculation with the bacteria alone, the results might suggest that *Enterobacter* 15S could have triggered the different gene regulation, including the modulation of molecular entities other than *PHT1* members. Indeed, although few works have studied the effects of PGPB on the regulation of Pi transporters, it is well-known that Pi acquisition and homeostasis can also be controlled by members of the *PHT2*, *PHT3*, *PHT4*, and *PHT5* families (Wang et al., 2017). Moreover, in plant-microbe interactions, in particular, in the case of AMF, AM-specific Pi transporters and AM-inducible Pi transporters identified in monocot and dicot species are essential to Pi transport (Zhang et al., 2019). Additionally, it cannot be excluded that the increased P accumulation observed in cucumber roots could also be a direct effect of the bacterium on plant metabolism, as previously reported by Saia et al. (2015) in wheat plants inoculated with the PGPB *Bacillus* species. Interestingly, in cucumber plants grown under P sufficient conditions, the expression of Pi transporters was not altered by the inoculant treatments. These findings might suggest that *Enterobacter* 15S has a better performance in dicots growing under a nutritional shortage.

On the other hand, in P-deficient maize plants, the expression of *ZmPT1* and *ZmPT5* was inhibited by inoculation with the bacterial biostimulant compared to the uninoculated controls. A similar result has been described by Liu et al. (2018) in the transcript level of *TaPT4* in wheat roots inoculated with *Pseudomonas* strain P34-L. The authors suggested that a better P nutritional state was induced by the bacterium colonizing the wheat rhizosphere (Liu et al., 2018). However, considering all the results described in the previous sections, we cannot state that the downregulation of maize Pi transporters in the inoculated P-deficient plants is due to a change in P nutrition due to PGPB interaction. However, the repression of maize Pi transporters might be triggered by the plant in response to the association with the bacterium, which could likely produce a direct effect on plant metabolism. Indeed, the fact that in inoculated maize plants under P-sufficient conditions, the *ZmPT5* gene was also downregulated might support this hypothesis. Nonetheless, since few studies have been focused on P transport in plant-PGPB interactions in P-deficiency, the mechanisms by which a specific PGPB alters the expression of Pi transporters remain unclear. Furthermore, some P transporters are also transcriptionally

regulated by stimuli other than P deficiencies or microbial associations, suggesting a more complex regulatory mechanism (Gu et al., 2016).

Clustered Heatmap of Plant Responses to Bacterial Biostimulant and P Supply

To present a visual comparison regarding the effect of inoculation with the bacterial biostimulant and levels of P supply on the growth and nutrition of cucumber and maize plants, a heatmap analysis condensing all the measured morpho-physiological, ionomic, and root exudation data was performed for each plant species (Figure 6). Both cucumber and maize plants showed different responses to the evaluated parameters. In cucumber plants, the main clustering factor responsible for different effects was P nutrition, albeit a clear effect of the bacterial biostimulant within the P levels was also observed

(Figure 6A). It is expected that, under P deficiency, plants undergo various morphological, physiological, and biochemical adaptations. Intense and significant effects have been observed in cucumber plants at the levels of root system architecture, root exudation, photosynthetic rates, and nutrients under P-deficient conditions when compared to P-sufficient plants (Ciereszko et al., 2002; Zhang et al., 2012; Naureen et al., 2018). Nonetheless, the inoculation of cucumber plants with PGPB in different P states has also shown a positive contribution to the improvement of plant growth and nutrition and the abilities of the plants to deal with P deficiency (Han et al., 2006; García-López et al., 2016). The results also revealed that *Enterobacter* 15S in combination with the insoluble phosphate (15SIP) showed positive effects in alleviating the stress produced by P deprivation in cucumber plants. Since neither non-inoculated plants (CIP) nor the bacterium alone (15S) under the same conditions did not

show significant effects on P nutrition, it is possible to suggest that *Enterobacter* 15S might have solubilized the $\text{Ca}_3(\text{PO}_4)_2$ available in the dialysis tube, thus allowing cucumber plants to cope with the P limitation. Consistently, previous studies have already described the ability of *Enterobacter* strains to solubilize insoluble phosphates and promote the growth of several plant species (Ramesh et al., 2014; Bendaha and Belaoui, 2020; Zuluaga et al., 2020).

In maize plants, both P fertilization levels and biostimulant treatments affected the parameters assessed. In combination with the insoluble phosphate, *Enterobacter* 15S induced similar effects on the plant growth and nutritional state of maize plants in both P levels. However, stronger effects were induced by the bacterium alone under P-limited conditions (Figure 6B). These results suggest that, in the interaction with P-deficient maize plants, the bacterial strain *Enterobacter* 15S might have triggered different mechanisms than those activated in cucumber plants to help plants coping with P deficiency. Although all plant species can establish a relationship with some PGPB, inoculation with a specific bacterium has shown differential responses in the plant stimulation between monocots and dicots (Hall et al., 1996). However, more comparative studies between plant types and bacterial strains are still lacking. Furthermore, most existing studies are focused on PGPB and its role in improving N nutrition in plants, whereas only few pieces of literature are concerned with the effects of PGPB inoculation on plants grown in different P-supply conditions. For this reason, it has been suggested that the P-solubilization trait could be acknowledged as the forgotten child of PGP bacteria (Granada et al., 2018).

CONCLUSION

The results of the present study underline those plant growth responses to inoculation with the bacterial biostimulant with *Enterobacter* 15S under specific P supplies vary between maize (a representative for monocots) and cucumber (a dicot) plants. The bacterial strain 15S induced cucumber plants to cope with P shortage by solubilizing the external source of insoluble P, which led to the modulation of root architecture, mineral nutrient uptake, root exudation of phenolics, and flavonoids, and the upregulation of P starvation-inducible Pi transporter genes. On the other hand, the ability of *Enterobacter* 15S to ameliorate the P

deficiency of maize plants was less remarkable than in cucumbers, albeit the strain showed better performance under P sufficiency. These results suggest that the bacterial biostimulant strain herein evaluated has an enhanced ability to alleviate P shortage in dicots. Nonetheless, its efficiency under normal P conditions can also be extended to cultivated monocots. Still, further studies are needed to evaluate the efficacy of *Enterobacter* 15S in alleviating P nutritional shortage under different soil conditions. The need for a rapid transition of agriculture toward sustainability makes the comprehension of these phenomena even more urgent, for their use as soon as possible in the field in favor of a better use of endogenous soil resources of nutrients by crops.

DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/Supplementary Material, further inquiries can be directed to the corresponding author/s.

AUTHOR CONTRIBUTIONS

MA, AM, YP, TM, and SC conceived the work and designed the experiment. MA, FV, and RT carried out the experiments and generated the data. MA and YP analyzed the data. MA wrote the first draft of the manuscript, which was intensively edited by all authors. YP, SC, TM, and AM reviewed the manuscript and carried out the English edition. All authors contributed to the article and approved the submitted version.

FUNDING

Funding for this research was provided by the Ministero dell'Istruzione, dell'Università e della Ricerca (MIUR) through the project PHOBOS coded 2017FYBLPP. This work was supported by the Open Access Publishing Fund of the Free University of Bozen-Bolzano.

Current research was conducted to explore the effects of liquiritoside on the growth and physiochemical features of Chinese flowering cabbage (*Brassica rapa* subsp. *parachinensis*) under lead (Pb) stress. Lead stressed *B. rapa* plants exhibited decreased growth parameters, chlorophyll, and carotenoid contents. Moreover, Pb toxicity escalated the synthesis of malondialdehyde (MDA), hydrogen peroxide (H₂O₂), flavonoids, phenolics, and proline in treated plants. Nevertheless, foliar application of liquiritoside mitigated Pb toxicity by decreasing oxidative stress by reducing cysteine, H₂O₂, and MDA contents in applied plants. Liquiritoside significantly increased plant height, shoot fresh weight and dry weight, number of leaves, and marketable value of Chinese flowering cabbage plants exposed to Pb toxicity. This biotic elicitor also enhanced the proline, glutathione, total phenolics, and flavonoid contents in Chinese flowering cabbage plants exposed to Pb stress compared with the control. Additionally, total glucosinolate content, phytochelatins (PCs), and non-protein thiols were effectively increased in plants grown under Pb regimes compared with the control plants. Overall, foliar application of liquiritoside can markedly alleviate Pb stress by restricting Pb translocation in Chinese flowering cabbage.

Keywords: Chinese flowering cabbage, flavonoids, glucosinolates, liquiritoside, lead

INTRODUCTION

Vegetables belonging to the Brassicaceae family show cherished health remunerations effects owing to the existence of biologically active and robust antioxidative ingredients. Chinese flowering cabbage (*Brassica rapa* subsp. *parachinensis*) is an annual cole crop belonging to the Brassicaceae family. The germination to harvest period of this vegetable is less than 60 days (Peng et al., 2015). Chinese flowering cabbage has valuable biological and nutritional properties (Aixia et al., 2015). Its above-ground parts, including leaves, stem, and inflorescence, can be cooked or consumed raw as salads. Its leaves contain adequate amounts of glucosinolates and polyphenolic compounds

(Chen et al., 2008). This rich chemical composition and scientifically proven biological activity has made Chinese flowering cabbage a famous culinary plant (Chung et al., 2016).

Glucosinolates (GLs) are primarily found in plants of the genus *Brassica*, which include crops of economical and nutritional importance. GLs are rich in sulfur and anionic secondary metabolites (Johnson, 2002). GLs have been extensively studied for their protective effect against herbivory in plants and chemotherapeutic activity in humans (Barba et al., 2016). The consumption of vegetables containing glucosinolates may confer protection against cancer in humans (Johnson, 2002). The hydrolytic breakdown products of glucosinolates have beneficial effects on human health, including cytotoxic and apoptotic effects in damaged cells, and reducing risks of degenerative diseases (Barba et al., 2021).

Lead contamination in soil has rapidly increased during the last decades (Sidhu et al., 2016). Metal pollution severely affects the growth and development of metal-affected plants (Borges et al., 2019). Pesticides, fertilizers, and automobile fuel are the major sources of Pb contamination. This non-essential toxic metal impedes appropriate plant nutrition (Lamhamdi et al., 2013). The edible parts of plants may uptake higher levels of metal contaminant from polluted soils and hence become a health risk for human beings and livestock consumers (Baghaie and Fereydoni, 2019). Metal toxicity enhances oxidative injury by intensifying the synthesis of reactive oxygen species (ROS) (Malar et al., 2014). Metal stressed plants increase the antioxidative system to detoxify ROS and maintain their ionic homeostasis (Fayez et al., 2014). Lead stress also affects photosynthesis, transpiration, and ionic homeostasis in stressed plants (Devi et al., 2013). As well, the plants subjected to Pb toxicity demonstrate a higher level of lipid peroxidation and ROS (Tauqeer et al., 2016). Phenolics are secondary metabolites deposited in plants facing stress and play a defensive role against a higher level of ROS synthesized in these plants (Fayez et al., 2017).

Lethal effects of synthetics pharmaceuticals have augmented the discovery and large-scale production of natural bioactive molecules. But, the resources of natural bioactive compounds are inadequate for various reasons. Conversely, the consumer entreaty for these compounds is growing gradually. Hence, the application of novel approaches to fulfill the current growing demand for natural bioactive compounds is of immense relevance. The use of conventional approaches to accelerate natural biosynthetic pathways in plants is shown to produce high levels of bio-active compounds, without the need of genetic engineering applications (Trejo-Téllez et al., 2019). Further, advances in technology have augmented the discovery of new biotic elicitors capable of increasing the production of secondary metabolites in plants.

Glycyrrhiza uralensis Fisch (Fabaceae), commonly known as licorice, is a traditional plant recognized through the ages for its multiple health benefits and medicinal uses (Kondo et al., 2007; Tanemoto et al., 2015). The roots of this plant are used to treat influenza, coughs, and liver damage in traditional medicinal formulations (Kondo et al., 2007). Liquiritoside also known as liquiritin, is the biologically active component of licorice. This

study was designed to investigate the influence of liquiritoside as a foliar spray to increase plant growth and concentration of specific biologically active substances such as proline, glucosinolates, phenolics, and flavonoids in Chinese flowering cabbage plants. In addition, Pb affects the growth of crop plants (Figlioli et al., 2019). However, there is a dearth of research work demonstrating the effect of Pb stress on *B. rapa* subsp. *parachinensis*. According to our information, the effect of Pb toxicity and the ameliorative role of liquiritoside in the mitigation of subsequent stress has never been studied before.

In the course of our study, foliar application of liquiritoside showed positive effects on the growth of Chinese flowering cabbage plants (data yet not published). Additionally, we observed that liquiritoside mitigated abiotic stress, improved biosynthesis of, glucosinolates besides, flavonoids and phenolics in treated plants (Akram et al., 2020). Yet, the application of exogenously applied liquiritoside in the mitigation of plant stress has never been inspected. Therefore, it was hypothesized that liquiritoside might also modulate the antioxidative system of plants to alleviate Pb toxicity. Henceforth, the fundamental purpose of the present study was to elucidate the impact of liquiritoside spray on the physiology and growth of the plants under Pb stress. The results of current research will help to identify the differences in physiochemical process in the liquiritoside applied Pb stressed plants, which will perhaps the valuable crop producers planning to use liquiritoside plants growing in Pb contaminated soils.

MATERIALS AND METHODS

Plant Material

A preliminary study was performed to optimize the dose of liquiritoside. Plants of Chinese flowering cabbage (*Brassica rapa* subsp. *parachinensis*) were raised in plastic pots (12-inch) containing sterilized commercial potting mix. The greenhouse experiment conducted in the present study entailed growing plants in pots containing sterilized Tref Jiffy (United States) media, which were placed in greenhouse at $20/25 \pm 3^\circ\text{C}$ (night/day) under a 16-h photoperiod. Commercial-grade liquiritoside of 99% purity was obtained from Riotto Botanicals, Shaanxi, China. Foliar formulations of the elicitor were prepared at different concentrations including 0, 0.15, 0.25, 0.50, 0.75 and 1 g/L. Control plants were sprayed with distilled water. The application was performed at the trifoliate stage. The relative growth rate (RGR) was calculated over 5 d time spans, after 1 week of elicitor application using the formula:

$$\text{RGR} = \frac{\ln W_2 - \ln W_1}{t_2 - t_1}$$

Where W_1 = initial shoot dry weight, W_2 = final shoot dry weight, $t_2 - t_1$ = growth period.

Greenhouse Experiment

Based on RGR, an experimental set up was designed (Figure 1) under the same greenhouse conditions. Details of treatments are provided in Table 1. Seeds of Chinese flowering cabbage were

sown in sterilized pots. An equal amount of water was supplied along with the recommended dose of fertilizers during the trial. The trial was carried out in a RCBD design containing 5 technical replicates of each treatment. Two independent greenhouse trials were conducted. No less than 10 plants were included in each treatment. Pb was added in the potting mix (75 mg/kg of potting mix) for artificial establishment of heavy metal stress according to the experiment design.

The elicitor was applied as a foliar application starting at the four-leaf stage and repeated on a fortnight basis. Plant growth parameters such as root/shoot length, root/shoot biomass, and the number of leaves were evaluated after 2 months of first foliar spray. The marketable value of plants was calculated using the following formula:

$$\text{Marketable value (\%)} = 100 - (100 \times \text{Percentage of injured or diseased plants} / \text{Percentage of healthy plants}).$$

A minimum of 20 plants was harvested from each treatment and was used for morphological and metabolomic analysis. Plant samples intended for metabolomics analysis were frozen in liquid nitrogen and kept at -80°C till examined.

Assessment of Total Phenolic, and Flavonoids and Photosynthetic Pigments

Chlorophyll and carotenoids content was determined by using a spectrophotometer according to Metzner et al. (1965). The total phenolic contents were analyzed by employing the standard Folin-Ciocalteu method (Pavel et al., 2006) and expressed as milligrams gallic acid equivalent per gram of dry weight tissue. The total flavonoid content was estimated using the aluminum chloride colorimetric method of Chang et al. (2002).

Analysis of the Nutritional Values of Leaves

Leaf samples for nutritional analysis were prepared as described by Mahmoud et al. (2019). Leaf samples were washed, stretched on paper towels, and air-dried for 60 min at room temperature. Thereafter, leaf samples were oven-dried at 70°C to ensure persistent weight. These dried samples were ground in a stainless-steel grinder and the following nutritional analyses were performed.

Estimation of H_2O_2 and MDA

The amount of H_2O_2 content was estimated with the help of a spectrophotometer as described by Jana and Choudhuri (1981). The MDA level, a product of lipid peroxidation was quantified according to Heath and Packer (1968), with slight alterations as suggested by Zhang and Kirkham (1994).

Assessment of Antioxidative Enzymes

The enzymatic activities of POD, SOD, and CAT were analyzed as described by Gao et al. (2005).

Estimation of Phytochelatins (PCs), Non-protein Thiols (NPT), Cysteine, and Glutathione (GSH)

The cysteine content in the plant sample was measured according to the methodology of Gaitonde (1967). The amount of non-protein thiols content was estimated by employing the technique of Ellmann (1959). The quantity of sulfur-assimilating compounds was analyzed by adopting the technique of Nagalakshmi and Prasad (2001).

The amount of phytochelatins in treated plants was assessed according to Bhargava et al. (2005) by eliminating the quantity of GSH from the amount of NPTs as follows:

$$\text{PCs} = \text{NPTs} - \text{GSH}$$

Quantification of Proline Content

The technique of Bates et al. (1973) was used for the estimation of proline content.

