IL-21 is a multifunctional cytokine linked with the pathophysiology of several autoimmune diseases, including type 1 diabetes. In this study, our aim was to examine plasma IL-21 levels in individuals at different stages of type 1 diabetes progression. We measured plasma IL-21 levels, as well as levels of other key pro-inflammatory cytokines (IL-17A, TNF- $\alpha$  and IL-6), from 37 adults with established type 1 diabetes and 46 healthy age-matched adult controls, as well as from 53 children with newly diagnosed type 1 diabetes, 48 at-risk children positive for type 1 diabetes-associated autoantibodies and 123 healthy age-matched pediatric controls using the ultrasensitive Quanterix SiMoA technology. Adults with established type 1 diabetes had higher plasma IL-21 levels compared to healthy controls. However, the plasma IL-21 levels showed no statistically significant correlation with clinical variables, such as BMI, C-peptide, HbA1c, or hsCRP levels, evaluated in parallel. In children, plasma IL-21 levels were almost ten times higher than in adults. However, no significant differences in plasma IL-21 levels were detected between healthy children, autoantibody-positive at-risk children, and children with newly diagnosed type 1 diabetes. In conclusion, plasma IL-21 levels in adults with established type 1 diabetes were increased, which may be associated with autoimmunity. The physiologically high plasma IL-21 levels in children may, however, reduce the potential of IL-21 as a biomarker for autoimmunity in pediatric subjects.

## KEYWORDS

autoimmunity, autoimmune diseases, interleukin-21, IL-21, human, type 1 diabetes

# 1 Introduction

Type 1 diabetes (T1D) is a chronic autoimmune disease, in which autoreactive T cells mediate the progressive destruction of insulin-producing beta cells in the pancreas. T1D is preceded by a preclinical phase of variable length, during which circulating autoantibodies (AAb) to islet autoantigens are almost invariably detected (1). It is well-established that T cells play a central role in the T1D disease process (2). However, the exact T-cell phenotypes or immune pathways involved remain largely elusive. Recently, the interleukin-21 (IL-21) pathway has gained attention, as it has been associated with the development of T1D both in murine models (3) as well as in human studies (4–6).

IL-21 is a pleiotropic cytokine with multiple functions. It is a hallmark cytokine of CD4<sup>+</sup>CXCR5<sup>+</sup> T follicular helper (Tfh) cells (7, 8). In addition, it is produced by Th17 cells (7) and a recently identified population, coined T peripheral helper (Tph) cells (9, 10). IL-21 has a fundamental role in B-cell helper functions. In order to activate, expand and produce antibodies, B cells are largely dependent on the help provided by IL-21-producing Tfh cells in lymph nodes (7, 8), and possibly also by Tph cells within inflamed tissues (10). Importantly, IL-21 is also known to support the effector functions and cytotoxicity of CD8<sup>+</sup> T cells (7). IL-21 produced by CD4<sup>+</sup> T cells may therefore contribute to the T1D disease process also by activating autoreactive CD8<sup>+</sup> T cells in the pancreas (11–13).

Interestingly, an expansion of circulating Tfh and Tph cells and increased IL-21 production by T cells has been observed both in children with newly diagnosed T1D (6, 14), as well as in adults with established T1D (4, 5). Moreover, Th17 cells, another potential source of IL-21, appear to be increased both in the blood and pancreatic lymph nodes of patients with T1D (15, 16). These findings implicate the IL-21 pathway to be an appealing candidate for immunotherapy of T1D. Promisingly, in a recently completed phase 2 trial, an anti-IL-21 antibody combined with liraglutide was shown to preserve beta-cell function in patients with recent-onset T1D (17).

Given the importance of IL-21 for autoimmunity, blood IL-21 levels could serve as a potential biomarker of disease activity in autoimmune disorders. Indeed, in some autoimmune diseases, such as Sjögren's syndrome (18) and systemic lupus erythematosus (SLE) (19), plasma and/or serum IL-21 levels are elevated in patients. Recently, limitations in the specificity and sensitivity of commercially available human IL-21 ELISA kits have been identified, and as a result, a new ultrasensitive assay for detecting IL-21 based on the Quanterix SiMoA (Single Molecule Array) technology was developed (20). With this assay, it was demonstrated that IL-21 concentrations in plasma and serum are considerably lower than previously published data using less sensitive and less specific assays suggested. Importantly, higher plasma IL-21 levels in patients with Sjögren's syndrome and SLE compared to healthy individuals were also validated with this ultrasensitive assay (20).

To our knowledge, plasma IL-21 levels have previously been investigated in a limited number of studies related to T1D, all of which have suggested that patients with T1D (21, 22) and AAb<sup>+</sup> at-risk children (23) have higher IL-21 levels in blood than controls. In this study, we analyzed plasma IL-21, as well as levels of other key pro-inflammatory cytokines (IL-17A, TNF- $\alpha$  and IL-6) with the

ultrasensitive Quanterix SiMoA technology at different stages of T1D development, utilizing samples from cross-sectional cohorts of adults with established T1D, children with newly diagnosed T1D, and AAb<sup>+</sup> at-risk children together with age-matched controls.

# 2 Materials and methods

## 2.1 Study subjects

The adult cohort comprised 37 patients with established T1D and 46 healthy age-matched controls (Table 1). The pediatric cohort consisted of 53 children with newly diagnosed T1D (0 to 7 days after clinical diagnosis), 48 autoantibody-positive (AAb<sup>+</sup>) at-risk children, and 123 healthy control children who were autoantibody-negative and age-matched with the T1D and AAb<sup>+</sup> cases (Table 2). The AAb<sup>+</sup> and healthy control children participated in the Finnish Type 1 Diabetes Prediction and Prevention (DIPP) follow-up study and carried HLA genotypes associated with increased risk for T1D. Autoantibody-positivity was analyzed, as previously described (24). Autoantibody-positivity was defined based on the presence of one or more biochemical autoantibodies (insulin autoantibodies [IAA], insulinoma-associated-2 antibodies [IA-2A] and glutamic acid decarboxylase antibodies [GADA]).

Plasma samples were collected between May 2013 and January 2016 for the pediatric cohort at the DIPP study center in Turku, Finland, and between February 2012 and March 2020 for the adult cohort at the University of Eastern Finland, Kuopio, Finland. Plasma was collected from heparinized peripheral blood samples after centrifugation at 700 x g for 10 min and stored at -80°C until analysis.

All participants and/or their legal guardians provided written informed consent, as mandated by the Declaration of Helsinki. The study was approved by local ethics committees of the University Hospitals of Turku and Kuopio, and for the DIPP study by the ethics committee of the Hospital District of Northern Ostrobothnia.

## 2.2 Quanterix SiMoA assays

The heparin plasma samples were randomized for plating, then thawed and aliquoted in batches to reduce freeze-thaw cycles. For all samples, assessment of IL-21 levels was performed using the Quanterix SiMoA assay as previously reported (20). Assessment of IL-17A, IL-6 and TNF- $\alpha$  levels was performed using the Cytokine 3 Plex B Quanterix SiMoA assay, according to manufacturer's instructions.

The spike recoveries were determined by comparing the spike samples of the observed back-calculated concentration from calibration curve against known spiked concentration. Limits of detection (LODs) were determined by the selection criteria of 75%–125% of the calibration recovery (i.e., comparing the calibration samples of the calculated concentration to expected concentration). Limits of Quantitation (LOQs) were determined by the selection criteria of 75%–125% of the spike recovery (i.e., comparing the spike samples of the calculated concentration to expected

concentration). The analyses for the adult cohort were performed in two batches, with slightly different LOD and Lower Limit of Quantitation (LLOQ) values, and batch correction was calculated using linear model in R (25).

## 2.3 C-peptide and hsCRP measurements

C-peptide was measured from heparinized plasma with electrochemiluminescence immunoassay (detection limit 0.007 nmol/L, Cobas, Roche Diagnostics) and high-sensitivity C-reactive protein (hsCRP) from heparinized plasma with particle enhanced immunoturbidimetric assay (detection limit 0.15 mg/L, Cobas, Roche Diagnostics).

## 2.4 Statistical analyses

Graphpad Prism version 9.1.0 (GraphPad Software, San Diego, California USA) was used for statistical analyses. Kruskal-Wallis test followed by Dunn's multiple comparison test was applied when comparing more than two groups. Mann-Whitney test or Wilcoxon matched-pairs signed-rank test was used when comparing two groups. No power calculations were made as the study was exploratory in nature with very limited previous data to support the calculations, and sample sizes were determined in part by feasibility. Spearman's correlation was calculated when relationships between plasma cytokine concentrations and different variables were assessed. Simple linear regression was used to calculate regression lines for each group. Slopes and intercepts of the regression lines were compared, and two-tailed P-values were calculated for them in Prism. P-values <0.05 were considered to indicate statistical significance.

## 3 Results

### 3.1 Plasma IL-21 levels are higher in adults with established type 1 diabetes than in healthy controls

Plasma IL-21, as well as IL-17A, TNF- $\alpha$ , and IL-6 levels were analyzed in 37 adults with established T1D and in 47 age-matched healthy controls. Plasma IL-21 levels were 2.5-fold higher in T1D patients (median 0.05 pg/mL) compared to healthy controls (median 0.02 pg/mL,  $P < 0.001$ , Figure 1A). Plasma IL-6 levels were also elevated in T1D patients compared to controls (median 1.03 pg/mL vs. 0.61 pg/mL,  $P < 0.05$ ), but plasma IL-17A and TNF- $\alpha$  levels were similar between the study groups (Supplementary Figure 1).

Next, we examined whether selected clinical variables were associated with plasma IL-21 levels. No correlations were observed between age, hsCRP, C-peptide levels, HbA1c values, body-mass index (BMI), or disease duration with plasma IL-21 levels in the T1D patients (Figure 1B, Supplementary Figure 1). However, plasma IL-21 levels correlated positively with both TNF- $\alpha$  ( $P < 0.001$ ,  $r=0.40$ ) and IL-6 ( $P < 0.05$ ,  $r=0.27$ ) levels. Moreover, IL-17A levels correlated with TNF- $\alpha$  ( $P < 0.001$ ,  $r=0.57$ ) and IL-6 ( $P < 0.001$ ,  $r=0.60$ ) levels, while TNF- $\alpha$  levels correlated with hsCRP ( $P < 0.05$ ,  $r=0.26$ ) (Supplementary Figure 1).

### 3.2 Plasma IL-21 levels are similar in children with newly diagnosed type 1 diabetes, children at-risk for type 1 diabetes and healthy controls

Next, we analyzed the plasma cytokine levels in samples from 53 children with newly diagnosed T1D and 48 AAB<sup>+</sup> at-risk children, as well as from 123 healthy age-matched controls. In the pediatric

cohort, plasma IL-21 levels (Figure 2A), as well as IL-17A, TNF- $\alpha$ , and IL-6 levels (Supplementary Figure 2) were similar between children with T1D, AAb<sup>+</sup> at-risk children, and healthy controls. Of note, plasma IL-21 levels in children (median 0.26 pg/mL for the whole pediatric cohort) were around ten-fold higher compared to those observed in the adult cohort (Figures 1A, 2A). Accordingly, a strong negative correlation between age and IL-21 levels ( $P < 0.001$ ,  $r = -0.35$ ), as well as to a lesser extent between age and IL-17A ( $P < 0.01$ ,  $r = -0.20$ ) and TNF- $\alpha$  ( $P < 0.001$ ,  $r = -0.24$ ) levels, was observed in the pediatric cohort (Figure 2B, Supplementary Figure 2). However, even after stratification with age, no differences in plasma IL-21 levels between the pediatric study groups were detected (Figure 2B, Supplementary Figure 2). Finally, these results were further corroborated by a stringent pairwise analysis of a subset of samples from T1D and AAb<sup>+</sup> children that were drawn and processed in parallel with a sample from an age-matched healthy control child on the same day (Supplementary Figure 3). In addition, we analyzed correlation between selected clinical variables and plasma cytokine levels in children with newly diagnosed T1D. We did not observe correlations between cytokine levels and clinical variables at diagnosis (plasma glucose, HbA1c, blood pH, or beta-hydroxybutyrate levels) (Supplementary Figure 2). Of note, similar to the adult cohort, IL-17A levels correlated with TNF- $\alpha$  ( $P < 0.001$ ,

$r = 0.66$ ) and IL-6 ( $P < 0.001$ ,  $r = 0.48$ ) levels also in the pediatric cohort (Supplementary Figure 2).

We have previously observed that the frequency of both circulating Tfh (6) and Tph (14) cells was increased in children with newly diagnosed T1D positive for at least two AAbs but not in those positive for one AAb or none. Hence, we next stratified both AAb<sup>+</sup> children and children with T1D into two subgroups based on the number of autoantibodies detected ( $\leq 1$  or  $\geq 2$ ) in these children. However, plasma IL-21, as well as IL-17A, TNF- $\alpha$ , and IL-6 levels were again similar in AAb<sup>+</sup> children and children with T1D positive for either  $\leq 1$  or  $\geq 2$  autoantibodies (Figures 2C, D, Supplementary Figure 4). In addition, we analyzed whether plasma cytokine levels differed between those AAb<sup>+</sup> at-risk children who had progressed to T1D (mean time to T1D after sampling  $2.6 \pm 1.4$  years) and those who had not. However, again, no differences were detected between the groups (Figure 2E, Supplementary Figure 5).

Finally, flow cytometry data were available on selected T-cell subset frequencies for the pediatric samples (6, 26). Hence, we examined the correlation between plasma IL-21 levels and selected T-cell subset frequencies. The frequencies of activated Tfh cells (PD-1<sup>+</sup>ICOS<sup>+</sup> of CXCR5<sup>+</sup> memory CD4<sup>+</sup> T cells) (6) positively correlated with plasma IL-21 levels ( $P < 0.001$ ,  $r = 0.29$ , Figure 2F). A weaker positive correlation was also observed with the frequency of

FIGURE 1

Plasma IL-21 levels are elevated in adults with T1D. (A) Plasma IL-21 levels in adults with established T1D and healthy controls. Mann-Whitney U-test was used for statistical analysis. (B) Correlation between age and log<sub>10</sub>-transformed plasma IL-21 levels was examined using Spearman's correlation by pooling the data from both study groups and is expressed together with the P value on the plot. The elevations of the linear regression lines were significantly different between the study groups ( $P = 0.001$ ). Medians and IQRs are shown in the (A).

regulatory T cells (Treg; CD25<sup>+</sup>CD127<sup>low</sup> of CD4<sup>+</sup> T cells) (26) and plasma IL-21 levels ( $P < 0.05$ ,  $r = 0.17$ , [Supplementary Figure 6](#)). However, no correlation was observed between the frequency of Th17 cells (CCR6<sup>+</sup>CXCR3<sup>-</sup> of memory CD4<sup>+</sup> T cells) (26) and plasma IL-21 levels ([Supplementary Figure 6](#)).

## 4 Discussion

In this study, we demonstrated that adults with established T1D had significantly elevated plasma IL-21 and IL-6 levels compared to age-matched controls. IL-21 levels did not correlate with the time from diagnosis or C-peptide levels, a marker of residual beta-cell function. Moreover, no correlation between plasma IL-21 levels and HbA1c levels, a marker related to glycemic control, or hsCRP, a marker related to inflammation, was observed. Therefore, the elevated plasma IL-21 levels do not appear to be associated with the extent of beta-cell destruction, hyperglycemia itself, or with underlying inflammation in T1D patients in the cohort studied.

In the pediatric cohort, we did not observe differences in plasma IL-21 levels between patients with newly diagnosed T1D, AAb<sup>+</sup> at-risk children, and healthy age-matched children. Similar to adults, no correlation between plasma IL-21 levels and clinical variables, such as level of hyperglycemia (blood glucose and HbA1c levels at diagnosis) or markers of ketoacidosis (blood pH and beta-hydroxybutyrate levels) were found in children with T1D. Moreover, no associations between plasma IL-21 levels and autoantibody status or the risk of progression to clinical T1D in AAb<sup>+</sup> at-risk children were observed.

An important observation in our study was that plasma IL-21 levels appear to be physiologically around ten-fold higher in children than in adults. Importantly, for the other cytokines, IL-17A, TNF- $\alpha$ , and IL-6, assessed in this study, no such phenomenon was observed. This observation could potentially explain the discrepancy that higher plasma IL-21 levels were observed only in adult T1D patients but not

in children with T1D. As the plasma IL-21 levels were only modestly elevated in adult T1D patients compared to controls, a corresponding small change would be masked by the considerably higher physiological background levels in children. Another interesting finding in the pediatric cohort was that plasma IL-21 levels correlated with the frequency of activated Tfh cells in blood, potentially implicating Tfh cells as a major source of plasma IL-21.

Three previous studies have reported slightly elevated plasma IL-21 levels in both adult and pediatric patients with T1D (21, 22), as well as in AAb<sup>+</sup> at-risk children (23). However, in these studies either ELISA or Luminex xMAP technologies were used, and the IL-21 levels reported were >100-fold higher than in our study using the ultrasensitive Quanterix SiMoA technology. Previous validation results strongly suggest that these conspicuously higher IL-21 levels reported in the previous studies may not accurately reflect physiological cytokine levels, as these older methods lack both the sensitivity and specificity required to detect endogenous IL-21 levels reliably (20).

In addition to using an ultrasensitive analysis method, the major strengths of our study are the large cohort sizes and the stringent matching with HLA background, age, and sampling date in the pediatric cohort, which all considerably strengthen the validity of our results. One caveat of our study is that we were only able to analyze cross-sectional cohorts. In the future, longitudinal analyses could potentially better detect subtle intraindividual alterations in cytokine levels occurring during T1D progression. Moreover, the analysis of patients with type 2 diabetes could help confirm whether the increased plasma IL-21 levels in adults with T1D are truly associated with autoimmunity and are not secondary to hyperglycemia and/or exogenous insulin use.

In conclusion, for the first time, IL-21 was quantified using an ultrasensitive and specific method and found to be elevated in adults with established T1D, supporting a potential role of IL-21 in the T1D disease process. In contrast, in the pediatric cohort, comprising children with newly diagnosed T1D, AAb<sup>+</sup> children at-risk for T1D,

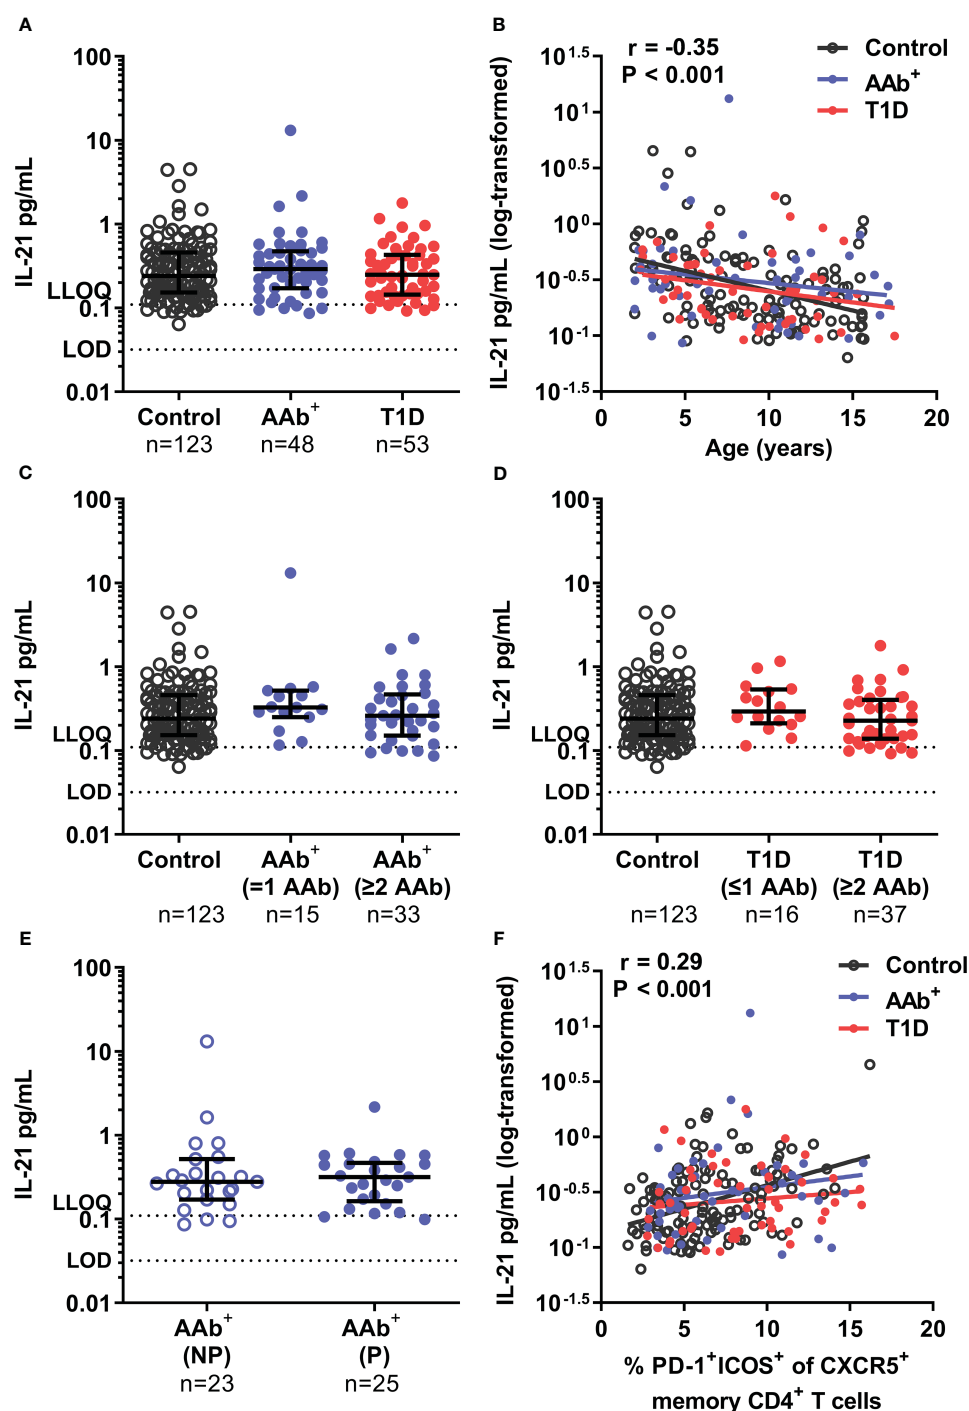

FIGURE 2

Similar plasma IL-21 levels in children with newly diagnosed T1D, AAb<sup>+</sup> at-risk children and healthy children. (A) Plasma IL-21 levels in children with newly diagnosed T1D, AAb<sup>+</sup> at-risk children and control children. (B) Correlation between age and log<sub>10</sub>-transformed plasma IL-21 levels was examined using Spearman's correlation by pooling the data from all study groups and is presented together with the P value on the plot. The elevations of the linear regression lines were comparable between the study groups. AAb<sup>+</sup> at-risk children (C) and children with newly diagnosed T1D (D) were stratified into two subgroups based on the number of persistent autoantibodies detected at sampling (positive for  $\leq 1$  autoantibodies and  $\geq 2$  autoantibodies). (E) AAb<sup>+</sup> at-risk children were divided into non-progressors (NP) and progressors (P) depending on whether they had later progressed to T1D during follow-up. Kruskal-Wallis with Dunn's multiple comparisons test or Mann-Whitney U-test was used for statistical analyses. Medians with IQRs are shown, and limit of detection (LOD) and lower limit of quantification (LLOQ) are represented with dotted lines in A, C–E. (F) Correlation between the frequency of circulating activated Tfh (PD-1<sup>+</sup>ICOS<sup>+</sup> of CXCR5<sup>+</sup> memory CD4<sup>+</sup> T cells) and log<sub>10</sub>-transformed plasma IL-21 levels was examined using Spearman's correlation by pooling the data from all study groups, and is expressed together with the P value on the plot. The elevations of the linear regression lines were comparable between the study groups.

and age-matched healthy controls, we did not observe differences in plasma IL-21 levels between the study groups. The physiologically higher plasma IL-21 levels in children may, however, mask potential changes caused by T1D autoimmunity. Taken together, the direct detection of plasma IL-21 levels, even by the ultrasensitive method capable of detecting fg/mL concentrations of cytokines employed here, may have limited potential as a biomarker of T1D progression, particularly in children.

## Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## Ethics statement

The studies involving human participants were reviewed and approved by local ethics committees of the University Hospitals of Turku and Kuopio and the ethics committee of the Hospital District of Northern Ostrobothnia. Written informed consent to participate in this study was provided by the participants or participants' legal guardian/next of kin.

## Author contributions

JPo, SM and SB measured the cytokines. RR, JPi, KN-S and JT provided the clinical research samples. MK and RV were responsible for the islet autoantibody analyses of the pediatric cohort. JI was responsible for the HLA screening of the pediatric study subjects. A-MS, JPo, SM, SB, LZ, RJB and TK analyzed the data and drafted the manuscript. TK is the guarantor of this work and, as such, had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. All authors contributed to the article and approved the submitted version.

Type 2 diabetes mellitus (T2DM) is no longer only a disease of humans, but also of domestic animals, and it particularly affects cats. It is increasingly thought that because of its unique characteristics, T2DM may belong not only to the group of metabolic diseases but also to the group of autoimmune diseases. This is due to the involvement of the immune system in the inflammation that occurs with T2DM. Various pro- and anti-inflammatory substances are secreted, especially cytokines in patients with T2DM. Cytokines secreted by adipose tissue are called adipokines, and leptin, adiponectin, resistin, omentin, TNF- $\alpha$ , and IL-6 have been implicated in T2DM. In cats, approximately 90% of diabetic cases are T2DM. Risk factors include older age, male sex, Burmese breed, presence of obesity, and insulin resistance. Diagnosis of a cat requires repeated testing and is complicated compared to human diagnosis. Based on similarities in the pathogenesis of T2DM between humans and cats, adipokines previously proposed as biomarkers for human T2DM may also serve in the diagnosis of this disease in cats.

## KEYWORDS

feline, diabetes mellitus, adipokines, leptin, adiponectin

## 1 Introduction

Chronic low-grade inflammation is common in pathologies such as obesity, cancer, type 2 diabetes (T2DM), and cardiovascular diseases (1). The immune system is usually described in terms of its protective function against infections and its role in the development of autoimmunity. In contrast, interactions between the immune system and metabolic processes have been reported for more than a decade, resulting in a field of research termed immunometabolism. So far, it has been shown (2) that the development of metabolic diseases can be linked to inflammation, which in some cases reflects the activation of immune responses. There are many evolutionarily conservative interactions between the immune response and metabolism. Proper maintenance of this delicate balance is critical for health and has important implications for many pathological conditions such as obesity, diabetes mellitus, and other chronic non-communicable

diseases (3). Metabolic dysregulation results in immune cell involvement. If the organism is obese, pro-inflammatory M1 macrophages make up the majority of the macrophage population in adipose tissue, with more anti-inflammatory M2 in lean individuals. They secrete pro-inflammatory cytokines (TNF- $\alpha$ , IL-6, IL-1 $\beta$ , IL-12, and MCP-1), which not only have a role in promoting insulin resistance but also recruit other immune cells to the site of inflammation (4). Among the cells recruited are neutrophils, lymphocytes, and innate lymphoid cells (ILC), including natural killer (NK) cells, mast cells, and eosinophils (4, 5). Elevated levels of neutrophils have been observed in both obese humans and mouse models fed a high-fat diet (HFD), and are therefore thought to be involved in modulating adipose tissue inflammation in the early stages of obesity (6). Lymphocytes are recruited to the site of inflammation by specific cytokines. In obesity, reduced levels of CD4 + CD25 + Foxp3+ lymphocytes are observed, indicating their depletion, which contributes to the development of insulin resistance. In contrast, CD8 T-lymphocyte levels increase in adipose tissue as early as 2 weeks of HFD feeding, and levels are high in obesity. The important role of CD8 T lymphocytes in the development of inflammation lies in their ability to induce the differentiation of macrophages from monocytes. B lymphocytes influence adipose tissue inflammation by modulating T lymphocyte activity (7). Mast cells have also been shown to be involved in the regulation of adipose tissue in obesity. Eosinophils, on the other hand, induce a faster rate of macrophage differentiation into the M2 phenotype by secreting the cytokines IL-4 and IL-13, which have an anti-inflammatory effect on adipose tissue inflammation (5).

The site of many inflammatory processes is in adipose tissue. Adipose tissue is classified as connective tissue, as a specialized tissue composed mainly of adipocytes (fat cells). Adipocytes are composed of a single, large lipid droplet with a thin envelope of cytoplasm between it and the plasma membrane (3). Currently, it is widely agreed that adipose tissue is a strongly active and complex hormonal and metabolic gland consisting of adipocytes, connective tissue matrix, neural tissue, stromal cells, and immune cells (8). The link between adipose tissue metabolism and the immune system is indicated by the fact that immune responses often lead to loss of body weight, and in obese individuals, the immune system malfunctions, causing them to suffer an increased incidence and severity of infectious diseases (9, 10). In obese individuals, only half the number of the monocytes mature into macrophages, compared to patients without obesity (10). In addition, macrophages contribute to the adipose organ in the generation of inflammation (11). Animal studies also yield similar data. Decreased immunocompetence, decreased activity of cellular immune components, decreased resistance to infection, and decreased macrophage killing capacity are observed in obese individuals (10).

Studies suggest (2) that T2DM, like type 1 diabetes (T1DM), may belong to the autoimmune diseases, and the two types of diabetes may have more in common than previously thought (3). In T2DM with obesity, adipocyte size is increased. This alters the levels of circulating pro-inflammatory cytokines contributing to the recruitment of immune cells to the site of inflammation, which is adipose tissue (12). Additionally, the insulin resistance in T2DM may be the result of attacks by immune system cells that are designed to produce antibodies that fight pathogens on body tissues (3). Although T2DM has been classified as a metabolic disease for more than 30 years, autoimmunity in T2DM is a growing topic (13). Chronic inflammation induced by obesity, a major causative factor in T2DM, affects the activation of innate and adaptive immunity, including the secretion of pro-inflammatory cytokines that activate T lymphocytes, B lymphocytes and macrophages. As a result of the strong impact of inflammatory and autoimmune reactions,  $\beta$ -cells undergo apoptosis, and impaired insulin secretion in  $\beta$ -cells affects the development of hyperglycemia (13, 14). Another important feature of autoimmunity in T2DM is impaired B lymphocyte function. People with T2DM do not secrete the anti-inflammatory cytokine, interleukin-10, and they secrete a much higher amount of pro-inflammatory cytokines (13, 14). Patients with T2DM have reduced resistance to infection, which may be due to the reduced ability of B lymphocytes to produce *de novo* antibodies (14). Additionally, T lymphocytes are an important aspect in autoimmunity in T2DM. Self-reactive T lymphocytes are in decline in patients with T2DM (13). T-cell receptors (TCRs), which are designed to recognize antigen and are differentially expressed in healthy individuals, are limited in T2DM patients (15). T-lymphocytes, together with macrophages, by releasing pro-inflammatory cytokines, contribute to increased pancreatic islet inflammation (13). A role for dysbiosis of the gut microbiota in toll-like receptor (TLR) activation in adipocytes and production of pro-inflammatory adipokines is also indicated (15). Current immunomodulatory therapies in T2DM target IL-1 $\beta$ , block the NF- $\kappa$ B pathway and increase circulating adiponectin with positive results (13).

Because of differences in the structure of adipose tissue in rodents, the most popular model organism for humans, research on it is not fully developed. Murine adipocytes differ in structure from those of humans: mouse adipocytes contain many fat droplets, while human adipocytes contain one (3). There are differences in adipogenesis too. Additionally, molecular differences adversely affect the use of mouse models: in mice, TNF- $\alpha$  is a major factor in haptoglobin expression, and in humans, it induces downregulation of haptoglobin mRNA (16). Cats, unlike rodents, develop all the symptoms of T2DM: insulin resistance, impaired  $\beta$ -cell function and reduced numbers of them, and pancreatic amyloid deposition (17).

## 2 T2DM in cats

In cats, T2DM is the most common among the various types of diabetes, with about 90% of diabetes cases being T2DM (18). By comparison, in dogs, most cases of diabetes are type 1 diabetes (19). T2DM is characterized by insulin resistance and decreased insulin secretion due to pancreatic  $\beta$ -cell failure (18, 20). Insulin resistance is differentiated by impaired tissue response to insulin and can lead to hyperglycemia and excessive pancreatic insulin secretion leading to balance (20). Although T2DM in cats is the most common type of DM and is very similar to human T2DM, unlike in humans, treatment may include insulin therapy (21). This is because DM in cats has been proposed to be divisible into insulin-dependent DM (IDDM) and non-insulin-dependent diabetes mellitus (NIDDM), and T2DM in cats qualifies as IDDM (22). In this paper, however, we will use the term T2DM and note that it is a type of IDDM in cats.

### 2.1 Risk factors

Risk factors for developing T2DM in cats include both genetic and environmental conditions, like advancing age, male sex (including being neutered), genetic aspects (breed), diet-dependent obesity and physical inactivity (18, 21, 23, 24).

#### 2.1.1 Age

The probability of cats developing DM has been shown to increase beyond the age of 6 years, and it is highest at 11–13 years (25–28). This may be because insulin sensitivity and  $\beta$ -cell functionality decrease with age, and amyloid deposition in the pancreas may be high (26).

#### 2.1.2 Sex

An increased risk of developing T2DM has been observed in male cats. The more their body weight increased, the higher the risk was. Interestingly, this pattern did not occur in female cats — despite increasing body weight, there was no significant increase in the risk of developing T2DM (25). This may be because male cats may be naturally more insulin resistant than female cats. Additionally, the mere fact of being a female purebred cat rather than a mixed-breed cat was protective against developing T2DM (25). Males, regardless of breed, were at the same risk of developing the disease (25). In males, neutering also appears to have an impact on the development of T2DM disease, as they are 2–9 times more likely to develop the disease than uncastrated males (21, 29). After neutering there are changes in hormone levels: an increase in prolactin, leptin, and insulin-like growth factor 1 (IGF-1), and a decrease in testosterone and estrogen. Among estrogens, estradiol has been shown to regulate normal food intake. In neutered males,

estradiol levels are significantly reduced, by up to half in plasma (30). Therefore, especially in males, ad libitum access to food is a large risk factor for the development of obesity and resulting T2DM. The exceptions are Burmese cats, in which the gender factor does not affect the chances of developing T2DM — both male and female cats are equally susceptible to the disease (29).

#### 2.1.3 Breed and other genetic factors

Remarkably, there is one breed that is particularly prone to developing diabetes: the Burmese cat (22, 23, 31). Type 2 diabetes is up to 4 times more common in Australian-bred Burmese cats (32), and the New Zealand population is also at increased risk (33). This is probably due to the presence of an inborn metabolic deficiency in certain of these cats. This results in postprandial hypertriglyceridemia after high-fat meals. In Burmese cats with postprandial hypertriglyceridemia, lipoprotein lipase (LPL) deficiency and elevated very-low-density lipoprotein (VLDL) concentrations have been observed (31). This may be because the breed was developed from a small number of individuals and the propensity for the disease is passed down generationally. A genetic factor is also indicated by the fact that USA-bred Burmese cats, a population quite isolated from others because Burmese breeders in Australia, New Zealand, and the United Kingdom have not approved Burmese cats from the USA for more than 20 years, do not suffer from an increased risk of developing T2DM (34). With further genetic studies of Burmese cats, it would be possible to locate the alleles responsible for the increased risk of developing type 2 diabetes in cats.

In addition to the Burmese breed, high incidence rates of DM risk were also found in the Russian blue, Norwegian forest cat, European shorthair, and Abyssinian breeds (27).

Additionally, in cats mutations in the sequence of the gene encoding the melanocortin 4 receptor (MC4-R), decreased expression levels of the insulin receptor substrate 1 (IRS-1), insulin receptor substrate 2 (IRS-2) and phosphoinositide 3-kinase (PI3-K) genes, or decreased expression levels of the gene encoding the glucose transporter type 4 (GLUT4) in muscle and adipose tissues have also been observed (21). As in cats, in humans genetic factors are also important in the pathogenesis of T2DM (33). A mutation in the gene encoding the melanocortin 4 receptor (MC4-R) causing it to be defective in humans is one of the most common causes of obesity, glucose intolerance and T2DM (35, 36). MC4-R inhibition leads to increased fat cell accumulation (37). Polymorphisms in the IRS-1 gene in humans are associated with an increased risk of developing gestational diabetes, and the gene itself is involved in the development of insulin resistance in T2DM (38). Notable among the polymorphisms in IRS-1 affecting the development of T2DM and insulin resistance are IRS-1 substitutions by Gly to Arg 972 (39). IRS-2 also plays an important role in the initiation and progression of T2DM. It has been shown that increasing its

expression in patients with insulin resistance can positively delay the development of diabetes (40), and its reduced expression can induce  $\beta$ -cell apoptosis (41). PI3-K is involved in the IRS substrate pathway, which is impaired by insulin inefficiency and hyperglycemia (42). GLUT4 is involved in glucose uptake in muscle and adipose tissues, and changes in its expression affect glycemic control in the human body (43). Similarities in the expression changes of genes involved in the pathogenesis of T2DM between humans and cats deserve special attention and suggest similarities in the pathogenesis of the disease.

### 2.1.4 Nutrition

In their natural environment, cats feed on small mammals and birds: food that is rich in protein, moderately rich in fat, and with minimal carbohydrates (19). Proteins in cats' diet are needed to maintain blood glucose levels, as cats do not have many adaptations to regulate carbohydrate digestion. Cats do not secrete salivary amylase and have low intestinal and pancreatic amylase and intestinal disaccharidase activity (19). In addition, hepatic glucokinase activity is low and is not adaptive to increased carbohydrate consumption and the feline liver does not secrete fructokinase. Consequently, the cat's body's ability to minimize hyperglycemia is severely compromised when there is a large amount of glucose in the diet (19, 25). Additionally, large amounts of carbohydrates in a cat's diet reduce the digestibility of proteins (19).

A high-protein/low-carbohydrate (HP) diet is recommended for feeding obese cats because its use affects the maintenance of normal insulin sensitivity of fat metabolism (44). The HP diet has the effect of increasing heat production and consequently facilitating fat loss (44). Cats fed an HP diet are less likely to develop obesity and show less insulin resistance compared to cats fed the same amount of calories but on a high-carbohydrate/low-protein (HC) diet (44). HC diets during obesity therapy have been shown to reduce lean body mass loss and promote fat loss (45–47). Additionally, compared to HP diets, HC diets decrease insulin sensitivity and cause hyperinsulinemia (24). As in obese cats, in cats with T2DM, the use of the HP diet is beneficial and leads to an improvement in insulin requirements (44).

The cat has a similar narrative in the "Carnivore Connection" theory as humans. This theory states that the cause of the current epidemic of obesity and diabetes in humans is potentially because, over the last two million years of evolution humans have consumed a predominantly low-carbohydrate, high-protein diet. As a result, they developed insulin resistance, which was beneficial with such a diet because it allowed them to control the balance of glucose levels and had a positive effect on fetal development. With the development of agriculture and the industrialization of the population, the diet changed, and man began to consume more cereals and starches. Populations that have recently adopted agriculture and have been on a high-carbohydrate diet

for a shorter time, such as the Pima Indians, are more likely to develop T2DM, while Europeans, who have used agriculture for 12,000 years, have a lower incidence of diabetes (48). Domestic cats may have experienced a similar situation with a change from a natural, protein-rich diet to a diet consisting primarily of high-carbohydrate commercial food. Although high-carbohydrate diets lead to elevated postprandial glucose and insulin levels, and low-carbohydrate diets have been shown to improve glycemic control in cats with DM, it cannot currently be concluded with certainty that a high-carbohydrate diet is a risk factor for the development of T2DM (49).

### 2.1.5 Obesity

The next risk factor, obesity is the condition of increased body fat mass due to too many nutrients being provided to the body than needed and may be a consequence of incorrect nutrition (20, 50). In cats, there is a strong link between obesity and diseases such as cancer, lower urinary tract diseases, especially feline idiopathic cystitis, constipation, lameness and orthopedic diseases, altered hemostasis, liver lipodosis, dermatological diseases, musculoskeletal diseases, hypertrophic cardiomyopathy, respiratory diseases, oral conditions, diabetes mellitus, atopic dermatitis, hypertension, asthma, diarrhea, ocular conditions, and allergic conditions (11, 30, 51).

Hoeing et al. (44) reported that 1 kilogram of weight gain in cats resulted in a loss of insulin sensitivity and glucose effectiveness by approximately 30% (44). Adipose tissue regulates the storage, release, degradation, and hydrolysis of fatty acids (FA). During the normal process of lipolysis, fatty acids esterify, resulting a decrease in their serum levels decrease. In obesity, there is impaired inhibition of lipolysis by insulin, resulting in increased levels of fatty acids and glycerol, and adipose tissue secretes cytokines and other pro-inflammatory molecules that antagonize the action of insulin and contribute to inflammation (52).

Additionally, the distribution of body fat in an animal is associated with insulin resistance. In cats, unlike humans, there is no gender difference in body fat distribution. Abdominal fat, which is the major site of fat accumulation in cats, is evenly distributed subcutaneously and in the abdominal cavity (44). In contrast, obese cats may deposit fatty acids into the muscle and have increased lipid levels there, which may be associated with insulin resistance (53).

It is important to note that not all obese cats develop T2DM because other genetic, environmental, and metabolic factors are involved in the pathogenesis of the disease. Obesity increases the diabetes risk by 3 to 5 times (24). However, obesity is considered to be one of the main factors in the development of T2DM and it is thought that this may be due to an increase in endogenous glucose production caused by hepatic insulin resistance, resulting in  $\beta$ -cell impairment and/or decreased insulin

secretion due to amyloid deposition in the pancreatic islets, and as a result of  $\beta$ -cell failure, hypoinsulinemia and increased EGP production by the liver (54, 55).

### 2.1.6 Insulin resistance development

In humans, obesity is thought to lead to the development of insulin resistance through a number of mechanisms. The first is the accumulation of FA in the liver and muscle as a result of abnormal FA transport and incomplete fatty acid oxidation. Additionally, oxidative stress and inflammatory response caused by adipocyte hypertrophy, including the release of pro-inflammatory cytokines resulting in elevated phosphorylation of insulin receptor substrates (iRSs). Subsequently, the secretion of adipokines by adipocytes, e.g., adiponectin increases insulin sensitivity. As the mechanism of insulin resistance in obese cats has not been studied in detail, it is presumed that its mechanisms are similar to those in obese humans. This may be indicated by reduced expression of GLUT-4 in muscle and adipose tissue, increased triglyceride content in muscle and liver, and high levels of muscle-fat ratio lipoprotein lipase expression. Unlike humans, cats (excluding the Burmese breed) do not have most of their fat stored in the abdominal cavity. In addition, insulin resistance in cats does not cause systemic inflammation as it does in humans (56).

As weight increases in the cat, insulin sensitivity and the effectiveness of insulin in lowering plasma glucose levels decrease (57, 58). As a result of the persistent state of producing excess insulin, the  $\beta$ -cells eventually become depleted and stop producing insulin (57). In a study by Appleton et al. (57), more than half of the cats also developed impaired glucose tolerance after gaining weight. A 30% decrease in insulin sensitivity was observed for each kilogram of excess body weight in cats (56). As mentioned, the development of insulin resistance is closely related to the development of obesity (59). This is a reversible mechanism and if the animal loses weight, the insulin resistance disappears (17, 59). Interestingly, not all obese cats develop diabetes, and the mechanisms of the obesity–insulin resistance–diabetes interaction are not yet fully understood (59). In cats with T2DM, insulin sensitivity is lower by about 6 times (17).

## 2.2 Complications of untreated type 2 diabetes in cats

The consequences of unrecognized and untreated type 2 diabetes in cats are severe. The main complications of diabetes that have been studied in cats are diabetic neuropathy and diabetic retinopathy. Diabetic neuropathy is one of the most common post-diabetic complications in cats. Although it affects 90% of individuals, only 10% of them show neurological signs. Neuropathy in cats mainly affects the pelvic limbs and motor nerve conduction, and clinical signs include hindlimb paresis,

muscle atrophy most prominent in the distal parts of the pelvic limbs, plantigrade posture, difficulty or inability to jump, abnormal postural responses, ataxia, poor patellar reflex, and increased flatulence and irritability in response to touch (60, 61). Damage in nerves includes changes in Schwann cells with cleavage and ballooning of the myelin sheath, followed by demyelination, and axons of myelinated fibers involving dystrophic accumulation of axoplasmic membrane debris and glycogen, and degenerative fiber loss (61, 62). The changes observed in Schwann cells seen in cats are similar to those seen in humans with diabetes (60). Diabetic retinopathy damages blood vessels in the retina. A model of oxygen-induced retinopathy in cats was proposed as early as the 1950s, but the long development time of diabetic retinopathy and limitations in research reagents means that it is not the most popular model (63). In feline diabetics, however, diabetic cataracts often develop along with linear opacification of the posterior cortex and cortical cataracts or posterior subcapsular plaques. Complete blindness due to diabetic cataracts is very rare in adult cats, but kittens can develop more severe cataracts resulting in blindness (64, 65). Diabetic nephropathy is a serious complication of diabetes in humans, but diabetes-induced nephropathy is rare in cats (66). However, since kidney disease in older cats can be as common as diabetes, it is difficult to determine whether it is due to damage from diabetes or whether it is a comorbid condition. The incidence of chronic kidney disease in cats ranges from 17 to 63%, and in cats newly diagnosed, 13% developed the disease during a follow-up 6-month study (67–69). In addition to the described complications, about one-third of cats with diabetes develop hypersomatotropism, resulting in the development of acromegaly. Diabetes may also be implicated in the increased development of heart disease and echocardiographic changes, but there are still few studies evaluating the impact of diabetes on heart disease in cats (70).

## 2.3 Diagnosis of type 2 diabetes in cats

Clinical signs of type 2 diabetes mellitus in cats include persistent hyperglycemia, polyuria, polyphagia, polydipsia, and decreased muscle mass with, as a consequent, weight loss, and liver enlargement (18, 22, 71).

The diagnosis of insulin sensitivity and type 2 diabetes mellitus in cats is not the same as in humans. In humans, the homeostatic model assessment (HOMA) and the quantitative insulin sensitivity method are used to assess insulin sensitivity (54). However, in cats the HOMA method is considered insufficient to reflect changes in insulin sensitivity (54). Additionally, stress-induced hyperglycemia has been observed in cats (71). A study by Ray et al. (72) showed that more than half of healthy cats without T2DM admitted to the hospital exhibited hyperglycemia (72). As cats are particularly susceptible to stress, it

can be triggered by several factors, e.g., travel, being in the waiting room of a veterinary clinic, or having blood drawn for a test (71). The increase in blood glucose levels due to stress is rapid - it is observed after about 5 minutes and can last for up to 3 hours (18). Because of this unique characteristic of cats, type 2 diabetes can be diagnosed using methods that are not as influenced by stress. To diagnose a cat, it is advisable to perform a general urine test with glucose detection and relative density and a serum fructosamine determination (71). Urinary glucose occurs when serum glucose levels in cats exceed 200-288 mg/dl (11-16 mmol/l). As for the relative density of urine, it is typically 1.026-1.035 (71). Fructosamine is defined as the total of plasma proteins that have undergone the process of protein glycation. Its concentration in the blood can determine the blood glucose concentration up to 2-3 weeks before its determination. Decreased fructosamine levels are also observed when plasma protein levels are decreased and in hyperthyroidism (71). Unfortunately, the use of fructosamine is not always effective because healthy cats with naturally elevated fructosamine levels and T2DM cats with normal fructosamine levels have been reported (18). Cats with suspected T2DM may also have glycosylated hemoglobin, which indicates glucose levels approximately 70 days before the test. Additionally, this method has disadvantages, the results may be reduced in the case of anemia, and the too-long time required to reflect blood glucose concentration makes it an ineffective diagnostic tool (71).

### 3 Adipokines

All substances secreted by adipose tissue are called adipokines, although the types differ. Adipokines can be hormones, such as leptin, adiponectin, plasminogen activator inhibitor-1 (PAI-1), or cytokines, such as interleukin 8 (IL-8) or tumor necrosis factor- $\alpha$  (TNF $\alpha$ ) and chemokines (73). Among adipokines, leptin, adiponectin, resistin, and omentin, as well as cytokines and chemokines (TNF- $\alpha$ , IL-6), result in chronic inflammation, which may play a key role in the development of insulin resistance and T2DM and increase the

risk of obesity-related cardiovascular disease, collectively referred to as the metabolic syndrome (1, 2, 74, 75).

The view of adipose tissue changed significantly after 1994, when the Ob gene and its product, leptin, were identified and characterized, and now adipose tissue is known to be an organ involved in endocrine function, the central nervous system, the immune system, and energy metabolism (8).

The observed increase in adipokines in obese patients includes cytokines, e.g., interleukin 6 (IL-6), interleukin 8 (IL-8), interleukin 18 (IL-18), TNF- $\alpha$ ; acute phase proteins, e.g., C-reactive protein (CRP), plasminogen activator inhibitor-1 (PAI-1), haptoglobin; and chemokines, e.g., monocyte chemoattractant protein-1 (MCP-1) (16, 76). The increase in adiponectin concentration is inversely proportional to body weight gain. It has been observed that there is diurnal variation in adiponectin levels, with an increase in the morning and a decrease at night (20). Adipokines play important roles in the pathophysiology of obesity and diabetes in humans (77). There is a need to determine what role they play in T2DM in cats and whether they could be used as biomarkers of disease progression in the future (Table 1).

#### 3.1 Leptin

Leptin is known as the central satiety signal because it regulates body composition and energy expenditure (20). It also influences sympathetic nervous system activity, hematopoiesis, and reproductive function and modulates the immune responses by having a pro-inflammatory effect and activating T cells (9, 16, 20). Additionally, is known to regulate nutritional intake, which may impact thermogenesis because it increases energy expenditure, stimulates lipolysis, and inhibits lipogenesis (24, 98). Leptin is produced by adipocytes and in minor amounts by the central nervous system (CNS), skeletal muscles, stomach, and placenta (20, 99). Although leptin has an inhibitory effect on adipose tissue cell differentiation, its secretion increases during adipocyte maturation from preadipocytes. Leptin release is initiated by TNF $\alpha$  and

TABLE 1 Changes in levels of selected adipokines in cats and humans with T2DM and obesity compared to healthy individuals.

Adipokine	T2DM cat	T2DM human	Obese cat	Obese human
Leptin	↑	↑	↑	↑
Adiponectin	↓	↓	↓	↓
Resistin	ND	↑	↑	↑
Omentin	ND	↓	–	↓
TNF- $\alpha$	ND	↑	↑	↑
IL-6	ND	↑	↑	↑

↑, increased levels; ↓, decreased levels; –, no change; ND, no data. Based on (17, 44, 58, 77–97). The similarities in the course of T2DM in humans and cats may allow us to predict how selected adipokines will change levels in T2DM in cats on the basis of data obtained in humans, but more studies are needed. Omentin, in particular, appears to be an interesting case, as it did not change the range of levels in obese cats, unlike its levels in obese humans. In the case given, one study was conducted. To obtain more data, additional studies should be conducted.

chemokines (9). High leptin levels are closely associated with high body fat mass and may lead to further weight gain and therefore the development of insulin resistance (100). Thus, along with IL-6, resistin, and TNF- $\alpha$ , leptin acts as an indicator of obesity initiation and insulin resistance (22).

In humans, leptin is a marker for the development of obesity, and as body fat increases, leptin levels increase (90). Additionally, it has been proposed as a biomarker for type 2 diabetes. In addition, although leptin levels increase in obese and T2DM patients, interestingly, it has been noted that diabetics with high BMI have lower leptin levels than non-diabetics with high BMI (85, 86). It has been indicated that low leptin levels have a significant effect on increasing the risk of developing insulin resistance and type 2 diabetes (86). Leptin affects the body's insulin sensitivity by decreasing the storage capacity of triglycerides in muscle tissues and increasing fatty acid oxidation (90). Because of these unique abilities, leptin has been proposed as a potential therapeutic agent in obesity and type 2 diabetes (101).

Correlations between increased leptin levels and increased BCS and body fat mass have been demonstrated in cats (44, 58, 78–80, 87–89). Leptin levels are not dependent on the sex of the animal (88). In a study by Zapata et al. (58), diabetic cats had leptin levels 221% higher than those in normal-weight cats. Healthy cats that were obese had levels 172% higher compared to those of normal weight (58). In a study by Appleton et al. (89), lower insulin sensitivity, with higher insulin concentrations and indices, was observed in healthy, lean cats aged 1–5 years driven to overweight/obesity. Following an increase in body weight, the cats that had the highest fasting plasma leptin concentrations also had the highest fasting insulin concentrations, along with decreased insulin sensitivity (89). Increased leptin levels are also correlated with increased cat insulin resistance not only in obese but also in lean individuals (24, 89). Additionally, increased insulin levels in obese cats stimulate leptin production as in other animal species (89). As the animal's weight decreased, serum leptin concentrations gradually decreased (81). Leptin levels in lean cats have been shown to increase with increasing age (102). It has been shown that the HC/HB diet has no effect on blood leptin levels in cats (44).

## 3.2 Adiponectin

Adiponectin is secreted by adipocytes in white adipose tissue (103). Adiponectin has anti-inflammatory effects (16). Adiponectin has several important functions, such as improving glucose and lipid metabolism, modulating insulin action, preventing inflammation, and preventing atherosclerosis (20, 104). Adiponectin receptors are located in the liver and skeletal muscle, and it has been suggested that the greatest increase in insulin sensitivity occurs in the liver. Adiponectin, together with AMP-activated protein kinase, increases glucose

uptake in skeletal muscle, oxidizes fatty acids in muscle and liver, initiates the insulin signal transduction cascade in these two tissues, and increases insulin sensitivity (20, 24). Hosogai et al. (104) showed that the presence of ER stress concurrently with obesity affects the downregulation of adiponectin mRNA (104).

In humans, adiponectin levels are lower in patients with obesity, insulin resistance, and T2DM and its reduced levels can be used to predict the development of these diseases (77). Adiponectin in humans has been proposed as a biomarker for diabetes-related cardiac complications and for assessing vascular changes in peripheral type 2 diabetes. Adiponectin levels have also been proposed as a risk factor for cardiovascular disease and coronary artery disease (91). Interestingly, adiponectin has also been indicated as a target for the treatment of type 2 diabetes (77, 91, 101).

Most studies have shown that, in cats, with increasing BCS, adiponectin levels decrease (44, 78–84). However, contrary studies have also been published (82, 105, 106). Adiponectin levels in cats are not dependent on the sex of the animal (88). According to the study by Öhlund et al. (107), adiponectin levels do not differ between healthy individuals of Burmese breed, prone to developing T2DM, and Birman breed with low risk of developing DM (107). In a study by Takashima et al. (81) on healthy cats with normal BCS suffering from obesity that then lost 8% of their weight during a 9-week weight-loss period, it was shown that adipokine levels did not significantly increase in association with weight loss (81). Therefore, the hypothesis was proposed that it is not the degree of obesity that affects adiponectin levels, but other factors, such as, for example, low muscle mass (81). In the same study, a correlation between adiponectin and insulin levels was not found (81). Zapata et al. (58) showed, that compared to healthy cats of normal weight, cats with diabetes had 61% lower adiponectin levels, and cats with diabetes had 45% lower levels compared to healthy obese cats. High molecular-weight (HMW) adiponectin multimers, which are associated with insulin sensitivity, account for approximately 80% of adiponectin in cats, whereas they only account for 30% in humans (17). It has been shown that the HC/HB diet had no effect on blood adiponectin levels in cats (44).

## 3.3 Resistin

Because resistin's mRNA has been detected in humans in circulating mononuclear cells, not adipocytes, and is released from non-fat adipose tissue cells, Fain (3) proposed that resistin is a cytokine secreted by cells of the immune system (3). Resistin is insulin-resistant and impairs glucose homeostasis. Its function is to downregulate inflammation in macrophages, peripheral blood mononuclear cell (PBMC) and vascular cells (108).

Resistin levels are elevated in obese humans, and also in humans with T2DM, but there are no data for cats with T2DM (91). Resistin is involved in the development of insulin resistance

and T2DM, and for this reason, it too has been proposed as a biomarker for these diseases. In addition, in humans, it has also been proposed as a biomarker for diabetes complications related to chronic periodontitis and cardiovascular disease (91, 109).

It has been reported that resistin levels increase with increasing BCS and body fat mass in cats (78, 79). Cats with obesity have higher resistin mRNA expression in adipose tissue compared to lean cats (78). In addition to adipose tissue, in cats resistin expression may also occur in the lung and spleen (81). However, in the previously described study by Takashima et al. (81), resistin levels also did not change significantly. Resistin was negatively correlated with insulin in the blood of the cats studied (81), which is confusing, since an important role in the pathogenesis of insulin resistance and T2DM has also been indicated (79).

### 3.4 Omentin

Omentin, although not yet studied in cats with T2DM, deserves consideration because of its unique properties. It has regulatory functions, modulates insulin secretion and insulin sensitivity, and can increase insulin action, affecting fat accumulation, adverse fat breakdown, and inflammation (55, 110). In humans, omentin-1 levels are lower in individuals with T2DM compared to healthy controls (110).

In people with obesity and T2DM, omentin levels are lower than in healthy people, but not in patients with type 1 diabetes (91, 92). Omentin has anti-inflammatory, anti-obesity and anti-diabetic properties, and these are indicated when omentin is proposed as a therapeutic target (90, 91). Omentin has also been proposed as a marker for predicting obesity and T2DM risk (90).

In cats, Williams et al. showed that blood concentrations of omentin are not dependent on BCS, but are 56% higher in males (88). In cats, omentin levels were also not correlated with insulin or glucose levels, as has been reported in humans (88).

### 3.5 TNF- $\alpha$

TNF- $\alpha$  has various important functions related to adipose tissue regulation, it responds to inflammation, induces apoptosis, stimulates lipolysis, modulates insulin sensitivity, induces insulin resistance, inhibits adipocyte differentiation, disrupts leptin homeostasis, and induces chemokine secretion (9, 16). TNF- $\alpha$  stimulates IL-6 and MCP-1 expression and inhibits adiponectin mRNA expression. Wang et al. (16) described the lack of effect of TNF- $\alpha$  on leptin expression in humans (16). Among the roles of TNF- $\alpha$  are also the promotion of lipid mobilization, inhibition of adipocyte differentiation, and reduction of lipid storage capacity (79).

In humans, TNF- $\alpha$  levels are elevated in people with T2DM and obesity, and TNF- $\alpha$  itself plays roles in the development of insulin resistance (93). TNF- $\alpha$  and its receptors have been

indicated to be biomarkers for the progression of diabetic kidney disease (111, 112) and for assessing the degree of diabetic retinopathy (93).

In cats, TNF- $\alpha$  levels increase with increasing BCS and body weight, and increased levels of TNF- $\alpha$  expression have been shown in adipose tissue and skeletal muscle in obese cats (94, 95). However, in a study by Hoenig et al. in cats that were driven to obesity, TNF- $\alpha$  levels did not show significant changes (80).

### 3.6 IL-6

IL-6 is a pro-inflammatory cytokine secreted from leukocytes, endothelial cells, and adipocytes. Its plasma levels in obese patients are directly proportional to weight loss and fat loss. It regulates the development of chronic diseases such as cardiovascular disease (CVD), where it induces the secretion of a risk marker, hepatic C-reactive protein, and type 2 diabetes mellitus (113). By decreasing lipoprotein lipase (LPL) activity, it increases blood lipid levels (113). By inhibiting the expression of the insulin receptor, insulin receptor substrate-1, and glucose transporter type 4 in 3T3-L1 adipocytes, IL-6 suppresses insulin activity (113). A correlation has been shown between increased IL-6 levels and the occurrence of insulin resistance (3). Additionally, attenuating adiponectin mRNA synthesis and secretion, and inhibition of insulin signaling in hepatocytes contribute to insulin resistance (113).

In humans, IL-6 levels increase in patients with T2DM and obesity (96, 97). IL-6 has been shown to be correlated with the development of complications in diabetes, including diabetic neuropathy, in which high levels of IL-6 are associated with increased nerve degeneration (90, 114).

Plasma IL-6 levels are elevated in obese cats (17). Here again, Hoenig et al. showed no significant changes in IL-6 levels in cats that had gained weight (80).

## 4 Conclusion

T2DM is a serious disease that an increasing number of domestic cats are suffering from. The multitude of factors that can cause this disease indicate its severity. Some of the risk factors, such as nutrition and the development of obesity, can be influenced by the pet's caregiver. Therefore, it is worthwhile for veterinary professionals to educate cat guardians on the proper management of the animal to limit the development of the disease.

The domestic cat is still a very poorly studied species in terms of the pathogenesis of diabetes mellitus. Most of the information on the subject is still based on data obtained from humans. This is enabled by the high similarity of feline diabetes to human T2DM. In order to better understand the exact mechanisms of the disease, especially regarding adipokines,

studies focusing not only on obesity, which is indeed also an important factor in the development of T2DM, but also on cats already suffering from diabetes themselves, are needed.

The data collected in the above review indicate a promising role for the presented adipokines as biomarkers of type 2 diabetes in cats. Adipokines may be a promising means to control disease progression and recovery in the animal. Notably, adipokines have been proposed as biomarkers of disease in humans, e.g., resistin as a biomarker for diabetes complications related to chronic periodontitis and cardiovascular disease. Biomarkers are useful in the course of disease progress, as they can be used not only for risk assessment and screening, but also to determine the severity of the disease and to select and monitor therapy (109). It is particularly important to discover rapid, sensitive and effective methods for risk assessment in feline type 2 diabetes.

**Background:** As a systemic skeletal dysfunction, osteoporosis (OP) is characterized by low bone mass and bone microarchitectural damage. The global incidences of OP are high.

**Methods:** Data were retrieved from databases like Gene Expression Omnibus (GEO), GeneCards, Search Tool for the Retrieval of Interacting Genes/Proteins (STRING), Gene Expression Profiling Interactive Analysis (GEPIA2), and other databases. R software (version 4.1.1) was used to identify differentially expressed genes (DEGs) and perform functional analysis. The Least Absolute Shrinkage and Selection Operator (LASSO) logistic regression and random forest algorithm were combined and used for screening diagnostic markers for OP. The diagnostic value was assessed by the receiver operating characteristic (ROC) curve. Molecular signature subtypes were identified using a consensus clustering approach, and prognostic analysis was performed. The level of immune cell infiltration was assessed by the Cell-type Identification by Estimating Relative Subsets of RNA Transcripts (CIBERSORT) algorithm. The hub gene was identified using the CytoHubba algorithm. Real-time fluorescence quantitative PCR (RT-qPCR) was performed on the plasma of osteoporosis patients and control samples. The interaction network was constructed between the hub genes and miRNAs, transcription factors, RNA binding proteins, and drugs.

**Results:** A total of 40 DEGs, eight OP-related differential genes, six OP diagnostic marker genes, four OP key diagnostic marker genes, and ten hub genes (TNF, RARRES2, FLNA, STXBP2, EGR2, MAP4K2, NFKBIA, JUNB, SPI1, CTSD) were identified. RT-qPCR results revealed a total of eight genes had significant differential expression between osteoporosis patients and control samples. Enrichment analysis showed these genes were mainly related to MAPK signaling pathways, TNF signaling pathway, apoptosis, and Salmonella infection. RT-qPCR also revealed that the MAPK signaling pathway (p38, TRAF6) and NF-kappa B signaling pathway (c-FLIP, MIP1B) were significantly different

between osteoporosis patients and control samples. The analysis of immune cell infiltration revealed that monocytes, activated CD4 memory T cells, and memory and naïve B cells may be related to the occurrence and development of OP.

**Conclusions:** We identified six novel OP diagnostic marker genes and ten OP-hub genes. These genes can be used to improve the prognostic of OP and to identify potential relationships between the immune microenvironment and OP. Our research will provide insights into the potential therapeutic targets and pathogenesis of osteoporosis.

osteoporosis, GEO, WGCNA, immune cells, bioinformatics analysis

## Introduction

Osteoporosis (OP) is a systemic bone disease characterized by low bone mass and destruction of bone microarchitecture (1), which increases the fragility of the bone and fracture risk (2, 3). OP is the fourth leading chronic disease after heart disease, dementia, and lung cancer (4). Bone homeostasis depends on osteoclast resorption and osteoblast formation, and an imbalance in this tightly coupled process can lead to the development of osteoporosis (5). Hip and vertebral fractures are two common osteoporotic fractures (6). Elderly patients with osteoporotic fractures often require hospitalization, resulting in poor quality of life, long-term medical care, disability, and even death (7). This creates a substantial economic and social burden worldwide and is a global public health challenge (8, 9). Due to its asymptomatic nature, patients with OP are often not diagnosed until the first osteoporotic fracture occurs. Therefore, it is very important to find biomarkers that enable early diagnosis.

In recent years, it has been established that bone and immune cells share the same progenitor cells and are affected by the same cytokines (3). They are functionally linked, and the infiltration of immune cells plays a vital role in the occurrence and development of OP (10). Factors such as the balance between Th1/Th2/Treg cells (3), inflammatory T cells (Th17) (4, 10), regulatory B cells (Bregs) (4), and macrophages (11) play an important role in regulating osteoblasts and osteoclast homeostasis, which in turn affects osteoporosis (12). Regarding the immune system, assessing the varying degrees of immune cell infiltration and identifying the compositional differences in the infiltrating immune cells can help elucidate the molecular pathological mechanism of OP and develop new immunotherapeutic targets.

In this study, to explore the potential diagnostic marker genes for OP, six OP diagnostic marker genes were screened for prognosis of OP, which can predict the prevalence of OP. First,

the two OP immune signature subgroups were divided using a consensus clustering method, and differential expression analysis was performed to obtain 40 differentially expressed genes (DEGs). Secondly, eight OP-related differential genes were screened using Weighted gene co-expression network analysis (WGCNA), Gene Ontology (GO) functional annotation, Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment, and Gene Set Enrichment (GSEA) analysis disease ontology (DO) disease annotation, and Gene Set Variation Analysis (GSVA) were performed on eight DEG. To conduct network analysis, we identified 10 hub genes using the cytoHubba function of Cytoscape software. RT-qPCR was performed on the plasma of osteoporosis patients and control samples. The results revealed a total of eight genes that had significantly different expression levels, and the following signaling pathways such as MAPK signaling pathway (p38, TRAF6) and NF-kappa B signaling pathway (c-FLIP, MIP1 $\beta$ ), had significant different expressions. Out of the eight OP-related DEGs, six diagnostic marker genes were tested using Least Absolute Shrinkage and Selection Operator (lasso) regression and random forest using the new dataset. The Cell-type Identification by Estimating Relative Subsets of RNA Transcripts (CIBERSORT) algorithm was used to evaluate the level of immune cell infiltration in the two clusters, and the results showed that there were significant differences in proportions of monocytes, CD4 memory activated T cells, memory, and naïve B cells. Based on six OP-related diagnostic marker genes, two distinct molecular subtypes were identified using a consensus clustering approach. Prognostic analysis was carried out, and four key diagnostic marker genes were identified. Finally, the interaction network with miRNA, transcription factors (TF), RNA binding protein (RBP), and the drugs were constructed for key genes. Our study suggests that targeting these six diagnostic marker genes and ten hub genes may enhance the diagnosis and treatment of OP.

## Materials and methods

### Data downloaded

Download GSE56815 (13), GSE7158 (14) and GSE56116 (15) datasets from GEO database, In which GSE56815 contains 40 osteoporosis samples (OP) and 40 control samples from GPL96 sequencing platform, GSE7158 contains 12 osteoporosis samples Osteoporosis samples (OP) and 14 control samples were obtained from the GPL570 sequencing platform, and GSE56116 included 10 osteoporosis samples (OP) and 3 control samples from the GPL1433 sequencing platform, all of which were human peripheral blood sample. The above data were integrated for downstream analysis, the R package sva (16) was used to correct for batch effects between different datasets and log2 normalization was performed, and then the batch-corrected expression distribution was visualized using boxplots, where 62 osteoporosis samples and 57 control samples were included.

In order to analyze the expression of osteoporosis-related genes in all samples, we first obtained osteoporosis-related genes from the GeneCards database (17) through the keyword “Osteoporosis”, a total of 4657 genes, and intersected with the existing expression profiles. All 4657 genes were retained.

### Unsupervised clustering of samples

The R package factoextra (18) was used to determine the optimal number of clusters. The k-means clustering method was used for unsupervised clustering of all patients based on the optimal number of clusters, and the samples were divided into two categories. Finally, the R package was used to see the final clustering effect. Heatmap was used to visualize the gene expression profile of the two groups. The R package ggpubr (19) was used to construct the grouping histogram based on the sample clustering label. The Wilcoxon rank-sum test method was used to study the statistically significant differences between the groups.  $P < 0.05$  was considered to be statistically significant.

### Immune infiltration analysis

CIBERSORT is a deconvolution algorithm based on the principle of linear support vector regression to study the expression matrix of immune cell subtypes. It uses RNA-Seq data to estimate the abundance of immune cells in a sample (20). CIBERSORT: R package was used to estimate the quantity of 22 immune cells between disease and control samples in the datasets. The immune cell composition was visualized using boxplots. Differences in immune cell proportions were

calculated using the Wilcoxon test, and  $P < 0.05$  was considered statistically significant.

Pearson correlation was used to investigate the correlation between the immune cell expression in all patients. The two genes were correlated if the absolute value of the correlation coefficient  $> 0.3$  and the  $P < 0.05$ . Correlations between matching gene pairs were plotted using the R package ggplot2 (21).

### Osteoporosis-related DEGs

In order to analyze the effect of different gene expression levels on patients with different subtypes of osteoporosis, the R package limma (22) was used to perform differential gene analysis between the two groups of patient samples in the integrated dataset. The significant differential genes (DEGs) were screened.  $\log_2$  (fold change) ( $\log_2FC$ )  $> 1.5$  and  $P_{adj} < 0.05$  was set as the thresholds of DEGs. Genes with  $\log_2FC > 1.5$  and  $P_{adj} < 0.05$  were up-regulated DEG, and genes with  $\log_2FC < -1.5$  and  $P_{adj} < 0.05$  were down-regulated DEG. The volcano plot shows the up-regulated DEG, and the R package pheatmap (23) shows the expression heat map of these DEG in all the samples. The R package ggpubr (19) was used to analyze the expression of osteoporosis-related genes in the two groups and construct grouped box plots based on the two subtype samples. Wilcoxon rank sum test method was used to test the statistically significant difference between the groups.  $P < 0.05$  was considered statistically significant.

### Weighted gene co-expression network analysis

Weighted gene co-expression network analysis (WGCNA) is a systems biology method used to describe gene association patterns between different samples, and can be used to identify gene sets with highly coordinated changes. And identify candidate biomarker genes or therapeutic targets based on the interconnectivity of gene sets and the association between gene sets and phenotypes. We used the R package WGCNA (24) to calculate the key gene sets associated with the disease and normal two groups of samples and used them for subsequent analysis.

### Functional enrichment analysis

To investigate the biological differences between sample groups, gene set enrichment analysis (GSEA) was performed on DEG. Gene Ontology (GO) enrichment analysis is commonly used for large-scale functional enrichment analysis of genes at different dimensions and levels, mainly:

biological process (BP), molecular function (MF), and cellular component (CC) (25). Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment analysis is widely used for storing information about genomes, biological pathways, diseases, and drugs (26). Disease Ontology (DO) is the annotation of genes in the context of the disease. All the significantly DEG were subjected to GO, KEGG pathway enrichment, and disease annotation using the R package clusterProfiler (27) and the DOSE: R Package (28) to identify significantly enriched biological processes. The enrichment results were represented as bubble graphs for visualization. The significance threshold for the enrichment analysis was set at a corrected p-value < 0.05.

Gene Set Enrichment Analysis (GSEA) is a computational method used to determine whether a predefined gene set shows statistical differences between the two biological states. It is typically used to estimate expression in a dataset sample, changes in biological process, pathways, and activity (29). To investigate the differences in biological processes between the two groups of samples, based on the gene expression profiling dataset, the reference gene sets “c5.go.v7.5.1.entrez.gmt” and “c2.cp.kegg.v7.5.1.entrez.gmt” were downloaded from the Molecular Signatures Database MSigDB (30), for enrichment analysis and visualization of the dataset using the GSEA method included in the R package “clusterProfiler.” Adjusted p-values < 0.05 were considered statistically significant.

Gene Set Variation Analysis (GSVA) (31), is a non-parametric unsupervised analysis method. It mainly converts the gene expression matrix between different samples into the gene expression sets between samples. Quantity matrices were used to evaluate gene set enrichment results from microarray transcriptome data. To evaluate whether different pathways are enriched in different samples, the “c5.go.v7.5.1.entrez.gmt” and “c2.cp.kegg.v7.5.1.entrez.gmt” gene sets were retrieved from the MSigDB. Further, GSVA was performed at the gene expression level to calculate the differences in functional enrichment between groups (disease and control groups).

## Validation of osteoporosis marker genes

The identified diagnostic marker genes were validated using the osteoporosis dataset GSE7429 (32) retrieved from the GEO. The sequencing platform used for this dataset was GPL96 for humans. Data was first log-normalized and then divided into disease and control groups based on gene expression data of each marker. Lasso regression analysis was performed for univariate and multivariate analysis. The receiver operating characteristic (ROC) curve was used to evaluate the performance of marker genes in predicting the groups. ROC curves were drawn using the R package pROC (33).

## Network analysis

The Search Tool for the Retrieval of Interacting Genes/Proteins (STRING) (34) database searches for interactions between known and predicted proteins. The STRING database was used to select genes with a combined score greater than 400 to construct a protein-protein interaction (PPI) network related to DEG. Cytoscape (v3.7.2) (35) is used to visualize the PPI network model. PPI network analysis was performed using the CytoHubba (36) function in Cytoscape.

## Estimation of key genes

Ridge regression was first used to screen for osteoporosis-related genes. The analysis was performed using the R package glmnet (37) and was used to select the best lambda value. Only genes with coefficients other than zero were retained after regression analysis. The genes were further screened using logistic regression. The genes used to construct the model, and their corresponding coefficients were displayed in the form of forest plots using the R package forestplot (38).

To examine the multivariate influence of eigengenes in the diagnostic model, a new logistic multivariate regression model was constructed using the R package rms (39) on the genes with significant absolute weights in the previous model. To verify the predictive grouping efficacy of key genes, the ROC package pROC (33) was used to draw the ROC curve of the model and calculate the area under the curve (AUC).

## Panorama of key genes

The R package RCircos (40) was used to map the location of genes on the chromosomes. The chromosome data were provided by the R package, and the information regarding the location of genes on chromosomes was downloaded from the ENSEMBL (41) database. Boxplot was constructed using R package ggplot2 to analyze the differences in the expression of key genes in all the patients. The Gene Expression Profiling Interactive Analysis (GEPIA2, 42) explores the RNA-seq expression data from tumor and normal tissues retrieved from TCGA and GTEx databases. GEPIA2 was used to obtain the expression of key genes in tumor and normal samples from various human tissues.

## Multidimensional network analysis of key genes

TF controls gene expression by interacting with target genes at the transcriptional stage. miRNet database (43) was used to

construct the regulatory network of key genes, TFs, and miRNAs. RBP is an important protein of the cells, which interacts with RNA by recognizing certain RNA binding domains. It is widely involved in RNA splicing, transport, sequence editing, intracellular localization, translation control, and post-transcriptional regulation. The regulatory network of key genes-RBP was constructed using the RBP2GO database (44). RNAactDrug database (45) was used to build a key gene-drug regulatory network.

## Real-time fluorescence quantitative PCR

Peripheral blood of four clinical osteoporosis patients and three healthy adults were obtained from the Second Affiliated Hospital of Inner Mongolia Medical University. (This study was performed in line with the principles of the Declaration of Helsinki. Approval was granted by the Ethics Committee of Second Affiliated Hospital of Inner Mongolia Medical University. The ethical review number: YKD202002055). 5ml peripheral venous blood was collected with EDTA-K2 anticoagulant blood collection tube. After centrifugation at 1500 r/min for 15 minutes, the uppermost plasma was obtained. Total RNA was extracted from plasma samples. The genomic DNA was removed from the RNA sample, and RNA was reverse transcribed using the PrimeScript<sup>TM</sup> RT reagent Kit with gDNA Eraser (RR047A, Takara, Japan). Real-Time quantitative PCR was performed using the SYBR<sup>®</sup> Premix Ex Taq (Takara, Japan, RR820A) kit using a real-time PCR machine (ABI-7500, Applied Biosystems, USA). The PCR amplification was carried out for a total of 42 cycles. The mean + standard error of three independent experiments were calculated, with each experiment repeated three times. Relative mRNA expression levels were calculated using *GAPDH* as an internal reference.

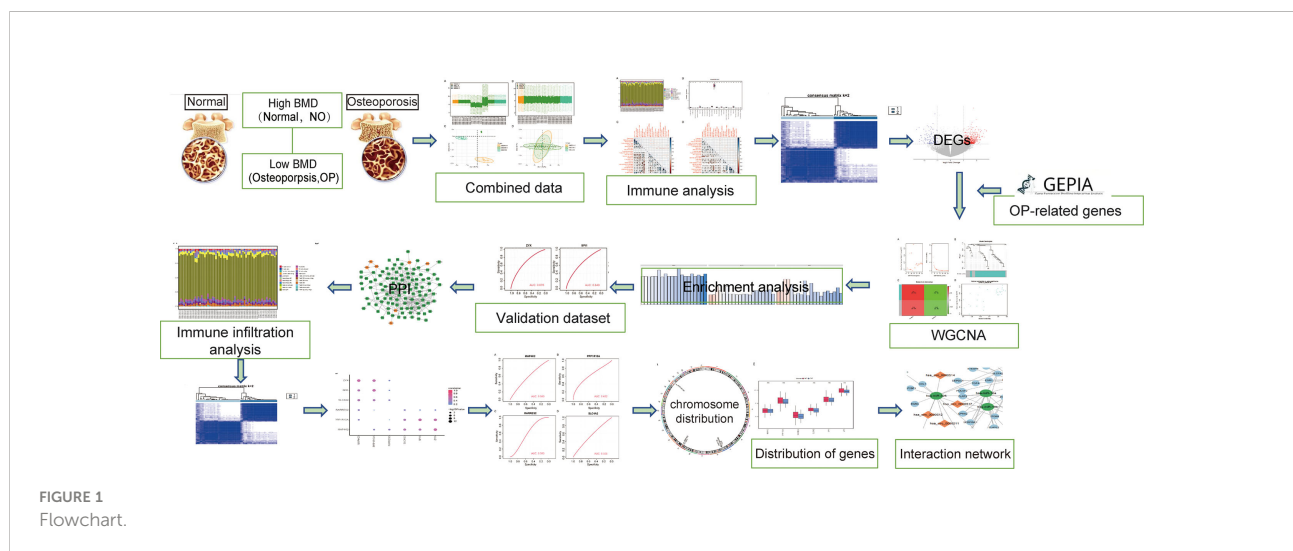

## Statistical analysis

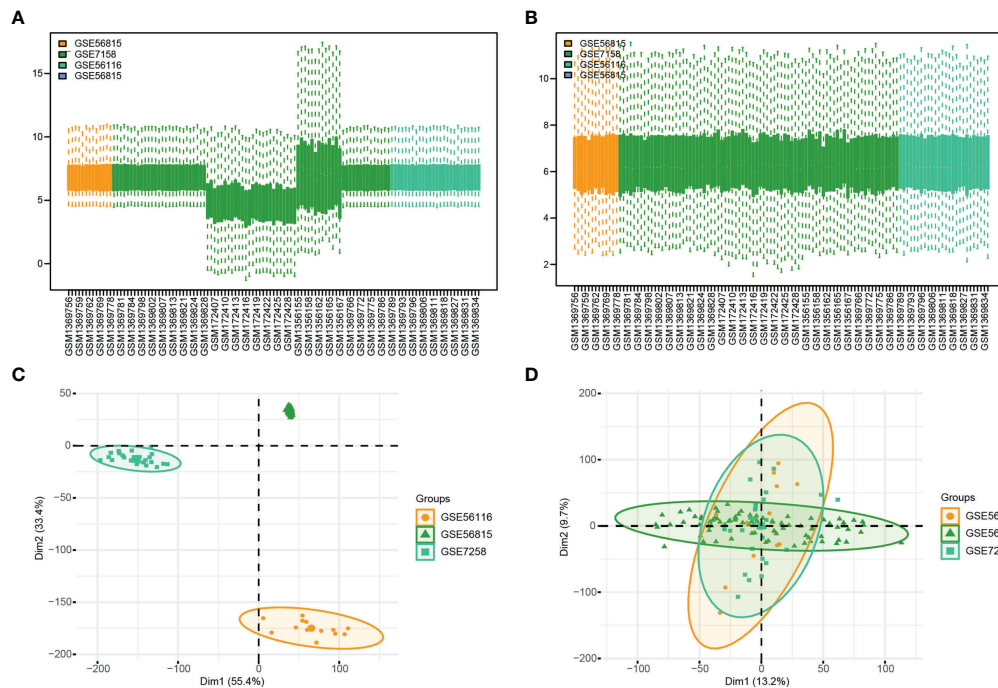

All data processing and analysis were conducted using R software (version 4.1.1). The student's t-test was used to compare the two continuous variables groups and evaluate the statistical significance of normally distributed variables. The independent and the differences among non-normally distributed variables were analyzed using the Mann-Whitney U test (i.e., the Wilcoxon rank sum test). Chi-squared test or Fisher's exact test was used to compare and analyze statistical significance between two groups of categorical variables. Correlation coefficients between different genes were calculated using Pearson correlation analysis. The t-test was used to compare the mean values of two groups of samples, and the analysis of variance (ANOVA) test was used to compare the mean values of multiple groups of samples. All statistical P values were two-sided.  $P < 0.05$  considered statistically significant.

## Results

### Gene Expression Omnibus data preprocessing

In order to clearly show the specific process of this study, the bioinformatics analysis process is specially summarized as shown in the figure (Figure 1). To construct a panorama of osteoporosis-related genes in all samples, the expression profiles of all three datasets were integrated. Datasets from different sources generally have severe batch effects. Hence the raw data was first analyzed and then corrected for batch effects and log normalization. Boxplots were drawn using the data OP and Normal groups retrieved from datasets GSE56815, GSE7158, and GSE56116 (Figures 2A, B). The results show that after batch correction and log normalization, the distribution of expression profiles of all the samples tends to be overall consistent, which

**FIGURE 2**  
Gene Expression Omnibus (GEO) data preprocessing. (A, B) are the differences in data distribution before and after data set processing. (C, D) results from PCA dimensionality reduction before and after data set processing.

was more conducive to improving the accuracy and robustness of the downstream analysis (Figure 2). The batch effect was removed to obtain an integrated dataset, which included 62 osteoporosis and 57 control samples.

## Overall immune level analysis and differential analysis of immune signature subtypes in osteoporosis

The immune microenvironment is a complex integrated system composed mainly of immune cells, inflammatory cells, fibroblasts, interstitial cells, various cytokines, and chemokines. The analysis of infiltrated immune cells in samples plays an important role in understanding the pathology, prognosis, and treatment of the disease. To analyze the differences in immune levels between normal and disease states, we analyzed the overall immune profile of normal (NO) and osteoporotic (OP) patient samples (Figures 3A–D). CIBERSORT analysis of immune infiltration analysis (Figure 3A) reveals that the content of monocytes was high in OP and normal samples. Compared to normal samples, the OP patient samples only showed significant differences in the expression levels of M0, M1 Macrophages, and activated dendritic cells (Figure 3B). Further, the correlation of immune cell content in normal and OP patient samples was

analyzed. The results revealed a significant correlation between the memory B cells and monocyte content in normal samples and various immune cells (Figure 3C). In OP patient samples, a significant correlation between the content of the activated mast cells and M0 macrophages, and various other immune cells (Figure 3D).

Here, a consensus clustering method commonly used in tumor typing is used. We wanted to use this method to divide the 62 OP patient samples from the 3 datasets into an appropriate number of subgroups. Furthermore, differential expression analysis was performed on its different subgroups. The obtained differential expression results can not only represent the difference between OP and normal samples, but also reflect the differential genes between different types (or grades) of OP. Different expression patterns were identified in 62 osteoporosis patient samples using a consensus clustering method (ConsensusClusterPlus package in the R software). Figures 3E, F show the matrix heatmaps for  $k=2$  and  $k=6$ , and the clustering results are better separated when  $k=2$ . Secondly, considering the consistent Cumulative Distribution Function (CDF) plot and the Delta Area Plot, the CDF at  $k=2$  had a lower slope of decline and a lower change in the AUC (Figures 3G, H). Two osteoporosis subtypes (cluster1 and cluster2) were finally identified (Figures 3E–H), with cluster 1 containing 34 samples and cluster 2 containing 28 samples. (Figure 3E).

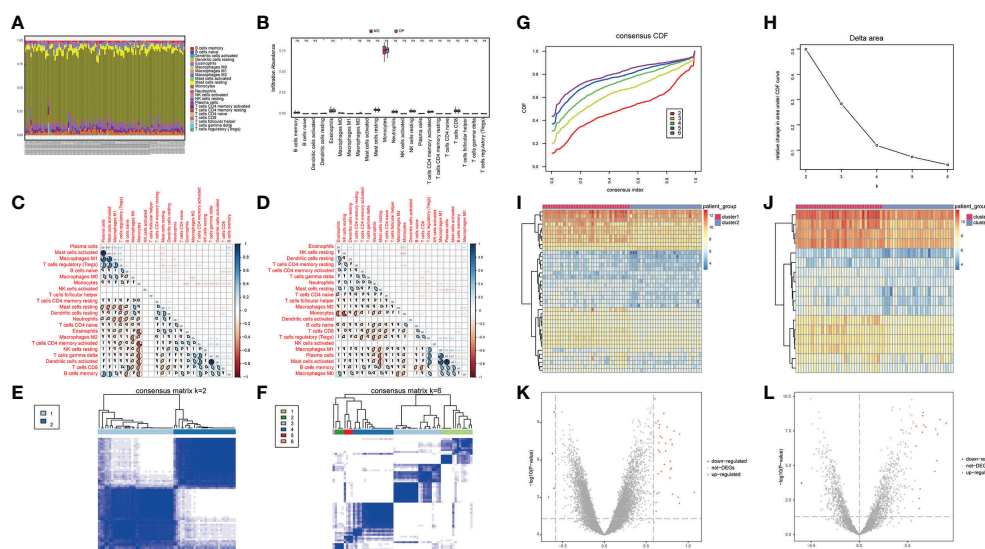

FIGURE 3

Overall immune level analysis and differential analysis of immune signature subtypes in osteoporosis. (A) The content of immune cells between the osteoporosis (OP) and the control group. Different colors represent different immune cells, and the horizontal axis represents the patient id. (B) Histogram of immune cell content, the horizontal axis represents immune cells, the vertical axis represents cell content, red represents the control group samples, and blue represents the disease group samples. (C-D) Correlation of immune cell content in the normal group (C) and disease group samples (D); red indicates a negative correlation, and blue indicates a positive correlation. (E, F) Consistent clustering result graph, different colors represented different groups. (G) Cumulative Distribution Function (CDF) plot of consensus clustering, showing the curve of the CDF as the number of clusters changes. (H) Delta Area plot, calculating the relative change in the area under the curve (AUC) of the CDF as the number of clusters increases. (I, J) Heatmaps of differentially expressed genes (DEG), where red is for cluster 1 and blue is for cluster 2. (K, L) the volcano plot for DEG, the abscissa is  $\log_2$ Fold Change, the ordinate is  $-\log_{10}$  (adjust P-value), red nodes indicate up-regulated DEG, gray nodes indicate genes that are not significantly differentially expressed, and blue nodes indicate down-regulated genes DEG.

To understand the biological differences between the two patient subgroups, the DEG analysis was first performed on the two patients' subgroups. The threshold was set as  $\text{padj} < 0.05$  and  $\text{foldchange} > 1.5$  or  $\text{foldchange} < -1.5$ , and a total of 40 DEGs were identified during the analysis. There were 36 up-regulated genes and four down-regulated genes (Figures 3I, K). The OP-related genes retrieved from GeneCards were intersected, and a total of 17 genes that were significantly different between the two groups of patients and related to OP were retained (Figures 3J, L).

## Functional enrichment analysis between samples

To explore the relationship between the differentially expressed OP-related genes, WGCNA analysis was performed on the DEG between the two groups of patients (Figure S1A). A co-expression module was identified (Figure S1B), and the gene set with the highest correlation was identified and subjected to subsequent analysis (Figures S1C, D) 1198 key genes were obtained. After intersecting with differentially expressed OP-related genes, eight genes were obtained for subsequent analysis (Table S1).

To explore the influence of the differential genes on the biological functions of different patient subtypes, GO enrichment analysis was performed on the differential genes. The biological processes enriched by these differential genes were myeloid cell differentiation, regulation of stress-activated MAPK cascade (Figure 4A), and cell groups such as vesicle lumen and tertiary granule (Figure 4B). The molecular functions enriched by these differential genes were ubiquitin protein ligase binding and ubiquitin-like protein ligase binding (Figure 4C). KEGG pathway enrichment analysis revealed these differential genes significantly enriched pathways such as Salmonella infection and MAPK signaling pathway (Figure 4D). In addition, Disease ontology analysis (DOSE) was performed on the differential genes. The results revealed that the DEG between different patient subtypes was significantly enriched in heart valve disease (Figures 4E, F).

GSEA analysis was performed on the differential genes, and the results revealed significant differences in the following biological processes between the two groups of patient samples. In cluster 1 patient samples, the regulation of response to stimulus, negative regulation of the cellular process, and negative regulation of biological and other biological processes were activated (Figures 4G, H).

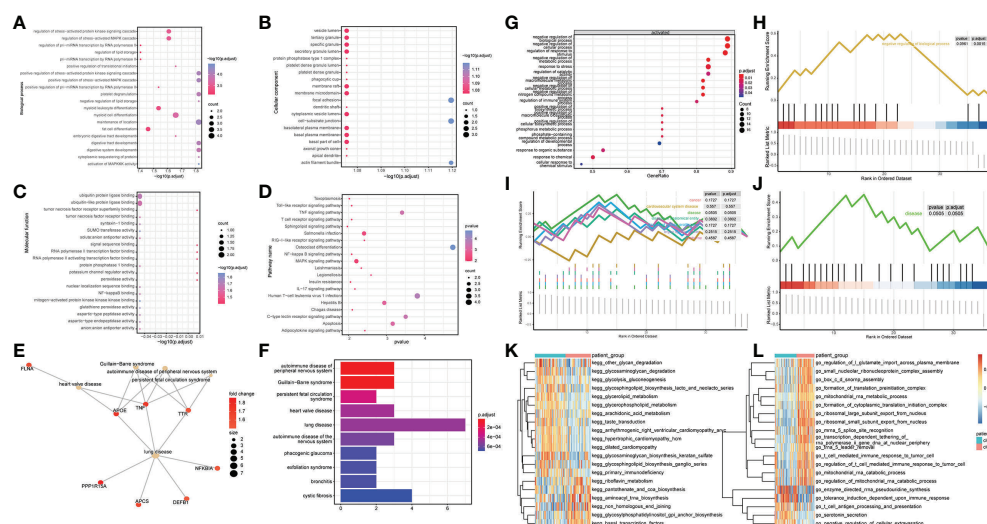

FIGURE 4

DEGs identification and functional enrichment analysis between samples. (A–C) GO enrichment analysis was performed on up-regulated, and down-regulated genes, and biological process (BP), molecular function (MF), and cellular component (CC) were displayed. Node size indicates the number of genes enriched in the pathway, and node color indicates  $-\log_{10}$  (p-value). (D) Results of KEGG pathway analysis, the node size represents the number of genes enriched in the pathway, and the node color represents the p-value. (E, F) DOSE enrichment results. (G) Overall Gene Ontology enrichment analysis results. (H) gsea-go enrichment pathway analysis results. (I, J) The overall and partial gsea\_dose enrichment results are displayed. (K, L) GSVA enrichment results.

Simultaneously, among the seven related pathways annotated by DOSE, the disease pathway was significantly annotated (Figures 4I, J).

The results of GSVA analysis showed that *go\_chloride\_transprt* was activated in the cluster 2 patient samples, and in the cluster 1 patient samples, *kegg\_ubiquitin\_mediated\_proteolysis* was inhibited (Figures 4K, L).

## Validation of diagnostic marker genes in a new dataset

To evaluate if the key identified genes could serve as diagnostic marker genes for osteoporosis and to test the robustness of the predicted diagnostic marker genes, new datasets (GSE7429, GPL96) were retrieved from GEO. The data were preprocessed consistently, and the association of genes with OP was first tested using lasso regression and random forest. Univariate analysis (Figures 5A–C) revealed that none of the eight key genes were significant associated (EGR2, RARRES2, ZYX, SLC4A2, MAP4K2, MAT1A, PPP1R15A, SPI1). Hence, the performance of key genes in predicting disease samples was evaluated by plotting the ROC curves of the key genes. There were eight key genes related to OP differences. ROC curves of each of the eight key genes associated with OP in normal and OP tissue samples were constructed. The

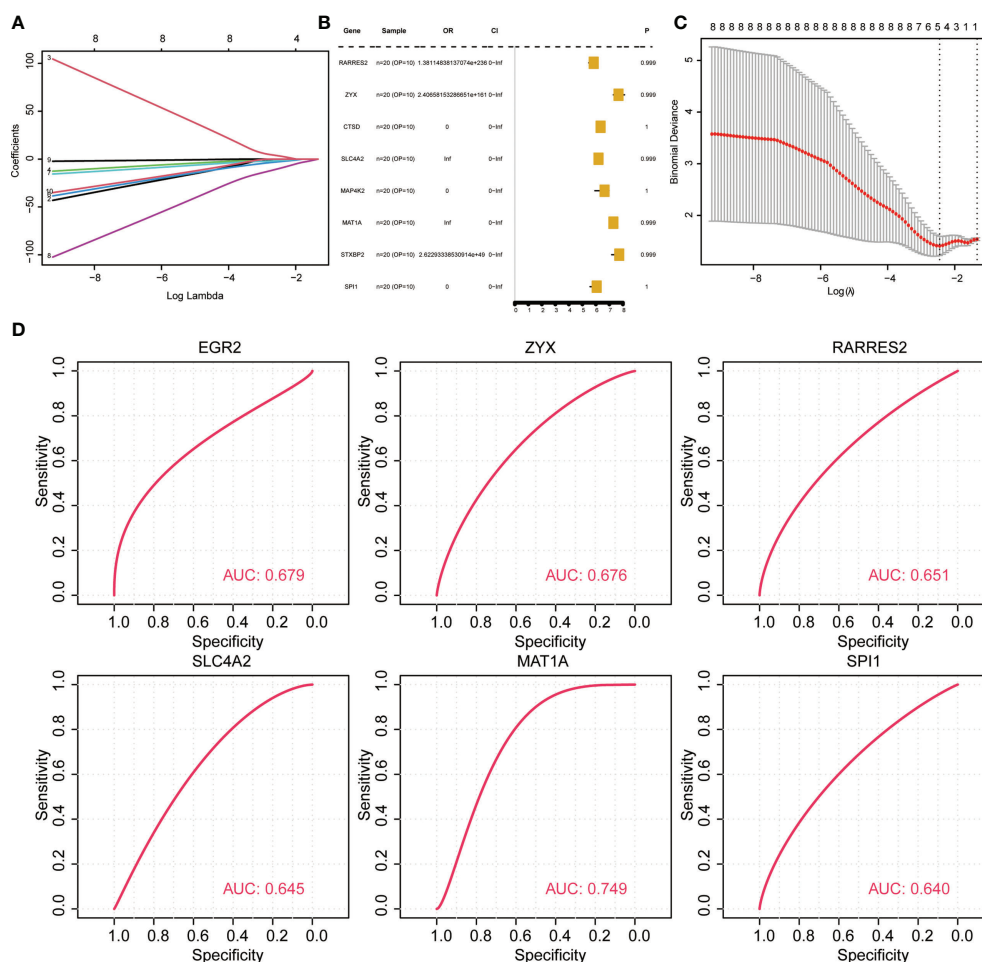

results revealed six key genes with predicted AUC > 0.6, namely RARRES2, ZYX, SLC4A2, EGR2, MAT1A, and SPI1 (Figure 5D). The results show that these six genes could successfully distinguish between OP and normal samples.

## Verification of Hub genes and signaling pathway molecules in clinical samples

To understand the relationship between the DEG-related to OP in the biological network, eight OP-related differential genes were analyzed using WGCNA, and 11 PPI regulatory networks were downloaded from the STRING database (Figure S2A). The regulatory relationship was imported into Cytoscape for network analysis, and the top ten hub genes were identified (Figure S2B). Hub genes were TNF, RARRES2, FLNA, STXBP2, EGR2, MAP4K2, NFKBIA, JUNB, SPI1, CTSD. Figure S2C shows the diagnostic genes that distinguish OP samples from control samples scattered in the PPI network, further reiterating that the research focus was still on validating the diagnostic genes.

The peripheral blood from clinical samples was collected to explore the expression of hub genes. The mRNA expression of TNF, RARRES2, FLNA, STXBP2, EGR2, MAP4K2, NFKBIA, JUNB, SPI1, and CTSD in the plasma of the control group and the OP group was detected (Figures 6A–J). The RT-qPCR results showed that compared to the control group, the mRNA

**FIGURE 5**  
Validation of diagnostic marker genes in a new dataset. (A, C) lasso regression analysis results. (B) Univariate analysis results. (D) ROC curve, indicating the diagnostic performance of the genes.

expression levels of TNF, RARRES2, FLNA, MAP4K2, and SPI1 in the plasma of the OP group were significantly increased, the mRNA expression levels of EGR2, JUNB, and CTSD were significantly decreased in the OP group. There was no significant difference in the mRNA expression levels of STXBP2 and NFKBIA between the two groups.

To further explore the expression of MAPK and NF-kappa B signaling pathway-related genes, the peripheral blood from clinical samples was collected, and total RNA was extracted to study the expression levels of c-FLIP, MIP1 $\beta$ , p38, and TRAF6 in the plasma of the control group (Control) and the osteoporosis group (OP) (Figures 6K–N). The results of RT-qPCR showed that compared to the control group, a significant decrease in the mRNA expression level of c-FLIP in the plasma of the OP group was observed, and a significant increase in the mRNA expression levels of MIP1 $\beta$ , p38, and TRAF6 was observed.

## Immune infiltration analysis and molecular subtype construction based on key OP-related diagnostic marker genes

The CIBERSORT results showed (Figure 7A) that the monocyte content was significantly high in the two groups of OP patients. Compared to cluster 1, OP patients in cluster 2 had lower levels of CD8 in Monocytes and T cells (Figure 7B). OP patients in cluster 1 had a low content of activated dendritic cells, resting mast cells, neutrophils, and activated CD4 memory T cells compared to cluster 2 (Figure 7B). The correlation between differentially expressed characteristic genes related to OP, the diagnostic marker genes, and immune cell content was analyzed. The results showed a significant positive correlation between the expression levels of monocytes and various differentially expressed

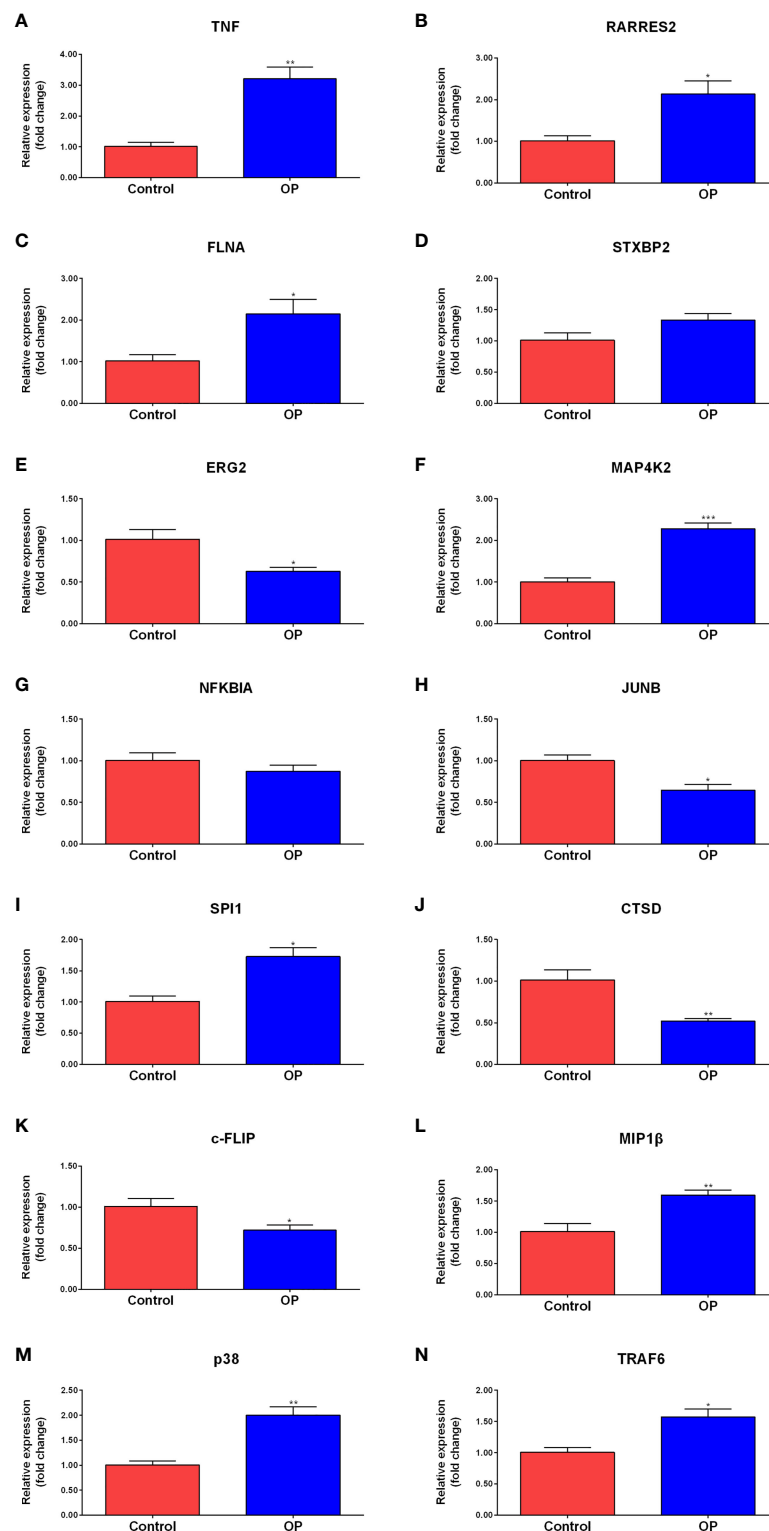

FIGURE 6

RT-qPCR results of the expression level of Hub genes and signaling pathway molecules. Comparison of mRNA expression levels of 10 Hub genes and 4 signaling pathway molecules in plasma of control group (n=3) and OP group (n=4). Among them, the mRNA expression levels of TNF (A), RARRES2 (B), FLNA (C), MAP4K2 (F), SPI1 (I), MIP1β (L), p38 (M), and TRAF6 (N) in the plasma of the OP group were significantly increased. The mRNA expression levels of ERG2 (E), JUNB (H), CTSD (J) and c-FLIP (K) were significantly decreased in the OP group. There was no significant difference in the mRNA expression levels of STXBP2 (D) and NFKBIA (G) between the two groups. P-values were calculated using a two-sided unpaired Student's t-test. (\*P < 0.05, \*\*P < 0.01, \*\*\*P < 0.001 vs. Control).

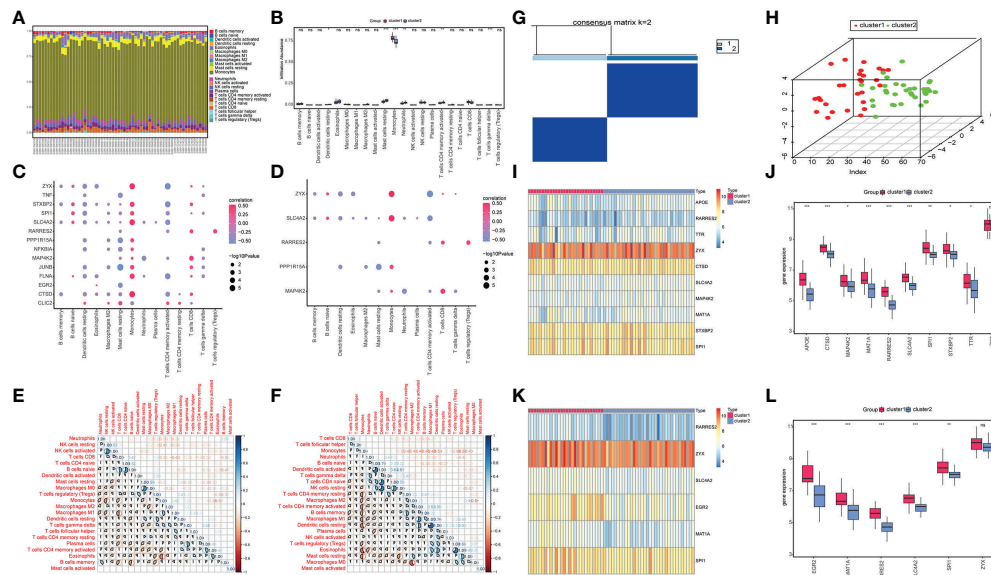

FIGURE 7

characteristic genes related to OP (Figure 7C). Monocytes positively correlated with multiple diagnostic marker genes, and a negative correlation was observed between activated CD4 memory T cells and multiple diagnostic marker genes (Figure 7D). Simultaneously, the correlation between the immune cell content of samples from patients in cluster 1 and samples from patients in cluster 2 was calculated. The results showed a significant correlation between the content of the memory B cells and various immune cells in samples from cluster 1 (Figure 7E). The content of monocytes in the samples significantly correlated with the content of various other immune cells (Figure 7F).

Based on the six OP-related diagnostic key genes, two different molecular subtypes and two patient subgroups (cluster1 and cluster2) were identified (Figure 7G) using a consensus clustering method ("ConsensusClusterPlus" package in the R software). Cluster 1 contained 28 samples, and cluster 2 had 34 samples. The PCA clustering results showed significant differences between the two clusters (Figure 7H).

The heatmaps and box plots were constructed based on the expression to observe changes in isoforms and gene expression. WGCNA analysis revealed a significant increase in the OP-related DEG in cluster1 (Figures 7I, J). Simultaneously, the

expression of diagnostic marker genes in cluster1 was significantly higher compared to cluster2 (Figures 7K, L).

## Key gene correlation analysis based on osteoporosis subtypes

To analyze the influence of key diagnostic genes on patients with different subtypes of OP, logistic univariate regression analysis was used to identify six genes with poor influence on OP (Figure 8C). Coefficients for six genes were calculated based on LASSO analysis (Figures 8A, B). The correlation between the expression of key genes was calculated, and the RARRES2 gene showed a significant positive correlation with multiple other genes (Figure 8D).

To analyze whether the key genes could better distinguish the two molecular subtypes, the gene expression was multiplied by the corresponding coefficient and added to establish the OP prediction score. The final prediction score of each sample was calculated. The results revealed that these four genes (RARRES2, SLC4A2, SPI1, ZYX) could better predict different subtypes of OP patients (Figures 8E–H).

## Discussion

In recent years, due to the lack of reliable early diagnostic tools and methods, most OP patients have suffered pathological fractures, which would require internal fixation and surgical interventions. This causes causing severe physical, mental, and economic burdens to the patients. Previous studies have shown that the immune microenvironment may play an important role in the occurrence

and development of OP (4, 11, 46). However, the specific targets and therapeutic mechanisms of OP remain unclear and require further investigation. Our study screened 40 DEGs, eight OP-related differential genes, ten hub genes, six OP diagnostic marker genes, and four OP diagnostic marker key genes. Furthermore, the correlation between OP prognostic models and immune signatures and immune cell infiltration profile revealed that the immune microenvironment might be involved in the pathogenesis of OP.

WGCNA analysis screened eight OP-related differential genes. GO, KEGG, GSEA, DOSE, and GSVA enrichment analysis was also performed. The results showed that OP-related genes mainly enriched the MAPK signaling pathway, TNF signaling pathway, apoptosis, and Salmonella infection. RT-qPCR results showed significant differences in the MAPK signaling pathway (p38, TRAF6) and NF-kappaB signaling pathway (c-FLIP, MIP1 $\beta$ ). Previous studies have shown that OPG/RANK/RANKL (9), IL-1 $\beta$  (47), TRAF6 (48), NFATc1, OSCAR and NF- $\kappa$ B (49), and other genes related to apoptosis, inflammation, and osteogenic differentiation (6). These genes regulate bone metabolism *via* the MAPK signaling pathway and TNF signaling pathway, which affects OP. Salmonella infection can lead to mild intestinal inflammation, which releases cytokines and other factors like interleukin-6 (IL-6), IL-8, IL-12, LPS-induced tumor necrosis factor alpha (LITAF) and interferon gamma (IFN- $\gamma$ ). The increases in expression of these pro-inflammatory cytokines affect bone metabolism, leading to bone loss (50). The above findings further corroborate the reliability of our analysis and prediction.

Further, the network analysis using the CytoHubba function in Cytoscape software identified ten hub genes. RT-qPCR results showed a significant increase in the mRNA expression levels of TNF, RARRES2, FLNA, MAP4K2, and SPI1 in the plasma of the OP patients group compared to the control group. Further, the mRNA expression levels of EGR2, JUNB, and CTSD were significantly decreased compared to the control sample group. Lastly, the mRNA expression levels of STXBP2 and NFKBIA were no significant difference. Previous studies have shown that TNF- $\alpha$  can act as an osteoclast factor, and TNF- $\beta$  acts as an anti-osteoclast factor (4), which affects bone metabolism by regulating RANKL expression (3). Han L et al. (51) showed that RARRES2 protein secreted by adipocytes (52) has an inhibitory effect on osteoblast differentiation and proliferation by inhibiting Wnt/ $\beta$ -catenin signaling and activating RANK signaling. Osteocyte differentiation and proliferation are stimulatory. Therefore, maintaining low RARRES2 levels could be a strategic approach for OP prevention and treatment. Yang C et al. (53) showed that FLNA accumulates in the osteoblasts, and the osteoclasts were observed in the human OP samples. A report suggests that negative regulation of FLNA in mice is age-related and postmenopausal osteoporosis *in vitro* osteogenic differentiation in OP promotes RANKL-induced osteoclast differentiation (54). Zhang X et al. (55) showed an increase in MAP4K2 expression upstream of JNK in aged osteoblasts. Yang C et al. (56) showed the involvement of SPI1 in OP development by regulating autophagy. Previous studies have shown that EGR2 is a zinc finger transcription factor, and EGFR signaling activates the MAPK/ERK pathway to stimulate EGR2 expression (57). Further, mounting evidence indicates that IL-27 inhibits RANKL-mediated osteoclast differentiation (8) in an

EGR2-dependent manner (10). A previous report suggests that BMP-2-induced Smad1 protein activation leads to JUNB synthesis, which is involved in the trans-differentiation of myoblasts to osteoblasts and contributes to bone repair after OP (58). CTSD deficiency can lead to lysosomal autophagy, which plays a protective role in OP development (59). Previous studies show that STXBP2 regulates vascular homeostasis in endothelial cells (60), along with various factors NFKBIA which significantly affect osteoclastogenesis (7, 61). However, in our study, there was no significant difference in the expression of STXBP2 and NFKBIA, as shown by RT-qPCR. Therefore, in the future, increasing the sample size would be a need for in-depth analysis. Taken together, it is suggested that the above molecules may play an important role in the diagnosis and treatment of OP.

In addition, for these eight OP-related differential genes, six diagnostic marker genes were tested by lasso regression and random forest using the new dataset. In recent years, osteoporosis treatment has focused on modulating the local immunity of the bone tissues. This provides a suitable microenvironment for positive regulation of bone metabolism, promotion of osteogenic differentiation, and inhibition of osteoclast differentiation (12). A report suggests that bone cells and the immune system share common progenitor cells, cytokines, and growth factors that interact during normal conditions and pathological states (3). However, the specific role of the immune system in OP is not fully understood. In this study, the CIBERSORT evaluated the immune cell infiltration in the two clusters. The results showed significant differences in monocytes, activated CD4 memory T cells, and memory and naïve B cells. Liu P et al (62) showed that monocytes express high levels of glucocorticoid receptors, which accumulate in the bone marrow during GC-induced osteoporosis, and have osteoclast differentiation potential. Gazzola L et al (63) revealed that higher levels of activated CD4+/CD8+ T cells are an independent predictor of osteopenia and osteoporosis. Titanji K et al (64) showed that individuals with HIV infection had significantly higher bone resorption and osteopenia, which were associated with B cell dysfunction. It is likely that a significant increase in RANKL-expressing B cells and a significant decrease in OPG-expressing B cells could be related to the induction of B cells naïve (46). Taken together, the immune microenvironment is under the tight regulation of cell-associated factors, which may play an important role in OP.

Moreover, two distinct molecular subtypes were identified using a consensus clustering approach based on six OP-related diagnostic marker genes. Prognostic analysis identified four key diagnostic marker genes (RARRES2, SLC4A2, MAP4K2, PPP1R15A). Among them, RARRES2, MAP4K2, and SPI1 could be used as hub genes, and significant difference in expression in OP have been established. ZYX can repair the

vascular endothelial injury by regulating endothelial cell exocytosis to reorganize the local actin network (65). Previous studies have shown that SLC4A2-mediated osteoclast anion exchange affects bone resorption by regulating pHi (66, 67). PPP1R15A promotes apoptosis, alleviating stress-induced osteoblast damage (68, 69). Finally, interaction networks with miRNAs, TFs, RBPs, and drugs for key genes were constructed. The study's results suggest that ten hub genes and six diagnostic marker genes could be used as diagnostic markers for OP.

However, this study has some obvious limitations. First, this study used bioinformatics analysis and proposed a theoretical diagnostic model. We have conducted a preliminary investigation to study the expression levels of Hub genes and pathway-related genes. A specific regulatory relationship needs to be further verified, for which a large sample size would be required to validate and enhance the clinical translational value of our diagnostic and prognostic model. Secondly, the immune characterization and cellular infiltration analysis were based on limited genetic data; thus, heterotypic cellular interactions and disturbances caused by different diseases may lead to bias in the immune analysis. Finally, further experimental validation using RT-qPCR, western blotting, and immunohistochemical analysis is required to fully understand the role of Hub genes and their underlying regulatory mechanisms associated with OP.

## Conclusion

In conclusion, we identified genes that may be differentially expressed in the OP and performed functional enrichment analysis on eight OP-related differential genes. CytoHubba function of Cytoscape software was used to conduct network analysis, and as a result, ten hub genes were identified. Further, RT-qPCR results confirmed that eight genes were significantly differentially expressed, of which MAPK signaling pathway (p38, TRAF6), NF-kappa B signaling pathway (c-FLIP, MIP1 $\beta$ ) were significantly differentially expressed between OP and control samples. The molecular features of OP prognosis based on six diagnostic marker genes were constructed. The immune infiltration analysis showed significant differences in monocytes, activated CD4 memory T cells, memory, and naïve B cells. Two different molecular subtypes of OP were identified using the consensus clustering method. Four key diagnostic marker genes were obtained from the prognostic analysis. Further, an interaction network with miRNA, TF, RBP, and drug was constructed for this purpose. We have identified a more accurate and reliable prognosis strategy for patients with early OP, which has enhanced our understanding of OP pathogenesis.

## Data availability statement

The datasets involved in the present study are available in the NCBI repository, accession numbers GSE56815, GSE7158, GSE56116 and GSE7429.

## Ethics statement

The studies involving human participants were reviewed and approved by the Second Affiliated Hospital of Inner Mongolia Medical University (ethical review number: YKD202002055). The patients/participants provided their written informed consent to participate in this study.

## Author contributions

XW, ZP, BZ and ZZ are responsible for the research concept and design. ZP and BZ wrote the manuscript. XW, ZP, TH, JA, SL, WH, XK, JC, ZZ, BZ participated in data collection and interpretation. All authors approved the final version of the manuscript. All authors contributed to the article and approved the submitted version.

**Background:** Systemic sclerosis (SSc) is an autoimmune connective tissue disease that affects multiple organs, leading to elevated morbidity and mortality with limited treatment options. The early detection of organ involvement is challenging as there is currently no serum marker available to predict the progression of SSc. The aptamer technology proteomic analysis holds the potential to correlate SSc manifestations with serum proteins up to femtomolar concentrations.

**Methods:** This is a two-tier study of serum samples from women with SSc (including patients with interstitial lung disease - ILD - at high-resolution CT scan) and age-matched healthy controls (HC) that were first analyzed with aptamer-based proteomic analysis for over 1300 proteins. Proposed associated proteins were validated by ELISA first in an independent cohort of patients with SSc and HC, and selected proteins subject to further validation in two additional cohorts.

**Results:** The preliminary aptamer-based proteomic analysis identified 33 proteins with significantly different concentrations in SSc compared to HC sera and 9 associated with SSc-ILD, including proteins involved in extracellular matrix formation and cell-cell adhesion, angiogenesis, leukocyte recruitment, activation, and signaling. Further validations in independent cohorts ultimately confirmed the association of specific proteins with early SSc onset, specific organ involvement, and serum autoantibodies.

**Conclusions:** Our multi-tier proteomic analysis identified serum proteins discriminating patients with SSc and HC or associated with different SSc subsets, disease duration, and manifestations, including ILD, skin involvement, esophageal disease, and autoantibodies.

## KEYWORDS

connective tissue disease, interstitial lung disease, proteomics, aptamer technology, immunology

## Introduction

Systemic sclerosis (SSc) is a connective tissue disease characterized by a pathogenetic triad composed of microangiopathy, immune system activation, and fibrosis. SSc is associated with significant morbidity and mortality largely dependent on the early detection of organ involvement including skin, lung, gastrointestinal tract, and heart (1–3).

Serum autoantibodies are the only available biomarkers for precision medicine in SSc as anti-centromere antibodies (ACA) are commonly observed in the limited form (lcSSc) and associated with an increased risk of pulmonary arterial hypertension (PAH) while anti-RNA polymerase III antibodies are linked to scleroderma renal crisis and anti-topoisomerase I (anti-Scl-70) antibodies are observed in the diffuse form (dcSSc) with a higher incidence of interstitial lung disease (ILD) (4, 5). However, autoantibodies are of limited use to predict the onset of specific complications (6–8); other biomarkers, such as uric acid and NT-ProBNP are instrumental to assess the risk of having PAH (9), KL-6 may predict the progression of SSc-ILD (10), while the combination of serum NT-ProBNP and troponins may be evocative of myocardial involvement (11, 12).

In recent years, proteomic analysis has been broadly used to identify biomarkers as it illustrated by the transcriptional profile changes associated with specific disease manifestations (13–19). Aptamers are short single-stranded oligonucleotides capable of folding into various structures, and have the ability to bind to proteins, peptides, and small molecules at concentrations ranging from femtomolar to micromolar, with high reproducibility and low variability rates (20) and holds promising in SSc to elucidate the molecular mechanisms of disease pathogenesis and internal organ involvement (21). We took advantage of proteomic aptamer analysis and different validation cohorts of SSc patients with and without ILD to identify biomarkers for SSc phenotypes.

## Methods

### Patients

Six patients who met the 2013 European League Against Rheumatism/American College of Rheumatology classification criteria for SSc (22) were enrolled from the Scleroderma Unit, Rheumatology and Clinical Immunology, IRCCS Humanitas Research Hospital in Rozzano, Italy. Clinical data were recorded, including organ involvement based on clinical features, laboratory results, and findings from diagnostic imaging (radiological imaging, echocardiography, lung function tests, and other relevant examinations). SSc-ILD was diagnosed based on high resolution computed tomography (HRCT) scans, following the guidelines set by the Fleischner Society (23). PAH was defined using right-heart catheterization in the presence of suspected/suggestive signs, symptoms, echocardiographic abnormalities, or pulmonary function abnormalities (24). Myocardial involvement was diagnosed based on compatible findings at cardiac magnetic

resonance (25) in patients with suspected/suggestive signs or symptoms, electrocardiographic and 24-hour Holter ECG alterations, or elevated serum myocardial enzymes (11, 12). Serum autoantibodies were assessed using commercially available kits in routine laboratory analysis. Early SSc was defined as a disease duration less than 3 years from the onset of the first non-Raynaud manifestation (26). Patients were naïve to any immunosuppressive or vasoactive treatment. Seven healthy controls (HC) were enrolled (2 females, 5 males, median age 54 years, interquartile 46–67 years).

We also used two separate and independent cohorts of SSc patients and HC to validate our findings, as described below.

In all cases and controls, serum samples were collected using serum separator tubes, allowed to clot, aliquoted, and stored at  $-80^{\circ}\text{C}$ .

This study was conducted in accordance with the Declaration of Helsinki, and the research protocol was approved by the local ethics committee (study number 831); all subjects provided their informed consent.

### Aptamer proteomic analysis

Serum aliquots of 150  $\mu\text{L}$  were prepared from all collected samples and subjected to proteome profiling using a high throughput multiplexing aptamer-based SOMAscan<sup>®</sup> assay, targeting 1310 serum proteins (Somalogic Inc., Boulder, CO), as previously described (27). The technique utilizes a panel of protein-specific Slow Off-rate Modified DNA aptamers (SOMAMers), which are constructed from chemically modified nucleotides capable of specifically recognizing and binding proteins with high specificity and affinity. The SOMAmer reagents are labeled with a 5' fluorophore and a biotin, immobilized on streptavidin coated beads, and incubated with serum samples. Complexes consisting of SOMAmer reagents and target proteins are formed on the beads. The SOMAmer reagents are then quantified through fluorescence using microarrays containing specific sequences. The relative intensity of fluorescence correlates to the amount of protein in the original sample.

### Validation with ELISA tests

Proteins that showed significantly different concentrations at the proteomic aptamer analysis (SomaSuite, *vide infra*) were selected for further validation and clinical correlations based on their pathogenic significance (as supported by previous literature) or if their relative fluorescence intensity was notably elevated. For validation, solid-phase enzyme immunoassays, ELISA tests, were employed to quantitatively determine the levels of the most relevant proteins in separate cohorts of SSc patients and HC. The following kits were used for ELISA testing: Human CD177, Eotaxin1, Leptin, Angiopoietin 2 (Ang2), Kininogen HMW, TPSB2, MMP12, IL-22BP (Raybiotech, USA), and Human Calpain 1, Aldolase A, BAFFR, Fractalkine, and Calgranulin B (S100 A9) (Mybiosource, Vancouver Canada), following the manufacturer's instructions. All

candidate proteins were first validated in an independent cohort of 30 patients with SSc and 10 HC (8 women, median age 71 years, interquartile range 62-74 years). Three proteins (Ang2, IL-22BP, and TPSB2) that exhibited statistical significance for multiple variables and displayed critical and innovative correlations with disease pathogenesis were further validated in an expanded cohort consisting of 89 patients with SSc and 43 HC (35 females, 8 males, median age 65 years, interquartile range 50-70 years).

## Statistical analysis

Data analysis of the SomaLogic results was conducted using SomaSuite software (Somalogic, Boulder, CO, USA). Statistical analysis of the ELISA data was performed using Stata16 software (StataCorp. 2019. Stata Statistical Software: Release 16. College Station, TX: StataCorp LLC). Non-parametric data were analyzed using the Wilcoxon rank-sum (Mann-Whitney) test for individual comparisons. To account for multiple comparisons, the Kruskal-Wallis correction was applied. A significance level of  $p < 0.05$  was considered statistically significant. Variables that reached statistical significance in the univariate analysis were entered into a logistic regression analysis with both forward and backward stepwise selection procedure to identify independent risk factors for selected variables.

Pathway analysis was performed by Reactome peer-reviewed pathway database (<https://reactome.org>) through the over-representation analysis: a statistical test (hypergeometric distribution) that determines whether certain Reactome pathways are over-represented (enriched) in the submitted data. The

probability score was corrected for false discovery rate using the Benjamini-Hochberg method.

## Results

### Patients

The characteristics of the three cohorts of patients, namely the SOMAscan, first ELISA validation, and extended ELISA validation groups, are illustrated in Table 1, with slight differences in terms of rarer organ involvements. Among the six patients studied with the SOMAscan proteomic aptamer analysis, all were female, with a median age of 64.5 years (interquartile range – IQR 41-73). One (17%) had dcSSc, 3 (50%) were ACA-positive, and 2 (33%) were anti-Scl-70 positive. Three patients (50%) had ILD and 5 (83%) had gastrointestinal involvement, while no patient had PAH.

In the first validation cohort there were 30 patients, with a median age of 63.5 years (IQR 48-75). Seven (23%) had dcSSc, 14 (47%) were ACA-positive, and 13 (43%) were anti-Scl-70 positive. Additionally, 3 (10%) had anti-RNA polymerase III antibodies. Out of the 30 patients, 14 (47%) were in the early stage of SSc, 12 (40%) had ILD, 6 (20%) had cardiomyopathy, 14 (47%) had gastrointestinal involvement, and 2 (7%) had PAH.

The extended validation cohort consisted of 89 patients, with a median age of 64 years (IQR 52-73.5). Seventeen (19%) had dcSSc, 47 (53%) were ACA-positive, and 30 (34%) were anti-Scl-70 positive. Moreover, 6 (7%) had anti-RNA polymerase III antibodies. Among the 89 patients, 38 (43%) were in the early stage of SSc, 30 (34%) had ILD,

17 (19%) had cardiomyopathy, 43 (48%) had gastrointestinal involvement, and 14 (16%) had PAH.

### Proteomics of SSc and SSc-ILD using aptamers

Our first-tier proteomic analysis using SOMAscan technology revealed significant differences in serum levels of 33 proteins between patients with SSc and HC (Table 2). Patients with SSc exhibited altered expression of proteins involved in various biological processes, including extracellular matrix formation and cell-to-cell adhesion (elevated Calpain, EphA5, IDS, MATN2, MMP-12, TNFR4, and reduced levels of desmoglein-1, SNP25), angiogenesis (increased levels of anti-angiogenic factors such as Ang2 and high molecular weight kininogen), lymphocyte recruitment, activation, and signaling (elevated levels of CXCL-1, LAG3 and decreased levels of SH21A), and overall inhibition of neutrophil function (decreased levels of G-CSF-R, CD177, calgranulin B; Figure 1). Nine proteins differentiated patients with SSc-ILD and without ILD or HC (Table 3). SSc-ILD patients showed elevated serum levels of proteins involved in intracellular signaling and cell cycle regulation (FCRL3, PDE11, Stratifin), as well as increased levels of MCP-3, a monocyte chemoattractant, and sICAM-5, the ligand for leukocyte adhesion protein LFA-1, compared to patients without ILD. Patients with SSc-ILD

exhibited higher levels of IL-22BP, the decoy receptor for IL-22, and lower levels of BAFF.

### Validation of protein biomarkers and association with disease manifestations

In the second-tier analysis, we selected 13 proteins from the first analysis to be validated in the independent cohort (Tables 4–7).

We observed significantly higher levels of serum Ang2 in SSc, especially in SSc-ILD compared to HC [median (IQR): 1.15 ng/mL (0.60–2.41) in SSc, 1.45 ng/mL (0.79–3.09) in SSc-ILD, 0.58 ng/mL (0.34–0.82) in HC;  $p = 0.0001$  for both comparisons]. IL-22BP was also present at higher concentrations in sera from patients with SSc-ILD [36.3 ng/mL (18.7–57.8)], with a progressive decrease in SSc without ILD [24.7 ng/mL (13.7–50.8)] and HC [20.4 ng/mL (13.9–37.6);  $p = 0.02$  SSc-ILD vs. HC].

Concentrations of MMP-12 were significantly lower in SSc, particularly in SSc-ILD, compared to HC [0.10 ng/mL (0.06–0.16) in SSc, 0.09 ng/mL (0.05–0.13) in SSc-ILD, 0.20 ng/mL (0.16–0.33) in HC;  $p = 0.003$  for SSc vs. HC and  $p = 0.01$  for SSc-ILD vs. HC].

In terms of skin involvement, patients with SSc were stratified into three subsets (28), namely dcSSc, lcSSc, and SSc *sine scleroderma* (Table 5). Higher levels of calgranulin B were observed in dcSSc compared to other SSc forms [65.7 ng/mL (62.2–81.8) in dcSSc vs. 25.6 ng/mL (16.6–40.8) in the other subsets;  $p = 0.02$ ]. In comparison to patients with skin involvement (i.e., dcSSc and lcSSc), patients with SSc *sine scleroderma* exhibited lower serum levels of leptin [0.18 ng/mL (0–1.21) in sine vs. 2.58 ng/mL (0.79–4.70) in the other subsets;  $p = 0.03$ ], and higher levels of aldolase A [123 ng/mL (116–148) in sine vs. 84.7 ng/mL (74.7–96) in the other subsets;  $p = 0.003$ ].

Results comparing disease duration (early SSc vs. long-standing disease) are illustrated in Table 6. Serum levels of MMP-12 were significantly lower in the early SSc group [0.07 ng/mL (0.03–0.10) in early SSc vs. 0.15 ng/mL (0.09–0.20) in long-standing disease;  $p = 0.003$ ] and CD177 [9.13 ng/mL (6.24–11.3) in early SSc vs. 12.3 ng/mL (9.34–20.0) in long-standing disease;  $p = 0.03$ ]. Multivariate analysis confirmed that MMP-12 is independently associated to early SSc [OR  $5.7 \times 10^{-10}$ ; 95% CI  $(7.2 \times 10^{-19} - 0.45)$ ;  $p = 0.04$ ].

Lower concentrations of fractalkine [1.62 ng/mL (10.8–3.22) vs. 2.95 ng/mL (2.77–4.61);  $p = 0.02$ ] and higher concentrations of eotaxin [1.16 ng/mL (0.88–3.12) vs. 0.74 ng/mL (0.43–1.08);  $p = 0.03$ ] were associated with gastrointestinal involvement, along with a non-significant increase in MMP-12 [0.13 ng/mL (0.09–0.20) vs. 0.09 ng/mL (0.03–0.14);  $p = 0.08$ ] (Table 6). No significant differences were found when stratifying patients with SSc based on the presence of PAH or cardiomyopathy (Table 6).

We also compared patients based on autoantibody profiling, specifically ACA, anti-Scl-70, and anti-RNA polymerase III (Table 7). Patients with ACA had significantly higher levels of MMP-12 [0.14 ng/mL (0.10–0.20) for ACA vs. 0.07 ng/mL (0.04–0.11) for anti-Scl-70 vs. 0.03 ng/mL (0.03–0.09) for anti-RNA polymerase III;  $p = 0.01$ ]. Calgranulin B showed the lowest values in ACA-positive subjects [24.2 ng/mL (15.2–33.1) for ACA vs. 59.7 ng/mL (28.2–75.7) for other antibodies;  $p = 0.01$ ] and the highest

levels with anti-Scl-70 [62.2 ng/mL (28.3-79.4) for anti-Scl-70 vs. 25.3 ng/mL (16.6-40.8) for other autoantibodies;  $p = 0.03$ ].

Discussion

The complex pathogenesis of SSc encompasses aberrant inflammation, dysregulated fibrosis, and microvascular disease (2). Comprehensive proteomic analysis is an ideal approach for identifying relevant molecules involved in various disease mechanisms, including potential prognostic factors, predictive molecules, and therapeutic targets. Proteomic analyses have already been performed and associated to clinical phenotype in SSc (29–32), as shown by the report that the higher expression of CXCL4 from peripheral blood and skin plasmacytoid dendritic cells in association with the incidence and progression of ILD and PAH in SSc (33). In addition, altered serum levels of collagen IV, endostatin, IGFBP-2, IGFBP-7, MMP-2, neuropilin-1, NT-proBNP, and RAGE have been described in SSc-PAH patients (34). Further, patients with a prominent signature based on CD40

ligand, CXCL4, and anti-PM/Scl-100 antibodies have shown a preferential positive response to treatment with the tyrosine kinase inhibitor imatinib (35).

Only a few studies have been conducted using the aptamer tools for proteomics in SSc (36–39). Within the studies investigating the preclinical phase of SSc (36, 39) one identified three proteins involved in the dysregulated angiogenesis and fibrosis being differentially expressed in patients with preclinical SSc at risk of evolving into overt disease, thus confirming the importance of microvascular disease in the earliest phases of SSc pathogenesis (36). Piera-Velazquez and Colleagues elegantly demonstrated that proteomic analysis of serum exosomes differs between patients with primary Raynaud’s phenomenon and patients with Raynaud’s phenomenon at risk of evolving into SSc (39). In the other two studies available (37, 38), the aptamer analysis was applied to describe longitudinal changes in patients with established SSc and organ damage. It was indeed demonstrated that serum levels of ST2 and spondin-1 predicted the changes in mRSS, also providing evidence of a peculiar cytokine signature (i.e., TNF, IFN- $\gamma$ , TGF- $\beta$ , and IL-13) (37). Additionally, chemerin was identified as a potential biomarker with pathogenic significance for increased pulmonary vascular resistances in patients with SSc-PAH (38). In another study, 82 proteins were found to be differentially expressed in sera from SSc-PAH patients compared to SSc patients without lung vascular involvement, including an IFN- $\gamma$  signature and two other proteins of interest, Midkine (implicated in the pathogenesis of arterial hypertension, renal disease, and lung fibrosis) and Follistatin-like 3 (FSTL3, regulated by TGF- $\beta$ ) in association with SSc-PAH (40). A composite three-biomarker index (including Ca15-3, surfactant protein D, and ICAM-1) has been recently described to predict ILD in patients with SSc, and is associated to disease severity (41). Several reasons could explain the differences found in the proteomic profile between previous studies and our results. First, the types of samples, such as whole blood, serum, and exosomes, is expected to provide different analytical outcomes. Second, the correlation between the duration of the disease

history and the timing of sample collection might have played a role, not only in the case of early vs. longstanding SSc but also in patients with isolated Raynaud's phenomenon at risk of evolving towards established disease. Third, such results ultimately reflect the heterogeneity of SSc, indicating various internal organ involvements, as well as multiple nuances of disease severity and rates of disease progression.

Our multi-tier study including an aptamer-based analysis and a validation on independent cohorts supports the alterations in different biomarkers to reflect abnormal extracellular matrix formation, angiogenesis, vascular remodeling, and immune cell recruitment and function, which recapitulate the fundamental pathogenic aspects of SSc and some of the proposed biomarkers (Ang2, IL-22BP, and TPSB2) require a detailed discussion.

Angiotensin-2 (Ang2) is a vascular growth factor secreted by endothelial cells that induces their own activation and promotes leukocyte chemotaxis. In the presence of a pro-inflammatory cytokine environment, this signaling pathway leads to vascular instability and endothelial inflammation (42). By stimulating the release of IL-6 and IL-8 from monocytes, Ang2 enhances the

inflammatory-driven fibrogenic process, a hallmark of SSc (43). Our analysis revealed significantly increased serum levels of Ang2 in SSc patients compared to HC, which is consistent with previous literature findings (44). Furthermore, we observed significantly higher levels of serum Ang2 in early SSc and SSc-ILD patients compared to HC. Previous studies have shown that serum Ang2

levels decrease after treatment with intravenous cyclophosphamide in SSc-ILD patients, and this reduction correlates with concentrations of KL-6, an established biomarker of lung involvement (45). Overall, these results support the crucial role of aberrant angiogenesis across the pathogenic processes underlying SSc since the earliest phases, throughout the development of established disease, along with providing further support for the correlation between serum Ang2 concentrations and SSc-ILD.

IL-22 is an inflammatory cytokine produced by CD4<sup>+</sup> T cells and innate T cells, including NKT,  $\gamma\delta$  T cells, and innate lymphoid cells (ILC) (46); IL-22BP is a soluble decoy receptor that acts as an IL-22 inhibitor (46). Ambivalent proinflammatory and modulating functions have been attributed to both IL-22 and IL-22BP in a tissue- and disease-dependent manner (47–49). A protective anti-inflammatory effect of IL-22 has been demonstrated in the case of pulmonary inflammation, with lower levels being detectable in the bronchoalveolar lavage fluid (BALF) of patients with acute respiratory distress syndrome and sarcoidosis (50). Moreover, IL-22 is essential to allow alveolar repair following Influenza pneumonia (51), while elevated IL-22BP expression increases the risk of severe pulmonary infections (52). On the other hand, a prominent IL-22-based inflammatory signature has been described in patients with SSc (53), with increased circulating Th22 cells (54) and serum IL-22 levels being associated with SSc-ILD (55). Expression of IL-22 in scleroderma skin is linked to both the inflammatory (56) and fibrotic responses that are responsible for disease progression (57). In our study, serum levels of IL-22BP were significantly increased in patients with SSc-ILD compared with HC. This points towards a role for reduced IL-22 function in the pathogenesis of SSc-ILD. A mouse model study reported that bleomycin-induced lung fibrosis leads to a decrease in IL-22, and administering exogenous IL-22 can inhibit the inflammatory and fibrotic process (58). We speculate that the protective role of IL-22 may be compromised in patients with SSc-ILD and modulating the IL-22/IL-22BP system could be a promising therapeutic target. Further studies are needed to clarify the role of cells producing IL-22 in the pathogenesis of scleroderma lung disease, with a particular focus on innate-like lymphocytes (59), which represent an intriguing crossroad between the environment, innate, and adaptive immunity.

Conflicting evidence has been reported regarding matrix metalloproteinase (MMP)-12, an enzyme with critical functions in extracellular matrix remodeling in animal models of lung fibrosis (60, 61). *In vitro* studies have shown that dermal fibroblasts from SSc patients overexpress MMP-12, thus affecting angiogenic homeostasis (62). Increased levels of MMP-12 in serum and tissue have been reported in SSc patients, and these levels are associated with longer disease duration and more severe skin and lung involvement (63). Furthermore, the rs2276109 polymorphism of the MMP-12 gene has been linked to SSc susceptibility in a large Italian cohort (64). Our results partially contrast with previous evidence. While we initially observed higher MMP-12 levels in SSc patients during SOMAscan analysis, we found significantly lower values during ELISA validation, especially in SSc-ILD, early SSc,

and anti-Scl-70 or anti-RNA polymerase III positivity, suggesting a potential correlation between serum MMP-12 levels and milder forms of the disease. Such observations could suggest the presence of an ineffective extracellular matrix turnover, as reflected by lower levels of MMP-12, in those patients with a higher burden of fibro-inflammatory lesions. This is notably the case of individuals with SSc-ILD, as well as rapidly progressive cutaneous fibrosis associated with anti-RNA polymerase III antibodies. However, due to the discrepancy of previous evidence, further research is warranted also in this case to clarify these associations.

Dysfunction of the myeloid cell compartment has been implicated in both the inflammatory and fibrotic phases of SSc pathogenesis (65). To support this view, we found significant differences in serum concentrations of myeloid-derived proteins in SSc patients compared to HC, including calgranulin B, and CD177. Calgranulin B is a calcium-binding protein expressed in neutrophils, monocytes, and macrophages, and it is overexpressed in the lungs of patients with idiopathic pulmonary fibrosis and nonspecific interstitial pneumonia (66). Our analysis showed that SSc-ILD patients and dcSSc patients have higher circulating levels of calgranulin B. CD177 is a neutrophil membrane molecule involved in the regulation of diapedesis (67), and CD177<sup>+</sup> neutrophils produce large amounts of IL-22 (68). As mentioned earlier, the ambivalent role of IL-22 may help explain the mild reduction in soluble CD177 that we observed in patients with early SSc. Further research is required to elucidate the role of the myeloid compartment in the pathogenesis of different subsets of SSc.

Two proteins associated with gastrointestinal involvement in patients with SSc are eotaxin and fractalkine. Eotaxin's role in recruiting eosinophils and mast cells has been extensively studied in asthma (69), and its pro-fibrotic effects have been demonstrated in both animal models (70) and human conditions (71, 72). Recently, Piera-Velazquez and colleagues demonstrated that patients with early SSc have higher levels of eotaxin in circulating exosomes compared to subjects with primary Raynaud's phenomenon (39). We are the first to report that increased serum levels of eotaxin and lower serum concentrations of fractalkine are significantly associated with esophageal involvement in patients with SSc.

Leptin warrants also a discussion as this is a metabolic hormone produced by adipose tissue cells and has potential, albeit conflicting, roles in autoimmune inflammation (73) and fibrosis (74). Its effects on the fibrotic process appear to be tissue- or organ-dependent (74). Contradictory data have been reported on serum leptin concentrations in patients with SSc (75–78), and it has been suggested that these variations may reflect heterogeneity in disease duration, activity, and different phenotypes and endotypes. We are the first to report low levels of leptin in patients with SSc *sine scleroderma* compared to subjects with cutaneous involvement (both lcSSc and dcSSc).

To our knowledge, this is the first study to investigate serum proteins using proteomic aptamer analysis in a deeply phenotyped and endotyped cohort of SSc patients to assess the potential pathogenetic roles, spanning from extracellular matrix formation, angiogenesis, and immune cell homing and function. The strength

of our study is that patient sera were obtained at the time of diagnosis, prior to any immunosuppressive or vasoactive treatment initiation, therefore our findings are expected to accurately represent the serum proteome of treatment-naïve individuals with SSc. Functionality assays, including gene expression and epigenetic studies, could serve as powerful tools to test and enhance the pathogenic validity of our observations. For instance, by studying the modulation of angiogenic pathways (mainly represented by Ang2 in our dataset), extracellular matrix remodeling (such as MMP-12), or myeloid cell function, we could gain a deeper understanding of whether these processes play a “disease-modifying” role at various stages of the disease or in different organs. Silencing IL-22 in mice-models of SSc lung disease may prove helpful to understand if IL-22 has a different role in the lung compared to the skin. Functionality analysis could reveal critical and potentially practice-changing information while the checkpoint driving dysregulated fibrosis could be intercepted, or it might be revealed that targeting certain pathways (e.g., aberrant angiogenesis, lymphocyte activation) is crucial but only in certain disease phases. Among the limitations of our study, the small sample size used for the aptamer analysis and the validation performed on a larger cohort should be noted, as well as the arbitrary choice of the candidate proteins, based on their presumed pathogenic significance and available data from previous literature. Furthermore, while the composition of the validation cohorts adequately reflects the distribution of different disease subsets and organ manifestations, this is not the case for the SOMAscan cohort due to the low prevalence of dcSSc, absence of subjects with SSc *sine scleroderma*, anti-RNA polymerase III antibodies, and PAH.

## Conclusions

Serum and tissue proteomics offer valuable tools for characterizing various aspects of the disease, aligning with the principles of precision medicine, while prospective validation of these biomarkers is warranted. The potential biomarkers that distinguish patients with SSc from HC identified in this work play functional roles in extracellular matrix metabolism, angiogenesis, and immune cell function, which are critical checkpoints in the pathogenesis of the disease. Biomarkers related to altered angiogenesis can differentiate patients with early SSc from HC, while other molecules exhibit differential expression in patients with SSc depending on factors such as disease subset, autoantibody profile, extent of skin fibrosis, and internal organ involvement, including ILD.

Crohn's disease (CD), a form of inflammatory bowel disease (IBD), is characterized by impaired epithelial barrier functions and dysregulated mucosal immune responses. IL-22 binding protein (IL-22BP) is a soluble inhibitor regulating IL-22 bioactivity, a cytokine proposed to play protective roles during CD. We and others have shown that IL-22BP is produced in IBD inflamed tissues, hence suggesting a role in CD. In this work, we extended the characterization of IL-22BP production and distribution in CD tissues by applying enzyme-linked immunosorbent assays to supernatants obtained from the culture of endoscopic biopsies of patients, and reverse transcription-quantitative polymerase chain reaction on sorted immune cell subsets. We reveal that IL-22BP levels are higher in inflamed ileums than colons. We observe that in a cell-intrinsic fashion, populations of mononuclear phagocytes and eosinophils express IL-22BP at the highest levels in comparison to other sources of T cells. We suggest the enrichment of intestinal eosinophils could explain higher IL-22BP levels in the ileum. In inflamed colon, we reveal the presence of increased IL-22/IL22BP ratios compared to controls, and a strong correlation between IL-22BP and CCL24. We identify monocyte-derived dendritic cells (moDC) as a cellular subtype co-expressing both cytokines and validate our finding using *in vitro* culture systems. We also show that retinoic acid induces the secretion of both IL-22BP and CCL24 by moDC. Finally, we report on higher IL-22BP levels in active smokers. In conclusion, our work provides new information relevant to therapeutic strategies modulating IL-22 bioactivity in CD, especially in the context of disease location.

## KEYWORDS

IL-22BP, IL-22, Crohn's disease, mononuclear phagocytes, eosinophils, disease location

## Introduction

Inflammatory bowel disease (IBD) is a group of chronic inflammatory conditions of the gastrointestinal tract, the main clinical entities of which are Crohn's disease (CD) and ulcerative colitis (UC) (1). IBD results from dysregulated mucosal immune responses against the microbiota, triggered by environmental factors in genetically susceptible individuals (2). Inflammatory responses in IBD alter the intestinal epithelial barrier, further amplifying immune pathogenicity. The cytokine interleukin-(IL) 22 is proposed to play central roles during IBD inflammation (3, 4). IL-22 is induced during IBD flares, as a result of increased production by CD4<sup>+</sup> T cells and group 3 innate lymphoid cells (ILC3) (5). IL-22 receptor (IL-22R) expression is mostly limited to epithelial cells and protective functions for IL-22 on the gut epithelium have been suggested in several rodent models of intestinal inflammation (6, 7). IL-22 supports gut epithelial barrier properties by inducing the secretion of antimicrobial peptides (6) and mucins (7), as well as intestinal epithelial cell (IEC) survival and proliferation (8). When dysregulated, however, IL-22 actions on IEC can promote tumor cell proliferation (9, 10). IL-22 binding protein (IL-22BP; encoded by the gene *IL22RA2*) is a soluble inhibitor specific for IL-22 (11), which regulates the level of IL-22 bioactivity *in vivo* (12, 13). Concordantly, we have observed increased IL-22-dependent protection against DSS-induced colitis in IL-22BP-deficient rats (14). In mice, IL-22BP worsens T cell-dependent colitis (15) but prevents tumorigenic long-lasting pro-proliferative actions of IL-22 (12). We and others have shown that the expression of *IL22RA2* is down-regulated during infectious colitis but not in IBD inflamed tissues, hence suggesting possible pathophysiological relevance for the IL-22BP-dependent modulation of IL-22 bioactivity (14, 15). IL-22BP is produced by various cell types, which include subsets of intestinal dendritic cells (DCs) and macrophages in the gut lamina propria (LP) and secondary lymphoid structures (12, 15–18). In human, we have revealed that IL-22BP is also produced by gut eosinophils in the LP of both healthy and inflamed IBD tissues (14). Finally, CD4<sup>+</sup> T cells have also been proposed to contribute to IL-22BP levels detected in IBD (15, 19).

Several layers of disease heterogeneity exist in CD. It has so far remained unclear whether the general findings about IL-22BP regulation in IBD discussed above can be extrapolated homogeneously to patients with CD, especially when considering intestinal segments of disease location. In the light of therapeutic strategies modulating IL-22 bioactivity in IBD that are currently under evaluation, we thus sought to extend further the characterization of IL-22BP production and distribution in intestinal tissues from a cohort of CD patients.

## Material and methods

### Patients

Patients were recruited, from January 2016 to October 2019, from the Institut des Maladies de l'Appareil Digestif (IMAD), the gastroenterology department and the digestive endoscopy unit at CHU Nantes Hospital. The protocol was approved, and informed consent was obtained from all participants in accordance with the institutional review board (DC-2008-402). A cohort 1 of CD patients was constituted to explore cytokine secretions in supernatants from *ex vivo* biopsy cultures. Cohort 1 included a total of 43 CD patients for whom endoscopic biopsies in involved areas were collected during colonoscopies planned for routine care (Supplementary Table 1). Control biopsies were also analyzed and collected from surgical specimens of colon cancers, on unaffected areas of the colon or the ileum, at least 10 cm distant from the tumor. A cohort 2 that included mesenteric lymph nodes and intestinal mucosa obtained from ileocecal resections of 6 patients with active CD was constituted for gene expression analyses in sorted immune cell subsets (Supplementary Table 2).

### *Ex vivo* cultures of gut biopsies

During the colonoscopy procedure, biopsies were collected with forceps directly in ice cold RPMI and processed within 2h. Biopsies (controlled for weight) were put into 4-well Petri dishes filled with in 500μL serum-free medium (RPMI 1640, Gibco™) supplemented with BSA (0.01%), 200μg/mL Penicillin/Streptomycin (Gibco™; ref 15140-122) and 0.25μg/mL Fungizone (Gibco™; ref 15290-026), and cultured *ex vivo* during 6 h at +37°C in a 95% O<sub>2</sub>/5% CO<sub>2</sub> atmosphere on a low-speed rocking platform. Supernatants were collected and stored at -80°C until use.

### ELISA assay for 22BP

IL-22BP quantification was performed with the Human IL-22BP ELISA DuoSet kit (R&D System, ref DY-1087-05) according to manufacturer's instruction. Briefly, a 96-well microplate was coated with a rabbit monoclonal anti-IL-22BP [4μg/mL] and incubated at room temperature (RT) overnight. The next day, after blocking with Reagent Diluent (R&D System, ref DY006), 100-μL standard dilutions and samples were added to each well and incubated 2 hours at RT. Then, 100μL/well of goat anti-IL-22BP [70ng/mL] were added and 2 h incubation at RT was performed. Finally, ELISA was revealed and plates were read at 450 nm with TECAN Spark® instrument. Of note, the combination of antibodies used in this assay has the potential to detect all three isoforms of IL-22BP existing in humans (20).

## Multiplex assay

Levels of soluble cytokines (CCL4, CXCL10, CXCL2, CCL24, CCL11, IFN $\gamma$ , IL-10, IL-17A, IL-22, IL-27, IL-6, IL-8, CCL2, OSM, CXCL1, CXCL11, CXCL5, CCL26, IL-1 $\beta$ , IL-18, IL-23, IL-33, IL-7, CXCL9, TNF) were quantified in supernatants obtained after *ex vivo* biopsy cultures with a multiplex assay from Biotechne (Rennes, France) and a Luminex MAGPIX<sup>®</sup> instrument (Supplementary Table 3).

## Eosinophil counts

Eosinophil counts were scored in a blinded fashion by a trained pathologist. Hematoxylin and eosin-stained slides from intestinal tissues of 36 CD patients were analyzed with an Olympus BH2 microscope. A high-power field (HPF) included an area of 0.196mm<sup>2</sup>. For each slide, eosinophil counts were defined by averaging the results obtained in 5 different HPFs selected randomly. Results of eosinophil counts were reported as the number of eosinophils/mm<sup>2</sup>.

## Isolation of intestinal lamina propria cells

Tissues from surgical resections were collected in ice cold RPMI 1640 (Gibco<sup>TM</sup>) and processed within one hour after the end of the surgery. The mucosa was stripped and cut into small pieces before transfer into complete RPMI media. Epithelial cells were dissociated in an EDTA-enriched dissociation medium (HBSS w/o Ca<sup>2+</sup> Mg<sup>2+</sup> (Gibco<sup>TM</sup>) - HEPES 10mM (Gibco<sup>TM</sup>) - EDTA 5mM at +37°C through two 15 min cycles of agitation at 100 rpm. After each cycle, intestinal fragments were hand-shaken for 30 s and vortexed vigorously for another 30 s. Epithelium-free fragments were washed in PBS, and transferred in the digestion medium (HBSS with Ca<sup>2+</sup> Mg<sup>2+</sup> - Fetal Calf serum (FCS) 2% - DNase I 0.1mg/mL (Sigma-Aldrich, ref 11284932001) - Collagenase IV 0.5mg/mL (Sigma-Aldrich, ref C5138) for 40 min at +37°C under 100 rpm agitation; and vortexing every 20 min. Cell suspensions were filtered through 70 $\mu$ m pore size cell strainers (BD Biosciences) and washed with FACS-buffer (with EDTA 1mM) twice before being processed for cell sorting.

## Intestinal mesenteric lymph nodes isolation

Tissues were collected in ice cold RPMI 1640 (Gibco<sup>TM</sup>) from the resected specimens and processed within one hour after

the end of the surgery. After removing the adipose tissue, mesenteric lymph nodes were cut in small pieces and transferred into the digestion medium (10mL of complete RPMI with Collagenase D (2mg/mL- Sigma-Aldrich, ref 1108882001) and DNase I (0,1 mg/mL)). After 30 min of incubation at +37°C 100 rpm, EDTA (1mM) was added to block the reaction. Cell suspensions were filtered through 70 $\mu$ m pore size cell strainers (BD Biosciences) and processed for cell sorting.

## Cells sorting

Single cell suspensions were incubated in PBS containing the flow cytometry antibody cocktail (Supplementary Table 4) for 20 min at 4°C in the dark. Dead cells were excluded by gating on 4',6-diamidino-2-phenylindole (DAPI)-negative cells. Cell sorting was performed on a BD FACS Aria Cell sorter (BD Biosciences) using the gating strategies shown in Figure 2.

## Real-time quantitative PCR

Sorted cells were suspended in TRIzol reagent (Thermo Fisher Scientific) and frozen at -80°C. Total RNA was extracted using an RNeasy mini kit (Qiagen,Valencia, CA) according to manufacturer's instructions. Reverse transcription was performed using Murine Moloney Leukemia Virus Reverse Transcriptase (Thermo Fisher Scientific) following manufacturer's instructions. Gene expressions were assessed with the TaqMan Fast Advanced Master Mix reagent (Applied Biosystems, Foster City, Calif). Primers and probes were from Applied Biosystems (Supplementary Table 5). With regard to *IL22RA2* mRNA detection, all three isoforms can be detected with the probe used in this study. Real-time PCR was performed using the StepOne Plus System (Applied Biosystems). Relative expression was normalized to hypoxanthine-guanine phosphoribosyltransferase and calculated using 2<sup>- $\Delta\Delta$ CT</sup> method. Results were expressed in arbitrary units (a.u.).

## Monocyte-derived dendritic cells

Monocytes from healthy volunteers were isolated either by elutriation of PBMCs (Clinical Development and Transfer Platform, Nantes, France) or by magnetic labelling (untouched cells, Human monocyte Isolation kit II). To obtain monocyte-derived DC (moDC), 2.5x10<sup>6</sup> monocytes were incubated in a 6-well plate in 5 mL of complete medium (RPMI 1640 medium containing 10% FCS, 1% L-glutamine, 1% antibiotics, 1mM Sodium Pyruvate, 1mM HEPES, 1% non-essential amino

acids) supplemented with recombinant human IL-4 (200U/mL) and recombinant human GM-CSF (100U/mL) for 6 days at 37°C with 5% CO<sub>2</sub>. When indicated, cells were treated with retinoic acid (RA) (100nM, Sigma Aldrich), LPS (1 µg/mL, Sigma Aldrich) and TNF (50 ng/mL, Miltenyi). After 6 days, moDC and supernatants were collected and frozen at -80°C until use.

## Immunofluorescence staining from mesenteric lymph nodes

Lymph nodes isolated from 3 CD patients were frozen in tissue-Tek. Sections were fixed for 15 min in paraformaldehyde. After rehydration, a 10 min step saturation was performed with H<sub>2</sub>O<sub>2</sub> (3%). For double staining, mouse IgG anti-hIL-22BP (MAB 1087 from R&D System, [1/800]) or isotype control (mouse IgG1, DDXCMO1P from Dendritic products [1/800]) were incubated at room temperature (RT) for 1 hour. After washing, several steps are carried out in order to amplify the IL-22BP signal: polymer enhancer (M023 from ImPath) then HRP-2 (M024 from ImPath) and finally Opal 650 (FP1496A from Akoya) following manufacturer's instruction. Then, after washing and a second step of saturation with goat serum 1.5%, a second purified antibody: rabbit anti-hCD3 (A0452 from Dako, [1/800]) or isotype control rabbit IgG (I-1000 from Vector) was added and incubated at RT during 1 hour. Purified antibody was revealed with adapted secondary antibody labelled with Alexa488 (goat anti-rabbit, A11008) from Life Technologies. After washing, DAPI (Molecular Probes, D1306) was incubated 30 min. Slides were mounted with Vectashield® Vibrance™ Antifade Mounting Medium (H-1700 Vector Laboratories). Images were obtained with A1 R Si Confocal microscope (MicroPiCell).

## Cytokine correlation plots

Pairwise correlations between cytokines were calculated and visualized as a correlogram using R function `corrplot`. Spearman's rank correlation coefficient ( $\rho$ ) was indicated by heat scale; significance was indicated by \* $P < 0.05$ , \*\* $P < 0.01$ , and \*\*\* $P < 0.001$ .

## Statistical analysis

Statistical analysis was performed with GraphPad Prism Software (GraphPad Software, San Diego, CA). Means comparisons of unpaired samples were performed using the Mann-Whitney U-test or the Kruskal-Wallis test with Dunn's post-test. The Wilcoxon signed-rank test was used for paired samples. P-values  $< 0.05$  were considered statistically significant.

Multiple linear regression analysis: Since, the distribution of IL-22BP values was not Gaussian, we transformed it by ranking the values and converting them to a normal distribution using the R function `qnorm`. Multiple linear regression was then performed using the `lm()` function. Adjusted P-values were calculated after multiple-comparison using *post hoc* Bonferroni correction.

## Results

### IL22BP levels are higher in the ileum than in the colon of Crohn's disease patients

Both IL-22 and IL-22BP mediate their biological functions as secreted soluble proteins (11, 21). To explore IL-22BP production in a biologically relevant manner in CD, we thus quantified secreted levels released after short *ex vivo* culture of intestinal biopsies. Soluble IL-22BP was consistently detected in supernatants from both controls and CD biopsies (see [Supplementary Table 1](#) for patient characteristics), and though means were not statistically significant, the highest levels were detected in a subset of CD patients ([Figure 1A](#)). To begin explore what factors would preferentially associate with IL-22BP heterogenous distributions in CD, we ran a multiple linear regression analysis that included several disease-relevant clinical parameters such as age, sex, disease location, disease phenotype and medication ([Table 1](#)). This analysis revealed disease location as the strongest factor (Bonferroni adjusted P-value  $< 0.0001$ ). Accordingly, higher levels of IL-22BP were detected in the supernatants of ileal vs. colonic CD biopsies ([Figure 1B](#)). IL-22 levels in turn, were similar between biopsy supernatants from both locations, which translated into IL-22/IL-22BP ratios, a surrogate to infer IL-22 bioactivity, higher in the colon as compared to the ileum of CD patients ([Figures 1C, D](#)). In fact, the analysis of IL-22BP and IL-22 in control patients indicated that both proteins were produced at higher levels in ileal vs. colonic biopsies ([Figures 1E, F](#)), an observation confirming previous reports about the physiological distribution of IL-22 across intestinal segments (22). Remarkably, however, IL-22 induction was largely limited to CD colons ([Figures 1G, H](#)). IL-22BP mean levels in turn, remained similar between controls and CD patients when controlling for gut segments ([Figures 1I, J](#)). Concordantly, in comparison to controls, IL-22/IL-22BP ratios were unchanged in the ileum but increased significantly in CD colons ([Figures 1K, L](#)).

Altogether, these results suggest that regional specialization in the intestine are characterized by higher levels of IL-22BP production in the ileum as compared to the colon in both controls and CD patients.

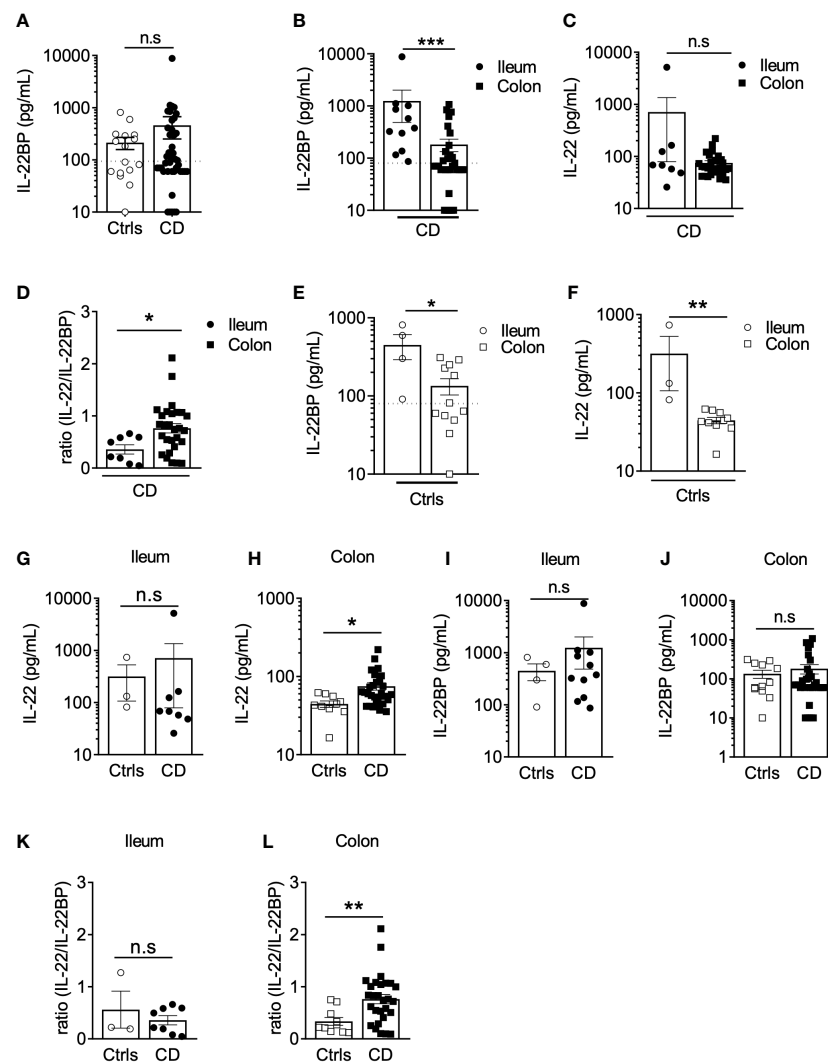

FIGURE 1

IL22BP levels are higher in the ileum than in the colon of Crohn's disease patients. (A) Levels of soluble IL-22BP were quantified by ELISA in the supernatant of gut (both ileum and colon locations) endoscopic biopsies from controls (Ctrls) ( $n=16$ ) and Crohn's disease (CD) ( $n=43$ ) patients after 6 hours of ex vivo culture. (B, C) Quantification of soluble IL-22BP (B) and IL-22 (C) in culture supernatants of biopsies from CD patients with inflamed lesions in the ileum ( $n=11$ ) or in the colon ( $n=32$ ). (D) Comparison of IL-22/IL-22BP ratios in the supernatants of CD patients with inflamed ileum and colon. (E, F) Quantification of soluble IL-22BP (E) and IL-22 (F) levels in the supernatant of gut biopsies from Ctrls ileum ( $n=4$ ) and colon ( $n=12$ ). (G, H) Comparison of IL-22 levels in the ileum (G) and the colon (H) of Ctrls and CD patients. (I, J) Comparison of IL-22BP levels in the ileum (I) and the colon (J) of Ctrls and CD patients. (K, L) Comparison of IL-22/IL-22BP ratios in the ileum (K) and the colon (L) of Ctrls and CD patients. Statistical significance for mean comparisons was assessed by the Mann-Whitney U-test in a two-sided manner, using a nominal significance threshold of  $P < 0.05$ . \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$  ns, not significant.

## The highest levels of IL22BP expression are detected in CD MNP and eosinophils

Various cell types can produce IL-22BP in IBD intestinal tissues, including populations of mononuclear phagocytes (MNP), which encompass dendritic cells (DCs) and macrophages, CD4<sup>+</sup> T cells and eosinophils (14, 15, 19). So

far, however, no systematic direct comparison of *IL22RA2* levels of expression by these different immune cell subsets has been performed specifically in intestinal tissues of CD patients. We thus analyzed *IL22RA2* expression in FACS-sorted populations of MNP (CD45<sup>+</sup> HLA-DR<sup>+</sup> CD11c<sup>+</sup>), eosinophils (CD45<sup>+</sup> SIGLEC-8<sup>+</sup>), CD4<sup>+</sup> T cells (CD45<sup>+</sup> CD3<sup>+</sup> CD4<sup>+</sup>), CD4<sup>+</sup> T cells (CD45<sup>+</sup> CD3<sup>+</sup> CD4<sup>+</sup>), and B cells (CD45<sup>+</sup> CD3<sup>+</sup> CD19<sup>+</sup>) isolated

**TABLE 1** Multiple linear regression to assess associations between clinical parameters of CD and IL-22BP levels.

Variable	Adj. P-value

Clinical score	0.01013

from surgically resected intestinal tissues of CD patients (Figures 2A, B; Supplementary Figure 1A). Compared to the three lymphocytes fractions, MNP and eosinophils expressed higher levels of IL-22BP mRNA (Figure 2B). We observed similar trends between MNP and T cells isolated from CD mesenteric lymph nodes (MLN) (Figures 2C, D; Supplementary Figure 1B). Of note, similar mRNA levels were detected between populations of naïve and non-naïve T cells. Using indirect immunofluorescence (IIF) approaches, we previously verified IL-22BP protein expression in major basic protein (MBP)<sup>+</sup> eosinophils and HLA-DR<sup>+</sup> MNP in the gut LP but not in CD3<sup>+</sup> T cells (14). We could not detect IL-22BP in CD3<sup>+</sup> MLN cells either (Supplementary Figure 1C), hence possibly reflecting a lack of method sensitivity to capture lower expression levels in T cells. Finally, while we could observe increased expression levels of activation-induced *IL2RA* (encoding for CD25) in sorted gut and MLN T cells upon simulation with PMA and ionomycin, no difference existed for *IL22RA2* (Supplementary Figures 1D-G).

Taken together, these data suggest that in a cell-intrinsic fashion, MNP and eosinophils express IL-22BP at the highest levels in intestinal tissues of CD patients.

## High levels of IL22BP in the ileum associate with higher proportions of eosinophils

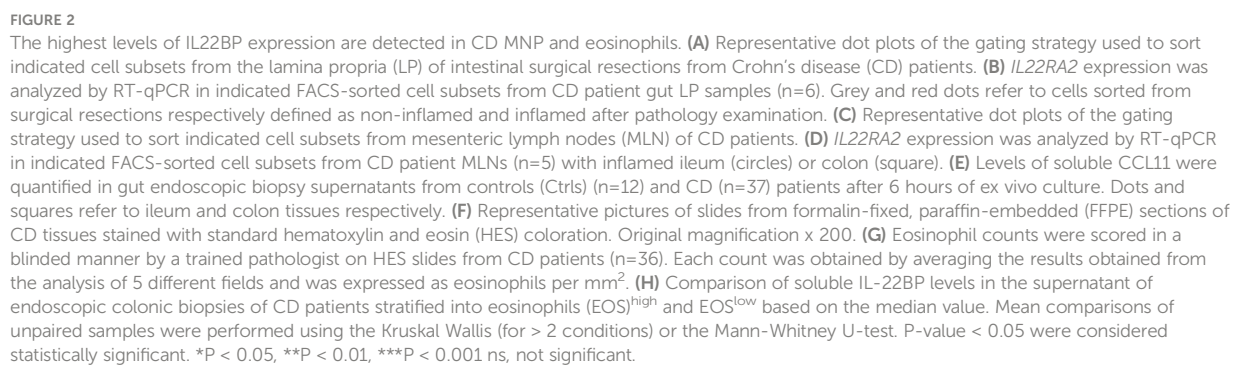

In inflamed CD tissues, the strongest factor linked to IL-22BP variability was disease location (Table 1), and as for controls, IL-22BP secretion in biopsy supernatants was higher in the ileum than in the colon (Figure 1). Interestingly, the levels of CCL11 (aka. eotaxin-1), the main driver of eosinophil

homeostatic recruitment in the intestine (23), were also higher in biopsy supernatants from the ileum than from the colon of controls (Figure 2E), concordant with the reported increased abundance of gut resident eosinophils in the small intestine (24–26). This suggested that the higher levels of IL-22BP we detected in inflamed CD ileums as compared to CD colons could in part be explained by the heterogenous distribution of resident-eosinophils across intestinal segments. Accordingly, we confirmed the existence of higher eosinophil numbers in CD ileums than in CD colons (Figures 2F, G). Blood-derived eosinophil infiltration has been reported during colonic inflammation, including in CD (27–29), and CCL11 levels were indeed moderately increased in CD colons as compared to controls (Figure 2E). Median-based stratification of colonic CD patients into eosinophil<sup>high</sup> and eosinophil<sup>low</sup>, however, did not reveal differences in IL-22BP production between the two subgroups (Figure 2H). Importantly, we previously reported that *IL22RA2* expression was undetectable in human peripheral blood eosinophils (14). This suggested that the contribution of eosinophil-derived IL-22BP detected in CD lesions could in fact reflect a pre-established production by tissue-imprinted gut-resident eosinophils but not by recently recruited eosinophils in inflamed tissues.

In consequence, our interpretation of these data is that homeostatic enrichment of tissue-resident eosinophil contributes to create an IL-22BP-rich environment that is maintained upon inflammation induction in CD ileums and participate to limit the extent of IL-22 bioavailability.

## IL22BP levels correlate with CCL24 produced by monocyte-derived dendritic cells in the colon of CD patients

In the colon of CD patients, IL-22BP detected in biopsy supernatants spanned a wide range of concentrations, and while means did not differ from controls, a subset of patients nevertheless exhibited levels reaching those observed in the ileum (Figures 1B). As described above, this variability could not be explained by colonic eosinophil abundance (Figure 2H), which suggested a role for other IL-22BP sources (i.e. MNP and/or T cells). We were unable to examine IL-22BP production by flow cytometry because in our hands none of the anti-IL-22BP antibodies commercially available could be confidently validated. To infer possible sources, we hypothesized that IL-22BP secretion should be correlated with other cytokines in biopsy supernatants, in part as a consequence of shared cellular origins. We characterized the cytokine milieu associated with IL-22BP secretion in the CD colon through a multiplex analysis on the same biopsy supernatants as used for IL-22BP quantification. We then realized a correlation matrix to identify possible

cytokines sharing similar regulation of expression as IL-22BP (Figure 3A). The strongest correlate of IL-22BP secreted levels was CCL24 (aka. eotaxin-2; spearman  $r=0.7$ ;  $P<0.0001$ ). Accordingly, the median-based stratification of CD patients based on their CCL24 levels in the colon showed that almost all CCL24<sup>low</sup> patients had IL-22BP levels below the lower limit of quantification, while it was the opposite for CCL24<sup>high</sup> patients (Figure 3B). We thus compared CCL24 expression between T cells and MNP isolated from the CD lamina propria. The highest levels were detected in MNP (Figure 3C), which suggested they could be the privileged source responsible for heterogenous IL-22BP secreted levels across colonic CD patients.

In an attempt to further refine the nature of a possible MNP subset producing both IL-22BP and CCL24, we reanalyzed a CD single-cell RNA-sequencing (scRNA-seq) dataset we published recently (30). While the contribution of eosinophils could not be evaluated in these data because of known technical limitations to capture intestinal granulocytes with the scRNAseq 10x Genomics Chromium Single Cell 3' v2 Chemistry [see (30, 31)], our analysis confirmed the highest expression levels of *IL22RA2* were present in MNP populations of DCs followed by lymphocyte populations including Type 3 cytokine-producing T cells, while CCL24 was preferentially detected in macrophages (Figure 3D) (see (30) for detailed description about cluster annotations). Interestingly, only monocyte-derived dendritic cells (moDC) displayed shared detectable expression of both genes (Figure 3D), and we validated that moDC differentiated *ex vivo* co-secreted IL-22BP and CCL24 (Figures 3E–G). Importantly, we previously showed that retinoic acid (RA) was a potent inducer of *IL22RA2* expression in moDC (16), which we could further confirm at the protein level in moDC supernatants (Figures 3E, F). Rather interestingly, the same held true for CCL24 (Figure 3G), suggesting IL-22BP and CCL24 inductions could share similar regulatory pathways, such as RA activity in moDC. In turn, the activation of moDC with LPS for 24h had no effect on CCL24 secreted levels but decreased the production of IL-22BP (Figures 3E, F), hence supporting ours and others previous observations (16, 32).