Estimation of Lead

The quantity of Pb from digested plant samples was evaluated according to Khan et al. (2017) by using Atomic Absorption Spectrophotometer.

Quantification of Glucosinolate Content

We used our recently devised method (Akram et al., 2020) for the identification and quantification of different types of glucosinolates from the leaves of Chinese flowering cabbage plants. Leaves from 10 plants were taken from each treatment and pooled together. Analysis was performed on an API 4000 QTrap mass spectrometer equipped with a TurboIonSpray probe (AB Sciex; Foster City, CA, United States) connected to a Shimadzu UFLC (Shimadzu, Kyoto, Japan). The mass spectrometer worked with triple quadrupole analyzer in the Multiple Reaction Monitoring (MRM) mode. Sinigrin does not exist in *B. rapa* and *B. napus* (Rangkadilok et al., 2002). In this study, it was used as an internal standard for quantitative analysis of glucosinolates (Jacobo-Velázquez et al., 2011).

Statistical Analysis

The data obtained were analyzed by taking variance with the help of DSAASTAT software. The Duncan's new multiple range test was employed for evaluation of the significant difference between means of all treatments. The study trials having three replicates were repeated twice, and values of means acquired are exhibited.

RESULTS

Influence of Liquiritoside on Plant Height, Number of Leaves, Root Biomass, Shoot Biomass, and Marketable Value of Chinese Flowering Cabbage Subjected to Pb Stress

In the absence of Pb, the liquiritoside (1 g/L) treatment significantly increased the plant height, the number of leaves,

FIGURE 1 | Effect of various doses of liquiritoside (g/L) on the relative growth rate (RGR) of Chinese flowering cabbage. Mean values of two independent experiments are presented. Vertical bars show standard error between different replicates of the same treatment. Data marked by different letters are significantly different at $p < 0.05$.

marketable value, dry weight of the roots and shoots by 26, 34, 3, 27, and 20%, respectively, as compared to untreated control (Table 1). Liquiritoside (0.5 g/L) treatment had no significant effect on plant height, the number of leaves, marketable value, shoot, and root biomass after and before Pb exposure. In the presence of Pb, liquiritoside (1 g/L) application remarkably increased plant length, number of leaves, marketable value, the dry weight of the shoots and roots of Chinese flowering cabbage in comparison with Pb control (Table 1).

Effects of Liquiritoside on Chlorophyll and Carotenoid Contents, Flavonoids, and Total Phenolics in Chinese Flowering Cabbage Under Pb Stress

As shown in Table 2, the contents of chlorophyll *a*, chlorophyll *b*, and carotenoids in plant tissues of the control treatment were 1.17, 0.47, and 2.78 mg g⁻¹, respectively. The Pb treatment decreased the chlorophyll *a* and *b* and carotenoids contents in Chinese flowering cabbage by 27, 28, and 24%, respectively, than that of the untreated control. On the other hand, liquiritoside (1 g/L) supplementation significantly improved the chlorophyll *a* and *b* and carotenoids levels of plants exposed to Pb stress compared with relevant control.

The results showed that Pb toxicity markedly augmented the level of both flavonoids, and phenolics by 32 and 38%, respectively, in Chinese flowering cabbage plants as compared to untreated controls. However, liquiritoside supplementation further boosted the magnitude of both flavonoids, and phenolics in the subject plants under Pb toxic and nontoxic conditions (Table 2). The Pb+liquiritoside (1 g/L) treatment accelerated the quantities of both flavonoids, and phenolics by 17 and 31%,

respectively, in Chinese flowering cabbage with respect to only Pb treated plants.

Impact of Added Liquiritoside on Antioxidant Enzyme Activities in Chinese Flowering Cabbage Under Pb Treatment

Lead stress attenuated the activities of antioxidant enzymes like SOD, CAT, and POD in Chinese flowering cabbage plants when compared with untreated control. While supplementation of liquiritoside at different concentrations further modulated the level of these antioxidant enzymes (SOD, CAT, and POD) in plants subjected to Pb stressed and non-stressed regimes. The Pb+liquiritoside (0.5 g/L) exhibited remarkable increment in the level of SOD, CAT, and POD by 24, 16, and 37, respectively, in Chinese flowering cabbage plants in contrast with only Pb treated ones (Figure 2).

Implications of Liquiritoside in the Modulation of GSH, PCs, Cysteine, and NPT Contents in Chinese Flowering Cabbage Exposed to Pb Toxicity

In the absence of Pb treatments, no obvious changes were observed in the GSH contents of plants with increased liquiritoside application, but the GSH contents were meaningfully different in plants raised under various liquiritoside treatments during Pb stressed conditions (Table 3). The pre-incubation of liquiritoside at the dose of 0.25, 0.50, and 1 g/L increased glutathione contents by 11, 14, and 18%, respectively, in Chinese cabbage plants raised under Pb regimes with respect to relevant controls. In the presence of Pb toxicity, sufficient and

Values presented are mean ± standard error of two independent experiments. Data marked by the different letters in the same column are significantly different at $p < 0.05$, C = Control, Pb = Lead (75 mg/kg soil).

excessive liquiritoside treatment obviously increased the PCs and NPT contents in Chinese flowering cabbage plants compared with those plants in the liquiritoside deficiency treatment group. The, Pb+liquiritoside (1 g/L) treatment significantly enhanced the level of PCs and NPT in subjected plants by 14 and 17%, respectively, with respect to only Pb treated ones (Table 3). These findings signposted that the biosynthesis of thiol metabolic compounds (NPT, GSH, and PCs) enhanced with increased liquiritoside application in Chinese flowering cabbage to alleviate Pb stress. During the current study, liquiritoside (1 g/L) treatment noticeably attenuated the cysteine contents of Chinese flowering cabbage under nontoxic and toxic regimes (Table 3).

Role of Liquiritoside on Total Glucosinolates and Proline Contents of Chinese Flowering Cabbage

Lead toxicity reduced the total glucosinolates by 26% in Chinese flowering cabbage plants than that of the untreated control. However, liquiritoside supplementation augmented the level of total glucosinolates during stressed and non-stressed conditions. The application of liquiritoside at the concentration of 0.5 and 1 g/L increased the value of total glucosinolates by 23 and 29%, respectively, in plants grown under metal regimes with respect to Pb control (Table 3). Present results depicted that lead stress remarkably

declined the level of glucosinolate contents including Progoitrin, Glucoalysyn, Gluconapin, Glucobrassicin, Neoglucobrassicin, 4-Hydroxyglucobrassicin and, 4-Methoxyglucobrassicin in Chinese flowering cabbage plants with respect to analogous untreated controls, respectively. Nevertheless, liquiritoside application enhanced the values of these glucosinolate contents in Chinese flowering cabbage plants under stressed and non-stressed regimes (Table 4).

During the present research, proline content was enhanced by 57% in Chinese flowering cabbage exposed to Pb stress when compared with untreated control. While, differential liquiritoside (0.25, 0.5, and 1 g/L) supplementation further increased the level of proline by 26, 32, and 39%, respectively, in the subject plants under contaminated regimes than that of Pb control treatment (Table 3).

Effect of Liquiritoside on MDA and H₂O₂ Concentrations in Chinese Flowering Cabbage Under Pb Stress

During the present investigation, Pb toxicity considerably augmented the contents of MDA and H₂O₂ in Chinese flowering cabbage with respect to untreated control. Nevertheless, excessive liquiritoside supplementation meaningfully declined the level of both MDA and H₂O₂ in plants during toxic and nontoxic circumstances. The Pb+ liquiritoside (1 g/L) treatment

FIGURE 2 | Effect of liquiritoside on the magnitudes of antioxidant enzymes such as SOD, POD, and CAT in Chinese flowering cabbage plants under lead stress. diminished the quantities of both H_2O_2 and MDA in Chinese flowering cabbage by 38 and 29%, respectively, as compared to concerned Pb treated groups (Figure 3).

Role of Liquiritoside on Pb Uptake in Roots and Shoots of Chinese Flowering Cabbage

The findings of the current study depicted that root tissues showed more Pb uptake compared with shoot tissues of Chinese flowering cabbage (Table 5). The higher Pb accumulation was noticed in roots and shoots of plants grown under only Pb treatment. The liquiritoside supplementation exhibited a

reduction of Pb uptake in the root and the shoot tissues of Chinese flowering cabbage as compared to only the Pb treatment group (Table 5). With the increase in liquiritoside doses (0.25, 0.5, and 1 g/L), a Pb uptake reduction was recorded in analyzed root and shoot tissues. The excessive dose liquiritoside (1 g/L) caused 28 and 43% decline of Pb uptake in root and shoot organs of Chinese flowering cabbage in contrast with non-supplemented stressed plants. The application of liquiritoside (1 g/L) significantly reduced the translocation factor and bio-concentration factor of Pb in subjected plants than that of non-supplemented ones. The plants grown under Pb regimes exhibited decreased value flowering cabbage plants in a dose dependent manner.

DISCUSSION

In the past few years, several studies have shown that exogenous elicitors can mediate plant growth and productivity (Bibi et al., 2016; Brockman and Brennan, 2017; Colla et al., 2017). To the best of our knowledge, the present study is the first to report the positive effects of liquiritoside on the growth and health-promoting elements of Chinese flowering cabbage grown under Pb stress. The application of genistein, a flavonoid improved growth and production of salted soya bean plants (Miransari and Smith, 2007). Likewise, coumarin, a phenolic compound enhanced the growth of wheat plants exposed to salt stress. Similarly, apigenin also enhanced biomass production and the growth of paddy plants under salt stress (Mekawy et al., 2018). Similarly, it was revealed that liquiritoside enhanced growth-related attributes and marketable value of Chinese flowering cabbage exposed to Pb regimes.

The increased growth rate of Chinese flowering cabbage plants observed under the influence of the foliar elicitor could be attributed to the capability of liquiritoside to modulate phytohormones, soluble sugars, amino acids, and mineral elements in applied plants. The liquiritoside may improve the yield and quality of Chinese flowering cabbage by affecting cellular metabolism. For example, it is known that sugars act as signaling molecules and improve plant growth and development (Smeekens et al., 2010). Amino acids provide improved stress tolerance in plants (Karabudak et al., 2014). Some organic acids present in plant extracts can chelate metal ions to stimulates root growth (Battacharyya et al., 2015). All these together could supply nutrition for cell growth, with a resulting increase in growth and vigor.

Chinese flowering cabbage plants under Pb stress exhibited a reduced level of photosynthetic pigments. Several other studies have revealed that Pb deteriorated chlorophyll structure and decreased chlorophyll synthesis by replacing Fe, Mg, and Cu (Akinci et al., 2010; Ashraf et al., 2016). Foliar application of liquiritoside positively affected total chlorophyll and carotenoids content in a dose-dependent manner (Table 2). The positive effect of liquiritoside on leaf pigment content could be attributed to the delay in leaf senescence or enhancement

in leaf pigment biosynthesis (Fan et al., 2013; Jannin et al., 2013). These beneficial effects are possibly due to the effect of liquiritoside on phytohormones. The physiological parameter of leaf pigment content also acts as indicators of improved quality of Chinese flowering cabbage that can be obtained by the application of exogenous elicitors. Analogous to our results, it was observed that apigenin-treated plants showed increased biosynthesis of photosynthetic pigments which improved the growth of paddy plants subjected to salinity stress (Mekawy et al., 2018). Moreover, the cinnamic acid applied plants also exhibited an increased amount of photosynthetic pigments besides increased growth of maize plants exposed to salt toxicity (Araniti et al., 2018).

The enzymatic and non-enzymatic antioxidants enable plants to thrive under abiotic stress conditions (Usman et al., 2020). The antioxidative compounds perform the role of sacrificial agents through their activity on ROS, thus defending plant biomolecules. Rutin as an antioxidative flavonoid, scavenge ROS, and enhance the growth of leguminous plants (Ismail et al., 2016). Quercetin synthesized by rutin has ROS scavenging capability because it acts as a substrate of guaiacol peroxidase (Amako et al., 1994). The detoxification of ROS in quercetin applied plants mitigated salt-induced stress and improved the growth of plants. The antioxidant enzymes such as POD, CAT, and SOD consume phenolics, including cinnamate, ellaglate and ferulate to alleviate plant stress (Abu Taleb et al., 2013; Singh et al., 2013). Similarly, our finding also exhibited obvious modulations in the activities of POD, CAT, and SOD for dilution of Pb toxicity in liquiritoside supplemented Chinese flowering cabbage plants.

Fayez et al. (2014) demonstrated that abiotic stress modulates physiochemical attributes of plants. Plants synthesize an elevated level of MDA and H₂O₂ under stress (Noctor et al., 2015). Lead stress enhanced the biosynthesis of ROS, leading to increased oxidative injury in plants (Hattab et al., 2016). Other studies also showed that Pb enhanced lipid peroxidation in plants causing oxidative injuries (Li et al., 2013). Plants engage the antioxidant system to mitigate metal-triggered oxidative stress (Shahid et al., 2014). Phenolics and flavonoids may reduce the biosynthesis of ROS, EL H₂O₂, and MDA to alleviate plant stress (Mekawy et al., 2018). The reduced level of ROS helps in the mitigation of

oxidative injury (Hossain et al., 2019). The improved synthesis of phenolics and flavonoids as well as antioxidant enzymes detoxify ROS and mitigate stress in gallic acid, and rutin treated plants under stress. Pheomphun et al. (2019) observed that reduced H_2O_2 , MDA, and enhanced activity of antioxidant enzymes in catechin supplemented plants for the alleviation of stress.

Higher proline has been observed in plants facing stress (Ahmad et al., 2018). However, exogenously applied quercetin and coumarin improve proline content, and LRWC in plants to mitigate stress (Saleh and Madany, 2015). The increased proline biosynthesis was attributed to reduced activity of proline dehydrogenase and increased activity of pyrroline-5-carboxylate synthase in coumarin supplemented plants (Pérez-Arellano et al., 2010; Szabados and Savoure, 2010). Hence, it is assumed that liquiritoside may mitigate metal stress in applied Chinese flowering cabbage plants in the same manner.

Phenolics scavenge ROS to reduce oxidative injury in plants (Soares et al., 2019). Our results showed that liquiritoside enhanced phenolic contents and triggered the activity of antioxidant enzymes. Phenolics detoxify ROS and metal toxicity by making metal complex in plants (Tolrà et al., 2009). The results of this study are in agreement with the findings of Ashraf et al. (2016), who observed that the foliar application of plant extracts increased the total phenolics and flavonoid content of *Raphanus sativus* plants. Baenas et al. (2014) showed that the nutritional quality of sprouts of brassica vegetables was improved by foliar application of biotic elicitors. Agati and Tattini (2010) reported that flavonoids decline in ROS levels in plants affected by abiotic stress. Similarly, other researchers have described the importance of GSH, flavonoids, and ascorbic acid in mitigation of plant stress through reducing ROS synthesis (Liang et al., 2018). The augmented synthesis of flavonoid alleviates drought stress in plants (Varela et al., 2016).

Current results showed that the levels of total GLS in Chinese flowering cabbage plants exposed to Pb toxicity were significantly increased under the influence of the foliar elicitor (1 g/L) (Table 3). Same types of increments of GLSs have been reported in Chinese flowering cabbage in previous studies (Bhandari et al., 2015; Liang et al., 2018). Metal stressed plants modulate the synthesis of thiol ligands, including phytochelatins (PCs), non-protein thiols, cysteine, and GSH for detoxification and chelation of metal (Kumar et al., 2016; Ahmad et al., 2020). Higher synthesis of thiols in root tissues compared to foliage of plants declines uptake and translocation of injurious metals from roots to shoots (Hasan et al., 2015). The thiol-containing groups of plants such as cysteine, NPT and PCs, have a higher affinity for metals and hence assist in homeostasis and detoxification of metals (Rabêlo et al., 2018). Similarly, cysteine, NPT, GSH, and PCs may have played their part reducing Pb translocation and subsequent detoxification in Chinese cabbage flowering plants.

Plant roots immediately come in contact with metals and hence exhibit relatively more metal content as compared to above-ground parts of plants. The increased demethylation and pectin level help in reduced translocation besides the

FIGURE 3 | Effect of liquiritoside on the amounts of malondialdehyde (MDA) and hydrogen peroxide (H_2O_2) in Chinese flowering cabbage plants under lead stress. Mean values of two independent experiments are presented. Vertical bars show standard error between different replicates of the same treatment. Data marked by the different letters in the same column are significantly different at $p < 0.05$. Pb, lead; C, Control.

TABLE 5 | Role of liquiritoside on Pb uptake in root and shoot tissues, bio-concentration factor (BCF), translocation factor (TF) and tolerance index (TI) of Chinese flowering cabbage plants under lead (Pb) stress.