Other myeloid-derived cytokines showed significant positive correlations with IL-22BP, though weaker than for CCL24 (Spearman;  $P<0.05$ ) (Figure 3A). These included IL-6, IL-27 and IL-23, the most potent inducer of IL-22 in CD4<sup>+</sup> T cells and ILC3 (33, 34). Concordantly, IL-22 correlated with IL-22BP and was also increased in CCL24<sup>high</sup> patients, hence leading to similar IL-22/IL-22BP ratios between the two subgroups of CCL24<sup>high</sup> and CCL24<sup>low</sup> patients (Figures 3H, I). The co-regulation of IL-22/IL-22BP secretion in the colon of CD patients was in agreement with previous results we and others reported in IBD (14, 15). Because CD4<sup>+</sup> T cells also produce IL-22BP in IBD tissues (15), it is thus possible that Type 3 cytokine-producing T cells contribute to increase both IL-22 and IL-22BP levels in the colon of CD patients.

## Higher levels of IL-22BP are detected in the colon of actively smoking CD patients

Finally, we analyzed IL-22BP secretion in the colon of CD patients based on their smoking status. The production of IL-22BP was significantly higher in actively smoking patients (Figure 3J). A role for tobacco smoking has been suggested for the reprogramming of macrophages into the production of more immunoregulatory molecules, including CCL24 among others (corresponding to *in vitro* so-called “M2” macrophages) (35–37). Because a strong association existed between IL-22BP and CCL24 secretions in CD colons, we compared the proportions of smokers and non-smokers between CCL24<sup>high</sup> and CCL24<sup>low</sup> CD patients and verified an enrichment of smokers in the CCL24<sup>high</sup> subgroup, though not reaching statistical significance (Figure 3K). While this would deserve further investigations, it is thus possible that tobacco-derived metabolites be part of the signals shaping moDC toward higher production of IL-22BP and CCL24 in the CD colon.

## Discussion

Our understanding of the pathophysiological functions assumed by the IL-22/IL-22BP axis in IBD is currently described in a rather homogenous way, frequently intermixing conclusions obtained from mouse and human studies, and including results generated in both CD and UC. By providing new insights focused on a more detailed characterization of IL-22BP biology in tissues from CD patients specifically, our study unravels a more complex picture arguing against a such generalization. Our work reveals that the distribution of IL-22BP production is not homogenous between CD patients and we suggest this could be the product of multiple factors related to IL-22BP complex biology in the human gut. First, we show that IL-22BP levels are higher in both control and inflamed ileums when comparing to control and inflamed colons of CD patients respectively, and we suggest this could be explained by distinct homeostatic distributions of gut resident-eosinophils between the two segments. This is of particular relevance as the injection of recombinant IL-22 is currently under evaluation in IBD clinical trials (NCT03650413), and it is thus unclear whether the IL-22BP-rich environment created in the ileum could lead to more interference with the biological actions of the drug in involved ileum vs. colon of CD patients. In addition, our data suggest that a raise of IL-22 bioactivity is more likely to be achieved in inflammatory responses developing in the colon, hence indicating that greater clinical benefits of IL-22 injections may nevertheless be expected in involved ileums of CD patients. More human studies will be needed to address this important question, as we previously showed that IL-22BP expression in

FIGURE 3

IL22BP levels correlate with CCL24 produced by monocyte-derived dendritic cells in the CD colon. (A) Spearman correlation and hierarchical clustering of indicated cytokines quantified in culture supernatants of endoscopic colonic biopsies from 28 CD patients. (B) Comparison of soluble IL-22BP levels in CD patients stratified into CCL24<sup>low</sup> and CCL24<sup>high</sup> patients based on the median level. (C) CCL24 expression was analyzed by RT-qPCR on FACS-sorted cells from CD lamina propria, as in Figure 2A. (D) Heatmap representing the expression of *IL22RA2* and CCL24 in indicated cell types using the clustering analysis of a previously published single-cell RNA-sequencing (scRNA-seq) dataset (Martin JC, Cell, 2019). (E–G) Human blood classical monocytes from healthy donors were differentiated into monocyte-derived DC (moDC) with GM-CSF and IL-4 for 6 days in the presence of indicated ligands. At day 6 of culture *IL22RA2* mRNA expression was analyzed by RT-qPCR in moDC (E), and levels of IL-22BP (F) and CCL24 (G) were quantified in culture supernatants. (H, I) Comparison of soluble IL-22 (H) and IL-22/IL-22BP ratios (I) in culture supernatants of colonic CD biopsies from CCL24<sup>high</sup> or CCL24<sup>low</sup> patients. (J) Comparison of soluble IL-22BP levels in culture supernatants of colonic CD biopsies (n=32) from patients stratified according to their smoking status. (K) Pie charts representing the proportion of active smokers vs. non-smokers in the colon of CCL24<sup>high</sup> or CCL24<sup>low</sup> CD patients. \*P < 0.05, \*\*P < 0.01, \*\*\*P < 0.001 ns, not significant.

gut resident-eosinophils is a feature not conserved in rodents (14). The reason why IL-22 is not induced in inflamed ileums despite higher homeostatic production in control tissues would also deserve more investigations. Beyond the difference of IL-22BP production created by regional specializations across gut segments, we also uncover additional heterogeneity in inflamed colons of CD patients. In particular, we observe a strong correlation between IL-22BP and CCL24 secretion and suggest this could be the consequence of a shared production by moDC with variable intensity across subsets of patients. Importantly, while, CCL24 was initially described as an eosinophil chemoattractant through the receptor CCR3, experiments in rodents suggested it was not involved in eosinophil infiltration during colitis (29, 38). Our data further suggest that IL-22BP variability among inflamed CD colons was likely not explained by the level of infiltration of blood-derived eosinophils but relied more on other IL-22BP cellular sources such as moDC. CCR3 is also expressed by subsets of T cells (39) and it is possible that CCL24-mediated T cell infiltration participates to the total production of IL-22BP in the colon of CD patients (15).

Importantly, three isoforms of IL-22BP exist in humans (11). Experimental evidences suggest that contrary to isoforms 2 and 3, IL-22BP isoform 1 is not spontaneously secreted owing to the presence of an additional 32-amino acids exon responsible for endoplasmic reticulum retention (20, 32, 40). Intracellular isoform 1 is in fact proposed to participate in the regulation of the unfolded protein response (20). Both isoforms 2 and 3, however, can antagonize IL-22, isoform 2 being the most potent, hence indicating secreted IL-22BP is necessarily bioactive (32). We showed in our previous studies that gut DC/Macs and eosinophils, as well as monocyte-derived dendritic cells dominantly express IL-22BP bioactive isoform 2, and to a lower extent isoform 1, but not isoform 3 (14, 16). Overall, this indicates that all three subsets produce bioactive IL-22BP, dominantly through their expression of IL-22BP isoform 2.

Supporting the existence of similar regulatory pathways for both IL-22BP and CCL24 in inflamed CD colons, we report that retinoic acid increases the secretion of both proteins by moDC. As suggested by the higher IL-22BP levels we noticed in tobacco smokers, it is likely that additional factors contribute to differential regulations of IL-22BP production across patients. In that regard, it is interesting to note that IL-22BP levels also correlated with those of IL-22 and IL-23, the main driver of IL-22 expression in lymphocytes. Recent evidence suggests that lymphotoxin (LT) $\alpha$ 1 $\beta$ 2 upregulates IL-22BP *via* the noncanonical NF- $\kappa$ B pathway in moDC (19). Because NF- $\kappa$ B is involved in the generation of IL-22-producing T cells, in part indirectly through the induction of IL-23 secretion in MNP (41), one may speculate that privileged cellular circuits exist in inflamed colons of a subset of CD patients, in which LT $\alpha$ 1 $\beta$ 2 from CD4 T cells drives both IL-22BP and IL-23 expression in

moDC (42, 43). The latter in turn can promote IL-22 production in CD4 T cells. While this would deserve further investigations, specific cellular niches in subsets of CD patients could thus participate to increase both IL-22 and IL-22BP global levels associated with a more localized impact on epithelial cell biology (44). Clarifying the existence, tissue distribution and pathophysiological actions of such cellular circuits would be especially relevant in light of the upcoming IL-23 blockers in the CD therapeutic armamentarium (45, 46).

In conclusion, our work provides new important information about the biology of IL-22BP in CD, which can open the way to therapeutically relevant future studies with regard to the modulation of the IL-22/IL-22BP axis in patients.

## Data availability statement

The original contributions presented in the study are included in the article/Supplementary Material. Further inquiries can be directed to the corresponding authors.

## Ethics statement

The studies involving human participants were reviewed and approved by Centre de Protection des Personnes Ouest IV - CHU de Nantes. The patients/participants provided their written informed consent to participate in this study.

## Author contributions

JCM, RJ, and AF designed experiments and interpreted the data; JCM wrote the manuscript; AF, RJ, and JCM edited the manuscript; AF, EL, TL, LD, SB, and GB performed experiments and analyses; CB and NS performed cytokine multiplex assays; EM and AM performed *in vitro* moDC experiments; JP and AB managed the biobank and selected the patients included in the study. All authors contributed to the article and approved the submitted version.

## Acknowledgments

The authors warmly thank Dr Mathieu Uzzan (Hopital Henri Mondor, Assistance Publique-Hôpitaux de Paris) for his critical reading of the manuscript and meaningful comments. The authors also warmly thank Dr Ephraim Kenigsberg (Icahn School of Medicine at Mount Sinai, New York, NY) for his critical help with statistical analyses. This work was supported

by grants Association Francois Aupetit (AFA), the European Crohn and Colitis Organization (ECCO), and Région Pays de la Loire (INSET) to RJ. JCM is supported by NExT “Junior Talent” and ANR JCJC (ANR-20-CE17-0009). AF was supported by a fellowship from CHU de Nantes (“Année supplémentaire d’Internat”).

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

**Background:** Recent *in vitro* studies strongly implicated mast cell-derived proteases as regulators of IL-33 activity by enzymatic cleavage in its central domain. A better understanding of the role of mast cell proteases on IL-33 activity *in vivo* is needed. We aimed to compare the expression of mast cell proteases in C57BL/6 and BALB/c mice, their role in the cleavage of IL-33 cytokine, and their contribution to allergic airway inflammation.

**Results:** *In vitro*, full-length IL-33 protein was efficiently degraded by mast cell supernatants of BALB/c mice in contrast to the mast cell supernatants from C57BL/6 mice. RNAseq analysis indicated major differences in the gene expression profiles of bone marrow-derived mast cells from C57BL/6 and BALB/c mice. In *Alternaria alternata* (Alt) - treated C57BL/6 mice the full-length form of IL-33 was mainly present, while in BALB/c mice, the processed shorter form of IL-33 was more prominent. The observed cleavage pattern of IL-33 was associated with a nearly complete lack of mast cells and their proteases in the lungs of C57BL/6 mice. While most inflammatory cells were similarly increased in Alt-treated C57BL/6 and BALB/c mice, C57BL/6 mice had significantly more eosinophils in the bronchoalveolar lavage fluid and IL-5 protein levels in their lungs than BALB/c mice.

**Conclusion:** Our study demonstrates that lung mast cells differ in number and protease content between the two tested mouse strains and could affect the processing of IL-33 and inflammatory outcome of *Alt*-induced airway inflammation. We suggest that mast cells and their proteases play a regulatory role in IL-33-induced lung inflammation by limiting its proinflammatory effect via the IL-33/ST2 signaling pathway.

IL-33, mast cells, allergy, type 2 inflammation, protease

## Introduction

Asthma is a heterogeneous inflammatory airway disease with different underlying pathophysiologic mechanisms and disease endotypes, which often manifest by similar clinical complaints (1, 2). In mild asthma, mostly the type 2 phenotype, an eosinophilic immune response is observed, while only a minor percentage of patients show a non-type 2 phenotype (3). In severe asthma, a mixed inflammatory phenotype is also characterized by increased IL-33 levels. Of interest, in children, severe asthma is more common in the case of sensitization to the fungus *Alternaria alternata* (*Alt*) and is strongly associated with increased IL-33 sputum levels (4). In this regard, a clinical trial has shown that IL-33 targeting could efficiently reduce exacerbations in patients with severe asthma (5). In contrast, patients with mild or moderate asthma have less clinical benefit from an IL-33 targeting therapy. IL-33 is an alarmin, which in allergic airway inflammation is mainly secreted by epithelial cells in response to aeroallergens and signals through a cell surface receptor complex of ST2 (IL-1 receptor-like 1, IL1RL1) and IL-1 receptor accessory protein (IL1RAcP) to stimulate cytokine production in type 2 ILCs and T helper 2 cell, inducing the production of IL-4, IL-5, and IL-13 (6–8). Endogenous serine proteases and cysteine proteases, such as calpains, were suggested to regulate the activity of IL-33 via enzymatic cleavage (9–11). Recently, we have demonstrated the contribution of neutrophilic proteases in IL-33 processing in an allergic asthma mouse model using *Alt* (12). IL-33 is produced as a full-length protein lacking a signal sequence by a not entirely clear release mechanism. The cleavage of full-length IL-33 (IL-33<sub>FL</sub>) by human mast cell tryptase, chymase, and cathepsin G *in vitro* results in cleaved IL-33 (IL-33<sub>C</sub>), which is up to 30-fold more potent towards innate lymphoid cells type 2 (ILC2s) (9). It is known that the functional, inflammatory parameters in severe asthma are linked to the presence of activated mast cells (13–15) which, via their release of cytokines, proteases, and alarmins, could potentially contribute to the persistence and the exacerbation of the airway inflammation (13, 16, 17); and possibly to the loss of corticosteroid sensitivity in severe asthma (18). In asthmatic patients, bronchoalveolar lavage fluid (BALF) contains increased levels of tryptase (19, 20). The presence of an active form of IL-33 acting on ST2-expressing immune cells could contribute to the sustained type 2 immune response in the airway epithelium (8,

21). Remarkably, in humans, the phenotype of mast cells seems to be different in the same disease with different inflammatory profiles: In mild asthma, tryptase-positive mast cells localize in the submucosa while in severe asthma, mast cells are mostly localized in the airway submucosa and epithelium and express chymase (13, 20). We showed earlier that different inbred mouse strains respond differently to an IL-33 mediated asthma model, using the bacterial allergen, *S. aureus* protease-like protein D (22).

In the current study, we analysed the link between the type of inflammatory response towards *Alt* and the characteristics of mast cells in the two inbred mouse strains C57BL/6 and BALB/c. The strain-dependent mast cell heterogeneity in the regulation of IL-33 processing *in vivo* was addressed.

## Results

### Differential inflammatory response of BALB/c and C57BL/6 mice towards *Alt*

The IL-33-dependent model of *Alt*-induced airway inflammation was chosen to evaluate an impact on the processing of IL-33 and inflammatory parameters in two commonly used mouse strains (6, 14, 23). C57BL/6 and BALB/c mice received six intratracheal (i.t.) applications of 20 µg *Alt* extract every 48 hours (Figure 1A), in a slightly modified application schedule from our previous work (14). The *Alt*-treated BALB/c and C57BL/6 mice showed higher numbers of total BALF cells compared to PBS-treated mice (Figure 1B). The BALF of *Alt*-treated C57BL/6 mice contained more eosinophils in BALF as compared to *Alt*-treated BALB/c mice (Figures 1C, D). In turn, BALB/c mice had higher neutrophil numbers in the BALF (Figures 1E, F). The percentage of CD4<sup>+</sup> (Figure 1G) cells was stronger increased in BALF of BALB/c mice compared to C57BL/6 mice. CD8<sup>+</sup> cells were higher in BALF of BALB/c mice (Figure 1H). Furthermore, in the lungs of both mouse strains, marked eosinophilia was observed (Figure 1I), while the percentage of neutrophils remained comparable between *Alt*-treated mice and controls of both mouse strains (Figure 1J). Of note, no major difference in the percentages of lung CD4<sup>+</sup> and CD8<sup>+</sup> cells was seen (Figures 1K, L). Serum IgE levels were higher in *Alt*-treated mice as compared to PBS-treated controls (Figure 1M).

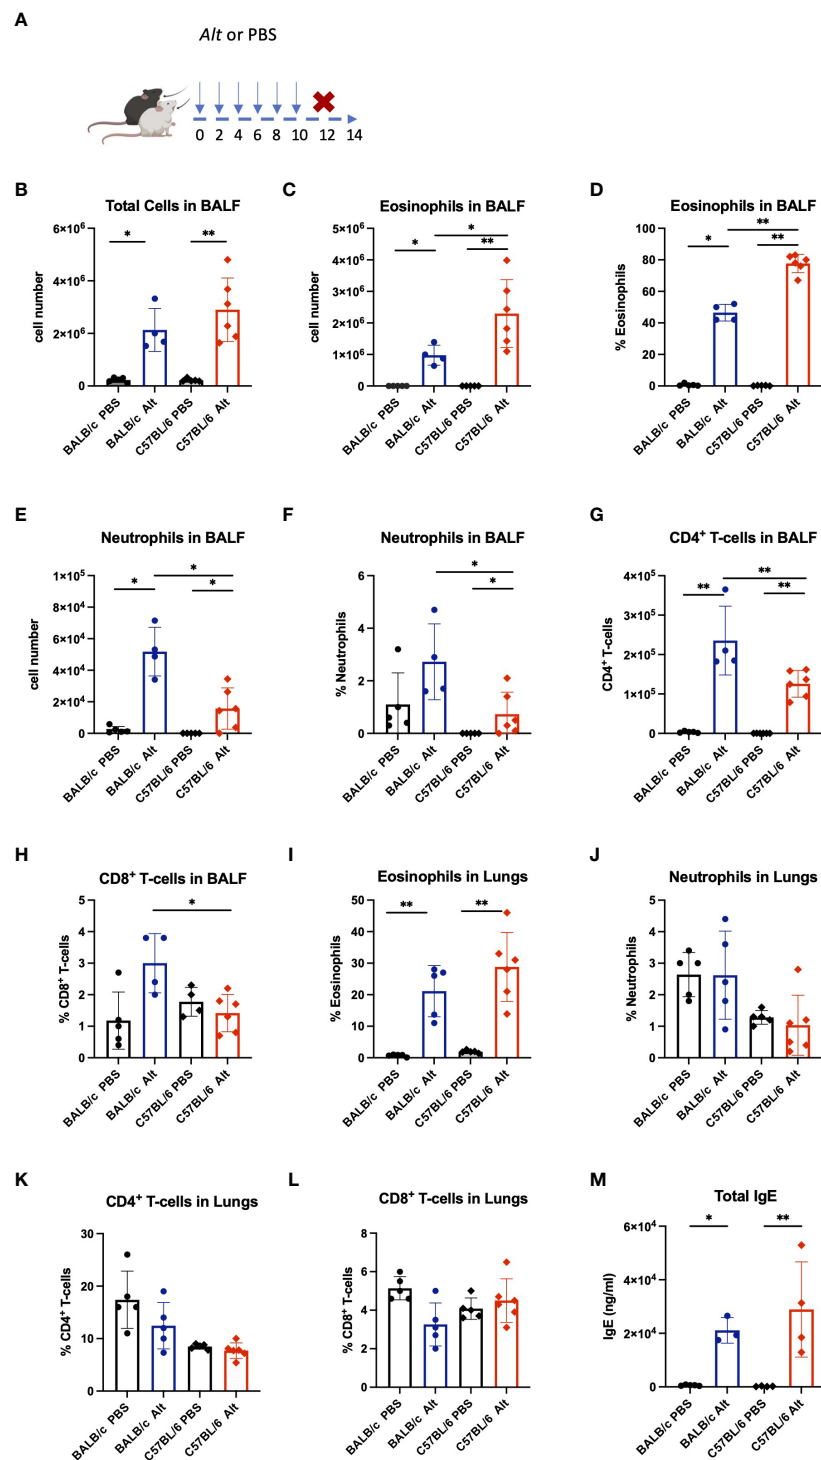

FIGURE 1

BALB/c and C57BL/6 mice were given six intratracheal applications of 20 µg *Alternaria alternata* (Alt) extract in PBS, controls received PBS alone. Forty-eight hours after the last application mice were sacrificed, and experimental samples were collected (A). The absolute cell numbers in the bronchial lavage fluid (BALF) are presented for total cell counts (B), eosinophils (C) and neutrophils (E) in BALF. The percentage of eosinophils (D) and neutrophils (F) in BALF are presented. The BALF and lungs were analysed by flow cytometry and the infiltration of eosinophils (I), neutrophils (J), CD4<sup>+</sup> T cells (G, K) and CD8<sup>+</sup> T cells (H, L) in the BALF and lungs are presented as percentage. Mouse serum was collected 48h following the final Alt application and the levels of total IgE in serum were determined using enzyme-linked immunosorbent assay (M). The data are presented as scatter plots ± standard deviation (S.D.). Statistical significance between the groups was determined by one-way ANOVA with Dunn's test for multiple comparisons. N=4-6 per group. \*p < 0.05, \*\*p < 0.01.

## Processing of IL-33 in *Alt*-induced allergic airway inflammation in C57BL/6 and BALB/c mice

Notably, despite the comparable degree of inflammatory response in the lungs of C57BL/6 and BALB/c mice, IL-33 levels were significantly higher in BALB/c than in C57BL/6 (Figure 2A). The expression of a cleaved/mature form of IL-33 (IL-33<sub>C</sub>; ~ 18 kDa) was higher in the lungs of BALB/c mice, while in C57BL/6 mice, the non-processed full-length form of IL-33 (IL-33<sub>FL</sub>; ~ 30 kDa) was more abundant (Figures 2B, C). IL-33 positive cells were abundantly present in the lungs of mice after *Alt* treatment (Figure 2D). RT-PCR didn't show differences between both strains in the respective treatment groups in the expression of IL-33 receptor *IL1RL1* (Figure 2E). Interestingly, IL-5 and IL-13 levels tend to increase in both mouse strains treated with *Alt* (Figures 2F, G), while IL-4 and G-CSF were slightly but not significantly

increased in both mouse strains, and IL-25 levels in the lungs were comparable in all experimental groups tested (Figure S1).

## Increased mast cell numbers and mast cell protease expression in the lungs of *Alt*-treated BALB/c mice

The lungs of *Alt*-treated BALB/c mice showed increased numbers of mast cells, positive for toluidine blue and chymase compared to PBS controls (Figures 3A-D). In agreement with the immunohistochemical staining, the lungs of BALB/c mice treated with *Alt* extract showed increased expression levels of genes encoding mast cell proteases such as *Mcpt1*, *Mcpt2*, *Mcpt4*, *Tpsab1*, *Tpsb2*, *Cma1*, *Cpa3* (Figures 3E-L). As expected, PBS-treated mice lacking significant numbers of mast cells did not express the proteases mentioned above. Only very few mast cells

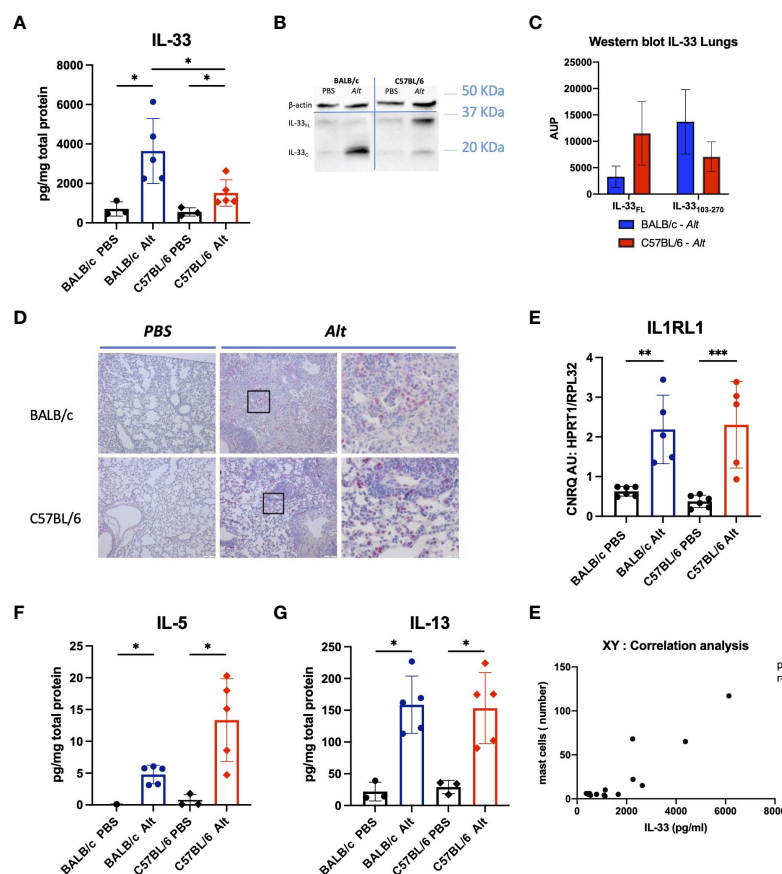

FIGURE 2

The analysis of cytokine response in the lungs of mice with intratracheal applications of 20  $\mu$ g of *Alt* extract and PBS-treated controls. The levels of IL-33 (A) in the lung homogenates were measured by Luminex. Full-length IL-33 (IL-33<sub>FL</sub>) and cleaved forms (IL-33<sub>C</sub>) were analysed by western blotting and one representative blot is shown (B) and area under the peak (AUP) was quantified using ImageJ software (C). Representative images of IL-33 immunostaining in the lungs of C57BL/6 and BALB/c treated with PBS or the *Alt* extract for six times every 48 hours (D). *IL1rl1* gene expression levels analysed in lungs by RT-qPCR (E). The levels of IL-5 (F), IL-13 (G) in the lung homogenates were measured by Luminex. The data are presented as scatter plot with a bar  $\pm$  standard deviation (S.D). Statistical significance between the groups was determined by one-way ANOVA with Dunn's test for multiple comparisons. N=4-6 per group. \* $p < 0.05$ , \*\* $p < 0.01$ , \*\*\* $p < 0.001$ .

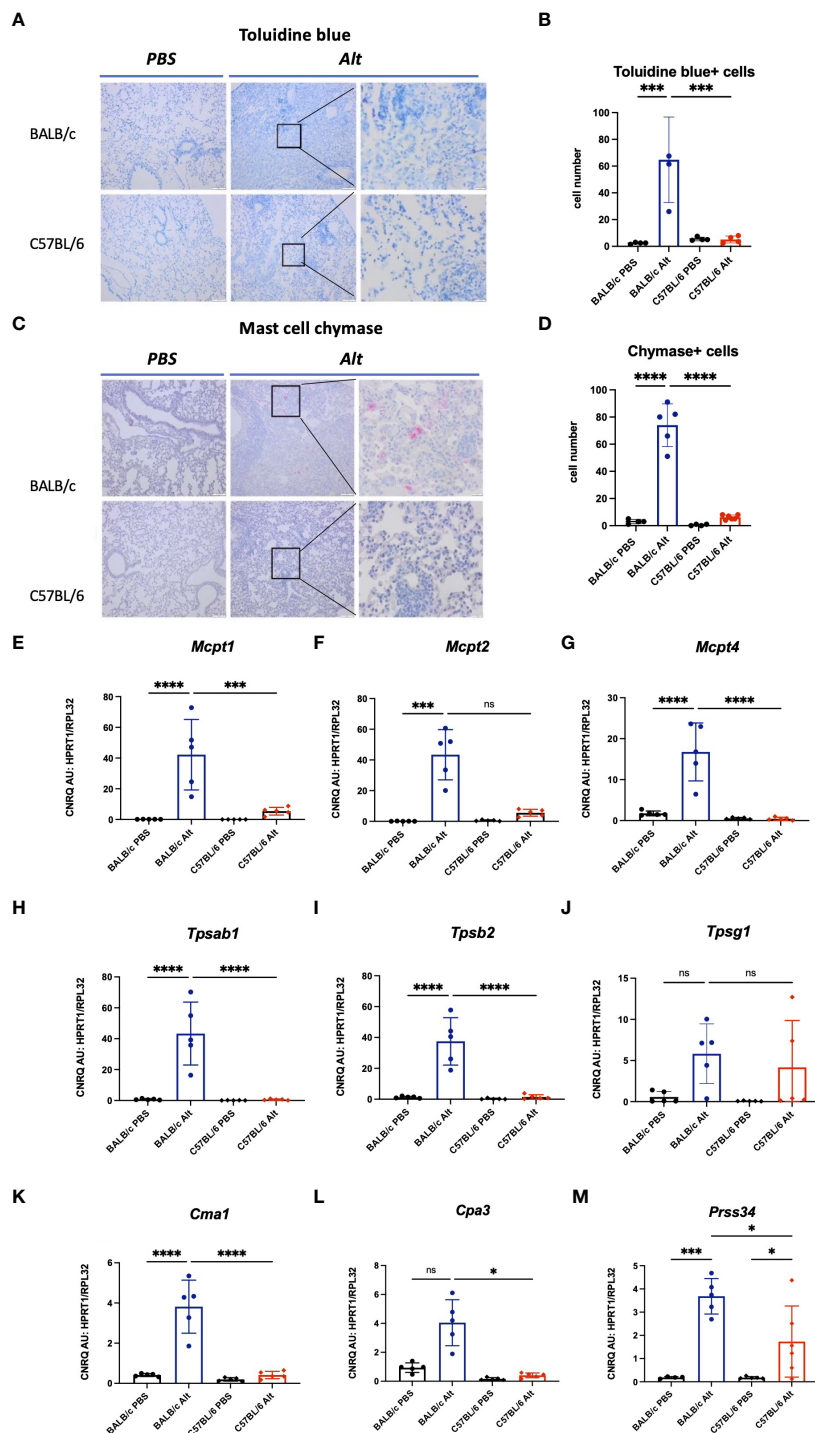

FIGURE 3

To visualize mast cells, formalin-fixed paraffin-embedded lung sections were stained with toluidine blue (A) and the number of mast cells was quantified in four different fields per mouse under magnification of forty times (B). Chymase - positive mast cells in the lungs of mice were visualized by immunohistochemistry (C) and quantified (D). Expression of mast cell proteases in the lungs of BALB/c and C57BL/6 mice treated with six intratracheal applications of 20  $\mu$ g *Alt* extract or PBS. Values of gene expression of *Mcpt1* (E), *Mcpt2* (F), *Mcpt4* (G), *Tpsab1* (H), *Tpsab2* (I), *Tpsg1* (J), *Cma1* (K), *Cpa3* (L) and *Prss34* (M) were normalised using reference genes *Hprt1* and *Rpl32*. The data are presented as scatter plot with a bar  $\pm$  standard deviation (S.D.). Statistical significance between the groups was determined by one-way ANOVA with Sidak's test for multiple comparisons. n=4-6 per group. \*p < 0.05, \*\*\*p < 0.001, \*\*\*\*p < 0.0001. ns, not significant.

could be found in the lung sections of PBS or *Alt*-treated C57BL/6 mice demonstrating nearly complete lack of mast cell response in C57BL/6 mice treated with *Alt* extract. The gene expression levels of mast cell proteases in the lungs of *Alt*-treated C57BL/6 mice were

almost undetectable. The gene expression levels of *Prss34* (*Mcpt11*) were upregulated in both mouse strains with slightly higher levels in *Alt*-treated BALB/c mice than in *Alt*-treated C57BL/6 mice (Figure 3M).

## Differential protease expression profiles in bone marrow-derived mast cells of BALB/c versus C57BL/6 mice

To test if the enzymatic content of mast cells from C57BL/6 mice might be different from BALB/c mast cells, we have used BMMCs differentiated *in vitro* in the presence of IL-3 as earlier described (24). The purity of BMMCs reached about 97% on day 20 and was consistent from day 20 to day 40 as analysed by expression of c-kit and FcεRI by flow cytometry (Figure 4A). The total RNA was isolated from BMMCs on days 20, 30, and 40 of *in vitro* culture,

and the expression levels of several mast cell proteases were tested. RT-qPCR showed a gradual increase from day 20 to day 40 in *Mcpt1*, *Mcpt2*, and *Mcpt4* gene expression in differentiating BMMCs of both mouse strains (Figures 4B–D). Remarkably, while BMMCs from BALB/c mice showed very high expression levels of *Tpsab1* at all differentiation stages tested (Figure 4E), the BMMCs from C57BL/6 mice had higher levels of *Tpsb2*, *Tpsg1*, and *Prss34* (Figures 4F–H). The gene expression of *Ctsg* and *Cma1* were significantly lower in BMMCs from C57BL/6 compared to BALB/c mice on days 30 and 40 (Figures 4I, J). Thus, despite identical culture conditions, mast cells differentiated *in vitro* from the bone

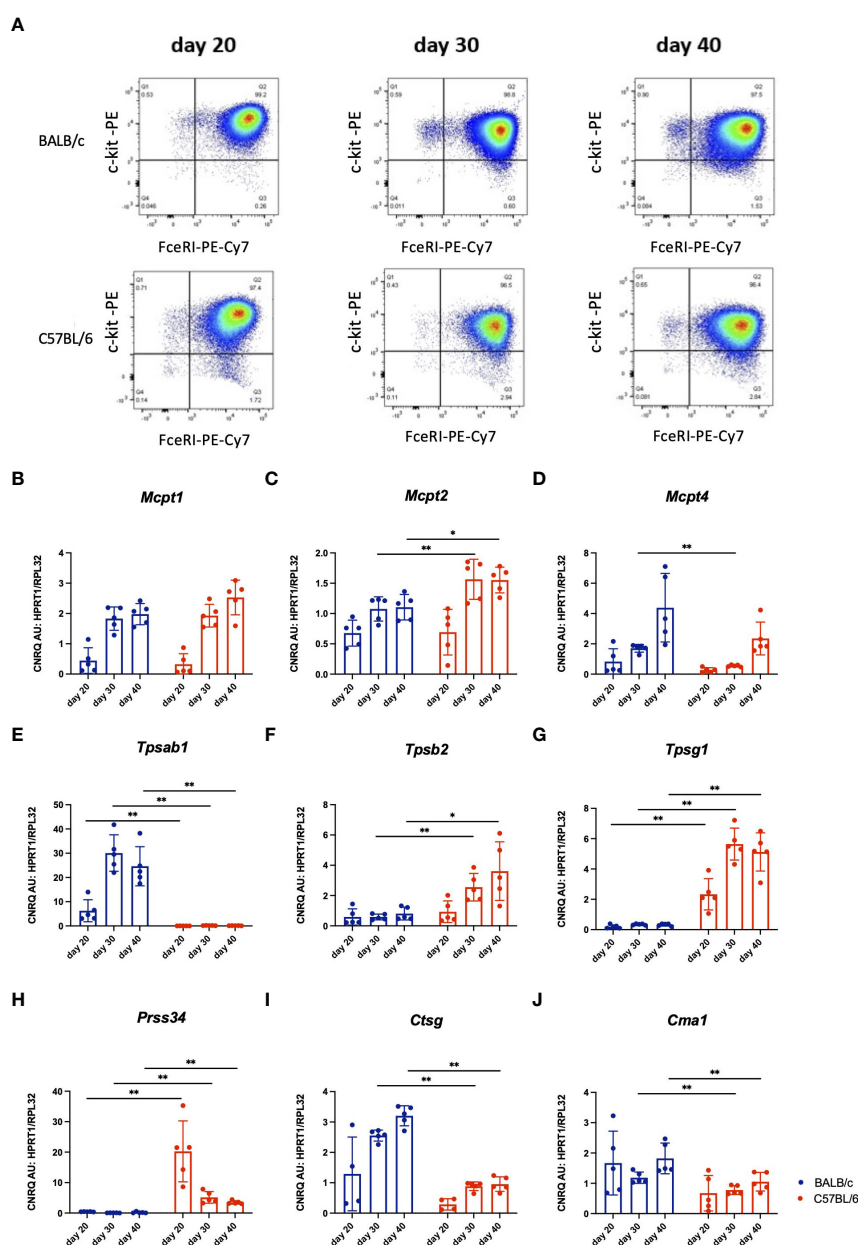

FIGURE 4

Representative dot plots of *in vitro* differentiated BMMCs from BALB/c and C57BL/6 mice cultured *in vitro* for 20, 30 or 40 days, respectively. Viable mast cells were analyzed for their expression of FcεRI and c-kit using flow cytometry (A). Next, gene expression analysis by RT-qPCR of mast cell proteases in these cultured BMMCs from BALB/c and C57BL/6 mice was performed. Values of gene expression of *Mcpt1* (B), *Mcpt2* (C), *Mcpt4* (D), *Tpsab1* (E), *Tpsb2* (F), *Tpsg1* (G), *Prss34* (H), *Ctsg* (I) and *Cma1* (J) were normalized to reference genes *Hprt1* and *Rpl32*. The data represent individual values, bars  $\pm$  standard deviation (S.D.). Statistical significance between the groups was determined by Mann-Whitney test comparing BALB/c and C57BL/6 mice at each individual time point. The BMMCs were collected from two separate experiments, n=5 per group. \*p < 0.05, \*\*p < 0.01.

marrow of C57BL/6 and BALB/c mice show a differential protease expression profile.

The difference observed on RT-qPCR between mast cells derived from C57BL/6 versus BALB/c prompted us to perform RNA sequencing (RNAseq) analysis to deeper characterize the phenotype of mast cells derived from different mouse strains. RNAseq analysis was performed in BMMCs of BALB/c and C57BL/6 mice on day 20. In total, 460 genes were upregulated and 263 downregulated in BMMCs of BALB/c mice compared to C57BL/6 mice. A full list of genes is provided in [Supplementary Data](#) and online repository, accession number GSE216642. 17 genes encoding proteases and 4 protease inhibitors that were differentially expressed between the BMMCs of BALB/c and C57BL/6 are summarized in (Table 1). Importantly, the expression of proteases involved in the cleavage of IL-33 is different between the two mouse strains at the baseline, showing that *Cma1* and *Cma2* were upregulated, while *Mcpt4* and *Ctsg* were downregulated in the BMMCs of C57BL/6 mice compared to BALB/c mice.

## BMMCs from BALB/c mice rapidly degraded IL-33

Next, we tested whether the full-length IL-33 protein could be processed *in vitro* by mast cell supernatants of BMMCs of both mouse strains. GFP-murine IL-33-mCherry fusion protein (Figure 5A) was used for a cleavage assay with BMMCs supernatants. DNP-IgE/DNP activated BMMCs of C57BL/6 mice did not degrade IL-33, while supernatants of similarly activated BALB/c BMMCs effectively degraded IL-33 after 10 min of co-incubation (Figures 5B, C). Importantly, the efficiency of IL-33 cleavage was linked to the degree of mast cell degranulation after IgE crosslinking. C57BL/6 BMMCs showed a much weaker release of  $\beta$ -hexosaminidase in response to IgE-DNP complex formation than BALB/c BMMCs (Figure 5D).

## Discussion

It is well-known that mast cells play a central role in mediating allergic diseases. Mast cells contribute to the activation of immune cells through their broad range of mediators. Next to proteases and histamine, they can also release cytokines. It is known that TNF- $\alpha$ , IL-4, and IL-13 release is triggered by IL-33 and drives the type 2 inflammatory pattern seen in asthma (25–29). We have previously shown that the inflammatory response to *S. aureus* protease like protein D (SplD) and *Alt* extract, which are IL-33 dependent asthma models, can vary among different genetic backgrounds in mice. In these models, a stronger eosinophilic response was found in C57BL/6 than BALB/c mice (12, 30, 31). Similar observations were made in other type 2 response inducing asthma models of ovalbumin-alum and house dust mite (32–35). We, therefore, hypothesized in this work that mast cells might differ between C57BL/6 and BALB/c mice, leading to a different inflammatory response.

In this study, we provide a comprehensive comparative analysis of BMMCs from BALB/c and C57BL/6 mice showing significant differences in expression of major mast cell proteases and protease inhibitors. RNA sequencing analysis of BMMCs *in vitro* from both strains has shown that tryptase genes were differentially expressed, namely C57BL/6 mice lacked *Tpsab1* expression but had higher levels of *Tpsb2* and *Tpsg1* instead, while *Ctsg* and *Cma1* were higher in BMMCs from BALB/c mice. It is known that mast cell chymase and cathepsin G can also generate more potent forms of IL-33 through its enzymatic processing (9). Some genetic differences were reported earlier, such as mutations in mMCP-7 of C57BL/6 mice that leads to its loss of expression (36). A frameshift mutation in the protease inhibitor *Serpina3i* that leads to a truncated and probably unfunctional protein in BALB/c mice (31). Their role in the differential regulation of IL-33 has been suggested (30).

Moreover, we here demonstrate *in vitro* that activated BMMCs from C57BL/6 and BALB/c mice show different enzymatic activity towards IL-33. Mast cells are known to regulate the processing of IL-33 in a dichotomic way: their proteases degrade IL-33 (37, 38) or generate active processed forms of IL-33 *in vitro* (9), generating a more functionally potent form of IL-33. The observed functional differences between mast cells of C57BL/6 and BALB/c mice could be explained by their different protease content and their IgE-dependent activation potential. A lower degranulation activity by IgE cross linkage of C57BL/6 bone marrow mast cells than BALB/c mast cells has also recently been demonstrated elsewhere (39). However, the exact mechanisms leading to this immune phenotypic difference need to be addressed in future studies. Mast cells of rodents are classically distinguished into two different phenotypes, mucosal and connective tissue mast cells. Connective tissue mast cells express high levels of chymases (Mcpt-4, Mcpt-5) and tryptases (Mcpt-6, Mcpt-7), while mucosal tissue mast cells mostly show an upregulation of Mcpt-1 and Mcpt-2 (40). The transcription program of mast cells varies depending on their differentiation stage (41, 42) and organ-specific localization (43). The studies were mostly performed in C57BL/6 mice, while the information on BALB/c mast cell expression profile is scarce (41, 42). In our experiments, we have seen an upregulation of markers characteristic for both types of mast cells in the lungs of BALB/c mice receiving *Alt* extract with a strong increase of *Mcpt-1*, *Mcpt-2*, *Mcpt-4*, *Mcpt-6* and *Mcpt-7* next to an upregulation of *Cma1* and *Cpa3*. In C57BL/6 mice, a nearly complete absence of mast cells and their proteases was seen in the lungs after the treatment with *Alt*. Even though *Prss34* expression was increased in *Alt*-treated C57BL/6 mice, BALB/c mice treated with the *Alt* extract had even higher levels of *Prss34*.

In our model, we repeatedly exposed mice to *Alt* extract as an *in vivo* mouse model of allergic IL-33-dependent airway inflammation, because *Alt* triggers the airway epithelium resulting in the release of alarmins, including ATP, IL-33, and TSLP, which induce ILC2 proliferation and a type 2-driven immune response (4, 44). In our study, BALB/c mice respond to *Alt* with features of allergic airway inflammation, including strong eosinophilic inflammation and neutrophilia in the BALF and lungs, in agreement with previous studies (4, 12, 44). Further, as seen previously, C57BL/6 mice presented an even higher eosinophilic

FIGURE 5

IL-33 degrading abilities of supernatants from C57BL/6 and BALB/c BMMCs. Schematic representation of the GFP-murine IL-33-mCherry fusion protein used for IL-33 cleavage assay with BMMCs supernatants (A). Supernatants from C57BL/6 or BALB/c BMMCs, which were either stimulated with IgE+DNP or left untreated were incubated with GFP-murine IL-33-mCherry for 1 h (B). IL-33 degradation was analysed by western blotting. Supernatants from IgE +DNP stimulated C57BL/6 or BALB/c BMMCs were incubated with GFP-murine IL-33-mCherry for 10, 30, 60, or 240 min at 37°C. IL-33 incubated only in buffer for 240 min at 37°C served as negative control. IL-33 degradation was analysed by western blotting (C). Beta-hexosaminidase degranulation assay of untreated or IgE+DNP stimulated BMMCs from C57BL/6J or BALB/c mice (D). Data are presented as mean  $\pm$  SEM.

response in the BALF as well as higher lung IL-5 levels than BALB/c mice. Based on the low numbers of mast cells and the low mast cell protease expression levels in the lungs of C57BL/6 mice compared to BALB/c mice, we suggest a protective effect of mast cells, that dampen IL-5 and the eosinophilic response in BALB/c mice.

Interestingly, IL-33 protein levels were remarkably higher in the lungs of BALB/c mice treated with *Alt*. We have noted before that IL-33 protein levels by Luminex, however, do not reflect the levels of cleaved IL-33 (IL-33<sub>C</sub>) found by western blotting (12). We demonstrated different processing patterns of IL-33 seen by western blotting between BALB/c mice with the prevailing IL-33<sub>C</sub> and C57BL/6 mice, where also full-length IL-33 was detected. Therefore, we hypothesize that this different cleavage pattern is a consequence of different proteolytic regulation of IL-33 by endogenous proteases upon intratracheal treatment with the *Alt* extract. Based on our previous results, we expect that Mcpt-4 present in the lungs of BALB/c mice degrades IL-33 (31). Next to mast cell proteases, also neutrophilic proteases, such as proteinase 3, and caspases can degrade IL-33 and inactivate it (10, 45). We recently demonstrated the importance of neutrophil proteases in the regulation of IL-33 in a comparable *Alt*-induced asthma model (12). Consistent with our previous results, we here showed that BALB/c mice respond with a stronger neutrophilic inflammation than C57BL/6 mice, which, in addition to the mast cell proteases, influences the IL-33 signaling pathway. In our previous study, depletion of neutrophils *in vivo* by *i.p.* injections of anti-Ly6G antibodies in *Alt*-treated BALB/c mice resulted in a significant decrease of elastase and reduced processing of IL-33<sub>C</sub> supporting the additional effect of neutrophilic proteases in the regulation of IL-33 processing (12). However, in our previously used SpID-induced asthma model, where C57BL/6 mice also presented a stronger eosinophilic response than BALB/c mice, the neutrophilic response was negligibly weak, and still IL-33 was processed in a comparable way to the here shown *Alt*-induced allergic airway inflammation model, which underlines the

importance of mast cell proteases in the regulation of IL-33 (22). Remarkably, the expression levels of ST2 receptor were comparable between the lungs of *Alt*-treated C57BL/6 and BALB/c mice, excluding the role of possible deficient IL-33/ST2 signaling axis in this regulation.

To conclude, our study demonstrates that mast cells differ in number and protease content between the two mouse strains most often used in asthma and allergy research. These differences might influence the phenotypic outcome in IL-33-dependent models of type 2 inflammation which are unlikely to be related to different efficiency of the IL-33/ST2 signalling axis. The mast cells and their proteases play a regulatory role in IL-33-induced inflammation by limiting its proinflammatory effect *via* the IL-33 signalling pathway because the models of allergic inflammation tested including BALB/c mice show a weaker eosinophilic response compared to C57BL/6 mice.

## Materials and methods

### Mice: experimental procedures

All experimental procedures were approved by the local Ethical Committee of Ghent University. Seven-week-old female BALB/c or C57BL/6J wild-type mice (Janvier, Saint-Berthevin, France) received six intratracheal applications of 50  $\mu$ l PBS alone or 20  $\mu$ g of *Alt* extract (Stallergenes Greer, London, UK) in 50  $\mu$ l PBS. Animals were kept in individually ventilated cages in a 12-hour/12-hour light/dark cycle. The experiments were performed under light gaseous anaesthesia with isoflurane/air (Ecuphar, Breda, The Netherlands). Mice were euthanized with an intraperitoneal (*i.p.*) injection of 150  $\mu$ l Dolethal (Vétoquinol, Lure, France). Lungs were perfused with 0.9% NaCl. For the cytokine analysis, a piece of the lung was snap-frozen in liquid nitrogen and stored at -80°C for further analysis. To perform immunohistochemical staining a piece

of the lung was immersed in 10% formalin and paraffin-embedded. The 5  $\mu$ m sections were cut and used for the subsequent staining.

## Flow cytometry

BALFs were collected with PBS containing protease inhibitor cocktail (Roche, Mannheim, Germany), 0.5% bovine serum albumin and ethylenediaminetetraacetic acid (EDTA) (Sigma-Aldrich, Bornem, Belgium). The lungs were enzymatically dissociated by incubation in 1 mg/ml collagenase type II (Worthington Biochemical, New Jersey, USA) at 37°C for one hour shaking to obtain single cell suspension. Red blood cells were lysed by cell lysis solution (VersaLyse Lysing solution, Beckman Coulter, Marseille, France).  $1 \times 10^6$  cells were stained with the following antibodies: purified CD16/CD32 (clone 93), CD4-FITC (clone RM4-4), CD8a-PerCP-Cy5.5 (clone 53-6.7), CD11c-PE-Cy7 (clone HL3), CD11b-PerCP-Cy5.5 (clone M1/70) and Gr1-FITC (clone RB6-8C5) purchased from Thermo Fisher Scientific and Siglec F-PE (clone ES22-10D8) from Miltenyi Biotec (Bergisch Gladbach, Germany). To exclude the dead cells the LIVE/DEAD Fixable Near-IR Dead Cell Stain Kit (Merck Millipore, Massachusetts, USA) was used. The following gating strategy was applied for flow cytometry to analyze eosinophils and neutrophils in BALF and lungs. First, the subset of viable cells was gated through the selection of singlets viable cells. Next from CD11c<sup>-</sup> population eosinophils were defined as CD11b<sup>+</sup>, SiglecF<sup>+</sup>, and neutrophils as SSC<sup>low</sup>, CD11b<sup>+</sup>, Gr1<sup>+</sup> as earlier described in (12). CD4<sup>+</sup> and CD8<sup>+</sup> T cells were gated as subsets of singlet/viable SSC<sup>low</sup> cells. Murine lungs and BALF were analysed by flow cytometry using the FACS Canto II (BD Biosciences, Erembodegem, Belgium).

## Luminex assays

A Luminex analysis was performed to measure the protein concentration of IL-4, IL-5, IL-13, IL-25, IL-33, and G-CSF in mouse lung homogenates. The mouse magnetic Luminex kit (R&D Systems, Minnesota, USA) was used and all steps were performed according to the manufacturer's protocol. The lung homogenates (1 mg/ml) were diluted 1/2 by adding 25  $\mu$ l of each sample to 25  $\mu$ l Calibrator Diluent RD6-52. A standard curve for each cytokine analysed was generated using a series of dilution (diluted 1/3) of the Standard Cocktails in Calibrator Diluent RD6-52. A diluted biotin-antibody cocktail and streptavidin- phycoerythrin (PE) solution were made according to the manufacturer's protocol in a 1/10 dilution. The plate was read using the Bio-Rad analyzer, Bioplex 200 system with Luminex xMAP technology (Bio-Rad, California, USA).

## Total IgE analysis

The levels of total IgE in serum of mice were analyzed with an ELISA kit from ThermoFisher Scientific according to manufacturer instructions. The reaction was read using automated

spectrophotometric plate reader and the SkanIt Software (Multiscan FC, Thermo Fisher Scientific).

## *In vitro* differentiation of murine bone marrow-derived mast cells

The mast cells were differentiated *in vitro* from BMMCs of naive wild type BALB/c and C57BL/6 mice. The BMMCs were differentiated for 40 days in Dulbecco's modified Eagle's medium with 10% fetal bovine serum, L-glutamine, penicillin/streptomycin and 1 mM sodium pyruvate (all from Thermo Fisher Scientific) supplemented with 5 ng/ml IL-3, 5 ng/ml IL-9, 1 ng/ml TGF- $\beta$ 1 and 30 ng/ml stem cell factor (all from PeproTech, London, UK). On days 20, 30 and 40 of the culture, the purity of obtained mast cells was tested by flow cytometry using anti-c-Kit-PE and anti-Fc $\epsilon$ RI-PE-Cy7 antibodies (Thermo Fisher Scientific). The representative dot plots are provided in Figure 4A. The experiment was repeated with four separate cultures. RNA from murine bone marrow-derived mast cells was isolated on days 20, 30 and 40.

## BMMCs stimulation

BMMCs were stimulated by DNP-IgE complex formation.  $2 \times 10^7$  cells/mL of BMMCs were preincubated with 0.15  $\mu$ g/mL anti-DNP IgE (Sigma-Aldrich) overnight and stimulated for 1 h with 200 ng/mL DNP-HSA (Sigma-Aldrich) in Tyrodes buffer (10 mM HEPES, 130 mM NaCl, 6.2 mM D-glucose, 3.0 mM KCl, 1.4 mM CaCl<sub>2</sub>, 1.0 mM MgCl<sub>2</sub> and 0.1% BSA, pH 7.15, sterile filtered) at 37°C. Supernatants were frozen and stored at -20°C until usage.

## IL-33 cleavage assay

Supernatants were incubated with 1  $\mu$ g of a full-length murine IL-33 GFP and mCherry fusion protein in a total volume of 20  $\mu$ L for 10, 30, 60 or 240 min. IL-33 degradation was detected by Western blot using mouse IL-33 antigen affinity-purified polyclonal goat IgG (dilution 1:300; R&D Systems) with polyclonal peroxidase labelled anti-goat IgG (H+L) (1:1000; Vector Laboratories Inc., Burlingame, CA, USA).

## Beta-hexosaminidase degranulation assay

Degranulation of BMMCs from C57BL/6 and BALB/c mice was tested as previously described (22).

## Immunohistochemistry

Formalin-fixed paraffin-embedded lung sections were deparaffinized and dehydrated. The slides were exposed to citrate buffer for antigen retrieval and endogenous peroxidase was blocked by incubation in 3% H<sub>2</sub>O<sub>2</sub>. Lung sections were stained with anti-

mast cell chymase (Abcam) and anti- IL-33 (R&D systems). The ImmPRESS<sup>®</sup>-AP Horse Anti-Goat IgG Polymer Detection Kit, Alkaline Phosphatase (Vectorlabs, Burlington, California, USA) and Dako REAL<sup>™</sup> Detection System, Alkaline Phosphatase/RED, Rabbit/Mouse (Agilent Technologies, Santa-Clara, California, USA) was used to visualize the binding. The slides were counterstained with haematoxylin and mounted with Aquatex (Sigma-Aldrich). The cells positive for IL-33 or chymase were counted in five power fields per mouse lung at magnification of forty times.

## Toluidine blue staining

Formalin-fixed paraffin-embedded murine lung sections were deparaffinized and dehydrated and stained for 15 minutes with toluidine blue (Sigma-Aldrich) working solution at pH 2.3. The slides were air-dried and mounted with a non-aqueous medium (Pertex, 00811, Histolab). The images were taken using Nikon Eclipse Ni-U upright microscope with NIS BR imaging software.

## Reverse transcription quantitative polymerase chain reaction

Snap frozen mouse tissue samples ( $\pm$  20-25 mg) were disrupt using a mortar and pestle containing liquid nitrogen and thawed directly into lysis solution (QIAGEN, Antwerp, Belgium), while murine bone marrow-derived mast cells were directly vortexed for 5 min in lysis solution. The lysate was then homogenized using a QIAshredder homogenizer (QIAGEN). The RNA isolation was further performed using the RNeasy Mini Kit (QIAGEN) following the manufacturer's instructions. The RNA concentration was measured with Nanodrop (Thermo Fisher Scientific, Waltham, Massachusetts, United States) and the quality of the RNA was assessed with the Fragment Analyzer<sup>™</sup> Automated CE System

(Agilent technologies, California, USA). 500 ng of the isolated RNA was transcribed into cDNA with the iScript Advanced cDNA Synthesis Kit (Bio-Rad) and subsequently diluted with nuclease-free water to 2.5 ng/ $\mu$ l cDNA (total RNA equivalent). Real-time PCR amplifications were performed in a 384-well plate LightCycler LC480 System (Roche Diagnostics, Mannheim, Germany). qPCR reactions (5  $\mu$ l) contain 5 ng cDNA, 2x SsoAdvanced Universal SYBR Green Supermix (Bio-Rad) and 250 nM forward and reverse primer (Table 2). The PCR protocol consisted of 2 minutes polymerase activation at 95°C and 44 cycles of 5 seconds at 95°C, 30 seconds at 60°C and 1 second at 72°C followed by a dissociation curve analysis from 60°C to 95°C. For murine BMMCs, RT-qPCR was performed for mouse mast cell proteases (*Mcpt1*, *Mcpt2*, *Mcpt4*), tryptase  $\alpha/\beta$ 1 (*Tpsab1*), tryptase  $\beta$ 2 (*Tpsb2*), tryptase  $\gamma$ 1 (*Tpsg1*), serine protease 34 (*Prss34*), cathepsin G (*Ctsg*) and mast cell chymase 1 (*Cma1*). For mouse lung tissue, RT-qPCR was performed for mouse mast cell proteases (*Mcpt1*, *Mcpt2*, *Mcpt4*), tryptase  $\alpha/\beta$ 1 (*Tpsab1*), tryptase  $\beta$ 2 (*Tpsb2*), tryptase  $\gamma$ 1 (*Tpsg1*), mast cell chymase 1 (*Cma1*), carboxypeptidase A3 (*Cpa3*) and serine protease 34 (*Prss34*). The primer sequences of all target genes were shown in Table 2. *IL1rl1* (encoding ST2) Taqman (QuantiTect Probe PCR kit; Mm00516117\_ml) was purchased from Applied Biosystems. The expression of 2 reference genes, hypoxanthine phosphoribosyltransferase 1 (*Hprt1*) and ribosomal protein L32 (*Rpl32*) was used to normalize for transcription and amplification variations among samples after a validation with geNorm (Biogazelle, Zwijnaarde, Belgium). The normalized relative quantities (NRQs) were calculated with the qBase<sup>+</sup> software (Biogazelle, Belgium) and the final gene expression levels are expressed as NRQs per 5 ng cDNA.

## Western blotting

Tissue homogenates of 20 - 25 mg of mouse lung tissue were made by a mechanical dissociation in a mixture of tissue lysis buffer

TABLE 2 List of primers used in the study.

Gene name	Primer sequence FW (5'-3')	Primer sequence RW (5'-3')
<i>Hprt1</i>	CCTAAGATGAGCGCAAGTTGAA	CCACAGGACTAGAACACCTGCTAA
<i>Rpl32</i>	GGCACCAGTCAGACCGATATG	CCTTCTCCGCACCCTGTTG
<i>Mcpt1</i>	AAAAACAGCATACATGGGAG	CATATGCAGAGATTCTGGTG
<i>Mcpt2</i>	CAATAGGACAAGGAGATTCTG	TAATAGGAGATTCCGGTGAAG
<i>Mcpt4</i>	CACTGTAGTGGAAGAGAAATC	GAGGAATTACATTCACAGAGG
<i>Tpsab1</i>	AAACCCTGTGAACATTCTG	TACACCATTGTCGATGTTAC
<i>Tpsb2</i>	GACATTGATAATGACGAGCC	GACAATGGGAAAATCATCTCC
<i>Tpsg1</i>	TTCTCTGGGTCTGTGAAC	GTTTTACAGTGGAGAAGTGG
<i>Prss34</i>	AGTCTATGGTGTCCTTAAC	ATGGTAAGGAGGGAATATGG
<i>Ctsg</i>	TGACCTTTATTCTACTCCAAGG	GTAACATTTATGGAGCTTCCC
<i>Cma1</i>	GTATACAAGGGAGACTCTGG	CAGAGTTAATTCTCCCTCAAG
<i>Cpa3</i>	ATGGCTACACATTCAACTG	TATTGGGCCGTAGATGTAAC

(Thermo Fisher Scientific) and protease inhibitor cocktail (Roche, Sigma-Aldrich, Merck KGaA, Darmstadt, Germany) with a TissueLyser LT (QIAGEN). The supernatant was collected and centrifuged for 10 min at 3000 rpm at 4°C. The tissue homogenate was stored in -20°C. For spectrophotometric determination of the concentration of total proteins in the tissue homogenate, a standard series of dilution with bovine serum albumin (Sigma-Aldrich, Merck KGaA, Darmstadt, Germany) was used. Homogenate samples were diluted 1:20 with NaCl (0.9%) (Versylene Fresenius). The dye solution was prepared by diluting 1 part protein assay dye reagent concentrate (Bio-Rad) with 4 parts distilled water. Subsequently, the optical density was measured at a wavelength of 570 nm using the SkanIt Software (Multiscan FC, Thermo Fisher Scientific). Samples of mouse lung homogenates were prepared for gel electrophoresis with 25 µg protein. For gel electrophoresis, Mini-protean TGX stain-free precast gels (Bio-Rad) were used and 10 µl of the Precision Plus Protein Dual Color Standards (Bio-Rad) was added. The proteins were blotted on a nitrocellulose membrane (Bio-Rad). After blotting, the membrane was washed with a washing buffer and adding a blocking buffer (5% skim milk powder in 1x TBST), the membrane was incubated with the primary antibody (goat anti-IL-33, 0.6 µg/ml) overnight at 4°C while shaking. After washing, the membrane was incubated with the appropriate secondary antibody (anti-goat IgG horseradish peroxidase (HRP) (1 µg/ml)). Visualization was done with the Chemidoc imaging system (Bio-Rad) after incubation with SuperSignal West Dura (Thermo Fisher Scientific).

## RNAseq analysis, RNAseq pipeline and data quantification

RNA was isolated from  $1 \times 10^6$  murine mast cells per condition as described above. The integrity of RNA was tested using Fragment Analyzer and 100 ng of total RNA was used for RNA sequencing analysis. The TruSeq Stranded mRNA kit (Illumina) was used to prepare a RNAseq library according to the manufacturer's protocol, followed by PE100 cycles sequencing on one lane of a NovaSeq 6000 S1 run (Illumina).

## Bioinformatics

All fastq files passed quality control with FastQC v0.11.5 (46). Salmon v0.8.2 (47) was used to align raw RNAseq reads against Ensembl *Mus musculus* GRCm39 and get quantification estimates at the transcript level. All subsequent analyses were conducted in R software v 4.0.3 (48). Differential analysis was computed using tximport v1.10.0 (49) and the negative binomial generalized linear modeling implemented in DESeq2 package version 1.30.1 (50). Genes were regarded to be differentially expressed when the q value cutoff (FDR adjusted p-value using Benjamini-Hochberg mode I (51)) was lower than 0.05. In order to obtain significantly different genes, we set the selection criteria as: the multiple of difference | Fold Change | > 2. To visualize the differentially -

expressed (DE) genes identified using the methods described above, the Bioconductor Enhanced Volcano (52) and g plots (53) packages were used. Enhanced Volcano was used to display each gene's shrunken log2 fold change (LFC) against its adjusted p-value. A gene classification and functional annotation analysis were performed using the 'Gene Functional Classification' and 'Functional Annotation Charts' tools of the Database for Annotation, Visualization and Integrated Discovery (DAVID Bioinformatics Resources 6.8, NIAID/NIH) (54). As annotation category, KEGG\_PATHWAYS was selected for pathways analysis.

## Statistical analysis

The data were analysed using D'Agostino & Pearson test for normal (Gaussian) distribution ( $\alpha = 0.05$ ). When three or more experimental groups were compared, the normally distributed data were analysed by parametric one-way ANOVA with Dunnett's multiple comparisons test. The data, which were not normally distributed, were analysed by non-parametric Kruskal-Wallis test with Dunn's test for multiple comparisons. Significance was determined as followed: \*  $p < 0.05$ , \*\*  $p < 0.01$ , \*\*\*  $p < 0.001$ , \*\*\*\*  $p < 0.0001$ .

## Data availability statement

The data presented in the study are deposited in the GEO repository, accession number GSE216642.

## Ethics statement

The animal study was reviewed and approved by Ethical Committee of Ghent University, Faculty of Medicine and Health Sciences.

## Author contributions

OK designed and performed experiments, analyzed data and wrote the original draft. DK and MI performed the bioinformatics analysis of the RNA sequencing dataset. AT performed experiments and revised the manuscript. JV, JS and AD collected experimental material, did immunohistochemistry and western blotting, analyzed data, revised the manuscript. SV contributed to the collection of the murine samples and revised the manuscript. GH performed and analyzed Luminex data. ND performed and analyzed RT-qPCR data. FC performed RNA seq analysis. HB provided a genetic construct encoding full length IL-33. MV, and DVK supervised the study, provided analysis tools, revised the manuscript. CB supervised the study, provided analysis tools, revised the manuscript. All authors discussed the results and approved the manuscript. All authors contributed to the article and approved the submitted version.

## Funding

The research was supported by FWO-Flanders 3G065319N to OK and CB. DVK lab is supported by Ghent University BOF (Special Research Fund 01/O3618; BOF/IOP/2022/033; BOF23/GOA/029). MV and MI acknowledge the Ministry of Science and Higher Education of the RF, agreement No. 075-15-2020-808.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Publisher's note

All claims expressed in this article are solely those of the authors and do not necessarily represent those of their affiliated

organizations, or those of the publisher, the editors and the reviewers. Any product that may be evaluated in this article, or claim that may be made by its manufacturer, is not guaranteed or endorsed by the publisher.

## Supplementary material

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fimmu.2023.1040493/full#supplementary-material>

### SUPPLEMENTARY FIGURE 1

The levels of IL-4 (A), G-CSF (B), and IL-25 (C) in the lung homogenates were measured by Luminex. The data are presented as a scatter plot with a bar  $\pm$  standard deviation (S.D). Statistical analysis was performed by one-way ANOVA with Dunn's test for multiple comparisons. N=4-6 per group.

### SUPPLEMENTARY TABLE 1

List of genes differentially expressed in RNA-Seq analysis of *in vitro* differentiated mast cells (BMMCs) from naïve BALB/c and C57BL/6 mice obtained from three biological replicates.

# Cause or consequence? The role of IL-1 family cytokines and receptors in neuroinflammatory and neurodegenerative diseases

Diana Boraschi<sup>1,2,3,4\*</sup>, Paola Italiani<sup>2,3,4</sup>, Paola Migliorini<sup>5</sup>  
and Paola Bossù<sup>6\*</sup>

<sup>1</sup>Shenzhen Institute of Advanced Technology (SIAT), Chinese Academy of Sciences (CAS), Shenzhen, China, <sup>2</sup>Institute of Biochemistry and Cell Biology (IBBC), National Research Council (CNR), Naples, Italy, <sup>3</sup>Stazione Zoologica Anton Dohrn (SZN), Napoli, Italy, <sup>4</sup>China-Italy Joint Laboratory of Pharmacobiotechnology for Medical Immunomodulation, Shenzhen, China, <sup>5</sup>Clinical Immunology and Allergy Unit, Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy, <sup>6</sup>Laboratory of Experimental Neuro-psychobiology, Department of Clinical and Behavioral Neurology, Santa Lucia Foundation, Rome, Italy

Cytokines and receptors of the IL-1 family are key mediators in innate immune and inflammatory reactions in physiological defensive conditions, but are also significantly involved in immune-mediated inflammatory diseases. Here, we will address the role of cytokines of the IL-1 superfamily and their receptors in neuroinflammatory and neurodegenerative diseases, in particular Multiple Sclerosis and Alzheimer's disease. Notably, several members of the IL-1 family are present in the brain as tissue-specific splice variants. Attention will be devoted to understanding whether these molecules are involved in the disease onset or are effectors of the downstream degenerative events. We will focus on the balance between the inflammatory cytokines IL-1 $\beta$  and IL-18 and inhibitory cytokines and receptors, in view of future therapeutic approaches.

IL-1 family cytokines, IL-1 family receptors, neuroinflammation, neurodegeneration, Alzheimer's disease, multiple sclerosis

## 1 Introduction

The interleukin-1 (IL-1) superfamily encompasses eleven structurally and evolutionarily related cytokines that mainly act by binding to specific receptors (1). The IL-1 receptor (IL-1R) complexes are formed by a ligand-binding chain and an accessory chain necessary for signal transduction. The IL-1R family comprises ten related transmembrane molecules with extracellular Ig-like domains and intracellular TIR (Toll-Like Receptor/IL-1 Receptor) domains (2). Most IL-1 and IL-1R molecules are involved in inflammation/immunostimulation and its regulation. It is notable that, while IL-1R are derived from invertebrate TIR-containing receptors involved in innate immunity, IL-1 cytokines only appeared in vertebrates (likely linked to the development of adaptive immunity) and the majority of them is only present in mammals (3, 4).

In mammals, eleven cytokines of the IL-1 family have been identified, the inflammatory IL-1 $\alpha$ , IL-1 $\beta$ , IL-18, IL-36 $\alpha$ , IL-36 $\beta$ , IL-36 $\gamma$ , and the regulatory/anti-inflammatory IL-1Ra, IL-33, IL-36Ra, IL-37 and IL-38 (overview in 1). IL-1 family cytokines mainly act by binding to receptor complexes, composed by a ligand binding chain and an accessory signal transducing chain. Signalling is initiated by the pairing of the intracellular TIR domains of the two receptor chains. Receptors of the IL-1R family are ten structurally related transmembrane proteins, which may also give rise to soluble receptors upon gene splicing or proteolysis of the membrane chains (overview in 2). IL-1R1 binds the agonist ligands IL-1 $\alpha$  and IL-1 $\beta$ , and its signalling depends on the engagement of the accessory chain IL-1R3. IL-1R1 also binds IL-1Ra but in this case fails to recruit the IL-1R3, and no activation occurs. Binding of IL-38 has also been reported. IL-1R2 is similar to IL-1R1 in its ligand binding capacity and IL-1R3 engagement, but it lacks the intracellular TIR domain and is therefore an inhibitory receptor. IL-1R4 is the receptor for IL-33, and uses the same IL-1R3 as accessory chain for signalling. IL-1R5 is the receptor for IL-18, and uses its specific accessory chain IL-1R7. It was reported that IL-37 also binds to IL-1R5 but is unable to recruit IL-1R7. IL-1R6 is the ligand binding chain for all the IL-36 isoforms (IL-36 $\alpha$ , IL-36 $\beta$ , IL-36 $\gamma$ ) and uses the promiscuous IL-1R3 as accessory chain. IL-1R6 also binds the receptor antagonist IL-36Ra and fails to engage the accessory chain. Binding of IL-38 has also been reported. IL-1R8 is an inhibitory receptor, which can interact with several IL-1R complexes and interfere with their signalling and may also act as inhibitory accessory chain for IL-37 bound to IL-1R5 and IL-38 bound to IL-1R6. IL-1R9 is an orphan receptor, although binding to IL-38 has been reported, predominantly expressed in neurons and likely involved in IL-1-independent neuronal functions. Likewise, IL-1R10 is abundantly expressed in the brain and has no IL-1-dependent functions (for complete references, please see the reference lists of 1, 2).

IL-1 and IL-1R molecules expressed in brain have as their main role the modulation of neuronal plasticity and function, in addition to mediating immune protective functions, in both physiologic and pathologic condition (5–8). IL-1, originally described as endogenous pyrogen or leukocytic pyrogen, is mainly produced in the hypothalamus in response to inflammatory agents and can induce fever by upregulating cyclooxygenase-2, the enzyme responsible for the synthesis of the vasoactive and inflammatory prostaglandin E<sub>2</sub> (9, 10). A central nervous system (CNS)-restricted expression of splice variants of different IL-1 and IL-1R family members, as truncated forms with regulatory functions, have been identified for both IL-1 (11) and IL-18 (12–14). In the case of IL-37, only one of its five splice variants (IL-37a) is present in the brain (15). Some IL-1R members are only present in the brain, including a particular variant of the accessory receptor chain IL-1R3 (IL-1R3b), expressed in neurons and involved in IL-1-mediated neuroprotection. Notably, the receptor complex for IL-1 $\alpha$  and  $\beta$  in the brain can be the canonical one (IL-1R1 plus IL-1R3, present everywhere in the body) that mediates inflammatory effects, or the alternative one (IL-1R1 plus IL-1R3b, specific for the brain) that mediates neuroprotective effects (2, 16–18). Other brain-specific receptors are the two orphan receptors IL-1R9 and IL-1R10, which are mostly expressed in neurons. IL-1R9 is likely involved in memory and learning capacity, as its mutations are linked to X-linked mental

retardation and autism (2, 19, 20). The functions of IL-18 in the brain are also peculiar, since the cytokine is active (inflammation and homeostasis) even in the absence of its receptor IL-1R5, while IL-1R5 seems to be involved in the pathogenesis of experimental allergic encephalomyelitis (EAE, the mouse model of multiple sclerosis) in the absence of its IL-18 ligand (21, 22). This suggests that a CNS-specific network of IL-1 family cytokines and receptors is crucial in maintaining brain homeostasis, thus highlighting the limitation of a simplistic inflammatory paradigm to explain the function of these cytokines in neuroinflammatory diseases.

In this perspective, we examine the available experimental and clinical evidence of the involvement of these molecules in two major neurodegenerative diseases, Alzheimer's disease (AD) and multiple sclerosis (MS), and propose a more global picture of the pathogenic and pathological role of the IL-1/IL-1R system.

## 2 Alzheimer's disease

### 2.1 Disease pathogenesis and inflammation

Alzheimer's disease (AD) in its sporadic form is the most common dementia diagnosis, characterized by a long progressive process of neuronal damage that affects memory and thinking and ultimately leads to death, in general preceded by a preclinical condition named mild cognitive impairment (MCI) (23).

The main pathological hallmarks of AD are the extracellular accumulation of amyloid  $\beta$  (A $\beta$ ) peptides and the intraneuronal neurofibrillary tangles (NFT) formed by aggregation of hyperphosphorylated tau proteins. Neuroinflammation is the third core feature of the disease (24, 25). Many inflammation-related genes have been identified as important AD risk factors (26), and increased inflammatory responses in the brain and periphery have been widely reported in AD (27, 28). Innate immune cells, primarily brain-resident microglia, have a dual role in AD neuroinflammation (29–33). Microglia have a protective function by releasing neurotrophic factors and clearing misfolded proteins, and can degrade A $\beta$  thereby reducing its accumulation. Indeed, a transition of microglia from homeostatic to disease-associated populations endowed with protective potential has been described as a function of the disease progression (34). However, during the course of AD, microglia can be hyperactivated by accumulating danger-associated molecular patterns (DAMPs), mainly A $\beta$  and tau, and secrete neurotoxic and inflammatory cytokines that cause persistent neuroinflammation and initiate/exacerbate neurodegeneration (35–38). The focus on neuroinflammation and inflammasome activation as cause of neuronal damage in AD (39–43) leads to assessing the role of the inflammatory cytokines generated by inflammasome activation, in particular the IL-1 family cytokines IL-1 $\beta$  and IL-18 (44).

#### 2.1.1 IL-1

In the brain, IL-1 $\beta$  is required for learning and memory processes, but, when expressed at aberrant levels, it is involved in infection- and sterile inflammation-induced cognitive dysfunction (45, 46). It has also been suggested that low levels of IL-1 act in the CNS to perform non-immunological functions, while higher

concentrations could engage brain non-neuronal cells to produce neuroinflammation (47). Notably, brain IL-1 $\beta$  is produced by and target different cells, ranging from microglia, infiltrating leukocytes, astrocytes, to neurons. By activating different specific cell types, including endothelial cells, neurons and choroid plexus cells, IL-1 may exert different functions of both immunological and non-immunological nature, and neuroinflammation itself may be the result of multiple responses to IL-1 by different brain cell types (8).

In AD, IL-1 $\beta$  is an important mediator of neuroinflammation (48, 49), but also a protective factor (50), able to influence the balance between beneficial and detrimental outcomes (51). In mice lacking the gene encoding the IL-1 inhibitor IL-1Ra the AD-like pathology is exacerbated (52), while the IL-1R1 blockade results in decreased neuroinflammation, attenuated tau pathology and reversal of cognitive deficits (53). Modulation of levels of IL-1Ra or different IL-1R has been observed in brain and blood of AD patients (54–58). Overall, the available experimental and clinical data do not support an exclusively detrimental role of IL-1-driven inflammation in AD.

### 2.1.2 IL-18

IL-18, its receptors IL-1R5 and IL-1R7 and its inhibitory protein (IL-18BP) are normally expressed in the brain and modulated in both experimental and clinical AD conditions (21). Similar to IL-1, IL-18 could exert both detrimental and protective functions in AD. Thus, while IL-18 dysregulation has been observed in AD patients in association with severity of symptoms and correlated to increased A $\beta$  production *in vitro* (59–62), a protective function has been also reported in IL-18-deficient mice in both physiological (63) and AD-like conditions (64).

### 2.1.3 IL-33

A third IL-1 family cytokine, IL-33, is being explored in CNS diseases (65). IL-33 is constitutively expressed in astrocytes and to a minor extent in oligodendrocytes, microglia and neurons; its receptor IL-1R4 is expressed on astrocytes, endothelial cells, glial cells and neurons (6). IL-33 can induce microglia cell proliferation and production of inflammatory IL-1 $\beta$  and TNF $\alpha$ , and anti-inflammatory IL-10 (66). In animal models, IL-33 decreases inflammatory responses and improves AD-like pathology (67). In patients, IL-33 expression in the brain is variably modulated relative to healthy subjects (68, 69). Patients with measurable circulating IL-33 levels have preserved cognitive functions, compared with those that do not express the cytokine (70). Eventually, in MCI patients treated with the neuroprotective compound homotaurine, the improvement of cognitive functions correlates with increased IL-33 plasma levels (71), confirming the potential protective role of this cytokine in AD development.

## 2.2 Mechanisms of IL-1/IL-1R family in AD pathology

IL-1 $\beta$ , IL-18 and IL-33 are dysregulated in AD and likely exerting a dual role: driving the inflammatory pathogenic processes associated with the disease and providing protection to

the damaged CNS. The functions of these mediators in brain homeostasis and pathology can be pleiotropic, redundant, synergic and cross-regulating, aiming to switch off or amplify the inflammatory response in a context-dependent manner. In this scenario, the IL-1R signaling could lead to the production of inflammatory cytokines and participate in A $\beta$ -induced inflammasome activation in microglia, while it might even increase the Amyloid Precursor Protein non-amyloidogenic processing in neurons, thereby preventing neurotoxic A $\beta$  generation (72). Overall, whether and when the different molecules belonging to the IL-1/IL-1R family are either beneficial or detrimental to neuronal function in the course of AD, and how their negative feedback mechanisms influence this, is still a matter of intense research (39). However, the general deregulation of IL-1 family members observed in patients consistently reflect the AD-linked activation of the innate immune system, strongly suggesting that an inflammatory condition, although not exclusively detrimental or beneficial, is indisputably present in AD.

It is likely that neuroinflammation is both a response to A $\beta$  and tau NFT that exacerbates their deleterious effects, and a cause of the disease, that increases brain deposit of A $\beta$  and tau phosphorylation starting before onset of symptoms (73, 74). Convincing new data in patients show that microglia activation and consequent neuroinflammation are associated with disease development and progression (75). The infectious hypothesis (76, 77) offers a fascinating explanation of the etiological meaning of inflammation in the disease and the underlying role of IL-1 family cytokines. According to the observation that A $\beta$  has antimicrobial functions (78), several microbial infections (herpesviruses, periodontal bacteria, gut microbiota dysbiosis) have been associated to AD. By inducing inflammasome activation, infectious agents can induce the release of IL-1 family cytokines, which can contribute to blood brain barrier alterations, amplify pre-existing inflammation in the brain, influence A $\beta$  pathology (note that infections upregulate A $\beta$  production) and tau-related neurodegeneration. Indeed, it has been proposed that the AD pathology can be modulated by innate immune mechanisms associated with infectious burden, including long-term innate memory, which affect epigenetic reprogramming of microglia and the release of IL-1 family cytokines (79, 80).

## 3 Multiple sclerosis

### 3.1 Pathology and inflammation

Multiple sclerosis (MS) is a chronic inflammatory neurological disorder driven by myelin-targeting CD4<sup>+</sup> T cells. The two main disease phenotypes are the relapsing-remitting form (RRMS) and the primary progressive MS, with a steady loss of function (PPMS) (81, 82). RRMS patients may evolve to a progressive disease course, diagnosed as secondary progressive MS (SPMS). The characteristic demyelinating lesions are localized in both white and grey matter, and contain an abundant inflammatory infiltrate with activated macrophages, microglia, CD8<sup>+</sup> and CD4<sup>+</sup> T cells, B and plasma cells (83). Inflammatory mediators released by innate and adaptive

immune cells lead to damage of oligodendrocytes, the cells responsible for myelin deposition, and axonal injury. A wealth of information, in particular in experimental models, suggests a role for the gut microbiota in bidirectionally modulating brain inflammation in MS, with changes in bacterial composition inducing upregulation vs. downregulation of the production of IL-1 $\beta$  and other inflammation-related factors (84–87).

### 3.1.1 IL-1 $\beta$

Acting on astrocytes and endothelial cells, IL-1 $\beta$  increases the permeability of the blood-brain barrier and allows leukocyte recruitment (88); acting on T cells, it induces the encephalitogenic phenotype of Th17 (89). *IL1B* transcript and IL-1 $\beta$  protein are detected in CNS lesions of MS patients (88), and microglia display an intense IL-1 $\beta$  staining (90). Changes in IL-1 levels in sera and cerebro-spinal fluid (CSF) are non-univocal, possibly due to patients' heterogeneity and the interference of therapies. Elevated serum levels of IL-1 $\beta$  were reported (91), and the difference with normal subjects was higher for untreated RRMS patients with active disease (92). Other authors report normal levels of IL-1 $\alpha$  and IL-1 $\beta$  in active patients, who however had received immunosuppressive therapy (93). Conflicting data have been obtained also in the analysis of CSF. Markedly increased levels of IL-1 $\beta$  in CSF were reported by some authors (91, 94) but not confirmed by others (95, 96). The possible relationship between IL-1 $\beta$  levels and disease activity is also challenged by the observation that in a group of active patients neither serum nor CSF levels were affected by high dose steroid treatment (91).

Soluble inhibitors and decoy receptors are also modulated in MS. IL-1Ra, undetectable in normal CNS, is expressed in lesional foamy macrophages, which also express the anti-inflammatory factors IL-10 and Transforming Growth Factor  $\beta$ , and markers typical of anti-inflammatory M2 macrophages (97). IL-1Ra levels are significantly higher in CSF but not in serum, and even if not correlated with disease activity, they are further increased by steroid treatment (91). IL-1Ra levels are strongly related with disability index, suggesting the potential role of IL-1Ra as serum biomarker of disease progression (98). On the contrary, the soluble decoy receptor IL-1R2 is not elevated in serum compared to normal controls, but steroid treatment induces an increase of its levels (91). In CSF, sIL-1R2 is undetectable irrespective of the disease stage. Finally, soluble IL-1R3 levels are significantly elevated in sera and CSF of MS patients, but not related to disease activity and not modulated by therapy.

### 3.1.2 IL-18

IL-18 levels were elevated in sera (99–101) and also in CSF, especially in patients with active lesions (99). The findings in CSF, however, were not confirmed in other studies (102). An increase in serum IL-18 levels is detected in untreated RRMS (93) but also in SPMS (102). As observed in most inflammatory disorders, the increase in IL-18 serum levels is accompanied by a parallel increase in its soluble inhibitor IL-18BP, aimed at counteracting the IL-18 inflammatory effects. Although free IL-18 was not evaluated, the IL-18BP/IL-18 ratio was higher in RRMS patients than in controls (93).

### 3.1.3 Other IL-1 family members

IL-33 has been extensively investigated in MS and EAE. The expression levels of both the cytokine and its receptor IL-1R4 are increased in lesions of MS patients and EAE mice (65, 103). Serum levels of IL-33 are elevated in patients and decreased by treatment with IFN $\beta$  (103). Longitudinal assessment of peripheral expression of IL-33 in RRMS revealed peak expression after relapses, but a clear correlation with clinical recovery was not demonstrated (104). In EAE mice, administration of IL-33 attenuates the disease, while antibody-mediated or genetic blockade exacerbates it (105–107). Similarly, IL-1R4 deficient mice develop a severe form of EAE. In this model, IL-33 induces M2 macrophage polarization indirectly, by stimulating mast cells to produce IL-13, and M2 cells then limit the expansion of pathogenic Th17 cells (108). The contribution of IL-1R4<sup>+</sup> Treg, activated by IL-33, should also be taken into account. Controversial results have been obtained on the direct effect of IL-33 on myelination (109, 110), but on the whole the data are consistent with the notion that IL-33 is involved in neuroprotection and repair.

Interesting data underline the role of IL-37, an anti-inflammatory member of the IL-1 family. Intracellularly, IL-37 acts as an anti-inflammatory transcriptional regulator. Extracellularly, IL-37 signaling is allegedly mediated by a receptor complex formed by IL-1R5 and IL-1R8. IL-37 is barely detectable in PBMC from normal or MS patients; in the brain, its low expression levels are further downregulated in active MS lesions (111). Notably, the level of IL-37 gene expression in PBMC of MS patients is associated with a lower number of relapses (112). IL-1R5 and IL-1R8 are expressed at similar levels in PBMC and brain from normal or MS patients, and the levels of IL-1R5 (which is also the receptor for IL-18) tend to increase in active lesions. In sera, IL-37 is detectable in 8% of RRMS patients in a stable disease phase and 42% in the active stage; its levels are increased by treatment with a disease-modifying agent, fingolimod (112). Data from patients suggest that the anti-inflammatory activity of IL-37 may be defective in MS, as also confirmed by animal experiments. EAE is milder in transgenic mice expressing human IL-37, with reduced inflammatory infiltrate and decreased numbers of Th1 cells and inflammatory macrophages in lesions (111). This beneficial effect of IL-37 on EAE is lost in mice lacking IL-1R8, indicating that the cytokine confers protection acting through the inhibitory receptor IL-1R8. Moreover, administration of recombinant IL-37 reduces neurological deficits and demyelination in EAE mice. Thus, IL-37 is protective in neuroinflammation and may represent a novel treatment in MS.

## 4 The NLRP3 inflammasome

The NOD-like receptor 3 (NLRP3) inflammasome, a multiprotein complex that regulates production and release of inflammatory cytokines, in the brain is mainly expressed in microglia but also in astrocytes and neurons. Besides being involved in protection from bacterial, fungal and viral agents, NLRP3 plays a role in neurodevelopment and neuroprotection, but its aberrant activation is crucial in neuroinflammation (113).

Different pathways, including impaired autophagy and dysregulated cell death mechanisms, upregulate NLRP3 activity in AD (114). A $\beta$  and tau can directly activate NLRP3 in microglia (115–117), and several compounds that ameliorate AD-associated pathology reduce NLRP3 activity.

Strong evidence points to a critical role of inflammasome activation in MS. Caspase-1 is more expressed in peripheral blood mononuclear cells (PBMC) of MS patients than in controls (118). Its serum levels can be considered a biomarker of MS, even if they do not identify more active or more severe patients (101). In untreated patients, upregulation of NLRP3 gene expression and higher caspase 1 activity were detected in circulating monocytes (119). NLRP3 upregulation characterized patients with PPMS and was associated with hyperexpression of several inflammatory chemokines and cytokines. IL-1 $\beta$  was one of the most expressed genes, correlated with faster disease progression in PPMS (119). There is a marked increase in the number of IL-1 $\beta$ , caspase-1, and gasdermin D (GSDMD)-positive cells in white matter of MS versus non-MS patients. GSDMD, activated by inflammatory caspases, forms membrane pores responsible for pyroptosis an inflammasome-driven programmed cell death (120). In MS lesions, inflammasome activation and pyroptosis are detected in microglia and oligodendrocytes, suggesting a role in demyelination. Inhibition of inflammasome activation and caspase-1-dependent IL-1 $\beta$  production have already been exploited in MS therapy: IFN $\beta$  treatment reduces NLRP3 activity and induces IL-10, thus decreasing the production of pro-IL-1 $\alpha$ , pro-IL-1 $\beta$  and mature cytokines (121).

In experimental autoimmune encephalomyelitis (EAE), the mouse MS model, blockade of caspase-1 expression or activity attenuates neuroinflammation (122). Caspase-1 inhibition also reduces GSDMD activation and pyroptosis, limiting oligodendrocyte death and demyelination (120). Similarly, NLRP3 KO or IL-18 KO mice have a less severe disease course, with a marked reduction of CNS inflammatory infiltrate (123, 124). Microglia-specific deletion of the gene encoding the NF $\kappa$ B regulatory protein A20 leads to microglial cell proliferation, susceptibility to LPS-induced inflammation and increased EAE severity, reversed by NLRP3 or caspase-1 genetic deletion (125), indicating a critical role of microglia in MS, mediated by inflammasome activation. The inflammasome involvement in neuroinflammation is also suggested by data in a cohort of MS patients, in which low penetrance mutations of the NLRP3 gene were detected in 16% of the cases (126). These mutations are associated with mild symptoms (suggestive of autoinflammatory disease) and increased production of IL-1 $\beta$  and IL-18 (127).

## 5 IL-1 family molecules in other main neurodegenerative diseases

Inflammation is involved in other neurological diseases, both neurodegenerative (see below) and of traumatic or other origin (trauma, stroke, autism, schizophrenia, epilepsy). Focusing on neurodegenerative disorders, these are classified in four main groups: amyloidoses, tauopathies, alpha-synucleinopathies, and

TDP (transactivation response DNA binding protein)-43 proteinopathies, all characterised by abnormal protein conformations and the formation of protein aggregates in neuronal cells in different brain areas (128, 129). AD is the most common and prevalent of both amyloidoses and tauopathies, along with frontotemporal dementia with parkinsonism and some forms of prion diseases. Main  $\alpha$ -synuclein-related diseases include Parkinson's disease (PD), Dementia with Lewy Bodies, and Multiple System Atrophy, while Amyotrophic Lateral Sclerosis (ALS) is mainly associated with TDP-43 pathology. The Huntington disease (HD) is associated with mutations in the huntingtin protein, which clumps within neurons provoking cell damage and death (130).

Although it is well known and documented that all neurodegenerative diseases share the chronic aberrant inflammation (131), less is known on the role of IL-1 family cytokines and receptors in specific neurodegenerative diseases (132). In addition to AD and MS, reviewed in the previous sections, here we will briefly examine the involvement of IL-1 family molecules in PD, HD, and ALS.

PD is characterised by the death of dopaminergic neurons in the *substantia nigra* and by the cytoplasmatic aggregation of fibrillar  $\alpha$ -synuclein in Lewy bodies (133). Increase of  $\alpha$ -synuclein released outside the cells drives the activation of microglia, and the microglia-dependent production of TNF- $\alpha$ , NO, and IL-1 $\beta$  sustains the neuroinflammatory process in PD (134). Recent results in the 6-OHDA mouse model showed that the increased levels of IL-1 $\beta$  and TNF- $\alpha$  have a different kinetics, with TNF- $\alpha$  appearing in the advanced disease stage, while increased level of IL-1 $\beta$  in serum were already evident with a moderate degree of lesion in *substantia nigra*, suggesting a prognostic value for this inflammatory cytokine (135). Although the results on the level and role of IL-1 $\beta$  in PD patients are conflicting (136), the activation of the NLRP3 inflammasome seems to be determinant for the development of PD at least *in vitro*. Indeed, when activated, the inflammasome can cause the aggregation of  $\alpha$ -synuclein in a neuronal cell model of PD, as caspase-1 directly cleaves  $\alpha$ -synuclein generating a truncated protein highly prone to aggregation and able to provoke cell death (137). The involvement of the NLRP3 inflammasome activation in PD also includes two additional mechanisms, the interaction with the parkin protein, whose mutations are responsible of autosomal recessive familial and sporadic early-onset PD (138, 139); and the association with mitochondrial dysfunction that affects neuron performance and favours neuronal degeneration (140). Although IL-1 $\beta$  is a major product of the NLRP3 inflammasome activation, its role in causing/sustaining inflammation in PD patients is still debated (141).

Increasing evidence suggest that inflammation contributes to the development of HD, but the involvement of IL-1 family is still poorly known. The role of IL-1 $\beta$  has been investigated in mice expressing a mutant and pathogenic huntingtin crossed with animals knocked out for IL-1R1 (142). These mice showed more severe neurological symptoms compared to control mice expressing IL-1R1, suggesting a protective role for IL-1R1 signalling in preventing the HD neuropathology. Whether IL-1 $\beta$  is the

molecule that activates IL-1R1 signalling is not known. Although IL-1 $\beta$  has been identified as one of the inflammation-related markers of the disease in the porcine HD model (143), its level does not increase in plasma of HD patients, at variance with IL-6 or other inflammatory factors (144, 145). An involvement of the NLRP3 inflammasome has been also suggested for HD, although evidence is still poor and mostly from pre-clinical studies (146).

ALS is a neuromuscular disorder characterized by the progressive loss of anterior-lateral horn spinal cord motoneurons (147). Sporadic ALS affects the 90–95% of patients, while the familiar form affects the remaining 5–10% of patients. The two most relevant genetic mutations associated with ALS are a defect in the hexanucleotide repeat expansion (HRE) in intron 1 of the *C9orf72* gene (which makes a protein that regulates actin dynamics and endosomal recycling of GluR1 at the synapse) (148), and in the free radical scavenging enzyme Cu,Zn-superoxide dismutase (SOD1) gene (149). The involvement of inflammation in the etiopathogenesis of ALS is starting to be investigated, but studies are still limited (150, 151). In a recent study, the authors suggest hyperinflammation and immunodeficiency as primary triggers of motoneuron death in ALS, and underline the complex link between the development ALS and T cell and monocyte profiles of patients, as well as polymorphisms in cytokine and chemokine receptors, suggesting a need for personalised therapies based on immunophenotyping (152). In this regard, recently new polymorphisms in the gene encoding IL-1 $\beta$  and in genes involved in oxidative stress (e.g., SOD2) have been identified as modifiers of

ALS progression (153). IL-1 $\beta$  is one of the main biomarkers of inflammation in ALS (151, 152). Even if it is not the best marker of ALS severity (154), its plasma levels negatively correlate with survival in ALS patients with genetic variant *C9orf72HRE* (155). Among the IL-1 family cytokines and receptors, it has been observed that only IL-18 is associated with sporadic ALS, whereas the serum levels of the cytokines IL-33 and IL-36 and the soluble receptors sIL-1R2 and sIL-1R4 were comparable between ALS patients and healthy controls, and IL-1 $\beta$ , IL-1Ra and IL-37 were below detection (156). The possible pathogenic role of IL-18 in ALS has been also recently underlined by a Whole Genome Sequencing study, which identified a genetic variant in a noncoding region of the gene encoding the IL-18 receptor accessory protein (*IL18RAP*) able to reduce mRNA stability and motor neuron neurotoxicity, thereby decreasing 5x the risk of developing ALS (157). A protective role has been suggested for another member of IL-1 family, IL-33 (158). In the ALS mouse model transgenic for G93A-superoxide dismutase 1 (*SOD1-G93A*), long-term IL-33 administration delays disease onset in females but not males, probably through peripheral Th2 response (159).

## 6 Conclusions and perspectives

The role of IL-1 family cytokines and receptors in the etiology and pathogenesis of neurodegenerative diseases is still poorly understood. However, there is strong evidence of their involvement in the initiation

FIGURE 1

IL-1 family involvement in Alzheimer's disease (AD) and Multiple Sclerosis (MS). IL-1 family cytokines and receptors are crucial in maintaining brain homeostasis, with an important role in the modulation of neuronal plasticity and function, in addition to mediating immune protective functions. In physiological conditions, many activities of IL-1 family cytokines depend on binding to specific receptors, but independent functions have been observed for both cytokines (e.g., IL-18) and receptors (e.g., IL-1R9). In disease conditions (AD, MS), IL-1 family members are substantially modulated during disease progression (triangles), associated with increased inflammation (partly dependent on inflammasome activation) and likely involved in all disease phases, from initiation and establishment to progression, without a clear association with either disease initiation or progression. MΦ, macrophages.

and regulation of inflammation associated to most CNS diseases, and their participation to neuroinflammation has been widely described in AD and MS. This is evident despite the limitations due to the current lack of reliable animal models that realistically recapitulate the pathological features of the human diseases, such as in the case of sporadic AD (160). In humans, longitudinal molecular monitoring of inflammation is also hampered by the reduced accessibility of human brain and the limited availability of clinical studies with extensive follow-ups (161, 162).

From the combined *in vivo* and *in vitro* functional and molecular evidence, it is clear that these factors play a homeostatic and neuroprotective role in healthy conditions. It is notable that the IL-1 family system in the CNS includes several molecules and functions that are CNS-restricted, implying tissue-specific needs and consequent functional adaptation. Disease conditions imply an imbalance of the IL-1 system network (Table 1).

From the available experimental and clinical evidence, we can draw the following conclusions and suggestions.

- IL-1 family cytokines and receptors are altered in AD and MS and related to the neuroinflammatory conditions.
- Alterations in the amount of produced inflammatory cytokines (IL-1, IL-18) likely switch their role from neuroprotection/homeostasis to pathological inflammation.
- The excess of inflammatory cytokines causes an excessive induction of feedback mechanisms, e.g., the production of

downregulating factors (IL-1Ra, IL-18BP, IL-33, IL-37), which however do not succeed in rebalancing the excessive inflammation.

- Unbalanced IL-1 family molecules contribute to alterations in adaptive immune responses, thereby amplifying the autoimmune aspects of neurodegenerative diseases.
- Whether anomalies in the IL-1 family cytokine and receptor network are cause or effect of neuroinflammation and neurodegeneration in AD and MS is not an appropriate question, as it seems that these factors are involved in all steps of disease, from its induction to its establishment and downstream symptoms (Figure 1).
- The CNS-restricted peculiarities of the network of IL-1 family cytokines and receptors suggest a tissue-specific physiological balance and pathological dysregulation. A more thorough understanding of the CNS specificities in the IL-1 family system will open the way to a precision rebalancing approach for therapeutic purposes.

## Author contributions

DB, PM, PI and PB wrote the manuscript and critically revised it. DB and PI contributed to figures and tables. All authors contributed to the article and approved the submitted version.

## Funding

This work was supported by the EU Commission H2020 projects PANDORA (GA671881) and ENDONANO (GA 812661) (PI, DB), the project MIUR/PRIN-20173ZECCM of the Italian Ministry of Research (PI) and the projects RC 2018-2021, ADIMB, CoEN 2019-Pathfinder IV and RF-2021-12374301 by the Italian Ministry of Health (PB).

## Conflict of interest

The reviewer JB declared a shared affiliation, with no collaboration, with one of the authors, DB, to the handling editor at the time of the review.

Intracellular recognition of self and non-self -nucleic acids can result in the initiation of effective pro-inflammatory and anti-tumorigenic responses. We hypothesized that macrophages can be activated by tumor-derived nucleic acids to induce inflammasome activation in the tumor microenvironment. We show that tumor conditioned media (CM) can induce IL-1 $\beta$  production, indicative of inflammasome activation in primed macrophages. This could be partially dependent on caspase 1/11, AIM2 and NLRP3. IL-1 $\beta$  enhances tumor cell proliferation, migration and invasion while coculture of tumor cells with macrophages enhances the proliferation of tumor cells, which is AIM2 and caspase 1/11 dependent. Furthermore, we have identified that DNA-RNA hybrids could be the nucleic acid form which activates AIM2 inflammasome at a higher sensitivity as compared to dsDNA. Taken together, the tumor-secretome stimulates an innate immune pathway in macrophages which promotes paracrine cancer growth and may be a key tumorigenic pathway in cancer. Broader understanding on the mechanisms of nucleic acid recognition and interaction with innate immune signaling pathway will help us to better appreciate its potential application in diagnostic and therapeutic benefit in cancer.

## KEYWORDS

innate immunity, inflammasome, cytosolic DNA, tumor microenvironment, AIM2 inflammasome

## Introduction

The innate immune system serves as the first-line defense against bacteria, viruses, and other pathogens(1). DNA is typically found in the nucleus of eukaryotic cells, and the presence of DNA in aberrant locations, such as the cytoplasm and endosomes triggers immune activation, sensed by a group of proteins collectively known as DNA sensors(2). We and others have reported that cytosolic DNA is found in cancer cells and tissues and not in healthy tissues, suggesting that it is a unique cancer phenotype (3). Whether the tumor cells or innate immune cells in the tumor microenvironment recognizes cancer derived cytosolic nucleic acids has been recently questioned, and the involvement of DNA sensors has appeared to be important both intrinsically and for tumor surveillance (4). Another class of DNA sensors are the inflammasomes and namely, the AIM2 inflammasome senses dsDNA(5) and has been implicated in the development (6) as well as regulation (7) of various cancers.

The inflammasomes are a family of oligomeric protein complex made up of the sensor component which, upon sensing of PAMPs and DAMPs, binds adaptor protein ASC, which activates caspase-1, and triggers the release of pro-inflammatory cytokines such as IL-1 $\beta$ , making the inflammasomes one of the critical drivers of inflammation(8). Inflammasomes are defined by their sensor, which include AIM2, Pyrin, and NLRP1 and NLRP3. The diversity and specificity of sensors allow responsiveness to a broad range of stimuli, either extrinsic (microbial molecules) or intrinsic (danger signals). Activation of inflammasomes requires two different signals, encompassing a priming step which usually involves microbial molecules which would induce nuclear factor kappa B (NF- $\kappa$ B)-dependent expression of the sensor protein and pro-IL-1 $\beta$  and a second signal provided by various structurally unrelated microbial molecules such as toxins or danger signals (e.g., DNA, ATP or uric acid), which, together with the first signal, will trigger inflammasome multimerization and activation(9). The AIM2 inflammasome consists of AIM2, an adaptor molecule ASC (apoptosis-associated speck-like protein containing a CARD), and pro-caspase-1. Upon inflammasome activation, caspase-1 is cleaved, which in turn, cleaves IL-1 $\beta$  and gasdermin-D which frees the N-terminal effector domain from the C-terminal inhibitory domain. Oligomerization of the gasdermin-D N terminal subsequently forms a pore in the membrane and leads to membrane rupture and pyroptosis.

As mentioned, AIM2 is a cytosolic DNA sensor protein which can have inflammasome dependent and independent functions. AIM2 has been implicated in the development of various cancers including prostate cancer, squamous cell carcinoma (10, 11), as well as non-small cell lung cancer through the regulation of mitochondrial dynamics (12) and renal cell carcinoma through FOXO3a-ACSL4 inhibition of ferroptosis(13). However, other studies have reported that AIM2 acts as a tumor suppressor gene in many cancers including colon cancer and endometrial cancer (6, 14), inhibiting cancer proliferation, invasion and migration through various mechanisms, including suppressing glioma-associated

oncogene-1 (GLI1) (15), inactivating PI3K/AKT/mTOR signaling (16). Moreover, the trigger mechanisms of the AIM2 inflammasome remain unknown. Cytosolic DNA, including ssDNA, dsDNA, and DNA/RNA hybrids, are present in all tested cancer cell lines and cancer samples (3, 17). Strikingly, cytosolic DNA is not found in healthy tissues, suggesting that it is a unique cancer phenotype and hence giving us a clue to study the link between cancer cells and AIM2 inflammasome activation.

Based on previous reports that cancer cells contain cytosolic nucleic acids (3) and cancer cells can activate macrophages, we hypothesized that macrophages can be activated by tumor-derived nucleic acids to induce inflammasome activation in the tumor microenvironment, which in turn, can affect cancer progression.

## Materials and methods

### Mice

All animal work was approved by the National University of Singapore Institutional Animal Care and Use Committee (IACUC), an AALAC accredited institution and was in accordance with the National Advisory Committee for laboratory Animal Research (NACLAR) Guidelines. TRAMP-C2 cells were injected subcutaneously into C57BL6 mice or AIM2<sup>-/-</sup> mice on the same background. Tumors were homogenized or treated with collagenase before isolating CD11b<sup>+</sup> cells through a column and incubating overnight, after which supernatants were collected for ELISA analysis.

### Cell lines, drugs and treatments

Human THP-1, U937, HeLa cells, A549, HCT-116, and mouse TRAMP-C2 cells were purchased from ATCC (USA). A549, HeLa and TRAMP-C2 cells were grown in DMEM medium (Invitrogen, USA), while HCT116 cells were cultured in McCoy's 5A medium (Invitrogen, USA), and both mediums are supplemented with 10% heat-inactivated FCS (Hyclone, USA) and 1% pen/strep (Invitrogen). THP-1 and U937 cells were cultured in RPMI medium (Hyclone, USA) supplemented with 10% heat-inactivated FCS (Hyclone, USA). All cells were grown at 37°C in a humidified 5% CO<sub>2</sub> incubator (Thermo Scientific, USA). THP1 cells were differentiated in PMA (#tlrl-pma, InvivoGen, USA) and stimulated with 1  $\mu$ g/ml LPS (#tlrl-pekips, InvivoGen, USA) overnight before fresh cell medium was replaced and the cells were either treated with 50% cancer CM or transfected with 1  $\mu$ g/ml poly (dA:dT) (#tlrl-patc, InvivoGen, USA) with Iyovec transfection reagent. *Inhibitors* THP1 Cells were primed with 100 ng/ml PMA, followed by LPS (1  $\mu$ g/ml) for 3 hours prior to treatment 1 hour with 1  $\mu$ g/ml Poly(dA:dT) complexes (AIM2 inflammasome inducer) or A549 tumor CM in the presence of ODN TTAGGG (A151; AIM2 inhibitor, 0.5  $\mu$ M) or MCC950 (NLRP3 inhibitor, 0.5  $\mu$ M). Cell supernatants were detected using ELISA.

## Bone marrow derived macrophage isolation and differentiation

Bone marrow derived macrophages (BMDMs) from mice were obtained by flushing the femurs and tibias of mice with DMEM media. Briefly, red blood cells were removed through osmotic lysis and the bone marrow cell suspension was washed twice with PBS and cultured with BMDM media (DMEM medium containing 10% FBS (v/v), 100 U/mL penicillin, 100 µg/mL streptomycin, 2 mM L-glutamine and 20% L-929-conditioned DMEM (v/v) as a source of M-CSF). After 3 days of culture, the cells were supplemented with fresh BMDM media. At day 7, culture media and non-adherent cells were removed, and the remaining adherent cells were replenished with fresh BMDM media before experiments.

## Tumor conditioned media preparation

A549, HeLa, MCF7 cells are cultured in T-75 flasks until 80% confluency before the existing media was replaced by new DMEM medium. The cells were grown for another 24 h in the new DMEM media before the conditioned media was collected and filtered using 0.45 µm filter (Millipore, USA) prior to use.

## Flow cytometry

Cells were stained with Fixable Viability Dye eFluor 506 (1:1000) in 1x PBS for 30 min at 4°C (Thermo Fisher Scientific, USA) before incubated with Fc block (BioLegend, USA) for 15 min at 4°C. Cells were stained with fluorescence-conjugated antibodies (BioLegend, USA) diluted in FACS buffer and incubated on ice for 30 min in the dark. Macrophages were identified as CD45+ Ly6G-Gr1- F4/80+ CD11b+ cells. Cells were analyzed on a BD LSRFortessa (BD Biosciences, USA) or Attune NxT Flow Cytometer (Thermo Fisher Scientific, USA). Data analysis was performed using FlowJo software (FlowJo, USA).

## Immunohistochemistry

Immunohistochemistry (IHC) was performed using the Leica Bond max autostainer (Leica Biosystems, Nussloch GmbH) and bond polymer refine detection kit (DS9800, Leica Biosystems) following the manufacturer's instructions. Briefly, tissues were fixed in formalin, dehydrated and cleared before adding paraffin (pre-heated to 60°C) and left overnight. Sectioning was performed with a microtome. Formalin-fixed tissue sections were de-waxed, rehydrated and antigen retrieval was achieved using citrate buffer at pH 6 for 20 minutes. Endogenous peroxidase activity was quenched in 0.3% hydrogen peroxide for 10 minutes and non-specific sites were blocked with 3% bovine serum albumin for 20 minutes. Further, single immunostaining with primary antibodies for CD68 (1:50, Bio-Rad), inducible nitric oxide synthase (iNOS, 1:50, Abcam), mannose receptor CD206 (1:200, Abcam) followed by incubation with

respective HRP-linked secondary antibodies (for CD68: goat anti-rat antibody Bio-Rad; for iNOS and CD206: goat anti-rabbit antibody, DAKO) was performed. 3,3'-diaminobenzidine (DAB) was used as the chromogen to obtain the brown colour. Counterstaining was with hematoxylin for 10 min. The mean score of five high-power fields (HPF) (×400) was counted for each slide under a light microscope (Olympus BX43) and digital images were acquired using Olympus cellSens Entry imaging software. In the IHC stained sections, macrophages observed with their cytoplasm stained tan or brown were considered positive.

## Immunofluorescence

Cytosolic dsDNA and DNA-RNA staining were performed as described previously (16). Briefly, 50% formamide (VWR International, USA) diluted in PBS was added for 10 mins at room temperature, followed by incubation for 15 mins at 75°C to denature dsDNA. Cells were washed with PBS and incubated with blocking buffer (1% BSA (Sigma Aldrich), 2% goat serum (Hyclone) in PBS) for 1 h to prevent non-specific binding of antibodies. Cells were then stained with dsDNA (1:200, Sigma-Aldrich, USA) or S9.6 DNA-RNA hybrids (1:100, Kerafast, Boston, USA) antibodies overnight in 4°C. Cells were subsequently washed with PBST (0.1% Tween) thrice followed by anti-mouse IgG coupled with Cy3 (Millipore, Singapore) or anti-rabbit IgG coupled to Alexa Fluor 488 (Invitrogen, Singapore). Finally, DNA fluorophore DAPI (0.5 µg/ml in PBS, KPL Inc., USA) was added for 10 min. Slides were washed once in PBS before mounted with Da-/- fluorescent mounting medium (Da-/-, UK). Confocal images of staining were captured using a Zeiss Axio Imager Z1 fluorescent microscope equipped with AxioVision 4.8 software (Carl Zeiss MicroImaging, USA) or confocal TCS SP5 (Leica, Singapore). Images were analyzed using Photoshop CS4 (Adobe, USA) or ImageJ. Colocalisation of AIM2 with DNA or other proteins were quantified using Metamorph (Metamorph NX, version 8.12, Molecular Devices, USA).

## Western blot

Cells were lysed with RIPA (Radio-Immunoprecipitation Assay) buffer containing protease inhibitors (Calbiochem, USA). 30 µg of total protein was loaded onto a SDSPAGE gel and electroblotted onto Hybond ECL membrane (GE Healthcare, UK). The blots were stained with primary antibodies (AIM2 (1:1000, Cell Signaling Technology, USA), NLRP1 (1:200, Santa Cruz Biotechnology, USA), NLRP2 (1:1000, Proteintech, USA), NLRP3 (1:1000, Adipogen, USA), NAIP (1:1000, Adipogen, USA), ASC (1:1000, Cell Signaling Technology, USA), Caspase 1 (1:200, Santa Cruz Biotechnology, USA), IL1β (1:1000, R & D, USA), Tubulin (1:1000, Cell Signaling Technology, USA), Actin (1:1000, Cell Signaling Technology, USA) overnight at 4°C after blocked with 5% low fat milk (Bio-Rad, USA). The blots were washed with TBST and incubated with a secondary HRP-linked antibody (1:5000, Santa Cruz Biotechnology, USA). Blots were

washed TBST before visualization using ECL reagents according to manufacturer's instructions (Perkin Elmer, USA). Each protein bands' intensities were normalized against its loading control band intensity for quantification using ImageJ. Briefly, an area of interest rectangle was created around each band and the integrated density was measured, background subtracted, and divided by its specific loading control band.

## ELISA assay

Cytokines in culture supernatant and tissue lysates were measured by ELISA using commercially available kits. Mouse IL-1 $\beta$  (88-7013, eBioscience, USA) and human IL-1 $\beta$  (88-7261-86, eBioscience, USA) were used in accordance with the manufacturer's protocol. Absorbance was read with a Tecan Spark 10M microplate reader (Tecan, USA) at absorbance values as indicated in the manufacturer's protocol.

## Isolation of CD11b+ tumor-associated macrophages

Tumors were mechanically dissociated and strained through a 40  $\mu$ m nylon mesh before digestion into single cells with collagenase type II (0.5 mg mL<sup>-1</sup>), collagenase type IV (0.5 mg mL<sup>-1</sup>), hyaluronidase (10 U/mL) and DNase I (0.01 mg mL<sup>-1</sup>) for 2 h at 37 °C. The dissociated cells were collected, lysed by RBC lysis buffer before CD11b+ tumor associated macrophages were isolated out of these suspensions by the MACS technology according to the manufacturer's instructions using 10  $\mu$ l CD11b microbeads (130049601; Miltenyi, USA) per 1x10<sup>7</sup> cells. The isolated CD11b+ cells were grown overnight in complete RPMI media overnight before the cells and cell supernatants were collected for analysis.

## siRNA transfection

AIM2-specific siRNA and scrambled siRNA (Thermo Fisher) were used according to manufacturer's instructions. THP-1 cells were seeded at a concentration of 5x10<sup>5</sup>/well in a 12 well plate (Greiner Bio-science) before silencing with a final concentration 10 nM of siRNA and grown overnight before treatment with or without 100ng/ml PMA, 1  $\mu$ g/ml LPS, and 50% A549 tumor conditioned media for another 24 h.

## MTT cell proliferation assay

A549 cells were seeded in 24 well plates and treated with IL-1 $\beta$  (#29-8018-65, Thermo Scientific, USA) at the indicated concentrations for 72 h, after which cell viability was measured using an MTT Cell Proliferation and Cytotoxicity Assay Kit (Boster Bio), according to the manufacturer's instructions. Absorbance was measured using a TECAN spectrophotometer (Tecan Trading AG, Switzerland) at 490 nm.

## Migration and invasion assay

A549 cells were seeded into cell migration chambers (SPL, Korea) of PET membrane with 8.0  $\mu$ m pore size. IL-1 $\beta$  was added to the cells and the chambers were incubated for 24 h in a humidified chamber at 37°C, 5% CO<sub>2</sub>. For the invasion assay, inserts were coated with 10% Matrigel prior to cell seeding. For co-culture, the bottom chamber was seeded with mouse BMDM cells stimulated with LPS (1  $\mu$ g/ml) one day prior to TRAMPC2 cell seeding before the chambers were incubated for 24 h. At the end of the incubation period, the inserts were washed using 1xPBS. Inserts were fixed with 100% methanol for 15 minutes before washing and air drying, followed by cell staining using 0.5% crystal violet (filtered) for 30 minutes. The upper membrane of the inserts was rinsed and cleaned to remove excess stain and non-migrated cells. Five microscopic fields of each insert were captured using Nikon Stereoscopic Microscope SMZ1500 and Digital Camera DXM1200F (Nikon, Melville, NY, USA).

## Statistics

Unpaired Student's T-Test or One-way/Two-way analysis of variance (ANOVA) with Tukey's post-test was performed when appropriate. Results are presented as mean values  $\pm$  standard error (SE).

A p-value of < 0.05 or less was deemed significant.

## Results

### Higher dsDNA and infiltration of CD68+ and CD206+ cells in the mouse mammary tumor microenvironment

The presence of nucleic acids have been reported in cancer tissues and cell lines (3) which could activate DAMPs in tumor associated macrophages (TAMs). We first confirmed the expression of dsDNA and in a spontaneous breast cancer mouse model which develops tumors at ~6-9 months of age- MMTV-Wnt+ mice, compared to non-tumor fat pads. Indeed, tumors expressed more dsDNA compared to normal mammary tissue (Figure S1A). We next investigated the tumor microenvironment in MMTV-Wnt+ fatpads and tumor (which developed at 9 months) and MMTV-Wnt- fat pads. Many more CD11b+F480+ cells were present in tumor tissue (Figure S1B). Interestingly macrophage infiltration occurs early before tumor development, confirmed by immunohistochemistry of MMTV-Wnt+ and MMTV-Wnt- fat pads stained with CD68 and counterstained with Haematoxylin (at 2,4,6 and 9 months of age). Figure 1A shows mouse mammary tissue composed of fat pads (black arrow), ducts (red arrow) and acinar structures (yellow arrow). MMTV-Wnt+ pads exhibit ductal and acinar proliferation with branching and budding, progressing from 2 months to 6 months in comparison to their respective age matched control littermates. Formation of malignant tumor is observed at 9 months which

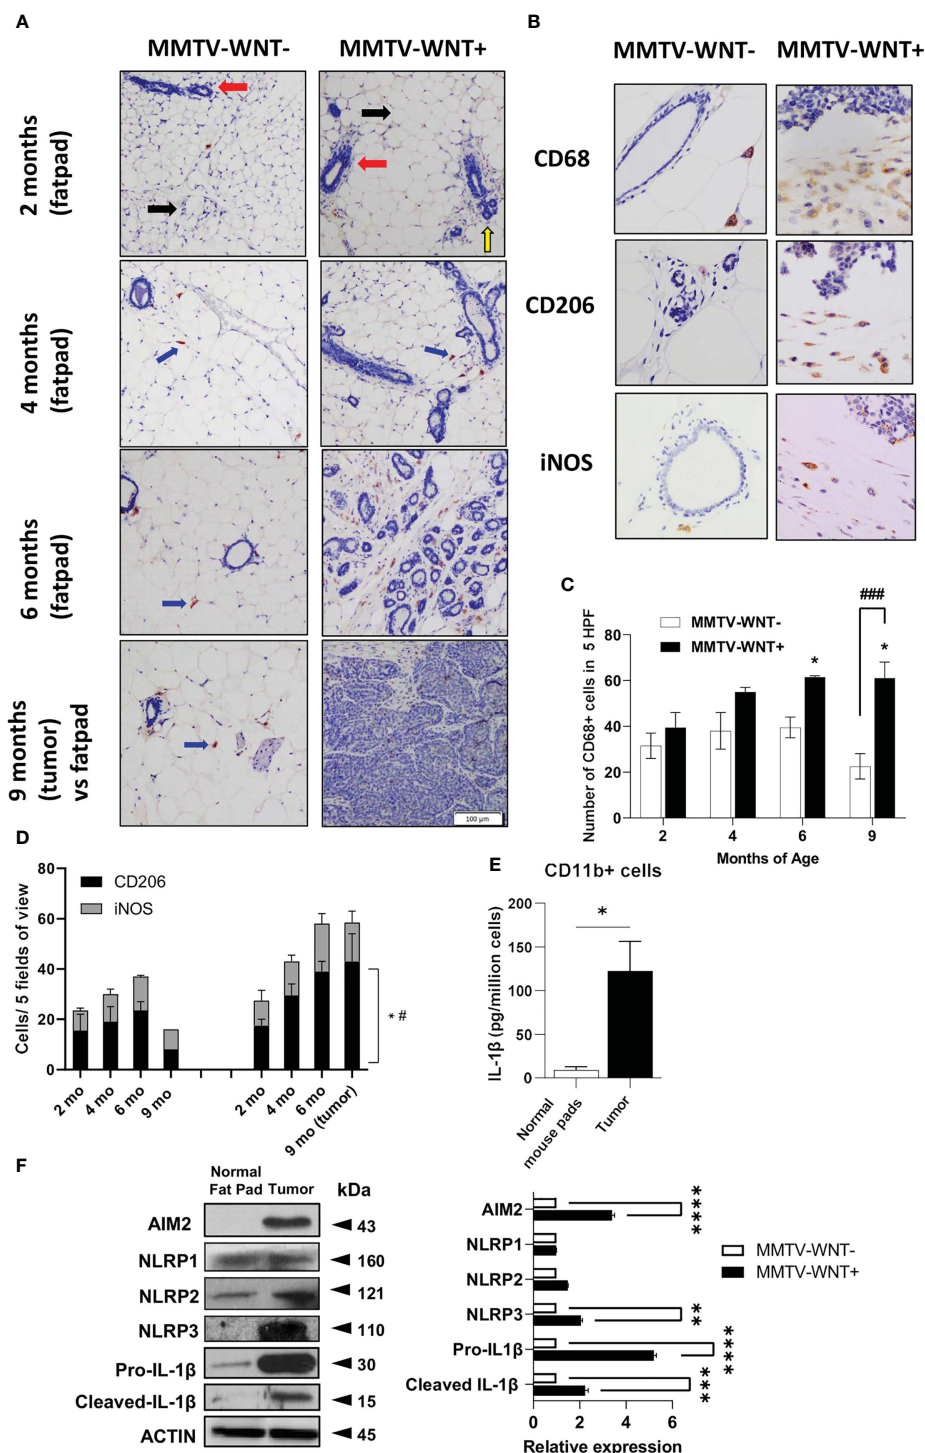

FIGURE 1

Higher dsDNA and infiltration of CD11b+ cells in the mouse mammary tumor microenvironment. (A) Immunohistochemical expression of CD68 and Haematoxylin and Eosin staining of MMTV-WNT- and MMTV-WNT+ mammary fat pads at 2, 4, 6 and 9 months and upon tumor resection at 9 months. (Magnification, 100x). (B) Immunohistochemical expression of CD68 in 9-month MMTV-WNT- mammary fat pads and MMTV-WNT+ tumors. Blue corresponds to nuclear staining and brown corresponds to positive staining (magnification, 400x). (C) CD68+ cells were counted in 5 high power fields. (D) iNOS+ and CD206+ cells were counted in 5 high power fields. \*  $P < 0.05$  vs 2 months; #  $P < 0.05$ , ###  $P < 0.001$  vs MMTV-WNT- at same time point. 2 replicates per age were performed (E) CD11b+ macrophages were isolated from normal mouse pads and MMTV tumors and grown overnight. IL1 $\beta$  production was analyzed using ELISA. (F) Inflammasome components (IL1 $\beta$ , AIM2, NLRP1,2,3) and activation (cleaved) were analyzed using western blotting. Graph shows the quantification of immunoblots using Image J (fold change vs Actin) \*  $P < 0.05$  from  $n = 3-4$  mice. \*\* $p < 0.01$ ; \*\*\* $p < 0.001$  \*\*\*\* $p < 0.0001$ .

shows atypical epithelial cells forming enlarged irregular glands with intraluminal papillary projections. At places, there is also formation of cysts filled with secretory material and many solid areas of tumor cells can be seen. Macrophages were stained with CD68 (400x) and a significant increase in CD68+ cells was seen in fat pads from MMTV-WNT+ mice progressing from 2-6 months and tumors at 9 months (Figures 1B, C). In addition, staining of sections with an inflammatory macrophage marker, iNOS or an alternatively activated macrophage marker CD206 demonstrated a time-dependent and significant increase in the number of CD206 expressing cells at 9 months of age, when the tumor had formed (Figure 1D). Next to assess if tumor-derived nucleic acids can activate the inflammasome in leukocytes in the tumor microenvironment, CD11b+ cells isolated and cultured overnight from MMTV-Wnt+ tumors secreted more IL-1 $\beta$  and expressed higher levels of inflammasome components AIM2 and NLRP3 as compared to CD11b+ cells derived from normal fat pads (Figures 1E, F).

## Tumor secretome increases IL-1 $\beta$ production from macrophages

To determine if tumors secrete mediators which can enhance the IL-1 $\beta$  and inflammasome activation in macrophages, we collected conditioned media (CM) from TRAMPC2 mouse prostate cancer cells overnight. TRAMPC2 CM induced a high level of IL-1 $\beta$  production in LPS-primed bone marrow derived macrophages (BMDM) (Figure 2A). This was confirmed with human monocytic THP-1 cells either resting (monocytic) or differentiated with PMA (macrophage-like) and stimulated with CM from several human cancer cells (Figure 2B). Monocytic THP1 cells did not secrete IL-1 $\beta$  in response to LPS or LPS + CM, while macrophage-like THP1 cells secreted more IL-1 $\beta$  basally, when stimulated with LPS and significantly more when stimulated with both LPS+CM (Figure S2A). In addition, A549 tumor CM significantly enhanced the cleavage and maturation of inflammasome components caspase-1 and IL-1 $\beta$  and upregulated AIM2 (Figures 2C, D). Surprisingly, despite the presence of cytosolic DNA or exogenous DNA transfection, epithelial cancer cells do not produce appreciable amounts of IL-1 $\beta$  compared to myeloid THP-1 cells, implying that the IL-1 $\beta$  in the tumor microenvironment does not originate from the tumor cells themselves (Figure S2B).

## Silencing or inhibiting AIM2 or NLRP3 in macrophages reverses IL1 $\beta$ production induced by tumor CM

Next, AIM2 was either silenced with siRNA ((Figure 3A) or treated with A151, an inhibitor of AIM2 and TLR9 (Figure 3B) which resulted in the inhibition of IL-1 $\beta$  and inflammatory components after A549 CM in human THP1 cells, with quantified densitometry (Figure 3C). AIM2-/- and caspase 1-/- BMDM, treated with LPS and either dsDNA or tumor CM, similarly produced significantly less IL-1 $\beta$  compared to WT BMDM (Figures 3D, E). This shows that

macrophage AIM2 is important for IL-1 $\beta$  secretion in response to tumor CM. However, as Caspase-1 plays a role here, we examined if other inflammasomes could also be involved. Inhibition of NLRP3 with MCC950 partially inhibited the release and cleavage of IL-1 $\beta$  and induced by LPS+ATP as well as A549 CM, indicating that the NLRP3 inflammasome activation is partially responsible (Figure S3).

## AIM2-dependent IL1 $\beta$ production stimulates tumor cell proliferation

Exogenous IL-1 $\beta$  stimulated proliferation of TRAMPC2 cancer cells, and addition of exogenous IL-1 $\beta$  stimulated proliferation of TRAMPC2 cancer cells similarly in the presence of WT and AIM2-/- or Caspase1/11-/- macrophages (Figure 4A). However, coculture of TRAMPC2 cancer cells with BMDM increased their proliferation which was AIM2 and Caspase 1/11 dependent as this was not observed with AIM2-/- or Caspase1/11-/- BMDM (Figures 4B, C). In addition, IL-1 $\beta$  enhanced the migration and invasion of TRAMPC2 cancer cells (Figure 4D) which implies a pro-tumorigenic role for IL-1 $\beta$ .

## Cytosolic DNA and DNA/RNA hybrids are increased in tumors and colocalize with AIM2

The presence of dsDNA and DNA-RNA hybrids has been reported in cancer tissues and cell lines (3, 17–19). We hypothesized that these cytosolic nucleic acids may act as intracellular ligands to stimulate AIM2 inflammasome activation. Therefore, we next determined if cytosolic DNA or DNA-RNA hybrids were present in the spontaneous mammary tumors in MMTV-Wnt+ mice by staining MMTV-Wnt+ tumors and non-tumor fat pads from MMTV-Wnt- for both DNA-RNA hybrids and dsDNA using immunofluorescence staining. Both cytosolic dsDNA and DNA-RNA hybrids are constitutively present in tumor tissues and are not found in non-tumor mammary fat pads (Figure 5A). In addition, AIM2 colocalized with cytosolic DNA and DNA-RNA hybrids in A549 cells (Figures 5B, C) as well as other tested cell lines (U937, THP-1, HeLa, and HCT-116, Figure S4).

To determine which nucleic acid species in the tumor CM could be responsible for inflammasome activation, DNAase, RNAase H, and RNAase A which degrade dsDNA, DNA-RNA hybrids, and dsRNA, respectively, was added to A549 CM prior to addition to THP-1 cells. Tumor CM stimulated the production of IL-1 $\beta$  which was significantly inhibited with RNAase H, and not RNAase A. Interestingly, only a slight reduction was observed with DNAase treatment (Figure 5D). Furthermore, treatment with RNAase H significantly reduced the maturation of IL-1 $\beta$ , and inhibited gasdermin D-N expression (Figure 5E). Treatment with DNAase, to a smaller extent, reduced the maturation of IL-1 $\beta$ , but did not inhibit the IL1 $\beta$  release, suggesting that DNA-RNA hybrids present in tumor CM, could be responsible for the IL-1 $\beta$  secretion and inflammasome activation in THP1 macrophages, rather than dsDNA.

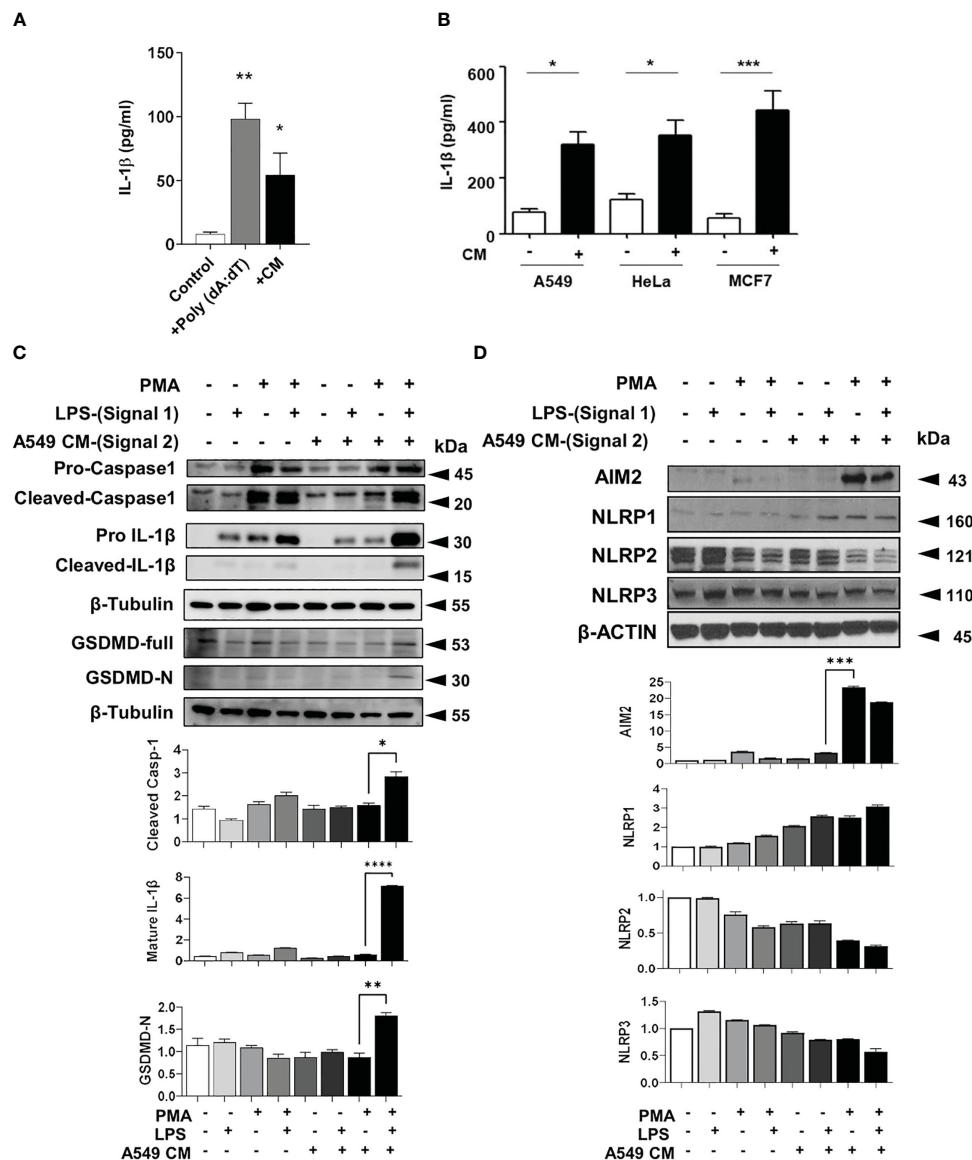

FIGURE 2

Tumor conditioned media stimulates inflammasomes in macrophages (A) IL-1β production in bone marrow derived macrophages primed with LPS and treated with either poly (dA: dT) or TRAMPC2 prostate cancer conditioned media (CM). (B) IL-1β production from PMA and LPS treated THP-1 treated with CM from A549, HeLa or MCF7 cells (+) or DMEM only for 24 h (-). (C, D) Inflammasome components from PMA and LPS treated THP-1 treated with CM from A549 cells. Graph shows the quantification of immunoblots using Image J (fold change vs Actin) \*p<0.05; \*\*p<0.01; \*\*\*p<0.001; \*\*\*\*p<0.0001. Data represents the mean ± SEM of at 3-5 independent experiments.

Finally, to validate that the AIM2 inflammasome can sense dsDNA and DNA-RNA hybrids, BMDM from WT and AIM2<sup>-/-</sup> mice were generated and transfected with different concentrations of DNA-RNA hybrids or dsDNA poly (dA: dT). The lowest concentration of DNA-RNA hybrid transfection (0.1 μg/ml) increased IL-1β secretion which was AIM2 dependent. Interestingly, transfection of DNA-RNA hybrids at higher concentrations (1 μg/ml and 5 μg/ml) did not increase IL-1β secretion compared to the transfected control. (Figure 5F). However, only higher concentrations of poly (dA: dT) stimulated

IL-1β production. This data suggests that AIM2 can respond to both DNA-RNA hybrids and dsDNA, but is more sensitive to DNA-RNA hybrids as compared to dsDNA

In summary, this study shows that macrophage AIM2 is activated by nucleic acids secreted from the cancer cells, which leads to inflammasome activation, IL-1β cleavage and release from macrophages. IL-1β and coculture of tumor cells with macrophages enhances the proliferation of tumor cells which is AIM2 and caspase 1/11 dependent (Figure 6). AIM2 is more sensitive to stimulation with DNA-RNA hybrids compared to dsDNA,

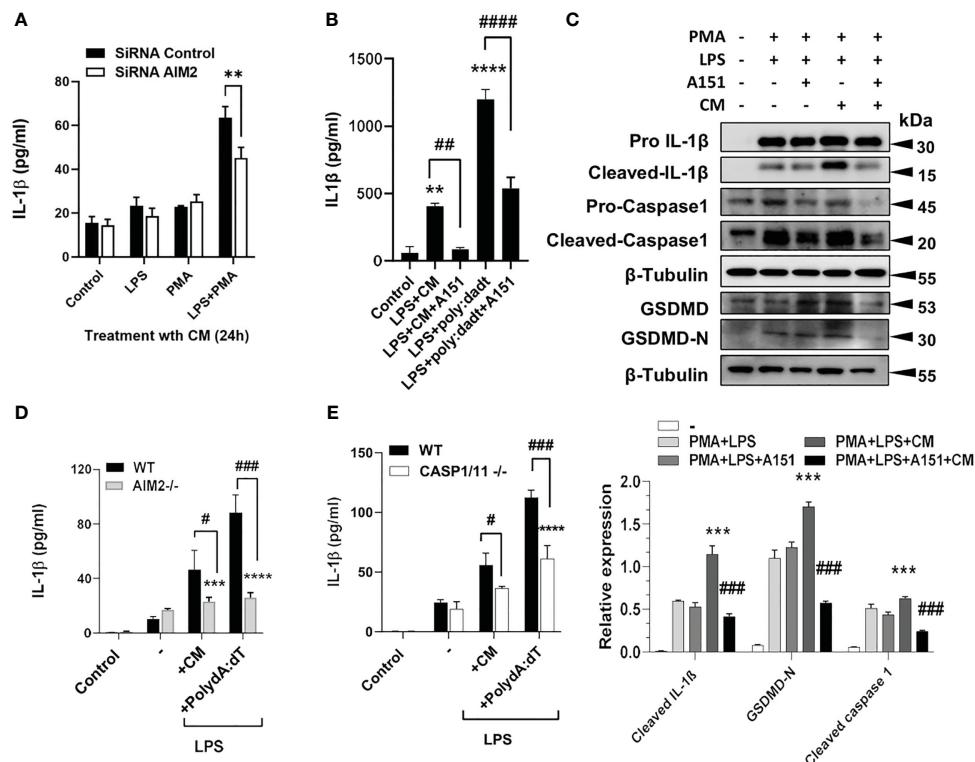

FIGURE 3

Silencing or inhibiting AIM2 in macrophages reverses IL1 $\beta$  production induced by tumor CM. (A) IL-1 $\beta$  levels from control, LPS or PMA Primed THP-1 cells transfected with AIM2 siRNAs or scrambled siRNAs (siRNA Control) and treated with A549 CM. (B, C) IL-1 $\beta$  levels and inflammasome activation in LPS and PMA primed THP-1 cells pre-treated with A151 for 1h prior to treatment with A549 CM. Graph shows the quantification of immunoblots using Image J (fold change vs Actin) (D,E) IL-1 $\beta$  levels in LPS-primed WT and AIM2 $^{-/-}$  or Caspase1/11 $^{-/-}$  BMDM treated with mouse TRAMP-C2 CM or Poly(dA:dT). Data represents mean  $\pm$  SEM of at least 3 independent experiments. \*\* $p$ <0.01; \*\*\* $p$ <0.001, \*\*\*\*  $p$ <0.0001. #  $p$ <0.05; ## $p$ <0.01; ### $p$ <0.001; #### $p$ <0.0001.

suggesting that both dsDNA and DNA-RNA hybrids can activate AIM2 inflammasome in tumor associated macrophages in the tumor microenvironment.

## Discussion

Understanding the tumor microenvironment and the intrinsic relationship between tumor cells and immune cells is essential for developing potential therapy options. The critical role of inflammation in the tumor microenvironment is beginning to be appreciated, with many tumor types showing an inflammatory signature (20). Although cancer inflammation is described as a double-edged sword (21), it is without question a key mediator of cancer development with both tumor-promoting and inhibiting properties. Inflammasomes are multimeric protein complexes that are key drivers of inflammation and can recognize DNA to trigger innate immune responses. The AIM2 inflammasome is a DNA sensor that has been reported to be activated by dsDNA (22). In particular, the AIM2 inflammasome has been reported to be an important tumor regulator with inflammasome-dependent and independent roles in cancer but its exact role remains unclear (6, 23–25). The complex role of AIM2 in the tumor microenvironment may be more complicated through its inhibition of several signaling

pathways including AKT (16) as well as STING-type 1 interferon signaling (7b). Most importantly, how AIM2 gets activated in cancer remains unknown.

A strength of the paper is the use of the MMTV-WNT mouse model as we wished primarily to look at spontaneous cancer growth. The MMTV-WNT mouse develops tumors at ~6–9 months of age so it was possible to determine if the numbers of infiltrating macrophages increases with time pre-tumor. *In vitro*, other tumor cell lines were used, such as human Hela (cervical cancer), human HCT116 (colon cancer) and human A549 (lung cancer) as well as mouse TRAMP-C2 (prostate cancer). This demonstrates that all cancer cell lines could stimulate AIM2 inflammasome activation in macrophages exposed to the conditioned media from these cell lines. Thus our observations are not tumor type specific, but we believe a reflection of cancer cells in general.

The role of IL-1 $\beta$  in cancer has both positive and negative functions and may be dependent on the cancer type and stage. Our study has shown that IL-1 $\beta$  enhances proliferation of prostate cancer cells at physiological concentrations. This is in line with studies showing that host IL-1 $\beta$  is required for *in vivo* angiogenesis and invasiveness of melanoma, prostate and breast tumor cells through the production of VEGF and cytokines by macrophages (26). Similarly, IL1 was shown to be produced by tumor infiltrating

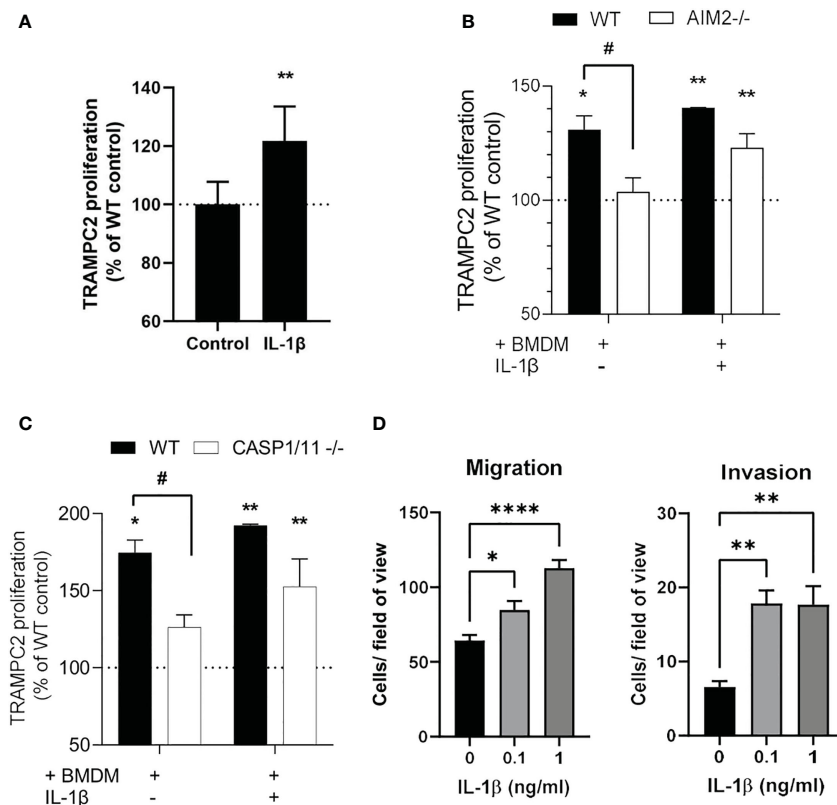

FIGURE 4

IL1 $\beta$  production from macrophages induces TRAMPC2 proliferation and migration/invasion (A–C) Proliferation rates of TRAMPC2 cells co-cultured with C57BL/6, AIM2 $^{-/-}$  or Caspase 1/11 $^{-/-}$  bone marrow derived macrophages for 24h, with and without 0.25 ng/ml mouse IL-1 $\beta$ . \* $p$ <0.05, \*\* $p$ <0.01 vs WT control; #  $p$ <0.05 vs WT+BMDM (D) Migration and invasion of TRAMPC2 cells cultured with IL-1 $\beta$ . Data are from  $n=3$  mice \* $p$ <0.05; \*\* $p$ <0.01; \*\*\*\* $p$ <0.0001.

myeloid cells in the tumor microenvironment and neutralizing IL1 receptor inhibits breast cancer progression *in vivo* in a humanized mouse model (27), indicating the importance of paracrine IL-1 $\beta$  in tumor growth and progression. In other studies, monocyte-derived IL-1 $\beta$  inhibited prostate cancer proliferation and induced apoptosis (28). However, interestingly, IL-1 $\beta$  inhibits differentiation and metastasis of metastasis initiating cells and among patients with lymph node-positive breast cancer, high primary tumor IL-1 $\beta$  expression is associated with better overall survival and distant metastasis-free survival (29).

The other players in the inflammasome pathway such as Gasdermin-D are also involved in the macrophage inflammasome-dependent proliferation of cancer where lung metastasis in Gasdermin D $^{-/-}$  mice was reduced (30). Similar to our study, macrophage gasdermin-D plays a role in the tumor microenvironment. In addition, Caspase-1 and Gasdermin-D deficient macrophages enhance the activation of cGAS-STING dependent type-1 interferon pathway. However, this was reported to be pyroptosis, IL1 and IL-18 independent and through K $^{+}$  depletion and suppression of cGAS activation (31). NLRP3 also has been reported in a multitude of studies to be involved in tumor growth and development both as an oncogene and as a tumor suppressor gene. (32). The spatial and temporal activation and expression of AIM2 and NLRP3 in varying tumor types may explain the conflicting

reports but more studies are needed to fully understand the importance of the inflammasomes and its components in cancer.

Although implicated in different types of cancer, the trigger for AIM2 in these cancers remains unknown. Our results show that DNA-RNA hybrids may be the trigger for AIM2 inflammasome in cancers. Firstly, macrophages exhibited a significant decrease in IL-1 $\beta$  release when treated with DNA-RNA hybrid-depleted tumor conditioned media. This effect is not seen using dsDNA-depleted tumor conditioned media. Secondly, AIM2 $^{-/-}$  macrophages have impaired levels of IL-1 $\beta$  following transfection with DNA-RNA hybrids. Thirdly, immunostaining revealed that AIM2 colocalizes with cytosolic DNA-RNA hybrids to a larger extent than dsDNA in various cells tested. Taken together, our results indicate AIM2 indeed interacts with DNA-RNA hybrids. To the best of our knowledge, DNA-RNA hybrids have not been previously linked to AIM2 inflammasome in cancer. However, AIM2 was reported to be activated by RNA viruses such as influenza viruses (33, 34), Chikungunya virus and West Nile virus (35). Given that DNA-RNA hybrids are generated as intermediates during replication of the various viruses within infected cells (36, 37), RNA viruses may activate AIM2 via direct sensing of the DNA-RNA hybrids produced when the viral RNA is reverse transcribed into DNA. However, one report finds that bacterial DNA-RNA hybrids from Enterohemorrhagic Escherichia coli are sensed by NLRP3

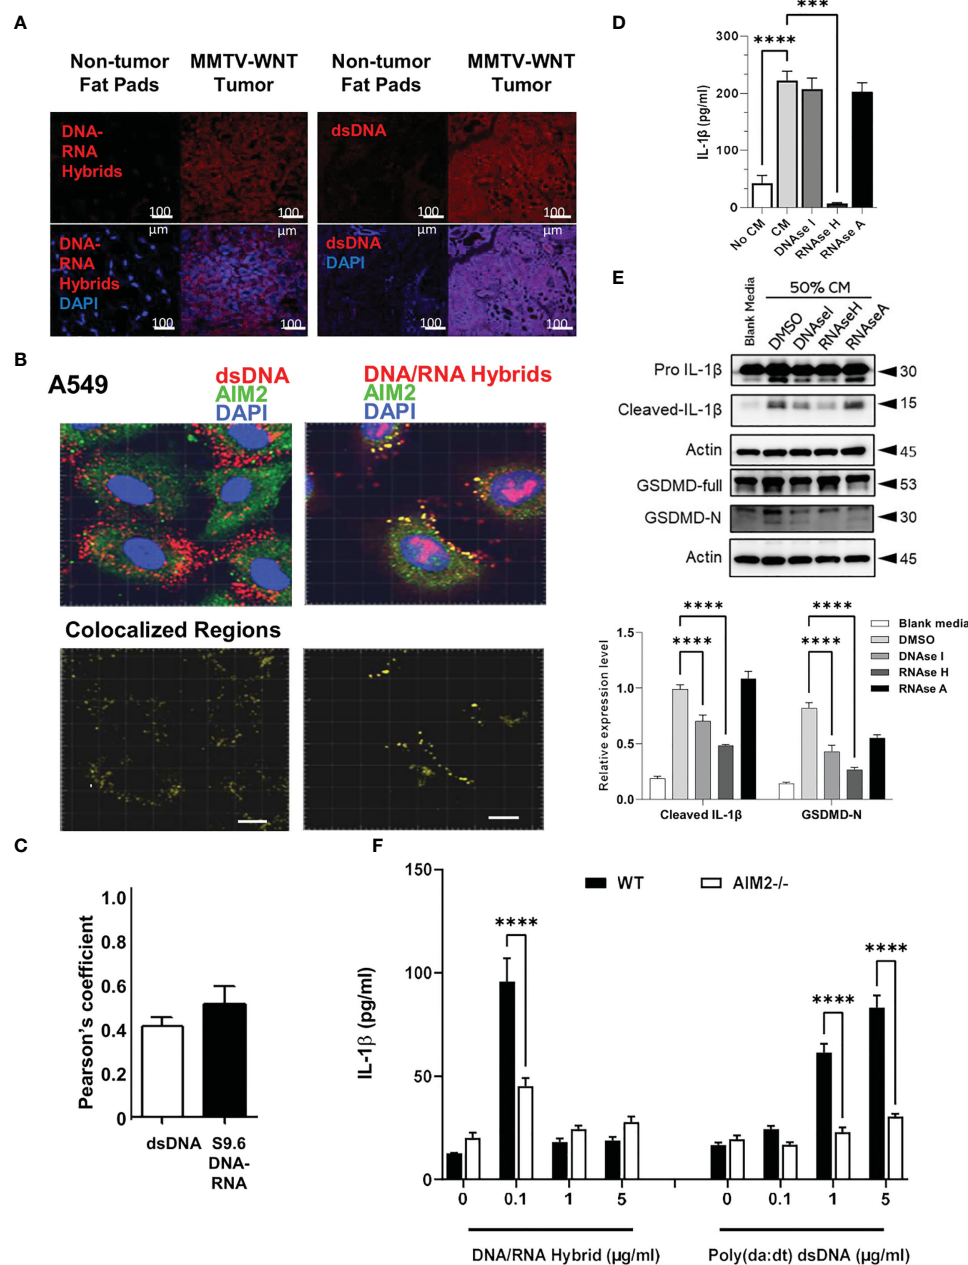

FIGURE 5

Tumor derived DNA-RNA hybrids activate AIM2 inflammasome. (A) MMTV Tissues and non-cancerous fat pads from mice were co-labelled for dsDNA or DNA/RNA hybrids (red) in the presence of DAPI (blue). (B, C) A549 cancer cells were co-labelled for AIM2 (green) and dsDNA (red) or -DNA-RNA hybrids (red) in presence of DAPI (blue). Co-localized regions are shown in yellow. Bar=20μm. Pearson's correlation of colocalization between AIM2 and either dsDNA or S9.6 DNA-RNA hybrids is shown. (D) A549 CM was treated with DMSO, sDNAase I (10 μg/ml), RNAase H (10U/ml) or RNAase A (10 μg/ml) for 2h and added to primed and differentiated THP-1 cells for 24h. Cell supernatants were collected and IL-1β levels analyzed using ELISA. (E) Cells were treated as above and inflammasome components (IL-1β and Gasdermin-D) and activation (cleaved, GasderminD-N) were analyzed using western blotting. Graph shows the quantification of immunoblots using Image J (fold change vs Actin) (F) AIM2<sup>-/-</sup> and WT BMDMs were treated with LPS (1 μg/ml) for 6h and increasing concentrations of DNA-RNA hybrids or Poly (dA: dT). Oligonucleotides were transfected with lyovec transfection reagent for the indicated time according to the manufacturer's recommendations. Cell supernatants were collected 24 h post- LPS priming, and IL-1β levels were quantified using ELISA. Data represents the mean ± SEM of at least 3 independent experiments. \*\*\*p<0.001; \*\*\*\*p<0.0001.

inflammasome (38). Our preliminary data indicates that while tumors express high levels of AIM2 and NLRP3, tumor CM increases the expression of AIM2, but not NLRP1, NLRP2 or NLRP3 inflammasomes, suggesting that AIM2 and NLRP3 inflammasomes may play complementary roles in inflammasome activation in response to tumor-derived mediators. It is important to

note that our model here reports AIM2 sensing of endogenous self-DNA-RNA hybrids and not foreign bacterial hybrids.

Given the understanding that AIM2 recognizes dsDNA (10, 39), our study is one of the first to describe AIM2 recognition of DNA-RNA hybrids and at a higher sensitivity than dsDNA. It may be possible that AIM2 is only capable of sensing dsDNA more than

80bp in length (40). While the length of dsDNA in the tumor cells we used (A549, HeLa, MCF-7) remains elucidated, it is certainly possible that the dsDNA present in these tumor cells is too short to trigger AIM2 activation in this model.

In summary, we show that tumors express cytosolic DNA and have higher numbers of infiltrating macrophages. Macrophages release IL-1 $\beta$  indicative of inflammasome activation after stimulation with LPS and tumor-CM, which is AIM2 dependent. IL-1 $\beta$  and coculture of tumor cells with macrophages enhances the proliferation of tumor cells which is AIM2 and Casp1/11 dependent. We propose that cancer cells release nucleic acids into the tumor microenvironment, which activates macrophages to produce an acute pro-tumor response (Figure 6). Accordingly, understanding paracrine tumor cytosolic DNA and immune cell interactions in cancer pathogenesis is a critical step for therapeutic development. Broader understanding of the mechanisms of nucleic acid interaction with innate immune signaling pathways would provide novel targets for anticancer research and future molecular therapy.

## Data availability statement

The original contributions presented in the study are included in the article/Supplementary Material. Further inquiries can be directed to the corresponding author.

## Ethics statement

The animal study was reviewed and approved by National University of Singapore IACUC, (AAALAC-accredited institution).

## Author contributions

ZC, LL: Conception and design. ZC, JC, KaS, KrS, and KK: Investigation. ZC, JC, and LL: Analysis and interpretation of data. ZC: Roles/Writing original draft. JC, SG, and LL: Writing, review & editing. HL, AK, SL: Administrative, technical, or material support. LL, and SG: Study supervision and funding acquisition. All authors contributed to the article and approved the submitted version.

## Funding

This research was funded by grants from the Ministry of Education (MOE2014T2-1-133) and (MOE2013-T2-2-032) awarded to LL. ZC was supported by a scholarship from the NUS Graduate School of Science and Technology.

## Acknowledgments

We would like to thank Prof Jenny Ting (University of North Carolina at Chapel Hill, USA) for providing the AIM2<sup>-/-</sup> C57BL/6 mice and Prof David Virshup (Duke NUS, Singapore) for providing MMTV-Wnt (Mouse Mammary Tumor Virus-Wingless-related integration site) mice, and Dr Chen Kaiwen for providing the Caspase 1/11<sup>-/-</sup> mice.

## Conflict of interest

Author SG was employed by company Roche.

The remaining authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

**Introduction:** The interleukin-1 (IL-1) family and the NLR family pyrin domain-containing 3 (NLRP3) inflammasome contribute to atherogenesis but the underlying mechanisms are incompletely understood. Unlike IL-1 $\beta$ , IL-1 $\alpha$  is not dependent on the NLRP3 inflammasome to exert its pro-inflammatory effects. Here, a non-genetic model was applied to characterize the role of IL-1 $\alpha$ , IL-1 $\beta$ , and NLRP3 for the pathogenesis of atherosclerosis.

**Methods:** Atherogenesis was induced by gain-of-function PCSK9-AAV8 mutant viruses and feeding of a high-fat western diet (WTD) for 12 weeks in C57Bl6/J wildtype mice (WT) and in IL1 $\alpha$ <sup>-/-</sup>, Nlrp3<sup>-/-</sup>, and IL1 $\beta$ <sup>-/-</sup> mice.

**Results:** PCSK9-IL1 $\alpha$ <sup>-/-</sup> mice showed reduced atherosclerotic plaque area in the aortic root with lower lipid accumulation, while no difference was observed between PCSK9-WT, PCSK9-Nlrp3<sup>-/-</sup> and PCSK9-IL1 $\beta$ <sup>-/-</sup> mice. Serum proteomic analysis showed a reduction of pro-inflammatory cytokines (e.g., IL-1 $\beta$ , IL-6) in PCSK9-IL1 $\alpha$ <sup>-/-</sup> as well as in PCSK9-Nlrp3<sup>-/-</sup> and PCSK9-IL1 $\beta$ <sup>-/-</sup> mice. Bone marrow dendritic cells (BMDC) of PCSK9-WT, PCSK9-Nlrp3<sup>-/-</sup>, and PCSK9-IL1 $\beta$ <sup>-/-</sup> mice and primary human monocytes showed translocation of IL-1 $\alpha$  to the plasma membrane (csIL-1 $\alpha$ ) upon stimulation with LPS. The translocation of IL-1 $\alpha$  to the cell surface was regulated by myristoylation and increased in mice with hypercholesterolemia. CsIL-1 $\alpha$  and IL1R1 protein-protein interaction on endothelial cells induced VCAM1 expression and monocyte adhesion, which was abrogated by the administration of neutralizing antibodies against IL-1 $\alpha$  and IL1R1.

**Conclusion:** The results highlight the importance of IL-1 $\alpha$  on the cell surface of circulating leucocytes for the development of atherosclerosis. PCSK9-IL1 $\alpha$ <sup>-/-</sup> mice, but not PCSK9-Nlrp3<sup>-/-</sup> or PCSK9-IL1 $\beta$ <sup>-/-</sup> mice, are protected from atherosclerosis after induction of hypercholesterolemia independent of circulating cytokines. Myristoylation and translocation of IL-1 $\alpha$  to the cell surface in myeloid cells facilitates leukocyte adhesion and contributes to the development of atherosclerosis.

## KEYWORDS

atherosclerosis, inflammation, hyperlipidemia, interleukin - 1, mouse model

## GRAPHICAL ABSTRACT

The role of cell-surface (cs) IL-1α in the initiation of atherosclerosis.

## Introduction

Atherosclerosis is a chronic inflammatory disease driven by intimal lipid accumulation (1, 2). Reactive oxygen species modify plasma lipoproteins in the subendothelial space, where they are engulfed and digested by macrophages (3). Processing of oxidized lipoproteins inside the cell leads to cholesterol crystal formation and activation of the NOD-, LRR- and pyrin domain-containing protein 3 (NLRP3) inflammasome, initiating the release of pro-inflammatory cytokines such as IL-1β (4, 5). During plaque progression, different subsets of leukocytes adhere to endothelial cells and infiltrate the atherosclerotic plaque contributing to the inflammatory environment (6, 7).

IL-1 cytokines are considered inflammatory mediators of atherosclerosis (8). Two related but distinct IL-1 genes, *IL1A*, and *IL1B*, encode IL-1α and IL-1β, respectively. Both share the same receptor, and upon binding of either cytokine, interleukin 1 receptor type I (IL1R1) associates with interleukin 1 receptor accessory protein (IL1RAP/IL1R3) to form a trimeric structure that mediates NfκB-dependent pro-inflammatory signaling (9). The inactive IL-1β precursor protein is cleaved by caspase 1 to the mature form of IL-1β (10).

In contrast to IL-1β, both the precursor and the cleaved form of IL-1α are biologically active. Pro-IL-1α can also be presented on the cell surface (csIL-1α) upon activation of the TLR, e.g., in the presence of lipopolysaccharides (LPS) (11). The precise mechanism of binding IL-1α to the outer cell membrane is incompletely understood (12). It was observed that csIL-1α plays a role in acute myocardial infarction (AMI) and chronic kidney disease (CKD) and is associated with an increased risk of cardiovascular events (13). However, its functional role in atherogenesis is not fully elucidated. Previous studies of atherogenesis in mice depended on cross-breeding with either Ldlr- or ApoE-deficient animals. Both models exhibit high plasma

cholesterol levels and the development of atherosclerotic lesions in susceptible areas (14). Studies on genes involved in atherosclerosis require inbreeding in either Ldlr<sup>-/-</sup> or ApoE<sup>-/-</sup> animals with the associated potential confounders. However, studies of gene candidates without the genetic bias of the atherosclerosis model itself were not available. We therefore applied a nongenetic gain-of-function PCSK9-AAV8 atherosclerosis model to address the question whether atherosclerosis development depends on IL-1α or the NLRP3 inflammasome and whether IL-1α expressed at the cell surface is involved in the development of atherosclerosis (15).

## Materials and methods

### Mice

Il1a<sup>-/-</sup> (n=6) and Il1b<sup>-/-</sup> (n=5) mice were a kind gift from Prof. Timotheus Speer (Goethe-Universität Frankfurt, Frankfurt am Main, Germany) (13). WT C57Bl6/J (n=10) and Nlrp3<sup>-/-</sup> (B6.129S6-Nlrp3tm1Bhk/J backcrossed to a C57BL/6J background, n=5) were purchased from Charles River (Sulzfeld, Germany). To induce atherosclerosis, the mice were injected with a mutated AAV8 virus, as described previously (15). Briefly, age-matched littermates were injected with rAAV8-PCSK9<sup>D377Y</sup> (1.0×10<sup>11</sup> viral genomes/mouse) or saline as control at 10 weeks (Figure 1A). Mice received a western high-fat diet (Ssniff, 21% fat, 0.21% cholesterol) one-week post-virus injection for 12 weeks (referred as PCSK9-WT). Saline-treated control mice were fed a normal chow diet. Body weights were measured weekly. Mice were sacrificed after the given time point, and organs were harvested. In brief, the mice were anesthetized with 4-5% isoflurane. The absence of the pedal reflex confirmed successful anesthesia. Afterward, blood was collected, and mice were perfused for organ harvest. All protocols were approved by the Institutional Animal Care

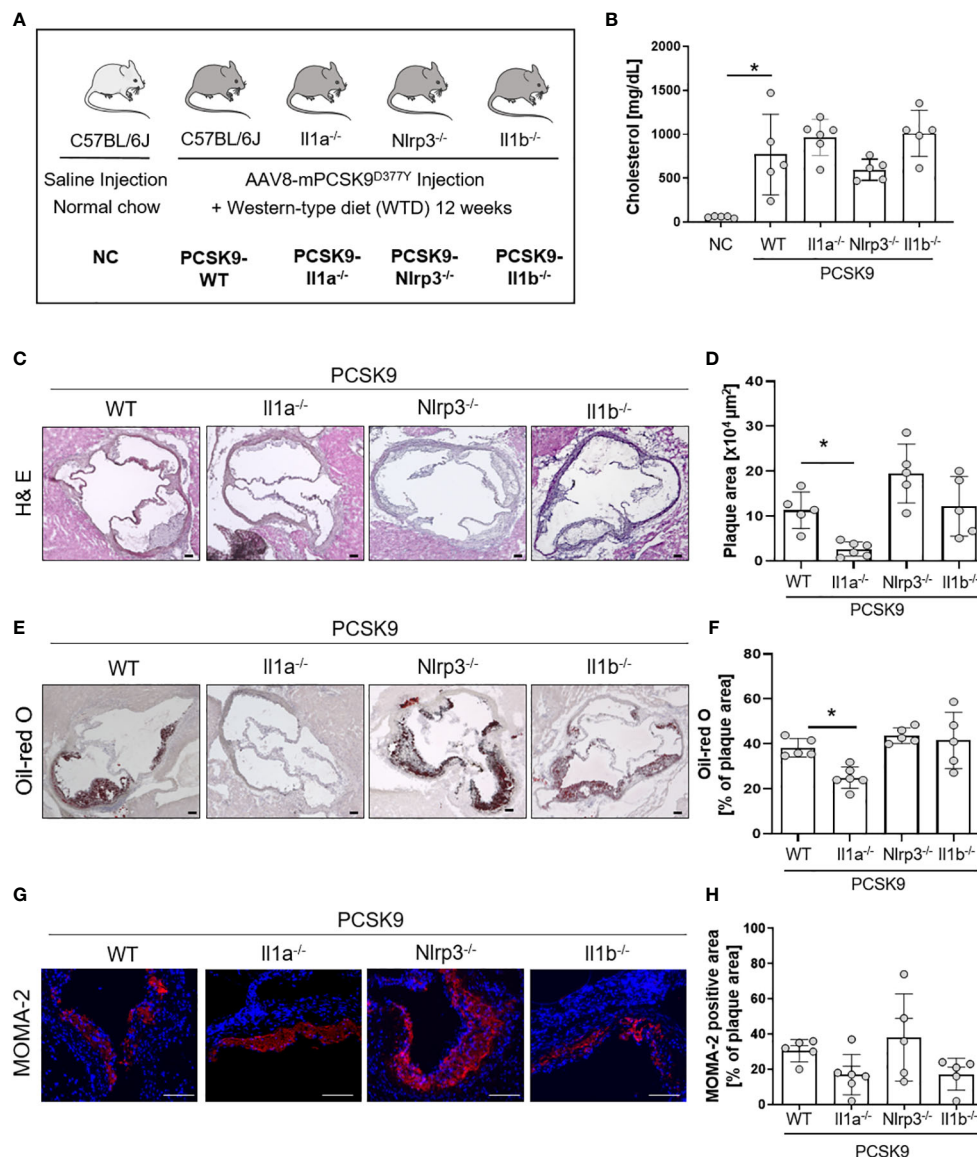

FIGURE 1

IL1a knockout mice are protected from hyperlipidemic-induced atherosclerosis independent of the NLRP3-inflammasome. (A) Schematic overview of the experimental groups. Mice were injected with either rAAV8-PCSK9<sup>D377Y</sup> or Saline. One-week post-injection, mice were fed a western-type diet (21% fat, 0.21% cholesterol) for 12 weeks. Saline-injected mice received a normal chow (NC) diet. (B) Bar graph of plasma cholesterol [mg/dL] after 12 weeks of diet intervention. (C–H): Representative histological images of the aortic root stained with Hematoxylin/Eosin (H&E, (C)), Oil-red O (ORO, (E)), and monocyte and macrophage (MOMA-2) staining (G) with their corresponding bar graphs (D, F, H). One-way ANOVA was performed with Sidak's multiple comparisons posthoc test (\**p* < 0.05). H&E and ORO stainings were imaged with 4 × magnification, scale bar 100 μm (C, E), MOMA-2 staining with 10 × magnification, scale bar 100 μm (G). Data are presented as mean ± SD of PCSK9-WT (*n* = 5), PCSK9-IL1a<sup>-/-</sup> (*n* = 6), PCSK9-Nlrp3<sup>-/-</sup> (*n* = 5), and PCSK9-IL1b<sup>-/-</sup> (*n* = 5) animals.

(42/2019, Veterinary Office of the Saarland) and were consistent with the guidelines from Directive 2010/63/EU of the European Parliament.

## Histology

Characterization of atherosclerotic lesions was performed in the aortic root. Cryopreserved sections (10 μm) were used for Hematoxylin and Eosin (H&E), MOMA-2, and Oil-red O (ORO) staining. MOMA-2 and ORO staining were performed as described

previously (15). H&E staining was performed by fixation of cryoslides with Xylene 3 × 5 min, followed by a descending series with alcohol. Slides were washed with H<sub>2</sub>O before the hematoxylin staining for 4 min. Then, sections were washed with H<sub>2</sub>O and incubated with Scott's bluing water for 20 seconds, followed by 1 min in 95% EtOH. Staining with Eosin was performed for 1 min, and sections were incubated in an ascending series of alcohol followed by 3 × 5 min in xylene. Stained sections were then covered with xylene-based mounting solution and coverslips. ImageJ software (Version 1.53k) was used for image analysis. MOMA-2 staining was imaged with a ZEISS Elyra microscope.

The percentage of MOMA-2 positive area per lesion was calculated by measuring the MOMA-2 positive area and dividing it by the plaque area.

## Isolation and culture of murine bone marrow-derived dendritic cells

Bone marrow cells were isolated from wildtype mice (16).  $2 \times 10^6$  bone marrow cells were plated on a 10-cm dish in RPMI-1640 medium (Sigma Aldrich, USA) containing 10% fetal calf serum (Gibco, Thermo Fisher Scientific, USA), 1% Penicillin-Streptomycin, and 50 mM  $\beta$ -Mercaptoethanol (Gibco, Thermo Fisher Scientific, USA). To induce dendritic cell differentiation, the medium was supplemented with 20 ng/ml GM-CSF (Preprotech, Thermo Fisher Scientific, USA) and 10 ng/ml IL-4 (Preprotech, Thermo Fisher Scientific, USA) (17). Cells were harvested on day 7 by collecting the suspension cells in the supernatant. Differentiation was confirmed using flow cytometry by detecting the MHC-II and Cd11c double-positive cells (min. 70% double-positive cells) (Figure S2A). Harvested cells were replated for further experiments in a fresh culture dish.

## Isolation and stimulation of human primary monocytes

Human primary monocytes were isolated from buffy coats of healthy volunteers via Ficoll (Cytiva, USA) gradient centrifugation. The study was conducted in accordance with the Declaration of Helsinki on Ethical Principles and was approved by the Ethical Committee of the Medical Faculty, University of Leipzig (ethics license: 272-12-13082012). Isolated PBMCs were incubated with CD14 beads (Milteny Biotec, Germany) for 15 min at 4°C and isolated with MACS magnetic separator. Isolated monocytes were cultured in RPMI-1640 (Sigma Aldrich, USA) with 10% Fetal calf serum and 10 mM Sodium Pyruvate (Merck, Germany). Cells were stimulated with 100 ng/ml ultrapure LPS (upLPS, Invivogen, USA) overnight.

## Culture of human umbilical vein endothelial cells

Human Umbilical Vein Cells (HUVECs) were cultured in EBM Endothelial Cell Growth Basal Medium (Lonza, Swiss) supplemented with EGMTM Endothelial Cell Growth Medium SingleQuots (Lonza, Swiss). Passages 4 to 8 were used for experiments.

## Serum analysis

Serum was collected for the measurement of plasma lipids and plasma proteins. 500–700  $\mu$ l of blood were collected from each mouse and centrifuged at  $3.500 \times g$  for 10 min at room temperature. Blood serum was transferred to a fresh 1.5 ml tube and snap-frozen in liquid

nitrogen. Cholesterol was measured using LabAssay Cholesterol (Fuji Film, Japan) following the manufacturer's instructions.

The Olink Mouse Exploratory Panel was used to measure circulating proteins. Serum was prepared according to the manufacturer's instructions (Olink, Sweden) and measured with the Mouse Exploratory 96 panel. Protein concentration was determined using the proximity extension assay (PEA) technology described elsewhere (18). Briefly, oligonucleotide-labeled antibodies bind to their target proteins where they come into proximity with other labeled antibodies that bind to the same target. The oligonucleotides hybridize in proximity and form a basis for qPCR and quantification. The number of qPCR cycles stands in relation to the protein concentration and gives the arbitrary unit normalized protein expression ("NPX") as the readout. To examine changes in the secretome in the hyperlipidemic mouse model vs. mice fed a normal chow (NC) diet, two-sided t-test was performed, followed by enrichment analysis of the significant regulated proteins (FDR cutoff= 0.1).

## Subcellular fractionation

Mouse BMDC were incubated overnight with culture medium or 100 ng/ml upLPS. Human monocytes were stimulated overnight with 100 ng/ml upLPS. Subcellular fractionation was performed using the Cell Signaling Kit (Cell signaling, USA) according to the manufacturer's instructions. NaK-ATPase was used as a marker for the membrane fraction and GAPDH for the cytoplasmic fraction in immunoblotting.

## Immunoblotting

Cytoplasm and membrane fractions were mixed with 4x Laemmli and  $\beta$ -mercaptoethanol. Equal volumes of fractions were directly loaded in a 4–12% pre-cast gradient gel (BioRad, USA) and separated by SDS-Page. Proteins were transferred to a nitrocellulose membrane (BioRad, USA), blocked with 5% non-fat dietary milk (NFDM, Carl Roth, Germany), and washed and incubated with the primary antibodies were either diluted in 5% NFDM or 5% bovine serum albumin (BSA, Serva, USA) overnight at 4°C: hIL-1 $\alpha$  (1:500, sc-271618, clone G10, Santa Cruz, USA), mIL-1 $\alpha$  (1:1,000, AF-400-SP, R&D, USA), GAPDH (1:5,000, sc-47724, clone 0411, Santa Cruz, USA), NaK ATPase (1:10,000, ab76020, Abcam, United Kingdom). The membrane was incubated with the secondary antibody coupled with horse radish peroxidase diluted in 5% NFDM for 1h on the following day. Classico Western HRP Substrate (Millipore) or SuperSigna West Femto (Thermo Fisher Scientific, USA) were used for development on iBright 1500 (Thermo Fisher Scientific, USA).

## Proximity ligation assay

Duolink *In Situ* Red Starter Kit Mouse/Rabbit (Sigma Aldrich, USA) was used and performed following the manufacturer's

instructions. Briefly, HUVEC cells were seeded on a  $\mu$ -slide Angiogenesis (ibidi, Germany) and were pre-stimulated with neutralizing IL1R1 antibody (10  $\mu$ g/ml, #AB-269-NA, R&D Systems, USA) as indicated for 1h. Unstimulated or upLPS-stimulated monocytes were then added for 4h per well. Monocytes were washed 4 times to eliminate residual upLPS before seeding on HUVEC cells. After 4h, the supernatant was aspirated carefully, and cells were fixed with ROTI Histofix 4% (Carl Roth, Germany) for 20 min at room temperature. The primary antibodies hIL-1 $\alpha$  (1:50, sc-271618, clone G10, Santa Cruz, USA) and IL1R1 Polyclonal Antibody (1:100, PA5-117479, Invitrogen, USA) were diluted in Duolink antibody dilution and stained overnight. 1  $\mu$ g/ml rabbit IgG (Dianova, RIgG, Germany) was included as an isotype control.

## Monocyte adhesion assay

To determine monocyte-to-endothelial adhesion, HUVEC cells were seeded on 96-well Flat Clear Bottom Black Polystyrene Microplates (Corning, USA). Isolated primary monocytes were stimulated with upLPS overnight or kept in culture medium. The next day, stimulated monocytes were pre-incubated with a neutralizing IL-1 $\alpha$  antibody (1  $\mu$ g/ml, mabg-hil1a-3, Invivogen, USA) as indicated for 1h. Afterward, monocytes were labeled with CellTrace™ Calcein Red-Orange, AM (Invitrogen, USA) for 30 min at 37° C. Monocytes were washed 4 times to eliminate residual upLPS and were co-incubated with HUVECs. After 4 h, fluorescence intensity was measured, as well as the remaining intensity after up to 4 washing steps. %adhesion of monocytes was calculated as stated:  $((F_{\text{remaining fluorescence}} - F_{\text{blank}}) / (F_{\text{total}} - F_{\text{blank}})) \times 100$ .

## Flow cytometry analysis of csIL-1 $\alpha$ and VCAM1

For the staining of cell-surface IL-1 $\alpha$  (12), cells were harvested and washed once with PBS. The cell number was adjusted to  $1 \times 10^6$ /ml, and cells were resuspended in FACS buffer (1% BSA, 0.05% sodium azide in PBS). Trustain mouse or human Fc block (1 $\mu$ g/ml, Biolegend, USA) was added and incubated for 10 min on ice. Anti-biotin IL-1 $\alpha$  antibody (human: 10 $\mu$ g/ml, #531304, Biolegend, USA; mouse: 10 $\mu$ g/ml, #512503, Biolegend, USA) or appropriate IgG isotype control (human: Goat IgG Biotinylated control, 10  $\mu$ g/ml, BAF108, Bio Techne, USA; mouse: Biotin Rat IgG1, 10  $\mu$ g/ml, #400403, Biolegend, USA) was added and incubated for 30 min on ice. Anti-Streptavidin PE was added (2.5  $\mu$ g/ml, eBioscience, USA) and incubated for 30 min on ice in the dark. Cells were incubated with 5  $\mu$ l of 7AAD (BD Bioscience, USA) for 10 min at room temperature; cells were immediately measured. For the assessment of total IL-1 $\alpha$ , cells were fixed after harvest with 250  $\mu$ l of Cytofix (Biolegend, USA) for 20 min at 4°C. Staining of IL-1 $\alpha$  was performed as described, but FACS buffer was exchanged with Permeabilisation buffer (Biolegend, USA). To detect VCAM1 on

HUVECs, cells were pre-stimulated with neutralizing IL1R1 antibody (10  $\mu$ g/ml, #AB-269-NA, R&D Systems, USA) as indicated for 1h. Unstimulated and upLPS-stimulated monocytes were added for 4h. Tnf $\alpha$  served as a positive control. Monocytes were washed 4 times to eliminate residual upLPS before seeding on HUVEC cells. Up-LPS stimulated HEK293 and handled as stimulated monocytes and were included as a control to verify the successful elimination of LPS (Figure S3A). After 4h, the supernatant was discarded, and cells were fixed with 0.5% Roti-Histofix (Carl Roth, Germany) and harvested. Staining was performed using 5  $\mu$ g/ml anti-human CD106 APC Antibody (#305810, Biolegend, USA) or mouse IgG2a kappa Isotype control (eBM2a) APC (5  $\mu$ g/ml, #17-4724-81, Thermo Fisher Scientific, USA) as the isotype control, for 45 min on a rotator at 4°C. Cells were measured at the BD FACS Lyrica. FlowJo® Software (Version 10.8.1) was used for further analysis.

## Myristoylation assay

Myristoylation was detected using a myristoylated protein assay kit (abcam, USA) following the manufacturer's instructions. Cells without myristic acid labeling served as background controls. To test the myristoylation inhibitor, cells were pre-incubated with 1  $\mu$ M n-myristoyltransferase inhibitor IMP-1088 (Cayman Chemical, USA) for 1h before stimulation with 100 ng/ml upLPS overnight.

## ELISA

Human (R&D Systems, USA) and mouse IL-1 $\alpha$  (R&D Systems, USA) DuoSet ELISA kits, as well as human (R&D Systems, USA) and mouse IL-1 $\beta$  (R&D Systems, USA) DuoSet ELISA kits, were used in combination with DuoSet ELISA Ancillary Reagent kit (R&D Systems, USA). The assays were performed following the manufacturer's instructions.

## Illustrations

Graphical abstract and schematic overviews were generated by using icons from Servier Medical Art, provided by Servier, licensed under a Creative Commons Attribution 3.0 unported license.

## Statistical analysis

Statistical analyses were performed with GraphPad Prism (version 8; GraphPad Software Inc., La Jolla, CA, USA). Data were tested for a gaussian distribution using the Kolmogorov–Smirnov or D'Agostino–Pearson normality test. Two-tailed unpaired t-test was performed to compare groups if not otherwise stated. One-way ANOVA with Sidak's multiple comparisons test was performed to compare more than two groups. The significance level was set to  $p < 0.05$ .

## Results

### PCSK9-Il1a<sup>-/-</sup> mice are protected from hyperlipidemia-induced atherosclerosis, whereas PCSK9-Nlrp3<sup>-/-</sup> and PCSK9-Il1b<sup>-/-</sup> mice are not

To investigate the role of IL-1 $\alpha$  and the NLRP3 inflammasome in a nongenetic mouse model of atherosclerosis, we induced hypercholesterolemia in WT, Il1a<sup>-/-</sup>, Nlrp3<sup>-/-</sup>, and Il1b<sup>-/-</sup> mice by a single injection of a hyperactive pro-protein convertase subtilisin/kexin type 9 (PCSK9)-adeno-associated virus (rAAV) followed by a Western-type diet (PCSK9) for 12 weeks (Figure 1A). PCSK9 control mice (PCSK9-WT) develop hypercholesterolemia and spontaneous atherosclerosis (Figures 1B–H), as recently described by our group (15). Cholesterol levels were similar in PCSK9-WT and PCSK9-Il1a<sup>-/-</sup>, PCSK9-Nlrp3<sup>-/-</sup>, and PCSK9-Il1b<sup>-/-</sup> animals (Figure 1B). PCSK9-Il1a<sup>-/-</sup> mice showed reduced atherosclerotic lesions (-76%) (Figures 1C, D) and lower lipid accumulation (Oil-red O, Figures 1E, F) than PCSK9 control mice. The development of atherosclerosis in PCSK9-Nlrp3<sup>-/-</sup> and PCSK9-Il1b<sup>-/-</sup> mice did not differ from the control wildtype animals (Figures 1C–F). No significant difference in macrophage infiltration in plaques (MOMA-2 positive cells) was observed in PCSK9-Il1a<sup>-/-</sup>, PCSK9-Il1b<sup>-/-</sup>, and PCSK9-Nlrp3<sup>-/-</sup> mice compared to PCSK9-WT animals (Figures 1G, H).

### PCSK9-Il1a<sup>-/-</sup>, PCSK9-Nlrp3<sup>-/-</sup> and PCSK9-Il1b<sup>-/-</sup> mice show reduced levels of circulating cytokines

To determine whether the atheroprotective effect in PCSK9-Il1a<sup>-/-</sup> mice are associated with changes in the serum protein profile, we used the Olink Target 96 Mouse Exploratory Panel. The 92 proteins measured encompass various biological processes and thus provide an overview of regulated signaling pathways. The serum of PCSK9-WT control mice showed increased proteins annotated to cell-activating signaling pathways and vasculature-regulating mechanisms (Figures 2A, B). PCSK9-Il1a<sup>-/-</sup> led to a significant downregulation of pro-inflammatory proteins, such as IL-6, IL-1 $\beta$ , and CCL-2, compared to PCSK9-WT (Figure 2C). IL-6 was also downregulated in PCSK9-Nlrp3<sup>-/-</sup> and PCSK9-Il1b<sup>-/-</sup> but both groups show similar plaque development to PCSK9-WT (Figure 1C). Normal chow control group (NC) and PCSK9-Il1a<sup>-/-</sup> animals did not share similar regulated proteins (Figure 2D). Even though IL-1 $\beta$  was significantly upregulated in PCSK9-WT group, serum IL-1 $\alpha$  levels did not show a significant difference between NC and PCSK9-WT (Figure 2E).

### Cell surface translocation of IL-1 $\alpha$ is not influenced by NLRP3 and IL-1 $\beta$ in murine BMDC

Since serum levels of IL-1 $\alpha$  were not increased in atherosclerotic PCSK9-WT mice (Figure 2E), we investigated the

membrane-bound form of IL-1 $\alpha$ . The shuttle from the cytoplasm to the plasma membrane requires *de-novo* synthesis of IL-1 $\alpha$ , mediated by the TLR/NF $\kappa$ B signaling pathway. BMDCs, as an important representative of circulating immune cells, were used to study the translocation of IL-1 $\alpha$  from the cytoplasm to the plasma membrane after a single stimulus of 100 ng/ml ultrapure LPS (upLPS) and cell fractionation (Figure 3A). Stimulation of the TLR leads to the accumulation of pro-IL-1 $\alpha$  in the plasma membrane fraction (Figures 3B, C). The purity of the cell fractions was confirmed with markers for cytoplasm (glyceraldehyde-3-phosphate dehydrogenase (GAPDH)) and for plasma membrane (sodium-potassium ATPase (NaK<sup>+</sup> ATPase)). GAPDH was not detected in the membrane fraction, confirming no contamination of cytoplasmic IL-1 $\alpha$ . The translocation to the plasma membrane was validated by flow cytometry on stimulated, unfixed cells (Figure 3D). 7-AAD was used to discriminate between dead and live cells and analyze the cell-surface IL-1 $\alpha$  only in unfixed 7-AAD negative cells (Figure 3D). LPS increased *de-novo* synthesis of total IL-1 $\alpha$  from 4.9  $\pm$  6.6% to 42.9  $\pm$  7.6% (fixed cells, Figure 3E) and induced the translocation of IL-1 $\alpha$  to the plasma membrane (unfixed 7-AAD<sup>-</sup> cells, Figure 3F). LPS did not increase the permeability of the cells (Figure 3G). FACS analysis demonstrated that 5.3  $\pm$  1.9% of the cells showed IL-1 $\alpha$  plasma membrane localisation after LPS stimulation (Figure 3F). Stimulated BMDCs of PCSK9-WT, PCSK9-Nlrp3<sup>-/-</sup>, and PCSK9-Il1b<sup>-/-</sup> expressed IL-1 $\alpha$  in their cytoplasm, which was translocated to the plasma membrane upon LPS stimulation (Figures 3H, I). Even though LPS alone was sufficient for the translocation of IL-1 $\alpha$  to the plasma membrane, BMDCs did not secrete IL-1 $\alpha$  or IL-1 $\beta$  to the extent of the positive control (LPS+ ATP, Figures S2B, C), which is in line with our *in vivo* findings.

### IL-1 $\alpha$ surface expression on human monocytes induces IL1R1-mediated VCAM1 expression and monocyte adhesion on endothelial cells

To confirm the interaction of monocytic csIL-1 $\alpha$  with endothelial IL1R1, a close proximity ligation assay (PLA) was performed. Incubation of LPS-stimulated monocytes with primary human endothelial cells (HUVEC) resulted in a positive PLA fluorescence signal which was not observed under control conditions (Figure 4A). To validate the pro-atherogenic effect of csIL-1 $\alpha$ , VCAM1 expression on HUVECs was measured after treatment with upLPS-stimulated monocytes. Stimulated monocytes increased VCAM1 expression compared to treatment with unstimulated monocytes (25.9  $\pm$  7.1% vs. 2.5  $\pm$  1.4% VCAM1 pos. cells) on HUVECs, which was significantly reduced by the administration of neutralizing IL1R1 antibody (18.6  $\pm$  6.3% VCAM1 pos. cells) (Figures 4B, C) indicating that csIL-1 $\alpha$ /IL1R1 binding and signaling plays a major role in VCAM1 expression and can be abrogated by blocking of IL1R1. In addition, the induced VCAM1 expression through csIL-1 $\alpha$ /IL1R1 binding promoted the adhesion of monocytes to HUVECs. Therefore, calcein-labeled monocytes were incubated with HUVECs, and the remaining

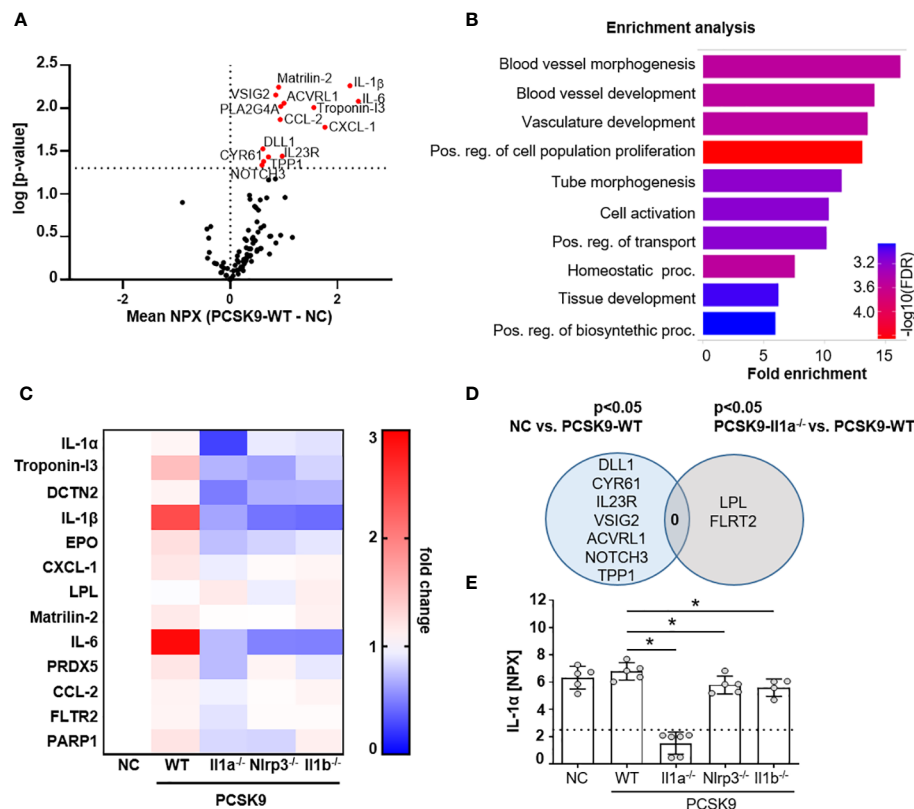

FIGURE 2

PCSK9-IL1a<sup>-/-</sup>, PCSK9-Nlrp3<sup>-/-</sup>, and PCSK9-IL1b<sup>-/-</sup> mice show reduced levels of circulating cytokines. **(A)** Volcano plot of proteins regulated in Olink mouse exploratory panel comparing serum protein levels of mice fed a NC vs. PCSK9-WT mice. Red data points indicate the difference of the NPX mean between PCSK9-WT and NC for each protein. The dashed line intersecting the y-axis indicates the significance of p < 0.05. **(B)** Shiny GO (19) (Version 0.77) enrichment analysis annotating the significantly regulated proteins to the Gene Ontology (GO) Biological Process (false detection rate (FDR) cutoff: 0.1). The top 10 regulated pathways are presented as a barplot with the colors indicating the -log<sub>10</sub> FDR, with red as the highest and blue as the lowest. **(C)** Heatmap depicting the dynamics of proteins significantly regulated in IL1a<sup>-/-</sup> compared to PCSK9-WT. Data is presented as fold change of PCSK9-WT, PCSK9-IL1a<sup>-/-</sup>, PCSK9-Nlrp3<sup>-/-</sup>, and PCSK9-IL1b<sup>-/-</sup> to NC. **(D)** Venn Diagram representing serum proteins specifically regulated in only NC or PCSK9-IL1a<sup>-/-</sup> animals compared to PCSK9-WT. Shared regulated proteins are displayed at the intersection of both areas. **(E)** Bargraphs of serum IL-1α levels measured in the Olink 96 mouse exploratory panel. The dashed line indicates the limit of detection of the assay. Data is presented with the Olink NPX value as mean ± SD, \*p < 0.05. PCSK9-WT (n = 5), PCSK9-IL1a<sup>-/-</sup> (n = 6), PCSK9-Nlrp3<sup>-/-</sup> (n = 5), and PCSK9-IL1b<sup>-/-</sup> (n = 4).

fluorescence after washing was measured (Figure 4D). Monocytes pre-stimulated with LPS showed more endothelial adhesion than non-stimulated monocytes ( $6.7 \pm 3.6\%$  vs.  $3.5 \pm 2.5\%$ ). To study whether monocyte adhesion is dependent on csIL-1α expression and binding on endothelial IL1R1, the cells were co-stimulated with neutralizing IL-1α antibody, which reduced the monocyte adhesion to baseline level (Figure 4E).

## Myristoylation regulates csIL-1α translocation in murine bone marrow cells and in human monocytes

The N-terminus of the 31-kDa IL-1α precursor is myristoylated on lysine residues Lys82 and Lys83 (20). Bone-marrow cells from the hyperlipidemic atherosclerotic mice (PCSK9-WT) showed significantly more protein myristoylation than cells from control mice on normal chow ( $10.0 \pm 4.0\%$  in control vs.  $76.0 \pm 35.7\%$  in PCSK9-WT mice) (Figure 5A). Blocking of N-myristoyltransferases 1 and 2 (NMT1/2) with IMP-1088

[1μM] reduced protein myristoylation by  $62 \pm 12.9\%$  (p < 0.05) (Figure 5B) in human monocytes under control conditions. Pre-incubation of human monocyte cells with IMP-1088 [1μM] for 1h before LPS treatment reduced the cell surface expression of IL-1α by  $35 \pm 8.7\%$ , p < 0.05 (Figure 5C).

## Discussion

The present study provides evidence for a significant contribution of IL-1α during the development of atherosclerosis. Our results revealed that circulating pro-inflammatory cytokines are not the only driving factor in atherogenesis. At the observed time points in early atherogenesis, IL-1α at the cell surface mediates leukocyte adhesion to endothelial cells independently of the NLRP3 inflammasome.

Cytokines are an important factor in immune cell activation and mediators of sterile inflammation. The study demonstrates that pro-inflammatory proteins such as IL-1β, IL-6, and CCL-2 are upregulated in the serum of PCSK9-WT animals (Figures 2D–F). However, PCSK9-Nlrp3<sup>-/-</sup> and PCSK9-IL1b<sup>-/-</sup> animals showed

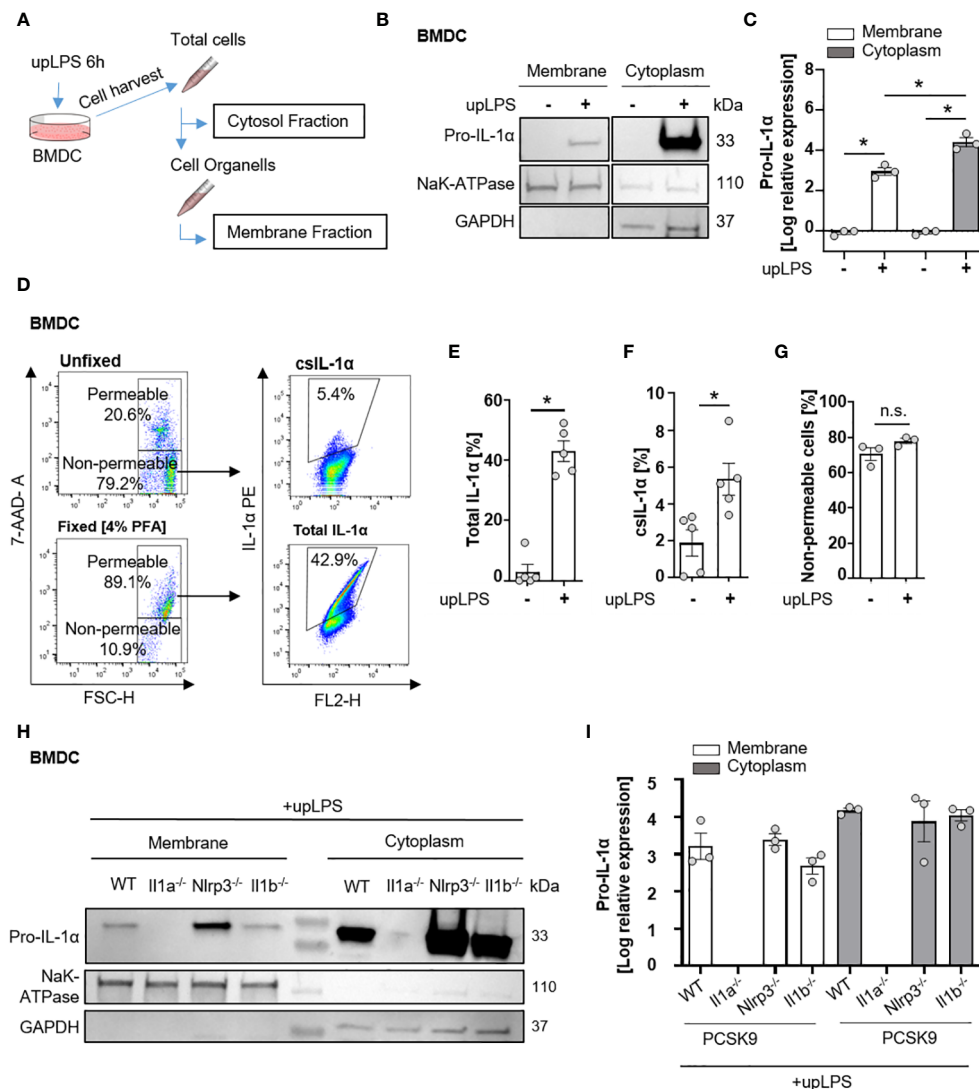

FIGURE 3

Cell surface translocation of IL-1 $\alpha$  is not influenced by NLRP3 and IL-1 $\beta$  in murine BMDC. (A) Schematic overview of the experimental setup. Bone marrow-derived dendritic cells (BMDCs) were replated after 7 days of differentiation and stimulated with 100 ng/ml ultrapure Lipopolysaccharide (upLPS) overnight. Afterward, cells were harvested, and fractions were isolated using a detergent-based method. (B) Representative immunoblot of the membrane and cytoplasmic fraction of BMDCs with or without upLPS stimulation. Protein levels of IL-1 $\alpha$ , GAPDH (glyceraldehyde-3-phosphate-dehydrogenase, cytoplasmic marker), and NaK ATPase (sodium-potassium ATPase, membrane marker) are presented. (C) Densitometric quantification of IL-1 $\alpha$  in cytoplasmic fraction normalized to GAPDH and IL-1 $\alpha$  in membrane fraction normalized to NaK ATPase. (D) Representative flow cytometry scatter plot of staining for IL-1 $\alpha$  on stimulated BMDCs after gating for viable, non-fixed (7AAD-) cells. Total IL-1 $\alpha$  was measured on fixed cells. (E) Barplot depicting the percentage of total IL-1 $\alpha$  positive monocytes (7AAD+) with or without upLPS stimulation. (F) Barplot depicting the percentage of csIL-1 $\alpha$  positive monocytes (7AAD-) with or without upLPS stimulation. (G) Barplot representing the percentage of non-permeable monocytes with or without upLPS stimulation. (H) Representative immunoblot of membrane and cytosolic fraction from upLPS-stimulated BMDCs of PCSK9-WT, PCSK9-II1a $^{-/-}$ , PCSK9-Nlrp3 $^{-/-}$ , and PCSK9-II1b $^{-/-}$  animals. Protein levels of IL-1 $\alpha$ , GAPDH (cytoplasmic marker), and NaK ATPase (membrane marker) are presented with corresponding densitometric quantification (I) of log-transformed IL-1 $\alpha$  expression. All data are presented as mean  $\pm$  SEM, \* $p$ <0.05.

significantly reduced serum protein levels of IL-1 $\beta$  and IL-6 compared to PCSK9-WT mice despite similar plaque areas. The novel observation is that plaque development after 12 weeks of a high-fat diet appears to be largely independent of circulating pro-inflammatory cytokines.

Interestingly, circulating IL-1 $\alpha$  was not significantly increased in PCSK9-WT animals (Figure 2C). However, the lack of Il1a resulted in a reduction in atherosclerotic lesions, suggesting a significant role of membrane-bound IL-1 $\alpha$  protein in

atherogenesis. Il1a knockout mice also had significantly lower serum levels of CCL-2 and CXCL-1 (Figures 2C, D). We also demonstrated that csIL-1 $\alpha$ /IL1R1 binding and signaling plays an important role in VCAM1 expression on endothelial cells and that this expression can be abrogated by blocking IL1R1. This finding highlights the important role of IL-1 $\alpha$  in monocyte adhesion and initiation of atherosclerosis.

PCSK9-II1a $^{-/-}$  animals also show a reduction in circulating IL-1 $\beta$  (Figure 2C, dashed line), which are consistent with results

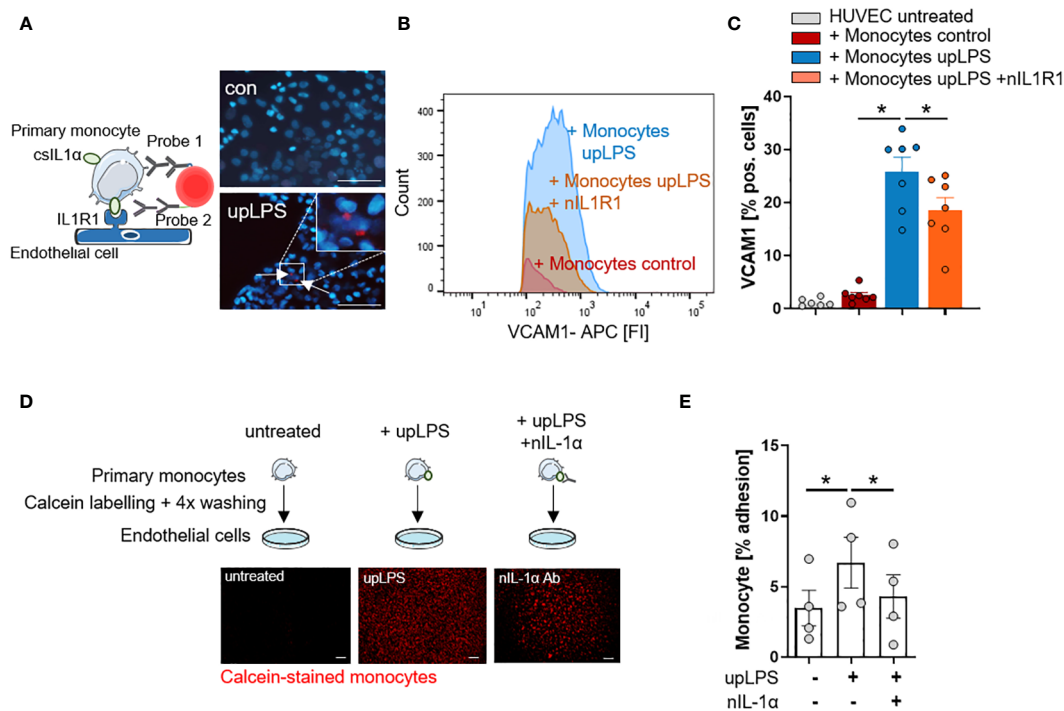

FIGURE 4

IL-1 $\alpha$  surface expression on human monocytes induces VCAM1 expression and leads to increased adhesion on endothelial cells. **(A)** Schematic principle of proximity ligation assay (PLA) and representative picture of PLA. Direct binding of csIL-1 $\alpha$  to the Interleukin-1 receptor 1 (IL1R1) leads to a fluorescence signal detectable at 594 nm. Human umbilical vein endothelial cells (HUVECs) were treated with monocytes for 6h, stimulated with and without upLPS (100 ng/ml). Cells were imaged at a 40x magnification (scale bar 50  $\mu$ m). HUVECs and monocytes are presented in blue, IL-1 $\alpha$ /IL1R1 PLA signal is visible as red dots. **(B)** Representative flow cytometry histogram of vascular cell adhesion molecule-1 (VCAM1) stained HUVECs after 4h treatment with upLPS-stimulated monocytes. 10  $\mu$ g/ml neutralizing IL1R1 (nIL1R1) antibody was added 1h before HUVEC-monocyte co-incubation. **(C)** Bar graph depicting the percentage of VCAM1- positive HUVECs after treatment with unstimulated and upLPS-stimulated monocytes. HUVECs were incubated with and without nIL1R1 antibody (10  $\mu$ g/ml) for 1h before co-incubation. Data are presented as mean  $\pm$  SEM of seven independent experiments; \* $p$  < 0.05. **(D)** Schematic experimental setup of monocyte adhesion assay. Primary monocytes were treated as indicated, labeled with Calcein and 4x washings. HUVECs were treated with and without 1  $\mu$ g/ml neutralizing IL-1 $\alpha$  antibody (nIL-1 $\alpha$ ) 1h before co-incubation. Then, HUVECs were treated with labeled monocytes for 4h. The initial fluorescence of adhering monocytes was measured as well as after two washes. Cells were imaged (4x magnification), scalebar 100  $\mu$ m. **(E)** Quantification of adhering monocytes to HUVECs presented as mean  $\pm$  SEM of four independent experiments. Repeated measure ANOVA was performed, followed by Sidak's multiple comparison test (\* $p$  < 0.05).

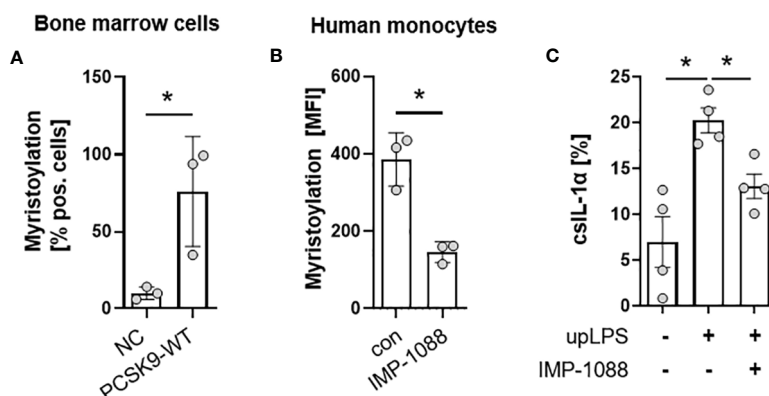

FIGURE 5

Myristoylation regulates csIL-1 $\alpha$  in murine bone marrow cells and human monocytes. **(A)** Barplot depicting the percentage of murine bone marrow cells with myristoylated proteins. Bone marrow cells were cultured and myristoylated proteins were labeled overnight. Data are presented as mean  $\pm$  SEM of NC (n=3) and PCSK9-WT (n=3), \* $p$  < 0.05. **(B)** Mean fluorescence intensity of human primary monocytes under culture conditions (con) or with overnight incubation of N-myristoyltransferase inhibitor IMP-1088 [1  $\mu$ M]. Data are presented as mean  $\pm$  SEM of three independent experiments. One-sided paired t-test was performed, \* $p$  < 0.05. **(C)** Percentage of csIL-1 $\alpha$  presenting monocytes stimulated with 100 ng/ml upLPS and 1  $\mu$ M IMP-1088 as indicated. Data are presented as mean  $\pm$  SEM of four independent experiments, \* $p$  < 0.05.

from previous publications (21, 22). However, although PCSK9-*Il1a*<sup>-/-</sup> animals show reduced IL-1 $\beta$  secretion, this does not appear to be the driving factor for atherosclerosis, because PCSK9-*Il1b*<sup>-/-</sup> animals do not show a reduction in plaque size.

Although *Il1a* knock out animals show greatly reduced atherosclerosis development compared with PCSK9-WT animals, macrophage infiltration per plaque is unchanged. We found no significant differences in MOMA-2 expression per plaque in the *Il1a*-deficient mice. Thus, *Il1a* is thought to play a critical role in monocyte adhesion to the endothelium but has no protective effect on macrophage infiltration in existing plaques. However, there are other risk factors, such as elevated cholesterol levels, which are also elevated in *Il1a* knockout mice, and may lead to endothelial damage and thus macrophage infiltration in plaques.

Chen et al. provided a mechanism for IL-1 $\alpha$  surface presentation via IL1R2 and GPI anchors (12). They showed that *Il1r2* deficiency in mice reduced levels of csIL-1 $\alpha$ , but the mechanism remained unclear. Our data show that csIL-1 $\alpha$  is reduced in primary monocytes by adding the myristoylation inhibitor IMP-1088 before stimulation (Figure 5C). Protein N-myristoylation is an essential fatty acylation catalyzed by N-myristoyltransferases (NMTs), which is vital for proteins participating in various biological functions, including signal transduction, cellular localization, and oncogenesis (23). Lately, myristoylated IL-1 $\alpha$  was linked to the mitochondrial membrane by binding to cardiolipin. The myristoylation at the lysine residues 82 and 83 increased the association between proteins and lipids and, thus, the integration of IL-1 $\alpha$  in the membrane lipid bilayer in the presence of Ca<sup>2+</sup> (24). CsIL-1 $\alpha$  levels do not return to baseline, indicating that the different mechanisms of tethering IL-1 $\alpha$  to the membrane are essential for the presentation, even though the exact mechanism of transport from IL-1 $\alpha$  to the membrane remains elusive. Metabolic stimuli and TLR ligands can induce csIL-1 $\alpha$  expression on myeloid cells, making this cytokine a considerable candidate in atherosclerosis initiation, driven by high levels of circulating free fatty acids or other metabolic stimuli, such as cholesterol or high glucose (25).

*Nlrp3* deficiency did not reduce atherosclerotic lesion size compared to PCSK9-WT animals in the presented data. Previous PCSK9-*Nlrp3*<sup>-/-</sup> studies are controversial and differ in their genetic background and diet composition. Using ApoE<sup>-/-</sup> mice crossed with either *Nlrp3*<sup>-/-</sup>, *Casp1*<sup>-/-</sup> or *Asc*<sup>-/-</sup>, mice did not show a reduction in plaque size, macrophage infiltration, or plaque stability after 11 weeks of high-fat diet compared to ApoE<sup>-/-</sup> mice (4). However, chimeric *Ldlr*<sup>-/-</sup> mice transplanted with bone marrow from *Nlrp3*<sup>-/-</sup>, *Asc*<sup>-/-</sup>, and *Il1a*<sup>-/-</sup> mice revealed reduced plaque area after 4 weeks of a high-fat diet (26). The PCSK9-AAV8 atherosclerosis model used in this study has the advantage of being independent of genetic alterations to induce atherosclerosis. Knockout of *Nlrp3* results in a reduction in circulating cytokines but not in plaque size, lipid accumulation, or macrophage infiltration. Thus, the study contributes to the observation that a constitutive *Nlrp3* knockout does not protect against the development of atherosclerotic plaques.

Previous studies have shown that csIL-1 $\alpha$  has an implication in different pathologies and is tested as a therapeutic target in different diseases. Monocytes from patients with acute myocardial infarction

(AMI) and chronic kidney disease (CKD) exhibit increased levels of csIL-1 $\alpha$ . The expression of csIL-1 $\alpha$  was associated with an increased risk for atherosclerotic cardiovascular disease events (13). Bermekimab (MABp1) is a human antibody targeting IL-1 $\alpha$  and was used in patients with refractory cancer. It was well tolerated and led to a decrease in plasma IL-6 (27). The antibody was also assessed in phase II clinical study with patients suffering from type II diabetes mellitus. MABp1 improved glycemia and reduced C-reactive protein, an important prognostic marker of systemic inflammation (28). Anakinra, an IL1R antagonist, has already been approved by the FDA and is beneficial for patients with rheumatoid arthritis and autoimmune diseases (29). Treatment of ApoE<sup>-/-</sup> mice with anakinra reduced plaque size of the aortic arch and serum triglycerides (30). However, anakinra blocks both IL-1 $\alpha$ /IL1R and IL-1 $\beta$ /IL1R signaling, which may exert differential or opposite functions in certain diseases. Due to the diverse nature of IL-1 $\alpha$  and its associated functions, it is critical to know precisely which IL-1 $\alpha$  isoform to target in immunotherapy. Therefore, it appears highly relevant to uncover the detailed role of IL-1 $\alpha$  isoforms and their regulation (e.g., by myristoylation) in various diseases.

Knockout of *Il1b* did not affect lesion size in the PCSK9-AAV8 model of hypercholesterolemia (Figure 1D). However, other studies show a plaque size reduction in ApoE<sup>-/-</sup>/*Il1b*<sup>-/-</sup> animals (31, 32). These controversies could be related to the animal model. *Ldlr*-deficient animals exhibit significantly smaller lesion sizes and necrotic cores than ApoE<sup>-/-</sup> mice at similar time points (33). In addition, Kamari et al. pointed out that *Il1b*<sup>-/-</sup> leads to only 32% plaque reduction, whereas *Il1a*<sup>-/-</sup> reduces plaque size by 52% in ApoE double knockout animals (32). Vromman et al. investigated the effects of monoclonal antibodies against IL-1 $\alpha$  and IL-1 $\beta$  in atherosclerosis *in vivo* which demonstrated that IL-1 $\beta$  has a profound effect on late-stage atherosclerosis by increasing IL-10 in the plasma. In contrast, IL-1 $\alpha$  appeared to be more critical in early atherosclerosis due to its influence on arterial outward remodelling (34). Therefore, the effect of *Il1b*-knockout might not be as pronounced in the PCSK9-AAV8 model compared to ApoE<sup>-/-</sup> animals but might be detectable at a later time point exhibiting progressed atherosclerotic lesions.

A limitation is that our study describes only a single time point in early atherogenesis (12 weeks). Our previous study observed that the inflammatory cytokines such as TNF- $\alpha$  increase significantly when comparing the PCSK9-AAV8 model at 12 weeks vs. 20 weeks (15). IL-1 $\beta$  may have a greater impact on atherosclerosis in established plaques. Therefore, it would be interesting to examine the changes in secretome as well as plaque characteristics in the applied knockout animals in combination with the PCSK9-AAV8 model at later time points in the future.

In conclusion, IL-1 $\alpha$  deficiency reduces atherosclerotic plaque development. Low levels of pro-inflammatory cytokines in the knockout animals indicated independence of plaque development from circulating cytokines at this time point of the disease since csIL-1 $\alpha$  mediates initial leucocyte-to-endothelial adhesion and activation of endothelial cells. Importantly, these data highlight the importance of IL-1 $\alpha$  in atherosclerosis and the need for detailed understanding of the mechanisms of the translocation and

presentation of IL-1 $\alpha$  to the plasma membrane as a target for novel therapies, such as myristoylation inhibitors.

## Data availability statement

The original contributions presented in the study are included in the article/**Supplementary Material**. Further inquiries can be directed to the corresponding author.

## Ethics statement

The studies involving humans were approved by Ethik-Kommission der Medizinischen Fakultät der Universität Leipzig. The studies were conducted in accordance with the local legislation and institutional requirements. The participants provided their written informed consent to participate in this study. The animal studies were approved by Veterinary Office of the Saarland. The studies were conducted in accordance with the local legislation and institutional requirements. Written informed consent was obtained from the owners for the participation of their animals in this study.

## Author contributions

CM and SG interpreted the experimental work and prepared the manuscript. AW and CM performed and conducted the *in vivo* experiments. CM and SG performed histological analyses and figure preparation. J-NB assisted with Olink Serum Analysis. SA and KS assisted in histology. MF and UL interpreted the data and assisted in manuscript preparation. UL, TS, and SG designed the study and assisted in manuscript preparation. UL and SG supervised the study. All authors contributed to the article and approved the submitted version.

## Funding

This work was supported by the German Research Foundation DFG (GA 3049/3-1 to SG).

Type I interferons (IFN) are pro-inflammatory cytokines which can also exert anti-inflammatory effects via the regulation of interleukin (IL)-1 family members. Several studies showed that interferon receptor (IFNAR)-deficient mice develop severe liver damage upon treatment with artificial agonists such as acetaminophen or polyinosinic:polycytidylic acid. In order to investigate if these mechanisms also play a role in an acute viral infection, experiments with the *Bunyaviridae* family member Rift Valley fever virus (RVFV) were performed. Upon RVFV clone (cl)13 infection, IFNAR-deficient mice develop a severe liver injury as indicated by high activity of serum alanine aminotransferase (ALT) and histological analyses. Infected IFNAR<sup>-/-</sup> mice expressed high amounts of IL-36 $\gamma$  within the liver, which was not observed in infected wildtype (WT) animals. In line with this, treatment of WT mice with recombinant IL-36 $\gamma$  induced ALT activity. Furthermore, administration of an IL-36 receptor antagonist prior to infection prevented the formation of liver injury in IFNAR<sup>-/-</sup> mice, indicating that IL-36 $\gamma$  is causative for the observed liver damage. Mice deficient for adaptor molecules of certain pattern recognition receptors indicated that IL-36 $\gamma$  induction was dependent on mitochondrial antiviral-signaling protein and the retinoic acid-inducible gene-I-like receptor. Consequently, cell type-specific IFNAR knockouts revealed that type I IFN signaling in myeloid cells is critical in order to prevent IL-36 $\gamma$  expression and liver injury upon viral infection. Our data demonstrate an anti-inflammatory role of type I IFN in a model for virus-induced hepatitis by preventing the expression of the novel IL-1 family member IL-36 $\gamma$ .

rift valley fever virus, type I interferon, interleukin-36 $\gamma$ , anti-inflammatory, immune pathology, dysregulation, liver injury

# 1 Introduction

Type I interferons (IFN) are a family of cytokines which are expressed early upon infection in order to guarantee the survival of the host until the adaptive immunity is activated. In order to elicit their pro-inflammatory function, type I IFN are induced e.g. upon sensing of pathogen-associated molecular patterns (PAMPs). PAMPs are recognized by pattern recognition receptors (PRRs) such as toll-like receptors (TLR) and the retinoic acid-inducible gene (RIG)-I-like receptors (RLR). Whereas most TLR signal via the adaptor protein myeloid differentiation primary response 88 (MyD88), signaling of RLR is dependent on the adaptor protein mitochondrial antiviral signaling protein (MAVS) (1). Type I IFN can be subdivided into 13 isoforms of IFN- $\alpha$ , one IFN- $\beta$ , as well as IFN- $\epsilon$ , IFN- $\tau$ , IFN- $\kappa$ , IFN- $\omega$ , IFN- $\delta$ , IFN- $\zeta$ , and IFN- $\nu$  (2). All type I IFN bind to a common type I IFN receptor (IFNAR) in order to regulate the expression of hundreds of IFN-stimulated genes (ISG) (2, 3). It has been shown by several studies in the past that a positive feedback loop via the IFNAR is necessary for the formation of robust type I IFN responses. Small amounts of early type I IFN, mainly IFN- $\alpha_4$  and IFN- $\beta$ , bind to the IFNAR in order to induce the production of high amounts of type I IFN (4–6). Nevertheless, depending on dose and route of infection, the IFNAR feedback loop is not strictly necessary for robust type I IFN expression upon infection with a variety of RNA-encoded viruses (7).

Even though type I IFN are generally considered as pro-inflammatory cytokines, they can also exert anti-inflammatory functions. Impaired induction of type I IFN in a model of TLR9 ligand-induced liver injury resulted in increased inflammation and liver damage. Here, the protective role of type I IFN was mediated via the attenuation of IL-1 $\beta$  expression and induction of the IL-1 receptor antagonist (RA) (8). Moreover, IL-1 family member-mediated immune pathology was shown for alcohol-induced hepatitis, fatty liver disease, as well as in a mouse model investigating lipopolysaccharide (LPS)/D-galactosamine (D-GalN)-induced liver injury (9, 10). In addition, in a previous study we showed that the artificial double-stranded RNA polyinosinic: polycytidylic acid (poly(I:C)) induced severe liver injury in IFNAR-deficient mice (IFNAR<sup>-/-</sup>). Deficient type I IFN signaling was associated with increased levels of IL-1 $\beta$ , which in turn was causative for the induction of severe liver damage as shown e.g. by high activity of serum alanine aminotransferase (ALT) (11, 12). As many viruses produce double-stranded RNA during their life cycle, poly(I:C) resembles a good model for a viral infection. To further explore the anti-inflammatory role of type I IFN upon a ‘real’ acute viral infection, we aimed to investigate the regulation of IL-1 family members in virus-induced hepatitis.

Rift Valley fever is an emerging zoonotic disease endemic in sub-Saharan African countries and the Arabian Peninsula. The disease is caused by the Rift Valley fever virus (RVFV), which is an enveloped virus with a segmented negative-sensed single-stranded RNA genome. It belongs to the *Bunyaviridae* family, genus *Phlebovirus*, and is primarily transmitted via *Aedes mcintoshi* mosquitos (13–18). RVFV outbreaks in the human population vary in extent, intensity, and location. Thus far, the largest outbreak was documented in Egypt 1977 with 10,000–20,000 cases and a mortality rate of up to 20% (16).

RVFV predominantly infects domestic ruminant animals including sheep, cattle, goats, and camels (16). In humans, infection with RVFV usually causes a self-limiting mild disease with influenza-like symptoms. Nevertheless, a small percentage of patients develop complications with clinical symptoms ranging from hemorrhagic fever to acute hepatitis, severe encephalitis, or thrombosis (13, 17, 19). The liver is considered the major target organ for RVFV and viral replication was shown to induce apoptosis in hepatocytes accompanied by necrosis (13, 15, 18). In line with that, RVFV pathogenesis in mice is associated with a loss of liver function due to liver necrosis and hepatitis (15, 16, 20).

RVFV was described to mainly infect epithelial cells (such as hepatocytes), mesenchymal cells, neural cells, hematopoietic cells such as mononuclear phagocytes, and cells morphologically consistent with dendritic cells (DC) (15). Other studies identified macrophages to be the primarily virus shedding cells while DC and granulocytes are additional target cells for RVFV replication (17).

The genome of RVFV consists of three segments: large (L), medium (M), and small (S) (16, 18). RVFV clone (cl)13 is an avirulent virus variant, which harbors a large deletion in the S segment. It is naturally attenuated and was obtained by plaque purification from a field isolate obtained from a nonfatal human case during an outbreak in 1974 (19). RVFV cl13 has no pathogenicity for mice or hamsters and the animals survive infections with up to 10<sup>6</sup> plaque-forming units (pfu) without developing any signs of disease. Nevertheless, type I IFN are critical for the survival of mice upon RVFV cl13 infection as IFNAR<sup>-/-</sup> mice show up to 100-fold higher titers when compared to their wildtype (WT) counterparts and finally succumb to infection (19).

In order to investigate if type I IFN also exert anti-inflammatory effects upon an acute viral infection, we used RVFV cl13 and analyzed the induction of IL-1 family members. Interestingly, data revealed a critical role for the novel IL-1 family member IL-36 $\gamma$  which was known thus far to play a pro-inflammatory role in some human disorders such as psoriasis, inflammatory bowel disease, pulmonary disease, or rheumatoid arthritis (21–24). IL-36 cytokines are new members of the IL-1 family which comprise IL-36 $\alpha$ , IL-36 $\beta$ , and IL-36 $\gamma$  (25–27). All bind to a heterodimeric receptor composed of the IL-36 receptor (IL-36R) and IL-1 receptor accessory protein (IL-1RAcP). IL-36 receptor antagonist (IL-36RA) and IL-38 have been shown to negatively regulate the IL-36 signaling pathway via competitive binding to IL-36R, suppressing agonist recognition and IL-1RAcP recruitment (21, 28–30). IL-36R is expressed in skin (especially on keratinocytes), epithelial cells within the lung, the gastrointestinal tract, and other tissues. Furthermore, several types of immune cells were shown to express IL-36R and respond to stimulation. In addition, human and mouse DC express IL-36R and binding of IL-36 promotes DC maturation and improves antigen presentation via upregulation of HLA-DR, CD83, and CD86 (21, 29, 31–33). IL-36 stimulates the production of various cytokines, chemokines, adhesion molecules, and pro-inflammatory mediators. IL-36 cytokines can be induced upon stimulation with different agents including cytokines, TLR ligands, bacterial or viral infections, or other pathological conditions (30, 34, 35).

In this study, we provide for the first time a mechanism for the type I IFN-mediated regulation of IL-36 $\gamma$  induction in the context of an acute viral infection.

## 2 Materials and methods

### 2.1 Mice

C57BL/6 WT mice were purchased from Harlan Winkelmann (Borchen, Germany). IFNAR<sup>-/-</sup> mice (6) were backcrossed at least 20 times on the C57BL/6 background. ISRE-eGFP mice express eGFP under the control of an interferon-stimulated response element (ISRE) (36). CD4Cre IFNAR<sup>flox/flox</sup> and CD19Cre IFNAR<sup>flox/flox</sup> mice (37), LysMCr IFNAR<sup>flox/flox</sup> mice (38), and CD11cCre IFNAR<sup>flox/flox</sup> (6) have been described before. To obtain MyD88<sup>-/-</sup>IFNAR<sup>-/-</sup> double-deficient mice and MAVS<sup>-/-</sup>IFNAR<sup>-/-</sup> double-deficient mice, MyD88<sup>-/-</sup> mice or MAVS<sup>-/-</sup> mice were intercrossed with IFNAR<sup>-/-</sup> mice as described before (7). All mice were bred under specific pathogen free conditions at the Zentrale Tierhaltung of the Paul-Ehrlich-Institut. Correct gene knock outs were verified by PCR analyses for all genotypes used. Health monitoring results of sentinel mice for all knock out mice showed no differences when compared to WT mice in our breeding. Fur structure, bearing, nutrition, and mating behavior of all knock out mice were inconspicuous. Mouse experimental work was carried out using 8 to 12 week old mice in compliance with regulations of German animal welfare.

### 2.2 Viruses and stimuli

For infection experiments RVFV cl13 (19) was used (under BSL2 conditions). Virus was propagated and titrated on Vero cells. Virus supernatants were harvested without further purification. Plaque assay analyses were performed as described earlier (39). *In vivo* infections were performed with 2x10<sup>4</sup> pfu RVFV cl13 in 200  $\mu$ l via the intraperitoneal (i.p.) route. Recombinant human IL-1RA (Anakinra, kindly provided by Swedish Orphan Biovitrum) was diluted in PBS and i.p. injected 6 hours before, simultaneously with, and 10 hours after infection with 100  $\mu$ g/g bodyweight in a maximal volume of 200  $\mu$ l. Recombinant mouse IL-36 $\gamma$ /IL-1F9 (aa 13-164; R&D) was diluted in PBS and intravenously (i.v.) injected (1  $\mu$ g in a volume of 200  $\mu$ l). Recombinant mouse IL-36RA (R&D) was diluted in PBS and i.v. injected 12 hours and 24 hours hours after infection (6  $\mu$ g in a volume of 200  $\mu$ l).

### 2.3 Quantification of cytokine production and ALT activity

To determine serum cytokine levels and ALT activity, peripheral blood was taken retro-orbitally upon anesthetization using Isofluran (CP-Pharma) and serum was prepared. IL-36 $\gamma$  was determined by enzyme-linked immunosorbent assay (ELISA) according to manufacturer's instructions (Cloud-Clone Corp).

Levels of eight different cytokines were measured via ProcartaPlex multiplex immunoassay kit (Thermo Fisher Scientific) according to manufacturer's instructions. ALT activity was determined using a commercially available kit (Hiss Diagnostics GmbH).

### 2.4 Histology

For histological analysis, livers were fixed in 10% buffered formalin and embedded in paraffin. Sections were stained with hematoxylin and eosin (H&E) as described before (11) and examined by light microscopy.

### 2.5 Quantitative real-time PCR

Total RNA was prepared from liver, spleen, and peritoneal exudate cells (PEC) using Trizol (Invitrogen)/chloroform extraction. Isolation of liver and spleen was described earlier (11). Samples were treated with DNaseI (Roche) for 15 min at 37°C. Absence of genomic DNA contamination was confirmed by standard PCR using a glyceraldehyde 3-phosphate dehydrogenase (GAPDH)-specific primer pair. Target- and reference-mRNA levels were examined by qRT-PCR using QuantiFast SYBR Green PCR kit (Qiagen). Primer pairs used were the following: GAPDH forward 5'-ACCACAGTCCATGCCATCAC-3', GAPDH reverse 5'-TCCACCACCCTGTTGCTGTA-3', pro-IL-1 $\beta$  forward 5'-TCTTTGAAGTTGACGGACCC-3', pro-IL-1 $\beta$  reverse 5'-TGAGT GATACTGCCTGCCTG-3', IL-1RA forward 5'-TCAGATCT GCACTCAATGCC-3', IL-1RA reverse 5'-CTGGTGTTT GACCTGGGAGT-3', IL-36 $\gamma$  forward 5'-CAGGCCCTT GTGACAGTTCCA-3', IL-36 $\gamma$  reverse 5'-TTAGCAGCAA GTAGGGTGTCCATTA-3', IL-36 $\alpha$  forward 5'-CCGATGAGC TGCCTGTTCTGC -3', IL-36 $\alpha$  reverse 5'-GTGGGCAGC TCCCTTTAGAGC -3', IL-36 $\beta$  forward 5'-AATGTCAAGC CTGTCATTCTTAGC -3', IL-36 $\beta$  reverse 5'-GTGGGCAGC CCCTTTAGAGC -3', IL-36RA forward 5'-CGCAGAGAAGG TCATTAAAGG -3', IL-36RA reverse 5'-AGCTCTTTGA TTCCTTGGC -3'. The expression levels of all target genes were normalized against GAPDH ( $\Delta$ Ct). Gene expression values were calculated based on the  $\Delta\Delta$ Ct method using the mean of the untreated control group as calibrator to which all other samples were compared. Relative quantities (RQ) were determined using the equation  $RQ = 2^{-\Delta\Delta Ct}$ .

### 2.6 Flow cytometry

Isolation of PEC was described elsewhere (7, 11). For FACS analyses, cells were stained for 20 min at 4°C with the following fluorochrome-labeled monoclonal antibodies: anti-CD11c-allophycocyanin (APC), anti-B220-PE (both from BD PharMingen), anti-CD11b-Pacific Blue (from Caltag/Invitrogen), and anti-F4/80-APC (AbD Serotec). Cells were washed and analyzed with a LSRII flow cytometer (Becton Dickinson). Analyses were performed using BD FACSDiva<sup>TM</sup> 8.0.1 and FlowJo® 7.6.5 and 10.7.1.

## 2.7 Statistics

For all animal experiments, the statistical evaluation was exploratory. All observed effects were described by specifying key statistical metrics (mean value, standard deviation, etc.). For normally distributed data, 95% confidence intervals are given for the mean estimates (also for mean differences). Statistical tests were decided at the two-sided significance level  $\alpha=5\%$ . For paired comparisons between several treatment groups, the associated *p*-values were adjusted. Data that are not normally distributed were transformed accordingly. If a transformation is not possible, non-parametric methods were used. All animal experiments were approved by the Regierungspräsidium Darmstadt with the license number F107\_1027.

Either Welch's *t*-test or Mann Whitney test were performed using GraphPad Prism 9.2.0. Values with  $p \leq 0.05$  are statistically significant which is illustrated by the number of stars: (\*) for  $p \leq 0.05$ , (\*\*) for  $p \leq 0.01$ , (\*\*\*) and for  $p \leq 0.001$ ; ns = not significant.

## 3 Results

### 3.1 IFNAR<sup>-/-</sup> mice develop severe liver damage upon infection with RVFV

As shown before (7), IFNAR<sup>-/-</sup> mice succumb to infection with RVFV cl13, which is accompanied by body weight loss and a drop in body temperature, while their WT counterparts survive the infection and do not show such symptoms (Figures 1A–C). In line with this, WT mice mount IFN- $\alpha$  responses 12 hpi while IFNAR<sup>-/-</sup> mice produced high amounts of IFN- $\alpha$  (up to ~4500 pg/ml) at 30 hpi indicating uncontrolled IFN- $\alpha$  production in the course of infection (Supplementary Figure 1). As given in Figure 1D, infection with RVFV induces viremia with high viral loads in all organs tested in IFNAR<sup>-/-</sup> but not WT mice resulting in the death of IFNAR<sup>-/-</sup> mice 30 hours post infection (7). In addition, IFNAR<sup>-/-</sup> but not WT mice show high ALT activity in the peripheral blood 30 h post infection indicating a severe liver injury in these animals (Figure 1E). In conclusion, IFNAR<sup>-/-</sup> but not WT mice develop a severe liver damage upon infection with RVFV cl13.

### 3.2 Liver damage in RVFV-infected IFNAR<sup>-/-</sup> mice is caused by IL-1 family member IL-36 $\gamma$

Next, we aimed to investigate if liver damage upon RVFV cl13 infection is mediated by a dysregulation of the IL-1 family members IL-1 $\beta$  and/or IL-1RA as it has been shown before for poly(I:C) treatment (11, 12). Thus, we isolated livers of IFNAR<sup>-/-</sup> and WT mice 30 hours post RVFV cl13 infection and analyzed IL-1 $\beta$  (Figure 2A) and IL-1RA (Figure 2B) induction by ELISA. Unlike poly(I:C)-treated animals (11, 12), RVFV cl13-infected IFNAR<sup>-/-</sup> mice showed high IL-1 $\beta$  as well as IL-1RA expression while WT mice did not show any IL-1 $\beta$  or IL-1RA induction upon infection.

To confirm that an IL-1 $\beta$ /IL-1RA imbalance is indeed not involved in RVFV cl13-mediated liver injury, RVFV cl13-infected IFNAR<sup>-/-</sup> mice were treated with recombinant IL-1RA (Anakinra) and analyzed for the development of liver damage by analyzing ALT activity within the serum (Figure 2C). Here, the administration of recombinant IL-1RA could not prevent the development of severe liver injury in RVFV cl13-infected IFNAR<sup>-/-</sup> mice indicating that IL-1 $\beta$ /IL-1RA are not involved in RVFV cl13-induced liver injury.

In a model of paracetamol (acetaminophen, APAP)-induced liver damage, the IL-1 family member IL-36 $\gamma$  and its antagonist IL-36RA were shown to play a role in the onset and regeneration of liver damage (40). Hence, we presumed that these IL-1 family members might be type I IFN regulated and thus involved in the RVFV cl13-induced liver damage in absence of IFNAR-signaling. To obtain a first insight, we analyzed the expression of IL-36 $\gamma$  upon RVFV cl13 infection by an ELISA method. As given in Figure 3A, IFNAR<sup>-/-</sup> but not WT mice show high levels of IL-36 $\gamma$  30 hours post infection. To investigate if IL-36 $\gamma$  is sufficient to cause liver injury, we i.p. injected WT animals with 1  $\mu$ g recombinant IL-36 $\gamma$  and analyzed ALT activity (Figure 3B). Indeed, WT mice developed a severe liver injury within 3 hours post IL-36 $\gamma$  injection as indicated by high ALT activity within the serum.

To further verify that IL-36 $\gamma$  was causative for the liver damage upon RVFV cl13 infection, RVFV cl13-infected IFNAR<sup>-/-</sup> mice were treated with recombinant IL-36RA 12 and 24 hours post infection (Figure 3C). Analyses of IFNAR<sup>-/-</sup> mice revealed that the administration of recombinant IL-36RA significantly reduced ALT activity (Figure 3C) and overall liver damage as indicated by histological analyses (Figure 3D). Of note, viral titers within all organs analyzed were not affected by IL-36RA treatment (Figure 3E). These data strongly indicate that the dysregulated IL-36 $\gamma$  expression in absence of type I IFN-signaling is causative for the liver injury observed upon RVFV cl13 infection.

### 3.3 Macrophage-like cells within the peritoneum are the main source of IL-36 $\gamma$ in the absence of type I IFN signaling

To gain insight in which cells or organs are the source of IL-36 $\gamma$  upon RVFV cl13 infection, we analyzed spleens (as an organ harboring many immune cells), livers (as the site where the damage occurs), and PEC (because of the intraperitoneal route of infection) of WT and IFNAR<sup>-/-</sup> mice. To ensure that both genotypes show a comparable basal expression of IL-36 $\gamma$ , we analyzed uninfected mice by qRT-PCR analysis. As given in Figure 4A, spleen, liver, and PEC of WT and IFNAR<sup>-/-</sup> mice showed comparable basal levels of IL-36 $\gamma$  mRNA. Next, we infected WT and IFNAR<sup>-/-</sup> mice with RVFV for 24 hours and isolated spleen, liver, and PEC RNA for qRT-PCR analyses. As shown in Figure 4B, IFNAR<sup>-/-</sup> mice express high levels of IL-36 $\gamma$  mRNA in all organs/cells tested with the highest expression in PEC (up to 4000-fold induction) while WT mice did not show upregulation in spleen and liver and only minor upregulation (up to 80-fold) in PEC. These results strongly indicate that PEC are the main source of IL-36 $\gamma$  in

IFNAR<sup>-/-</sup> mice upon RVFV cl13 infection and that type I IFN signaling in these cells prevents IL-36 $\gamma$  induction.

In order to clarify which cells within the peritoneum directly sense type I IFN upon infection, we used reporter mice expressing eGFP under the control of the ISRE for further experiments. Flow cytometric analyses of PEC derived from RVFV-infected mice demonstrated that eGFP-positive cells are mainly CD11b<sup>+</sup>F4/80<sup>+</sup> and therefore show a myeloid/macrophage-like phenotype (Figure 4C).

To investigate if sensing of type I IFN in myeloid/macrophage-like cells is critical for IL-36 $\gamma$  expression, we used conditional knockout mice, deficient for the IFNAR in certain types of immune cells (DC-IFNAR<sup>-/-</sup> with specific IFNAR deletion in DC, Mye-IFNAR<sup>-/-</sup> with specific IFNAR deletion in myeloid cells, T-IFNAR<sup>-/-</sup> with specific IFNAR deletion in T cells, whereas all other cell types remain IFNAR-competent as described in (11)) and

infected these mice with RVFV cl13. IFNAR<sup>-/-</sup> mice served as control. As given in Figure 5A, mice deficient for the IFNAR in myeloid cells (Mye-IFNAR<sup>-/-</sup>) and DC (DC-IFNAR<sup>-/-</sup>) develop a severe liver injury upon infection which was even more pronounced when compared to IFNAR<sup>-/-</sup> mice. In contrast, T-IFNAR<sup>-/-</sup> control-mice did not show enhanced ALT activity upon infection. In line with this, qRT-PCR analyses of PEC derived from those animals show IL-36 $\gamma$  induction in Mye-IFNAR<sup>-/-</sup> (350-fold) and DC-IFNAR<sup>-/-</sup> (500-fold) which was not observed in T-IFNAR<sup>-/-</sup> mice. As shown before, IFNAR<sup>-/-</sup> mice strongly upregulate IL-36 $\gamma$  mRNA upon infection (1000-fold) (Figure 5B). Of note, IL-36 $\gamma$  induction in Mye-IFNAR<sup>-/-</sup> mice was comparable to IFNAR<sup>-/-</sup> mice. These results indicate that upon RVFV cl13 infection the absence of IFNAR-signaling in myeloid cells/DC results in IL-36 $\gamma$  expression, which in turn mediates a severe liver damage.

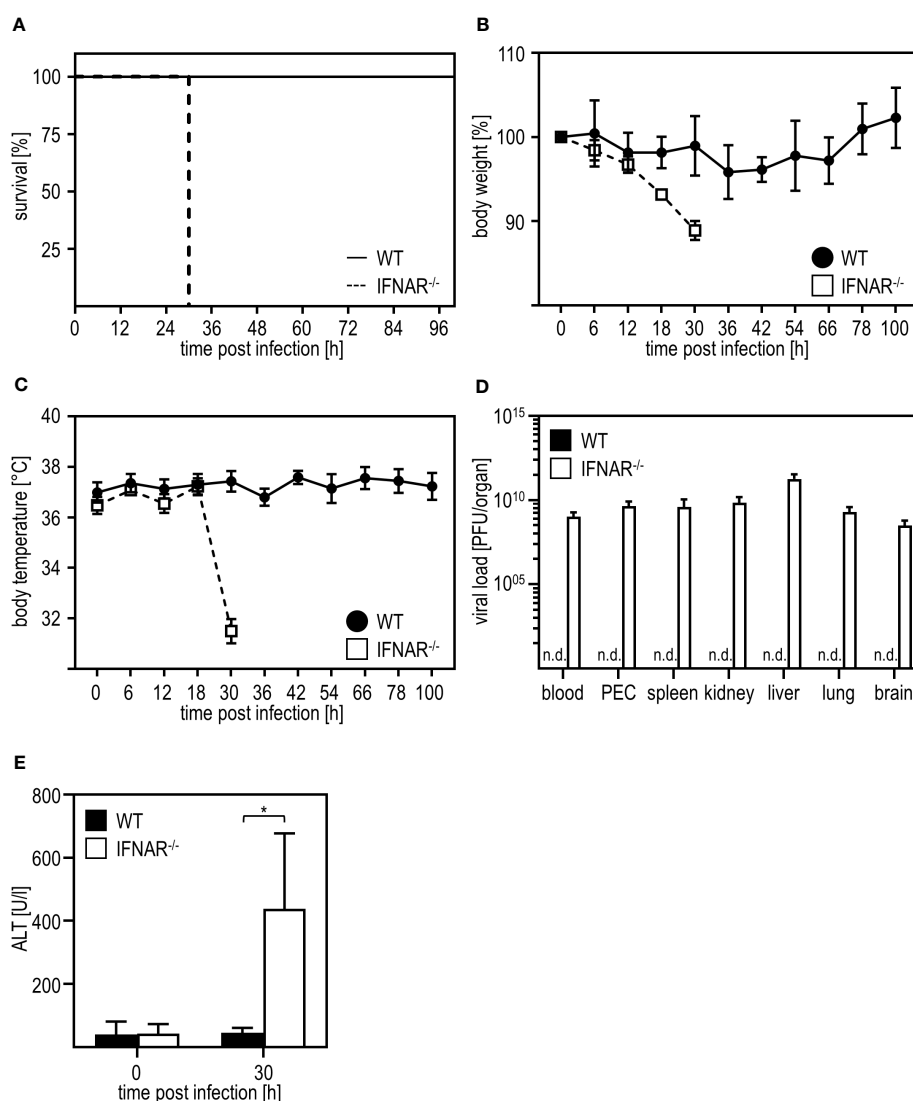

FIGURE 1

Infection with RVFV cl13 induces liver damage in type I IFN-deficient mice. C57BL/6 (WT) and IFNAR<sup>-/-</sup> mice were i.p. infected with  $2 \times 10^4$  pfu/200  $\mu$ l RVFV cl13 (n=4-7) and (A) survival, (B) body weight, and (C) body temperature was monitored at the indicated time points post infection. (D) Viral loads were analyzed 30 hours post infection (hpi) in the indicated organs by plaque assay (n=4). (E) ALT activity was measured 30 hpi within the serum of WT and IFNAR<sup>-/-</sup> mice (n=6). Error bars indicate standard deviations. \* < 0.05 (Welch's t-test); n.d., not detectable.

FIGURE 2

Liver injury in RVFV cl13-infected IFNAR<sup>-/-</sup> mice is not mediated by a dysregulation of IL-1 $\beta$ /IL-1RA. C57BL/6 (WT) and IFNAR<sup>-/-</sup> mice were i.p. infected with  $2 \times 10^4$  pfu/200  $\mu$ l RVFV cl13. Levels of IL-1 $\beta$  (A) and IL-1RA (B) were measured 30 hpi within the serum by an ELISA method (n=4-13). (C) WT and IFNAR<sup>-/-</sup> mice were infected with  $2 \times 10^4$  pfu/200  $\mu$ l RVFV cl13. Then, a subset of infected IFNAR<sup>-/-</sup> animals was treated with 100  $\mu$ g recombinant IL-1RA (Anakinra) per g body weight as described in material methods. ALT activity was measured 30 hpi within the serum (n=4-13). Error bars indicate standard deviations. \*\* < 0.01; \*\*\* < 0.001 (Welch's t-test); n.s., not significant.

### 3.4 MAVS is critically involved in the production of IL-36 $\gamma$ upon RVFV infection of IFNAR<sup>-/-</sup> mice

Viral infections can be sensed via different pathways such as those involving TLR or RLR (41, 42). To uncover which signaling pathway is involved in IL-36 $\gamma$  induction and liver damage upon RVFV infection, we used IFNAR<sup>-/-</sup> mice additionally deficient for MyD88 (MyD88<sup>-/-</sup>IFNAR<sup>-/-</sup> affecting most TLR pathways) and IFNAR<sup>-/-</sup> mice additionally deficient for MAVS (MAVS<sup>-/-</sup>IFNAR<sup>-/-</sup> not capable of using the RLR pathway). qRT-PCR analysis of PEC derived from those mice revealed that MAVS<sup>-/-</sup>IFNAR<sup>-/-</sup> did not induce any IL-36 $\gamma$  mRNA upon RVFV cl13 infection while IFNAR<sup>-/-</sup> and MyD88<sup>-/-</sup>IFNAR<sup>-/-</sup> showed high levels of IL-36 $\gamma$  mRNA. Interestingly, IL-36 $\gamma$  mRNA-levels were even significantly higher in MyD88<sup>-/-</sup>IFNAR<sup>-/-</sup> mice when compared to IFNAR<sup>-/-</sup> mice (Figure 6A). These data show that for IL-36 $\gamma$  mRNA expression by IFNAR<sup>-/-</sup> PEC, the MAVS-adapted RLR pathway is used while the MyD88-adapted TLR are of no relevance. Finally, we analyzed the ALT activity in the serum of these different knockout mice. While MyD88<sup>-/-</sup>IFNAR<sup>-/-</sup> showed

levels comparable to those in IFNAR<sup>-/-</sup> mice, no ALT activity was detected in MAVS<sup>-/-</sup>IFNAR<sup>-/-</sup> mice indicating that these mice were indeed protected from the RVFV cl13-induced IL-36 $\gamma$ -mediated liver injury. Of note, plaque assay analyses revealed high viral loads in all organs tested, irrespective of the genotype of mice investigated (Figure 6C). Of note, higher levels of IL-36 $\gamma$  expression in MyD88<sup>-/-</sup>IFNAR<sup>-/-</sup> could not be correlated with increased viral loads in these mice.

In conclusion, our study demonstrated a critical role for the IL-1 family member IL-36 $\gamma$  for the induction of liver damage in the course of viral infection. In line with results obtained using the artificial double-stranded RNA poly(I:C), the dysregulation of IL-1 family members in the absence of type I IFN results in severe liver injury independent of viral titers.

## 4 Discussion

It was shown before that members of the IL-1 family, especially IL-1 $\beta$ , play an important role in liver injury (11, 43). The current study demonstrates a pathological role for IL-36 $\gamma$  upon an acute

viral infection. The pro-inflammatory cytokine IL-36 $\gamma$  was known before to be critically involved in several inflammatory disorders such as psoriasis (29, 44, 45), inflammatory bowel disease (23, 32, 44), rheumatoid arthritis (21), or systemic lupus erythematosus (SLE) (24). Accumulating evidences suggest that IL-36 $\gamma$  also plays a role during infectious diseases (24). Nevertheless, it is not fully understood yet if it promotes infection, drives immune-pathology, or rather plays a protective role.

A study by Wang et al. using a mouse model for influenza A virus (IAV) infection revealed that IL-36 contributes to lung damage and mortality by promoting inflammation. Mice deficient for the IL-36R were protected from IAV-induced lung injury and mortality. Furthermore, IL-36R<sup>-/-</sup> mice showed reduced lymphocyte

activation, accumulation of myeloid cells, reduced permeability of the alveolar epithelial barrier, and less production of pro-inflammatory cytokines and chemokines (24, 46). In line with that, patients with IAV-induced acute respiratory syndrome (ARDS) show higher concentrations of IL-36 $\gamma$  in the plasma when compared to healthy individuals (47). In addition, IL-36 $\gamma$  and IL-36 $\alpha$  are significantly upregulated in patients with pulmonary tuberculosis, bacterial pneumonia, or chronic hepatitis B virus (HBV) infection (47, 48).

Others reported a protective role for IL-36. Upon infection of mice, pretreatment with IL-36 $\gamma$  increased the resistance against Herpes simplex virus (HSV)-2 infection and disease (21). Mice lacking IL-36 $\gamma$  showed increased morbidity and mortality upon IAV

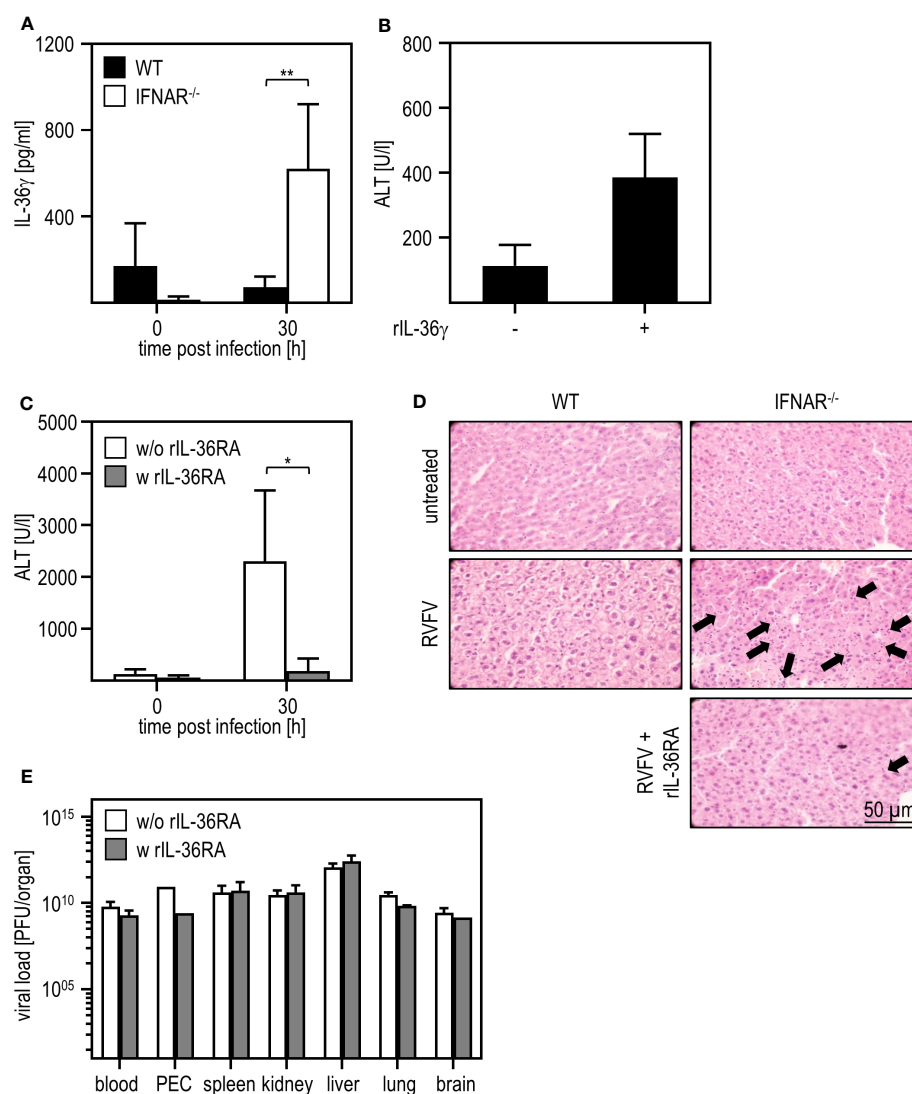

FIGURE 3

IL-36 $\gamma$  is causative for the liver injury in RVFV c13-infected IFNAR<sup>-/-</sup> mice. C57BL/6 (WT) and IFNAR<sup>-/-</sup> mice were i.p. infected with  $2 \times 10^4$  pfu/200  $\mu$ l RVFV c13. (A) IL-36 $\gamma$  was measured 30 hpi within the serum using an ELISA method (n=4-6). (B) C57BL/6 (WT) mice were i.v. injected with 1  $\mu$ g recombinant IL-36 $\gamma$ . ALT activity within the serum was measured 3 hours post treatment (n=3). (C) RVFV c13-infected IFNAR<sup>-/-</sup> mice were i.v. injected with 6  $\mu$ g rIL-36RA in 200  $\mu$ l 12 and 24 hpi. RVFV c13-infected IFNAR<sup>-/-</sup> mice served as control. ALT activity was measured 30 hpi (n=5). (D) Histological analyses were performed using H&E staining. Liver sections of RVFV c13-infected WT and IFNAR<sup>-/-</sup> mice were prepared 30 hpi as described earlier (11). Additionally, RVFV c13-infected IFNAR<sup>-/-</sup> mice were rIL-36RA-treated (all n=2). Untreated animals served as controls. Arrows exemplarily indicate apoptotic bodies within the tissue. (E) Organs of WT and IFNAR<sup>-/-</sup> mice were harvested 30 hours post RVFV infection and analyzed for the viral load by plaque assay (n=2-6). Error bars indicate standard deviations. \* < 0.05; \*\* < 0.01 (Welch's t-test).

infection which was associated with increased virus titers and higher levels of inflammatory cytokines (46). Furthermore, IL-36 $\gamma^{-/-}$  mice showed higher bacterial load in the lung, systemic dissemination, and higher mortality upon infection with *Staphylococcus pneumoniae* when compared to WT mice (45). Blocking IL-36 $\gamma$  receptor binding and using recombinant IL-36 $\gamma$  (see Figure 3), we found IL-36 $\gamma$  to be causative for the liver damage induced upon infection with RVFV cl13 in absence of intact type I IFN signaling. Interestingly, neither IL-36 $\alpha$ , IL-36 $\beta$ , nor IL-36RA were elevated in organs of RVFV cl13-infected IFNAR $^{-/-}$  mice when

compared to untreated IFNAR $^{-/-}$  or WT mice (see Supplementary Figure 2).

IL-36 $\gamma$  was shown before to play a role in drug-induced liver injury. In a model of acetaminophen (APAP)-induced hepatitis, Scheiermann et al. showed elevated levels of IL-36 $\gamma$  within the liver of IFNAR $^{-/-}$  mice. However, application of IL-36RA increased the late phase of liver injury indicating a potential role for IL-36 $\gamma$  as a cytokine contributing to the decision between tissue damage and liver regeneration (40). Moreover, treatment with IL-36RA significantly reduced the production of pro-inflammatory

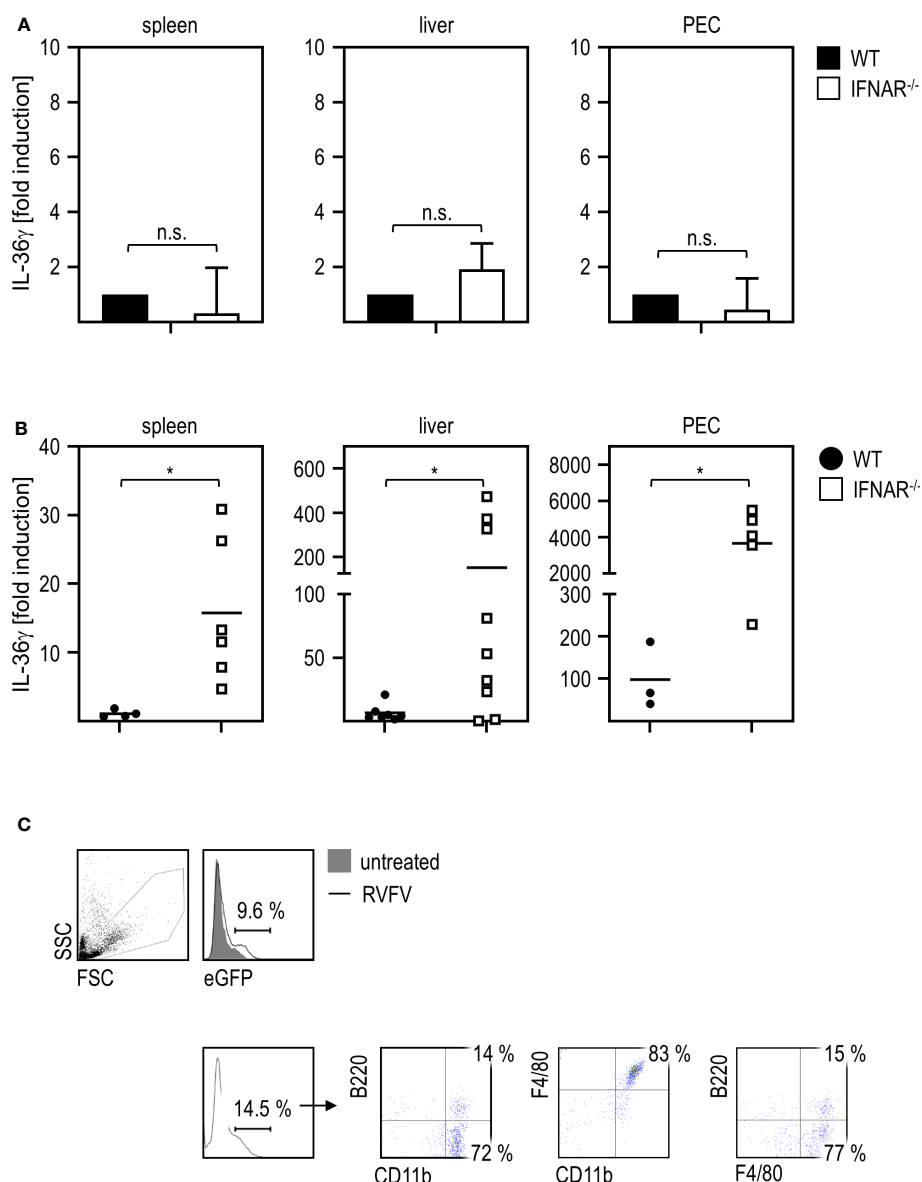

FIGURE 4

PEC are the main source of IL-36 $\gamma$  upon RVFV cl13 infection of IFNAR $^{-/-}$  mice. (A) To exclude genotype-specific differences in basal expression levels, spleen, liver, and peritoneal exudate cells (PEC) of C57BL/6 (WT) and IFNAR $^{-/-}$  mice (each n=4) were isolated and RNA was prepared as described elsewhere (11). Expression of IL-36 $\gamma$  was determined by qRT-PCR analyses. All values were normalized to WT animals; n.s.=not significant (Mann Whitney test). (B) C57BL/6 (WT) and IFNAR $^{-/-}$  mice (n=4-9) were i.p. infected with  $2 \times 10^4$  pfu RVFV cl13 in 200  $\mu$ l. Spleen, liver, and PEC were isolated 24 hpi infection and RNA was prepared as described earlier (11). Expression of IL-36 $\gamma$  was determined by qRT-PCR analyses. (C) ISRE-eGFP mice were either left untreated or infected with RVFV cl13 for 30 hours. PEC were isolated and analyzed for eGFP expression by flow cytometry. eGFP-positive cells were further characterized as CD11b $^{+}$ F4/80 $^{+}$  (one representative staining out of three is shown). Error bars indicate standard deviations; \* < 0.05 (Welch's t-test); n.s., not significant.

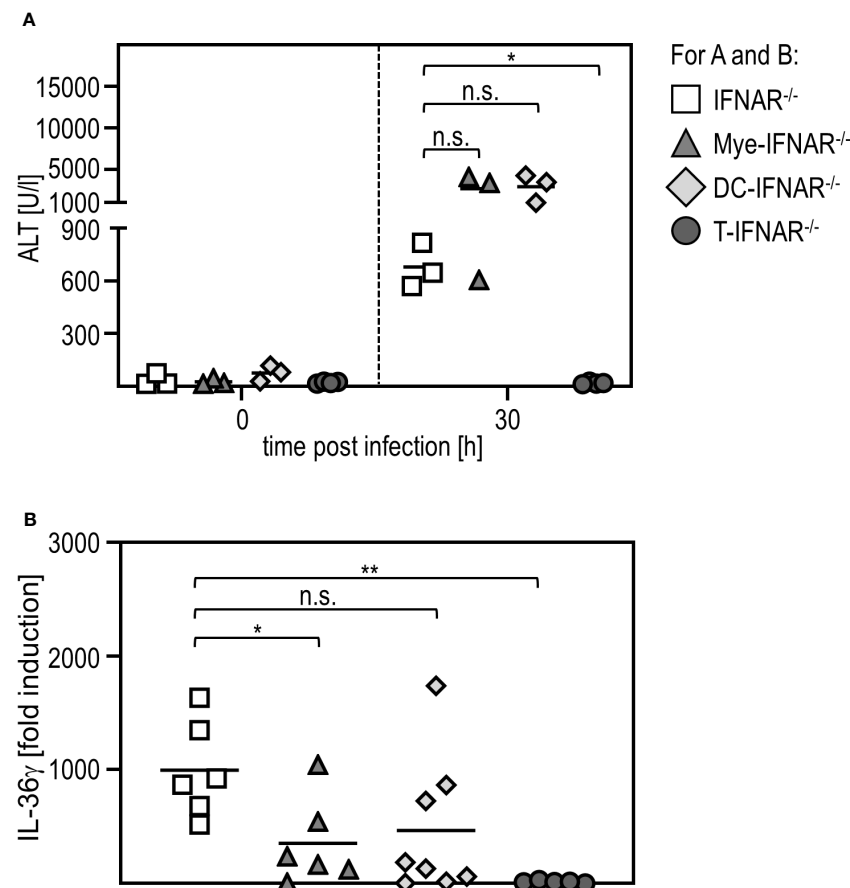

FIGURE 5

Myeloid cells need to sense type I IFN in order to protect from IL-36 $\gamma$ -mediated liver injury. IFNAR<sup>-/-</sup>, Mye-IFNAR<sup>-/-</sup>, DC-IFNAR<sup>-/-</sup>, and T-IFNAR<sup>-/-</sup> mice were i.p. infected with 2x10<sup>4</sup> pfu RVFV cl13 in 200  $\mu$ l. (A) ALT activity was measured 0 and 30 hpi infection (n=3-4). (B) Induction of IL-36 $\gamma$  within the PEC was determined by qRT-PCR analyses (n=5-8); \* < 0.05; \*\* < 0.01 (Welch's t-test); n.s., not significant.

cytokines in BALB/c mice in a model of Concanavalin (Con)A-induced liver injury (49). ConA-treated IL-36R<sup>-/-</sup> animals exhibited exaggerated T cell responses as shown by increased infiltration of effector T cells into the liver accompanied by the production of pro-inflammatory cytokines (29).

Interestingly, in our study, IL-36 $\gamma$ -mediated liver injury upon RVFV infection was completely independent from viral loads in various organs tested. In particular, while viral titers in MAVS<sup>-/-</sup> IFNAR<sup>-/-</sup> animals are comparable to those in IFNAR<sup>-/-</sup> mice (Figures 1, 6), ALT activity in these double-deficient mice is comparable to WT animals (Figure 6). This suggests an immunopathology caused by IL-36 $\gamma$  expression in an IFNAR-deficient situation, whereas the hepatocellular tropism of RVFV and thus a virus-induced hepatitis seem to play a minor role.

Upon drug-induced liver injury, hepatocytes were shown to be the major source of IL-36 promoting the inflammatory response (50). In line with this, IL-6, TNF- $\alpha$ , and IFN- $\gamma$  were slightly elevated in RVFV cl13-infected IFNAR<sup>-/-</sup> mice when compared to RVFV cl13-infected WT mice (for all p-value = 0.0571, Mann-Whitney-Test). In addition, a minor expression of IL-12p70 and IL-18 was observed in RVFV cl13-infected IFNAR<sup>-/-</sup> mice while other cytokines such as IL2, IL-4 or IL-5 did not differ between RVFV

cl13-infected IFNAR<sup>-/-</sup> and WT mice (Supplementary Figure 3). Our study revealed that type I IFN sensing by macrophages as well as DC is critical for the prevention of IL-36 $\gamma$  production and thus the IL-36 $\gamma$ -induced liver injury upon RVFV cl13 infection (see Figure 5). The protective role of myeloid cells was also shown before for poly(I:C)-induced liver damage. Here, myeloid-derived suppressor cells infiltrated the liver in a type I IFN-dependent manner in order to produce IL-1RA and therefore prevent IL-1 $\beta$ -mediated liver injury (11). Interestingly, in the current study, no enhanced IL-36RA expression was detected in qRT-PCR analyses of organs of WT mice (see Supplementary Figure 2) indicating that other factors are involved in order to regulate the expression of IL-36 $\gamma$ . Within the poly(I:C)-induced model of liver damage as well as in our current study, myeloid cells within the peritoneum are of particular importance. Along this line, deficient type I IFN signaling was associated with decreased liver recruitment of DC in a model of TLR9 ligand-induced liver damage (8). In addition, a study by Pinto et al. demonstrated that deletion of the IFNAR on subsets of myeloid cells such as macrophages and DC, resulted in uncontrolled replication of West Nile virus (WNV), production of pro-inflammatory cytokines, organ damage, and death (51). Interestingly, particularly cells of the macrophage lineage show

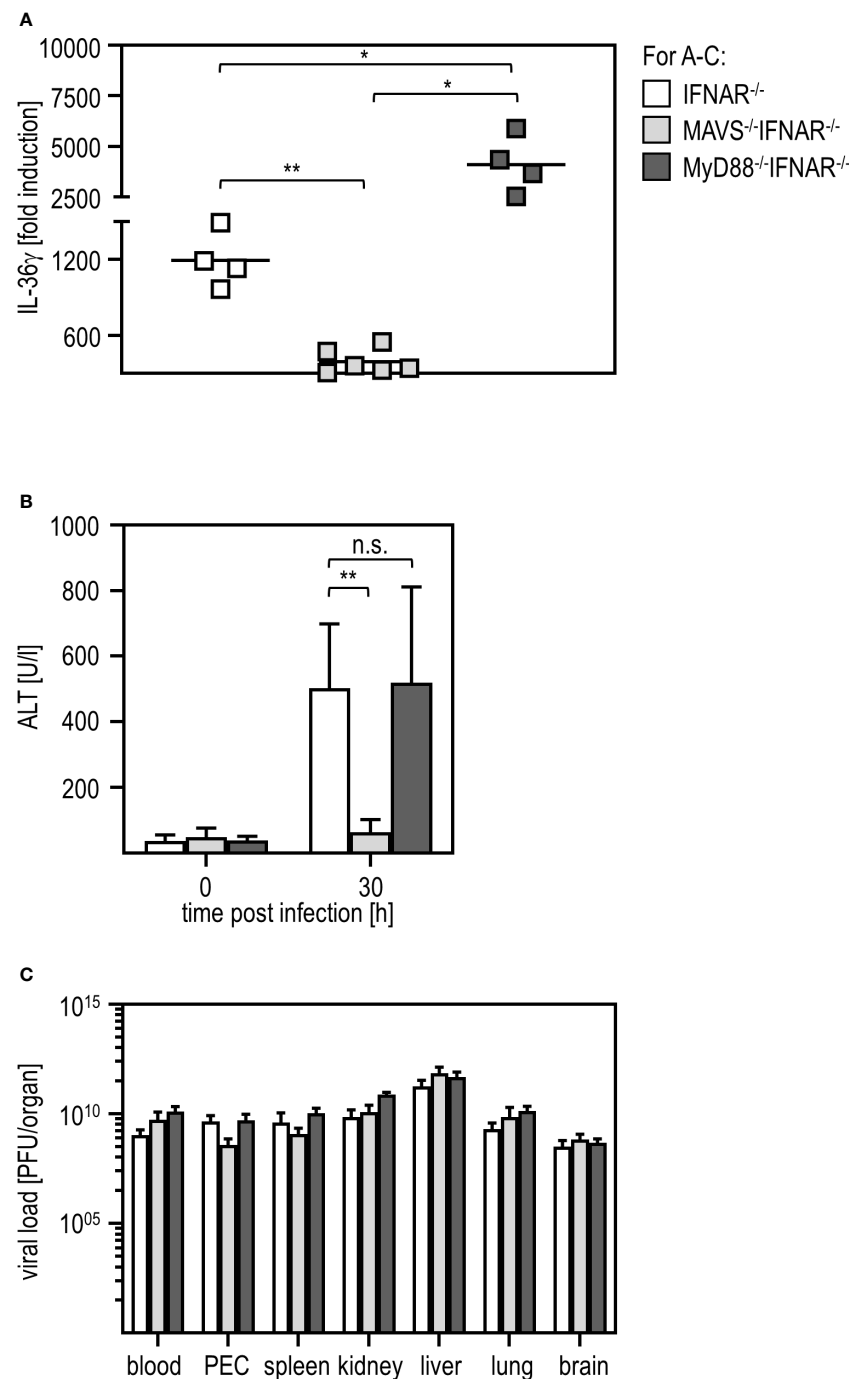

FIGURE 6

MAVS is critically involved in IL-36 $\gamma$  induction and IL-36 $\gamma$ -mediated liver injury upon RVFV cl13 infection of IFNAR<sup>-/-</sup> mice. IFNAR<sup>-/-</sup>, MAVS<sup>-/-</sup>IFNAR<sup>-/-</sup>, and MyD88<sup>-/-</sup>IFNAR<sup>-/-</sup> mice were i.p. infected with  $2 \times 10^4$  pfu RVFV cl13 in 200  $\mu$ l for 30 hours. (A) IL-36 $\gamma$  induction was investigated by qRT-PCR analyses of the PEC (n=4-6). (B) ALT activity was measured in serum samples at 30 hours post infection (n=4-8). (C) Viral load in different organs was analyzed by plaque assay (n=4-7). Error bars indicate standard deviations; \* < 0.05; \*\* < 0.01; n.s., not significant.

increased susceptibility to RVFV cl13 infection in the absence of type I IFN. During initial stages of infection of IFNAR<sup>-/-</sup> mice, RVFV cl13 replicates within macrophages and DC (17). Ermler et al. demonstrated that murine conventional DC and macrophages express type I IFN in response to RVFV cl13 (14, 18).

In addition, RVFV cl13-infected human monocyte-derived macrophages were shown to secrete TNF- $\alpha$  and type I IFN (18).

This together with our data implies that production as well as sensing of type I IFN by myeloid cells such as macrophages and DC, is critical in order to prevent IL-36 $\gamma$  production and thus the IL-36 $\gamma$ -induced liver damage upon RVFV cl13 infection. Besides immune cells, human lung fibroblasts and human bronchial epithelial cells were shown to produce IL-6 and CXCL8 upon treatment with IL-36 (30). Thus, other cells than immune cells such as hepatocytes might

contribute to a production of pro-inflammatory cytokines and dysregulated immune reaction upon RVFV cl13 infection.

It was shown in several studies that myeloid cells sense PAMPs rather via RLRs than TLRs. For example, Dutta et al. revealed that MAVS signaling in myeloid cells was critical for the resistance to Ebola virus infection in mice (52). In line with this, a variety of RNA-encoded viruses were shown to induce IFNAR-independent type I IFN responses in a MAVS-dependent manner (7). Here, we show that IL-36 $\gamma$  production and accordingly liver damage were dependent on MAVS in RVFV cl13-infected IFNAR<sup>-/-</sup> mice while MyD88-adapted TLR are of no importance for IL-36 $\gamma$  production (see Figure 6). Along this line, others showed that upon infection with WNV no cytokine production was observed in MAVS<sup>-/-</sup> IFNAR<sup>-/-</sup> mice (51). Of note, production of pro-inflammatory cytokines by DC or fibroblasts upon IL-36 $\gamma$  stimulation was shown to be dependent on MyD88 indicating that induction and sensing of IL-36 $\gamma$  can be mediated by different pathways (23, 45).

The interaction between type I IFN and IL-36 was previously observed also in psoriasis patients. Here, the expression of IL-36 strongly correlated with type I IFN overexpression (53). In addition, IL-36 serum levels in patients correlate with SLE disease activity, a disorder characterized by an enhanced type I IFN signature (53). In epithelial cells, IL-36 was shown to increase antiviral immunity by enhancing the expression of type I IFN stimulated genes (ISG) via the IFNAR (54). This mechanism may have evolved in order to control viruses that developed immune evasion strategies by blocking the production of type I IFN.

In conclusion, our study demonstrated that pro-inflammatory IL-36 $\gamma$  is causative for the observed liver injury in IFNAR<sup>-/-</sup> mice upon an acute viral infection. The expression of IL-36 $\gamma$  is regulated by type I IFN, which need to be sensed by myeloid cells in order to prevent liver damage.

## Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## Ethics statement

The animal study was approved by Regierungspräsidium Darmstadt, license number F107-1027. The study was conducted in accordance with the local legislation and institutional requirements.

## Author contributions

All authors contributed either to research design (MA, ZW, and GK) and/or the acquisition (MA, MN, EK, MD, SK, IB, SO-I), data analysis (MA, ZW, MN, EK, MD, SK, IB, SO-I), or interpretation of data (all authors). MA and ZW drafted the manuscript, which was

critically revised by all other authors. All authors contributed to the article and approved the submitted version.

## Acknowledgments

We thank Dorothea Kreuz, Björn Becker, and Yvonne Krebs for expert technical assistance.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Publisher's note

All claims expressed in this article are solely those of the authors and do not necessarily represent those of their affiliated organizations, or those of the publisher, the editors and the reviewers. ## Supplementary material

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fimmu.2023.1194733/full#supplementary-material>

### SUPPLEMENTARY FIGURE 1

RVFV cl13-infected IFNAR<sup>-/-</sup> mice express high levels of IFN- $\alpha$  in the serum 30 hpi while WT mice show low amounts 12 hpi. C57BL/6 (WT) and IFNAR<sup>-/-</sup> mice (n = 2-14) were i.p. infected with 2x10<sup>4</sup> pfu RVFV cl13 in 200  $\mu$ l. Serum was collected prior to infection as well as 30 hpi and tested using a multiplex kit for the presence of IL-6, TNF- $\alpha$ , and IFN- $\gamma$  as described in the material and methods section. Error bars indicate standard deviations; \* < 0.05; \*\* < 0.01; \*\*\*\* < 0.0001 (Welch's t-test); n.s., not significant.

### SUPPLEMENTARY FIGURE 2

Spleen, liver, and PEC of RVFV cl13-infected IFNAR<sup>-/-</sup> mice do not upregulate IL-36 $\alpha$ , IL-36 $\beta$ , or IL-36RA when compared to WT mice. C57BL/6 (WT) and IFNAR<sup>-/-</sup> mice (for IL-36 $\alpha$  and IL-36 $\beta$  n = 3-5; for IL-36RA n = 2-11) were i.p. infected with 2x10<sup>4</sup> pfu RVFV cl13 in 200  $\mu$ l. Spleen, liver, and PEC were isolated 24 hpi infection and RNA was prepared as described earlier (11). Expression of IL-36 $\alpha$ , IL-36 $\beta$ , and IL-36RA was determined by qRT-PCR analyses. n.s., not significant (Welch's t-test).

### SUPPLEMENTARY FIGURE 3

RVFV cl13-infected IFNAR<sup>-/-</sup> mice show slightly enhanced levels of IL-6, TNF- $\alpha$ , and IFN- $\gamma$  within the serum when compared to WT mice. C57BL/6 (WT) and IFNAR<sup>-/-</sup> mice (n = 3-4) were i.p. infected with 2x10<sup>4</sup> pfu RVFV cl13 in 200  $\mu$ l. Serum was collected prior to infection as well as 30 hpi and tested using a multiplex kit for the presence of a panel of eight different cytokines as described in the material and methods section. n.s., not significant (Mann-Whitney-Test).

## Glossary

ALT	alanine aminotransferase
APAP	acetaminophen
CD	cluster of differentiation
cl	clone
ConA	concanavalin A
DC	dendritic cell(s)
D-GalN	d-galactosamine
ELISA	enzyme-linked immunosorbent assay
Figure	figure(s)
GFP	green fluorescent protein
HBV	hepatitis B virus
hpi	hours post infection
HSV	herpes simplex virus
IAV	influenza A virus
IFN	type I interferon(s)
IFNAR	type I interferon receptor
IL	interleukin
IL-1RA	interleukin-1 receptor antagonist
IL-1RAcP	interleukin-1 receptor accessory protein
IL-36RA	interleukin-36 receptor antagonist
i.p.	intraperitoneal
ISG	IFN-stimulated gene(s)
i.v.	intravenously
LPS	lipopolysaccharide
MAVS	mitochondrial antiviral-signaling protein
MyD88	myeloid differentiation primary response 88
RVFV	Rift Valley fever virus
PAMP	pathogen associated molecular pattern
PBMC	peripheral mononuclear cells
PEC	peritoneal exudate cells
poly(I:C)	polyinosinic-polycytidylic acid
PRR	pattern recognition receptor(s)
RIG	retinoic acid-inducible gene
RLR	retinoic acid-inducible gene RIG-I-like receptors
SLE	systemic lupus erythematosus
TLR	toll like receptor(s)
WT	wildtype

**Introduction:** Interstitial lung disease (ILD) is a heterogeneous group of lung disorders where destruction and incomplete regeneration of the lung parenchyma often results in persistent architectural distortion of the pulmonary scaffold. Continuous mesenchyme-centered, disease-relevant signaling likely initiates and perpetuates the fibrotic remodeling process, specifically targeting the epithelial cell compartment, thereby destroying the gas exchange area.

**Methods:** With the aim of identifying functional mediators of the lung mesenchymal-epithelial crosstalk with potential as new targets for therapeutic strategies, we developed a 3D organoid co-culture model based on human induced pluripotent stem cell-derived alveolar epithelial type 2 cells that form alveolar organoids in presence of lung fibroblasts from fibrotic-ILD patients, in our study referring to cases of pulmonary fibrosis, as well as control cell line (IMR-90).

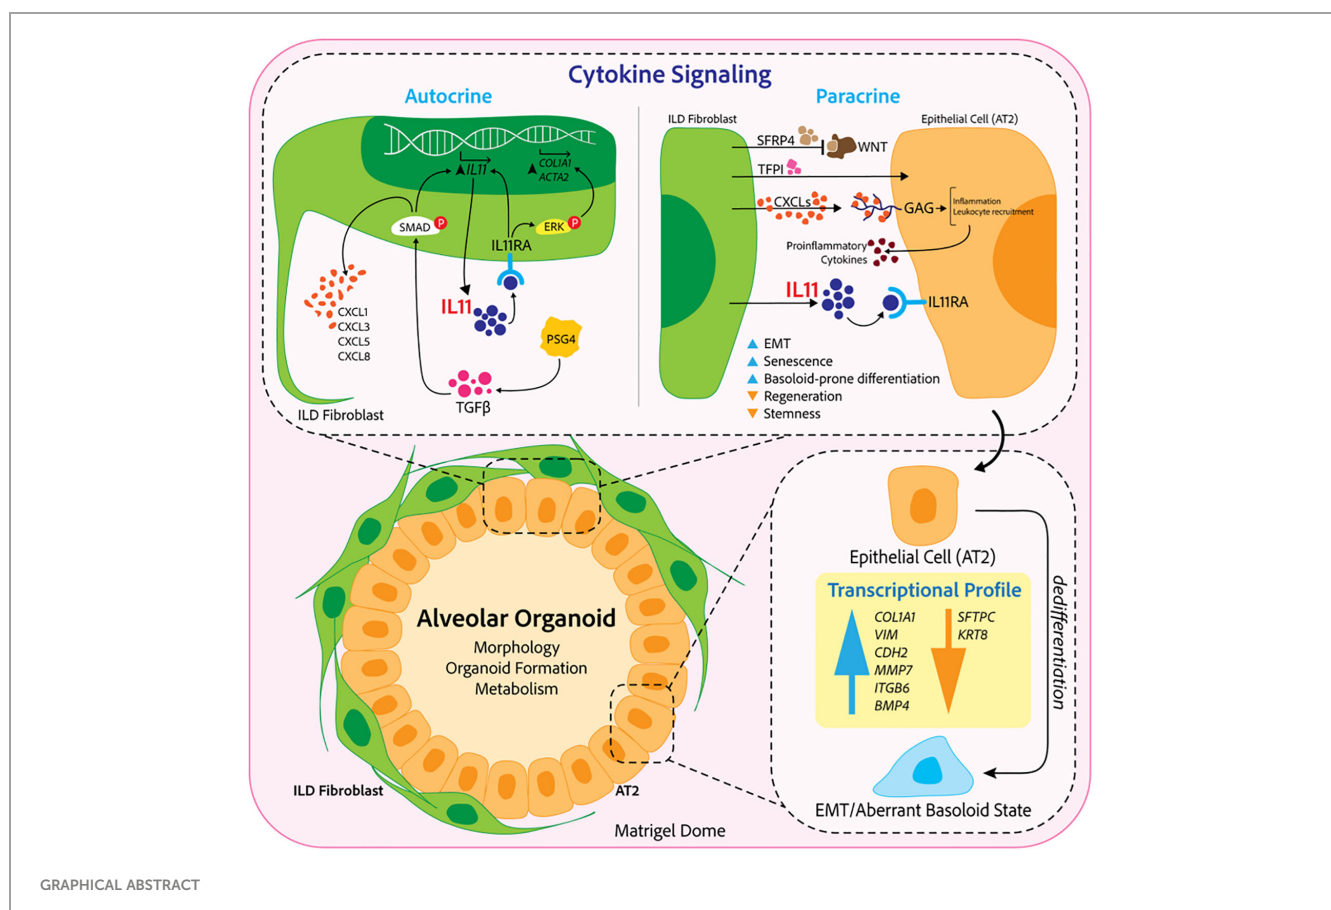

**Results:** While organoid formation capacity and size was comparable in the presence of fibrotic-ILD or control lung fibroblasts, metabolic activity was significantly increased in fibrotic-ILD co-cultures. Alveolar organoids cultured with fibrotic-ILD fibroblasts further demonstrated reduced stem cell function as reflected by reduced Surfactant Protein C gene expression together with an aberrant basaloid-prone differentiation program indicated by elevated Cadherin

2, Bone Morphogenic Protein 4 and Vimentin transcription. To screen for key mediators of the misguided mesenchymal-to-epithelial crosstalk with a focus on disease-relevant inflammatory processes, we used mass spectrometry and characterized the secretome of end stage fibrotic-ILD lung fibroblasts in comparison to non-chronic lung disease (CLD) patient fibroblasts. Out of the over 2000 proteins detected by this experimental approach, 47 proteins were differentially abundant comparing fibrotic-ILD and non-CLD fibroblast secretome. The fibrotic-ILD secretome profile was dominated by chemokines, including CXCL1, CXCL3, and CXCL8, interfering with growth factor signaling orchestrated by Interleukin 11 (IL11), steering fibrogenic cell-cell communication, and proteins regulating extracellular matrix remodeling including epithelial-to-mesenchymal transition. When in turn treating alveolar organoids with IL11, we recapitulated the co-culture results obtained with primary fibrotic-ILD fibroblasts including changes in metabolic activity.

**Conclusion:** We identified mediators likely contributing to the disease-perpetuating mesenchymal-to-epithelial crosstalk in ILD. In our alveolar organoid co-cultures, we were able to highlight the importance of fibroblast-initiated aberrant epithelial differentiation and confirmed IL11 as a key player in fibrotic-ILD pathogenesis by unbiased fibroblast secretome analysis.

#### KEYWORDS

cytokine, *IL11*, secretome, interstitial lung disease, organoids, human pluripotent stem cells, disease modeling, co-culture model

# 1 Introduction

Interstitial lung diseases (ILDs) comprise a variety of chronic pulmonary conditions that are characterized by structural remodeling of the gas exchange area (1). ILD pathophysiology is centered on sustained inflammation and progressive scarring, ultimately resulting in irreversible tissue destruction and organ failure. Despite the exact pathogenesis of ILD still being unclear, genetic predisposition, age, sex and environmental exposure are known drivers of the disease (2, 3).

In ILD pathogenesis, fibroblast activation occurs through the impact of exogenous stimuli side-by-side with their activation through innate immune cells, especially monocytes and neutrophils, communicating *via* growth factor signaling and cytokine secretion. Subsequently, lactic acid release from fibroblasts as well as epithelial cells, induced by matrix metalloproteinases (MMPs), fibroblast growth factors and metabolic changes in turn further enhances fibroblast activation and accumulation (4). As a result, fibroblasts become the main loci of extracellular matrix (ECM) production and deposition. Induced by repeated inflammatory epithelial injury that leads to further leucocyte attraction and infiltration of the airspace and further perpetuating the pro-fibrotic circle of events, activated fibroblasts are discussed to induce epithelial-to-mesenchymal transition (EMT) in alveolar epithelial cells *via* SMAD and MAPK signaling (5), (6).

Driving and upholding the outlined pathophysiologic processes in ILD that ultimately result in severe tissue destruction and loss of the alveolar epithelium in end-stage ILD, a tightly knit crosstalk between the activated fibroblast and the damaged epithelium has been proposed (7–9). Here, the role of pathologic growth factor signaling and secreted cytokines such as *transforming growth factor*  $\beta$  (TGF- $\beta$ ) and *Interleukin 17* (IL17) were highlighted.

Adding to their detrimental role, activated fibroblasts – next to their capacity for pro-fibrotic signaling and EMT induction – have been shown to alter repair and regeneration of the injured gas-exchange area by affecting alveolar epithelial type 2 stem cell potential (10).

To address apparent knowledge gaps in the cytokine-driven, disease-relevant mesenchymal-to-epithelial crosstalk, we used lung organoids derived from human induced pluripotent stem cells (hiPSCs) through chemical directed differentiation into a sophisticated co-culture model. hiPSC-derived alveolar type 2 cells (iAT2s) are recognized as a useful tool to study lung diseases and regeneration capacities, and are recently emerging as a novel tool in environmental and occupational hazard assessment (11, 12). iAT2-derived alveolar organoids recapitulate the characteristic three-dimensional (3D) structure of alveoli and are thereby ideal to mimic important functions of the gas exchange area *in vitro*. Their potential to study pulmonary disease *in vitro* (13, 14) is particularly versatile when targeting underlying molecular mechanisms (3).

By the integration of this sophisticated methodology in a novel co-culture model, we were able to investigate the impact of primary lung fibroblasts from ILD patients, in our study referring to cases of

pulmonary fibrosis, on critical functions of hiPSC-derived alveolar organoids. The combination of this approach with unbiased secretome analysis allowed us to delineate functionally relevant signals of the pathologic crosstalk from the lung mesenchyme towards the alveolar epithelium with the aim to identify potential therapeutic targets.

# 2 Material and methods

## 2.1 Human induced pluripotent stem cells (hiPSCs) and directed differentiation into lung progenitors

The hiPSC line BU3NGST was kindly provided by Prof. Darrell Kotton, Boston University, Center for Regenerative Medicine. This cell line is a dual-reporter construct composed of fluorochrome-encoding cassettes targeted to the endogenous NKX2.1 and SFTPC loci (BU3 NKX2.1<sup>GFP</sup>; SFTPC<sup>tdTomato</sup>) (15). hiPSCs were maintained in mTeSR1 (StemCell Technologies), on Matrigel (Corning) coated cell culture plates at 37°C/5% CO<sub>2</sub> in a cell culture CO<sub>2</sub> incubator. Cells were subcultured by using ReLeSR (StemCell Technologies) or Gentle Cell Dissociation Reagent (StemCell Technologies) (16, 17).

BU3NGSTs were differentiated into NKX2.1<sup>+</sup> lung progenitor cells and iAT2s as described previously by Jacob et al. (16, 17). In short, hiPSCs were checked for their pluripotency *via* Alkaline Phosphatase staining (ES Cell Characterization Kit, CHEMICON International) or immunofluorescence staining of TRA 181 and SSEA 4 (ES cell characterization Kit, CHEMICON International). Induction of definitive endoderm was conducted *via* STEMdiff Definitive Endoderm Kit, (StemCell Technologies). On day 14 of differentiation, lung progenitor specification was evaluated by immunofluorescence staining of NKX2.1 (Invitrogen) and Albumin (ALB, R&D Systems). NKX2.1<sup>GFP+</sup> lung progenitor cells were enriched by GFP signal for NKX2.1 based on a previously described protocol. The sorting was performed by FACS cell sorting at MACSQuant Tyto Cell Sorter (Miltenyi Biotec). For data evaluation FlowJo Version 7.2.1 and v10 was used. Purified lung progenitors were seeded in Matrigel (Corning) domes at a cell density of 50 cells/ $\mu$ L and passaged every second week. To increase SFTPC<sup>tdTomato+</sup> cells CHIR withdrawal and addback was performed. At day 45 of differentiation, iAT2s were enriched by flow cytometry (MACSQuant Tyto Cell Sorter, Miltenyi Biotec) using tdTomato signal for SFTPC expression and subsequently cultured as 3D alveolar organoids. Differentiated SFTPC<sup>tdTomato+</sup> iAT2s in 3D Matrigel were grown in CK+DCI medium, with media changes every 48 – 72 h. Alveolar organoids were passaged every 14 days.

## 2.2 Primary human fibroblast culture

Primary human lung fibroblasts from ILD patients, in our study referring to cases of pulmonary fibrosis, and non-CLD (P4) for co-culture experiments (ILD fibroblasts) and MS based secretome

analysis (ILD and non-CLD fibroblasts) were isolated according to a published protocol (18) and obtained through the CPC-M bioArchive at the Comprehensive Pneumology Center in Munich, Germany.

All patients underwent surgery at the LMU Hospital and the Asklepios Pulmonary Hospital Munich-Gauting. Tissue from ILD patients ( $n = 3$ , Table 1) was provided through lung transplantation. Control fibroblasts were derived from lung tissue resections of age-matched non-CLD patients (female  $n = 1$ ,  $n = 3$ , male  $n = 2$ ).

The study was approved by the local ethics committee of the Ludwig-Maximilians University of Munich, Germany (Ethic vote #333-10) and written informed consent form was obtained for all study participants.

Human fetal lung fibroblasts (IMR-90, P8) for control co-cultures were obtained from ATCC (Catalog # CCL-186<sup>TM</sup>) and grown in Dulbecco's Modified Eagle Medium: Nutrient F-12 (DMEM/F12; Gibco) with 20% fetal bovine serum (FBS SUPERIOR, Sigma) and 1% penicillin-streptomycin (Pen Strep, Gibco).

Cells were seeded in 6-well plates, at a density of  $1 \times 10^5$  cells in 2 mL media (DMEM/F12, 20% FBS, 1% penicillin/streptomycin) per well until reaching 80% confluency. Once confluent, each well was washed three times with a 15-minute incubation per wash with 1 mL of FBS-free culturing medium (DMEM/F12, 1% penicillin/streptomycin) to eliminate remaining FBS. Fibroblasts were cultured for 48 h in FBS-free medium, supernatants were collected and stored at  $-80^\circ\text{C}$  for further analysis.

## 2.3 Secretome analysis by mass spectrometry

### 2.3.1 Sample preparation for proteomics

Each 500  $\mu\text{L}$  supernatant was subjected to tryptic digest applying a modified filter aided sample preparation procedure (19, 20). After protein reduction and alkylation using DTT and iodoacetamide, samples were denatured in UA buffer (8 M urea in 0.1 M Tris/HCl pH 8.5) and centrifuged on a 30 kDa cut-off filter device (PALL or Sartorius) and washed thrice with UA buffer and twice with 50 mM ammoniumbicarbonate (ABC). Proteins were proteolysed for 2 h at room temperature using 0.5  $\mu\text{g}$  Lys-C (Wako) and subsequently for 16 h at  $37^\circ\text{C}$  using 1  $\mu\text{g}$  trypsin (Promega). Peptides were collected by centrifugation and acidified with 0.5% trifluoroacetic acid.

### 2.3.2 Mass spectrometric measurements

LC-MSMS analysis was performed on a Q-Exactive HF mass spectrometer (Thermo Scientific) each online coupled to a nano-RSLC (Ultimate 3000 RSLC; Dionex). For subsequent analysis on the Q-Exactive HF, tryptic peptides were accumulated on a nano trap column (300  $\mu\text{m}$  inner diameter  $\times$  5 mm, packed with Acclaim PepMap100 C18, 5  $\mu\text{m}$ , 100  $\text{\AA}$ ; LC Packings) and then separated by reversed phase chromatography (nanoEase MZ HSS T3 Column, 100  $\text{\AA}$ , 1.8  $\mu\text{m}$ , 75  $\mu\text{m}$   $\times$  250 mm; Waters) in a 80 minutes non-linear gradient from 3 to 40% acetonitrile in 0.1% formic acid at a flow rate of 250 nL/min. Eluted peptides were analyzed by the Q-Exactive HF mass spectrometer equipped with a PepSep PSS1 source. Full scan MS spectra (from  $m/z$  300 to 1500) and MSMS fragment spectra were acquired in the Orbitrap with a resolution of 60,000 or 15,000 respectively, with maximum injection times of 50 ms each. The up to ten most intense ions were selected for HCD fragmentation depending on signal intensity (TOP10 method). Target peptides already selected for MS/MS were dynamically excluded for 30 seconds. Data are available *via* ProteomeXchange with identifier PXD039554 (21, 22).

### 2.3.3 Protein identification and label-free quantification

Proteome Discoverer 2.5 software (Thermo Fisher Scientific; version 2.5.0.400) was used for peptide and protein identification *via* a database search (Sequest HT search engine, SequestHT score:1) against Swissprot human database (Release 2020\_02, 20432 sequences), considering full tryptic specificity, allowing for up to two missed tryptic cleavage sites, precursor mass tolerance 10 ppm, fragment mass tolerance 0.02 Da. Carbamidomethylation of Cys was set as a static modification. Dynamic modifications included deamidation of Asn, Gln and Arg, oxidation of Pro and Met; and a combination of Met loss with acetylation on protein N-terminus. Percolator was used for validating peptide spectrum matches and peptides, accepting only the top-scoring hit for each spectrum, and satisfying the cutoff values for false discovery rate (FDR)  $< 5\%$ , and posterior error probability  $< 0.01$ .

The quantification of proteins was based on abundance values for unique peptides. Abundance values were normalized on total peptide amount and protein abundances were calculated summing up the abundance values for admissible peptides. The final protein ratio was calculated using median abundance values. The statistical significance of the ratio change was ascertained employing the T-test approach

TABLE 1 Patient characteristics.

Patient	Diagnosis	Age at sample collection (years)	Sex	Surgery	Smoking history
1	Connective Tissue Disease related ILD	48	F	Lung transplantation (single)	no
2	Idiopathic pulmonary fibrosis	62	M	Lung transplantation (single)	no
3	Hypersensitivity Pneumonitis, Rheumatoid arthritis	57	F	Lung transplantation	no

described in 23 (23), which is based on the presumption that we look for expression changes for proteins that are just a few in comparison to the number of total proteins being quantified. The quantification variability of the non-changing “background” proteins can be used to infer which proteins change their expression in a statistically significant manner. Proteins with increased or decreased abundance were filtered with the following criteria: proteins were considered to be decreased in abundance below an abundance of ratio of 0.5 fold and increased abundance above 2 fold, proteins identified with a single peptide were excluded and just significant proteins were considered ( $P$  value  $< 0.05$ ,  $P$  values were adjusted for multiple testing by Benjamini-Hochberg correction). Additionally, at least two MSMS identifications had to be identified to include the protein ratio.

### 2.3.4 Enrichment analysis

Pathway enrichment analyses were performed in Cytoscape (3.9.0) with the ClueGo plugin (v2.5.8) for significantly increased or decreased proteins. The following ontologies were used: KEGG (8093), GO\_MolecularFunction-EBI-UniProt (18336), GO\_BiologicalProcess-EBI-UniProt (18058). Accession IDs were used as identifiers and the analysis was performed with the standard software settings provided in the ClueGo app (24).

## 2.4 Mesenchymal-epithelial co-culture

Primary lung ILD fibroblasts and IMR-90 (control fibroblast cell line) were grown in cell culture flasks until 70% confluency. A single cell suspension was prepared using 0.25% EDTA-Trypsin (Gibco). iAT2s were grown into alveolar organoids for up to two weeks in Matrigel domes. Single cell suspension was obtained with Dispase (Corning) and 0.25% EDTA-Trypsin as described by Jacob et al. (17). Human ILD and IMR-90 fibroblasts as well as iAT2s were counted and directly seeded either in equal 1:1 ( $F_{low}$ ) or 1:5 ( $F_{high}$ ) iAT2s to fibroblasts seeding densities in undiluted Matrigel domes in 8-chamber wells (20  $\mu$ L Drops, Falcon), 96-well plates (50  $\mu$ L Drops, Greiner) or 12-well plates (50  $\mu$ L Drops, Greiner). Co-cultures used CK+DCI media that was changed every 48 h to 72 h for up to 12 days of cultivation.

## 2.5 Immunofluorescence microscopy

3D alveolar organoids mono- and co-cultures as described in section 2.1 (mono-culture) and 2.4 (co-culture) were cultured in 8-chamber wells for immunofluorescence analysis (Nunc Lab-Tek Chamber Slide System, 8-well, Permaxox slide, 0.8  $\text{cm}^2/\text{well}$ ). After alveolar organoids were formed, fixation was achieved with ice cold methanol and acetone (1:1v/v) for 5 minutes at  $-20^\circ\text{C}$ . Cells were washed with PBS and stained with the respective primary antibody in buffer containing 0.1% BSA and 0.1% Triton X-100 overnight at  $4^\circ\text{C}$ . The next day, cells were washed 3 times with PBS and incubated in buffer with the respective fluorescent conjugated secondary antibody at a dilution of 1:500 and DAPI diluted 1:1.000 overnight at  $4^\circ\text{C}$ . The following day, cells were washed

gently, growth camber removed and remaining microscope slide mounted with fluorescent mounting media (Dako) and covered with a coverslip. Slides were stored at  $4^\circ\text{C}$  until imaging. Imaging was performed using a confocal laser scanning microscope (CLSM) Zeiss LSM 880 with Airyscan and edited afterwards using ZEN 2.5 software (Zeiss). Detailed information on the primary and secondary antibodies are given in [Supplementary Table 1](#).

## 2.6 Operetta high content imaging and Napari organoid counter

Live imaging of all alveolar organoid mono- and co-cultures was performed using the Operetta CLS high-content analysis system (Operetta CLS, PerkinElmer) at time points 5, 8 and 12 days during the co-culture experimental set-up. Pictures were analyzed by the Harmony 3.5.2 high-content imaging and analysis software with PhenoLOGIC.

Multi-plane confocal 3D images were visualized in Napari image viewer (Python) as maximum intensity projections and the automatic measurements obtained from the “Napari organoid counter” (25) were visually checked and manually curated, resulting in output of size and numbers of formed alveolar organoids between iAT2s and human fibroblasts (ILD and control IMR-90). The Canny Edge Detection (26) algorithm is used for identifying the organoids, while pre- and post-processing steps have been included, to ensure the image matches the detector’s expected input and the number of detected organoids along with their size is returned. More specifically, the organoids are approximated to ellipses and the algorithm fits orthogonal bounding boxes around each, with the height and width of each box corresponding to the two diameters of the organoid which are then in turn used to approximate the object’s area. Quantitative real-time PCR

Co-cultures were lysed in RLT Plus Lysis Buffer (Qiagen) and RNA isolation was performed with the RNeasy Mini Kit (Qiagen) according to the manufacturer’s instructions. Cell lysis from organoids and co-culture assays was performed with peqGOLD TriFast (VWR Life Science) as recommended by the manufactures followed by RNA isolation with the RNeasy Mini Kit (Qiagen). RNA was transcribed into cDNA by reverse transcriptase using the High-Capacity cDNA Reverse Transcription Kit (Thermo Fisher Scientific) according to the manufacturer’s instructions. 5 ng of cDNA was added to a final concentration volume of 10  $\mu$ L, Random Nonamers (Metabion) and master mix (Invitrogen, Thermo Fisher Scientific) was added to each RNA sample. cDNA was diluted with ultrapure  $\text{H}_2\text{O}$ . qPCR was performed in 96-well format using the quantitative real-time PCR System (Roche 480 LightCycler). 2  $\mu$ L cDNA were added to a final reaction volume of 10  $\mu$ L containing  $\text{H}_2\text{O}$ , 480 SYBR Green (LightCycler, Roche Diagnostics) and the primer mix (100  $\mu\text{M}$ ). Gene expression was normalized to  $\beta$ -Actin control for genes *Vimentin* (VIM), *Integrin Subunit Beta 6* (ITGB6) and *Cadherin 2* (CDH2), and normalized to an average of  $\beta$ -Actin and *HRPT* control for genes *Surfactant Protein C* (SFTPC), *Keratin 8* (KRT8), *Collagen 1A1* (Col1A1), *Matrix Metalloproteinase* (MMP7) and *Bone*

*Morphogenic Protein 4 (BMP4)*, the fold change was calculated using the  $2^{-\Delta(-\Delta C_T)}$  method. Sequence information of used primers are given in [Supplementary Table 2](#). Data obtained from qPCR are presented relative to respective control co-cultures, to demonstrate influence of disease background.

## 2.7 Metabolic activity estimated by WST-1 assay

WST-1 assays were performed at day 2, 3, 5 and 7 of alveolar organoid co-cultures (human ILD or IMR-90 control fibroblasts). WST-1 reagent (Roche Diagnostics) was added to the culture medium in a 1:10 dilution. The culture medium was used as background control. After 2 h of incubation at 37°C and 5% CO<sub>2</sub>, 100 µL of media from every sample was transferred to a microplate (Thermo Scientific; Fisher Scientific) and the absorbance of the sample against the background was measured with a TECAN reader (TECAN; infinite M200 PRO).

## 3 Results

### 3.1 Fibroblast induced changes in organoid formation and metabolic activity in co-cultured alveolar organoids

An overview of the experimental workflow is provided in [Supplementary Figures 1A–C](#). iAT2s ([Figure 1A](#)) were successfully co-cultured with both ILD, in our study referring to cases of pulmonary fibrosis, or IMR-90 control fibroblasts, resulting in the formation of proliferative alveolar organoids ([Figure 1B](#)). Cell-cell contact of iAT2s and fibroblasts in (ILD) co-culture was demonstrated by partial encapsulation of alveolar organoids by  $\alpha$ -SMA expressing fibroblasts ([Figure 1C](#), white arrows).

Image analysis of the 3D co-cultures revealed a reduction in organoid formation capacity in the presence of human fibroblasts ([Figure 1D](#)). Although alveolar organoid size was not significantly affected by fibroblast co-culture ([Figures 1B, E](#)), quantitative assessment of organoid size (area,  $\mu\text{m}^2$ ) and number of images obtained from alveolar organoids and co-cultures with either ILD or IMR-90 control fibroblasts in 1:1 ( $F_{\text{ILD/Control low}}$ ) or 1:5 ( $F_{\text{ILD/Control high}}$ ) seeding density ([Figures 1B, D](#)) demonstrated a negative correlation of fibroblast seeding density (ILD or IMR-90) with the alveolar organoid formation capacity.

In contrast, co-culture with ILD fibroblasts significantly increased metabolic activity of alveolar organoid in comparison to IMR-90 control co-cultures ([Figure 1F](#)).

### 3.2 Presence of ILD fibroblasts leads to aberrant epithelial gene expression changes

In order to relate the observed changes in organoid formation capacity and metabolic activity ([Figure 1](#)) to changes in gene

expression, we measured critical markers of stem cell function and epithelial differentiation in co-cultured organoids.

Indicating changes in (stem) cell function and epithelial injury, we showed decreased expression of the alveolar stem cell marker *SFTPC* in the presence of ILD fibroblasts in both seeding ratios ( $F_{\text{low}}$  and  $F_{\text{high}}$ ; [Figure 2A](#)). In line with this, *Keratin 8 (KRT8)* expression levels were reduced under the impact of ILD primary fibroblasts ([Figure 2A](#)). Further, the distal epithelial marker *Integrin Subunit Beta 6 (ITGB6)* as well as *Bone Morphogenetic Protein 4 (BMP4)* showed increased transcription in ILD co-cultures when high seeding densities were applied ([Figure 2A](#)). Genes associated with regulation of extracellular matrix formation and remodeling including *Collagen 1A1 (Col1A1)*, *N-Cadherin 2 (CDH2)* and *Vimentin (VIM)* showed increased expression in alveolar organoids co-cultured with ILD fibroblasts in high seeding ratios ([Figure 2B](#)). Likewise, expression levels of *Matrix Metalloproteinase 7 (MMP7)* were increased in ILD co-cultures compared to control co-cultures. ([Figure 2B](#)).

### 3.3 ILD fibroblast secretome reveals proinflammatory signaling converging on *IL11* stimulating epithelial remodeling

To characterize fibroblast driven communication resulting in gene expression and phenotypical changes in the alveolar epithelium in ILD, supernatants of ILD and non-CLD fibroblasts were subjected to mass spectrometry (MSMS).

MS analysis detected an overall of 2625 expressed proteins, of which 47 were significantly more and 55 significantly less abundant when comparing ILD-derived fibroblast to non-CLD controls ([Supplementary Table 3, 4, Figure 3A](#)). The top 15 differentially expressed proteins (increased and decreased abundance) are listed in [Supplementary Tables 1, 2](#).

Proteins with increased abundance predominantly belonged to the C-X-C motif chemokine family (*CXCL1*, *CXCL3*, and *CXCL8*), as well as to the interleukin family (*IL13RA*, *IL11*) and included gap junction proteins (*connexin 43*, *GJA1*). Further, *Pregnancy Specific Beta-1-Glycoprotein 4 (PSG4)* as well as WNT signaling modulator *SFRP4* were found amongst the top 15 proteins.

Accordingly, pathway enrichment analysis of proteins with increased abundance classified the responses as cytokine activity, chemokine-mediated signaling pathway and TNF-signaling pathway. Furthermore, cellular/response to chemokines, *IL17* signaling pathways and neutrophil chemotaxis were identified, indicative of a strong inflammatory response.

ClueGo, a Cytoscape plug-in for network analysis, highlighted proteins associated with rheumatoid arthritis, a disease often complicated by the development of lung fibrosis and characterized by the presence of inflammatory chemokines ([Figure 3B](#)).

Proteins with decreased abundance in the in ILD secretome were dominated by candidates involved in ECM production, ECM assembly or ECM reorganization as well as coordination of myofibroblast differentiation (*PDGFRL*) together with a downregulation of proteins involved in complement and coagulation cascade pathways ([Figure 3C](#)).

(A) Representative maximum intensity projections from high-content images of iAT2s growing as alveolar organoids at day 12. Scale bar 500 μm. (B) Immunofluorescence of 3D co-culture of iAT2s with IL2D fibroblasts at day 12 (α-SMA: red, DAPI: cyan). Scale bar 50 μm. (C) Representative maximum intensity projections from high-content images of different co-culture conditions showing iAT2s growing with human fibroblasts for 12 days. Scale bar 500 μm. Zoom-ins show a 3x optical magnification. (D) Scatter plots (dashed black lines: median) indicate size (μm<sup>2</sup>) of organoids in co-cultures at day 12 across three independent biological replicates. (E) Number of formed organoids in co-cultures at day 12, N = 3. (F) Metabolic activity of co-cultured organoids at 5, 8 and 12 days of co-culture. Results show the increase in percentage across two biological replicates in comparison to d5 iAT2 organoids alone, representing the baseline of 100% metabolic activity (dashed grey line across dataset). Statistics: unpaired t-Test, \*p<0.05, \*\*p<0.01.

### 3.4 *IL11* acts as a driver for aberrant signatures in hiPSC-derived alveolospheres

Based on the MSMS secretome analysis, *IL11* emerged as a top player in the mesenchymal-to-epithelial disease crosstalk. In consequence, we exposed alveolar organoids (Figure 4A) to *IL11*

in order to investigate its functional relevance. Experiments (Dose<sub>low</sub> = 0.5 ng/mL, Dose<sub>high</sub> = 5 ng/mL) (Figures 4B–D) recapitulated the results observed in epithelial-fibroblasts co-cultures (section 3.1), i.e., we demonstrated reduced organoid formation capacity (Figures 4Biii, C) and increased metabolic activity (WST-1) in *IL11* treated alveolar organoids (treatment

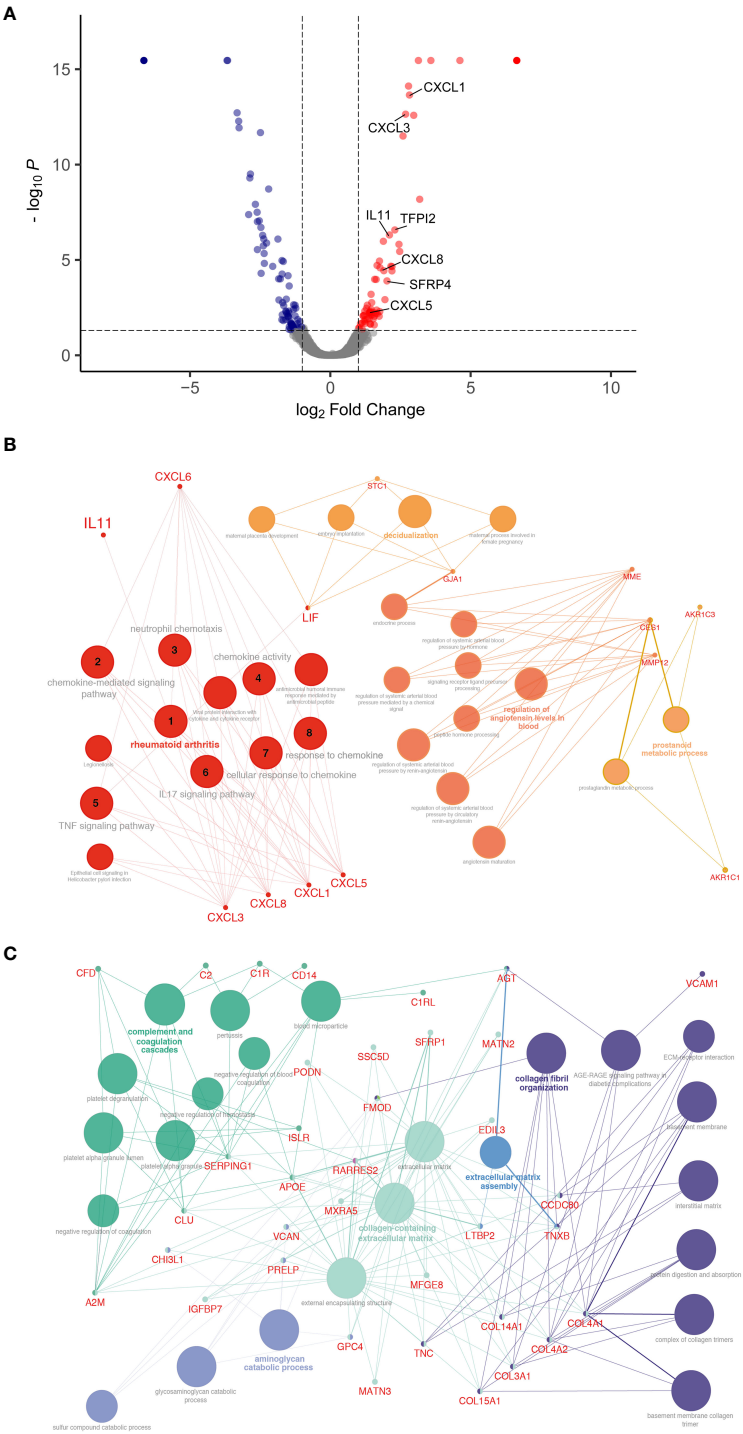

**FIGURE 2**  
Relative gene expression at day 12 measured in AT2s co-cultures with ILD or IMR90 control fibroblasts in two seeding densities (high or low) compared to reference gene expression (HK; average of  $\beta$ -Actin (*ACTB*) and hypoxanthine guanine phosphoribosyl transferase (*HRPT*)). **(A)** Epithelial and stem cell markers and **(B)** Genes associated with aberrant differentiation of epithelium. N = 3, unpaired t-Test, \*\*p<0.005, \*\*\*p<0.0005.

from day 7 - 14 of culture) (Figure 4D). In addition, treatment of growing alveolar organoid monocultures with *IL11* (20 ng/mL) led to an increase in alveolar organoid size followed by apoptosis within 5 days of culture.

## 4 Discussion

In ILD, sustained inflammation and scarring of the gas exchange area ultimately result in destruction of the pulmonary

**FIGURE 3**  
Differential protein expression comparing ILD fibroblasts ( $F_{ILD}$ ) vs. non-chronic lung disease fibroblasts ( $F_{control}$ ). **(A)** Volcano plot visualizing significantly regulated proteins (47 up, 55 down) detected by MS secretome analysis of ILD or non-CLD control fibroblasts. Data showing  $\log_2$  fold change against the adjusted P value [ $\log_{10}$ ]. Significantly upregulated proteins are depicted in red and significantly downregulated proteins in blue. (Total: 102 significantly regulated proteins with 5% FDR < 0.05, adj. p-value < 0.05). Pathway enrichment and protein interaction network of proteins with **(B)** increased and **(C)** decreased abundance using the Cytoscape plugin ClueGo. The following ontologies were used: KEGG, molecular functions and biological processes. The connectivity of the pathways is described by functional nodes and edges that are shared between proteins with a kappa score of 0.4. Only enriched pathways are visualized and the node size indicates the p-value (p-value  $\leq$  0.05). Proteins from the same pathway share the same node color and the bold fonts indicate the most important functional pathways that define the names of each group. Enriched Pathways: 1. rheumatoid arthritis, 2. chemokine-mediated signaling pathway, 3. neutrophil chemotaxis, 4. chemokine activity, 5. *TNF* signaling pathway, 6. *IL17* signaling pathway, 7. cellular response to chemokine, 8. response to chemokine.

(B) Representative maximum intensity projections from high-content images of (i) untreated alveolar organoids, (ii) 0.5 ng/mL or (iii) 5 ng/mL *IL11* treatment. Treatment started at day 7 of culture every 48h. Scale bar, 500  $\mu$ m. (C) Organoid formation capacity of alveolar organoids treated with 0.5 or 5ng/mL *IL11*. (D) Metabolic activity of alveolar organoids treated with 0.5 or 5ng/mL *IL11*. (C, D) Each value is graphed as percentage of the respective starting culture at day 7 set to 100%.

scaffold and organ failure. Excessive deposition of ECM as well as epithelial damage and dedifferentiation is widely transmitted by the misguided interaction of fibroblasts and epithelial cells (27). Therefore, improved understanding of the mesenchymal-to-epithelial crosstalk remains a centerpiece in finding new avenues to monitor and treat ILD. However, signaling factors with functional relevance and their distinct role in ILD pathogenesis remain understudied.

This study aimed at deciphering disease-relevant candidates of mesenchymal-to-epithelial crosstalk that could serve as potential targets for future therapeutic strategies. By advancing a sensitive human iPSC-derived alveolar organoid culture into a human fibroblast co-culture model, we successfully demonstrated the importance of fibroblast-driven, cytokine-centered signaling in inducing the impairment of key epithelial cell functions, including differentiation and metabolism. In combination with an unbiased proteomic approach, we were able to identify important mediators

that translate these effects such as *IL11*, one of the top 15 proteins with increased abundance in ILD, in our study referring to cases of pulmonary fibrosis. The previously identified role of *IL11* in chronic inflammatory lung diseases in line with its potential to drive pro-fibrotic mesenchymal-epithelial crosstalk, supported the relevance of our approach on the one hand, while we were able to contribute the important functional consequences of its signaling in our human alveolar organoid model on the other (7, 8, 28).

In our *in vitro* co-culture approach, primary human pulmonary fibroblasts and iAT2s formed alveolar organoids that successfully recapitulated tissue characteristics of the distal lung in three dimensions, in contrast to 2D, plastic culture conditions (Figure 1). Primary human fibroblasts, both ILD-derived and IMR-90 control cells, demonstrated effects that correlated with seeding density leading to reduced organoid number and increased organoid size after 12 days of co-culture. The findings indicate that the co-culture with fibroblasts per se is able to change

the microenvironment of iAT2s, thereby impacting organoid formation. As studies indicated, that the activation of primary lung fibroblasts in a disease-comparable fashion is easily achieved (29), our findings likely explain the disease-independent fibroblast effects in alveolar organoids.

In contrast, the significant increase in metabolic activity was provoked by diseased human fibroblasts in high-seeding ratios, indicating their potential to impact on the metabolic program of the epithelial cell, potentially indicating epithelial dedifferentiation or EMT (30–32). These considerations are supported by the expression signature characterizing the co-cultures: The decrease in *SFTPC* expression (33–36) we observed in the ILD co-cultures points towards the loss of epithelial stem cell characteristics, as *SFTPC* expression is sensitive to epithelial inflammation and injury, lately supported by studies in Sars-CoV-2 infected alveolar organoids (10). Differentiation of AT2s is key for regeneration in injured alveoli marked by their expression of transient basaloid features such as *Keratin 5* (*KRT5*) and the amount of alveolar *KRT5*<sup>+</sup> basaloid cells directly correlates with disease progression in pulmonary fibrosis (29, 37, 38), mirrored by the decreased expression observed in our study. Closely related, downregulation of *KRT8*, an important marker of AT2 to (pre)AT1 transdifferentiation during epithelial regeneration (38, 39) was associated with the increased expression of EMT markers in a murine bleomycin lung injury model including pro-fibrogenic proteins such as *ITGB6* (39). In line with these findings, we demonstrated increased *ITGB6* expression in ILD co-cultures. Its release from the plasma membrane potentially reflects the activation of EMT-like processes in lung organoids, accompanied by the decrease of expressed *KRT8*. Further supporting these findings, we showed the elevated expression of *BMP4* and *MMP7*, critical regulators of EMT in pulmonary fibrosis (40), in lung organoids co-cultured with ILD fibroblasts. *MMP7* has furthermore been highlighted for its function as a plasma biomarker in idiopathic pulmonary fibrosis (33, 41), in line with its detection in our study.

Co-culture of alveolar organoids with ILD fibroblasts also specifically changed the expression of genes involved in ECM biosynthesis including the increased transcription of *Col1A1*, *VIM* and *CDH2*, well-known players in fibrotic lung disease (33, 34) (38), as compared to organoid monocultures. Linking back to the indications of aberrant basal transdifferentiation in fibroblast co-culture discussed above (29), the basaloid cells show increased ECM protein expression, next to their increase in *BMP4* and *ITGB6* expression, again successfully detected in our model.

We next were able to provide deeper insight into the relevant mediators of mesenchymal-to-epithelial crosstalk related to the observed changes in organoid phenotype by screening the supernatant of ILD or control fibroblasts using mass spectrometry (42). Cytokines that belong to the C-X-C motif family dominated the protein signature in the secretome, demonstrating their increased abundance in ILD. These signaling molecules act on the *CXCR1* and *CXCR2* receptor, as well as regulate the expression of cytokines from the interleukin family, central to the pathogenesis of fibrotic and inflammatory lung diseases such as IPF and acute respiratory distress syndrome (3, 8, 36, 43). The majority of the differentially abundant proteins are proinflammatory cytokines that

primarily act on neutrophil, monocyte or lymphocyte recruitment (*CXCL1*, *CXCL3*, *CXCL5*, *CXCL8*). The proinflammatory response is complemented by the regulation of proteins that play a role in cellular senescence and activation of *TGF-β* such as the Pregnancy-Specific Glycoprotein (PSG) family, *PSG 4*, *5*, *6* or in the induction of a hypercoagulable tissue state (*TFPI2*). Other important proteins such as *SFRP4* directly inhibit WNT signaling, thereby modulating cell growth and differentiation, particularly of AT2s to AT1s (44). WNT serum levels are discussed as biomarkers for lung fibrosis and EMT. WNT modulation and *TGF-β* solubilization in particular could account for the change in organoid number and size and support our observations in gene expression levels that indicate epithelial transdifferentiation into aberrant basaloid cells or EMT in the presence of ILD fibroblasts.

*IL11*, centrally orchestrating the ILD protein profile as observed by pathway enrichment, was identified among the top 15 candidates in the ILD fibroblast secretome. *IL11* is known to be expressed in pro-inflammatory fibroblasts extracted from IPF lungs. The cytokine belongs to the *IL6* family and is induced by *TGF-β* and other proinflammatory mediators [*IL1β*, *IL17*, *IL22*, reactive oxygen species (ROS)]. It can either activate fibroblasts to differentiate into myofibroblasts in an autocrine fashion through ERK/SMAD canonical signaling, which results in pro-fibrotic protein expression (*COL1A1*, *ACTA2*), or it stimulates epithelial cells (paracrine loop) through activating *ERK* signaling cascades, thereby inducing cellular senescence, EMT, cellular dysfunction and impaired regeneration (8). Results from our co-culture model indicate both autocrine and paracrine signaling of *IL11* as we demonstrated indication of EMT, stem cell dysfunction as well as ECM production, i.e., upregulation of collagen expression in line with 8 (8). Similar to the results obtained from ILD fibroblast co-culture in different seeding densities, *IL11* treatment of alveolar organoid monocultures resulted in a dose dependent increase in metabolic activity, elevated expression of mesenchymal markers and decreased AT2 stemness and identity. Dose-dependent, *IL11* even induced apoptotic cell death, in line with its role in senescence and stem cell function observed in alveolar organoids (36). Similarly, *IL11* alone induced fibrotic changes in healthy alveolar organoids whereas knock-out of *IL11* expression in diseased organoids reversed organoid fibrosis in a model of the Hermansky-Pudlak syndrome-associated interstitial pneumonia, a disease with high similarity to IPF (3). Supporting our co-culture findings in this regard, *IL11* exposure impacts on AT2 progenitor function, thereby likely suppressing the formation of mature AT2s as described by Kortekaas and colleagues (35, 36).

Taken together, our results strongly support the central role of *IL11* signaling as the cytokine holds the potential to strongly influence the intricate crosstalk between the (then activated (myo)) fibroblasts and the injured epithelium, central in the progression of fibrosis in ILD. We successfully demonstrated the potential of our lung organoid co-culture model derived from hiPSCs and primary fibroblasts to display critical consequences of the malfunctional crosstalk such as aberrant dedifferentiation and basaloid-prone signatures (33, 45). In this context, *IL11* likely holds an important role in misguided alveolar function, differentiation

and thereby regeneration, important functions as a potential therapeutic target to regain alveolar crosstalk homeostasis (46).

## Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article. The mass spectrometry proteomics data presented in the study have been deposited to the ProteomeXchange Consortium via the PRIDE partner repository with the dataset identifier PXD039554.

## Ethics statement

The studies involving human participants were reviewed and approved by Ludwig-Maximilians University of Munich, Germany. (Ethical vote #333-10). The patients/participants provided their written informed consent to participate in this study.

## Author contributions

MK, AH and CV conceived and planned the experiments. MK, EG-R, PC and EMG carried out the main experiments. FS and SA contributed to sample preparation. A-CK and SH performed the mass spectrometry analysis. LH performed additional data analysis and figure composition. CB, GB, MP and ML conceived, discussed and developed the AI based organoid counter. RAH headed patient sample retrieval and documentation and contributed clinical background to the study. MK, CV, TS, A-CK, SH, JB and AH contributed substantially to the interpretation of the results. MK and CV took the lead in writing the manuscript. All authors provided critical feedback and helped shape the research, analysis and drafting of the manuscript.

## Funding

This project was supported by the Research Training Group GRK2338 of the DFG, LMU Munich. Further funding was received by the German Center of Lung Research (DZL) and Helmholtz Munich.

Endometriosis is an estrogen dominant, chronic inflammatory disease characterized by the growth of endometrial-like tissue outside of the uterus. The most common symptoms experienced by patients include manifestations of chronic pelvic pain- such as pain with urination, menstruation, or defecation, and infertility. Alterations to Leukemia Inhibitory Factor (LIF), a cytokine produced by the luminal and glandular epithelium of the endometrium that is imperative for successful pregnancy, have been postulated to contribute to infertility. Conditions such as recurrent implantation failure, unexplained infertility, and infertility associated diseases such as adenomyosis and endometriosis, have demonstrated reduced LIF production in the endometrium of infertile patients compared to fertile counterparts. While this highlights the potential involvement of LIF in infertility, LIF is a multifaceted cytokine which plays additional roles in the maintenance of cell stemness and immunomodulation. Thus, we sought to explore the implications of LIF production within ectopic lesions on endometriosis pathophysiology. Through immunohistochemistry of an endometrioma tissue microarray and ELISA of tissue protein extract and peritoneal fluid samples, we identify LIF protein expression in the ectopic lesion microenvironment. Targeted RT qPCR for LIF and associated signaling transcripts, identify *LIF* to be significantly downregulated in the ectopic tissue compared to eutopic and control while its receptor, *LIFR*, is upregulated, highlighting a discordance in ectopic protein and mRNA LIF expression. *In vitro* treatment of endometriosis representative cell lines (12Z and hESC) with LIF increased production of immune-recruiting cytokines (MCP-1, MCP-3) and the angiogenic factor, VEGF, as well as stimulated tube formation in human umbilical vein endothelial cells (HUVECs). Finally, LIF treatment in a syngeneic mouse model of endometriosis induced both local and peripheral alterations to immune cell phenotypes, ultimately reducing immunoregulatory CD206<sup>+</sup> small peritoneal macrophages and T regulatory cells. These findings suggest that LIF is present in the ectopic lesions of endometriosis patients and could be contributing to lesion vascularization and immunomodulation.

## KEYWORDS

leukemia inhibitory factor (LIF), endometriosis, vascularization, cytokine, immunomodulation, infertility

# 1 Introduction

Endometriosis, a chronic inflammatory gynaecological disease, is defined by the growth of endometrial like tissue outside of the uterus (1). Lesions, referred to as ectopic tissue, can manifest throughout the abdominal cavity constituting the subtypes of endometriosis based on lesion placement and depth: superficial peritoneal, deep infiltrating, and ovarian (2). While lesion presentation provides a means for categorizing disease stage, there is currently no relationship between endometriosis subtype and patient symptomatology. Symptoms such as chronic pelvic pain, pain with urination, and infertility, vary across patients and disease stages (3, 4). Of note, infertility is experienced by approximately 30–50% of endometriosis patients (5). The cause and effect are still unclear surrounding the association between infertility and endometriosis, however there are numerous mechanisms that have been proposed. In this context, Leukemia Inhibitory Factor (LIF) has been implicated as a contributor to endometriosis associated infertility (6, 7).

LIF is a pleiotropic cytokine of the interleukin (IL)-6 family, with involvements in reproductive processes such as embryo implantation and decidualization, as well as regulation of the immune response. LIF is produced by the endometrial luminal and glandular epithelium during the mid to late secretory phase and is imperative for successful pregnancy through the orchestration of stromal cell decidualization (8, 9). Pivotal findings determined that LIF knock out mice were unable to support blastocyst implantation, implicating a critical role for LIF in fertility (10). As such, LIF mRNA and protein, both content and localization within the endometrium, have been studied in a variety of infertility cohorts including unexplained infertility (11, 12), recurrent implantation failure (13, 14), as well as in diseases associated with infertility such as adenomyosis (15, 16) and endometriosis (6, 7). Consistently it has been shown through immunohistochemistry (IHC) of the endometrium that the infertile cohorts- regardless of cause, have reduced endometrial LIF protein expression compared to fertile controls. This is in concert with cervical lavage samples from infertile adenomyosis patients obtained during the mid to late secretory phase, which had significantly lower LIF protein compared to fertile controls (15). In patients with mild to moderate endometriosis who are experiencing infertility, LIF expression was reduced in endometrial samples obtained during the mid-secretory phase, combined with elevated IL-6 and IL-1 $\alpha$  in the peritoneal fluid (PF) (7). These inflammatory mediators were hypothesized to be a contributor to patient infertility yet the broader implications of LIF dysregulation within endometriosis pathophysiology have not been speculated upon and remain to be explored.

The role of LIF throughout the body is dynamic. In development, LIF is a regulator of embryonic stem cells, facilitating their pluripotency (17). In adults, LIF is produced in the uterus (18), lung (19), and central nervous system (20, 21), situated as a mediator between neuro-immune crosstalk and a

regulator of anti-inflammatory pathways. The LIF receptor (LIFR) can be found on various cell types such as stromal, endothelial, epithelial, and immune cells- most notably T cells and macrophages (9, 22). However, the specific function of LIF is dependent on the local microenvironment, leading to both an inflammatory and anti-inflammatory response. LIF signaling activates three primary pathways known as- janus kinase (JAK)- signal transducer and activator of transcription (STAT3), mitogen activated protein kinase (MAPK), phosphatidylinositol-3 kinase (PI3k), which are associated with cellular proliferation and self-renewal (17). LIFs activation of these pathways has been demonstrated not only within reproductive processes and homeostatic immune regulation but additionally, within the pathological context of cancer. Specifically, breast (23–25), ovarian (26), pancreatic (27), and nasopharyngeal cancers (28), have demonstrated that LIF overexpression by tumours contributes to tumor growth and metastasis as mediated by the STAT3 pathway. Within these contexts, LIFs' capacity to modulate immune phenotypes serves to promote immune evasion and treatment resistance. LIF has been shown to induce regulatory phenotypes in both myeloid and lymphoid cells, primarily working through alternatively activated macrophages (M2) to increase T regulatory (Treg) cell function (29–31). These mechanisms of tissue maintenance, growth, and immune evasion can be paralleled with endometriosis pathophysiology. Thus, LIFs production by ectopic tissue and potential contribution to lesion sustainment and immunomodulation warrants investigation.

To date, LIF has only been studied within the context of endometriosis-associated infertility however its potential contributions to disease pathophysiology remains to be understood. Through human patient data, endometriosis representative human cell lines, and a syngeneic mouse model of endometriosis, we demonstrate that LIF is present in the lesion microenvironment of endometriosis patients and could be contributing to endometriosis-associated lesion vascularization and immune dysregulation. These findings provide novel insight to the role of LIF within endometriosis.

## 2 Methods

### 2.1 Ethics statement

Ethics was approved for this study by the Health Sciences Research Ethics Board at Kingston Health Sciences Centre (KHSC), Queen's University (Kingston, Ontario, Canada), Greenville Health System (Greenville, South Carolina, USA), the University of North Carolina at Chapel Hill (Chapel Hill, North Carolina, USA), and Wake Forest Baptist Health (Winston-Salem, NC, USA). Human ectopic and eutopic samples from endometriosis patients and control samples, from healthy fertile women, were collected as per institutional approved protocols and guidelines. Written, informed consent was acquired from all patients before acquisition and storage of samples.

## 2.2 Detection of LIF in endometriosis patient peritoneal fluid and tissue samples using ELISA

Endometriosis patient PF (n=5) and tissue protein extract (matched ectopic (n=13) and eutopic (n=12)) were analyzed to determine the concentration of LIF using an ELISA kit (BMS242, ThermoFisher). Protein extract and PF samples were obtained from separate endometriosis patient cohorts, resulting in n=17 samples. Briefly, 37mg of tissue was weighed and manually homogenized using ceramic power bead tubes (13113-50, QIAGEN) with the addition of tissue protein extraction reagent (78510, ThermoFisher) and protease inhibitor cocktail (535140, Sigma-Aldrich). Protein content was determined using a microplate bicinchoninic acid (BCA) protein assay kit (23532, ThermoFisher) and normalized to the lowest concentration (1202ug). For the ELISA, standards and samples were added to the plate and incubated at room temperature for 2hrs on a plate shaker. After incubation, the plate was washed with wash buffer before the addition of streptavidin and then incubated for 1hr in the same conditions. After washing, horseradish-peroxidase (HRP) was added, and the plate incubated for 30mins. Finally, a substrate solution of tetramethyl-benzidine was added and incubated for 10mins in the dark, after which stop solution was added. The plate was analyzed in a SpectraMax iD5 microplate reader (Molecular devices, California, USA) at an absorbance of 450nm with a reference wavelength of 620nm.

## 2.3 Immunohistochemistry for LIF on an endometrioma tissue microarray

A tissue microarray (TMA) was created with human patient samples from Kingston General Hospital as previously outlined (32). From a separate patient cohort, matched ectopic (endometrioma samples) and eutopic tissues collected from endometriosis patients (n=19) were compared to endometrium from healthy controls (n=22). Patients were identified as one of three menstrual states by pathologist review: proliferative, secretory, or inactive. The breakdown of patients by menstrual stage are as follows: Endometriosis (proliferative = 7, secretory = 8, inactive= 4), controls (proliferative= 18, secretory= 7, inactive= 1). For IHC, a 5µm section of the TMA was taken, subjected to xylene, and rehydrated with various concentrations of ethanol and citrisolv solutions. Antigen retrieval was performed with a citrate buffer for 20mins and subsequently stained with a polyclonal LIF antibody (26757-1-AP, ThermoFisher, 1:500) using a Leica Bond RX autostainer (Leica Biosystems- Microsystems Inc., IL, USA). The slide was scanned using an Olympus VS120 Virtual Slide Microscope (Olympus, USA) and analyzed using HALO image analysis software (Indica Labs, USA). Quantification of percent area positive for anti-LIF stain was performed on the total core area and the luminal and glandular epithelium respectively. As LIF is produced within the luminal and glandular epithelium, this delineation in area quantification provided a more accurate

representation of LIF staining as cores differed in their stromal and epithelial composition.

## 2.4 Targeted RT qPCR array for LIF associated genes in endometriosis and control tissues

Total RNA was extracted from patient samples (n=8 matched endometriosis eutopic/ectopic tissues, n=9 healthy controls) using a total RNA isolation kit (17200, Norgen Biotek Corp., ON, Canada). Briefly, 20mg of tissue was added to a ceramic power bead tube (13113-50, QIAGEN, Hilden, Germany) with 600µL lysate buffer solution and digested using the Omni Bead Ruptor (PerkinElmer Comp., GA, USA). Samples were subsequently centrifuged at 10000g for 5min to pellet tissue debris. The resultant supernatant was aspirated and passed through a pre-assembled column to remove genomic DNA and collect total RNA. RNA was purified and reverse transcribed into complimentary DNA (cDNA) using a RT<sup>2</sup> First Strand Kit (330401, QIAGEN). Quality of RNA and cDNA samples were tested using a Nanodrop 2000 Spectrophotometer (ThermoScientific, MA, USA). cDNA was used with targeted RT<sup>2</sup> qPCR custom array plates (CLAH41769-(330171)), QIAGEN) to detect 19 key gene transcripts for downstream LIF family proteins and transcription factors, selected after extensive literature review. RT qPCR was conducted using the LightCycler 480 Real-Time PCR system (Roche Molecular Systems, Inc. Basel, Switzerland) with QuantiTect SYBR Green PCR mastermix (330501, QIAGEN). Relative gene expression values were calculated by delta delta CT method after normalization to housekeeping genes (*ACTB* and *GAPDH*). Primers for the following proteins and transcription factors were used: *LIF*, *LIFR*, *OSM*, *IL-6*, *IL6ST*, *CNTF*, *PRL*, *IGFBP-1*, *SOX2*, *SOCS3*, *JAK1*, *MAPK1*, *AKT*, *mTOR*, *POU5F1*, *PTPN11*, *PI3KR1*, *NANOG*, *STAT3*.

## 2.5 Human cell lines

Immortalized human endometriotic epithelial- 12Z cells (provided by Dr. Anna StarzinskiPowitz), human umbilical vein endothelial cells (HUVEC; CRL-1730, ATCC, VA, USA), and human endometrial stromal cells (hESCs; T0533 ABM, BC, Canada). Immortalized 12Z cells were maintained in DMEM/F-12 (11320033, ThermoFisher) supplemented with 10% fetal bovine serum (FBS; 97068-085, VWR), 1% penicillin/streptomycin (15140122, ThermoFisher) and 1% (100mM) sodium pyruvate (11360070, ThermoFisher). HUVEC cells were maintained with complete endothelial cell growth medium (211-500, Cell Application). hESCs were maintained in PriGrow (TM004, ABM) with 10% charcoal stripped FBS (12676029, ThermoFisher), 1% L-glutamine (A2916801, ThermoFisher) and 1% penicillin/streptomycin. All cell lines were cultured in T75 flasks and maintained until 70-80% confluence, with media changes every 2-3 days. Cells were kept in a humidified cell culture incubator at 37°C and with 5% CO<sub>2</sub>.

## 2.6 Multiplex cytokine analysis of endometriosis representative cell lines following rhLIF treatment

12Z, HUVEC, and hESCs were cultured in 24-well plates at  $2.5 \times 10^4$  cells/well. Cells were rested for 24hrs prior to treatment with PBS or rhLIF in the following concentrations: 1, 20, and 100ng/mL. Following a 24hr incubation period, cell supernatant was collected and stored at  $-80^\circ\text{C}$  prior to multiplex cytokine analysis (HD-48 plex, EveTechnologies, AL, Canada). Exhaustive cytokine list as follows: sCD40L, EGF, Eotaxin, FGF-2, Flt-3 ligand, Fractalkine, G-CSF, GM-CSF, GRO $\alpha$ , IFN $\alpha$ 2, IFN $\gamma$ , IL-1 $\alpha$ , IL-1 $\beta$ , IL-1ra, IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-8, IL-9, IL-10, IL-12p40, IL-12p70, IL-13, IL-15, IL-17A, IL-17E/IL-25, IL-17F, IL-18, IL-22, IL-27, IP-10, MCP-1, MCP-3, M-CSF, MDC (CCL22), MIG, MIP-1 $\alpha$ , MIP-1 $\beta$ , PDGF-AA, PDGF-AB/BB, RANTES, TGF $\alpha$ , TNF $\alpha$ , TNF $\beta$ , VEGF-A.

## 2.7 Proliferation and apoptosis assays in endometriosis representative cell lines treated with rhLIF

Cell proliferation and apoptosis were measured in 12Zs, HUVECs, and hESCs following treatment with PBS or varying concentrations of recombinant human LIF (rhLIF; 7734-LF, R&D Systems, MN, USA). Briefly, cells were seeded at  $5 \times 10^3$  cells/well in 96 well plates (hESCs and 12Zs used phenol red free DMEM F-12 (21041025, ThermoFisher) and rested for 24hrs. Media was then changed with media containing either PBS or rhLIF at 1, 20, or 100ng/mL, and incubated for an additional 24hrs. Proliferation was determined using a WST-1 assay (0501594400, Sigma-Aldrich, MO, USA) and apoptosis determined using Caspase Glo 3/7 reagent (G8091, Promega, WI, USA). Briefly, 10 $\mu$ L of WST-1 reagent was added per well to achieve a 1:10 dilution before a 2hr incubation at  $37^\circ\text{C}$ . To determine apoptosis, 100 $\mu$ L of Caspase Glo 3/7 reagent was added per well to achieve a 1:1 dilution before incubation at room temperature for 2hrs. A SpectraMax iD5 microplate reader (Molecular Devices) was used to obtain the absorbance and luminescence for the proliferation and apoptosis assays respectively. The absorbance of formazan dye produced during the WST-1 reaction was recorded at 450nm with a reference wavelength of 650nm. Each proliferation and apoptosis experiment was repeated at least 3 times per individual cell line, thus data shown is representative.

## 2.8 Endothelial tube formation assay

HUVEC cells were utilized for a tube formation assay as per the protocol of the manufacturer in a  $\mu$ -slide assay format. Briefly, IBIDI microplates (81506 Ibbidi, Germany) were loaded with 10 $\mu$ L of Matrigel<sup>TM</sup> (354230, Corning, USA) and incubated for 1hr to allow for Matrigel<sup>TM</sup> polymerization. HUVEC cells were plated in triplicates at  $1 \times 10^4$  cells/well above the polymerized Matrigel<sup>TM</sup> in 50 $\mu$ L of media with one of the following treatments: VEGF, PBS, LIF (1, 20, 100ng/mL). Cells were incubated at  $37^\circ\text{C}$  and with 5%

CO<sub>2</sub> for 4hrs. Images were taken on a Nikon TE200 inverted epifluorescence microscope using a 10 $\times$  objective and a cooled CCD camera and analyzed by WimTube: Tube Formation Assay Image Analysis Solution (33).

## 2.9 Murine model of endometriosis

Seven-to-eight-week-old female C57BL/6 mice (n=17; Charles River Laboratories, MA, USA) were housed in conventional housing with an automated watering system and 12-hr light-dark cycle at 3-4 animals per cage. To induce endometriosis, uterine horns were harvested from donor mice (n=3) and dermal biopsy punches (3mm<sup>3</sup>) were used to obtain uterine fragments to be explanted into recipient mice. For surgery, mice were anesthetized with 2.5% isoflurane. Briefly, an incision was made into the abdomen to allow access to the peritoneum, upon which two 3mm<sup>3</sup> uterine fragments were attached with Vetbond adhesive (1469SB, 3M, MN, USA) to the peritoneal wall. A suture and two staples were used to close the peritoneum and skin respectively. To understand the influence of LIF on endometrial lesion growth and immune cell populations, mice received daily intraperitoneal (i.p) injections of either PBS (control; n=6) or recombinant mouse LIF (rmLIF; n=6; 8878-LF-100/CF, R&D Systems) for 14 days. This experiment was duplicated with varying rmLIF doses (300ng and 1 $\mu$ g). On day 14, animals were sacrificed and peritoneal lavage was performed with ice-cold PBS before the spleen, uterine horns, and endometriosis-like lesions were excised. Lesions were placed in 4% paraformaldehyde and kept in  $4^\circ\text{C}$  for 24hrs. Fixed lesions were then transferred to 70% ethanol before processing for paraffin embedding. PF and splenocytes were used for flow cytometry. Spleens were excised and immediately placed in RPMI 1640 supplemented with 5% FBS. To isolate splenocytes, spleens were mechanically digested through a 70 $\mu$ m strainer and centrifuged at 300g for 5min at  $4^\circ\text{C}$ . Both PF and splenocytes were pelleted and resuspended in FBS with 10% dimethyl sulfoxide (DMSO; Sigma-Aldrich) for cryopreservation.

## 2.10 Flow cytometry

Mouse PF and splenocytes were thawed in a water bath at  $37^\circ\text{C}$  and reconstituted in 15mL of FACs buffer (PBS with 10% FBS). Cells were centrifuged at 300g for 5min  $4^\circ\text{C}$  and supernatant decanted. Following the addition of DNase 1 (10104159001, Millipore Sigma; 100 $\mu$ g/ $\mu$ L) samples were incubated for 10min at  $4^\circ\text{C}$  as per manufacturers guidelines. Cells were neutralized with 10mL of FACS, centrifuged at 300g for 5min  $4^\circ\text{C}$ , then resuspended for cell counting by an automated cell counter (Countess 3, ThermoFisher). Samples of  $5 \times 10^5$  cells were used for staining for flow cytometry. To limit non-specific antigen binding, samples were stained with anti-mouse TruStainFcX (101320, BioLegend; 1:50) and incubated for 10min at  $4^\circ\text{C}$ . Subsequently, extracellular staining for myeloid and lymphoid markers was performed with a 30min incubation period. All products were obtained from BioLegend unless otherwise stated: fixable viability dye, eFluor780 (65-0865-14, ThermoFisher; 1:500), Brilliant Violet (BV)510-anti-CD3 (100234; 1:40), BV785-anti-CD4

(100552; 1:80), BV605-anti-CD8 (100744; 1:40), FITC-anti-CD25 (102005; 1:50), PB- anti-CD11b (1012224; 1:50), PE-Cy7-anti-F4/80 (123114; 1:80), AF700-anti-MHCII (107621; 1:200). Cells were fixed and permeabilized using a FOXP3 Fixation and Permeabilization Kit (00-5523-00, eBioscience) following the manufacturers recommendation. After permeabilization, cells were stained intracellularly with PE-anti-FOXP3 (126404; 1:20) and APC-anti-CD206 (141708; 1:40). Following a 30min staining incubation, cells were washed with FACS.

All data was acquired on the CytoFLEX S flow cytometer (Beckman Coulter, CA, USA) and analyzed using FlowJo software (version 10). Half-heat killed cells were used to detect viability and fluorescence minus one (FMO) controls used to set positive population gates.

## 2.11 Immunohistochemistry of mouse lesions

Paraffin embedded blocks were sectioned to 5µm thickness and subjected to deparaffinization with xylene before rehydration with various concentrations of ethanol and citrisolv solutions. Antigen retrieval was performed with citrate buffer for 20mins and subsequent staining with polyclonal antibodies for mouse Ki67 (ab15580, Abcam, 1:1000), CD31 (77699S, New England Biolab, 1:100), LIF (PA5-115510, Invitrogen, 1:50), and LIFR (101228, Abcam ab, 1:2000) were completed using a Leica Bond RX autostainer. Lesions were analyzed using a singular computer-generated algorithm created for each stain (Ki67, CD31, LIF, LIFR). Percent area quantification for positive stain was used for CD31, LIF, and LIFR. A cytonuclear algorithm was used to detect individual cell expression of Ki67 after which the percent of proliferating cells (Ki67<sup>+</sup>) could be expressed as a percent of the total cells. Slides were scanned using an Olympus VS120 Virtual Slide Microscope (Olympus) and image analysis performed using HALO image analysis software (Indica Labs).

## 2.12 Statistics

All statistical analyses were performed on GraphPad Prism9 (CA, USA). Unpaired students T-test used for analysis between two groups, and one way-ANOVA with Tukey *post-hoc* used for multiple group comparisons. A p value equal or less than 0.05 was considered statistically significant.

## 3 Results

### 3.1 LIF is present in the ectopic lesions of endometriosis patients and is dysregulated across the ectopic and eutopic tissues

Previous reports have analyzed LIF within the endometrial tissue of endometriosis patients as it pertains to fertility status, however it has yet to be identified within the ectopic lesion. To gain

insight into the presence of LIF within the lesion microenvironment, endometriosis patient tissues and PF samples were analyzed for LIF by ELISA. LIF was detected in all tissue extracts (Figure 1A) and PF samples (Figure 1B) at varying levels; ectopic =  $45.08 \pm 28.34$ , eutopic =  $43.52 \pm 20.87$ , PF =  $50.49 \pm 46.48$ . No significant differences in protein expression were found between the eutopic and ectopic tissues of endometriosis patients. PF samples from healthy, fertile controls could not be obtained due to logistical difficulties; however, demonstrating the presence of LIF in the PF of women with endometriosis represents a novel finding in and of itself as it demonstrates that LIF is present in the endometriotic microenvironment.

Our next step was to gain spatial understanding of LIF within the lesion microenvironment, thus, IHC was performed on a TMA of endometrioma and control endometrium samples (endometriosis matched; n=19, controls; n=21) (Figures 1C–K). When specified to the epithelium, eutopic tissues demonstrated significantly less percent area positive for LIF stain than the control (p=0.0096), as previously noted in literature (Figure 1I). Percentage positive for LIF stain was elevated in ectopic lesions compared to eutopic but was not statistically significant. However, when patients were stratified by menstrual phase, there was a significant difference between ectopic and eutopic LIF staining (p<0.001) (Figure 1K) illustrating a dysregulation in the production of LIF within endometriosis patients during the secretory phase.

Finally, we performed targeted RT qPCR using a custom array with select genes involved in the LIF signaling pathway and including members of the IL-6 family of cytokines, to identify differentially expressed transcripts (Figure 2). Of the 19 genes studied, *LIFR*, *IL-6*, *NANOG* were upregulated and *LIF*, *IGFBP-1* were downregulated in the ectopic tissue, compared to the eutopic endometrium from endometriosis patients and healthy controls (Figures 2A, B).

### 3.2 LIF treatment promotes the production of immune recruiting cytokines and induces tube formation in human umbilical vein endothelial cells

LIF is a known immunomodulator, working as both an inflammatory and anti-inflammatory cytokine depending on the microenvironment. Additionally, as LIF can promote vascularization and proliferation, we sought to determine the effects of LIF on endometriosis lesion representative cell lines. We used 12Zs- an endometriotic epithelial cell line, and hESCs- a human endometrial stromal cell line, to represent the two primary cellular components of the endometrium and ectopic tissue being epithelial and stromal cells. Additionally, we utilized HUVECs- human umbilical vein endothelial cells, as they are a well-established model for angiogenesis. All cell lines were treated with varying rhLIF concentrations (1, 20, 100ng). Proliferation and apoptosis were measured using a WST-1 and caspase 3/7 glo assay respectively. LIF treatment did not result in detectable proliferation in any of the cell lines, but rather at the lowest dose decreased proliferation compared to the PBS control (Figures 3A–C). This

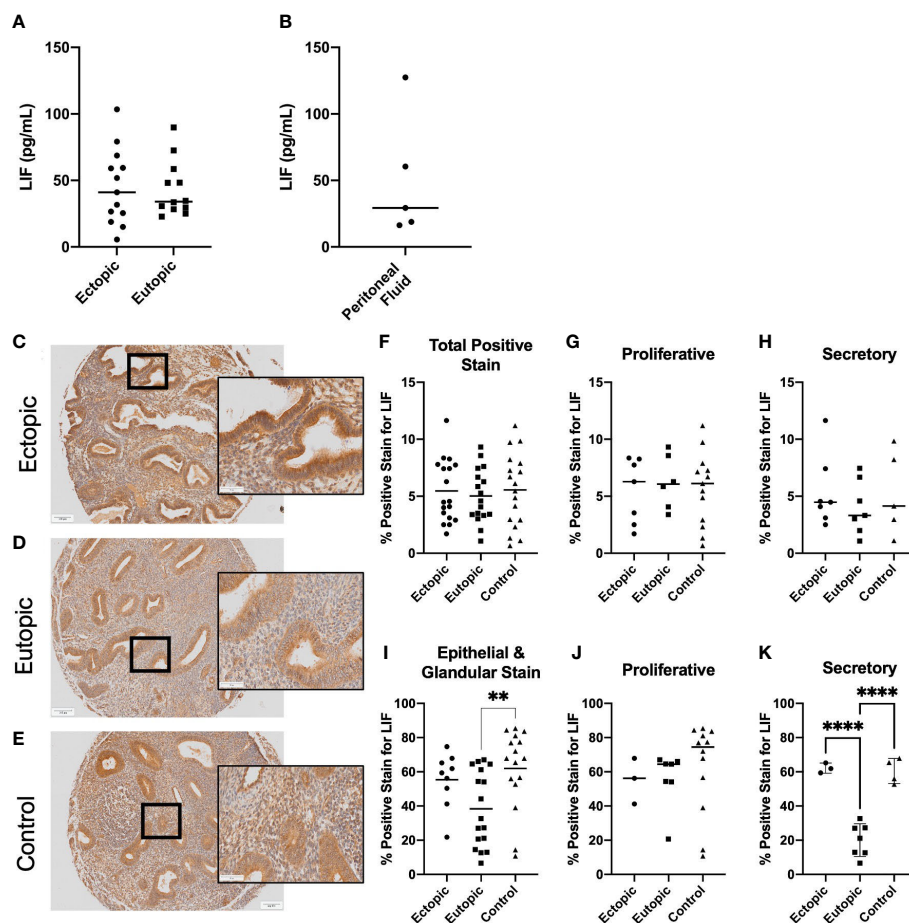

FIGURE 1

LIF is present in the ectopic lesion microenvironment of endometriosis patients. Ectopic and eutopic tissues (A) and PF (B) from endometriosis patients contain LIF as detected through ELISA. No significant differences in LIF values were seen across tissue type. Analysis performed as unpaired Student's T-test. (C–E), Endometrioma TMA of matched endometriosis (eutopic and ectopic;  $n=19$ ) and control endometrium ( $n=22$ ) was stained with an anti-LIF antibody. Area quantification of percent positive stain was calculated for the total core area (F–H) and luminal and glandular epithelium (I–K) respectively. Patients were stratified by menstrual phase- proliferative (G, J) and secretory (H, K), for both area quantifications. Patient samples used in (A–C, E) reflect 3 separate patient cohorts. Magnification provided at 4x and 20x; scale bar 100 $\mu$ m. Analysis performed as one-way ANOVA with Tukey post-hoc, \*\* $P<0.01$ , \*\*\*\* $P<0.0001$ .

reduced proliferation was not attributed to apoptosis, however, as the caspase assay showed no alterations to apoptosis regardless of the dose of LIF treatment (Figures 3D–F).