Treatments	Root Pb uptake	Shoot Pb uptake	BCF	TF	TI
	mg kg ⁻¹	mg kg ⁻¹	–	–	%
C	0.86 ± 0.052c	0.52 ± 0.028c	0.55 ± 0.021c	0.60 ± 0.035a	–
Liquiritoside (0.25 g/L)	0.72 ± 0.045c	0.43 ± 0.021c	0.46 ± 0.024cd	0.59 ± 0.027a	1.21 ± 0.057ab
Liquiritoside (0.50 g/L)	0.58 ± 0.028c	0.31 ± 0.019c	0.35 ± 0.017cd	0.53 ± 0.024ab	1.27 ± 0.073ab
Liquiritoside (1 g/L)	0.47 ± 0.031b	0.23 ± 0.012c	0.28 ± 0.016c	0.48 ± 0.022b	1.35 ± 0.083a
Pb	41.09 ± 2.53a	25.64 ± 1.06a	0.87 ± 0.051a	0.62 ± 0.034a	0.69 ± 0.025c
Pb+ liquiritoside (0.25 g/L)	39.74 ± 2.62ab	18.87 ± 0.85ab	0.78 ± 0.042ab	0.47 ± 0.026bc	0.78 ± 0.038bc
Pb+liquiritoside (0.50 g/L)	36.28 ± 2.54ab	15.96 ± 0.79b	0.69 ± 0.034b	0.43 ± 0.021c	0.89 ± 0.056bc
Pb+liquiritoside (1 g/L)	29.83 ± 1.97b	14.68 ± 0.64b	0.59 ± 0.035bc	0.49 ± 0.025b	0.95 ± 0.047b

Values presented are mean ± standard error of two independent experiments. Data marked by the different letters in the same column are significantly different at $p < 0.05$, C = Control, Pb = Lead (75 mg/kg soil).

fixation of metal within the root cell walls (Liu et al., 2019). Perhaps, this strategy reduced Pb translocation from root to shoot of the plants and should be explored in further studies (Bharwana et al., 2013).

CONCLUSION

This study demonstrates that liquiritoside could be used as an effective plant growth bio-stimulant. Our findings indicate that

the nutritional and medicinal contents in leaves of Chinese flowering cabbage plants can be augmented by foliar application of liquiritoside at a rate of 0.5 g/L. The supplementation of liquiritoside alleviated Pb stress of plants by improving growth/photosynthetic pigments, glucosinolates, antioxidants, and reducing MDA, H₂O₂, cysteine, and Pb uptake. Further studies are required to understand the mechanism underlying the crop's growth effect, promoting biotic elicitor's use in organic agriculture.

Most old roses are difficult to root when propagated by cuttings. This research focused on the response of stem cuttings of *Rosa* “Hurdal” to plant origin preparations used as rhizogenesis enhancers through changes to the anatomical structure of the basal part of the stem. Cuttings derived from shoots in four phenological stages were prepared for the experiment: flower buds closed (H1); fully flowering (H2); immediately after petals have fallen (H3); 7–14 days after petals have fallen (H4). The cuttings were treated with 0.4% indole butyric acid (IBA; Ukorzeniacz A_{aqua}) or 0.2% naphthalene acetic acid (NAA; Ukorzeniacz B_{aqua}), and with plant origin preparations: Algae extract (Bio Rhizotonic), Organic preparation (Root JuiceTM), and Plant extract (Bio Roots). A high rooting percentage in comparison to the control (27.5%) was obtained after treatments of the H1 cuttings with Algae extract (90%), Organic preparation (80%), and Plant extract (75%). The H4 cuttings did not root, probably as a result of an overgrowing callus and limited xylem formation. The anatomical structure of the shoot differed in subsequent phenological stages during the period of rooting in various ways, depending on the rooting enhancer used for treatment. Numerous correlations between rooting percentage and anatomical structure were proved, including the key role of vascular bundles in increasing rooting percentage by widening the vessel diameter.

Keywords: adventitious roots, biostimulant, root enhancer, tracheids, vessel, xylem

INTRODUCTION

Roses belong to the oldest and most important cultivated ornamental plants (Smulders et al., 2019), and have been significant in many fields of human life for thousands of years (Gustavsson, 1999). The majority of once-blooming old roses are valued for their winter hardiness (Gustavsson, 1999; Monder, 2014) and high resistance to pests and disease. The majority of old roses can also be successfully cultivated in the temperate zone in a climate with harsher winters on their own roots without budding on the rootstock (Gustavsson, 1999). Their maintenance in cultivation is important for biodiversity conservation and the preservation of the heritage of garden plants, and so for the implementation of the provisions of the Convention on Biological Diversity (CBD) made in Rio de Janeiro on 5 June 1992. Although old roses are commonly cultivated, they should, nevertheless, be used more often to revitalize historical

properties and urban greeneries (Gustavsson, 1999; Monder, 2021). “Hurdal” is a valuable old rose and, originally, an Alba or Villosa Hybrid. This cultivar has been more widely known since it was brought to Norway in the second half of the nineteenth century. The shrubs are ca 3-m high, with long, almost thornless stems, and big grayish leaves. The flowers are deep pink, with 15–25 petals and a mild fragrance (**Figure 1A**). The hips are oval, ca 2-cm diameter, and red-orange. The shrubs exhibit great frost hardiness and are appropriate for cultivation in a hard Scandian climate (Gustavsson, 1999).

The use of single-node leafy stem cuttings is easy and economical, and it is the most common method of rose propagation used to grow shrubs on their own roots. However, the forming of adventitious roots in the cuttings of vascular plants is a very complicated process connected with exogenous and endogenous factors (Hartmann et al., 2011), whereby rhizogenesis in cuttings of wild (Hoşafçi et al., 2005) and old roses is believed to be especially difficult (Hoşafçi et al., 2005; Ginova et al., 2012), time-consuming, and often resulting in failure (Ginova et al., 2012; Monder et al., 2016). The process of rhizogenesis, prolonged to 12 weeks, exposes the cuttings to many stress factors, and their success is also strictly connected with the content of bioactive components in stock plants (Monder et al., 2016). The anatomical structure of the shoot (Amissah et al., 2008; Bryant and Trueman, 2015) is a crucial endogenous factor in adventitious root formation for the majority of vascular plants, including roses (Monder et al., 2017).

The growth and the development of plants in the growing season are connected with many changes in their biology. Phenology is a visible effect and a source of knowledge of periodic changes in plants (Meier et al., 2009) affected by additional environmental factors (Zheng et al., 2016), including roses (Monder, 2014, 2021). The crucial role of the phenological stage of shoots in roses harvested for the preparation of cuttings has been shown a few times (Pihlajaniemi et al., 2005; Monder et al., 2016, 2019; Monder and Pacholczak, 2018). The flowering time in once-blooming roses is followed by changes in carbohydrates, soluble proteins, chlorophyll a/b, and carotenoids content (Monder et al., 2016) as well as changes in the anatomical structure (Monder et al., 2017).

Various rooting enhancers, including plant hormones (Pihlajaniemi et al., 2005; Ginova et al., 2012) and biostimulants (Monder and Pacholczak, 2019; Monder et al., 2020) were used to encourage the natural ability of cuttings to undergo rhizogenesis and also to improve the quality and physiological parameters of rooted cuttings. Some of the preparations important in nursery production contained indole butyric acid (IBA) or naphthalene acetic acid (NAA) as standard rooting enhancers in the procedure of rooting cuttings (Hartmann et al., 2011). Previous research has proven the influence of a few substances used as rooting enhancers on anatomical structure, e.g., benzyladenine and naphthalene-1-acetic acid in Fuchsias (Wróblewska, 2013), Dogwood (Pacholczak et al., 2012), and Euphorbia hybrids (Fascella and Zizzo, 2009) or carbon dioxide (Costa et al., 2007), IBA, and NAA in roses (Dawa et al., 2018; Monder et al., 2019). However, the abovementioned research did not establish which changes in anatomy had an influence on the effectiveness of the process of rhizogenesis.

Synthetic chemicals used for plant production, protection, and cultivation are often replaced, or their usage is reduced, by preparations of natural origin that includes humic acids, seaweed, and Plant extracts. Their use provides a number of benefits in stimulating growth and protecting against biotic and abiotic stresses (Oosten et al., 2017). Preparations of natural origin are preferred in sustainable eco-friendly agriculture and recommended by the Official Journal of the European Union (OJEU, 2009a,b), the National Organic Program USDA (USDA, 2017), and the Organic Materials Review Institute (OMRI, 2021). The effect of their use depends on their composition and, especially, on phytohormones (Oosten et al., 2017). Three commercial plant origin preparations recommended by their manufacturers for rooting and replanting were used in the present research and named for the purposes of this work: Bio Rhizotonic—Algae extract (Canna Continental, Los Angeles, USA, 2021), Root Juice™—Organic preparation (BioBizz Worldwide B.V., Groningen, The Netherlands, 2017), and Bio Roots—Plant extract (General Hydroponics Europe/T.A. Terra Aquatica, Fleurance, France). More detailed information on these preparations is presented in **Table 1**. These preparations were produced with Plant extract as their base and contain many biologically active substances. The content of humic substances could lead to higher nutrient content in the tissues of the cuttings as well as positive metabolic changes (Nardi et al., 2015). The above preparations affected the content of chlorophyll a, b, carotenoids, soluble proteins (Monder et al., 2020), and carbohydrates in roses (Monder and Pacholczak, 2018) and can indirectly influence the effectiveness of rhizogenesis.

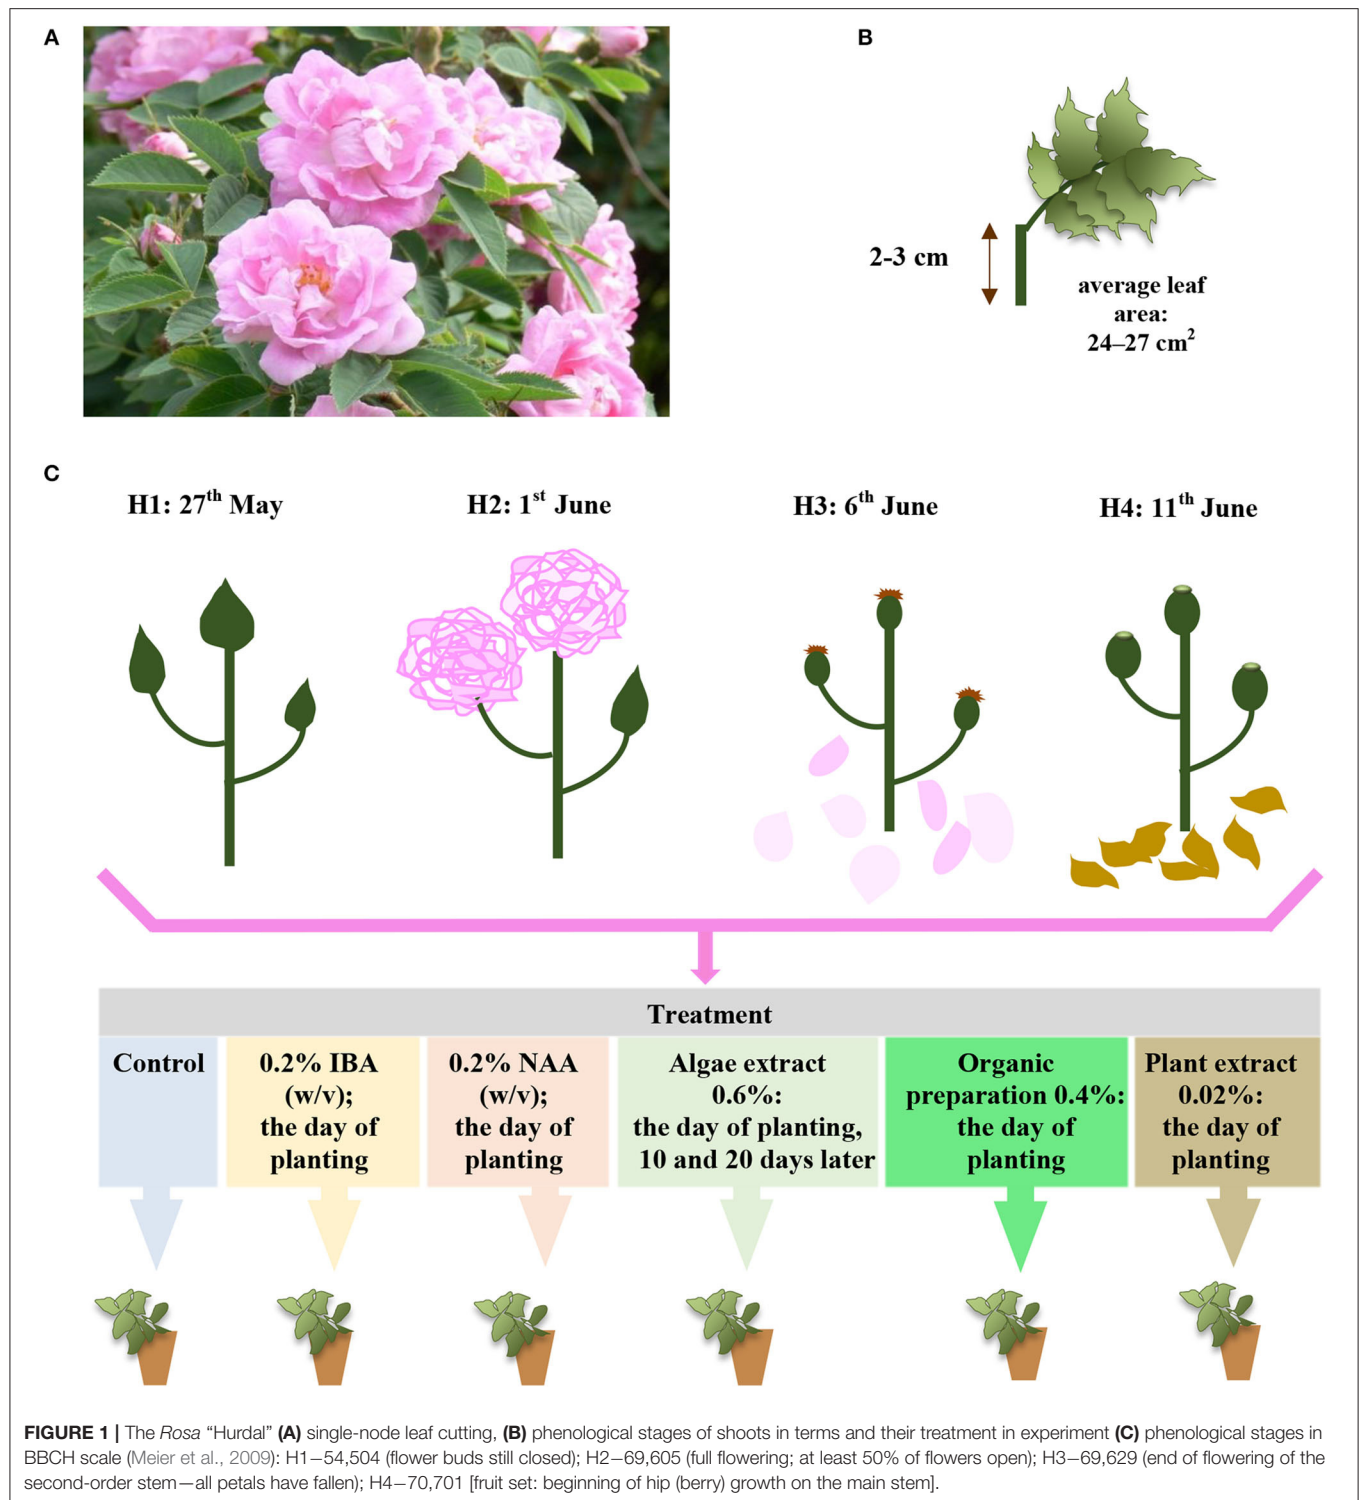

The aims of this research were to recognize the response of cuttings *Rosa* “Hurdal” in anatomical structure to the plant origin preparations during the process of rhizogenesis. Moreover, we hypothesized that the response of cuttings prepared from shoots in four phenological stages may be different. Consistently, the various anatomical changes occurring in stock plants during the flowering period can affect rooting effectiveness and the quality of rooted cuttings. Analysis of changes in anatomical structure before and after the rooting process could reveal the reason for difficulties in the rooting of some rose cuttings.

MATERIALS AND METHODS

Plant Material and Experimental Conditions

The plant material of *R. “Hurdal”* (Germany–Norway; origin unknown, *Rosa* × *alba* × *Rosa villosa*, **Figure 1A**) was obtained from shrubs growing in the National Collection of Rose Cultivars in the Polish Academy of Sciences Botanical Garden Center for Biological Diversity Conservation in Powsin, Warsaw, Poland.

The single-node leafy semi-hardwood shoot cuttings of *Rosa* “Hurdals” (Gustavsson, 1999) with an original leaf (leaf area 24–27 cm²) (**Figure 1B**) were taken from the middle part of flowering shoots (three to five buds) in four phenological stages (**Figure 1C**) according to BBCH scale in roses (Meier et al., 2009). In the present study, the letter H, accompanied by a subsequent number, was used to designate

the phenological stage of shoots harvested for the experiment in four periods: H1—May 27, 54 504 (flower buds still closed), H2—June 1, 69 605 (full flowering; at least 50% of flowers open), H3—June 6, 69 629 (end of flowering of

the second-order stem: all petals fallen), H4—June 11, 70 701 (fruit set: beginning of hip growth on the main stem) (**Figure 1C**). The shoots all had similar diameters, ranging from 5 to 6 mm.

TABLE 1 | Rooting enhancers used in the rooting of *Rosa* "Hurdal."