Cell supernatant, collected in response to rhLIF treatment (1, 20, 100ng/mL), was analyzed using a multiplex cytokine array for predominant pro-inflammatory/immunoregulatory cytokines, chemokines, and growth factors (Figures 3G–M). Significant production of immune recruiting cytokines such as monocyte chemoattractant protein (MCP)-1 and MCP-3 were produced in 12Zs and HUVECs upon LIF treatment (Figures 3J–L), but not in hESCs. Further, 12Zs secreted significantly higher concentrations of vascular endothelial growth factor (VEGF) with all treatment doses compared to PBS, indicating LIF as a potential promoter of angiogenesis *in vitro* (Figure 3G). Additional cytokines detected in the cell supernatants can be found in Supplemental Figure 1.

To determine LIFs influence on angiogenesis, a tubulogenesis assay was performed with HUVECs (Figure 4). Significantly

elevated tube length ( $p<0.05$ ) and number of total branching points ( $p<0.05$ ) were seen with the 100ng rhLIF treatment compared to the PBS control (Figures 4F, G).

### 3.3 LIF treatment in a syngeneic mouse model of endometriosis alters the local and peripheral immune response

To understand the influence of LIF on immune cell recruitment and polarization, we surgically induced endometriosis in C57BL/6 mice and performed daily i.p. injections of recombinant mouse LIF [rmLIF; 300ng and 1 $\mu$ g, based on available literature (28, 30)] or PBS for 14 days. To capture alterations to the local and peripheral immune response, PF (Figure 5) and splenocytes (Figure 6) were harvested for flow cytometric analysis of myeloid and lymphoid immune cell subsets. With LIF treatment, regardless of dose, there

FIGURE 2

LIF gene expression is significantly downregulated in ectopic tissue compared to eutopic and control. Volcano plots showing differentially expressed genes in the LIF signaling pathway between (A) ectopic (n=9) and control (n=10), (B) ectopic and eutopic (n=9), (C) eutopic and control tissue samples. Vertical dashed lines indicate a fold change of  $\pm 1$  and horizontal blue line denotes a significance value of  $P=0.05$ .

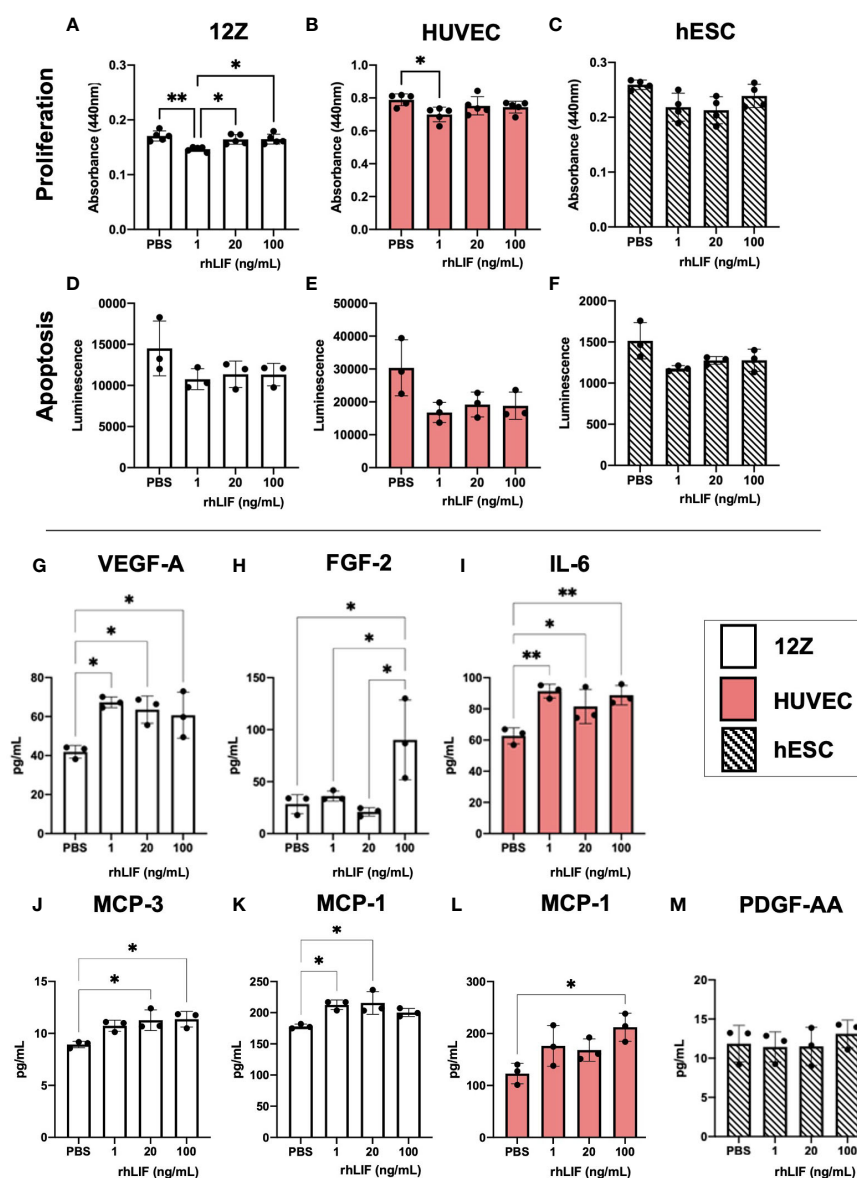

FIGURE 3

LIF treatment *in vitro* did not alter proliferation or apoptosis in endometriosis representative cell lines but stimulated the release of growth factors and immune recruiting cytokines. WST-1 (A–C) and Caspase (D–F) assays were conducted in endometriosis representative cell lines– 12Zs (white bars), HUVECs (red bars), and hESCs (dashed bars), to detect LIF influence on proliferation and apoptosis respectively. (G–M), Cell lines were treated for 24hrs with PBS or varying rhLIF concentrations (1, 20, 100ng/mL) and supernatant analyzed for 48 cytokines pertaining to angiogenesis, inflammation, and cell growth (HD48-Multi-plex Analysis, EveTech). Analysis performed as one-way ANOVA with Tukey *post-hoc*,  $*P<0.05$ ,  $**P<0.01$ .

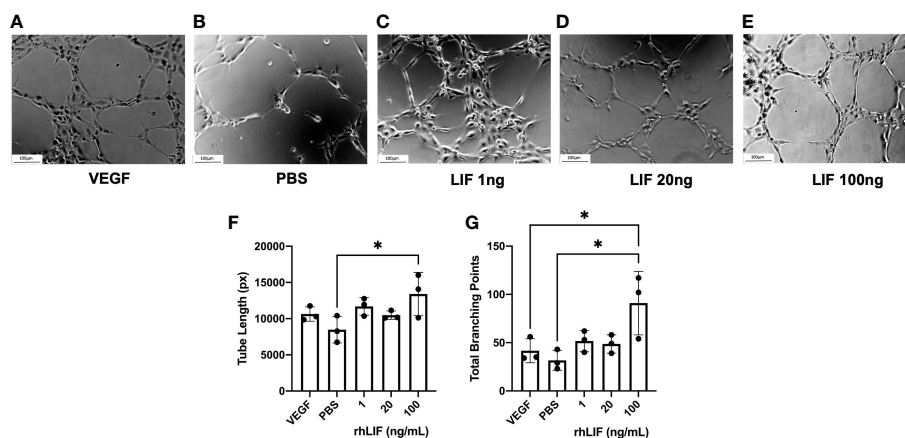

FIGURE 4

LIF treatment promotes tubulogenesis in HUVEC cell line. HUVEC were treated with VEGF, PBS, or rhLIF (1, 20, 100ng/mL) and incubated for 4hrs before image acquisition- representative images provided for each treatment condition (A–E). Images were analyzed by WIMASIS Software to determine metrics of tube formation including (F) tube length and (G) total branching points. Analysis performed as one-way ANOVA with Tukey post-hoc, \* $P < 0.05$ . Scale bar 100 $\mu$ m.

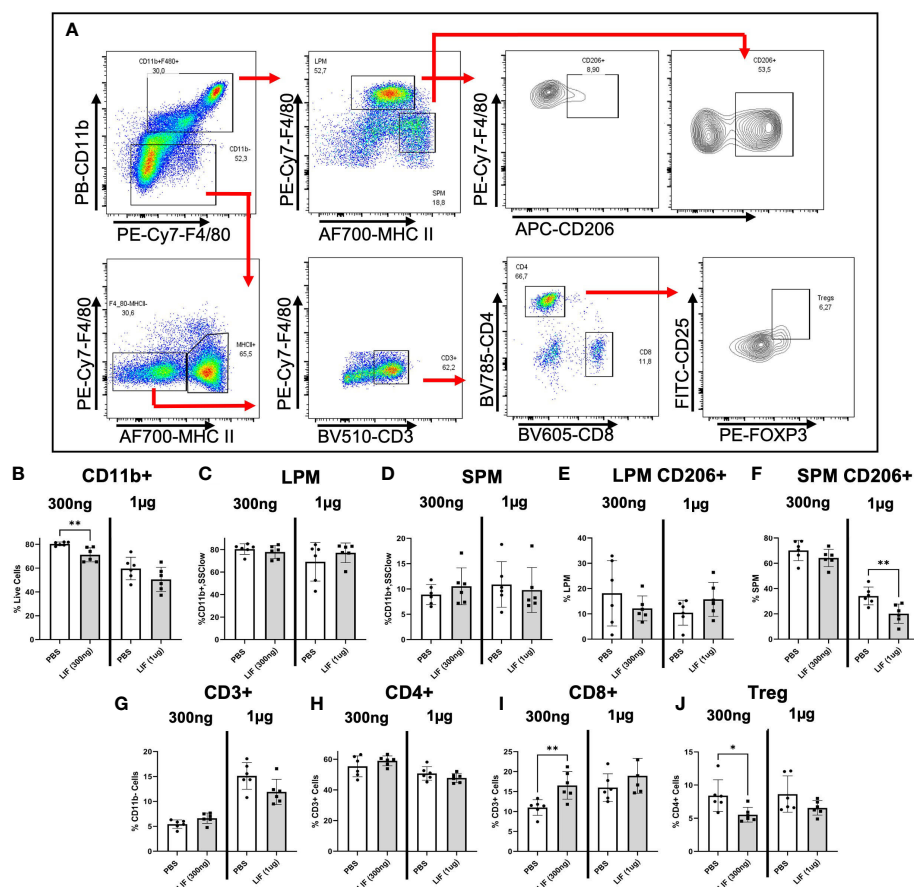

FIGURE 5

LIF treatment in a mouse model of endometriosis alters the local peritoneal immune response. (A) Gating strategy for flow cytometric analysis of myeloid (B–F) and lymphoid (G–J) markers on immune cells from the PF of mice injected i.p. with PBS (white bars) or rmLIF (grey bars; 300ng, 1 $\mu$ g) for 14 days. LPM gated as: single cells, live, SSC<sup>low</sup>, CD11b<sup>+</sup>, F4/80<sup>hi</sup>, MHCII<sup>low</sup>, SPM gated as: single cells, live, SSC<sup>low</sup>, CD11b<sup>+</sup>, F4/80<sup>mid</sup>, MHCII<sup>hi</sup>. Tregs gated as: single cells, live, SSC<sup>low</sup>, CD11b<sup>+</sup>, F4/80<sup>+</sup>, MHCII<sup>+</sup>, CD3<sup>+</sup>, CD4<sup>+</sup>, CD25<sup>+</sup>, FOXP3<sup>+</sup>. Results reflect duplicate experiments- one per rmLIF dosage. Analysis performed as unpaired Student's T-test, \* $P < 0.05$ , \*\* $P < 0.01$ . LPM, large peritoneal macrophages, SPM, small peritoneal macrophages.

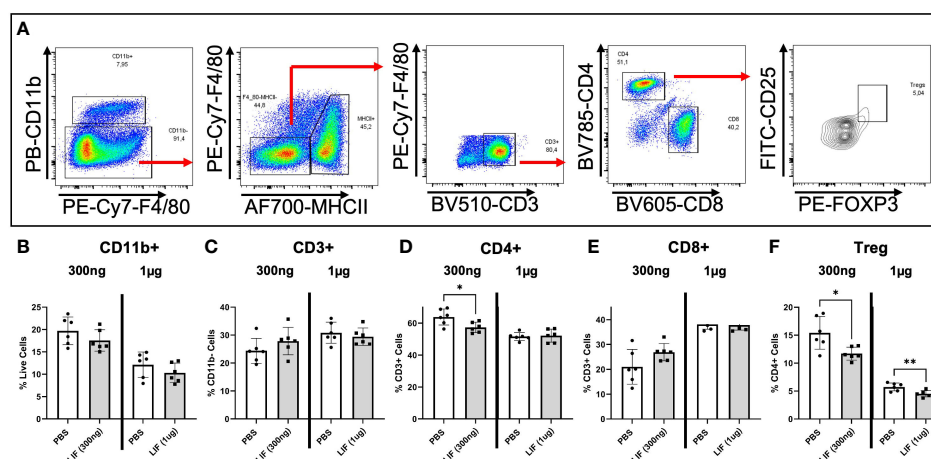

FIGURE 6

LIF treatment in a mouse model of endometriosis alters the peripheral immune response. (A) Gating strategy for flow cytometric analysis of myeloid (B) and lymphoid markers (C–F) on immune cells from the spleen of mice injected i.p. with PBS (white bars) or rmLIF (grey bars; 300ng, 1µg) for 14 days. Tregs gated as: single cells, live, SSC<sup>low</sup>, CD11b<sup>+</sup>, F4/80<sup>+</sup>, MHCII<sup>+</sup>, CD3<sup>+</sup>, CD4<sup>+</sup>, CD25<sup>+</sup>, FOXP3<sup>+</sup>. Results reflect duplicate experiments - one per rmLIF dosage. Analysis performed as unpaired Student's T-test, \*P<0.05, \*\*P<0.01.

was a reduction in immunoregulatory phenotypes in the PF and spleen. In the PF, CD206<sup>+</sup> small peritoneal macrophages (SPMs; gated as: singlet, live, side scatter (SSC)<sup>low</sup>, CD11b<sup>+</sup>, F4/80<sup>mid</sup>, MHCII<sup>hi</sup>, CD206<sup>+</sup>) and Treg (gated as: singlet, live, SSC<sup>low</sup>, CD11b<sup>+</sup>, F4/80<sup>+</sup>, MHCII<sup>+</sup>, CD3<sup>+</sup>, CD4<sup>+</sup>, CD25<sup>+</sup>, FOXP3<sup>+</sup>) cells were significantly decreased compared to PBS control (Figures 5E, J). Similarly in the spleen, Treg cells were significantly reduced with LIF treatment, as were CD4<sup>+</sup> cells (Figures 6D, F). Of note, the PF of mice receiving the low LIF dose had significantly more CD8<sup>+</sup> T cells compared to PBS (p<0.01) (Figure 5I).

### 3.4 LIF treatment did not alter lesion associated proliferation or angiogenesis in a syngeneic mouse model of endometriosis

LIF has been shown to promote tumor growth and vascularization in cancer, thus we sought to determine if those effects were withstanding in our syngeneic mouse model of endometriosis. Lesions harvested from LIF (300ng and 1µg) and PBS treated mice were fixed in paraformaldehyde and embedded in paraffin for IHC. Lesions were stained for markers of angiogenesis-CD31 and proliferation- Ki67, as well as LIF and LIFR (Figure 7). No differences were detected in any of the markers regardless of LIF dosage.

## 4 Discussion

Foundational knowledge of LIF is centered on its role in maintaining embryonic stem cell pluripotency (17), facilitating successful pregnancy through stromal cell decidualization and trophoblast implantation (8, 34), and participation in neuroimmune modulation (21). These situate LIF as a primary

regulator of various homeostatic and pathologic signaling pathways within the body. Recent cancer literature has revealed that LIF is a contributor to immune evasion and facilitation of tumor growth and metastasis (28, 35). In endometriosis, LIF has only been investigated for its contributions to infertility (6, 7) however its presence within the lesion microenvironment and impact on lesion maintenance and the immune contexture remained unexplored.

Our findings identify LIF in the lesion microenvironment, with detection of LIF in the PF and protein extracts of both ectopic and eutopic endometriosis tissues. Spatial localization of LIF in endometriosis patients and control tissues, as provided by our IHC data, further corroborates that LIF is present in ectopic lesions with LIF staining localized to the luminal and glandular epithelium. Across both the proliferative and secretory phases, LIF expression by the ectopic luminal and glandular epithelium is similar to that of the control endometrium. Interestingly, within the secretory phase, ectopic LIF expression is significantly greater than eutopic. This reduced eutopic LIF expression is in accordance with infertility research (7), demonstrating that the endometrium of endometriosis patients has aberrant LIF expression during the secretory phase. Together, these results indicate that ectopic LIF production is rescued in endometriosis patients, highlighting a dysregulation of LIF between endometriosis tissues. The mechanism behind this rescued phenotype requires further investigation as does the source of LIF production within the lesion microenvironment. LIF is produced by a variety of cell types including but not limited to endometrial luminal and glandular epithelium, endothelial cells (36), macrophages, and T cells (21). As patient PF and tissue protein extract consist of contributions from heterogeneous cell types, continued investigation into the primary contributors of LIF to the lesion microenvironment is needed.

Targeted RT qPCR data provides further insight into LIF production within ectopic lesions. Our findings revealed that *LIF* gene expression is significantly downregulated while its primary

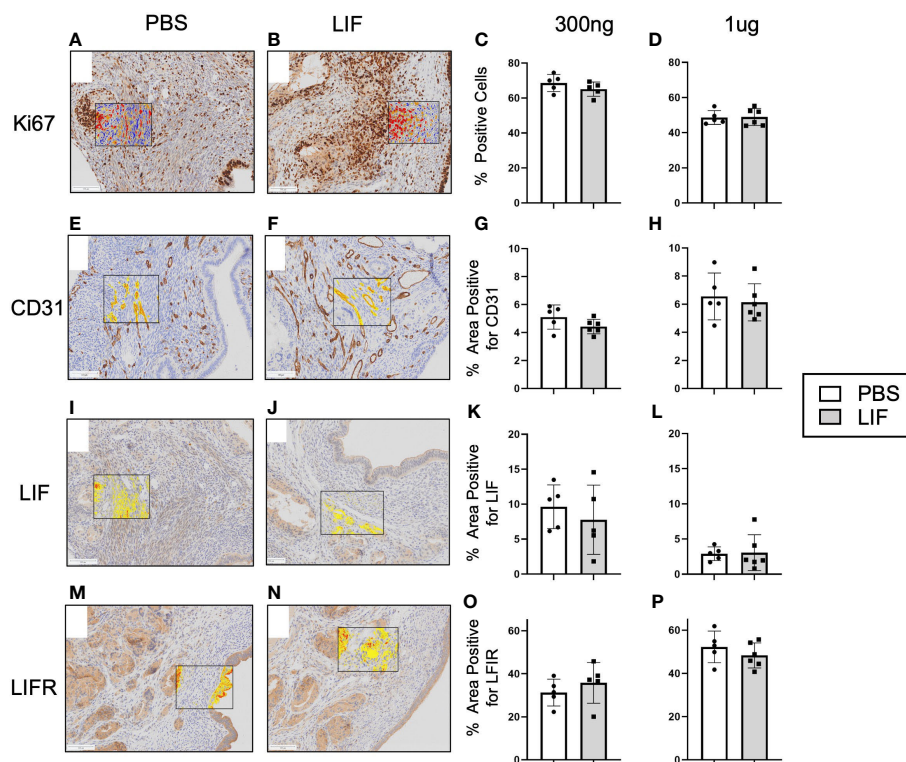

FIGURE 7

LIF treatment did not alter lesion growth or proliferation in a mouse model of endometriosis. I.p injections of PBS (white bars) or rmLIF (grey bars; 300ng, 1μg) were administered to C57BL/6 mice (n=6 for all groups) for 14 days, one week after endometriosis inducing surgery. Endometriosis-like lesions were collected upon sacrifice and subjected to IHC for markers of proliferation-Ki67 (A, B) and angiogenesis-CD31 (E, F), as well as LIF (I, J) and LIFR (M, N). Representative stain analysis provided for each marker from both the PBS and LIF treatment groups. Ki67 was analyzed as percent of cells expressing Ki67 over the total cell number as detected by a cytonuclear algorithm (C, D), while all other stains (CD31, LIF, LIFR) were analyzed by percent area quantification of stain (G, H, K, L, O, P). No statistical differences were detected across the four stains. Analysis performed as unpaired Student's T-test. Scale bar 100μm.

receptor *LIFR* is upregulated in the ectopic tissue compared to eutopic and healthy control samples. This suggests that ectopic tissue is likely receptive to LIF but not producing it, potentially due to the high levels of LIF detected within the lesion microenvironment. In support of LIF signaling, *NANOG*, a downstream transcription factor of LIF associated with the maintenance of cell stemness, was significantly upregulated in the ectopic tissues compared to control and upregulated, though not significantly, compared to eutopic tissue. *NANOG* production is present in embryonic stem cells to maintain cell pluripotency and if present in adult tissues, serves as an oncogene, contributing to tumorigenesis (37). Our findings are in accordance with other endometriosis literature identifying downstream LIF targets *NANOG*, *OCT-3/4*, and *SOX2* to be elevated in ectopic lesions compared to control endometrium (38, 39). These studies however do not mention LIF as a mediator of these pathways, thus our findings offer a novel perspective to view the activation of these stemness transcription factors within endometriosis. It is notable however, that *NANOG* can be regulated in the absence of LIF. E-cadherin can signal through *STAT3* to increase *NANOG* transcription, while *p53* can inhibit *NANOG* transcription through binding of its promoter region (37, 40). Thus, further investigation is required to confirm whether the upregulation of

*NANOG* is due specifically to LIF signaling or other mediators in endometriosis.

Additionally, it is worth noting that other IL-6 family proteins (such as ciliary neurotrophic factor (CNTF) and oncostatin-M (OSM)) use the LIF receptor for signaling and have been implicated in various aspects of endometriosis. CNTF has been investigated for its potential association with sensitization and pain (41, 42), while OSM has been shown to inhibit endometrial stromal cell growth, with endometriotic stromal cells being resistant to this inhibitory effect (43). Our customized RT qPCR array included both CNTF and OSM to determine whether IL-6 family proteins or LIF specifically were dysregulated within endometriosis. Our findings demonstrate a significant upregulation of CNTF within the ectopic tissue compared to eutopic and significant downregulation in the eutopic tissue compared to the control. While OSM is upregulated, though not significantly, within the ectopic tissue compared to control. These findings suggest that the IL-6 family proteins are dysregulated within the ectopic tissue, with further research needed to determine the impact on lesion sensitization and growth.

LIF has been shown to promote tumor growth and metastasis through carcinoma cell proliferation, however in our *in vitro* models there were limited alterations to proliferation across

various cell types- 12Z, hESC, and HUVEC. Yet treatment of these endometriosis representative cell lines with rhLIF yielded the production of immune recruiting and inflammatory cytokines MCP-1, MCP-3, and IL-6, as well as the angiogenic factor VEGF. The role of LIF as an angiogenic factor is contentious throughout the literature, reflecting the nuances through which microenvironments modulate LIF signaling. LIF has been demonstrated to regulate vascularization in concert with oxygen availability, meaning that it can prevent or promote the formation of blood vessels as seen in mouse models of ocular vascularization (44). Our findings suggest that LIF is a promoter of angiogenesis both indirectly through the promotion of the angiogenic factor VEGF from 12Zs and directly by increasing endothelial tube formation in HUVECs. We sought to visualize these effects of LIF treatment within our mouse model through examination of indirect alterations to lesion architecture including proliferation and angiogenesis, however no significant changes were found. This discordance in angiogenesis can in part be attributed to temporal variations in experimental end points, where the tubulogenesis assay demonstrated short term response and our mouse model captures a more chronic response. Additionally, these are varying endothelial cell types, thus further investigation of LIF specifically on endometriotic endothelial cells is needed to elucidate its role within endometriosis.

LIFs role as an immunomodulator is co-opted in pathologies like cancer, as the immunoregulatory environment perpetuates tumor immune evasion and promotes resistance to treatment (23, 28). As our human data highlights the presence of LIF in the lesion microenvironment and our *in vitro* evidence suggests a role in angiogenesis and immune recruitment, we wanted to understand the impact of elevated LIF on lesion development and the immune contexture in our syngeneic immunocompetent mouse model of endometriosis. LIF treated mice did not demonstrate an increased number of infiltrating immune cells, but the composition of immune cell phenotypes was altered both locally and systemically. At both a low (300ng) and high (1μg) dose of rmLIF, there were significant reductions in immunoregulatory myeloid and lymphoid phenotypes, mainly CD206<sup>+</sup> SPMs and Tregs. Further, CD8<sup>+</sup> T cells were upregulated in the PF of the low dose rmLIF treated group. LIF has been demonstrated to assist in polarizing macrophages to an M2 phenotype and works through these cells to increase Treg functioning (29–31). Further, LIF provides barriers to CD8<sup>+</sup> T cell infiltration due to its influence on M2 macrophages. In a mouse model of breast cancer, LIF was shown to operate through M2 like- tumor associated macrophages to silence CD8<sup>+</sup> T cells *via* epigenetic modification (30). Our results appose these findings, potentially providing insight into a novel endometriosis associated LIF pathway whereby LIF intervention is reducing immunoregulatory phenotypes and promoting a potential cytotoxic response. Further phenotypic characterizations are needed to clarify the activation status of the CD8<sup>+</sup> T cells present. Notably IL-6 has been identified as a key factor in assisting LIF polarization of macrophages to an M2 phenotype (26). Multiplex cytokine analysis of the PF demonstrated undetectable or negligible levels (<4pg/mL) of IL-6 (data not shown) suggesting that IL-6 was not produced in sufficient quantities in our mouse model with this

treatment and time course for macrophage polarization to occur. Finally, direct comparison between rmLIF doses was not possible due to batch effect variations. Despite this limitation, the trend of reduced immunoregulatory phenotypes was consistent between LIF treatments supporting its role as an immunomodulator within endometriosis.

While we provide previously unexplored dimensions of LIF in endometriosis pathophysiology beyond infertility, we acknowledge some of the limitations of the work that are inherent to endometriosis research. Access to representative patient samples from each disease subtype and severity is limited. Additionally, as most patients have irregular menstrual cycles, there are limitations to identifying specific occurrences within defined menstrual phases. Due to limited access to PF samples from healthy controls only endometriosis LIF expression in the PF was shown. While we present this data to document LIF presence in endometriosis PF samples, future studies are needed to provide a comparison between endometriosis and control samples. Further, infertility is not a symptom that all patients experience yet it is one that is common, being present in around 30-50% of cases (5). Within our patient samples fertility status was not known preventing us from including this as a factor within our analysis. Thus, continued investigation is needed to determine whether LIF dysregulation is specific to endometriosis patients with infertility or whether it can be found in fertile patients as well. Finally, as the endometrioma TMA data was more conclusive for LIF presence within the ectopic tissue than the ELISA data (which contained mixed endometriosis subtypes), perhaps the type of endometriosis is a factor in the degree of LIF dysregulation, thus further investigation within endometriosis subtypes is needed.

In conclusion, this study demonstrates that LIF is present in ectopic endometriosis lesions and provides insight to the potential contributions it has to endometriosis pathophysiology. While it is known that some endometriosis patients experience alterations to eutopic LIF production, it is still not known whether this is a consequence of endometriosis associated infertility or whether this contributes to endometriosis pathophysiology. Ultimately, further investigation into the role of LIF across endometriosis subtypes and stages is required to better address its role within both endometriosis-associated infertility and pathophysiology.

## Data availability statement

The original contributions presented in the study are included in the article/[Supplementary Material](#). Further inquiries can be directed to the corresponding author.

## Ethics statement

The studies involving human participants were reviewed and approved by Health Sciences Research Ethics Board at Kingston Health Sciences Centre, Queen's University Health Sciences Research Ethics Board, Greenville Health System, and Wake Forest Baptist Health. The patients/participants provided their

written informed consent to participate in this study. The animal study was reviewed and approved by Queen's University Animal Care Committee.

## Author contributions

KZ conceived and conducted experiments, analyzed data, and wrote the manuscript. DS, JM, and HL conducted experiments. TC, OB, and BL contributed human patient samples. CT contributed reagents, conceived experiments, provided financial support. All authors read and edited the manuscript.

## Funding

This research was supported with funds from the Canadian Institutes of Health Research (CIHR 394570, CT).

## Acknowledgments

We thank Lee Boudreau in the Department of Pathology and Molecular Medicine (Queen's University) for his technical contributions to all IHC processing. We also thank Dr. Bruce Banfield (Queen's University) for the use of his Nikon TE200

inverted epifluorescence microscope and Safara Holder for assistance in image acquisition.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

NKG2D ligands play a relevant role in Natural Killer (NK) cell -mediated immune surveillance of multiple myeloma (MM). Different levels of regulation control the expression of these molecules at cell surface. A number of oncogenic proteins and miRNAs act as negative regulators of NKG2D ligand transcription and translation, but the molecular mechanisms sustaining their basal expression in MM cells remain poorly understood. Here, we evaluated the role of the growth arrest specific 6 (GAS6)/TAM signaling pathway in the regulation of NKG2D ligand expression and MM recognition by NK cells. Our data showed that GAS6 as well as MERTK and AXL depletion in MM cells results in MICA downregulation and inhibition of NKG2D-mediated NK cell degranulation. Noteworthy, GAS6 derived from bone marrow stromal cells (BMSCs) also increases MICA expression at both protein and mRNA level in human MM cell lines and in primary malignant plasma cells. NF- $\kappa$ B activation is required for these regulatory mechanisms since deletion of a site responsive for this transcription factor compromises the induction of *mica* promoter by BMSCs. Accordingly, knockdown of GAS6 reduces the capability of BMSCs to activate NF- $\kappa$ B pathway as well as to enhance MICA expression in MM cells. Taken together, these results shed light on molecular mechanism underlying NKG2D ligand regulation and identify GAS6 protein as a novel autocrine and paracrine regulator of basal expression of MICA in human MM cells.

## KEYWORDS

GAS6, AXL, MERTK, MICA, NKG2D ligand, multiple myeloma, natural killer cells, bone marrow stromal cells

## Introduction

Natural Killer (NK) cells are innate lymphocytes playing a prominent role in antitumor-immune response (1, 2). A complex repertoire of activating and inhibitory receptors controls their ability to recognize and kill target cells (3). Because high tumor-associated expression of ligands MICA, MICB and ULBPs, the stimulatory receptor NKG2D strongly contributes to NK cell response against solid and hematologic cancers (4, 5), including multiple myeloma (MM) (6), a neoplasia caused by accumulation of malignant plasma cells (PCs) in the bone marrow (BM). Advanced-stage MM is associated with defective recognition of cancerous PCs and suppression of NK cell function (7). Indeed, promising strategies to treat this incurable cancer include NK cell therapeutic approaches (8, 9). To this aim, several studies have focused on the comprehension of mechanisms underlying the expression of NKG2D ligands on MM cells. Of note, a number of oncoproteins, such as Hsp90, STAT3, IRF4, C-MYC and IKAROS/AIOLOS, emerged as negative regulators of *MICA* gene transcription (10–13). However, pathways driving basal expression of these ligands on MM cells remain largely unexplored. It is also completely unknown whether BM microenvironment plays a role in these mechanisms. The survival, proliferation and drug resistance of malignant PCs depend on autocrine and paracrine loops involving many cellular and non-cellular components of BM (14, 15). In particular, adhesive interaction as well as soluble factors released by BM stromal cells (BMSCs) strongly promote MM pathogenesis and progression (16). Our recent findings identified BMSCs as regulators of NK cell anti-MM response. We reported a role for IL-8-bearing microvesicles released by BMSCs in the regulation of the expression of Poliovirus receptor (PVR/CD155) (17), a ligand of the receptors DNAM-1, TIGIT and TACTILE/CD96 expressed by NK cells (18, 19).

Accumulating evidence demonstrated the contribution of GAS6/TAM pathway as an oncogenic signaling in MM pathogenesis (20–23). The TAM subfamily of tyrosine kinase receptors (RTK) includes TYRO3, AXL and MERTK (TAM) which are able to bind two vitamin-K dependent proteins, Growth arrest-specific gene 6 (GAS6) and Protein S (PROS1). Ligand binding induces dimerization and autophosphorylation of TAM receptors, followed by activation of many downstream pathways like MEK/ERK, PI3K/AKT and JAK/STAT signaling (24, 25).

MM cells express TAM receptors, mainly MERTK, and produce high amount of GAS6, which is also largely secreted by BMSCs (20, 22). In MM cells, TAM receptor activation triggers MAPK/ERK, PI3K/Akt and NF- $\kappa$ B signaling and promotes the survival and proliferation. Blockade of MERTK on MM cells or pharmacologic targeting of GAS6 reduces myeloma burden and increases survival of mice bearing an

orthotopic myeloma model (22). Such effects support a role for GAS6/TAM receptors as novel therapeutic targets for this malignancy.

Importantly, TAM pathway can exert a direct regulatory activity on diverse immune cells, including NK cells. It is required for NK cell development and functional maturation in human and mice (26, 27). NK cells isolated from TAM-deficient mice have poor cytotoxic activity because of impaired expression of inhibitory and activating receptors. On the other hand, TAM-mediated signaling was shown to attenuate NK cell response in mouse metastasis models in a Cbl-b-dependent manner (28, 29). More recently, it was reported that activated human NK cells rapidly acquired TYRO3 from tumor cells *via* trogocytosis and become more cytotoxic (30).

However, the role of GAS6 and its receptors TYRO3, AXL and MERTK in the regulation of activating ligands and immunosurveillance of MM is unknown.

In this study, we investigated the impact of GAS6/TAM pathway on NKG2D-dependent recognition of MM cells. We demonstrated that defective TAM signaling causes a selective reduction of surface MICA expression on MM cells, compromising their ability to induce NKG2D-dependent NK cell degranulation. We also found that BMSC-derived GAS6 can promote the expression of this NKG2D ligand on MM cell lines and primary PCs *via* activation of NF- $\kappa$ B pathway.

Our findings provide evidence of a role for GAS6 protein as a novel autocrine and paracrine regulator of basal expression of MICA in human MM cells.

## Materials and methods

### Cell lines and clinical samples

Human MM cell lines SKO-007(J3) and ARP-1 were kindly provided by Prof. P. Trivedi (Sapienza, University of Rome, Italy). The human MM cell line U266 was kindly provided by Prof. Nicola Giuliani (University of Parma, Italy). These cell lines were maintained at 37°C and 5% CO<sub>2</sub> in RPMI 1640 (Life Technologies, Gaithersburg, MD) supplemented with 10% FCS, and were authenticated by IRCCS Azienda Ospedaliera Universitaria San Martino-IST, S.S. Banca Biologica e Cell factory (Genova, IT). The human 293T embryonic kidney cells were purchased from ATCC (Manassas, VA) and were maintained in Dulbecco's modified Eagle's supplemented with 10% FCS. All cell lines were mycoplasma-free (EZ-PCR Mycoplasma Test Kit, Biological Industries).

Bone marrow (BM) samples from MM patients were managed at the Division of Haematology, Department of Translational Medicine and Precision, Sapienza University of Rome. Informed consent in accordance with the Declaration of Helsinki was obtained from all patients, and approval was obtained from the

Ethics Committee of the Sapienza University of Rome (RIF.CE: 5191). BM aspirates were processed as described in (31). MM cells were selected using anti-CD138 magnetic beads (Miltenyi Biotec, Auburn, CA, USA). More than 95% of the purified cells expressed CD138 and CD38. Bone Marrow Stromal Cells (BMSCs) were obtained from CD138<sup>+</sup> fraction, phenotypically characterized and assessed for their capacity of osteogenic and adipogenic differentiation as previously described (17).

## Reagents and antibodies

Monoclonal antibodies (mAbs) anti-CD138/FITC, anti-CD38/APC, anti-CD107a/APC, anti-CD45/Pecy7, anti-CD3/APC-H7, CD14/APC-H7, CD19/APC-H7 anti-CD56/BV421, anti-MERTK/BB700 (125518) and anti-Axl/BV711 (108724) were purchased from BD Biosciences (San Jose, California, USA). Unconjugated mAbs anti-MICA (MAB159227), anti-MICB (MAB236511), anti-ULBP1 (MAB170818), anti-ULBP2/5/6 (MAB165903), anti-ULBP3 (MAB166510), anti-NKG2D (MAB149810), anti-B7/H6 (MAB71444), anti-ICAM-1 (BBA3), anti-MICA/AF488 (MAB159227) and anti-Tyro3/AF488 (FAB859G) conjugated mAbs were all purchased from R&D System (Minneapolis, USA). Anti-PVR (SKIL4) was kindly provided by Prof. M. Colonna (Washington University, St Louis, MO). Anti-MHC class I (W6/32) mAb was purchased from ATCC (Manassas, Virginia, USA). Allophycocyanin conjugated with goat anti mouse (GAM-APC) (Poly4053) mAb was purchased from Jackson Immuno-Research Laboratories (Cambridgeshire, UK). Anti-GAS6 (D3A3G) mAb, anti-phosphorylated p65, anti-phosphorylated AXL and anti-AXL were purchased from Cell Signaling Technology (Danvers, MA, USA). Anti-p65 was purchased from Santa Cruz Biotechnologies (Dallas, TX, USA). Anti- $\beta$ -Actin (AC-15) mAb was purchased from Sigma-Aldrich (St. Louis, MO, USA). Donkey anti-rabbit (NA934V) or sheep anti-mouse (NA931V) secondary Hrp-linked mAbs were purchased from GE Healthcare (Wisconsin, MA, USA). The inhibitor UNC2250 was purchased from Selleck (Houston, TX, USA).

## Flow cytometry and degranulation assay

MM cell lines ( $1.5 \times 10^5$  cells/mL) were cultured for 72h in complete medium or in BMSC-conditioned medium (BMSCs-CM). Cells were stained with anti-MICA mAb followed by secondary goat anti-mouse APC Ab. In all experiments, cells were stained with Propidium Iodide (PI) (1  $\mu$ g/mL) in order to assess cell viability (always higher than 90% after the different treatments). Nonspecific fluorescence was assessed by using an isotype-matched irrelevant mAb (R&D System, Minneapolis, USA) followed by the same secondary Ab. Patient-derived plasma cells ( $2 \times 10^6$  cells/mL) were cultured for 48h in BMSC-

CM or complete medium supplemented with IL-3 (20 ng/mL) and IL-6 (2 ng/mL). The membrane expression of MICA was analyzed by immunofluorescence staining with anti-MICA/AF488 or matched isotype control. All samples were also stained with Fixable Viability Stain 450 (FVS450) (BD Biosciences, San Jose, California, USA) to discriminate cell viability.

NK cell-mediated degranulation was evaluated using the lysosomal marker CD107a as previously described (32, 33). As source of effector cells, we used PBMCs purified from healthy donor blood by Ficoll-Hypaque centrifugation or freshly cultured NK cells. SKO-007(J3) cells were incubated with PBMCs or with NK cells at effector:target (E:T) ratio of 1:1 and 2.5:1 respectively, in a U-bottom 96-well tissue culture plate in complete medium at 37°C and 5% CO<sub>2</sub> for 2h. When PBMCs were used, cells were stained with Fixable Viability Stain APC-H7, anti-CD3/APC-H7, anti-CD19/APC-H7, anti-CD14/APC-H7, anti-CD45/Pecy7, anti-CD56/BV421 and anti-CD107a/APC. When cultured NK cells were used, cells were stained with Fixable Viability Stain APC-H7, anti-CD3/APC-H7, anti-CD56/BV421 and anti-CD107a/APC. In some experiments, cells were pre-treated for 20 min at room temperature with anti-NKG2D neutralizing mAb. Fluorescence was analyzed using a FACSCanto or FACS LRSFORTESSA flow cytometer (BD Biosciences, San Jose, California, USA) and data were analyzed by FlowJo V10 Cytometric Analysis Software (BD Biosciences, San Jose, California, USA).

## Western-blot analysis

For Western-Blot analysis, whole cell extracts were obtained from SKO-007(J3) cells as previously described (34). Protein concentration was determined by the BCA method (Thermo Fisher Scientific, Waltham, MA USA). Thirty to 50  $\mu$ g was resolved by SDS-PAGE and transferred to nitrocellulose membranes (Whatman GmbH, Dassel, Germany). After blocking in bovine serum albumin, membranes were probed with specific Abs. An HRP-conjugated secondary Ab and an ECL detection system (Amersham, GE Healthcare, Wisconsin, MA, USA) were used to reveal immunoreactivity.

## Plasmids

The pGL3 Basic -270bp MICA and -270bp MICA/Luc DEL 1 promoter constructs have been already described in (10). The lentiviral vector pHAGE-3xNF-kB-LUC-GFP expressing the green fluorescence gene insert and containing the luciferase gene driven by NF-kB-responsive consensus sequences and the plasmids pVSG-5, pPAX2, pGag-Pol-Env, and pTK-Green Renilla (TK Renyl) were purchased from Addgene (Cambridge, Massachusetts, USA). The lentiviral vectors pLKO.1sh-GAS6, pLKO.1sh-AXL and pLKO.1sh-PROS1

expressing a short hairpin RNA for GAS6, AXL and PROS1 respectively, and the puromycin gene resistance, were generated by inserting shRNA sequences in pLKO.1 lentiviral vector purchased from Addgene (Cambridge, Massachusetts, USA). The following forward and reverse shRNA sequences were used: human GAS6 shRNA forward, 5'-CCGGGCAGACAATCTCTGTTGAGGACTCGAGTCCTCAACAGAGATTGTCTGCTTTTTG-3'; human GAS6 shRNA reverse: 5'-AATTCAAAAAGCAGACAACCTCTGTTGAGGACTCGAGTCCTCAACAGAGATTGTCTGCTGC-3'; human AXL shRNA forward: 5'-CCGGCGAAATCCTCTATGTCAACATCTCGAGATGTTGACATAGAGGATTTTCGTTTTTG-3'; human AXL shRNA reverse: 5'-AATTCAAAAACGAAATCCTCTATGTCAACATCTCGAGATGTTGACATAGAGGATTTCG-3'; human PROS1 shRNA forward, 5'-CCGG CCTACAAATGACAGTTTCAATCTCGAGATTGAAACTGTCATTTGTAGGTTTTTG-3'; human PROS1 shRNA reverse: 5'-AATTCAAAA CCTACAAATGACAGTTTCAATCTCGAGATTGAAACTGTCATTTGTAGG-3'. All constructs were verified by DNA sequence analysis. For knocking down MERTK, we used pLKO.1-shMERTK (TRCN0000442967) lentiviral vector and the control vector pLKO.1 non-targeting shRNA (MISSION<sup>TM</sup> Sigma-Aldrich, St. Louis, MO, USA).

## DNA transfections, virus production and *in vitro* transduction

For virus production, HEK293T was transfected with viral DNA together with packaging vectors, using Lipofectamine 2000 (Life Technologies, Gaithersburg, MD) as previously described (35). SKO-007(J3) and BMSCs cells were infected as previously described (17). SKO-007(J3) cell stable clones expressing pHAGE-3xNF- $\kappa$ B-LUC-GFP were previously described (17). For GAS6, PROS1, AXL and MERTK silencing, MM cell lines were allowed to expand for 24 h and were then selected for 3 days for puromycin resistance (1  $\mu$ g/mL). SKO-007(J3) cells were transfected using Amaxa nucleofection procedure (Lonza Bioscience, Morrisville, USA) as already described (17) and treated with BMSC-conditioned medium. After 48h, cells were collected, and protein extracts were prepared for the luciferase assay. A TK-renilla expression vector was co-transfected each time to normalize DNA uptake. Luciferase and renilla activity were read using Dual-Luciferase Reporter Assay and the Glomax Multi Detection System (Promega, Madison, USA) following the manufacturer's instructions.

## RNA isolation and quantitative real-time polymerase chain reaction (qRT-PCR)

Total RNA was extracted using the total RNA mini-Kit following instructions provided by the manufacturer (Geneaid

Biotech Ltd, Taiwan) and 2  $\mu$ g were used for cDNA first-strand synthesis in a 25  $\mu$ l reaction volume according to the manufacturer's protocol for M-MLV reverse transcriptase (Promega, Madison, USA). MICA, GAS6 and GAPDH mRNA expression were analyzed by real-time PCR using the following specific TaqMan Gene Expression Assays (Applied Biosystems, Foster City, CA): MICA (Hs00792195\_m1), GAS6 (Hs1090305\_m1), PROS1 (Hs00165590\_m1) and GAPDH (Hs03929097\_g1) conjugated with fluorochrome FAM.

The level of expression was measured using Ct (threshold cycle). Relative expression of each gene versus the housekeeping gene was calculated according to the  $2^{-\Delta\Delta C_t}$  method. The analysis was performed using the SDS version 2.4 software (Applied Biosystems, Foster City, CA).

## Annexin V

Apoptotic cell death was evaluated using APC Annexin-V Apoptosis Detection Kit with PI (Thermo Fisher Scientific, Waltham, MA USA). Briefly,  $1.5 \times 10^4$ /mL SKO-007(J3) cells infected with lentivirus pLKO.1-shRNA-GAS6 or non-target shRNA were culture in 24-well plates for 72h. Cells were then stained using Annexin-V/APC and PI according to the manufacturer's instruction. Cell populations were acquired using FACS Canto II flow cytometer (BD Biosciences, San Jose, California, USA). Flow cytometric analysis was performed using Flow Jo Flow Cytometric Analysis Software.

## Enzyme-linked immunosorbent assay (ELISA)

BMSC-conditioned medium and bone marrow plasma were analyzed for GAS6 by ELISA following instructions provided by the manufacturer (R&D System, Minneapolis, USA). BMSC-CM was collected from 72h culture of  $20 \times 10^3$  BMSCs in 1 mL of serum free-medium in a 24-well plate. Absorbance was measured at 450/540nm with Victor2 Microplate Reader (Perkin Elmer – GMI Waltham, Massachusetts, USA), and GAS6 concentration was calculated in correlation to a standard curve of control samples.

## Preparation of BMSC-CM

Medium collected from 72h-culture of confluent BMSCs ( $2 \times 10^4$  cells) (BMSCs-CM) was used to stimulate MM cell lines for 72h. In some experiments, BMSCs-CM was treated with Proteinase K (250 $\mu$ g/mL) (Sigma-Aldrich, St. Louis, MO, USA) for 1h at 65°C. BMSCs-CM and complete RPMI1640 medium were separated in different fractions by Amicon Ultra-15 centrifugal filter devices (Merck Millipore,

Darmstadt, Germany) according to the manufacturer's instructions.

## Statistical analysis

Statistical significance between two groups was determined by performing two-tailed, Student's t-test, Anova. Prism 6 (GraphPad) software was used. Graphs show mean values, and error bars represent the SD or SEM. We used non-parametric t-test (Mann Whitney test). P-value of < 0.05 (\*), < 0.01 (\*\*), < 0.001 (\*\*\*), and < 0.0001 (\*\*\*\*) was considered statistically significant, when not indicated, data were not statistically significant. Multiple comparisons were performed using univariate analysis of variance (Two-way Anova with Bonferroni's post-test).

## Results

### GAS6/TAM signaling pathway regulates MICA expression in human MM cells

GAS6 and its receptors TYRO3, AXL and MERTK contribute to MM pathobiology (21, 22), however the role of these molecules in the regulation of immune attack of malignant PCs remains to be elucidated.

Here, we investigated the effect of GAS6/TAM signaling pathway on the regulation of NKG2D ligands in three MM cell lines [SKO-007(J3), U266 and ARP1]. Among TAM receptors, these MM cell lines lack TYRO3 but express MERTK, while AXL is present only on SKO-007(J3) cells (Supplementary Figures 1A, 2A–E). Thus, we performed a flow cytometric analysis on MM cells silenced for the ligands GAS6 and PROS1 or the receptors AXL and/or MERTK by lentiviral-transduced small-hairpin RNAs (shRNAs). Since stable depletion of these proteins is cytotoxic for MM cells (20, 22), these experiments were performed using transient infection without any significant effect on cell viability (as assessed by Annexin V staining) (Supplementary Figure 1C). We found that knockdown of GAS6, PROS1, AXL or MERTK was able to significantly reduce MICA surface levels in MM cell lines (Figures 1C, E, G, I and Supplementary Figures 2B, C, F, G). Differently, depletion of GAS6 did not affect the expression of other NKG2D ligands (MICB and ULBPs), NKp30 ligand B7/H6, DNAM-1 ligand PVR, MHC class I and of the adhesion molecule ICAM-1 (Supplementary Figure 1B).

These results indicate a role for TAM pathway in sustaining the basal expression of MICA in MM cells.

We then examined whether MICA downregulation could be the consequence of a decreased mRNA expression. To this aim, total RNA was isolated from SKO-007(J3) cells infected with lentivirus pLKO.1-shRNA GAS6, PROS1, AXL or MERTK or

non-target shRNA, and analyzed by real-time quantitative RT-PCR. Consistent with FACS analysis, silencing of these proteins decreased basal MICA mRNA levels (Figure 1J).

To evaluate the functional consequences of changes in MICA expression, we analyzed the degranulation of healthy donor NK cells against SKO-007(J3) cells or U266 infected with lentivirus pLKO.1-shRNA GAS6 or non-target shRNA (pLKO.1-control). As shown in Figures 2B–E, expression of CD107a on NK cells was decreased when co-cultured with GAS6 depleted-SKO-007(J3) or U266 target cells. Moreover, a blocking anti-NKG2D mAb impaired NK cell degranulation against SKO-007(J3) or U266 pLKO.1-control, and U266 pLKO.1-GAS6 shRNA; however, it failed to reduce the activation of NK cells contacting SKO-007(J3) pLKO.1-GAS6 shRNA.

In lines with previous studies (6, 10, 11, 36), these findings demonstrate that constitutive NK cell degranulation against MM cells involves NKG2D. More importantly, they indicate that MICA downregulation on GAS6 depleted- SKO-007(J3) and U266 cells compromises their NKG2D-dependent recognition by NK cells.

### BMSC-derived GAS6 increases MICA surface expression in MM cells

Myeloma BM microenvironment is highly enriched in GAS6 (22), which is also largely produced by BMSCs and tumor cells (Figure 3A and Supplementary Table 1). We thus analyzed the possible effects of MM patient derived-BMSCs on MICA expression in MM cells. We observed that conditioned medium (BMSCs-CM) collected after 72h culture of MM-BMSCs could induce AXL phosphorylation in SKO-007(J3) (Figure 3B) and up-regulated the basal membrane expression of MICA on SKO-007(J3), ARP-1 and U266 cell lines (Figures 3C, D). Moreover, we found that MM patient-derived PCs cultured in autologous or heterologous BMSC-CM for 48h expressed higher levels of MICA than primary myeloma cells cultured in RPMI1640 medium alone (Figure 3E and Supplementary Table 2). However, BMSC-CM did not affect the expression of MICB on these cells (data not shown). Consistently, BMSC-CM-treated SKO-007(J3) were more capable to activate NK cell degranulation. This effect was significantly inhibited by a blocking anti-NKG2D mAb, indicating that stimulation of NK cell degranulation was dependent on NKG2D activation (Figures 3F, G).

To gain insight into the nature of the BMSCs-derived factor(s) capable of enhancing MICA expression on MM cells, BMSC-CM was pre-treated with the serine protease Proteinase K for 1h before to be used to stimulate SKO-007(J3) cells for 72h. As shown in Figure 4A, we found that pre-treatment with this enzyme able to degrade proteins abolished the capability of BMSC-CM to increase the expression of MICA on MM cells. These findings indicate that soluble factor(s) produced by

BMSCs involved in these mechanisms are protein(s). Then, using centrifugal filtration with a semi permeable membrane of different molecular weight cutoff, we separated BMSC-CM and complete RPMI1640 medium, used as a control, into fractions ranging from 100 to 10 KDa. Fractioned BMSC-CM or complete RPMI1640 medium were used to stimulate SKO-007(J3) cells for 72h. In line with our data implying GAS6 (75 KDa) in MICA up-regulation, we observed that this NKG2D ligand augmented in SKO-007(J3) cells exposed to the fraction >50KDa (Figure 4B). Consistently, CM derived from BMSCs lacking GAS6 (Figures 4C, D) was not able to augment MICA expression on SKO-007(J3) cells (Figure 4E).

Taken together, these results demonstrate that autocrine and paracrine production of GAS6 is implicated in the regulation of MICA on MM cells.

## Role of NF- $\kappa$ B in MICA up-regulation by BMSCs

To examine the molecular mechanisms underlying MICA up-regulation, we performed real-time quantitative RT-PCR on total RNA isolated from SKO-007(J3) cells and PCs isolated from different MM patients cultured in BMSC-CM for 48h. We found a significant increase of *MICA* mRNA levels in treated MM cells (Figures 5A, B). Thus, we investigated the direct effect of BMSC-CM on the activity of the *MICA* promoter. As shown in Figure 5C, by transient transfection assays, we observed that BMSC-CM enhanced the luciferase reporter activity driven by a 270bp 5'-flank of *MICA* promoter.

Collectively, these data indicate that *MICA* mRNA expression and promoter activity are enhanced by BMSC-CM in MM cells.

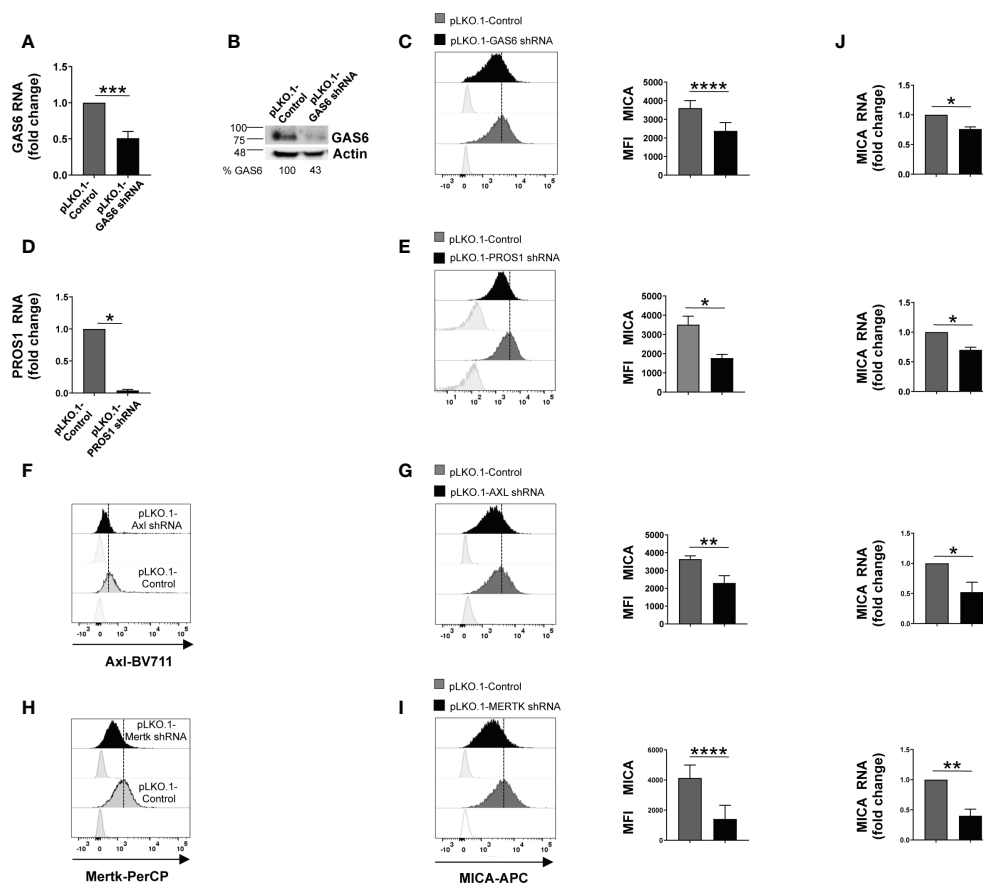

FIGURE 1

Silencing of GAS6, PROS1 or TAM receptors reduces MICA expression in SKO-007(J3) cells. Total mRNA and protein extracts obtained from SKO-007(J3) pLKO.1-GAS6 shRNA or pLKO.1-PROS1 shRNA and pLKO.1-Control were analyzed for GAS6 or PROS1 expression by real-time PCR (A–D) and Western Blot (B). AXL and MERTK receptor expression was analyzed by FACS on SKO-007(J3) pLKO.1-Control, pLKO.1-AXL shRNA (F) or pLKO.1-MERTK shRNA (H). MICA expression was analyzed by flow cytometry and real-time PCR in SKO-007(J3) pLKO.1-GAS6 shRNA (n=6) (C), pLKO.1-PROS1 shRNA (n=3) (E), pLKO.1-AXL shRNA (n=6) (G), pLKO.1-MERTK shRNA (n=6) (I) or pLKO.1-Control. Histograms represent the MFI of specific mAb subtracted of MFI of isotype control. Data are shown as mean  $\pm$  SD (\*\*\*\*p < 0.001; \*\*\*p < 0.005; \*\*p < 0.01; \*p < 0.05 Mann-Whitney Test). For real-Time PCR analysis (J), data, expressed as fold change units, were normalized with GAPDH and referred to pLKO.1-Control, considered as calibrator. Data are shown as mean  $\pm$  SD (\*\*p < 0.01; \*p < 0.05; Mann-Whitney Test).

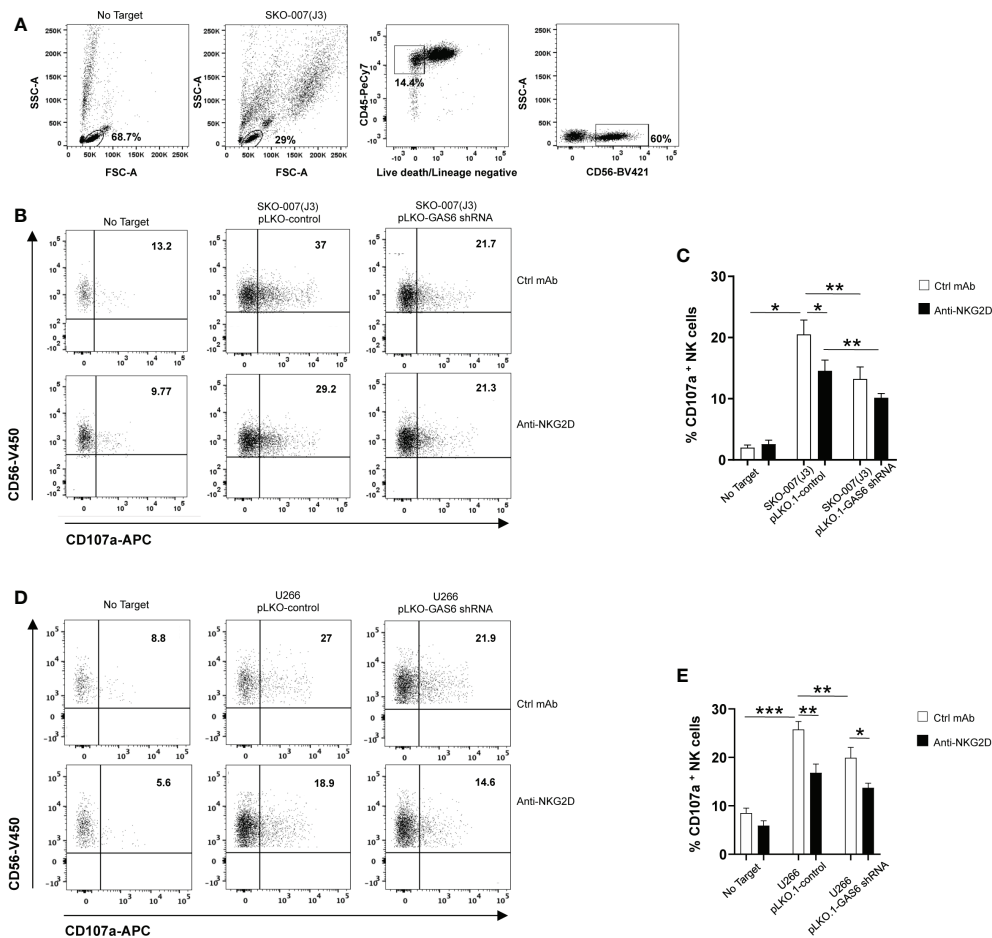

FIGURE 2

Impaired NKG2D-dependent recognition of GAS6-depleted MM cells. Healthy donor-derived PBMCs were incubated with SKO-007(J3) (A–C) or U266 (D, E) pLKO-1-GAS6 shRNA or pLKO-1-Control at E/T ratio of 1:1. CD107a expression was analyzed on CD3<sup>+</sup>CD19<sup>+</sup>CD14<sup>+</sup>CD45<sup>+</sup>CD56<sup>+</sup> NK cells as shown in (A, B). To evaluate the role of NKG2D, the assay was performed in parallel treating NK cells with blocking anti-NKG2D or anti-IgG mAb used as control (Ctrl). Results are expressed as the percentage of CD107a<sup>+</sup> NK cells. A representative experiment for each MM cell line is shown in (B, D). Histogram represents the mean  $\pm$  SD from three independent experiments (C, E) (\* $p$  < 0.05; \*\* $p$  < 0.001; \*\*\* $p$  < 0.005 ANOVA).

Previous reports demonstrated a role for NF- $\kappa$ B in the regulation of MICA expression in different types of cells (e.g. T lymphocytes, endothelial cells and MM cells) (37, 38) NF- $\kappa$ B proteins are constitutively active in MM cells but BMSCs produce many soluble factors, including GAS6, which further trigger this signaling pathway in these tumor cells (16, 20, 39, 40). For this reason, we investigated the role for NF- $\kappa$ B in MICA regulation by BMSCs.

First, we observed that GAS6 depleted-BMSC-CM has a reduced capability to induce phosphorylation of p65 and to enhance NF- $\kappa$ B transcriptional activity in SKO-007(J3) cells; moreover, the TAM receptor inhibitor UNC2250 partially blocks phosphorylation of p65 by BMSC-CM in these cells (Figures 5D, E). Accordingly, we found reduced levels of

phosphorylated p65 in GAS6 silenced SKO-007(J3) cells (Figure 5F). These findings indicate a direct contribute of autocrine and paracrine GAS6 as a regulator of NF- $\kappa$ B pathway in MM cells.

Second, we revealed that the stimulatory effect of BMSC-CM was significantly diminished on a mutated version of MICA promoter (indicated as DEL1), in which a putative NF- $\kappa$ B site (41) was removed by site-directed mutagenesis (Figure 5G), thus indicating that binding of this transcription factor to this region is required for promoter activation.

Taken together, these findings demonstrate that NF- $\kappa$ B can act as an activator of MICA expression in MM cells in response to GAS6 secreted by BMSCs.

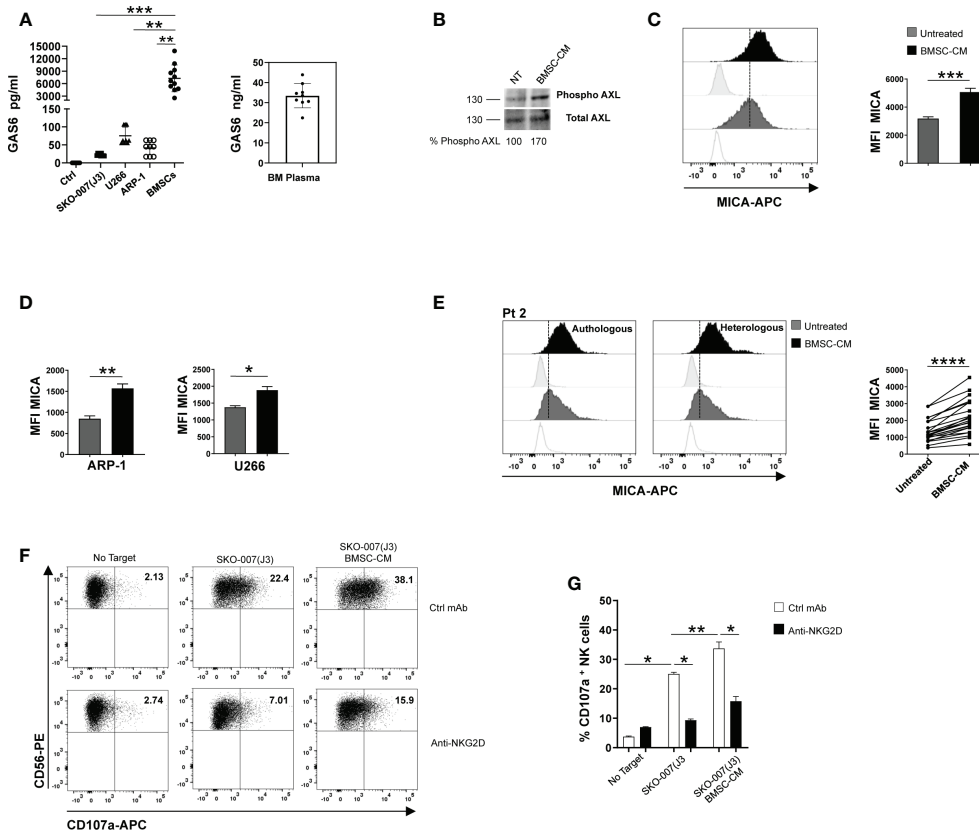

FIGURE 3

BMSC-CM up-regulates MICA surface expression in MM cells. GAS6 protein was quantified by ELISA in conditioned medium (CM) derived from the indicated MM cell lines, BMSCs and plasma from BM aspirates of MM patients. Serum free medium was used as control (Ctrl) (A). Total protein extracts obtained from SKO-007(J3) untreated or treated for 1h with BMSC-CM were analyzed for phosphorylated and total AXL expression by Western Blot (B). Numbers represent densitometric analysis of phosphorylated AXL normalized relative to untreated cells. MICA surface expression was analyzed by flow cytometry in SKO-007(J3) (n=8) (C), ARP-1 (n=6) or U266 (n=5) MM cell line (D) or in primary malignant PCs (n=12) (E) untreated or treated with BMSC-CM for 72h or 48h, respectively. A representative experiment is shown. Histograms represent the MFI of specific mAb subtracted of MFI of isotype control. Data show mean  $\pm$  SD (\*\*\*\* $p$  < 0.001; \*\*\* $p$  < 0.005; \*\* $p$  < 0.05; Mann-Whitney Test). NK cells derived from healthy donor PBMCs were incubated with SKO-007(J3) cells, untreated or cultured for 72h with BMSC-CM and used as target cells in a degranulation assay as described above. Results are expressed as the percentage of CD107a<sup>+</sup> NK cells (F). A representative experiment is shown in (E). Histogram represents the mean  $\pm$  SD from three independent experiments (G) (\* $p$  < 0.05; \*\* $p$  < 0.001 ANOVA).

## Discussion

Natural Killer cells are important effectors of anti-MM immune response. Yet, malignant PCs acquire the ability to elude NK cell recognition and suppress their function (7, 42). To overcome NK cell dysfunctions associated to disease progression, innovative treatments include the adoptive NK cell therapy and monoclonal antibodies to enhance NK cell-versus-MM effect (8, 9); in parallel, tumor modulating agents able to render MM cells more susceptible to NK cell attack also represent promising therapeutic tools. NKG2D is a key activating receptor involved in these mechanisms (6, 43), thus understanding how expression of its ligands is regulated on malignant PCs could be helpful to address these approaches.

Regulation of NKG2D ligand expression in MM cells mainly relays on transcriptional and post-translational mechanisms (44). A number of transcription factors, highly expressed and active in these tumor cells, where they control aberrant and malignancy-specific gene expression program, are also involved in the regulation of NKG2D ligand expression. Our group identified Hsp90, STAT3, IRF4, C-MYC and IKAROS/AIOLOS as repressors of *MICA* and/or *MICB* gene transcription (10–13). These findings indicate that MM cells have developed the capability to exploit the same pathways to promote their growth as well as to reduce immune recognition. Further, a relevant immune escape mechanism is represented by the down-regulation of NKG2D ligands on the surface of MM cells by proteolytic shedding (45). In particular, soluble MICA is

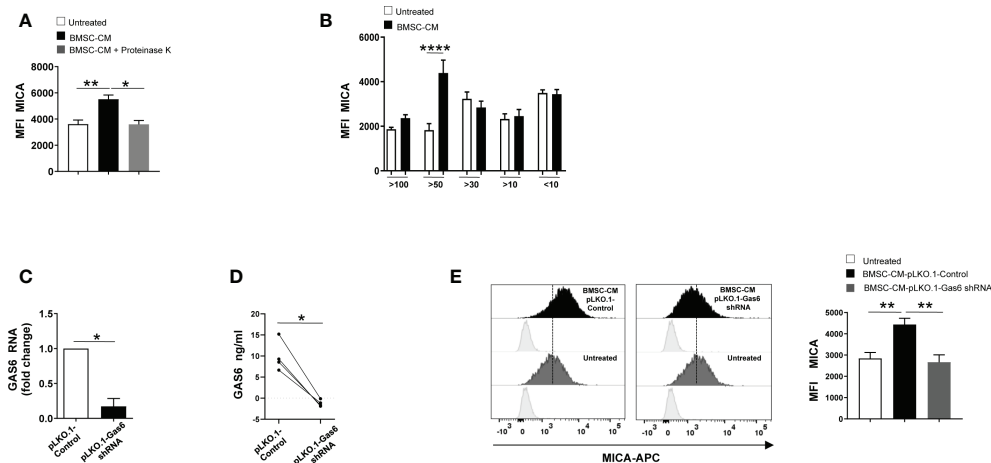

FIGURE 4

GAS6 controls MICA up-regulation in BMSC-CM-treated MM cells. Flow cytometry analysis of MICA surface expression on SKO-007(J3) cells cultured for 72h in BMSC-CM, pre-treated or not with proteinase K (A), or in fractions of different molecular weight obtained from BMSC-CM (n=8) (B). Histograms represent the MFI of specific mAb subtracted of MFI of isotype control. Data show mean  $\pm$  SD (\* $p$  < 0.05; \*\* $p$  < 0.005; \*\*\* $p$  < 0.001; ANOVA). Analysis of GAS6 mRNA (C) and protein (D) in BMSCs infected with lentiviral vector expressing GAS6 shRNA (pLKO.1-GAS6 shRNA) or scramble control (pLKO.1-Control) (n=4). Data show mean  $\pm$  SD (\* $p$  < 0.05; Mann-Whitney Test). MICA surface expression was analyzed by FACS on SKO-007(J3) treated for 72h with CM derived from BMSCs pLKO.1-GAS6 shRNA or pLKO.1-Control (n=3) (E). Histograms represent the MFI of specific mAb subtracted of MFI of isotype control. Data show mean  $\pm$  SEM (\*\* $p$  < 0.001; ANOVA).

overexpressed in the serum of MM patients, and its levels correlate with tumor progression (46).

However, little is currently known about signaling events and molecular mechanisms responsible for basal expression of NKG2D ligands in MM cells.

Here, we provide first evidence that surface MICA expression is regulated by GAS6/TAM pathway in MM cells. We demonstrate that: (1) GAS6/AXL and MERTK signaling, in a cell-autonomous way, sustains MICA expression in MM cells; (2) GAS6 secreted by BMSCs augments membrane MICA expression on MM cells at transcriptional level; (3) NF- $\kappa$ B pathway mediates MICA up-regulation by GAS6.

GAS6/TAM signaling components are overexpressed in MM cells and support their survival and proliferation (20, 22). We found that MM cells silenced for the ligand GAS6 or PROS1, or the receptors AXL and MERTK by lentiviral-transduced shRNAs express reduced levels of MICA, both at protein and mRNA level, and are less susceptible to NKG2D mediated-recognition by NK cells.

The contribution of soluble factors in the regulation of this ligand has been previously described. A number of cytokines and growth factors, such as TGF- $\beta$ , IL-10, IFN- $\gamma$  and EGF function as regulators of MICA expression in different types of cancer cells (47–50).

Here, we demonstrate that a peculiar regulatory circuitry, involving both autocrine and paracrine GAS6, assures MICA expression on MM cells. Indeed, MM BM microenvironment is highly enriched in GAS6 (22), which is largely produced by

BMSCs. We found a significant up-regulation of membrane MICA expression on MM cell lines as well as on patient-derived PCs by BMSC-CM. However, knockdown of GAS6 in BMSCs abolished these effects. Interestingly, we have already described that BMSCs enhance PVR surface expression on MM cells and promote their NK cell-mediated recognition (17). Our novel findings confirm that expression of NK cell activating ligands on malignant PCs is highly dependent on BM microenvironment.

Our data also indicate that the transcription factor NF- $\kappa$ B is critically involved in MICA regulation by GAS6/BMSCs.

NF- $\kappa$ B was found to be a positive regulator of *MICA* gene in different cellular contexts. In activated T lymphocytes and epithelial cancer cell lines, NF- $\kappa$ B acts by binding to a specific sequence in the long intron 1 of the *MICA* gene (37, 38). Furthermore, in human endothelial cells TNF- $\alpha$ -induced NF- $\kappa$ B binds a regulatory control site at -130 bp upstream of the *MICA* transcription start site (41).

Here, we first observed reduced NF- $\kappa$ B activation in MM cells lacking GAS6 and after treatment with GAS6 depleted-BMSC-CM, thus revealing that TAM receptor signaling controls NF- $\kappa$ B activity in these tumor cells. Second, by a site-directed mutagenesis approach, we proved that deletion of an NF- $\kappa$ B responsive element (41) compromises the induction of *MICA* promoter by BMSC-CM. Based on these observations, we propose a role for NF- $\kappa$ B as a direct positive regulator of *MICA* promoter in MM cells.

Previous studies have described a negative impact of TAM pathway on immunological visibility of tumor cells *via*

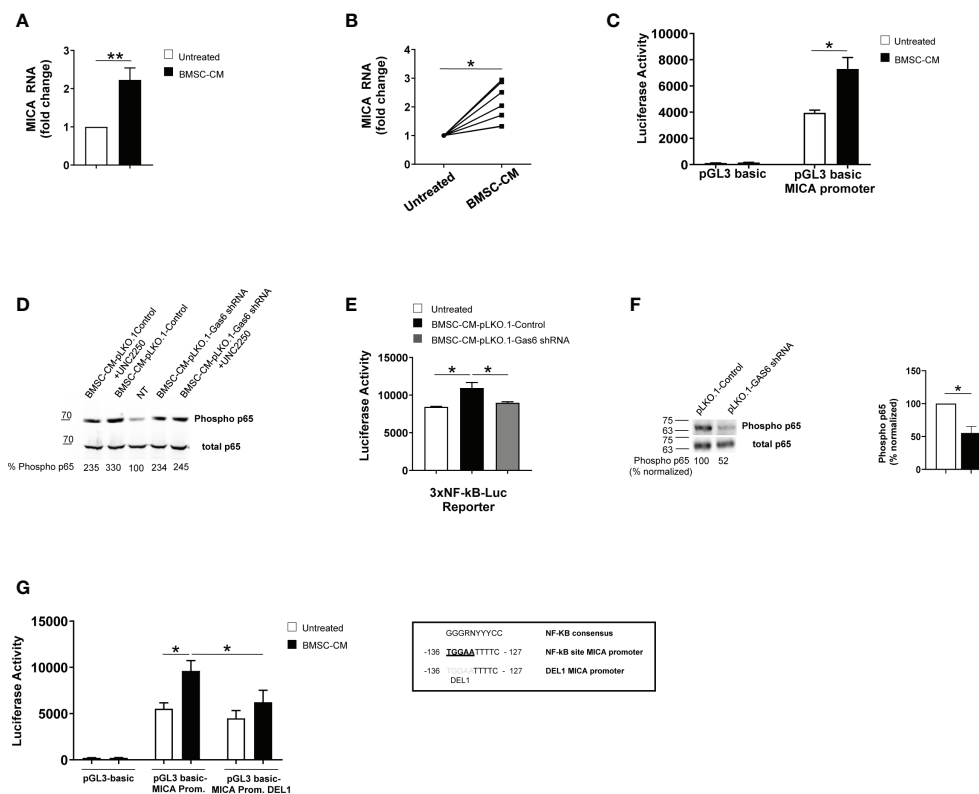

FIGURE 5

BMSC-CM increases *MICA* mRNA expression and promoter activity via NF-κB activation. Real time PCR analysis of total mRNA obtained from SKO-007(J3) cells (A) or patient-derived PCs (B) after 48h stimulation with BMSC-CM or complete medium. Data, expressed as fold change units, were normalized with GAPDH and referred to the untreated cells, considered as calibrator. For SKO-007(J3) cells, histograms represent the mean  $\pm$  SD from six independent experiments. For primary PCs, data from 7 MM patients are shown where each dot represents a single patient. (\* $P < 0.05$ ; \*\* $P < 0.005$ ; Mann-Whitney Test). SKO-007(J3) cells were transiently transfected with pGL3 basic empty vector/*MICA* 270bp promoter plasmid (C) and/or a DEL1-270bp *MICA* promoter plasmid (in which a putative NF-κB site indicated in the figure was removed by site-directed mutagenesis) (G) or infected with lentivirus pHAGE-3xNF-κB-LUC-GFP (E) as described in materials and methods. After 48h of treatment with BMSC-CM, SKO-007(J3) cells were harvested, and protein extracts were prepared for the luciferase assay. Data, expressed as relative luciferase activity, were normalized to protein concentration and renilla activity and represent the mean  $\pm$  SEM from three independent experiments (\* $p < 0.05$ ; ANOVA). Total protein extracts obtained from SKO-007(J3) treated with CM derived from BMSCs pLKO.1-GAS6 shRNA or pLKO.1-Control in the absence or in the presence of UCN2250 (1  $\mu$ M) (D) or SKO-007(J3) infected with lentivirus pLKO.1-GAS6 shRNA or pLKO.1-Control (F) were analyzed for phosphorylated and total p65 expression by Western Blot. Numbers represent densitometric analysis of phosphorylated p65 normalized relative to untreated cells.

upregulation of NK cell inhibitory ligands. As an immune evasion mechanism, AXL signaling was shown to increase surface expression of MHC-class I molecules and PDL-1 in lung, renal and breast cancer cell lines (51–53). In our experimental setting, either silencing of GAS6 or culture with BMSC-CM did not affect MHC-class I expression in MM cells, while the possible effects on other NK cell inhibitory ligands were not investigated. However, the absence of GAS6 in MM cells reduces their capability to activate NK cells, whereas BMSC-CM renders MM more susceptible to recognition by both NK cells from healthy donors and MM patients (17). Such functional consequences do not suggest any relevant change of inhibitory pathways by GAS6/TAM signaling in

MM cells, but further studies are needed to address this possibility.

Although unexpected, our data are not the first demonstration on the positive regulation of *MICA* by an oncogenic pathway. Another major cell-autonomous component of tumor progression, EGFR, was shown to drive basal expression of NKG2D ligands in epithelial cancer cells (50). Together these and our observations indicate that oncogenic signaling pathways may be relevant at the early stages of cancer when they become dysregulated, and expression of activating ligands is key for immune surveillance.

Remarkably, GAS6/TAM pathway is also a key regulator of immune homeostasis (25). Innate and adaptive immune cells, in

humans and mice, express TAM receptor/ligands and blocking TAM signaling causes severe defects in the clearance of apoptotic cells, widespread inflammation and over-activation of the immune system, and development of systemic autoimmunity (54).

This axis signaling is also known to regulate NK cell differentiation and function. Binding of GAS6 to TAM receptors inhibits murine NK cell function by phosphorylating Cbl-b, which promotes the degradation of LAT1. Consistently, administration of GAS6 or TAM receptor inhibitors leads to rejection of metastatic tumors (28, 29). However, to our knowledge, there is no evidence of these inhibitory effects on human NK cells. In contrast, a recent study proposed TYRO3 as an NK cell activating receptor showing that activated human NK cells can acquire the receptor upon contact with tumor cells *via* trogocytosis and that TYRO3<sup>+</sup> NK cells are more cytotoxic and produce more IFN- $\gamma$  (30). Activating effects were also reported for MERTK in human CD8<sup>+</sup> T cells, where the receptor functions as a co-stimulatory signal promoting proliferation and generation of memory T cells (55).

The role of TAM receptors in the regulation of NK cells in MM has never been investigated. In the context of a study on NK cells from newly diagnosed and refractory relapsed MM, an RNA seq analysis showed a reduction of *AXL* and *GAS6* gene expression (56), thus suggesting that inhibitory signals generated by GAS6/TAM components may not be related to NK cell dysregulation in this malignancy. However, these mechanisms remain to be studied.

Due to their pro-oncogenic and putative immune-inhibitory effects, TAM receptors have emerged as promising targets for cancer therapy. Indeed, many clinical trials are currently investigating TAM targeting therapies in solid and hematologic cancers. However, further investigations are required to elucidate the contribute of different TAM receptors on distinct immune cell types during anti-tumor immune response. Indeed, the impact on immune system and immune surveillance are relevant aspects to evaluate in design drugs targeting cancer cells. In this context, our data suggest that the modulation of MICA on tumor cells may be a potential limiting effect of GAS6/TAM inhibitors on immune surveillance. To this regard, a recent report demonstrated the feasibility of using autologous NK cells bearing NKG2D-CAR to treat MM. These cells have robust cytotoxic activity against MM cells *in vitro* and exhibit high efficiency *in vivo* in a mouse model of MM (57). In this therapeutic perspective, it would be important to preserve and/or enhance NKG2D ligand expression on tumor cells, and our finding could be helpful in setting the right combined therapy.

Overall, these data reveal a novel immunoregulatory role for the GAS6/TAM pathway and shed light on molecular mechanisms underlying basal MICA expression in MM cells.

## Data availability statement

The original contributions presented in the study are included in the article/**Supplementary Material**. Further inquiries can be directed to the corresponding authors.

## Ethics statement

The studies involving human participants were reviewed and approved by RIF.CE: 5191. The patients/participants provided their written informed consent to participate in this study.

## Author contributions

CF, AK, AM, LL, and HS performed the experiments and analyzed the results; HS, ASO, AZ, and MC contributed with analytic tools and analyzed the results; MP and FF provided and managed bone marrow samples from patients; AG and ASa critically reviewed the manuscript. CF and HS contributed to design research and write the manuscript. All authors contributed to the article and approved the submitted version.

## Funding

**Purpose:** Polymorphisms in complement genes are risk-associated for age-related macular degeneration (AMD). Functional analysis revealed a common deficiency to control the alternative complement pathway by risk-associated gene polymorphisms. Thus, we investigated the levels of terminal complement complex (TCC) in the plasma of wet AMD patients with defined genotypes and the impact of the complement activation of their plasma on second-messenger signaling, gene expression, and cytokine/chemokine secretion in retinal pigment epithelium (RPE) cells.

**Design:** Collection of plasma from patients with wet AMD (n = 87: 62% female and 38% male; median age 77 years) and controls (n = 86: 39% female and 61% male; median age 58 years), grouped for risk factor smoking and genetic risk alleles *CFH* 402HH and *ARMS2* rs3750846, determination of TCC levels in the plasma, *in vitro* analysis on RPE function during exposure to patients' or control plasma as a complement source.

**Methods:** Genotyping, measurement of TCC concentrations, ARPE-19 cell culture, Ca<sup>2+</sup> imaging, gene expression by qPCR, secretion by multiplex bead analysis of cell culture supernatants.

**Main outcome measures:** TCC concentration in plasma, intracellular free Ca<sup>2+</sup>, relative mRNA levels, cytokine secretion.

**Results:** TCC levels in the plasma of AMD patients were five times higher than in non-AMD controls but did not differ in plasma from carriers of the two risk alleles. Complement-evoked Ca<sup>2+</sup> elevations in RPE cells differed between patients and controls with a significant correlation between TCC levels and peak amplitudes.

Comparing the  $\text{Ca}^{2+}$  signals, only between the plasma of smokers and non-smokers, as well as heterozygous (*CFH* 402YH) and *CFH* 402HH patients, revealed differences in the late phase. Pre-stimulation with complement patients' plasma led to sensitization for complement reactions by RPE cells. Gene expression for surface molecules protective against TCC and pro-inflammatory cytokines increased after exposure to patients' plasma. Patients' plasma stimulated the secretion of pro-inflammatory cytokines in the RPE.

**Conclusion:** TCC levels were higher in AMD patients but did not depend on genetic risk factors. The  $\text{Ca}^{2+}$  responses to patients' plasma as second-messenger represent a shift of RPE cells to a pro-inflammatory phenotype and protection against TCC. We conclude a substantial role of high TCC plasma levels in AMD pathology.

#### KEYWORDS

retinal pigment epithelium, terminal complement complex, age-related macular degeneration, AMD serum, genetic risk factors

## 1 Introduction

Age-related macular degeneration (AMD) is one of the major causes of vision loss in industrialized countries (1). The disease shows two clinically defined end stages. One is the loss of cells of the retinal pigment epithelium (RPE) and photoreceptors, which progresses slowly. This form, the so-called “dry AMD” or geographic atrophy, accounts for approximately 80% of the cases but due to its low progression for approximately 20% of blindness. The other end stage is characterized by the proliferation of endothelial cells, resulting in pathologic neo-angiogenesis that leads to bleeding due to low grade of blood vessel differentiation and thus too fast loss of vision (2). This end stage, the so-called choroidal neovascularization or “wet AMD”, represents the majority of cases of blindness. AMD is a multifactorial disease for which environmental risk factors like smoking and genetic risk factors like polymorphisms in genes such as *ARMS2* (age-related macular susceptibility-2) or genes of the complement components are known (3–5).

The identification of complement deposits in drusen as well as polymorphisms in complement genes as risk factors suggested that the complement system is associated with the development of AMD. Recent reports confirmed that an over-activated complement system due to reduced regulation represents a risk for AMD (3, 4, 6–10). However, recent clinical trials failed to establish a complement inhibition-based therapy for the dry form of AMD (11–13). Therefore, the role of activated complement proteins is more complex, and the chronic AMD-associated complement activity is still not fully understood (12).

Another reason why complement-targeting clinical trials failed might be the fact that the systemic over-activity of the complement cascade has a life-long impact on the retina. This would explain why acute intervention into complement activity might not immediately reverse chronic events that have affected the outer retina for

decades (12). Complement activation may have a lifelong systemic impact on the outer retina with strong local pathologic changes. The impact of the end product of the complement cascade, the terminal complement complex (TCC; also termed C5b-9), is not clear so far. The TCC is a complex of five different proteins (C5b, C6, C7, C8, and C9). When this complex is formed on a cell surface, several C9 components are aggregated and form a ring, inserting a pore into the cell membrane, which leads to cell lysis and is also called membrane attack complex (MAC). Indeed, depending on age, AMD status, and risk allele, TCC accumulates in the outer retina. TCC is increasingly found in the tissue complex of the choroid, Bruch's membrane, and RPE during its lifetime (14–17). AMD patients with C9 risk alleles show increased plasma levels of C9 or TCC compared to healthy non-carriers (18–20), although no differences were reported among AMD with or without C9 risk alleles. This might be explained by the fact that AMD patients with the absence of C9 risk alleles generally display increased systemic complement activities (21–23). In the plasma of patients carrying various C9 risk alleles, higher levels of C9 but no differences in TCC plasma levels were found (19). When comparing different C9 risk alleles, it appeared that some are associated with higher C9 or TCC plasma levels (20). This suggests an important role of TCC in AMD pathology.

Acting as MAC, the consequence of TCC accumulation in the outer retina would destabilize RPE cells, which results in the loss of RPE cells (24–26). The RPE itself is a close interaction partner of the light-sensitive photoreceptors, supporting their function and even contributing to visual function (27). Thus, the loss of RPE cells in AMD ultimately causes loss of photoreceptors and blindness. Several observations about the general nature of TCC effects and the concept of the specific complement impact on the RPE are still unclear. In the RPE, the human plasma-derived complement ignites a well-orchestrated  $\text{Ca}^{2+}$  signal that depends on the activation of endogenously expressed  $\text{Ca}^{2+}$  and  $\text{K}^{+}$  channels. The induction of an

unspecific pore could not be detected in measurements of the membrane conductance by means of the patch-clamp technique (28). The different complement activation products' consequence is that the RPE cells change their gene expression pattern toward a more pro-inflammatory profile in response to anaphylatoxins via the Akt-kinase pathway and the transcription factor FoxP3 (29–33).

TCC's influence on gene expression emerged as the concept of sub-lytic MAC in studies that investigated the effects of different TCC concentrations and combinations at various cell types (25, 34–39). The concept bases on the ability of cells to remove MAC from the plasma membrane. As long as the cell's ability to remove MAC from the plasma membrane can cope with the rate of extracellular TCC formation and membrane insertion, the cell will not undergo lysis (35). Soluble TCC is generally accepted as a marker of *in vivo* complement activation (40). These studies defined TCC concentrations that do not lyse cells but lead to functional changes as sub-lytic (34, 35, 37, 38). The functional changes require intracellular signaling such as an increase in intracellular  $\text{Ca}^{2+}$ , activation of different types of kinases, and even the activation of G proteins (25, 34, 35, 37–39, 41). The activation of these intracellular signaling pathways then lead to secondary effects such as changes in the gene expression profile and represent the basic sub-lytic MAC effects onto cellular functions. Several studies demonstrated functional changes of the RPE by sub-lytic MAC, mainly in the secretory activity of, e.g., VEGF-A or MCP-1, or reduced stress response (5, 30, 33, 42, 43). This might be explained by CD59, which inactivates MAC formation (7, 44) and represents a target for further therapeutic approaches (26). However, Cipriani et al. found no risk association of TCC regulators CD46, CD55, and CD59 with AMD, especially not for CD59 (45).

As a consequence, the enhanced generation of TCC in AMD patients might not directly lead to RPE cell death but promote a change of the RPE's immunogenic phenotype toward low-grade chronic inflammation. To test this concept, we have used human plasma from AMD patients with defined genetic risk factors as a complement source to test RPE cell reactions to dysregulated complement. Depending on the patients' genotype, these plasma contained different levels of TCC and caused different  $\text{Ca}^{2+}$  signals as well as different regulatory effects on gene expression. Our hypothesis is that TCC complexes in AMD patients generate  $\text{Ca}^{2+}$  signals with profound physiological changes in the RPE.

## 2 Materials and methods

### 2.1 Blood samples and determination of TCC concentration

A total of 87 AMD patients with wet AMD (62% female and 38% male) with a mean age of 77.9 years (median = 77 years) and 86 age-matched controls (39% female and 61% male) with a mean age of 55.1 years (median = 58) were included; further information is presented in the tables of [Supplementary Material Suppl. 1, 2](#). The samples were anonymized. Blood samples were collected with EDTA and centrifuged, and plasma was stored at  $-80^{\circ}\text{C}$ . The

concentration of TCC was determined by ELISA as previously described (46). In brief, plasma samples were pre-incubated ( $37^{\circ}\text{C}$ ; 15 min) and incubated on lipopolysaccharide (LPS)-coated plates. Plates were analyzed at 450-nm wavelength using TCC mAB from TECOmedical (Sissach, Switzerland). The polymorphisms in this patient cohort were determined as described earlier for *ARMS* (47) and *CFH* (9, 48).

### 2.2 RPE cell culture

For our study, the ARPE-19 cell line was used, which shows limitations for conclusions about native RPE cells. Here, these cells were used to monitor the biological activity of activated complement proteins in human plasma rather than to investigate specific RPE cell functions. The cells were grown on glass coverslips to confluence prior to the  $\text{Ca}^{2+}$  imaging experiments. The culture conditions were using Dulbecco's modified Eagle medium (DMEM)/F12 (Thermo Fisher, Darmstadt, Germany) with GlutaMAX (stable glutamine) supplemented with 10% fetal calf serum (FCS) and 50 U penicillin/50 mg streptomycin at  $37^{\circ}\text{C}$  and 5%  $\text{CO}_2$ . The medium was changed twice a week.

### 2.3 $\text{Ca}^{2+}$ imaging experiments

As a readout of biological responses to the activated complement, intracellular free  $\text{Ca}^{2+}$  as a second messenger was measured by means of  $\text{Ca}^{2+}$  imaging techniques based on fluorescence microscopy using the  $\text{Ca}^{2+}$ -sensitive fluorescence dye fura-2. Confluent ARPE-19 cells grown on glass coverslips were incubated in the membrane-diffusible fura-2 ester fura-2-AM (2  $\mu\text{M}$ ) for 40 min at room temperature. Fura-2 loaded cells were mounted onto the stage of a Zeiss Axiovert 40 CFL inverted microscope (Carl Zeiss, Oberkochen, Germany) with an attached Visitron Polychromator (Visitron Systems, Puchheim, Germany) and a high-sensitivity color event camera (CED) camera (CoolSNAP EZ, Photometrics, Tucson, AZ, USA). Experiments were conducted using the MetaFlour software (Visitron Systems, Puchheim, Germany). The cells were bathed in an extracellular solution containing (mM): 138 NaCl, 5.8 KCl, 0.41  $\text{MgSO}_4$ , 0.48  $\text{MgCl}_2$ , 0.95  $\text{CaCl}_2$ , 4.17  $\text{NaHCO}_3$ , 1.1  $\text{NaH}_2\text{PO}_4$ , and 25 HEPES; pH = 7.2 adjusted with Tris base. Fura-2 fluorescence was measured at 505-nm wavelength and excited by the wavelengths 340 and 380 nm through a semiconducting mirror. The changes in intracellular free  $\text{Ca}^{2+}$  were given as fluorescence ratio (dF/F) from baseline (ddF/F) between the excitation wavelengths 340 and 380 nm. Human plasma samples were directly applied to the cells on the stage of the microscope at a concentration of 20%. C6-depleted plasma was purchased from CompTech (Complement Technology, Tyler, TX, USA).

### 2.4 qPCR

In order to assess the functional consequences of complement-activated intracellular  $\text{Ca}^{2+}$  signaling, gene expression activity was

measured by quantification of mRNA in ARPE-19 cells. Confluent ARPE-19 cells were exposed to different human plasma and in some conditions in combination with L-type channel blocker nifedipine (10  $\mu$ M). After cell harvest, RNA isolation and cDNA synthesis were performed using RNeasy Mini and QuantiTect Reverse Transcription Kit (Qiagen, Hilden, Germany). mRNA levels were measured in triplicates for the target genes and GAPDH as a housekeeping gene for standardization in a Rotor-Gene Q (Qiagen, Hilden, Germany) by using the Rotor-Gene SYBR Green PCR Kit (Qiagen, Hilden, Germany); primer sequences are shown in [Table 1](#). The mRNA levels of the target genes were calculated and presented as a comparative CT (threshold cycle,  $\Delta\Delta$ CT) method using Rotor-Gene Q software 2.2.3 (Qiagen) (49). Of note, the primers for *CFH*, IL-1 $\beta$ , and CD46 showed reduced efficacy in the presence of dimethyl sulfoxide (DMSO) needed for the solubilization of nifedipine; thus, respective results from nifedipine-treated cultures could not be obtained.

## 2.5 Cytokine secretion of ARPE-19 cells in response to human plasma

ARPE-19 cells were grown in 96-well plates to confluency. Three days later, cultures were switched to serum-free DMEM/Ham's F12 medium for 24 h before triplicate cultures were set up with 10% human plasma from smokers or non-smokers who were either homozygous (*CFH* 402HH) or heterozygous (*CFH* 402YH) or low-risk allele carriers (*CFH* 402YY), respectively, and incubated for another 3 days. Identical cultures were set up with 50  $\mu$ M PI3 K-inhibitor LY294002 (Cayman Chemical, Ann Arbor, MI, USA). Plasma from age-matched, non-AMD donors without *CFH* mutations was used as the control.

Supernatants were collected after 24, 48, and 72 h; immediately shock frozen at  $-80^{\circ}\text{C}$ ; pooled in equal volumes before being tested for cytokines by human Bio-Plex bead analysis (Bio-Rad Laboratories, Inc., Hercules, CA, USA); and measured with a Bio-Plex 200 reader (Bio-Rad Laboratories, Inc.) according to the manufacturer's instruction. Tested analytes were IL-1 $\beta$ , IL-1RA, IL-6, IL-8/CXCL8, IL-10, IL-12(p70), IFN-gamma, MCP-1/CCL2, and VEGF. Only results from those cytokines and chemokines that were secreted by the ARPE-19 cells are shown. Experiments were performed twice with ARPE-19 cells from different sources in different passages (as indicated, p6, p15, and p25) with comparable results. Data are shown as means + SE from triplicate

cultures of one representative experiment with two different cell lines; experiments were performed twice.

## 2.6 Data analysis and statistical testing

All data are presented as mean values  $\pm$  SEM or  $\pm$  SD. Statistical significance was calculated using Mann-Whitney *U* test for  $\text{Ca}^{2+}$  imaging data and qPCR data ( $*p < 0.05$ ,  $**p < 0.01$ , and  $***p < 0.005$ ). All calculations were performed in SPSS 26 and Excel 2010.

## 3 Results

To re-test the hypothesis of systemic complement activation in AMD, the TCC plasma levels in probes from AMD patients (the details of the patient cohort and controls in [Supplementary Material Tables S1, S2](#)) were compared with probes from age-matched controls ([Figure 1](#)) and found significantly, approximately five times, higher levels of TCC in AMD patients ( $0.44 \pm 0.06$  versus  $2.15 \pm 0.08$   $\mu\text{g/ml}$ ;  $p < 0.001$ ) ([Figure 1A](#)). The levels of TCC in healthy donors were in accordance with those that we published earlier (46). However, when comparing TCC concentrations in plasma from AMD patients carrying risk alleles, a different picture evolved. Comparing carriers of the low-risk allele of *ARMS2* versus high-risk allele carriers (*ARMS2* rs3750846) revealed no differences between low-risk and heterozygous or homozygous carriers ([Figure 1B](#)). Similar results were obtained among *CFH* polymorphism carriers with no differences between low-risk (*CFH* 402YY), heterozygous high-risk (*CFH* 402YH), or homozygous high-risk (*CFH* 402HH) allele carriers in AMD patients. Furthermore, no differences between the *ARMS2* and the *CFH* risk carriers were identified. The same applies to the environmental risk factor that we have analyzed in more detail, the smoking status ([Figure 1D](#)). In AMD patients without these genetic risk factors, no differences in the TCC concentrations were observed depending on their smoking status.

To test the biological relevance of increased TCC levels in the plasma of AMD patients, we used  $\text{Ca}^{2+}$  imaging techniques to explore the acute reaction of ARPE-19 cells on the patients' plasma. Earlier studies showed that an increase in intracellular free  $\text{Ca}^{2+}$  that was evoked by exposure to human plasma as the source of complement reflects the concerted activity of all activated complement factors (28). Thus, changes were expected in

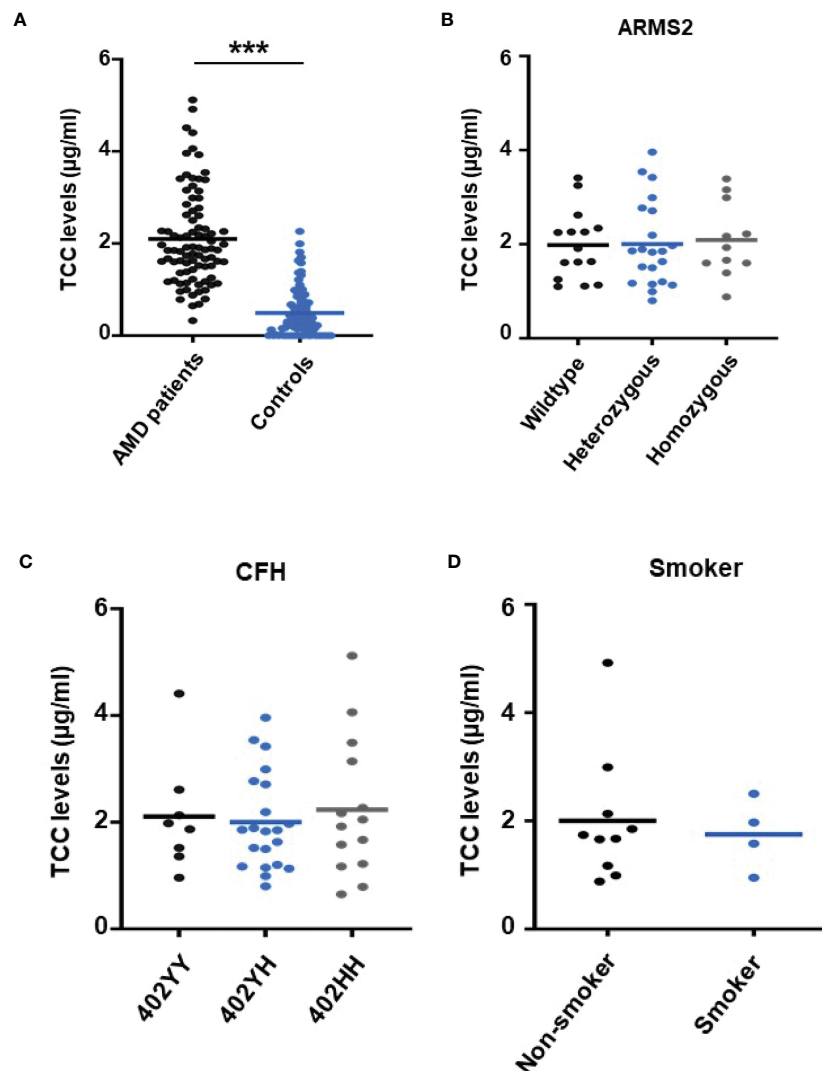

FIGURE 1

Plasma levels of terminal complement complex (TCC) in plasma from healthy donors and age-related macular degeneration (AMD) patients with AMD risk alleles. (A) Plasma levels of TCC ( $\mu\text{g/ml}$ ) in AMD patients ( $n = 87$ ) vs. healthy controls ( $n = 86$ ) showing significantly higher TCC levels in AMD patients ( $p < 0.001$ ). (B) TCC levels stratified for Age-related maculopathy-susceptibility 2 (*ARMS2*) risk alleles, with all patients carrying one *Complement factor H* (*CFH* 402YH) risk allele. No significant difference in TCC levels among patients with no (wild type (WT),  $n = 15$ ), one (heterozygous,  $n = 21$ ), and two (homozygous,  $n = 11$ ) *ARMS2* risk alleles existed. (C) TCC levels stratified for *CFH* risk alleles, with all patients carrying one *ARMS2* risk allele. No significant difference in TCC levels among patients with no (*CFH* 402YY,  $n = 8$ ), one (*CFH* 402YH,  $n = 21$ ), and two (*CFH* 402HH,  $n = 14$ ) *CFH* risk alleles. The horizontal lines represent the means of the TCC levels. \*\*\* $p < 0.001$  (Mann–Whitney *U* test). (D) TCC levels stratified for the risk factor smoking and non-smoking among patients who do not carry one of the investigated genetic risk alleles. As the “heterozygous patients” are heterozygous for *CFH* (*CFH* 402YH) and *ARMS2*, the same set of plasma samples from these patients was used for the comparison with homozygous deficient *CFH* (B) and *ARMS2* (C) as well as with respective WT plasma.

intracellular  $\text{Ca}^{2+}$  transients by human plasma from AMD patients. As a first step, we investigated whether the  $\text{Ca}^{2+}$  response to human plasma was dependent on TCC in normal human plasma (NHP). We compared  $\text{Ca}^{2+}$  transients induced by C6-depleted plasma with those induced with NHP (Figure 2). Indeed, without C6, the plasma induced a  $\text{Ca}^{2+}$  response half in amplitude compared to that of the control plasma (Figures 2A, B). As the peak in C6-depleted plasma is much smaller, the peak in C6-depleted plasma is reached in a shorter time (Figure 2C). Furthermore, C6-depleted plasma failed to develop a sustained phase of an intracellular  $\text{Ca}^{2+}$  increase (Figure 2D).

Since C6-depleted human plasma indicated a substantial contribution of TCC in a complement-induced  $\text{Ca}^{2+}$  increase, the plasma from AMD patients versus control plasma was then tested in a similar experiment (Figure 3). The waveform of  $\text{Ca}^{2+}$  transients evoked by AMD patients’ plasma was different from that of control plasma (Figure 3A). Although the peak was slightly reduced (Figure 3B) and the same level was reached in the sustained phase (Figure 3C), the latency was shorter, and the slope of the  $\text{Ca}^{2+}$  was steeper with a faster time-to-peak (Figure 3D) in response to AMD patients’ plasma. To find out whether the patients’ plasma evoked  $\text{Ca}^{2+}$  increases that resulted exclusively from activated

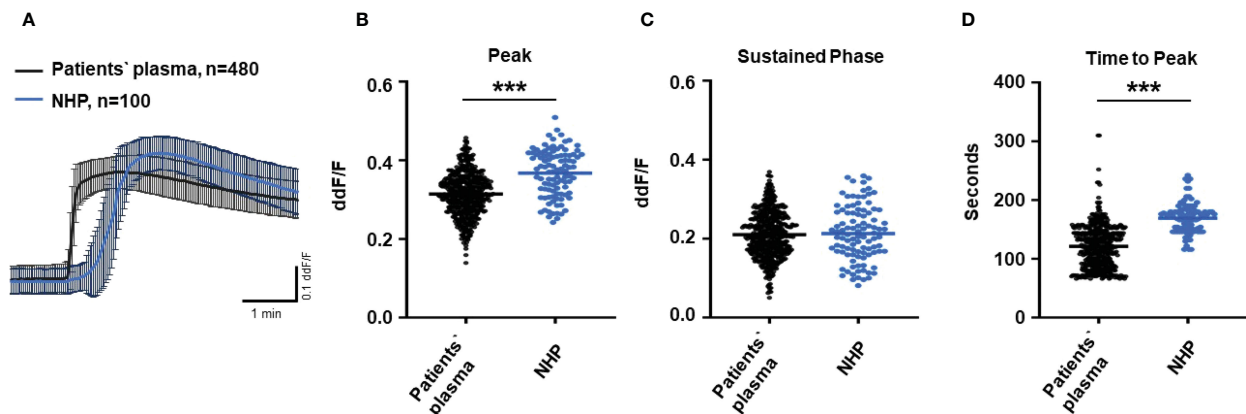

FIGURE 2

Changes in  $\text{Ca}^{2+}$  transients activated by C6-depleted plasma and normal human plasma (NHP) in ARPE-19 cells. **(A)**  $\text{Ca}^{2+}$  transients are given as differences to the baseline in fluorescence ratio between the two excitation wavelengths 340 and 380 nm; plasma concentrations were 10%. Data are mean  $\pm$  SEM. **(B–D)**  $\text{Ca}^{2+}$  transient changes at the initial peak phase and the late sustained phase. C6-depleted plasma induced a significantly lower change in intracellular free  $\text{Ca}^{2+}$  compared to NHP. The horizontal line represents the mean change in  $\text{Ca}^{2+}$  transients from baseline. \*\*\* $p < 0.001$  (Mann–Whitney  $U$  test).

complement proteins, heat-inactivated plasma was used as a control in a similar experiment. Complement as a heat-labile component of the plasma in AMD patients was denatured by incubation at  $57^{\circ}\text{C}$  for 45 min. The heat-inactivated patients' plasma showed a strongly reduced  $\text{Ca}^{2+}$  reaction when compared to the untreated plasma from the same AMD patients. The resulting levels did not significantly differ from the baseline before the application of heat-inactivated plasma (Supplementary Material Figure S2). These results suggest that the observed differences in the  $\text{Ca}^{2+}$  signals mainly depended on activated complement components, where some minor effects of other heat-labile plasma compounds cannot be fully excluded. Therefore, a correlation analysis between measured plasma TCC levels and the peak of the single plasma-induced  $\text{Ca}^{2+}$  signal (Figure 4) was performed. For that purpose, TCC levels were compared with the  $\text{Ca}^{2+}$  amplitude in a scatter plot, and the data were analyzed using a generalized estimating equation (GEE) model. The analysis revealed a significant negative correlation between TCC levels and the  $\text{Ca}^{2+}$  peak amplitude: the higher the TCC level, the lower the  $\text{Ca}^{2+}$  peak, which correlates with the significantly lower  $\text{Ca}^{2+}$  peaks induced by patients' plasma compared to the controls (Figures 2, 3).

To further evaluate the role of TCC, we investigated the  $\text{Ca}^{2+}$  responses from AMD patients' plasma with defined risk alleles (Figures 5, 6). According to the lack of differences among plasma levels of TCC, we also expected no differences in the  $\text{Ca}^{2+}$  signals evoked by the patients' plasma. Indeed, we observed no differences between plasma from heterozygous and homozygous carriers of *ARMS2* risk alleles (Figures 5A–C), as well as with plasma from heterozygous or homozygous carriers of *CFH* risk alleles (Figures 6A–C). However, we observed subtle differences between the plasma samples of patients with the two investigated risk haplotypes *ARMS2* and *CFH*. We found a higher  $\text{Ca}^{2+}$  level at the sustained phase of the  $\text{Ca}^{2+}$  signal in response to plasma of homozygous *CFH* 402YY compared to heterozygous (*CFH*

402YH) individuals, in contrast to plasma derived from patients with the *ARMS2* risk allele.

As smoking is a relevant risk factor for AMD, we compared smokers and non-smokers within the AMD patients' cohort (Figure 7). Plasma from smokers and non-smokers induced  $\text{Ca}^{2+}$  signals in ARPE cells with the same latency and slope of  $\text{Ca}^{2+}$  increase reaching the same peak. However, plasma from smokers revealed significantly higher sustained phases of the  $\text{Ca}^{2+}$  signal when compared to that of non-smokers. We observed a comparable effect on the plasma-evoked  $\text{Ca}^{2+}$  increase with plasma from patients who were homozygous carriers of *CFH* 402HH.

So far, our experimental results suggest a potential impact of TCC on the RPE. To mimic the effects of chronic complement stimulation, we pre-incubated ARPE-19 monolayers for 24 h with patients' plasma before we measured  $\text{Ca}^{2+}$  increases (Figure 8). Pre-stimulation with patients' plasma led to a marked increase in evoked  $\text{Ca}^{2+}$  transients (Figure 8A) with significantly higher peaks and sustained phases (Figure 8B). As the patients' plasma contents caused ARPE-19 cells to be more sensitive to complement, this "pathological" effect was further analyzed by varying the pre-incubation conditions and using control plasma (NHP) for pre-incubation of the cells. In addition, pre-incubation with NHP changed the  $\text{Ca}^{2+}$  transients evoked by patients' plasma but in a different way (Figure 8C). Again, the peak was significantly increased, but the sustained phase was markedly reduced (Figure 8D). Normal human plasma seemed to lack those components, which were required for complement sensitization. This was also seen in the comparison of the subsequently evoked  $\text{Ca}^{2+}$  transients with patients' plasma after pre-incubating the cells with either standard control plasma or patients' plasma (Figure 9A). The peaks from both pre-incubation conditions looked very similar, but the sustained phase of cells pre-incubated with patients' plasma was substantially higher than that of cells pre-incubated with normal humans (Figure 9B). A central paradigm in  $\text{Ca}^{2+}$  signaling is that  $\text{Ca}^{2+}$  signals specify the cell

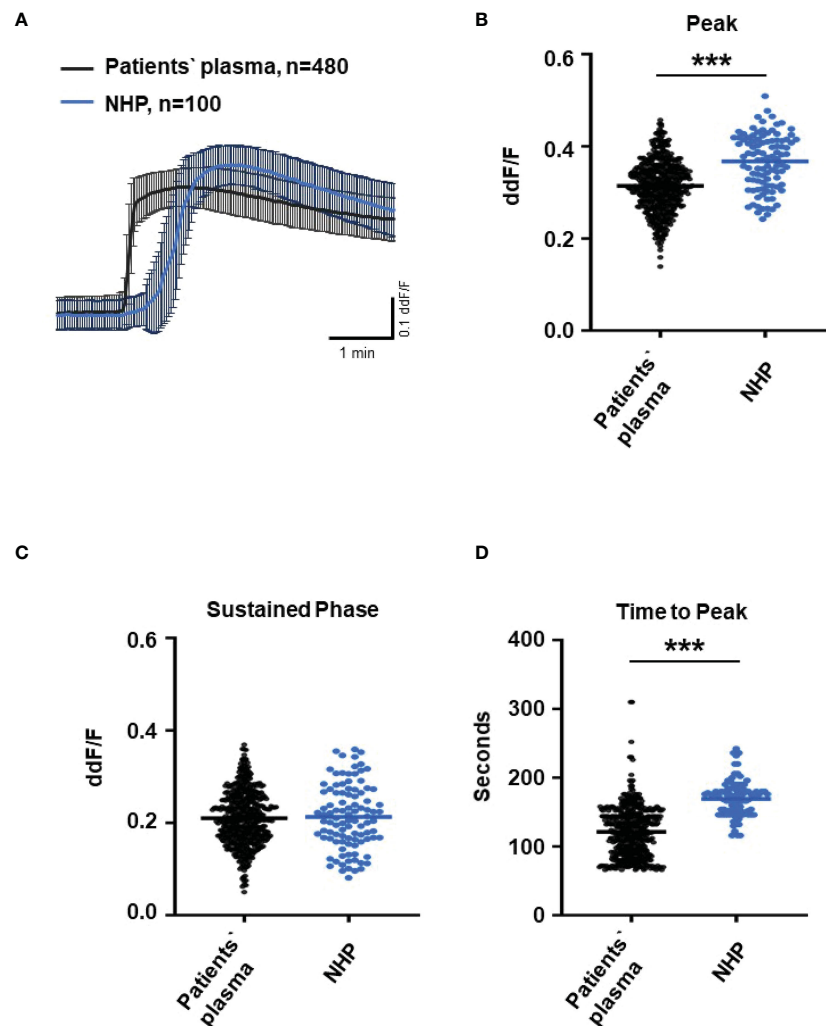

FIGURE 3

Changes in  $\text{Ca}^{2+}$  transients activated by plasma from age-related macular degeneration patients. (A)  $\text{Ca}^{2+}$  transients are given as differences to the baseline in fluorescence ratio between the two excitation wavelengths 340 and 380 nm. Experiments were conducted with plasma (10%) from 16 different patients (30 cells per patient) and normal human plasma (NHP) in ARPE-19 cells. Data are mean  $\pm$  SD. (B)  $\text{Ca}^{2+}$  transient changes at the initial peak phase and the late sustained phase. NHP induced a significantly higher change in intracellular free  $\text{Ca}^{2+}$  in the initial phase compared to patients' plasma. (C, D) Mean time until maximum  $\text{Ca}^{2+}$  transient change. Patients' plasma induced significantly faster maximum  $\text{Ca}^{2+}$  transients to change compared to NHP. The horizontal line represents the mean change in  $\text{Ca}^{2+}$  transients from baseline (B) and mean time until peak (C). \*\*\* $p < 0.001$  (Mann–Whitney  $U$  test).

function changes by its waveform and spatial distribution as a code (50–52). Thus, differences in the waveforms have different effects on the cell's function. These waveform differences might change intracellular signaling and gene expression profiles. Therefore, gene expression activities in ARPE-19 cells stimulated by patients' plasma and control plasma were quantified, as well as cells that were kept overnight under plasma-free conditions (Figure 10), thereby concentrating our analysis on genes of the complement system, the pro-inflammatory cytokine IL-1 $\beta$ , and the surface receptors CD46 (cleavage of C3b and C4b), CD55 (accelerated decay of complement proteins), and CD59 (TCC formation inhibition).

To identify the contribution by L-type channels, nifedipine (10  $\mu\text{M}$ ), an L-type  $\text{Ca}^{2+}$  channel blocker, was used. Incubation of cells with patients' plasma resulted in an upregulation of C5, C5aR, CD55, CD59, and CFH (Figure 10A). In parallel, C3 and IL1- $\beta$  were downregulated

(Figure 10A). The differential regulation by patients' plasma of C3, C5, C5aR, and CD59 was nifedipine sensitive, indicating that these expression changes depend on complement action, with a great likelihood of the presence of TCC. Comparing standard control plasma with plasma/plasma-free conditions, we found that the ARPE-19 cell reacted with a selective downregulation in the C5aR 1 (there are two C5a receptors) and CFH expression but an increase in the expression of C3aR and IL-1 $\beta$  (Figure 10B) in response to control plasma.

To substantiate the hypothesis that the patients' plasma promotes an immune stimulatory phenotype of RPE cells, we analyzed the secretory profile of ARPE-19 cells under 3 days of stimulation with AMD patients' plasma (Figure 11). Here, we used plasma from patients heterozygous (CFH 402YH) or homozygous (CFH 402HH) for the CFH risk allele who were additionally differentiated by their smoking status. In a third, independent assay, we tested plasma pools

from elderly patients of different age groups but without AMD for the induction of cytokine secretion by ARPE-19 cells (see [Supplementary Material](#)).

Using the multiplex technology, we analyzed a broad profile of immune and angiogenesis-relevant factors. We plotted only those factors that were induced by patients' plasma in ARPE-19 cell lines from two different laboratories: one in passage 25 ([Figures 11A, C](#)) and the other in passage 15 ([Figures 11B, D](#)). In general, we found induction of IL-6, IL-8/CXCL8, MCP-1/CCL2, and VEGF-A, with the predominant secretion of VEGF-A and MCP-1, while the other tested cytokines, IL-1 $\beta$ , IL-1RA, IL-10, IL-12(p70), and IFN- $\gamma$ , were not detected.

Among the risk types with homozygous *CFH* deficiency (*CFH* 402HH) or smoker status, we found comparably strong induction of cytokine secretion. However, an exception appeared to be the group of non-smokers with *CFH* polymorphisms. In this group, we found increased MCP-1 levels compared to the smoker group, especially when the donors were homozygous for *CFH* 402HH. The MCP-1 secretion was twice as high as in the heterozygous *CFH* 402YH non-smoker group and increased three- to fourfold compared to the group of smokers with *CFH* 402HH risk polymorphism. Concerning VEGF secretion, homozygous *CFH* 402HH donors, irrespective of their smoking status, displayed a slightly decreased secretion when compared to the heterozygous groups. The addition of the PI3K inhibitor resulted in a significantly reduced secretion to less than 50%, while the pattern of secretion remained the same.

In our experiments, ARPE-19 cells of the higher passages 15 and 25 secreted higher levels of cytokines than those of passage 6 ([Supplementary Material Figure S3](#)), potentially reflecting the situation of aged RPE.

## 4 Discussion

As polymorphisms in complement genes are associated with the risk of AMD, it is questioned whether this leads to systemic or only

local effects. Chirco et al. (17) did not find a difference in TCC levels in the plasma of AMD patients with low-risk and high-risk *CFH* alleles, whereas in the retinas of patients with high-risk *CFH* alleles, higher local TCC concentrations were detected. The current literature indicates an important role of TCC in the etiology of AMD in two ways. On the one hand, systemic changes by increased complement activity and higher TCC levels in AMD patients are discussed, as well as higher risks for AMD associated with polymorphisms in C9. On the other hand, the exploration of complement affecting RPE cells at a cellular level followed the concept of "sub-lytic" MAC influencing cell function. Our study provides a direct link between the mechanistic levels: the patients' observations and the cellular effects of isolated TCC on RPE cells. The most relevant observation of our study is that AMD patients showed higher plasma levels of TCC when compared to age-matched controls, but there were no differences among carriers with different risk alleles of complement genes. These systemic changes affect the  $\text{Ca}^{2+}$  signaling that regulates the expression activity of complement genes in the RPE and thus the control of the local activity of the complement system.

In our study, we investigated the TCC levels from the plasma of AMD patients and compared them with those from the plasma of AMD patients and age-matched controls as well as carriers of risk alleles *CFH* and *ARMS2*. Whereas AMD patients' plasma showed higher TCC levels, there were no differences between plasma from AMD patients with either *CFH* or *ARMS2* risk alleles. The same applies to the comparison between smokers and non-smokers in the patients' cohort. This observation matches well with that from other publications. First, our data confirmed the conclusions by Chirco et al. (17), who found no differences in TCC levels in the plasma between carriers of polymorphism *CFH* 402HH and *CFH* 402YY controls. Thus, the increased TCC levels in the plasma correlate with the diagnosis of AMD and, thus, clinically relevant degenerative changes in the retina. This assumption would also explain why there are no differences between AMD patients in the comparison of genetic and smoking-associated risk profiles. In the measurement of complement activity markers in the plasma, such as C3d/C3 ratio, C3a-desarg, or TCC, the different risk allele *CFH*, *ARMS*, or *CFI* carriers display comparable levels of those markers, while healthy donor's plasma displayed increased levels of complement activity (18, 19, 21, 23, 53–58). Increased markers for complement activity were found when compared to those in control plasma in both patients with dry and wet AMD. Our study included patients with wet AMD showing that not only dry AMD patients are affected by increased complement activity in the plasma. In contrast to these data, the C9 risk alleles have differential effects on TCC or C9 plasma levels (19, 20, 58). C9 risk allele carriers show higher levels of TCC when comparing AMD versus non-AMD patients, and also among AMD patients, the carriers of the C9 risk allele have higher TCC levels than non-carriers, which also varies within the group of C9 risk allele carriers depending on specific polymorphisms. Thus, considering our data and data from existing literature, we conclude that increased TCC or C9 levels in the plasma are associated with the disease AMD. However, the increased plasma levels originate at different steps of the complement cascade: either at the insufficient control of the

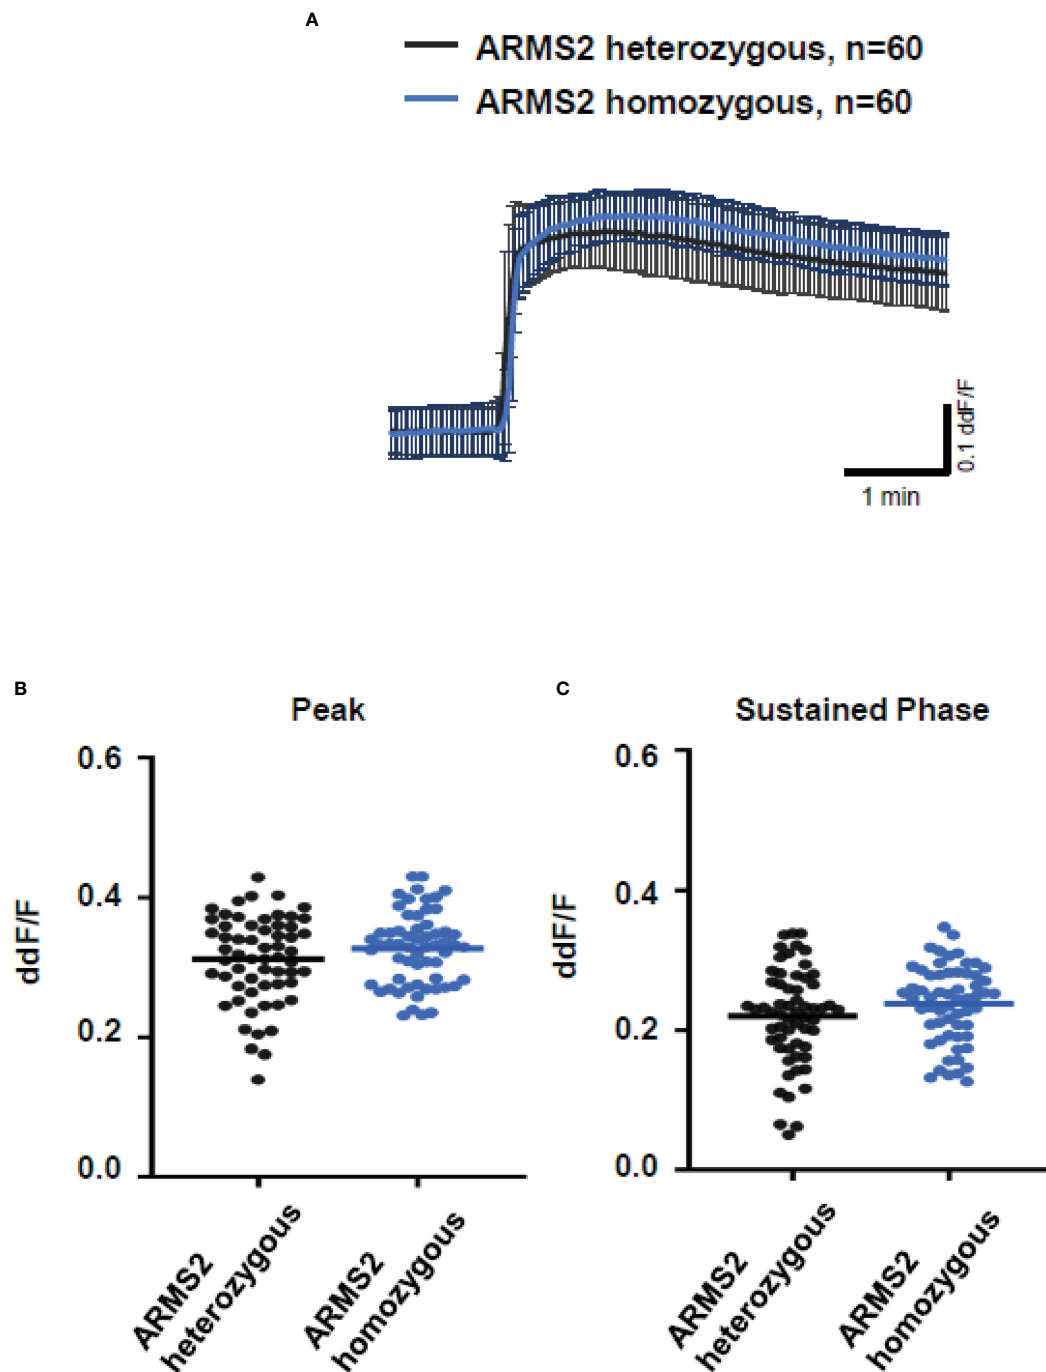

FIGURE 5

Changes in  $\text{Ca}^{2+}$  transients activated by plasma from age-related macular degeneration patients, stratified for age-related maculopathy susceptibility 2 (*ARMS2*) risk allele status. Plasma from patients carrying one (heterozygous) vs. two (homozygous) *ARMS2* risk alleles (2 different patients per risk allele status, 30 cells per patient). All patients were age-matched and had no additional *Complement factor H* risk alleles. (A)  $\text{Ca}^{2+}$  transients are given as differences to the baseline in fluorescence ratio between the two excitation wavelengths 340 and 380 nm; plasma was used in concentrations of 10%. Data are mean  $\pm$  SD. (B, C)  $\text{Ca}^{2+}$  transient changes at the initial peak phase and the late sustained phase induced by plasma from patients with one vs. two *ARMS2* risk alleles, showing no significant differences in induced  $\text{Ca}^{2+}$  transients. The horizontal line represents the mean change in  $\text{Ca}^{2+}$  transients from baseline.

alternative activation pathway or directly by determining the gain-of-function effects by altered C9 proteins. In summary, our data further support the prominent role of the TCC in the etiology of AMD.

To determine whether these differences in plasma TCC levels are of biological relevance, we incubated these plasma probes with ARPE-19 cells. Although this RPE cell line is under debate for being representative of the native RPE and might thus limit our

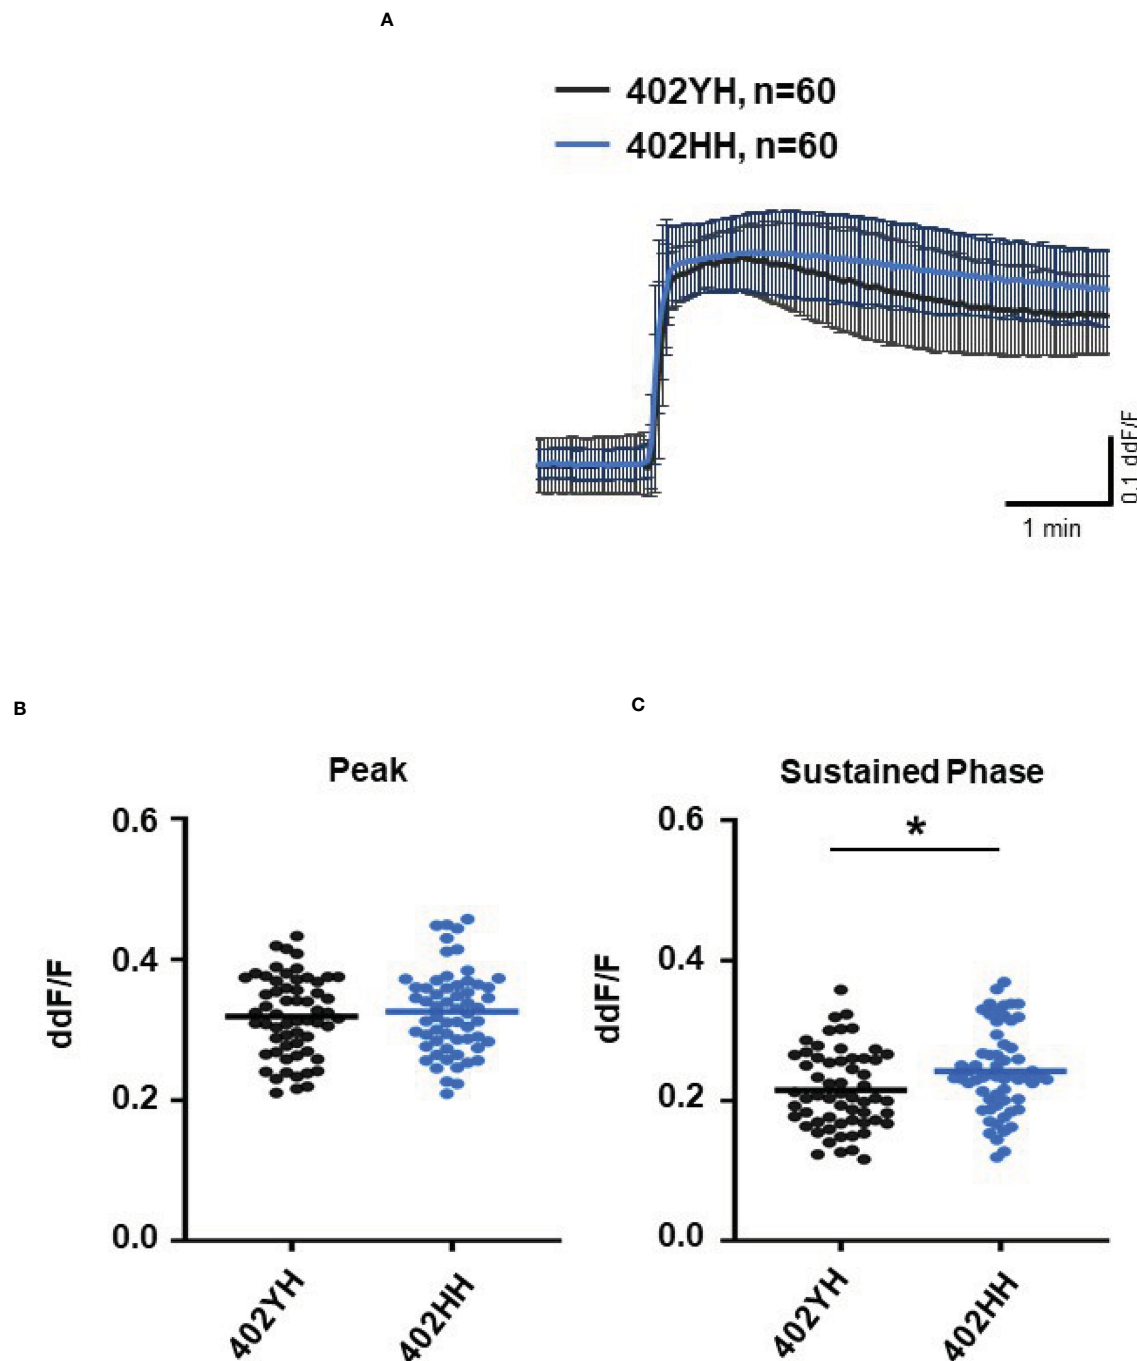

FIGURE 6

Changes in  $\text{Ca}^{2+}$  transients activated by plasma from age-related macular degeneration patients, stratified for *Complement factor H* (CFH) risk allele status. Plasma from patients CFH 402YH carriers vs. CFH 402HH carriers (2 different patients per risk allele status, 30 cells per patient). All patients were age-matched and had no additional *Age-related maculopathy susceptibility 2* (ARMS2) risk allele. Data are mean  $\pm$  SD. (A)  $\text{Ca}^{2+}$  transients are given as differences to the baseline in fluorescence ratio between the two excitation wavelengths 340 and 380 nm; plasma was used in concentrations of 10%. (B, C)  $\text{Ca}^{2+}$  transient changes at the initial peak phase and the late sustained phase. Plasma from CFH 402HH carriers induced a significantly higher change in intracellular free  $\text{Ca}^{2+}$  in the sustained phase compared to plasma from carriers of CFH 402YH. The horizontal line represents the mean change in  $\text{Ca}^{2+}$  transients from baseline. \* $p < 0.05$  (Mann–Whitney  $U$  test).

conclusions for the pathogenic mechanisms possibly taking place *in vivo*, these cells will reflect the differences in the biological activity of patients' plasma. As in many other and also in our own recent studies, we used the  $\text{Ca}^{2+}$  imaging technique to monitor the cell reactions to plasma as a complement resource (28, 35, 59). We

know from our own studies that activated complement compounds produced by the complement cascade induced by human plasma evoke orchestrated  $\text{Ca}^{2+}$  signals by activation of endogenously expressed ion channels (28). The central paradigm for coding the desired specific change of cell function activated by an increase in

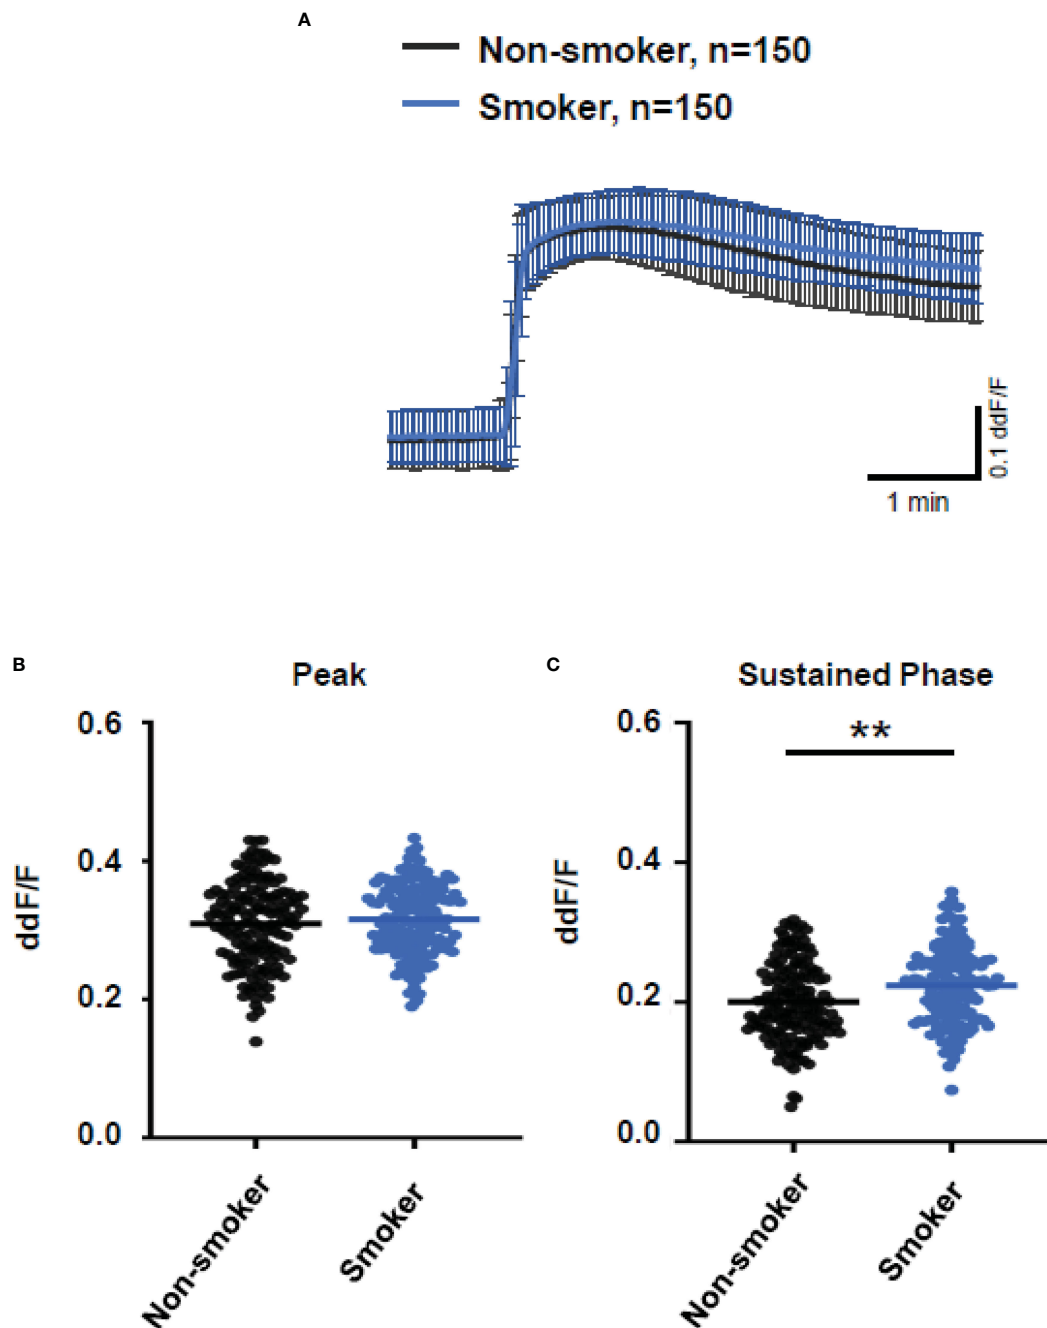

FIGURE 7

Changes in  $\text{Ca}^{2+}$  transients activated by plasma from age-related macular degeneration patients, stratified for smoking status (non-smoker vs. smoker). Plasma from five different patients per group was compared, with 30 cells per patient. All patients were matched for age, *age-related maculopathy susceptibility 2*, and *complement-factor H* risk alleles. Data are mean  $\pm$  SD. (A)  $\text{Ca}^{2+}$  transients are given as differences to the baseline in fluorescence ratio between the two excitation wavelengths 340 and 380 nm; plasma was used in concentrations of 10%. (B, C)  $\text{Ca}^{2+}$  transient changes at the initial peak phase and the late sustained phase. Plasma from smoking patients induced a significantly higher change in intracellular free  $\text{Ca}^{2+}$  in the sustained phase compared to plasma from non-smoking patients. The horizontal line represents the mean change in  $\text{Ca}^{2+}$  transients from baseline.  $**p < 0.01$  (Mann–Whitney *U* test).

intracellular free  $\text{Ca}^{2+}$  states its origins in the time-dependent shape and the spatial distribution of the signal (50–52). Thus, differences in shape and distribution represent different changes in cellular functions.

Considering the importance of the shape of  $\text{Ca}^{2+}$  transients to represent specific cellular functions (50–52) and taking into account

the reproducibility of complement-evoked  $\text{Ca}^{2+}$  increases (28, 33), we tested the effects of patients' plasma on intracellular free  $\text{Ca}^{2+}$  as a second messenger. Before we used patients' plasma, we tested C6-depleted plasma to identify the parts of the  $\text{Ca}^{2+}$  signal under the influence of TCC. The  $\text{Ca}^{2+}$  signal evoked by C6-depleted plasma was strongly reduced in peak amplitude and showed an absence of a

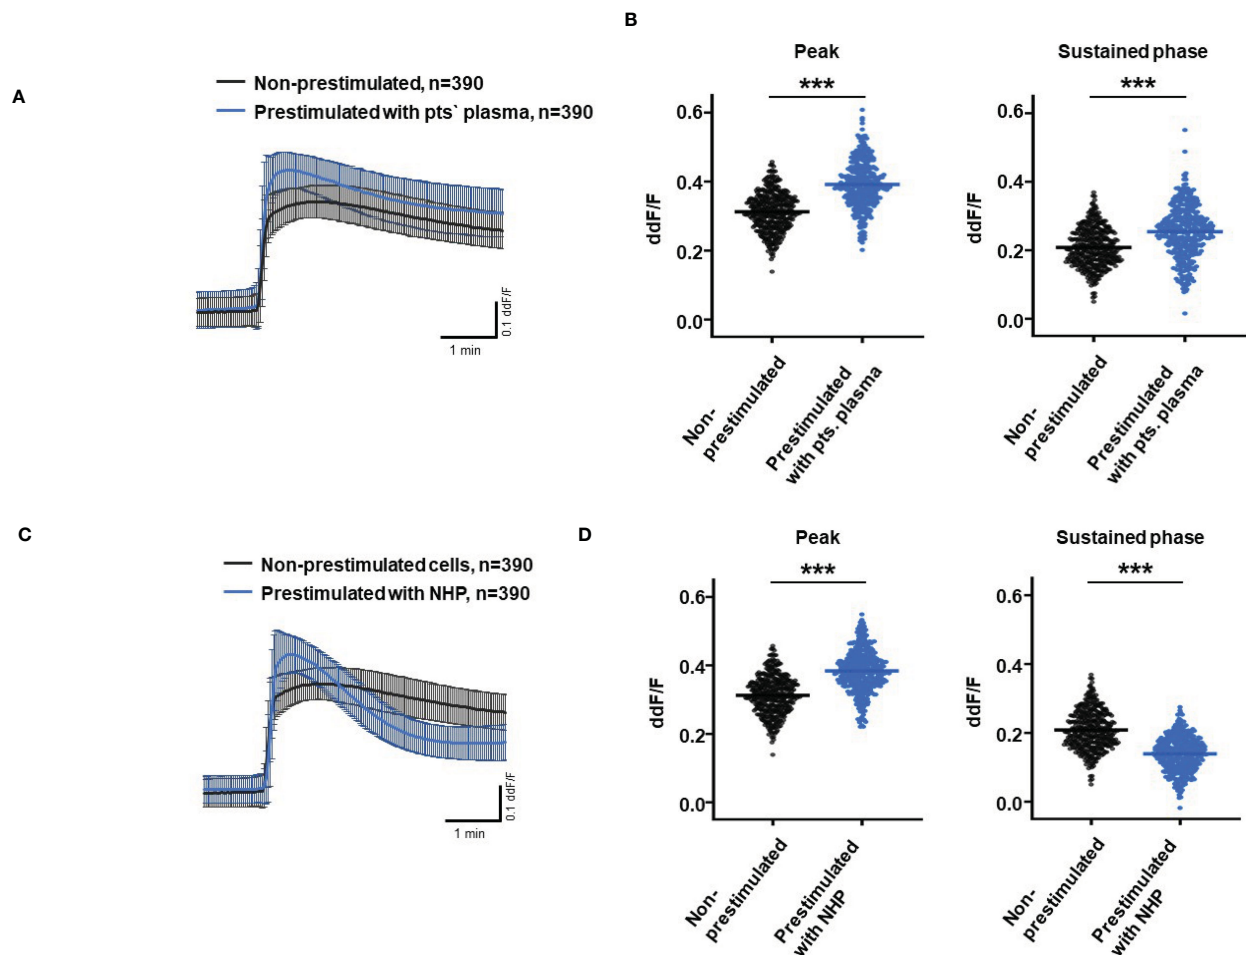

FIGURE 8

Effects of pre-stimulation with either plasma from age-related macular degeneration patients or controls on  $\text{Ca}^{2+}$  transients in ARPE-19 cells. The experimental conditions were pre-incubation with serum-free media (A–D), media with 10% patients' (pts.) plasma (A, B, E, F), or media with 10% normal human plasma (NHP; C–F) for 24 h. Data are mean  $\pm$  SD. (A, C)  $\text{Ca}^{2+}$  transients are given as differences to the baseline in the fluorescence ratio between the two excitation wavelengths 340 and 380 nm. (B, D)  $\text{Ca}^{2+}$  transient changes at the initial peak phase and the late sustained phase. Cells, pre-stimulated with patients' plasma, showed a significantly higher change in intracellular free  $\text{Ca}^{2+}$  compared to non-pre-stimulated cells (B). Cells pre-stimulated with NHP showed a significantly higher change in intracellular free  $\text{Ca}^{2+}$  at the initial peak phase but a significantly lower amplitude in the sustained late phase compared to non-pre-stimulated cells (D). The horizontal line represents the mean change in  $\text{Ca}^{2+}$  transients from baseline. \*\*\* $p < 0.001$  (Mann–Whitney  $U$  test). The dataset for “non-prestimulated” for “peak” and “sustained” were statistically tested two times: Once against “pre-stimulation patients' plasma” and a second time against “pre-stimulated NHP”; thus, the data for “non-stimulated” “peak” and “sustained” in the (B, D) are identical.

sustained phase. Thus, TCC that is formed in human plasma during the first seconds of exposure to the cells already determines the first phase of the  $\text{Ca}^{2+}$  increase and additionally paves the full development signal. As the later parts of the plasma-induced  $\text{Ca}^{2+}$  are activated by anaphylatoxins (28, 33), the early increase by TCC is of importance for anaphylatoxin signaling. In a recent study, we showed that isolated anaphylatoxins exhibit monophasic  $\text{Ca}^{2+}$  transients with amplitudes (33) that are far smaller than those of complete plasma, which shows biphasic  $\text{Ca}^{2+}$  transients consisting of an initial peak and a sustained phase (28). Thus, the C6-depleted plasma indicates that especially the early increase of intracellular  $\text{Ca}^{2+}$  stems from the presence of TCC.

Indeed, comparing  $\text{Ca}^{2+}$  transients evoked from control plasma to those evoked from patients' plasma, we found that the  $\text{Ca}^{2+}$

transients from AMD plasma increased faster with shorter latency and a steeper increase to a slightly reduced peak, whereas the sustained phases remained unchanged. For the peak level of the  $\text{Ca}^{2+}$  signals, we found a negative correlation with the TCC levels in the plasma of individual patients. Thus, the plasma with higher levels of TCC especially showed changes in the first phase of the signal as hypothesized from the data with C6-depleted plasma. Heat inactivation of patients' plasma to inhibit complement activity revealed no increased intracellular free  $\text{Ca}^{2+}$ , which suggests that the  $\text{Ca}^{2+}$  signal from patients' plasma depends on the activity of complement, although the minor contribution of other heat-labile factors cannot be fully excluded. Indeed, we found a correlation between the plasma TCC levels in the patients and the peak amplitude of the  $\text{Ca}^{2+}$  increase, evidencing that the major

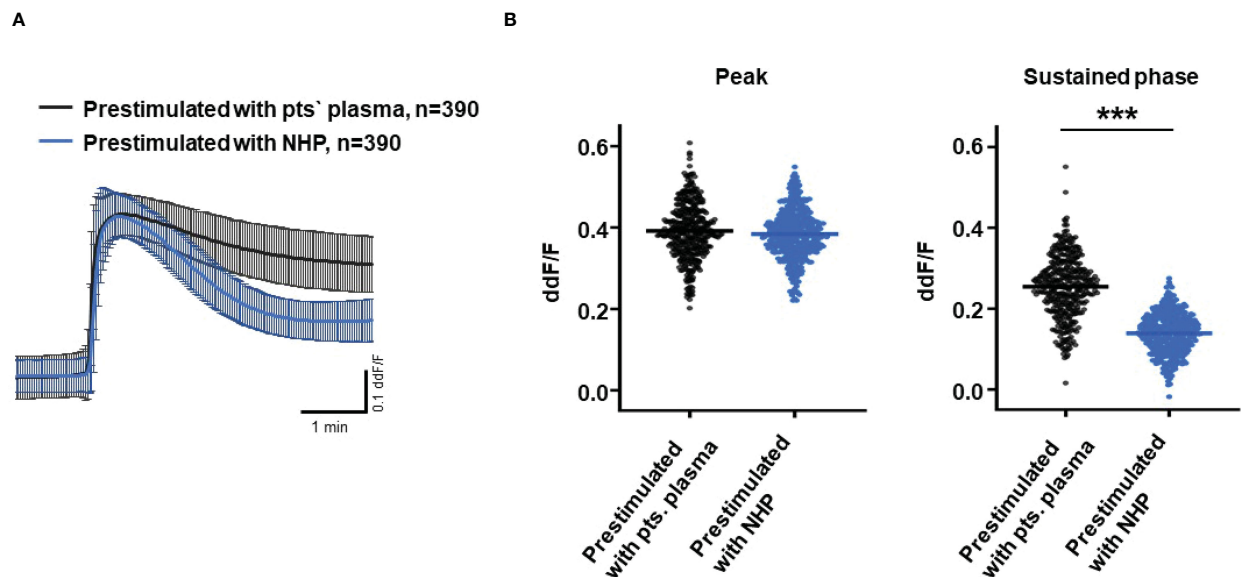

FIGURE 9

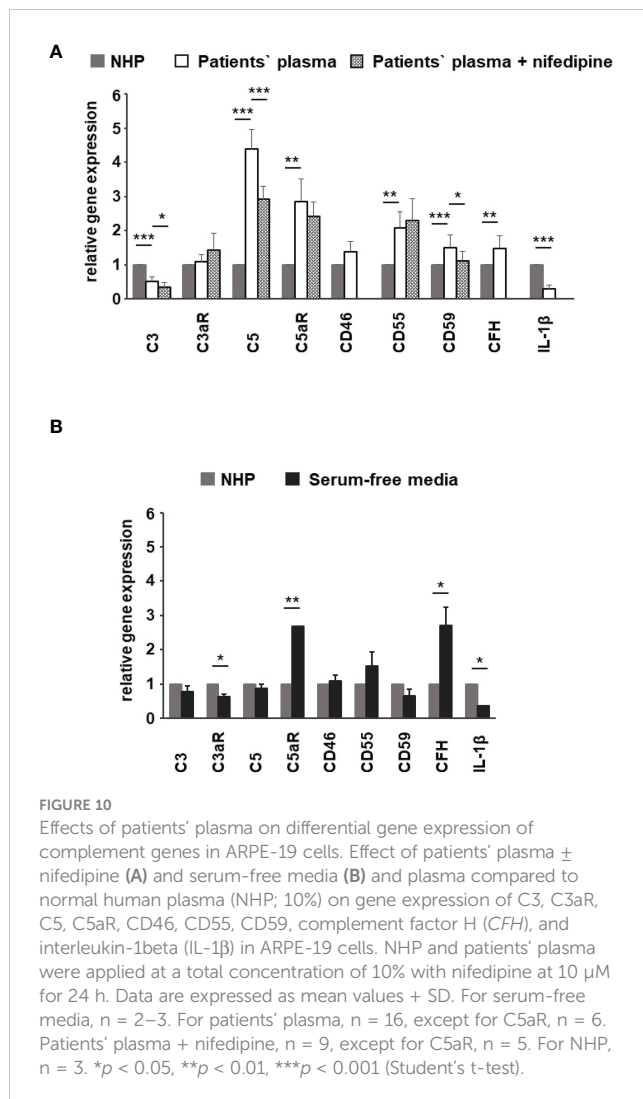

Direct comparison of pre-stimulation effects between patients' plasma and control plasma on  $\text{Ca}^{2+}$  transients in ARPE-19 cells. (A)  $\text{Ca}^{2+}$  transients are given as differences to the baseline in the fluorescence ratio between the two excitation wavelengths 340 and 380 nm; plasma was used in concentrations of 10%. Data are mean  $\pm$  SD. (B) Compared to pre-stimulation with normal human plasma (NHP), cells showed a significantly higher change in intracellular free  $\text{Ca}^{2+}$  in the sustained phase after pre-stimulation with patients' plasma. The horizontal line represents the mean change in  $\text{Ca}^{2+}$  transients from baseline. \*\*\* $p < 0.001$  (Mann–Whitney  $U$  test).

differences in the  $\text{Ca}^{2+}$  signals between control plasma and patients' plasma result from the differences in the plasma TCC levels. Thus, any changes resulting in  $\text{Ca}^{2+}$  signals and also changes in gene expression should be attributed to the higher TCC levels in the patients' plasma.

In general, we found no differences in the plasma TCC levels between the carriers of risk alleles *ARMS2* and *CFH*. However, when comparing the plasma-evoked  $\text{Ca}^{2+}$  signals from carriers of different risk alleles, we observed subtle differences. With *ARMS2* genotypes, the  $\text{Ca}^{2+}$  signals were indistinguishable between heterozygous and homozygous carriers, while the *CFH* 402HH carrier's plasma showed higher amplitudes in the late phase than plasma from *CFH* 402YH individuals. We observed the same when comparing plasma from smokers with non-smokers. In addition, only the late phase was increased. A decreased CFH efficiency to control the alternative complement pathway by either polymorphic CFH or by cigarette smoke (3, 6, 7, 44, 60–62) leads to increased complement activity markers in the patients' sera (57, 60, 63). Because of this, we assume that sera of smokers or patients carrying *CFH* risk alleles contain higher levels of anaphylatoxins, which in turn increase the late  $\text{Ca}^{2+}$  signals. The study by Smailhodzic et al. supports this conclusion (21). The study reports that sera from *CFH* risk allele carriers show higher systemic complement activity determined as C3d/C3 ratio compared to *ARMS2* risk allele carriers. However, we found no differences in the TCC levels in the plasma of mutated *CFH* and *ARMS2* allele carriers. We explain this difference by the fact that C3d/C3 measurements reflect a more dynamic parameter based on complement factors that are more unstable than TCC.

Given the above conclusions, the  $\text{Ca}^{2+}$  transients evoked in ARPE-19 cells by plasma as a complement source represent integrals of the biological activity of activated complement. To shift these observations toward more translational conclusions, we performed pre-stimulation experiments with plasma to mimic a sustained exposure to complement as it likely occurs in the patients' eye. After pre-incubation with patients' plasma, both the peak and sustained phases are higher than those without pre-stimulation. Thus, the pro-inflammatory complement composition in the patients' sera sensitizes ARPE-19 cells for complement reactions. In contrast, after pre-stimulation with control plasma, the patients' sera show a differentially regulated response. Although the peak increases in the same manner, the sustained phase is much smaller in amplitude. Thus, control plasma also sensitizes the cells for the initial reaction but leads to a faster termination of the  $\text{Ca}^{2+}$  signal. The composition of activated complement in control sera maintains the immune inhibitory activity of RPE cells against the pro-inflammatory complement activity of patients' sera.

To support this conclusion, we investigated gene expression profiles of ARPE-19 cells in response to stimulation by control and patients' sera. The RPE cell reaction to complement under healthy conditions includes the secretion of CFH to prevent local complement reactions at the moment they would occur (44, 62–66). Thus, we investigated the effects of the patients' sera on complement gene expression in ARPE-19 cells. In previous publications, we have shown that the complete  $\text{Ca}^{2+}$  signal evoked by complement is blocked by the inhibition of L-type channels (28). Furthermore, the steepness of the  $\text{Ca}^{2+}$  increase was profoundly reduced. This matches well with the kinetic

alterations associated with patients' plasma that contains higher levels of TCC. However, when investigating the  $\text{Ca}^{2+}$  signals evoked by isolated anaphylatoxins, we found that these  $\text{Ca}^{2+}$  signals were insensitive to L-type channel blockers (33). Thus, the blocking effects of the L-type channel blocker nifedipine indicate the contribution of TCC to gene expression. We compared gene expression using control plasma versus plasma-free conditions and observed a decrease in the C3aR expression, in parallel to an increase in C5aR and CFH expression. Furthermore, the IL-1β expression decreased. This effect on IL-1β expression might result from anaphylatoxin C5a as shown by Brandstetter et al. (67), who also reported that the expression profile induced by C5a increased further inflammasome priming by IL-1β. When studying the effects of the isolated anaphylatoxins, we found no effects on the C3, C5, or anaphylatoxin receptor expression (33). Thus, the additional presence of TCC is required to produce the differential gene expression changes as shown by Brandstetter et al. (67), and in our study, such an interactive effect between activated complement components that we have previously described (33) demonstrates

interactive signaling of C3a and C5a. In combination with our new data, the picture is widening to an effect in which control plasma causes the cell reactions to have a higher sensibility for the C3 convertase level: more signaling with C3aR and increased C3 convertase activity by CFH downregulation and likely less C5aR1 and C5aR2 signaling. In contrast, with patients' plasma incubation, the expression of C3 decreased, but C5 is now more strongly expressed. This goes along with increases in C5aR1 expression and increased expression of TCC surface inhibitors CD55 and CD59. Thus, in contrast to control plasma, AMD plasma shifts the cell activity toward the C5 convertase level with higher C5a signaling and preparation for higher levels of TCC. Compared to control plasma, IL-1β expression is further decreased. These observations and the observations of Brandstetter et al. (67) led us to the conclusion that the patients' plasma turns the expression profile into a more pro-inflammatory phenotype in ARPE-19 cells. The reduction in C3 expression along with increases in C5 and CD59 expression is sensitive to the L-type channel blocker nifedipine and thus induced under contribution by TCC. With an increased production of C5, the RPE would at the same time lead to more formation of TCC and thus increase its protection against TCC impact. Our observations of the secretory activity under the influence of patients' plasma support this conclusion. Also, under treatment with AMD plasma, ARPE-19 cells showed increased secretion of pro-inflammatory cytokines IL-1, IL-6, IL-8, MCP-1, and the angiogenic factor VEGF-A; among them, the secretion of MCP-1 and VEGF-A was the highest. Interestingly, we found differences between smokers and non-smokers for MCP-1 secretion. The non-smoker group showed generally higher MCP-1 secretion rates with differences between the CFH risk haplotypes when compared to the smoker group, in which we also found no differences between the CFH haplotypes. This corresponds to the differences in the  $\text{Ca}^{2+}$  signal patterns. The comparison between smokers and non-smokers showed no differences in the peak, only in the sustained phase, whereas the peak was dependent on the TCC concentration. This indicates that there is no general pattern of secretion activity associated with the different risk factors, but, in general, the risk factors lead to increased secretion of pro-inflammatory cytokines. Thus, under the influence of TCC, the RPE's phenotype is changing into a pro-inflammatory one including a self-protection of the RPE against TCC.

Here, we have investigated the reaction of ARPE-19 cells to AMD patients' plasma, which indicated a biological impact on the cells, rendering the immune reactions toward a more pro-inflammatory type. Although the ARPE-19 cell line might not reliably represent properties of RPE cells *in vivo*, we can principally draw conclusions on the capabilities of the patients' plasma themselves. Here, the main conclusion is that in AMD, a systemic impact like the complement system acts on vulnerable cells of the outer blood–retina barrier. AMD risk alleles exacerbate local immune reactions, and the systemic pre-activated complement system might affect the outer retina even without local complement activity. The TCC might play an important role among the systemic factors, leading to a local effect on the tissue,

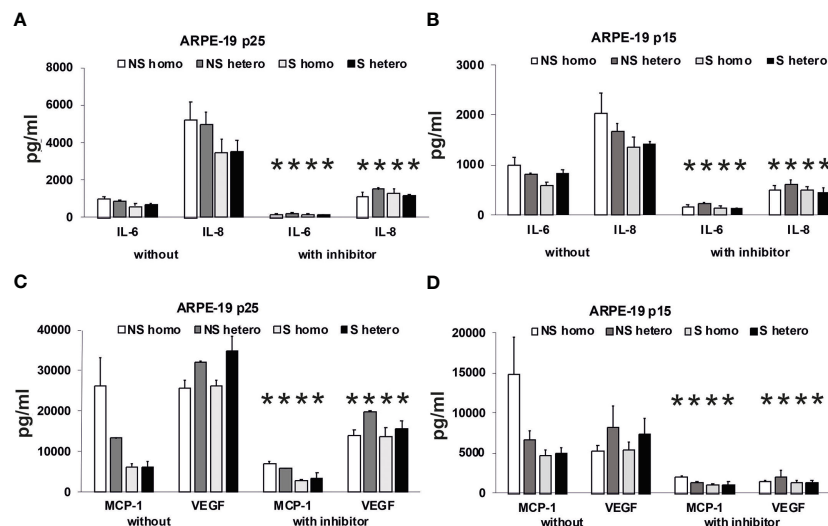

FIGURE 11

Effects of plasma on differential secretion activities of ARPE-19 cells. Cytokine and chemokine secretion of ARPE-19 cell lines. (A, C) ARPE-19 in passage 25. (B, D) ARPE-19 in passage 15. (A–D) Plasma (all 10%) from non-smoking (NS) or smoking (S) age-related macular degeneration (AMD) patients, carriers *CFH* 402HH versus carriers *CFH* 402YH. Plasma samples with or without PI3K-inhibitor LY294002 (50  $\mu$ M) were incubated with ARPE-19 cells and cyto-/chemokine concentrations determined from culture supernatants.  $n = 2–4$  for CHF mutant plasma (\* =  $p < 0.05$  for all respective values of supernatants from cultures with inhibitor vs. without).

which might not be primarily fatal for RPE cells. We assume that this effect drives the chronic low-grade inflammation known to occur in AMD patients and is reflected by observations such as a life-long accumulation of TCC in the outer retina (15–17) by increased levels of terminal complement complex in the blood (20, 21, 68).

## Data availability statement

The original contributions presented in the study are publicly available. This data can be found here: <https://doi.org/10.5281/zenodo.7797381> or DOI 10.5281/zenodo.7797381 (Zenodo repository).

## Ethics statement

The studies involving human participants were reviewed and approved by Charité ethics committee, registration number EA2/004/14. The patients/participants provided their written informed consent to participate in this study.

## Author contributions

Conceptualization: CB, PZ, AJ, CS and OS. Methodology: CB, SR, AS, LP, CH and MG. Formal analysis: CB, SR, LP, CS, GW and OS. Investigation: CB, SR, AS, LP, CH and MG. Writing—original draft preparation: OS, CB, CS and GW. Writing—review and editing: OS, SC, GW and JP. All authors contributed to the article and approved the submitted version.

### SUPPLEMENTARY FIGURE 1

Tables of patients' and risk factors. Upper table shows the age and gender distribution in the patients cohort and the group of healthy donors. The lower table shows the distribution of risk factors among the AMD patient cohort.

### SUPPLEMENTARY FIGURE 2

Properties of patients whose plasma was used for  $\text{Ca}^{2+}$  imaging, qPCR and secretion assay. Table shows detailed properties of the patient donors whose plasma was used for biological analyses. Note: the numbers are not suitable to identify certain patients.

### SUPPLEMENTARY FIGURE 3

Heat-inactivation control for patient's plasma. Changes in  $\text{Ca}^{2+}$  transients activated by plasma from age-related macular degeneration patients (16 different patients, 30 cells per patients) and heat-inactivated patients' plasma (16 different patients, 10 cells per

patients).  $\text{Ca}^{2+}$  transients are given as differences to the baseline in fluorescence ratio between the two excitation wavelengths 340 nm and 380 nm. Data are mean  $\pm$  SD.

### SUPPLEMENTARY FIGURE 4

Complement-dependent activation of basal secretion by ARPE-19 cells. ARPE-19 cells in passage 6 were stimulated with normal human plasma (NHP, 10%) from age-matched, non-smoking donors without AMD, *CFH* mutations unknown. Secretion of different cytokines was measured in supernatants with a multiplex bead assay; cytokine concentrations are given as mean  $\pm$  SEM;  $n = 17$ . In a second, independent experiment, pooled plasma samples of age-matched donors without AMD were tested for their ability to induce cytokine secretion by ARPE-19 cells in their sixth passage. In this experiment, the plasma pools displayed slight differences in their ability to induce cytokine secretion in ARPE-19 cells, the "oldest" pool (mean donor age: 82.7 years) induced more IL-6 and IL-8 and less MCP-1 compared to the pools of younger donors (means of 77.4 and 73 years, respectively). Data not shown. Interestingly, the used plasma pools already contained a high concentration of MCP-1, which decreased fivefold during the incubation with ARPE-19 cells, suggesting that MCP-1 was obviously used by the ARPE-19 cells, while IL-8 was produced by the RPE cells themselves and not provided by the plasma. VEGF concentrations remained unaltered, not allowing any conclusion on use or production by the ARPE-19 cells.

Cytotoxic lymphocytes kill target cells through polarized release of the content of cytotoxic granules towards the target cell. The importance of this cytotoxic pathway in immune regulation is evidenced by the severe and often fatal condition, known as hemophagocytic lymphohistiocytosis (HLH) that occurs in mice and humans with inborn errors of lymphocyte cytotoxic function. The clinical and preclinical data indicate that the damage seen in severe, virally triggered HLH is due to an overwhelming immune system reaction and not the direct effects of the virus *per se*. The main HLH-disease mechanism, which links impaired cytotoxicity to excessive release of pro-inflammatory cytokines is a prolongation of the synapse time between the cytotoxic effector cell and the target cell, which prompts the former to secrete larger amounts of cytokines (including interferon gamma) that activate macrophages. We and others have identified novel genetic HLH spectrum disorders. In the present update, we position these newly reported molecular causes, including CD48-haploinsufficiency and ZNF1-deficiency, within the pathogenic pathways that lead to HLH. These genetic defects have consequences on the cellular level on a gradient model ranging from impaired lymphocyte cytotoxicity to intrinsic activation of macrophages and virally infected cells. Altogether, it is clear that target cells and macrophages may play an independent role and are not passive bystanders in the pathogenesis of HLH. Understanding these processes which lead to immune dysregulation may pave the way to novel ideas for medical intervention in HLH and virally triggered hypercytokinemia.

## KEYWORDS

hemophagocytic lymphohistiocytosis, inflammation, hyperinflammatory syndromes, cytotoxic lymphocytes, cytokines, immune dysregulation, inborn errors of immunity

# 1 Introduction

Over the last few years, the use of whole-exome and whole-genome sequencing has broadened the spectrum of HLH disorders. In-depth characterization of genetic causes and related molecular dysfunctions in hemophagocytic lymphohistiocytosis (HLH) provides us with a better understanding of immune regulation processes. HLH is a unique clinical entity. Primary forms of HLH (pHLH) are caused by genetic defects that impair lymphocytes' cytotoxic machinery. For instance, individuals with deleterious mutations in the gene coding for perforin (*PRF1*) develop HLH (1, 2). pHLH disorders include autosomal recessive mutations in genes involved in the perforin-dependent cytotoxic lymphocyte granule release, causing familial HLH (FHL) and other genetic defects such as *RAB27A*, *LYST* and *SH2D1A* mutations. Moreover, HLH-like manifestations can occur in association with other genetic defects, i.e. inborn errors of immunity (IEI). In these cases, HLH is often considered as an acquired event secondary to the concomitant disease, even though patients may fulfil the HLH diagnostic criteria (3).

Primary forms of HLH are distinct from autoinflammatory diseases. Despite clinical manifestations can be similar, posing a challenge to the clinicians during initial assessments, the genetics and underlying causes of pHLH and autoinflammatory diseases are different. Autoinflammatory diseases are caused by dysregulation that mainly affect the innate immune system and the activation of pro-inflammatory pathways; they include inflammasomopathies, interferonopathies, and a group of non-inflammasome-related diseases associated with the nucleotide-binding oligomerization domain-containing protein 2 (NOD2) pathway and the interleukin (IL)-1 $\beta$  pathway leading to sustained cytokine release by innate cells. In genetic terms, both polygenic and monogenic autoinflammatory diseases have been described (4). A viral infection leading to hyperinflammation is not an autoinflammation, because auto-inflammation, by definition, requires a lack of infectious trigger. This is in contrast to pHLH, which is known to be triggered by viruses.

The release of granules containing cytolytic effector molecules by cytotoxic lymphocytes is not only essential in the host's defense against viruses and other pathogens but also serves to terminate immune responses (5). The latter is evidenced by the development of systemic hyperinflammation in patients who lack perforin, the pore-forming molecule delivered to target cells during granule-mediated cytotoxicity (1, 2). This sepsis-like disease is characterized by a number of clinical and laboratory criteria that include fever, splenomegaly, bicytopenia, hemophagocytosis, and hyperferritinemia, among others. According to the current diagnostic criteria (HLH-2004), HLH is diagnosed in a patient when fulfilling the following criteria: either 1) a molecular diagnosis consistent with a mutation previously associated with HLH or 2) 5 of 8 of the following clinical parameters: fever; splenomegaly; bicytopenia, affecting at least two of three lineages in peripheral blood (hemoglobin <90g/L (in infants <4 weeks: hemoglobin <100 g/L), platelets < 100 $\times 10^9$ /L, neutrophils <1.0 $\times 10^9$ /L); hypertriglyceridemia (fast triglycerides >265mg/dl) and/or

hypofibrinogenemia (fibrinogen  $\leq 1.5$ g/L); hemophagocytosis in the bone marrow or spleen or lymph nodes; low or absent natural killer (NK) cell activity; high ferritin levels ( $\geq 500\mu$ g/L); high levels of soluble CD25 ( $\geq 2,400$ U/mL) (6).

HLH can also occur in individuals with germline mutations in genes not related to any defect in the cytotoxic machinery. Furthermore, the so called "acquired" forms of HLH develop concomitantly to other infectious, malignant, autoimmune and rheumatological diseases such as systemic juvenile idiopathic arthritis (sJIA) (7, 8). By contrast to pHLH, these forms have been also named secondary HLH (sHLH). In particular, sHLH associated with rheumatologic/autoimmune conditions is often named macrophage activation syndrome (MAS). pHLH and MAS share clinical symptoms but MAS lacks the familial link and/or genetic causative mutation.

HLH is a cytokine storm syndrome. pHLH and MAS cause similar clinical manifestations and share some (but not all) impairments in immune pathways. Episodes of pHLH and episodes of MAS can both be triggered by infections (9). The immune responses to the trigger become persistent and go out of control, which leads to multiorgan damage and a sustained hyperinflammatory response - the main dangers, rather than impaired clearance of the viral trigger. However, in some disorders with HLH (e.g. XLP-1), the initial viral infection is poorly controlled. The immune dysregulation in HLH leads to an exaggerated, prolonged immune activation. This prompts the cytotoxic cell to secrete larger amounts of cytokines (including IFN $\gamma$ ), which directly activate macrophages. The defects in granule-mediated cytotoxicity in HLH compromise the ability of NK cells and CD8 $^+$  T cells to kill their target cells. Perforin-deficient CD8 $^+$  T cells interact with APCs for longer than usual (10, 11). Defective disengagement between the cytotoxic cell and its target leads to repetitive calcium release in the cytotoxic lymphocyte and increased production of proinflammatory cytokines. IFN $\gamma$  and TNF $\alpha$  (a) stimulate hemophagocytic activity in macrophages, (b) continuously activate T cells during antigen presentation, and (c) induce the production of other proinflammatory cytokines, leading to a cytokine storm. Macrophage-secreted cytokines (such as IL-1 $\alpha$ , IL-1 $\beta$ , IL-6, IL1 $\beta$  and IL-18, in MAS) maintain the CD8 $^+$  T cells in an activated state and thus create a cytokine storm feedback loop.

Reduced fratricide killing furthermore contributes to the pathogenesis of HLH: during viral infections, NK cells have an immunoregulatory role by controlling overactivated CD4 $^+$  and CD8 $^+$  T cells (12, 13), a function which is disabled in the context of defective granule-dependent cytotoxicity.

The characterization of novel monogenic HLH disorders has revealed additional disease mechanisms. On one hand, APC resistance to killing may inhibit timely resolution of inflammation. Target cells themselves have an active role in determining susceptibility to granule-mediated cytotoxicity, through the cell-surface expression of cytotoxicity receptor ligands (14). On the other hand, cell-intrinsic overproduction of cytokines or dysregulated cytokine control may contribute to HLH. Systemic hyperinflammation can be triggered by inflammasome activation or by the dysregulation of cytokine mRNA transcription (15–18).

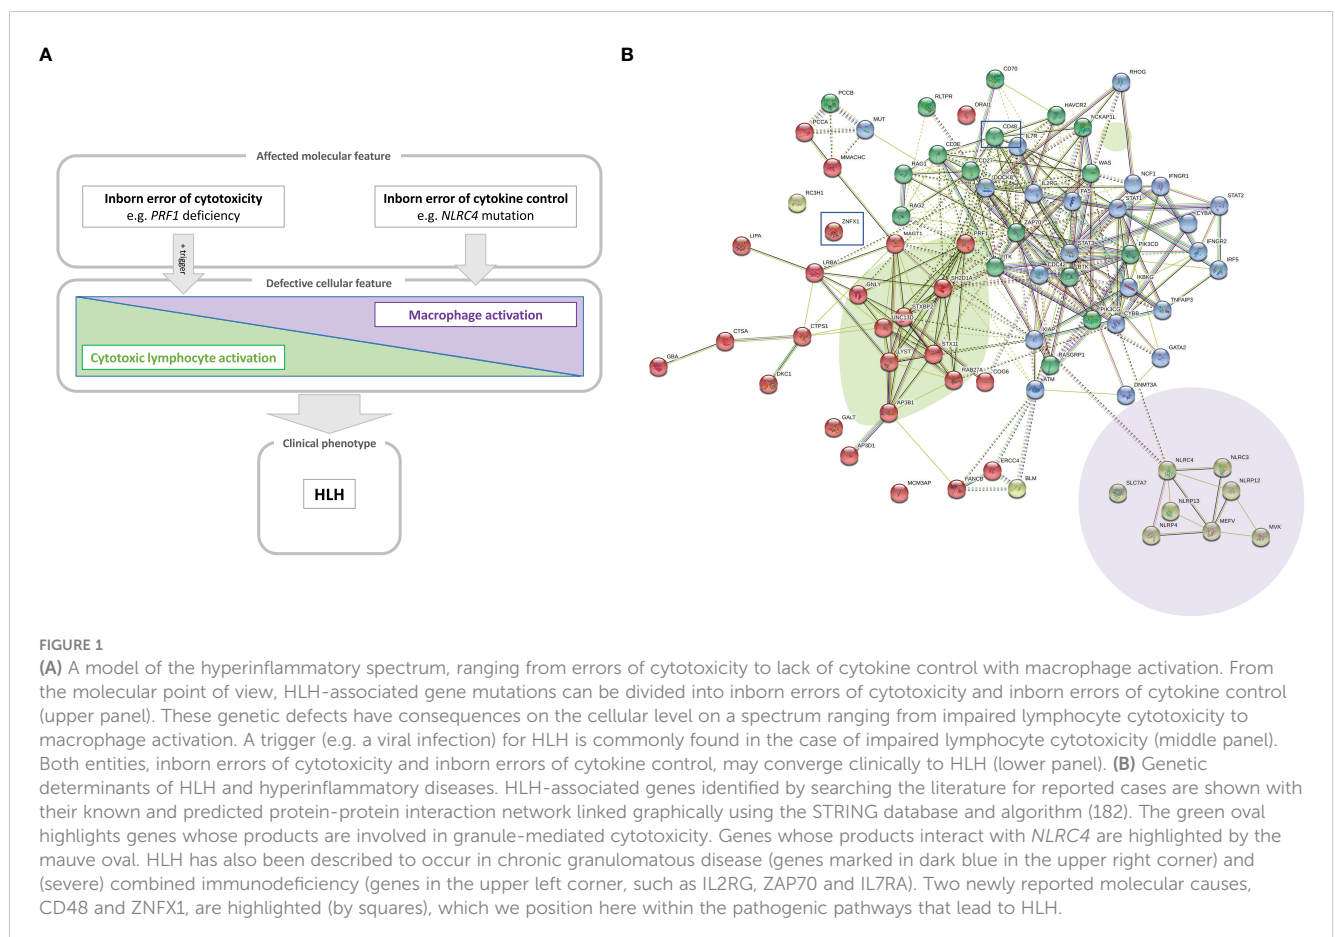

Thus, HLH can occur in a whole array of clinical settings and so is considered as a group of inflammatory disorders. Whole-exome and whole-genome sequencing methods have immensely amplified the ability to identify novel, pathogenic gene variants causing IEL (19). We and others have used these technologies to discover novel genetic inflammatory syndromes with HLH (14, 15, 20–22). Here, we propose a model that positions a number of conventional and novel monogenic inflammatory disorders on the HLH spectrum that ranges from inborn errors of cytotoxicity to inborn errors of cytokine control – all of which converge clinically to HLH (Figure 1A).

## 2 Cytotoxic lymphocyte subsets and granule-mediated cytotoxicity

Cytotoxic lymphocytes correspond to various subsets of innate and adaptive cells that recognize and attack malignant, stressed or virally infected cells. These include innate NK cells, adaptive cytotoxic T lymphocytes (CTLs), and other less abundant unconventional T lymphocytes. NK cells and CTLs are both capable of death receptor activation and the release of granules containing cytolytic effector molecules. These cytotoxic cells also produce proinflammatory cytokines, such as interferon gamma (IFN $\gamma$ ). CTLs have a CD8 complexed T cell-receptor (TCR) that recognizes peptides derived from (for example) intracellular

pathogens or malignant cells. The peptides are presented by major histocompatibility complex (MHC) class I molecules on APCs (23). Specific peptide recognition triggers CD8<sup>+</sup> T cell activation, the acquisition of cytotoxic effector functions, and the development of the CTL memory program (24).

As an evasion strategy, some pathogens and malignant cells can downregulate MHC I expression. However, NK cells (the main innate lymphoid cell subset) complement CTLs by detecting and killing target cells that have downregulated their cell-surface expression of MHC class I. Furthermore, the cytotoxic activities of CTLs and NK cells have complementary time scales; whereas NK are innate cells that rapidly induce cell cytotoxicity, adaptive CTL responses require an antigen encounter and the development of effector status (25). As innate immune cells, NK cells lack specific, rearranged lymphocyte receptors and mount rapid, first-line effector responses against infected, malignant or stressed cells. They integrate signals of an array of germline-encoded HLA-specific and non-HLA-specific activating and inhibitory receptors. An NK cell combines and integrates the inputs of its various receptors, which fine-tunes its effector outcome (25, 26). For example, the lack of MHC class I ligands (detected by inhibiting receptors such as killer immunoglobulin (Ig)-like receptors and NKG2A) triggers cytotoxicity. The detection of ligands present in altered cells by activating receptors (e.g. NKG2D and natural cytotoxicity receptors) also promotes cytotoxicity. CD16 is another activating receptor present in the CD56<sup>dim</sup> cytotoxic

subset of NK cells; it binds the Fc portion of IgG antibodies in antibody-coated target cells and triggers antibody-dependent cell cytotoxicity (ADCC). Other activating and inhibitory receptors (including 2B4, CD2, DNAX accessory molecule-1 (DNAM-1) and T cell immunoglobulin and mucin domain-containing protein 3 (TIM-3)) help to fine-tune NK cell cytotoxicity and are discussed below because of their roles in immune regulation and hyperinflammation. Despite the NK cells' clear role in innate immunity, it has recently been discovered that these cells also develop "memory-like" responses. Hence, NK cell subsets can expand, contract and later vigorously respond to previously encountered haptens, viral antigens and vaccines (27). This exciting new discovery has changed the paradigm for the link between immune memory and adaptive responses. However, the mechanisms that contribute to the NK cells' immune memory have not yet been identified and characterized in detail (28).

Other less abundant cytotoxic cell subsets are important for immune regulation in hyperinflammatory diseases. Unconventional T cells (such as NKT cells,  $\gamma\delta$  T cells, invariant NKT (iNKT) cells, and mucosa-associated invariant T cells) share features of both NK and T cells. They recognize antigens other than classic peptides (such as microbial metabolites or lipid antigens) presented by non-polymorphic molecules other than MHC (such as CD1d and butyrophillins) and semi-invariant or  $\gamma\delta$  TCRs (29, 30). Peripherally induced regulatory T cells can also exert cytotoxicity towards myeloid APCs in a perforin-, granzyme B- and HLA class I-dependent manner, assisted by lymphocyte function-associated antigen 1, CD2-CD58, and CD226-CD155 (31, 32).

Granule-mediated cytotoxicity is the cytotoxic lymphocyte's main killing mechanism. Upon activation, cytotoxic lymphocytes polarize secretory lysosomes that are anchored to microtubules and contain cytotoxicity effector molecules. The secretory lysosomes and the microtubule-organizing center move progressively towards the immune synapse formed between the killer cell and the target cell. Cytotoxic granules dock at the inner leaflet of the effector cell plasma membrane, near a cluster of TCRs (the central supramolecular activation cluster) and release their contents into the synaptic cleft *via* exocytosis (5). Perforin is a pore-forming protein present in the lymphocytes' cytotoxic granules. It is released as a monomer but can form oligomeric pre-pores that can dock with (but do not insert into) the target membrane (33). Insertion into the target membrane occurs only upon a conformational change of the perforin, enabling polymerization and formation of 22-mer pores in the target cell membrane, which then facilitate the entry of soluble cytotoxic effectors into the target cell (34). Although both target and killer cell are exposed to perforin in the immune synapse, only the target cell membrane is disrupted. Indeed, two protective mechanisms prevent the CTL from being killed during the cytotoxicity response: (i) the formation of highly ordered lipid rafts, and (ii) the exposure of negatively charged phosphatidylserines, which inactivate residual perforin (35).

Granzymes are the main cytotoxic effectors in secretory granules. Of the various types of granzymes, granzymes A and B are the most abundant and best characterized. Granzyme B engages caspase-dependent apoptosis of the target cell and cleave initiator pro-caspases, such as pro-caspase-3 and the pro-apoptotic molecule

Bid. Granzyme A triggers caspase-independent cell death *via* the disruption of mitochondrial metabolism and the generation of reactive oxygen species, which enable the formation of the SET complex of nucleases. Upon translocation to the nucleus, Granzyme A cleaves and releases SET complex nucleases, which eventually leads to DNA damage (36). The less studied granzyme K is present in the immunoregulatory CD56<sup>bright</sup> NK cell subset (37). The latter are also able to kill autologous activated T cells in a granzyme K dependent manner (38). Interestingly, CD56<sup>bright</sup> NK cells expand during disorders of hyperinflammation and cytotoxic cell disturbance (14, 39). Perforin and granzymes have a synergistic effect on granule-mediated cell cytotoxicity. Granzymes A, K and M are differentially expressed on cytotoxic T and NK cell subsets (37). Data from experiments in granzyme-deficient mouse models indicate that the granzymes have redundant functions, in order to overcome viral evasion strategies (37, 40). Redundant, compensatory granzyme functions can mediate tumor rejection in granzyme-deficient mice (41). It is noteworthy that only mice lacking both granzymes A and B are susceptible to lymphocytic choriomeningitis virus (LCMV) and the poxvirus ectromelia but are still resistant to other viruses. In contrast, perforin has an essential, non-redundant role in cytotoxicity (41, 42). This might also be why granzyme deficiency has not (yet) been linked to HLH *per se*, given that most gene-hunting workflows in the field of IEI are based on a monogenic disease hypothesis.

Granulysin is another membrane-disrupting effector molecule present in cytotoxic granules of CTLs and NK cells. It primarily attacks cardiolipin-rich microbial cell membranes rather than cholesterol-rich mammalian cell membranes (43) but does appear to be somehow involved in human cell cytotoxicity (44). However, granulysin has not been studied in the context of HLH.

In addition to granule-mediated cytotoxicity, cytotoxic cells can also induce target cell killing through death receptors. The main death receptors are Fas (CD95) and TNF-related apoptosis-inducing ligand (TRAIL) receptors. After ligand binding, Fas ligand and TRAIL transmembrane death receptors recruit Fas-associated protein with death domain (FADD) adapter proteins to their death receptor domain and activate caspase-dependent apoptosis (45). A small proportion of NK cells can kill several target cells consecutively. This process is known as "serial killing" and is important for the elimination of infected and malignant cells (46). During serial killing, cytotoxicity mechanisms are tightly regulated by NK cells. The first kills result from granule-mediated fast cytotoxicity, whereas later events switch to slower death receptor killing following upon a decrease in the granule count and the upregulation of FAS ligand (47). Both mechanisms are enhanced by cytokines like IL-2, IFN $\gamma$  and tumor necrosis factor alpha (TNF- $\alpha$ ), which also promote inflammation. The importance of FAS and FAS ligand for immune regulation is obvious in patients with autoimmune lymphoproliferative syndrome (ALPS) due to mutations in the *FAS* and *FASLG* genes (48). Although perforin deficiency is a fatal disorder, patients with ALPS easily reach adulthood.

Cell death caused by limited availability of growth factors, such as following the resolving of an immune response, is more dependent on the proapoptotic factor BCL-2 interacting mediator

of cell death (BIM) (49, 50). This is independent of other death receptors, such as FAS. Therefore, BIM-dependent cell death has been implicated in controlling lymphocyte contraction following resolution of an immune response, where conditions of lower pro-inflammatory cytokines and growth factors are created. On the other side, during chronic infections, where antigen persists and lymphocyte expansion is promoted, lymphocyte expansion is mainly controlled by FAS-dependent cell death (51). BIM could also be implicated in the resolution of lymphoproliferation in ALPS (52). In humans, a common deletion polymorphism in BIM that enables the synthesis of an alternatively spliced isoform has been associated to low efficacy of tyrosine kinase inhibitors in cancer (53). In addition, mice experiments have shown a role of this protein in controlling autoimmunity, but also in controlling APCs expansion (54), therefore raising a possibility of a predisposition for HLH.

An additional indirect mechanism that cytotoxic lymphocytes use to promote killing is the production of proinflammatory cytokines, such as IFN $\gamma$  and TNF $\alpha$ . IFN $\gamma$  directly enhances the cytolytic activity of NK cells and CTLs (55). TNF $\alpha$  binds to TNF receptors 1 and 2 and can thus trigger cell death upon FADD adaptor recruitment or trigger pro-inflammation through nuclear factor kappa B activation (56). Lastly, another indirect mechanism is the competitive advantage given to activated CD8 $^{+}$  T cells by homeostatic cytokines such as IL-2, to the detriment of regulatory T cells (Tregs) in the context of HLH (57, 58).

### 3 HLH and HLH-like hyperinflammatory syndromes

HLH corresponds to a clinical phenotype with diverse triggers and disease mechanisms. A comprehensive overview of the functional networks of proteins encoded by genes reportedly linked to HLH is given in Figure 1B.

#### 3.1 Primary HLH

Primary HLH (pHLH) corresponds to a group of disorders caused by IEI affecting genes, whose products are involved in granule-mediated cytotoxicity. The signs and symptoms of pHLH usually appear at an early age, although the disorder may also develop later in life. The clinical manifestations of pHLH include fever, hepatosplenomegaly, and multiorgan infiltration and damage (e.g. bone marrow failure and damage to the central nervous system) (59–61). The presence of tissue macrophages with hemophagocytic activity (referred to as histiocytes) is a hallmark of pHLH. Other observed clinical abnormalities include bicytopenia, hypercytokinemia, overactivated T lymphocytes, elevated ferritin levels, and elevated levels of soluble interleukin 2 (IL-2) receptor  $\alpha$  (also referred to as soluble CD25 (sCD25)). Primary HLH is diagnosed when the patient meets at least five of the eight established clinical criteria (6) or has compatible molecular findings. The estimated incidence of pHLH is 1 per 3000 inpatients in tertiary care pediatric hospitals and 1 per 50000

newborns (59, 62). Primary HLH is a potentially fatal sepsis-like disease; for survival, immunosuppressive treatment and then hematopoietic stem cell transplantation (HSCT) are generally required (63). Episodes of hyperinflammation are caused by uncontrolled, excessive immune responses, mostly upon exposure to viral or bacterial triggers (9). However, a triggering event or infection cannot be found in all individuals with HLH, e.g. some patients with intrauterine HLH. Rather than being a direct effect of an infectious trigger, pHLH develops because of impaired regulation of inflammation and lacking termination of immune responses by the granule-mediated cytotoxicity pathway (64).

Primary HLH is caused by inherited pathogenic variants in genes involved in different stages of the perforin-dependent granule-mediated cytotoxic pathway. Familial HLH type 2 (FHL2) is caused by biallelic deleterious mutations in the gene coding for perforin (*PRF1*). To date, more than 120 different *PRF1* mutations have been described (65) and account for 20–50% of cases of pHLH. However, some mutations are found also in healthy older adults – sometimes even in their homozygous form (66). The perforin knock-out mouse infected with LCMV is the “gold standard” model of pHLH and has provided valuable information on the pathogenesis of this disorder (58, 64, 67, 68).

Other HLH-associated mutations affect genes whose products are involved in the docking, priming and membrane fusion of cytotoxic granules (64, 69, 70). Familial HLH (FHL) type 3 (FHL3), type 4 (FHL4) and type 5 (FHL5) patients show degranulation defects. FHL3 is caused by pathogenic variants in the *UNC13D* gene encoding the Munc13-4 protein involved in priming the secretory granules. *UNC13D* mutations account for 30–35% of pHLH cases, although the prevalence varies as a function of the ethnicity and the geographic area; for example, the prevalence of *UNC13D* mutations is higher in northern Europe (71). FHL4 patients present mutations in the syntaxin 11 gene (*STX11*) involved in the membrane fusion between the cytotoxic granule and the target cell (72). Mutations in the *STXBP2* gene (coding for syntaxin-binding protein 2, which assists membrane fusion in exocytosis) cause FHL5 (73). There is also a related group of disorders characterized by concomitant HLH and hypopigmentation. For instance, Griscelli syndrome type 2 is caused by pathogenic variants of the *RAB27A* gene; the encoded GTPase signaling protein is expressed in many (but not in the central nervous system (74)) and is involved in late granule exocytosis stages. Hence, *RAB27A* pathogenic gene variants affect not only cytotoxic granules but also melanosome degranulation. Some patients also present neuropathy associated with the sequelae of HLH (75). Chediak-Higashi syndrome is another rare disease associated with hypopigmentation, HLH, impaired cytotoxicity, and the presence of enlarged lysosomal structures in cells and hair shafts. In this syndrome, pathogenic gene variants of *LYST* (coding for a lysosomal traffic regulator) impair the release of cytotoxic granules into the immune synapse. Lysosomal trafficking is an important process in neurons. Some *LYST* mutations are associated with neuronal affectations. Moreover, a mouse model bearing a mutation in the *LYST* protein's conserved WD40 domain shows a neurodegenerative phenotype with Purkinje cell loss, rather than alterations in the immune system (76). Furthermore, patients with Chediak-Higashi syndrome may

develop a neurodegenerative disease marked by cerebellar ataxia and peripheral neuropathy – even after successful HSCT (77). Hermansky-Pudlak syndrome 2 is another rare, multisystem disorder associated with HLH. It is caused by *AP3B1* pathogenic gene variants that affect lysosomal protein sorting and lead to cytotoxic lymphocyte defects in patients. A summary of the genetic, epidemiological, clinical and immunological characteristics of pHLH, together with secondary and novel forms of HLH are compiled in Table 1.

### 3.2 X-linked lymphoproliferative disease

X-linked lymphoproliferative disease (XLP-1) is a life-threatening lymphoproliferative disorder that arises in male patients with mutations in the X-linked *SH2D1A* gene (78, 79). The incidence of XLP-1 is 1 to 3 per million males, and 45-70% of

patients with XLP-1 develop HLH (78, 79). Patients with XLP-1 have an impaired ability to clear EBV infections. The seroprevalence of EBV in adults is 90%. Diseases caused by EBV are mild in children, moderate-to-severe in teenagers and immunocompetent adults but life-threatening in patients with *SH2D1A* mutations; the survival rate in the latter is 20%, and the disease features lymphoproliferation, multiple organ infiltration and multiple organ failure (80). 25-30% of patients with XLP-1 develop B-cell lymphoma associated with EBV infection (80). In addition, 35% of patients have not been exposed to EBV but are diagnosed because of their family medical history (81). At the time of writing, 100 patients with XLP-1 have been described in the literature (82). It is not completely understood how viral infections trigger HLH episodes in susceptible individuals. Putative mechanisms include the direct interference of antiviral responses with cytokine balances, the direct infection of cytotoxic cells or other key cells in HLH, disturbance of immune homeostasis, the capacity of viruses to

TABLE 1 Conventional and novel HLH, HLH-like and HLH-associated disorders: genetics, epidemiology, clinical manifestations, and immune dysregulations.

Disease	Gene symbol	Protein name (s)	Cellular expression	Impaired function	Clinical manifestations and concomitant diseases	Trigger	Mouse model
Primary HLH (FHL1)	Unknown	Unknown	Unknown	Cytotoxicity	HLH	Intracellular infections (viruses, bacteria, parasites)	Not described
Primary HLH (FHL2)	<i>PRF1</i>	Perforin-1 (PERF)	Cytotoxic lymphocytes	Cytotoxicity	HLH	Viruses (EBV, CMV, other herpesviruses, parvovirus B19, adenoviruses)	Perforin-deficient mice infected with LCMV
Primary HLH (FHL3)	<i>UNC13D</i>	Protein unc-13 homolog D (Munc13-4)	Leukocytes, lung, placenta	Degranulation, cytotoxicity	HLH	Viruses (EBV, CMV, other herpesviruses, parvovirus B19, adenoviruses)	<i>Unc13d</i> mutated “jinx” mice infected with LCMV
Primary HLH (FHL4)	<i>STX11</i>	Syntaxin-11 (STX11)	Cytotoxic lymphocytes	Degranulation, cytotoxicity	HLH	Viruses (EBV, CMV, other herpesviruses, parvovirus B19, adenoviruses)	<i>Stx11</i> -deficient mice infected with LCMV
Primary HLH (FHL5)	<i>STXBP2</i>	Syntaxin-binding protein 2 (STXBP2, Munc18-2)	Cytotoxic lymphocytes, intestinal and renal epithelium	Degranulation, cytotoxicity	HLH	Viruses (EBV, CMV, other herpesviruses, parvovirus B19, adenoviruses)	Not described
Griscelli syndrome type 2	<i>RAB27A</i>	Ras-related protein Rab-27-A (RAB27A)	Leukocytes and melanocytes	Degranulation, cytotoxicity	HLH. Concomitant hypopigmentation.	Viruses (EBV, CMV, other herpesviruses, parvovirus B19, adenoviruses)	<i>Rab27a</i> -deficient <i>ashen</i> mice infected with LCMV
Chediak-Higashi syndrome	<i>LYST</i>	Lysosomal-traffic regulator (LYST)	Leukocytes, melanocytes and neurons	Lysosome trafficking, cytotoxicity	HLH. Concomitant hypopigmentation.	Viruses (EBV, CMV, other herpesviruses, parvovirus B19, adenoviruses)	<i>Lyst</i> mutated mice ( <i>souris</i> strain) infected with LCMV
Hermansky-Pudlak syndrome type 2 (HPS2)	<i>AP3B1</i>	Adaptor protein complex 3	Multiple cell types, including	Lysosome storage and trafficking, cytotoxicity	Multisystem disease. Concomitant	Viruses (EBV, CMV, other herpesviruses,	<i>Ap3b1</i> -deficient <i>pearl</i> mice infected with LCMV

CMV, cytomegalovirus; EBV, Epstein-Barr virus; FHL, familial hemophagocytic lymphohistiocytosis; HLH, hemophagocytic lymphohistiocytosis; LCMV, lymphocytic choriomeningitis virus; MAS, macrophage activation syndrome; MHV-68, murine gammaherpesvirus 68; NFX, nuclear transcription factor X-box binding; NOCARH, neonatal onset of pancytopenia, autoinflammation, rash, and episodes of hemophagocytic lymphohistiocytosis; STAT, signal transducer and activator of transcription; XIAP, X-linked inhibitor of apoptosis; XLP, X-linked lymphoproliferative syndrome.

encode anti-apoptotic proteins delaying the apoptosis of infected immune cells or the chronic stimulation of pattern recognition receptors. Other viral evasion strategies that might promote HLH are the downregulation of MHC class I on NK cells or the suppression of the cytotoxic function of NK cells by downregulating the expression of perforin and SAP or encoding Fc receptors that block viral-specific antibodies diminishing antibody-dependent cell cytotoxicity (9).

*SH2D1A* encodes SAP, a small intracellular molecule belonging to a family of adaptors containing a Src homology 2 domain and a short C-terminal tail, that includes Ewing's sarcoma-activated transcript-2 (EAT-2) and EAT-2-related transduced. SAP binds to phosphorylated immunoreceptor tyrosine-based "switch" motifs (ITSM) of the SLAM family (SLAMF) of receptors within the CD2 family of leukocyte surface receptors, triggering lymphocyte cytotoxicity upon recruitment of the tyrosine kinase FynT and also preventing the binding of other inhibitory phosphatases (83, 84). The impediment to bind SAP to 2B4 SLAMF receptor enables the binding of other inhibitory proteases to intracellular 2B4 ITSMs, triggering the receptor's inhibitory function rather than the SAP-mediated activating signal (85). Various *SH2D1A* mutations have been described as affecting the binding to interactants (such as SLAMF receptors and FynT) or decreasing the half-life of the SAP protein (86, 87). Along with the molecular identification of SAP mutations, other methods for the rapid diagnosis of XLP-1 have been suggested. However, the measurement of intracellular SAP expression might not be relevant for mutations affecting SAP's function or half-life.

SAP pathogenic gene variants lead to a reduction in NK cell cytotoxic activity (79, 88–91). Patients with XLP-1 have abnormally low levels of NK and CD8+ T cell cytolytic activity towards EBV-infected B cells. A rapid screen that combines intracellular SAP expression and a 2B4-directed reverse ADCC (R-ADCC) assay of murine Fc receptor-expressing target cells has shown promising results (92). In this study, SAP<sup>-</sup> and SAP<sup>+</sup> NK clones from healthy female heterozygous carriers of SAP mutations provided information on the molecular defects in SAP deficiency. SAP<sup>-</sup> clones showed low cytotoxic activity towards CD48<sup>+</sup> target cells

in an R-ADCC assay triggered by 2B4 crosslinking. In contrast, SAP<sup>+</sup> NK clones exerted cytotoxicity upon 2B4 crosslinking, giving an overall neutral response at a polyclonal level in bulk populations (92). Patients with XLP-1 have defective NK cell cytotoxicity towards SLAMF-expressing hematopoietic cells. Moreover, SAP-deficient mice and patients with XLP-1 display enhanced NK responses to non-hematopoietic cells (93). This difference has been attributed to a defect in NK cell education (a mechanism for fine-tuning the NK cells' sensitivity to activating and inhibitory signals) in XLP-1 (94). Signaling during NK cell education is mediated by SLAMF6 and depends on SAP, which blocks the binding of the inhibitor phosphatase SHP1 to the SLAMF receptor. As mentioned before, SAP not only mediates SLAMF-activated signaling but also prevents inhibitory SH2-containing proteases from binding to SLAMF receptors (84, 95). Natural cytotoxicity receptors (such as NKp46 and CD16) have compensatory activity in patients with XLP-1 (93). SAP is crucial for the development of NKT cells because the latter are absent in patients with XLP-1 and in SAP-deficient mice (78, 96). Mice with a SAP mutation that abolishes the recruitment of Fyn have a defect in NKT cell development in the thymus and a lack of invariant NKT (iNKT) cells (97). NKT developmental defects have been found in mice with mutations in all SLAMF receptors (98–100). NKT cells are also absent/very reduced in patients. For instance, NKT cells showed undetectable levels with  $\alpha$ -galactosylceramide-loaded CD1d tetramers and/or antibodies targeting the invariant V $\alpha$ 24 V $\beta$ 11 TCR, when compared with controls or patients with other IEL (101). Thus, it has been suggested that low/absent NKT cell frequencies could be a diagnostic parameter for XLP1. However, data from other studies indicate that the frequency of NKT cells in adult and pediatric XLP1 patients is variable and point against the use of NKT cell levels to exclude a diagnosis of XLP1 (102). In SAP-deficient patients, high levels of T cell proliferation have been observed upon viral infection, despite the inability to eliminate virus-infected cells or to produce IFN $\gamma$ . In mice, T cells proliferate and survive the acute infection (88). SAP-deficient mice have problems controlling chronic LCMV infections, due to defects in humoral response (89). These defects can be rescued by

reconstitution with wild-type CD4<sup>+</sup> T cells (103). Patients with XLP-1 also have profound defects in the humoral response. 50% of patients with XLP-1 have hypogammaglobulinemia (82). Defective T follicular helper (TFH) and T helper 2 (Th2) cell development and defective Th2 cytokine production are also observed (88, 89, 91, 104). SAP-deficient mice have a defect in TFH cell development in the germinal centers. The TFH cell type is crucial for the generation of high-affinity antibody responses (78). In the absence of SAP, SLAM family receptor signaling to TFH is inhibitory, since mice with mutations in all the SLAM family receptors do not have a defect in TFH development (98). XLP1 patients also display a deficiency in the formation of germinal centers in the spleen (105). In tune with this defect, patients show a reduction of germinal center-dependent isotype-switched CD27<sup>+</sup> memory B cells in peripheral blood. However, despite this reduction, the few patient's IgM<sup>+</sup> CD27<sup>+</sup> B lymphocytes present in circulation have the capacity to undergo somatic hypermutation (105).

The XLP-1-related disorder XLP-2 has been linked to a deficiency of X-linked inhibitor of apoptosis (XIAP) protein, caused by pathogenic gene variants in the *XIAP/BIRC4* gene. More than 90 such mutations have been described since 2006 (106, 107). XIAP deficiency has similarities with SAP deficiency, such as EBV-triggered HLH, splenomegaly, cytopenia and hypogammaglobulinemia. However, patients with XLP-2 do not suffer from lymphoma; Other inflammatory symptoms (such as colitis, hepatitis, uveitis and arthritis) are considered a hallmark of XLP-2 (81). The anti-apoptotic protein XIAP is involved in innate immune signaling of pattern recognition receptors like dectin-1 and nucleotide oligomerization domain (NOD)-like receptors and also the regulation of the NOD-, LRR- and pyrin domain-containing protein 3 (NLRP3) inflammasome (106). Indeed, a functional assay demonstrating the XIAP-deficient monocytes' inability to produce TNF $\alpha$  upon NOD2 stimulation had been established as a diagnostic tool (107, 108). XIAP also regulates adaptive immune functions such as activation-induced cell death (AICD), an important homeostatic mechanism for controlling and limiting activated T cells in conventional and unconventional T cells. In XLP-2 patients, AICD is also impaired in T cells (106). In contrast to XLP-1, patients with XLP-2 have a normal iNKT cell compartment (106). Regarding the humoral compartment, one third of XLP-2 patients experience mild hypogammaglobulinemia but the switched B cell compartment is not affected (106).

### 3.3 Secondary HLH or MAS

The term sHLH (or sometimes "sporadic" or "acquired" HLH) has generally been used to describe patients with (i) a disease meeting the clinical criteria for a diagnosis of HLH, (ii) none of the genetic defects mentioned in the above section on pHLH, and (iii) no XLP-1/2 syndrome. In addition and as later discussed, sHLH can also occur in patients with other IEI not related to cytotoxicity defects. Most patients with sHLH suffer from an inherited or acquired underlying disease or are receiving treatment that predisposes them to immune dysregulation. Secondary HLH can occur in autoinflammatory

syndromes and is most frequently reported in systemic juvenile idiopathic arthritis (sJIA). Many rheumatologists prefer to use the term macrophage activation syndrome (MAS), rather than sHLH (8, 109–111). MAS appears later in life than pHLH but may also be life-threatening. pHLH and MAS have similar clinical manifestations. Although patients with pHLH have a permanent impairment in the granule-mediated cytotoxic activity of T lymphocytes and NK cells, there might be no impairment of granule-mediated cytotoxicity in patients with MAS or the impairment is only partial or transient. Animal models of MAS have been established by stimulating toll-like receptors in wildtype and IL-6 transgenic mice; these experiments highlighted the importance of IFN $\gamma$  in MAS, while lymphocytes were not required for the induction of the disease, although critical to induce maximal disease (112–114).

In contrast to pHLH, inflammasome activation and IL-18 hypercytokinemia are the hallmarks of MAS pathogenesis in patients with *NLR4* pathogenic gene variants. While impaired lymphocyte cytotoxicity is essential for a diagnosis of pHLH, intrinsically activated macrophages are essential for MAS in *NLR4*-mutated patients. Furthermore, new mutations in the inflammasome-associated gene *NLR4* reportedly cause some of the features of MAS (16, 17). We suggest a model in which *NLR4*- and perforin pathogenic gene variants represent the two prototypes in this hyperinflammatory spectrum (Figure 1A). *NLR4* triggers the formations of inflammasomes, i.e. multimeric complexes assembled after stimulation by pathogens and that lead to the production of IL-1 $\beta$  and IL-18 and pyroptosis cell death after caspase-1 activation. Indeed, IL-18 hypercytokinemia has been linked to MAS in patients with sJIA and in animal models (115, 116). CD163, a scavenger receptor associated with phagocytosis in macrophages, is also a biomarker associated with MAS and EBV-triggered HLH (117). Strikingly, the A91V *PRF1* variant and mutations in *UNC13D* are more prevalent in patients with sJIA who developed MAS (118, 119). MAS is the most severe complication of sJIA and adult-onset Still's disease and is also observed in patients with systemic lupus erythematosus. sJIA is a chronic, autoinflammatory disease of childhood characterized by the clinical features arthritis, fever, rash, swollen lymph nodes, hepatomegaly, and serositis. MAS-associated symptoms are observable clinically in 10% of sJIA cases and subclinically in 30–40% of cases. Nonsteroidal anti-inflammatory drugs constitute the first-line treatment, and corticosteroids and methotrexate are used as a second-line treatments. In treatment-resistant cases and in patients with sHLH, HSCT and monoclonal antibodies against the pathogenic proinflammatory cytokines are used. However, the treatment of sJIA has not been standardized.

In addition to MAS, patients infected with intracellular pathogens and patients being treated with immunomodulatory monoclonal antibodies or chimeric antigen receptor T cells may develop a cytokine release syndrome that resembles HLH. Secondary HLH can also develop in patients with inborn errors of metabolism, such as lysinuric protein intolerance, multiple sulfatase deficiency, galactosemia, Gaucher disease, Pearson disease, galactosialidosis, propionic acidemia, Niemann-Pick disease, and congenital disorders of glycosylation (120, 121).

### 3.4 Novel genetic inflammatory syndromes with HLH

The area of cell-cell contact between the cytotoxic lymphocyte and its target cell, the so called immunological synapse, is a highly organized area involving cytoskeletal rearrangement. Efficient killing by T cells and NK cells requires function of the actin cytoskeleton. Several mutations in genes with a role in active cytoskeleton remodeling have been associated with HLH. Indeed, pathogenic gene variants in *WAS*, *DOCK8* and *NCKAP1L* genes coding for cytoskeleton regulators in immune cells cause hyperinflammatory disorders with HLH hyperinflammation (20). Another novel HLH disorder associated with hematological impairments and features of autoinflammation was recently identified in five patients with a unique *de novo* missense mutation in the cell division cycle 42 (*CDC42*) gene (22, 122). This one specific mutation was associated with neonatal onset of cytopenia, autoinflammation, rash, and episodes of HLH (NOCARH). *CDC42* is a Ras-homologous (Rho) signaling GTPase protein involved in cytoskeleton rearrangement and cell migration. The p.R186C missense mutation identified affected the subcellular localization of the protein -aberrantly concentrated in the Golgi apparatus-, cell polarity, migration, proliferation and signaling. It profoundly affected hematopoiesis and compromised the normal composition and migration of bone marrow cells. This is a multisystem inflammatory disease with a strong autoinflammatory component, with characteristics similar to NLR4 inflammasopathies. The autoinflammatory symptoms were attributed to the high spontaneous release of IL-18 by mononuclear cells from the bone marrow and the high IL-1 $\beta$  levels. In addition, the 4 identified patients developed HLH, lethal in all the patients but one, that survived upon anti-IFN $\gamma$  treatment with emapalumab and HSCT. Indeed, IL-18 is a co-stimulatory factor for IFN $\gamma$  production. An additional mechanism contributing to HLH in this novel hyperinflammatory syndrome was the defect in the NK cell capacity to form conjugates and to migrate, that diminished its cytotoxic potential (111, 116, 123). Differently than the NOCARH and HLH responsive to anti-IFN $\gamma$  caused by the p.R186C mutation in the *CDC42* gene, novel additional mutations in *CDC42* C-terminus region have been recently associated to a clinical autoinflammatory syndrome responsive to IL-1 inhibitors (124).

Over the last few years, the establishment of novel associations between inborn errors of immunity (IEI) and HLH has broadened to beyond genes involved in cytotoxicity, cytoskeleton reorganization, and inflammasome activation, but also to the ones involved in checkpoint control, receptor signaling, and mRNA regulation. For instance, a novel association between HLH and loss-of-function mutations in the *HAVCR2* gene (coding for T cell immunoglobulin and mucin domain-containing protein 3 (TIM-3)) was identified in patients with subcutaneous panniculitis-like T cell lymphoma with associated HLH. TIM-3 is an inhibitory molecule expressed by T lymphocytes and other immune cells (21, 125). The TIM-3 negative checkpoint is a critical regulator of innate immunity and inflammatory responses and suppresses effector T cells by decreasing IFN $\gamma$ -driven inflammation. The predisposition

to HLH in individuals with defective TIM-3 function might therefore be explained by a defect in downregulating the T-cell response to IFN $\gamma$ . Importantly, TIM-3 also regulates monocyte/macrophage activation. Thus, it is possible that TIM-3 deficiency leads in multiple ways to an increased inflammatory response and thereby to HLH.

Lymphocyte cytotoxicity is triggered upon contact with a target cell if sufficient activating signals are received. This implies that target cells are not passive bystanders during granule-dependent cytotoxicity. Indeed, we could gain insight in the role of resistance to cytotoxicity in the pathogenesis of HLH by studying a patient with a novel IEI affecting the 2B4-CD48 interaction. 2B4 (CD244) is a SLAMF receptor that signals through SAP and is crucial for controlling CTL responses to EBV (126). 2B4 is the SLAMF receptor with greatest number of ITSM SAP-binding motifs and is also the only heterotypic SLAMF receptor. Thus, 2B4 is not a self-ligand, but it interacts with CD48. In mice, signaling through 2B4 can be either costimulatory or coinhibitory, whereas there is evidence of a predominantly activating role in human subjects (127, 128). We recently identified a novel hyperinflammatory disorder with HLH caused by a *de novo* heterozygous mutation in the *CD48* gene (*CD48*<sup>S220Yhet</sup>) (14). This disorder is characterized by recurrent episodes of hyperinflammation, rash and IL-6 hypercytokinemia, while only moderately elevated sCD25 levels. A similar inflammatory pattern was triggered by LCMV infection in *CD48*<sup>+/+</sup> and *CD48*<sup>-/-</sup> mice (14). *CD48* is expressed by almost all leukocytes (except for some long-term hematopoietic stem cell precursors) and functions mainly as a co-stimulatory and adhesion molecule (129). The *CD48*<sup>S220</sup> residue is essential for the protein's subcellular localization and serves as the attachment site for a glycosylphosphatidylinositol cell surface anchor. The S220Y pathogenic gene variant is associated with lower cell-surface *CD48* expression and a lower cytotoxic ability for NK cells. The diminished expression of *CD48* appears to be involved in a novel mechanism that contributes to hyperinflammation; target cells are less susceptible to killing and *CD48*-haploinsufficient immune cells are more resistant to elimination by granule-mediated cytotoxicity. Along with these functional alterations, maturation defects were also observed in cytotoxic lymphocytes. Thus, target cells' resistance mechanisms to cytotoxicity can significantly contribute to immune dysregulation.

A novel homozygous mutation in the *RC3H1* gene (coding for roquin-1, a post-transcriptional regulator of mRNAs involved in immune responses) led to HLH and hyperinflammation in a patient and in a mouse model (18).

Signal transducer and activator of transcription 1 (STAT1) mediates both type I and type II IFN responses. Patients with a gain-of-function (GOF) mutation in *STAT1* can occasionally present HLH, despite the absence of IFN $\gamma$  hypercytokinemia (130, 131). Conversely, *Stat1* knock-out mice develop multiorgan immune infiltration and hypercytokinemia upon LCMV infection (132). This data seem to be paradoxical. In the experimental *Stat1* knock-out mice model challenged with LCMV, the lethal multi-organism infiltration is dependent on highly expanded antigen-specific CD4<sup>+</sup> T cells. In the clinical setting, *STAT1* GOF mutations have been linked to a permanent phosphorylated status of the transcription factor due

to an impaired dephosphorylation and are associated to a broad clinical spectrum, from infection susceptibility to autoimmune manifestations, this later probably due to a strong type I IFN signaling mediated by the hyperphosphorylated STAT1 (131). In the clinical case with *STAT1* GOF linked to HLH, the hyperphosphorylated status of STAT1 was associated with a persistent overactivity of APCs, previously activated by innate immune receptors in the context of an infection (130). Interestingly, deficiencies in STAT2 and IRF9, the other two components that together with STAT1 form the heterotrimeric complex named Interferon Stimulated Gene Factor 3 (ISGF3), induce a prolonged type I IFN response due to lack of negative feedback of the IFN receptor (133). STAT2 and IRF9 mutations have been also recently linked to HLH episodes (134, 135).

ZNFX1 (NFX1-type zinc-finger-containing 1) is a highly conserved IFN-stimulated dsRNA sensor that restricts the replication of RNA viruses in mice and contributes to transgenerational inheritance in *C. elegans*, by binding to mRNA complexed to short non-coding RNAs (15, 136, 137). In humans, homozygous ZNFX1 destabilizing pathogenic gene variants were associated with multisystem inflammation, including HLH, monocytosis, and a predisposition to viral infections and mycobacterial disease (15, 138). Recent studies on patients suffering from COVID19 propose an anti-SARS-COV-2 role for ZNFX1 and other ZNF proteins, where ZNF protein activity positively correlated with the abundance of multiple immune cells implying an effective antiviral response (139). While the underlying mechanisms still need further investigation, the role of ZNFX1 in immune regulation highlights the importance of time and context in tuning innate response, to allow for proper elimination of viral material while preventing hyper-inflammatory responses. With regards to the spatial context, ZNFX1 has been shown to localize to liquid-like perinuclear condensates in *C. elegans* germ cells (136, 137), to stress granules of virally or chemically stressed cells (138), and to the proximity of the outer mitochondrial membrane in steady-state (137). We have shown that in the absence of ZNFX1, the half-life of the mRNA of interferon sensitive genes is prolonged (15). We therefore propose a mechanism whereby the helicase function of ZNFX1 is needed to remove mRNAs which has been formed in consequence of a viral infection. In the absence of ZNFX1, the mRNA of interferon sensitive genes remains more stable, allowing it to be translated again instead of being degraded. This prevents a return to homeostasis leading to the described hyperinflammatory syndrome. Overall, ZNFX1 plays a central role at both the very early and late stages of nucleic acids driven interferon responses, by regulating sensing and the return to homeostasis. As a consequence, patients with homozygous ZNFX1 destabilizing mutations suffered from multisystem inflammation, including HLH, and a predisposition to viral infections (118).

The molecular changes caused by inborn errors of granule-mediated cytotoxicity or cytokine control contribute variably to cellular impairments (such as impaired lymphocyte cytotoxicity or macrophage activation) that lead to uncontrolled

hyperinflammation. Thus, the pathophysiological spectrum of HLH-associated disorders ranges from impaired lymphocyte cytotoxicity to macrophage activation (Figure 1A).

## 4 HLH-like manifestations in other immune-mediated diseases

### 4.1 Inborn errors of immunity

As described above, biallelic *PRF1* pathogenic gene variants cause pHLH. However, *PRF1* mutations concomitant to other IEI have been also described. ALPS is an immune dysregulation disorder that causes splenomegaly, lymphadenopathy, autoimmunity, susceptibility to lymphoma, and blood accumulation of double-negative CD4<sup>+</sup> CD8<sup>+</sup> T cells. Diansani autoimmune lymphoproliferative disease (DALD) is a variant of ALPS that lacks the expansion of double-negative CD4<sup>+</sup> CD8<sup>+</sup> T lymphocytes (140). In most cases, ALPS is caused by a genetic mutation related to the FAS-mediated pathway of apoptosis. More than 70% of the mutations affect the *FAS* gene directly but mutations in *FASLG*, *CASP10*, *CASP8* and other genes have also been observed (48). A combination of a heterozygous *PRF1* mutation and a *FAS* mutation was identified in an ALPS patient with aggressive lymphoma (141). A larger study found that 2 of 14 ALPS patients and 6 of 28 DALD patients had an FHL-associated *PRF1* mutation, leading to diminished NK cell activity (121). Perforin-dependent activation-induced cell death operates as a compensatory mechanism in FAS-deficient T cells from ALPS patients (142). Mutations in the FHL3-associated *UNC13D* gene have been detected in six ALPS/DALD patients; although the patients' NK cells showed normal levels of activity, granule exocytosis release was impaired in transfected cell lines (143). Furthermore, a SAP polymorphism affecting a key methylation site for the protein's expression was significantly more frequent in ALPS/DALD patients than in controls (144).

A multicenter analysis identified 63 patients with other IEI meeting the diagnostic criteria for HLH (6). In a systematic evaluation of the patients' clinical and immunological features, 30 had combined immunodeficiencies (including 12 with severe combined immunodeficiencies (SCIDs)) and 22 had chronic granulomatous disease (CGD) (145). 80% of patients with other IEI and who met the diagnostic criteria for HLH had either SCID or CGD. Although this study did not cover all known IEI, it is noteworthy that SCID and CGD were markedly over-represented because they account for only 15% of IEI overall. The remaining 20% (i.e. those not meeting the diagnostic criteria for HLH) included two patients with ALPS due to *FAS* mutations. In 79% of the affected cases, the HLH episode was associated with an infectious trigger. When comparing the subgroups with regard to their immunological and clinical variables, the serum level of sCD25 was lower in patients with T cell-dependent IEI than in patients with FHL. Thus, the study of other IEI associated with HLH provides data on the respective contributions of leukocyte subsets

to hyperinflammatory diseases. In addition to rare complications of CGD and SCID (146, 147), rare cases of HLH have been also reported among patients with DiGeorge syndrome and Wiskott-Aldrich syndrome (148, 149).

## 4.2 The role of perforin in immune system cancers and bone marrow diseases

Inherited *PRF1* pathogenic gene variants cause FHL in early childhood. However, compound heterozygous missense *PRF1* mutations that do not fully abrogate perforin activity may have effects later in life (150). Granule-mediated cell cytotoxicity is a crucial mechanism for killing tumor cells. One study identified biallelic *PRF1* mutations in 4 out of 29 patients with primary lymphoma (151). Another study showed that 50% of cases of late-onset of FHL presented with lymphoma or leukemia. Interestingly, the mutations were not fully deleterious but caused protein misfolding that could be restored by a permissive protein folding temperature in *in vitro* assays (150). Missense mutations are also linked to a predisposition to cancer (152). *PRF1* mutations and decreased NK cell cytotoxic activity have been observed in patients with acquired aplastic anemia (a form of bone marrow failure) (153).

## 5 Novel insights into pathogenesis

Different dysregulated pathways contribute to HLH development. Deficient perforin-granule-dependent cytotoxicity leads to (i) reduced clearance of triggering intracellular pathogens within APCs, which leads to an increase in the CTL-APC synapse time and repetitive  $\text{Ca}^{2+}$  release within (and thus activation of) the CTL (11) and (ii) defective fratricidal killing (12); both resulting in excessive cytokine production by CTLs. Tregs are crucial regulators of immune responses and express high levels of CD25, the  $\alpha$  subunit of the high affinity receptor for IL-2. The growth factor IL-2 is essential for T lymphocytes. A Treg dysfunction has been postulated in both patients with pHLH and in experimental models of pHLH, due to the preferential consumption of IL-2 by abundant, highly activated  $\text{CD25}^{\text{high}}$   $\text{CD8}^{+}$  T cells (58). The precise role of Tregs in HLH needs further characterization. An important feedback loop which is critical for immune homeostasis and which fails in perforin-deficiency is the elimination of antigen-presenting dendritic cells. In a murine model of HLH has been shown that the persistence of potent, immunostimulatory dendritic cells, contributes to the pathogenesis (154), thus demonstrating a reciprocal relationship between perforin in CTLs and APCs' function. This is consistent with our own observations made in a patient with heterozygous pathogenic gene variant in CD48 suffering from recurrent hyperinflammation (25). We have shown that reduced CD48 expression leads to an increased resistance of human APCs to killing. This provides evidence that immunostimulatory APCs contribute to the pathogenesis of HLH, also in humans. A hallmark of HLH is macrophage activation. On

one hand excessive cytokine production by CTLs leads to macrophage activation in HLH. On the other hand, a defect in cytokine control, as in NLRC mutations and ZNFX1 deficiency can, independently of CTLs, lead to macrophage activation in an HLH context. Disease mechanisms linking deficient cytotoxicity and deficient cytokine control to HLH spectrum diseases are summarized in Figure 2.

## 5.1 Dysregulation of CD48-triggered SLAMF-dependent cytotoxicity in HLH

As in the case for other IEL, monogenic HLH diseases are excellent models for improving our knowledge of how the immune system works. In-depth studies of immune dysregulation in patients with HLH and animals models of conventional HLH have provided invaluable information on the important role of granule-mediated cytotoxicity in eliminating virus-infected cells and in terminating immune responses. The newly identified CD48 haploinsufficiency and XLP-1 are clinically distinct but immunologically related disorders. Both CD48 and SAP mutations affect the 2B4-triggered cytotoxicity pathway, by either diminishing cell-surface expression of the 2B4 ligand or affecting the stability or binding capacity of a signaling adapter molecule (14, 79). SAP and CD48 pathogenic gene variants cause partially overlapping features, such as cytotoxicity defects and hyperinflammation. However, the disorders differ with regard to clinical signs, the extent of cytotoxicity impairment, and the immune compensatory mechanisms (Figure 3 and Table 1). While in XLP-1 all SAP-dependent pathways are impaired, in CD48 haploinsufficiency only CD48-triggered 2B4-dependent SAP signaling is affected. This is probably the underlying mechanism setting the differences between these two disorders.

The viral triggers associated with HLH and hyperinflammatory syndromes are mainly DNA herpesviruses (such as EBV and human cytomegalovirus (CMV)) and more rarely herpes simplex virus, human herpesvirus 6 and 8, and varicella zoster virus (9). Hyperinflammatory episodes in CD48 haploinsufficiency are not currently known to be associated with greater vulnerability to a specific pathogen (14). CD48 haploinsufficiency appears to be less aggressive clinically and immunologically than XLP-1. This novel disorder is characterized by normal perforin-dependent T cell cytotoxicity and an NK cell degranulation towards K562 cells within reference values but lower cytotoxicity towards autologous EBV-immortalized lymphoblastoid cells. Phenotypic and functional analyses of the NK cells of patient with CD48 haploinsufficiency have nevertheless evidenced an impact of CD48 on NK cell maturation, since the patient presented a high number of immunoregulatory-immature  $\text{CD56}^{\text{bright}}$   $\text{CD94}^{\text{high}}$  NK cells, high levels of  $\text{IFN}\gamma$  production by NK cells upon IL-12 stimulation, and a low number of the more differentiated, highly cytotoxic  $\text{CD56}^{\text{dim}}$   $\text{CD94}^{\text{low}}$  cells. Interestingly, a similarly immature NK profile has been observed in patients with an IEL affecting the IL-2/CD25 pathway (39). It is noteworthy that HLH-episodes in CD48 haploinsufficiency were not associated with high serum sCD25 levels as opposed to the high levels observed in FHL (14).

FIGURE 2

Five major disease mechanisms linking defective cytotoxicity and error in cytokine control with HLH (1). reduced clearance of triggering intracellular pathogens within APCs, which leads to an increase in the CTL-APC synapse time and repetitive  $\text{Ca}^{2+}$  release within (and thus activation of) the CTL (11); (2) defective NK-cell- and CTL-mediated immune regulation by fratricidal killing (12, 155), (3) excessive consumption of IL-2 by CTLs, which deprives Tregs, postulated by Humblet-Baron et al. (58), (4) persistence of immunostimulatory APCs (either due to increased resistance of APCs to killing as shown in a patient with CD48 deficiency (14) or due to persistence of immunostimulatory APCs due to CTL defect as demonstrated by Terrell & Jordan (154) in a murine model, and (5) error in cytokine control leading to macrophage activation.

A remarkable novelty that CD48 haploinsufficiency provided to HLH knowledge is the importance of the target cell in perforin-dependent cytotoxicity. Of note, CD48 is expressed on both the cytotoxic cell and the target cell. In CD48 haploinsufficiency, the target cells themselves might have an active role in the pathogenesis of HLH because CD48 expression might be a “kill me” signal as a ligand for 2B4 receptors on the killer cell promoting cytotoxicity. A similar mechanism has been described for controlling activated CD155-expressing T cells upon DNAM-1 interaction on NK cells, in the context of immune regulation in autoimmunity (156). Indeed, cell-surface CD48 expression in target cells determines the degree of susceptibility to NK cell killing in hyperinflammation, as shown by experiments on cell lines transfected with a plasmid encoding wildtype and mutated CD48 or experiments in which the target cell is pre-coated with blocking antibodies (14). The interactive feedback loop between target cells and cytotoxic lymphocytes is crucial for the elimination of APCs and a return to immune homeostasis (154).

CD48 signaling defects affect also T lymphocytes. In a CD48 knock-out model, low  $\text{CD4}^{+}$  and  $\text{CD8}^{+}$  T cell proliferation has been observed (157). However, it must be born in mind that CD48 has an additional low affinity receptor (CD2) which, in humans, has a high affinity ligand (CD58); this is not the case in mice. In patients, it has not yet been established whether CD48-associated alterations are mediated by low-affinity CD2 receptor signaling. AICD is impaired in CD48 haploinsufficiency, as in SAP mutations (158, 159). CD48 protects against restimulation-induced cell death by maintaining basal autophagy and inhibiting p53 signaling in a SAP-independent manner (160). Finally and concerning the humoral branch of the adaptive immune system, CD48 haploinsufficiency causes slight alterations in IgG subtypes (such as low IgG2 levels) but not profound hypogammaglobulinemia (14).

## 5.2 Dysregulated cytokine control in novel HLH spectrum disorders

HLH is characterized by hypercytokinemia and systemic inflammation.  $\text{IFN}\gamma$  is a key pathogenic cytokine in both pHLH

and MAS (161) and is produced by overactivated CTLs (67, 68). In pHLH, a mouse model with genetically depleted  $\text{IFN}\gamma$  demonstrates that this cytokine is responsible for the hematologic features of the disease, such as anemia (162). Indeed, the monoclonal anti- $\text{IFN}\gamma$  antibody emapalumab is the first cytokine-targeted therapy approved for pHLH patients that have a refractory or relapsing disease or do not tolerate first-line therapies (63, 163). This contrasts with low  $\text{IFN}\gamma$  responses to EBV-infected B cells in patients with XLP-1 (164). Patients with XLP-2 present elevated levels of cytokines such as  $\text{IFN}\gamma$ , IL-6,  $\text{TNF}\alpha$  and IL-18 (106).

The cytokine IL-33 is released by stressed and necrotic cells. Thus, it is considered an “alarmin” that activates immune responses upon injury. IL-33 binds its receptor ST2 resulting in a MyD88-dependent signaling. In the context of HLH, experimental models blocking ST2 have demonstrated that IL-33 enhances the  $\text{IFN}\gamma$ -driven pathology in HLH (165).

IL-6 is another proinflammatory cytokine associated with HLH hyperinflammation. In CD48 haploinsufficiency, PBMCs upregulate the linker for activation of T cells-regulated cytokine and phospholipase  $\text{C}\gamma$  transcript upon activation (14). This disorder is associated with IL-6 hypercytokinemia, both in the patient with CD48 deficiency and in the CD48 knock-out mouse model upon LCMV infection. In HLH, defective killer cell-target cell disengagement promotes persistent activation of the killer cells and the production of proinflammatory cytokines that induce IL-6 secretion by macrophages. Interestingly, IL-6 hypercytokinemia and cytotoxicity defects were observed during the cytokine storms in severe COVID-19 (166) and MAS (167) – two hyperinflammatory disorders with overlapping features. Monoclonal antibodies against the IL-6 receptor,  $\text{IFN}\gamma$  and Janus kinases 1 and 2 (which act downstream of the cytokines) are being tested as an immunomodulatory treatment for HLH (81, 163, 168, 169). In MAS, lack of cytotoxicity-induced apoptosis in target cells favors the lytic death of the latter; this releases alarmins that activate inflammasomes and leads to a hyperinflammatory situation (170).

Mutations in genes involved in the regulation of cytokine transcription have been recently linked to HLH (Figure 4). NLR4 is an intracellular pattern recognition receptor that activates inflammasomes. NLR4-triggered inflammasomes

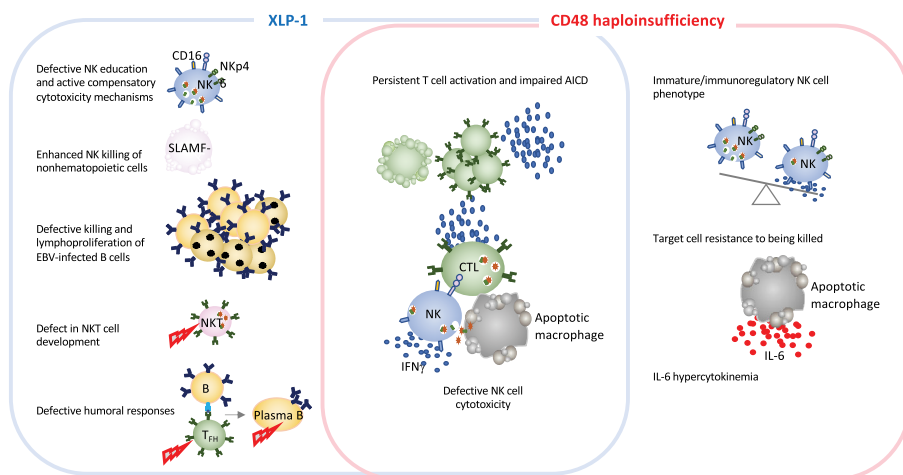

FIGURE 3

Schematic representation of immune defects in two related inborn errors of cytotoxicity: XLP-1 (SAP deficiency) and CD48 haploinsufficiency. In humans and animal models, XLP-1 and CD48 haploinsufficiency are related because SAP is an adapter molecule for the high-affinity CD48 receptor. However, the two diseases also present differences. XLP-1 disorder in humans and/or SAP deficiency in mice (in the blue box) cause NK cell abnormalities, such as the defective killing of EBV-infected target cells, subsequent EBV-infected B cell lymphoproliferation and NK education defects. These affects are partially countered by compensatory NK killing mechanism. Profound NKT cell developmental defects and defective humoral responses are also hallmarks of XLP-1. SAP deficiency and CD48 haploinsufficiency (in the red box) trigger some of the same generic dysregulations, such as defective NK cell cytotoxicity and impaired activation-induced cell death. Furthermore, CD48 haploinsufficiency impairs the maturation of NK cells. Given that CD48 is a ligand of the cytotoxicity triggering receptor 2B4, CD48 haploinsufficiency enables the target cell to better resist granule-mediated cytotoxicity. Moreover, the hypercytokinemia in this disease is characterized by a high serum IL-6 level, as observed in a CD48 haploinsufficient patient and the CD48<sup>-/-</sup> mouse model (11).

induce the activation of caspase 1 and the production of proinflammatory cytokines IL-1 $\beta$  and IL-18 (171). *NLR4* pathogenic gene variants have been linked to spontaneous inflammasome activation and IL-1 $\beta$  and IL-18 hypercytokinemia (16). An imbalance between IL-18 and its natural antagonist (IL-18 binding protein) might be related to the development of MAS (172). In contrast, IL-10 appears to have a protective role (112). CXCL9 is an inflammatory chemokine induced by IFN $\gamma$  recently linked to MAS as disease biomarker (173, 174). In addition to the cytokine effect per se, novel hyperinflammatory disorders with HLH disorders highlight the importance of post-transcriptional RNA regulators of cytokine transcripts to control hyperinflammation. For instance, genetic mutations responsible for a deficiency in roquin-1 (a regulator of RNA transcripts involved in immune responses) can also cause a dysregulation in cytokine synthesis and lead to hyperinflammation as described above for ZNFX1 (18).

## 6 Concluding remarks and open questions

A better understanding of the genetic disease mechanisms underlying HLH is essential for more accurate, more personalized diagnoses. Pathway-related pathogenic gene variants associated with HLH (such as inborn errors of cytotoxicity or cytokine

control) can manifest themselves to different extents with regard to aggressiveness, clinical signs, and immune cell defects.

CTLs and NK cells are crucial cytotoxic lymphocytes for controlling overactivated immune responses, as has been demonstrated for HLH. NK cells have been extensively studied in HLH and are widely used to screen for cytotoxicity and degranulation defects in HLH (175). In the future, research should also focus on the roles of CD8<sup>+</sup> CTLs and unconventional cytotoxic T cells (such as polyclonal cytotoxic CD4<sup>+</sup> T terminally differentiated cells, which are enriched in pHLH) (176, 177).

Two novel HLH disease mechanisms have been revealed by the identification and characterization of additional monogenic immune disorders with HLH. The target cell's active role in susceptibility to killing (by regulating the expression of cytotoxicity receptor ligands) is a novel HLH-associated dysregulation seen in CD48 haploinsufficiency. CD48 is also a candidate molecular target for controlling not only HLH but also autoimmunity (156), and cancer (178). The cell-intrinsic production of cytokines caused by inborn errors of cytokine control might also improve our understanding of systemic hyperinflammation in other fields, such as autoinflammatory diseases or severe COVID-19.

The enormous power of whole-exome and whole-genome sequencing will certainly help to identify links between novel genetic mutations and HLH in the future. However, in order to confirm novel genetic associations and characterize their phenotypical consequences,

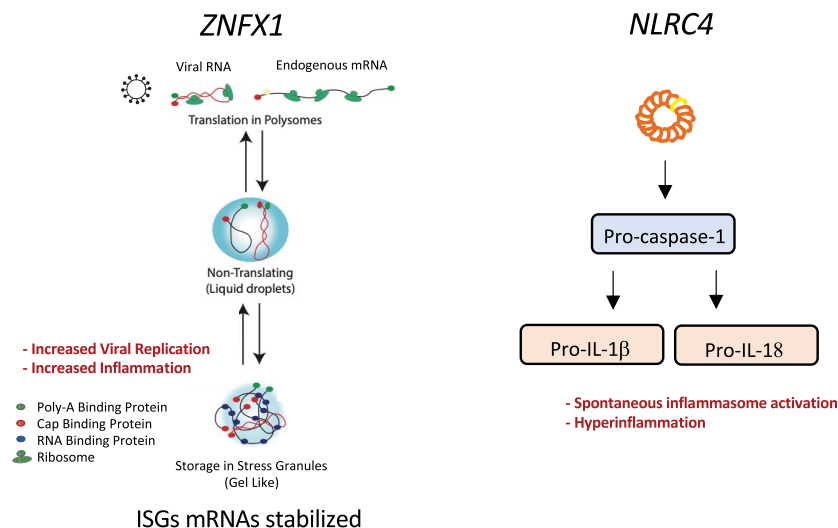

FIGURE 4

Graphical representation of the molecular pathways affected by two inborn errors of cytokine control leading to HLH: *ZNFX1* and *NLRC4* pathogenic gene variants. *ZNFX1* deficiency (left panel) causes susceptibility to viral infections. At later stages of infection, increased expression of interferon-stimulated genes is driven by greater mRNA stability; this prevents a return to homeostasis and leads to hyperinflammation and multiple organ failure. *ZNFX1* localizes to stress granules. We hypothesize that *ZNFX1*'s helicase function is needed to remove mRNAs stored in stress granules formed upon viral infection. In the absence of *ZNFX1*, the more stable mRNA is translated and not degraded, preventing a return to homeostasis and leading to a hyperinflammatory syndrome. *NLRC4* mutations can cause intrinsic macrophage activation (right panel). A mutation in the nucleotide-binding domain of the *NLRC4* sensor activates inflammasomes and leads to pro-caspase-1 cleavage. Subsequent caspase-1 dependent activation of pro-IL-1 $\beta$  and pro-IL-18 results in macrophage activation and hyperinflammation.

it will still be necessary to continue the development of functional immunological assays and animal models. For instance, novel autoinflammatory syndromes with HLH due to IIE evidence the need to better understand what to what extend HLH and autoinflammation overlap, in order to provide disease-specific treatments. Hypercytokinemia contributes to link this two disorders, with a predominant role for IL-18 and IL-1 in autoinflammation that enhance the production of IFN $\gamma$ , key effector molecule in HLH immunopathology. Translational studies from patients with autoinflammation and/or HLH responsive to cytokine oriented therapies will help dissecting the role for IL-18, IL-1, IFN $\gamma$  and others (IL-6) in different hyperinflammatory disorders. In addition to IFN $\gamma$  hypercytokinemia, viral triggers, poor viral control -sometimes associated with IIE- and defects in cytotoxic lymphocytes are other key factors more specifically contributing to HLH development. Larger, collaborative studies of patients with the novel genetic disorders with HLH will also be essential for defining typical and atypical disease manifestations and developing personalized therapies.

## Author contributions

RP wrote the manuscript and prepared figures. MF collected and visualized clinical data and figures. SV contributed to manuscript writing and prepared figures. JPS wrote the manuscript and prepared figures. All the authors reviewed and edited the manuscript. All authors contributed to the article and approved the submitted version.

## Funding

This work was funded by the Swiss National Science Foundation (Project number: 320030\_205097) and the University of Zurich (the University Research Priority Program ITINERARE – Innovative Therapies in Rare Diseases (to JS) and the Clinical Research Priority Program CYTIMM-Z (to RP and JS).

## Conflict of interest

JPS received honorary from Pharming for participation in a data monitoring committee DMC for Leniolisib. MF received a grant by Jazz Pharmaceuticals.

The remaining authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Oncostatin M (OSM) is a pleiotropic cytokine involved in a variety of inflammatory responses such as wound healing, liver regeneration, and bone remodeling. As a member of the interleukin-6 (IL-6) family of cytokines, OSM binds the shared receptor gp130, recruits either OSMR $\beta$  or LIFR $\beta$ , and activates a variety of signaling pathways including the JAK/STAT, MAPK, JNK, and PI3K/AKT pathways. Since its discovery in 1986, OSM has been identified as a significant contributor to a multitude of inflammatory diseases, including arthritis, inflammatory bowel disease, lung and skin disease, cardiovascular disease, and most recently, COVID-19. Additionally, OSM has also been extensively studied in the context of several cancer types including breast, cervical, ovarian, testicular, colon and gastrointestinal, brain, lung, skin, as well as other cancers. While OSM has been recognized as a significant contributor for each of these diseases, and studies have shown OSM inhibition is effective at treating or reducing symptoms, very few therapeutics have succeeded into clinical trials, and none have yet been approved by the FDA for treatment. In this review, we outline the role OSM plays in a variety of inflammatory diseases, including cancer, and outline the previous and current strategies for developing an inhibitor for OSM signaling.

## KEYWORDS

oncostatin M (OSM), oncostatin M receptor beta (OSMR $\beta$ ), inflammatory diseases, cytokine, cancer, metastasis, drug development, therapeutics

## 1 Introduction

Oncostatin-M (OSM) is an interleukin-6 (IL-6) family cytokine first isolated in 1986 from human histiocytic lymphoma U937 cells (1). It was initially identified as a cytostatic protein for melanoma cells, thus deriving its name ('onco' for cancer and 'statin' for inhibitor) (1). Other than OSM, the IL-6 family members consist of the parent protein IL-6, leukemia inhibitory factor (LIF), IL-11, IL-27, cardiotrophin-1 (CT-1), ciliary neurotrophic factor (CNTF), and cardiotrophin-like cytokine factor 1 (CLCF1). The human OSM gene encodes for a 2 kb mRNA transcript that is translated and cleaved into a soluble 227 amino acid pro-OSM polypeptide with a 28 kDa molecular weight (2). Mature OSM is synthesized

after a C-terminal cleavage of 31 amino acids, yielding a 196 amino acid, ~22kDa protein (3, 4). OSM, like all other IL-6 family members, has a crystal structure consisting of a four alpha-helical up-up-down-down configuration (5). LIF and OSM are structurally and genetically the most similar members of the IL-6 family, resulting from an ancestral gene duplication event (6). Similar to other IL-6 family cytokine members, OSM utilizes the shared receptor protein membrane glycoprotein 130 (gp130; also known as IL-6R $\beta$ ) and a unique receptor protein to create a complete signaling receptor complex (7–10). In the case of OSM, it possesses the capability to interact and transduce signaling through two separate complexes (7–10). OSM first binds to the extracellular cytokine-binding homology region (CHR) domain of gp130 with a high affinity ( $\sim 10^{-8}$  M) and subsequently recruits either the leukemia inhibitory factor receptor beta (LIFR $\beta$ ) or oncostatin M receptor beta (OSMR $\beta$ ); to form either a type I or type II receptor complex (LIFR $\beta$ /gp130 and OSMR $\beta$ /gp130, respectively) (Figures 1A, B) (11–16). While the OSMR (type II) complex has been studied extensively in various human cell lines, it remains

unclear how OSM interacting with the LIFR (type I) complex affects signaling or disease progression; however, recent research has indicated that OSM binds to LIFR with significantly lower affinity than its specific receptor (17, 18). After binding to the OSMR complex, several signaling pathways are activated, including the Janus-activated kinase/signal transducer and activator of transcription 3 (JAK/STAT3), the mitogen-activated protein kinase/extracellular regulator kinase (MAPK/ERK), the c-Jun N-terminal Kinase (JNK), and the phosphatidylinositol-3-kinase/protein kinase B (PI3K/AKT) pathways (Figure 1C) (19–21). To a lesser extent OSM signaling may also activate additional STAT proteins, including STAT1 and STAT5, depending on the cell type (22, 23). OSM is synthesized and secreted by a variety of cells; primarily activated macrophages, monocytes, T cells, dendritic cells, and neutrophils (1, 2, 24). OSM acts in a pleiotropic fashion, contributing towards a variety of physiological functions such as hematopoiesis, stem cell differentiation, liver regeneration, and inflammation. While some of these effects are similar to other IL-6 family members, many are unique (5, 11, 15). Over the course of

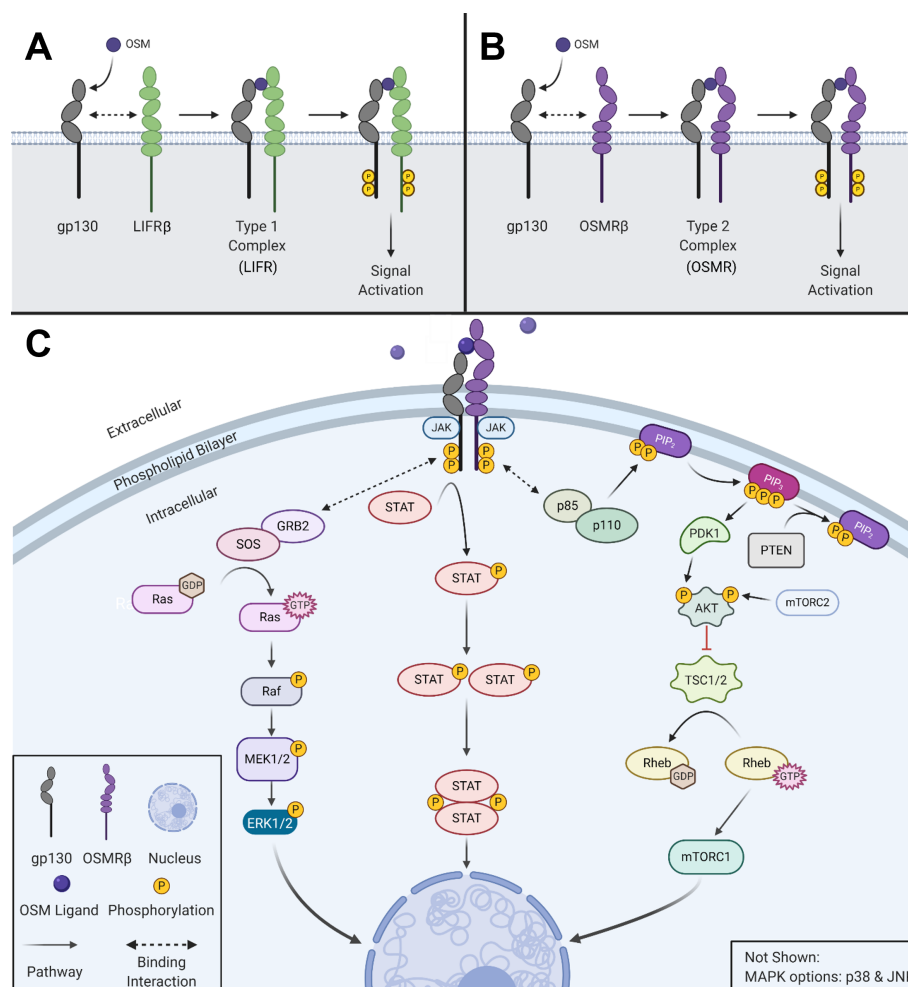

FIGURE 1

OSM activates multiple signaling cascades. (A) OSM binds to gp130 and then recruits LIFR $\beta$  to form a type I complex (LIFR). (B) OSM binds to gp130 and then recruits its major receptor complex subunit OSMR $\beta$  to form a type II complex. (C) Visual representation of the signaling pathways used by OSM type II complex. Created with [BioRender.com](https://www.biorender.com).

the last 30 years OSM has been demonstrated to play a significant role in a variety of processes and diseases, yet successful development of an anti-OSM clinical therapeutic has not yet reached FDA approval despite mounting evidence that such a therapeutic is necessary for a multitude of diseases. In this review, we will describe: i) the different roles that OSM plays within the human body regarding its function in inflammatory diseases; ii) the role of OSM in multiple cancer types; and iii) a detailed analysis of current targeted therapies designed to disrupt OSM signaling.

## 2 OSM in diseases

A significant difficulty with developing treatment strategies to block OSM stems from the pleiotropic nature of the cytokine. As indicated in [Table 1](#), OSM has a variety of positive and negative effects on several diseases in the body. Systemic inhibition of OSM signaling in the body for extended periods of time may be beneficial with respect to some diseases, but detrimental in cases that rely on the proinflammatory response for healing. This section will describe the role OSM plays in a variety of diseases.

### 2.1 Arthritis

Arthritis is a disease referring to chronic inflammation in one or more joints of the body, with the two most common and studied types being: rheumatoid arthritis and osteoarthritis. Rheumatoid arthritis (RA) is a chronic autoimmune disease involving inflammation of the lining of joints. It has been shown that the presence of OSM and another proinflammatory cytokine, interleukin-1 $\beta$  (IL-1 $\beta$ ), play an important role in development of the rheumatoid joint ([25](#), [26](#)). In multi-cell culture systems, OSM-mediated signaling has been identified as an initiator of extracellular matrix (ECM) turnover as well as human cartilage degradation; potentially through the secretion of matrix metalloproteinase (MMP) -1 and -13 ([23](#)). Through regulation of various proinflammatory mediators, OSM in rheumatoid arthritis synovial fibroblasts (RAFLS), increases the detrimental effects of tumor necrosis factor alpha (TNF $\alpha$ ) via activation of STAT3 signaling ([27](#)). Inhibition of JAK/STAT signaling with tofacitinib (a JAK inhibitor) resolved inflammation through metabolic reprogramming of biopsied RALFS ([28](#)). *In vivo* studies demonstrated that both collagen-induced and pristane-induced

TABLE 1 OSM in Diseases.

Disease	Type	Impact of OSM	References
<b>Diseases associated with OSM signaling</b>

arthritis mouse models, showed significant improvement in severity ( $p < 0.01$ ) and number of affected paws ( $p < 0.01$ ) when administered an anti-OSM antibody (29). In response to the strong association of OSM with RA, two clinical therapeutics have entered clinical trials (GSK315234 and GSK2330811) discussed in further detail below (see Anti-OSM Therapeutics).

The effects of OSM are not limited to rheumatoid arthritis, as studies have shown its effects in the development of the much more prevalent osteoarthritis (OA). OA is characterized by articular cartilage destruction and an inflammatory response due to mechanical wear on joints (30). *In vitro* analysis in primary OA osteoblasts has demonstrated that degradation and inflammation could be due to endothelin-1 (ET-1) trans-activating OSM via Ets-1 (31). Increased levels of OSM in synovial tissues induce bone formation through osteoblast proliferation and differentiation following cartilage degradation by inhibition of Notch signaling (32). Currently no clinical trials have evaluated the efficacy of anti-OSM therapeutics for OA.

## 2.2 Bone

OSM signaling regarding bone tissue is complicated, as there is evidence to suggest benefit and harm from its activation. It is well known that OSM induces differentiation of mesenchymal stem cells (MSCs) into osteoblasts through the STAT3 signaling pathway (17, 33, 34). This can be beneficial in respect to new bone formation in osteoporosis and arthritis as well as remodeling of bone during fracture repair (33). However, there is significant research suggesting that OSM has an overall negative effect in respect to bone. While osteogenesis is being stimulated, the anabolic signal suppresses the reabsorption signal-controlled receptor activator of nuclear factor-kappa beta ligands (RANKL) signaling, repressing osteoblast-mediated osteoclast differentiation in bones (34). OSM-mediated STAT3 signaling has also been associated with the development of neurogenic heterotopic ossifications, which is the formation of bone tissue in periarticular muscles, an incapacitating complication of traumatic brain and spinal cord injuries (35). Other studies have indicated that STAT3 signaling through OSM is necessary for osteoclast formation and subsequent bone resorption (36, 37). It is clear that OSM plays a role in bone remodeling, however there is evidence suggesting it promotes the differentiation of both osteoblasts and osteoclasts, leading to some potential questions about the true effects of OSM signaling among bones.

## 2.3 Inflammatory bowel disease

Inflammatory bowel disease (IBD) is a collective term describing disorders that involve chronic inflammation of the small intestine. The two main forms of IBD are ulcerative colitis (UC) and Chron's disease (CD) (38). It has been demonstrated that OSM and OSMR are overexpressed in many IBD lesions (39). While anti-tumor necrosis factor alpha (TNF $\alpha$ ) antibodies such as infliximab, adalimumab, certolizumab, and golimumab have long been available as treatment

strategies for CD and UC, they are far from perfect. Approximately one third of patients do not respond to infliximab initially, and between 23% and 46% develop resistance to anti-TNF $\alpha$  therapies within 12 months of treatment (40, 41). A recent retrospective cohort study demonstrates that patients with increased levels of OSM had a lower chance of remaining in remission 1 year after starting anti-TNF $\alpha$  therapies (42). There are other IBD treatment options available, some of the more viable options include JAK/STAT inhibitors, indicating OSM inhibition upstream may be beneficial (43). In a study analyzing over 200 patients with IBD, those with high OSM and OSMR expression before treatment with infliximab demonstrated reduced efficacy of the therapy from 69-85% to just 10-15% (39). *In vivo* IBD mouse studies comparing wildtype and *Osm*<sup>-/-</sup> showed that lack of OSM signaling led to a decrease in overall pathology ( $p < 0.0001$ ), leukocyte infiltration ( $p < 0.0001$ ), epithelial and goblet cell disruption ( $p < 0.0001$ ), area affected ( $p < 0.0001$ ), and severity of disease features ( $p < 0.0005$ ) (39). Additionally, OSM has been shown to mediate STAT3-dependent upregulation of serine protease inhibitors (SERPINS), which have anti-apoptotic effects in intestinal epithelial cells that lead to inflammation and a disrupted intestinal epithelial barrier (44). Recent studies have also shown that the use of berberine, an isoquinoline alkaloid used to treat chronic UC, interferes with the production of OSM from T cells, neutrophils, dendritic cells, and macrophages, as well as inhibiting OSM activation of stromal cells and recruitment of immune cells (45). As seen in other diseases with inflammation as a hallmark, OSM signaling is a key component in disease pathogenesis, and in this case, it also appears to interfere with pharmacological treatments.

## 2.4 Lung diseases

OSM plays an important role in the development and progression of pulmonary fibrosis and chronic lung inflammatory diseases such as asthma. OSM levels are upregulated in patients with pulmonary fibrosis, due to increased lung inflammation as well as accumulation of ECM proteins (46). Evidence suggests that an increase in OSM and IL-6 leads to the accumulation of profibrotic macrophages, in turn increasing bleomycin-induced lung fibrosis (47). Chronic inflammatory diseases of the lung such as asthma also showed a significant increase in OSM expression (48). In severe asthma, poor disease prognosis is characterized by an increase in number of epithelial mucus producing cells, peribronchial fibrosis, and smooth muscle contractility through follistatin-like 1 induction of OSM expression (49). Recent studies have also demonstrated that overexpression of OSM leads to an increase in resistin-like molecule alpha in airway epithelial cells, leading to rearrangement of the ECM in mouse lungs (50). The increase in OSM signaling in the lungs with respect to these chronic inflammatory diseases demonstrates its potential to be used as a therapeutic target.

## 2.5 Cutaneous inflammatory diseases

Being the human body's largest organ, and our first line of defense, the skin plays an important role in inflammatory processes

and responses. Diseases such as psoriasis and atopic dermatitis are chronic inflammatory skin diseases that affect over 7.5 million individuals within the United States and are characterized by keratinocyte hyperplasia, proliferation, and altered differentiation (51, 52). These diseases demonstrate an increase in skin infiltrating T lymphocytes that lead to secretion of OSM and an increase in OSMR $\beta$  on keratinocytes, increasing keratinocyte activation through STAT3 signaling (52). When OSM is overexpressed in the skin, its proinflammatory effects have been demonstrated both *in vitro* and *in vivo* (53). Studies conducted in mice show that intradermal injection of OSM, but not IL-6, regulates the expression of genes responsible for skin inflammation and epidermal differentiation, including S100A8/9, cytokeratin-10, filaggrin, and a number of other cytokines (52). Additionally, OSM has recently been identified as a significant contributor to chronic pruritus (itching). *Tsen and Hoon et al.* discovered that OSMR $\beta$  is preferentially expressed by itch-selective sensory neurons and that OSM can directly modulate itch-selective neurons during chronic skin inflammation (54). Functional studies showed that OSM acts in a unique fashion compared to other pruritogens, being that OSM causes potentiation of neural response to pruritogens and that OSM increases sensitization of sensory neurons, resulting in tonic action potential firing of itch-selective neurons. Another study showed that OSM and IL-31 stimulate dermal cells expressing IL-31RA and OSMR $\beta$ , which may further promote itch and inflammation in patients with prurigo nodularis, a chronic skin dermatosis (55).

Scleroderma is an inflammatory autoimmune disease that is characterized by increased activation of fibroblasts leading to accumulation of connective tissue that results in chronic inflammation on the surface on the skin and internal organs (56). Elevated OSMR $\beta$  levels have been found in fibroblasts as well as dermal endothelial cell of scleroderma patients. *In vitro* of human dermal microvascular endothelial cells treated with OSM and IL-6 displayed induced cell migration and proliferation, as well as stimulation of proinflammatory genes, and genes associated with endothelial to mesenchymal transition including STAT3, ET-1, zinc finger protein SNAI1 (SNAIL1), transforming growth factor- $\beta$  3 (TGF $\beta$ 3), and its receptor TGF $\beta$ 3R (57). There is currently a clinical trial for a monoclonal antibody against OSM, in patients with systemic scleroderma, which will be discussed in greater detail in Anti-OSM therapeutics.

## 2.6 Oral diseases

OSM and other cytokines play an important role in the progression of periodontal disease, a gum infection typically caused by poor brushing and flossing habits. In studies investigating levels of OSM in patients' gingival crevicular fluid, OSM concentrations increase as disease severity progresses from early-stage disease to chronic periodontitis (58–60). Another study focused on T-helper type 1 (Th1) cells, which have detrimental effects in regard to periodontal disease through the stimulation of alveolar bone loss (61). OSM and IL-1 $\beta$  together increased the expression of chemokine (C-X-C motif) ligand 10 (CXCL10), a chemokine related to Th1 cell migration, as well as intracellular

adhesion molecule 1 (ICAM-1) that is important in retention and activation of Th1 cells in inflamed tissue (62). CXCL10 and ICAM-1 expression were both suppressed when inhibitors of NF- $\kappa$ B and STAT3 were introduced, indicating that OSM-mediate STAT3 signaling and IL-1 $\beta$ -mediated NF- $\kappa$ B signaling may promote infiltration and retention of Th1 cells, leading to periodontal disease (62). Overall OSM signaling continues to demonstrate negative downstream effects through activation of several different signaling molecules.

## 2.7 Liver

Inflammation is a key driver in liver disease, and it has been demonstrated that OSM plays a profibrogenic role in the progression of chronic liver disease (63–65). Administration of OSM to human hepatocellular HepG2 cells in culture increased expression of GP73 (a glycoprotein biomarker for cirrhosis and hepatic cell carcinoma), indicative of the effects OSM has on promoting chronic liver disease progression (63). OSM's role in fibrosis is characterized by promoting the expression of tissue inhibitor of metalloproteinase 1 (TIMP-1), which both suppresses fibrinolysis in hepatic stellate cells (HSCs) as well as promotes fibrogenesis through induction of Type 1 collagen expression (64). Recent research also suggests that OSM promotes fibrosis in non-alcoholic fatty acid liver disease (NAFLD) through stimulating migration of hepatic myofibroblasts (MFs) that originate from HSCs (65). A recent study analyzed serum levels of 83 patients with NAFLD and non-alcoholic steatohepatitis (NASH) who also have hepatocellular carcinoma (HCC) and found that the presence of HCC further increased OSM concentrations (66). It has also been found in chronic hepatitis C that antigen presenting cells release OSM following interaction with CD40L present on active CD4+ T cells (67). This OSM does not result in a large notable effect, as OSMR $\beta$  and LIFR expression is also downregulated both *in vitro* and in patients with chronic hepatitis C; however, the increase in ligand is thought to be noteworthy (67).

In addition to affecting liver fibrosis and progression of chronic liver disease, OSM also plays an important role in liver regeneration (64, 68–71). Following acute liver injury, it is primarily oval cells that are responsible for liver regeneration (72). More research has shown that OSM is able to induce the differentiation of these oval cells into hepatocytes *in vitro* (69). *In vivo* studies demonstrated that OSMR $\beta$  knockout mice had impaired hepatocyte proliferation and tissue remodeling following induced liver injury, indicating its importance in regeneration (71). Furthermore, administration of OSM in wild type mice mitigated liver injury through prevention of apoptosis and tissue destruction (71). It was also demonstrated that OSM gene therapy in rats effectively increases proliferation and the anti-apoptotic effects of on hepatocytes, leading to liver regeneration (70). Through the upregulation of hypoxia-inducible factor 1  $\alpha$  (HIF1 $\alpha$ ) and HIF1 transcription, OSM demonstrates its importance as an upstream mediator of vascular endothelial growth factor (VEGF) and plasminogen activator inhibitor 1 (PAI1), both of which are important for angiogenesis and tissue remodeling respectively (68). While OSM does appear to play an important role

in regeneration following acute liver injuries, continuous activation of OSM has a very different effect with respect to fibrosis and chronic liver disease suggesting its prolonged presence may be harmful.

## 2.8 Central nervous system

In diseases related to the central nervous system, research has indicated that OSM plays various roles with both detrimental and beneficial outcomes. Studies have been conducted displaying various negative effects that OSM has on the central nervous system. Diseases such as HIV-1-associated neurocognitive disorders and Alzheimer's disease have displayed elevated levels of OSM (73). Specifically, through JAK/STAT3 signaling, OSM inhibits glutamate uptake in astrocytes resulting in neuronal excitotoxicity (73). OSM also induces blood brain barrier impairment in mice, through prolonged STAT3 signaling in pericytes (74). As discussed previously, STAT3 activation initiated through OSM signaling *in vivo* has also been shown to increase neurogenic heterotrophic ossifications in damaged muscles following spinal cord injuries (35).

In diseases characterized by the loss of myelination such as multiple sclerosis, overexpression of OSM has been shown to mediate the expression of tissue inhibitor of TIMP-1, promoting a beneficial remyelination (75). Following mild and severe spinal cord injuries, elevated OSM signaling results in improved recovery and neuroprotective effects by promoting neurite outgrowth, increasing serotonergic fiber plasticity, and protecting primary neurons from cell death (76). OSM also stimulates the expression of myeloid cell leukemia-1 (MCL-1), in turn enhancing mitochondrial bioenergetics and increasing neuroprotective effects against 3-nitropropionic acid in cortical neurons (77). The pleotropic nature of OSM is clearly demonstrated with respect to the central nervous system, especially concerning the inflammatory response following spinal cord injuries.

## 2.9 Heart

When it comes to function of the heart, research has indicated that OSM plays various roles with both detrimental and beneficial outcomes. Regarding atherosclerosis development and progression, the vast majority of research suggests that prolonged STAT3 activation through OSM signaling has a negative impact on arterial vessels, which leads to atherogenesis (78–81). However, one recent study showed that chronic OSM administration in mice reduced atherosclerosis development, and patients with higher levels of serum OSM had improved coronary heart disease survival probability (82). This differing research continues to cloud the role OSM plays in the heart.

Cardiomyocytes are the workhorse of the heart, and OSM plays a key role in the dedifferentiation of cardiomyocytes (83, 84). This dedifferentiation leads to protective effects during and following acute myocardial infarction (MI) (83–85). Knockout of OSM signaling following MI in mouse models suppressed

cardiomyocyte dedifferentiation, resulting in decreased heart function, while OSM treatment induced remodeling, stem cell marker expression, and improved cardiac function (84). Inhibition of OSM treatment reduced cardiomyocyte function following MI, however, improved performance in dilated cardiomyopathy (DCM) indicates negative effects of OSM long-term (84). Other studies done in mice have shown that OSM increases cardiac function following MI through the inhibition of apoptosis and fibrosis, while stimulating angiogenesis. OSM treated mice had significantly increased capillary density as well as increased expression of pAKT and the angiogenic factors, VEGF and basic fibroblast growth factor (bFGF) (85). More *in vivo* studies have indicated that OSM alleviates post MI dysfunction by enhancing cardiomyocyte autophagy through the inhibition of mammalian Ste20-like kinase 1 (Mst1) (86). Activation of Mst1 has been shown to cause (DCM) as well as inhibit cardiomyocyte autophagy (86). OSM signaling is a crucial component to the heart's response to acute stressors, but when its presence is prolonged, it can have other effects.

## 2.10 Wound healing

It is well known that following almost any cut or abrasion an inflammatory response is triggered. OSM has been shown to be an important player in the early stages of the wound healing process under normal and diabetic-impaired healing conditions *in vivo* (92). This increase in OSM at the site of inflammation has been tied to the early influx of polymorphonuclear neutrophils into the wound site, but if OSM is around for too long it can actually impair the healing process in chronic diabetic wound conditions (92). Other studies have demonstrated the role OSM has in the scarring process (93, 94). Hypertrophic and keloid scars are both abnormal wound responses to trauma, inflammation, surgery, or burns. Keloid scars are typically considered worse than hypertrophic scars as keloid scars often increase in size, can develop months after surgery, and fail to improve appearance over time even with surgical intervention (93). Increased levels of OSM have been found in hypertrophic scars but not keloid scars, and it has been demonstrated that the increase in OSM served as protection against excessive scarring through suppression of TGFβ1-induced ECM protein expression (94). Other studies have shown similar benefits that OSM has in respect to late and early wound healing, differentially demonstrating an anti-inflammatory effect (95). It again seems that in the case of wound healing and scarring, more research is needed to clarify the contributions of OSM.

## 2.11 Pregnancy

A lot of changes take place in a person's body during pregnancy. Studies done in humans have shown OSM is present in high concentrations in pregnant women when compared to non-pregnant women, as well as in placental tissue in all three trimesters (96). OSM is especially relevant in the early stages of

pregnancy through the upregulation of human chorionic gonadotropin, demonstrating importance in placental endocrine function (96). Through STAT3 and ERK1/2 signaling, OSM and LIF are responsible for trophoblast invasion and placental development, both important steps in the early stages of pregnancy (97). *In vitro* studies show trophoblast invasion is induced through the upregulation of matrix metalloprotease 2 (MMP2) and MMP9 by both OSM and LIF, either synergistically or separately, in some but not all cell types used (97). Other studies also suggest that OSM increases protein expression and enzymatic activity of MMP2 and MMP9, leading to the invasion of primary trophoblasts through STAT3 signaling under hypoxic conditions typically found during trophoblast invasion in early pregnancy (98). While OSM presence is increased during pregnancy and is a known STAT3 activator, there is more research suggesting LIF signaling is primarily responsible during early pregnancy.

## 2.12 Cytokine storm and COVID-19

The coronavirus disease 19 (COVID-19) is caused by the novel severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and has sparked a global pandemic since its introduction in humans in late 2019. It is well known that cytokines play an important role in developing an innate immune response during viral infection. There has been evidence suggesting that cytokine storms, characterized by an excessive and dysregulated immune response, play a significant role in pathogenesis of SARS-Cov-2 infection (87–89). Retrospective research studies conducted around the world have shown that a hyperinflammatory state, indicated by the presence of IL-6, IL-10, and TNF- $\alpha$ , is a significant predictor of mortality (89). A different study found increased OSM along with a number of other inflammatory proteins present in lung and spleen tissue in 13 postpartum subjects with fatal COVID-19 infections (90). Other retrospective studies done in Hong Kong and Atlanta Georgia have demonstrated an increase in cytokines and proinflammatory mediators such as IL-6, TNSF14, EN-RAGE, and OSM are correlated with disease severity (91). While there is a lot to be said about the role of cytokines in COVID-19, OSM's role has yet to be fully elucidated.

## 3 OSM in cancer

As previously stated, the pleiotropic nature of OSM causes it to exert differing effects on various cell types. While OSM has been investigated in a multitude of diseases, a particular area of interest is cancer biology. In the tumor environment, OSM often acts in a deleterious fashion through multiple different mechanisms, though it is noted that OSM can have a positive effect on specific cancer types, making it a particularly interesting cytokine to study (99–101). In this section, we will provide a thorough analysis of the role OSM plays in a multitude of cancers. Table 2 provides a list of the cancers that will be discussed in the following section.

### 3.1 Breast

Breast cancer is the most common cancer among women, and the second leading cause of cancer-related deaths in the United States. While OSM has historically been identified as an inhibitor of breast cancer proliferation (15, 102, 103), overexpression of OSM and OSMR $\beta$  has been linked to decreased overall survival, decreased recurrence-free survival and decreased metastasis free survival in breast cancer patients (104–107). Immunohistochemical analysis in benign human breast lesions have shown low expression of OSMR $\beta$  (11.7%) and gp130 (23.5%) proteins. However, in infiltrating carcinomas; high expression of OSMR $\beta$  (77.5%) and gp130 (74.1%) proteins have been seen, with OSM localized in 100% of tumor samples studied (107). At the molecular level, OSM via STAT3 signaling has been shown to inhibit c-Myc expression in human mammary epithelial (HMEC) cells, but constitutively overexpressing c-Myc HMEC cells gain the capacity for anchorage-independent growth in the presence of OSM-mediated PI3K-AKT signaling, suggesting c-Myc acts as a molecular switch to alter response of mammary epithelial cells (108). OSM has also been shown to promote a cancer stem cell (CSC)-like phenotype and pro-survival phenotype for breast cancer cells (36, 109). It can also create a pre-metastatic environment in bone by inducing osteoclast differentiation, increasing the possibility of bone metastases for breast cancer cells expressing a high level of OSM suggesting that the role of OSM in breast cancer is not tumor proliferation, but rather migration and invasion (36, 110, 111).

Examining patient tissue using microarray analysis, OSM expression was revealed to be the highest in patients with ductal carcinoma *in situ* (DCIS) (109). This highlights the possible role that OSM could have in progressing early grade tumors. Paracrine and autocrine signaling of OSM has been shown *in vivo* to increase the amount of circulating tumor cells (CTC), epithelial to mesenchymal transition (EMT), as well as increased metastasis to lungs and decreased survival (109). OSM can also induce CD44<sup>high</sup>/CD24<sup>low</sup> phenotype allowing OSM to promote a CSC-like property, as well as increase detachment and migration of ER+ cells, while EMT remains independent of CD44 induction (112).

Recently, there has been increasing evidence that OSM operates differently in the varying subtypes of breast cancer (104, 106). At diagnosis, breast cancer patients are categorized into different subtypes based on expression of three receptors: estrogen receptor-alpha (ER $\alpha$ ), progesterone receptor (PR), and human epidermal growth factor receptor 2 (HER2) (113–120). ER $\alpha$  status is important for clinical management of breast cancer since tumor cells that are ER $\alpha$ + are usually less aggressive and can be treated with endocrine therapies (121). OSM has shown the ability to downregulate the expression of ER $\alpha$ , which in turn increases the OSM signaling cascade and migratory effects that its pathways have *in vitro* (105). *In vivo*, high OSM expression was correlated with decreased ER $\alpha$  ( $p < 0.01$ ) and PR ( $p < 0.05$ ) expression, and a shorter recurrence-free survival ( $p < 0.0001$ ) (105). OSM has also been shown to promote secretion of IL-6 in ER $\alpha$ - cells and not in ER $\alpha$ + cells, further suggesting that OSM plays unique roles in ER $\alpha$ + versus ER $\alpha$ - breast cancer (104, 106). This illustrates that OSM can

TABLE 2 OSM in Cancer.

Location	Cancer Type	Impact of OSM	Reference
<b>Pro-tumorigenic Effects of OSM</b>			
Breast	Ductal Carcinoma	Overexpression linked with poor prognosis and creates a more CSC phenotype; Increases EMT, motility, invasion, and metastasis; Recruits neutrophils and surrounding tissue to express OSM	(20, 102–135)
Cervical	Squamous Cell Carcinoma	OSMR $\beta$ overexpression leading to EMT and increased skeletal metastasis	(135–143)
Ovarian	Epithelial Carcinoma	Auto/paracrine signaling loop in malignant OC; Increased proliferation, and metastasis dependent on STAT3 Increase in keratinocyte proliferation and differentiation	(144–148)
Prostate	Ductal Adenocarcinoma	Increased VEGF and u-PA expression and induced EMT in prostate epithelial cells	(149–155)
Testicular	Leydig Cell Carcinoma	Upregulation of OSM in functioning neoplasms	(156, 157)
Colon	Adenocarcinoma	More advanced and aggressive CRC have higher OSM serum level and lower survival; OSMR $\beta$ polymorphisms	(158–163)
Gastrointestinal	Adenocarcinoma	Differential expression of OSM in the grades of GI cancers could be used as biomarker.	(164–169)
Pancreatic	Ductal Adenocarcinoma	Overexpressed OSM in the serum, causes EMT, and greater metastasis to the lung <i>in vivo</i> dependent on STAT3	(170–175)
Bladder	Urothelial	Genetic mutations can cause an overexpression of the OSMR $\beta$ , leading to increased signaling	(176–178)
Lung	Adenocarcinoma	Induce EMT, increase fibroblast activation, OSMR $\beta$ overexpression is correlated to poor prognosis	(179–187)
Brain	Astrogloma, astrocytoma, adenoma, glioblastoma, glioma, medulloblastoma, meningioma	Three-fold increase in VEGF, seven-fold when in conjunction with IL-1 $\beta$	(52, 182–184, 188–198)
Squamous Cell Carcinoma	Cutaneous & Oral Squamous Cell Carcinoma	Promotes proliferation, migration, and inflammation <i>in vitro</i> and <i>in vivo</i>	(199–210)
Kaposi's Sarcoma	Sarcoma	Mitogen and autocrine growth factor, promoter of bFGF	(4, 136, 211–217)
Misc. Sarcomas	Osteosarcoma, Chondrosarcoma, Ewing Sarcoma	Increased MMP2, VEGF, and proliferation	(218–227)
Melanoma	Melanoma	Antigen-silencing, resistance to inhibitory OSM singling in > Stage 3 patients	(225, 228–240)
<b>Anti-tumorigenic Effects of OSM</b>			
Multiple	Chondrosarcoma	Cell cycle arrest through JAK3/STAT1 signaling, decreased proliferation and enhanced apoptosis	(225)
Skin	Melanoma	Activates STAT5B and MAPK inhibiting proliferation; Increased SOCS3 with decreased OSMR $\beta$ expression	(225, 228–240)

increase the metastatic potential of breast cancer cells as well as make them more difficult to treat in a clinical setting.

Triple negative breast cancers (TNBCs) are highly aggressive, metastatic, and therapeutically difficult to treat due to their lack of, or low expression of receptors commonly targeted for therapeutics (122, 123). It has been shown that patients with TNBC and high OSM expression have a greater abundance of cells with a cancer stem cell (CSC) phenotype due to OSM/STAT3/SMAD3 signaling, which promotes growth of the tumor and leads to poor clinical outcomes for patients (111, 124). Similar research also evaluated OSM-mediated MEK/ERK signaling and found that blocking ERK abolished the growth inhibition characterized by OSM, but only in triple-negative MDA-MB-231 cells (21). Interestingly, interferon- $\beta$  (IFN- $\beta$ ) can repress this OSM-mediated tumor initiation and CSC phenotype, but mRNA of endogenous IFN- $\beta$  is repressed

directly by OSM. IFN- $\beta$  is suggested as a possible therapeutic to OSM in TNBCs, following a more comprehensive investigation of the relationship between these two cytokines (125). OSM can also perpetuate a chronic inflammatory environment that is detrimental to the prognosis of breast cancer patients due to the recruitment and/or induction of other inflammatory cytokines that are known to promote a metastatic phenotype in breast cancer. Induction of IL-6 is directly caused by the synergistic effects of both OSM and IL-1 $\beta$  (106). Analysis of The Cancer Genome Atlas (TCGA) breast cancer dataset shows that these three cytokines in high concentrations lower patient's survival rate ( $p < 2.2 \times 10^{-23}$ ) (106).

The tumor microenvironment (TME) plays a large role in the progression of breast cancer, through the complex interactions of tumor cell-to-cell communications, secretions of infiltrating

immune cells, and communications of surrounding tissues (126–129). OSM has been shown to directly bind to extracellular matrix proteins, which can protect it from proteases and preserve bioactive accumulation of OSM near within the TME for long periods of time (130). Stromal OSM production has also been recently shown to play a significant role in breast cancer progression by reprogramming fibroblasts within the TME towards a more tumorigenic phenotype and increase proinflammatory myeloid cell recruitment (131). OSM signaling also leads to TME remodeling in breast cancer as OSM induces the expression of lysyl-oxidase like 2 (LOXL2), which leads to crosslinking and alignment of collagen I fibers present in the stromal ECM (132). Presence of OSM within the breast tumor microenvironment has been shown to be provided by tumor associated neutrophils (TAN's), tumor associated macrophages (TAM's), and monocytes. Stromal OSM/OSMR $\beta$  has recently been shown to play a distinct role in breast cancer progression (131). TAN's co-cultured with human breast cancer cell lines have also been shown to increase TAN-mediated secretion of OSM throughout the tumor microenvironment, which in turn leads to increased secretion of the pro-angiogenic factor VEGF from human breast cancer cells (133). Neutrophils co-cultured with human breast cancer cells, MDA-MB-231 and T47D, also increased the number of viable cells that underwent detachment and increased invasive capacity *in vitro*, as measured by cell-cell/cell-substratum detachment and Matrigel invasion assays (133). This suggests that TANs can increase the expression of OSM at the site of the tumor and promote angiogenesis and metastasis of breast cancer cells.

Adipose tissue has also been shown to play a role in the progression of breast cancer, with obese post-menopausal women having twice as high of a mortality rate as compared to low body-mass-index post-menopausal women (134). Breast cancer-associated adipose tissue from patient tumors display high secretion of OSM, alluding to the paracrine signaling that could initiate a metastatic phenotype in breast cancer cells (20). When co-cultured with breast cancer cells, the adipose tissue induced EMT and increased the invasiveness of the breast cancer cells in a STAT3 dependent manner (20). Another direct target for OSM/STAT3 signaling is fascin, an actin-bundling protein that localizes to filopodia and functions in cell-to-cell interactions and cellular motility. STAT3 can directly bind to the promoter region of the fascin gene to upregulate its expression to increase cellular migration (241).

All of this evidence collectively highlights the role OSM has in breast cancer progression and metastasis. As metastatic breast cancer has the poorest survival rate at 29% (135), developing a therapeutic to inhibit OSM may dramatically prolong the life of patients and lead to better survival outcomes.

## 3.2 Cervical cancer

Cervical carcinoma ranks as the second most common cause of cancer deaths among women, with approximately 270,000 deaths per year globally (135). A vast majority of cervical carcinomas are squamous cell carcinomas (SCC) that arise from precursor

squamous intraepithelial lesions (199). In 2007, Ng *et al* evaluated potential genes showing high-frequency copy number-driven changes in expression in cervical SCC and discovered that the OSMR gene was significantly higher in cervical SCC cases when compared to patients with precursor cervical squamous intraepithelial lesions and gain of OSMR was significantly associated with adverse overall patient survival, ( $p=0.046$ ) and may increase radio-resistance in cervical SCC (242). Additional work by this group directly examined the consequences of OSMR overexpression *in vitro* and discovered that OSM signaling dramatically increases cell migration, invasion, and induction of tumorigenic factors such as IL-6, HIF2- $\alpha$ , VEGF, and transglutaminase 2 (TGM2) a calcium-dependent crosslinking enzyme that catalyzes post-translational protein modifications, yet no evidence of OSMR overexpression improving radio-resistance was found (243–245). A separate group investigated the sensitivity of cisplatin therapy of cervical SCC cells and found that while STAT3 phosphorylation dramatically increased in pre-cancerous cervical cancer lesions, it declined when comparing to cervical SCC, and cervical SCC cells pre-treated with OSM were more responsive toward cisplatin-based chemoradiotherapy, via upregulation of STAT3-mediated interferon-regulatory factor 1 (IRF1) expression (246, 247). More recent work has also evaluated OSMR overexpression utilizing clinical data from the TCGA CESC (cervical cancer) database and found that patients with high OSMR expression display increased expression of mesenchymal makers such as SNAI1, SNAI2 and zinc finger E-box-binding homeobox (ZEB1) (248). Additionally, using 3D culture models and mouse *in vivo* models and found that OSMR $\beta$ -overexpressing cervical SCC cells exhibit increased EMT, stem cell-like properties as well as increased lung colonization and skeletal metastases *in vivo* (248). These studies together suggest that cervical cancer cells with increased OSM signaling and OSMR $\beta$  overexpression are more aggressive, and lead to worse overall survival in cervical SCC patients. While few studies have implicated a possible radioresistant role for high OSMR $\beta$  patients, it has not been fully evaluated. Nonetheless, OSMR $\beta$  overexpression may be a potential clinical marker for cervical cancer patients, HER2 in breast cancer, and an anti-OSMR $\beta$  monoclonal antibody could improve outcome for patients with cervical cancer.

## 3.3 Ovarian

Ovarian cancer is the fifth most common cancer in woman and the leading cause of death among gynecological cancers (135). While IL-6 family cytokine members have been evaluated in the progression of ovarian cancer, OSM has not been extensively studied (136). A small study consisting of 29 malignant ovarian carcinoma patients revealed OSM was expressed in all 29 primary malignant ovarian carcinomas (MOC). Additionally, the same group analyzed 25 primary ovarian carcinomas samples (OC) for LIFR $\beta$  and OSMR $\beta$  expression and found all 25 primary OC samples expressed LIFR $\beta$  and 14 out of 25 expressed OSMR $\beta$  (137). Overexpression of both LIFR $\beta$  and OSMR $\beta$  in turn has been shown to constitutively activate STAT3 nuclear signaling in

74% of MOC's tested, suggesting OSM signaling is frequently present in malignant ovarian carcinoma (137). *Li et al.* further supported this work, showing that OSM treatment enhanced proliferation of OC cells *in vitro* in a STAT3 dependent manner (138). Interestingly, in contrast to these studies, a group evaluating 239 epithelial ovarian cancer patients (19 with low stage and 220 with high stage) and 169 controls identified that OSM was significantly downregulated (-2.62-fold change in early stage and -2.65 in late stage) in the leukocytes fraction of ovarian cancer patients compared to healthy patients (139). More recent research however has further evaluated the role of OSM in ovarian cancer and found that *OSMR* is highly expressed in ovarian cancer cells, cancer associated fibroblasts, and endothelial cells of patient samples, and is highly expressed when compared to normal adjacent tissues. Additionally, this study showed human ovarian cancer cell lines overexpressing *OSMR* were found to promote colony formation, migration, invasion, and spheroid-forming capabilities, and that an anti-*OSMR* monoclonal antibody reduced the growth and peritoneal spread of ovarian cancer cells using a mouse *in vivo* ovarian cancer model (140). From this evidence, while the presence of OSM in ovarian cancer patients is not confounded, OSM-mediated STAT3 signaling does impact ovarian cancer progression. It could be hypothesized that similarly to cervical cancer, *OSMR* rather than OSM is the more favorable target against ovarian cancer metastasis and could be used as a clinical marker for disease progression and patient outcomes.

### 3.4 Prostate

Prostate cancer (PC) is both the second most common cancer and second leading cause of cancer related deaths in men. PC is one of the four most common cancer types, and with reduction rates within the population plateauing, there is a need to better understand the mechanisms that PC utilizes to persistently remain present within the population (141).

OSM treatment on prostate carcinoma cells (DU145) *in vitro* has been shown to increase the amount of urokinase-type plasminogen activator (u-PA), a serine protease that degrades ECM proteins leading to increased invasion and metastasis *in vitro*, as well as VEGF measured by means of ELISA (142). This correlation was also seen clinically evaluating 47 male patients: 20 with benign prostatic hyperplasia (BPH), 20 with non-metastatic PC, and 7 with metastatic PC. Patients with metastatic PC displayed a significant increase in plasma levels of IL-6 ( $p < 0.0001$ ), OSM ( $p < 0.009$ ), VEGF ( $p < 0.016$ ), and u-PA ( $p < 0.0001$ ) compared to the other disorders (142). Interestingly, OSM was also shown to induce tumorigenic properties, including EMT progression and migration of non-transformed human prostate epithelial cells via STAT3 signaling (143). A separate study also highlighted miR-181b-5p as a potential inhibitor of OSM-mediated prostate cancer progression using *in vitro* mouse prostate cancer cell lines. In the presence of OSM, miR-181b-5p was shown to inhibit proliferation, invasion and metastasis of mouse cell lines, while also repressing the levels of osteoclastogenic factors such as IL-6, AREG, and OPG that could prevent prostate cancer metastasis to bone (144).

PC commonly starts as an androgen-dependent tumor, making androgen-depriving therapeutics a useful first-round treatment strategy; however, 20-30% of patients exhibit recurrence of PC with a more aggressive androgen-negative phenotype that is difficult to treat (142, 145). Recent research has examined how exercise affects patients with advanced prostate cancer or patients receiving androgen deprivation therapy and have noticed elevated levels of OSM (146, 147). The implications of this, however, are not very well understood. All of this evidence combined shows that the OSM plays a pivotal role in the development and progression of prostate cancer and could be a valuable therapeutic target to improve stage outcomes in PC patients.

### 3.5 Testicular carcinoma

Testicular cancer is relatively rare, affecting only 1 in 250 males, however it develops in patients at a younger age, with an average diagnosis age at 33 years old (135). The role of OSM in testicular cancer has not been extensively studied, however *De Miguel et al.* in 1999 evaluated the presence of OSM in Leydig cells (cells in the testes responsible for testosterone production) as well as in various testicular carcinomas, including carcinoma-*in-situ* (CIS), germ cell tumors, and benign functioning Leydig cell tumors (148). OSM has been shown to cause a two-fold increase in the amount of Leydig cell progenitors, through stem Leydig cell differentiation in normal tissue samples. It was also found to be present in normal functioning and differentiated Leydig cells, therefore suggesting a role in normal Leydig cell differentiation and maintenance as shown by immunohistochemical staining (148, 149). OSM was also found within Leydig cells of patients with carcinoma-*in-situ* and in the parenchyma of neoplastic cells, however immunoreaction between cancerous and non-cancerous controls were similar, indicating OSM did not affect immune cell recruitment (148). Interestingly, functioning Leydig cell neoplasms showed a very strong immunoreaction to OSM, suggesting an upregulation of OSM in Leydig cell carcinoma may impact recruitment of immune cells (148). These preliminary studies evaluating OSM in testicular cancer suggest a possible role for OSM in Leydig cell differentiation and function of mature Leydig cells and recognize the presence of OSM in Leydig cell carcinoma and carcinoma *in situ*. However, no studies have yet to evaluate the tumorigenic properties of OSM in testicular cancer.

### 3.6 Colon

Colon cancer is the third most common type of malignancy and third leading cause of cancer-related deaths among men and women world-wide (135). The first connection of OSM in colorectal cancer was through discovering that the *OSMR* gene is highly methylated in non-invasive colorectal cancer patients, but not in normal controls, and has been suggested as a highly specific prognostic marker for colon cancer detection and severity of disease (150–152). In addition, a direct correlation between colorectal carcinoma (CRC) tumor grade and OSM expression level has

been identified after examining the blood serum levels of OSM in colorectal cancer patients. High T staged CRCs (stages 3 and 4) have significantly higher levels ( $p < 0.001$ ) of OSM present in the serum compared to low stage CRC as well as in healthy patient controls (153). Additionally, *Rajamaki et al.* identified hypomethylation and subsequent overexpression of *OSMR* in inflammatory bowel disease-associated CRC (IBD-CRC) patients, which may result in EMT of CRC cells and promote resistance to anti-TNF $\alpha$  therapies (mentioned in the Inflammatory Bowel Disease section) (154).

Camptothecin (CPT) is a chemotherapeutic agent frequently used in CRC and is aimed at the inhibition of topoisomerases (153). CPT has been shown to increase the expression of programmed death-ligand 1 (PD-L1) as well as other cytokines, including OSM (155). Examination of the TCGA colorectal cancer (COAD) and pan-cancer (PANCAN) database of ~4500 patients where high and low OSM expression was analyzed showing that high OSM expression was correlated with decreased patient survival ( $p < 0.001$ ) further correlating the role of OSM in progression and metastasis in CRC (155).

### 3.7 Gastrointestinal

Every year, almost 1 million patients are diagnosed with gastric cancer worldwide, and almost 750,000 die, making it the second most common cause of cancer death worldwide (156–158). The role of OSM in gastric cancer has yet to be studied, but OSM has been shown to be overexpressed in pre-cancerous lesions and in gastric cancer (GC) when compared to normal gastric tissue, as well as in cancer-derived mesenchymal stem cells isolated from patients (159, 160). OSM expression in gastric high-grade intraepithelial neoplasia (HGIN) and early gastric cancer (EGC) tissues was significantly higher than that of low-grade intraepithelial neoplasia (LGIN) tissues based on expression profiling ( $p < 0.001$ ) (159). RT-qPCR analysis of the OSM gene in EGC patients had a higher expression of OSM mRNA than that in HGIN ( $p < 0.05$ ) and LGIN ( $p < 0.01$ ), while immunohistochemical staining of OSM in LGIN was significantly lower than that in HGIN ( $p = 0.008$ ) and EGC ( $p = 0.044$ ) (159). These studies show that OSM could be a useful independent biomarker for possible staging of gastric cancer, and that the difference in OSM staining between HGIN and LGIN could be used as an early marker for gastric cancer.

*OSMR $\beta$*  has also been shown to be overexpressed in GC, highlighting the possibility of increased OSM-OSMR signaling in GC patients (161). Treatment with OSM increased proliferation and EMT *in vitro*. GC cells transfected with shRNA to knockdown *OSMR $\beta$*  expression had a reduction in the rate of proliferation (37.5%) as well as a reversal of EMT (161). These effects have been shown to be dependent on the activation of STAT3, FAK, and SRC through OSM-OSMR signaling (161). Treatment with OSM increased GC tumor size and incidence of peritoneal dissemination *in vivo* with attenuation being reached through *OSMR $\beta$*  inhibition (161). These findings underline the effects of OSM within GC, resulting in increased proliferation, cell migration, invasion, and EMT dependent on OSM-OSMR signaling, as well as its potential as a T staging biomarker.

### 3.8 Pancreas

While pancreatic cancer has a low incidence rate due to lack of symptoms and early detection screening methods, pancreatic cancer has one of the worst prognosis rates, with 5-year survival at 12% for late-stage pancreatic cancer (135). OSM has been shown to play an important role in the progression of pancreatic ductal adenocarcinoma (PDAC), the most common form of pancreatic cancer originating from ductal cells within the pancreas by promoting EMT and by creating a more CSC phenotype in the pancreatic tumor microenvironment (162). Treatment of multiple human pancreatic cancer cell lines with recombinant human OSM (rhOSM) induced EMT via reduction of E-cadherin and induction of ZEB1 as well as upregulation of *OSMR $\beta$* , leading to a positive feedback loop of increased OSM-mediated STAT3 signaling that maintains the malignant phenotype of these cells (162). *In vivo* analysis using xenografts of OSM producing PDAC cells showed that increased amounts of OSM in the TME caused greater primary tumor burden, increased metastatic spread, and led to a greater capacity to colonize the lungs (162). Co-culture models of human pancreatic cancer cells (HPAC) and human fibroblast overexpressing OSM also induced a CSC phenotype when compared to HPAC cells co-cultured with control fibroblasts (162). *Lee et al.* also found that OSM-OSMR signaling induces inflammatory fibroblasts within the TME in an *in vivo* PDAC model and promotes tumor growth and metastasis (163). A separate study also identified that similarly in breast cancer, OSM induces *LOXL2* expression, subsequent collagen fiber alignment, and metastasis *in vivo* (164). Due to the low survival rate of PDAC patients, and lack of screening methods for early diagnosis, OSM, along with an array of other cytokines, have been shown to be overexpressed in the serum of pancreatic cancer patients and recent bioinformatics data has implicated OSM to promote radio resistance and poor prognosis in patients (163, 165, 166). This suggests OSM may be a useful clinical marker for diagnosis, and a therapeutic may increase survivability for pancreatic cancer patients. In contrast to these studies, *Nistal-Villan et al.* developed two oncolytic virus models encoding human OSM and, when administered to an aggressive orthotopic pancreatic cancer model in Syrian hamsters, was found to stimulate immune responses against cancer cells and had a significant anti-tumor effect (167). This work has not been examined further but may suggest a possible mechanism for recruitment of anti-tumorigenic immune cells to prevent cancer progression in pancreatic cancer.

### 3.9 Bladder

According to the American Cancer Society, in 2022 there are expected to be over 80,000 patients diagnosed with bladder cancer and nearly 17,000 deaths (135). While the role of OSM in bladder cancer has not been extensively studied, in 2019 *Deng et al.* published a study of 306 bladder cancer patients of Han residents within the Sichuan province of China and identified two novel single nucleotide polymorphisms (SNPs) within the promoter region of the *OSMR* gene (168). The two SNPs identified,

rs2278329 and rs2292016 were identified in bladder cancer patients as well as healthy control patients. While rs2278329 allele variants showed no risk factors for bladder cancer progression, and patients with rs2292016 allele variants were associated with higher tumor grade and higher recurrence rate when compared to healthy control patients (168). Furthermore, a recent study performing whole exome sequencing of patients with bladder squamous cell carcinoma, also displayed significantly higher expression of OSM, OSMR $\beta$ , and IL-31, suggesting both OSM-OSMR and IL-31-OSMR signaling may impact bladder cancer progression (169). Recent evidence also suggests upregulation of OSM in metastatic bladder cancer patients (170). These studies illustrate that while the role of OSM and OSMR $\beta$  in bladder cancer has yet to be fully elucidated, OSMR $\beta$  allele variants may serve as a biomarker prognosis test for patients with bladder cancer, and therapeutics targeting OSMR $\beta$  may be a beneficial target for bladder cancer patients.

### 3.10 Lung

Lung cancer is the leading cause of cancer related deaths in both men and women, and the second most commonly diagnosed cancer (135). The current body of literature is conflicted on the role OSM plays in lung cancer progression. Some studies suggest OSM may repress lung cancer growth (171), but can promote lung cancer metastasis via activation of STAT3 and STAT5, thus increasing expression of tumorigenic factors such as tissue type plasminogen activator (tPA) (172, 173). Early work examining OSM in lung adenocarcinoma suggested it as a tumor promoter, including *in vitro* work showing OSM, and IL-6 to a lesser degree, as a potent inducer of human lung cancer differentiation. OSM combined TGF- $\beta$ 1 was also shown to regulate hyaluronan and may modulate lung cancer metastasis (174, 175). More recent work has also identified OSM as a tumor promoter *in vivo*. Adenovirus vector expressing mouse OSM induced a 13-fold increase in lung tumor burden and an increase in tumor size when compared to control cell lines. This effect was mitigated in OSMR $\beta$  KO mice, suggesting OSM-OSMR $\beta$  signaling is necessary (176). Other studies confirmed the pro-metastatic nature of OSM, demonstrating that it induces EMT in non-small cell lung cancer. Additionally, when lung cancer cells were co-cultured with cancer associated fibroblasts, there was an upregulation of phosphorylated-STAT3, OSMR $\beta$ , and LIFR $\beta$ , coupled with the downregulation of E-cadherin, suggesting an important role for fibroblasts in the activation of OSM signaling and the progression of lung tumors while protecting the cells from targeted therapies in an OSMR $\beta$ /JAK1/STAT3 dependent manner (177). This theory is also supported by Wysoczynski *et al.* who showed that lung cancer cells secrete an increased number of microvesicles when in the presence of stress factors like hypoxia and irradiation. Increased microvesicles lead to the activation of cancer associated fibroblasts and subsequent overexpression of pro-angiogenic factors such as OSM, IL-8, IL-11, VEGF, LIF, MMP-9, and tissue-type plasminogen activator (tPA) (172, 178). Shien *et al.* also analyzed patient data using the TCGA and PROSPECT lung adenocarcinoma databases and found a positive correlation of OSM, IL-6 and LIF in lung cancer patients, while also showing

high OSMR $\beta$  expression had a significantly poorer prognosis compared to patients with a low OSMR $\beta$  expression ( $p = 0.0096$  for recurrent-free survival), indicating that OSM and OSMR $\beta$  play a significant role in lung cancer (177). However, there is research that suggests OSM can suppress lung metastasis by inhibiting the EMT promoter SLUG, modulating mesenchymal-epithelial transition of lung cells by reducing EMT markers via STAT1 (179, 180). This combined research has not yet fully parsed out the mechanism of OSM in lung cancer, however patient data suggests a pro-tumorigenic and pro-metastatic role for OSM. Additionally, a study published by Chen *et al.* evaluated the expression of a short non-functioning form of OSMR $\beta$ , dubbed OSMRs, that is highly expressed in lung cancer patients, and acts a decoy receptor for OSM and thus resulting in mitigating OSMs oncogenic capabilities (181). This confounding factor may explain the contradictory results in lung cancer.

### 3.11 Brain

Brain cancer is a blanket term related to a variety of tumors based upon the cell type that becomes cancerous and includes both benign and malignant tumors. OSM has been shown to play a factor in a variety of brain tumor types including astroglomas, astrocytomas, pituitary adenomas, glioblastomas, gliomas, medulloblastomas, and meningiomas (182–186, 189, 249). *In vitro*, OSM mediates tumorigenesis by activating STAT3 or STAT1 thus promoting expression of genes responsible for cell migration, ECM remodeling, and angiogenesis including, PLAU (plasminogen activator of urokinase), CHI3L3 (chitinase-like protein 1) and VEGF in several different human brain tumor cell types (183, 187, 249). In astrogloma cells, OSM induces an approximately three-fold increase in VEGF, while OSM and IL-1 $\beta$  together induce an approximately seven-fold increase of VEGF after 48 hours in astrogloma cells, in a STAT3 dependent manner (183). Additionally, OSM stimulation has been shown initiate the activation of the RelB/p50 proteins of the NF- $\kappa$ B pathway both *in vitro* and *in vivo*, perpetuating a tumor inflammatory environment in brain cancer cells (183). OSM-OSMR signaling mediated through STAT3, promoted MMP-9 upregulation over two-fold and increased the invasive potential of glioblastoma cells. OSM itself, however, did not influence tumor cell viability or proliferation (183). Two studies in fact suggest OSM may inhibit proliferation of glioma, astrogloma, and glioblastoma, although these studies have not been further evaluated (190, 191). Interestingly, Jahani-Asl *et al.* identified that OSMR $\beta$  is an essential co-receptor for EGFRvIII, and knockdown of OSMR $\beta$  strongly suppressed cell proliferation and tumor growth in mouse glioblastoma cells and human brain tumor stem cells in a xenograft mouse model (184). Waters M. R., *et al.* analyzed the correlation of OSM in brain cancer using brain tumor TCGA database and found OSM expression was most strongly correlated with poor glioblastoma multiforme (GBM; a heterogeneous mixture of cells containing brain tumor stem cells that are both tumorigenic and self-renewing) patient survival (182). They also discovered that OSM is produced in the brain solely by macrophages and microglia, and that chronic elevation of OSM

leads to the progression of GBM (182). Macrophage-derived OSM has been shown to increase the mesenchymal like phenotype of OSM, mediated via STAT3 signaling both *in vitro* and *in vivo* (183, 186). Most recently, *Chen et al.* found that high OSM level is correlated with poor prognosis in several cancers, particularly with GBM, and found that OSM promotes migration and invasion of U251 glioblastoma cells while also exhibiting a more mesenchymal phenotype indicative of aggressive disease (192). OSMR $\beta$  has also been shown to be overexpressed in aggressive GBMs via STAT3 signaling and is correlated to a decrease in survival among patients (183, 184). Studies targeting OSMR $\beta$  and STAT3 suggest that a clinical therapeutic that disrupts OSM/OSMR $\beta$ /STAT3 signaling can repress brain tumor growth and increase chemoresistance in aggressive brain tumors (183, 249).

### 3.12 Squamous cell carcinoma

Cutaneous squamous cell carcinoma (cSCC) is the second most common keratinocyte malignancy, being responsible for 20% of skin-cancer deaths due to the lack of therapies (193). While OSM has not been extensively analyzed in all varieties of skin cancer, OSM has been shown to promote normal keratinocyte proliferation, migration, skin inflammation, and epidermal hyperplasia both *in vitro* and *in vivo* (52). OSM has also been shown to be overexpressed in cSCC patients, and overexpression of OSM *in vitro* and shown to induce STAT3 and ERK phosphorylation and activation, as well as increased proliferation and migratory capacity *in vitro* (194–196). Interestingly, during *in vivo* studies OSM was not found in the keratinocyte cells, but rather, it was found in large quantities at the periphery of the tumor due to infiltration of neutrophils, macrophages, and other inflammatory cells that secrete OSM in a paracrine fashion (194). OSM has also been shown to be highly expressed in keratoacanthoma; originally believed to be a benign form of skin cancer, but rare cases act in a similar form to skin SCC have been reported (195). In OSM-knockout mice, cSCC tumor volume was reduced by approximately 30% when compared to wild-type mice after one month, however there were still significant amounts of IL-6, IL-1 $\beta$ , IL-23 $\alpha$ , CXCL1, IL-4, and IFN $\gamma$  present in the tumor tissue compared to normal skin (194). The most understood environmental cause of cSCC is ultraviolet (UV) radiation (197). OSM signaling has been shown to suppress UV induce apoptosis of human keratinocytes and may be crucial towards early cancer progression *in vitro* via an increase in cell motility through ECM remodeling (197). This indicates that OSM may not only be crucial for cSCC progression, but also may lead to a higher incidence of squamous cell carcinoma, via repression of apoptosis in keratinocytes.

In addition to cSCC, OSM has also been implicated in oral squamous cell carcinoma (OSCC). In OSCC cells, treated with the known oral carcinogen arecoline, induced the expression of IL-6, STAT3, and c-Myc (198). The upregulation of c-Myc has been shown to suppress the expression of micro-RNA-22 (MiR-22) subsequently leading to an upregulation of OSM (198). This is reinforced by the observation that the expression of OSM and MiR-22 are inversely related (198). MiR-22 overexpression was able to suppress cell proliferation and migration by directly inhibiting

OSM, suggesting the role of OSM in OSCC may be dependent on miRNA regulation (198).

Esophageal squamous cell carcinoma (ESCC) is the seventh most common malignancy in the world and is common among Asian populations (199). Due to difficulties of early screening, nearly half of patients are diagnosed as having locally advanced disease (200). The effect of OSM in ESCC has not been extensively studied, and preliminary reports suggest OSM plays a minor role. A recent study evaluating inflammation biomarkers in ESCC patients in Japan identified OSM as negatively correlated to the disease, while another study evaluating 173 cases in the ESCC TCGA dataset correlated OSM with a worse prognosis (201, 202). However, *Kausar et al.* identified a soluble form of OSMR $\beta$  (sOSMR $\beta$ ) to be present in 9 out of 11 cell ESCC cell lines, and the presence of sOSMR $\beta$  protein was detected in the sera of patients. Furthermore, while high expression of OSM (94% of patients) was confirmed via IHC, full length OSMR $\beta$  was only detected in 23% of patients, suggesting that sOSMR $\beta$  may be acting as a neutralizing receptor for OSM in ESCC (203).

### 3.13 Kaposi's sarcoma

OSM was first identified as a major growth factor in Kaposi's sarcoma (KS) in 1992 when evaluating media from patients with AIDS-associated KS (4). Kaposi's sarcoma is a relatively rare form of cancer but is endemic in several regions of the world and is estimated to be the leading cause of cancer incidence and mortality in several countries in Southern and Eastern Africa (199). When evaluating AIDS-KS cell lines, OSM was found to be a potent mitogen and autocrine growth factor (204, 205). Other studies showed OSM as a promoter of basic fibroblast growth factor (bFGF) which in turns promotes growth of Kaposi's sarcoma and endothelial cells through activation of AP-1 response elements in the bFGF promoter (206, 207). It has also been proposed that KS-encoded cyclin K inhibits the anti-proliferative effects of OSM by directly inhibiting STAT3, although previous work suggests OSM signaling promotes growth via MAPK/ERK and JNK signaling (208, 209). Further studies also suggest that in KS, OSM and bFGF induce RAFTK, a focal adhesion kinase downstream of JNK, which acts as a convergence site for intracytoplasmic kinases and adapter molecules and increase cytokine signaling cascades and promoting cell growth (210). Additionally, AIDS-associated KS cells have been shown to express OSMR $\beta$  but not LIFR $\beta$  or IL-6 receptor, and inhibition of gp130 blocks the growth stimulating effects of OSM in AIDS-KS cells suggesting inhibition of OSM signaling may be beneficial strategy for patients with KS (211).

### 3.14 Miscellaneous sarcomas

Osteosarcoma (OSA) is the most common malignant bone disease in humans (135). *Fossey et al.* discovered that several OSA cell lines express OSM, OSMR $\beta$ , and gp130 receptor complex proteins, but interestingly not IL-6 or IL-6R. Activation of these receptor complexes occur with the binding of OSM leading to a

time dependent increase in the levels of pSTAT3, pJAK2, and pSrc. While OSM does not increase proliferation of OSA cells (212–214), it does increase invasion via expression of glial fibrillary acidic protein (GFAP); a protein responsible for cytoskeletal reorganization in osteoblasts, MMP-2, cathepsin secretion and activity, as well as VEGF in a STAT3 dependent manner (212, 215–217). These features of OSM in OSA can increase the metastatic potential of OSA cells *in vivo*.

Chondrosarcomas (CSA) are difficult to treat, with chemotherapy and radiotherapy resistance, surgery remains the singular treatment option (218). Treatment with OSM induced cell cycle arrest in the S phase of murine SRC cell line *in vitro* and in G0/G1 of three other cells *in vitro* and is dependent on the JAK3/STAT1 pathway (218). Overexpression of OSM in the tumor cells, by adenovirus gene transfer, led to decreased tumor proliferation and enhanced apoptosis *in vivo* (218). These findings show that OSM treatment locally to the tumor environment of CSA could be a possible therapy to improve the prognosis of CSA patients.

Very little evidence exists for OSM and Ewing sarcoma (ES); however, the OSM gene has been shown to be differentially methylated in an ES microarray dataset (65% compared to healthy patients), although this did not significantly correlate with survival rate (219). Unlike OSA or CSA, OSM has been shown to increase the proliferation of ES cells in an OSMR $\beta$ /STAT3 dependent manner via upregulation of c-Myc (220). Based on the information given above, OSM inhibition would benefit CSA patients but burden OSA and ES patients.

### 3.15 Melanoma

Invasive melanoma accounts for only 1% of all skin cancer cases but is responsible for the vast majority of skin cancer deaths (135). Historically, OSM has been identified as a strong inhibitor of melanoma (221–223). Exogenous OSM has been shown to activate STAT3, STAT5b and the MAPK pathways via OSMR $\beta$  to strongly inhibit the proliferation of melanoma cells (221, 222, 224–226). OSM is also able to bind to collagens in a bioactive form and inhibit proliferation of A375 melanoma cells *in vitro* (227). Interestingly, OSM has also been shown to promote LIF expression, which could prolong the inflammatory effects of OSM (228). OSM also increases expression of membrane bound ICAM-1 *in vitro*, which also may suggest higher immune surveillance in human myeloma (229).

As melanoma reaches an advanced stage, cells appear to become resistant to the inhibitory effects of OSM (225). This has been shown *in vitro* and *in vivo* to be partly caused by the constitutive expression of suppressor of cytokine signaling-3 (SOCS-3) mRNA and subsequent high level of SOCS-3 protein (230). Accompanying the increase in SOCS-3 mRNA/protein is a downregulation of the OSMR $\beta$  subunit, due to a decrease in the amount of histone acetylation in the promoter region of the OSMR $\beta$  gene (231). Paracrine signaling of OSM in antigen-negative melanoma cells to antigen-positive will lead to antigen-silencing, possibly affecting the outcome of antitumor vaccine immunotherapies (232). OSM sensitivity in human melanoma cells also has importance for

tumor-infiltrating lymphocyte (TIL) treatment of stage 3 melanoma (233). Patients that were unresponsive to OSM expressing TILs due to phosphorylation defects of STAT3 on Ser-727, as well as activation of AKT on Ser-473, were shown to have an increased resistance to OSM anti-proliferative activity (233). The development of OSM resistance in melanoma cells has a significant role in creating a more aggressive phenotype, which appears to be specific to melanoma. This could be treated by increasing the amount of OSM ligand in the system through the use of an OSM therapeutic.

## 4 Therapeutic intervention of OSM

As mentioned in the previous sections, developing an effective targeted therapeutic against OSM signaling could be crucial for the treatment of numerous diseases, including a variety of cancers. While several therapies have been developed and approved that target IL-6 and other IL-6 family members, currently no FDA approved treatments exist for OSM. This section will outline previous and current strategies for developing effective therapeutics against OSM and OSM receptor, including unique strategies that are in early stages of testing. The specific drugs and patents for drugs against OSM and OSMR $\beta$  are described in Table 3.

### 4.1 Anti-OSM therapeutics

In 2000, Deller *et al.* published the first molecular structure for OSM, paving the way for the development of potential anti-OSM therapeutics (5). OSM's tertiary structure consists of four  $\alpha$ -helical bundles (helices A-D; Figure 2A) and has two distinct sites responsible for receptor complex binding (Figure 2B) (5). The Site II motif, consisting of regions of helices A and C, is responsible for OSM's binding to gp130. Site-directed mutagenesis has revealed four amino acid residues: Gln-16, Gln-20, Gly-120, and Asn-124, shown to be the primary residues responsible for this interaction (5, 16). The Site III epitope, located within a loop between helices A-B (Figure 2A), and near the N-terminal end of helix D, is the primary site by which OSM binds to OSMR $\beta$  and LIFR $\beta$ . This region is highly conserved for both OSM and LIF, thus making it difficult to generate a specific therapeutic against OSM. However, recent research efforts have shown that OSM possesses a unique amino acid composition that is necessary for specific interactions with OSMR $\beta$ . Alanine-scanning experiments and substitution experiments comparing OSM and LIF revealed that Tyr-34, Gln-38, Gly-39, and Leu-45 (in AB loop) and Pro-153 (in helix D) are responsible for OSMR $\beta$  binding, while Phe-160 and Lys-163 of D-helix are necessary for interaction with both OSMR $\beta$  and LIFR $\beta$  (16, 234, 235).

The pharmaceutical giant GlaxoSmithKline (GSK) has supported the production of two separate anti-OSM neutralizing antibodies, both of which target the Site II region of OSM, and to date, these are the only anti-OSM therapeutics to advance into clinical trials. GSK315234 is a humanized anti-OSM IgG

monoclonal antibody developed for the treatment of patients with active rheumatoid arthritis (RA), designed to bind to the Site II region of OSM and prevent dimerization with gp130 (236). A phase two clinical trial was initiated with the goal of investigating the safety, pharmacokinetics (PK), and pharmacodynamics (PD) of

GSK315234 in patients with RA. The study contained a total of 135 patients with RA, was divided into four groups (double-blind, placebo-controlled, and randomized, and evaluated the following: i) an intravenous (IV) method of delivery, ii) a subcutaneous (SC) method of delivery, iii) a single dose delivery (single versus multiple

FIGURE 2

OSM structure and receptor binding sites. (A) OSM is a four  $\alpha$ -helical bundle protein consisting of helices A (red; aa 10–37), B (green; aa 66–90), C (purple; aa 106–131), and D (blue; aa 159–185) (truncated X-ray crystallography PDB:1EVS). (B) Site-directed mutagenesis experiments have identified two separate binding sites responsible for receptor-ligand interactions. Site II is located near the N-terminal region in helices A and C, and three amino acids (Gly-16, Gly-20, Asn-124) have been identified as crucial for OSM interaction with gp130. Site III is located in the A–B loop with a small portion of the D helix (dark purple) that is responsible for binding of OSM to LIFR $\beta$  and OSMR $\beta$ . Substitution experiments with OSM and LIF revealed that Lys-163, and Phe-160 are required to bind to both receptor complexes, but Tyr-34, Gln-38, Gly-39 and Leu-45 are specifically needed for interactions with OSMR $\beta$ .

delivery) and iv) a multiple dose delivery, all over a period of 154 days. Patients selected to participate in the study were required to have active RA with a Disease Activity Score 28 (DAS28) of  $> 4.2$  at screening. DAS28 is a composite score analyzing the number of swollen/tender joints (that includes 28 joints), as well as examining concentration of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) in the blood stream. Patients selected to participate in the study were also required to have had previously received at least three months of treatment with methotrexate.

Overall, evidence from this study suggests that repeated dosing with GSK315234 did not demonstrate statistically significant efficacy. While there appears to be minimal toxicity in patients who received GSK315234, the monoclonal antibody exhibited poor binding affinity (2.5 nM) and a rapid off-rate ( $1.73 \times 10^3$ ) when compared to the higher affinity of OSMR $\beta$  (approximately 150 pM). Interestingly, patients in the group which received a single 3 mg/kg dose of GSK315234 by IV displayed a statistically significant reduction in DAS28 score compared to the placebo group ( $p$ -value  $< 0.05$  at days 56, 84, and 91), as did the patients that received a 10 mg/kg dose by IV (at day 84). However, groups receiving larger single doses (20 and 30 mg/kg IV), repeated dosing (6 mg/kg IV), or SC injection (500 mg) exhibited no significant difference in clinical score. Due to the high off-rate and binding affinity, as well as the poor significance and inconclusive results in the study, GSK315234 clinical trials were halted.

Another GSK anti-OSM monoclonal antibody, GSK2330811, has entered clinical trials for treatment of systemic sclerosis (237, 238). A phase one, randomized, double-blind, placebo-controlled SC administered clinical trial with 30 healthy subjects showed a favorable safety profile in participants. Patients were divided into 6 groups, with patients given either placebo or varying concentration of a single SC dose of GSK2330811 (0.1, 0.3, 1, 3 or 6 mg/kg respectively). No clinically relevant change from baseline laboratory values were observed in any of the groups, and GSK2330811 exhibited pharmacokinetics over all five of the dose ranges with a binding affinity estimated at approximately 0.58 nM (95% CI 0.455, 0.710). This drug has recently finished evaluation in phase two clinical trials for patients with diffuse cutaneous systemic sclerosis involving 35 patients randomized to placebo receiving 100 mg or 300 mg treatment subcutaneously every other week for 12 weeks. There were no clinical differences between GSK2330811 and placebo groups. Additionally, all patients in the 300 mg treatment group reported at least one adverse effect; including decreased hemoglobin, anemia of varying severity, decreased platelet counts, decreased neutrophil counts, and thrombocytopenia (239). A separate clinical trial (NCT04151225) was also initiated with GSK2330811 for patients with Crohn's disease; however, the study was halted by an internal sponsor before patient enrollment began due to a potentially narrow therapeutic window (238, 240, 250).

In addition to the previously mentioned monoclonal antibodies that have advanced to clinical trials, GlaxoSmithKline possesses a patent (US7858753B2) (240) for another anti-OSM antibody. While the previous ones were designed to specifically interact with Site II of OSM (Figure 2), this is designed to inhibit OSM/gp130 interaction without directly binding to any amino acids within Site II. Instead, it is

designed to interact with amino acids; Pro82, Ser83, Glu84, Leu90, Gly94, Pro112, Gln115, Asp122, Leu123, and Cys152 of OSM. It is unclear how this antibody interferes with OSM/gp130 dimerization, but further studies may reveal its mechanism. Within a separate patent (US6706266B1) (240), GlaxoSmithKline also has RNA aptamer designs that are highly specific towards OSM with a  $K_D$  at approximately 7 nM; however, both of these patents have yet to be tested *in vitro*, *in vivo*, or through clinical trials.

Researchers at the Universite de Poitiers have also developed a patent (WO2020127884A1) relating to specific binding proteins, such as an antibody, that binds specifically to OSM to inhibit interaction with OSM and gp130, and/or LIFR, to be used with any disease associated with elevated levels of OSM, with a particular interest in inflammatory skin diseases and cancer (251).

A different patent, submitted by the University of Padua (US20170327573A1) (252), is designed to develop an anti-OSM therapeutic that will increase mobilization of bone marrow stem cells in patients with diabetes. This patent allows for the design of a variety of inhibitors that would inhibit OSM production or OSMR $\beta$  signaling at the cellular level such as enzyme inducers, an enzyme or receptor inhibitor, a ligand for a receptor, a compound that is toxic for cells, or an antisense RNA.

Utilizing a separate approach, Boise State University has submitted a patent (US9550828B2) (253) developing small molecule inhibitors against the Site III region of OSM, preventing OSM binding to OSMR $\beta$ . The compounds proposed in this patent are designed to reduce tumor cell detachment, invasion, and metastasis. Recently, a specific small molecule inhibitor named SMI-10B was characterized and shown to bind to specific amino acids within Site III of OSM via HSQC-NMR (260), and was subsequently confirmed by an independent group using molecular dynamics simulation (261). To date, this is the only patent designed for small molecule inhibition of OSM.

## 4.2 Anti-OSMR $\beta$ therapeutics

As outlined in Figure 1, OSM interacts with gp130, which then results in the dimerization of both LIFR $\beta$  and OSMR $\beta$ , however it is thought that human OSM binds with a much stronger affinity to OSMR $\beta$  than to LIFR $\beta$ . Another cytokine, IL-31, also uses OSMR $\beta$  as part of its receptor complex (along with its receptor IL-31RA), making OSMR $\beta$ , specifically, a beneficial target to inhibit OSM as well as IL-31 signaling (262, 263). Challenges exist for this strategy due to the unknown structure of OSMR $\beta$ . Recent work utilizing computational *in silico* analysis and homology modeling of the structurally similar LIFR $\beta$  has provided framework for structural modeling of the OSM-OSMR complex, providing more detailed information for those designing therapeutics against OSMR $\beta$  (257). Furthermore, with the recent advancement in molecular modelling, particularly with *AlphaFold*, a predicted structure for OSMR $\beta$  has been created, which may help pave the way for specific targets against the receptor protein (264, 265). Currently, no therapeutics targeted against OSMR $\beta$  are clinically available, and to date, none have advanced into clinical trial stages. However, several patents have

been submitted for a variety of compounds designed as inhibitors of OSMR $\beta$  and will be outlined below (see Table 3).

As highlighted previously, OSM has been shown to play a role in various inflammatory skin diseases. To combat this, Kiniksa Pharmaceutical currently has two patents, all describing monoclonal antibodies, that are designed to inhibit OSMR $\beta$  in inflammatory skin conditions. The first (US9663571B2) (254) is designed for the treatment of atopic dermatitis and chronic puritis in patients who have yet to receive treatment with a corticosteroid, or for patients with serum IgE levels lower than 300 IU/mL. Both OSM and IL-31 have been linked to atopic dermatitis. OSMR $\beta$ , which is part of the receptor complex for both proteins, makes it a desirable target to inhibit both OSM and IL-31 signaling. This patent outlines three separate antibodies that describe an IC<sub>50</sub> range between 157 pM and 1.35 nM and an average K<sub>D</sub> of 0.2 nM. Kiniksa Pharmaceutical's second patent, (US10493149B2) (255) is also a monoclonal antibody is for unspecified diseases. Furthermore, two other patents have been developed for inflammatory skin disorders. Wakayama Medical University has submitted a patent (WO2013168829A1) (256) for a monoclonal antibody against OSMR $\beta$  designed to inhibit both OSM and IL-31 induced inflammation in patients with atopic dermatitis. Universit   D'angers has also written a patent (US20090300776A1) (257) for a small interfering RNA (siRNA) that is designed to inhibit OSMR $\beta$  mRNA expression in keratinocytes that would subsequently result in repressed inflammation in a variety of inflammatory skin diseases. This patent also encompasses molecules designed to inhibit a variety of cytokines linked with keratinocyte-mediated inflammation, including OSM, IL-17, TNF $\alpha$ , IL-31, and IFN- $\gamma$ .

Additionally, two pharmaceutical companies have patents targeting OSMR $\beta$  in both cancer and heart disease. Raven Biotechnologies has developed an anti-OSMR $\beta$  antibody (US7572896B2) (258) designed for diagnosis of human cancers with high OSMR $\beta$  expression, as well as treatment for a variety of human cancers. Mouse model experiments using human ovarian and lung cancer cells indicate this antibody is effective at reducing proliferation both *in vitro* and *in vivo*. Furthermore, the Max Plank Society has written a patent (WO 2010139742A1) to develop an anti-OSMR $\beta$  therapeutic for the treatment and/or prevention of heart failure (259). The patent is broad in nature, and is written to encompass an aptamer, siRNA, shRNA miRNA, and/or ribozyme. While current efforts for an anti-OSM or anti-OSMR $\beta$  drug have not yet succeeded in making it through clinical trials, it is clear that a therapeutic is needed for a variety of diseases. Developing novel therapies that target OSM or OSMR $\beta$  with high specificity and low toxicity will hopefully provide the necessary therapeutics for patients with abnormal OSM or OSMR $\beta$  expression.

## 5 Discussion

Throughout the course of this review, we have shown the important role OSM plays in a variety of diseases including many types of cancer. OSM activates several signaling pathways, frequently leading to inflammation, migration, or regeneration and differentiation (19–23). OSM can be produced and secreted by

many different cell types, mostly activated immune cells such as macrophages and neutrophils, to intensify some inflammatory diseases, as shown in Table 1 (1, 2, 24). Several studies have linked OSM overexpression with an overall worse prognosis for a variety of diseases, including arthritis, IBD, and most recently COVID-19 (25, 26, 39, 42, 90). However, OSM expression has the possibility to be beneficial to healing injuries, particularly regarding the CNS, bone, liver, heart, and general external skin wounds (33, 37, 64, 68–72, 75–77, 83–85, 92). Negative effects due to chronic expression of OSM may outweigh its positives, yet inhibiting the signaling systemically may cause issues within other physiological processes.

The role of OSM in cancer has also been mysterious (see Table 2). While OSM was initially discovered as an inhibitor of cancer cell growth in melanoma cells (221–223), OSM has been shown to play an important role in cancer progression. In fact, while OSM expression has been shown to repress tumor growth in some cancer types it also may promote tumor growth in other types (15, 102, 103, 161, 162, 171). The specific mechanisms by which OSM operates under different cancer subtypes has yet to be fully explored. However, increased OSM signaling has been shown to increase the proliferation, motility, and metastatic potential of multiple cancers (36, 109, 140, 143, 162, 177, 183, 186, 248). It is also interesting to consider OSM or OSMR $\beta$  as a possible biomarker for certain types of cancers such as cervical, colon, GI, and pancreatic cancer (153, 159, 165, 242). Overexpression of OSM and/or OSMR $\beta$  is seen more commonly in a multitude of advanced tumors and is linked to decreased patient survival in several cancer types, including breast, cervical, colon, pancreatic, lung, and brain cancer (109, 153, 165, 177, 192, 242). Patients in a clinical setting could benefit greatly from an anti-OSM therapeutic, but the market remains empty for oncologists and their patients.

There are several therapeutics currently in development designed to inhibit the OSM signaling cascade, some by binding to OSM and others by binding its receptor, OSMR $\beta$  (see Table 3). The current strategies being implemented represent diverse and novel approaches to develop the most effective inhibitor. Significant inhibition of cytokines has proven to be a challenge clinically. To date, IL-6 remains the only member of its family to have FDA approved clinical therapeutics (266, 267). Targeting OSM, however, has proven to be more challenging. While two monoclonal antibodies against OSM have been the only potential therapies to reach clinical trial stages, both struggled with poor binding affinity and lack of clinical significance (236, 237). It is possible an alternative strategy is needed for an effective anti-OSM therapeutic. Monoclonal antibodies tend to have lengthy half-lives (on the order of days or weeks) that may affect normal inflammatory response mechanisms in cases of infection or injury, and serious wound healing might require pausing therapy (268). In the case of GSK2330811, the half-life was reported to be approximately 24 days (237). Furthermore, both clinical trials of GSK315234 and GSK233081 reported long-term accumulation of OSM-mAb complexes, directly resulting from their long half-life, which in combination with rapid off rate and poor binding affinity, may result in lengthening active OSM in the bloodstream of subjects (236, 237). The wide variety of techniques being implemented, including small molecule inhibitors, aptamers, and other biologics, may eliminate long-term issues with accumulation, provide a highly

specific and minimally toxic therapeutic for patients, and allow for therapy to be paused when necessary.

In addition to targeting OSM, several drugs are currently in development to inhibit OSMR $\beta$  rather than OSM. While targeting OSMR $\beta$  is a valid strategy, and several attempts have been initiated, none of them have entered into clinical trials. As a target, OSMR $\beta$  possesses its own unique challenges, lacking a completed crystalized structure; forcing medical chemists to rely on computational modeling for targeting amino acids necessary for OSM/OSMR $\beta$  (269). Furthermore, targeting the other OSMR subunit gp130 itself is a risky venture due to its diverse role in all IL-6 family cytokine receptor complexes, although one group is investigating inhibition of gp130 for specific cytokines in the context of inflammatory diseases and multiple cancers (270–272).

## 6 Conclusion

Throughout this review, we have outlined the evidence for identifying OSM as a therapeutic target for numerous diseases, as well as a variety of cancers. While efforts have been initiated to develop clinical therapeutic for patients, to date, none exist. Creating an anti-OSM or an anti-OSMR $\beta$  therapeutic is a much-needed venture for patients and clinicians alike, and work must be continued to synthesize and generate an FDA approved therapeutic.

Skin malignant melanoma is a highly aggressive skin tumor, which is also a major cause of skin cancer-related mortality. It can spread from a relatively small primary tumor and metastasize to multiple locations, including lymph nodes, lungs, liver, bone, and brain. What's more metastatic melanoma is the main cause of its high mortality. Among all organs, the lung is one of the most common distant metastatic sites of melanoma, and the mortality rate of melanoma lung metastasis is also very high. Elucidating the mechanisms involved in the pulmonary metastasis of cutaneous melanoma will not only help to provide possible explanations for its etiology and progression but may also help to provide potential new therapeutic targets for its treatment. Increasing evidence suggests that tumor-associated macrophages (TAMs) play an important regulatory role in the migration and metastasis of various malignant tumors. Tumor-targeted therapy, targeting tumor-associated macrophages is thus attracting attention, particularly for advanced tumors and metastatic tumors. However, the relevant role of tumor-associated macrophages in cutaneous melanoma lung metastasis is still unclear. This review will present an overview of the origin, classification, polarization, recruitment, regulation and targeting treatment of tumor-associated macrophages, as well as the soluble mediators involved in these processes and a summary of their possible role in lung metastasis from cutaneous malignant melanoma. This review particularly aims to provide insight into mechanisms and potential therapeutic targets to readers, interested in pulmonary metastasis melanoma.

## KEYWORDS

tumor-associated macrophages (TAMs), pulmonary metastatic melanoma, targeted therapy, soluble mediators, melanoma

## Introduction

Cutaneous melanoma is a fatal skin malignant tumor derived from skin melanocytes. It is highly aggressive and is a major cause of skin cancer-related mortality; most patients have metastases the first time coming into the hospital (1, 2). The typical characteristics of cutaneous melanoma are early dissemination and subsequent metastatic colonization of multiple organs, for instance, lymph nodes, lung, liver, bone, and brain are common metastatic sites of skin melanoma (3). It's worth noting that metastatic melanoma is the main cause of its high mortality and among multiple organs that may be colonized by cutaneous melanoma, the lung is one of the most common distant metastatic sites of melanoma (3–6). The incidence of pulmonary metastasis of melanoma accounts for 5% of all malignant metastases, and the mortality rate of pulmonary metastasis of melanoma is also very high (7). Primary melanoma is another condition of pulmonary melanoma, but the incidence of primary melanoma is only 0.01%, and its pathophysiology and therapeutic intervention are still unclear (7, 8). This review focuses on pulmonary metastatic melanoma, which accounts for the majority of cases of pulmonary melanoma. Hoping this review could provide some possible explanations for the relationship between melanoma lung metastases and TAMs, which may not only help provide possible explanations for cutaneous melanoma lung metastases but also provide potential new therapeutic targets for the treatment of melanoma lung metastases.

Tumor metastasis is not only driven by the intrinsic changes of tumor cells, the implicated cross-talk between tumor cells and their altered microenvironmental components all also play an important role in tumor metastasis. In addition, tumor cell metastasis is usually a stepwise cascading process, which mainly includes (1) tumor cell invasion in the primary site, (2) tumor cells intravasated into the vasculature, (3) tumor cell survival in the circulations, (4) tumor cells extravasated out of the vasculature, (5) tumor cells adapt, colonize and grow at the metastatic site (9, 10). The tumor microenvironment (TME) is considered to have a strong influence on tumorigenesis and the occurrence of tumor metastasis. The macrophages that accumulate around the TME are usually called tumor-associated macrophages (TAMs) (11). A large number of studies have shown that the TEM significantly promotes tumor metastasis usually caused by the increasing infiltration of TAMs, and TAMs are almost involved in the five cascade steps of tumor metastasis (12, 13). Recent studies have found that TAMs play an important role in tumor metastasis. For example, Prune-1 enhances the M2 polarization of TAMs in triple-negative breast cancer (TNBC) and promotes TNBC lung metastasis (14). In the development, metastasis, and invasion of ovarian cancer, programmed death-ligand 1 (PD-L1), an immunomodulation point factor of tumor-associated

macrophages, plays an important role (15). Moreover, a study suggests that genetic variants in TAMs can predict clinical outcomes of bevacizumab therapy in patients with metastatic colorectal cancer (16). The elevated number of TAM in the melanoma TEM is often correlated with its poor prognosis, and TAMs targeted drugs have several clinical trials in the targeted therapy of melanoma, breast cancer, pancreatic cancer, prostate cancer, and other tumors (17–19). However, there is no definite hypothesis on the role of TAMs in the mechanism and targeted therapy of melanoma pulmonary metastasis at present.

This article will review the origin, classification, polarization, recruitment, regulation and targeting of TAMs, as well as the soluble mediators involved in these processes, and summarize their possible role in pulmonary metastases from cutaneous malignant melanoma. This review shall provide some possible mechanistic explanations and potential targeted therapy options for TAMs in pulmonary metastasis melanoma for readers.

## TAMs definition, origin, classification, and recruitment

### TAMs definition

Macrophages are a highly heterogeneous class of immune cells that are found in almost all tissues. Macrophages clustered around the TEM are called tumor-associated macrophages (TAMs) and are the most common immune cells in the TEM (20, 21). A large number of studies have shown that the increased accumulation of TAMs in tumor tissue is related to the poor prognosis of tumor patients (15, 22). With increasing the infiltration of TAMs, the tumor cell proliferation, and invasion could be promoted and angiogenesis could be stimulated. Moreover, TAMs can exert anti-tumor immune responses by mediating the production of growth factors, chemokines, and other immune components by T cells, thus regulating tumor metastasis (15, 22–25).

### TAMs origin

Blood monocytes derived from bone marrow hematopoietic stem cells were previously considered the generic origin of macrophages (20, 26). However, recent studies revealed that tissue macrophages of various organs such as the lung, brain, and liver embryonically originate from yolk sac progenitor cells (27). Consistent with this, there are two possible explanations for the origin of TAMs (1) tissue-resident TAMs: yolk sac progenitor-derived macrophages in various tissues may alter their phenotype or activation during tumorigenesis status; (2) tumor-induced TAMs (Monocyte-derived TAMs): Monocytes themselves undergo a distinct differentiation stage during tumor

growth and eventually become macrophages (26, 28). In different stages of tumorigenesis and development, the source of dominant macrophages may be different. Tissue-resident TAMs may predominate in the early stages of tumor growth, while tumor-induced TAMs may predominate in the later stages of tumor growth. About 30% of tumor cells in melanoma are TAMs mainly derived from circulating monocytes, which are considered to be the most abundant leukocytes in melanoma lesions (29).

## TAMs classification

Macrophages are generally classified according to their function and their response to polarizing agents. Naive/unpolarized macrophages are called M0, and polarized macrophages are generally divided into M1 (classically activated macrophages) and M2 (alternatively activated macrophages), M2 macrophages can be further divided into Ma, Mb, Mc, Md subtypes (30, 31). Although, with the deepening of the understanding of macrophage polarization conditions, numerous new macrophage phenotypes, for example, Christian A. Gleissner, et al. identified M4 macrophages by comparing the transcriptome of M-CSF (macrophage colony-stimulation factor) and CXCL (4CXCL Chemokine Ligand 4) induced macrophages *in vitro*, providing a novel starting point for atherosclerosis and other disease-related research; macrophages defined as M17 for secreting IL17 are also new macrophage phenotypes that have been recently identified (32, 33). The continued discovery of new macrophage phenotypes amply demonstrates the heterogeneity and plasticity of macrophages; however, the commonly used classification remains M1-M2, which differ in metabolic characteristics, markers, and gene expression profiles (31). M1 macrophages are involved in the anti-infective response together with helper T1 cells (Th1). It exerts its pro-inflammatory and anti-tumor effects by secreting pro-inflammatory cytokines such as interferon (IFN)- $\gamma$ , IL-6, IL-12, tumor necrosis factor (TNF)- $\alpha$ , lipopolysaccharide (LPS) or molecules that regulate inflammation, and by producing substances such as nitric oxide synthase (NOS, a synthase involved in arginine metabolism) and reactive oxygen species (ROS) (15, 34). While the characteristics of M2 macrophages tend to favor tissue repair and tumor progression. M2 macrophages exert anti-inflammatory effects by secreting anti-inflammatory cytokines, such as IL-4, IL-10, IL-13, and TGF- $\beta$ , and producing scavenger receptors and other substances; promoting proliferation, invasion and metastasis of tumor cells by inhibiting T-cell activity (15, 35, 36). The biological process of conversion between M1 (anti-tumor) and M2 (pro-tumor) in response to microenvironmental signals is termed “macrophage polarization” (35). Studies have shown that TAMs exist either two phenotypes on the tumor, for example, a study revealed that malignant melanoma TAMs as a heterogeneous phenotype with both M1 and M2 markers (37); However, the

term “TAMs” now mainly refers to M2 macrophages because the functional characteristics of TAMs are more similar to M2 macrophages rather than to M1 macrophages (38).

## TAMs recruitment

Expansion of tissue-resident TAMs and/or increased recruitment of monocyte-derived TAMs are important features of cancer. Cytokines, chemokines, growth factors, and other signals from tumor cells and stromal cells can induce the recruitment of TAMs to tumor sites (22, 39, 40). Several studies have found high levels of accumulation of tissue-resident macrophages and monocyte-derived macrophages in tumors such as glioblastoma, hepatocellular carcinoma and lung cancers (41–43). We therefore pondered whether the recruitment of TAMs also plays an important role in melanoma lung metastasis?

Colony-stimulating factor 1 (CSF-1), also known as macrophage colony-stimulating factor (M-CSF), is a secreted cytokine that differentiates hematopoietic stem cells into monocytes, macrophages, or other related cell types (44). CSF-1 acts as a major lineage regulator of macrophages and is also a recognized recruiter of macrophages. CSF-1 affects macrophages and monocytes through increased phagocytic, chemotactic activity and tumor cytotoxicity or other ways to affect macrophages and monocytes (44). Extensive overexpression of CSF-1 can be observed at the invasive edge of the various tumor, and it is involved in the polarization of M2 macrophages by interacting with its ligand CSF-1R; Its overexpression is also associated with a significant increase in metastasis (22, 45). Depletion of CSF-1/CSF-1R was shown to significantly inhibit tumor progression and metastasis in various tumor models (22, 44, 46). On the contrary, restoration of CSF-1 expression can accelerate tumor progression and metastasis in a CSF-1 mutant mouse xenograft model (46).

CCL2 is another well-established macrophage recruiter and M2 stimulator in addition to CSF-1. It is reported that CCL2 could induce the differentiation of macrophage into protumor phenotypes through CC chemokine receptor 2 (CCR2); In mouse tumor models such as colorectal cancer, prostate cancer, and melanoma, CCL2 recruit TAMs to tumor sites through ligand-receptor interactions with CCR2 or other forms of action (47–50). When the CCL2/CCR2 interaction was blocked, the metastatic dissemination of tumors in the mouse was significantly inhibited, the survival of the mouse was prolonged and the expression levels of tumor-promoting cytokines were reduced (47, 51). In a study by Xiaojing Chen, Yuanrun Deng et al. CCL8 act as another ligand for CCR2 was found to be highly overexpressed in human cervical cancer, which involved in the recruitment of TAMs in hypoxic regions (52). Moreover, the high expression of CCL2 in tumors such as esophageal carcinogenesis and clear cell renal cell carcinoma is associated with increased TAMs infiltration and metastatic events (53, 54).

It is well known that hypoxia promotes malignant tumor behavior through multiple mechanisms, including promoting glycolysis, antagonizing apoptosis, inducing immune escape, and inducing drug resistance, and is a common feature of most solid tumors (55–57). Studies have shown that hypoxia has an important impact on the recruitment of TAMs and that hypoxia captures disseminated macrophages by downregulating chemokine receptors expressed on macrophages (38). In addition, TAMs are recruited to the hypoxic TME through CCL2, VEGF-A, endothelin-2, semaphorin 3A (SEMA3A), stromal cell-derived factor 1 $\alpha$  (SDF1 $\alpha$ ), and oncostatin M, etc. (38, 58, 59). TAMs are involved in angiogenesis and tumor spread through upregulation of hypoxia-inducible factor (HIF)-1 $\alpha$  and HIF-2 $\alpha$  when they are recruited to the hypoxic environment (38). The recruitment of TAMs by hypoxia facilitates the conversion of the TME into more hospitable sites for a tumor cell.

Besides, ligand-receptor interactions such as CCL3/CCR1, CCL3/CCR5, CCL5/CCR5, CX3CL1/CX3CR1, and VEGF-A/VEGFR1 and chemokines such as CCL7, CCL8, CCL9, CCL18, CCL20, IL-13...all can contribute to the survival, progression, and metastasis of various tumor including melanoma by recruiting TAMs to TEM (40). For example, the chemokine CCL20 is recognized by the CCR6 ligand expressed in melanoma and promotes melanoma growth and metastasis *in vivo* (60). It is reasonable to speculate that the recruitment of TAMs has a potential role in pulmonary metastatic melanoma. We still further describe the source, function, classification, and

recruitment of TAMs in detail, as shown in Figure 1, hoping to better help readers understand the relevant definitions of TAMs.

## The roles of TAMs in pulmonary metastatic melanoma

### Pulmonary metastatic melanoma

Invasion and metastasis are the main causes of tumor death, and it is reported that the mortality caused by malignant tumor metastasis accounts for more than 90% of cancer mortality (61). Metastasis generally refers to the migration and spread of cancer cells from the primary sites to surrounding and distant organs; most malignant solid tumors could metastasize from the primary organ to other organs, such as the lung, liver, brain, and bone. Such a metastatic process is a gradual process termed the “metastatic cascade” (62). Like most solid tumors, melanoma also metastasizes to other organs. Early lymph node metastasis is one of the typical features of melanoma, the lung is one of the most common distant metastases of melanoma, and it is reported that about 18% of melanoma patients developed lung metastases during follow-up (63, 64). Moreover, the clinical prognosis of melanoma lung metastases is poor, and the 1-year survival rate of patients with melanoma lung metastases has been reported to be only about 30%-60% (65).

FIGURE 1

The source, function, classification, and recruitment of TAMs. The picture displayed that TAMs are derived from blood mononuclear cells from bone marrow hematopoietic stem cells, called monocyte-derived TAMs (or tumor-induced TAMs) and yolk sac progenitors, and reside in organs such as the lung, brain, liver, and skin. Macrophages polarized in tumors are divided into M1 (classically activated macrophages) and M2 (alternatively activated macrophages), and M2 macrophages can be further divided into M2a, M2b, M2c, and M2d subtypes. M1 macrophages are characterized by the secretion of pro-inflammatory cytokines involved in anti-infective responses, and the immunosuppressive phenotype of M2 macrophages tends toward tissue repair and tumor progression; TAMs are activated by cytokines, growth factors, etc. can be recruited to tumor sites.

Epithelial-mesenchymal transition (EMT) is the process by which epithelial cells acquire mesenchymal properties and is associated with multiple functions such as tumour progression, metastasis and drug resistance (66). Recently, a series of studies have shown that TAMs are involved not only almost in each step of the metastatic cascade, such as the formation of pre-metastatic ecological niches, infiltration of tumour cells, survival of circulating tumour cells, extravasation and colonization of tumour cells, but also in the regulation of the EMT process (12, 15, 67–69). TAMs exhibit many important biological functions from different aspects during tumor progression. Here, we mainly focus on the role of TAMs in the process of pulmonary metastasis of melanoma. TAMs are involved in almost every step of metastasis as described below, also shown in Figure 2.

## Pulmonary metastatic melanoma and TAMs

### TAMs promote invasion of melanoma tumor cells

Invasion is generally considered to be the initiation of tumor metastasis. EMT and TAMs plays an important role in tumor invasion. On the one hand, EMT is a major event in the morphological transformation of tumor cells that acquire the invasive ability to escape from the border of the basement membrane to the surrounding mesenchyme, which contributes to tumor cells invasion and metastasis (70). On the other hand,

compatibility factors secreted by TAMs, such as IL-8, TNF- $\alpha$ , and transforming growth factor- $\beta$  (TGF- $\beta$ ), are involved in the regulation of the EMT process and promote metastasis (67, 71).

Abundant shreds of evidence indicate that the proportion of TAMs infiltrating melanoma is increased, and the high expression level of macrophage markers in melanoma tissue is closely related to poor prognosis (72, 73). A study suggests that high levels of reactive oxygen species (ROS) in primary melanoma may increase cytokine-tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) secretion through MAPK/ERK kinase 1-mediated peroxisome proliferator-activated receptor  $\gamma$  (PPAR $\gamma$ ) translocation to the nucleus, and it thus enhanced the invasion of TAMs in melanoma (37). These studies all provide favorable evidence to support the idea that TAMs promote invasion and cause melanoma lung metastasis.

### TAMs promote vascularization of melanoma tumor cells

The process of forming new blood vessels from existing blood vessels is called angiogenesis. Angiogenesis is a vital condition for tumor cell proliferation and generation (74). Many tumors, including melanoma, metastasize through the vascular system and/or the lymphatic system. Existing evidence strongly supports that TAMs drive tumor angiogenesis through vascular endothelial growth factor (VEGF) matrix metalloproteinase (MMP9); TAMs stimulate the remodeling of established vasculature into a more tortuous and leaky form, which is beneficial to tumors dissemination of cells (15, 75, 76). When TAMs are absent, vessel density can be reduced by approximately 40% (76). In addition,

FIGURE 2

TAMs are involved tumor metastasis. The picture illustrated that TAMs are involved in every step of the metastatic cascade, including the formation of pre-metastatic ecological sites, invasion of tumor cells, survival of circulating tumor cells, extravasation and colonization of tumor cells, and the involvement of TAMs in regulating the epithelial-mesenchymal transition (EMT) process that promotes the formation of liver, brain, lung, bone and lymph node metastases.

studies have shown that pro-angiogenic molecules such as nitric oxide (iNOS), MMP7, CXCL8, IL1, and fibroblast growth factor (FGF)-2 can regulate tumor angiogenesis through TAMs (75, 77).

Studies show that the process of VEGF-C (tumor overexpressed ligand)/VEGFR-3 (receptor for VEGF-C expressed on TAMs) promotes lymphangiogenesis by directly affecting the activity of lymphatic endothelial cells (lymphatic endothelial cells) or indirectly increasing the secretion of ductal proteins to promote lymphangiogenesis, which supports the hypothesis that lymphangiogenesis is closely related to TAMs and also further suggests that TAMs play an important role in tumor invasion and metastasis (78, 79). The research carried out by Peiwen Chen et al. shows that TAMs promote angiogenesis and melanoma growth through paracrine and autocrine adrenomedullin. When adrenomedullin levels are reduced or secretion is inhibited, angiogenesis and melanoma growth *in vivo* are correspondingly inhibited (80). Monocyte chemoattractant protein-1 (MCP-1) is a member of the CC-motif chemokine family (as CCL2); MCP-1, a chemokine, is also one of the key agonists in the recruitment of macrophages to tumor sites (81). Both *in vivo* and *in vitro* studies have demonstrated that MCP-1 triggers a rich vascular network through M2 macrophages, and targeting TAMs to inhibit MCP-1 reduces angiogenesis and tumor growth in human melanoma xenografts (47).

Taken together, TAMs play an important role in regulating tumor angiogenesis and promote the vascularization of tumor cells (including melanoma cells) through different pathways, which may provide some explanation for melanoma lung metastasis.

### TAMs promote the intravasation, survival in the circulation, and extravasation of melanoma tumor cells

Intravasation is defined as the process by which tumor cells leave the primary tumor and enter the circulation (generally into the blood circulation); tumor cells that enter the circulation survive and participate in the circulation and then leave the circulatory system, and the process of entering the secondary site from the primary tumor is called extravasation (82). Intravasation, survival, and extravasation of tumor cells in the circulatory system are all important steps in the cascade of events leading to tumor metastasis. Multiphoton *in vivo* imaging experiments showed that macrophages were mainly concentrated in the periphery of the tumor, and the density of macrophages in the center of the tumor decreased; the macrophages in the tumor were localized to the blood vessels and assisted the intravasation of tumor cells (83). Another study found that the intravasation of tumor cells was always accompanied by macrophages within one cell diameter (84). These studies provide strong evidence that TAMs enhance the ability of cancer cells to invade adjacent normal tissue.

Clinical observations suggest that the tumor metastasis microenvironment (TMEM) is composed of tumor cells, TAMs,

and endothelial cells (15). In TMEM, TAMs can produce EGF (epidermal growth factor) and secrete chemokine CCL18, and tumor cells can also secrete chemokine CCL18 and produce cytokine CSF-1, all of which play important roles in the process of tumor cell invasion. For example, a study by Jingqi Chen et al. found that CCL18 secreted by TAMs in breast cancer induces integrin accumulation in cancer cells, which further promotes the adhesion of integrin-aggregated cancer cells to the extracellular matrix and then intravasation (85). The chemokine CCL18 produced by melanocytes itself can be increased and released under the induction of long non-coding RNA (LncRNA) CRNDE, and promote the proliferation, invasion, and metastasis of melanoma (86).