Name in work	Preparation and producer	Characteristic	Certificate
IBA	Ukorzeniacz A _{aqua} (Himal, Poland)	0.4% IBA (indolebutyric acid)	Organic Materials Review Institute (OMRI)
NAA	Ukorzeniacz B _{aqua} (Himal, Poland)	0.2% NAA (naphthaleneacetic acid)	
Algae extract	Bio Rhizotonic (Canna Continental, Los Angeles, USA, 2021)	Seaweed-based, 100% organic, N 0.6%, P 0.2%, K 0.6% vitamins such as B ₁ , B ₂ , and other biologically active substances	
Organic preparation	Root Juice TM (BioBizz Worldwide B.V., Groningen, The Netherlands, 2017)	Combination of humic acid and seaweed extracts, N 0.1%, P ₂ O ₅ 0.1%, K ₂ O 0.1%, Mg 0.03%, Fe 0.013%, Mn 0.002%, Zn 0.004%, B 0.025%, Cu 0.001%	National Organic Program (NOP); Control Union Certified EU; Good Soil Quality Mark; Point Vert; Organic Materials Review Institute (OMRI), Clean Green Certified
Plant extract	Bio Roots (GHE, France/T.A. Terra Aquatica, 2021)	Amino acids and oligosaccharins, fruit oil up to 1%; humic acids 1%; pectinate 1%; sodium alginate 3%; seaweed species 10%, organic matter 84%	European regulation EC No 834/2007 on organic agriculture (Certificaat Bio Roots, 2014)

The cuttings were inserted into multipot trays (6.6 × 6.6 cm) in peat (Karaska, Poland) sand (Vistula river) medium (mixture v:v 1:1; pH 6–6.5). The cuttings were treated with 0.4% IBA (Ukorzeniacz A_{aqua}) or 0.2% NAA (Ukorzeniacz B_{aqua}), and with plant origin preparations: Algae extract (Bio Rhizotonic), Organic preparation (Root JuiceTM), and Plant extract (Bio Roots). The treatment and watering process is presented in detail in **Figure 1C**. Before planting, the basal parts (1 cm) of the stem were dipped in commercial rooting powder, containing 0.4% IBA or 0.2% NAA. The remaining cuttings were watered with plant origin preparations or, in the case of the control, water. The watering was performed with 10 cm³ per pot (98 cm³) according to the schema of the experiment. During the 10th and 20th days of rooting, the cuttings were watered with 10 cm³ water or Algae extract per pot (98 cm³) (**Figure 1C**). The rooting enhancers used in the experiment were purchased from companies in the sector (**Table 1**).

The experiment on rooting cuttings was conducted in the commercial nursery of M&M Kryt in Wola Prażmowska (51.56°N, 20.28°E), Poland. The rose cuttings were rooted in a foil tunnel with an electronically controlled misting system that maintained optimal climatic conditions (air temperature, 23–25°C; ambient relative humidity, 80–90%). The shading material limited the photosynthetic photon flux density to 130 μmol·m⁻²·s⁻¹. To prevent fungal diseases, the following fungicides were applied to the cuttings regularly every 7–9 days starting from the day of planting: Previcur Energy 840 SL (propamocarb, 47.28%; fosetyl, 27.65%; Bayer, Poland), Amistar[®] 250 SC (azoxystrobin, 250 g·dm⁻³; Syngenta, Poland), and Score 250 SC (difenoconazole, 250 g·dm⁻³; Syngenta, Poland).

The Data Set of the Growth Parameters of the Cuttings

After 12 weeks, in the first days of August, the cuttings were dug out and cleaned from the medium. The rooted cuttings were earmarked for further evaluation.

The rooting percentage and the percentage of cuttings with a callus only were calculated (%) in relation to the number of planted cuttings.

The fresh weight (g) of the root system and the aboveground part were estimated for rooted cuttings, using an analytical balance (PS 6000/C/2, RADWAG, Poland). The root length (cm) was measured with a caliper from the origin of the root to the apical meristem of the primary and longest root.

Anatomical Evaluation

Samples of shoots from cuttings were retrieved for anatomical research two times for every treatment in each phenological stage: before being planted in the rooting medium and on the 25th day of the rooting process. Moreover, the samples were harvested and observed separately after 12 weeks of rhizogenesis. The shoot fragments were protected and stabilized in a mixture of anhydrous glycerine and 96% ethyl alcohol (v/v 1:1) in PAS Botanical Garden CBDC in Powsin, Warsaw, Poland. Slides were cut with a sledge microtome (pfm SLIDE 4003E, pfm medical AG, Germany) into slices 15- to 30 μm thick with cross- and longitudinal sections from the basal parts of shoots, in which rhizogenesis would have taken place. The scraps were cross-dyed with a solution of safranin. The studies were carried out using the light Olympus BX41 microscope (Olympus America Inc., New York, USA) with the Olympus DP25 digital camera connected to a computer with specialist Cell*B software (The Institute of Wood Sciences and Furniture, Warsaw University of Life Sciences—WULS, Warsaw, Poland) and an Olympus Vanox AHBT3 (Olympus America Inc., New York, USA) microscope. The measurements of cells and tissue elements were conducted with the specialist Cell*B software and cellsSens Standard 1.7.1. software in PAS Botanical Garden CBDC in Powsin, Warsaw, Poland. The width of the xylem, phloem, pith rays, and cortex, and, additionally, the early- and late-wood vessel diameter, were measured before and after 25 days of rooting cuttings and, in the shoots of the stock plant, cut on 5 August. The width of tissues between xylem and cortex was noted and observed after 25 days of rooting cuttings. All the observations were carried out on the basal part of the cuttings: 2–2.5 cm below buds in shoots.

Statistical Analysis

The experiments were constructed as randomized complete block design (RCBD) for each maturity phase and involved 24 combinations altogether for two variables (treatment, phenological stage). Each combination of treatment in four phenological stages of shoots (**Figure 1**) included four replicas of 10 cuttings. A total of 960 cuttings were planted. Additional 10 cuttings earmarked for anatomical research were planted in each combination. Moreover, the anatomical research data were collected for each phenology stage of shoots before rooting them, also from the 10 cuttings.

The values in percentage were transformed by using the function $\text{ARCSIN}(x)^{1/2}$ according to Bliss or $y = x^2 + (x^2 + 1)^2$ to compare the means and carry out analyses. The data of anatomical parameters were analyzed by using two-factorial analysis of variance (ANOVA), and Duncan's honest significant difference test was used to determine the significance of differences between the means ($\alpha = 0.05$) for two variables—the phenological stage and the rooting enhancer. For data of growth parameters, two-way analysis of variance (ANOVA) and Tukey's HSD were used ($\alpha = 0.05$) for the same variables, respectively. Correlations between the data parameters of growth and anatomical structure in cuttings were carried out for each phenological phase and treatment together and separately.

The STATISTICA 10 software package (StatsoftPolska, Cracow, Poland) was used for statistical analysis.

RESULTS

The Anatomy of the Shoots of *Rosa* “Hurdal” Stock Plants Changes Across the Different Phenological Stages That Cuttings Were Prepared in

The periderm consisted in (i) a cork cambium with undifferentiated cells (phellogen), (ii) an outer layer (epidermis) with cells in regular rows and thick walls, and (iii) living cells with thickening walls in an inner layer arranged in three to four rows. The cortical parenchyma had a similar width to the vascular bundle ring visible on cross sections of all four phenological stages of shoots. The parenchyma consisted of large cells, uneven in size, and tightly arranged along the circumference of the shoot (**Figure 2**). The width of the cortex decreased from H1 to H4 (**Figure 3**).

The vascular bundles were separated from the cortex sclerenchyma layer by irregularly arranged cells with very thickened walls and were different widths. Moreover, the ring of vascular bundles was partially irregular and with a few vascular bundles located outside. These irregular bundles were observed, especially in shoots H1 and H2. The structure visible on cross- and longitudinal sections of shoots in subsequent stages showed a progression of the lignification process (**Figure 2**). Stems collected from shoots in stages H3 and H4 had a wider wood region (**Figure 4**) where thick-walled fibers dominated, providing mechanical strength.

The width of xylem tissue increased with each fallow phenological stage. The vessels and tracheids of the xylem

were located radially on the cross section in regular rows. No significant differences were found between the mean vessel diameter of early- and late-wood in H1, H2, and H3, while the means in H4 were significantly higher. There were a few cells of latewood in H1, mostly tracheids with thick walls. The layers of latewood were much wider in fallow phenological stages, and the vessels of latewood were significantly larger in diameter in H4 shoots. The width of xylem tissue increased in the shoots of stock plants until August, however without any increase to the diameter of the vessels. The last cells of visible latewood were mainly tracheids, with only a few large vessels (**Figure 4**).

The cambium layer in shoots before rooting consisted in three to four cells in H1, four to five in H3, and three to four in H4 (**Figure 2**). The cambium of stock plants in August was made up of five to six cells.

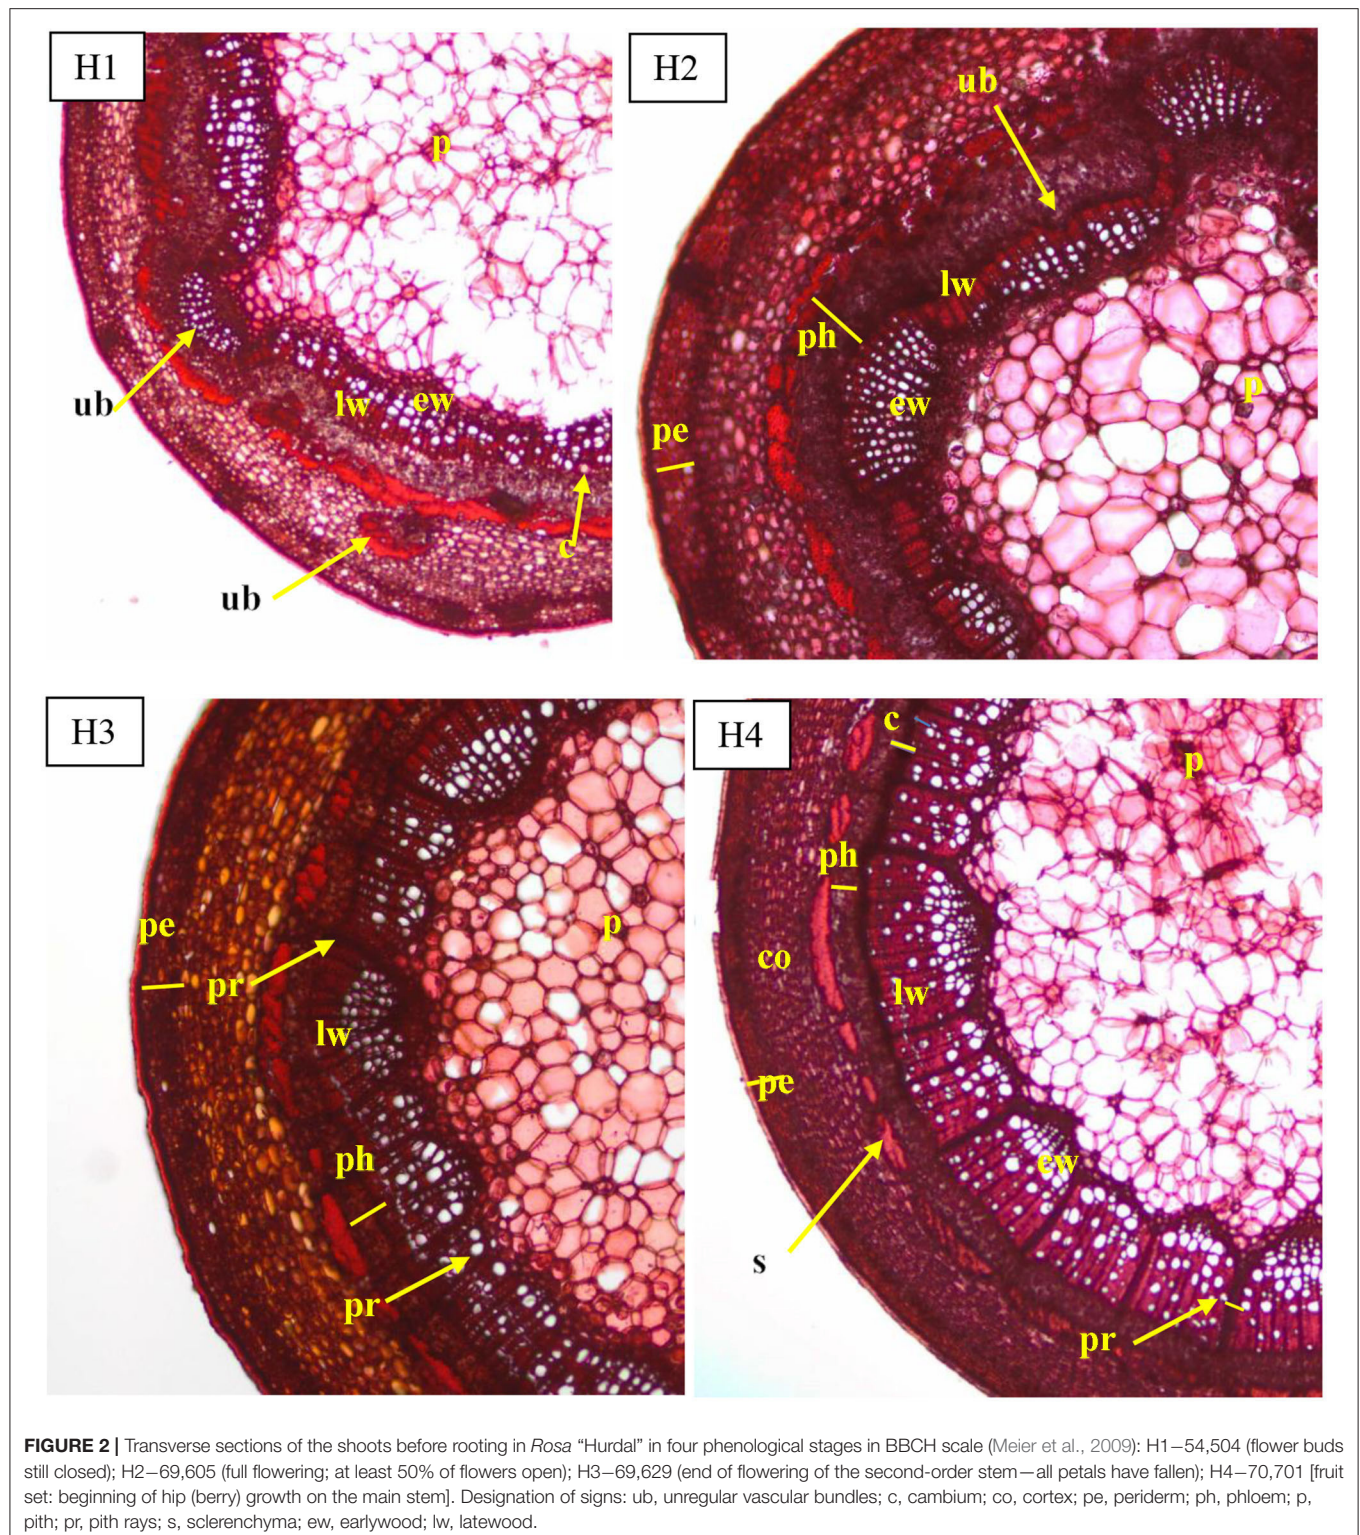

The pith rays were narrow, made up of three to five rows of the cells. Numerous starch grains were visible in pith rays in comparison with their smaller number of companion cells of phloem, xylem fibers, and cortical parenchyma (**Figure 2**). The pith rays widths were similar throughout the four phenological stages (**Figure 5**).

The pith consisted of big living irregular cells, loosely stacked in starred form around small cells, with starch grains in cross sections and in rows on longitudinal sections (**Figure 2**).

Rooting Enhancers Have a Varied Effect on Changes to the Anatomy of Stem Cuttings Harvested in Four Phenological Stages

Visible callus tissues appeared in the rhizogenesis process at the basal part of cuttings in the place of wounding after 10–14 days, and the first visible roots were spotted in week 4 near these places. On the cross sections, the roots most often appeared on the cambial zone near the pith rays and phloem. The forming roots were growing in outside, omitting the phloem and sclerenchyma layers. At the same time, numerous callus cells appeared, intensively filling the space between the first ring of xylem and sclerenchyma, and consequently growing outside through the cortex layer. The callus cells were also observed in the cambium zone and as a product of phellogen differentiation (**Figure 6**). The overgrowing of callus cells was also visible in the place of the pith on the base of the cutting (**Figure 7**). The roots probably also formed in the region of the phloem and pericycle, as was also observed after 12 weeks, without omitting the basal part of cuttings covered by a callus (**Figure 8**).

The width of the xylem tissue in control cuttings derived from shoots H1 was small compared to cuttings on which NAA preparation, Algae extract, or Organic preparation was used, and the width was even smaller in cuttings treated with Plant extract. This variable was also higher in control cuttings from shoots H2 for which Organic preparation or Plant extract was used as well as for cuttings obtained from shoots H3 treated with NAA, Organic preparation, and Plant extract. The width of xylem tissue in cuttings H4 was similar when using IBA and NAA preparations and Algae extract. The use of Organic preparation and Plant extract resulted in an increase in the width of xylem tissue. Xylem was dominated by large, thin-walled vessel elements of

earlywood. However, with time, the wood cells became more regular in shape, smaller, thick-walled tracheids, with a tendency for the size of vessels to decrease in diameter in the cross section due to the use of rooting enhancers (Figure 4).