Tumor cells, which intravasated the circulation, also need to survive and circulate in the circulatory system. On the one hand, tumor cells evade recognition and killing by cytotoxic immune cells by clustering with platelets in the circulatory system; On the other hand, the survival of many tumor cells is protected by chemokines or cytokines secreted by macrophages (87, 88). Regarding the involvement of TAMs in tumor cell extravasation and tumor cell colonization, existing evidence supports that when tumor cells interact, macrophages have a higher extravasation rate. Therefore, the number of tumor cells that occurs extravasation was significantly reduced when macrophages are depleted (89).

Are TAMs also involved in promoting the endocytosis, circulating survival and extravasation of melanoma cells during pulmonary metastasis of melanoma? Based on the results of the above-mentioned studies, we believe that the answer is more than likely also in the affirmative.

### TAMs prepare sites for melanoma tumor cells: pre-metastatic niches

The favorable microenvironment created by the primary tumour for secondary organs and/or tissues to which it subsequently metastasizes (metastatic target organs or tissues) is known as the pre-metastatic niche (PMN). The PMN is initiated and established through a complex interaction between growth factors, inflammatory factors, chemokines, bone marrow-derived cells and local stromal components in the primary tumour (90). Studies have shown that macrophages are one of the key determinants of PMN formation. Tissue-resident TAMs, such as osteoclasts and alveolar macrophages, are involved in PMN formation (91, 92). What's more, soluble mediators such as CSF-1, VEGF, TGF- $\alpha$ , and exosomes and tissue inhibitors of metalloproteinase (TIMP) that are involved in the recruitment of TAMs can also mobilize TAMs to aggregate in PMNs (92).

TAMs interact with dendritic cells (DC) and T helper cells (Th1 cells), impairing the antigen presentation and antitumor behavior of these immune cells; TAMs regulate tumor angiogenesis and extravasation through matrix-derived factors

(SDFs) and matrix metalloproteinases, etc., which in turn promote the formation of PMNs from tumor cells (CTCs) (15, 92, 93). Considering the preferential metastasis of lung-homing melanoma cells in melanoma metastasis and the important regulatory role of PNM in tumor metastasis, it is reasonable to speculate that TAMs and soluble mediators play an important role in melanoma lung metastasis by promoting PMN formation.

## TAMs regulation and pulmonary metastasis melanoma

It has been reported that affecting TAM regulation at the transcriptional, epigenetic and metabolic levels could be an effective cancer treatment modality. The regulation of TAMs can influence its production, phenotype, and function, which in turn affect tumor development and metastasis, and drug resistance. The clinical application of corresponding activators or inhibitors for different regulatory modalities and related pathways is expected to target TAMs to improve the efficacy of tumor immunotherapy. We present the modalities of TAMs regulation in Figure 3.

We speculate whether regulating the production, phenotype and function of TAMs influence pulmonary metastasis from melanoma. Accordingly, does the application of activators or inhibitors that modulate key factors also improve the efficacy of therapy for lung metastases from melanoma?

## Epigenetic regulation of TAMs and pulmonary metastasis melanoma

Epigenetics refers to developmental or environment-induced modifications that control the expression of information encoded in DNA in a tissue- and environment-specific manner without altering the genetic code (94). Various cellular functions, such as cell differentiation, cell activation, and transformation, are regulated by epigenetic changes in gene expression. Epigenetic dynamics of DNA methylation and histone modifications (such as methylation, acetylation, and phosphorylation) are associated with altered gene expression (95). The development, polarization, and activation of macrophages are also controlled by DNA and histone modifications. For example, DNA methylation and myeloid differentiation, Histone modifications in M1 macrophage activation, and M2 macrophage polarization by Jmjd3 (an H3K27-specific demethylase) are currently clear mechanisms for the epigenetic regulation of macrophage phenotype and function (96). In addition to the epigenetic effects of DNA methylation and histone modification on the phenotype and function of TAMs, emerging data suggest that epigenetic changes in noncoding RNAs also have regulatory effects on TAMs. For example, many miRNAs involved in the production of IL-10 and the expression of PD-L1 in TAMs exert immunosuppressive effects in an epigenetic manner, helping to identify new therapeutic targets and providing a research reference for improving tumor sensitivity to immune responses (97).

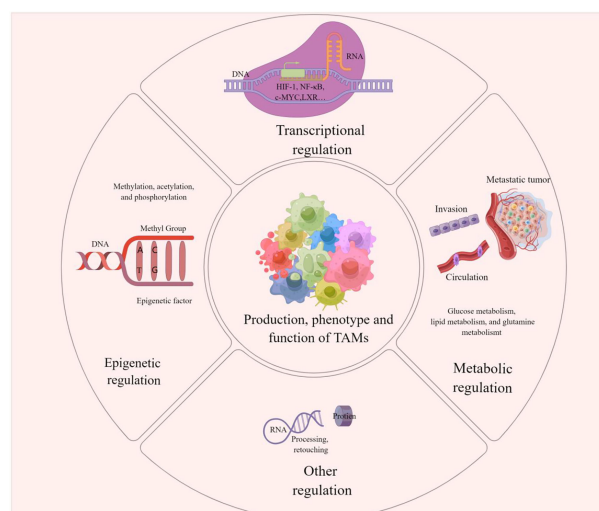

FIGURE 3

TAMs regulation This picture demonstrates that the production, phenotype and function of TAMs are regulated in epigenetic, transcriptional, metabolic or other different ways. These modulations influence tumorigenesis, metastasis and drug resistance on Pulmonary metastases in melanoma can also be influenced by the regulation of TAMs.

It is noteworthy that changing epigenetic regulation in macrophages selectively targets M2 macrophages and removes tumor-promoting TAMs while retaining only tumor-suppressed M1 macrophages (98, 99). Pharmacological modulators of many epigenetic enzymes are currently in clinical use and can be used to treat tumors with high TAM infiltration (99). Much research has been done on the epigenetic enzymes of M1s and their regulators, but much less is known about the epigenetic regulation of M2s, especially about cancer (99).

Taken together, epigenetic regulation affects tumorigenesis, progression, and metastasis by affecting the phenotype and function of TAMs. Given that melanoma is also one of the tumors subject to epigenetic regulation, it is reasonable to speculate that epigenetic regulation in TAMs may be an important reference direction for studying the mechanism and treatment of pulmonary metastatic melanoma.

## Transcriptional regulation of TAMs and pulmonary metastasis melanoma

It is well known that malignant tumors usually have hypoxia, and the activation of two transcription factors, hypoxia-inducible factor-1 (HIF-1) and nuclear factor kappa b (NF- $\kappa$ B) is closely related to the occurrence of hypoxia. Circulating hypoxia affects the expression of angiogenesis-inducing cytokines such as VEGF-A, CCL2/MCP-1, etc., and recruits various cells into the tumor niche, where they are transformed into tumor-associated macrophages (TAM) involved in tumorigenesis, etc. Through the regulation of transcription factors HIF-1 and NF- $\kappa$ B and their related pathways, regulating the generation of TAMs may be one of the potential tumor-targeted therapeutic options (100). STAT-3 is also one of the key factors to initiate the transcriptional program of TAMs (101). In addition, research shows that transcription factor EB (TFEB) expression is significantly reduced in breast cancer. TFEB controls the phenotype and function of TAMs through multiple autophagy/lysosome-dependent and independent pathways, thereby promoting breast tumor development; Conversely, activation of TFEB is expected to be a target for TAMs for tumor immunotherapy strategies including breast cancer (102). The Liver X receptor (LXR) is one of the transcription factors in the nuclear receptor family that is activated by oxysterols and synthetic high-affinity agonists; A study shows that in a mouse model of lung cancer, pharmacological LXR activation can regulate TAM gene expression, thereby exerting an anti-tumor effect (103). In addition, studies show that the transcription factor c-Maf is a key controller of immunosuppressive macrophage polarization and function in cancer; Numerous M2 macrophage-related genes are controlled by c-Maf, which in turn promotes M2 macrophage-mediated T cell suppression and tumor progression. In a subcutaneous LLC tumor model, inhibition

of c-Maf partially overcomes resistance to anti-PD-1 therapy; Likewise, c-Maf is expressed in human M2 and tumor-infiltrating macrophages/monocytes as well as circulating monocytes in human non-small cell lung cancer (NSCLC) patients and plays an important role in regulating its immunosuppressive activity (104).

Overall, various transcription factors including c-MYC, LXR, TFEB, etc., regulate the phenotype and function of TAMs in solid tumors such as lung cancer and breast cancer, thereby affecting tumor progression and metastasis. The clinical application of corresponding transcriptional activators or transcriptional inhibitors is expected to provide a new strategy for targeting TAMs in the treatment of tumors. Lung metastatic melanoma derived from melanoma has a close relationship with TAMs. The role of TAMs in pulmonary metastatic melanoma through transcriptional regulation needs more research, which not only contributes to providing a certain explanation for the development of pulmonary metastatic melanoma but may also provide possible strategies for targeting TAMs in the treatment of pulmonary metastatic melanoma.

## Metabolic regulation of TAMs and pulmonary metastasis melanoma

As an important immune cell in TME, TAMs are closely related to poor tumor prognosis, drug resistance, enhanced angiogenesis, and tumor metastasis; A complete interpretation of the pro-tumor and anti-tumor metabolic switches in TAMs is critical for understanding immune escape mechanisms in cancer (105). Currently, a few of researches have been done on the intertwined relationship between metabolism and macrophages in the context of cancer, and the interaction between the two is not fully defined. Considering that pulmonary metastatic melanoma is closely related to TAMs like many solid tumors, the study of the regulation of TAMs may provide some explanation for the mechanism of pulmonary metastatic melanoma and its therapeutic direction.

A tumor hypoxic environment induces transcription of genes related to glucose and nitrogen metabolism. Hypoxia of the TME increases the levels of arginase-1 and mannose receptor (CD206) on TAMs, and TAMs present in hypoxic regions induce the expression of HIF-1 $\alpha$ , which induces a switch to glycolytic fermentation (106). Furthermore, a study shows that hypoxic TAMs strongly upregulated the expression of Redd1 (a TOR complex 1-MTORC1 inhibitor), a negative regulator of the mechanistic target of rapamycin (mTOR, a key nutrient, and energy sensor); Metabolic changes promote tumor angiogenesis and metastasis by inhibiting the glycolysis of hypoxic TAMs, inhibiting their angiogenesis and immunosuppressive effects (107). Moreover, exosomes derived from tumor cells can affect the differentiation of macrophages by altering the miRNA profiles of TAMs. For example, in the study of ovarian cancer,

it was found that hypoxia induced the expression of miR-940 in tumor exosomes and stimulated macrophages polarized toward the M2 phenotype; This also suggests that the metabolic program in TAMs is a combination of hypoxia and cytokines in the microenvironment (108, 109). Glucose metabolism, lipid metabolism, and glutamine metabolism all play an important role in the regulation of TAMs metabolism, and therapeutics targeting metabolic pathways in TAMs is also one of the alternative strategies for cancer treatment (105).

In general, some studies have shown that metabolic alterations of TAMs in a variety of solid tumors promote or inhibit their progression and metastasis. The metabolic effects on substances such as sugar and liposomes in melanoma TEM may also cause alterations in TAMs, which may affect melanoma lung metastasis. How alterations in the metabolism of TAMs affect their phenotype and function, and their impact on tumor growth and metastasis, including melanoma, remains to be revealed by more studies. The role of metabolic regulation of TAMs in pulmonary metastatic melanoma is also worthy of further investigation, as this may provide possible mechanistic explanations and even potential therapeutic targets for pulmonary metastatic melanoma.

## TAMs targeted treatment strategies in pulmonary metastatic melanoma

As a key component of TEM and/or TMEM, TAMs infiltration is closely related to the survival rate and poor

prognosis of tumor patients, and targeting TAMs is becoming an attractive tumor therapeutic intervention strategy (19, 60, 110). Multiple studies have demonstrated that inhibiting the recruitment or proliferation of TAMs, TAMs depletion, TAMs reprogramming, and targeting TAMs-related immune checkpoints are all effective strategies to target TAMs for tumor therapy, the specific treatment methods are shown in Figure 4.

### Inhibiting the recruitment or proliferation of TAMs

The recruitment or proliferation of TAMs, which cause the number of TAMs to increase, is a key link in promoting the occurrence, development, and metastasis of tumors. Inhibiting the recruitment or proliferation of monocyte-derived TAMs is considered to be an effective anti-tumor therapeutic strategy targeting TAMs.

Targeting the soluble mediators CSF-1/CSF-1R and CCL2/CCR2, which induce recruitment of TAMs as described above, are currently the main potential targets to inhibit recruitment of TAMs for antitumor effects (111). CSF-1 (CSF-1) interacts with its ligand CSF-1R to promote tumour progression and metastasis by participating in the phenotypic differentiation of M2-type macrophages. Anti-CSF-1R antibodies and CSF-1R inhibitors retard tumour progression by regulating the polarization of TAMs (112, 113). Currently, CSF-1R inhibitors such as PLX3397 and ARRY-382 and anti-CSF-1R antibodies

FIGURE 4

TAMs targeted treatment strategies The picture showed that inhibition of recruitment or proliferation of TAMs, depletion of TAMs, reprogramming of TAMs and targeting of TAMs-associated immune checkpoints are all capable of targeting TAMs for effective anti-tumor therapy. These strategies can likewise be referred to for targeting TAMs for the treatment of pulmonary metastatic melanoma.

FPA008 and RG7155 are under clinical development or evaluation (114–116). In the mouse xenograft model, the combination of CSF-R inhibitor and anti-PD-1 antibody showed a good therapeutic effect on melanoma (117).

Targeting the CCL2/CCR2 axis exhibits antitumor therapeutic effects by inhibiting the recruitment and polarization of TAMs. The anti-CCL2 antibody Carlumab (CNT0888) can cause a temporary decrease in the level of CCL2 in patients with prostate cancer so that the patient's disease state can be stabilized (118); CCR2 inhibitor PF-04136309 Combined with FOLFIRINOX (Oxaliplatin + Irinotecan + Leucovorin + Fluorouracil), the clinical outcome of patients with pancreatic adenocarcinoma was significantly improved (18). However, there may also be side effects, when CCR2 inhibitors are combined with chemotherapy or another therapeutic method (119). In a mouse melanoma model, combined treatment of CCR2 inhibitor RS504393 and anti-PD-1 improved the efficacy of melanoma lung metastases in mice (120).

In addition, targeting the CD40 receptor, targeting CX3CL1/CX3CR1, etc. have also been revealed to exert anti-tumor effects by effectively inhibiting the recruitment or proliferation of TAMs (111, 121, 122). CD40, which is expressed on antigen-presenting cells such as dendritic cells, is a member of the TNF receptor superfamily. CD40 plays an anti-tumor effect by promoting the activation of anti-tumor T cells and the polarization of M1 phenotype cells (123). Usually CD40 agonists are used in combination with anti-CSF-1R antibodies to enhance anti-tumor responses by inducing an increase in pro-inflammatory macrophages and eliminating the effects of populations that cause suppressive immune responses (124). For example, a phase I trial of the CD40 agonist APX005M (sotigalimab) and cabiralizumab in combination or not with the PD-1/PD-L1 inhibitor nivolumab for the treatment of anti-PD-1/PD-L1 resistant melanoma, kidney cancer and non-small cell lung cancer (125). There are also multiple clinical trials underway with anti-CD40 antibodies and recombinant CD40 ligands, alone or in combination with other treatments. Such as SGN-40, SEA-CD40, ADC-1013, etc (126).

Overall, Antibodies or small molecules targeting TAMs, alone or in combination with other therapeutic modalities, to inhibit the recruitment or proliferation of TAMs have proven to be a promising therapeutic technique for the treatment of solid tumors including melanoma lung metastases. However, inhibiting the recruitment or proliferation of TAMs also has side effects, so other strategies to target TAMs are also in full swing.

## Depletion of TAMs

Since TAMs are involved in different stages of cancer development and progression, reducing or depleting TAMs is

an attractive cancer treatment strategy. Elevated TAM numbers in TEM are often associated with poor prognosis in melanoma patients, therefore, reducing or depleting TAMs can be an effective targeted therapy for melanoma (127, 128).

Numerous of antitumor drugs have cytotoxic effects on TAMs while killing tumor cells (31, 129). Non-cytotoxic doses of commonly used chemotherapeutic drug paclitaxel have been reported to have inhibitory effects on immunosuppressive macrophages in mouse melanoma models, reducing bone marrow-derived suppressor cells (MDSCs), and even blocking the immunosuppressive potential of MDSCs (130). Due to the short biological half-life and renal toxicity of the drug itself, the direct use of TAMs cytotoxic drugs is limited. Combining TAMs cytotoxic drugs with nanomaterials can effectively improve the above problems (131–134). For example, novel clodronate-containing liposomes significantly reduced the number of lung nodules in a B16/F10 lung metastatic melanoma model; This study demonstrated that deletion of TAMs exhibited antitumor effects in metastatic melanoma by inhibiting angiogenesis and regulating inflammation-related cytokines (127). In addition, inhibition of M-CSF receptors can also deplete TAMs and enhance antitumor therapeutic effects (135).

In general terms, TAMs depletion therapy holds great potential as novel cancer (including pulmonary metastatic melanoma) treatment. However, the therapy has also caused a reduction in the number of systemic macrophages, which are the first line of defense for the innate immune response, which can cause adverse effects on the organism (131, 132, 136). Nanomaterials that reduce or deplete TAMs could largely limit the adverse effects of this therapeutic approach on the organism, and as such, much research is underway to target TAMs depleting nanomaterials, which also promises to provide better options for treating lung metastases from melanoma.

## TAMs reprogramming

Due to the plasticity of macrophages themselves and the functional characteristics of TAMs more similar to M2 (pro-tumorigenic) macrophages rather than to M1 (anti-tumorigenic) macrophages, reprogramming M2-like macrophages into M1-like macrophages (also known as “repolarization”) is one of the most attractive antitumor therapeutic modalities for targeting TAMs.

Activation of CD206 (mannose receptor) and toll-like receptors (TLRs) plays an important role in the repolarization of M2 macrophages to M1 macrophages. Studies have shown that activation of CD206 promotes the conversion of M2 to M1 through endocytosis, phagosome-lysosome formation, and autophagy, and enhances the phagocytosis of tumor cells (137). Moreover, studies have shown that the U.S. Food and Drug Administration (FDA)-approved clinical TLR agonist TLR

agonist Imiquimod has shown significant antitumor activity in preclinical models of melanoma (138, 139). Another study revealed that the FAD-approved cancer-common chemotherapy drugs sorafenib and paclitaxel can cause repolarization of TAMs (140, 141). Furthermore, if NF- $\kappa$ B inhibition, TAMs differentiate into M2 macrophages, and upon NF- $\kappa$ B activation, TAMs can be redirected to an M1-like phenotype with tumoricidal activity. Studies suggest that immunomodulators such as type I IFN (IFN- $\alpha$ , IFN- $\beta$ ) and type II IFN (IFN- $\gamma$ ) are effective in repolarizing TAMs in skin tumors such as melanoma (142, 143). It has been reported that the M2-specific clearance receptor MARCO is associated with poor prognosis in malignant tumors such as non-cellular lung cancer and metastatic melanoma, suggesting that targeting MARCO may promote the repolarization of M2 macrophages to M1 macrophages (144).

Overall, reprogramming of TAMs is showing promise as a novel anti-tumor targeted therapeutic strategy for advanced or metastatic tumors including melanoma lung metastases. However, clinical data on the therapeutic effect of repolarizers are limited, and more strong evidence is needed to support the efficacy and safety of repolarizers.

## Targeting TAMs-associated immune checkpoints

Immune checkpoint inhibitors (ICIs) are a promising tumor immunotherapy approach for a variety of advanced/metastatic solid tumors, including melanoma, and are now widely accepted by clinicians (145, 146). Numbers of literature show that TAMs involvement in the failure of anti-tumor immune surveillance, as well as the failure of ICIs immunotherapy (146), suggests that targeting TAMs-related immune checkpoints can provide more options for tumor immunotherapy.

Immune checkpoint molecules such as programmed cell death 1 (PD-1), programmed cell death protein ligand 1 (PD-L1) and cytotoxic T lymphocyte-associated protein 4 (CTLA-4) are the most common immune checkpoints in clinical practice's target. Anti-PD-1/PDL-1 or anti-CTLA-4 therapy mainly maintains an effective immune system against cancer cells by activating tumor-specific cytotoxic T cells (147, 148). One study found that TAMs expressed PD-1 in both mouse and human tumor models; the phagocytic ability of TAMs in a mouse tumor model was negatively correlated with PD-1 expression. When PD-1/PD-L1 expression was inhibited, the phagocytic ability of TAMs *in vivo* was increased, tumor growth was delayed, and mouse survival was prolonged (149). In addition, studies have shown that a specific metabolic enzyme, indoleamine 2,3-dioxygenase (IDO), is involved in T cell exhaustion, which can serve as a target to avoid TAMs-mediated immune escape and improve anti-ICIs

efficacy. The combination of IDO and pembrolizumab has good efficacy in the treatment of advanced and metastatic melanoma, and it is worthy of further evaluation (150). A completed Phase 1/2 clinical trial (NCT02073123) of the IDO inhibitor indoximod in combination with ICIs (ipilimumab, pembrolizumab, and nivolumab) in adult patients with metastatic stage III/IV melanoma, the results of the study showed that although the combined treatment method had side effects of fatigue, nausea, and itching, the patients showed good tolerability and efficacy.

Taken together, targeting TAMs-related immune checkpoints has attracted much attention as one of the options for tumor immunotherapy or adjuvant therapy. Regarding the targeting of immune checkpoints related to TAMs, there are not only many mechanism studies but also several clinical trials underway. Immunotherapy is still the common clinical treatment modality for melanoma, especially for advanced and metastatic melanoma. Can targeted TAMs therapy improve the efficacy of conventional immunotherapy? This is undoubtedly worthy of investigation and anticipation.

## Other TAMs targeted therapy strategies and pulmonary metastatic melanoma

Targeted anti-tumor therapy for TAMs in addition to the above-mentioned methods, for example, because TAMs play a key role in angiogenesis and phagocytosis in the process of tumor development and metastasis, there are also corresponding targeted therapy methods (122).

Studies suggested that milk fat globule epidermal growth factor 8 (MFG-E8) promotes melanoma growth by stimulating mesenchymal stromal cell-induced angiogenesis and the differentiation of TAMs to the M2 phenotype, so targeting MFG-E8 to inhibit melanoma angiogenesis may be one of the effective targets for anti-melanoma therapy (151). Monocyte chemoattractant protein (MCP)-1, a chemokine, is one of the key agonists for attracting macrophages to tumors, and a study shows that in melanoma xenografts, inhibition of MCP-1 can inhibit TAMs recruitment and anti-angiogenesis, which is a highly anticipated melanoma therapeutic target (47). In addition, studies revealed a new mechanism by which TAMs promote angiogenesis and melanoma growth through derived adrenomedullin (ADM), which is expected to provide a potential target for melanoma therapy (80).

TAMs have a good phagocytic function for nanomaterials. Studies show that some nanomaterials can induce the intrinsic activity of macrophage phenotype differentiation so that TAMs can repolarize to the M1 phenotype to achieve the purpose of anti-tumor therapy (152, 153). For example, a hyaluronic acid-coated, mannan-conjugated MnO<sub>2</sub> nanoparticle (Man-HA-

MnO<sub>2</sub> NPs) repolarized TAMs to the M1 phenotype, alleviated tumor hypoxia by significantly enhancing tumor oxygenation, and thus Anti-tumor therapeutic effect; and this nanomaterial combined with doxorubicin can synergistically inhibit the growth and proliferation of tumor cells (154). Nanomaterials can also resist the progression of melanoma by anti-tumor angiogenesis and other means (94, 154, 155).

The above studies suggest that targeting TAMs therapy is an attractive and potential cancer treatment strategy. However, the specific choice of a treatment strategy for melanoma lung metastases or other different types of tumors should be based on the actual situation of the tumor and the role of targeted TAMs.

## Conclusion and perspective

It is generally believed that macrophages play an important role in the development and metastasis of various solid tumors, including melanoma. Early dissemination and late multi-organ metastasis colonization are typical features of melanoma. Among the multiple organs that skin melanoma may colonize, the lung is one of the most common distant metastatic sites of melanoma. Lung metastases from melanoma account for 5% of all malignant metastases and have a high lethality rate. The macrophages involved in the lung metastasis of melanoma can refer to the macrophages in the occurrence and development of other tumors, and their sources may be monocyte-macrophages or tissue sources. Generally divided into two types: M1 macrophages and M2 macrophages. M1 has pro-inflammatory and anti-tumor properties, while M2 has anti-inflammatory and pro-tumor properties. TAMs are considered to belong to the M2 phenotype because their functions in promoting tumorigenesis, tumor angiogenesis, and metastasis are more similar to M2 macrophages.

Several studies have revealed the effect of TME on tumorigenesis and development and the effect of TMEM on tumor metastasis. TAMs, as the main component of the TME and TMEM, is a complex heterogeneous population of cells that contribute to the malignant features of solid tumors. This paper summarizes the role of TAMs in promoting tumor cell invasion and in participating in various steps of the tumor metastasis cascade, and the ways in which regulation such as epigenetics affects the function of TAMs and thus tumor progression and metastasis, which may provide some explanation for the role of TAMs in melanoma lung metastasis. In addition, the heterogeneity and specificity of TAMs lay the foundation for the development of therapeutic approaches targeting TAMs. In this paper, we also

summarized anti-tumor therapeutic approaches targeting TAMs such as, inhibiting the recruitment and proliferation of TAMs, depleting TAMs, reprogramming TAMs and targeting angiogenesis. It is also worth noting that in solid tumors including melanoma, both basic and clinical trials on TAMs are in full swing, suggesting that targeting TAMs strategies are expected to form a precise treatment and will be a valuable anti-tumor treatment strategy in the future.

In conclusion, TAMs have diverse functions in TME and TMEM and play complex roles in various solid tumors. Studying the role of TAMs in the process of melanoma pulmonary metastasis and the therapeutic strategies targeting TAMs is expected to provide more possible mechanism explanations and treatment options for melanoma pulmonary metastasis.

## Author contributions

KX and SC drafted an outline of the manuscript. KX drafted the abstract, generated the figure, and edited the manuscript. MQ drafted the discussion and edited the manuscript. TS edited the manuscript. JZ added to and edited the manuscript. All authors contributed to the article and approved the submitted version.

## Funding

This work was supported by the National Natural Science Foundation of China (under Grants 82073018, and 82073019) and also funded by the Shenzhen Science and Technology Innovation Committee (JCYJ20210324114212035).

Acute myeloid leukemia (AML) is a highly heterogeneous malignancy of the blood and bone marrow, characterized by clonal expansion of myeloid stem and progenitor cells and rapid disease progression. Chemotherapy has been the first-line treatment for AML for more than 30 years. Application of recent high-throughput next-generation sequencing technologies has revealed significant molecular heterogeneity to AML, which in turn has motivated efforts to develop new, targeted therapies. However, due to the high complexity of this disease, including multiple driver mutations and the coexistence of multiple competing tumorigenic clones, the successful incorporation of these new agents into clinical practice remains challenging. These continuing difficulties call for the identification of innovative therapeutic approaches that are effective for a larger cohort of AML patients. Recent studies suggest that chronic immune stimulation and aberrant cytokine signaling act as triggers for AML initiation and progression, facets of the disease which might be exploited as promising targets in AML treatment. However, despite the greater appreciation of cytokine profiles in AML, the exact functions of cytokines in AML pathogenesis are not fully understood. Therefore, unravelling the molecular basis of the complex cytokine networks in AML is a prerequisite to develop new therapeutic alternatives based on targeting cytokines and their receptors.

## KEYWORDS

acute myeloid leukemia, cytokine signaling, inflammation, tumor microenvironment, cytokine inhibitors

## Introduction

Acute Myeloid Leukemia (AML) is a highly aggressive and heterogenous hematological cancer characterized by the accumulation of molecular and cytogenetic mutations within hematopoietic stem and/or progenitor cells (HSPCs), leading to the establishment of leukemic stem cells (LSCs). LSCs are the source of immature myeloid progenitor cells, so-called myeloblasts or leukemic blasts, which accumulate in the bone marrow (BM), displace normal HSPCs, impair normal hematopoiesis, and eventually

spread into the peripheral blood (PB), lymph nodes, liver, spleen, testes, and central nervous system (1–4). Whereas many AML patients follow an aggressive clinical course with an overall 5-year survival rate of only 28%, individual patient survival strongly depends on the underlying tumor-driving genetic alterations and individual risk factors, including age, gender, prior chemotherapy, radiation exposure and genetic predisposition (1, 2, 5–8). However, irrespective of the molecular driver mutations initiating the disease, AML onset and development always go hand in hand with significant remodeling of the BM into a tumor-promoting microenvironment that supports and protects LSCs at the expense of normal HSPCs (9–15). In this review we discuss how cytokine signaling networks contribute to these maladaptations, fuel AML tumorigenesis and progression, and enable chemoresistance and immune evasion. We further shed some light on promising therapeutic approaches targeting cytokine signaling to irradiate the LSC population and prevent relapse after chemotherapy.

## Role of cytokines in AML

Within the healthy BM microenvironment, hematopoietic stem cells (HSCs) are normally maintained in a delicate balance between quiescence, self-renewal, and differentiation to ensure life-long steady-state hematopoiesis and replenishment of the blood effector cell population under stress conditions such as infection, acute and chronic inflammation, aging or bleeding (16). During infection and inflammation, an array of cytokines, including Interleukin (IL)-1 $\beta$  (17, 18), IL-3 (19, 20), IL-6 (21–23), Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) (24–27) and Interferon (IFN) (28, 29) together with hematopoietic growth factors (HGFs) such as M-CSF, G-CSF and GM-CSF (17, 30), orchestrates the switch from steady-state to emergency hematopoiesis (31–33). In patients with preleukemic and leukemic conditions, including AML, the tight regulation of these cytokines is impaired, leading to aberrant cytokine secretion (32–38). Studies evaluating pro- and anti-inflammatory cytokine and growth factor levels in serum revealed that GM-CSF, IL-1 $\beta$ , IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12p70, IL-27, IL-35, osteopontin and stem cell factor (SCF) are upregulated in all or in distinct AML patient groups compared to age-matched controls (39–43). In contrast to most cytokines, TRAIL and TGF- $\beta$  levels are decreased in the serum of AML patients (39, 43, 44). To gain insights into the specific functions of individual cytokines and growth factors in AML, numerous studies have characterized the effects of recombinant cytokines and HGFs on proliferation and colony formation of primary AML cells and cell lines *in vitro*, thereby establishing *ex vivo* AML cell culture conditions (see Table 1).

Suggestive of a supportive feedback loop, some patient-derived LSCs and blasts can produce a variety of cytokines

(e.g., IL-1 $\beta$ , IL-1 $\alpha$ , IL-6, GM-CSF, and TNF- $\alpha$ ) and proliferate *in vitro* without the addition of exogenous cytokines and HGFs (99–101). In particular, IL-1 $\beta$  was shown to act as an autocrine growth factor for AML blasts by inducing the production of HGFs and cytokines, including GM-CSF and IL-6 (50, 59, 99, 102–105). Moreover, IL-1-stimulated AML blast cells secreted increased levels of TNF- $\alpha$ , which synergized with IL-3- or GM-CSF-induced AML cell proliferation and colony formation (106). Of note, increased autonomous and/or HGF- and cytokine-induced *in vitro* proliferation of patient-derived leukemic cells correlated with negative clinical outcomes, including lower complete remission rates, higher risk for relapse, and shorter AML patient survival (107–109). *In vivo*, however, LSC and blast growth, survival, and protection from therapeutic agents do not exclusively rely on endogenous cytokine signaling, but strongly depend on AML cell interactions with the leukemic BM microenvironment and the latter's provisioning of supporting ligands and soluble factors, including cytokines (Figure 1), some of which are discussed in the following sections (110).

## AML supporting cytokines

### Osteopontin

Osteopontin, a secreted matrix glycoprotein produced by many cell types (e.g., stomal, endothelial, epithelial and immune cells), is crucial for the regulation and/or induction of inflammation, angiogenesis, proliferation, migration, and apoptosis throughout the body. During normal hematopoiesis, osteopontin is predominantly produced by osteoblasts within in the endosteal BM region, to guide and maintain healthy HSCs within supportive niches (111). Interestingly, PB and BM osteopontin levels were significantly increased in AML patients compared to healthy controls, and high osteopontin BM levels were associated with reduced overall and event-free survival (82, 83). Osteopontin was not, however, exclusively expressed by cells of the osteolineage within the leukemic BM, although it was strongly expressed by AML blasts (82). Additionally, it was shown that AML patient-derived mesenchymal stromal cells (MSCs) or healthy MSCs co-cultured with AML cells undergo osteogenic differentiation and produce increased amounts of osteopontin (112). Functionally, osteopontin was shown to upregulate AKT, mTOR, PTEN, and  $\beta$ -catenin mRNA expression in AML cells *in vitro* (113) and increase AML LSC self-renewal, proliferation, and expression of anti-apoptotic and cell-cycle-associated genes, thereby leading to accelerated disease progression in an MLL-AF9 driven AML mouse model (84). Direct targeting of osteopontin is difficult due to its ubiquitous expression and, so far, has been limited to approaches utilizing RNAi or blocking antibodies and aptamers in breast cancer models. Although delivered without specificity to cell type, these

TABLE 1 Cytokines and growth factors supporting or inhibiting AML cells.

Cytokine	Expression in AML patients compared to healthy individuals	Physiologic function	Function <i>ex vivo</i> in AML cell culture
G-CSF	Not determined	Hematopoietic growth factor	Supports AML cell proliferation and clonogenicity (45–48)
GM-CSF	Elevated PB plasma levels and unchanged BM levels (42, 49)	Hematopoietic growth factor	Supports AML cell growth and self-renewal (44, 45, 50)
IFN- $\alpha$	Not determined	Anti-/Pro-inflammatory cytokine	Reduces AML cell proliferation and IL-1, IL-6, GM-CSF expression (51, 52)
IFN- $\gamma$	Unchanged PB levels and reduced BM levels (39, 53)	Pro-inflammatory cytokine	Reduces AML cell proliferation and survival; increases spontaneous clonogenicity of AML cells (54, 55)
IL-1Ra	Elevated PB and reduced BM serum levels (42, 56)	Anti-inflammatory cytokine	Reduces AML cell proliferation (57, 58)
IL-1 $\beta$	Unchanged or elevated PB and unchanged BM levels (39, 41, 42)	Pro-inflammatory cytokine	Supports AML cell proliferation and survival; increases GM-CSF, IL-6 and TNF expression (41, 45, 50, 51, 59, 60)
IL-3	Elevated PB levels (43)	Pro-inflammatory cytokine	Supports AML cell proliferation and self-renewal (45, 47, 61–63)
IL-4	Elevated PB levels in patients > 65 years (39, 53)	Anti-inflammatory cytokine	Inhibits IL-1- and HGF-induced AML cell proliferation (60, 64, 65)
IL-6	Elevated plasma levels (39, 53, 66)	Pro-inflammatory cytokine	Partially supports AML cell proliferation (45, 48, 67–71).
IL-8	Elevated PB and BM levels (39, 44, 66, 72)	Chemoattractant cytokine (chemokine)	Not determined
IL-10	Elevated PB levels (39, 53, 56, 73)	Anti-inflammatory cytokine	Inhibits AML cell proliferation; reduces IL-1 $\alpha$ , IL-1 $\beta$ , IL-6, GM-CSF and TNF- $\alpha$ expression (74–76)
IL-12p70	Elevated PB levels in patients > 65 years (39)	Pro-inflammatory cytokine	Inhibits AML cell-induced angiogenesis; supports T cell-mediated cytotoxicity and possibly AML tumor growth (77–79)
IL-27	Elevated PB and BM levels (40)	Anti-inflammatory cytokine	Not determined
IL-35	Elevated PB and BM levels (40, 80, 81)	Anti-inflammatory cytokine	Supports AML cell proliferation and survival; promotes Treg function (80)
Osteopontin	Elevated PB and BM levels (44, 82, 83)	Matrix glycoprotein with pro-inflammatory cytokine properties	Supports AML cell self-renewal, proliferation and survival (84)
SCF	Elevated PB and BM levels (42)	Hematopoietic growth factor	Supports AML cell proliferation and survival (85–87)
TGF- $\beta$	Reduced PB and BM levels (39, 53)	Anti-inflammatory cytokine	Inhibits AML cell proliferation and survival (88–90)
TNF- $\alpha$	Elevated PB levels (39, 44, 56, 66)	Pro-inflammatory cytokine	Supports AML cell chemoresistance and maintains proliferating LSCs (91)
TRAIL	Reduced PB levels (44)	Pro-inflammatory cytokine	Not determined
CXCL12	Reduced expression in AML blasts (92–94)	Chemoattractant cytokine (chemokine)	Promotes AML cell growth, survival, chemoresistance and adhesion (95–98)

Importantly, not all patient-derived AML cells or cell lines respond to HGF and cytokine treatment equally well. These observations reflect AML heterogeneity and suggest the presence of leukemic cell subpopulations. PB: peripheral blood; BM: bone marrow.

initial treatment studies confirm the antitumoral effect of osteopontin inhibition (114) and call for testing in AML disease models.

## Interleukin-1

Due to its pleiotropic effects, IL-1-mediated signaling is recognized as a central hub between inflammation and cancer, including leukemia development and progression (32, 115–119). In AML patients, multiple studies have reported increased levels of IL-1 $\beta$  and IL-1 receptors as well as decreased levels of interleukin-1 receptor antagonist (IL-1RA) in PB and BM (41, 42, 56, 120). In an MLL-AF9-driven leukemic mouse model, chronic exposure to IL-1 $\beta$  accelerated leukemia progression and impaired normal

hematopoiesis by modulating stromal niche support. Using both *in vitro* and *in vivo* AML models it was shown that depletion or deletion of IL-1RA resulted in reduced expansion of AML progenitor cells and partially restored normal hematopoiesis (121). This was confirmed by targeting IL-1 receptor signaling *via* inhibition of p38 MAPK, which enabled normal HSPCs to expand in the presence of IL-1 $\beta$  (41). Of note, *in vivo* AML development was curbed by knockout of IL-1 receptor in the MLL-AF9 mouse model but was increased in FLT3-ITD-driven leukemic mice (122), suggesting different dependencies on IL-1 signaling. Additionally, it was shown that AML HSPCs express high levels of IL-1 receptor accessory protein (IL-1RAP), which contributed to increased IL-1 $\beta$  production, AML cell proliferation and survival, but reduced normal hematopoiesis. This phenotype was further promoted when co-culturing AML CD34<sup>+</sup> HSPCs on MSCs (123, 124).

FIGURE 1

Cytokines supporting AML progression. Osteoblasts, myeloblasts and mesenchymal stromal cells (MSCs) secrete osteopontin. This in turn promotes AML cell proliferation and disease progression. CXCL12 is mainly secreted by perivascular stromal cells (PSCs), and osteoblasts and promotes growth and survival of AML blasts cell via the chemokine receptor CXCR4. IL-1 $\beta$  acts on myeloblasts and HSPCs, which express the IL-1 receptor (IL-1R) as well as the IL-1 receptor accessor protein (IL-1RAP), thereby enhancing IL-1 $\beta$  production, AML cell proliferation and survival. IL-1 signaling can be blocked by Canakinumab, a human monoclonal antibody targeting IL-1 $\beta$ . IL-8 is constitutively produced by AML myeloblasts and acts in an autocrine way. MSCs and myeloblasts are potent sources of IL-6, which can be blocked by IL-6-blocking antibodies such as Siltuximab. Created with [Biorender.com](https://www.biorender.com).

Inhibition of IL-1RAP signaling antagonized this effect and enabled HSC proliferation in the presence of AML cell-conditioned media (124). In line with these AML cell-supporting functions, gene expression analysis revealed reduced overall survival (OS) of AML patients who expressed high levels of IL-1RAP (123). These observations suggest an important role for the IL-1 $\beta$  signaling pathway in the pathogenesis of AML and encourage studies to evaluate the therapeutic effects of targeting IL-1 signaling (117, 120). Multiple US Food and Drug Administration (FDA)-approved IL-1 blockers [Anakinra (Kineret); Rilonacept (Arcalyst); Canakinumab (Ilaris)] are already available. In particular, the effect of Canakinumab is being intensely evaluated in the CANTOS trial (NCT01327846), a randomized, double-blind, placebo-controlled phase 3 study involving 10,061 patients with solid tumors as well as hematological malignancies like chronic myelomonocytic leukemia (CMML) and myelodysplastic syndrome (MDS) (125, 126). However, additional studies will be required to fully understand the therapeutic value of targeting IL-1 and in particular IL-1 $\beta$  in hematological malignancies, including AML.

## Interleukin-6

IL-6 is a potent pro-inflammatory cytokine which is crucial for a rapid and coordinated immune response during

infections and tissue injuries, but also helps to maintain the hematopoietic system (127–129). Deregulated expression of IL-6 is associated with inflammatory and autoimmune diseases as well as skewed hematopoiesis and leukemia (104, 127, 130). In AML patients with reduced OS, blood and BM serum levels of IL-6 are increased (39, 53, 131). Further studies confirm these findings and suggest that IL-6 levels correlate with poor prognosis, rapid disease progression, and resistance to chemotherapy (39, 132–134). The combined assessment of PB IL-6 and FLT3-ligand levels during AML induction therapy revealed that patients with persistent high IL-6 levels display lower survival rates compared to patients with decreasing IL-6 and increasing FLT3-ligand levels (134). Similarly, low IL-6 levels accompanied by high IL-10 levels have been linked to better prognosis (39). Although AML blasts are clearly exposed to microenvironment-derived (135–137) and self-produced IL-6 (104), it is disputed how IL-6 contributes to AML progression. Curiously, all AML samples express the IL-6 receptor but only a subset responds to IL-6 treatment *in vitro* (48, 67, 69, 70, 131, 138). However, multiple studies suggest that IL-6-induced STAT3 signaling promotes AML by inducing chemoresistance (132, 135, 139). Hou and colleagues showed that BM MSCs promote chemoresistance against daunorubicin and cytosine arabinoside (Ara-c) by increasing IL-6 secretion and

activation of STAT3 signaling and the oxidative phosphorylation metabolic pathway in AML cells (135). Zhang et al. showed that IL-6-induced STAT3 signaling promotes CD36 expression, CD36-mediated uptake of fatty acids, and chemoresistance against Ara-c (139). Several IL-6 or IL-6 receptor-blocking antibodies have demonstrated promising results in (pre-) clinical studies for the treatment of cancers, chronic inflammation, and autoimmune diseases (130). While Siltuximab (CNTO 328; IL-6-blocking antibody) has been proposed as a treatment option for myelodysplastic syndrome (MDS) and multiple myeloma and is FDA-approved for the treatment of idiopathic multicentric Castleman's disease (140), Siltuximab in the AML setting has so far only been investigated in an AML xenograft mouse model that mimics end-stage BM failure. In that study, Siltuximab treatment antagonized AML-induced anemia and BM failure and prolonged mouse OS (141).

## Interleukin-8

IL-8 (CXCL8) belongs to the CXC family of chemokines and is best known for its role as a chemoattractant for neutrophils (142). While production of IL-8 can be induced by various stimuli, including lipopolysaccharide, IL-1, and TNF in healthy cells, many tumor cells express IL-8 constitutively (142) or in a hypoxia-, acidosis-, or chemotherapy-induced manner, leading to anti-apoptotic and growth-supporting MAPK, PI3K, FAK and SRC18 signaling (143). In AML, constitutive production of IL-8 has been observed in both AML cell lines and primary AML samples, together with expression of functional IL-8 receptors [IL-8RA (CXCR1) and IL-8RB (CXCR2)] (144–146). Interestingly, AML cell-derived IL-8 also signals in a paracrine manner and affects neighboring non-leukemic cells in the BM microenvironment. Hypoxia-induced IL-8 secretion by AML cells resulted in increased migration of MSCs into the leukemic BM niche (147). MSCs, in turn, prevent apoptosis and confer drug resistance on leukemic cells by up-regulation of anti-apoptotic proteins and secretion of growth factors, cytokines, and extracellular vesicles (148, 149). Importantly, it has been shown that IL-8 production and secretion by MSCs, fibroblasts, and endothelial cells is induced or increased upon their co-culture with AML cells, thereby contributing to reduced apoptosis and increased proliferation and chemoresistance of the AML cells (150–152). In patients, this bidirectional signaling seems to result in elevated IL-8 levels in PB and BM levels (72), which additionally might contribute to impaired neutrophil migration and hematopoiesis (153). However, further confirmation, especially in the context of AML, is required. Inhibition of the IL-8–IL-8R axis has been proposed as a novel therapeutic intervention targeting the aberrant leukemic BM

microenvironment. Blocking the IL-8 pathway with neutralizing antibodies has been shown to restore the sensitivity of malignant cells to chemotherapeutics and reduce AML cell proliferation (150, 151). Using knockdown or pharmacological inhibition approaches, Schinke and colleagues showed that inhibition of IL-8RB-mediated signaling leads to a significant reduction in proliferation and G0/G1 cell cycle arrest in several leukemic cell lines and primary MDS/AML samples (119).

## CXC motif chemokine 12

The chemotactic cytokine (chemokine) CXCL12, also referred to as SDF-1, is secreted by a variety of cells including stromal cells, fibroblasts, and epithelial cells (154). CXCL12 initiates signaling by binding to its receptors CXCR4 and CXCR7 and plays a crucial role in regulating hematopoiesis (proliferation, differentiation, survival) and hematopoietic cell trafficking to and within the BM (95, 155), but also contributes to tumor growth, survival, metastasis, vascularization, and chemoresistance of several types of cancer (95, 156–160). In AML, low expression of CXCL12, high expression of CXCR4 and low to intermediate expression of CXCR7 have been measured on AML blasts in comparison to normal HSPCs (92–94). Interestingly, decreased CXCL12 and increased CXCR4 expression by AML blasts was associated with reduced patient relapse-free and overall survival OS (161–164). Within the healthy BM, CXCL12 is mainly secreted by perivascular stromal cells [mesenchymal stem and CXCL12-abundant reticular (CAR) cells], endothelial cells, and osteoblasts, thereby guiding, retaining, and regulating HSPCs to and within supportive BM niches (16). Within the AML BM microenvironment, it has not yet been determined which and to what extent cell populations produce and secrete CXCL12. *In vitro*, CXCL12 was shown to promote AML cell growth, survival, and chemoresistance (95–98) by activating or inducing the pro-survival proteins PI3K/AKT, MAP3K/ERK1/2, MYC, Bcl-2, and Bcl-XL (93, 96, 165). *In vivo*, however, while the deletion of CXCR4 in AML MLL-AF9<sup>+</sup> HSPCs prolonged leukemic mouse survival, deletion of CXCL12 within the AML microenvironment did not alter the development and progression of the disease (166). This surprising finding suggests that CXCR4 signaling can support AML cells in a CXCL12-independent manner. Nevertheless, blocking the CXCL12/CXCR4 axis represents an attractive therapeutic strategy and several CXCR4 and CXCL12 inhibitors have been developed and used in preclinical and clinical models to induce the mobilization of the AML cells from the BM into the circulation with the aim of increasing their exposure to chemotherapeutic agents (95, 167). Plerixaflor (NCT01319864,

NCT01352650, NCT01027923), LY2510924 (NCT02652871), and PF-06747143 (NCT02954653) are among the antagonists that have been under Phase 1 clinical trials to test for safety, tolerability and clinical activity, either alone or in combination with standard chemotherapy in AML patients.

## AML inhibiting cytokines

### Interferon- $\gamma$

Interferon- $\gamma$  (IFN- $\gamma$ ) is one of the lead cytokines of cellular immunity. It is mainly secreted by activated lymphocytes (168) and orchestrates tumor defense by regulating AML blast survival and apoptosis (118). While T cells obtained from AML patients at primary diagnosis exhibit increased IFN- $\gamma$  production, strongly reduced levels of IFN- $\gamma$  were observed in CD8<sup>+</sup> T cells from patients who developed relapsed AML after allogeneic HCT (allo-HCT), whereas patients without relapse did not show reduced IFN- $\gamma$  production (169). This suggests that lower IFN- $\gamma$  levels may elevate the risk of relapse. An early phase 1 trial was recently started to evaluate the potential of IFN- $\gamma$  treatment in AML patients with reoccurring disease after allo-HCT (NCT04628338). However, manipulation of IFN- $\gamma$  levels in AML patients should be carefully assessed, because systemic administration of IFN- $\gamma$  is limited by rapid IFN- $\gamma$  clearance and insufficient distribution to tumor sites. Moreover, while IFN- $\gamma$  can restore T cell-mediated anti-cancer immunity and the surface expression of HLA class II molecules, the loss of which has been shown to impair AML recognition by donor T cells (170), IFN- $\gamma$  is also capable of promoting PD-L1 and PD-L2 expression in AML (171, 172). Indeed, high expression of PD-L1 and PD-L2 is associated with poor OS in AML patients (173, 174). Binding of PD-L1/PD-L2 to the receptor PD-1 increases T cell exhaustion, promotes effector T cell apoptosis, induces the resistance to effector T cell-mediated killing (175) and increases the conversion and development of Tregs which have strong immune-suppressive abilities (176). Thus, the potential induction of PD-L1 and PD-L2 by IFN- $\gamma$  may have unfavorable consequences, because the PD-1/PD-L1/PD-L2 axis helps the tumor to maintain an immunosuppressive microenvironment, thereby promoting immune evasion and survival of cancer cells (177). In addition to T cells, innate lymphoid cells type I (ILC1s) are another potent source of IFN- $\gamma$  in healthy individuals. ILCs are important players of innate immune responses by reacting promptly to signals, or inducer cytokines, expressed by tissue-resident cells. ILC1s function as a first line of defense against

intracellular pathogens, such as viruses, and tumors (178). By secreting IFN- $\gamma$ , healthy ILC1s induce apoptosis and block differentiation by modulating JAK-STAT or PI3K/AKT signaling. However, in AML, ILC1s exhibit reduced IFN- $\gamma$  secretion and lose their ability to suppress the development of LSCs and antagonize AML progression (179). ILC1s thus seem pivotal as an anti-cancer immune cell, and administration of *ex vivo*-expanded ILC1s could provide a new immunotherapeutic approach to ensure that IFN- $\gamma$  levels are locally increased within leukemic niches. Importantly, this approach would significantly decrease toxicity for AML patients in comparison to systemic delivery of IFN- $\gamma$  (179).

### Interleukin-4

IL-4 is a signature cytokine of type II inflammation and regulates many aspects of Th2-mediated immunity (180). In epithelial cancers, IL-4 is generally considered to have pro-tumorigenic and pro-metastatic functions, suggesting that inhibition of the IL-4/IL-4R axis may be beneficial to limiting diseases (181, 182). Yet, in hematological cancers, a tumor-promoting role of IL-4 is controversial. Already in the early 1990s there were studies reporting that IL-4 might also have tumor-limiting functions, by suppressing IL-1-induced proliferation of AML cells (60, 64, 65). More recent findings substantiate those earlier observations and show that IL-4 has the potential to inhibit survival of AML cell lines as well as patient-derived AML cells, irrespective of their cytogenetic status and French-American-British (FAB) subtype, without affecting normal HSPCs. Anti-leukemic effects of IL-4 are at least partially dependent on STAT6 and Caspase-3, which agrees with the crucial role of STAT6 in mediating IL-4's effects downstream of the IL-4 receptor (183). In addition, IL-4-induced STAT6, in cooperation with the nuclear receptor protein proliferator-activated receptor gamma (PPAR $\gamma$ ), upregulates the expression of prostaglandins. In particular, COX (cyclooxygenase)-dependent prostaglandins, so-called CyPGs, play an important role in apoptosis (184). After stimulation by IL-4, these lipid mediators are increasingly produced *via* the COX/prostaglandin axis, which leads to activation of p53 and caspase-3 and subsequently stimulates apoptosis of leukemic cells (185). The fact that IL-4 treatment specifically acts on AML blasts, but does not affect HSCs, even upon long-term treatment, makes IL-4 an interesting candidate for therapeutic intervention in AML. Yet, despite its promising role as an anti-leukemic cytokine, IL-4 additionally promotes the differentiation of immune cells, including M2 macrophages, which are regarded as having a leukemia-supporting

phenotype. M2 macrophages release various cytokines and growth factors that promote blast survival and proliferation, induce proangiogenic effects and can directly inhibit CD8<sup>+</sup> T cell-mediated killing of blast cells (186, 187). Therefore, more detailed studies are required to assess the value of IL-4 as an antileukemic molecule.

## Interleukin-10

IL-10, an anti-inflammatory cytokine produced by several immune cells, is crucial for limiting immune responses and damage caused by long-lasting inflammation (188). In AML patients, significantly higher levels of plasma IL-10 are observed (53, 56, 73) which directly correlate with prolonged overall patient survival, event-free survival and higher complete remission rates (39, 189, 190). *In vitro*, IL-10 treatment of AML blasts inhibited spontaneous AML blast proliferation and colony formation by negatively affecting the production and secretion of pro-leukemic cytokines (IL-1 $\alpha$ , IL-1 $\beta$ , TNF- $\alpha$ , GM-CSF, GM-CSF, and IL-6) (74–76, 191). However, contrary to these findings, there is also evidence that IL-10 together with IL-35 — the latter a CD4<sup>+</sup> and CD8<sup>+</sup> T cell-suppressing and T regulatory cell (Treg)-supporting cytokine upregulated in AML (118) — promotes AML cell proliferation, survival and chemoresistance. So far, ICOS1<sup>+</sup> and PD1<sup>+</sup> Treg cells as well as BM-MSCs have been suggested as a source for IL-10 in the AML microenvironment (176, 192), contributing to the establishment of an IL-10-induced immunosuppressive and anti-inflammatory niche which ensures LSC survival and stemness (193, 194). Therefore, despite the direct correlation between IL-10 serum level and prolonged patient survival and treatment response (39, 189), antagonizing IL-10 signaling could support current chemotherapeutic approaches to irradiate LSCs and decrease the patient relapse rate (195). However, so far, no combinatory studies have been performed. Interestingly, Chen et al. recently highlighted the IL-10 receptor as a potential candidate for AML immunotherapy as it is significantly upregulated on AML cells in patients and is required for LSC stemness. CAR-T cells harboring an IL-10 peptide structure within their antigen-binding domain were shown to recognize and bind to the IL-10 receptor of multiple AML cell lines (MV4-11, Kasumi-1, U937, THP-1 and MOLM-13) and primary AML cells, thereby inducing the CAR T-cell mediated killing of these cells *in vitro* and *in vivo* (196). Although the function of IL-10 may be patient-dependent, immunomodulatory agents that block IL-10 could offer an interesting approach for treatment of AML.

## Interleukin-12p70: a new trick for an old cytokine

More than a decade ago, IL-12p70 was shown to inhibit the angiogenic potential but not the survival or proliferation of AML cells (77) and to increase T-cell proliferation and cytotoxicity against leukemic cells *in vitro* (78, 79). Multiple *in vitro* co-culture studies overexpressing IL-12p70 in dendritic cells have confirmed these findings (197, 198) and paved the way for initial immunotherapies using genetically modified dendritic cells (phase 1 clinical trial NCT01734304) (199), thereby trying to avoid the toxicity of systemic administration of IL-12. Recently, another elegant therapeutic approach based on transplantation of genetically modified AML blasts constitutively expressing IL-12 in a vaccine-like manner was successfully established in murine and human cells (197) and is currently under investigation in a phase 1 clinical trial (NCT02483312).

## Conclusion and future perspectives

Despite intensive research leading to new and targeted therapeutic strategies for AML in recent years, the prognosis for a large proportion of patients remains poor. Due to the highly heterogeneous nature of AML, current therapies often only eliminate specific subclones but cannot permanently halt disease progression. As in many other cancers, chronic inflammation, characterized by the release of pro-inflammatory cytokines and growth factors, which significantly influence the interaction of tumor and immune cells in the tumor microenvironment, can also be observed in AML. On the one hand these cytokines may ensure survival of cancer cells by promoting tumor cell proliferation while inhibiting the antitumor immune responses; on the other hand, some cytokines contribute to cancer cell elimination by supporting the body's own immunological defense mechanisms. Therapeutic application of cytokines, or therapies that specifically target cytokines and/or their receptors, may provide new avenues for the treatment of AML patients in the coming years. In particular, IL-1 $\beta$ , IL-6 and CXCL12 might be promising new druggable targets. However, due to the pleiotropic effects of most cytokines, which control both tumor growth and anti-tumor immune responses, we are faced with the challenge of establishing new therapies, which on the one hand inhibit tumor growth and at the same time specifically enhance the anti-tumor response. The use of combination therapies, in which potential inhibitors of inflammatory cytokines are combined with other therapeutic molecules and agents, may prove promising for this purpose.

# A natural goldmine of binding proteins and soluble receptors simplified their translation to blockbuster drugs, all in one decade

Daniela Novick\*

Molecular Genetics, The Weizmann Institute of Science, Rehovot, Israel

Human urinary proteins are a goldmine of natural proteins a feature that simplifies their translation to biologics. Combining this goldmine together with the ligand-affinity-chromatography (LAC) purification method, proved a winning formula in their isolation. LAC specificity, efficiency, simplicity and inherent indispensability in the search for predictable and unpredictable proteins, is superior to other separation techniques. Unlimited amounts of recombinant cytokines and monoclonal antibodies (mAb) accelerated the “triumph”. My approach concluded 35 years of worldwide pursuit for Type I IFN receptor (IFNAR2) and advanced the understanding of the signal transduction of this Type of IFN. TNF, IFN $\gamma$  and IL-6 as baits enabled the isolation of their corresponding soluble receptors and N-terminal amino acid sequence of the isolated proteins facilitated the cloning of their cell surface counterparts. IL-18, IL-32, and heparanase as the baits yielded the corresponding unpredictable proteins: the antidote IL-18 Binding Protein (IL-18BP), the enzyme Proteinase 3 (PR3) and the hormone Resistin. IFN $\beta$  proved beneficial in Multiple Sclerosis and is a blockbuster drug, Rebif®. TNF mAbs translated into Remicade® to treat Crohn’s disease. Enbrel® based on TBPII is for Rheumatoid Arthritis. Both are blockbusters. Tadekinig alfa™, a recombinant IL-18BP, is in phase III clinical study for inflammatory and autoimmune diseases. Seven years of continuous compassionate use of Tadekinig alfa™ in children born with mutations (NLRC4, XIAP) proved life-saving and is an example of tailored made medicine. IL-18 is a checkpoint biomarker in cancer and IL-18BP is planned recently to target cytokine storms resulting from CAR-T treatment and in COVID 19.

## KEYWORDS

ligand affinity chromatography, TBPII, IFNAR2, IL-18BP, Enbrel®, Rebif®, Tadekinig alfa™, COVID 19

## 1 Introduction

Soluble cytokine receptors and binding proteins are present in normal body fluids is the concept I established in 1989 once I isolated four such receptors in one month: TNF Binding Proteins I and II (TBPI and TBPII), interferon gamma receptor (IFN $\gamma$ R) and IL-6 receptor (IL-6R) (1, 2). The others, interferon alpha/beta receptor (later named IFNAR2) (3), a soluble fragment of LDL receptor (LDLR) (4), IL-18 Binding Protein (IL-18BP) (5), IL-32 Binding Protein, the enzyme Proteinase 3 (PR3) (6) and Heparanase Binding Protein, the hormone Resistin (7), quickly followed. My approach involved the use of a body fluid, the urine, reflecting naturally occurring proteins, and a highly specific and efficient separation method, ligand affinity chromatography (8). Urine and plasma contain similar repertoire of proteins yet urine has an advantage over plasma since it hardly contains albumin and immunoglobulins, that are too big to be filtered by the kidney, thus stands a concentration of 1000-fold, which is crucial when targeting proteins present in traces amount. Moreover, employing ligand affinity chromatography as the separation method rather than methods based on the chemistry of the target proteins, promises not only the isolation of all binding proteins to a given ligand but also points to its biological activity since it binds the ligand through its active site and also preserves its bioactivity. Yet strategy does not suffice to guarantee success. High amounts of the relevant cytokines and the corresponding monoclonal antibodies are required for purification, monitoring and characterization of the products and we worked out these tools prior to the endeavor of isolation of binding proteins (9). We developed concomitantly the corresponding ELISAs thus we could establish worldwide collaborations to measure the levels of the cytokines and their binding proteins in real life, namely, in health and disease. Moreover, we introduced the concept of free cytokine levels in pathology and calculated it. Free cytokine results from an imbalance of the players and is most probably responsible for the pathology (10, 11). Drug companies recognized the therapeutic potential of the various soluble receptors and binding proteins and translated some into drugs.

## 2 The discovery of cytokine receptors and binding proteins

In 1987, encouraged by the isolation of the EGF receptor *via* affinity chromatography (12), I purified the IFN $\gamma$ R. The protein source was a detergent-extract of huge batches of primary cells ( $10^{11}$  foreskin fibroblasts/batch) and the separation method was ligand affinity chromatography, namely, a column of an in-house recombinant IFN $\gamma$  covalently coupled to a resin (13). Based on this experience I was confident that ligand affinity chromatography would work for other target proteins too provided ligands in milligram amounts are available and so is a rich source of naturally occurring proteins. From now on the source was 500 to 1000-fold concentrated normal human urine.

Soluble receptors are by definition homologous to the extracellular domains of their cell surface counterparts and are thus encoded by the same genes and are generated by a mechanism of alternative splicing or protease cleavage. Binding Proteins deviate

from this definition, are not the corresponding receptors and are encoded by separate genes. The advantage of my approach is that it isolates both types of these molecules provided a given ligand has a sufficient affinity to the putative soluble receptor or binding protein.

### 2.1 Soluble TNF receptors (1989) and anti TNF therapy

The ultimate proof that my strategy works beyond expectations was the isolation of TBPI and TBPII. 20,000-fold purification in one step and over 80% recovery of bioactivity were achieved (1). It should be noted that purification *via* the canonical multistep laborious and inefficient chromatographic procedures yielded TBPI only (14). Of particular note is the fact that my approach, namely ligand affinity chromatography of urine on covalently coupled TNF to a resin, yielded not only the TBPI but also the novel at that time TBPII and it was the TBPII that proved beneficial in patients with Rheumatoid Arthritis. TBPI and TBPII were hypothesized to be soluble receptors and indeed based on their amino acid sequence their cell surface counterparts were easily cloned. Discovered in 1975, the TNF cytokine (15) proved with years to be a master cytokine involved in opposing biological activities. Together with its receptors and transcription factors TNF was shown to play a role in cell death and cell survival, to regulate immune functions and to be involved in many pathologies (16). TNF blockers were spotted by drug companies and translated to biologics that soon became blockbuster drugs. The TBPII was translated into Etanercept/Enbrel<sup>®</sup>, a fusion protein with the Fc portion of immunoglobulin, for the treatment of mainly Rheumatoid Arthritis but also other autoimmune and inflammatory pathologies such as Psoriatic arthritis, Juvenile idiopathic arthritis and Ankylosing spondylitis. TNF mAbs were translated into e.g. Remicade<sup>®</sup> and Humira<sup>®</sup> for the treatment of Crohn's disease and Ulcerative Colitis in addition to the pathologies treated by Enbrel<sup>®</sup>. The difference in the mechanism of action between these TNF blockers is addressed by Levin AD et al. (17). In a way, I had been involved in the monoclonal antibody anti TNF therapy too. In 1985 Hahn et al. generated anti TNF mAbs (18). I contributed a unique screening procedure for the selection of these mAbs, a screening developed by our laboratory for the selection of mAbs to various interferons (9). As stated later on, this screening assay was a crucial step in the selection of the TNF mAbs.

The discovery of the TNF receptors lead to a flood of world-wide research on the mechanism of action, signal transduction, immune response, cross talk with other cytokines and involvement in health and disease and this is what placed TNF high in the hierarchy of master cytokines. Biologics that neutralize TNF are amongst the most successful drugs for the treatment of chronic inflammatory and autoimmune pathologies (19, 20). In 1998 a modification of our TBPII and our anti TNF mAbs were the first TNF blockers to be approved by the FDA. I had the privilege to have a major part in their discovery and development.

### 2.2 Soluble receptors to IL-6 and IFN $\gamma$ (1989)

I had no doubt that in addition to the TBPs urine contains other soluble receptors. Indeed, using different baits, my approach pulled

out two additional proteins, the soluble IL-6 receptor (IL-6R) and the soluble Type II interferon receptor (IFN $\gamma$ R). To our surprise, unlike the antagonistic soluble receptors to TNF and to IFN $\gamma$ , the soluble IL-6R behaved as an agonist (21). In a mechanism named trans-signaling it was shown that it binds its corresponding ligand, the circulating IL-6, and presents it directly to the transducing IL-6R chain, gp130, present on cells that lack the binding IL-6R chain (22). The discovery of this player, the soluble IL-6R, uncovered this additional mode of signaling of IL-6 on top of the IL-6 classical signaling. It also added an important dimension in the development of inhibitors to IL-6 and IL-6R yet additional treatment for Rheumatoid Arthritis and a variety of inflammatory and autoimmune diseases (23, 24).

The type II IFN, IFN $\gamma$ , named also and immune IFN, is also a master cytokine and is involved in pro-inflammatory and autoimmune pathologies. Obviously, we and others generated monoclonal antibodies to these cytokines and their receptors (9). Anti IFN $\gamma$  mAbs developed by others translated to Emapalumab<sup>®</sup>, a drug approved in 2018 for primary hemophagocytic lymphohistiocytosis (HLH) (25). In the current pandemic these blocking agents are being considered for the treatment of severe cases of COVID 19.

## 2.3 Soluble IFN $\alpha$ / $\beta$ Receptor (1992)

Type I interferons were discovered by Isaacs and Lindenmann in 1957 (26) but it took 35 years to uncover their receptor though laboratories all over the world were engaged in seeking it. Once again, my unique approach of isolation came to rescue and my “goldmine” yielded both the desired receptor and an eureka moment for me that I will never forget. Passing an equivalent of 500 Liter of normal human urine on a resin to which IFN $\alpha$  or IFN $\beta$  were covalently coupled yielded a few micrograms of a soluble Type I IFN receptor. By definition a soluble receptor is homologous to the extracellular domain of the cell bound receptor, thus the N-terminal amino acid sequence of our soluble receptor served to clone its self-surface counterpart. Two cell bound ligand binding receptors were discovered, ours, named IFN $\alpha$ / $\beta$  receptor, a decoy receptor with a short intracellular domain (3) and the transducing receptor with the full intracellular length, later named IFNAR2 (27).

The discovery of the Type I IFN receptor was followed by a burst of publications on the mechanism of action of this yet another master cytokine. We showed the stepwise ligand induced formation of the trimeric complex (28) that include the IFN that first binds the ligand binding chain (IFNAR2) and then the chain, discovered earlier by Uze et al., that transduces the signal joins (29). We were the first to demonstrate the physical interaction of the ligand binding receptor with the transcription factor JAK1 (3), and our neutralizing mAbs raised against this receptor pointed to the fact that the JAK-STAT pathway does not explain all tested biological activities of Type I IFN (30).

JAKs have a pivotal role in a variety of immune mediated inflammatory and autoimmune diseases thus their targeted inhibition results in effective disease control (31). The use of JAK blocking drugs is extended in the present pandemic and there are ongoing clinical studies with these agents aiming at attenuation of the over-production of proinflammatory cytokines in severe Covid 19 (32).

Type I IFN was discovered 65 years ago as an antiviral agent. Being a bridge between innate and adaptive immunity, being essential in host defense and involved in cancer and autoimmunity, placed interferon in the limited list of master cytokines. As such it is being continuously revisited and is a source for drug discovery (33).

Forty years after the discovery, one of the Type I IFNs, IFN $\beta$ , had been approved for the treatment of multiple sclerosis (34). My persistence and daring paid, and in 1982 I generated monoclonal antibodies to this IFN (9, 35). These tools accelerated the CHO-expressed recombinant IFN $\beta$  characterization, monitoring of its scaled-up production, and submission of its file to the FDA. I am proud to have a part in its translation to a blockbuster drug, the REBIF<sup>®</sup>.

Interferons are extensively studied in the present pandemic, the SARS-2 Covid 19. Big data analyses revealed interferon deficiency, inborn errors in IFN signaling and autoantibodies to Type I IFN in severely ill patients. The latter accounts for more than 10% of these patients (36–42).

## 2.4 IL-18 Binding Protein (1997)

Having isolated 5 soluble receptors, gave me confidence that my approach would yield any unknown receptor provided it is present in the goldmine, the urine. But here I experienced a twist to my story. Based on my expertise I had been asked by Prof. Charles Dinarello, known in the field of IL-1, to isolate the receptor for an additional member of the IL-1 family, the pro-inflammatory cytokine, IL-18, first named IFN $\gamma$  inducing factor (IGIF). To my surprise, all my attempts to isolate the soluble IL-18 receptor from the concentrated urine failed not because it does not exist but because in retrospect it turned out that its concentration in the urine and its affinity to the IL-18 are too low. Characterization of the protein that I did pull out instead, revealed a novel family of proteins, the Binding Proteins, osteoprotegerin being then its only member. These proteins bind the same ligand as the corresponding receptor does, but are encoded by a separate gene and have no cell surface counterpart. The protein I isolated was a unique binding protein, that we named IL-18BP (5). It has an exceptionally high affinity to its ligand (0.4 nM or 0.05 nM) (43, 44) and as such was proposed to serve as an antidote in a fatal inherited IL-18BP deficiency in human fulminant viral hepatitis A caused by toxic levels of IL-18 (45). Serono (Merck) translated recombinant IL-18BP to a drug and named it Tadekinig alfa<sup>TM</sup>. There is an ongoing phase III clinical trial by AB2 bio (<https://www.ab2bio.com>) in children born with a mutation in the inflammasome e.g. *NLR4* and in *XIAP/BIRC4* (ClinicalTrials.gov Identifier: NCT03113760). These mutations lead to an over expression of IL-18 that results in organ damage due to Macrophage Activation Syndrome (MAS) or hemophagocytic lymphohistiocytosis (HLH). On a compassionate basis Tadekinig alfa<sup>TM</sup> saved several children lives and let them lead almost normal life by being treated continuously for 7 years now. A successful phase II clinical study in the autoimmune Still's disease is completed and awaiting phase III. Tadekinig alfa<sup>TM</sup> treatment protocol was also submitted to the FDA to be tested in patients succumbing to a devastating MAS, resulting from cancer and viral diseases that otherwise has no cure and has up to 50% mortality. Tadekinig

alfa<sup>TM</sup> is considered in the treatment of a cytokine storm in patients undergoing CAR T therapy (46) and in severe cases of COVID 19 (47). The complete story referring to IL-18BP discovery can be found in my recent review (9).

## 2.5 Soluble LDL receptor, IL-32 and heparanase binding proteins

My approach proved indispensable in the isolation of binding proteins not only to cytokines but also to other key molecules such as LDL and heparanase. We found that a soluble LDL receptor, present in urine, has an unanticipated antiviral activity and that its cell surface counterpart, present in all types of cells, is the entry receptor of VSV (4, 48). These findings explain the pantropism of this virus used successfully in gene therapy.

An attempt to isolate the receptor to the IL-18 induced proinflammatory cytokine, the IL-32, failed and I isolated Proteinase 3 (PR3) instead (6). PR3 is the auto-antigen of an autoimmune blood vessel disease, Wegener's disease renamed Granulomatosis with polyangiitis (GPA). Blood levels of IL-32 were reported to be upregulated in these patients.

The receptor to heparanase was not isolated either but instead we have shown that the human resistin, present in urine, binds heparanase specifically and with a high affinity (7). Resistin is an adipogen in mice and a pro-inflammatory cytokine in humans (49, 50). The heparanase receptor is unknown till today.

## 3 Concluding remarks

The notion coined back in 1968 by Cuatrecasas et al. (8) that almost any given biomolecule has an inherent recognition site through which it recognizes a partner molecule served as the basis to my approach. My findings upgraded the status of normal human urine to a goldmine position, and the convenience in its handling placed it high in the list of sources of natural proteins such as soluble receptors and binding proteins. No doubt being self-proteins facilitated their translation into drugs.

It is clear now that the balance between the cytokines and their antagonists, agonists, or carrier proteins, namely, the soluble receptors and binding protein, dictate the outcome of a pathology. This is where I introduced the concept of a free cytokine (10, 51).

A spectacular comeback at the present pandemic, SARS-2 Covid 19, of these master cytokines and their receptors reminded all how

crucial they are. TNF, IL-6, both types of IFNs and IL-18 were reported to be involved in the cytokine storm of severely ill Covid 19 patients. Blockers of these cytokines are being tested as possible therapeutic agents.

Though the journey taken to generate the tools and to discover the various receptors and binding proteins seems simple and straightforward it was not. The details of the “struggle” that lead to my success where others failed, my discoveries, the rationale behind and the “tricks” engaged, are described in my historical review titled “Nine receptors and binding proteins, four drugs, and one woman: Historical and personal perspectives” (9). I should stress that at those days all our research was basic-science oriented with a desire to solve Nature's enigmas yet also with a remote dream that part of it will prove beneficial to humanity. Mine did in a form of Rebif<sup>®</sup>, Enbrel<sup>®</sup>, Remicade<sup>®</sup> and Tadekinig alfa<sup>TM</sup>.

## Author contributions

DN is the sole author. She conceived and wrote the manuscript.

BCG is the most efficient adjuvant therapy for high-risk, non-muscle-invasive bladder cancer (NMIBC). Both innate and adaptive immune responses have been implicated in BCG-mediated effects. BCG vaccination can boost innate immune responses via trained immunity (TI), resulting in an increased resistance to respiratory viral infections. Here we evaluated for the first time whether intravesical application of BCG triggers increased immunity against SARS-CoV-2 in patients with high-risk NMIBC. Serum and peripheral blood mononuclear cells (PBMCs) from heparinized whole blood samples of 11 unvaccinated SARS-CoV-2-naïve high-risk NMIBC patients were collected at baseline and during BCG treatment in a pre-COVID-19 era. To examine B-cell or T cell-dependent adaptive immunity against SARS-CoV-2, sera were tested for the presence of SARS-CoV-2 neutralizing antibodies. Using a SARS-CoV-2 peptide pool, virus-specific T cells were quantified via IFN $\gamma$  ELISpot assays. To analyze innate immune responses, mRNA and protein expression levels of pro- and anti-inflammatory cytokines were measured after a 24-hour stimulation of PBMCs with either BCG or SARS-CoV-2 wildtype. ATAC-sequencing was performed to identify a potential epigenetic reprogramming in immune cells. We neither identified SARS-CoV-2 neutralizing antibodies nor SARS-CoV-2-reactive T cells, indicating that intravesical BCG did not induce adaptive immunity against

SARS-CoV-2. However, a significant increase in mRNA as well as protein expression of IL-1 $\beta$ , IL-6 and TNF $\alpha$ , which are key cytokines of trained immunity, could be observed after at least four intravesical BCG instillations. Genomic regions in the proximity of TI genes (*TLR2*, *IGF1R*, *AKT1*, *MTOR*, *MAPK14*, *HSP90AA1*) were more accessible during BCG compared to baseline. Although intravesical BCG did not induce adaptive immune responses, repetitive intravesical instillations of BCG induced circulating innate immune cells that produce TI cytokines also in response to SARS-CoV-2.

#### KEYWORDS

BCG, bladder cancer, COVID-19, SARS-CoV-2, trained immunity, viral infections

## Introduction

Intravesical *Bacillus Calmette-Guérin* (BCG) immunotherapy has been considered the most successful adjuvant treatment in preventing recurrence and progression of high-risk non-muscle-invasive bladder cancer (NMIBC) for more than 40 years (1, 2). Urology practices have also been affected by the global COVID-19 pandemic (3, 4). Clinical adjustments in the use of BCG schedule in high-risk NMIBC were the consequence of the COVID-19 pandemic. In detail, BCG maintenance ongoing for longer than 1 year could be safely terminated for high-risk NMIBC patients, according to the EAU's COVID-19 recommendations to protect both patients and healthcare workers (3, 4).

The protective effect of BCG against several viral respiratory infections is mediated via a process termed trained immunity (TI). TI comprises epigenetic as well as metabolic reprogramming of innate immune cells, facilitating the enhanced production of the pro-inflammatory TI cytokines IL-1 $\beta$ , IL-6 and TNF $\alpha$ , when challenged with a secondary irrelevant bacterial or viral stimulus (5, 6). Through TI, BCG vaccination can boost innate immune responses, resulting in reduced viremia, increased TI cytokine production and faster viral elimination (5, 7). Consequently, the development of TI is desirable to generate protection against COVID-19. First data already indicate that BCG might also provide protection against COVID-19 infection (7–9). However, these observational reports cannot confirm a causal association between BCG vaccination and decreased COVID-19 infection as well as mortality rate. Thus, various randomized controlled clinical trials are still ongoing (NCT04384549, NCT04659941, NCT04461379) to determine whether BCG vaccine can prevent COVID-19 infection and severity, especially in healthcare workers or elderly people (10).

When focusing on bladder cancer, the repetitive intravesical BCG application induces a local immune response that ultimately translates into TI. Consequently, intravesical BCG has not only a local but also systemic effects. Recently, BCG-induced TI has been shown to significantly decrease the risk for respiratory viral infections in NMIBC patients (11, 12). However, a possible protective effect also against SARS-CoV-2 through intravesical

BCG-induced TI in NMIBC has not been shown to date. We hypothesized that boosting innate immune cells by intravesical BCG instillations with induction of TI could also induce innate immunity against SARS-CoV-2 in NMIBC patients. Therefore, the objective of this study was to analyze, for the first time, the innate and adaptive immune responses against SARS-CoV-2 wildtype in blood samples of patients with (very) high-risk NMIBC who underwent intravesical BCG treatment in the pre-COVID-19 era.

## Materials and methods

### Patients

To rule out preexisting immunity to SARS-CoV-2 either by vaccination or infection, we used blood samples from our biobank of consecutive patients with the diagnosis of a primary or recurrent (very) high-risk papillary NMIBC (Ta high-grade or T1) with or without concomitant carcinoma *in situ* (CIS) of the bladder during a pre-COVID-19 era (2014–2015). The SARS-CoV-2-naïve status was confirmed in all patients by testing cellular and humoral adaptive immunity (neutralization assay and IFN $\gamma$  ELISpot). All patients were free of visible papillary tumor at the start of BCG induction as determined via second TURB (except primary, isolated CIS) or negative cystoscopy and/or cytology at most 4 weeks before start of BCG therapy. The study was approved by the local ethical committee of the Medical University of Innsbruck (study number AN2014-0121; 336/4.3).

### Interventions, follow-up and blood sample collection

The BCG treatment schedule at the Department of Urology of the Medical University of Innsbruck was based on a standard regimen of a 6-week induction course followed by 3-weekly maintenance courses at 3, 6, 12, 18, 24, 30, and 36 months according to the current EAU guidelines (1). Each instillation contained  $2 \times 10^8$  –  $3 \times 10^9$  viable units from live attenuated BCG

bacteria strain seed RIVM derived from seed 1173-P2 (BCG Medac, Wedel, Germany). Follow-up examinations were performed according to institutional practice including cystoscopy and cytology (voided urine as well as bladder washing) 3-monthly for 2 years and every 6 months thereafter until 5 years, and then yearly. Upper urinary tract imaging (CT urography) was performed once a year or in case of recurrence (1). Blood sample collection was performed in the pre-COVID-19 era (2014-2015) as described previously (13). In brief, serum and heparinized whole blood (40-50 mL in EDTA tubes) was collected before each BCG bladder instillation. Peripheral blood mononuclear cells (PBMCs) were prepared from heparinized whole blood by Ficoll density centrifugation and aliquots ( $5 \times 10^6$  cells) were cryopreserved in liquid nitrogen. Serum samples were obtained under standard conditions, clotted at 4–8°C and then centrifuged at 3200 rpm for 6 min. Aliquots of 1.8 mL were stored at –80°C (13). For this follow-up study, we selected 4 samples at 4 different time points for each patient: baseline (before

the first BCG induction) and during BCG (1-2 weeks/early, 3-4 weeks/mid and 6-12 weeks time interval/late) treatment. The study flow chart is presented in Figure 1.

## Determination of SARS-CoV-2 RBD-specific antibody titers

Sera from BCG treated patients as well as untreated but SARS-CoV-2 recovered individuals were analyzed for SARS-CoV-2 RBD-

specific antibodies using SARS-CoV-2 IgG II Quant Assay (Abbott, USA). Results from this chemiluminescent microparticle immunoassay (CMIA) were calculated to BAU/mL and the cut-off value for positive results was defined at 7.1 BAU/mL according to manufacturer instructions.

## Virus neutralization assay

Serum was serially diluted (1:8 – 1:2048) and incubated with replication competent SARS-CoV-2 wildtype virus (SARS-CoV-2 USA/WA1/2020,  $2.5 \times 10^2$  PFU/mL) for 1 h at 37°C as described previously by our group (14). The dilutions were used as inoculum on Vero-TMPRSS2-ACE2 cells for 1 h at 37°C, 5% CO<sub>2</sub>. After medium exchange, cells were further cultivated for 16 h. Subsequently, plaque forming units (PFU) were measured after fixation and permeabilization using immunofluorescently labelled antibodies targeting SARS-CoV-2 nucleocapsid. Imaging and counting were performed using an ImmunoSpot analyser (Cellular Technology Limited, OH, USA).

## SARS-CoV-2 or BCG-specific T cell response (IFN $\gamma$ ELISpot)

PBMCs ( $0.5 \times 10^5$ ) were treated with CEF/CEFTA (1  $\mu$ g/mL each) as positive control, SARS-CoV-2 peptide pool (spike, matrix and nucleocapsid proteins, Mabtech, Sweden) or a mixture of

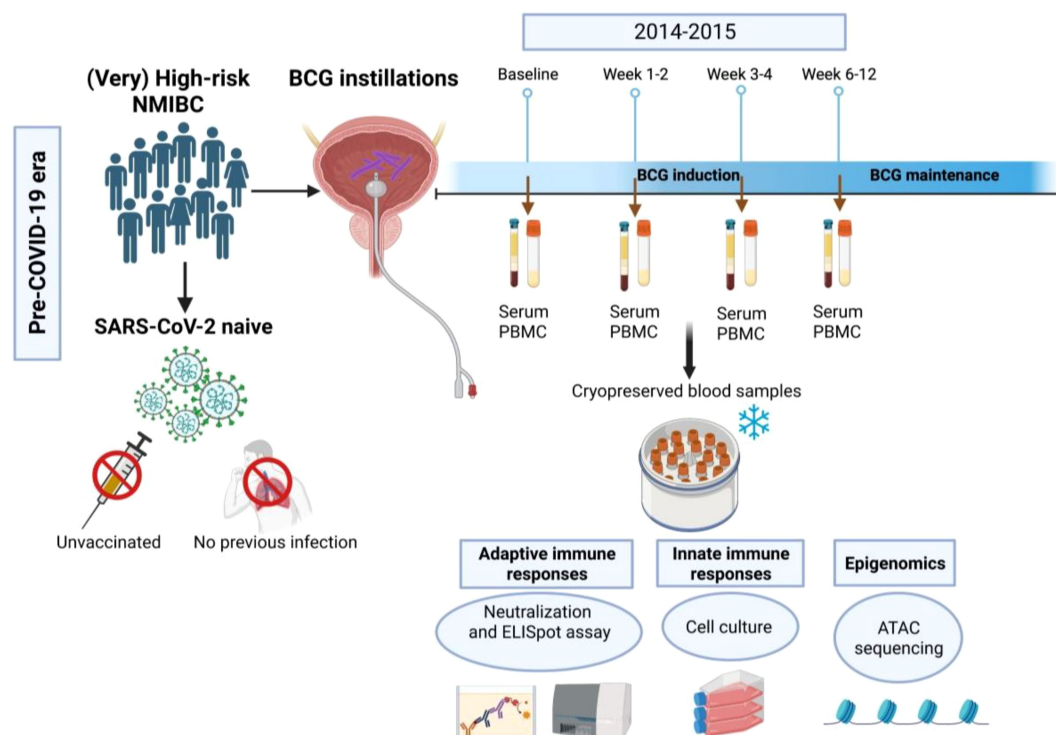

FIGURE 1

Flow chart of the study. In this study we used blood samples that have been collected from (very) high-risk NMIBC patients undergoing intravesical BCG therapy in the pre- COVID-19 era (2014-2015) using four time points (baseline, 1-2 weeks, 3-4 weeks and 6-12 weeks during BCG).

*Mycobacterium tuberculosis* peptides for 24h as previously described (15, 16). The CEF peptide pool consists of 23 MHC class I-restricted viral peptides from human CMV, EBV, and influenza virus induces cytokine secretion from antigen-specific human CD8 T cells. The CEFTA peptide pool consists of 35 MHC class II-restricted peptides from human CMV, EBV, influenza virus, tetanus toxin, and adenovirus 5 to induce cytokine secretion of specific CD4 T cells. The SARS-CoV-2 peptide pools is a mixture of 100 peptides from the viral spike, membrane and nucleocapsid respectively and used at a concentration of 1 µg/ml each. The *Mycobacterium tuberculosis* peptide pool consists of a mixture of peptides pools from the antigenic targets ESAT-6, CFP-10 and EspC (1µg/ml each). After IFN $\gamma$  detection, spots were imaged and counted using an ImmunoSpot analyser (Cellular Technology Limited, OH, USA).

## In vitro induction of trained immunity

PBMCs (3 x 10<sup>6</sup>) from three healthy donors were isolated using Ficoll isolation and primed for 24h with LPS (100 ng/ml), BCG (MOI 0.1) or left untreated (unprimed). Cells were then incubated at 37°C and 5% CO<sub>2</sub> for 5 days before a 24h re-stimulation with LPS (100 ng/ml), BCG (MOI 0.1), SARS-CoV-2 (MOI 0.1) or mock treatment. Trained immunity was assessed by measuring the IL-1 $\beta$  mRNA expression levels in each condition and calculation of the delta delta CT as previously described by Livak et al. (17), relative to the unprimed and untreated cells.

## Cell culture and cytokine analysis

Frozen PBMC stocks of each donor and each time point were thawed and cultured in RPMI- 1640 medium supplemented with 10% FCS and 1% L-glutamine for 2-3h before treatment (all reagents were obtained from Sigma Aldrich, MO, USA). Cells were then either left untreated, stimulated with LPS (*E. coli* O26: B6, 100 ng/ml, Sigma Aldrich, St. Louis, MO, USA) a live attenuated BCG strain RIVM (BCG Medac, Wedel, Germany; MOI: 1) or replication competent SARS-CoV-2 wildtype virus (SARS-CoV-2 USA/WA1/2020; MOI: 0.1) for 24h. For quantification of cytokine mRNA expression PBMCs were harvested and lysed 24h after treatment and RNA was extracted using a commercially available kit (Dr. P Kit, BioChain, CA, USA) following cDNA synthesis (LunaScript RT Supermix, New England Biolabs, MA, USA). Expression of IL-1 $\beta$ , IL-6, TNF $\alpha$ , IL-12A, IL-18, IFN $\gamma$  and IL-10 mRNA was analyzed by PrimePCR Assays via multiplex qPCR using iQ Multiplex Powermix (Bio-Rad laboratories, CA; USA). Relative quantification of target genes was performed using the delta-delta CT method as previously described and normalized to the respective untreated controls (18). Cytokine protein concentrations of IL-1 $\beta$ , IL-6, IL-10, IL-18, TNF $\alpha$  and IFN $\gamma$  in cell culture supernatants 24h post stimulation were measured using Bio-Plex systems (Bio-Rad Laboratories, CA, USA) according to the manufacturers' instructions.

## Next generation sequencing

Assay for transposase accessible chromatin (ATAC), including tagmentation, library preparation and sequencing were performed by Genewiz (Azenta Life Sciences, MA, USA) on PBMCs from two BCG-treated NMIBC patients (responder) at baseline and during BCG (mid) as well as from two healthy donors. Raw data were preprocessed including mapping to the hg38 reference genome using bowtie2 and peak calling by MACS2. Differentially accessible regions in proximity to annotated genes including TI genes (TIDB) between the two time points (during BCG versus baseline) were identified using the R packages csaw and edgeR. We only focused on consensus regions with sufficient normalized counts (logCPM>1), which were more than three-fold enriched and annotated in the promoter or intron of coding genes excluding X, Y chromosomes and blacklisted regions. Overrepresentation analysis of biological processes (GO) and pathways (Reactome) were performed using DAVID, ConsensusPathDB, and ClueGO (Supplementary dataset S1).

## Statistical analysis

All statistical analyses were performed on GraphPad Prism 9 (GraphPad Software Inc., San Diego, CA, USA). Paired t-test was used for neutralization assays comparing patients' sera before and after BCG treatment or Mann-Whitney test for SARS-CoV-2 vaccinated/unvaccinated individuals. ELISpot data were analyzed via 2-way ANOVA with Šidák's correction for multiple comparisons. For cytokine analysis, non-parametric Kruskal Wallis test with Dunn's correction for multiple comparisons was applied. A *p*-value of < 0.05 was considered significant. Graphics were produced with BioRender ([www.biorender.com](http://www.biorender.com)).

## Results

Dynamic blood samples of eleven high-risk NMIBC patients during intravesical BCG treatment were available for further analysis. Descriptive patient and tumor characteristics are shown in Table 1. All patients were classified as BCG responders during a mean (range) follow-up of 41 (18-50) months, respectively.

To examine adaptive immune responses, we analyzed plasma antibodies against SARS-CoV-2 RBD and found no positive titers in all tested patients regardless of BCG instillation time interval, Figure 2. Next, we performed virus neutralization and IFN $\gamma$  ELISpot assays. We found no cross-reactive antibodies against SARS-CoV-2 wildtype in BCG-treated NMIBC patients at baseline and during BCG therapy (mean, 228.8 vs. 215.6 PFU/mL; *p*=0.266), Figure 3A. As a control, we performed neutralization assays also in healthy, non-NMIBC blood donors who were either COVID-19 unvaccinated (*n*=8) or 3x COVID-19 vaccinated (*n*=8). Neutralizing antibodies could only be detected in vaccinated individuals (mean, unvaccinated vs. 3x vaccinated: 242.9 vs. 0.9 PFU/mL; *p*<0.0001), Figure 3B. Furthermore, to evaluate a potential cross-reactive T cell induction,

we challenged T cells with either SARS-CoV-2 wildtype-specific or BCG-specific peptide pools as well as CEF/CEFTA as positive control for 24h and measured the presence of pathogen-specific T cells via IFN $\gamma$  ELISpot assays. We could not detect SARS-CoV-2 reactive T cells in our patients, [Figure 3C](#).

Next, we investigated whether BCG instillations result in altered innate immune responses in patients with NMIBC. After a 24h stimulation of PBMCs with either BCG or SARS-CoV-2 wildtype, cytokine mRNA and protein expression levels were measured via multiplex qPCR. We found a significant increase in mRNA expression of the pro-inflammatory cytokines IL-1 $\beta$ , IL-6 and TNF $\alpha$  in response to BCG stimulation relative to the respective

untreated controls, [Figure 4A](#), lower panel, blue bars. The highest peak of these cytokines was detected after at least four BCG instillations (late time interval), while no response was detected during the early or mid-time intervals, [Figure 4A](#). A very similar cytokine profile was observed after 24h exposure with SARS-CoV-2 wildtype, [Figure 4A](#), upper panel, orange bars. No change in IL-12A, IL-18, IFN $\gamma$  and IL-10 mRNA expression was identified in response to stimulation with BCG or SARS-CoV-2 wildtype relative to untreated, [Figures 4B, C](#).

In accordance with the increase of mRNA expression, we also found significantly elevated secretion of IL-1 $\beta$  but also of IL-6 and TNF $\alpha$  protein after at least four BCG instillations (late time interval), [Figure 5A](#). Importantly, these cytokines are considered the key markers of trained immunity. However, expression of the Th1 cytokines IL-18 and IFN $\gamma$  as well as the anti-inflammatory cytokine IL-10 did not change, [Figures 5B, 5C](#). To test if these changes are specific to the BCG or SARS-CoV-2 stimulus, we included a bacterial LPS treatment as potent activator of innate immune cells and observed a strong induction of the pro-inflammatory cytokines IL-1 $\beta$ , IL-6 and TNF $\alpha$  after 24h, independent of patient or instillation time interval, [Figure 6](#).

To establish our experimental protocol for assessing trained immunity, we initially investigated the *in vitro* induction of trained immunity as described by Arts et al. (19) with LPS and BCG using PBMCs from fresh, healthy human blood donations. Cells were primed for 24h with LPS (100 ng/ml) or BCG (MOI: 0.1) or left untreated (i.e. unprimed). After 5 days, cells were re-stimulated with the same conditions and additionally with SARS-CoV-2 (MOI 0.1). We measured the IL-1 $\beta$  mRNA expression in these cells and calculated the fold-change compared to the unprimed and

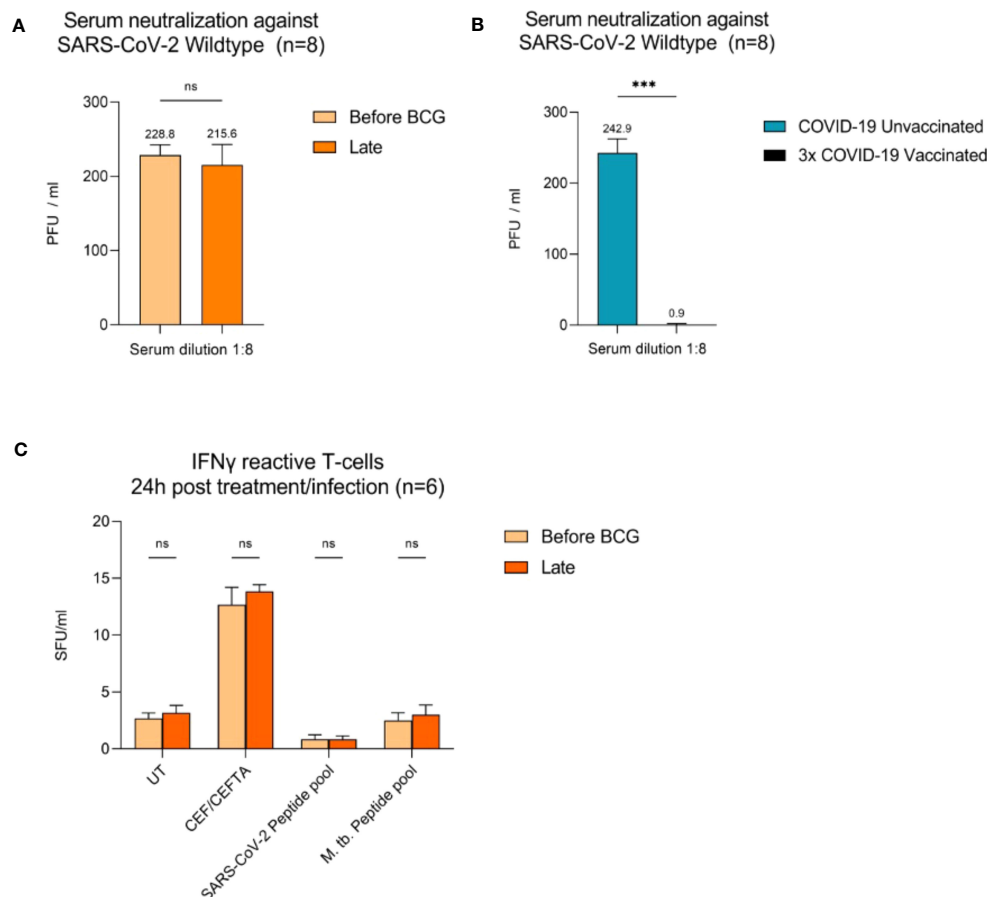

FIGURE 3

Virus neutralization assays and SARS-CoV-2/BCG specific IFN $\gamma$  T cell responses. (A) Serum neutralization against SARS-CoV-2 wildtype in eight BCG-treated high-risk NMIBC patients (baseline and during BCG). (B) Serum neutralization in the internal control group (COVID-19 unvaccinated and 3x vaccinated patients, n=8). (C) IFN $\gamma$  reactive T cells 24h post BCG/SARS-CoV-2 peptide pool (n=6). PBMCs ( $0.5 \times 10^5$ ) were treated with CEF/CEFTA as positive control. Data represent mean with SD; \* $p < .05$ , \*\* $p < .01$ ; \*\*\* $p < .001$ .

untreated condition, Figure S1, black bars. We observed a strong induction of IL-1 $\beta$  expression in the unprimed but LPS-treated conditions (Figure S1, LPS treated, black bars) which was greatly enhanced (>3 times more) when cells previously primed with LPS, Figure S1, LPS treated, pink bars. Similar results were obtained for cells treated with BCG, Figure S1, turquoise bars. Here, IL-1 $\beta$  mRNA expression was higher (>5 times more) in cells that were previously primed and stimulated with BCG compared to unprimed cells, Figure S1, BCG, turquoise bars. At the same time, in BCG-primed cells we could also observe a stronger cytokine induction in presence of SARS-CoV-2, which is in line with the results using our patient samples. One basis of trained immunity are epigenetic changes to facilitate a rapid and increased innate immune response. To address this aspect, we performed ATAC-seq analysis. Comparing two time points (during BCG vs. baseline), we identified differentially accessible genomic regions in proximity to 1697 genes. Among 64 TI candidate genes, 6 genes were overlapping (*TLR2*, *IGF1R*, *AKT1*, *MTOR*, *MAPK14*, *HSP90AA1*), Figure 7A. We also performed an analysis of the overrepresented immune-related pathways and biological processes of the more accessible genes during BCG compared with baseline. Especially, myeloid differentiation was affected (Figure 7B). We particularly

assessed an H3K4me3 signal in the identified regions near the TI genes, confirming H3K4me3 modifications at a more accessible region near transcription start site of all 6 genes. Next, as an example we show TLR2, which is one of the two BCG-specific toll-like receptors (TLR), Figure 7C.

## Discussion

Despite 40 years of clinical research (2), the exact immune mechanism of BCG-mediated antitumor activity is still not fully established (17). However, activation of a predominant Th1-type immune response by infiltrating effector cells into the bladder wall is essential for a subsequent clinical BCG response (13, 20–22). Accordingly, BCG responders showed a significant increase of Th1-type urinary cytokines during BCG therapy (13, 20, 21). In contrast, BCG was totally ineffective in IFN $\gamma$  or IL-12 knockout mice in a syngeneic orthotopic model of bladder cancer (23). The Th1-type immune response is elicited by dendritic cells, which are the most potent antigen presenting cells. BCG induces the activation/maturation of dendritic cells (24), and thus initiates the Th1-type immune cascade (20, 21). In summary, intravesical BCG elicits a

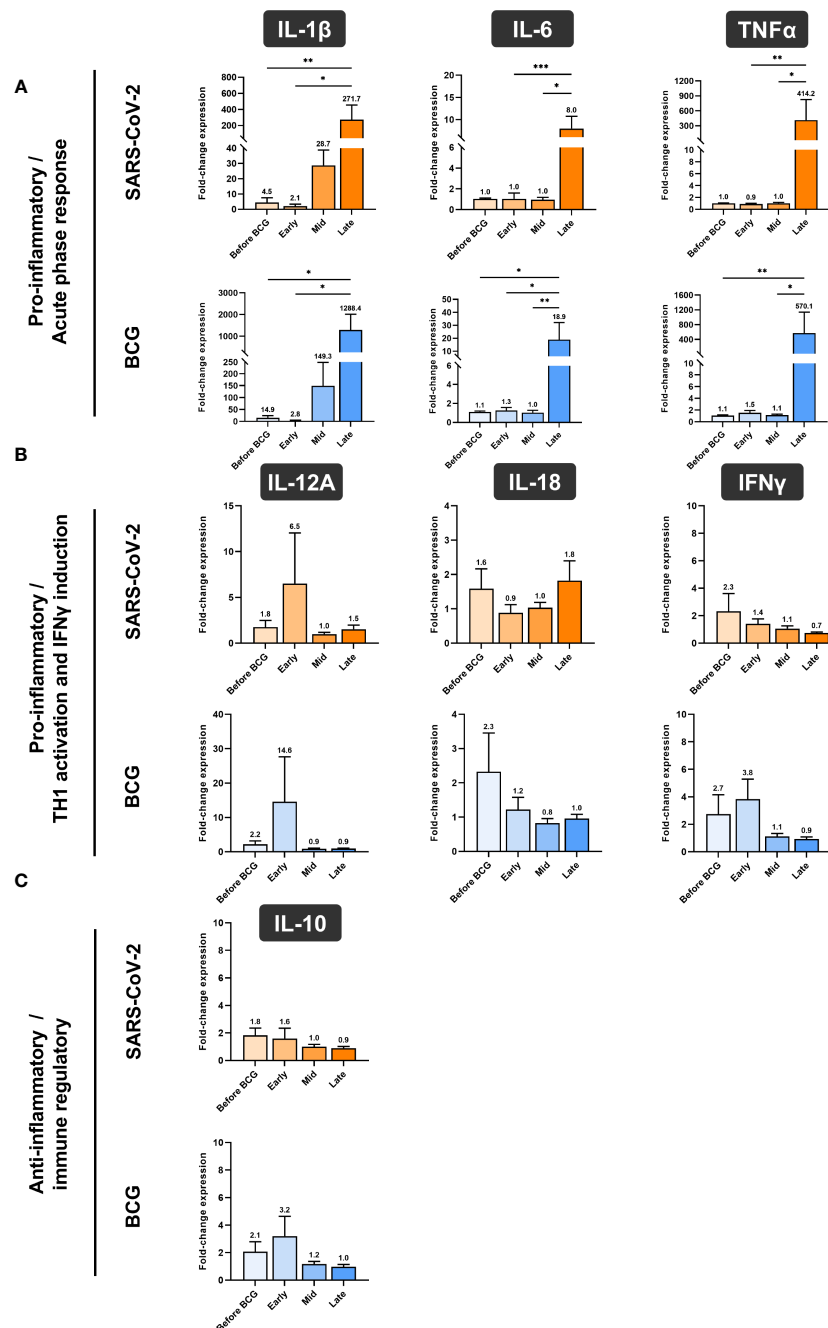

FIGURE 4

Relative quantification of cytokine mRNA expression by multiplex qPCR. (A) Pro-inflammatory cytokines IL-1β, IL-6 and TNFα, (B) cytokines associated with Th1 response IL-12A, IL-18 and IFNγ and (C) anti-inflammatory cytokine IL-10 after a 24h stimulation of PBMCs with either BCG or SARS-CoV-2 wildtype are shown. PBMCs were taken before the start of BCG induction (baseline) and at early, mid and late time intervals during BCG treatment. Data is presented as fold-change expression relative to untreated control group (mean with SEM and mean values annotated above each individual bar; \**p* < .05, \*\**p* < .01; \*\*\**p* < .001). Time points: baseline (before BCG induction), 1–2 weeks/early, 3–4 weeks/mid and 6–12 week-interval/late during BCG.

potent local immune response and recruits effector T cells into the NMIBC tumor microenvironment, suggesting that T lymphocytes are critical to BCG-mediated clinical efficacy resulting in BCG response (25). Our ClueGO analysis, including BCG responders, supports these findings, highlighting a strong alteration in lymphocyte differentiation and T cell response as well.

Activated myeloid cells such as dendritic cells and macrophages can further increase Th1 immune responses by producing cytokines

such as IL-1β, IL-6, TNFα, as well as IL-12 and IL-18 after stimulation of toll-like and NOD-like receptors by BCG (26, 27). Myeloid cells can also develop TI following BCG vaccination. TI is characterized by an epigenetic and functional reprogramming, which facilitates the production of the pro-inflammatory cytokines IL-1β, IL-6 and TNFα, in response to a secondary irrelevant bacterial or viral stimulus (28, 29). Although monocytes, macrophages and NK cells have dominant roles in innate immune

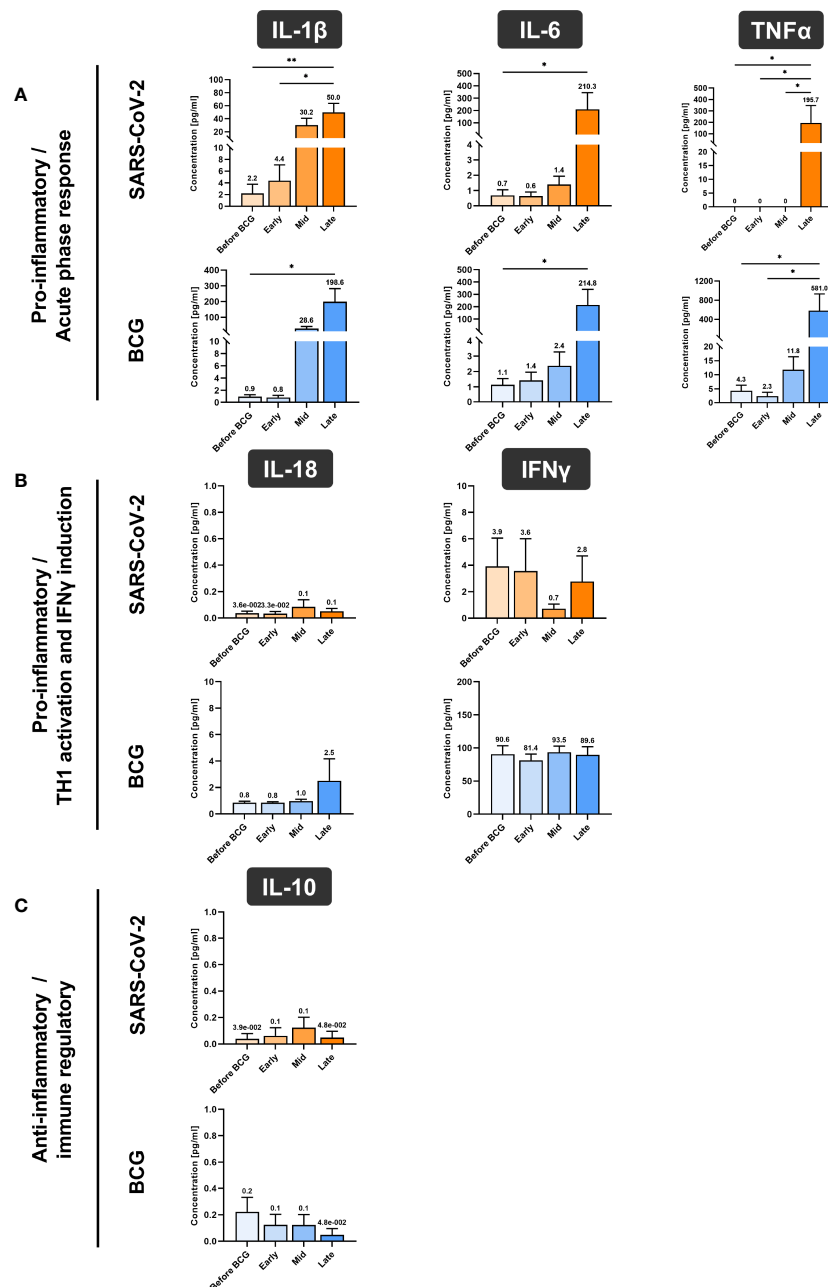

FIGURE 5

Cytokine quantification using Luminex xMAP technology. (A) Pro-inflammatory cytokines IL-1 $\beta$ , IL-6 and TNF $\alpha$ , (B) cytokines associated with Th1 response IL-18 and IFN $\gamma$  and (C) anti-inflammatory cytokine IL-10 were measured in cell culture supernatant of PMBCs after 24h stimulation with either BCG or SARS-CoV-2 wildtype are presented. PBMCs were prepared before the start of BCG induction (baseline) and at early, mid and late time intervals during BCG treatment. Data represent means with SEM and mean values annotated above each individual bar (\* $p < .05$ , \*\* $p < .01$ ; \*\*\* $p < .001$ ). Time points: baseline (before BCG induction), 1–2 weeks/early, 3–4 weeks/mid and 6–12 week-interval/late during BCG. IL-12A data are not shown as their levels were not detectable and samples for repetition were no more available.

memory, other mature innate immune cells, but also hematopoietic stem cells as well as progenitor cells have been implicated in TI (30). BCG is the most potent agent that induces TI through TLR2 and TLR4 activation and downstream signaling via Akt/mTOR and NOD2. Both pathways are required for epigenetic modifications of H3K4me3, thus facilitating an increased pro-inflammatory cytokine production (Figure 8) (31). Enhanced neutrophil function through

BCG vaccination is associated with genome-wide epigenetic modification of H3K4me3 (32). Moreover, macrophages are trained to increase the expression of various pattern recognition receptors, chemokine receptors and costimulatory and/or signaling molecules that also correlated with modification of H3K4me3 (33). Accordingly, we also demonstrated H3K4me3 modifications at a more accessible region near transcription start site of TI genes such

FIGURE 6

IL-1β, IL-6 and TNFα mRNA expression after 24h of LPS (100 ng/ml) treated PBMCs from patients before and during various time-points of BCG treatment. Data is presented as foldchange expression relative to untreated control group (mean with SEM). Time points: 1-2 weeks/early, 3-4 weeks/mid and 6-12 week-interval/late during BCG.

as the BCG receptor *TLR2* induced by BCG instillations. Arts et al. showed that BCG-induced TI was accompanied by a metabolic shift towards glycolysis through activation of the Akt/mTOR pathway (34). Thus, BCG-induced epigenetic and metabolic reprogramming influence each other. This fact means that inhibition of metabolism can reverse epigenetic changes in an *in vitro* TI model, resulting in reduced cytokine responses upon re-stimulation (35).

The repetitive activation of innate immune cells with BCG is the most important driver of enhanced innate immune responsiveness.

Along this line, repetitive BCG administration has been shown to decrease the susceptibility to respiratory viral infections with respiratory syncytial virus, influenza A virus and herpes simplex virus type 2 (36, 37). This prompted us to test whether intravesical BCG might also induce TI-like innate immunity against SARS-CoV-2 in NMIBC. Several observational studies have already attempted to show a possible link between intravesical BCG instillations and COVID-19 infections (5, 38–40). No differences in the incidence of COVID-19 infections in BCG-treated NMIBC patients could be

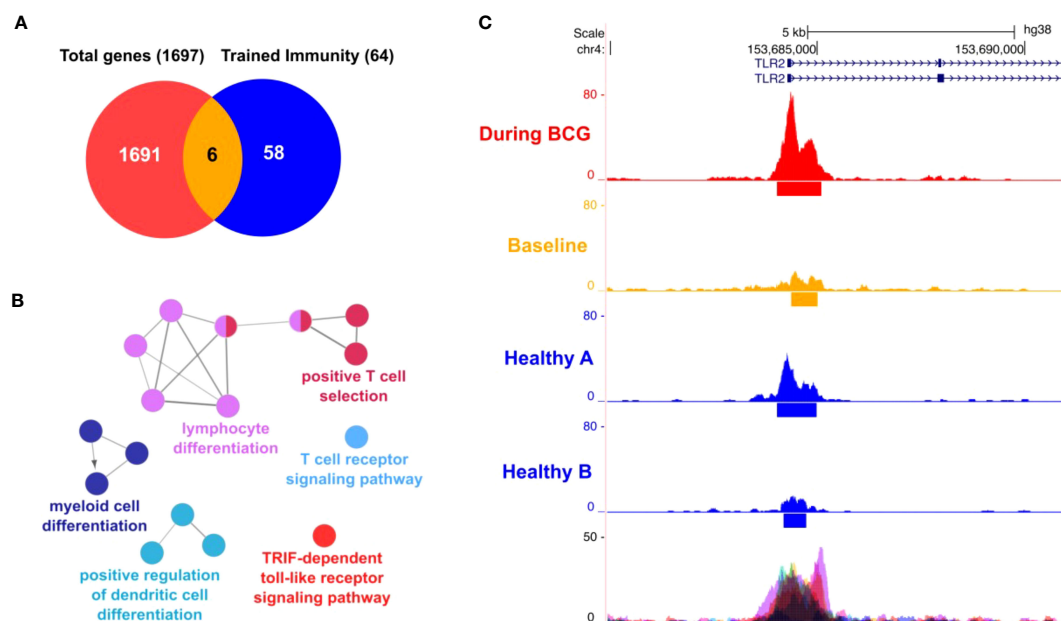

FIGURE 7

ATAC-seq analysis. (A) Venn diagram showing 6 genes (*AKT1*, *HSP90AA1*, *IGF1R*, *MAPK14*, *MTOR*, *TLR2*) overlapping between 64 trained immunity genes and 1697 genes with differentially accessible regions in their promoter or introns. (B) Differential affected immune system related processes (during BCG versus baseline) using ClueGO (C) Representative sequencing tracks for the *TLR2* locus showing significantly higher ATAC-seq peaks at the promoter during BCG compared with baseline. Modifications of H3K4me3 were shown at the same region near the transcription start site of *TLR2*.

FIGURE 8

Schematic overview of BCG-induced trained immunity (TI). Innate immune cells such as monocytes, NK cells, dendritic cells, neutrophils, macrophages and their progenitor cells can be trained through repetitive BCG administration, which induces epigenetic and metabolic reprogramming of these cells. BCG is binding to the toll-like receptors (TLR)2 and TLR4 and thus leads to downstream epigenetic modifications at H3K4me3 through both the Akt/mTOR and NOD2 pathways. As a consequence, this specific modification of H3K4me3 facilitates the enhanced production of IL-1 $\beta$ , IL-6 and TNF $\alpha$ , known as the key cytokines of trained immunity (26–28). During a secondary bacterial or viral stimulation trained innate immune cells display an increased capacity to produce pro-inflammatory cytokines, resulting in improved protection also against unrelated pathogens. Importantly, in our study intravesical instillations as a route of BCG administration were suitable to induce TI, reflected by increased production of TI cytokines after at least four BCG instillations at mRNA and protein levels. BCG administration also resulted in epigenetic modifications of TI-related metabolic genes and of the gene encoding TLR2, which is a specific receptor for BCG. Most importantly, we demonstrated for the first time that high-risk NMIBC patients undergoing intravesical BCG showed an increased SARS-CoV-2 innate immune responsiveness indicative of TI.

shown. However, these findings must be interpreted with caution because they did not examine causal and mechanistic associations between intravesical BCG application and immunity against SARS-CoV-2 (5, 38–40). With regard to severity of the disease, we believe that BCG-induced TI may indeed help prevent detrimental hyperinflammation associated with viremia. Severe cases of Covid-19 tend to have lower lymphocyte counts (lymphopenia) (41). Intriguingly, a recent study also assessed short-term effects of BCG on innate immune responses during the BCG induction regimen and found that one week after the first BCG instillation the total number of white blood cells in the circulation was significantly increased compared to pre-BCG-1. Obviously, BCG treatment also appears appropriate to counteract lymphopenia and may thus improve the clinical course of Covid-19. In addition, the early local innate response to SARS-CoV-2 infection, which is facilitated by TI, may support rapid virus control, keeping systemic inflammation low and enabling recovery. In contrast, absence of TI may increase the risk of hyperinflammation and severe complications associated with

viremia (7).

In the present study we show for the first time that intravesical BCG also induces innate immune responses against SARS-CoV-2. The major new findings of the present study are: (i) BCG did not induce B cell or T cell-dependent adaptive immunity against SARS-CoV-2; (ii) BCG-treated NMIBC patients expressed key cytokines of trained immunity at the mRNA and protein levels after stimulation with SARS-CoV-2; (iii) ATAC sequencing revealed that repeated BCG instillations cause an increased accessibility of important TI genes (*TLR2*, *IGF1R*, *AKT1*, *MTOR*, *MAPK14*, *HSP90AA1*). Collectively, intravesical BCG indeed causes TI, which is the basis of innate immunity against SARS-CoV-2 (Figure 6). An important aspect of our findings is that the local administration of BCG into the bladder also promotes systemic immunity after at least six BCG instillations, reflected by the increased responsiveness of circulating immune cells. In general, epigenetic and metabolic reprogramming leading to TI needs some time. With regard to BCG instillations in

NMIBC patients, repetitive administrations are required to observe an increase in innate immunity. In our study, TI cytokines appeared after 6 weeks. This is in accordance with recent work proposing TI as a molecular mechanism for BCG immunotherapy in bladder cancer (11). Although van Puffelen and coworkers assessed numbers of circulating leukocytes in whole blood early, i.e. one week after BCG1, changes in cytokine production were also not reported before BCG6 (11). The authors argue that late time points of cytokine measurements are most informative for TI (42).

In accordance with our current findings, a recent study has also shown that intravesical instillations of BCG induce TI at a systemic level (11). While these authors observed BCG-induced immunity against pneumonia and common cold in bladder cancer patients (11), we report for the first time on BCG-driven innate immunity against SARS-CoV-2. Of note, all blood samples analyzed in our study have been collected from NMIBC patients in the pre-Covid-19 era (2014–2015), most likely excluding the possibility of previous contact with SARS-CoV-2, which is also supported by the complete absence of RBD specific antibodies in these individuals. Accordingly, SARS-CoV-2-induced pro-inflammatory cytokine production could not be detected in control samples collected before BCG initiation. On the contrary, repetitive BCG administration was required to observe SARS-CoV-2-induced production of TI cytokines. Moreover, we could not detect adaptive immune responses (neutralizing antibodies, T cells) against SARS-CoV-2 excluding the existence of virus-specific memory lymphocytes.

One limitation of the study is the small number of patients, which is due to the fact that we used samples from a pre-COVID-19 era. Moreover, our data cannot be generalized as different BCG strains with immune-reactive differences in elicited immune responses are used in clinical practice (43). However, the BCG strain RIVM which was used in this study is mainly adopted across all EU countries.

Finally, our data reinforce the fact that adjustments to BCG induction and maintenance schedules, as recommended at the early onset of the COVID-19 pandemic (3, 4), are not necessary in clinical practice. Although our data support the development of BCG-induced TI, we did not have the opportunity to study TI-mediated protection against SARS-CoV-2 infection. However, it should be emphasized that research leading to the discovery of TI has been prompted by epidemiological studies showing that BCG vaccination at birth results in reduced child mortality and by subsequent randomized controlled trials demonstrating, that the beneficial effects of BCG were mainly due to protection against neonatal sepsis and respiratory infections (19). The BCG-induced TI observed in our study that includes responsiveness against SARS-CoV-2 in NMIBC patients is thus likely to mediate protection against Covid-19. Thus, every effort should be made to administer full BCG maintenance in high-risk NMIBC patients as recommended even during the pandemic period. Moreover, BCG-induced trained immunity could be one of the most important mechanisms mediating efficacy to BCG in bladder cancer (11, 44). Thus, further trials are urgently needed to evaluate how trained immunity influences the antitumor immune responses in BCG-

treated NMIBC patients, improving personalized medicine in NMIBC (11, 44).

## Conclusions

Here we present the first study showing that repetitive intravesical BCG instillations in high-risk NMIBC also induces innate immune responsiveness against SARS-CoV-2 via mechanisms of TI. The increased fitness of the innate immune system that is induced by repetitive BCG administrations may be important in the context of various therapeutic and preventive strategies.

## Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: <https://zenodo.org/record/7825968>.

## Ethics statement

The studies involving human participants were reviewed and approved by AN2014-0121; 336/4.3. The patients/participants provided their written informed consent to participate in this study.

## Author contributions

RP, GD, JK, MT and WP processed and analyzed data and wrote the manuscript. RP, LM, DD, EL, AM, BP, FS, WK, MM, FG and JT were involved in patient recruiting, collection processing and analysis of samples and clinical data. GD, JK and WP performed and analyzed cell culture, neutralization and ELISpot assays. HH performed and analyzed ATAC sequencing. GD and JK performed experiments and analyzed data. MT, WP, MM, LM, DD, AM and FS helped with manuscript preparation, provided expertise and discussed the data. MT and WP were responsible for supervision. All authors contributed to the article and approved the submitted version.

## Funding

This work was supported by the Austrian Science Fund (FWF; P34070-B13 to WP). JK receives DOC Fellowship from the Austrian Academy of Sciences.

## Acknowledgments

We thank our technicians Sophie Ann Erckert, Viktoria Kozubowski, Christina Witting, Andrea Windisch (Institute of

Hygiene and Medical Microbiology, Medical University of Innsbruck, Innsbruck, Austria), as well as Hubert Gander and Andrea Rahm (Immunotherapy Unit, Department of Urology, Medical University of Innsbruck, Innsbruck, Austria) for their valuable help and support regarding this study. SARS-Related Coronavirus 2, Isolate USA-WA1/2020 NR-5228 was deposited by the Centers for Disease Control and Prevention and obtained through BEI Resources, NIAID, NIH.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

The innate immune sensing of nucleic acids using effective immunoadjuvants is critical for increasing protective immune responses against cancer. Stimulators of interferon genes (STING) and toll-like receptor 9 (TLR9) agonists are considered promising candidates in several preclinical tumor models with the potential to be used in clinical settings. However, the effects of such treatment on tumor stroma are currently unknown. In this study, we investigated the immunotherapeutic effects of ADU-S100 as a STING agonist and CpG ODN1826 as a TLR9 agonist in a preclinical model of colon carcinoma. Tumor-bearing mice were treated intratumorally on days 10 and 16 post-tumor inoculation with ADU-S100 and CpG ODN1826. Cytokine profiles in the tumor and spleen, tumor cell apoptosis, the infiltration of immune cells, and cancer-associated fibroblasts (CAFs) in the tumor microenvironment (TME) were evaluated to identify the immunological mechanisms after treatment. The powerful antitumor activity of single and combination treatments, the upregulation of the expression of pro-inflammatory cytokines in the tumor and spleen, and the recruitment and infiltration of the TME by immune cells revealed the synergism of immunoadjuvants in the eradication of the colon carcinoma model. Remarkably, the significant downregulation of CAFs in the TME indicated that suppression of tumorigenesis occurred after immunoadjuvant therapy. The results illustrate the potential of targeting the STING and TLR9 pathways as powerful immunoadjuvants in the treatment of preclinical colon carcinoma and the possibility of harnessing these pathways in future therapeutic approaches.

## KEYWORDS

STING, TLR9, immunoadjuvants, CAFs, colon carcinoma

# 1 Introduction

Despite extensive research and recent improvements in prognosis, prevention, and treatment, cancer is a leading cause of death worldwide. Colon carcinoma is the third most prevalent cancer and the second most lethal cancer in the world (1–3).

It is well known that immunotherapy, as a promising strategy, modulates the immune system for the treatment of cancer by stimulating the body's immune response against tumor growth and metastasis (4). However, there is still a need for the development and improvement of more effective therapies.

In immunotherapy, multiple approaches and different compounds have been studied so far, several of which work by inducing innate immune responses (5, 6). Nucleic acid-based immunoadjuvants are regarded as safe and powerful immunostimulatory compounds in therapeutic and vaccine settings. CpG oligodeoxynucleotides (CpG ODNs) are synthetic ligands of toll-like receptor 9 (TLR9), which is located in the endosomal compartment of cells (7). CpG ODNs, as an adjuvant approved by the U.S. Food and Drug Administration (FDA), demonstrate remarkable efficacy in phase I clinical trials of infectious diseases and cancer (8–10). As a result of CpG ODN binding to the TLR9 receptor, the myeloid differentiation primary response 88–interferon regulatory factor 7 (MyD88–IRF7) pathway is activated and stimulates the production of type I interferons (IFNs), thereby promoting the pro-inflammatory status of cells in a nuclear factor kappa B (NF- $\kappa$ B)-dependent manner (11). Moreover, CpG ODNs can trigger Th1-type immune responses through the polarization of plasmacytoid dendritic cells (pDCs) to produce type I IFNs, thereby enhancing the recruitment of T cells, induction of B cells, and pDC activation, which consequently promotes effector antitumor immunity (8, 12). A class B CpG ODN that is distinct for mouse TLR9 is CpG ODN1826, containing a full phosphorothioate backbone that is nuclease-resistant and has been well studied in several preclinical studies so far (8, 13).

Another well-known immunostimulatory compound is the stimulator of interferon genes (STING), which is present in the endoplasmic reticulum and activated by double-stranded DNA (dsDNA) (14–16). The production of type I interferon and pro-inflammatory cytokines by a variety of cells in the TANK-binding kinase 1–interferon regulatory factor 3 (TBK1–IRF3)- and TBK1–NF $\kappa$ B-dependent pathways is a consequent cascade of STING activation (17, 18), leading to the polarization of antigen-presenting cells (APCs) and the recruitment of cytotoxic T cells (19, 20).

Studies have revealed that DNA sensing by STING has a significant function in the immune recognition of tumors, which is crucial to effective cancer immunotherapy (21).

The application of the STING agonist cyclic GMP-AMP (cGAMP) as an immunoadjuvant in cancer is partially limited because it does not penetrate the cell membrane (22). To overcome the limitations of natural cGAMP, rational modifications of cyclic dinucleotides (CDNs) led to the introduction of a newly synthesized CDN called ML RRS2 CDA (MIW815 or ADU-S100), which had improved features such as

high stability and lipophilicity and demonstrated stronger antitumor effects in various cancer models (23, 24). It induced effective tumor regression via intratumoral injection in the B16 melanoma, CT-26 colon cancer, and 4T1 breast cancer models (20, 25–30). In addition to mouse STING, this compound is able to activate all known human STING allelic variants. This agonist shows significant potential as a therapeutic agent to promote tumor microenvironment (TME) activation in many tumor types by activating efficient and lasting antitumor CD8<sup>+</sup> T cell responses (20).

The TME includes an extracellular matrix and a variety of cells consisting of infiltrating inflammatory cells, endothelial cells, and cancer-associated fibroblasts (CAFs) (31). CAFs form the dominant component of many tumors and promote tumorigenesis and cancer metastasis in several ways, including the production of growth factors, cytokines, and chemokines; the degradation of extracellular matrix (ECM) proteins; the promotion of angiogenesis; and the immunosuppression and prevention of drug penetration (31–35). Recent studies have demonstrated the presence of a heterogeneous population of CAFs in the TME, including tumor-promoting CAFs and tumor-restraining CAFs (34, 35). Different biomarkers such as vimentin (VIM), alpha-smooth muscle actin ( $\alpha$ -SMA), fibroblast activation protein (FAP), fibroblast-specific protein 1 (FSP1), and platelet-derived growth factor receptor (PDGFR), have been used to identify CAFs (33, 35).

Myofibroblasts' contractile abilities, led by the expression of  $\alpha$ -SMA, which is an isoform of actin, induce a positive feedback loop that amplifies the fibrotic cycle, which in turn results in tumor growth (36). There are different methods for detecting CAFs and their heterogeneity in tissues, which corresponds to their biological functions and subtypes. The CAFs are clustered into three subpopulations, namely antigen-presenting CAFs (apCAFs), myofibroblastic CAFs (myCAFs), and inflammatory CAFs (iCAFs) (37–39). Single-cell RNA-sequencing, multiplex immunostaining, and genetic mouse models have been used for the identification and biological functions of different subtypes of CAFs in pancreatic ductal adenocarcinoma (PDAC), colorectal cancer (CRC), breast cancer, and liver fibrosis progression (40–44).

Although several recent studies have highlighted the importance of combination therapy using STING and TLR agonists in preclinical cancer models (45–48), the relationship between such immunoadjuvants and CAFs as key players in stromal tumorigenesis has not yet been determined. Therefore, in this study, the synergistic effects of STING and TLR9 agonists and the immunological mechanisms underlying tumor regression and CAFs' infiltration of the TME were studied in a preclinical colorectal tumor model. In addition, several important cellular markers of immunity, pro-inflammatory cytokine expression, apoptosis, and pro-tumorigenesis were studied.

Our results suggest that the combination of ADU-S100 and CpG ODN1826 shows synergistic therapeutic effects with enhanced antitumor immune responses and suppressed tumorigenesis markers and, therefore, can be considered a promising target for further cancer immunotherapy investigation.

## 2 Materials and methods

### 2.1 Cell line

The CT-26 cell line was purchased from The Research Institute of Biotechnology (Mashhad, Iran) and cultured in Roswell Park Memorial Institute (RPMI) 1640 medium (Gibco®, Grand Island, NE, USA), supplemented with 10% heat-inactivated fetal bovine serum (Gibco), 2 mM L-glutamine (Invitrogen, San Diego, USA), 25 mM β-mercaptoethanol (Merck, Munich, Germany), and 100 IU/mL penicillin/streptomycin (Gibco) at 37°C and in a 5% CO<sub>2</sub> atmosphere.

### 2.2 Animals

Female BALB/c mice (6–8 weeks old) were obtained from the Royan Institute (Tehran, Iran). All the animals were kept at the animal housing of the Faculty of Veterinary Medicine, Ferdowsi University of Mashhad, Mashhad, Iran. The *in vivo* experiments were reviewed, approved, and conducted in accordance with the ethics guidelines of the Animal Care and Use Committee of Ferdowsi University of Mashhad (license number 46013-M).

### 2.3 *In vivo* tumor model

The CT-26 adenocarcinoma cells ( $3 \times 10^5$ ) were injected subcutaneously (SC) into the right flank of the mouse in 100 μL of phosphate-buffered saline (PBS). Every other day, the tumor size was measured with a digital caliper for a total of 30 days, and the tumor volume was calculated using the equation 1:

$$V = (L \times W^2)/2 \quad (1)$$

where the letter “L” represents the large diameter and “W” represents the small diameter of the tumor (49, 50). The mice were divided into five groups ( $n = 7$ ), as depicted in Table 1, and treatment with ADU-S100 (MedChemExpress, South Brunswick Township, NJ, USA) and CpG ODN1826 (InvivoGen, San Diego, CA, USA) was administered intratumorally on days 10 and 16 post tumor inoculation. The mice were euthanized on day 30 post-tumor induction and their body weights were recorded. Subsequently, the tumors were extracted and weighed. After conducting a necropsy of the mice, samples of their tumor, spleen, and liver tissues were

taken. The tumor inhibition rate was calculated using the equation 2 (6):

$$\text{Tumor inhibition rate (\%)} = [(\text{mean tumor weight of control group} - \text{mean tumor weight in treated group}) / \text{mean tumor weight of control group}] \times 100\% \quad (2)$$

The spleen index was calculated using the equation 3 (51):

$$\text{Spleen index} = \text{weight of spleen (mg)} / \text{body weight (g)} \quad (3)$$

### 2.4 RNA extraction and quantitative real-time polymerase chain reaction analysis

Total RNA was extracted from the spleen and tumor tissues using a total RNA isolation kit (DENArist Asia, Mashhad, Iran). The extracted total RNA was subjected to 1U of DNase I (RNase free) (Thermo Scientific Fisher, Waltham, MA, USA) at 37°C for 15 min. The inactivation of the DNase was conducted by adding 1 μL of 50 mM ethylenediaminetetraacetic acid (EDTA) (Merck). Moloney murine leukemia virus (M-MLV) reverse transcriptase (Thermo Fisher Scientific) was used to convert RNA samples to cDNA. The quantitative real-time polymerase chain reactions (qRT-PCR) were carried out using RealQ Plus 2x Master Mix Green (Ampliqon A/S, Odense, Denmark) in a Rotor-Gene® Q real-time PCR cycler (QIAGEN, Hilden, Germany). The amplification steps were as follows: 15 min at 95°C (1 cycle), followed by 30 s at 95°C, 30 s at 58°C–62°C, and 25 s at 72°C (35–40 cycles). Three replicates were considered for qRT-PCR readout. The β-actin gene served as the internal control. Table 2 gene-specific primers and their accession numbers used in this study.

### 2.5 Hematoxylin and eosin staining

The samples obtained from the tumor, liver, and spleen tissues were fixed in 10% neutral buffered formalin (Merck) for 24 h. The 4-μm-thick sections of the tissue samples were stained with hematoxylin and eosin (H&E) (Merck), mounted on the slide, and finally, examined under a light microscope (Labomed Inc., Los Angeles, CA, USA). The mitotic cells were counted in 10 fields of the tumor slides, and, subsequently, the mean number of mitotic cells was calculated.

### 2.6 Immunohistochemical staining of tumor tissues

Sections of formalin-fixed paraffin-embedded tumor tissues were prepared. The sections were deparaffinized and rehydrated, and the retrieval of antigens was carried out using Tris-ethylenediaminetetraacetic acid (EDTA) buffer (10 mM Tris base, 1 mM EDTA solution, 0.05% Tween 20, pH 9.0) (Merck) for 20 min at 98°C. Subsequently, the slides were quenched using 0.3% [volume to volume (v/v)] methanol-diluted hydrogen peroxide (Merck). The sections were incubated for 30 min with different concentrations of primary antibodies, e.g., anti-CD8-α (1 out of 200) (cat. number sc-

7970; RRID: AB\_627208; Santa Cruz Biotechnology, Dallas, TX, USA), anti-cleaved caspase 3 (1 out of 300) (cat. number 9661; RRID: AB\_2341188; Cell Signaling Technology, Danvers, MA, USA), anti-vimentin (1 out of 400) (cat. number 5741; RRID: AB\_10695459; Cell Signaling Technology), anti-CD45 (1 out of 3,200) (cat. number sc-53665, RRID: AB\_629093; Santa Cruz Biotechnology), and anti-α-SMA (1 out of 500) (cat. number 65001, RRID: AB\_2920672; Progen, Heidelberg, Germany). After washing with Tris-buffered saline (TBS) (0.5M Tris base, 9% NaCl, pH 8.4) (Merck), the slides were incubated with secondary antibodies in accordance with the protocol. Images of the stained slides were obtained using a light microscope from 10 different fields of high-power fields (×400 overall magnification) and then analyzed using QuPath software (RRID: SCR\_018257). The caspase-3 labeling index was calculated using the following equation (52):

Caspase-3 labeling index = (number of activated caspase-3-positive cells × 100)/total number of nuclei. (4)

## 2.7 Measurements of hematological parameters

Before the animals were euthanized on day 30, whole blood was immediately collected from the hearts of the mice in a tube containing an anticoagulant. A complete blood count (CBC) analysis was performed using a cell counter (Nihon Kohden, Nima Pouyesh Teb, Iran).

## 2.8 MTT test

The CT26 cells were seeded in 96-well culture plates at  $7 \times 10^3$  cells per well. The cells were incubated with different concentrations of ADU-S100, CpG ODN (10 µg/mL, 20 µg/mL, 40 µg/mL, and 60 µg/mL), or ADU-S100 (20 µg/mL) + CpG ODN (20 µg/mL) at 37°C for 24 h. The cells were further incubated with 10 µL per well of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2H-tetrazolium bromide

(MTT) (5 mg/mL; Sigma, USA) for 3 h. Subsequently, the medium was removed and 100 µL per well of dimethyl sulfoxide (DMSO) was added. The absorbance was measured at 490 nm. The experiment was conducted in triplicate ( $n = 3$ ).

## 2.9 Statistical analysis

Statistical analysis was conducted using GraphPad Prism software version 9.0 (RRID: SCR\_002798; GraphPad Software Inc., San Diego, CA, USA). One-way analysis of variance and Mann-Whitney U-tests were used to analyze the data. The results are shown as mean ± SD and a  $p$ -value ≤ 0.05 is considered to be statistically significant. The relative expression software tool version 2.0.13 (REST 2009; RRID: SCR\_023755) was used to analyze the qRT-PCR results by way of a pairwise fixed reallocation randomization test. Significant differences among the groups were indicated as \*\*\*\* $p \leq 0.0001$ , \*\*\* $p \leq 0.001$ , \*\* $p \leq 0.01$ , and \* $p \leq 0.05$ .

## 3 Results

### 3.1 Inhibition of tumor growth and increased survival rate of colon adenocarcinoma-bearing mice by single or combination therapy with CpG ODN1826 and ADU-S100

ADU-S100 is a STING agonist with a potent antitumor effect that has been validated in several preclinical tumor models. We hypothesized that the combination of ADU-S100 and CpG ODN 1826 at a reduced (i.e., 50% lower) concentration, compared with a single form of the agonist, would have an additive and robust anticancer effect in suppressing the tumor growth in a CT-26 colon cancer model. The cytotoxic effects of a single, or a combination of, agonist(s) were evaluated using an MTT assay. ADU-S100 and CpG ODN1826, alone or in combination, did not show any adverse

effects on the viability of CT-26 cells *in vitro* (Figure S1). The injection of a CT-26 cell suspension was administered subcutaneously into the right flanks of the mice. When palpable tumors appeared, mice were treated with intratumoral injections of PBS, ADU-S100 (20  $\mu$ g and 40  $\mu$ g), CpG ODN1826 (40  $\mu$ g), or a combination of ADU-S100 (20  $\mu$ g) and CpG ODN1826 (20  $\mu$ g). Every other day, tumor volumes and mouse weights were recorded. To evaluate the immunological mechanisms underlying tumor regression, in a second experiment, all mice were euthanized on day 30 post tumor inoculation (Figure 1A). The standard survival curve (Kaplan–Meier), which describes the direct effects of treatment on tumor growth, showed that both single and combination therapy were able to prolong the survival rate of tumor-bearing mice. Notably, the combination treatment eradicated all CT-26 tumors. Specifically, the combination treatment group exhibited a higher survival rate (100%) than the

single treatment groups treated with ADU-S100 (40  $\mu$ g) (86%), CpG ODN (40  $\mu$ g) (71%), and ADU-S100 (20  $\mu$ g) (43%) (Figure 1B). Figures 1C, D illustrate how the tumor volume in all treatment groups was significantly reduced in comparison to the control group. The combination group [ADU-S100 (20  $\mu$ g) + CpG ODN (20  $\mu$ g)] showed the highest growth inhibition, from 1,952  $\text{mm}^3$  to 32  $\text{mm}^3$ , and was therefore more effective than a single injection of each compound. In addition, in the ADU-S100 (40  $\mu$ g) group, the tumor regression size reached 44.8  $\text{mm}^3$  and 144  $\text{mm}^3$  in the CpG ODN (40  $\mu$ g) treatment group. These results indicate that the antitumor effects of ADU-S100 when combined with CpG ODN are approximately equal to those of monotherapy with ADU-S100 when administered at higher doses (i.e., at twice the concentration). The average tumor weight was significantly reduced from 2.09 g in the control group to 0.08 g and 0.1 g in the combination and the ADU-S100 (40  $\mu$ g) groups, respectively (Figure 1E). The curve of

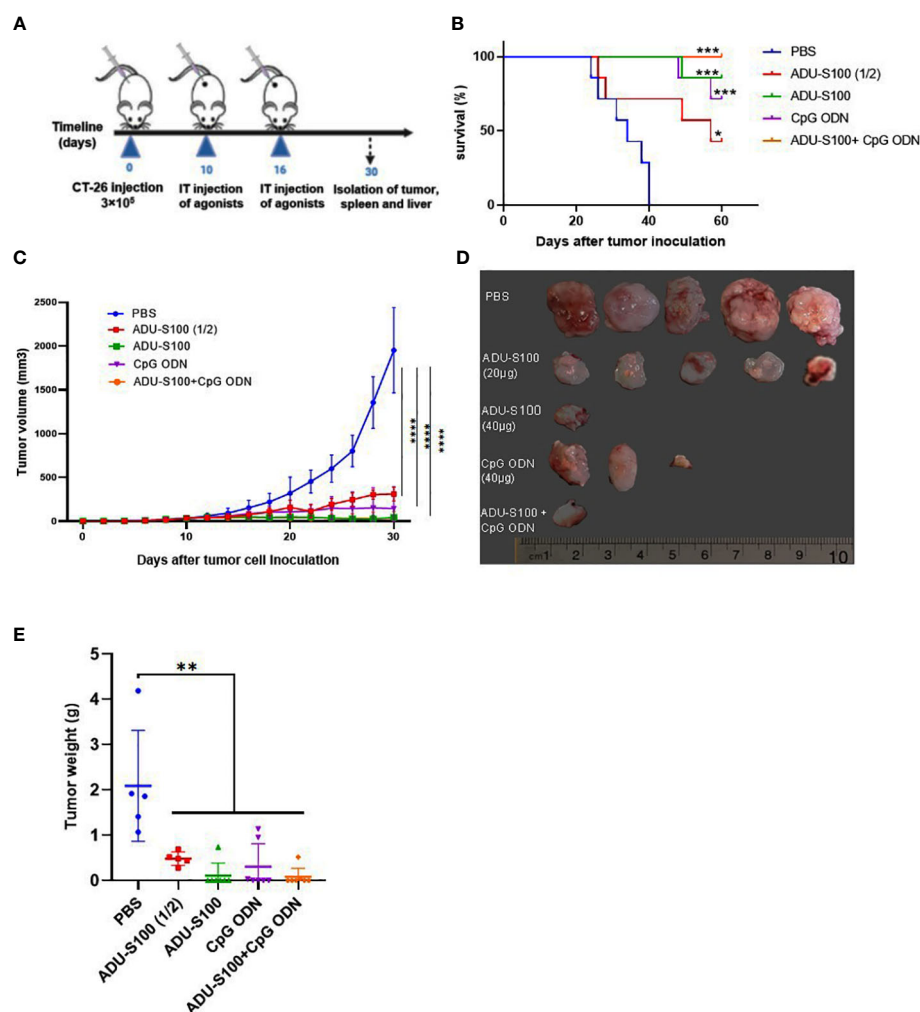

FIGURE 1

Intratumoral (IT) administration of ADU-S100 and CpG ODN1826 reduces tumor volume in the CT-26 adenocarcinoma model. (A) Mice were injected subcutaneously with  $3 \times 10^5$  CT-26 cells (in 100  $\mu$ L of PBS) on day 0. On days 10 and 16, mice were given IT injections of PBS, ADU-S100 (20  $\mu$ g or 40  $\mu$ g), CpG ODN (40  $\mu$ g), ADU-S100 (20  $\mu$ g) + CpG ODN (20  $\mu$ g) ( $n = 7$ ). (B) Kaplan–Meier survival curve of the animals. (C) Tumor volumes were monitored every other day for 30 days. (D) Photographs of dissected tumor tissues from treated mice on day 30 of treatment. (E) Average tumor weight in different treatment groups at the end of the experiment. Data are presented as mean  $\pm$  SD. Significant differences in the survival plot were measured using a weighted log-rank test. Other data were analyzed using one-way ANOVA and Mann–Whitney tests. Statistically significant differences are indicated as \*\*\*\* $p \leq 0.0001$ , \*\*\* $p \leq 0.001$ , \*\* $p \leq 0.01$ , and \* $p \leq 0.05$ . PBS, phosphate-buffered saline.

the tumor inhibition rate is displayed in **Figure S2A**. The results show that ADU-S100 exhibited powerful antitumor activity that is dose-dependent, meaning that ADU-S100 at 20  $\mu\text{g}$  suppressed CT-26 tumor growth by 77% on day 30, whereas for the 40- $\mu\text{g}$  dose, the tumor inhibition rate was 95%. Furthermore, the combination of ADU-S100 and CpG ODN1826 showed the highest tumor inhibition rate (96%), whereas in the CpG ODN (40- $\mu\text{g}$ ) group, the tumor inhibitory rate was decreased to 85%. In the second *in vivo* experiment, on day 30 post-tumor inoculation, mice were sacrificed, and their spleens and tumors were removed and weighed for further immunological analysis. Owing to the importance of the spleen as an extramedullary hematopoietic tissue that produces immunosuppressive myeloid cells in tumor-bearing mice (53), we measured the spleen index (mg/g) in this study. The curve of the spleen index is presented in **Figure S2B** and shows that the spleen index was positively correlated with tumor weight. Furthermore, during the immunotherapy period, the body weight of the mice was recorded, and no considerable weight change was observed compared with the control group (**Figure S2C**). Overall, these data suggest that either the ADU-S100 treatment or the combination treatment had a profound inhibitory effect on the tumor growth progression, but that the combination of ADU-S100 (20  $\mu\text{g}$ ) + CpG ODN (20  $\mu\text{g}$ ) at a reduced concentration (i.e., 50%

lower) was able to effectively control tumor growth and significantly prolong the survival of CT-26 tumor-bearing mice.

### 3.2 Upregulation of pro-inflammatory cytokine expression in tumor tissues

The induction of pro-inflammatory cytokine expression by CpG ODNs and CDNs has already been reported (46, 54). To determine whether ADU-S100 and CpG ODN1826 could induce effective immune responses and generate antitumor immunity, we evaluated the expression of several key pro-inflammatory cytokines (e.g., IFN- $\beta$ , IFN- $\gamma$ , TNF- $\alpha$ , IL-12, and IL-6) using qRT-PCR analysis. We observed that in tumor tissues, the combination treatment [ADU-S100 (20  $\mu\text{g}$ ) + CpG ODN (20  $\mu\text{g}$ )] upregulated the expression level of IFN- $\beta$ , IL-12, and TNF- $\alpha$  in a synergistic manner compared with the other treatments (**Figures 2A–E**). All treatment groups displayed a significant upregulation of IFN- $\beta$  expression compared with the control group ( $p \leq 0.05$ ) (**Figure 2A**). The expression level of IFN- $\gamma$ , as one of the most potent cytokine hallmarks of antitumor immunity, was significantly upregulated in the combination [ADU-S100 (20  $\mu\text{g}$ ) + CpG ODN (20  $\mu\text{g}$ )] and CpG ODN groups compared with the control group ( $p \leq 0.05$ )

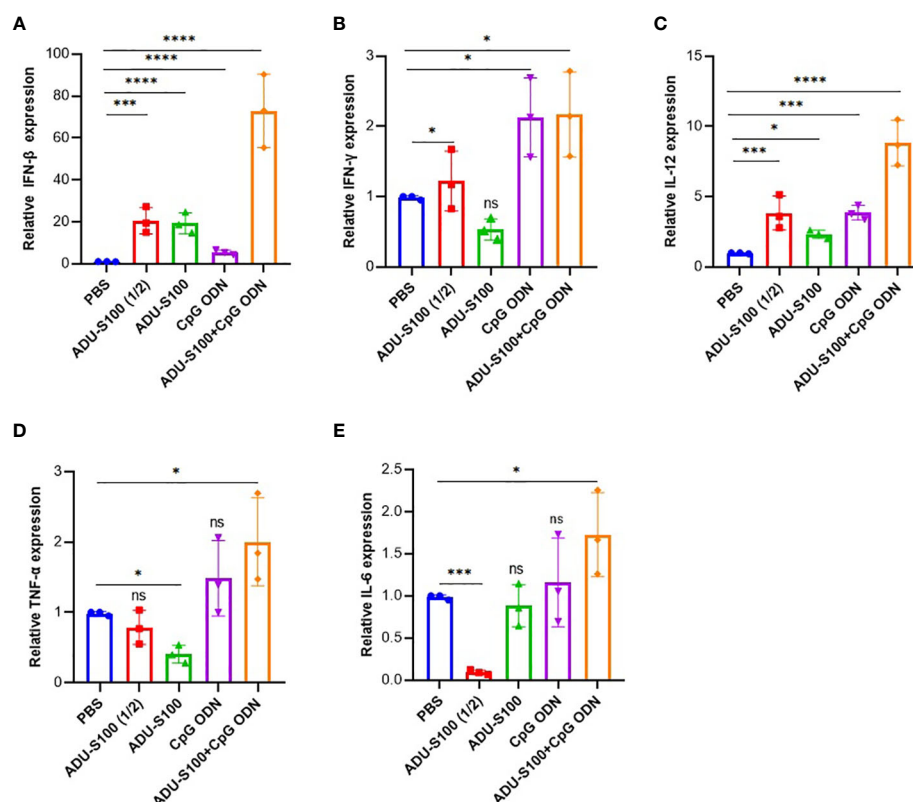

FIGURE 2

Expression profile of pro-inflammatory cytokines in the tumor. Quantitative real-time polymerase chain reaction (qRT-PCR) analysis of (A) IFN- $\beta$ , (B) IFN- $\gamma$ , (C) TNF- $\alpha$ , (D) IL-12, and (E) IL-6 in tumor tissues of treated mice on day 30 post tumor inoculation ( $n = 3$  independent experiments). The transcripts for each gene were quantified relative to  $\beta$ -actin expression levels in each group. Data are presented as mean  $\pm$  SD. Data were analyzed using REST software and statistically significant differences are indicated as \*\*\*\* $p \leq 0.0001$ , \*\*\* $p \leq 0.001$ , and \* $p \leq 0.05$ . IFN- $\beta$ , interferon beta; IFN- $\gamma$ , interferon-gamma; IL-12, interleukin 12; IL-6, interleukin 6; qRT-PCR, quantitative real-time polymerase chain reaction; TNF- $\alpha$ , tumor necrosis factor-alpha.

(Figure 2B). In our experiment, IL-12 expression was significantly upregulated in all treatment groups compared with the control group ( $p \leq 0.05$ ) (Figure 2C). In addition to the combination group, which showed the highest level of expression of TNF- $\alpha$  and IL-6 compared with the control group, the CpG ODN group also showed increased expression of these cytokines compared with the control group, although the difference was not significant (Figures 2D, E). These results demonstrated that immunoadjuvant therapy with ADU-S100 and CpG ODN promotes the robust and synergistic expression of several important pro-inflammatory and immune-effector cytokines in CT-26 tumor tissues.

### 3.3 Upregulation of pro-inflammatory cytokine expression in the spleen

The spleen is the largest lymphoid organ in the body and contains many immune cells with a crucial role in immune response. In addition to the tumor, we measured the expression profile of pro-inflammatory cytokines (IFN- $\gamma$ , IFN- $\beta$ , TNF- $\alpha$ , IL-12, and IL-6) in the spleen tissue as the main secondary host lymphoid compartment (Figure 3). In the spleen, the highest level of

expression of IFN- $\beta$  and IL-6 was observed in the combination group [ADU-S100 (20  $\mu$ g) + CpG ODN (20  $\mu$ g)], which was increased compared with the control group (Figures 3A, E). The group treated with CpG ODN displayed the highest level of expression of IFN- $\gamma$  and IL-12 compared with the control group ( $p \leq 0.05$ ) (Figures 3B, C). The highest level of TNF- $\alpha$  expression was observed in the ADU-S100 (20  $\mu$ g) group, which displayed a larger tumor size than the other treatment groups (Figure 3D).

### 3.4 Immunohistochemical and histological analysis of tumor tissues showed typical features of apoptosis and inflammation after immunotherapy

To explore the primary effects of immunoadjuvants in tumor tissue, H&E staining was performed. The tumor cells were characterized by scarce eosinophilic cytoplasm with a round, polygonal, spindle-like polymorphic nucleus of variable size. They contained one or more nuclei, within a scarce stroma (Figure 4). The tumor tissues of all mice treated with ADU-S100 (20  $\mu$ g and 40  $\mu$ g), CpG ODN (40  $\mu$ g), and combination groups [ADU-S100 (20

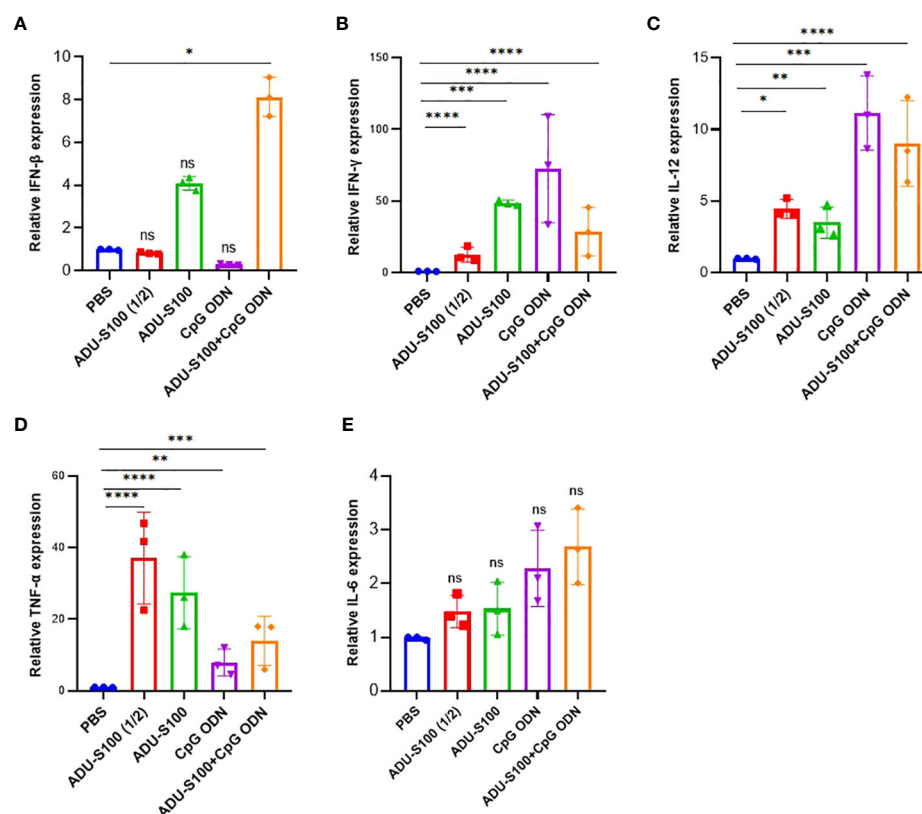

FIGURE 3

Expression profile of pro-inflammatory cytokines in the spleen. We conducted qRT-PCR analysis of (A) IFN- $\beta$ , (B) IFN- $\gamma$ , (C) TNF- $\alpha$ , (D) IL-12, and (E) IL-6 in the spleen tissues of treated mice on day 30 post-tumor inoculation ( $n = 3$  independent experiments). The expression levels were quantified relative to  $\beta$ -actin as a reference gene. Data are presented as mean  $\pm$  SD. Data were analyzed by REST software and statistically significant differences are indicated as \*\*\*\* $p \leq 0.0001$ , \*\*\* $p \leq 0.001$ , \*\* $p \leq 0.01$ , and \* $p \leq 0.05$ . IFN- $\beta$ , interferon beta; IFN- $\gamma$ , interferon-gamma; IL-12, interleukin 12; IL-6, interleukin 6; qRT-PCR, quantitative real-time polymerase chain reaction; REST, relative software expression tool; TNF- $\alpha$ , tumor necrosis factor- $\alpha$ .

FIGURE 4

Microphotographs of tumor tissues in the (A) control, (B) ADU-S100 (20 µg), (C) ADU-S100 (40 µg), (D) CpG ODN (40 µg), and (E) ADU-S100 (20 µg) + CpG ODN (20 µg) groups. Scale bars = 50 µm. (A–E, H&E staining,  $\times 400$  magnification). Tumor cells undergoing mitosis (black arrows), apoptotic tumor cells (yellow arrows), pleomorphism of the tumor cells (white arrows), tumor cells with one or more nucleoli (red arrows), and mononuclear inflammatory cells infiltrating into the tumor tissue (lymphocytes, green arrows) are shown. (F) The mean number of mitotic cells in the tumor tissues ( $n = 3$ ). Statistically significant differences were analyzed using Mann–Whitney tests and indicated as \*\*\*\* $p \leq 0.0001$ , \*\*\* $p \leq 0.001$ , and \* $p \leq 0.05$ . H&E, hematoxylin, and eosin.

µg) + CpG ODN (20 µg)], showed typical features of apoptosis and inflammation, indicating the effectiveness of the treatment in tumor clearance (Figures 4B–E). The number of mitotic cells in the control group was significantly increased compared with those in the treatment groups (Figure 4F). In addition, features of malignancy, such as hemorrhage and necrosis, were observed in the control group (Figure S3A). However, no tumor malignancies were observed in the treatment groups (Figures S3B–E).

Histopathological analysis of the liver and spleen was performed using H&E staining to assess the probability of tumor metastasis and toxicity linked to the treatment. The microstructure of the spleen in the control and all treatment groups was normal with no histological changes. The liver tissue displayed metastasis in control mice (Figures 5A, B), but treatment groups were normal (Figures 5C–F). To confirm that the necrotic cells observed in H&E-stained sections were apoptotic, cleaved caspase-3 expression was detected in the tumor tissues using immunohistochemistry (IHC). The results showed a remarkable and highly significant increase of cleaved caspase-3 as the main apoptotic marker in the combination group [ADU-S100 (20 µg) + CpG ODN (20 µg)]. Furthermore, we observed a significant caspase-3 increase in the single-agonist treatment groups compared with the control group (Figure 6).

### 3.5 Immunohistochemical analysis showed the abundant infiltration of tumor tissues by CD45<sup>+</sup> and CD8<sup>+</sup> cells after immunotherapy

To assess how ADU-S100 and CpG ODN1826 eradicated tumor growth and increased mice survival rate, immune cell infiltration of the tumor tissues was performed using IHC. CD45, as the most important marker of all nucleated hematopoietic cells (except platelets and erythrocytes), was used to sort the immune cells by IHC. The results showed that in all treatment groups, the level of CD45 expression was significantly increased compared with that of the control group ( $p \leq 0.05$ ). However, the most abundant expression of this biomarker was observed in the combination group represented (Figure 7). Furthermore, due to the crucial role of CD8<sup>+</sup> T cells in antitumor activity, the expression of this cellular marker was determined using IHC, which exhibited a significant upregulation in the recruitment of CD8<sup>+</sup> cells in tumor tissues in all treatment groups. The greatest increase in recruitment was observed in the combination group [ADU-S100 (20 µg) + CpG ODN (20 µg)], compared with the control group ( $p \leq 0.05$ ), followed by the CpG ODN (40 µg), ADU-S100 (20 µg), and ADU-S100 (40 µg) groups, respectively (Figure 8). These results were

FIGURE 5

Histologic structures of liver tissues in the control and treatment groups. consistent with a CBC analysis that showed that the number of lymphocytes in the combination group was significantly increased compared with the control group ( $p \leq 0.05$ ). In addition, in the CpG ODN (40 µg) and ADU-S100 (20 µg) groups, the level of total blood lymphocytes exhibited a greater than twofold increase compared with the control group (Figure S4).

### 3.6 Synergistic effect of ADU-S100 and CpG ODN in the suppression of CAFs' infiltration of tumor tissues

CAFs, as the most important stromal cells in the TME, contribute to tumor growth and metastasis through the production of growth factors and cytokines (31). To address the effects of ADU-S100 and CpG ODN on CAF abundance, the

expression of  $\alpha$ -SMA and VIM were assessed in the formalin-fixed paraffin-embedded tumor tissues using IHC (Figures 9, 10). The results indicated that the expression of these CAF biomarkers was significantly reduced in all treatment groups in comparison to the control group. This reduced expression of  $\alpha$ -SMA and VIM was highly significant in the combination group [ADU-S100 (20 µg) + CpG ODN (20 µg)] compared with the other treatment groups. Therefore, the combined effect of the two agonists was remarkably effective in increasing tumor eradication and inhibiting the infiltration of the TME by tumor-supporting cells.

## 4 Discussion

Despite the recent advances and progress made in our understanding of cancer immunotherapy, the field still faces

FIGURE 8

many challenges. Preclinical tumor models, the TME, and their expressed and secreted molecules are considered essential components to better understanding anticancer targeted therapy. This study revealed the immunotherapeutic effects of powerful innate immunity agonists in a mouse model of colon cancer. Tumor-bearing mice were treated intratumorally on days 10 and 16 post-tumor inoculation with ADU-S100, as a STING agonist, and CpG ODN1826, as a TLR9 agonist; both of these are powerful, safe, and effective immunoadjuvants with clinically translational potential. Several mechanistic studies, including on cytokine profiles, immune cells, and CAFs' infiltration of the TME, were performed to investigate the immunological mechanisms of tumor eradication and the extended survival rate after treatment. The results revealed the powerful antitumor activity of combination treatment even with a reduced (i.e., 50% lower) dose of each agonist and the upregulation of pro-inflammatory cytokine expression and

recruitment and infiltration of the TME by immune cells. A remarkable finding of this study was that the level of CAFs in the TME was significantly reduced after immunotherapy with STING and TLR9 agonists.

CT-26 is a non-inflamed and cold tumor of the gastrointestinal tract exhibiting low levels of cytokine expression and a lack of immune cell infiltration (55). The underlying mechanism, according to our data, is that ADU-S100 combined with CpG ODN initiates local inflammation in the CT-26 tumor, which subsequently establishes systemic immune responses, for example, cellular immunity as observed in the TME and spleen. This result is consistent with previous findings that STING and TLR9 agonists promote robust antitumor inflammatory responses (8, 45–47). This revealed the promising outcomes of combination therapy in extending survival rate, inhibiting tumor growth, and suppressing tumorigenesis, accompanied by a stronger inflammatory state within the tumor

FIGURE 10

Vimentin expression analyzed by IHC in tumor tissues. Data are presented as mean ± SD. Statistically significant differences were analyzed using Mann–Whitney tests and indicated as \*\*\*\* $p \leq 0.0001$  and \*\*\* $p \leq 0.001$ . Scale bars = 50 μm. IHC, immunohistochemistry; PBS, phosphate-buffered saline.

and spleen due to the increased expression of pro-inflammatory cytokines, which play a key role during the initial inflammation and the transition to T cell-mediated immune responses.

In this study, for the first time, we present evidence of biomarkers of tumor progression inhibition in CT-26 colon carcinoma following immunoadjuvant therapy. To our knowledge, although several preclinical studies have investigated the efficiency and immunological mechanisms of innate immunoadjuvant therapy in preclinical colon carcinoma models (56–58), the effect of such treatment on CAFs' infiltration of the TME has not been reported.

CAFs, as the key component of tumor stroma, play a significant role in many features of tumor biology, such as collagen deposition, tumor development, and immunosuppression (39).

CAFs are abundant in colorectal cancer and, within CT-26 tumors, constitute 25% of all live cells (55). CAFs, as important components of the TME, are associated with poor prognosis and therapeutic resistance (59).

Considering the upregulation of immune cell infiltration, cytokine production, and robust antitumor responses obtained by the combination of ADU-S100 and CpG ODN1826, we observed the downregulation of  $\alpha$ -SMA and VIM as the main biomarkers of CAFs and predictive markers of cancer progression (Figures 9, 10), suggesting that immunoadjuvant therapy employing STING and TLR9 agonists in single or combination forms suppresses the tumorigenesis potential of CAFs in the colon carcinoma model. Although there are alternative methods for detecting CAFs,  $\alpha$ -SMA, as the most studied marker, is used for determining the heterogeneity and phenotype of CAFs in tumor types (35, 60). In this study, we observed that tumor growth inhibition is directly related to  $\alpha$ -SMA and VIM expression. The combination of ADU-S100 and CpG ODN1826 exhibited the greatest downregulation of these markers, which was accompanied by the highest tumor inhibition rate (96%) in comparison to a single form of agonist (Figure S2A and Figures 9, 10).

The significant decrease in the levels of CAFs in all treatment groups is probably due to the activation of the STING signaling pathway, as Kabashima et al. demonstrated that in pancreatic ductal adenocarcinoma tissues, the activation of the cyclic GMP-AMP synthase (cGAS)–STING pathway led to an increase in the markers of tumor-suppressing CAFs and the infiltration of tumor tissues by immune cells (34). The intravenous injection of a chemically modified STING agonist (diABZI) in an established CT-26 tumor model abolished 98% of the CD140b<sup>+</sup> CAFs in the tumor stroma (55). Consistent with these data and our findings, the assumption relies on the interplay between the activation of the STING and TLR9 pathways and direct killing effects on CAFs in the TME. However, the underlying mechanisms of these findings have yet to be identified.

IL-6, as a cytokine produced by CAFs (39), demonstrated contrasting effects in our study. While monotherapy with ADU-S100 (20  $\mu$ g) led to the downregulation of IL-6 compared with the control group, in the combination group the expression of IL-6 was significantly upregulated compared with the control group. This may be due to the direct effect of STING pathway activation on the inhibition of CAFs in the TME in monotherapy treatment, as in

combination with CpG ODN1826, we found that IL-6 simultaneously diminished the abundance of CAFs and participated in the activation and proliferation of lymphocytes, as suggested in previous studies (6, 39, 61).

Type I and type II IFNs play a critical role in both innate and adaptive immunity and are essential for antitumor immune responses (62). The STING and TLR9 signaling pathways led to the production of type I IFNs in the TME (63, 64). Type I IFNs stimulate the apoptosis of tumor cells and prevent tumor cell proliferation and metastasis. The robust upregulation of IFN- $\beta$  expression in the tumor and spleen tissue, along with the increased infiltration of CD8<sup>+</sup> cells and reduced tumor cell mitosis observed in our study, was mainly due to the synergetic effect of STING and TLR9 agonists when administered in combination forms (Figures 2A, 3A, 4F, 8). Type I IFNs enhance the accumulation of DCs in the TME and promote their maturation and migration into lymph nodes for activation of CD8<sup>+</sup> T cells (65). In contrast to the spleen, in tumor tissues, the combined effects of STING and TLR9 agonists resulted in an approximately 70-fold increase in IFN- $\beta$  expression compared with the control group, which is a remarkable finding and indicates the pro-inflammatory status in the TME (Figures 2A, 3A).

The basal expression of type-I IFN by DCs resulted in the secretion of IFN- $\gamma$  (6). Alternatively, activated T lymphocytes, as a result of the type I interferon signaling pathway, produce IFN- $\gamma$ , which plays a crucial role in antitumor immunity (62). In our study, the tumoral expression of IFN- $\gamma$  in the combination group was upregulated approximately twofold compared with the control group (Figure 2B). We also identified IL-12 as an important pro-inflammatory cytokine that regulates innate and adaptive immune responses and showed that IL-12 was upregulated in the tumor and spleen tissues of mice in all treatment groups (Figures 3C, 4C) and that it may be effective in the induction of Th1 responses along with type I IFN production, in turn leading to the observed antitumor effects.

As a result of STING and TLR9 signaling pathways and the production of type I and II IFNs, the cross-priming of tumor antigens by CD8<sup>+</sup> T cells facilitates antitumor immune responses (66–68). Our results suggest that the synergistic effects of immunoadjuvants toward polarization of T-cell-mediated immunity within the TME are evident by the IHC analysis of CD8<sup>+</sup> cell infiltration and TNF- $\alpha$  expression (Figures 8, 2D). As a hallmark cytokine in CD8<sup>+</sup> T-cell activation and tumor infiltration (69), the synergistic effects of the combination treatment with both immunoadjuvants increased the tumoral expression of TNF- $\alpha$  twofold, whereas reduced expression of this cytokine was detected when single forms of immunoadjuvants were administered (Figure 2D). Consistent with this finding, the expression of CD8<sup>+</sup> cells in the combination group was 59% higher than in the control group, which was remarkable compared with a single form of agonist (Figure 8). On the other hand, an increase in CDN concentration led to a decrease in T-cell infiltration of the tumor (70, 71). In support of these findings, our IHC results indicated that there was decreased infiltration by CD8<sup>+</sup> cells in the ADU-S100 (40- $\mu$ g) group. However, when a lower dose of ADU-S100 (20  $\mu$ g) was used as a monotherapy or in the combination group, a greater than twofold increase in CD8<sup>+</sup> cell

infiltration of the TME was observed. These results are consistent with the expression of IFN- $\gamma$  in the tumor. In addition, the expression of CD45, which has an essential function in regulating immune responses, showed similar level of upregulation in all groups treated with a single agonist. However, the synergy of the agonists led to a higher (twofold) increase in CD45 expression, which was probably due to the greater recruitment of T cells to the TME in this group (Figure 7). H&E staining, along with the expression of cleaved caspase-3 as a positive marker for the efficiency of cancer treatment (72), revealed that there was a remarkable increase in the apoptotic index of caspase-3 in the combination group, suggesting *in situ* cell apoptosis compared with treatment with single agonists (Figure 6).

Studies showed that STING and TLR9 agonists promote the activation of DCs in the spleen (6, 45). We showed that, despite the intratumoral injection of agonists, the upregulation of cytokines occurred in the spleen, indicating a systemic immune response to agonists. In the combination group, the splenic expression of all cytokines was significantly upregulated compared with the control (Figure 3). It probably indicates the additive effects of both agonists on the activation of immune cells within the secondary lymphoid tissues. However, the splenic expression of IFN- $\gamma$ , IL-12, and TNF- $\alpha$  in the combination group showed different results. The expression of IFN- $\gamma$  in the combination group was lower than in the ADU-S100 (40  $\mu$ g) and CpG ODN (40- $\mu$ g) groups. The CpG ODN (40  $\mu$ g) group showed the highest level of splenic expression of IL-12, followed by the combination group. The splenic expression of TNF- $\alpha$  in the combination group was lower than in the ADU-S100 (20  $\mu$ g) and ADU-S100 (40  $\mu$ g) groups. These results might be due to the different inflammatory properties of immunoadjuvants in single or combination forms in secondary lymphoid tissues when they are administered locally in the tumor. Studies have shown that the intratumoral injection of the STING agonist developed systemic immune responses in the spleen and tumor-draining lymph nodes, which were indicated by increased levels of IFN- $\gamma$ -producing CD8<sup>+</sup>T cells in these organs (73). In addition, in mice immunized with ovalbumin/STING/TLR7/8 agonists, the activation of antigen-specific CD8<sup>+</sup>T cells in the spleen and lymph nodes was induced, which was significant compared with that observed in the control group, whereas a significant increase was not observed in the mice treated with a single form of agonist (74). Furthermore, this combination induces enhanced infiltration of T cells into distant tumors, indicating that systemic immune responses occurred (75). Contrary to these findings, we observed a lower level of splenic expression of IFN- $\gamma$ , IL-12, and TNF- $\alpha$  in the combination group after local immunotherapy, and, therefore, this suggests that further studies are required to explore the detailed mechanisms behind the splenic expression of these cytokines after intratumoral immunotherapy with ADU-S100 and CpG ODN1826. In conclusion, our results demonstrated that monotherapy with either CpG ODN or ADU-S100 and a combination of both agonists induced tumor regression, extended survival, and reduced infiltration of the TME by CAFs, underscoring the potential of immunoadjuvant therapy in inhibiting CAF-induced tumorigenesis. Mechanistic studies can reveal how the STING and

TLR9 signaling pathways modulate and inhibit CAFs' tumorigenicity and immunosuppressive state. Therefore, CAF-mediated immune modulation may be considered a potential cellular target in immunotherapy strategies for colorectal cancer. Considering the heterogeneity and plasticity of CAFs and their crosstalk with immune and cancer cells, are key challenges that must be addressed for effective clinical translation of these findings.

## Data availability statement

The original contributions presented in the study are included in the article/Supplementary Material. Further inquiries can be directed to the corresponding author.

## Ethics statement

The animal study was approved under the ethical guidelines of the Animal Care and Use Committee of Ferdowsi University of Mashhad (license number 46013-M). The study was conducted in accordance with the local legislation and institutional requirements.

## Author contributions

# Modulation of innate immunity in airway epithelium for host- directed therapy

Iwona T. Myszor<sup>1\*</sup> and Gudmundur Hrafn Gudmundsson<sup>1,2\*</sup>

<sup>1</sup>Faculty of Life and Environmental Sciences, Biomedical Center, University of Iceland,  
Reykjavik, Iceland, <sup>2</sup>Department of Laboratory Medicine, Karolinska Institutet, Stockholm, Sweden

Innate immunity of the mucosal surfaces provides the first-line defense from invading pathogens and pollutants conferring protection from the external environment. Innate immune system of the airway epithelium consists of several components including the mucus layer, mucociliary clearance of beating cilia, production of host defense peptides, epithelial barrier integrity provided by tight and adherens junctions, pathogen recognition receptors, receptors for chemokines and cytokines, production of reactive oxygen species, and autophagy. Therefore, multiple components interplay with each other for efficient protection from pathogens that still can subvert host innate immune defenses. Hence, the modulation of innate immune responses with different inducers to boost host endogenous front-line defenses in the lung epithelium to fend off pathogens and to enhance epithelial innate immune responses in the immunocompromised individuals is of interest for host-directed therapy. Herein, we reviewed possibilities of modulation innate immune responses in the airway epithelium for host-directed therapy presenting an alternative approach to standard antibiotics.

## KEYWORDS

innate immunity, airway epithelium, microbiota metabolites, epigenetics, innate immune memory

## Introduction

The airway epithelium of the respiratory tract is constantly exposed to particles and microbes inhaled with each breath that could possibly endanger the host. Hence, the highly specialized system of the host innate immune defenses is indispensable, as it keeps pathogens at bay and can limit the damaging effect of environmental pollutants. The airway epithelial cells together with stromal cells and tissue-residing immune cells shape immune responses in the local environment. Those immune responses protect the host from invading pathogens and maintain the local tissue homeostasis by producing signals for cell renewal and regeneration upon damage (1–4). In the first part of this review article, we provided an overview on innate immune functions of the airway epithelial cells covering recent developments like the identification of new cell types by single-cell transcriptomics.

In the second part, we described pathogens strategies to subvert host front-line defenses followed by the third part, where we reviewed research on how pathogens subversion mechanisms can be circumvented through modulation of host epithelial innate immune responses by different inducers for host-directed therapy.