The diameter of the vessels of early- and late-wood in H1 cuttings was higher in the control and after use of Algae extract as compared with other enhancers. In the case of H2 and H3 cuttings, the diameter of earlywood vessels was similar for all

FIGURE 3 | Width of *Rosa* “Hurdal” tissues between wood and cortex (A), phloem (B), and cortex tissue (C) in stems before rooting; cuttings after 24 days of the rhizogenesis process; and stems of stock plants cut in first days of August. Control—control cuttings without rooting enhancers; IBA 0.4%—Ukorzeniacz A_{aqua} (0.4% IBA); NAA, 0.2%—Ukorzeniacz B_{aqua} (0.2% NAA); Algae extract—watering with 0.6% Bio Rhizotonic (10 ml) after planting and 10 and 20 days later; Organic (Continued)

FIGURE 3 | preparation—watering with 0.4% Root Juice™ (10 ml) after planting; Plant extract—watering with 0.02% Bio Roots (10 ml) after planting. H1—54 504 (flower buds still closed); H2—69 605 (full flowering; at least 50% of flowers open); H3—69 629 (end of flowering of the second-order stem—all petals have fallen); H4—70 701 [fruit set: beginning of hip (berry) growth on the main stem]. Different small letters indicate significant interactions between the phenological stage and treatment (two-way ANOVA). Different capital letters indicate significant differences between phenological stages. Duncan's test ($\alpha = 0.05$) was used.

treatments. The diameter of latewood vessels of H2 after the use of Organic preparation was smaller than in the control cuttings. Compared to the control, H3 latewood vessels were larger in diameter after the use of an Organic preparation and Plant extract, and lower when using IBA and Algae extract. In the case of H4 cuttings, only the Plant extract affected the increase of earlywood diameter, while no latewood vessels were determined at this stage. The differentiation in new vessels and new ring had probably also inhibited (Figures 4, 9, 10).

The above results were compared with measurements of the xylem tissue in stock plants in August—the mean was higher than obtained by rhizogenesis in all stages H1–H4 (Figure 4). The cause for such results was the strong expansion of callus tissue compressing the xylem tissues of the first ring in rooted cuttings. This phenomenon probably also caused the separation of individual vascular bundles outside the first ring. A fragmentary new second ring with rows of vessels and tracheid cells was visible around and above the first ring (Figure 7).

The cambium zone in rooted cuttings was difficult to identify (Figures 6–10).

The process of rhizogenesis is characterized by intensive growth of the layer between the xylem and the cortex, especially high means were obtained for the cuttings H1, excluding those treated with Plant extract, for which the means were lowest. The growth of this layer decreased in control cuttings, following phenological stages from H2 up to H4, in which it was lowest. The preparations in H2–H4 cuttings had a different effect, with the tendency for NAA to decrease means (Figure 4).

The mean width of phloem tissue for rooted cuttings was highest in H1. The width of phloem tissue in H1 control-rooted cuttings was lower than after the use of rooting enhancers, excluding Plant extract. In the case of H4 rooted cuttings, the results were similar in all treatments, excluding Plant extract, for which the mean was higher (Figure 4).

The cortex grew intensively in H1 cuttings after the use of all rooting enhancers, and their widths were greater compared with the control. In the case of H2 cuttings, a higher mean as compared to the control was noticed as a result of the use of Plant extract only. In the case of H3 cuttings, the means after treatment by Organic preparation, Plant extract, and NAA were higher compared to the control. The use of IBA, NAA, and plant preparation affected the increase of the mean of the width of cortex tissue in H4 cuttings (Figure 4).

The widths of pith rays changed in the process of rhizogenesis, depending on the phenological stage and treatment. However, the means obtained for all cuttings indicated that the rooting enhancers caused a decrease in the width of pith rays compared to control cuttings (Figure 5).

The growth of cortex tissue and tissues between the cortex and the xylem was connected with the growth of callus tissue

and auxiliary root formation visible on cross and longitudinal sections of the basal part of shoots (Figures 6–8).

The Essential Role of the Phenological Stage of the Shoot and Plant Origin Preparations in Rooting the Cuttings of *Rosa* “Hurdal”

The highest natural ability to root was shown for cuttings H3, and was lower for cuttings cut from shoots H1 and H2. The cuttings from shoots H4 did not root, and none of the rooting enhancers increased rooting ability (Figure 11).

In the case of cuttings H1, a 2- to 3-fold increase of rooting percentage was obtained through the use of IBA and preparations of plant origin compared to the control cuttings and treated NAA. The lower (control, IBA, and plant origin preparations) or similar (NAA) percentage of cuttings with a callus only was noticed. The use of rooting enhancers for cutting H2 decreased the percentage of cuttings with the callus only. The rooting percentage increased after the use of plant origin preparations compared to the control cuttings. Organic preparation and Plant extract had a similar effect on H3 cuttings (Figure 11).

The rooting enhancers did not affect the root length, the weight of the root system, or the aboveground part of cuttings H1. In the case of H2 stage cuttings, the use of NAA preparation and all the preparation of plant origin increased the weight of the aboveground part of the plants, while the Algae extract and Plant extract affected the weight of the root systems. The use of IBA and all preparation of plant origin increased the root length. The use of an Organic preparation resulted in higher root length, weight of the aboveground part as compared to the remaining combination of rooted H3-stage cuttings. In the case of cuttings derived from shoots at this phenological stage, none of the rooting enhancers affected the weight of the root system (Figure 12).

Changes in Anatomy Structure Contra Rooting Percentage Results in the Propagation of *Rosa* “Hurdal”

Correlation analysis for the rooted cuttings in all phenological stages (H1–H3) showed that an increase in rooting percentage was only strictly connected to a decrease of the percentage of cuttings with a callus only. Moreover, a higher percentage of rooted cuttings correlated positively with a higher root length, weight of the root system, and aboveground part of cuttings, and also higher mean width of tissues between the xylem and cortex, a greater diameter of early- and late-wood vessels, and wider phloem and cortex layers. In the case of the percentage of cuttings with a callus only, higher results were obtained when the root length, weight of the root system of cuttings, width of

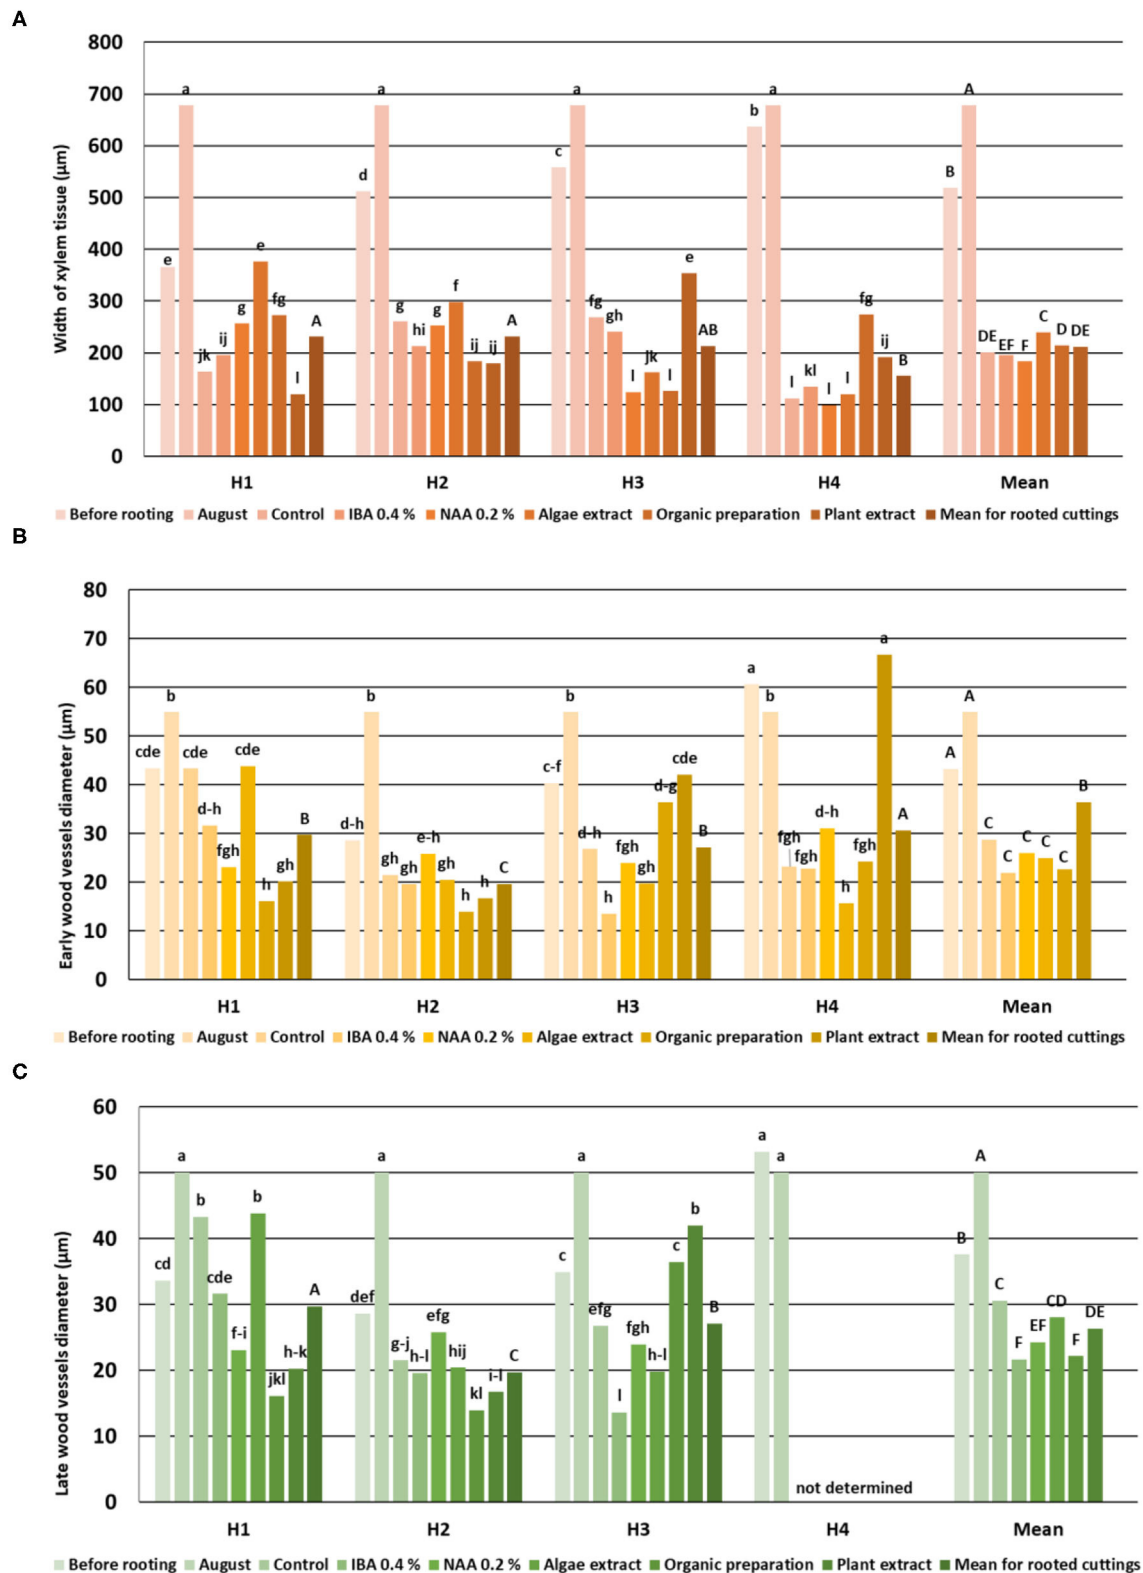

FIGURE 4 | Width of *Rosa* “Hurdal” xylem tissue (A), early- (B), and late-wood (C) vessels in stems before rooting, cuttings after 24 days of the rhizogenesis process and in stems of stock plants cut in the first days of August. Control—the control cuttings; IBA 0.4%—Ukorzeniacz A_{aqua} (0.4% IBA); NAA, 0.2%—Ukorzeniacz B_{aqua} (0.2% NAA); Algae extract—watering with 0.6% Bio Rhizotonic (10 ml) after planting and 10 and 20 days later; Organic preparation—watering with 0.4% Root Juice™ (Continued)

FIGURE 4 | (10 ml) after planting; Plant extract—watering with 0.02% Bio Roots (10 ml) after planting. H1—54 504 (flower buds still closed); H2—69 605 (full flowering; at least 50% of flowers open); H3—69 629 (end of flowering of the second-order stem—all petals have fallen); H4—70 701 [fruit set: beginning of hip (berry) growth on the main stem]. Different small letters indicate significant interactions between the phenological stage and treatment (two-way ANOVA). Different capital letters indicate significant differences between phenological stages. Duncan's test ($\alpha = 0.05$) was used.

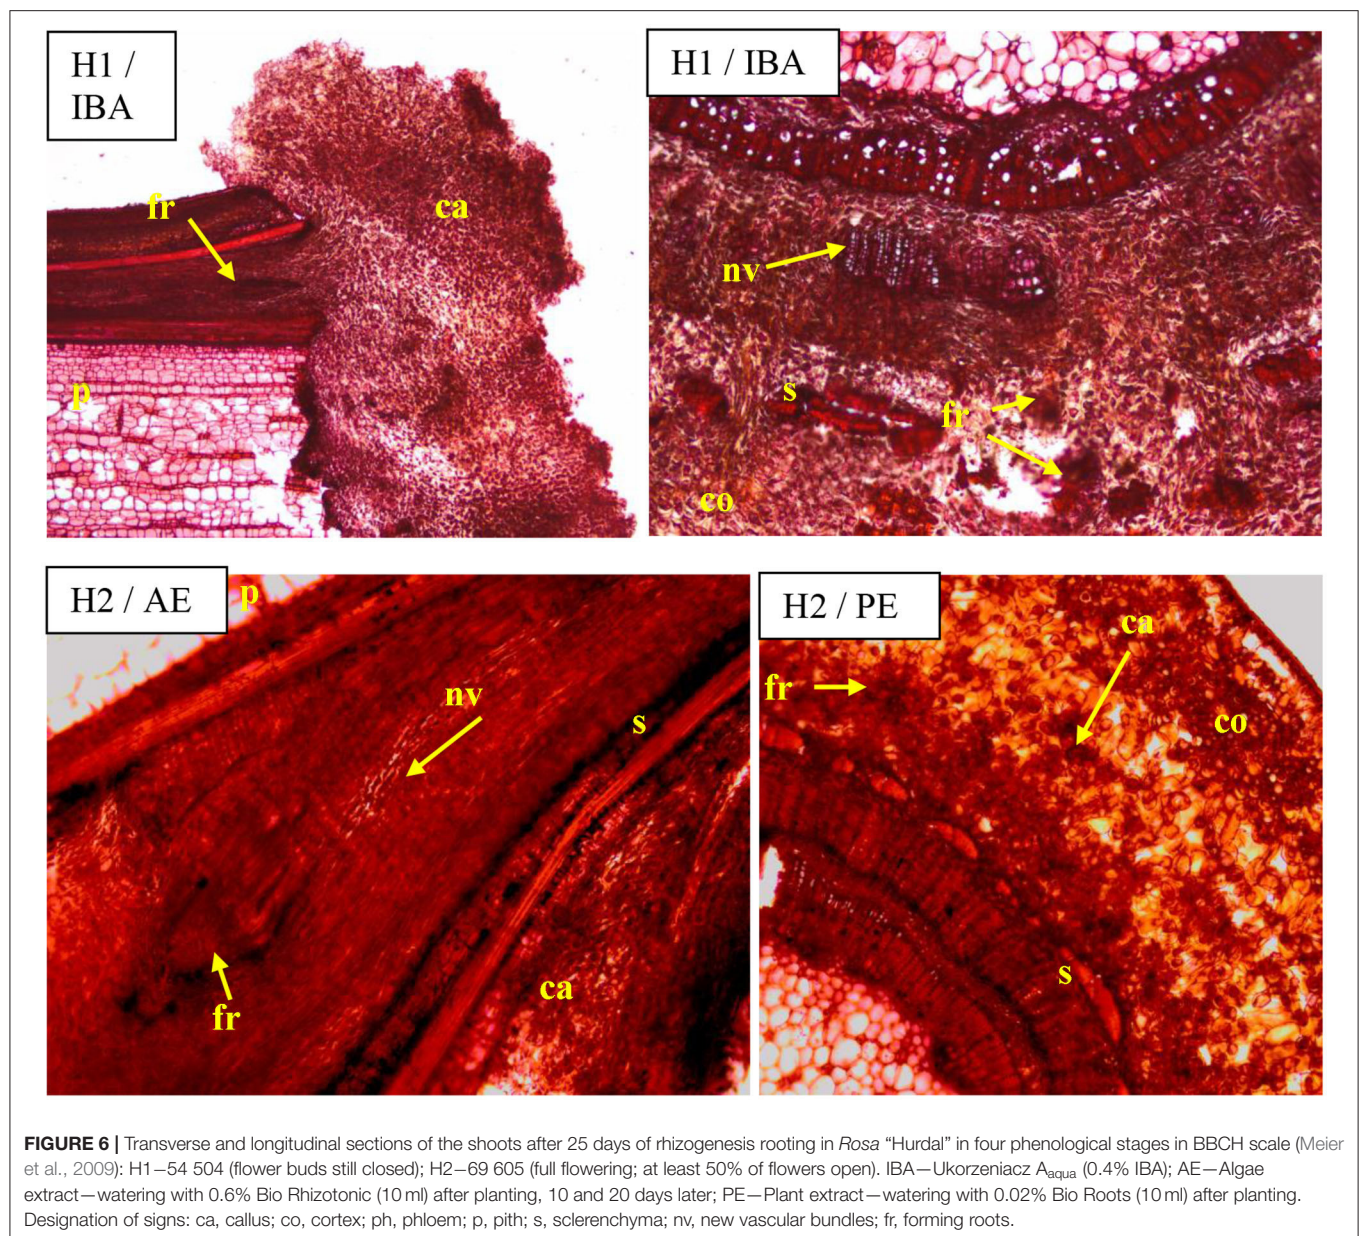

tissues between xylem and cortex, and the diameter of early- and late-wood vessels were decreased and the phloem layer was getting narrower. The increase in length root correlated with the increase in diameter of early- and late-wood vessels, and the wider phloem layer. Correlation analysis showed a positive relationship between the weight of the root system and the aboveground part of cuttings. The anatomy parameters were also interconnected (Table 2).

Correlation analysis for cuttings derived from shoots with flower bud closed H1 showed a relationship between rooting percentage and estimated parameters in subsequent treatments. A larger diameter of latewood vessels in shoots before rooting was correlated with rising rooting percentage in control cuttings, treated with Algae extract, and Organic preparation, and decreasing rooting percentage with the use of NAA and Plant extract. A higher rooting percentage correlated with increase in early- and late-wood vessel diameters in cuttings 25 days after rooting, treated with Algae extract, and Organic preparation, while decreasing these parameters and the width of phloem tissue in control cuttings. The increase in rooting percentage was correlated with an increase in the percentage of cuttings with a callus only in the control, while with a decrease in this parameter when IBA, NAA, Algae extract, and Plant extract was used. An increase in rooting percentage was connected with an increase in

fresh weight of the aboveground part and root system of cuttings after the use of Algae extract, while a decrease was associated with the use of Organic preparation. The higher rooting percentage was correlated with an increase in weight of the root system after the use of IBA and of the aboveground part in control cuttings. Moreover, the increase of rooting percentage correlated with the increase of root length in control and, after the use of all rooting enhancers, excluding Algae extract (Table 3).

The rooting percentage of H2 stage cuttings was correlated with the anatomical structure parameters of the shoots before rooting. A higher rooting percentage of control cuttings correlated with an increase in the width of xylem tissue and in the diameter of early- and late-wood vessels, but with a decrease in the width of phloem tissue in shoots before rooting cuttings. The increase in rooting percentage by the use of NAA and plant origin preparations correlated with a decrease in the width of xylem tissue in shoots before rooting. The increase in rooting percentage by the use of IBA was correlated with the increase in the diameter of early- and late-wood vessels, but a decrease in the width of phloem and cortex tissue before rooting. In the case of the use of Organic preparation and Plant extract, the increase of the width of phloem and cortex tissue and the decrease of the diameter of early- and late-wood vessels before rooting positively correlated with rooting percentage. After 25 days of

rooting, an increase in the early- and late-wood vessel diameter and a decrease in the width of phloem tissue through the use of Organic preparations were correlated with the increase of rooting percentage. Correlation analysis for H2 cuttings showed a relationship between the increase of rooting percentage and the decrease of the percentage of cuttings with a callus only in control cuttings and after the use of NAA preparation, but with the increase by the use of Organic preparation and Plant extract. An increase in rooting percentage was correlated with an increase in the fresh weight of the root system and aboveground part of the rooted cuttings in the case of control cuttings and after the use of IBA. A decrease of the weight of the root system by the use of NAA caused the rooting percentage to increase. The increase in rooting percentage was correlated

with an increase in the root length in the case of control cuttings and after the use of IBA, NAA, Algae, and Plant extract (Table 4).

In the case of cuttings derived from shoots immediately after petals had fallen (H3), correlations between rooting percentage and parameters of growth, as well as anatomical structure, were proved. Increasing rooting percentage was shown to correlate with the width of xylem tissue in shoots before rooting, where increase in the case of control cuttings and decrease in rooting enhancers were used. The larger diameter of earlywood in shoots before rooting correlated with rising rooting percentage for control cuttings and cuttings treated with Plant extract and decreasing in the case of treatment with NAA and Organic preparations. A decrease in the width of

cortex tissue in control cuttings and in the latewood vessel diameter in shoots before rooting correlated with an increase in rooting percentage for cuttings treated with IBA, NAA, and Algae extract. The increasing of width of the cortex layer in shoots before rooting was positively connected with rooting percentage where NAA, Algae extract, and Organic preparations

were used. The increasing of width of the xylem tissue, early- and late-wood diameters, and phloem tissue after 25 days of rooting was correlated with higher rooting percentage in the case of control cuttings. Moreover, the rise in the diameter of early- and latewood vessels after 25 days in cuttings treated with Algae extract and Organic preparation correlated positively with

rooting percentage. In the case of cuttings rooted with the use of a Plant extract, a correlation was found between the increase of rooting percentage and the decrease of the early- and late-wood vessel diameter and width of pith rays and cortex tissue in cuttings after 25 days of rooting. The increase of rooting percentage was strictly correlated with a decrease in percentage of cuttings with a callus only both in control cuttings and after the use of any rooting enhancer. Moreover, the increase of rooting percentage correlated with the decrease of fresh weight of the root system for the control cuttings and treated auxins, while with the increase of the weight of the aboveground parts of cuttings treated with the NAA. Additionally, the rooting percentage increased with increase in the root length in the case of control cuttings and after the use of IBA, NAA, Algae, and Plant extract (Table 5).

DISCUSSION

Changes in the seasonal cambial activity and morphophysiological status of stock plants affected the adventitious root formation of cuttings of *Artemisia arborescens* (Fascella et al., 2012), *Ficus infectoria* (Anand and Heberlein, 1975), *Juniperus* L. (Torchik, 2015), olive (Abousalim et al.,

1993), and roses (Monder et al., 2017). The different periods of delivery and rooting of cuttings suggested changes in various groups of roses (Hoşafçi et al., 2005; Pihlajaniemi et al., 2005; Monder et al., 2016).

The 1-year shoots of *R. “Hurdal”* used for cuttings in all phenological stages before and after rhizogenesis were characterized by an anatomical structure typical for woody plants of *Rosaceae* and the genus *Rosa* (Zhang, 1992). The diameters of the vessels measured by Zhang (1992) were 70–400 (mostly 114–192) μm , 40–96% solitary, round to oval, or angular, whereby the tangential diameter of earlywood vessels was 35–155 (40–250) μm and tangential latewood vessels—19–52 (15–130) μm . The means of this parameter were low for *R. “Hurdal”*. The mean diameter of the earlywood vessel before rooting depends on the phenological stage and reaches a mean from 28.66 μm in H2 to 60.59 μm in H4. The latewood vessel diameter showed a tendency to increase and reach a mean from 28.86 μm in H2 to 53.2 μm in H4. Low values of the diameter can limit the transport of water (Rosell et al., 2017), and, additionally, single-node leafy stem cuttings have limited storage capacity due to the small size of the shoot, which hinders the survival of the cuttings (Costa et al., 2007). However, the vessel diameter in woody plants is affected by many factors (Rosell et al., 2017). Moreover, the tracheids of *R. “Hurdals”* had thick walls and a very small diameter. However,

TABLE 3 | Effect correlations between percentage of rooted cuttings and measured parameters of growth and anatomical structure in *Rosa* “Hurdal” before and after 25 days of rooting cuttings derived from shoots H1, with flower buds closed (BBCH 54 504).

the callus in *Rosa Madelon*[®] had differentiated vessels that can contribute to water transport before new roots take over this function (Costa et al., 2007).

The natural reaction of a cambium to wounding caused by cutting is a callus formation at the base, both in woody (Strzelecka, 2017) and herbaceous plants (Wróblewska, 2013). The callus proliferation precedes root initiation. The proliferation of parenchyma or phloem tissue (callus) is crucial to root formation and better rooting of shoot cuttings. The new parenchyma tissue (callus) can grow rapidly through cambial meristematic activity before forming adventitious roots, as in the stem cuttings of *Rosa Madelon*[®] (Costa et al., 2007). The adventitious roots formed by *Rosa rugosa* stem cuttings are preceded by callus tissue at the cut surface of the stem base (Fouda and Schmidt, 1994). A callus can prevent the entry of pathogenic organisms at the wound (Cline and Neely, 1983), affect positively the hydration of a cutting (Scagel, 2004), and reduce susceptibility to stem rot (Howard and Harrison-Murray, 1995). However, callus overgrowth could be an unfavorable phenomenon in *R. “Hurdal,”* and result in a high percentage of cuttings with calluses only. Vessel measurement after 25 days suggested a decrease in such cuttings, probably because their tissues had been squeezed by growing callus cells; however, the vessel diameter of latewood in H4 was not determined due to the lack of unambiguous differentiation between the cells. The effects

of preparations were different and depended on the phenological stage in *R. “Hurdal”* as in *Rosa begeriana* “Polstjärnan” and *Rosa helenae* “Semiplena” (Monder et al., 2019). The IBA and NAA preparations decreased the width of xylem tissue, probably because of overgrowth of callus cells.

The shoots of *R. “Hurdals”* grew intensively up to the appearance of flower buds and harvest time for cuttings. The lignifying process of the shoots progressed and stem lignification and regular tissue arrangement were characteristics in rooted cuttings during all of the H1–H4 phases. The same observations were also visible on both once-flowering *R. “Polstjärnan”* and *R. “Semiplena”* (Monder et al., 2019).

The experiment conducted on *R. “Hurdals”* show the crucial role of the phenological stage of shoots of the stock plant in which the cuttings were prepared, both in terms of propagation and anatomical changes. The changes to anatomical structure in subsequent phenological stages of flowering before the cuttings were prepared affected the response to rooting enhancers and consequently the effectiveness of rhizogenesis.

The experiment also shows that the changes in anatomical structure before rooting cuttings affected the changes in anatomy structure in response to IBA, NAA, and plant origin preparations in the process of rhizogenesis. It suggested that the specific anatomic structure of shoots before rooting led to favorable or unfavorable changes caused by rooting enhancers, including

TABLE 4 | Effect correlations between percentage of rooted cuttings and measured parameters of growth and anatomical structure in *Rosa* “Hurdal” before and after 25 days of rooting cuttings derived from shoots H2, in full flowering; at least 50% of flowers open (BBCH 69 605).

plant origin preparations. Changes in the structure of the cambium zone, where the cells differentiate, are of particular importance. Changes to cortex tissues, where the cells of phellogen can also differentiate, are equally significant.

The overgrowth of a callus may squeeze the first ring of xylem tissue, consequently decreasing the vessel diameter and causing new irregular bundles to appear in the zone between the sclerenchyma and late-wood xylem after 25 days and new ring vascular bundles to form in 12 weeks. These phenomena were not observed either in *R. beggeriana* “Polstjärnan” or *R. helenae* “Semplena”, which had a high rooting percentage (Monder et al., 2019) compared with *R. “Hurdal.”* Callus overgrowth was not observed in both cultivars. Neither of the rooting enhancers under study (excluding the NAA preparation of *R. “Semplena”*) stimulated callus proliferation (Monder et al., 2019).

In contrast to *R. “Hurdal,”* both *R. “Polstjärnan”* and “Semplena” had a tendency for adventitious root formation along the stem, omitting its calloused basal part (Monder et al., 2019). “Hurdal” has a high tendency to an overgrowing callus, with a high percentage of cuttings developing a callus only. The use of plant origin preparations decreased the percentage of cuttings with a callus only, while the use of IBA increased it for H1 cuttings. However, none of the rooting enhancers caused an increase in the rooting ability on the internode or along the stem of *R. “Hurdal.”* The roots in “Hurdal” appeared at the base only and were obstructed by callus overgrowth. The roots of

the *Rosa* “Semplena” and “Polstjärnan” also started appearing on the basal part after the 3–4 weeks of rooting, and, later, after 6–8 weeks, they appeared in the node (“Polstjärnan”) and along the internode (“Semplena”) (Monder et al., 2019). These phenomena were not noted for the “Hurdal” rooted cuttings, and roots were observed only at the basal part of cuttings independent of rooting enhancers.

Despite the above, the research on *R. “Hurdal”* confirmed previous observations concerning *R. “Polstjärnan”* and “Semplena” (Monder et al., 2019). The adventitious roots omitted the sclerenchyma layer, which did not form the regular ring in any of the abovementioned roses (Monder et al., 2019). The role of sclerenchyma in difficulties in root formation has not been sufficiently proven. Pericyclic sclerenchyma can be correlated with difficulty in the rooting of some woody species (Beakbane, 1969); however, rooting capabilities are connected more with the natural ability to root easily, as in *Ficus pumila*, than with the presence of sclerenchyma tissue (Davies and Joiner, 1982).

Callus overgrowth was probably one of the main reasons for the low percentage of rooted cuttings *R. “Hurdals.”* The callus formation at the basal part of the shoot of cuttings is one of the first histological reactions occurring in response to wounding caused by severance in woody plant species (Costa et al., 2007, Amissah et al., 2008). The high percentage of cuttings with a callus only, calculated after 12 weeks, resulted in a high ratio

TABLE 5 | Effect correlations between percentage of rooted cuttings and measured parameters of growth and anatomical structure in *Rosa* “Hurdal” before and after 25 days of rooting cuttings derived from shoots H3, immediately after petals have fallen (BBCH 69 629).

Variable	Percentage of rooted cuttings

Marked correlations are significant at $p < 0.05$. Correlation significance: *0.08–0.29—very low; **0.30–0.49—low; ***0.50–0.69—restrained; ****0.70–0.89—high; ***** >0.90—very high.

compared with the rooting percentage in the same combination. Simultaneously, the strong growth of callus cells caused a high percentage of cuttings to develop a callus only, especially after treatments with IBA and NAA preparations and in the case of control cuttings, with a high ratio to rooted cuttings. The overgrowing callus also filled the place of the pith and broke the vascular bundles of the first ring, which were visible on cross sections after 12 weeks. The numerous callus cells may have caused compression of the first ring of wood tissue and, probably, quickly established the second ring, enabling the maintenance of wood vessel function in a changed anatomical structure. Vessels wide in diameter and wide pith rays were noted. The mean width of the pith rays for all the phenological stages of cuttings was higher for control cuttings and those treated with IBA and NAA preparations than preparations of the plant origin. In the case of H4 stage cuttings of “Hurdal,” a decrease of formation was observed in latewood. These cuttings did not root, and none of the rooting enhancers increased rooting ability.

According to previous research, the cambium has a crucial role in adventitious root formation; however, it is still not known whether new parenchyma tissues are a part of the cambium, phloem, or xylem (Fouda and Schmidt, 1994; Costa et al., 2007), also in *Rosa* “Hurdals.” Roots primordia have appeared in the cambium zone in *Rosa* “Semi-plena” and “Polstjarnan” (Monder et al., 2019). Roots in woody plants can be also formed in the

phloem and the pericycle zone (Haissig, 1974), as was observed in *R. “Hurdal”* 25 days after cutting and after 12 weeks of rooting.

In the present study, each of the rooting enhancers had a different influence on anatomy structure. These results are contrary to research on *Rhododendron ponticum*, where rooting powders with IBA and NAA did not affect anatomical changes in the structure of cuttings, or did so only slightly (Strzelecka, 2017). However, the results do confirm previous research on “Polstjarnan” and “Semi-plena.” The application of NAA preparation caused a decrease in the wood cell diameter and the width of xylem, cambium, and phloem tissue in “Polstjarnan” cuttings as well as of the wood cell diameter and width of xylem tissue in “Semi-plena.” The use of NAA, IBA, and plant origin preparations in “Semi-plena” cuttings caused phloem tissue to widen (Monder et al., 2019).

The plant origin preparations positively affected the rooting percentage of *R. “Hurdal”* as well as the quality (the weight of the root system and the aboveground part) of rooted cuttings. Moreover, by the use of the aforementioned preparations, a lower percentage of cuttings with a callus only was noted. These results have certainly indicated the possibility for use of these preparations in the rooting of “Hurdal” rose cuttings and may be recommended as alternative preparations of natural origin in the ecological propagation (91/414/EEC, 2009/128/WE; OJEU), compared to the classic synthetic stimulators. Plant

origin preparations could positively influence changes in the condition of cuttings and the content of bioactive components in roses (Monder and Pacholczak, 2018, 2019; Monder et al., 2020) due to supplementation with nutritive substances or unknown rooting cofactors and IAA-like substances present in the bio preparations (Nardi et al., 2015; Oosten et al., 2017). Most bio preparations of plant origin contain different substances similar to auxins in various concentrations (Crouch and Van Staden, 1993; Thorsen et al., 2010; Pacholczak et al., 2016).

Differential Effects of Exogenous
Glomalin-Related Soil Proteins on
Plant Growth of Trifoliolate Orange
Through Regulating Auxin Changes.
Front. Plant Sci. 12:745402.
doi: 10.3389/fpls.2021.745402

Multiple functions of glomalin released by arbuscular mycorrhizal fungi are well-recognized, whereas the role of exogenous glomalins including easily extractable glomalin-related soil protein (EE-GRSP) and difficultly extractable glomalin-related soil protein (DE-GRSP) is unexplored for plant responses. Our study was carried out to assess the effects of exogenous EE-GRSP and DE-GRSP at varying strengths on plant growth and chlorophyll concentration of trifoliolate orange (*Poncirus trifoliata*) seedlings, along with changes in root nutrient acquisition, auxin content, auxin-related enzyme and transporter protein gene expression, and element contents of purified GRSP. Sixteen weeks later, exogenous GRSP displayed differential effects on plant growth (height, stem diameter, leaf number, and biomass production): the increase by EE-GRSP and the decrease by DE-GRSP. The best positive effect on plant growth occurred at exogenous EE-GRSP at $\frac{1}{2}$ strength. Similarly, the GRSP application also differently affected total chlorophyll content, root morphology (total length, surface area, and volume), and root N, P, and K content: positive effect by EE-GRSP and negative effect by DE-GRSP. Exogenous EE-GRSP accumulated more indoleacetic acid (IAA) in roots, which was associated with the upregulated expression of root auxin synthetic enzyme genes (*PtTAA1*, *PtYUC3*, and *PtYUC4*) and auxin influx transporter protein genes (*PtLAX1*, *PtLAX2*, and *PtLAX3*). On the other hand, exogenous DE-GRSP inhibited root IAA and indolebutyric acid (IBA) content, associated with the downregulated expression of root *PtTAA1*, *PtLAX1*, and *PtLAX3*. Root IAA positively correlated with root *PtTAA1*, *PtYUC3*, *PtYUC4*, *PtLAX1*, and *PtLAX3* expression. Purified EE-GRSP and DE-GRSP showed similar element composition but varied in part element (C, O, P, Ca, Cu, Mn, Zn, Fe, and Mo) concentration. It concluded that exogenous GRSP triggered differential effects on growth response, and the effect was associated with the element content of pure GRSP and the change in auxins and root morphology. EE-GRSP displays a promise as a plant growth biostimulant in citriculture.