## Innate immunity components of the human respiratory epithelium

The airway epithelial cells are central players in the communication between the host and the external environment and together with stromal and immune cells present in local tissues, shape immune responses during homeostasis and disease. This is possible because of a highly complex innate immune system consisting of several components that we review in this section. All those components work together to provide protection of the host mucosal surfaces from the external environment and tissue regeneration upon damage (1–4).

### Human airway and alveolar epithelium

The airway epithelium lining the upper and lower respiratory tract is composed of different types of epithelial cells forming a single-cell layer of pseudostratified epithelium with tight physical links to the basal lamina and communicating with underlying stromal cells, such as fibroblasts, airway smooth muscle cells, periendothelial (pericytes), and endothelial cells embedded in the connective tissue matrix (2, 4, 5). The four major types of cells in the airway epithelial layer are secretory club cells, goblet cells, ciliated cells, and basal cells (Figure 1) (3). Secretory club cells are columnar non-ciliated cells producing factors responsible for the neutralization of inhaled toxic substances and displaying immunomodulatory functions (6). In a mouse model, club cells were shown to act as self-renewing stem cells and as progenitors for ciliated cells that constitute the majority in the airway epithelium (7, 8). Club cells can also differentiate to mucus-producing goblet cells in response to allergens (9). Basal cells are small cuboidal cells that replenish different types of mature cells maintaining epithelial cell turnover during homeostasis and regenerating damaged epithelial barrier (10, 11). In respect to the important role in self-renewal and tissue regeneration, the basal cells seem to be protected from directed exposition to the lumen of the airways by other epithelial cells (Figure 1). Additional protection is provided by advanced innate host defense mechanisms. The proportion of each cell type occurring in human airways varies depending on the diameter of the airways, which results in diverse innate immune responses at different levels of the anatomical and histological organization of the respiratory system. For instance, mucus-secreting goblet cells occurring in submucosal glands of the human trachea and large bronchus are replaced by secretory club cells in terminal bronchioles (8, 12). The submucosal glands are composed of four major types of the airway epithelial cells and myoepithelial cells that together form a sophisticated machinery releasing fluids, mucus, and antimicrobial effectors into the luminal space of the airways (1).

Additional types of the airway epithelial cells have been recently described (Figure 1) based on the increasing accessibility of the single-cell RNA sequencing, changing our view on the cellular landscape of the airway epithelium that is more heterogeneous than previously thought (3–5, 13). Rare types of airway epithelial cells were distinguished including brush cells (also called tuft cells) and solitary chemosensory cells identified in the human trachea and nasal cavity, respectively (14). The function of brush cells in humans remains largely uncharacterized and, based on the mouse studies, indicates regulation of type II immune responses, such as release of IL-25 in the nasal epithelium and protective reflexes, such

FIGURE 1

Innate immunity components of the human respiratory epithelium in the distal part of the respiratory tract. The upper panel shows an overview on the different types of cells composing respiratory epithelium of the distal part of the airways including ciliated cells, ionocytes, club cells, basal cells, brush (tuft) cells, pulmonary neuroendocrine cells (PNEC), and goblet cells. The lower panel represents magnified area showing a part of the respiratory epithelium with innate immunity components marked; beginning from the top: mucus layer with host defense peptides (HDPs) entrapping bacteria, and pollutants removed by beating cilia in the periciliary layer. The constant renewal of the mucus layer is provided by goblet cells. Transport of molecules through the paracellular space between neighboring cells is regulated by tight junctions (TJs) and adherens junctions (AJs). Danger signals are recognized by pathogen recognition receptors (PRRs) and cytokine/chemokine receptors. Intracellular components of the innate immunity in the respiratory epithelium include production of reactive oxygen species (ROS) and autophagy eliminating intracellular intruders and particles. Created with [BioRender.com](https://www.biorender.com).

as sneezing (14, 15). Interestingly, brush cells do not occur in the healthy human alveolar epithelium. Expansion of brush cells in the upper airways and their *de novo* formation in the lower airways were observed after viral infections with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and influenza A subtype H1N1, respectively (15). Chemosensory cells in the human nasal epithelium detect and mediate reflex reactions in response to irritants and pathogens to prevent their passage down to the lower airways (16). Another rare cell type in the human airway epithelium are pulmonary neuroendocrine cells (PNECs) clustered into neuroendocrine bodies (NEB) (2, 17). Apart from olfactory epithelium in the nasal cavity (18), PNECs are the only cells in the airways supplied with nerves; therefore, they participate in the neurotransmission, act as sensory cells for the oxygen level, and detect and respond to inhaled allergens (2, 17). Another recently identified rare cell types are the ionocytes, showing high expression level of cystic fibrosis transmembrane receptor (CFTR), regulating the ionic microenvironment of the mucus (19, 20). In addition, novel subtypes of progenitor cells were identified, such as precursors of ciliated cells—deuterosomal cells containing numerous centrioles and mucous-ciliated differentiation intermediate cells (3). Moreover, the population of basal cells is more heterogeneous than what was thought. The new intermediate cells were distinguished between basal and 1) club cells—suprabasal cells, 2) PNEC, ionocytes, and brush cells—parabasal cells, and 3) luminal secretory cells—Hillock cells (3, 5, 11).

The distal part of human airways ends with terminal bronchioles mainly composed of club and ciliated cells with very few rare types of cells and almost no basal cells present (8). One can argue that only few basal cells are present in the distal part of human airways because, in principle, the portion of air reaching alveoli should be warmed, moistened, and cleared from pollutants, as the vital function of the alveolar epithelium is the gas exchange provided by epithelial alveolar type 1 cells (also known as AT1, ATI, and type I pneumocytes) (2). Frequently, these defense mechanisms of the proximal part of the respiratory system are not sufficient. Therefore, alveolar innate immune defense mechanisms are activated to protect the host, such as surfactant proteins produced by alveolar type 2 cells (also known as AT2, ATII, and type II pneumocytes), that also function as progenitor cells for AT1 cells in the adult lung (1, 2, 21). Overall, the recent advances in transcriptomic and proteomic analyses opened a new avenue for further characterization of innate immune functions of new epithelial cells subtypes and the signaling pathways guarding their differentiation.

## Host defense peptides

Numerous antimicrobial effectors are produced by the airway epithelial cells for effective host innate defenses. Among them are host defense peptides (HDPs) (Figure 1), previously commonly called antimicrobial peptides (AMPs), divided into two main families of cathelicidins and defensins (22–24). HDPs can be produced constitutively and induced upon stimuli. Their constitutive expression can be enhanced upon stress conditions,

like infection or injury. Most of HDPs are stored in the cellular granules as a pro-form, which is further released and processed upon a danger signal (22, 25). Human cathelicidins have one dominant mature peptide LL-37 encoded by *CAMP* gene (cathelicidin antimicrobial peptide). Human cathelicidin is produced as a pro-form (hCAP18; pro-LL-37) containing N-terminal cathelin domain that is cleaved off by serine proteases, such as kallikreins in the skin and proteinase 3 from neutrophils to release the mature LL-37 peptide (25–28). LL-37 has an  $\alpha$ -helical structure and a cationic, amphipathic character and can be processed in the skin to shorter peptides (26, 29). Human cathelicidin is constitutively expressed at rather low protein levels in airway epithelial cells showing only the pro-form to be secreted when the cells are cultured *in vitro*. The expression of cathelicidin is enhanced upon stimuli, indicating a highly responsive inducible system for host defense (30–32). During inflammation, the migration of neutrophils to the site of infection contributes to the processing of the pro-form hCAP18 to the active LL-37 peptide in the lung, as neutrophils are loaded with proteinase 3 and other enzymes. However, whether the processing of constitutively expressed pro-form hCAP18 to the active LL-37 peptide takes place on the airway epithelial surfaces in physiological conditions during homeostasis remains to be further elucidated, as the *in vitro* studies with the airway epithelial cells do not closely recapitulate the *in vivo* environment. On the other hand, the analysis of the airway surface liquid (ASL) indicated the presence of mature LL-37 (33). However, one may argue about fact that the source of mature LL-37 peptide in ASL might come from immune cells present in lungs. Therefore, the dynamics of the cathelicidin processing to the mature LL-37 peptide in the homeostatic conditions of the lung epithelium remains to be further investigated, similar to the identification of potential lung tissue specific enzymes responsible for the cleavage and confirmation if LL-37 is processed to shorter peptides with characterization of their potential role in shaping local lung innate immune responses. In contrast to cathelicidins, human defensins have several members and are divided in  $\alpha$ -,  $\beta$ -, and  $\theta$ -defensins (34). Alpha- and beta-defensins are produced in the airway epithelium constitutively and inducible as inactive precursors that undergo further processing to the active form (21, 22, 35, 36). In human genome, there are genes encoding the third group of  $\theta$ -defensins; however, proteins are not produced because of premature codon stop (37). The expression of antimicrobial effectors in each cell type present in the airway epithelium has been explored and is available in Human Protein Atlas (HPA). According to HPA, the main sources of cathelicidin in bronchus are basal respiratory cells (<https://www.proteinatlas.org/ENSG00000164047-CAMP/single+cell+type/bronchus>).

The primary function of the HDPs is their bactericidal effect at the range of micromolar concentrations on both Gram-positive and Gram-negative bacteria, but they are also effective against viruses and fungi (26, 35, 38). The common antimicrobial activity of HDPs is associated with their cationic and amphipathic properties. Positively charged HDPs can strongly interact through electrostatic and hydrophobic interactions with negatively charged phospholipids of the bacterial cell membrane and pathogen-associated molecular patterns (PAMPs), such as LPS of Gram-

negative bacteria (39, 40). The interaction of HDPs with the bacterial membrane causes disruption, leakage of the intracellular components, and bacterial cell death (24). Another, less known antimicrobial mechanism of HDPs is the translocation of peptides through the membrane and binding to bacterial intracellular targets, for example, cardiolipin resulting in bacterial cell death (41). Furthermore, human  $\beta$ -defensin 3 has been shown to disrupt bacterial cell wall biosynthesis by binding to lipid II, which makes bacteria more vulnerable to damage (42). Hence, peptides have different activities against bacteria, but the membrane disruption seems of a major general importance. In case of the viral infections, HDPs bind and destabilize viral structures like viral envelope of influenza viruses, respiratory syncytial virus (RSV), Zika virus (38, 43, 44), and viral capsid of rhinoviruses (45). Similar mechanism takes place during fungal infections, like with *Candida albicans*, where HDPs permeabilize yeast cell membrane (46). Of note, at physiological concentrations, the HDPs do not damage human cell membranes due to its lack of negative charge in the outer leaflet of the membrane and presence of cholesterol (47). However, HDPs at higher concentrations might be able to damage host's cells, for instance when granulocytes are recruited to the site of infection in the lung (48, 49). Interestingly, recently, it has been described that the fragments of LL-37 peptide (17–29 aa residues) can cluster together to form highly organized oligomers resembling fibril-like tubules of unknown function (50). Some pathogens, such as *Staphylococcus aureus*, produce similar tubules what is recently discussed as an example of the bacterial mimicry, perhaps to evade host antimicrobial responses potentially exerted by such HDPs fibril-like oligomers (51). However, the existence and physiological relevance of such LL-37 fibrils in the lung epithelial surfaces have not been described so far.

Apart from antimicrobial activity, HDPs display immunomodulatory functions (24). HDPs are chemoattractant for immune cells, e.g., human  $\beta$ -defensin 2 (hBD2) is a chemoattractant for mast cells (52) and LL-37 for neutrophils, monocytes, and T cells (53, 54). HDPs also indirectly recruits leukocytes to the local site of infection or injury by inducing release of chemokines and cytokines (24). For instance, defensins can induce expression of proinflammatory IL-8, a chemoattractant for neutrophils, in human A549 lung epithelial cell line and therefore display proinflammatory function *in vitro* (55). HDPs interfere with the cell signaling cascades while displaying at the same time a dual pro- and anti-inflammatory role, depending on the local environment and the phase of infection. During infection when nuclear factor kappa B (NF- $\kappa$ B) pathway is activated by bacterial LPS binding Toll-like receptor 4 (TLR4) receptor, LL-37 peptide can selectively inhibit production of proinflammatory tumor necrosis factor (TNF) and reactive oxygen species (ROS) while at the same time stimulate IL-8 production in epithelial cells to attract immune cells (56). HDPs have pro- and anti-inflammatory effects that seem to be exerted depending on the stage of infection. In the early stage of bacterial infection with *Pseudomonas aeruginosa*, LL-37 enhances proinflammatory response in airway epithelial cells (57). Cathelicidins are also able to prevent activation of TLR2 and TLR4 signaling in macrophages by non-viable bacteria and their products at later stage of infection,

resulting in reduced production of proinflammatory response that might protect local tissue from the injury (58). Therefore, HDPs can play a dual role in shaping both pro- and anti-inflammatory response and maintaining tissue homeostasis. HDPs also display additional functions by enhancing phagocytosis, ROS production, and participation in neutrophil extracellular trap (NET) formation, contributing to enhancement of the bacterial clearance (24). HDPs also initiate T-cell response by promoting Th17 differentiation (59) and could, therefore, play a role in the intersection of innate and adaptive immunity. Furthermore, local environment also affects immunomodulatory function of HDPs by their post-translational modifications (PTMs). The citrullinated LL-37 peptide was detected in human bronchoalveolar lavage; however, citrullination affected the net charge of the peptide that lost the ability for bacterial killing (60). Another evidence is citrullination of LL-37 by peptidyl arginine deaminase, where the peptide loses its ability to enhance proinflammatory response in macrophages (61). These studies indicate that PTMs regulate the mode of action of HDPs for the maintenance of the local tissue homeostasis, and future exploration of how additional PTMs affect function of HDPs in lungs is of interest.

Apart from HDPs, there are also several antimicrobial proteins like lysozyme, degrading bacterial peptidoglycans, and bacteriostatic lipocalin 2 and lactotransferrin (21). The bacteriostatic effect of lipocalin 2 and lactoferrin are linked to the inhibition of iron uptake by bacteria from the local environment, as they bind bacterial iron-chelating molecules. Lipocalin 2 has been shown to be effective against *Escherichia coli* causing pneumonia (62), and mutant mice lacking lipocalin 2 were more susceptible to *Klebsiella pneumoniae* infections (63). Similarly, S100A7 (psoriasin) protein from S100 protein family containing several antimicrobial effectors (e.g., S100A8/9 protein known as calprotectin) has been shown to kill *E. coli* by  $Zn^{2+}$  chelation (64). Airway epithelial cells and alveolar macrophages constitutively express S100A7 that is enhanced upon *S. aureus* challenge (65). Interestingly, the mechanical strain generated during breathing enhances expression of S100A7 protein in alveolus-on-chip model through activation of mechanosensitive ion channel TRPV4 (transient receptor potential vanilloid-type 4). Moreover, when TRPV4 and the S100A7 target receptor—receptor for advanced glycation end products (RAGE)—were blocked by inhibitors, the viral load of H3N2 influenza was increased, demonstrating the importance of S100A7 for lung defenses (66). Furthermore, antiproteases like secretory leukocyte protease inhibitor (SLPI) and elafin exhibit antimicrobial properties against pathogens *P. aeruginosa* and *S. aureus* in lung epithelial cells (67–69) and have anti-inflammatory potential, e.g., by inhibition of NF- $\kappa$ B pathway through reducing degradation of I $\kappa$ B $\alpha$  in macrophages and endothelial cells (70). Ribonuclease 7 (RNase7) discovered in the skin where it displays antimicrobial effects against several pathogens has also been shown to be expressed in human respiratory tract (71). Interestingly, the primary source of RNase7 in human airways are basal cells that express RNase7 upon stimulation with inactivated *H. influenzae* and cigarette smoke, therefore indicated as a second line of front-line defenses in case of injury of mature differentiated epithelial cells (72). Similarly, RNase7 has been induced in airway epithelial cells

upon infection with *Mtb*, where it marked intracellular bacteria to a limited extent. However, the direct effect of RNase7 on elimination of *Mtb* was not shown and requires further investigation (73). Additional components of the innate immunity in the lung epithelium are collectins, surfactant protein A and D (SP-A and SP-D), produced by alveolar type 2 cells (21). They tag bacteria for opsonization to increase phagocytosis by the alveolar macrophages (74). The immunomodulatory function of collectins can be exemplified by the inhibitory effect of the SP-A on the production of IL-8 by eosinophils present during allergic response (75). The antimicrobial and immunomodulatory functions are also displayed by plate-lung-nasal-clone (PLUNC) proteins shown to have antibacterial effect against *Mycoplasma pneumoniae* and reduce production of proinflammatory cytokine IL-8 (76). Of note, several chemokines like CXCL9 and CXCL11, present in the lung epithelium as a result of interferon gamma (IFN $\gamma$ ) stimulation, have antibacterial functions against *E. coli* and *L. monocytogenes* (77). Host defense effectors produced by club cells such as club cell protein 10 (CC-10) inhibit NF- $\kappa$ B signaling pathway and production of proinflammatory cytokines and chemokines in bronchial epithelial cells (78). Similar to CC-10, club cell secretory protein (CCSP) was shown to reduce inflammation and viral load during RSV infection (79). Next, the levels of secretoglobulin A1A (SCGB1A1) also produced by club cells were reduced in the airways of patients with asthma in comparison to healthy individuals (80). Allergen-specific immunotherapy increased expression of SCGB1A1 considered as anti-inflammatory mediator in the lower airways (81). Secretoglobulin A1A was also shown to affect alveolar macrophages by attenuation of the surge of inflammatory cytokines during activation of TLR receptors. Deficiency of secretoglobulin A1A facilitated development of proinflammatory M1 phenotype of pulmonary macrophages, indicating the importance of physiological levels of SCGB1A1 for innate immune defense and maintenance of local tissue homeostasis (82). Another important indirect link to HDP activity is the expression and function of CFTR and the non-gastric H<sup>+</sup>/K<sup>+</sup> adenosine triphosphatase (ATP12A) in lung epithelial cells, including recently identified ionocytes. Both CFTR and ATP12A regulate pH of the airway surface liquid (ASL) by secretion of HCO<sub>3</sub><sup>-</sup> and H<sup>+</sup>, respectively, that is detrimental for antimicrobial activity of HDPs (83, 84).

A further important element of the innate immunity in the airway epithelial cells is the production of reactive oxygen species (ROS) (Figure 1). For many years, ROS were attributed to the lung tissue damage and tissue aging as a result of the oxidative stress (85, 86) but in fact ROS play an important function in the elimination of invading pathogens (21). Dual oxidases (DUOX) are key enzymes responsible for the generation of ROS in the lung epithelium, including superoxide and hydrogen peroxide, for effective pathogen elimination (87, 88). In addition, the protective role of NOX1 activity have been shown to limit inflammatory response and lung tissue damage exerted by influenza A at early stage of infection in mice (89) even though the NOX1 activity in different circumstances, such as hyperoxia, can cause tissue damage (85). The view on ROS generation and redox signaling in epithelial cells is developing to better understand their role in pathological

situations and demonstrate that the physiological levels of ROS are important for cellular signaling during homeostasis (86, 90).

## Mucus and mucociliary clearance

A physical component of the innate immune system is the airway surface liquid (ASL) composed of the mucus and periciliary layer on the airway epithelium (Figure 1) (91). The ASL provides a physical and chemical barrier for the invading pathogens and inhaled particles protecting the airway tissue from the damage (92). The chemical barrier of ASL is provided by the low salt content (93), pH maintained by HCO<sub>3</sub><sup>-</sup> and H<sup>+</sup> (94, 95), and hydration maintained by Na<sup>+</sup> and Cl<sup>-</sup> ion gradient (96). This environment facilitates the formation of MUC5B bundles (12) and keeps HDPs active for killing of entrapped pathogens in the mucus layer (83, 84) for their removal by mucociliary clearance of beating cilia (21, 93). The periciliary layer of ASL composed of transmembrane mucins and periciliary liquid reduces the friction of the constantly moving mucus that clears airways from bacteria and pollutants during homeostasis (12). The dynamic process of mucociliary clearance keeps the airways almost devoid of bacteria in healthy individuals (12, 93) causing the characterization of any existing lung microbiome very difficult and so far confirmed only by detection of bacterial nucleic acids (97, 98). In addition, the anaerobic bacterial fermentation products were detected in the lungs of patients with HIV (99, 100); however, those ground-breaking evidence shall be carefully interpreted and further confirmed by the characterization of additional microbiota metabolites and their original source of production. Impairment of the mucociliary clearance by primary ciliary dyskinesia (101) or defects in the function of ion channels in cystic fibrosis (CF) (92) cause clogging of the airways with mucus, creating a favorable environment for bacterial growth (12). Therefore, pre-existing bacteria during chronic respiratory diseases are sometimes referred in the literature as “lung microbiota” (102), although it should be emphasized that this terminology is used in the context of pathological conditions. In general, the studies on the mucus composition and physiology together with the interaction of innate immunity components with mucus are of interest and one of the future directions in the field investigating host defenses.

## Pathogen recognition receptors

One of the initial functions of innate immunity in the airway epithelium is pathogen detection by pathogen recognition receptors (PRRs) (Figure 1), recognizing PAMPs. Upon stimulation, PRRs activate signaling cascade leading to the inflammation and clearance of the pathogens. Among different types of the PRRs, present in the airway epithelium are TLRs, NOD-like receptors (NLRs), RIG-I-like receptors (RLRs), C-type lectin receptors (CLRs), and formyl-peptide receptors (FPRs) (21, 103–105).

In the airway epithelium, all types of the TLRs (TLR2/1, TLR2/6, TLR3, TLR4, TLR5, TLR7, TLR8, TLR9, and TLR11) are present, anchored in the cell membrane and endosomes (21). However,

the mapping of TLRs with their exact spatial distribution within airway epithelial cell membranes at different regions of the respiratory tract, similar to the study done for the intestinal epithelium (106), is still missing. TLRs recognize bacterial lipopeptides, lipopolysaccharide (LPS), flagellin, DNA, and RNA by the leucine-rich repeat (LRR) motif that is linked through a single transmembrane domain to Toll/IL-1 receptor (TIR) intracellular motif. The activation of the receptor requires binding of the adaptor protein MyD88 or TIR-domain-containing adapter-inducing interferon- $\beta$  (TRIF) to the TIR domain. MyD88 is an adaptor protein for all TLRs, except TLR3 and TRIF for TLR3 and TLR4. Other adaptor proteins like TIR domain containing adaptor protein (TIRAP), translocation associated membrane protein 1 (TRAM), sterile alpha and TIR motif containing (SARM) have been shown to be involved in the TLR signaling. The stimulation of TLRs initiates NF- $\kappa$ B and mitogen-activated protein kinase (MAPK) downstream signaling, leading to induction of proinflammatory cytokines and type I interferons (21, 107).

Unlike TLRs, apart from cell and endosomal membranes, NLRs occur as soluble receptors in the cytoplasm. In the airway epithelium, NLRs with caspase recruitment domain (CARD) are represented by NOD1 and NOD2 receptors, recognizing bacterial peptidoglycans and working in synergy with TLRs towards activation of NF- $\kappa$ B and MAPK pathways (108). The other types of NLRs, containing PYD (pyrin) and NLRB (baculovirus inhibitor of apoptosis protein) domains form inflammasome controlling cleavage of IL-1 $\beta$  and IL-18 pro-forms by caspase-1 (21, 103). For instance, in human lung epithelial cells NLRP3 receptor harboring pyrin domain forms NLRP3 inflammasome responsible for cleavage of IL-1 $\beta$  upon *C. albicans* or influenza A virus infection (109, 110).

Human airway epithelial cells have also cytoplasmic receptors for the detection of pathogen's nucleic acids (21). Among them are RIG-I-like receptors (RLRs), recognizing viral ss/dsRNA of influenza and paramyxoviruses causing respiratory diseases, e.g., RSV (111, 112). The group of RLR receptors include retinoic acid inducible gene-I (RIG-I), melanoma differentiation-associated gene 5 (MDA5) and RIG-I-like receptor dsRNA helicase (LGP2) (103). With the involvement of the adaptor proteins, e.g., mitochondrial antiviral-signaling protein (MAVS), RIG-I and MDA5 receptors transduce signals activating NF- $\kappa$ B, interferon regulatory factor 3 and 7 (IRF3 and IRF7) pathways leading to the production of proinflammatory cytokines and interferons (108). Other cytoplasmic receptors recognize bacterial DNA and bacterial signaling molecules such as cyclic dinucleotides (CDNs) (21). A prominent member of this family is the stimulator of IFN genes (STING) located on the ER membrane. STING recognizes CDNs and is an adaptor protein for other cytoplasmic receptors like interferon gamma inducible protein 16 (IFI16) recognizing *Streptococcus pneumoniae* dsDNA (113). Moreover, STING can be activated by cyclic GMP-AMP (cGAMP) synthesized by cGAMP synthase (cGAS) in human airway epithelial cells upon detection of not only microbial/viral DNA in the cytoplasm but also by self-DNA coming from the nucleus or damaged mitochondria (114).

Additional PRRs are C-type lectin receptors (CLRs) on the airway epithelial cells recognizing carbohydrates present on the pathogens and activating proinflammatory response (21, 103). The

CLRs occur as membrane-anchored receptors like Dectin-1 recognizing *Haemophilus influenzae* and *Aspergillus fumigatus* infections (115, 116). The second form of CLRs are soluble collectins containing C-type lectin domain like SP-A and SP-D exhibiting antimicrobial activity through opsonization of bacterial, viral, and fungal pathogens (21). Formyl-peptide receptors (FPRs) are also expressed on the epithelial cells of the respiratory tract, where they recognize not only bacterial formylated peptides but also host-derived stimulants, such as mitochondrial proteins from damaged cells that chemoattract leukocytes promoting inflammation. Host LL-37 has also been shown to activate FPR2 (aka FPRL1) and is considered as a proinflammatory stimulus in chronic obstructive pulmonary disease (COPD). Depending on the local tissue environment, activation of FPRs can have a dual pro- or anti-inflammatory role, and it has been associated with the tissue regeneration and wound healing (105, 117).

Interestingly, it has recently been shown that PTMs of PRRs can be considered as contributing to a fine-tuning mechanism limiting inflammation; for instance, palmitoylation of NLR family pyrin domain containing 3 (NLRP3) prevents activation of inflammasome (118). Studies on how different PTMs affect PRRs downstream signaling in response to pathogens and during inflammation is one of the future directions for research in the host-pathogen interactions field.

## Cell junctional complexes

The structural elements of the airway epithelial barrier integrity are tight (TJs) and adherens junctions (AJs) that determine the polarization of the epithelial cells into the apical and basolateral site providing physical barrier regulating paracellular flux through epithelial layers (119). Hence, the epithelial barrier integrity provided by TJs and AJs can be considered as part of the epithelial defense system (Figure 1). TJs and AJs are composed of transmembrane proteins, such as occludin, tricellulin, claudins, and junctional adhesion molecules (JAMs) and many others present in TJs together with E-cadherin and nectins in AJs. Transmembrane proteins of TJs interact with the proteins of the intracellular junctional plaque containing multiple interaction domains, such as zonula occludens-1 (ZO-1)—a well-defined protein from the junctional plaque complex—and its deletion is lethal in the mouse embryos. The examples of AJs intracellular junctional plaque proteins are  $\alpha$ - and  $\beta$ - and p120 catenins and afadin (AF6) displaying similar functions. The intracellular junctional plaque proteins are coupled to cytoskeleton proteins, for example to actin through C-terminal domain of ZO-1 (119). The importance of the functional epithelial barrier sealing the deeper tissues from the external environment for the maintenance of the local tissue homeostasis seems to be explained by the epithelial barrier hypothesis (120). It highlights that the leaky epithelial layer caused by disruption of TJs and AJs by detergents, pollutants, allergens, and pathogens (121–125) contributes to increased incidence of allergies, asthma, and autoimmune diseases (120). The exposure to such environmental insults creates a positive feedback loop of further epithelial layer destruction. This process

includes a subsequent translocation of the microbiota and opportunistic pathogens through a disrupted epithelial layer to the lamina propria that activates macrophages and T cells, ultimately leading to inflammation (120). During inflammatory response, cytokines cause further disintegration of tight junctions in the airway epithelium (126, 127), exacerbating the inflammatory response that may become a chronic state. Therefore, the disruption of the net of TJs and AJs can be considered as one of the early onsets of the disease. Hence, the maintenance of the epithelial barrier integrity is crucial for balanced innate and adaptive immune responses in the airway epithelium.

## Autophagy

Autophagy is a complex process involving interaction of several different proteins, leading to engulfment of the cytoplasmic cargo during autophagosome formation and its subsequent degradation upon fusion with lysosomes. Autophagy is one of the key cellular processes maintaining balance in cells exposed to a constantly changing environment. It plays a major “housekeeping” function on the cellular level where it is responsible for the degradation of damaged organelles and unfolded/misfolded proteins (128). An important function of the autophagy process in respect to innate immunity is the degradation of invading pathogens, when the initial innate immunity barrier—mucus, HDPs, and TJs—was not sufficient to halt the pathogen entering the cells (129). Pathogenic *P. aeruginosa* (130), conidia of *Aspergillus fumigatus* (131), and influenza A virus (132) can be effectively eliminated or restricted by autophagy in airway epithelial cells. Therefore, autophagy can be considered as part of cell autonomous innate immunity and an intracellular defense mechanism of the “last chance” for the prevention of pathogen dissemination and progression of infectious disease (133). The commonly used cell model to study the role of autophagy in innate immunity are phagocytic professional cells, such as macrophages. However, the importance of autophagy in epithelial cells should be highlighted due to the vital role of epithelial cells in the first line of the host defense and epithelial homeostasis (Figure 1). During homeostasis, autophagy can control ciliogenesis and ciliary function by regulating the length of motile cilia in airway cells (134). The biogenesis of primary cilia is regulated by autophagic degradation of centriole and centriolar satellite protein OFD1 (135) and the function of motile cilia by degradation of kinesin family member 19 (Kif19)—an essential protein controlling ciliary length that should be inhibited to maintain the correct length of cilia (136).

Moreover, the importance of autophagy in human lung is demonstrated in CF patients whose autophagy is impaired due to aggregating Beclin-1. In the cell and animal models of CF, this phenotype can be rescued upon Beclin-1 restoration, suggesting a key role of autophagy in the lung homeostasis (137). Autophagy was shown as a central contributor to IL-13-mediated mucus hypersecretion by airway epithelial cells in COPD and asthma (138). Moreover, autophagy regulates apical localization of DUOX1 in airway epithelial cells and ROS production in response to chronic IL-13 exposure (139). Furthermore,

autophagy maintains the airway progenitor cells pool and regulates cell differentiation for epithelial regeneration (140). In addition, one of the clinical symptoms of the Hermansky–Pudlak syndrome type 1, a rare genetic disorder impairing vesicle trafficking, is lung fibrosis and impaired innate immune antimicrobial responses due to amplified mechanistic target of rapamycin kinase (mTOR) signaling resulting in reduced bacterial clearance, indicating autophagy as a key cellular process in physiological and pathological conditions (141, 142). Autophagy in the airway epithelium can be considered as a double-edge sword because in particulate-matter-induced airway inflammation, autophagy contributes to the epithelial injury (143). The basic research on the autophagy process and its regulation in different conditions remain future perspectives for the development of novel strategies for treating respiratory tract diseases.

## Epigenetics and innate immunity

Innate immune responses in the airway epithelium are also regulated by epigenetic modifiers of DNA methylation and post-translational modifications of histones. The epigenetic regulation of gene expression by modulation leading to chromatin opening allows for a rapid response to environmental changes. These processes are tightly regulated by the equilibrium of epigenetic enzymes and their counterparts, for example by histone acetyltransferases (HATs)—histone deacetyltransferases (HDACs) and DNA methyltransferases (DMTs). The importance of the DNA methylation status seems to be highlighted by the studies showing that DNA methylation pattern is changed in respiratory tract diseases, such as increased DNA methylation in *NLRP3* gene of COPD patients (144). On the other hand, decreased methylation in the promoter region of *TLR2* contributed to enhanced inflammatory responses in the airway epithelium of CF patients in response to bacterial peptidoglycan (145). Different PTMs of histones can modulate the front-line innate immune defenses in response to pathogen invasion (Figure 2). For example, acetylation of histones allows for more permissive chromatin structure facilitating gene expression. Upon stimulation with LPS, the activation of MAPK pathway leads to phosphorylation of H3S10 and additional acetylation of H3S10K14 at the promoter of *IL12*, leading to chromatin opening for NF- $\kappa$ B and induction of IL-12 expression (146). Furthermore, an increased acetylation of H3K18 was observed in *STAT6* locus in the airway epithelial cells of asthmatic patients (147). Although that study did not show increased *STAT6* expression, it is known that *STAT6* signaling is affected in asthma and, together with elevated levels of IL-4 and IL-13 driven by Th2 immune responses, leads to mucus hypersecretion in mice, which is a characteristic for asthma, COPD, and CF (148). Moreover, the treatment of asthmatic airway epithelial cells with IL-4 and IL-13 caused the impairment of the airway epithelial barrier integrity concomitant with enhanced expression of HDACs (1 and 9) and sirtuins (SIRT6 and 7). Interestingly, inhibition of HDACs in asthmatic airway epithelial cells by quisinostat (class I and II HDAC inhibitor) improved the epithelial barrier integrity by increasing the expression of TJ proteins (149). On the other hand, inhibition of

HDACs for example, by deletion of *Hdac1* in mice exposed to the allergen caused more stable Th2 immune responses resulting in mucus hypersecretion by goblet cells, demonstrating an important role of HDAC1 in allergic diseases (150). The enzyme HDAC2 can suppress NF- $\kappa$ B and AP-1 signaling leading to the inhibition of proinflammatory response caused by stimulation of TLR4. Interestingly, the downregulation of HDAC2 in lungs of COPD patients and rats exposed to cigarette smoke suggest that HDAC2 expression is modulated in response to environmental factors and protects from inflammation and mucus hypersecretion during homeostasis (148, 151, 152). Unlike HDAC2, exposition to cigarette smoke increased expression of HDAC6 enhancing autophagy. Rapid protein turnover due to increased autophagy led to shortening of the ciliary length that contributes to impaired

mucociliary clearance observed in COPD. These effects were diminished in *Hdac6*<sup>-/-</sup> mice exposed to cigarette smoke, suggesting the inhibition of HDAC6 as a potential therapeutic target for COPD treatment (153, 154). Apart from HDAC6, many epigenetic modifiers are suggested to regulate autophagy processes (155), such as EZH2 methyltransferase responsible for the trimethylation of H3K27 shown to inhibit autophagy (156). The importance of EZH2 was demonstrated to regulate differentiation of airway epithelial stem cells that is aberrant in *Ezh2*-deficient mice resembling an altered airway epithelial cell differentiation typical for COPD (157). Overall, the epigenetic regulation of innate immune responses is intensively investigated, and the studies showing epigenetic regulation of HDPs in the lung epithelium are ongoing (158).

## How pathogens subvert host innate immune defenses in lungs

Efficient innate immune responses in airway mucosa are essential for maintaining respiratory functions. The mucosal surface of the airways is also an initial site for pathogens interaction with the host. Many pathogens can subvert airway mucosal defense mechanisms and cause disease, especially in immunocompromised individuals. In this section, we will discuss those strategies based on the selected examples of respiratory pathogens that mainly concentrate on bacteria, as those were extensively studied throughout the years in comparison to viruses and fungi. Viral subversions mechanisms of host innate immune responses in lungs has recently gained more attention due to SARS-CoV-2 pandemic, while little is known about fungal strategies that seems to be relevant, especially in the development of severe fungal infections in immunocompromised individuals.

## Bacteria

*Pseudomonas aeruginosa* (Pa) is an opportunistic pathogen usually harmless for healthy people; however, it can cause pneumonia in vulnerable immunocompromised individuals like patients with chronic respiratory diseases, such as CF, COPD, and hospitalized patients with supportive mechanical ventilation. Pa is known to use different strategies and virulence factors for the effective colonization of the host mucosal surfaces (159). The bacteria utilize flagellin for movement and pili for adhesion to the host cells. Once the host-pathogen adhesion is established, Pa injects bacterial toxins, such as ExoS to the host cells by type 3 secretion system (T3SS) causing acute infection (160). Furthermore, lung tissue damage in pneumonia is caused by disruption of the airway TJs and AJs integrity by Pa elastase that also degrades collectins (SP-A and SP-D), collagen, complement components, and LL-37 (159, 161). Pa rhamnolipids also disrupt TJs integrity in the airway epithelium facilitating Pa invasion (162). As an additional virulence factor, pyocyanin impairs ciliary function and inhibits host catalase, which contributes to the oxidative lung damage (163, 164). Furthermore, Pa competes for the iron source

with host antimicrobial effectors, necessary for the activity of antimicrobial effector, lactoferrin, in the airway epithelium (165). Depending on the local environment of the host airway epithelium, especially during mucus clogging in CF and COPD, Pa can switch strategy of host colonization, from the invasive to a more adaptative one by formation of the biofilm. Quorum-sensing mechanisms allow for the communication of bacteria thriving in the biofilm and involve bacterial molecules, such as acyl homoserine lactones (AHL). At the same time, bacterial molecules involved in quorum sensing affect host cells; for example, AHL facilitates apoptosis of neutrophils but not the host's airway epithelial cells (166). In addition, 2-aminoacetophenone enhances the host's HDAC1 activity suppressing proinflammatory response that facilitates bacterial survival (167). Moreover, Pa in biofilm produces alginate, a mucopolysaccharide used for bacterial encapsulation increasing bacterial fitness to persist on the mucosal surfaces of CF patients (168). These bacterial biofilm subversion and evasion mechanisms of the host's innate immune defenses facilitate chronic Pa infection that can be very difficult to eliminate by antibiotics and contributes to development of antibiotic resistance. Many opportunistic pathogens have gained resistance to antibiotics routinely used for the treatment of infections. Therefore, Pa has been included in a group of ESKAPE pathogens (ESKAPE stands for the group of pathogens: *Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter* spp.) that cause nosocomial infections (169).

*Klebsiella pneumoniae* (Kp) is another pathogen from the ESKAPE group causing pneumonia. Kp is well-known to contain several antibiotic resistance genes, including extended-spectrum beta-lactamase (ESBL), and carbapenemase encoding genes, which is referred to as a multidrug-resistant (MDR) Kp. Apart from gaining antibiotic resistance genes, Kp utilizes a variety of well-described strategies to evade host innate immune responses, especially affecting host innate immune cells (170), for instance, by interference with TLR signaling in macrophages exerted by targeting sterile alpha and TIR motif containing 1 (SARM1) protein to reduce inflammation and enhance IL-10 production (171). The interaction of Kp with the airway epithelial cells remains the first step of infection that is not well-characterized, and it is likely that Kp utilizes several strategies to compromise host epithelial front-line defenses. Kp secretes yjfl virulence factor that alters cytoskeleton organization in human and mouse airway epithelial cells by disassembling microtubules network (172). Kp translocation through airway epithelium mediated by induction of IFN- $\lambda$  reduces the host airway epithelial barrier integrity that can facilitate bacterial invasion (173). Furthermore, the encapsulation of Kp with a polysaccharide coat has been considered as a determinant of bacterial virulence. Kp encapsulation limits bacterial binding by the complement component present on the airway mucosal surfaces and reduces bacterial clearance by the host epithelial cells (174). Recent studies showed that encapsulation helps Kp to overcome mouse innate immune defenses in the upper airways primed by microbiota through stimulation of IL-17A expression (175). Interestingly, a recent study indicates that asymptomatic colonization of the gut with MDR-Kp exacerbates pneumonia

caused by Pa infection. Altered signaling on the gut-lung axis is caused by MDR-Kp-mediated dysbiosis resulting in reduced production of short-chain fatty acids (SCFAs) and reduced numbers of macrophages and DCs in the lung (176).

*Streptococcus pneumoniae* (Sp) is a respiratory pathogen frequently causing pneumonia (177). The virulence of Sp is associated with secretion of toxin, pneumolysin, exhibiting cytotoxic effect on the host cells accompanied with disintegration of TJs between host epithelial cells for Sp translocation (178). In addition, the cytotoxic effect of pneumolysin is caused by DNA damage associated with the cell cycle arrest (179). Another bacterial virulence factor is pyruvate oxidase SpxB responsible for H<sub>2</sub>O<sub>2</sub> production and release of pneumolysin (180). Both virulence factors, pneumolysin with contribution of SpxB, were shown to reduce the host innate immune signaling through epigenetic mechanisms. Infection of mice and human airway epithelial cells with Sp led to the activation of the host phosphatase PP1 by its dephosphorylation, which further dephosphorylated histone 3 on serine 10 in the host cells promoting Sp intracellular expansion (181). Sp modifies a component of the cell wall, lipoteichoic acid, to increase its charge to resist host HDPs. Moreover, Sp serine protease PrtA is suggested to cleave HDPs (182, 183). The use of PrtA virulence factor as an antigen has been suggested to develop new vaccines in combination with other antigens to resolve problems of pneumococcal serotype specificity based on the fact that PrtA can also induce protective immunity in certain animal infection models (184). Another study by Biswas et al. showed that group A *Streptococcus*, mainly responsible for necrotizing fasciitis and rarely pneumonia, cleaves the host defense peptide LL-37 with ScpN protease into two shorter peptides that retained bactericidal properties. However, LL-37 cleavage products lost their immunomodulatory properties connected to the activation of P2X7 and EGFR signaling involved in neutrophil bacterial clearance and tissue regeneration, respectively (185, 186).

The respiratory pathogen *Mycobacterium tuberculosis* (Mtb) can bypass host immune defenses by hijacking host cell signaling in macrophages, neutrophils, and DCs. This way, Mtb creates a favorable intracellular niche where bacteria can replicate and infect other cells or persist for decades in a latent state (187). In the initial step of bacterial colonization, Mtb infects respiratory epithelial cells and macrophages, while 7 days post-infection, the bacteria are present only in macrophages, indicating that bacteria do not replicate in epithelial cells (188). Interestingly, in the zebrafish model, a lipid component of *Mycobacterium marinum* outer membrane phthiocerol dimycocerosate (PDIM) spreads into the epithelial cell membrane and inhibits TLR/MyD88 signaling limiting recruitment of monocytes (189). In humans, Mtb selectively targets uptake by pulmonary macrophages that translocate to the lung interstitium and infect other types of cells. This process is mediated by Mtb virulence factor Esx-1 and the host IL-1 $\beta$  signaling (188). Despite activation of additional host innate immune components connected to the redox signaling, Mtb produces KatG and NuoG virulence proteins that neutralize and inhibit further production of ROS by macrophages and neutrophils (190, 191). Moreover, CpsA allows Mtb to escape autophagic clearance in macrophages by blocking NADPH oxidase

recruitment to the Mtb-containing phagosomes and activation of LC3-associated phagocytosis (192). Mtb creates its own intracellular niche for survival by altering host lipid metabolism, creating the formation of foamy macrophages with characteristic lipid droplets (193). Mechanisms of Mtb evasion and subversion of host immune responses in macrophages and other immune cells are thoroughly described in a recent review (187) that explains why only approximately three Mtb bacterial cells are sufficient for effective colonization of the host (194), indicating a highly advanced Mtb virulence system.

A better understanding of how bacteria breach the host innate defenses on the airway mucosal surfaces to further hijack the host cellular machinery for intracellular survival could result in the development of more efficient therapies. Studies on the molecular mechanism of bacterial virulence factors for host colonization are especially important in the context of immunocompromised individuals suffering from severe infections.

## Viruses

Viruses use a variety of different strategies to compromise the host innate immune defenses and effectively replicate within the host cells or remain in the latent state. Due to the recent pandemic, the majority of research has concentrated on the strategies used by SARS-CoV-2 coronavirus to evade host innate immune responses (195). Yin et al. showed that the host IFN response mediated through intracellular PRRs—MDA5, LGP2, and NOD2—is delayed by several hours in comparison to the kinetics of the viral replication, indicating the viral-strategy-limiting effects of IFNs (196). Moreover, SARS-CoV-2 produces viral endonuclease EndoU that cleaves viral RNA and blocks phosphorylation of STAT1 and STAT2 and their nuclear translocation to inhibit host innate immune responses (197, 198). Subsequently, the virus produces ORF8 protein that disrupts PTMs of host histones promoting closed chromatin state and suppression of host innate anti-viral responses, allowing for viral replication (199). Another virus commonly causing respiratory tract infections, especially harmful for newborns and infants, is RSV, and there is no vaccine available (200). An effective RSV replication within host cells is achieved by initial induction of autophagy and then by blocking autophagosome–lysosome fusion in human airway epithelial cells. This strategy most likely allows to form a replication-favorable niche for the virus inside the autophagosome vesicle (201). The “mimicry” of host chemokines is used to promote infection by RSV, more precisely by the interaction of viral G protein binding receptor with CX3CL1 that facilitates RSV infection (202). The group of Rhinoviruses are the common group of pathogens attacking the host respiratory system causing cold (203). Human rhinoviruses C group (HRV-C) were shown to disrupt epithelial barrier integrity and to alter host metabolism towards glycolysis and fatty acid biosynthesis, facilitating viral replication (204). Rhinoviruses also target another RNA RLRs, such as STING trafficking into viral replication organelles through interaction with PI4P (205). Interestingly, recently, it has been shown that disruption of the circadian clock and expression of

immune response genes encoding chemokine receptors (Ccr2, Ccr3, Ccr5, Ccr6, etc.) due to sleep deprivation make mice more susceptible to viral infections, highlighting the importance of environmental factors determining host immune responses against viral infections (206).

## Fungi

Fungal pathogens have developed specific strategies to evade the host immune responses (207). Among them are *C. albicans* triggering oropharyngeal candidiasis, *Aspergillus* spp. causing pulmonary aspergillosis, and *Pneumocystis* and *Cryptococcus* causing pneumonia (208). *Candida albicans* avoids host responses by neutralization of the host complement components by proteolytic cleavage with aspartyl proteases (209). Moreover, *Aspergillus*, *Mucorales*, and *Candida* spp. cause coronavirus disease (COVID)-associated fungal infections, and aspergillosis was the most prevalent in the group of patients treated with corticosteroids and tocilizumab (210). *Cryptococcus neoformans* evades host innate immune responses, for example, by encapsulation with polysaccharides glucuronoxylomannan (GXM) that inhibits NETs formation (211). Furthermore, *C. neoformans* also produces giant fungal cells, the so-called titan cells, to avoid phagocytosis and killing by ROS, hence considered as a fungal strategy used to establish pulmonary infections (212). Fungal infections are often a complication of the antibiotic treatment because of microbiota dysbiosis, where opportunistic fungal species, such as mentioned *C. albicans*, expand on the host mucosal surfaces forming a biofilm. Those biofilms composed of fungal and bacterial components are hard to eradicate, especially in CF and immunocompromised patients (24); therefore, development of new therapies against such biofilms is needed.

## Modulation of lung innate immunity to overcome pathogen subversion mechanisms

Pathogens quickly adapt to the changing environment, and this includes the presence of antibiotics. The excessive use of antibiotics in the healthcare and animal husbandry has led to the selection for antimicrobial resistance (AMR), which resulted in a global problem that caused 4.95 million of AMR-associated deaths in 2019 (213). Antibiotic resistance occurs in most countries, and many opportunistic pathogens have gained resistance to antibiotics routinely used for the treatment of infections. It is estimated that 63.5% of all infections caused by multidrug-resistant strains were connected to the healthcare (214). Despite of the increasing social awareness on the proper antibiotic use, general reduction in prescribed antibiotics, and a better control of nosocomial infections, the spreading of AMR genes in some pathogens remained unchanged (215, 216). In addition, the development of new antibiotics is a long and costly process, taking several years until the new drug is introduced to the market resulting, in only few developed drugs in the last decades (217). Therefore, alternative

strategies for the treatment of infectious diseases have gained more attention. By deciphering molecular pathways of host innate immunity and pathogen's infection strategies, an opportunity of modulating these mechanisms might result in the development of novel alternative treatment approaches, limiting and/or reducing the use of antibiotics and thereby reducing the selection of AMR strains. Therefore, in our research, we postulate the concept of host-directed therapy (Figure 2) executed through the modulation of epithelial and macrophages innate immune responses by enhancing expression of HDPs, improvement of the epithelial barrier integrity, and stimulation of autophagy. Our concept of host-directed therapy can be extended to the restoration of mucociliary clearance and ion balance, training innate immune system *via* controlled TLR stimulation and epigenetic modulation of host innate immune responses. The approach of host-directed therapy does not anticipate replacement of the antibiotics—it is rather a supplementary treatment that can reduce time of antibiotic use in case of persistent infections requiring a long antibiotic treatment, such as tuberculosis and infections requiring prolonged treatment due to poor bioavailability of the drug in the tissue (218). In this section, we will discuss different angles of host-directed therapy for modulation of lung epithelial innate immune responses.

One of the directions in the field is the direct use of HDPs and their analogues, mainly for topical administration (219). Synthetic analogues of HDPs have also been tested in a mouse model of severe lung infection caused by highly virulent *P. aeruginosa*. Nasal instillation of IDR-1002 peptide followed by bacterial infection reduced bacterial count in bronchoalveolar fluid and inflammatory response, indicating therapeutic potential of preventive administration of HDP analogues (220). Although promising, this approach usually uses only one peptide monotherapy, which carries a risk of development bacterial resistance to HDPs, which has been claimed to be limited, however a possible scenario (221). Therefore, the use of HDPs mixture would be a better strategy than a single peptide monotherapy to avoid AMR development, which seems to be highlighted by the fact that in physiological conditions, pathogens usually encounter a mixture of different antimicrobial effectors present on mucosal surfaces. Another aspect is the cost of the production of synthetic peptides and their purification on a bigger scale. Therefore, we suggest an alternative approach by inducing expression of natural HDPs in the epithelial cells and tissue-residing immune cells, which has several advantages in comparison to using synthetic HDPs and their derivatives. First, several antimicrobial effectors are induced, at the same time limiting the risk for the selection of antibiotic resistance. Second, using different innate immune modulators allows for the precise regulation of the HDPs induction and its cessation if needed. Third, the use of different non-peptide inducers for host-directed therapy is expected to reduce the cost of production, making it more accessible for pharmacological use. Those innate immune inducers/modulators were explored by our research group and collaborators and initially included nutrients and bacterial metabolites (like vitamin D3 and butyrate) and further expanded to synthetic chemical compounds (such as aroylated phenylenediamines (APDs)) (Figure 2) (218). Among the

nutrients, vitamin D3 was shown to induce cathelicidin expression *via* activating vitamin D receptor (VDR) from the group of nuclear receptors binding to the vitamin D responsive elements (VDRE) present in human cathelicidin gene promoter (222, 223). Lung epithelial cells were shown to express the enzyme CYP27B1 involved in conversion of a precursor 25-hydroxyvitamin D3 to an active 1 $\alpha$ ,25-dihydroxyvitamin D3 that induced cathelicidin expression, indicating the importance of the vitamin D3 levels for mucosal antimicrobial defenses (30). Interestingly, VDREs are absent in mouse *CRAMP* promoter, making the translation of research on vitamin D3 inducer to mouse models difficult. For that reason, the novel transgenic model of humanized mice was established recently and contains human VDRE in the promoter of mouse *CRAMP* gene, opening a new avenue for the studies on vitamin D3 (224). Another inducer of cathelicidin expression in lung epithelium and macrophages is butyrate, a short-chain fatty acid produced by microbiota commensal bacteria from Firmicutes phylum (225). Butyrate constitutes the primary energy source for colonocytes, exerting local immunomodulatory effects on the colonic epithelia, tissue residing immune cells, and gastrointestinal (GI)-distant organs because butyrate is distributed with blood similar to other microbiota metabolites (218, 226). Butyrate is known from its strong odor; therefore, 4-phenylbutyrate (hereafter phenylbutyrate or 4-PBA) was used in the studies as an odorless butyrate derivative, which is an FDA-approved drug for treatment of the urea cycle disorders used as ammonia scavenger (227). Phenylbutyrate was shown to induce cathelicidin expression in the airway epithelium (Figure 2) and induced autophagy in Mtb-infected macrophages through induction of LL-37 acting *via* P2X7 receptor (228, 229). Phenylbutyrate also counteracted the downregulation of cathelicidin expression in lungs of *Shigella*-infected rabbits, mitigating pathogens strategy of effective host colonization (230, 231). Phenylbutyrate is an inhibitor of histone deacetylases (HDACs)—histone-modifying enzymes facilitating chromatin opening state by acetylation of histones. Although *CAMP* gene expression was induced by phenylbutyrate, the increased acetylation of histone 3 and histone 4 was not observed in the promoter of *CAMP* gene (228). Therefore, the detailed mechanism of *CAMP* induction by phenylbutyrate remains unknown, perhaps requiring analysis of more specific histone modifications in *CAMP* promoter. The combination of 1,25-dihydroxyvitamin D3 and 4-PBA is so far the most potent inducer of cathelicidin expression in the human model of the lung epithelium, most likely by combing transcriptional regulation of vitamin D3 and epigenetic modulation by 4-PBA. Importantly, the combination of vitamin D3 and 4-PBA has clinical translational potential and was shown to be effective in the clinical trial of the Mtb treatment combined with standard antibiotics. Patients with tuberculosis receiving phenylbutyrate and vitamin D3 showed faster clearance of Mtb in sputum samples than the group receiving placebo, indicating beneficial effects of host-directed therapy combined with antibiotics (232, 233).

Moreover, in respect to the lung epithelium, other inducers of HDPs were tested from a novel class of compounds called aroylated phenylenediamines (APDs) (Figure 2). Two synthetic APD-compounds, derivatives of Entinostat, which is another HDAC

inhibitor known to induce *CAMP* gene expression, were shown to induce expression of antimicrobial effectors cathelicidin, calprotectin, lipocalin, and defensins. Of note, APDs were less toxic than Entinostat and did not induce proinflammatory responses (32, 234). Furthermore, innate immune inducers 4-PBA, vitamin D3, and APD compound were able to sensitize MDR *K. pneumoniae* to conventional antibiotics. The intracellular bacterial killing mechanism in infected macrophages was cathelicidin dependent for 4-PBA and vitamin D3 and ROS dependent for APD compound (235). This approach presents another angle on host-directed therapy, utilizing modulation of host innate immune responses and sensitization of multidrug-resistant pathogens to conventional antibiotics. Moreover, APD-compound induced autophagy in the differentiated lung epithelial cells through the epigenetic modulation of the H3K27 acetylation and AMP-activated protein kinase (AMPK) signaling (236). The preventive treatment of differentiated lung epithelial layers with APD compound enhanced the epithelial barrier integrity provided by tight junction's proteins occludin and ZO-1 when differentiated monolayer cells were challenged with *P. aeruginosa*-conditioned medium (32). Interestingly, one of the most often prescribed antibiotics, azithromycin, was shown independently of its microbicidal properties to modulate host's epithelial cell responses by strengthening epithelial integrity in the lung (Figure 2). This can be paradoxically considered as a positive side effect of azithromycin treatment that benefits cystic fibrosis patients by improving their condition (237). Azithromycin was shown to enhance epithelial barrier integrity by increasing trans-epithelial electrical resistance (TEER) and counteract the disruptive effect of *P. aeruginosa*-conditioned medium (238). Furthermore, azithromycin was shown to have a barrier protective effect and counteract proinflammatory response inflicted on the bronchial epithelia by cyclical mechanical stress during mechanical ventilation generated by a cyclical pressure air-liquid interface device (CPAD) (239). The supporting evidence suggest that the protective effect of azithromycin on lung epithelia is exerted by increased lamellar body formation and stimulation of epidermal differentiation (240). However, azithromycin is an antibiotic; therefore, prolonged use of azithromycin to strengthen the epithelial barrier is restricted because of the risk for antibiotic resistance development. Importantly, the mechanism behind strengthening of the lung epithelial barrier integrity by azithromycin and APDs remain unknown, and it is a subject of the ongoing research (32, 235, 236, 239, 240). On the contrary, vitamin D3 did not have this functional effect on the epithelial barrier strengthening while administered over the course of lung epithelial differentiation. Instead, it led to thickening of the lung epithelial layer *in vitro* displaying features of squamous metaplasia, indicating that this effect in the lung is tissue specific and is contrary to what has been observed in the gut (241). The group of Jun Sun showed that vitamin D3 regulates expression of a tight junction protein claudin-2, demonstrating the potential of VDR to regulate gut epithelial barrier integrity (242, 243). Different effects of innate immune inducers have been described depending on the tissue type, which may suggest possible epigenetic regulation of the epithelial barrier function. This concept seems to be additionally supported

by the fact that many different respiratory tract diseases are associated with changes in the expression of histone-modifying enzymes, such as increased expression of histone deacetylases, HDACs (1 and 9) and sirtuins (SIRT6 and 7), in asthmatic bronchial epithelial cells. Inhibition of the HDACs with quisinostat (JNJ-26481585) in bronchial epithelial cells from asthmatic patients and allergic rhinitis improved epithelial barrier integrity by affecting expression and reorganization of TJs (149, 244). Recently, azithromycin was shown to attenuate wheezing in patients recovering from pulmonary inflammation. Azithromycin treatment helped to reduce time of wheezing for those patients, and these changes were associated with reduced expression of EZH2 (histone methyltransferase responsible for methylation of H3K27me3), reduced methylation of H3K27me3, and reduced expression of p65, suggesting that azithromycin exerts anti-inflammatory properties through epigenetic regulation (245). Overall, epigenetic modulation is part of the natural physiological regulation of innate immune responses in epithelial tissues and immune cells exerted by microbiota-produced metabolites of dietary products, highlighting the future directions for modulation of host innate immune responses through epigenetic therapies utilizing natural and synthetic epigenetic modulators. It is important to keep in mind that epigenetic therapies may exert off-target effects on other tissues, making the precise regulation difficult to control. However, transient epigenetic modulation over a short period of time with relatively rapidly degraded synthetic compounds and natural products, such as microbiota-produced butyrate, seems to be a reasonable approach.

In line with host-directed therapy is the concept of trained immunity responses for the treatment and prevention of respiratory tract infections. A type of immunotherapy with Broncho-Vaxom, a lyophilizate of the dead bacterial strains causing respiratory tract infections, such as *K. pneumoniae*, *S. aureus*, *Streptococcus pyogenes*, and *Neisseria catarrhalis*, is used to train immune responses in patients suffering from recurrent infections of upper and lower respiratory tract (Figure 2). Broncho-Vaxom showed efficiency in reducing recovery time and course of disease in pediatric patients with recurrent respiratory tract infections (246, 247). Beneficial effects of Broncho-Vaxom® (OM-85 BV) on human sinonasal epithelial cells were mediated through stimulation of the taste-receptor T2R signaling, leading to the production of nitric oxide (NO) responsible for direct bacterial killing and increased ciliary beating (248). Treatment of bronchial epithelial cells with bacterial lysates of Broncho-Vaxom protects epithelia from SARS-CoV-2 entry by reducing expression of host receptors used by the virus such as angiotensin-converting enzyme 2 (ACE2) (249, 250), suggesting that this form of host-directed therapy can be used as a preventive strategy to limit acute respiratory disease, for example in constantly exposed health workers (ClinicalTrials.gov Identifier: NCT04496245).

The concept of trained immunity refers to innate immunological memory previously attributed only to the adaptive immune responses. Trained immunity boosts secondary responses to infections or sterile inflammation after initial contact with the stimuli for the next faster and more efficient host responses. Although trained immunity responses are T- and B-cell

independent, they complement the adaptive immune responses to maximize chances for the host survival. The innate immunological memory can be achieved by stimulation of innate immune cells, such as macrophages, NK cells, DCs, fibroblasts, and tissue-specific stem cells (251, 252). The primary example of trained immunity is *Bacillus Calmette–Guérin* (BCG) vaccination used routinely in vaccination against tuberculosis and shown to reprogram hematopoietic stem cells to differentiate towards monocytes/macrophages with enhanced capabilities of Mtb clearance. Unlike subcutaneous BCG vaccination, intravenous BCG administration enhanced myelopoiesis and rewired epigenetic program in bone-marrow-derived macrophages connected to the changes in the H3K27ac and H3K4me3 marks for more efficient Mtb clearance that was IFN $\gamma$  dependent (253). Microbiota metabolites have also been identified as elicitors of trained immunity. One of them is butyrate that affects the trajectory of antimicrobial responses in macrophages by imprinting antimicrobial program in differentiating macrophages through HDAC3 inhibition, resulting in the induction of calprotectin and enhanced bacterial clearance through autophagy (254). Another microbiota metabolite, deoxycholic acid (DCA), a secondary bile acid detected in the bloodstream, is shown to enhance differentiation of granulocyte-monocyte precursors in the bone marrow through epigenetic alterations, providing innate protection against parasite *E. histolytica*. Interestingly, DCA in sera of children from Bangladesh who previously have documented history of amebiasis had lower levels of DCA than those who never suffered from infection (255). Trained immunity was also described in the lung in the context of the allergic inflammatory memory inflicted on basal lung stem cells by IL-4 and IL-13 exposure. The chronic exposure of respiratory epithelial progenitor cells to the inflammatory type 2 immune responses shifts their differentiation program causing epithelial barrier dysfunction observed in chronic allergic diseases, resulting in rhinosinusitis and taking more extreme form of nasal polyps (256). Overall, trained immunity can be achieved by exposition of tissue-specific stem cells and their progenitors to different stimuli imprinting innate immune responses through metabolic and epigenetic reprogramming (257).

## Future perspectives

Innate immunity of the lung epithelial surfaces is a complex system working together with the adaptive immune responses for host defense and survival. Many aspects of the innate immune regulation and the link between innate and adaptive immune responses remain to be further elucidated. These include characterization of the role of new types of cells in the respiratory epithelium identified by single-cell RNA sequencing in shaping local innate immune responses and epigenetic modulation of such responses. An exciting avenue is the exploration of how different

microbiota metabolites shape host immune responses in lung epithelial cells for better protection against pathogens with defining molecular mechanism that can be further extended to the development of the synthetic compounds for host-directed therapy. Defining pathogen's effectors subverting host innate immune responses, especially in the context of compromised host innate immunity, include future steps of interest for the development of new treatment strategies. Furthermore, the concept of trained immunity mainly characterized in respect to immune cells remains to be further investigated in lung epithelial cells answering the questions on programming our epithelial cells, how innate immune memory confers to better host protection mechanisms, and whether there are any links to the development of chronic inflammatory diseases with defining environmental stimuli that shape such responses.

## Author contributions

The conceptualization of the manuscript was based on ITM's PhD dissertation thesis from year 2021. ITM wrote and edited the manuscript including figures created with BioRender.com under license agreement. GHG commented and edited the manuscript. All authors contributed to the article and approved the submitted version.

## Funding

GHG was supported by grants from Icelandic Research Fund (RANNÍS) and University of Iceland Research Fund.

## Conflict of interest

GHG is a founder and stockholder in Akthelia Pharmaceuticals that holds a patent on APD compounds Patent No. US 9,957,226 B2.

The remaining author declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Publisher's note

**Introduction:** Brain death (BD) and steatosis are both risk factors for organ dysfunction or failure in liver transplantation (LT)

**Material and methods:** Here, we examine the role of interleukin 6 (IL-6) and IL-10 in LT of both non-steatotic and steatotic liver recovered from donors after brain death (DBDs), as well as the molecular signaling pathways underlying the effects of such cytokines.

**Results:** BD reduced IL-6 levels only in nonsteatotic grafts, and diminished IL-10 levels only in steatotic ones. In both graft types, BD increased IL-1 $\beta$ , which was associated with hepatic inflammation and damage. IL-6 administration reduced IL-1 $\beta$  only in non-steatotic grafts and protected them against damage and inflammation. Concordantly, IL-1 $\beta$  inhibition via treatment with an IL-1 receptor antagonist caused the same benefits in non-steatotic grafts. Treatment with IL-10 decreased IL-1 $\beta$  only in steatotic grafts and reduced injury and inflammation specifically in this graft type. Blockading the IL-1 $\beta$  effects also reduced damage and inflammation in steatotic grafts. Also, blockade of IL-1 $\beta$  action diminished hepatic cAMP in both types of livers, and this was associated with a reduction in liver injury and inflammation, then pointing to IL-1 $\beta$  regulating cAMP generation under LT and BD conditions. Additionally, the involvement of nitric oxide (NO) in the effects of interleukins was evaluated. Pharmacological inhibition of NO in LT from DBDs prompted even more evident reductions of IL-6 or IL-10 in non-steatotic and steatotic grafts, respectively. This exacerbated the already high levels of IL-1 $\beta$  seen in LT from DBDs, causing worse damage and inflammation in both graft types. The administration of NO donors to non-steatotic grafts potentiated the beneficial effects of endogenous NO, since it increased IL-6 levels, and reduced IL-1 $\beta$ , inflammation, and damage. However, treatment with NO donors in steatotic grafts did not modify IL-10 or IL-1 $\beta$  levels, but induced more injurious effects than the induction of BD alone, characterized by increased nitrotyrosine, lipid peroxidation, inflammation, and hepatic damage.

**Conclusion:** Our study thus highlights the specificity of new signaling pathways in LT from DBDs: NO–IL-6–IL-1 $\beta$  in non-steatotic livers and NO–IL-10–IL-1 $\beta$  in steatotic ones. This opens up new therapeutic targets that could be useful in clinical LT.

brain death, liver transplantation, nitric oxide, steatotic liver grafts, IL-10, IL-6, IL-1, ischemia-reperfusion

## 1 Introduction

At present, some 80% of hepatic grafts used in liver transplantation (LT) are recovered from donors after brain death (DBDs) (1, 2). It is well known that brain death (BD) of the donor is a factor that drastically increases the chance of a liver graft experiencing preservation/reperfusion injury and decreases graft survival rate (3). In clinical situations, there is a shortage of donors of hepatic grafts for LT (4). In order to reduce the time patients spend waiting for LT, many clinical centers are exploring ways in which to broaden the criteria used to decide if an organ from a so-called marginal donor can be accepted for LT (5, 6). Data from different countries such as USA, France, Australia, or Chile have indicated that as many as 30%–50% of livers recovered from deceased donors are in a state of steatosis, which is one of the key variables that predict negative outcomes after LT (6–10). This is because the risk of hepatic dysfunction and indeed of primary non-function of transplanted liver grafts that are steatotic is greater than that for liver grafts that are not steatotic (11). It is also the case that steatosis is becoming even more prevalent, which means that more steatotic livers are discarded, particularly if the infiltration of fat is severe. Clearly, this exacerbates the current shortage of donors, which has already been described as critical (12). Thus, in order to reduce the LT waiting lists, we need therapeutic strategies that will reduce the post-LT risks of organ dysfunction or failure that are inherent to steatotic livers from DBDs.

The multifunctional cytokine interleukin-6 (IL-6) has been recognized as playing an important role in providing hepatoprotection against warm I/R injury, particularly in reduced-size LT (13, 14). In addition, interleukin-10 (IL-10) has shown protective effects in non-steatotic and steatotic livers that undergo warm ischemia (15, 16). To the best of our knowledge, no study to date has assessed the role of both IL-6 and IL-10 in LT from DBDs. Of interest, a regulation mechanism could exist between IL-6 or IL-10 and interleukin-1 (IL-1), the latter being an interleukin that promotes processes of inflammation and damage (15), including when both steatotic and non-steatotic livers are subjected to warm ischemia-reperfusion (I/R) (15–17). A potential relationship setting up a signaling mechanism between IL-6, IL-10, and IL-1 should not be ruled out, as an interaction between IL-6 and IL-1 has been previously reported in several pathologies (18, 19), and the administration of IL-10 reduced IL-1 $\beta$  levels in both steatotic and non-steatotic livers under warm ischemic conditions (15, 16).

On the other hand, several studies show that nitric oxide (NO) is a crucial mediator of I/R injury in many organs, such as the heart, liver, lung, and kidney (20). NO action decreasing the expression of cytokines has been demonstrated (21–23); for instance, endogenous NO decreased IL-1 hepatic expression in the setting of ischemic preconditioning, thus reducing the deleterious effects of I/R injury (15, 23). In the same way, a relation between IL-10 and IL-6, on the one hand, and NO, on the other, has been reported in several I/R experimental models (15, 24, 25). Thus, in myocardial ischemia, inhibition of NO production resulted in an increase in IL-6 and a reduction in IL-10 (24). In the case of hepatic warm I/R, the therapeutic strategy of ischemic preconditioning triggered NO production, which, in turn, induced IL-10 in non-steatotic and steatotic livers alike (15). In partial LT with steatotic livers, application of venous-systemic oxygen persufflation with NO gas entering the grafts during cold storage caused a reduction in plasma IL-6 levels in the reperfusion period, which was associated with an improvement of graft viability and protection against hepatocellular damage (25).

Taking all this information into account, the current study aimed to evaluate (a) the role of IL-10 and IL-6 in LT of both non-steatotic and steatotic liver recovered from DBDs; (b) the involvement of IL-1 as part of signaling pathways underlying IL-10 and IL-6 effects in this pathology; and (c) if NO might affect the levels of such ILs in LT from DBDs. The results of this study could therefore lead to a description of the molecular signaling mechanisms for both non-steatotic and steatotic livers in LT from DBDs. This, in turn, could result in identifying therapeutic targets that would potentially improve post-LT outcomes in the case of marginal liver grafts recovered from DBDs. Clearly, findings such as these would potentially be of great importance in clinical settings where, as we have said, some 80% of LT grafts are obtained from BD donors, and moreover, it is estimated that hepatic steatosis is present to an important degree in some 30%–50% of deceased donors.

## 2 Materials and methods

### 2.1 Experimental animals

We carried out the study using homozygous (obese: Ob) and heterozygous (lean: Ln) Zucker rats (Iffa Credo, L'Arbresle, France) when they were aged 12 to 14 weeks. In such Zucker rats,

steatosis has not been associated with inflammation (26). However, the Ob rats do show severe macrovesicular and microvesicular infiltration of fat into the hepatocytes (>60% steatosis) (27–31), whereas the Ln rats do not show any signs of steatosis (32). We performed all the procedures in accordance with the European Union regulations pertaining to animal experiments (Directive 86/609 EEC).

## 2.2 Experimental design

- 1) **Sham** ( $n = 12$ , 6 Ln and 6 Ob). Ob and Ln Zucker rats were anesthetized, ventilated, and maintained normotensive for 6 h (26, 32).
- 2) **LT** ( $n = 24$ , 12 transplantations: 6 with non-steatotic grafts and 6 with steatotic grafts). In subgroup 2.1, Ln Zucker rats were anesthetized, ventilated, and maintained normotensive for 6 h. Then, the non-steatotic livers were flushed with University of Wisconsin (UW) solution, isolated, preserved in ice-cold UW solution for 4 h, and implanted into Ln Zucker rats. In subgroup 2.2, the same surgical procedure was repeated, but with Ob Zucker rats as donors and Ln Zucker rats as recipients (26).
- 3) **BD+LT** ( $n = 24$ , 12 transplantations: 6 with non-steatotic grafts and 6 with steatotic grafts). In subgroup 3.1, Ln Zucker rats were anesthetized and ventilated. To induce BD, a frontolateral trepanation was performed in the rats and a balloon catheter was introduced in the extradural space (26, 32). The intracranial pressure was increased by inflating the balloon for 1 min, which induced rapid brain injury, leading to immediate BD. Then, the rats were maintained normotensive for 6 h (32–34). Next, the non-steatotic livers were flushed with UW solution, isolated, preserved in ice-cold UW solution for 4 h, and implanted into Ln Zucker rats (26, 32–34). In subgroup 3.2, the same surgical procedure of BD and LT was repeated, but with Ob Zucker rats as donors and Ln Zucker rats as recipients.
- 4) **BD+IL-1ra+LT** ( $n = 24$ ). Same as group 3, but donors were treated with Anakinra, an IL-1 receptor antagonist (Amgen, Thousand Oaks, CA) at doses of 40 mg/kg (i.v.) just after BD was induced (15, 23, 35).
- 5) **BD+anti-IL-6+LT** ( $n = 24$ ). Same as group 3, but the donors were treated with an anti-IL-6 antibody (R&D Systems, Minneapolis, MN) at doses of 16.6 µg/kg (i.p.), just after BD was induced (36–38).
- 6) **BD+anti-IL-10+LT** ( $n = 24$ ). Same as in group 3, but the donors were treated with an anti-IL-10 antibody (Biosource International, Camarillo, CA), at doses of 0.5 mg/kg (i.v.) just after BD was induced (15).
- 7) **BD+anti-IL-6+IL-1ra+LT** ( $n = 12$ ). Same as group 3.1, but the donors were treated with an anti-IL-6 antibody (R&D Systems) at doses of 16.6 µg/kg (i.p.), and with Anakinra, (Amgen) at doses of 40 mg/kg (i.v.) just after BD was induced (15, 23, 35–38).
- 8) **BD+anti-IL-10+IL-1ra+LT** ( $n = 12$ ). Same as group 3.2, but the donors were with an anti-IL-10 antibody (Biosource International), at doses of 0.5 mg/kg (i.v.) and with Anakinra (Amgen) at doses of 40 mg/kg (i.v.) just after BD was induced (15, 23, 35).
- 9) **BD+IL-6+LT** ( $n = 24$ ). Same as group 3, but the donors were treated with recombinant rat IL-6 (R&D Systems, Minneapolis, MN) at doses of 500 µg/kg (i.p.), 24 and 12 h before BD was induced (14, 39).
- 10) **BD+IL-10+LT** ( $n = 24$ ). Same as group 3, but the donors were treated with recombinant rat IL-10 (Peprotech EC Ltd., Rocky Hill, NJ) at doses of 10 µg/kg (i.v.), just after BD was induced (15, 40, 41).
- 11) **BD+IL-6+IL-1+LT** ( $n = 12$ ). Same as group 3.1, but the donors were treated with recombinant rat IL-6 (R&D Systems) at doses of 500 µg/kg (i.p.), 24 and 12 h before BD was induced and with recombinant rat IL-1β (Peprotech EC Ltd.) at doses of 10 µg/kg (i.v.), just after BD was induced (14, 15, 19, 39).
- 12) **BD+IL-10+IL-1+LT** ( $n = 12$ ). Same as group 3.2, but the donors were treated with recombinant rat IL-10 (Peprotech EC Ltd.) at doses of 10 µg/kg (i.v.) and with recombinant rat IL-1β (Peprotech EC Ltd.) at doses of 10 µg/kg (i.v.), just after BD was induced (15, 19, 39).
- 13) **BD+NAME+LT** ( $n = 24$ ). Same as group 3, but the donors were treated with N-nitro-L-arginine methyl ester hydrochloride (NAME), an inhibitor of NO synthesis (Sigma Chemical Co., St. Louis, MO) at doses of 10 mg/kg (i.v.) immediately after BD was induced (15).
- 14) **BD+NO+LT** ( $n = 24$ ). Same as group 3, but the donors were treated with a NO donor, spermine NONOate (Cayman Chemical, Ann Arbor, MI), at doses of 10 mg/kg (i.v.), just after BD was induced (23).

Blood and liver samples were collected at the end of protocols; this was 4 h post-LT. Blood was extracted via the infrahepatic vein in the afternoon and collected in tubes with heparin. Then, blood samples were centrifugated and plasma was immediately frozen in dry ice. Rats were fasted before the extraction. We chose the conditions under which the study was performed, such as doses and the administration times of the pretreatments for the drugs that were used, in accordance with previous studies cited above and also with the results of some preliminary studies we performed. In clinical practice, it is typical for a hepatic donor to be kept in an ICU for a period of 6 h once BD has been diagnosed. During this time, inflammatory alterations tend to occur, which have a negative effect on the quality of the liver, in terms of LT outcomes. A cold ischemia period of 4 h is long enough to induce damage after transplantation in non-steatotic and steatotic liver grafts and to allow high survival at 4 h after reperfusion. For these reasons, we believe that the conditions we used in the experiments that form part of our study were the best based on the available evidence and in order to assess the effects of the different ILs we studied on hepatic damage and also on the molecular signaling pathways of those ILs in both non-steatotic and steatotic livers from DBDs.

Considering that IL-6 and IL-10 might be generated in intestine and adipose tissue in the context of different liver diseases (42–44), we evaluated whether in addition to the liver, such tissues were contributing to the generation of both IL-6 or IL-10 observed in non-steatotic and steatotic liver grafts, respectively, at 4 h post-LT. For this, the levels of IL-1 and IL-6 were measured in adipose tissue and intestine from experimental groups 1, 2, and 3.

To explore at what point in the surgical process cytokines were originated in each type of liver, experiments on the following groups were performed:

- 15) **CI** ( $n = 12$  rats, 6 Ob and 6 Ln Zucker rats): Animals were anesthetized, and livers were subsequently flushed with UW solution, isolated, and maintained in cold ischemia in UW solution for 4 h.
- 16) **BD** ( $n = 12$  rats, 6 Ob and 6 Ln Zucker rats): Animals were anesthetized and ventilated. After BD induction, rats were maintained normotensive with colloid infusion for 6 h.
- 17) **BD+CI** ( $n = 12$  rats, 6 Ob and 6 Ln Zucker rats): Animals were anesthetized and ventilated. After BD induction, rats were maintained normotensive with colloid infusion for 6 h, and then livers were flushed with UW solution, isolated, and maintained in cold ischemia in UW solution for 4 h.

To investigate whether differences in the levels of IL-1 $\beta$  are observed at earlier reperfusion times than 4 h, experiments on the following groups were carried out:

- 18) **LT 1h** ( $n = 24$ ). Same as group 2, but reperfusion was allowed for 1 h.
- 19) **BD+LT 1h** ( $n = 24$ ). Same as group 3, but reperfusion was allowed for 1 h.
- 20) **BD+anti-IL-6+LT 1h** ( $n = 12$ ). Same as group 3.1, but the donors were treated with an anti-IL-6 antibody (R&D Systems, Minneapolis, MN) at doses of 16.6  $\mu\text{g/kg}$  (i.p.), just after BD was induced (27–29), and reperfusion was allowed for 1 h.
- 21) **BD+anti-IL-10+LT 1h** ( $n = 12$ ). Same as in group 3.2, but the donors were treated with an anti-IL-10 antibody (Biosource International, Camarillo, CA), at doses of 0.5 mg/kg (i.v.) just after BD was induced (9), and reperfusion was allowed for 1 h.
- 22) **LT 2h** ( $n = 24$ ). Same as group 2, but reperfusion was allowed for 2 h.
- 23) **BD+LT 2h** ( $n = 24$ ). Same as group 3, but reperfusion was allowed for 2 h.
- 24) **BD+anti-IL-6+LT 2h** ( $n = 12$ ). Same as group 3.1, but the donors were treated with an anti-IL-6 antibody (R&D Systems, Minneapolis, MN) at doses of 16.6  $\mu\text{g/kg}$  (i.p.), just after BD was induced (31–33), and reperfusion was allowed for 2 h.
- 25) **BD+anti-IL-10+LT 2h** ( $n = 12$ ). Same as in group 3.2, but the donors were treated with an anti-IL-10 antibody (Biosource International, Camarillo, CA), at doses of 0.5

mg/kg (i.v.) just after BD was induced (13), and reperfusion was allowed for 2 h.

Liver and blood samples were collected from groups 15 to 25 at the end of the protocol.

## 2.3 Biochemical determinations

We followed standard experimental procedures to determine plasma levels of transaminases [alanine aminotransferase (ALT) and aspartate aminotransferase (AST)]. We established plasma levels of alkaline phosphatase (ALP), the total level of bilirubin, the Von Willebrand factor (vWF), and hyaluronic acid (HA) levels using the appropriate assay kits: colorimetric (ALP: Abcam, Cambridge, United Kingdom) or immunosorbent (Total Bilirubin: MyBioSource Inc., San Diego, CA; vWF: Cusabio, Wuhan, China; HA: R&D Systems, Minneapolis, MN). To determine hepatic edema, we weighed liver samples and then placed them in a drying oven at 55°C until they reached a constant weight. The increase in the wet-to-dry weight ratio represents hepatic edema (45, 46).

Hepatic levels of lipid peroxidation were determined via measurements of malondialdehyde (MDA) formation by using the thiobarbiturate reaction (45, 47). For this, frozen tissue samples were homogenized in 2 ml of Tris buffer at pH 7. For protein precipitation, 0.25 ml of 40% trichloroacetic acid was added to 0.25 ml of homogenate. After mixing and centrifuging at 3,000  $g$  for 15 min at 4°C, 0.25 ml of 0.67% thiobarbiturate solution was added to the supernatant, and this mixture was boiled for 15 min. After cooling, optical density was read at 530 nm (48).

To function as an index of the level of accumulation of neutrophils, we determined hepatic levels of myeloperoxidase (MPO) photometrically using a substrate of 3,3',5,5'-tetramethylbenzidine (45, 47). For this, liver samples were homogenized in phosphate buffer (0.05 M  $\text{KH}_2\text{PO}_4$ , pH 6) with 0.5% hexadecyltrimethylammonium bromide (HTBA), then sonicated for 30 s at 20% power. After spending three freeze/thaw cycles in dry ice, the samples were incubated for 2 h at 60°C to eliminate the activity of non-specific peroxidases and MPO inhibitors that could affect the determination. After incubation, the samples were centrifuged for 12 min at 4,000  $g$  at 4°C, and the supernatant was recovered. Then, 10  $\mu\text{l}$  of tetramethylbenzidine reagent dissolved in dimethyl sulfoxide at a concentration of 5 mg/ml was added to 5  $\mu\text{l}$  of the supernatant. At time zero (t:0), 70  $\mu\text{l}$  of phosphate buffer (8 mM  $\text{KH}_2\text{PO}_4$ , pH 5.4) with 0.05%  $\text{H}_2\text{O}_2$  was added, and the MPO enzymatic kinetics were determined, reading the absorbance for 3 min every 15 s at a wavelength of 630 nm. One enzyme unit was defined as the amount of enzyme that produces an increase of one absorbance unit per minute (47).

We measured hepatic nitrotyrosine to function as a peroxynitrite formation index, using commercial kits (MyBioSource Inc.) (32). For the determination of nitrotyrosine levels in liver tissue, samples were homogenized in 1 ml of 50 mM  $\text{Na}_2\text{HPO}_4$  buffer, pH 7.4, at 4°C, then centrifuged at 20,000  $g$  for 30 min at 4°C, and the supernatant was recovered for determination of

nitrotyrosines (48). cAMP was extracted and quantified with the cAMP enzyme-linked immunosorbent assay (Abcam, Cambridge, United Kingdom) according to the manufacturer's protocol (49). To obtain liver lysates, frozen tissue was homogenized in 0.5 ml of 0.1 M HCl. After that, lysates were centrifuged at top speed for 5 min and the supernatant was stored at  $-80^{\circ}\text{C}$  for subsequent determination of cAMP.

Finally, we measured levels of ILs (IL-1 $\alpha$ , IL-1 $\beta$ , IL-6, and IL-10) using enzyme-linked immunosorbent assays, as reported elsewhere, with commercial kits (R&D Systems) (15, 23). To determine IL-1 $\alpha$ , IL-1 $\beta$ , and IL-10, frozen liver samples were homogenized in 50 mM phosphate buffer at pH 6, containing 2 mM PMSF, 1 mg/ml antipain, 1 mg/ml leupeptin, and 1 mg/ml pepstatin A. The homogenates were centrifuged at 100,000 g for 1 h at  $15^{\circ}\text{C}$ , and the supernatants were stored at  $-80^{\circ}\text{C}$  for subsequent determination of interleukins (15). To determine IL-6, liver samples were homogenized in a buffer made up of 50 mM Tris-HCl, 150 mM NaCl, Triton X-100, and a cocktail of protease inhibitors (Complete mini, Merck, Darmstadt, Germany). The homogenate was centrifuged at 3,000 g for 15 min at  $4^{\circ}\text{C}$ . Finally, the supernatant was recovered to perform the IL-6 measurement (50).

## 2.4 Histology

Before performing experiments in experimental groups, we determined steatosis level in biopsy specimens of liver tissue from lean and obese Zucker rats ( $n = 12$ , 6 Ln and 6 Ob). Since an association between liver fibrosis and adverse LT outcome has been reported (14), assessment of fibrosis was also performed in Zucker rats. The removed livers were immediately fixed in a 10% phosphate buffered formalin solution and then embedded in paraffin. Samples were cut and stained with hematoxylin–eosin (HE) stain reagent for light microscopic observation. Histopathological findings were evaluated by scoring methods according to the report of Kleiner et al. (51) through a microscope (Nikon, Tokyo, Japan) at  $\times 100$  and  $\times 200$  magnification. Steatosis was graded 0–3 according to the percentage of cells with fatty droplets (0,  $<5\%$ ; 1,  $5\%–33\%$ ; 2,  $>33\%–66\%$ ; 3,  $>66\%$ ). Lobular inflammation was graded 0–3 according to overall assessment of all inflammatory foci (0, no foci; 1,  $<2$  foci per  $\times 200$  field; 2, 2–4 foci per  $\times 200$  field; 3,  $>4$  foci per  $\times 200$  field). Liver cell injury was graded 0–2 according to ballooning degeneration (0, none; 1, few balloon cells; 2, many cells/prominent ballooning). Fibrosis was graded 0–4 according to the extent of fibrosis (0, no fibrosis; 1, zone 3 fibrosis; 2, zone 3 and portal fibrosis; 3, zone 3 and portal fibrosis with bridging fibrosis; and 4, cirrhosis). These scores were added, and the sum was used as a histopathological score (52–55). This assessment was carried out by three independent researchers who were unaware of the experimental conditions. Average values of the three mean scores assessed by these researchers were then used as a histopathological score for each animal. The pathological findings of obese Zucker rats used in the study were classified into severe simple steatosis with neither inflammation nor fibrosis, and histological findings of lean Zucker rats were classified as normal. This difference of steatosis in the Ob versus Ln Zucker rats was confirmed by using

specific lipid staining such as red oil staining. Liver tissue was frozen and red oil O staining was used according to standard procedures. The hepatic steatosis was determined by quantifying cells with stained lipid droplets in 30 randomly chosen high-power fields per section. Data were expressed as the percentage of stained cells with respect to the total number of hepatocytes. Ob Zucker rats showed severe and macrovesicular and microvesicular fatty infiltration in hepatocytes. In contrast, Ln Zucker rats show no evidence of steatosis (15, 45, 56). In addition, we also evaluated fibrosis presence or absence with Sirius Red staining in paraffin-embedded liver samples, as this staining is one of the best understood techniques able to selectively highlight collagen networks (57). The percent area of collagen deposition was calculated as collagen area/total area – vascular lumen area  $\times 100$  (26). Ln and Ob Zucker rats showed no evidence of fibrosis, which is in agreement with reports describing that Ob Zucker rats show resistance to developing fibrosis (58, 59).

In liver samples obtained from all experimental group studies, we assessed the degree of liver injury also by staining paraffin-embedded liver sections with H&E and then using a method of counting points to determine a histological score (47). An experienced pathologist blinded to the allocation of animals into different experimental groups reviewed biopsy specimens and scored the histologic findings according to the following scale: grade 0, zero or minimal evidence of injury; grade 1, the injury is mild, showing cytoplasmic vacuolation and focal nuclear pyknosis; grade 2, the injury is moderate ranging to severe with extensive nuclear pyknosis, cytoplasmic hypereosinophilia, and the loss of intercellular borders; grade 3, severe necrosis showing disintegration of the hepatic cords, hemorrhage, and neutrophil infiltration; and finally grade 4, very severe necrosis exhibiting disintegration of the hepatic cords, hemorrhaging, and neutrophil infiltration (41, 45).

## 2.5 Statistics

In all determinations represented in figures, biological replicates were used. That is, in each experimental group that was represented in the graphs, samples from six different transplants with the same treatment were included. Data are expressed as mean  $\pm$  standard error of mean. We applied non-parametric Kruskal–Wallis tests to determine statistical significance when treating differing variables. In contrast, we used Mann–Whitney  $U$  tests for groups that showed significant differences, and we calculated adjusted  $p$ -values by the false discovery rate (FDR) method ( $p < 0.05$  was considered significant).

## 3 Results

### 3.1 The role played by IL-6 and IL-10 in LT of non-steatotic and steatotic grafts recovered from DBDs

First, we determined the levels of endogenous IL-6 and IL-10 in steatotic and non-steatotic LT from DBDs.

Concerning alterations in anti-inflammatory interleukins (ILs), we observed increased levels of IL-6 and IL-10 in LT of both non-

Then, we assessed the role played by endogenous IL-6 and IL-10. To this end, we inhibited the action of either IL-6 or IL-10, always in liver grafts from DBDs, and evaluated the effects on inflammation and damage. The administration of antibodies against IL-6 (BD+anti-IL-6+LT) raised parameters of damage

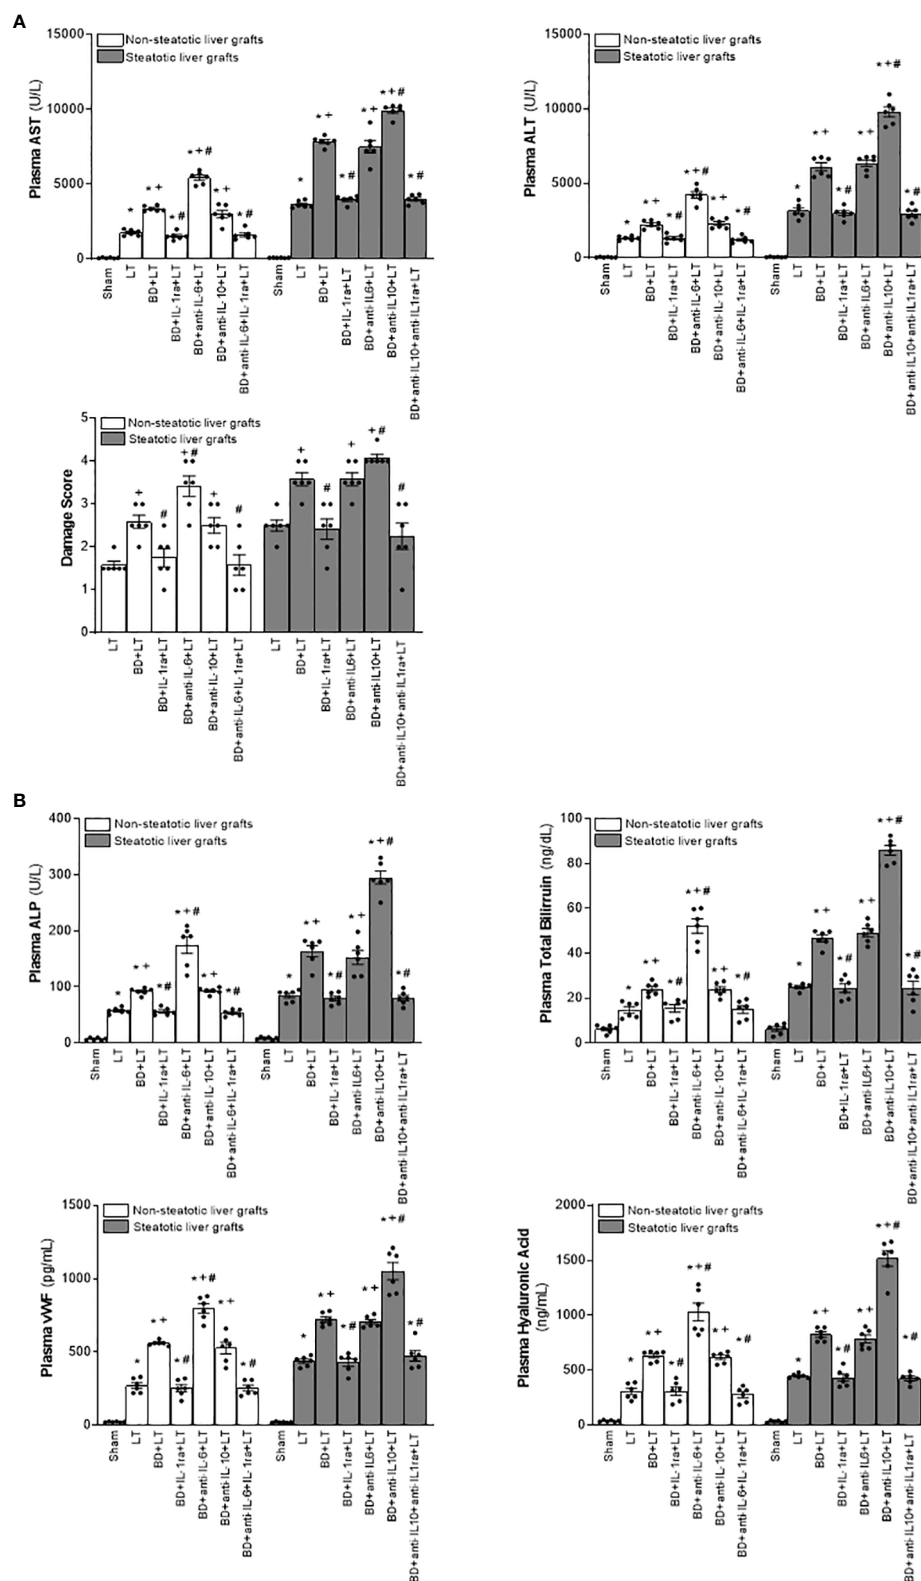

FIGURE 2

(levels of transaminases, damage scores, ALP, total bilirubin, and also endothelial cell damage determined by vWF and HA levels) and inflammation (degree of neutrophil accumulation as measured by MPO, edema formation, and oxidative stress assessed using MDA) in non-steatotic grafts from DBDs, with respect to the results of the BD+LT group (Figures 2, 3). On the other hand, in steatotic liver grafts, no changes were observed in parameters of inflammation and damage (Figures 2, 3) when comparing the results of the BD+anti-IL-6+LT group to those of the BD+LT group. When we addressed the effects of endogenous IL-10, we observed that this cytokine was protective only in steatotic grafts since the administration of antibodies against IL-10 exacerbated hepatic damage and inflammation in steatotic liver grafts from DBDs, in comparison with LT from DBDs without treatment (that is, BD+anti-IL-10+LT vs. BD+LT) (Figures 2, 3). On the other hand, in the absence of steatosis, we observed that levels of these same parameters reflecting damage and inflammation were similar in the BD+anti-IL-10+LT group and in the BD+LT group. Thus, these results indicate that the protection offered by endogenous IL-6 and IL-10 is specific, according to the liver type: IL-6 provides

protection in non-steatotic grafts and IL-10 in steatotic ones, within the context of LT from DBDs.

In consideration of the protection provided by endogenous IL-6 and IL-10 in LT from DBDs, we decided to evaluate whether treatments based on the administration of exogenous IL-6 and IL-10 might potentiate the benefits induced by the former regarding hepatic damage and inflammation in non-steatotic and steatotic livers, respectively. The administration of exogenous IL-6 (BD+IL-6+LT) increased IL-6 levels in both types of livers (Figure 1A) but livers obtained from DBDs were only protected against damage and inflammation in the absence of steatosis. In fact, for the BD+IL-6+LT group with non-steatotic livers, the liver injury parameters (levels of transaminases, damage scores, ALP, levels of total bilirubin, vWF, and HA; Figure 4) and inflammation indicators (MPO, edema, and MDA; Figure 5) were lower than those of the BD+LT group, while no changes were observed in those same experimental groups (BD+IL-6+LT and BD+LT) when steatotic grafts were used, when they were compared. The exogenous IL-10 supplementation (BD+IL-10+LT) increased IL-10 in non-steatotic and steatotic liver grafts (Figure 4); however, it did not abrogate the rise in parameters, indicating hepatic

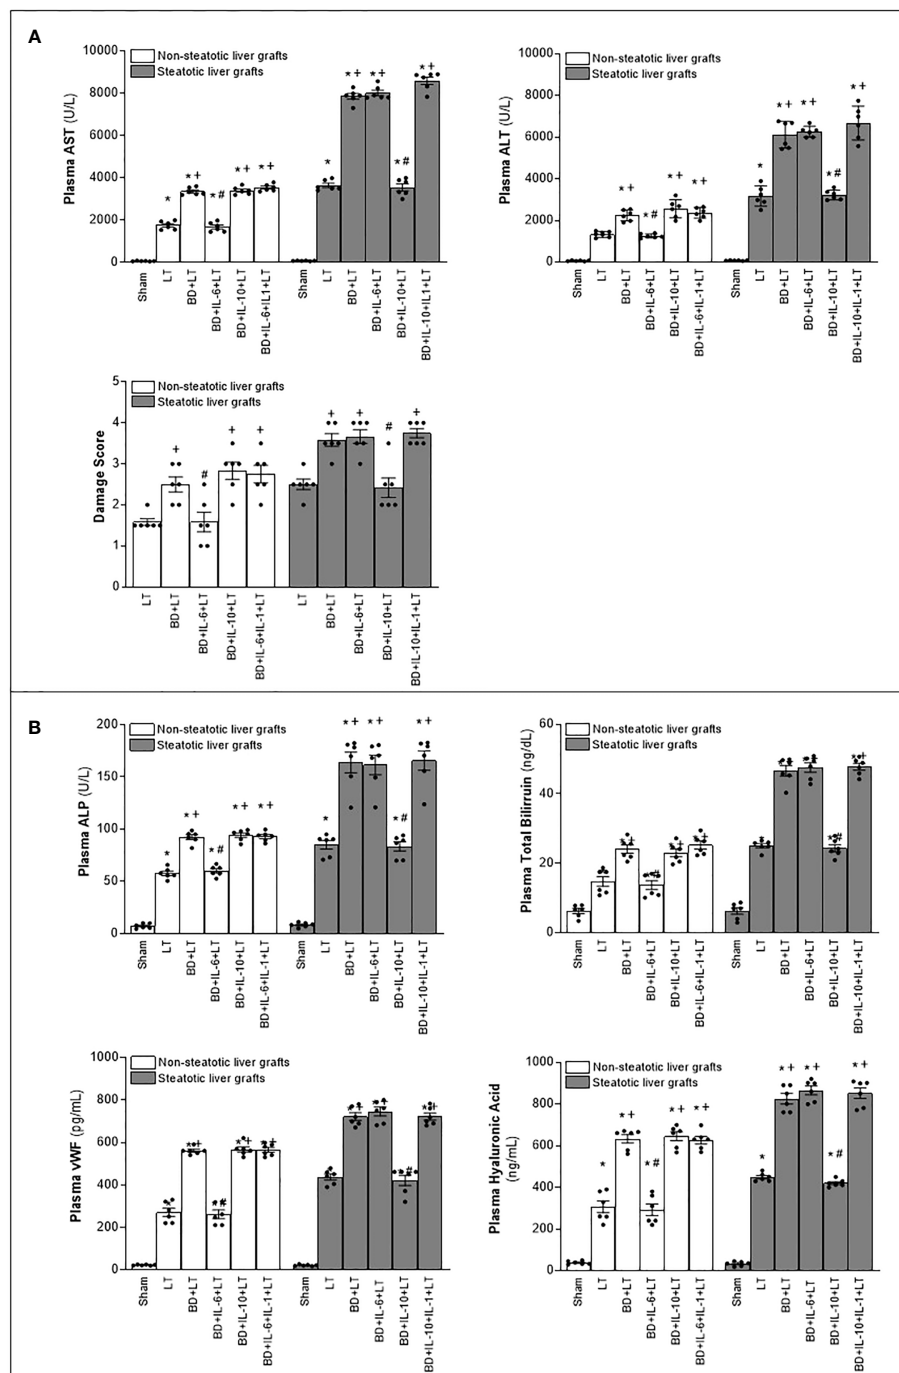

FIGURE 4

Relevance of exogenous IL-6 and IL-10 for damage in steatotic and non-steatotic LT from DBDs. (A) ALT and AST levels in plasma and liver damage score. (B) ALP, total bilirubin levels, vWF, and HA levels in plasma. For A and B, six transplants per group in each measurement. \* $p < 0.05$  versus Sham; # $p < 0.05$  versus LT; + $p < 0.05$  versus BD+LT.

damage and inflammation in grafts obtained from DBDs in the absence of steatosis compared with the results of the BD+LT group (Figures 4, 5). In contrast, this intervention was effective as a therapeutic strategy in the presence of steatosis, since, in the BD+IL-10+LT treatment group, we observed reduced transaminase levels, damage scores, ALP, total levels of bilirubin, vWF, HA, MPO, edema, and MDA in grafts in the presence of steatosis with

respect to the results of the BD+LT group (Figures 4, 5). Therefore, the benefits from exogenous IL-6 and IL-10 seem to be dependent on the type of liver: IL-6 was useful in non-steatotic livers and IL-10 was useful in steatotic ones. The dose of IL-6 and IL-10 used in the current study was the most effective because our preliminary results indicated that if these doses were increased threefold, this was not associated with more protection against damage (data not shown).

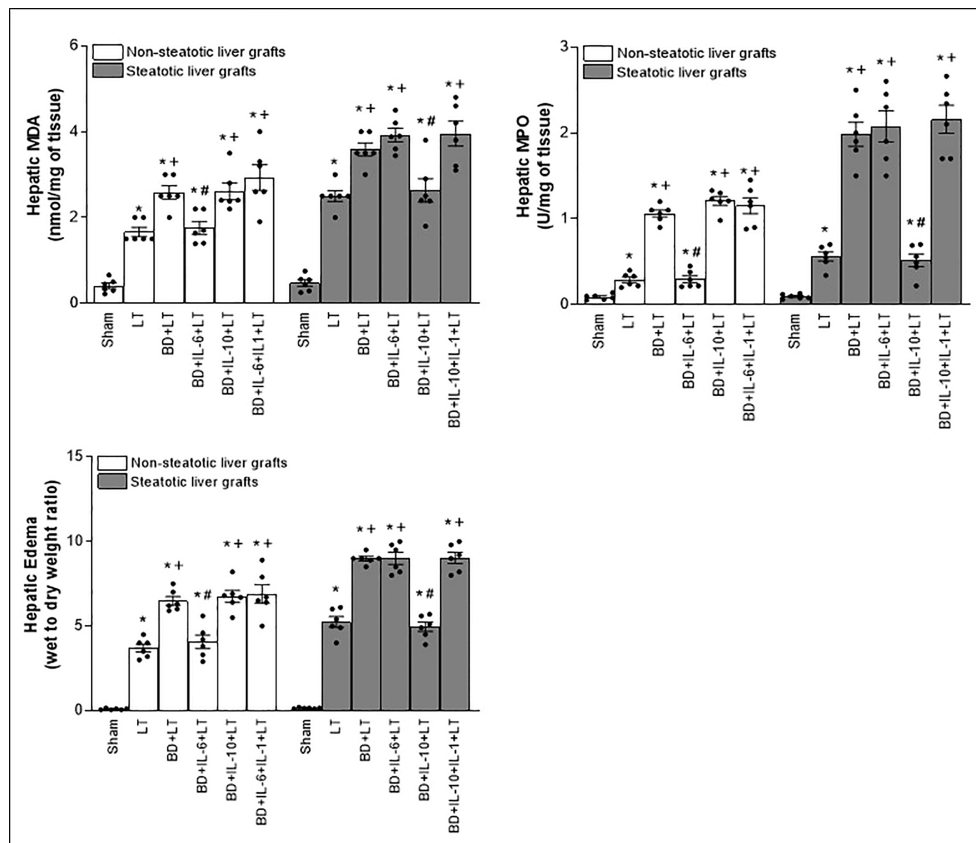

FIGURE 5

### 3.2 Protective mechanisms of IL-6 and IL-10 in LT of non-steatotic and steatotic grafts recovered from DBDs

Considering previous publications that reported a regulatory role of IL-6 and IL-10 on IL-1 (11, 12, 14, 15), IL-1 was investigated as a possible mediator involved in signaling mechanism underpinning IL-6 and IL-10 beneficial effects. For this, hepatic levels of IL-1 $\alpha$  and IL-1 $\beta$  in LT and BD surgical settings were first determined. Our results indicated that IL-1 $\alpha$  does not mediate I/R injury in liver. This is because we observed levels of IL-1 $\alpha$  in both non-steatotic and steatotic grafts obtained from DBDs (BD+LT), as well as in those grafts used in LT that had been obtained from donors that had not undergone BD (LT), similar to those of IL-1 $\alpha$  in the Sham group (Figure 1B). Notwithstanding this, we did observe significant increases in levels of hepatic IL-1 $\beta$  in both grafts that were steatotic and those that were non-steatotic in the BD+LT group, compared to either the Sham group or the LT group (again, see Figure 1B). Then, the involvement of IL-1 $\beta$  in the damaging effects induced by BD in both types of liver grafts was evaluated. When we administered an IL-1 receptor antagonist (BD+IL-1ra+LT), we observed that damage in both types of liver was attenuated since, when compared to the BD+LT group, and all the following parameters were reduced: levels of transaminases, damage

scores, ALP, total bilirubin, and endothelial cell damage (as determined by vWF and HA levels) (Figure 2). In conjunction with these effects, we also observed a reduced inflammatory response in both steatotic and non-steatotic grafts in the BD+IL-1ra+LT group compared to those of the BD+LT group, which was indicated by lower degrees of neutrophil accumulation (as measured by MPO), edema formation, and oxidative stress (as measured using MDA) (Figure 3). Thus, we observed that both in the presence and in the absence of steatosis, inhibition of IL-1 action was an effective strategy to reduce injury.

After demonstrating that IL-1 $\beta$  was involved in liver damage in LT with DBDs, we next evaluated whether IL-1 $\beta$  would be acting as a downstream mediator of IL-6 or IL-10. For this, we inhibited the action of either IL-6 or IL-10 in liver grafts from DBDs, to evaluate the effect of these endogenous cytokines on IL-1 $\beta$ . The administration of antibodies against IL-6 (BD+anti-IL-6+LT) increased IL-1 $\beta$  in non-steatotic grafts from DBDs, compared to those from the BD+LT group (this is shown in Figure 1B). In contrast to these findings, in grafts from steatotic livers, we found no changes in the levels of IL-1 $\beta$  when we compared the BD+anti-IL-6+LT group to the BD+LT group. Regarding endogenous IL-10, the administration of antibodies against IL-10 increased IL-1 $\beta$  in steatotic liver grafts from DBDs, in comparison with LT from DBDs without treatment (that is, BD+anti-IL-10+LT vs. BD+LT), whereas

the levels of IL-1 $\beta$  in liver grafts where there was an absence of steatosis were found to be similar in the BD+anti-IL-10+LT group and in the BD+LT group (Figure 1B). In addition, we investigated whether the benefits of exogenous IL-6 in non-steatotic livers and IL-10 in steatotic ones might be explained by their effects on IL-1 $\beta$ . In this sense, administration of IL-6 (BD+IL-6+LT) resulted in reduced IL-1 $\beta$  levels only in non-steatotic livers, whereas treatment with IL-10 (BD+IL-10+LT) led to reduced IL-1 $\beta$  levels only in steatotic livers (Figure 1B).

The above results showed that there is a relationship between IL-6 and IL-1 $\beta$  in non-steatotic grafts and between IL-10 and IL-1 $\beta$  in steatotic grafts, always from DBDs. Then, the relevance of such signaling pathways in liver inflammation and damage was investigated. For this, we evaluated whether the increased IL-1 $\beta$  levels were responsible for the exacerbated damage induced by the inhibition of either IL-6 or IL-10 action in liver grafts from DBDs, in the absence and presence of steatosis, respectively. We also found that, whereas blockade of IL-6 (BD+anti-IL-6+LT) increased IL-1 $\beta$  and damage in non-steatotic livers from DBDs more than in the BD+LT group, the inhibition of the action of both IL-6 and IL-1 $\beta$  (BD+anti-IL-6+IL-1ra+LT) gave rise to parameters that reflected liver damage and inflammation (Figures 2, 3), which were lower than those of the BD+LT group. In steatotic grafts from DBDs, suppression of IL-10 (BD+anti-IL-10+LT) increased IL-1 $\beta$  and the parameters of hepatic damage and inflammation when compared to the results in the BD+LT group, but no such effect was observed when both IL-10 and IL-1 $\beta$  effects were suppressed (BD+anti-IL-10+IL-1ra+LT). Indeed, the parameters of hepatic damage and inflammation in steatotic grafts from DBDs were decreased in the BD+anti-IL-10+IL-1ra+LT group, when we compared them with those of the experimental group BD+LT (Figures 2, 3). All of this confirms that in LT and BD, IL-6 in non-steatotic or IL-10 in steatotic livers reduces IL-1 $\beta$  levels, which is necessary to limit liver injury in each type of liver. If IL-6 in non-steatotic livers or IL-10 in steatotic ones is inhibited, IL-1 $\beta$  is increased and liver damage is more exacerbated than is seen with BD+LT. If IL-6 in non-steatotic grafts or IL-10 in steatotic grafts is inhibited but the action of IL-1 $\beta$  is also inhibited, there is no aggravated liver damage.

Next, we investigated whether the benefits of exogenous IL-6 in non-steatotic livers and IL-10 in steatotic ones might be explained by their effects on IL-1 $\beta$ . As previously described, administration of IL-6 (BD+IL-6+LT) resulted in reduced IL-1 $\beta$  levels and liver injury only in non-steatotic livers, whereas treatment with IL-10 (BD+IL-10+LT) led to reduced IL-1 $\beta$  levels and hepatic damage only in steatotic livers. In non-steatotic grafts from DBDs, IL-1 $\beta$  administration to the BD+IL-6+LT group (BD+IL-6+IL-1 $\beta$ +LT) increased IL-1 $\beta$  levels (Figure 1B) and this totally reversed the benefits seen from administration of IL-6 on hepatic damage and inflammation (Figures 4, 5). Similarly, in steatotic grafts from DBDs, IL-1 $\beta$  supplementation in the BD+IL-10+LT group (BD+IL-10+IL-1 $\beta$ +LT) raised IL-1 $\beta$  levels and abolished the benefits induced by IL-10, concerning liver injury and inflammatory response (Figures 1B, 4, 5). This demonstrates that IL-1 $\beta$  is a downstream mediator of IL-6 and IL-10 and its regulation is crucial as part of the signaling mechanisms to achieve the

beneficial effects of IL-6 in non-steatotic grafts and IL-10 in steatotic ones when both are subjected to BD+LT.

To delve into the IL-6/IL-1 $\beta$  and IL-10/IL-1 $\beta$  signaling mechanism, we also investigated the IL-1 $\beta$  downstream mediator. Cyclic adenosine 3',5'-monophosphate (cAMP) is produced by adenylate cyclase and acts as an intracellular second messenger for IL-1 $\beta$  (60, 61). In fact, it has been reported that IL-1 $\beta$  increased cAMP (61). When we measured hepatic cAMP levels, our results indicated that cAMP was higher in steatotic and non-steatotic livers of the BD+LT group when compared with the LT group. Of interest, the levels of cAMP were higher in experimental groups with steatotic livers than in those with non-steatotic ones. The inhibition of IL-1 $\beta$  effects through administration of IL-1 $\beta$  receptor antagonist (BD+IL-1ra+LT) reduced cAMP levels in both types of livers (Figure 6A). Then, blockade of IL-1 $\beta$  action and diminished hepatic cAMP were associated with a reduction in all parameters of hepatic damage and inflammation evaluated in the current study. Noticeably, the hepatic levels of cAMP induced by IL-1 $\beta$  were in parallel with the levels of liver damage observed in each type of graft; that is, steatotic livers subjected to LT or BD+LT have higher cAMP levels, compared to the levels recorded in non-steatotic livers. Hence, IL-1 $\beta$  regulates cAMP generation, and suppression of these both mediators downstream IL-6 or IL-10 was responsible for the protective effects of IL-6 in non-steatotic and IL-10 in steatotic livers in conditions of LT and BD.

### 3.3 Origin of IL-6, IL-10, and IL-1 $\beta$ in non-steatotic and steatotic LT from DBDs

Since IL-6 and IL-10 might be generated in intestine and adipose tissue in the context of different liver diseases (42–44), we evaluated whether, in addition to the liver, such tissues were contributing to the increased levels of both IL-6 or IL-10 observed in non-steatotic and steatotic liver grafts, respectively. In view of that, IL-6 and IL-10 were measured in adipose tissue and intestine. Our results showed that levels of IL-6 and IL-10 in intestine and adipose tissue in recipients with either non-steatotic or steatotic grafts, respectively, were similar in all experimental groups analyzed (Figure 6B). Therefore, neither adipose tissue nor intestine were responsible for changes in both ILs observed in liver grafts at 4 h post-LT.

We then considered that under experimental conditions of LT and BD, IL-6 and IL-10 are generated in liver tissue. Next, we explored whether these cytokines were originated in each type of liver at graft procurement, or just after BD procedure, and if the expression of IL-1 $\beta$  in liver tissue (which is induced by IL-6 or IL-10 in the experimental conditions evaluated in the present study) was already altered at those points in the surgical process. Results demonstrated that the levels of IL-6, IL-10, and IL-1 $\beta$  were similar in Sham (without any surgical intervention), CI (livers with cold ischemia, but without BD), BD (livers with BD but without cold ischemia), and in the BD+CI group (liver grafts experiencing BD and cold ischemia) (Figure 7A). Thus, hepatic levels for these three cytokines increase during the reperfusion in the recipient, and this means that IL-6, IL-10, or IL-1 $\beta$  did not

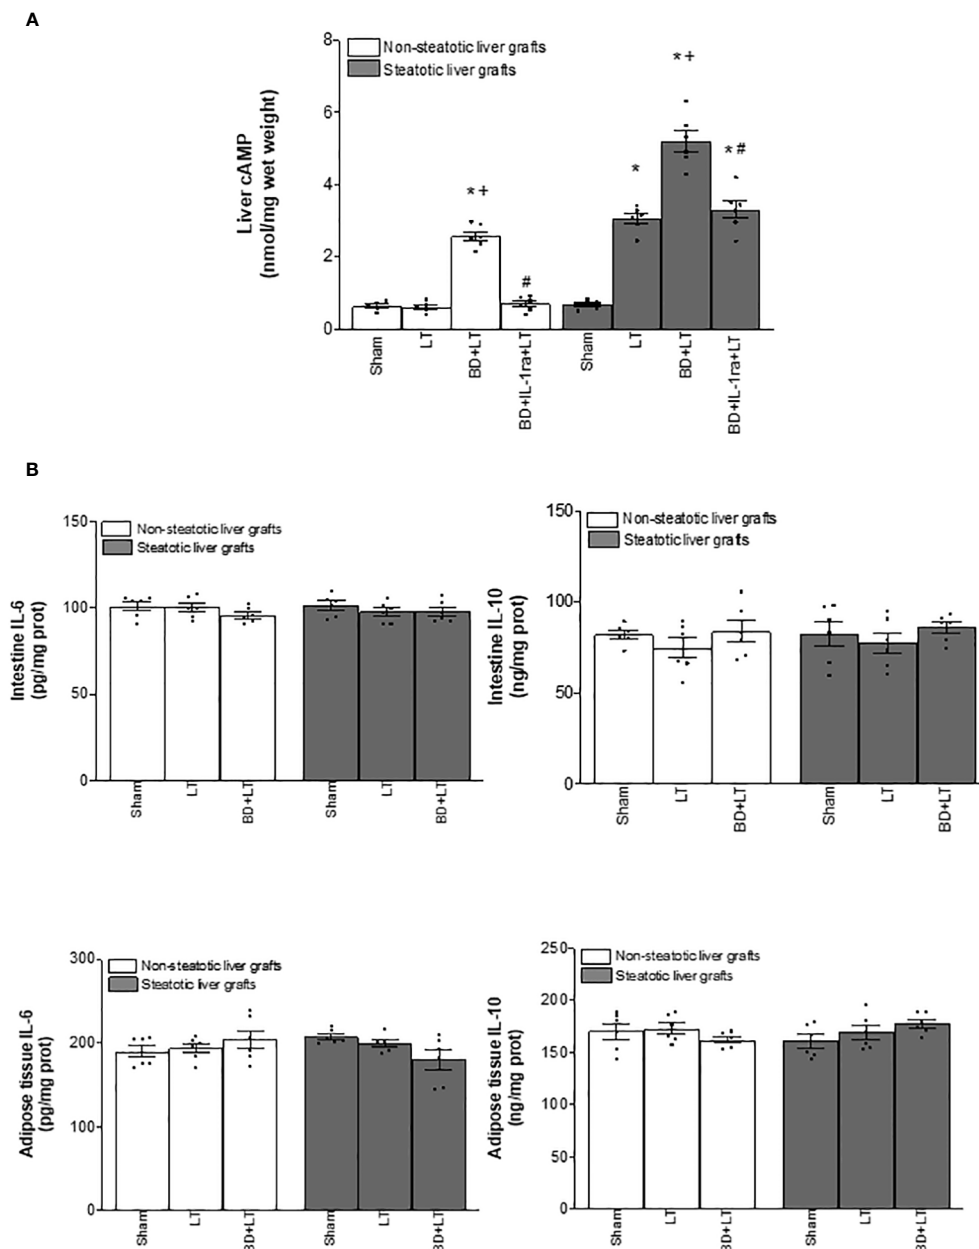

FIGURE 6

Effects of IL-1 $\beta$  on cAMP (A) and source of IL-6, IL-10, and IL-1 $\beta$  (B) in steatotic and non-steatotic LT from DBDs. (A) Hepatic levels of cAMP. (B) IL-6, IL-10, and IL-1 $\beta$  in intestine and adipose tissue. For A and B, six transplants per group in each measurement. \* $p < 0.05$  versus Sham; # $p < 0.05$  versus LT; \* $p < 0.05$  versus BD+LT.

originate before the implantation of liver grafts in recipients, regardless of whether the graft comes from a BD or non-BD donor.

Finally, we evaluated whether differences in the levels of IL-1 $\beta$  altered by IL-6 or IL-10 were observed at earlier reperfusion times than 4 h in steatotic and non-steatotic livers. Then, liver samples were collected at 1 h and 2 h post-LT. Levels of IL-6 and IL-10 in non-steatotic and steatotic livers, respectively, gradually diminished as reperfusion occurs (Figure 7B). As it happened at 4 h of reperfusion, at 1 and 2 h of reperfusion, induction of BD (BD+LT) led to lower IL-6 levels in non-steatotic grafts than those observed in the LT group. In non-steatotic BD+LT groups, the higher levels of IL-6 were recorded at

1 h, whereas the lower levels were recorded at 4 h of reperfusion. On the other hand, in steatotic grafts, IL-6 levels were similar in BD+LT and LT groups at 1, 2, and 4 h of reperfusion (Figure 7B). In the case of IL-10, induction of BD (BD+LT) resulted in no changes for this interleukin in non-steatotic livers when compared to the LT group, at neither 1, 2, nor 4 h after reperfusion. However, when steatosis was present, a progressive reduction in the levels of IL-10 was observed as the reperfusion time proceeds. We observed reduced hepatic IL-10 in the BD+LT group, in comparison with the LT group, at 1, 2, and 4 h of reperfusion. Of interest, in BD+LT groups with steatotic livers, IL-10 was more elevated at 1 h and fewer at 4 h of reperfusion (Figure 7B).

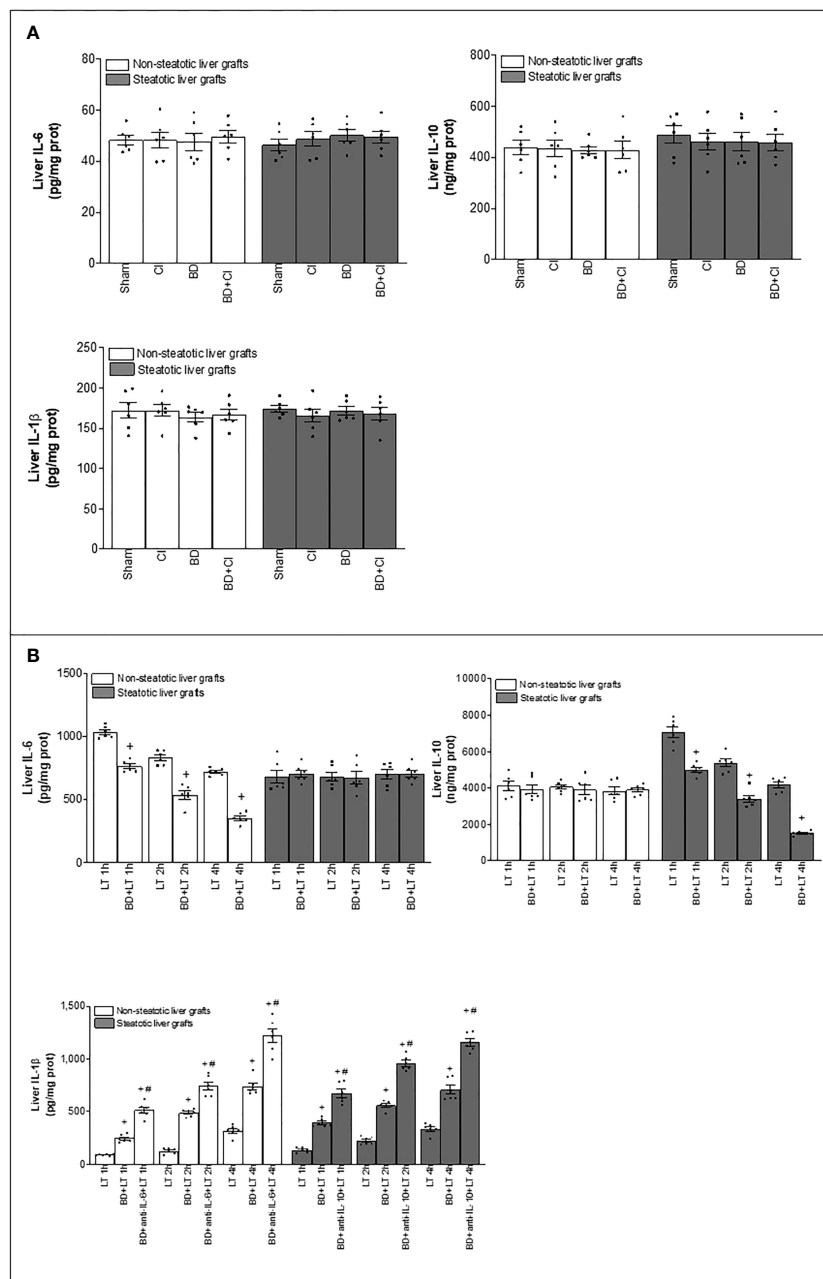

FIGURE 7

Generation of IL-6, IL-10, and IL-1 $\beta$  in the different stages of steatotic and non-steatotic LT from DBDs. **(A)** Hepatic levels of IL-6, IL-10, and IL-1 $\beta$  before implantation of liver grafts. **(B)** IL-6, IL-10, and IL-1 $\beta$  in liver grafts after transplantation. For A, six Ln or six Ob animals per group in each measurement; and for B, six transplants per group in each measurement. \* $p < 0.05$  versus Sham; \* $p < 0.05$  versus LT; # $p < 0.05$  versus BD+LT.

Concerning IL-1 $\beta$ , hepatic levels were increased as reperfusion went on, and interestingly, at reperfusion times shorter than 4 h, hepatic IL-1 $\beta$  was higher in steatotic livers than in non-steatotic ones. In both types of liver from DBDs, IL-1 $\beta$  increased in the recipient at 4 h after LT (LT+BD groups), with such IL-1 $\beta$  levels being similar to steatotic and non-steatotic livers (Figure 7B). Treatment with antibodies against IL-6 (BD+anti-IL-6+LT) in non-steatotic livers, and against IL-10 (BD+anti-IL-10+LT) in steatotic grafts, augmented IL-1 $\beta$  even more compared to those levels from its respective BD+LT group, and levels were similar in the absence or presence of steatosis, at that reperfusion time (4 h

post-LT) (Figure 7B). At 2 h after LT, levels of IL-1 $\beta$  were also higher in the BD+LT than in the LT group for non-steatotic and steatotic livers, but hepatic IL-1 $\beta$  in experimental groups with steatotic livers was more elevated than that recorded in respective analogous groups with non-steatotic livers (Figure 7B). In line with the above, when IL-6 in non-steatotic livers and IL-10 in steatotic livers were inhibited at 2 h post-LT, IL-1 $\beta$  levels increased in the BD +anti-IL-6+LT in grafts without steatosis and in the BD+anti-IL-10 +LT group in grafts with steatosis, compared with their respective BD+LT groups. Similar to what occurred in groups without cytokine modulation, the levels of IL-1 $\beta$  recorded were higher in

the group with steatotic livers than in non-steatotic ones (Figure 7B). Finally, when evaluating the hepatic levels of IL-1 $\beta$  in experimental groups at 1 h of reperfusion, the same pattern as observed at 2 and 4 h was registered between BD+LT and LT in both types of graft, as well as in BD+anti-IL-6+LT vs. BD+LT in non-steatotic livers and in the case of BD+anti-IL-10+LT vs. BD+LT in steatotic livers. Once again, in all the experimental groups analyzed at 1 h of reperfusion, the levels were higher in the presence of hepatic steatosis (Figure 7B). Contrary to what was observed during the reperfusion period for IL-6 and IL-10, the lowest levels of IL-1 $\beta$  in both types of grafts were recorded at 1 h of reperfusion, while the highest levels were observed at 4 h post-LT. These results demonstrated that IL-1 $\beta$  in non-steatotic and steatotic liver grafts is already being regulated by IL-6 and IL-10, respectively, at 1 h post-reperfusion. Remarkably, unlike what occurred in non-steatotic livers, the damaging effects of IL-1 $\beta$  are more intense as early as 1 h in steatotic livers, since IL-1 $\beta$  levels are higher in this type of liver at the start of reperfusion. This could be related to the exacerbated damage shown by steatotic livers in the conditions evaluated in the present study.

In different experimental groups, IL-1 receptor antagonist is administered to the donor since the liver graft obtained is the one that must be prepared to abolish high levels of IL-1 $\beta$  that will be generated later at reperfusion time. If the antagonist is administered to the recipient prior to transplantation, taking out the recipient's liver would remove a significant amount of the IL-1 receptor antagonist. Then, after implanting the donor-derived graft, the effects of the IL-1 $\beta$  inhibitor would no longer be present in the recipient at concentrations adequate to eliminate the effects of IL-1 $\beta$  that will be generated rapidly at the beginning of reperfusion in the liver graft obtained from the donor. On the other hand, our preliminary control experiments demonstrated that when IL-1 receptor antagonist administration was performed in the recipient just after reperfusion, no effect was observed (data not shown). Then, it seems that this antagonist needs more than 4 h to exert its activity, and in consequence, when we administered IL-1 receptor antagonist immediately after reperfusion, no effect was demonstrated at the time of 4 h when the sacrifice is performed. Moreover, we tried to take advantage of the time frame between the declaration of BD and organ retrieval to prevent the side effects of the drug in other organs of the recipient. Because of this, in LT from DBD, a pharmacological treatment that could be administered in the donor that will be beneficial to the recipient would be most appropriate, as we performed in the case of IL-1 receptor antagonist.

Similarly, recombinant IL-1 $\beta$  was administered just after BD was induced since our experience and preliminary control assays indicated that it was the optimal pretreatment time to eliminate the protective effects of IL-6 or IL-10, which occur during reperfusion time in liver grafts. From our preliminary control experiments, we observed that administration of IL-1 $\beta$  just after induction of BD in the donor induced an increase of such cytokine in liver tissue after 6 h of BD, and this was maintained after 4 h of cold ischemia. In this sense, levels of IL-1 $\beta$  in steatotic and non-steatotic liver of the BD group (6 h after BD induction) were similar to those of the Sham group. However, an increase in IL-1 $\beta$  was observed in steatotic and non-steatotic livers of the BD+IL-6+IL-1, BD+IL-10+IL-1, BD+IL-6+IL-1+CI, and BD+IL-10+IL-1b+CI groups when compared with

the results of either the Sham or BD group (data not shown). In this way, steatotic and non-steatotic grafts from DBDs had high levels of IL-1 $\beta$  to eliminate the protective effects of IL-6 or IL-10 that will be exercised precisely in those same grafts obtained from donors at the reperfusion stage. Moreover, supplementation of IL-1 $\beta$  just after BD induction in donors did not affect plasma levels at 6 h since BD, as IL-1 $\beta$  in plasma samples from experimental groups where it was technically possible to obtain them (Sham, BD, BD+IL-6+IL-1, and BD+IL-10+IL-1) was unchanged in all groups (at Sham levels, data not shown). Since liver grafts are isolated from circulation in BD+IL-6+IL-1+CI and BD+IL-10+IL-1+CI groups, it is not possible to collect plasma samples from them. These findings would mean that when recombinant IL-1 $\beta$  is administered in donors just after BD, it is not present in the circulation but in liver tissue, and then it would not have deleterious effects on other organs, which would be beneficial in the clinical context of LT. As it was the rationale for IL-1 $\beta$  receptor antagonist, if we deliver IL-1 $\beta$  to the recipient prior to LT, recipient liver extraction would remove a significant part of the recombinant IL-1 $\beta$ , so that after implanting the donor-derived graft, the IL-1 $\beta$  would no longer be present in the recipient at concentrations adequate to eliminate the effects of IL-6 or IL-10 during reperfusion time. From our previous control experiments, we observed that when administering IL-1 $\beta$  in the recipient post-LT, an increase in IL-1 $\beta$  levels in the plasma from recipients of groups BD+IL-6+IL-1+LT and BD+IL-10+IL-1+LT was registered at 4 h of reperfusion (data not shown). Therefore, we tried to avoid these high plasma IL-1 $\beta$  levels, in order to avoid a potential negative effect of this recombinant interleukin in other tissues from the recipient, which is crucial in the clinical scenario of LT.

### 3.4 Role of NO on IL levels in LT of steatotic and non-steatotic grafts recovered from DBDs

In consideration of the previous data that suggest that the effects resulting from NO could involve signaling mechanisms requiring interleukins (12, 16, 17, 19–21), we evaluated whether endogenous NO affects IL-6, IL-10, and IL-1 $\beta$  in non-steatotic and steatotic grafts from DBDs.

In non-steatotic grafts from DBDs, NO inhibition (BD+NAME+LT) resulted in reduced IL-6 and high IL-1 $\beta$  (Figure 8), and exacerbated liver injury and inflammatory response in comparison to the experimental group BD+LT (Figures 9, 10). In steatotic grafts, suppression of NO (BD+NAME+LT) reduced hepatic IL-10 and worsened hepatic damage and inflammation in comparison to the BD+LT group; all of this was associated with more elevated IL-1 $\beta$  levels than those in the BD+LT group (Figures 8–10).

In light of the beneficial effects of endogenous NO for hepatic grafts obtained from DBDs, we decided to assess if administration of exogenous NO would increase the benefits observed for endogenous NO. In grafts in the absence of steatosis obtained from DBDs, we observed that the administration of exogenous NO (BD+NO+LT) increased IL-6 and that this was associated with reduced IL-1 $\beta$  levels and protection against hepatic damage and inflammation, compared to the BD+LT group (Figures 8–10). In

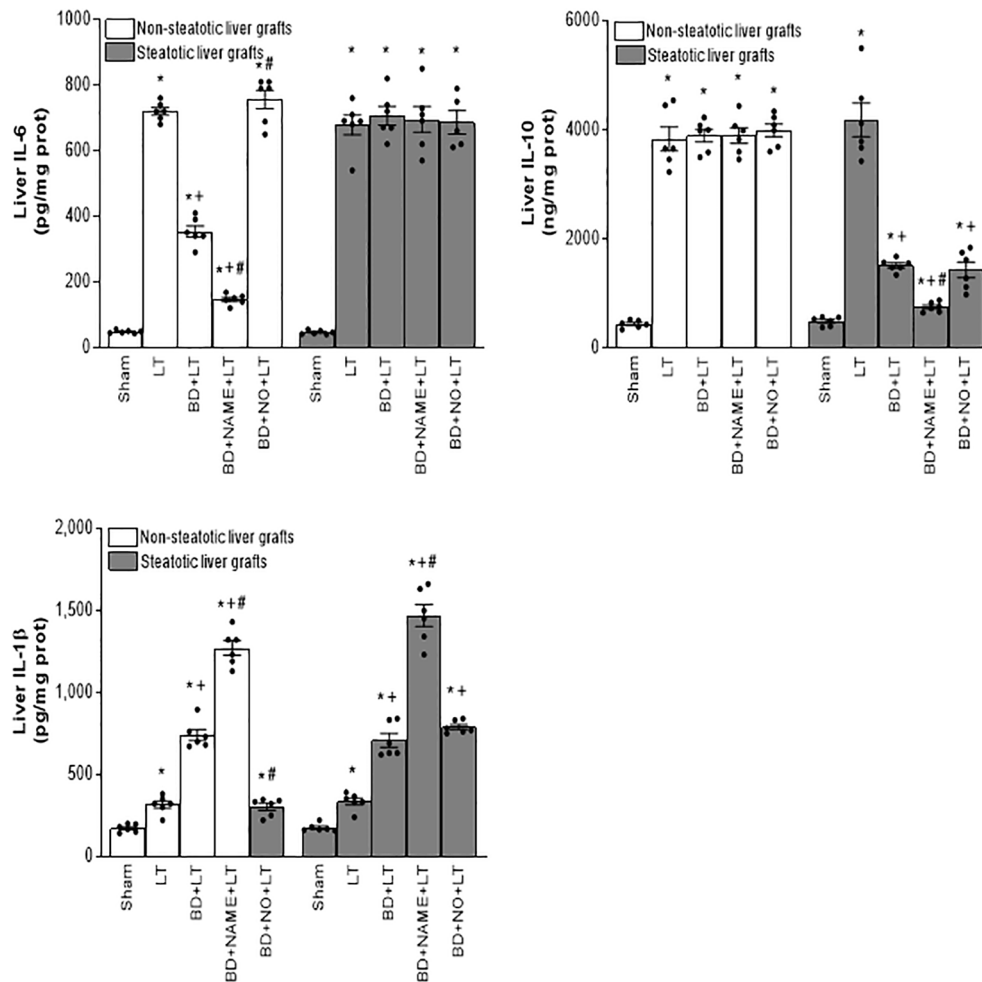

FIGURE 8

Effect of endogenous and exogenous NO on interleukin levels in steatotic and non-steatotic LT from DBDs. IL-6, IL-10, and IL-1β in liver. For A and B, six transplants per group in each measurement. \* $p < 0.05$  versus Sham; + $p < 0.05$  versus LT; # $p < 0.05$  versus BD+LT.

hepatic grafts from DBDs in which steatosis was present, the same level of administration of NO (BD+NO+LT) did not have an effect and was unable to induce changes in either IL-10 or IL-1β with respect to the experimental group BD+LT, without any treatment (Figure 8). In addition, NO supplementation severely aggravated all the parameters of hepatic damage and inflammation more than in the BD+LT group (Figures 9; 10). The effect induced by NO supplementation in steatotic grafts was related to an excess in nitrotyrosine generation, indicative of an increase of oxidative stress involving peroxynitrite ( $\text{ONOO}^-$ ) formation, a highly oxidizing and cytotoxic reactive species. Thus, nitrotyrosine levels were notably increased in the experimental group BD+NO+LT, in comparison with the BD+LT group, for liver grafts in which steatosis was present; however, this did not occur with the same treatment in non-steatotic grafts from DBDs (Figure 10).

In Figure 11, we show representative histological images from the different interventions performed in the study aimed at protecting steatotic and non-steatotic liver grafts from DBDs. Our histological assessment of non-steatotic livers in the BD+LT group revealed a moderate presence of multifocal areas of coagulative necrosis and neutrophil infiltration, whose distribution across the

parenchyma appeared to be random. In contrast to this, the necrotic areas in non-steatotic grafts from the experimental groups BD+IL-1ra+LT, BD+IL-6+LT, and BD+NO+LT were observed to be reduced in extent and number. In steatotic liver grafts from the BD+LT and BD+NO+LT groups, we observed areas with coagulative necrosis that were confluent, extensive, and severe. In contrast, there were fewer necrotic areas whose extent was reduced in grafts in which steatosis was present from the BD+IL-1ra+LT and BD+IL-10+LT groups.

## 4 Discussion

Herein, we show new endogenous signaling pathways in LT from DBDs, namely, IL-6/IL-1β in non-steatotic liver grafts and IL-10/L-1β in steatotic ones; these different mechanisms that depend on the presence of steatosis had not been reported to date. Our results indicated that when endogenous IL-6 in non-steatotic livers and IL-10 in steatotic livers, always from DBDs, are pharmacologically inhibited, then IL-1β is increased and the damage and inflammation are exacerbated. Thus, endogenous

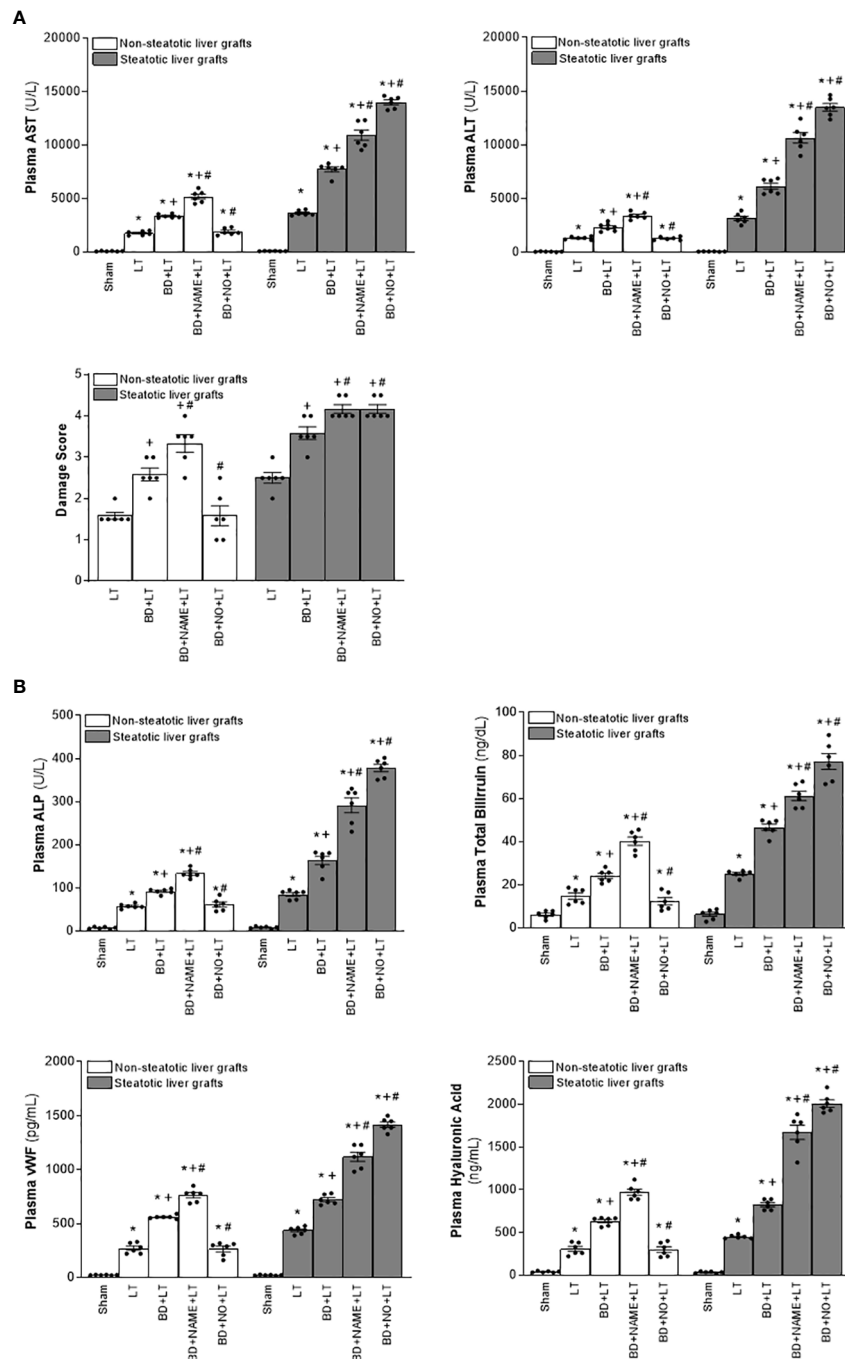

FIGURE 9

Involvement of interleukins in the effects of NO on damage in steatotic and non-steatotic LT from DBDs. **(A)** ALT and AST levels in plasma and liver damage score. **(B)** ALP, total bilirubin levels, vWF, and HA levels in plasma. For A and B, six transplants per group in each measurement. \* $p < 0.05$  versus Sham;  $^{\dagger}p < 0.05$  versus LT;  $^{\#}p < 0.05$  versus BD+LT.

IL-6 (for non-steatotic livers) and endogenous IL-10 (for steatotic ones) exert benefits through IL-1 $\beta$  inhibition, which, in turn, lessens cAMP generation. The suppression of both mediators (IL-1 $\beta$  and cAMP) downstream IL-6 or IL-10 is responsible for the protective effects of these cytokines. In addition, present research evidenced that NO is upstream of the endogenous IL-6 or IL-10 in the setting of LT from DBDs, thus defining the following endogenous signaling pathways: NO/IL-6/IL-1 $\beta$  in non-steatotic grafts from DBDs,

and NO/IL-10/IL-1 $\beta$  for steatotic grafts from DBDs. Inhibition of NO synthesis abrogated the benefits of endogenous IL-6 and IL-10 in non-steatotic and steatotic grafts, respectively, consequently increasing hepatic IL-1 $\beta$  and cAMP, and exacerbating inflammation and damage, more than BD did by itself in LT.

In contrast to studies in the literature that report that there is a possible benefit of both exogenous IL-10 (15) and IL-6 (19) in both liver types under warm ischemia conditions, the results of the

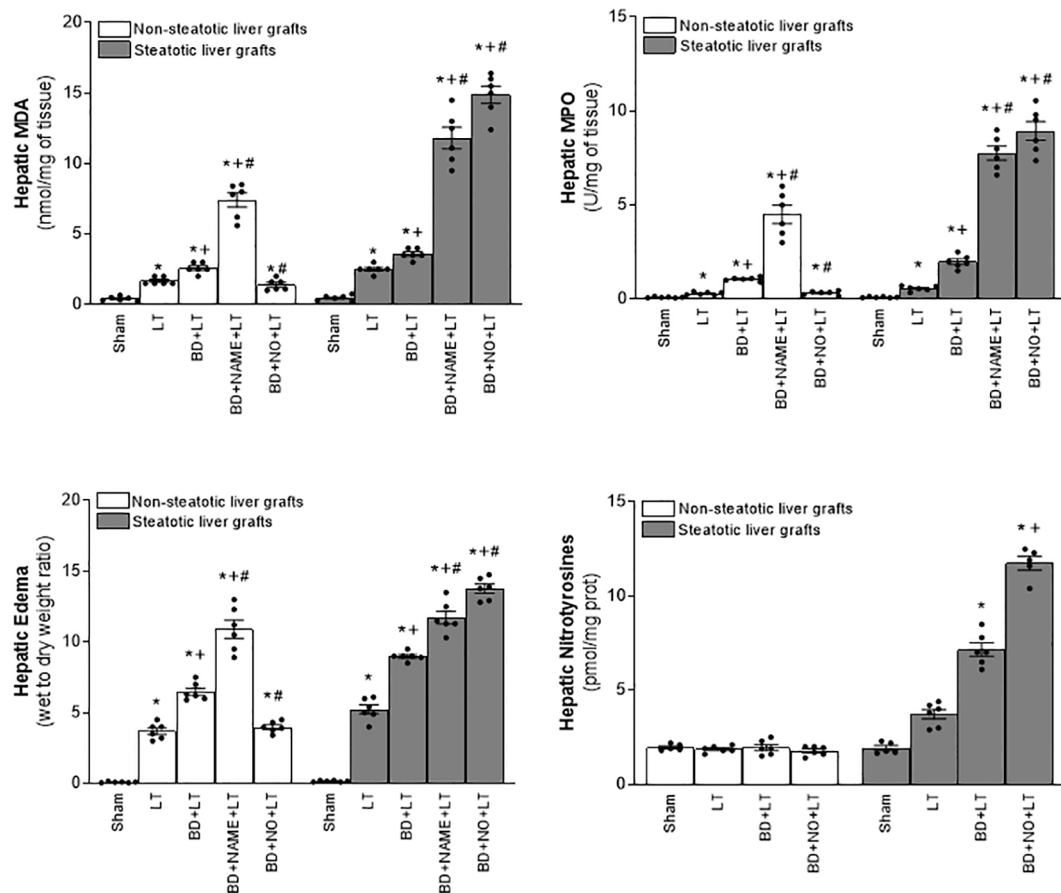

FIGURE 10

Involvement of interleukins in the effects of NO on inflammation in steatotic and non-steatotic LT from DBDs. Hepatic levels of MPO, edema, MDA, and nitrotyrosines. current study in LT from DBDs indicate the specificity of IL-6 and IL-10 to protect each type of the liver. Such differential effects of IL-6 and IL-10 are not surprising considering the huge amount of evidence concerning different signaling pathways underlying injuries of the type I/R in liver that are either steatotic or non-steatotic (62–65). In addition, the type of surgical procedure (warm I/R versus LT from DBDs) should be taken into account, since the pathogenic mechanisms underlying warm I/R and LT from DBDs are quite different (26, 66). In the same way, different ischemia times (60 min in warm I/R versus 4 h in LT from DBDs) and the presence or absence of BD, among other aspects, are known to distinctly affect the underlying signaling pathways of hepatic damage (67–69).

In the present study, hepatic IL-1 $\beta$  levels seem to be similar in LT groups of non-steatotic and steatotic grafts, while liver damage was higher in groups with steatotic grafts. Although these results might seem incongruous, it should be noted that IL-1 $\beta$  levels in liver tissue do not determine the contribution to liver injury and/or the vulnerability of steatotic livers subjected to transplantation. In the present study, the participation of IL-1 $\beta$  in the exacerbated liver damage observed in steatotic livers is demonstrated from the evidence that we next describe. First of all, the involvement of a mediator in liver damage is evidenced by pharmacologically

modulating such mediator and verifying if the liver damage parameters are altered, as we have previously demonstrated in numerous research works from our group (48, 68, 70–72). In this sense, the present study investigated the role of IL-1 $\beta$  in the damaging effects induced by BD in both steatotic and non-steatotic liver grafts. Thus, treatment with an IL-1 receptor antagonist (BD+IL-1ra+LT) attenuated damage in both types of liver since when compared to the group without that intervention (BD+LT), all parameters for hepatic injury and inflammatory response were reduced. Thus, we observed that inhibition of IL-1 $\beta$  action reduced injury both in the presence and in the absence of steatosis, which means that IL-1 $\beta$  is involved in hepatic damage induced by BD and LT, in both types of grafts. In the case of steatotic grafts, inhibition of IL-1 $\beta$  resulted in a greater degree of reduction in liver damage and inflammation compared to the magnitude of reduction seen in non-steatotic livers. Then, our results show that IL-1 $\beta$  is responsible for the exacerbated damage observed in steatotic grafts when they are subjected to BD and LT, since when the action of this cytokine is inhibited, the higher liver damage recorded in the BD+LT group with steatotic grafts is absent. In the present study, the effect of the IL-1 $\beta$  antagonist in the LT groups without BD was not analyzed, since the investigation is

FIGURE 11

Representative photographs of histological changes in non-steatotic livers and steatotic LT from DBDs. In the BD+LT group, histological evaluation of non-steatotic livers showed moderate multifocal areas of coagulative necrosis and neutrophil infiltration, randomly distributed throughout the parenchyma, whereas the extent and the number of necrotic areas were reduced in the BD+IL-1ra+LT, BD+IL-6+LT, and BD+NO+LT groups (4x). Steatotic liver grafts from the BD+LT and BD+NO+LT groups showed extensive and confluent areas of coagulative necrosis, while the extent and the number of necrotic areas were reduced in the BD+IL-1ra+LT and BD+IL-10+LT groups (4x).

focused on the surgical context of BD+LT, which are the most approximate conditions to what is presented in clinical practice. Researching these two combined experimental settings could yield the best results, which are of translational interest. Secondly, in the context of liver damage associated with transplantation, it has been reported that equal levels of a mediator, for instance when administering NO or cortisol at the same dose, can cause different effects on hepatic injury in steatotic and non-steatotic livers (2, 48). In the present research, similarly to that occurring with IL-1 $\beta$  at 4 h after transplantation, supplying a NO donor at the same dose in

both liver types led to different results: NO donor was beneficial in non-steatotic livers but resulted in detrimental effects in the presence of steatosis. Indeed, the steatotic livers show more vulnerability to the generation of peroxynitrites in the presence of NO donors than non-steatotic ones. Therefore, considering the above and the fact that steatotic livers are considered pathological (73), it is not surprising that at the same hepatic levels of IL-1 $\beta$ , the damaging effects of this cytokine may be more evident in steatotic livers, than in the case of normal livers. This is not unexpected owing to the widely documented differences that exist between

steatotic and non-steatotic livers, with respect to molecular mechanisms, and morphological and functional differences underlying I/R liver injury, which inevitably occurs when both types of grafts undergo transplantation (74, 75). Additionally, it is important to mention that in the surgical setting of LT and BD, signaling mechanisms downstream IL-1 $\beta$  involved different levels of cAMP depending on the type of liver, and this occurred even though both steatotic and non-steatotic livers have similar levels of IL-1 $\beta$ . Our results indicated that levels of cAMP were higher in experimental groups with steatotic livers than in those with non-steatotic ones submitted to LT and BD, and it was demonstrated (through an experiment involving inhibition of IL-1 $\beta$  action) that IL-1 $\beta$  was responsible for cAMP generation in such experimental conditions. Noticeably, hepatic levels of cAMP induced by IL-1 $\beta$  was in parallel with degree of liver damage observed in each type of graft, that is, higher cAMP levels in steatotic livers subjected to LT and BD, compared to the levels recorded in the homologous group with non-steatotic livers. This agrees with a previous study evaluating the role of cAMP in LT from donors without BD, which indicated that increases in cAMP observed in steatotic grafts were responsible for the vulnerability of steatotic livers to I/R and exacerbated damage (76). Finally, we also explored levels of IL-1 $\beta$  at earlier reperfusion times than 4 h in steatotic and non-steatotic livers. We found that IL-1 $\beta$  in liver increased as reperfusion occurs and such enhancement was more apparent in the presence of steatosis. After 1 and 2 h after LT, levels of IL-1 $\beta$  increased in livers with and without steatosis when undergoing LT and BD, but hepatic IL-1 $\beta$  was more elevated in steatotic livers than those recorded in respective analogous groups with non-steatotic livers. These results indicate that, unlike what occurred in non-steatotic livers, the damaging effects of IL-1 $\beta$  are more intense as early as 1 h in steatotic livers, thus reinforcing the conclusion that IL-1 $\beta$  contributes to the exacerbated damage shown by steatotic livers in the conditions evaluated in the present study.

We postulated that the mechanism of action of IL-6 or IL-10 in non-steatotic and steatotic livers, respectively, is the inhibition of IL-1 $\beta$  production, which, in turn, downregulates cAMP. Abolition of IL-1 $\beta$  was crucial to achieve benefits of IL-6 or IL-10 against liver injury. Several findings that support the existence of this signaling mechanism are further revealed. In non-steatotic livers undergoing LT and BD, we found that if IL-6 is inhibited (BD+anti-IL-6+LT), hepatic levels of IL-1 $\beta$  are increased only in non-steatotic livers and liver damage is exacerbated in this type of liver. All of this means that in LT and BD in non-steatotic livers, IL-6 reduces IL-1 $\beta$ , which is necessary to limit liver injury. If IL-6 is inhibited but the action of IL-1 $\beta$  is also inhibited, there is no aggravated liver damage. On the other hand, administration of exogenous IL-6 (BD+IL-6+LT group) reduced damage parameters and decreased hepatic IL-1 $\beta$  in non-steatotic liver. Benefits from IL-6 were abolished if we administered IL-1 $\beta$ . This demonstrates that IL-1 $\beta$  is a downstream mediator of IL-6 and its regulation is a fundamental part of the signaling mechanisms underlying beneficial effects of IL-6 in non-steatotic grafts subjected to LT and BD. In the case of steatotic livers subjected to LT and BD, suppression of IL-10 (BD+anti-IL-10+LT) increased damage, inflammation, and IL-1 $\beta$  in liver. Such effects were not observed when both IL-10 and IL-1 $\beta$  effects were

repressed. Therefore, in steatotic liver grafts from LT and BD, IL-10 decreases IL-1 $\beta$  levels, and this is required to restrain hepatic damage. When IL-10 is hindered, IL-1 $\beta$  increases and injury is impaired in steatotic livers. Provided that IL-10 is inhibited but also prevents IL-1 $\beta$  action, then intensified injury is absent in that type of liver. Treatment steatotic liver grafts with exogenous IL-10 reduced injury and inflammation and decreased IL-1 $\beta$  levels in that type of liver. These advantageous effects in steatotic livers were abolished if we administered IL-1 $\beta$ . Hereby, IL-1 $\beta$  is a downstream mediator for IL-10 and its regulation is crucial as it is part of the signaling pathway necessary to accomplish protection from IL-10 in steatotic grafts subjected to LT and BD. Last, we explore whether cAMP could be a mediator downstream IL-1 $\beta$ . In this sense, we observed that (a) cAMP levels increased in both steatotic and non-steatotic grafts from DBDs and transplanted, and (b) in conditions of pharmacological modulation of IL-1 $\beta$ , cAMP levels were not affected. These findings confirmed that, downstream of IL-6 in normal livers and IL-10 in steatotic livers, cAMP is a mediator of the deleterious effects of IL- $\beta$ . Interestingly, hepatic cAMP levels reflected the different degrees of injury seen between steatotic and non-steatotic livers subjected to the same surgical conditions evaluated in the present study. Accordingly, previous reports described that cAMP affected the main mechanisms responsible for the vulnerability of steatotic livers to I/R damage (without BD), including oxidative stress, endothelial cell damage, and edema (45). Hence, in our hands, cAMP also appears to be related to the exacerbated damage suffered by livers with steatosis in LT and BD, although more experiments need to be performed to verify this.

The present investigation suggests that in LT of grafts from DBDs, the source of IL-6, IL-10, and IL-1 $\beta$  is the liver itself, without involving other organs as a source of these cytokines. Hepatic levels for these three cytokines were modified during the reperfusion in the recipient, and none of them suffered changes either in the donor with BD or during back table surgical procedures (before the implantation of liver grafts in recipients). In fact, our results indicated that after transplantation in recipients from DBDs, IL-6 and IL-10 in non-steatotic and steatotic livers, respectively, gradually diminished as reperfusion occurs. Contrary to this, IL-1 $\beta$  in such both liver types increased as reperfusion progressed. All of this demonstrated that IL-1 $\beta$  in non-steatotic and steatotic liver grafts is already being regulated by IL-6 and IL-10, respectively, at early reperfusion times. Then, during reperfusion in LT from DBDs as IL-6 or IL-10 decreases in each type of liver, the production of IL-1 $\beta$  also increases. Remarkably, unlike what occurred in non-steatotic livers, the damaging effects of IL-1 $\beta$  were more intense as early as 1 h in steatotic livers, since IL-1 $\beta$  levels are higher in this type of liver beginning reperfusion. As previously mentioned, this could be related to exacerbated damage shown by steatotic livers in the conditions evaluated in the present study.

Several investigations have found in murine and cell-based studies that IL-6 signaling for more than 24 h induces insulin resistance in adipose and hepatic tissue (77–79). Similarly, clinical and experimental studies have also shown that IL-10 is directly related to insulin action, *in vivo*, and that exogenous IL-10 could improve insulin action in skeletal muscle and liver (80–82). In our hands, treatment with either IL-6 or IL-10 did not induce changes

in plasma levels of glucose, insulin, or lipid profile parameters (including HDL, LDL, triglycerides, and cholesterol) from recipients transplanted after 4 h of reperfusion, when compared with animals without treatment (that is, BD+IL-6+LT and BD+IL-10+LT vs. BD+LT) with steatotic and non-steatotic liver grafts from DBDs (data not shown). Therefore, modulation of either IL-6 or IL-10 does not have effects on the metabolic profile of the recipients under the conditions evaluated in the present study, the early period of reperfusion. Such opposite results concerning literature reports (77–82) are not surprising considering the facts described below. One of the cited studies used a model of 3T3-L1 adipocytes or isolated human fat cells (79). It is widely known that experimental models based on isolated cell cultures do not reproduce the clinical setting of LT from DBDs (in which the response of a single cell type is not observed but rather, a response produced by the complex interrelationship of various cell types). Therefore, it is foreseeable that the results obtained in the study of a single isolated cell type will not be reproduced in the *in vivo* experimental conditions of our study. In another cited study, IL-6 was administered continuously in a mouse model without any liver injury, and biochemical features of insulin resistance were observed immediately after cessation of IL-6 supplementation for 5 to 7 days (78). In our experimental conditions, the administration of IL-6 was performed only twice, 24 h and 12 h before the induction of BD, which means that IL-6 would affect livers experiencing the detrimental effects of BD and I/R injury associated with transplantation. In this latter experimental setting, IL-6 had no effect on insulin resistance. All this points to the fact that the effect of IL-6 on insulin resistance and metabolic profile could depend on liver pathology as well as the different experimental conditions. This is not surprising due to the widely documented differences that exist between livers undergoing I/R and those that are not subjected to this type of damage, with respect to molecular signaling and functional differences (83, 84). Regarding IL-10, in a study with mice presenting severe hepatic steatosis and defective insulin signal transduction plus diabetes, animals were treated with two daily doses of an IL-10 inhibitor for 5 days. Upon such time, mice exhibited worsening of insulin signaling and the activation of gluconeogenic and lipogenic pathways, suggesting that IL-10 exerts a protective role for liver insulin resistance associated with steatosis (82). Under the conditions evaluated in our study, the administration protocol to modulate the action of IL-10 was different and shorter, in addition to the fact that although animals with steatotic livers were used in some of our experimental groups, they did not present diabetes and instead were subjected to the injurious consequences of BD and cold ischemia. These marked differences in the experimental settings could explain why, in our investigation, IL-10 has no effect on insulin resistance at 4 h post-transplantation. On the other hand, insulin resistance and alterations in adipokines such as adiponectin and leptin might have a central role in liver metabolic damage after transplantation, as stated in a recent clinical study by Eshraghian et al. (85). Regulation of adipocytokines has been shown as a promising strategy for reducing I/R injury in steatotic livers, based on adipocytokines' effects on inflammation, steatosis, fibrosis, and molecular pathways of liver damage and regeneration (86).

However, a role for adipokines and insulin resistance in pathogenesis of steatosis does not occur at least in the conditions evaluated in our study, since levels of glucose, insulin, and adiponectin were similar in plasma at 4 h of reperfusion in experimental groups BD+IL-6+LT, BD+IL-10+LT, BD+anti-IL-6+LT, BD+anti-IL-10+LT, and BD+LT, with steatotic and non-steatotic liver grafts from DBDs (data not shown). Noticeable differences between the clinical study of Eshraghian et al. and ours might account to explain such results. We evaluated biochemical parameters at 4 h after transplantation, as usually performed in investigations evaluating injurious effects of hepatic I/R inherent with liver surgery; meanwhile, in the clinical study, alterations were evaluated at a mean time of 38 months after LT. Also, in our experimental model, all recipients of LT were lean animals without any pathology, whereas recipients in Eshraghian et al.'s research had diverse liver pathologies before undergoing transplantation.

The mechanisms through which IL-6 and IL-10 modulate the generation of IL-1 $\beta$  were not part of the objectives of the present study. On the other hand, the possibility that IL-6 or IL-10 influenced Kupffer cells and infiltrated recipient-derived macrophages after transplantation should not be discarded. In fact, according to data reported in the literature, IL-6 and IL-10 are strongly related to Kupffer cells' action (16, 87–89). It has been reported that IL-10 may regulate proinflammatory mediators' release in a liver perfusion model or in isolated Kupffer cells (89) and that IL-10 via Kupffer cells protected steatotic livers modulating the production of IL-1 $\beta$  in a mouse model of warm ischemia (16). Because of this relation between IL-6 and IL-10 and Kupffer cells in such surgical conditions, the involvement of the regulation of Kupffer cells by IL-6 and IL-10 in the experimental model presented in this research could not be discarded. Thus, elucidating the participation of Kupffer cells as a mediator through which IL-6 or IL-10 induces IL-1 $\beta$  production might deserve future intensive investigations.

Results presented in the present manuscript indicate that both IL-6 and IL-10, through the regulation of IL-1 $\beta$ , affect infiltration and accumulation of neutrophils. This conclusion was reached, since MPO levels were affected when the cytokines IL-6, IL-10, and IL-1 $\beta$  were pharmacologically modulated, either separately or in combination (depending on the type of livers in which they were shown to exert their action). Additionally, there are many reports in the literature indicating that IL-6 and/or IL-10 are capable of also modulating macrophages and chemokines (90–98), and therefore, the possibility that this is also happening under the conditions of the present study cannot be dismissed. IL-6 and IL-10 have been identified as important modulators of macrophage activity in the context of liver injury and disease (91–98). Under similar conditions of hepatic injury, IL-10 inhibited production of various CXC chemokines (90, 92), and in a rat model of orthotopic LT, IL-10 modulated CXCL2 chemokine or macrophage activity, thus affecting the early period after I/R (91). Regarding IL-6, it upregulated CXCL1 chemokine in conditions of injury in several tissues including liver (93, 94), and in experimental models of hepatic I/R injury, CXCL10 and IL-6 were strongly correlated (96). Also, IL-6 would be related to the activity and

ligands of CXCL2/CXCR2 chemokine in partial hepatectomy and I/R (95). Interestingly, a correlation between CXCL10 and IL-6 has been recently reported in human subjects after solid organ transplantation with BD donors (97). Thus, it would be valuable to explore issues related to chemokines and macrophages in future research that are currently outside the scope of this manuscript.

Other immune cells such as natural killer (NK) cells, dendritic cells (DCs), T lymphocytes (LT) CD4+ and CD8+, or Kupffer cells (KC) seem to have an important role in mechanisms underlying injurious postoperative outcomes in the setting of LT (99), and thus, a relationship between signaling pathways described in the present research (IL-6/IL-1b or IL-10/IL-1b) and such immune cells, in the context of LT from DBDs, should not be discarded. NK cells have been reported as modulators of I/R injury and, according to different authors, the infiltration of these immune cells into the liver exacerbates liver injury, promoting other inflammatory cells' infiltration in the graft (100). A relation has been established between NK cells and IL-6 or IL-10. IL-6 prevents liver inflammation via suppression of NK cells, since administration of IL-6 markedly attenuated the ability of NK cells to kill hepatocytes *in vitro*, which has been suggested to play an important role in the pathogenesis of hepatitis (101). In addition, IL-10 has been reported as an inhibitor of NK cells and their receptors, downregulating its cytotoxic activity in LT (100). Recently, compelling evidence has delineated the role of DCs in hepatic I/R injury and several results support that DCs modulate levels of IL-6 and IL-10 in liver submitted to ischemia injury (102, 103). T lymphocytes (CD4+) produce chemokines that amplify KC activation, which promote neutrophil recruitment and adherence into the liver sinusoids, aggravating IR injury (104). CD4+ T cells accumulate rapidly in mouse LT following cold storage, and in this sense, as early as at 1 h post-transplant, a massive infiltration of liver graft with CD4 T cells is found. In such conditions, CD4+ T cells express TIM-1 and modulation of this signaling mediator has resulted in the regulation of IL-6 and IL-10 production, and amelioration of cold hepatic ischemia-mediated LT inflammation and damage (105). After I/R injury, steatotic livers have showed increased infiltrating CD8+ cells in association with high levels of parameters of liver damage and proinflammatory cytokines (106). As occurring in the case of CD4+ cells, some reports have indicated that CD8+ cells may also regulate IL-6 and IL-10 in liver tissue (107, 108). Interestingly, induction of IL-6 expression in the liver prevented CD8+ T cell-mediated liver injury (109). All this constitutes interesting topics to be addressed in years to come, in order to better comprehend multiple complex interrelations between immune cells and inflammatory mediators that are established in liver grafts suffering from I/R inherent with LT and injurious effects of BD.

The data provided in this study determined that IL-6/IL-10 protects liver grafts from DBDs and, thus, hepatocytes, in an indirect way, if considering that the benefits of IL-6/IL-10 can only be achieved through the regulation of IL-1 $\beta$ . The mechanisms triggered downstream of the NO/IL-6/IL-1 $\beta$  pathway in non-steatotic livers and of the NO/IL-10/IL-1 $\beta$  pathway in steatotic ones resulted in beneficial effects such as reduction of endothelial

damage, neutrophil accumulation, oxidative stress, and cellular edema. Surely, the attenuation of these cellular events protects the integrity of hepatocytes, and indeed, the detrimental effects of endothelial damage, neutrophil accumulation, and oxidative stress on hepatocytes are well known (62, 86, 110). In this sense, the reduction of such parameters was precisely associated with a decrease in graft damage parameters directly related to hepatocytes, such as ALT levels (released from hepatocytes) and damage score (evaluated directly in a liver tissue sample in which it is possible to observe the integrity or destruction of hepatocytes). Some studies have indicated that both IL-6 (in a rat model of partial LT) and IL-10 (in a rat model of hepatic I/R injury) have beneficial effects on hepatocytes, since they demonstrated that these cytokines promoted the proliferation of hepatocytes (111, 112). In these terms, there is the possibility that in the model of the present study (liver transplant with grafts from DBDs) IL-6 and/or IL-10 could also exert a direct action on the functionality and integrity of the hepatocyte. On the other hand, it is important to mention that to determine a direct hepatocyte response to IL-6 or IL-10 modulation, evaluation in an *in vitro* model is required, to isolate hepatocytes from the influence of non-parenchymal liver cells. Therefore, in the *in vivo* model used in the present investigation, it is not possible to conclude whether a cell type is being directly affected by IL-6 or IL-10, since the damage and inflammation parameters obtained from the LT from the DBD model are the result of the interaction of all cell types present in the liver. Although some aspects of I/R inherent to LT have been replicated *in vitro* to determine direct effects on hepatocytes (113–115), they are by no means the same conditions that occur when LT is performed in clinical practice. The great relevance of *in vivo* models is that they allow mimicking what occurs in clinical settings, where an interaction between different cell types occurs, and not the effects of a single cell type. Our study is an investigation of translational medical science, and in this field, what is sought is to reproduce as faithfully as possible in an experimental model what happens in clinical practice. This is extremely important so that in the short or medium term, the results can have an application in the clinical setting (116, 117) and, in that way, contribute to solving problems in LT from DBD that arises in our investigation.

Some studies in myocardial ischemia (24) and warm hepatic I/R (15) indicate that NO can induce IL-10 production, and in the setting of partial LT, NO has been shown to have the capacity to regulate generation of IL-6 (25). Moreover, I/R experimental models have also previously been used to demonstrate that NO inhibits the production of IL-1 (15), as is also the case when LPS induces hepatotoxicity (118). As data from the present research pointed to NO being upstream of IL-6 or IL-10, we investigated whether exogenous NO administration could confer protection against injury in LT from DBDs by stimulating IL-6 release in non-steatotic livers and IL-10 in steatotic ones. In our hands, in non-steatotic grafts from DBDs, exogenous NO increased IL-6, and this reduced IL-1 $\beta$ , thereby protecting against oxidative stress, inflammation, and damage. However, treatment with exogenous NO did not modify the levels of either IL-10 or IL-1 $\beta$  in steatotic

grafts from DBDs, but worsened oxidative stress, inflammation, and damage.

It is known that NO can act as an antioxidant, a vasodilator, and an antineutrophil, which means that this molecule has important potential to provide protection (48, 119). In contrast, it is also known that when combined with superoxide ( $O_2^-$ ), the same NO molecule can form the detrimental ONOO<sup>-</sup> ion (120). If *in vivo* production of NO as well as  $O_2^-$  are at high levels, then ONOO<sup>-</sup> may be formed, with the well-known concomitant oxidative and cytotoxic effects (48, 121, 122). Antioxidant defenses in cells are reduced by ONOO<sup>-</sup>, and it can also inactivate certain enzymes and in some proteins lead to nitration of tyrosine residues, which can have negative effects on different functions and also interfere with the process of signal transduction (123). Also, ONOO<sup>-</sup> promotes an inflammatory response in the liver, which includes, among other cellular events, the accumulation of neutrophils and cellular edema (124, 125). Interestingly, our results concerning nitrotyrosine hepatic levels indicate that ONOO<sup>-</sup> is potentially one of the most important reactive oxidants when we are considering steatotic liver grafts from DBDs. In agreement with this finding, we also found that when dealing with steatotic liver grafts obtained from DBDs, an increase in the levels of nitrotyrosine was also related to the negative effects that substances that are exogenous donors of NO had in terms of liver injury, inflammation, and levels of oxidative stress. This could partly explain why exogenous NO is harmful in the surgical setting of steatotic LT from DBDs. In contrast, in non-steatotic liver grafts from DBDs, exogenous NO (which was not associated with nitrotyrosine generation) protected against damage, oxidative stress, and inflammation. As previously mentioned, ONOO<sup>-</sup> is formed when the condition of high production of both NO and  $O_2^-$  occurs. In steatotic grafts from DBDs, these conditions come about when exogenous NO is administered, since these grafts generate reactive species intensely in LT from DBDs, and therefore, peroxynitrites are formed and liver damage is exacerbated. On the other hand, in the case of non-steatotic grafts from DBDs, since far fewer ROS are produced in LT from DBDs, when they are treated with exogenous NO, the conditions necessary to form ONOO<sup>-</sup> do not occur, and for this reason, no detrimental outcomes are observed. This hypothesis explains the differential effect of exogenous NO on the two types of grafts. Given such circumstances, it may be possible to develop some preventive strategies based on the use of NO donors for application in circumstances of non-steatotic grafts from DBDs used in LT; however, if steatosis is found to be present, then this same treatment would not be appropriate.

From our study, for the first time, we described signaling pathways underlying the I/R injury inherent to LT from DBDs that were specific depending on the presence or absence of steatosis in the liver graft. We showed that the fact that a liver is initially either steatotic or non-steatotic prior to graft collection may prove to be the determining factor for the endogenous signaling pathway. The fact that, in both types of liver grafts, we saw that proinflammatory and anti-inflammatory ILs were not well balanced as a result of BD induction could explain, at least

partially, the detrimental effects induced by BD. Indeed, the results derived from the different pharmacological treatments indicate that the reduced ability to generate anti-inflammatory ILs (IL-6 in non-steatotic livers and IL-10 in steatotic ones) and the subsequent higher IL-1 $\beta$  levels in both types of liver grafts from DBDs were associated with the development of more severe liver injuries and inflammation, in both steatotic and non-steatotic LT from DBDs. Unfortunately, liver grafts from DBDs exhibit a decreased ability to endogenously generate such anti-inflammatory interleukins, as demonstrated by the results of the present study. This situation causes the grafts from DBDs to be unable to limit the high levels of IL-1 $\beta$  that were registered in both types of grafts, and consequently high levels of inflammation and damage occur.

The discovery of these mechanisms of action of IL-6 in non-steatotic livers and IL-10 in steatotic grafts allowed us to identify possible therapeutic targets whose effectiveness in reducing liver damage was evaluated in our research. Given such results and previous reports indicating that IL-1 $\beta$  is involved in the upregulation of reactive oxygen species (ROS) (15) and the production of inflammatory mediators (62, 126) observed in I/R liver injury, it could be useful to treat non-steatotic liver grafts with exogenous IL-6 or adopt a strategy based on supplementation with NO, and to treat steatotic ones with exogenous IL-10, with the purpose of limiting the inflammation and oxidative stress induced by IL-1 $\beta$ . Because of the results of the present research, the application of NO donors in steatotic liver grafts from DBDs would not be appropriate. Herein, we demonstrate a differential effect of NO supplementation depending on the type of liver graft from DBDs, since such a pharmacological strategy only protects non-steatotic grafts against damage through regulating the IL-6–IL-1 $\beta$  pathway, while in contrast, NO supplementation exacerbates oxidative stress, inflammation, and damage and does not affect the IL-10–IL-1 $\beta$  pathway in steatotic liver grafts.