Keywords: auxin, carrier protein, citrus, glomalin, mycorrhiza, IAA, transporter protein

INTRODUCTION

Arbuscular mycorrhizal fungi (AMF) in the soil are extensively reported to colonize the roots of roughly 80% of terrestrial plants, forming arbuscular mycorrhizas (AMs). AMs help the host plant to absorb water and nutrients, whereas the host delivers the photoassimilates to the mycorrhizal fungi in the root for their growth (Huang et al., 2021a). Such mycorrhizal symbiosis represents important functions on promoting plant growth, improving stress resistance, enriching rhizospheric microbial diversity, and stabilizing ecosystems (Zhao et al., 2015; Wang et al., 2018). Spores and mycelium of AMF release an N-linked glycoprotein (glomalin) into the soil, popularly known as glomalin-related soil protein (GRSP) according to the Bradford assay (Rillig, 2004; Rillig and Mummey, 2010). GRSP is primarily divided into two fractions, viz., easily extractable GRSP (EE-GRSP) and difficultly extractable GRSP (DE-GRSP) (Koide and Peoples, 2013; Wu et al., 2014). EE-GRSP is considered to be newly produced by AMF and relatively more labile, whereas DE-GRSP originates from the turnover of EE-GRSP and thus represents a comparatively older glomalin of an inactive nature (Koide and Peoples, 2013; Wu et al., 2015a). Earlier studies indicated that GRSP promoted the storage of soil organic carbon (SOC), improved the distribution and stability of soil water-stable aggregate (WSA), enhanced the drought tolerance of plants, and reduced the metal toxicity of soil (Zou et al., 2014; Gao et al., 2019; He et al., 2020; Meng et al., 2020). The direct contribution of GRSP on WSA stability was much stronger than mycorrhizal extraradical hyphae or root mycorrhizal colonization (Rillig et al., 2001; Wu et al., 2014).

Studies have shown that GRSP was composed of 3–5% N, 36–59% C, 4–6% H, 33–49% O, 0.03–0.1% P, 0.8–8.8% Fe, and other cations (e.g., K, Ca, Si, Cu, and Mg), depending upon soil properties (Rillig et al., 2001; Lovelock et al., 2004; Nichols, 2008; Zhang et al., 2017a). Schindler et al. (2007) observed that the GRSP of peat soil contained aromatic hydrocarbons (42–49%), carboxyl groups (24–30%), and carbohydrates (4–16%) evident from the analysis of nuclear magnetic resonance (NMR). GRSP is, thus, a mixture, rich in various elements, essential to plant growth and development. Based on the mineral elements in GRSP, it is reasonable to hypothesize that GRSP as a biostimulant potentially improves plant growth responses. To confirm this hypothesis, Wang et al. (2015) firstly observed that the concentration of exogenous EE-GRSP was curvilinearly related with plant biomass yield in potted trifoliate orange (*Poncirus trifoliata* L. Raf.), with $\frac{1}{2}$ strength of EE-GRSP exhibiting the highest magnitude of growth responses. Wu et al. (2015b) through a field study proved that exogenous EE-GRSP treatment produced a significant increase in SOC and soil phosphatase activity in 27-year-old Satsuma mandarin grafted on trifoliate orange. Chi et al. (2018) reported that $\frac{1}{2}$ strength of exogenous EE-GRSP improved leaf gas exchange, iron-superoxide dismutase activity, abscisic acid, indole-acetic acid (IAA), and methyl jasmonate concentrations in leaves of potted trifoliate orange seedlings exposed to soil drought stress. These studies demonstrated the ability of exogenous EE-GRSP in improving plant growth response (Zou et al., 2015).

Although these experiments have shown an improved effect of exogenous EE-GRSP on plants, the underlying mechanisms remain still unclear. It is also unknown whether DE-GRSP, another fraction of GRSP, has a similar beneficial response on plant growth. Therefore, the present work aimed at evaluating the response of exogenous EE-GRSP and DE-GRSP at varying strengths on the growth of trifoliate orange seedlings, and at revealing the mechanism of GRSP affecting plant growth by analyzing the changes of auxins, gene expression, and mineral elements of purified GRSP fractions.

MATERIALS AND METHODS

Preparation of Exogenous EE-GRSP and DE-GRSP

Soil samples were collected from a citrus orchard (located at the campus of Yangtze University), air-dried, sieved through 4-mm nylon, incubated with 20 mmol/L citrate buffer (pH 7.0) (m:v = 1:8) at 121°C and 0.11 MPa for 30 min and centrifuged at $10,000 \times g$ /min for 5 min. The supernatant was collected as an exogenous full-strength EE-GRSP solution. The residues of EE-GRSP extraction in the centrifugal tube was continued to incubate with the same volume of 50 mmol/L sodium citrate buffer (pH 8.0) at 121°C and 0.11 MPa for 60 min, and centrifuged at $10,000 \times g$ /min for 10 min (Wu et al., 2015a). The second supernatant was collected as a full-strength DE-GRSP solution. The soluble protein concentration was 0.24 and 0.36 mg/L in full-strength EE-GRSP and DE-GRSP solution, as put forward by the Bradford (1976) assay. A total of about 12 L of full-strength EE-GRSP and DE-GRSP solution were collected, respectively, along with 1.5 kg of the soil used.

Experimental Design

In a completely randomized design, the experiment consisted of seven treatments: (i) control with 20 mmol/L citrate buffer (pH 7.0) (0 GRSP), (ii) quarter-strength EE-GRSP ($\frac{1}{4}$ EE-GRSP), (iii) half-strength EE-GRSP ($\frac{1}{2}$ EE-GRSP), (iv) full-strength EE-GRSP (1 EE-GRSP), (v) quarter-strength DE-GRSP ($\frac{1}{4}$ DE-GRSP), (vi) half-strength DE-GRSP ($\frac{1}{2}$ DE-GRSP), and (vii) full-strength DE-GRSP (1 DE-GRSP). The $\frac{1}{2}$ and $\frac{1}{4}$ EE-GRSP was diluted with the full-strength EE-GRSP with 20 mmol/L citrate buffers (pH 7.0), and the $\frac{1}{2}$ and $\frac{1}{4}$ DE-GRSP was prepared using the full-strength DE-GRSP by diluting with 50 mmol/L citrate buffers (pH 8.0). Each treatment was replicated four times, and each replicate consisted of two pots, resulting in a total of 56 pots (corresponding to 168 seedlings).

Plant Setup

Three four-leaf-old trifoliate orange seedlings grown in autoclaved sand were transplanted into a plastic pot (2.1-L), in which 1.6 kg of autoclaved (121°C, 0.11 MPa, 2 h) soil sieved with 4-mm-size nylon was supplied. After 2 weeks of plant acclimatization, exogenous GRSP treatments were initiated. A 50 ml of exogenous EE-GRSP or DE-GRSP solution as per the proposed strength was applied into the corresponding pot at weekly intervals, for a total of 16 times. The experiment was carried out in an intelligent artificial climate chamber (AGC-P,

Zhejiang QiuShi Artificial Environment Co., Ltd., Hangzhou, China) from March 22 to July 21, 2018, where the photon? ux density was 900 $\mu\text{mol}/\text{m}^2/\text{s}$, day/night temperature 28/20°C, and relative air humidity 68% during the experiment.

Determination of Plant Growth and Chlorophyll Concentrations

Plant height, stem diameter, and leaf number were recorded before harvest. The seedlings were divided into shoots and roots. The intact roots were scanned using the Epson Perfection V700 Photo Dual Lens System (J221A, Seiko Epson Corporation, Jakarta Selatan, Indonesia). The scanned root images were analyzed using the WinRHIZO software (Regent Instruments Inc., Montreal, QC, Canada) to obtain root morphological variables including total length, surface area, and volume. Subsequently, shoot and root biomass was weighed after drying at 75°C for 48 h. The total chlorophyll concentration was determined by the procedure suggested by Arnon (1949).

Determination of Root Nutrient Acquisition

Root samples were digested in H_2SO_4 and H_2O_2 . Subsequently, N content was determined by a chemical analyzer (Smartchem 200, Scientific Instruments Limited, Weston, FL, USA), and other mineral elements were assayed with the help of the ICP-Spectrometer (IRIS Advantage, Thermo Fisher Scientific Inc., Waltham, MA, USA).

Determination of Root Auxins

Root IAA and indolebutyric acid (IBA) were extracted according to the method outlined by Dobrev and Kamínek (2002) with minor modification. The 0.2 g of root samples was ground in liquid nitrogen, extracted by adding 1 ml of pre-cooled extracting solution (methanol, distilled water, and formic acid, 15/4/1, v/v/v) for 12 h at 4°C, and centrifuged at $8,000 \times g/\text{min}$ for 10 min. The centrifuged residue was re-extracted with 0.5 ml of the extracting solution for 2 h at 4°C. After centrifugation, two supernatants were combined, evaporated at 40°C under reduced pressure to near dryness (~0.5 ml), and decolorized three times with 0.5 ml of petroleum ether. After discarding the upper ether phase, the down phase was evaporated to the dryness at 40°C under reduced pressure, and 0.5-ml mobile phase (methanol and ddH_2O in a ratio of 2:3) was added to dissolve. The content of IAA and IBA was determined with the help of high-performance liquid chromatography (HPLC; LC-100, Shanghai Wufeng Scientific Instrument Co., Ltd., Shanghai, China). The injection volume was 10 μl , the flow rate was 0.8 ml/min, the column temperature was 35°C, the sampling time was 40 min, and the detection wavelength was 254 nm.

Expression Levels of Genes Associated With IAA

The extraction of total RNA from the roots and the reverse transcription of RNA were carried out according to the protocol previously described by Liu et al. (2018a). Four genes associated with IAA synthesis (*PtTAA1*, *PtTAR2*, *PtYUC3*, and *PtYUC4*) and four influx transporter protein genes of auxins (*PtAUX1*, *PtLAX1*, *PtLAX2*, and *PtLAX3*) were associated with

the IAA synthesis and transport in trifoliolate orange (Liu et al., 2018b) and selected according to the genome database of trifoliolate orange (<http://citrus.hzau.edu.cn/orange/index.php>) (Huang et al., 2021b). The primers (Table 1) of these selected genes were designed with Primer 5. The β -actin was used as the housekeeping gene. The quantitative reverse transcription (qRT)-PCR was carried out using the conditions described by Liu et al. (2018a). The relative quantitative expression of genes was calculated by the $2^{-\Delta\Delta\text{CT}}$ method as suggested by Livak and Schmittgen (2001).

Determination of Nutrient Elements in Purified EE-GRSP and DE-GRSP

We chose to purify the full-strength GRSP solution in order to study the difference in nutrient composition between exogenous EE-GRSP and DE-GRSP. The purification of EE-GRSP and DE-GRSP was performed according to the method described by He et al. (2020). The extracted full-strength GRSP solution was precipitated with HCl solution, dissolved with NaOH solution, dialyzed in a dialysis bag (MD 44-1000) with ddH_2O , centrifuged at $5,000 \times g/\text{min}$ for 5 min, and then freeze-dried. The nutrient elements, viz., C, H, O, S, and N contents of purified EE-GRSP and DE-GRSP, were analyzed by the Automatic Element Analyzer (Euro Vector EA3000, Shanghai Woolong Instrument Co., Ltd, Shanghai, China), whereas other elements were determined as per the ICP-Spectrometer (Optima 8000, PerkinElmer, Melville, NY, USA).

Statistical Analysis

The generated data were statistically analyzed by ANOVA through the SAS software (v8.1; SAS Institute Inc., Cary, NC, USA). The significant difference between treatments was compared with Duncan's multiple range test at 0.05 levels. Pearson's correlation coefficient was calculated with the help of the SAS software.

RESULTS

Changes in Growth Performance

Compared with the control (0 GRSP), exogenous EE-GRSP significantly increased plant height, leaf number, stem diameter, and shoot and root biomass of trifoliolate orange seedlings, with 1/2 EE-GRSP treatment having the most significant effect, increasing 17, 19, 22, 52, and 38%, respectively (Figure 1 and Table 2). By contrast, the growth response of DE-GRSP treatment was completely different from that of exogenous EE-GRSP, resulting in a significant inhibition in these plant growth parameters. The inhibiting effect of DE-GRSP on growth increased with the increase of DE-GRSP concentrations. Compared with 0 GRSP, 1 DE-GRSP significantly reduced plant height, leaf number, stem diameter, and shoot and root biomass by 61, 52, 50, 71, and 41%, respectively.

Changes in Chlorophyll Concentration

Application of exogenous EE-GRSP significantly increased leaf total chlorophyll concentration, independent of the concentrations, with 1/2 EE-GRSP treatment displaying the

Gene accession number is from the genome database of trifoliate orange.

FIGURE 1 | Growth performance of trifoliate orange by exogenous EE-GRSP and DE-GRSP at varying strength. DE-GRSP, difficultly extractable glomalin-related soil protein; EE-GRSP, easily extractable glomalin-related soil protein.

highest magnitude of response (**Figure 2**). Nevertheless, all the DE-GRSP treatments significantly reduced total chlorophyll concentration compared with 0 GRSP treatment. In a regression analysis between chlorophyll concentration and EE-GRSP and DE-GRSP concentration, a quadratic relationship was observed with exogenous EE-GRSP treatments, showing the highest total chlorophyll concentration occurring between 0.012 and 0.018 mg protein/ml (**Figure 3A**). And with exogenous DE-GRSP treatment conditions, total chlorophyll concentration was negatively and linearly correlated with DE-GRSP concentration (**Figure 3B**).

Changes in Root Mineral Element Contents

Application of exogenous GRSP influenced the root nutrient acquisition to varying proportions. Compared with the control (0 GRSP), $\frac{1}{4}$ EE-GRSP treatment significantly increased root N, P, K, Ca, Mg, Zn, and Fe content by 7, 43, 42, 342, 8, 32, and 5%, respectively; $\frac{1}{2}$ EE-GRSP treatment dramatically increased root N, P, K, Ca, Mg, Cu, and Fe content by 21, 23, 60, 314, 84, 50, and 12%, respectively; 1 EE-GRSP significantly increased root N, P, K, and Zn content by 12, 84, 12, and 35%, respectively (**Table 3**). However, compared with 0 GRSP, $\frac{1}{4}$ DE-GRSP treatment significantly reduced root N, P, K, Mg, Cu, Zn, and Fe content by 22, 31, 23, 17, 27, 22, and 78%, respectively; $\frac{1}{2}$ DE-GRSP decreased root N, P, K, Mg, Cu, Zn, and Fe content

by 21, 15, 34, 19, 3, 32, and 70%, respectively; and 1 DE-GRSP treatment reduced root N, P, K, Mg, Cu, Zn, and Fe content by 20, 29, 31, 25, 46, 32, and 59%, respectively. However, EE-GRSP and DE-GRSP displayed no significant effect on root Mn content.

Changes in Root Morphology

Compared with the control, $\frac{1}{4}$ EE-GRSP treatment had no significant effect on root total length, root surface area, and root volume, whereas $\frac{1}{2}$ EE-GRSP treatment significantly increased root total length, surface area, and volume by 25, 35, and 43%, respectively (**Figures 4A–C**). Application of 1 EE-GRSP distinctly increased root total length and surface area by 27 and 17%, respectively, with no significant effect on root volume. Exogenous application of DE-GRSP, however, almost significantly decreased root total length, surface area, and volume compared to the control, with increasing DE-GRSP strength, except that there was no difference in root volume between $\frac{1}{4}$ DE-GRSP and the control.

Changes in Element Composition of Purified GRSP

From the purified EE-GRSP and DE-GRSP, we collectively detected C, H, O, N, P, K, Ca, Mg, Cu, Al, Mn, Mo, Zn, and Fe, and some elements were below a detection concentration (**Figures 5A–C**). A significant difference in element content

Data (mean ± SD, $n = 4$) followed by the different letters among treatments indicate significant differences at $p < 0.05$.

DE-GRSP, difficultly extractable glomalin-related soil protein; EE-GRSP, easily extractable glomalin-related soil protein.

FIGURE 2 | Effects of exogenous EE-GRSP and DE-GRSP on total chlorophyll concentration in leaves of trifoliate orange seedlings. Data (mean ± SD, $n = 4$) followed by different letters above the bars indicate significant differences ($p < 0.05$). DE-GRSP: difficultly extractable glomalin-related soil protein; EE-GRSP: easily extractable glomalin-related soil protein.

between purified EE-GRSP and purified DE-GRSP was observed. H, N, K, Al, and Mg content were not significantly different between two GRSP fractions. Purified DE-GRSP showed higher C, Ca, Cu, Mn, Zn, and Fe content than purified EE-GRSP by 52, 41, 43, 45, 38, and 55%, respectively. Purified EE-GRSP, however, had 9, 40, and 334% significantly higher O, P, and Mo content, respectively, than purified DE-GRSP.

Changes in Root Auxins

Compared with the control treatment, ¼ EE-GRSP treatment significantly reduced root IAA and IBA content by 25 and 23%, respectively (Figure 6); ½ EE-GRSP treatment registered an increase in root IAA and IBA content by 121 and 87%, respectively; and 1 EE-GRSP treatment recorded the increase in root IAA content by 40%, but decreased root IBA content by 10%. On the other hand, exogenous DE-GRSP application showed a decreasing trend on root IAA and IBA content. Compared

with 0 GRSP treatment, ¼ DE-GRSP, ½ DE-GRSP, and 1 DE-GRSP treatment reduced root IAA content by 51, 40, and 33%, respectively, with the corresponding reduction in root IBA content by 52, 41, and 30%, respectively.

Changes in Expression of Root Genes Associated With Auxin Synthesis

Compared with the control, root *PtTAA1* expression was induced by exogenous ¼ EE-GRSP and ½ EE-GRSP, whereas it was inhibited by exogenous DE-GRSP with full strength (Figure 7A). Root *PtTAR2* expression was not affected by exogenous EE-GRSP, whereas it was downregulated by ¼ and 1 DE-GRSP application, accompanied by upregulated expression of *PtTAR2* by ½ DE-GRSP (Figure 7B). The *PtYUC3* expression was upregulated by exogenous EE-GRSP, along with increased expression with an increase in the concentration of EE-GRSP, but the *PtYUC3* expression remained unaffected by exogenous DE-GRSP, independent of its concentration (Figure 7C). The *PtYUC4* expression was increased by exogenous ¼ EE-GRSP but inhibited by ¼ DE-GRSP (Figure 7D).

Changes in Expression Levels of Root Auxin Influx Transporter Protein Genes

Application of ¼ and ½ EE-GRSP treatment upregulated *PtLAX1* and *PtLAX2* expression, coupled with downregulated expression of *PtLAX1* with ¼ DE-GRSP and *PtLAX2* with 1 DE-GRSP, compared with the control (Figures 7E,F). Root *PtLAX3* expression was increased by ½ EE-GRSP while reduced by ½ DE-GRSP (Figure 7G). Root *PtAUX1* expression was induced by 1 DE-GRSP, whereas inhibited by ¼ and ½ DE-GRSP (Figure 7H).

Correlation Between Root IAA Concentration and Gene Expression Levels

Root IAA was significantly and positively correlation with *PtTAA1* ($p < 0.01$), *PtYUC3* ($p < 0.01$), *PtYUC4* ($p < 0.05$), *PtLAX1* ($p < 0.01$), and *PtLAX3* ($p < 0.01$), respectively (Table 4). However, there was no any significant correlation of root IAA with *PtTAR2*, *PtLAX2*, and *PtAUX1*.

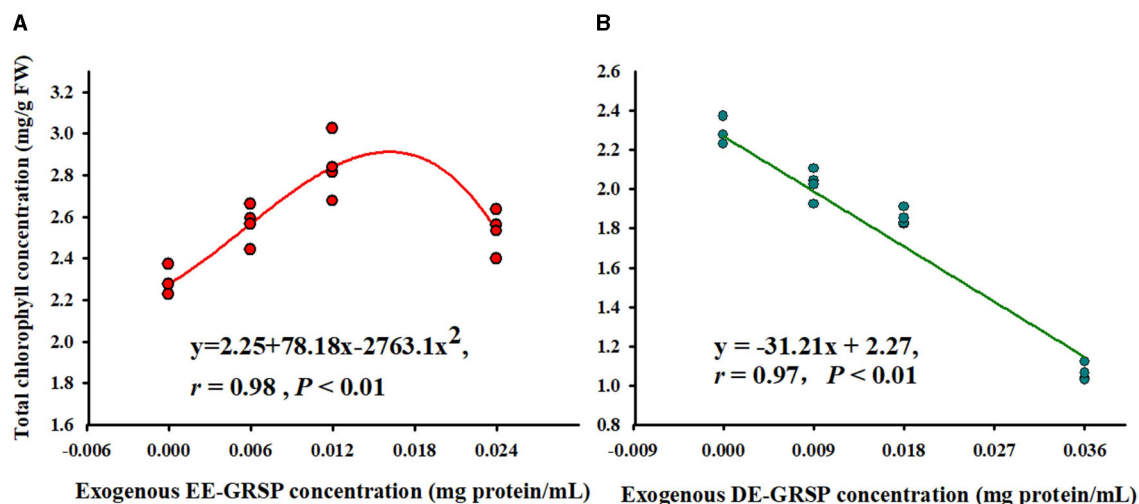

FIGURE 3 | Correlation between exogenous EE-GRSP (**A**) and exogenous DE-GRSP (**B**) and total chlorophyll concentration ($n = 16$). DE-GRSP, difficultly extractable glomalin-related soil protein; EE-GRSP, easily extractable glomalin-related soil protein.

DISCUSSION

In this study, we firstly observed a difference in plant growth response of trifoliate orange with exogenous application of

two GRSP fractions. Exogenous EE-GRSP strongly promoted plant growth, whereas exogenous DE-GRSP distinctly inhibited plant growth. Such results provide important clues in favor of EE-GRSP functioning as a growth promoter of trifoliate

orange. The increase in plant growth response to EE-GRSP treatments was consistent with the findings of Wang et al. (2015). It is well-known that GRSP contained an amount of humic acid (Gadkar and Rillig, 2006), similar to NMR spectrum-based humic acid (Schindler et al., 2007). Humic acid as an important component of humic substance, a part of natural organic matter, could improve the growth performance of various plants (Spohn and Giani, 2010; Mora et al., 2012; Xu et al., 2012; Duan, 2014; Dong et al., 2016). It is believed that EE-GRSP having a parallel NMR spectrum-based humic acid-like substance, functions in increasing plant growth. On the other hand, plant height, stem diameter, leaf number, and biomass production decreased significantly after the application of DE-GRSP, and the inhibitory effect increased with the increase of exogenous DE-GRSP concentration. Perhaps DE-GRSP contains some impurities (Gillespie et al., 2011) that are detrimental to plant growth, but it is not clear about the nature of those

impurities responsible for such undesirable plant responses. EE-GRSP, an active form of newly produced glomalin, and DE-GRSP, a recalcitrant and older glomalin (Wu et al., 2015a), also contribute primarily toward difference in magnitude of plant response. More studies have to be conducted to analyze the difference in molecular structure and relevant properties between EE-GRSP and DE-GRSP.

In the present study, leaf total chlorophyll content was differentially affected by EE-GRSP and DE-GRSP. Exogenous EE-GRSP significantly increased total chlorophyll content, and the most significant effect was observed with $\frac{1}{2}$ EE-GRSP. In contrast, exogenous DE-GRSP caused a significant decrease in total chlorophyll content. Our study also revealed that GRSP contained many mineral elements, such as Fe and Mg, which are part of chlorophyll (Schindler et al., 2007). In addition, EE-GRSP as a heat-shock protein-like substance could keep the stability of PSII complexes and thylakoid membrane, which plays

FIGURE 7 | Effects of exogenous EE-GRSP and DE-GRSP on relative expression levels of auxin synthetase genes (A–D) and transporter protein genes (E–H) in roots of trifoliate orange seedlings. Data (mean \pm SD, $n = 4$) followed by different letters above the bars indicate significant differences ($p < 0.05$). DE-GRSP, difficultly extractable glomalin-related soil protein; EE-GRSP, easily extractable glomalin-related soil protein.

an important role in chlorophyll functioning. Chi et al. (2018) proposed that EE-GRSP as a molecular chaperone improved plant photosynthetic efficiency. On the contrary, DE-GRSP is an inert substance recalcitrant in the soil, which possibly induced a disadvantageous influence on chlorophyll production. The content of Fe in purified DE-GRSP was significantly higher than that in purified EE-GRSP. Nevertheless, it still showed that exogenous DE-GRSP inhibited the chlorophyll content, hinting toward another unknown mechanism to be perused as future research.

We investigated the elemental composition alongside their concentrations of purified GRSP, revealing the presence of as many 14 elements, of which P, K, Mo, and O were higher in purified EE-GRSP than in purified DE-GRSP. Other nutrients, viz., C, Ca, Cu, Mn, Zn, and Fe, displayed higher concentrations in purified DE-GRSP than in purified EE-GRSP. The variation in element contents of two GRSP fractions constituted different organic substances (e.g., tyrosine, tryptophan, fulvic acid, humic acid, nitrobenzoxadiazole, and calcofluor) (Zhang et al., 2017b), thus presenting such contrasting growth responses.

TABLE 4 | The Pearson's correlation coefficient between root IAA and expressions of auxin synthetase genes and carrier genes ($n = 28$).

	Genes associated with auxin synthesis				Auxin influx carrier genes

The root nutrient acquisition of trifoliate orange was differentially regulated by exogenous GRSP: an increase in N, P, K, Ca, and Fe under EE-GRSP application conditions and a reduction in N, P, K, Mg, Cu, Zn, and Fe under DE-GRSP application conditions. As reported by Chi et al. (2018), $\frac{1}{2}$ EE-GRSP improved the morphological establishment of trifoliate orange roots under normal water and drought stress. Exogenous EE-GRSP also improved soil aggregate stability and soil enzyme activity (Wang et al., 2015), both of which are beneficial to plant growth and nutrient acquisition. Root Fe was elevated by exogenous EE-GRSP, amounting to 1.8–4.9%, and inhibited by exogenous DE-GRSP, amounting to 59.1–77.9%. However, purified DE-GRSP possessed 55% higher Fe than purified EE-GRSP, gluing more Fe into an organic state to render Fe into inaccessible form to be absorbed by plant roots. Our study also showed that EE-GRSP-applied plants maintained a relatively higher root total length, surface area, and volume than the control plants, with $\frac{1}{2}$ EE-GRSP presenting the best effect. However, DE-GRSP dramatically inhibited the root morphology, and the root morphology declined with the increasing concentration of DE-GRSP. The changed trend of root morphology was surprisingly consistent with the plant growth performance and chlorophyll changes triggered by GRSP application. As a result, it was concluded that changes in plant growth response and root nutrient acquisition under GRSP application are associated with root morphology triggered after GRSP application.

Plant growth response is closely linked to endogenous auxins (Zheng et al., 2013; Chen et al., 2016). In the present study, exogenous $\frac{1}{2}$ and 1 EE-GRSP significantly increased root IAA and IBA contents, due to the presence of tryptophan (the precursor of auxins) in purified EE-GRSP (Zhang et al., 2017b), accelerating the synthesis of auxins. Chi et al. (2018) also observed an increase of IAA in trifoliate orange under soil water deficit conditions, following the application of exogenous EE-GRSP. However, exogenous application of DE-GRSP deteriorated the soil environment for roots to absorb nutrients (Zhang, 2009), thus hampering the bidirectional transport of IAA in the phloem.

The synthesis of IAA in plants starts with the conversion of L-tryptophan into 3-indole pyruvic acid (IPyA) in the presence of tryptophan transcarbamylase (tryptophan aminotransferase related, TAA1/TAR), which is then converted into IAA under the influence of flavin monooxygenase-like enzymes (YUCs) (Brumos et al., 2014). In the present study, exogenous application of EE-GRSP induced root *PtTAA1*, *PtYUC3*, and *PtYUC4* expression, depending upon the concentration of EE-GRSP used, whereas exogenous DE-GRSP inhibited the relative expression

of *PtTAA1* and *PtYUC4*. The GRSP-regulated IAA change was related to the expression of GRSP-induced auxin-related synthase genes (*PtTAA1*, *PtYUC3*, and *PtYUC4*), based on the correlation analysis. TAA is involved in the conversion of tryptophan into IpyA, and then YUCs convert IpyA into IAA (Brumos et al., 2014). It indicates that the two processes were regulated by exogenous GRSP. Indeed, the IAA synthesis process is regulated by various transcription factors, such as the phytochrome-interacting factor 4 (*PIF4*) for direct regulation of *TAA1* gene expression and the *PIF7* for regulation of *YUCs* (Li et al., 2012; Sun et al., 2012), implying that exogenous GRSP regulated *PIF* transcription factors to modulate the expression of *TAA* and *YUCs*. However, the evidence of direct involvement is lacking in our study, and further research is needed in this direction.

In plants, IAA enters into cells in the form of anion under the influence of endocytosis carrier genes (Delbarre et al., 1996). *Auxin residue 1/like AUX1 (Aux/LAX)* genes play an important role in auxin influx (Yoshihiro and Keiichi, 2012). The results of our study showed that the application of exogenous EE-GRSP with quarter and half strength upregulated the expression of *PtLAX1* and *PtLAX2* and did not affect the expression of *PtAUX1*, suggesting *LAX* genes could be induced by EE-GRSP. However, exogenous DE-GRSP, to some extent, decreased the expression of *PtLAX* genes, dependent on the combination of DE-GRSP concentration and gene species, likely to reduce the flow of IAA from shoot parts to roots. A positive correlation of root IAA with *PtLAX1* and *PtLAX3* suggested the stimulating effect of GRSP on the expression of IAA influx carrier genes. The *AtLAX1* in *Arabidopsis thaliana* was expressed in the vascular system of the primary root maturation zone but weakly expressed at the root tip (Peret et al., 2012). The expression of *AtLAX3* at the cortex of the newly lateral root primordia mediated auxin transport during lateral root primordia development, making the formation and development of lateral roots easier (Swarup et al., 2008). Higher expression of *PtLAX1* and *PtLAX3* in EE-GRSP-treated plants indicated better polar auxin transport and lateral root formation, as seen in greater root morphology in EE-GRSP-treated plants. Such results also showed that the change of root IAA in response to the GRSP application is associated with regulation of IAA in polar transport from shoots to roots, besides aiding in the formation of lateral roots.

CONCLUSION

Exogenous GRSP triggered differential effects on plant growth response of trifoliate orange: the increase by exogenous EE-GRSP and the reduction by exogenous DE-GRSP. The change in

plant growth under GRSP application conditions was associated with the element content of pure GRSP, the auxin content of the plant, and root morphology. GRSP-regulated IAA changes were associated with the GRSP regulation of *TAA* and *YUC* gene expression in the IAA synthesis pathway and polarity transport of IAA. These results provide the future possibility of using EE-GRSP as a plant growth promoter for citrus production. However, more field studies coupled with elaboration on the physiological basis of GRSP functioning and mechanism of growth response by GRSP are mandatory before such efforts become an accepted field practice as a technological novelty.

Space availability and the maintenance of adequate phosphorus (P) supply in the root zone are essential for achieving high yield and P-use efficiency in maize production by manipulating the root morphology and arbuscular mycorrhizal (AM) fungi colonization. A major trade-off exists between root growth and AM colonization that is influenced by soil P supply intensity and space availability. However, how soil P manipulates the root morphological characteristics and AM colonization to compensate for the limitation of root-growth space induced by high-planting density is not clear. Therefore, pot experiments were conducted to investigate interactions between the root growth and AM fungi by optimizing soil P supply to compensate for limited root growth space induced by high-planting density. Similar shoot biomass and P uptake values were obtained in P200 (200 mg P kg⁻¹ soil) under D = 40 (i.e., diameter of the pot is 40 cm) and P400 under D = 30, and similar values were obtained for root length, tap root length, root angle, lateral root density, and AM colonization. However, the improvement in P supply in the root zone, shoot biomass, and P uptake in P400 under D = 20 were lower than in P200 under D = 30, and there were no significant differences in the root parameters between P200 and P400 under D = 20; similarly, the root growth and AM colonization exhibited similar trends. These results suggest that optimizing P supply in the root zone to regulate the interaction between root morphological traits and AM colonization can compensate for limited root-growth space. Although P supply in the root zone increased after the root-growth space was compressed, it could not meet the P demand of maize; thus, to achieve the most efficient use of P under intensive high-density maize production, it is necessary to optimally coordinate root growth space and P supply in the root zone.

Keywords: AM colonization, maize, phosphorus supply intensity, space availability, trade-off

INTRODUCTION

The sustainable use of phosphorus (P) is a major challenge in agricultural production, especially in high-density planting systems (Testa et al., 2016). High planting density reduces the growth space of maize roots per plant; such conditions are often accompanied by smaller roots per plant, reduced soil volume occupied by the root system, and decreased the total root length (Wang et al., 2020). Maize plants primarily depend on the root morphological traits to enhance P acquisition in

the soil (Lambers et al., 2015; Wang et al., 2020). The low root growth spaces are induced by high planting density, which results in difficulty in acquiring P from the soil (Shao et al., 2018). Artificially increasing P supply is an effective method of regulating the P absorption capacity of plants to meet the P demand of high-density populations (Poorter et al., 2012). In intensive agriculture, smallholders often employ the insurance approach, that is, large amounts of mineral P fertilizer are applied in excess to increase the P availability to crop plants, resulting in low P-use efficiency (PUE) (Dhillon et al., 2017; Zhang et al., 2019), with considerable adverse environmental impacts, such as non-point source pollution of surface waters (Ni et al., 2015). Therefore, both the P supply and root growth space availability should be considered when attempting to increase the PUE under intensive high-density planting maize systems.