In our view, it would be more appropriate to use pharmacological strategies with benefits in both types of livers (whether steatotic or non-steatotic), as there are no effective methods to distinguish between the presence and the absence of steatosis, or the degree of steatosis in the clinical context of DBDs (127). In such a case, given the preclinical results presented in the current study, the use of exogenous IL-6 or IL-10 and NO donors as therapeutic strategies may not be appropriate because of their specificity to only protect one type of graft and even NO donors can be prejudicial if steatosis is indeed present. Highlighting this type of disadvantage is extremely important for clinical surgical teams, because some studies have established that if a drug is useful in a model of hepatic I/R (whatever it may be), it could be used in all other settings involving liver injury from I/R (128–130). In this sense, the findings of the present study contribute to support the idea that, in the context of hepatic I/R, different therapeutic strategies have to be applied depending on each clinical context of I/R and dependently of the type of the liver (steatotic versus non-steatotic liver). Based on all of this, when performing LT, protection against the negative effects of BD may be provided by treatment

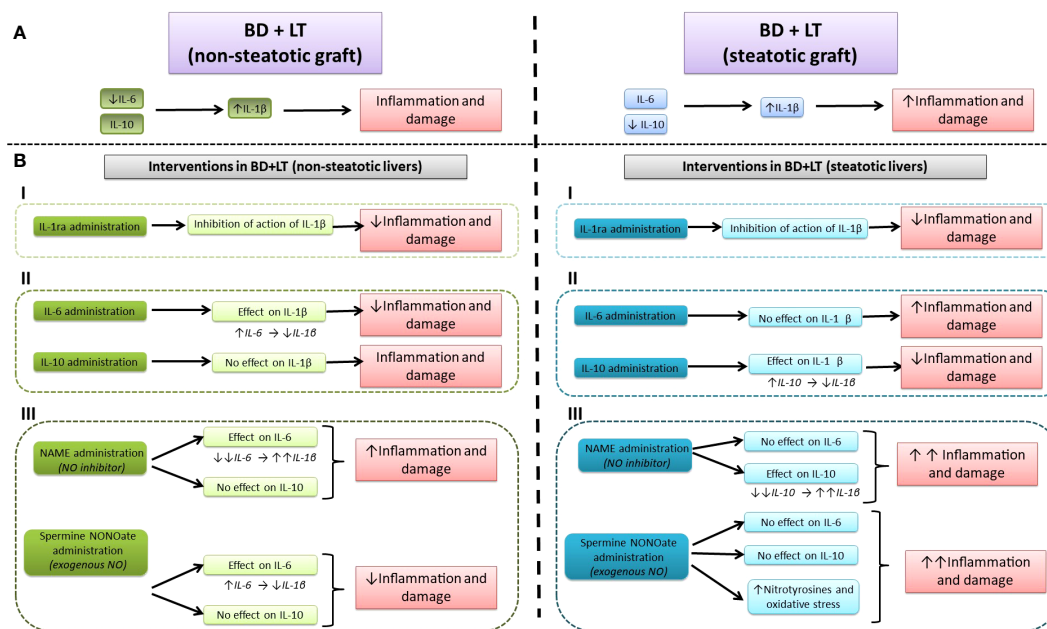

FIGURE 12

Signaling pathways highlighted by the current study. **(A)** Schematic representation of the role of interleukins in liver injury during transplantation with steatotic and non-steatotic grafts from DBDs. **(B)** Different pharmacological interventions: (I) effect of IL-1 receptor antagonist, modulating the action of IL-1β; (II) effect of IL-6 and IL-10, modulating IL-1β levels; (III) effect of NO, modulating levels of IL-6, IL-10, and IL-1β.

adopting a strategy based on inhibiting the action of endogenous IL-1β, since such a strategy has been shown to be beneficial in liver grafts from DBDs both in the presence and in the absence of steatosis. The findings derived from the present investigation indicate that the administration of an IL-1β receptor antagonist would be an effective therapeutic strategy that potentially could be used in real clinical situations of LT from DBD. Since IL-1β inhibition has been shown to be equally effective in the presence or absence of steatosis, clinicians did not have to worry about knowing the degree of fatty infiltration that a liver graft that is going to undergo transplantation could have.

In conclusion, results from our research showed that the fact that a liver is initially either steatotic or non-steatotic prior to graft collection may prove to be the determining factor for the signaling pathway in livers undergoing LT from DBDs. This is the NO/IL-6/IL-1b pathway in non-steatotic livers, and the NO/IL-10/IL-1b pathway in steatotic ones (summarized in Figure 12). From this, the usefulness of a therapy based on inhibiting the effects of IL-1β (using an IL-1 receptor antagonist) was demonstrated, which was effective in protecting against damage in both types of graft. Findings from the current study might be of considerable clinical relevance and could make a great contribution to the field of developing effective and efficient strategies that result in a reduction of the incidence of complications after LT in the case of grafts obtained from deceased donors, whether steatosis is present or not. In addition to the above, the present research established that the time frame between the declaration of BD and organ retrieval provides an important window for protective

intervention, thus avoiding possible side effects in the recipient. From all of the above, it is clear that the results from the present investigation are of scientific and clinical relevance. Undoubtedly, further research beyond the scope of the present study will be necessary to determine whether the benefits of these strategies demonstrated in experimental models could reach clinical practice.

## Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## Ethics statement

All procedures were approved by the Laboratory Animal Care and Use Committee of the University of Barcelona and by the Generalitat de Catalunya (DAAM 9353). European Union regulations (Directive 86/609 EEC) for animal experiments were respected.

## Author contributions

CP designed the study; CP, AC-R, and MM-C performed the groups of experiments, and biochemical and histological analyses; CP, AC-R, and MM-C contributed to data interpretation; AC-R,

CM-S, and AS-G gathered the related literature and prepared the figures; AC-R drafted the manuscript; AT reviewed the manuscript and aided in its writing; CP provided a critical appraisal of the manuscript, expertise, and review. All authors contributed to the article and approved the submitted version.

## Funding

The Spanish Ministerio de Ciencia supported this research (PID2021-123123OB-I00) as did the European Union (via the European Regional Development Fund “Una manera de hacer Europa”).

**Background and Aims:** Intestinal epithelial cells separate the luminal flora from lamina propria immune cells and regulate innate immune responses in the gut. An imbalance of the mucosal immune response and disrupted intestinal barrier integrity contribute to the evolution of inflammatory bowel diseases. Interleukin (IL)-37 has broad anti-inflammatory activity and is expressed by the human intestinal epithelium. Mice ectopically expressing human IL-37 show reduced epithelial damage and inflammation after DSS-induced colitis. Here, we investigated the impact of IL-37 on the innate immune response and tight junction protein expression of mouse intestinal organoids and the modulation of *IL37* expression in human intestinal organoids.

**Methods:** Murine intestinal organoids were generated from IL-37tg and wildtype mice. Human ileal organoids were generated from healthy young donors.

**Results:** Expression of transgene IL-37 or recombinant IL-37 protein did not significantly reduce overall proinflammatory cytokine mRNA expression in murine intestinal organoids. However, higher *IL37* expression correlated with a reduced proinflammatory cytokine response in murine colonic organoids. *IL37* mRNA expression in human ileal organoids was modulated by proinflammatory cytokines showing an increased expression upon TNF- $\alpha$ -stimulation and decreased expression upon IFN- $\gamma$  stimulation. Transgene IL-37 expression did not rescue TNF- $\alpha$ -induced changes in morphology as well as ZO-1, occludin, claudin-2, and E-cadherin expression patterns of murine jejunal organoids.

**Conclusions:** We speculate that the anti-inflammatory activity of IL-37 in the intestine is mainly mediated by lamina propria immune cells protecting intestinal epithelial integrity.

## KEYWORDS

innate immune response, inflammatory bowel disease, IL-37, intestinal organoid, intestinal barrier, tight junctions, cytokines

## Introduction

The intestinal epithelium is the largest epithelial layer in the human body that is in contact with the environment (1). Intestinal epithelial cells (IEC) form the barrier between the intestinal luminal microbiome and the lamina propria immune cell compartment and mediate innate immune responses of the gut (2). Cytokines secreted by either resident or infiltrating immune cells modulate epithelial proliferation, apoptosis, and barrier function, and vice versa, epithelial cells themselves can initiate immune responses at the mucosal level (3). IEC express a variety of cytokine receptors and receptors to sense pathogens or pathogen-associated molecular patterns (2, 4, 5). Subsequent signaling pathways induce cytokine and chemokine secretion by IECs to recruit immune cells to the site of inflammation (2, 4–6) with destructive (7–12) or beneficial effects (13–15) on the intestinal epithelial barrier.

The functional crosstalk between IEC and immune cells via cytokines and chemokines is tightly balanced in the healthy gut (3). In contrast, an impaired gut barrier integrity and imbalance of the mucosal immune response can contribute to inflammatory bowel diseases (16–21). The imbalance of mucosal immune responses may be caused by an exaggerated immune activation or the loss of anti-inflammatory, protective immune mechanisms. As such, it has been shown that, i.e., the overproduction of interleukin (IL)-12 by macrophages (22), genetic variants of NOD2 overactivating NF- $\kappa$ B in monocytes (23), or alterations in TLR expression (20) are associated with Crohn's disease. On the other hand, reduced anti-inflammatory mechanisms such as disturbed TGF- $\beta$  signaling in inflammatory bowel disease (IBD) patients (24), reduced number of regulatory T cells in peripheral blood in patients with ulcerative colitis (25) or IL-10 or IL-10 receptor deficiency in pediatric patients with early-onset enterocolitis (26) are examples of a harmful, overactivated immune response in the gut.

IL-37, an anti-inflammatory member of the IL-1 family, is attributed to balancing the intestinal immune response, and a homozygous loss-of-function variant has been shown to be associated with infantile-onset IBD (27). IL-37 acts via two different pathways. Extracellular IL-37 binds to the IL-18 receptor 1 (IL-18RI) and a single IL-1R-related molecule (SIGIRR), forming the tripartite complex and suppressing MyD88-dependent proinflammatory signals (28, 29). Intracellular IL-37 interacts upon caspase-1 cleavage with Smad3, translocates to the nucleus, and reduces the production of proinflammatory cytokines (30, 31).

IL-37 reduces proinflammatory cytokine secretion in mouse macrophages, human monocytes, and epithelial cells upon stimulation with LPS or IL-1 $\beta$  (30) and inhibits systemic inflammation in various murine disease models (30, 32–35). IL-37 also displays an anti-inflammatory role within the epithelium, as shown in experiments on T84 colonic carcinoma cells (36), human and murine intestinal organoids (37), and dextran sodium sulfate (DSS)-colitis mice (32). Studies even showed that IL-37 expression was increased in the human intestinal epithelium of IBD patients (38, 39).

Inflammation compromises the integrity of the gut barrier (16, 17, 40). Several proinflammatory cytokines were shown to regulate the expression of tight junction (TJ) proteins, leading to decreased transepithelial electrical resistance (TEER) and increased

paracellular permeability (7–12), while anti-inflammatory cytokines protect the intestinal barrier integrity (13–15). The role of IL-37 on the intestinal epithelial proinflammatory response and the intestinal epithelial barrier is not well understood yet.

The aim of this study is to analyze the impact of transgene IL-37 (tgIL-37) on innate immune response and TJ protein expression in murine intestinal organoids and to investigate the regulation of IL37 expression in human intestinal organoids.

## Materials and methods

### Chemicals and reagents

Reagents were purchased from Sigma-Aldrich GmbH (Munich, Germany) [ethylenediaminetetraacetic acid (EDTA), bovine serum albumin (BSA), sucrose, D-sorbitol], Thermo Fisher Scientific (Munich, Germany) [Dulbecco's Phosphate - Buffered Solution (DPBS), Hank's Balanced Salt Solution (HBSS)], Merck Life Science KGaA (Darmstadt, Germany) (Na<sub>2</sub>HPO<sub>4</sub>, KH<sub>2</sub>PO<sub>4</sub>, NaCl, KCl), or other manufacturers as indicated.

### Generation of human organoids

Human intestinal forceps biopsies were taken during routine endoscopies from the terminal ileum of two patients without intestinal inflammation (boy, 16 years; girl, 16 years) at Charité - Universitätsmedizin Berlin and collected in HBSS. Patients and legal guardians gave written consent (EA/134/19).

After sampling, ileum biopsies were incubated in EDTA (2.5 mM), followed by vigorous pipetting to isolate crypts, and then Matrigel was added for organoid culture as described (41). Plates were incubated at 37°C and 7% CO<sub>2</sub>. Organoid medium was prepared as described (Supplementary Table S1) and replaced every other day (41). Organoids were passaged every 10 to 14 days.

### Generation of murine organoids, passage, and freezing

C57BL/6J mice expressing human IL-37 (IL-37tg) have been described previously (30). Age-matched mice from the congenic control line (WT) were used as controls. IL-37tg and WT mice were bred under specific pathogen-free conditions. Three 8–14-week-old mice of each genotype were used for organoid generation.

Jejunal organoids from middle jejunal tissue and colonic organoids from distal colonic tissue were generated as previously described with modifications (42, 43). Gut segments were rinsed with ice-cold DPBS, opened longitudinally, cut into 10-mm pieces, and washed by vortexing several times until the supernatants became clear. Crypts were isolated as described (42) but with an incubation of 20 min for the jejunum and 90 min for the colon in small intestinal or colonic crypt isolation buffer (42). After incubation, biopsies were washed in DPBS. Crypts were then released by vigorously shaking the tissue segments in DPBS, and the supernatant was collected in 0.1% BSA/PBS and centrifuged at 300  $\times$ g for 5 min at 4°C. Crypts were

diluted to 200 crypts per  $\mu\text{l}$  in Matrigel (Corning Limited-Life Sciences, Amsterdam, The Netherlands, 354230) and seeded as 20  $\mu\text{l}$  domes in 48-well plates. Culture plates were incubated for 30 min at 37°C. The respective organoid culture medium ([Supplementary Table S2](#)) was then added. The medium was supplemented with Y-27632 (Merck Millipore) for the first 2 days. Organoid cultures were maintained at 37°C and 5%  $\text{CO}_2$ . The medium was changed every other day, and colonic organoids were passaged every 5–6 days and jejunal organoids every 4–5 days. A detailed description of organoid generation, passage, and freezing is described in the [Supplementary material](#).

## Stimulation of murine jejunal and colonic organoids

Jejunal and colonic organoids were thawed as previously described ([42](#)), cultured, and passaged at least once before experiments were performed. For experiments, only cultures from passages four to nine were chosen. Jejunal organoids were stimulated with  $\text{TNF-}\alpha$  (Gibco, Thermo Fisher Scientific) and colonic organoids were stimulated with LPS (O55:B5, Sigma), as indicated in the figure legends.

## Gene expression analysis

Organoids were harvested for mRNA isolation 4 h after stimulation. Culture medium was removed, and Matrigel domes were washed in DPBS. Organoids of four to five domes were resuspended in 1 ml of Trizol (Invitrogen, Carlsbad, CA, USA), incubated at room temperature for 10 min, and vortexed. mRNA was purified from the aqueous phase following the manufacturer's protocol, including DNase digestion (GenElute™ Mammalian Total RNA Miniprep Kit, Sigma). Reverse transcription into cDNA was done using 1  $\mu\text{g}$  of total RNA (Applied Biosystems, Carlsbad, CA, USA). Quantitative PCR (qPCR) was performed using the SYBR Green Master Mix (Applied Biosystems). Primer sequences are summarized in [Table 1](#). Measurements were quantified using Quant Studio Design and Analysis software (Applied Biosystems). Gene expression was normalized to *Hprt* expression and untreated control condition.

## Western blotting

For Western blotting, jejunal organoids were harvested 48 h after stimulation. Matrigel domes were dissolved by incubating for 30 min in organoid harvesting solution (Cultrex, R&D systems, Abingdon, UK), centrifuged, and washed in ice-cold DPBS. Pelleted organoids were resuspended in a lysis buffer containing protease inhibitors. The total protein amount was quantified using the bicinchoninic acid assay kit (Thermo Fisher). Each lane of any kD Mini-Protein TGX precast gel was loaded with 17  $\mu\text{g}$  of protein samples and transferred to the PVDF membrane. After blocking (5% milk powder in Tris- buffered saline/0.05% Tween 20), the

membrane was stained with mouse monoclonal antibodies against  $\alpha$ -claudin-2 (Thermo Fisher; clone 12H12; 1:500),  $\alpha$ -occludin (Thermo Fisher; mouse OC-3F10; 1:1,000),  $\alpha$ -ZO-1 (Thermo Fisher; clone 1A12; 1:500), and  $\alpha$ -actin (Santa Cruz, Biotechnology, Heidelberg, Germany; clone 1A4; 1:1,000). Densitometric analysis was performed with ImageJ, and signal densities were normalized to the signal density of actin.

## Immunofluorescence

For immunofluorescence microscopy, jejunal organoids were harvested with organoid harvesting solution 48 h after stimulation. As previously described ([44](#)), 5-  $\mu\text{m}$  slides of paraffinized agarose domes containing organoids were generated. After rehydration, antigen retrieval was performed in boiling Tris-EDTA Tween buffer. Slides were incubated in 10% donkey serum/DPBS containing 0.3 % Triton X-100 and with primary antibodies ([Supplementary Table S4](#)) overnight at 4°C. The next day, slides were stained with secondary antibodies ( $\alpha$ -rabbit Alexa488 or  $\alpha$ -mouse Alexa647) (Invitrogen; donkey; 1:1,000) for 1 h at room temperature and counterstained with DAPI. Image acquisition was performed with  $\times 25$  glycerol immersion on a Zeiss confocal LSM980 NLO microscope with Airyscan, and images were analyzed using Zen software.

## Statistical analysis

Results are expressed as the mean values with 1 standard deviation (SD). A paired Student's *t*-test was applied to compare treated versus untreated conditions in one experimental group. An unpaired Student's *t*-test was used for comparisons between organoids generated from WT and IL-37tg mice. For data that were not considered as normally distributed using the Shapiro–Wilk test, the corresponding nonparametric tests (Wilcoxon signed-rank test or Mann–Whitney *U* test) were performed. For correlation analysis, statistical significance was tested with Pearson's correlation and the Student's two-tailed *t*-test. Outliers were defined by ROUT ( $Q = 1\%$ ) and Grubbs ( $\alpha = 0.05$ ) test. All tests were performed using GraphPad Prism software (version 9.3.1). A *p*-value of 0.05 or less was considered significant.

## Results

### Cytokine response and the expression of IL-37 and its receptor components in WT and tgIL-37 intestinal organoids

To corroborate whether *IL37* impacts the immune response of intestinal epithelial cells, we stimulated intestinal organoids generated from IL-37tg and WT mice with  $\text{TNF-}\alpha$  and IL-1 $\beta$ , as well as LPS and flagellin. Murine jejunal organoids were most potently stimulated by  $\text{TNF-}\alpha$  and colonic organoids by LPS, inducing the highest mRNA expression levels of *Cxcl1*, *Cxcl2*,

*Ccl20*, and *Tnf* within a 4-h stimulation period (Supplementary Figure S1; Figures 1A, B).

TgIL-37 expression was not associated with a significant change in proinflammatory cytokine mRNA expression in jejunal and colonic organoids before and after stimulation, despite a trend toward reduced *Cxcl1*, *Cxcl2*, and *Tnf* mRNA levels in colonic IL-37tg-derived organoids (Figures 1A, B).

Jejunal and colonic organoids generated from IL-37tg mice showed a trend toward higher *IL37* expression after stimulation with TNF- $\alpha$  and LPS, respectively (Figure 1C). Similarly, *IL37* expression was threefold induced by TNF- $\alpha$  in human ileal organoids but not by LPS or IL-1 $\beta$ , while IFN- $\gamma$  downregulated the expression of *IL37* (Figure 1D). *IL37* expression in human ileal organoids was gradually induced by TNF- $\alpha$  over a 24-h period (Supplementary Figure S2).

Baseline *IL37* expression was higher in murine colonic (CT mean: 32.4) versus jejunal organoids (CT mean: 34.4) (Supplementary Table S5). In colonic organoids, higher *IL37* mRNA expression was associated with reduced *Cxcl2* and *Tnf* mRNA expression, as indicated by the significant correlation between *IL37*- $\Delta$ Ct-values of stimulated IL-37tg-derived organoids and their relative *Cxcl2* and *Tnf* mRNA expression (Figure 1E).

The lack of correlation between *IL-37* expression and the inflammatory response of jejunal organoids could be due to differences in anti-inflammatory IL-37 signaling. We therefore analyzed the mRNA expression of IL-37 receptor components in jejunal and colonic organoids. *Il18r1* expression was eight times higher in WT colonic organoids compared to WT jejunal organoids before and 10 times higher after stimulation with TNF- $\alpha$  (Figure 1F). Baseline *Il18r1* mRNA expression was higher in IL-37tg-derived colonic organoids compared to WT-derived colonic organoids (Supplementary Figure S3). *Sigirr* is highly expressed in both jejunal and colonic organoids (CT mean: 25.2 and 26.2) (Figure 1G), and the expression was two times higher in WT

jejunal organoids compared to WT colonic organoids before and after stimulation (Figure 1F). The relation of *Il18r1* and *Sigirr* mRNA expression between jejunal and colonic organoids was similar in IL-37tg organoids and WT organoids (Supplementary Figure S4).

## RhIL-37 protein does not modulate the proinflammatory cytokine response in murine jejunal organoids

IL-37 has intra- and extracellular functionality (28, 30, 31, 45). In order to test the impact of extracellular IL-37 on proinflammatory cytokine expression in gut epithelial cells, we added rhIL-37 to jejunal organoids derived from WT mice (Figure 2). rhIL-37 did not modulate the mRNA expression of *Cxcl1*, *Cxcl2*, *Ccl20*, and *Tnf* in jejunal organoids after TNF- $\alpha$  treatment (Figure 2).

## Morphologic changes of WT and IL-37tg-derived organoids after TNF- $\alpha$ treatment

Since *IL37* expression did not markedly alter the intestinal epithelial immune response (Figures 1A, B), we evaluated the impact of IL-37 on the morphology of organoids derived from WT and IL-37tg mice during inflammation. Under untreated conditions, the morphology of WT and IL-37tg-derived murine organoids was similar (Figure 3A). Jejunal organoids grew as buds and colonic organoids in a spherical shape (Figure 3A). After TNF- $\alpha$  treatment, jejunal WT and IL-37tg-derived organoids displayed spherical rounding (Figure 3B), while the gross morphology of colonic organoids remained similar after LPS treatment. The shape of organoids was similar in both genetic traits.

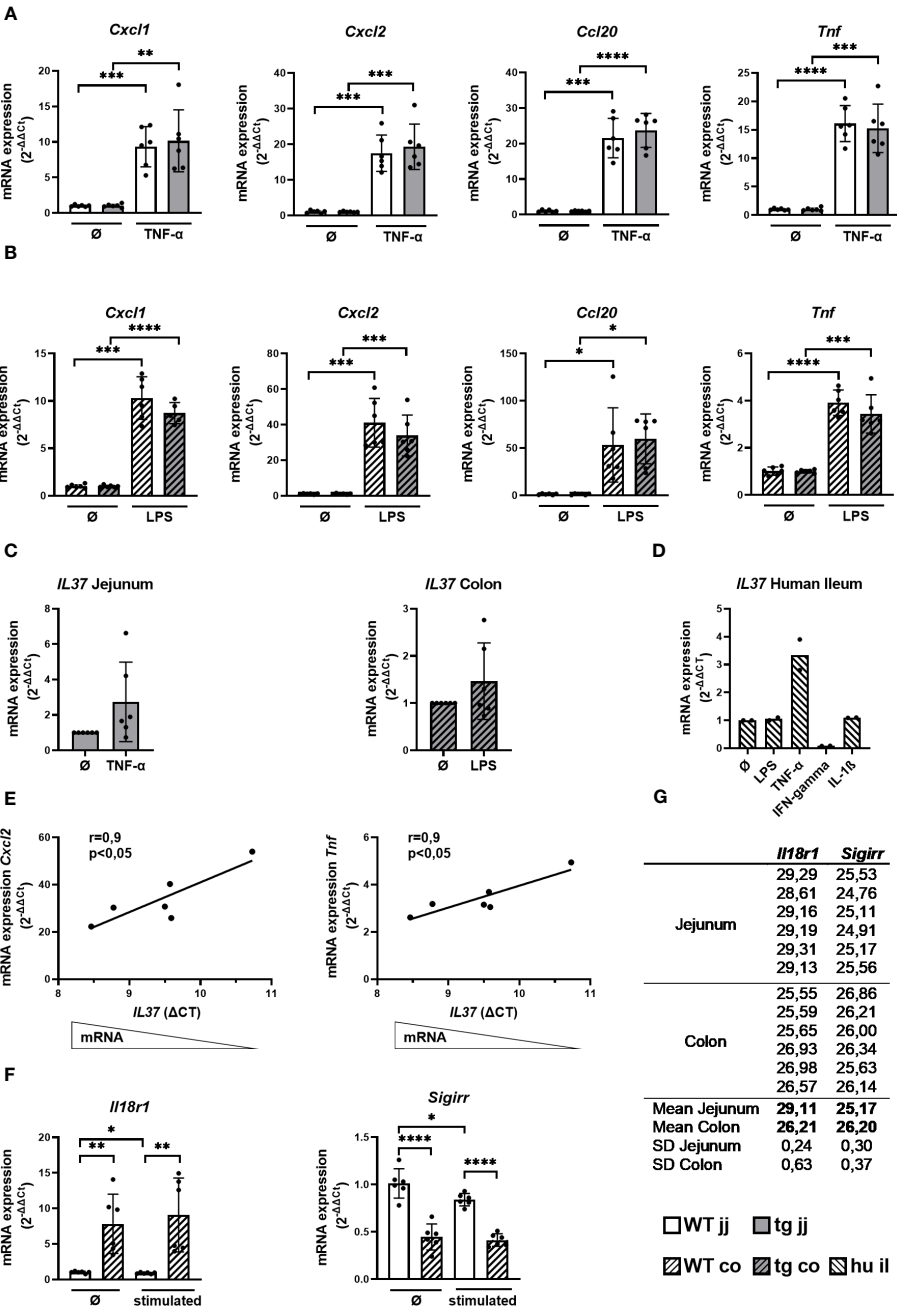

FIGURE 1

Cytokine response and the expression of IL-37 and its receptor components in WT and tgIL-37 intestinal organoids. Jejunal and colonic organoids derived from IL-37tg and WT mice were stimulated for 4 h with murine TNF- $\alpha$  (10 ng/ml) or LPS O55:B5 (1,000 ng/ml) (37) in culture medium. mRNA expression of cytokines in (A) jejunal and (B) colonic organoids was measured by qPCR and expressed as fold change relative to the mean of unstimulated organoids of the respective mouse ( $2^{-\Delta\Delta CT}$ ). (C) Induction of IL37 mRNA expression in stimulated IL-37tg-derived organoids was measured by qPCR and expressed as fold change relative to unstimulated organoids ( $2^{-\Delta\Delta CT}$ ). (D) Human ileal organoids (il,  $n = 2$ , two donors) were stimulated for 24 h with LPS O55:B5 (1,000 ng/ml), human TNF- $\alpha$  (10 ng/ml), human IFN- $\gamma$  (20 ng/ml), and human IL-1 $\beta$  (10 ng/ml) in the culture medium. mRNA expression of IL-37 was measured by qPCR and expressed as fold change relative to unstimulated organoids ( $2^{-\Delta\Delta CT}$ ). (E) Correlation of cytokine mRNA expression relative to mean of unstimulated colonic organoids of the respective mouse ( $2^{-\Delta\Delta CT}$ ) with IL37- $\Delta CT$ -values of stimulated colonic organoids derived from IL-37tg mice. (F) mRNA expression of *Il18r1* and *Sigirr* in jejunal and colonic WT organoids was measured by qPCR and expressed as fold change relative to mean of unstimulated jejunal organoids ( $2^{-\Delta\Delta CT}$ ). (G) Mean CT-values of *Il18r1* and *Sigirr* qPCR duplicates in jejunal and colonic WT organoids. Each experiment was performed with organoid lines of two different mice and repeated three times (in total  $n = 6$ ). Open bars: organoids derived from WT mice (WT); grey bars: organoids derived from IL-37tg mice (tg); no pattern: jejunal organoids (jj); striped pattern: colonic organoids (co). Each data point represents a single organoid line. Data are expressed as the mean with SD. \* $p \leq 0.05$ ; \*\* $p \leq 0.01$ ; \*\*\* $p \leq 0.001$ ; \*\*\*\* $p \leq 0.0001$ .

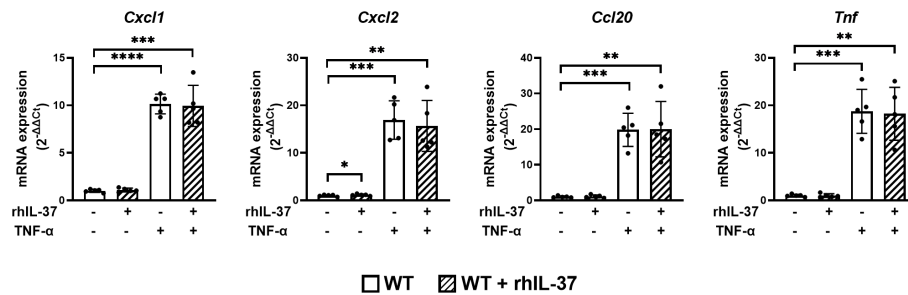

FIGURE 2

RhIL-37 protein does not modulate the proinflammatory cytokine response in murine jejunal organoids. Jejunal WT-derived organoids were stimulated for 4 h with TNF- $\alpha$  (10 ng/ml) with or without rhIL-37 (100 pg/ml; R&D systems). mRNA expression of cytokines was measured by qPCR and expressed as fold change relative to the mean of unstimulated organoids of the respective mouse ( $2^{-\Delta\Delta C_T}$ ). Open bars: organoids derived from WT mice (WT); striped: organoids treated with rhIL-37 (WT + rhIL-37). Each data point represents a single organoid line. Data are expressed as the mean with SD. \* $p \leq 0.05$ ; \*\* $p \leq 0.01$ ; \*\*\* $p \leq 0.001$ ; \*\*\*\* $p \leq 0.0001$ .

## Downregulation and disassembling of intestinal barrier proteins in murine organoids after treatment with inflammatory stimuli are not modulated by tgIL-37 expression

Spherical rounding of small intestinal organoids after TNF- $\alpha$  treatment can be caused by increased TJ permeability (46). Therefore, we analyzed ZO-1, occludin, and claudin-2 mRNA and protein expression in organoids derived from WT and IL-37tg mice before and after respective treatments. There was no significant difference in TJ protein expression between WT- and IL-37tg-derived organoids on mRNA and protein levels before and after stimulation (Figures 4A, B, D). Changes in barrier protein expression and distribution, analyzed by immunofluorescence analysis, were similar in WT- and IL-37tg-derived organoids (Figure 4E).

On the mRNA level, *Tjp1* expression, encoding ZO-1, was unchanged after TNF- $\alpha$  treatment in jejunal organoids (Figure 4A) and colonic organoids (Figure 4B). Expression of *Ocln*, encoding occludin, was reduced by 8% in IL-37tg-derived jejunal organoids (Figure 4A), by 9% in WT-derived colonic organoids (Figure 4B), and by 8% in IL-37tg-derived colonic organoids (Figure 4B). Expression of *Cldn2*, encoding claudin-2, was reduced by 28% in WT-derived jejunal organoids (Figure 4A), by 32% in IL-37tg-derived jejunal organoids (Figure 4A), by 47% in WT-derived colonic organoids (Figure 4B), and by 40% in IL-37tg-derived colonic organoids (Figure 4B).

Western blot analysis (Figures 4C, D) showed a trend toward reduction of ZO-1 in IL-37tg-derived organoids after TNF- $\alpha$  treatment but not in WT organoids. Occludin was reduced by 35% in WT- and by 36% in IL-37tg-derived organoids, and claudin-2 was not significantly reduced by 43% in WT- and by 51% in IL-37tg-derived organoids. Claudin-2 baseline expression is highly varied between single organoid lines, independent of the genotype (Supplementary Figure S5).

In the immunofluorescence analysis (Figure 4E), ZO-1, occludin, and claudin-2 displayed a strong signal at the apical side of epithelial cells, indicating expression within the TJs. Additionally, occludin showed basolateral staining and claudin-2 an intracellular staining. E-cadherin was highly enriched at the

basolateral side and at the lateral membranes, indicating expression within the adhering junctions. ZO-1, occludin, and claudin-2 expression patterns were largely disrupted by TNF- $\alpha$  treatment. E-cadherin staining was restricted to the basolateral side and less detectable at the lateral membranes and at the apical sides after TNF- $\alpha$  treatment. Other than ZO-1, occludin, and E-cadherin, claudin-2 was not expressed homogenously within the organoids but was predominately located within crypt domains (Supplementary Figure S6).

## Discussion

In this study, we show that IL-37 does not modulate the gross cytokine response of murine intestinal organoids after immune stimulation with TNF- $\alpha$  or LPS by using tgIL-37 mice or treatment by rhIL37. However, we show that *IL37* expression is upregulated upon proinflammatory stimulation in murine and human organoids. More subtle analyses demonstrate a negative correlation between *IL37* expression and proinflammatory cytokine response in murine colonic organoids. IL-37 did not alter the TNF-dependent downregulation and structural alteration of TJ proteins in murine jejunal organoids.

There was no significant change in proinflammatory cytokine mRNA expression by IL-37tg jejunal or colonic organoids after TNF- $\alpha$  or LPS stimulation. In accordance with these results, we could also not observe differences in cytokine response after treatment with rhIL-37. This indicates that IL-37, expressed within the intestinal epithelium, does not grossly limit the immune response of IEC in an auto- or paracrine manner. Differences within the experimental approach might explain the contrasting results to the observation of Allaire and colleagues describing a downregulation of proinflammatory *Ccl20* and *Cxcl2* in flagellin- and IL-1 $\beta$ -stimulated murine colonic organoids by treatment with rhIL-37 protein (37). Accordingly, Güntalay et al. showed that CRISPR/Cas knockdown of *IL37* increases the spontaneous chemokine expression in T84 IECs (36). We previously reported that hematopoietic-derived IL-37 from bone marrow transplantation is sufficient to ameliorate the severity of DSS-induced colitis in WT mice (32). This indicated the relevance of

FIGURE 3

Morphologic changes of WT and IL-37tg-derived organoids after TNF- $\alpha$  treatment. (A) Representative light microscope images of murine jejunal and colonic organoids in extracellular matrix on days 3 to 4 under baseline conditions. (B) Representative light microscope images of jejunal organoids in extracellular matrix with or without 48 h TNF- $\alpha$  (10 ng/ml) stimulation. One representative picture out of six independent stimulation experiments is shown.

tgIL-37 expressed by immune cells to control mucosal inflammation. Since neither tgIL-37 nor rhIL-37 protein modulated the epithelial immune response in our organoid model, we speculate that predominantly extracellular IL-37, released from IECs at the site of tissue inflammation, contributes to the control of the immune response of intestinal mucosa-associated immune cells.

IL37 expression in IL-37tg mice is driven by a constitutively active CMV-promotor (30). However, like in healthy human tissue, baseline levels of IL-37 mRNA and protein are low in unstimulated

IL-37tg mice, which is due to mRNA instability elements within the coding region of IL-37 (30, 47). IL37 expression is also low in resting jejunal and colonic organoids generated from IL-37tg mice, but we were able to show a trend toward increased levels after stimulation. In human ileal organoids, only TNF- $\alpha$  but not LPS or IL-1 $\beta$  induced IL37 expression, while IFN-gamma reduced IL37 expression. This is consistent with observations on T84 epithelial colon carcinoma cells (38). Upregulation of IL37 by TNF- $\alpha$  is also in line with a high epithelial IL37 expression in IBD correlating with higher disease

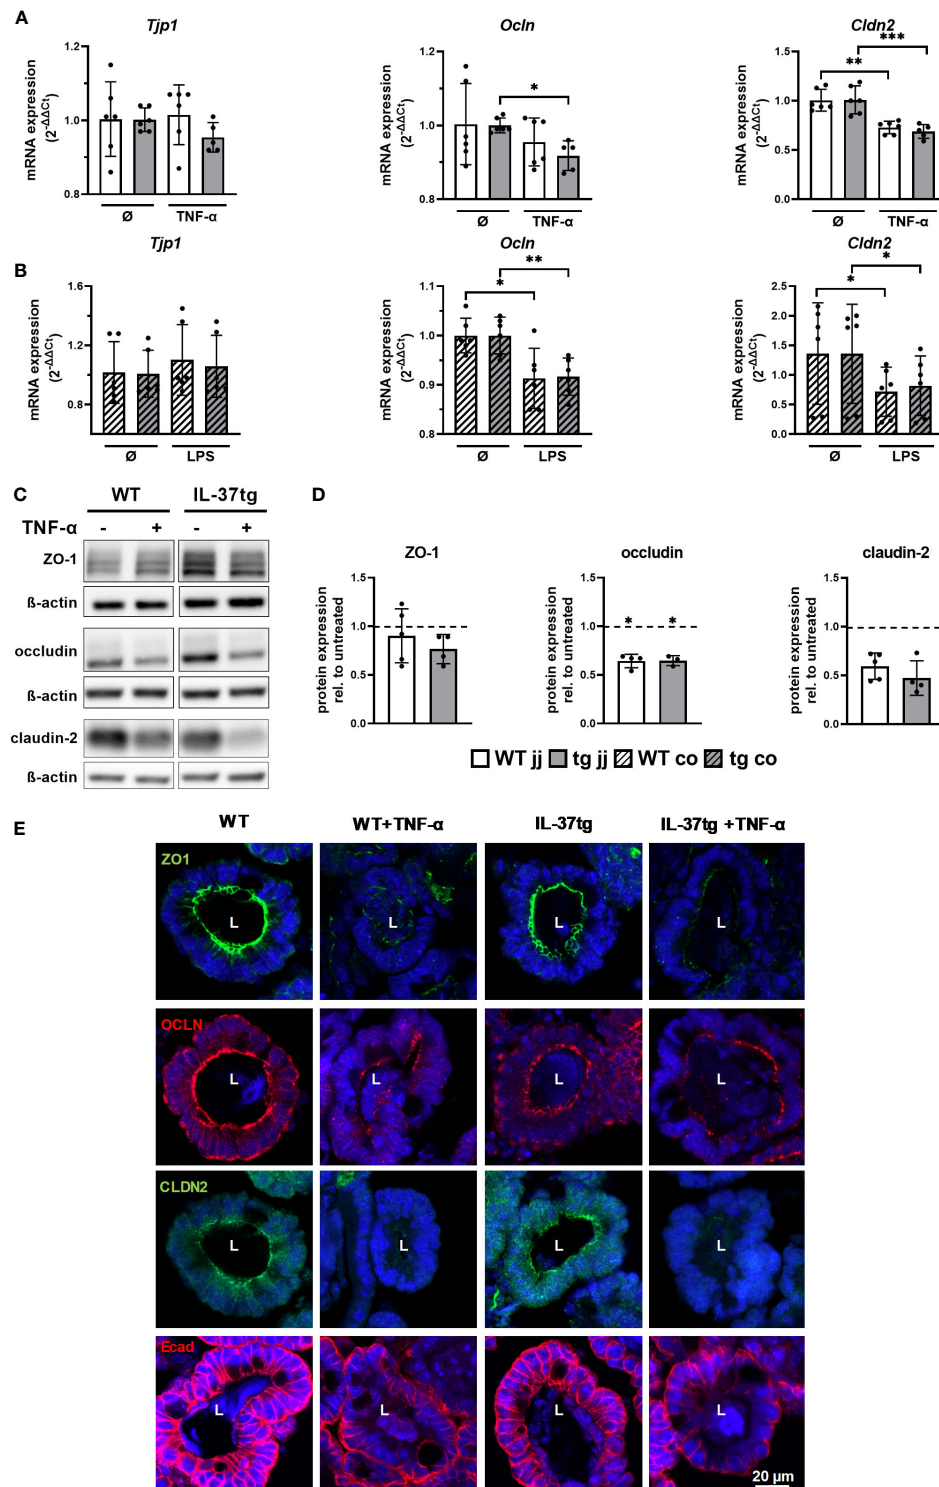

FIGURE 4

Downregulation and disassembling of intestinal barrier proteins in murine organoids after treatment with inflammatory stimuli is not modulated by tgIL-37 expression. Jejunal and colonic organoids were stimulated for 4 h with TNF-α (10 ng/ml) or LPS (1,000 ng/ml). mRNA expression of TJ proteins ZO-1 (*Tjp1*), occludin (*Ocln*), and claudin-2 (*Cldn2*) in (A) jejunal and (B) colonic organoids was measured by qPCR and expressed as fold change relative to mean of unstimulated organoids of the respective mouse ( $2^{-\Delta\Delta C_T}$ ). For Western blot and immunofluorescence analysis, jejunal organoids were stimulated for 48 h with TNF-α (10 ng/ml). (C) Representative Western blots of TJ proteins in jejunal WT- and IL-37tg-derived organoids. (D) Densitometric analysis of Western blots of TJ proteins in TNF-α-treated jejunal WT- and IL-37tg-derived organoids. Protein expression is represented as relative to untreated organoids (dotted line). Stars indicate the significance of downregulation after stimulation. (E) Representative immunofluorescence images of barrier proteins in WT- and IL-37tg-derived jejunal organoid crypt domains stained with ZO-1 (ZO1, green), occludin (OCLN, red), claudin-2 (CLDN2, green), and E-cadherin (Ecad, red). L, lumens. Open bars: organoids derived from WT mice (WT); closed bars: organoids derived from IL-37tg mice (tg); no pattern: jejunal organoids (jj); striped: colonic organoids (co). Each data point represents a single organoid line. Data are expressed as the mean with SD. \* $p \leq 0.05$ ; \*\* $p \leq 0.01$ ; \*\*\* $p \leq 0.001$ .

activity (38, 48). In murine and human small intestinal organoids, there was only a minor inflammatory response to LPS, which might be caused by low expression of TLR4 in both and missing TLR4-associated accessory protein expression in human organoids [Supplementary Figure S1 and as previously shown (49)]. Insufficient immune stimulation could therefore explain the lack of *IL37* induction after LPS treatment in human ileal organoids. The induction of *IL37* by TNF- $\alpha$  in human ileal organoids was similar to that in murine jejunal organoids, corresponding to a high immune stimulation by TNF- $\alpha$  in murine and may be as well in human small intestinal organoids (Supplementary Figure S1).

Increasing levels of tgIL-37 mRNA, induced by proinflammatory signals, correlated with a lower *Cxcl2* and *Tnf* response in LPS-stimulated colonic organoids. This negative correlation was not observed in jejunal organoids after stimulation. Since SIGIRR is evenly expressed throughout the murine gut (50), as similarly seen in our jejunal and colonic organoids, we speculate that a higher expression of the IL-37 receptor component *Il18r1* (51–53) in colonic organoids sensitizes for autologous, anti-inflammatory IL-37 signaling. Indeed, polymorphisms in the IL18RI-IL18RAP locus are associated with adult and early-onset IBD (54–56), underlining the relevance of the IL-18RI for human disease activity to target both proinflammatory IL-18 and anti-inflammatory IL-37 immune pathways. In addition, tgIL-37 expression itself is associated with a markedly higher *Il18r1* expression in our IL-37tg colonic organoids, suggesting a regulatory effect of IL-37 on bona fide *Il18r1* expression (Supplementary Figure S3). Pretreatment with rhIL-37 was shown to induce SIGIRR expression in humans, LPS-stimulated PBMCs and M1 macrophages (45) indicating that IL-37 induces upregulation of its receptor components to increase its anti-inflammatory capacity.

TJ proteins claudin-2, ZO-1, or occludin are key determinants of epithelial integrity against mucosal inflammation in IBD (17, 18, 40, 57). The impact of TNF- $\alpha$  on epithelial barrier function was extensively studied in 2D cell culture models (10–12, 58). 3D organoid models are a good representation of the epithelial architecture, with a villi-like structure and composition of a variety of epithelial subtypes. However, studies of TJ proteins and IL-37 in organoids are scarce. In our model, TNF- $\alpha$  and LPS caused significant changes in TJ protein expression and morphology in jejunal and colonic organoids. Nevertheless, overall TJ protein expression and organoid morphology were similar between WT- and IL-37tg-derived organoids before and after stimulation. This indicates that tgIL-37 expression in IEC does not prevent the disturbance of TJ protein expression during inflammation.

In summary, our 3D intestinal organoid model enabled us to investigate the impact of IL-37 on IEC innate immune responses and intestinal barrier function, irrespective of epithelial immune cell activation. We show that *IL37* expression is induced in intestinal epithelial cells but has no major impact on modulating IEC innate immune responses itself and does not prevent murine intestinal organoids from altered barrier protein expression after stimulation. We conclude that the protective effect of IEC-derived IL-37 on the intestinal epithelial barrier in murine models of IBD and potentially the human gut is more mediated by downregulating the release of proinflammatory mediators from lamina propria immune cells than intestinal epithelial cells.

## Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## Ethics statement

The studies involving humans were approved by Ethics committee Charité Universitätsmedizin Berlin. The studies were conducted in accordance with the local legislation and institutional requirements. Written informed consent for participation in this study was provided by the participants' legal guardians/next of kin. The animal study was approved by Landesamt für Gesundheit und Soziales Berlin. The study was conducted in accordance with the local legislation and institutional requirements.

**Introduction:** The antinociceptive and pharmacological activities of C-Phycocyanin (C-PC) and Phycocyanobilin (PCB) in the context of inflammatory arthritis remain unexplored so far. In the present study, we aimed to assess the protective actions of these compounds in an experimental mice model that replicates key aspects of human rheumatoid arthritis.

**Methods:** Antigen-induced arthritis (AIA) was established by intradermal injection of methylated bovine serum albumin in C57BL/6 mice, and one hour before the antigen challenge, either C-PC (2, 4, or 8 mg/kg) or PCB (0.1 or 1 mg/kg) were administered intraperitoneally. Proteome profiling was also conducted on

glutamate-exposed SH-SY5Y neuronal cells to evaluate the PCB impact on this key signaling pathway associated with nociceptive neuronal sensitization.

**Results and discussion:** C-PC and PCB notably ameliorated hypernociception, synovial neutrophil infiltration, myeloperoxidase activity, and the periarticular cytokine concentration of IFN- $\gamma$ , TNF- $\alpha$ , IL-17A, and IL-4 dose-dependently in AIA mice. In addition, 1 mg/kg PCB downregulated the gene expression for T-bet, ROR $\gamma$ , and IFN- $\gamma$  in the popliteal lymph nodes, accompanied by a significant reduction in the pathological arthritic index of AIA mice. Noteworthy, neuronal proteome analysis revealed that PCB modulated biological processes such as pain, inflammation, and glutamatergic transmission, all of which are involved in arthritic pathology.

**Conclusions:** These findings demonstrate the remarkable efficacy of PCB in alleviating the nociception and inflammation in the AIA mice model and shed new light on mechanisms underlying the PCB modulation of the neuronal proteome. This research work opens a new avenue to explore the translational potential of PCB in developing a therapeutic strategy for inflammation and pain in rheumatoid arthritis.

## 1 Introduction

Rheumatoid arthritis (RA) stands as a persistent autoimmune disease, marked by widespread synovitis and, at times, by relentless bone deterioration (1). The ensuing joint abnormalities, which include rigidity and deformity, precipitate a distressing setback of mobility in RA-afflicted individuals and eventually lead to varying degrees of bone decomposition, harm to ligaments and tendons, and skeletal muscle weakening (2).

The initiation and extension of chronic RA inflammation involves both adaptive and innate immune cells. Neutrophils have been identified as the predominant leukocyte in the joints of individuals with active RA (3). Their role in the disease's pathogenesis includes tissue damage and the discharge of proinflammatory cytokines as well as an important crosstalk with other immune cells such as T cells and dendritic cells (DCs) (4–6). Animal models of arthritis have provided more direct evidence of neutrophil involvement in this disease. In the K/BxN mouse RA model, neutrophil depletion led to the complete reversion of the joint inflammation, showing no signs of swelling either in the forefeet or the ankle joints (7). Likewise, chemokines commonly found in rheumatoid synovial fluid drew neutrophils into the affected joints in an arthritis mice model induced by collagen, while the neutrophil depletion also completely prevented the disease development in this model (8).

Furthermore, impairment of the resolution of inflammation acquires a prominent role in perpetuating clinical dysfunction in chronic diseases such as RA. It has been noted that a persistent

failure in neutrophil death is correlated with an increased severity of experimental arthritis in mice (9). Even when neutrophils die, their disposal is dependent on the expression of “eat-me” signals that trigger the engulfing activity of phagocytes, a process called efferocytosis, which may also fail during RA (10). Therefore, considering the diverse roles of neutrophils uncovered in the development of RA, it comes as no surprise that they have become crucial focal points for potential novel disease-modifying treatments.

The prevailing symptom of RA is pain, as confirmed by noteworthy data showing that 97% of individuals with early RA experience pain, and this serves as the primary cause for their initial consultation with healthcare practitioners (11). The onset of pain precedes the visible signs of RA (12, 13), leading to psychological affliction and disturbances in sleep patterns (14). Furthermore, pain emerges as a pivotal factor that influences crucial aspects of daily life. Even when the pain intensity is mild, it can significantly impede regular activities (15). The joint's synovium and capsule primarily house the peripheral afferent fibers stemming from the dorsal root ganglion (DRG). Within these regions, a considerable population of primary A $\alpha$  and A $\beta$  sensory neurons are engaged in mechanosensation, while A $\delta$  and C fibers are responsible for nociception (16). Additionally, sensory periphery nerves are also distributed throughout the joint capsule, lateral area of the meniscus, subchondral bone, ligaments, tendon sheaths, and muscles. All these areas also contribute significantly to the emergence of arthritic pain by exposing their innervating nerves to sensitizing factors secondary to the arthritic progressive tissue

erosion (17). Notably, synovitis within the joint stands as a key pathophysiological mechanism of RA pain generation, directly engaging and sensitizing the afferent nerves of the periphery through a range of soluble mediators, including bradykinin, prostaglandins, cytokines, and the main excitatory neurotransmitter glutamate (18, 19).

Indeed, glutamatergic signaling in the joints has emerged as a major factor in the pathophysiology of arthritic pain. Numerous studies have consistently reported a significant increase in glutamate concentration in the synovial fluid of humans with RA (20, 21) and in animal models of this disease (22). In one study, a single intra-articular injection of a glutamate receptor antagonist successfully inhibited allodynia, a type of pain that arises from a typically non-painful stimulus, in rats with complete Freund's adjuvant-induced arthritis (23). The accumulation of glutamate in the arthritic joint is believed to originate from the peripheral dorsal root ganglion (DRG) nerve terminals due to a marked increase in the production of glutaminase, the primary glutamate synthetic enzyme in neurons (24). This excess glutamate is subsequently released into the extracellular space, leading to an autocrine or paracrine sensitization process. Additional evidence supporting this conclusion comes from studies showing that inhibiting glutaminase peripherally has potent analgesic effects in rats with carrageenan-induced paw inflammation (25).

In parallel to this peripheral sensitization, the mechanisms that regulate pain in the central nervous system are also critically dependent on the sensitization of neurons present in the dorsal horn of the spinal cord, which receive input from the DRG A $\delta$  and C fibers. This central sensitization, caused by the hyperexcitability of spinal neurons, accompanied by a shortage or augmentation of descending inhibitory or facilitatory pathways, respectively, leads to the amplification of the receptive field and an increase in pain sensitivity (26). Distinctive phases occurring in this spinal sensitization of RA pain have been postulated. In the acute phase of the disease, this phenomenon is dictated by the enhanced release of glutamate from the DRG afferent presynaptic endings, which acts on its ionotropic (NMDA, AMPA, kainite) and metabotropic receptors present in the postsynaptic neurons of the spinal dorsal horn (27). In the long-lasting stage of RA, a marked influence of microglia and astrocyte activity on synaptic processing has been documented in diverse chronic models of this malady (28).

Based on these premises, it is reasonable to investigate how neurons respond to excitatory glutamatergic stimulation to predict the possible mediators of inflammatory pain processing. Proteomics studies have proven to be a valuable tool in identifying important cellular markers and pathways of neuronal responses and translatability at a mechanistic level (29). Among those extensively studied cellular models is the human SH-SY5Y neuronal cell line, known for its predictability in assessing neuronal glutamate receptors excitability (30) and responses to inflammatory stimuli such as lipopolysaccharide (31) or cytokines (32). Utilizing this model provides an appropriate experimental framework to detect distinct changes in proteomic profiles under glutamatergic stimulation, potentially leading to new mechanistic hypotheses.

The primary objective of RA therapy is to attain disease remission by easing its symptoms and enhancing the overall quality of life. RA treatment currently involves five main drug classes: pain relievers, non-steroidal anti-inflammatory drugs, glucocorticoids, biologic disease-modifying antirheumatic drugs (bDMARDs), and non-biologic or synthetic DMARDs (33). Despite their usefulness, these treatment approaches often come with undesirable side effects, and approximately 20–40% of patients with RA do not exhibit a positive clinical response to these therapies (34). As a result, there is a pressing need for innovative treatment alternatives to achieve this unmet need in RA treatments.

C-Phycocyanin (C-PC) is the main protein composing the phycobilisomes of *Spirulina platensis* microalgae. This phycobiliprotein is constituted by the  $\alpha$  and  $\beta$  subunits, polypeptides with molecular weights of 17.6 and 18 kDa, respectively, which contain as a prosthetic group, a tetrapyrrolic ring structure named Phycocyanobilin (PCB) that is linked by thioether bonds to cysteines 84 ( $\alpha$  chain), 82 and 153 ( $\beta$  chain) (35). This compound functions as the chromophore of the protein complex for energy transduction in the cyanobacteria's phycobilisomes, and it is associated with the antioxidant (36) and immunomodulatory (37) activities of C-PC. The beneficial properties of *Spirulina platensis* extracts, the natural source of C-PC/PCB, have been studied in several animal models of arthritis (38). By exerting a combination of antioxidant, antiangiogenic, and anti-inflammatory actions, the raw preparations of *Spirulina platensis* have shown promising evidence for alleviating arthritic injuries (39–41). However, to the best of our knowledge, there is no previous report describing the antinociceptive and inflammopharmacological activities of PCB in the context of inflammatory arthritis.

Considering their properties, here we provide evidence that PCB, either administered in pure form or released *in vivo* from its prodrug, the biliprotein C-PC, has protective actions in an experimental setting that mimics several hallmarks of the human disease RA in mice, with emphasis on arthritis-associated nociception and inflammation. This hypothesis was demonstrated through observations that highlight this therapy's potential to effectively cope with functional, immunological, and pathological arthritic injuries. Furthermore, we aimed to assess the effects of PCB on glutamate-induced proteome changes in SH-SY5Y neurons, seeking novel mechanistic insights that may explain the counteractive actions of this molecule against arthritis nociception.

## 2 Materials and methods

### 2.1 Reagents

Sigma-Aldrich (St. Louis, USA) was the commercial supplier of the reagents for most experiments, except in those accordingly indicated. The raw material of *Spirulina platensis* was a kind gift from Genix (Labiofam, Havana, Cuba). The extraction of C-PC from this biomass followed the procedures already standardized and published by our group, which are confirmed by an aqueous two-phase separation

system (42). The final C-PC purity solution was higher than 4 (analytical grade) and this stock was kept refrigerated at 4°C during the duration of the experiments. The working dilutions of C-PC were prepared with sterile phosphate buffer saline (PBS) pH 7.4 immediately before its administration to mice. PCB was commercially obtained in powder (Cat. No. SC-396921, Santa Cruz Biotechnology, Inc., Dallas, USA), diluted with sterile PBS pH 7.4 at 5 mg/mL, and stocked in frozen aliquots (-20°C). Immediately before the administration, the PCB solutions (light-protected) were diluted from the stock according to the scheduled dose.

## 2.2 Laboratory mice

Male C57BL/6 mice (6-8 weeks old) provided by the Federal University of Minas Gerais (UFMG) (43), Belo Horizonte, Brazil, were maintained in the animal rooms of the Immunopharmacology Laboratory, Department of Biochemistry and Immunology at UFMG. Animals received standard food and filtered water *ad libitum* with temperature and humidity-controlled conditions. All procedures involving animal care and handling were approved by the UFMG ethics committee (CEUA UFMG:165/2009).

## 2.3 Antigen-induced arthritis in mice and treatment schedules

AIA was induced following a previously described procedure (43). Briefly, mice were intraperitoneally anesthetized with a mixture of 100 mg/kg of ketamine and 10 mg/kg of xylazine (44) and then immunized by an intradermal shot at the tail base of an emulsion containing 500 µg of methylated bovine serum albumin (mBSA; Sigma) and 100 µL of saline plus Freund's complete adjuvant (CFA; Sigma) at 1:1 ratio (v:v). After two weeks, the challenge with 10 µg of mBSA (in 10 µL sterile saline) was performed by injecting it intra-articularly in the right knee joint of anesthetized mice. At the appropriate time points, euthanasia of the mice was carried out as permitted according to Annex IV of Directive 2010/63/EU, with an anesthetic overdose (180 mg/kg of ketamine and 24 mg/kg of xylazine, intraperitoneally).

Three separate experiments and different outcome assessments were performed. In the first experiment, five groups of mice (n=5-6 each one) were separated at random and divided into groups composed of the control mice receiving an injection of 10 µL sterile saline in the same joint and mice with AIA treated intraperitoneally either with vehicle (PBS pH 7.4) or with C-PC at 2, 4, or 8 mg/kg one hour before the antigen challenge. In the second experiment, the same treatment schedule and route of administration were used, and the mice were allocated at random into four groups (n=6 each one) made up of, in addition to the control, the diseased animals treated with increasing doses of PCB (0.1 or 1 mg/kg), or with PBS pH 7.4 (defined as the vehicle). In the first two experiments, the hypernociception (a pain index measured in the affected right paw), the myeloperoxidase (MPO) activity, and

the neutrophil infiltration in the affected knee cavity were determined following previously described procedures (45).

Finally, the third experiment used a similar design to the second. It included the control, the AIA + vehicle, and the AIA + PCB 1 mg/kg groups (n=4-6 each one) but the experiment aimed to perform a histopathological evaluation of the diseased knee.

## 2.4 Evaluation of hypernociception

An electronic pressure device equipped with a polypropylene tip (4.15 mm<sup>2</sup>) transducer was utilized (Insight Instruments, Ribeirão Preto, Sao Paulo, Brazil). Prior to the study, mice were subjected to a 30-min room adaptation when housed in acrylic cages (12 x 10 x 17 cm high) with a wired floor. Mechanical stimulation was realized while the mice were completely calm, by applying a force with the transducer tip to the central field of the affected paw. Consequently, the bending of the femorotibial joint was produced, accompanied by the retraction of the stimulated paw. The device registered the force intensity when the paw retreat was completed, and the results were expressed as the change in withdrawal threshold (in grams) (46).

## 2.5 Determination of MPO activity and CXCL1 levels

The assessment of the MPO activity and the CXCL1 protein levels was performed in the periarticular tissue homogenate coming from the right knee joint and processed by Ultra-Turrax (Ika, Minas Gerais, Brazil). The MPO activity was evaluated as described (47), by the enzymatic reaction of 25 µL of sample in the presence of 25 µL of 3,3'-5,5'-tetramethylbenzidine (TMB) at 1.6 mM as the color reagent, followed by the spectrophotometric measurement of the reaction product at 450 nm. The absorbance values were interpolated in a standard curve made with a simultaneous assay on 5% casein peritoneal-induced neutrophils, and results were expressed as relative arbitrary units.

CXCL1 was measured by an ELISA kit as indicated by the supplier instructions manual (Duo-Set kits, R&D Systems, Minneapolis, MN, USA).

## 2.6 Intra-articular neutrophil quantification

The cavity of the right knee was cleansed with sterile PBS (two times with 5 µL), added to 90 µL sterile PBS, and stored on ice. The total quantity of leukocytes was immediately counted with a Neubauer chamber when the samples (10 µL) were stained with Turk's solution. The remaining samples were mounted on slides through a cytopsin instrument (Shandon III; Thermo Shandon, Frankfurt, Germany). Differential leukocyte assessment in these slides was performed with a May-Grünwald-Giemsa staining following standard morphologic parameters (48).

## 2.7 Real-time PCR

Total RNA was extracted from popliteal lymph nodes (LNs) with TRIzol reagent (Invitrogen, Rockville, MD) (49). All qPCR assays were done in triplicate with gene-specific primers (Supplementary Table S1), which were used at 300 nM (OriGene Technologies, USA). The reaction products were detected with Fast SYBR Green PCR Master Mix in the Applied Biosystems 7900HT Fast Real-Time PCR System (Applied Biosystems, Foster City, CA, USA). Bi-distilled water was used as a negative control for all assays, either for the target or for the housekeeping genes. The results were calculated following the  $2^{-\Delta\Delta C_t}$  method (50).

## 2.8 Cytometric Bead Array

After careful dissection of the periarticular tissues, these were homogenized with Ultra-Turrax (Ika, Minas Gerais, Brazil) in the presence of a protease-inhibitor mix in PBS pH 7.4. Supernatants were obtained by centrifugation at 13,000g for 10 min at 4 °C and frozen-stored (-70 °C) until needed for the CBA assay. Four cytokines were evaluated (TNF- $\alpha$ , IFN- $\gamma$ , IL-17A, and IL-4) following the kit's protocol (BD™ CBA Mouse Inflammation Kit, BD Biosciences, San Diego, CA), and quantified on a FACS Calibur flow cytometer (Becton Dickinson, San Jose, CA).

## 2.9 Histopathological analysis

The right knee joints were collected for histological evaluation. After the fixation step in 10% buffered formalin (pH 7.4), a 30-day decalcification phase was done by incubating the samples in 14% EDTA pH 7.2 at 20–25 °C prior to paraffin embedding, cutting in sections, and staining with 5  $\mu$ M hematoxylin/eosin. A pathology specialist blindly analyzed two sections/knee joints with a light microscope and assigned a score to each of the following parameters: hyperplasia of the synovium, immune cell infiltration, and bone erosion. The arthritis index was calculated by summing the score of each of these parameters, ranging from 0 to 8, with a higher index indicating an increased injury (51). Representative images for each experimental group were taken with a microscope-coupled digital camera and processed with Image J software (National Institutes of Health, Bethesda, MD).

## 2.10 Isotopic labeling

The radioactive labeling was accomplished with  $^{125}$ I using the Iodogen method (52). Briefly, an Iodogen coated 0.5 mL microtube (Eppendorf, USA) was placed in 1 M phosphate buffer (pH 7.0), using 37 MBq [ $^{125}$ I]-NaI (Isotop, Hungary) in 1 M NaOH and gently stirred for 5 min. Afterward, the labeling was done through the addition of 100  $\mu$ g of C-PC dissolved in 100  $\mu$ L of purified water. Then, the radiolabel was continued for an additional time of 20 min. The labeled C-PC was separated from the reaction medium

in a Sephadex G25 column (GE Healthcare, USA) previously equilibrated in 1 M phosphate buffer (pH 7.0). Finally, the blue fractions with radiochemical purities of at least 90% were pooled and stored at 4°C until use. Blood samples (70  $\mu$ L) were collected from the retro-orbital plexus by means of a heparinized capillary in anesthetized rats at 1, 15, and 30 min after the administration of 5 mg/kg C-PC. All samples were centrifuged at 10,000 rpm for 5 min. The 20  $\mu$ L plasma aliquot was added to 0.5 mL of 0.1% bovine serum albumin and 0.5 mL of 20% trichloroacetic acid. The insoluble material obtained by centrifugation at 10,000 rpm for 5 min (Eppendorf, Germany) was analyzed in a gamma counter (Berthold, Germany).

## 2.11 Biodistribution and pharmacokinetics of C-PC

Lewis rats were used to evaluate the biodistribution and pharmacokinetics of C-PC administered by four different routes: intraperitoneal (ip), intravenous (i.v.), intranasal (i.n), and oral. For the i.v. and i.n. routes, a unique dose of 1mg/kg was used. The samples were taken at 1, 4, 8, 12, and 24 h post-administration in the five rats of this subgroup. For the i.n. scheme, the samples were also collected at 1, 10, and 30 min after receiving the compound, in addition to long-time sampling at 1, 2, 4, and 24 h. In all experiments, tissue distribution was determined at 24 h by euthanasia under narcosis overdose. Percent of accumulated dose per sample was calculated with respect to 1 mL of standard dilution of administered dose measured in the same condition in a well-type scintillation counter calibrated for the energy of  $^{125}$ I. Results are expressed as percent of uptake relative to total radioactivity dose (% D) or percent of uptake per mass of tissue (%D/g).

Pharmacokinetic analysis was carried out following the non-compartmental approach using Pkanalix (Monolix Suite 2021R2, Lixoft, France).

## 2.12 Cell culture and experimental groups

Human SH-SY5Y cells were maintained in culture DMEM/F12 medium supplemented with fetal bovine serum, penicillin, streptomycin, and L-glutamine. The study was divided into three groups, each one containing  $4 \times 10^6$  SH-SY5Y cells: 1) non-treated cells (used as a control), 2) PCB plus Glutamate, and 3) Glutamate. After 24 h of pre-stimulation with 0.1  $\mu$ M PCB, the medium was replaced with freshly prepared 0.01  $\mu$ M PCB plus 60  $\mu$ M Glutamate (group 2) or 60  $\mu$ M Glutamate alone (group 3) for another day. Afterward, the medium was removed; cells were washed using cold PBS and processed to conduct proteomic expression analysis. Three biological replicates were used per group.

## 2.13 Differential protein expression

Proteins were extracted in 1.5% SDS/50 mM DTT with boiling for 10 minutes. Samples were filtered by FASP according to Wisniewski

(53) after the reaction of cysteines with iodoacetamide. Overnight Lysyl endopeptidase and 6 h Trypsin digestions were performed at 37 °C. Samples (1 µg) were analyzed in a Thermo Exploris 480 mass spectrometer via LC-ESI-MS/MS. A nanoLC Ultima 3000 coupled through a Pepmap column (75 µm x 150 mm) to the MS was used. Gradients of 80% acetonitrile in 0.1% formic acid were performed in 120 min at 300 nL/min flow rate. The mass spectrometer was operated in data-dependent analysis (DDA) mode with dynamic exclusion of 30 s and full-scan MS spectra ( $m/z$  350–1650) with a resolution of 120,000 ( $m/z$  200), followed by fragmentation of the most intense ions within 1 s cycle time with high energy collisional dissociation (HCD), normalized collision energy (NCE) of 30.0, and resolution of 15,000 ( $m/z$  200) in MS/MS scans.

Identification of peptides and proteins was based on the match-between-runs procedure using MaxQuant software (v1.6.14.0) (54), considering oxidation (M), deamidation (NQ), and N-terminal acetylation as variable modifications. Alignment of chromatographic runs was allowed with a 20-min alignment window and a time matching of 5 min between runs. Filtering and quantification were performed in the Perseus computational platform (v1.6.14.0) (54). Student's t-test was employed to identify statistically significant changes (p-values lower than 0.05) in protein levels, after filtering for two valid values in each group.

## 2.14 Bioinformatics analysis

Differentially modulated proteins associated with inflammation, pain, arthritis, neurodegenerative diseases, and glutamatergic transmission were identified by a literature search in the Pubmed database (<https://pubmed.ncbi.nlm.nih.gov/>). To retrieve the information contained in Pubmed, the text mining tools Chilibot (chip literature robot) (<http://www.chilibot.net/>) and GeneCUP (<https://genecup.org/>) were used (55, 56). The data mining study was complemented with the information retrieved from the Diseases 2.0 database (<https://diseases.jensenlab.org/>). Such a database provides confidence scores to disease-gene associations annotated using text mining and data integration tools (57). Diseases related to differentially modulated proteins were also retrieved from DisGeNET (<https://www.disgenet.org/>) and GAD\_Disease databases by using the DAVID functional annotation tool (<https://david.ncifcrf.gov/>) (58, 59). Interactions among differentially modulated proteins were retrieved using the STRING database (<http://string-db.org/>) (60). In such analysis, all STRING interaction sources were selected and the confidence score was fixed at 0.4. The biological network of functional associations was visualized using Cytoscape software (v.3.5) (61).

## 2.15 Statistical analysis

The statistical analysis was carried out with the GraphPad Prism software version 9.5.1 (GraphPad Software Inc., CA, USA). All data was expressed as the mean  $\pm$  standard error of the mean (S.E.M.). Data from the control and the AIA + vehicle groups obtained from different experiments were pooled for the statistical analysis of the hypernociception, the neutrophil quantification, and the MPO

activity. The normality of the data was assessed, and when appropriate, it was analyzed by one-way ANOVA and Tukey's multiple comparisons test (parametric). Non-Gaussian measurements were analyzed by Kruskal-Wallis and Dunn's multiple comparisons tests (non-parametric). Differences between groups were considered statistically significant at  $p < 0.05$  (Supplementary Table S2).

## 3 Results

### 3.1 C-PC ameliorates AIA-induced injury

We started our study with the evaluation of C-PC in the AIA mice model, with the assumption that this biliprotein acts as a prodrug during its *in vivo* administration by releasing the pharmacologically active compound PCB into the body. The tetrapyrrole PCB is linked to the specific cysteine residues in C-PC through thioether linkages. Its unbinding could be by means of enzymatic activities as proteases in the form of short peptides or inclusive by the direct rupture of the thioether bond. Another form implies the acidic pH in the stomach, in which this chemical bond is unstable. Nevertheless, the PCB could be linked to another plasmatic protein (i.e., albumin) to facilitate its transport to target cells.

As observed in Figure 1A, the AIA mice that received the vehicle treatment presented a significantly increased nociception in comparison with the control group. The prophylactic administration of either of the three doses of C-PC (2, 4, or 8 mg/kg) was able to significantly reduce the hypernociception in AIA mice one day following the antigen challenge, in comparison with the AIA + vehicle (Figure 1A). AIA also produced a notable increase of neutrophil infiltration, as well as MPO activity in the periarticular tissue of vehicle-treated mice (Figures 1B, C). The treatment with C-PC at the three doses evaluated significantly curtailed the entrance and accumulation of neutrophils in the affected synovial cavity (Figure 1B) and the MPO activity (Figure 1C). In addition, C-PC significantly diminished the CXCL1 chemokine concentrations at all doses assessed with respect to the diseased animals that received the vehicle. (Figure 1D). It is noteworthy that a dose-response effect for the range of doses of C-PC evaluated was not observed.

### 3.2 Biodistribution and pharmacokinetics of C-PC

A radioactive assessment was conducted to determine the C-PC's biodistribution in various tissues. In the i.p., i.v., i.n., and oral routes, radioactivity was detected at levels representing less than 2% of the total administered dose. Conversely, as expected upon oral administration, the accumulation of C-PC was notably higher within the digestive tract, particularly in the large intestine (Figure 2). The pharmacokinetic analysis revealed that i.v. administration led to an exponential decline in plasma C-PC levels. This decay was characterized by an average clearance of 8.9 mL/h and a distribution volume at the stationary phase of 295 mL, which closely matched the body mass of the experimental subjects.

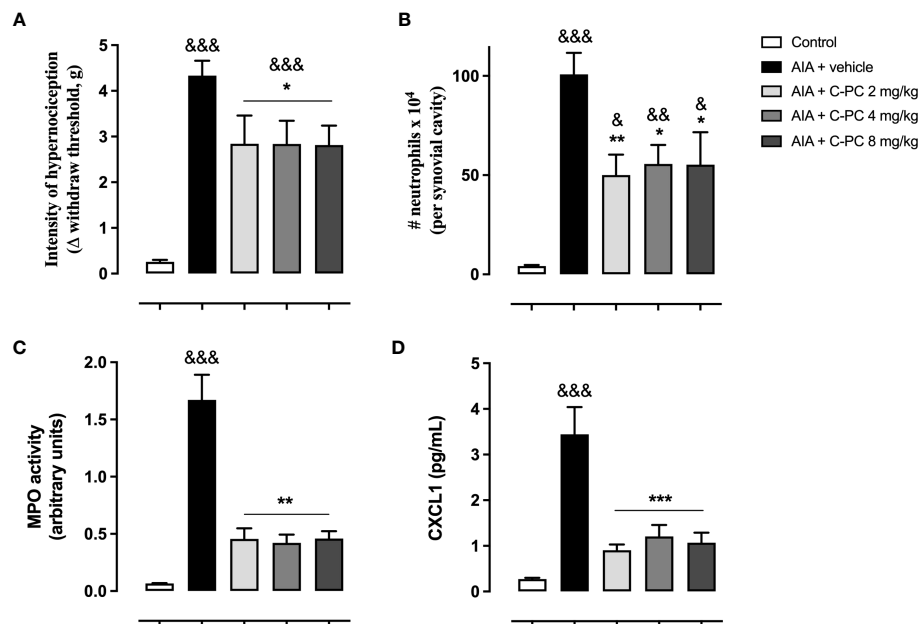

FIGURE 1

C-Phycocyanin reduces the hypernociception (A), neutrophil infiltration (B), MPO activity (C), and CXCL1 levels (D) in AIA mice. Data are mean  $\pm$  SEM of 5–11 mice/group. \* $p$ <0.05, \*\* $p$ <0.01, \*\*\* $p$ <0.001, compared with vehicle-treated arthritic mice;  $^{\circ}$  $p$ <0.05,  $^{\circ\circ}$  $p$ <0.01,  $^{\circ\circ\circ}$  $p$ <0.001, compared with control (ANOVA + Tukey's tests).

Elimination was nearly complete 24 h after i.v. administration, as indicated by an area under the curve of 22.7 h  $\cdot$   $\mu$ g/mL. Oral and i.n. administrations demonstrated similar trends in the plasmatic C-PC levels, with the maximum concentration reached at 1 and 4 h, respectively. However, the maximum concentration was much higher in the case of i.n. administration, reaching the value of 12.0  $\mu$ g/mL, compared to the value of 6.8  $\mu$ g/mL achieved by the oral route at these time points. Indeed, when comparing the areas under the curve, a clear increase was evident for the i.n. route with 226 h  $\cdot$   $\mu$ g/mL, whereas for the oral route, it was 77 h  $\cdot$   $\mu$ g/mL (Supplementary Figure S1).

### 3.3 Dose-response effects of PCB against hypernociception and neutrophil infiltration in mice with AIA

The prophylactic PCB treatment was effective in ameliorating the arthritis-induced hypernociception in mice following one day of antigen challenge, with respect to the AIA animals receiving the vehicle (Figure 3A). The quantification of the leucocyte infiltration into the inflamed knee revealed that the pretreatment with PCB significantly lessened the neutrophil agglomeration in the synovial space, showing a response associated with the used doses, when

Data are mean  $\pm$  SEM of 5–11 mice/group. \*\*\* $p < 0.001$ , compared with vehicle-treated arthritic mice; <sup>a</sup> $p < 0.01$ , <sup>b</sup> $p < 0.001$ , compared with control (ANOVA + Tukey's tests).

statistically contrasting with the vehicle AIA mice (Figure 3B). Similarly, PCB produced a decline in the MPO activity in relation to the AIA mice that were injected with vehicle solution. (Figure 3C). Importantly, this effect of PCB followed a dose-response behavior.

### 3.4 PCB effects on cytokine production and T cell markers expression in mice with AIA

On the other hand, a significant downregulation of PCB at 1 mg/kg on the transcriptional factors T-bet (Th1), ROR $\gamma$  (Th17),

and the proinflammatory cytokine IFN $\gamma$  was observed compared with the AIA + vehicle group, as determined by qPCR analysis of popliteal lymph nodes (Figure 4A). Likewise, PCB treatment dose-dependently restricted the expression of cytokines mediating a proinflammatory Th1 phenotype in periarticular tissue homogenate as assessed by CBA: IFN- $\gamma$  with a significant difference and a clear trend towards a reduction for TNF- $\alpha$  when the AIA + PCB 1 mg/kg was compared with the AIA + vehicle (Figure 4B). Furthermore, a significant drop was also achieved with the treatment of 1 mg/kg PCB, the uppermost dose used, for the cytokine IL-17A (Figure 4B). Interestingly, treatment with both PCB amounts tested (0.1 and 1 mg/kg) produced a significant reduction of the cytokine IL-4, characteristic

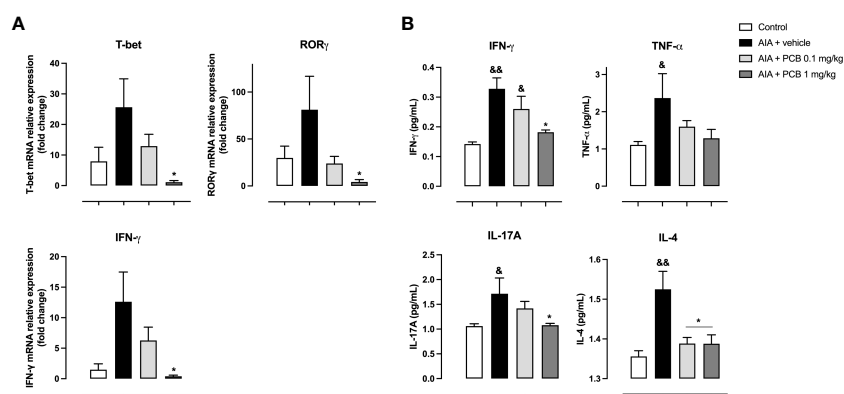

FIGURE 4

Data are mean  $\pm$  SEM of 5–6 mice/group. \* $p < 0.05$ , compared with vehicle-treated arthritic mice; <sup>a</sup> $p < 0.05$ , <sup>b</sup> $p < 0.01$ , compared with control. ANOVA + Tukey tests for IFN- $\gamma$  (mRNA and protein), T-bet, ROR $\gamma$ , and IL-4; Kruskal-Wallis + Dunn tests for TNF- $\alpha$  and IL-17A.

of a Th2 response, in AIA mice compared with diseased animals receiving the vehicle (Figure 4B).

### 3.5 PCB reduces the tissue damage in the lesioned joint of mice with AIA

Based on this encouraging evidence, we then decided to perform a histological assessment of the affected knees to confirm the protective activity of PCB on the tissue structure. The healthy control is shown in panel 5A (Figure 5A). On the contrary, those animals affected by the disease and receiving the vehicle treatment showed a rise of the arthritis index, with a distinctive synovial accumulation of polymorphonuclear cells (Figure 5B). This feature was counteracted by 1 mg/kg PCB, which dramatically reduced the leucocyte exudate in the joint space (Figure 5C). Accordingly, the arthritis index showed a significant reduction in diseased animals treated with PCB at 1 mg/kg compared with AIA + vehicle group (Figure 5D).

### 3.6 PCB regulates the proteome profile in glutamate-exposed SH-SY5Y neuronal cells

To identify the array of proteins under the regulation of PCB, we conducted quantitative proteomic analysis on SH-SY5Y

neuronal cells. These cells were exposed to the excitatory neurotransmitter glutamate and subsequently treated with or without PCB over a 24-hour period. Out of a total of 4,511 identified proteins, 19 proteins displayed differential modulation in cells treated with PCB (Table 1, Figure 6, and Supplementary Table S3). An additional comparative study was performed to quantify the proteins modulated by either the PCB treatment or the glutamate injury independently by using non-treated SH-SY5Y cells as the control condition (Supplementary Table S4 and Supplementary Figure S2).

For a better understanding of putative cellular processes affected by PCB, the 19 differentially modulated proteins were classified using the information from disease databases and text mining tools (Supplementary Table S4). As shown in Figure 7, besides proteins related to neurodegenerative diseases, PCB treatment downregulates proteins involved in arthritis and pain. Furthermore, proteins that play a role in glutamatergic transmission and inflammation were also modulated in response to PCB treatment.

## 4 Discussion

The first-ever published observations regarding the beneficial actions of *Spirulina* extracts against arthritis were published in 2002

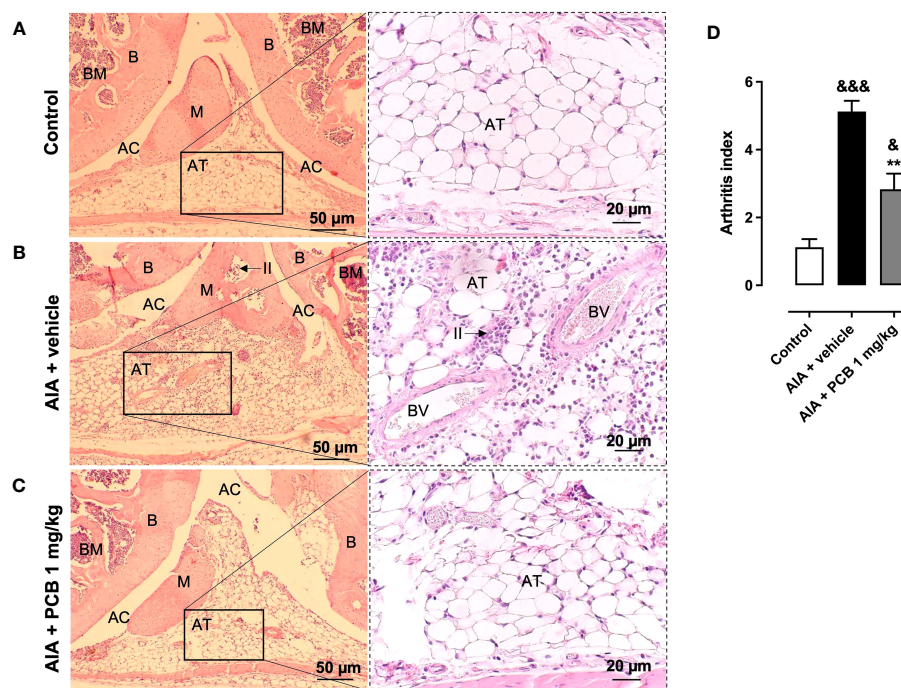

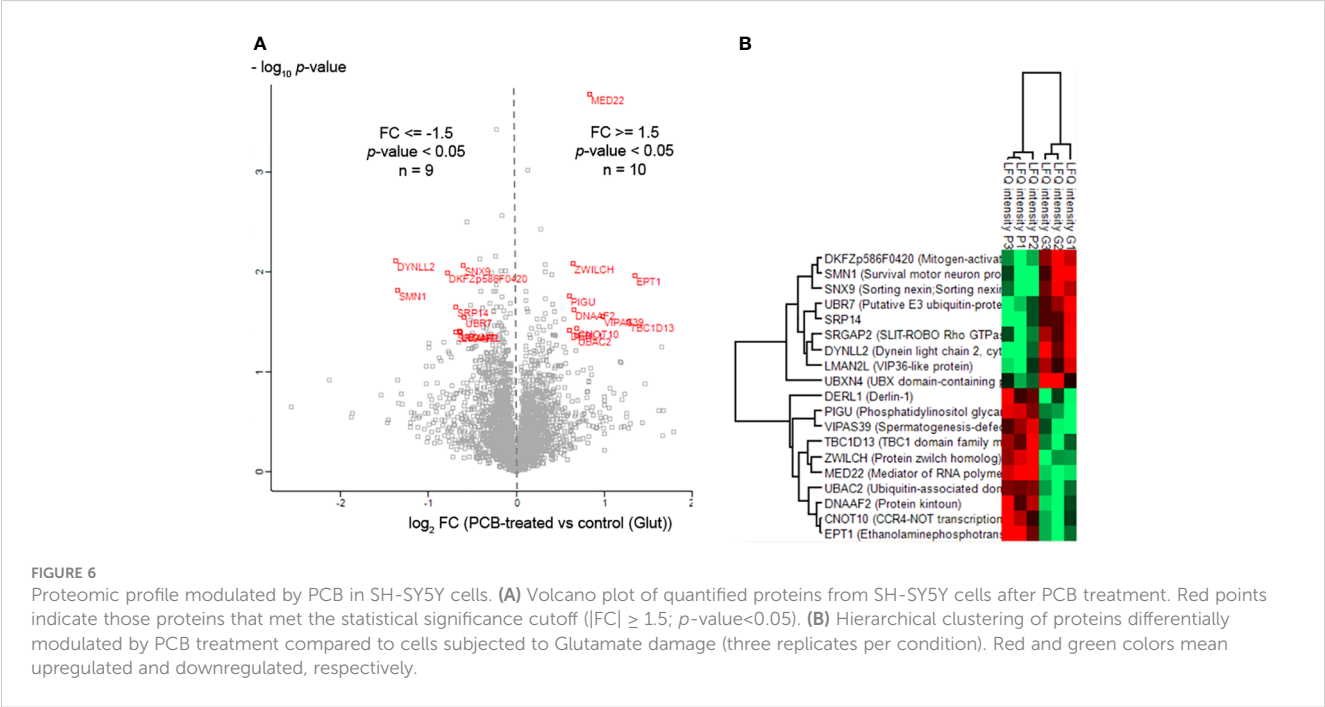

FIGURE 5

Histological assessment of PCB on the knee joint in AIA mice. Photographs are representative of (A) Control, (B) AIA + vehicle, and (C) AIA + 1 mg/kg PCB. (D) Quantitative evaluation of PCB effects on the arthritic index. The right panels are magnified 2.5 times the respective region in the left panel for (A-C). Histopathological confirmation of the AIA-caused joint inflammation is evident on panels (B), such as the occurrence of inflammatory infiltrate (II), indicated by arrows, in the adipose tissue (AT) and inside the meniscus (M). It is also observed in panels (B) an increase in blood vessels (BV) with their red blood cells inside the AT and the modification of tissue morphology when examining in relation to the other panels (A, C). AT, Adipose Tissue; AC, Articular Cavity; B, Bone; BM, Bone Marrow; M, meniscus; and II, Inflammatory Infiltrate. Data are mean  $\pm$  SEM of 4-6 mice/group. \*\* $p < 0.01$ , compared with vehicle-treated arthritic mice; \* $p < 0.05$ , \*\*\* $p < 0.001$ , compared with control (ANOVA + Tukey's tests).

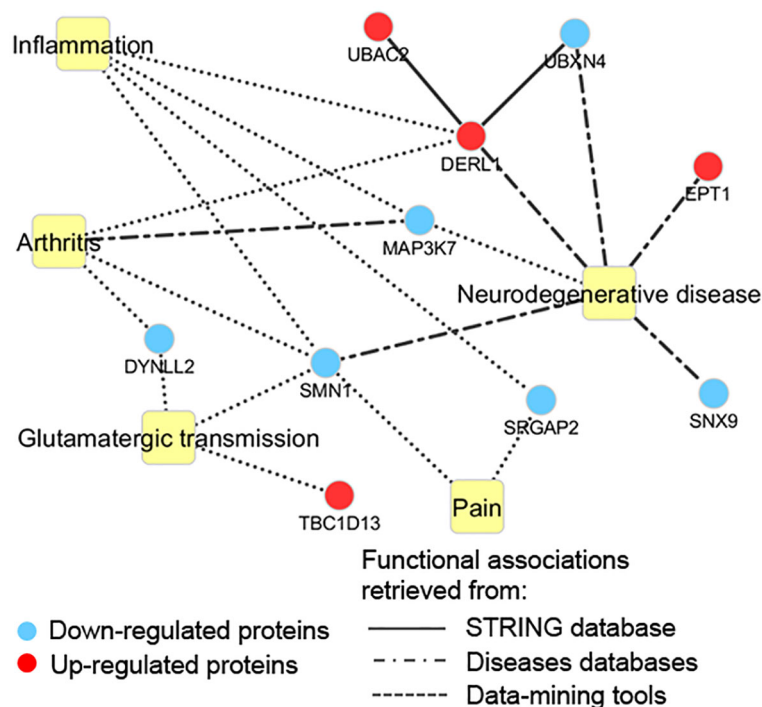

FIGURE 7

Functional terms associated with the proteomic profile modulated by PCB. Edges types are represented according to the data source.

by a Cuban group in a model of this disease in mice induced by zymosan (62). This group attributed the observed effect to C-PC, which constitutes around 15% of *Spirulina* dry biomass (63). Our group has studied the actions of C-PC in animal models of multiple sclerosis, such as the Experimental Autoimmune Encephalomyelitis, in which we have reported positive outcomes of this biliprotein, in a manner dependent on the dose, in the range of 2, 4, and 8 mg/kg, when administered intraperitoneally (64). Using the same experimental setting, we tested three PCB amounts (0.1, 0.5, and 1 mg/kg), and a dose-response positive activity was also obtained (65). Thus, previous observations have confirmed that PCB is the main responsible agent for the biological activities of C-PC (66), as demonstrated in different experimental scenarios such as ischemic stroke (66) and acute kidney damage (67). Following this reasoning, we first intended to evaluate if the administration of C-PC could alleviate AIA in mice. Then, we questioned whether the application of PCB may counteract the AIA-induced injury by assessing different outcomes: functional (hypernociception), immunological (neutrophils and cytokines), biochemical (MPO activity), gene expression, and histopathological. The doses of PCB used in the present study were calculated in function of the C-PC composition. As mentioned above, this biliprotein contains three PCBs attached. Although the lower PCB dose evaluated (0.1 mg/kg) is equivalent to 2 mg/kg C-PC, we highlight the fact that the higher PCB dose used in this study (1 mg/kg) is equivalent to a 2.5-fold increase of 8 mg/kg C-PC (higher evaluated dose). Since a dose-response effect was not observed with these C-PC administered amounts, we increased the PCB dose to better detect the dose dependence of its pharmacological activity against AIA.

Our observations confirmed a significant C-PC-promoted reduction of pain and joint inflammation in AIA mice. Reports of anti-arthritis properties of this compound have been demonstrated with other arthritis models. These anti-arthritis properties of the compound are attributed to its selective inhibitory property on COX-2, its efficacy in eliminating free radicals, and inhibiting lipid peroxidation (68). C-PC can prevent osteoarthritis by attenuating the oxidative stress in chondrocytes induced by  $H_2O_2$  (69). Interestingly, a similar property has also been reported by our group for the PCB treatment inhibiting the  $H_2O_2$  damage in PC12 cells (70). C-PC has been shown to act on fundamental processes such as inflammation, chondral degeneration, and oxidative stress in canine *in vitro* osteoarthritis (71). Our study evidenced that C-PC significantly reduced the alpha chemokine CXCL1 in the AIA model. CXCL1 has been shown to have neutrophil chemoattractant activity in inflamed tissue in arthritis following activation of the CXCR2 receptor (72). Notably, antagonism of this CXCR2 receptor has resulted in an inhibition of neutrophil migration strongly associated with reduced injury in rats experiencing AIA (73). In patients with RA, the rise of CXCL1 expression correlated with the accumulation of neutrophils (74). This evidence suggests that the inhibition of the CXCL1 expression could mediate the protective actions of C-PC in AIA mice, via the decreased infiltration of neutrophils to the injured joint tissue.

The biodistribution of C-PC following i.v., i.p., and i.n. administration exhibited notably low levels across all examined tissues. However, in the case of oral administration, significant levels of the radioactive-labeled product were detected along the entire digestive tract. Notwithstanding, at least 50% of the product

appears to be absorbed and redirected by blood flow. This result is consistent with the way that the molecule goes to its target sites. An important point to consider is that radiolabeling occurs mainly at the residues His and Tyr of the protein by nucleophilic aromatic substitution (75). This reaction is not possible in PCB due to the absence of aromatic carbon-hydrogens as part of its structure. However, PCB is released from C-PC after proteolysis (76), and it could reach the bloodstream and be transported throughout the body in solution given its stability (77) or attached to serum albumin (78), in a chemical association that appears to be mutually protective against oxidative damage, keeping the antioxidant activity and the chemical structure of this tetrapyrrole.

Furthermore, the pharmacokinetic results are in line with the significant chemical and biological disparities between the digestive tract and the nasal route. As mentioned above, oral administration of C-PC is followed by the degradation of its polypeptide moieties, resulting in the liberation of PCB. This tetrapyrrole has been identified as the active molecule accountable for the observed pharmacological effects of C-PC (67). Consequently, it becomes plausible that the radioactivity detected in plasma after oral administration comprises short peptides covalently linked to PCB. Supporting this observation are the clearance values of 5.6 mL/h following the i.n. administration and 21.0 mL/h for the oral route. Such elevated clearance values are indicative of compounds with lower molecular weights. Additionally, the potential shielding effect of the polypeptide moieties on the prosthetic group could explain the prolonged retention in plasma of the initially administered protein through the i.n. route. Taken together, the biodistribution and pharmacokinetics behavior of C-PC across different routes of administration contribute to understanding how this compound, and its derivative PCB, interacts with different tissues and how the body processes it. This essential data can also guide future dosing strategies and the design of drug delivery systems to ensure that the drug reaches its intended target. In this line of thinking, we can envision the application of nanotechnology for improving the controlled delivery of PCB toward targeted tissues. The nanotechnology-enabled PCB delivery systems, such as liposomes or nanoparticles, can enhance the bioavailability and stability of this tetrapyrrole, leading to prolonged therapeutic effects in RA (79).

RA is a pathology associated with impairment in the redox and immunological balances, and neutrophils are key mediators in both processes (80). In this study, we observed that both molecules, C-PC and PCB, limit the severity of AIA due to, at least in part, inhibiting the migration of neutrophils to the affected synovial cavity. In this context, neutrophils may directly damage knee structures, such as the bone and the cartilage, through the production of proteases and reactive oxygen species (ROS). Additionally, neutrophils could also dictate some inflammation processes either by antigen presentation or by the release of soluble factors, including prostaglandins, chemokines, cytokines, and leukotrienes (81). Dysregulated activation of neutrophils and their derived ROS production are implicated in tissue damage and destruction in RA (82).

The distinctive harm caused by RA to the cartilage and bone of the knee is associated with synovial exudate of immune cells and a disproportionate increase of proinflammatory factors such as TNF- $\alpha$ , IFN- $\gamma$ , and IL-17A (83, 84). Our results demonstrated that a

PCB-mediated effect was detected by qPCR on the T-bet (Th1 phenotype) and ROR $\gamma$  (Th17 phenotype) transcriptional factors expression, as well as IFN- $\gamma$  cytokine in popliteal lymph nodes. At the protein level, PCB also reduced the concentration of the proinflammatory cytokines TNF- $\alpha$ , IFN- $\gamma$ , and IL-17A in periarticular tissue.

IFN- $\gamma$  and IL-17A are versatile cytokines widely involved in inflammatory diseases, mediating both immune activation and tolerance. In our study, a protective role of PCB in AIA mice was demonstrated, which could be associated with a reduction of both cytokines, critical components of the inflammatory damage induced by AIA (85).

These cytokines were measured in periarticular tissue homogenate, suggesting that a diverse set of immune cells, other than neutrophils, may also be locally involved in the AIA-induced acute synovial inflammation. Our observations point to an involvement of IL-17A-producing T cells, known as Th17 cells, in this pathological scenario. Accumulated evidence has shown the pivotal role of Th17 cells in diverse pathological conditions encompassing the immune system. These specialized cells have demonstrated their involvement in various autoimmune disease models (86). Notably, they have been linked to the progression of experimental autoimmune encephalomyelitis (EAE) (87), and collagen-induced arthritis (88). Furthermore, Th17 cells facilitate the recruitment of neutrophils in airways and in collagen-induced arthritis (89, 90), contributing to the perpetuation of the inflammatory milieu in arthritis. Moreover, Th17 plays a significant role in osteoclastogenesis, as it efficiently upregulates the expression of RANKL on osteoclast precursors (91, 92). This molecular modulation sets the stage for the induction of osteoclast formation and bone resorption, contributing to the pathogenesis of arthritis.

Th17 cells *in vitro* differentiation from naïve CD4<sup>+</sup> T subset is dependent on the cytokines TGF- $\beta$ , IL-6, and IL-23 via induction of the transcription factor ROR $\gamma$  (93). We have previously demonstrated that PCB inhibits the proliferation of antigen-activated encephalitogenic CD4<sup>+</sup> T cells in rats and in 2D2 mice (56). This supports the results of the current study, in which we observed a downregulation effect of PCB on the Th17 master transcriptional factor ROR $\gamma$  in popliteal lymph nodes. Thus, PCB may inhibit the proliferation of naïve activated CD4<sup>+</sup> T precursor cells leading to a reduced number of differentiated Th17 in the periphery, which consequently will provoke their limited migration into the affected joint. In addition, it has been demonstrated an inductor activity of C-PC/PCB on the differentiation of regulatory T cells (Treg) (94). Treg inhibits the activity and differentiation of Th17 cells and favors the amelioration of experimental inflammatory arthritis (95, 96).

On the other hand, over the past few years, intriguing findings have advanced the insight of neutrophils from mere short-lived first responders of the innate immune system, towards active participants in adaptive immunity, particularly in chronic inflammatory disorders such as RA (97). In this newfound role, neutrophils serve as accomplices, not just bystanders of cells from the adaptive immune response such as T cells and DCs. The decisive role of neutrophils in guiding the trajectory of T-cell development,

orchestrated by DCs, towards Th17 cells, relies on potent factors present within their granule content, which include neutrophil elastase (98) and lactoferrin (99). Our data suggest that by inhibiting the neutrophil accumulation and activity in the inflamed joint, C-PC/PCB may indirectly curtail the Th17 cell development driven by the interaction between neutrophils and DCs.

Furthermore, a direct effect of PCB on the function of human monocyte-derived DCs has been reported. Pre-treatment of human DCs *in vitro* with PCB before stimulation with lipopolysaccharide led to a significant reduction in the supernatant levels of cytokines IL-12p70 and IL-23, accompanied by a reduced expression of costimulatory molecules CD83 and CD40 (100). When these lipopolysaccharide-stimulated DCs were treated with PCB and cocultured with allogeneic CD4<sup>+</sup> T cells, Basdeo et al. (2016) observed a significant decrease of more than 50% in the production of IFN- $\gamma$ , which is characteristic of Th1 cell polarization, compared to the untreated control (89). This evidence suggests that PCB halts the maturation of DCs, leading to a drop in their production of polarizing cytokines, ultimately downregulating the adaptive inflammatory response. Thus, PCB may also prevent the development of synovial inflammation by directly inhibiting the professional antigen-presenting functions of DCs recruited into the affected synovium (101), along with the consequent reactivation of CD4<sup>+</sup> T cells (102).

It is noteworthy to mention our results indicating the decreasing effect of both PCB doses on the cytokine IL-4, a cytokine that is known for its anti-inflammatory properties, is produced by Th2 and Tc2 cells, but the action of IL-4 on other types of T cells, such as CD8<sup>+</sup>, Tregs, and Th9 T cells, has been also described. Furthermore, a versatile effect of IL-4 is known on B cells (103). The regulatory function of IL-4 on inflammation depending on the context of RA is known (104). Though this cytokine is frequently reported to mediate anti-inflammatory events, its proinflammatory actions have also been described as probably controlled by Th cells. This biphasic IL-4 activity could, therefore, restrain immunity when cellular components are involved, while fostering the humoral component of the immune response, in a context-specific manner (105). Interestingly, the IFN- $\gamma$ /IL-4 ratio (106) could better express the Th1/Th2 balance that explains the effect of PCB on AIA.

In addition to the biological actions of PCB here observed, this organic molecule presents other advantages in relation to C-PC when considering its pharmaceutical development (1): it can be obtained either by chemical synthesis (107, 108) or by genetic engineering of its synthesizing enzymes in *E. coli* (109) (2), chemical products such as PCB avoid exhaustive bioequivalence studies because a well physicochemical characterization is enough to introduce it as therapeutic agents (3), PCB could be attached to protein drugs in combined therapies (4), PCB is more stable than C-PC under proteases attack, and (5) due to the small size of PCB (relative to C-PC), it may overpass many body compartments prohibited to large macromolecules, such as the blood-brain barrier. Because of all of the above, we decided to carry out our experiment with this tetrapyrrole to evaluate its effects as a possible treatment for RA.

In this study, we performed a proteomic profiling of glutamate-exposed SH-SY5Y neuronal cells as an *in vitro* model to evaluate the effects of PCB on one of the main excitatory signaling in nociception and neurodegeneration. The modulation of proteins related to biological processes such as inflammation, glutamatergic transmission, and pain were evaluated. Those associated with pathologies such as arthritis and neurodegenerative diseases were also considered. After the analysis, we found that only 19 proteins were differentially modulated in SH-SY5Y cells treated with both PCB and glutamate. It is worth noting that the concentration of glutamate used (60  $\mu$ M) was relatively high (110, 111), which may be a limitation of the present study. However, the evidence obtained may have opened new insights regarding the PCB effects on neuronal excitatory states.

Through a protein network analysis, we identified that the proteins influenced by PCB treatment were interconnected with diseases and implicated in biological processes. One notable finding was the PCB downregulation of Mitogen-activated protein kinase 7 (MAP3K7) or a ubiquitin-dependent kinase of MKK and IKK (TAK1) (112). MAP3K7 is a serine/threonine kinase that integrates many biochemical signals. This protein is involved in numerous cellular processes such as proliferation, differentiation, transcriptional regulation, and development. As a part of the mechanism of this kinase, after activation by extracellular stimuli, it translocates to the nucleus and regulates gene expression by phosphorylating various transcription factors (113, 114). MAP3K7 has also been strongly implicated in many of the processes underlying the pathology of rheumatoid arthritis (115, 116) and neurodegenerative diseases (117) in which inflammation (118, 119) is implicated. The current findings suggest that MAP3K7 downregulation may also contribute to the PCB effects on the reduction of neuroinflammation-induced microglial dysfunction as was identified in our previous study. Furthermore, MAP3K7 plays a crucial role in pain signaling from various causes, including inflammation. Notably, the utilization of the MAP3K7 inhibitor takinib demonstrated its capacity to mitigate inflammatory, neuropathic, and primary pain, in animal models established through intraplantar administration of complete Freund's adjuvant, chronic constriction injury, and systemic introduction of catechol-O-methyltransferase, respectively (120). MAP3K7 inhibition was also able to diminish the expression of pain-associated mediators in synovial cells isolated from arthritis patients, suggesting its important role in managing peripheral sensitization in arthritis nociception (121). Therefore, by downregulating MAP3K7 expression, PCB may act on the amelioration of arthritis pain.

Neutrophils in the synovial fluid of patients with arthritis exhibit a reduced ability to suppress activated T cells, possibly related to changes in proteins involved in cell-cell contact and inflammation (122). Among the proteins involved in the interaction between neutrophils and T cells is Dynein light chain 2 (DYNLL2) (123), which regulates the dynein 1 function and subsequently the cargo and movement of vesicles and organelles through microtubules (124). This protein has also been documented to play a central role in the interaction of the NMDA receptor-associated scaffold complex and the enhancement of the synaptic

NMDA receptor activity (125). In our study, we identified a downregulation of the DYNLL2 protein in SH-SY5Y cells treated with PCB. One possible explanation could be associated with key elements in the mechanisms that underlie the protective effects of PCB, such as the reduction of oxidative stress through the inhibition of NADPH oxidase (42) and the amelioration of inflammation.

Another protein that displayed downregulation was the Survival Motor Neuron Protein 1 (SMN1), a constituent of a complex catalyzing the assembly of small nuclear ribonucleoproteins (snRNPs). The expression of this protein was associated with levels of inflammatory cytokines (IL-1 $\beta$  and TNF- $\alpha$ ) in osteoarthritis (126). Thus, the limited expression of SMN1 induced by PCB may contribute to keeping the levels of these proinflammatory cytokines during arthritis under control, as a previously observed effect of PCB on these cytokines in a model of experimental autoimmune encephalomyelitis (65). On the other hand, PCB also induced a downmodulation of SLIT-ROBO Rho GTPase-activating protein 2 (SRGAP2) in SH-SY5Y cells treated with glutamate. This protein participates in neuronal morphogenesis and is also linked with neuronal migration during cerebral cortex development (127, 128). In this context, it has been reported that the elimination of endogenous expression of SRGAP2 promotes neurite growth in differentiated cells (129) and contributes to the restriction of osteoclastogenesis during arthritis-related inflammation (130).

Another modulated process was identified as mediated by Derlin-1 (DERL1), a protein that serves as a functional component of endoplasmic reticulum-associated degradation of misfolded proteins (131). Its disruption hampers neurite outgrowth and nervous system development, ultimately leading to brain atrophy (132). In our study, we observed an upregulation of the DERL1 in glutamate-exposed SH-SY5Y cells treated with PCB, which may impact functions related to the endoplasmic reticulum. One study reported that DERL1 colocalized with neurofibrillary tangles in the brain of patients with Alzheimer's disease and could play an important role in endoplasmic reticulum-associated neurodegeneration (133). Another protein that has been shown to interact with DERL1 is the mutated superoxide dismutase 1 (SOD1), which accumulates and misfolds in motor neurons in amyotrophic lateral sclerosis (134), another neurodegenerative disease, and the interaction with DERL1 is involved in the disease pathophysiology (135). Another DERL1 interacting protein is the NADPH oxidase subunit p22phox, and a previous report has shown that this interaction regulates the partner degradation of p22phox, with potential implications in the reactive oxygen species-producing capacity of this enzyme (136). This accumulated evidence suggests that PCB could potentiate the adequate functioning of endoplasmic reticulum quality control by upregulating DERL1, and thus preventing the associated cellular dysfunction (132). In this sense, it has been suggested that inhibitors of endoplasmic reticulum stress could mitigate chondrocyte damage and reduce arthritis degeneration (137).

Another interesting result of our study was the upregulation of the ethanolamine phosphotransferase 1 (EPT1) protein by PCB in SH-SY5Y cells. This enzyme transfers phosphoethanolamine from cytidine diphosphate-ethanolamine to lipid acceptors to form ethanolamine glycerophospholipids via the 'Kennedy' pathway (138). This kinase is part of the enzymes required to synthesize

phosphatidylethanolamine within the myelin membrane (139). Studies in a patient with spastic paraplegia revealed hypomyelination and brain atrophy demonstrating its role in the myelination process and in maintaining normal phospholipid homeostasis (140). These studies are consistent with the reported effect of PCB on myelin in an animal model of experimental autoimmune encephalomyelitis (141).

## 5 Conclusion and future perspectives

In summary, the data presented in this study demonstrate that the preemptive administration of C-PC and PCB effectively mitigates mBSA-induced arthritic injuries in mice. This was achieved by limiting hypernociception and reducing neutrophil infiltration and MPO activity, all of which are closely linked to the inflammatory injury occurring in the knee during RA. Moreover, PCB exhibits the ability to modulate the local concentration of proinflammatory cytokines and the inflammatory infiltrate within the affected joint, thereby preserving the structural integrity of the tissue.

The evidence presented here regarding the biodistribution of C-PC opens an intriguing perspective when considering the future administration of its derivative PCB for RA. As follow-up research, exploring the oral route of PCB administration could potentially offer advantages such as improved patient compliance, reduced invasiveness, and enhanced systemic delivery.

The significance of glutamatergic signaling in joint-related pain in RA is well-known. In the context of this study, the integration of bioinformatics tools facilitated the *in vitro* assessment of PCB's impact on the neuronal proteome when subjected to glutamate excitation. This approach led to the identification of proteins associated with pivotal biological processes including pain, inflammation, and glutamatergic transmission, which hold substantial relevance for pathologies such as RA.

The findings from this investigation point toward a potential application of PCB as an innovative therapeutic approach for RA. Furthermore, the study provides insights into the potential mechanisms of action and therapeutic targets associated with the effects of PCB. Ultimately, these results offer promising avenues for further exploration and development of this novel treatment for RA and related conditions involving inflammatory pain.

## Data availability statement

The original contributions presented in the study are included in the article/[Supplementary Material](#). Further inquiries can be directed to the corresponding author.

## Ethics statement

Ethical approval was not required for the studies on humans in accordance with the local legislation and institutional requirements because only commercially available established cell lines were used.

The animal study was approved by Federal University of Minas Gerais (UFMG) ethics committee (CEUA UFMG:165/2009). The study was conducted in accordance with the local legislation and institutional requirements.

Cytokines, demyelination and neuroaxonal degeneration in the central nervous system are pivotal elements implicated in the pathogenesis of multiple sclerosis (MS) and its nonclinical model of experimental autoimmune encephalomyelitis (EAE). Phycocyanobilin (PCB), a chromophore of the biliprotein C-Phycocyanin (C-PC) from *Spirulina platensis*, has antioxidant, immunoregulatory and anti-inflammatory effects in this disease, and it could complement the effect of other Disease Modifying Treatments (DMT), such as Interferon- $\beta$  (IFN- $\beta$ ). Here, our main goal was to evaluate the potential PCB benefits and its mechanisms of action to counteract the chronic EAE in mice. MOG<sub>35-55</sub>-induced EAE was implemented in C57BL/6 female mice. Clinical signs, pro-inflammatory cytokines levels by ELISA, qPCR in the brain and immunohistochemistry using precursor/mature oligodendrocytes cells antibodies in the spinal cord, were assessed. PCB enhanced the neurological condition, and waned the brain

concentrations of IL-17A and IL-6, pro-inflammatory cytokines, in a dose-dependent manner. A down- or up-regulating activity of PCB at 1 mg/kg was identified in the brain on three (*LINGO1*, *NOTCH1*, and *TNF- $\alpha$* ), and five genes (*MAL*, *CXCL12*, *MOG*, *OLIG1*, and *NKX2-2*), respectively. Interestingly, a reduction of demyelination, active microglia/macrophages density, and axonal damage was detected along with an increase in oligodendrocyte precursor cells and mature oligodendrocytes, when assessed the spinal cords of EAE mice that took up PCB. The studies *in vitro* in rodent encephalitogenic T cells and *in vivo* in the EAE mouse model with the PCB/IFN- $\beta$  combination, showed an enhanced positive effect of this combined therapy. Overall, these results demonstrate the anti-inflammatory activity and the protective properties of PCB on the myelin and support its use with IFN- $\beta$  as an improved DMT combination for MS.

#### KEYWORDS

interferon- $\beta$ , proinflammatory cytokines, remyelination, antioxidants, experimental autoimmune encephalomyelitis, multiple sclerosis, phycocyanobilin

## Introduction

The discovery of neuroprotective molecules that can promote remyelination in animal models has currently generated expectations for the development of new drugs for multiple sclerosis (MS). This is a central nervous system (CNS) disease that comprises chronic autoimmune-related demyelination and neurodegeneration producing sensorimotor dysfunction with high prevalence in young adults (1). MS has been classified according to its clinical presentation in: relapsing-remitting (RRMS), secondary progressive (SPMS), primary progressive (PPMS), and progressive relapsing MS (PR). Eighty percent of the patients with MS express the RRMS form which in turn, after 10–20 years, progresses to the SPMS form (2). Few disease-modifying therapies (DMT) have been found for the treatment of the main clinical forms (RRMS and SPMP) and even fewer for PPMS (3). MS pathogenesis has been associated with two processes, i.e. one related to the inflammatory response induced by a dysfunction of the immune system and the other related to the neurodegenerative events. DMTs that have received authorization for clinical use are directed against targets of the immune system, having little or no direct impact on neuroglial injury processes (4). Therefore, the development of drugs targeting myelin protection and/or remyelination or the use of combined therapies are relevant strategies in the therapeutic arsenal of this disease.

In this context, Phycocyanobilin (PCB), a linear tetrapyrrolic chromophore of C-Phycocyanin (C-PC) from the cyanobacterium *Spirulina platensis* could be a therapeutic candidate for MS. Our group has previously shown the beneficial effects of C-PC and PCB in nonclinical models of

neurological diseases, such as the experimental autoimmune encephalomyelitis (EAE) model of MS (5–7) as well as rodent models of cerebral ischemia (8–10). Their effects were mediated by a diverse antioxidant, immunomodulatory, anti-inflammatory and myelin-protective/remyelinating capabilities (11).

In MS, the disruption of the blood-brain barrier (BBB) enables the cerebral infiltration of autoreactive T cells, increasing the levels of proinflammatory cytokines. As consequence, the molecular and cellular cascade initiated produces the CNS immune self-attack, which is most prominent at the first phases of MS in which the activated microglia and infiltrating macrophages destroy oligodendrocytes (OD) and promote demyelination (12). Indeed, the chief pathological feature of MS is the axonal demyelination and damage, which interrupts or decelerates the propagation of the action potential through the axons (13). The reverse process is the remyelination in which oligodendrocyte precursor cells (OPC) create new myelin sheaths on axons of the CNS. In the remyelination process, the neuronal functional recovery is fostered by either endogenous, through boosting neuronal repair processes, or exogenous, through stimulating OPC, the cells that produce myelin in the CNS (14). The remyelination is a very effective process in normal people and even at the early stages of MS, however it fails in the chronic stage of the disease (15), showing the importance of developing myelin-targeted therapies.

Hence, the objectives of our study were to understand the molecular and cellular mechanisms induced by PCB on the EAE inflammatory response and on the myelin protection and/or remyelination, specifically its effect on the activation, migration

and differentiation of OPC. Furthermore, we investigated the potential benefit of the pharmacological combination of PCB with IFN- $\beta$  (the first-ever approved DMT for MS) as a novel therapy for MS.

## Material and methods

### Reagents

The PCB (Cat. No. SC-396921, Santa Cruz Biotechnology, Inc., Dallas, USA) was solubilized with sterile PBS pH 7.4 at a concentration of 5 mg/mL. This stock solution was stored at -20 °C until use. When needed, a stock aliquot was diluted at the working concentration, preserved in dark, and immediately applied to the experiment. Unless otherwise indicated, every other reagent was acquired from Sigma-Aldrich (St. Louis, MO, USA) with its highest grade.

### Animals

This study used female C57BL/6 mice (8–10 weeks old) provided by the Animal Care Facilities of the Federal University of Minas Gerais, Belo Horizonte, Brazil. The standard husbandry conditions included food and water ad libitum and a light/dark cycle of 12 h. All national and international regulations for the procedures involving mice were followed, and the animal ethics committee of the Federal University of Minas Gerais approved this study protocol (No. CEUA - 255/2015).

### Establishment of EAE model

EAE was induced as previously described (16). Mice were subcutaneously (s.c.) injected with 0.1 mL emulsion, which contained 100  $\mu$ g of murine MOG<sub>35–55</sub> (CIGB, Havana, Cuba) diluted in 50  $\mu$ L saline and 50  $\mu$ L Freund's Complete Adjuvant (CFA), and supplemented with 4.0 mg/mL of *Mycobacterium tuberculosis* H37RA (Difco Laboratories, Detroit, MI, USA), followed by two intraperitoneal (i.p.) administrations (day 0 and day 2 after immunization) of 300 ng pertussis toxin diluted in 200  $\mu$ L saline. Control mice were treated with saline instead of the emulsion following a similar procedure. The neurological dysfunction was scored daily in a double-blind way using a modified scale (17). The score of 0 denoted no clinical signs, 0.5: tail tone reduction distally, 1: complete flaccid tail, 1.5: tail paralysis and walking imbalance, 2: tail paralysis and hind limb frailty (unilateral), 2.5: tail paralysis and hind limb frailty (bilateral), 3: hind limb paralysis (bilateral), 3.5: hind limb paralysis (bilateral) of and fore limbs frailty, 4: paralysis of hind and fore limbs (bilateral), and 5 indicated death. The

area under the curve (AUC), representing clinical severity, was analyzed.

### Treatment schedules

Five experimental groups of mice were randomly distributed (n=6–7 per group). These included non-immunized animals (naïve), and EAE disease mice receiving the following i.p. treatments daily, once a day: sterile PBS (vehicle) or PCB at 0.1, 0.5, or 1 mg/kg, from day 0 until day 26 post-immunization. In follow-up experiments, animals (n = 9–10 each) received the vehicle or 1 mg/kg PCB daily by the oral route (intragastric gavage) once a day, or mouse 5000 U IFN- $\beta$  (Cat. No. K00020, PBL, USA) subcutaneously (s.c.) every second day or the combination of both compounds. In these latest experiments, two schedules were assessed:

Prophylactic: PCB and IFN- $\beta$  treatments were administered from day 0 of the induction to the end of the experiment (24 days)

Late therapeutic: PCB and IFN- $\beta$  treatments were administered starting at 14 days post-induction until the end of the experiment (24 days)

### Histological and immunohistochemistry analysis of the mice spinal cords

Humane euthanasia was performed at the end of the study (day 26), followed by the perfusion with ice-cold PBS, and the fixation of the dissected spinal cords by immersion in 4% paraformaldehyde. The examined region of the spinal cord was the lumbar part, which is frequently and rapidly affected in EAE (18), and contains motor neurons that innervate the hindlimb muscles (19). The tissue was embedded in paraffin, and between 9–10 serial sections of 1–3  $\mu$ m thickness were cut at 100  $\mu$ m intervals in the rostral to caudal direction, from paraffin blocks using a sliding microtome and used for staining. Demyelination was evaluated by staining with Luxol fast blue combined with periodic acid-Schiff (LFB-PAS). The inflammatory markers were assessed by immunohistochemistry (IHC) with the following primary antibodies for T cells and macrophages/activated microglia, respectively: anti-CD3 (1:150, Cat. No. C1597C01, DCS, Hamburg, Germany) and anti-Mac-3 (CD107b) (1:200, Cat. No. 553322, BD Bioscience, Franklin Lakes NJ, USA). Additionally, an anti-amyloid precursor protein (APP) (1:2000, Cat. No. MAB348, Chemicon, Temecula, CA, USA) was used for evaluating the axonal injury. Moreover, an anti-tubulin polymerization-promoting protein (TPPP/p25) (1:500, Cat. No. 92305, Abcam, Cambridge, UK) and an anti-Olig2 (1:300, Cat. No. 18953, IBL, Hamburg, Germany) were used for detecting mature OD and OPC, respectively. A streptavidin-biotin protocol

(biotinylated secondary antibodies and streptavidin conjugated to horseradish peroxidase) was performed to reveal the antigen-primary antibody binding with 3,3'-diaminobenzidine as the chromogen.

## Morphometric analysis

The stained spinal cord sections were photographed by using a digital camera (Software Cell Sens Dimension v.1.7.1, DP71, Olympus, Germany) coupled with a light microscope (Olympus BX51, Germany). The Image J software (v. 1.46r, NIH, USA) was used for the measurement of the areas and the number of marked cells. The percentage of demyelinated area, as well as the densities of immunostained cells for each marker (CD3, Mac-3, TPPP/p25, Olig2 and APP) were determined in relation to the total area of the white matter, and expressed as % or # cells/mm<sup>2</sup>, respectively.

## Quantification of the brain levels of IL-17A, IL-6 and IL-10

After performing the animals' euthanasia once anesthetized on day 26 post-immunization, both mice's cerebral hemispheres were dissected and divided sagittally at 2.0 mm lateral from bregma. The cerebral tissue closest to the sagittal suture was mechanically homogenized (IKA Works Ultra-Turrax, USA) by mixing 100 mg of tissue in 1 mL of an ice-cold extraction solution (0.4 M NaCl, 0.05% Tween 20, 0.5% bovine serum albumin, 0.1 mM phenylmethylsulfonylfluoride, 0.1 mM benzonium chloride, 10 mM EDTA and 20 KIU aprotinin, prepared in PBS pH 7.4). After centrifugation at 15,000 ×g for 10 min at 4°C, the supernatants were stored at -70°C until use. The assessment of IL-17A, IL-6, and IL-10 levels was accomplished with the adequate ELISA Kit (R&D Systems, Minneapolis, MN, USA), following the supplier's protocols.

## Quantitative real-time PCR

The dissected cerebral tissues after concluding the study (day 26) were conserved in RNAlater (Ambion Inc., Applied Biosystems, Foster City, CA, USA), homogenized, and provided for RNA isolation by using TRIzol (Invitrogen, San Diego, CA, USA). The cDNA synthesis was performed with 1 µg of RNA (High-Capacity cDNA Archive Kit, Applied Biosystems, Foster City, CA, USA) and then used for Quantitative Real Time PCR (qPCR) in triplicate, in accordance with the Minimal Information for Publication of qPCR Experiments (MIQE) guidelines (20). The BLAST algorithm was implemented for designing the gene-specific primers (Supplementary Table 1), which were used at 300 nM (Metabion, Martinsried, Germany).

The detection system consisted in the Fast SYBR Green PCR Master Mix and the Applied Biosystems 7900HT Fast Real-Time PCR System (Applied Biosystems, Foster City, CA, USA). Bi-distilled water, used as reaction control, did not generate any signal for either the target or the housekeeping genes. The 2-ΔΔCt method (21) implemented in the REST<sup>®</sup> software (22) was used for the analysis and quantification of the mRNA levels.

## Measurement of Treg

The mice spleens were collected in HBSS under sterile conditions in a biosafety cabinet, minced with scissors, and passed through a steel mesh to homogenize the cell suspension containing red blood cells (RBCs). This was then subsequently lysed (9 parts of Milli-Q water and 1 part of sterile PBS 10X) and centrifuged (177× g, 10 min at 4°C). The resulting pellet was washed three times with ice-cold PBS 1X, and finally resuspended in RPMI-1640 medium supplemented with 10% fetal bovine serum (FBS) and 1% penicillin-streptomycin. The cell viability was assessed by the trypan blue technique and resulted above 95%. The single-cell suspensions were resuspended in the final concentration to 1 × 10<sup>7</sup> cells/mL and marked for Fc receptor block (Innovex, NB309). After Fc block, the cells were co-incubated for 20 minutes at 4°C with cy-chrome (Cy), phycoerythrin (PE) or fluorescein isothiocyanate (FITC)-labeled antibodies that detect the cell surface markers CD4 or CD25, or with an anti-isotype control (eBioscience, and BD Pharmingen, San Diego, CA, USA). Thereafter, the cells were fixed with 2% formaldehyde, permeabilized and marked with a phycoerythrin (PE)-conjugated anti-Foxp3 monoclonal antibody by using the eBioscience<sup>™</sup> Foxp3/Transcription Factor Staining Buffer Set (eBioscience, CA, USA). The appropriate controls (PE-labeled antibody and unstimulated cells) were incorporated in all assays. The signal acquisition was carried out with FACS CantoII (Becton & Dickinson, San Jose, CA, USA) above the 50 000 gated events on the lymphocytes population given the low frequency of positive events, and processed through the Diva<sup>®</sup> software (Becton & Dickinson, San Jose, CA, USA).

## Analysis of the flow cytometry results

The analysis of the patterns and frequencies of CD4<sup>+</sup> CD25<sup>high</sup> T lymphocytes was performed with the FlowJo program (Tree Star, Ashland, OR, USA). Three different fluorochromes were used for each set of analyses, for example, anti-CD25-FITC, anti-Foxp3-PE, and anti-CD4-PE-Cy5.5 for Treg cells. The lymphocytes gate was selected, encompassing the upper right region of the dot-plot in which the double-positive cells for CD25-FITC and CD4-PE-Cy5 were present, and a new dot-plot was generated for selected the cells positive for Foxp3-

PE (23). The quadrant markers were always limited based on the negative populations, the isotype controls and the fluorescence minus one control (FMO).

## Proliferation assay

The cell line ( $T_{MBP-GFP}$ ) was cultured and stimulated as previously reported (24). This line was previously established following a technique in which rat  $CD4^+$  T lymphocytes specifically reactive to myelin basic protein (MBP), were retrovirally engineered to produce green fluorescent protein (GFP) (25).  $T_{MBP-GFP}$  cells ( $4 \times 10^4$  cells/well, 96-well plates) were co-cultured with irradiated rat thymocytes (5000 rad,  $10^6$  cells/well) in complete DMEM/1% rat serum with 10  $\mu\text{g/mL}$  MBP, with either of the following experimental conditions: PCB alone at 50, 100 or 200  $\mu\text{g/mL}$ , IFN- $\beta$  alone at  $10^3$  U/mL, and the combination of  $10^3$  U/mL IFN- $\beta$  + PCB at 50, 100 or 200  $\mu\text{g/mL}$ . After 48 h of incubation, MTT (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide) at 0.5 mg/mL was incorporated to the medium, and cultured for another 4 h.  $CD4^+$  T cells from the spleen and lymphonodes of 2D2 mice were seeded at  $2 \times 10^5$  cells/well in RPMI medium with 10% fetal calf serum (FCS) and co-stimulated with 2  $\mu\text{g/mL}$  anti-CD3/anti-CD28 at 37°C, 5% CO<sub>2</sub>. Purified  $CD4^+$  T cells were incubated with  $5 \times 10^3$  U/mL IFN- $\beta$  alone, PCB alone at 10, 50 or 250  $\mu\text{g/mL}$  or together with  $5 \times 10^3$  U/mL IFN- $\beta$ . Two days later,  $CD4^+$  T cells were split 1:2 by using the same medium containing IL-2 at 10 ng/mL of final concentration, and incubated again for one day. Then, the cells were cultured with MTT at 0.5 mg/mL (by adding to the medium) for additional 4 h. After that, the medium was discarded, the formazan crystals were dissolved in 150  $\mu\text{L}$ /well of dimethyl sulfoxide (DMSO), and a microplate reader (Perkin Elmer, Victor 2) was used for measuring the absorbance at 570 nm.

## Intracellular localization of PCB

$T_{MBP-GFP}$  cells ( $5 \times 10^5$  cells/well) were seeded in 12-well plates together with irradiated rat thymocytes (5000 rad,  $1.25 \times 10^7$  cells/well) in complete DMEM/1% rat serum with 10  $\mu\text{g/mL}$  MBP and 200  $\mu\text{g/mL}$  PCB for 3 h. Immediately afterwards, the nuclear DNA of T cells was labeled with DAPI following a previously described procedure with minor changes (26). Briefly, T cells were collected in 15 mL tubes, centrifuged at 400 g, at room temperature for 3 min, washed with PBS 1X (0.5 mL) and fixed during 10 min at 4°C with 4% paraformaldehyde (0.5 mL). T cells were treated first with 0.2% Triton X-100 (0.5 mL) and later with 1  $\mu\text{g/mL}$  DAPI (0.5 mL) at room temperature for 5 and 10 min, respectively, with three washes of PBS 1X (0.5 mL) between them and again after completing the DAPI staining. By

using a cytospin device (800 rpm, 3 min), T cells were transferred to microscope slides and cover slips were mounted with Fluoromount-G. Images acquisition was performed with a confocal microscope (Leica) for DAPI ( $\lambda_{\text{ex}}=359$  nm,  $\lambda_{\text{em}}=461$  nm) and PCB ( $\lambda_{\text{ex}}=550$  nm,  $\lambda_{\text{em}}=591\text{--}641$  nm) fluorescence. The Fiji software was used for analysis (27).

## Statistical analysis

The statistical analysis was carried out with the GraphPad Prism software 6.0 (GraphPad Inc., CA, USA). Data are expressed as the mean  $\pm$  S.E.M. Kolmogorov-Smirnov normality test were applied to all data sets. One-way-ANOVA followed by Newman-Keuls tests, or Kruskal-Wallis followed by Dunn's tests for multiple comparisons between three or more groups were used when appropriate. Statistical comparison for qPCR data was done with the REST<sup>®</sup> software. P values of  $p < 0.05$  (\*),  $p < 0.01$  (\*\*), and  $p < 0.001$  (\*\*\*) were considered statistically significant.

## Results

### PCB delayed and attenuated the clinical signs progression of EAE mice

The daily motor behavior of EAE mice receiving the intraperitoneal (i.p.) administration of either the vehicle or PCB at different doses was evaluated from the day of immunization until the end of the study (Figure 1). Interestingly, on average, the EAE + vehicle group presented the onset of the disease on day  $9.8 \pm 1.14$ , with the first animal being sick on day 7 following the immunization (Figure 1A). In contrast, the treatment with PCB at 0.1, 0.5 and 1 mg/kg postponed the beginning of clinical symptoms, on average, until the days  $13.57 \pm 1.82$ ,  $15.57 \pm 1.81$  and  $15.29 \pm 1.92$  post-induction, respectively. Notably, the delay of the disease onset was statistically significant when the 0.5 and 1 mg/kg doses of PCB were compared with the vehicle-treated EAE mice ( $p < 0.05$ , Kruskal-Wallis + Dunn's multiple comparisons test, Supplementary Table 2). On the other hand, Figure 1B shows the quantification of the area under the curve of clinical progression, which represents the EAE neurological severity. EAE animals treated with the vehicle showed an area of  $43.04 \pm 10.65$  (arbitrary units), while this parameter decreased to values of  $25.46 \pm 4.46$ ,  $24.14 \pm 5.92$  and  $18.39 \pm 4.55$  for PCB at 0.1, 0.5 and 1 mg/kg, respectively. Statistically significant differences were observed between the EAE vehicle- and the EAE PCB-treated animals at the highest dose. This result indicates that the i.p. administration of PCB was able to retard the appearance of the disease's symptoms and to reduce the EAE neurological severity.

FIGURE 1

Effect of PCB in a murine model of chronic progressive EAE. (A) Daily clinical assessment of the mice. (B) Clinical severity determined by the area under the curve (in arbitrary units). MOG<sub>35–55</sub> immunized mice received a daily i.p. injection of PBS (vehicle) or PCB at 0.1, 0.5 or 1 mg/kg, from day 0 until day 26 post-immunization. A numeric scale with the ascending graveness was used to score every day the clinical signs of the mice, ranging from 0 (no disease) to 5 (death). The naïve group (non-immunized animals) remained healthful during the entire study period (score 0). Data are expressed as the mean  $\pm$  S.E.M (n=6–7 per group). The asterisk (\*) is indicative of significant differences with vehicle-treated EAE mice (\*p<0.05, ANOVA + Newman-Keuls tests).

## PCB reduces pro-inflammatory cytokines in the brain of mice with EAE

To further investigate the impact of PCB treatment on the expression of IL-17A, IL-6 (pro-inflammatory), and IL-10 (anti-inflammatory/immunoregulatory) cytokines in the brain of mice with EAE, an ELISA protocol has been used (Figures 2A–C). EAE vehicle-treated mice showed significantly higher levels of all measured cytokines compared to healthy naïve animals. Animals with EAE that received 0.5 and 1 mg/kg PCB evidenced a significant decline in the levels of IL-17A and IL-6 pro-inflammatory cytokines compared to the vehicle-treated EAE mice. These results suggest an anti-inflammatory action of PCB against the EAE progression in mice brains.

## PCB positively modulates the expression of genes related to remyelination/demyelination processes in mice brains

We evaluated the genes modulation in the brain of EAE animals treated with PCB at 0.1, 0.5 and 1 mg/kg (Figure 3). We observed an up-regulation of genes that could mediate myelin damage (*LINGO1*, *NOTCH1* and *TNF- $\alpha$* ), accompanied by the down-regulation of genes that may be involved in myelin preservation (*CXCL12*, *MAL*, *MOG*, *NKX2-2*, and *OLIG1*) in vehicle-treated EAE mice compared with naïve animals. In this ratio, a statistically significant difference was obtained for *TNF- $\alpha$*  (up), *CXCL12* (down) and *MOG* (down). The PCB-treated EAE animals at all doses, were compared to the EAE vehicle group. PCB at 0.1 mg/kg, regarding the genes that may influence the

myelin destruction, only the *TNF- $\alpha$*  reversed its modulation (downward). On the contrary, all the myelin-favorable genes (except the *MAL* gene) inverted their modulation (upward), although no statistically significant differences were observed at this dose. When the sick mice received 0.5 mg/kg PCB, a similar modulation was detected in myelin-adverse genes. Finally, a dose-dependent effect of PCB was observed, which reached an inverse modulation for all genes studied at the highest dose of PCB (1 mg/kg). Moreover, a statistical difference was found for the *TNF- $\alpha$*  gene (down) and the *CXCL12* gene (up).

## PCB reduces demyelination and neuroinflammation in the spinal cords of EAE mice

Several areas of demyelination (purple area) were observed in EAE animals treated with the vehicle, also present (in a lesser proportion) with the lowest dose of PCB 0.1 mg/kg (Figure 4A). In contrast, intact myelin (expressed as an intense blue area) was observed in healthy mice (image not shown). Demyelination in the spinal cord white matter was clearly ameliorated in the diseased animals treated with all doses of PCB, particularly those of 1 and 0.5 mg/kg (Figure 4A). These results express the dose-dependent effect of PCB in reducing demyelination. The quantification of the demyelinated areas resulted in a significant decrease in this parameter in the EAE animals treated with the highest doses of PCB, 0.5 and 1 mg/kg, compared to those treated with the vehicle. On the other hand, immunostaining for Mac-3, a microglial and macrophages marker, and for the T lymphocytes marker CD3,

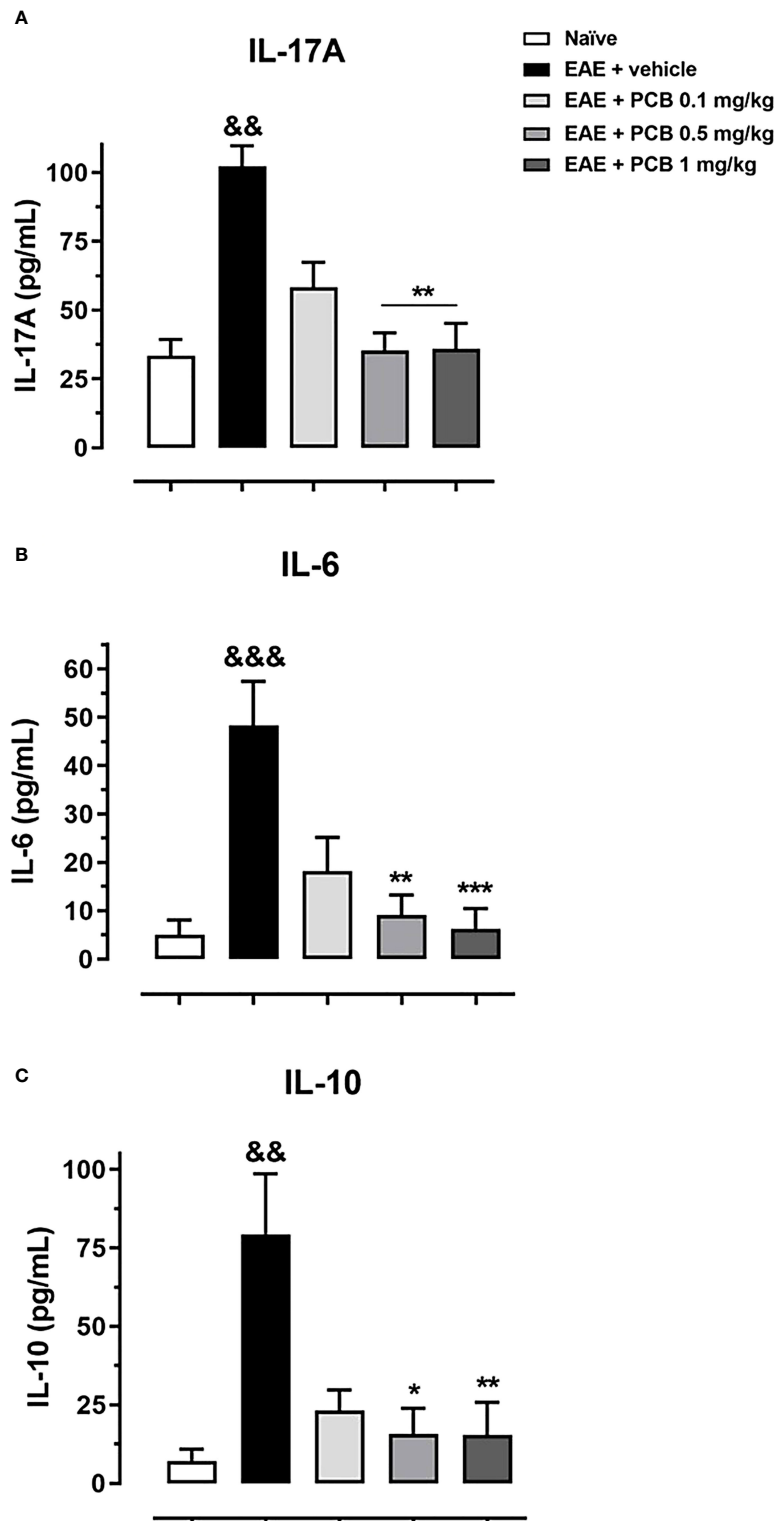

FIGURE 2

Evaluation of the PCB effect on the brain expression of cytokines in EAE mice. MOG<sub>35–55</sub> immunized mice received a daily i.p. injection of PBS (vehicle) or PCB at 0.1, 0.5 or 1 mg/kg, from day 0 until day 26 post-immunization. At this moment, the protein levels of the cytokines (A) IL-17A, (B) IL-6, and (C) IL-10 were assessed by the respective ELISA commercial kits. Data are expressed as mean  $\pm$  S.E.M. (n=6–7 per group). The ampersand (&) and asterisk (\*) are indicative of significant differences with non-immunized naïve and vehicle-treated EAE mice, respectively (\*p<0.05, \*\*p<0.01, \*\*\*p<0.001; <sup>&&</sup>p<0.01, <sup>&&&</sup>p<0.001, Kruskal-Wallis + Dunn's tests).

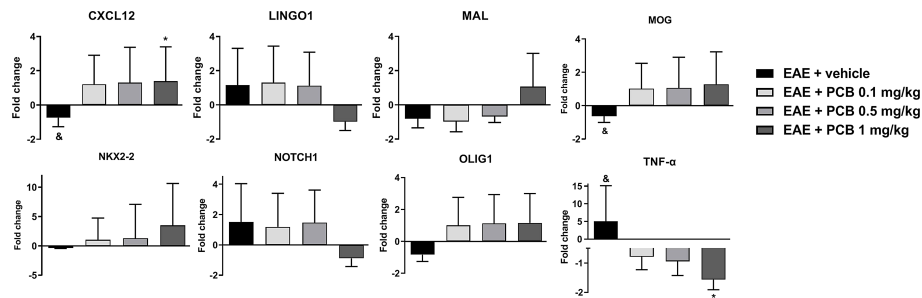

FIGURE 3

Effect of PCB on expression levels of demyelinating/remyelinating-related genes assessed by Real Time PCR in the brain of EAE mice. The panels show the mRNA levels of *CXCL12*, *LINGO1*, *MAL*, *MOG*, *NKX2-2*, *NOTCH1*, *OLIG1* and *TNF-α*. MOG<sub>35–55</sub> immunized mice received a daily i.p. injection of PBS (vehicle) or PCB at 0.1, 0.5 or 1 mg/kg, from day 0 until day 26 post-immunization. Data are expressed as mean  $\pm$  S.E.M. (n=4 per group). The ampersand (&) and asterisk (\*) are indicative of significant differences with non-immunized naïve and vehicle-treated EAE mice, respectively (\*p<0.05, <sup>†</sup>p<0.05, REST<sup>®</sup> software).

were also carried out. The results expressed a significant inhibitory effect of PCB on both markers (Figures 4B, C). Representative images show the high density of Mac-3 and CD3 expression (brown spots) in the EAE + vehicle, which is lower in the groups of EAE mice that received PCB. No immunostaining for Mac-3 or CD3 was detected in the spinal cords of healthy mice (image not shown). Statistical analyses confirmed a significant dose-dependent diminution of the densities of Mac-3 and CD3 in PCB-treated EAE animals at all doses compared to those receiving the vehicle.

## PCB increases OPC, matured OD and reduces axonal damage in the spinal cords of EAE mice

OPC and mature OD identification in the white matter of spinal cords was performed using an anti-Olig2 antibody (Figure 5A) or an anti-TPPP/p25 (Figure 5B), respectively. IHC was also performed for the APP as a marker of axonal damage (Figure 5C). A dose-dependent effect of PCB on the levels of these three markers was found when compared to the EAE animals treated with the vehicle. PCB at the highest dose (1 mg/kg) showed a statistically significant increase of both oligodendrocyte markers (Olig2 and TPPP/p25). Furthermore, there was a statistically significant rise of Olig2 in both the lowest and the intermediate doses of PCB (0.1 and 0.5 mg/kg). Regarding TPPP/p25, there was also an increase of this marker in the EAE + PCB 0.5 mg/kg group, but not at the dose of 0.1 mg/kg of PCB. Moreover, PCB also showed a dose-dependent effect on the APP density. At the intermediate and the highest dose of PCB, this treatment significantly reduced APP levels. However, there was no difference in APP density between the EAE mice treated with lowest doses of PCB compared to those treated with the vehicle (Figure 5C).

## "In vitro" and "in vivo" effects of PCB and its combination with IFN-β

The inhibitory effects of PCB and its combination with IFN-β was assessed in rat T<sub>MBP-GFP</sub> cells and in T cells isolated from the spleen of 2D2 mice. There was a clear trend that PCB alone was able to inhibit the proliferation of MBP-stimulated rat T<sub>MBP-GFP</sub> cells dose-dependently. However, when cultured with IFN-β alone at 10<sup>3</sup> U/mL, no anti-proliferative action of this drug was observed. Remarkably, the combination of both compounds showed a statistically significant effect and the dose-dependent inhibition of T<sub>MBP-GFP</sub> cell proliferation (Supplementary Figure 1). Furthermore, PCB also inhibited the proliferation of CD4<sup>+</sup> T cells isolated from 2D2 mice. The results showed a clear tendency to reduction in the proliferation of these activated CD4<sup>+</sup> T cells when treated with PCB alone at 10, 50 and 250 µg/mL (Supplementary Figure 2). However, this inhibitory effect was not evident with the treatment of 10<sup>3</sup> U/mL IFN-β alone, but it was significant when combined with 250 µg/mL PCB (Supplementary Figure 2). On the other hand, the intracellular localization analysis revealed that PCB was accumulated in the perinuclear region of T<sub>MBP-GFP</sub> cells (Supplementary Video 1).

In the next set of experiments, we evaluated the PCB/IFN-β combination in the mouse model of EAE. When the prophylactic regimen was implemented, two EAE-treated groups (PCB and the combination) showed a significant decrease in the clinical severity as evidenced by the area under the curve of disease progression with respect to the EAE + vehicle group. However, when the administration was in the therapeutic schedule, starting at day 14 post-immunization once the disease symptoms were already present, no differences in the neurological progression between groups were found (Figure 6). Accordingly, when the expression of some cytokines were assessed after concluding the prophylactic regimen, the EAE vehicle-treated mice showed significantly higher expression of

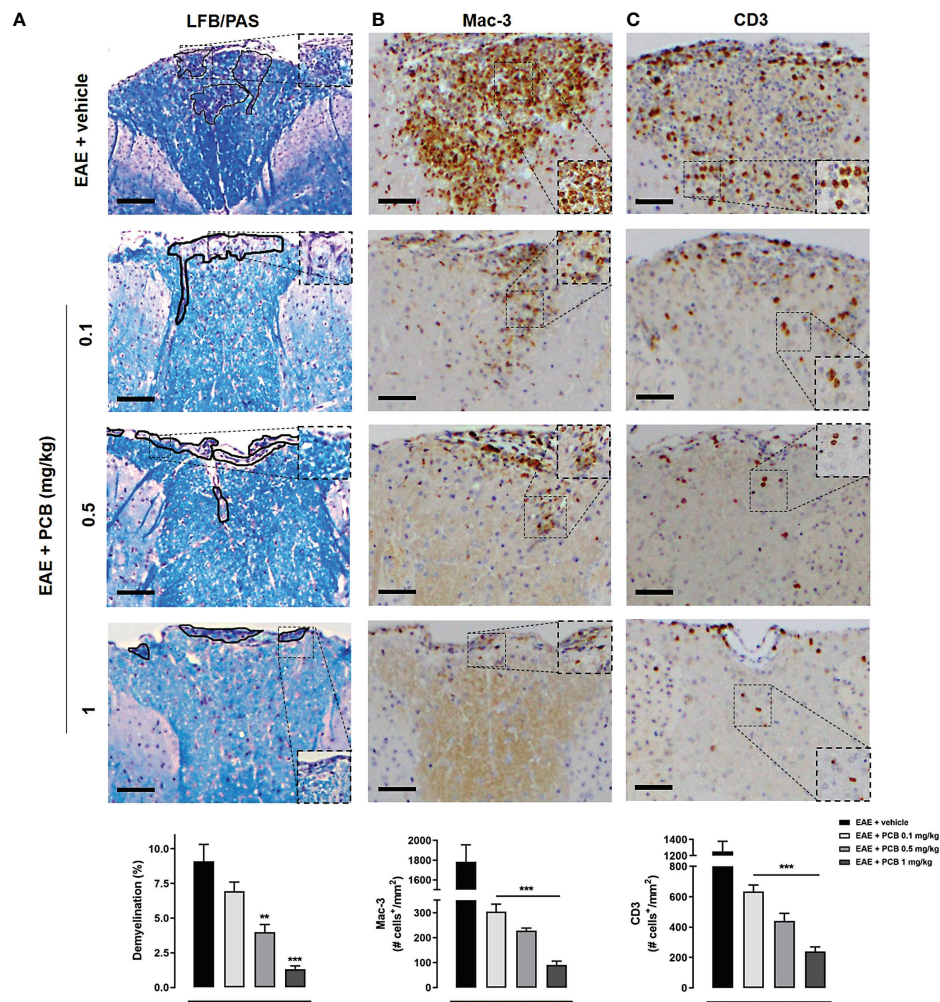

FIGURE 4

The representative cross-sectional images and the respective morphometric evaluation per variable are shown in each panel. **(A)** Demyelination (LFB/PAS). **(B)** Macrophages/activated microglia (Mac-3). **(C)** T cells (CD3). MOG<sub>35–55</sub> immunized mice received a daily i.p. injection of PBS (vehicle) or PCB at 0.1, 0.5 or 1 mg/kg, from day 0 until day 26 post-immunization. The areas marked with black pencil indicate demyelination. The percentage of demyelination and the cell densities (number of positive marked cells per mm<sup>2</sup>) were calculated by dividing with total area of the white matter in transversal sections. Data are expressed as mean ± SEM (n=4–7 per group). The asterisks indicate statistically significant differences vs. EAE + vehicle group (\*\*p<0.01, \*\*\*p<0.001, Kruskal-Wallis + Dunn's tests for LFB/PAS and Mac-3, ANOVA + Newman-Keuls tests for CD3). Bar: 50 µm.

IL-17A, IL-6, and IL-10 when compared to the naïve group (Figure 7A). On the contrary, the EAE mice treated with the PCB/IFN-β combination significantly reduced the brain expression levels of these cytokines compared with EAE vehicle-treated mice, reaching levels comparable to those of naïve animals (Figure 7A). The individual treatments also significantly reduced IL-10, and for IL-17A and IL-6, only IFN-β was evident to be significant, although a clear decreasing trend was detected with PCB alone (Figure 7A). Interestingly, a significant induction of Treg was found, as evidenced by the mean fluorescence intensity in the spleen of

animals treated with the PCB/IFN-β combination (Figure 7B). Regarding the gene modulation in the brain, we found that *LINGO1* and *MAL* genes were up- or down-regulated, respectively, in the EAE vehicle-treated versus untreated animals (Figure 7C). For the *MAL* gene, an inverse modulation (upward) was obtained only for the EAE animals treated with the PCB/IFN-β combination, but not with the separate treatments, compared to EAE vehicle-treated group (Figure 7C). However, the *LINGO1* gene remained down-regulated with either the individual or the combined treatments (Figure 7C).

**FIGURE 5**

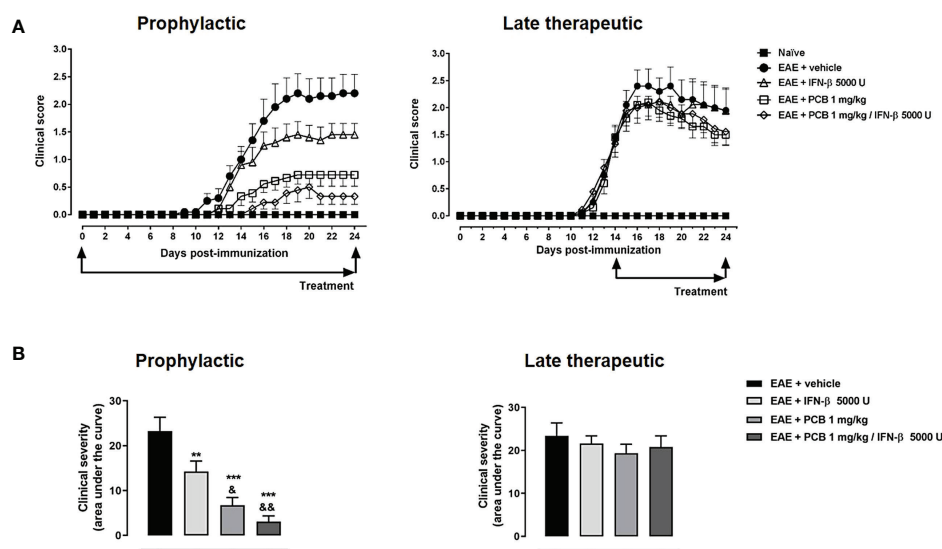

FIGURE 6

Effect of the treatment with the combination PCB/IFN- $\beta$  and each compound individually on the clinical progression of EAE mice. (A) Daily clinical assessment of the mice. (B) Clinical severity determined by the area under the curve (in arbitrary units). MOG<sub>35–55</sub> immunized mice were treated either with oral PCB at 1 mg/kg daily (once a day), with subcutaneous IFN- $\beta$  at 5000 U every other day, or with their combination, initiating at day 0 (prophylactic schedule), or after the occurrence of the first disease symptoms at day 14 post-induction (late therapeutic schedule), lasting until day 24 post-immunization. A numeric scale with the ascending graveness was used to score every day the clinical signs of the mice, ranging from 0 (no disease) to 5 (death). The naïve group (non-immunized animals) remained healthful during the entire study period (score 0). Data are expressed as the mean  $\pm$  S.E.M. (n=9–10 per group). The ampersand (&) and asterisk (\*) are indicative of significant differences with IFN- $\beta$ -treated or vehicle-treated EAE mice, respectively (\*\*p<0.01, \*\*\*p<0.001, <sup>†</sup>p<0.05, <sup>††</sup>p<0.01, ANOVA + Newman-Keuls tests).

## Discussion

In the present study, the outcomes and underlying mechanisms of the PCB administration were assessed in the EAE-MOG<sub>35–55</sub> model of MS. We selected this model as appropriate for the PCB evaluation given the presence of both main components of the MS pathogenesis: immune dysfunction and neurodegeneration (5, 6, 11). Previously, we have reported that the anti-inflammatory and antioxidant properties of PCB and C-PC mediate their neuroprotective effects in animal models of cerebral ischemia (8–10). Such observations, therefore, suggest that these natural molecules might also curtail the pathogenesis of MS by acting on those pivotal deleterious processes.

Cytokines are mediators of both the innate and adaptive immunity (28). In this report, the administration of PCB in the MOG<sub>35–55</sub> murine EAE model evidenced a significant dose-dependent reduction of cerebral expression of IL-17A and IL-6 in with respect to vehicle-treated EAE subjects. IL-17A and IL-6 are pro-inflammatory cytokines reported to play a key role in EAE (29). In this regard, several experimental models support the role of inflammatory cytokines in EAE; for example: anti-IL-17A antibodies cause a delay in disease progression in the EAE model (30), while the IL-17A blockade attenuates EAE (31), and mice either deficient of IL-17A or that received anti-IL-17A were

protected from EAE establishment (32). In the same line, anti-IL-6 receptor monoclonal antibodies inhibited the development of EAE (33). Such evidence supports the positive impact of the cytokines reduction promoted by PCB in EAE. Moreover, we identified an increase in the IL-10 immunoregulatory cytokine in vehicle-treated EAE animals (similar to the IL-17A and IL-6 proinflammatory cytokines), which also decreased significantly with the PCB treatment. A possible explanation for this observation is that the immune system produces IL-10 as a negative feedback mechanism to maintain immune homeostasis from pro-inflammatory overreactions. Indeed, it has been shown that the IL-17 cytokine could also be produced not only by Th17 cells, but also by macrophages and T cells lacking either IL-10 or IL-10 receptor expression (34). The presence of recombinant IL-10 in the culture of these immune cells abrogates the production of IL-17, thus demonstrating the critical immune regulating role of IL-10 (34). Then, when the PCB treatment counteracts the overproduction of the pro-inflammatory cytokines (IL-17A and IL-6), the immunoregulatory component (IL-10) is also reduced as a balancing immune response.

Moreover, in our study, we inspected the dose-dependent outcome of PCB on the modulation of different genes related to the myelin physiology. We grouped them into genes whose products may injure the myelin in specific conditions (*LINGO1*,

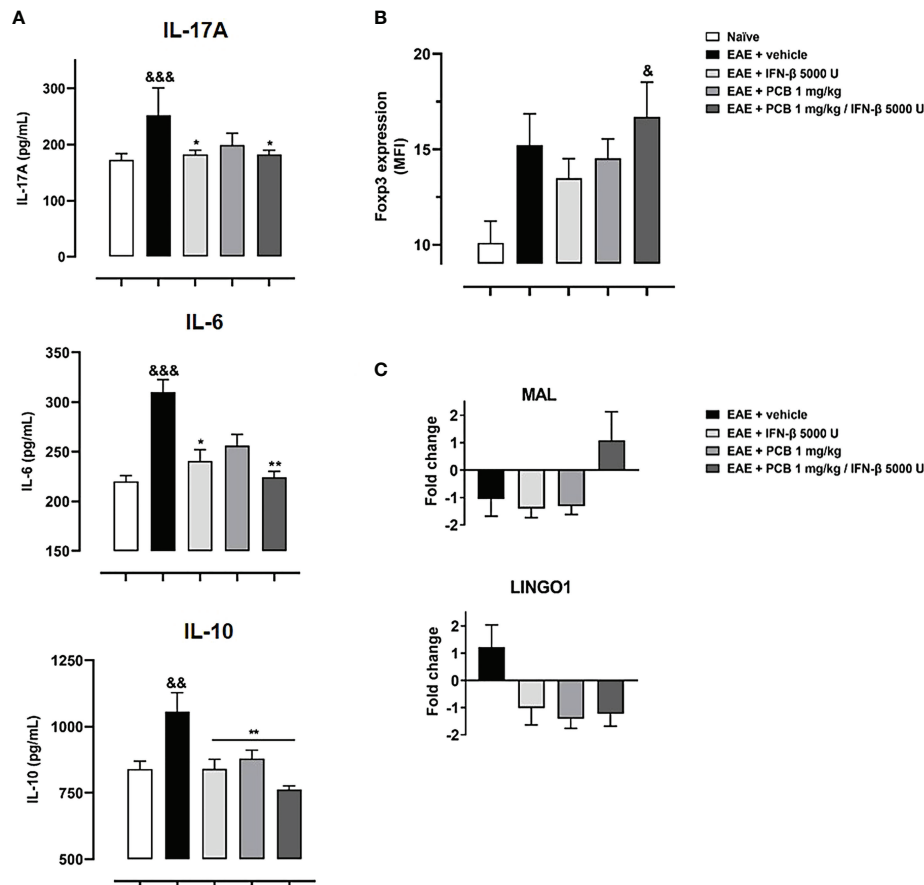

FIGURE 7

Effect of the treatment with the combination PCB/IFN- $\beta$  and each compound individually on the cerebral expression of cytokines (protein levels) and of demyelinating/remyelinating-related genes (mRNA levels), as well as on the Treg levels in spleen of EAE mice. Panels show (A) the cytokines levels IL-17A, IL-6 and IL-10 from brain as assessed by ELISA, (B) Treg cells from mice spleen analyzed in the CD4<sup>+</sup> CD25<sup>high</sup> gate and expressed as Foxp3 Mean Fluorescence Intensity (MFI), (C) mRNA levels of *LINGO1* and *MAL* genes as assessed by quantitative Real Time PCR from the mice brain. MOG<sub>35–55</sub> immunized mice were treated either with oral PCB at 1 mg/kg daily (once a day), with subcutaneous IFN- $\beta$  at 5000 U every other day, or with their combination, initiating at day 0 (prophylactic schedule), or after the occurrence of the first disease symptoms at day 14 post-induction (late therapeutic schedule), lasting until day 24 post-immunization. Data are expressed as mean  $\pm$  S.E.M. (n=4–7 per group). The ampersand (&) and asterisk (\*) are indicative of significant differences in comparison to non-immunized naïve and to vehicle-treated EAE mice, respectively. (\*p<0.05, \*\*p<0.01, <sup>a</sup>p<0.05, <sup>ab</sup>p<0.01, <sup>abc</sup>p<0.001, Kruskal-Wallis + Dunn's tests when compared with EAE + vehicle group for IL-17A and IL-16, or according to ANOVA + Newman-Keuls tests for IL-10 and MFI of Foxp3).

*NOTCH1*, and *TNF- $\alpha$* ) and those that could preserve it or participate in the myelogenesis multi-step process (*CXCL12*, *MAL*, *MOG*, *NKX2-2*, *OLIG1*).

The *TNF- $\alpha$*  cytokine has been shown to be a pleiotropic cytokine. In the cuprizone model of demyelination, animals deficient in *TNF- $\alpha$*  showed a significant delay in remyelination along with a significant decline in the number of mature OD (35). In contrast, the treatment of cuprizone-fed mice with XPro1595, a specific inhibitor of soluble *TNF- $\alpha$*  able to enter into the CNS, promoted early remyelination and impeded motor behavior deterioration (36), which suggests the relevant role of this cytokine in MS remyelination failure. That being so, it was also confirmed that the selective inhibition of soluble *TNF- $\alpha$*  improves recovery in the EAE mice model (37). In our study in

diseased EAE animals (vehicle-treated), the *TNF- $\alpha$*  gene was up-regulated, however, EAE animals treated with the three doses of PCB showed down-regulation of the *TNF- $\alpha$*  gene. This suggests that PCB may favor the remyelination process by limiting the expression of *TNF- $\alpha$* .

On the other hand, both the *LINGO1* and the *NOTCH1* genes, were up-regulated in the vehicle- or the PCB (0.1 and 0.5 mg/kg)-treated EAE animals, but both genes were down-regulated by the highest dose of this compound (1 mg/kg). It has been shown that the loss of the *LINGO1* function in EAE mice led to a neurological improvement (38), while in the cuprizone animal model, an anti-*LINGO1* antibody improved remyelination and neurobehavioral performance (39). Furthermore, the intranasal delivery of siRNA-loaded chitosan

nanoparticles targeting LINGO1 was associated with signs of repair, neuroprotection, and remyelination in rats with ethidium bromide-triggered demyelination (40). On the other hand, by using the cuprizone animal model it was showed that inhibition of the *NOTCH1* gene expression by using an specific siRNA, accelerated remyelination mainly through increasing the mature OD in the brain lesions (41). In another study, with the aim of establishing whether NOTCH-JAGGED signaling regulated the rate of remyelination, young and adult animals were compared in the cuprizone model and no significant differences were found (42). Similarly, other authors have found that both NOTCH1 receptor and its ligand JAGGED1 were notably expressed in demyelinated areas of mice with EAE (43). Although the mechanistic role of LINGO1 and NOTCH1 in demyelination/remyelination processes in MS is yet to be fully elucidated, the available reports point to a deleterious action on the myelogenesis (44). Thus, the downregulation of these genes by PCB at the highest dose suggests a positive effect in promoting the formation of new myelin.

Furthermore, we identified the downregulation of the *CXCL12*, *MOG*, *NKX2-2*, *OLIG1* and *MAL* genes in the brain of sick EAE animals receiving the vehicle and an upregulation of the four first genes when those were treated with the three doses of PCB. The exception was found with the *MAL* gene in which its expression was increased only in the group EAE + PCB 1 mg/kg.

It has been observed that the lentivirus-mediated overexpression of *CXCL12* in the *corpus callosum* with cuprizone-induced demyelination enhances OPC proliferation (45). Another study in which neonatal OPCs were isolated from rats showed that *CXCL12* induces the activation of MEK/ERK and PI3K/AKT signaling in OPC promoting their migration (46). On the other hand, the primary physiological function of *MOG*, a protein exclusively present on the surface of myelin sheaths and OD processes, is not yet clearly established. However, its expression at the beginning of the myelination events and throughout the OD maturation process supports a likely involvement of this protein in the correct structural integrity of the myelin sheaths (47).

Other relevant protein in these aspects is *NKX2-2*, an important transcriptional factor for OPC differentiation. The expression of this gene has been detected in early CNS demyelinated lesions caused by ethidium bromide in rats, but not in old adult animals which have the slowest myelination speed. Thus, this evidence supports the notion that the abundance of *NKX2-2* could accelerate remyelination in damaged CNS regions (48). In another study, by using *in situ* hybridization, immunofluorescence, and co-immunoprecipitation, it was demonstrated that the protein domains of *NKX2-2* is critically present in OD differentiation (49). Similarly, another important mediator of myelin formation is *OLIG1*. It has been reported that when a neural progenitor cell (NPC) transplantation was performed in *OLIG1*<sup>-/-</sup> and *OLIG1*<sup>+/+</sup> mice infected with mouse hepatitis virus, only wild-type recipients exhibited extensive

remyelination and differentiated preferentially in OPC (50). Previous reports have also suggested the potential involvement of *OLIG1* in brain ischemia repair mechanisms when observed that its expression pattern was closely associated with endogenous remyelination (51). Besides these mediators, the *MAL* protein is predominantly expressed in OD, and it has been shown through genetic ablation procedures its relevant role in the axon-myelin interaction (52). Interestingly, a positive modulation of the *MAL* gene expression was also found in studies of our team using C-PC and PCB in animal models of MS (6) and cerebral ischemia (9), respectively. Therefore, the evidence shown above expresses the positive effects of PCB on these pro-myelinating genes and their potential involvement in myelin restoration in mice with EAE.

Accordingly, the LFB staining analysis of spinal cords revealed the presence of extensive demyelinated areas in mice of the EAE vehicle group, in agreement with previous reports (53, 54), as well as the significant increase of activated microglia, macrophages and T cells, supporting the inflammatory features involved in EAE (55, 56). In contrast, a significant reduction of CNS microglia/macrophages was observed in EAE animals that received any of the three PCB doses, and thus confirms its role in the action mechanisms for resisting this disease (57, 58). In the context of MS, activated microglia also contribute to neuronal and OD injury by acting as a paramount source of reactive oxygen species (ROS) (59). Indeed, microglial NADPH oxidase has been demonstrated to be one of the main sources of ROS in active MS lesions (60). The oxidative damage to lipids and DNA of the OPC, OD, and neurons, is closely associated with CNS demyelination and neurodegeneration (61). In this sense, PCB can inhibit the microglial NADPH oxidase (62). The inhibition of this enzyme is considerably beneficial in this context because it produces the superoxide anion radical which later reacts with nitric oxide favoring the rapid production of peroxynitrite, a key mediator of myelin and axon toxicity (63). PCB can also reduce oxidative damage by acting as a peroxynitrite scavenger (64). Therefore, the antioxidant activities of PCB may restore the redox balance in EAE mice and contribute to the myelin/axonal repair mechanisms.

Under pathological conditions, the activated microglia favors the infiltration of pro-inflammatory immune cells in the CNS by secreting matrix metalloproteinases (MMPs), mediators of BBB breakdown (65). Thus, the PCB treatment may prevent such events by limiting the rise in activated microglia. In addition, PCB can have a positive neuroaxonal effect by reducing the microglial secretion levels of pro-inflammatory cytokines, such as IFN- $\gamma$  and TNF- $\alpha$  (66), and cytokines involved in the Th1 and Th17 response such as IL-12, IL-6 and IL-23 (67). The cytokines that mediate the inflammatory responses in MS and EAE may also directly impact on the myelinating capacity of OD (68). Indeed, IFN- $\gamma$  and TNF- $\alpha$  act as pro-apoptotic inducers in human oligodendroglial cells, and furthermore, they potentiated the extent of cell death when co-incubated together (69).

In our study, an increase in OPC (identified by the Olig2 marker) and mature OD (evidenced by TPPP/p25) mediated the effects of PCB, suggesting the pro-myelination action of PCB, given that Olig2 functions as a transcription factor during the development of OD (70). Previously, it has been observed that the specific overexpression of Olig2 in OPC under demyelinating conditions promotes their migration to the CNS lesions and their differentiation into mature OD, which lead to an early remyelination process in lysophosphatidylcholine-intoxicated mice (71). Although this strongly suggests that PCB may induce the formation of new myelin in EAE mice, further evidence in this regard could be assessed in non-immunological demyelination models, such as the cuprizone or the lysophosphatidylcholine mice models.

The increase in the expression of Olig2 and TPPP/p25 caused by PCB indicates that this molecule favors the proliferative and migratory functions of OPC and their final differentiation into mature OD capable of myelinating the injured axons. The optimal expression of TPPP/p25 plays key physiological roles in the differentiation of OPC to mature myelinating OD (72). The TPPP/p25 protein is essential in the dynamics of the regeneration of the microtubule system during the elongation process previous to the myelin sheath structuring (73). These microtubules are essential for the structural stability and plasticity of myelinating OD. Furthermore, the evidence suggests that TPPP/p25 is also involved in the cellular metabolism, because its expression produces an increase in ATP levels (74). In MS patients, an increase in TPPP/p25 was detected in remyelinating lesions (73). OD that express TPPP/p25 extensively are able to form a compact myelin sheath that wraps the axon. The novel-formed myelin cover may physically curtail the direct action of immune cells and inflammatory molecules that mediate the damage to the axon, and it may also restore the trophic support to it (75).

Here, the axonal protecting activity of PCB was also evaluated, and its dose-dependent benefit at 0.5 and 1 mg/kg was demonstrated in animals with EAE. This could be related to the rapid restoration of the myelin trophic support that enables the survival and functionality of the axons. Therefore, it reduces axonal damage and the occurrence of intrinsic axonal defects that mediate physical and biochemical signals preventing myelination (76). The reduction of the abnormal accumulation of APP indicates that the axons are viable and rapid anterograde transport of APP occurs through them (77). The transported APP exerts trophic and synaptogenic roles, suggesting a restoration of the synapse (78), which is affected during demyelination (79).

On the other hand, *in vitro* studies in T<sub>MBP-GFP</sub> encephalitogenic cells, demonstrated that PCB (and its combination with IFN- $\beta$ ) was able to inhibit the proliferation of these cells. Similarly, in these cells, the perinuclear location of the PCB was identified using the confocal microscope.

IFN- $\beta$  is a standard treatment for MS, but it comes with limitations (80). In order to surpass this, the combination of IFN- $\beta$  with other compounds acting on targets from either the immune or the nervous systems can potentially be a better therapeutic strategy for MS than IFN- $\beta$  alone (81, 82). Hence, certain studies show the effects of IFN- $\beta$  when co-administered with other DMTs. For example, one study showed a synergistic effect of IFN- $\beta$  and dimethyl fumarate in EAE (83). A second study showed that the addition of a 1 $\alpha$ ,25-dihydroxyvitamin D3 analog with IFN- $\beta$  produced additional immunomodulatory effects for the prevention of EAE (84). A third study demonstrated that the IFN- $\beta$ -secreting mesenchymal stem cells and minocycline combination considerably reduced the clinical deterioration of EAE (85). A fourth study reported that the combined therapy of high doses of methylprednisolone with IFN- $\beta$  had a synergistic effect in EAE (86). Our group demonstrated with a microarray assay of the brain of EAE mice that C-PC modulated additional desirable biological processes compared to IFN- $\beta$  (6). Following this line of reasoning, here we report the beneficial effects of the PCB/IFN- $\beta$  combination in EAE, thus supporting its complementarity.

The efficacy of IFN- $\beta$  was assessed in the setting of EAE while combined therapies have also been tested in the EAE model demonstrating their effects (85, 87). In our study, the combined therapy of PCB/IFN- $\beta$ , was, therefore, evaluated in the animal model of EAE. PCB in the combined therapy was administered orally, the efficacy of which had been previously demonstrated by our group when it was applied individually at different doses to EAE mice (7). This aspect is relevant for the potential clinical translation since the Spirulin-derived PCB administered orally has been issued the US Food and Drug Administration category of Generally Recognized As Safe (GRAS) (88).

A superior clinical effect was identified here in EAE animals treated with the PCB/IFN- $\beta$  combined therapy when both molecules are administered prophylactically. However, no beneficial effect was observed when both molecules were administered in a late therapeutic regimen, which then open the perspective of a further evaluation with higher doses of these compounds. In our study, we have identified that both IFN- $\beta$  and PCB, and to a greater extent, the treatment using both molecules, reduced the cerebral expression of pro-inflammatory cytokines IL-17A and IL-6. Consistently, the effectiveness of IFN- $\beta$  in the EAE model induced by rodent recombinant MOG<sub>35-55</sub> (independent of B cells) has been clearly related to the diminution of CNS pro-inflammatory cytokines (89). Another study also shows that the effectiveness of IFN- $\beta$  is related to an inflammasome-dependent EAE model (90). Additionally, a greater induction of Treg in the spleen of the animals was achieved with the PCB/IFN- $\beta$  combined therapy. A similar result on Treg was previously obtained by our group with the treatment of C-PC of peripheral blood mononuclear cells

isolated from patients with MS (5). Along these lines of evidence, Treg can promote the differentiation of OPC and, consequently, favor their remyelination capability in the injured CNS (91). Interestingly, the PCB/IFN- $\beta$  combined treatment differentially modulated the cerebral expression of *MAL* (upregulation) and *LINGO1* (downregulation) genes, supporting the remyelinating advantage of this pharmacological combination. PCB adds to this combination its anti-inflammatory, antioxidant, and remyelinating capabilities as have been shown in rodent models of EAE, and in other models of neurodegenerative diseases (92).

## Conclusion

There is an urgent need to identify MS drugs that target demyelination, which is a “gap” in the DMTs available thus far. PCB is well known for its neuroprotective and anti-inflammatory properties. In this study, we elucidated for the first time important clues of the mechanism by which PCB can promote remyelination in mice suffering EAE, comprising the stimulation of both the OPC and the mature OD. Moreover, PCB had also an advantageous impact on the reduction of axonal damage. On the other hand, the effect of PCB on the reduction of pro-inflammatory cytokines and its relationship with demyelination/remyelination processes is also highlighted in this study. Finally, the herein identification of the clinical superiority of the combination PCB/IFN- $\beta$ , its associated reduction of pro-inflammatory cytokines and the increase of Treg, supports its potential application as a new feasible therapy for MS.

GM-D, investigation and project administration. GG-N, methodology, project administration, and funding acquisition. EP-A, methodology and writing. MMT, methodology, writing, and funding acquisition. GP-R, conceptualization, writing, original draft, project administration, methodology, and funding acquisition. All authors contributed to the article and approved the submitted version.

## Funding

This work was partially supported by the Federal Ministry of Education and Research of Germany (BMBF) (Project number: 01DN18042) and the Science without Borders Program of Brazil (Project No. 405878/2013-3).

## Acknowledgments

We would like to thank Prof. Naoto Kawakami and Dr. Isabel Bauer for their technical assistance and contribution to the grant from BMBF.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Publisher's note

All claims expressed in this article are solely those of the authors and do not necessarily represent those of their affiliated organizations, or those of the publisher, the editors and the reviewers. Any product that may be evaluated in this article, or claim that may be made by its manufacturer, is not guaranteed or endorsed by the publisher.

## Supplementary material

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fimmu.2022.1036200/full#supplementary-material>

## SUPPLEMENTARY FIGURE 1

Effects of the combination PCB + IFN- $\beta$  on rat encephalitogenic T<sub>MBP-GFP</sub> cells. Effect on the proliferation: T<sub>MBP-GFP</sub> cells ( $4 \times 10^4$  cells/well) were cultured for 48 h in different treatment conditions in 96-well plate with the presence of irradiated rat thymocytes (5000 rad,  $10^6$  cells/well). Complete DMEM/1% rat serum with 10  $\mu$ g/mL MBP was used. Immediately after, 0.5 mg/mL MTT was added to the medium and cultured for another 4 h. After medium removal, the resulting formazan was solubilized and its absorbance was measured at 570 nm. Data is presented as mean  $\pm$  S.E.M. Ampersand (&) and asterisk (\*) indicate significant differences in comparison to  $10^3$  U/mL IFN- $\beta$  and control, respectively (\*\*p<0.01, \*\*\*p<0.001 vs control; <sup>a</sup>p<0.05, <sup>ab</sup>p<0.01 vs IFN- $\beta$ , according to Kruskal-Wallis + Dunn's tests).

## SUPPLEMENTARY FIGURE 2

Effects of the combination PCB + IFN- $\beta$  on the proliferation of CD4<sup>+</sup> T cells from 2D2 mice. PCB was incubated with purified CD4<sup>+</sup> T cells at different concentrations in the presence of absence of  $5 \times 10^3$  U/mL IFN- $\beta$ . A seeding density of  $2 \times 10^5$  cells/well was used for the co-stimulation

of CD4<sup>+</sup> T cells with anti-CD3 and anti-CD28 at 2  $\mu$ g/mL in 96-well plate. Two days later, CD4<sup>+</sup> T cells were incubated with IL-2 at 10 ng/mL for another 24 h. Then, MTT assay was performed and its cellular reduction was measured by the absorbance at 570 nm. Positive and negative controls indicate the absence of the drugs in the medium or no incubation with anti-CD3/anti-CD28/IL-2/drugs, respectively. Data is presented as mean  $\pm$  S.E.M. Ampersand (&) and asterisk (\*) indicate significant differences in comparison to  $10^3$  U/mL IFN- $\beta$  and control, respectively (\*\*\*p<0.001 vs control; <sup>ab</sup>p<0.01 vs IFN- $\beta$ , according to Kruskal-Wallis + Dunn's tests).

## SUPPLEMENTARY VIDEO 1

T<sub>MBP-GFP</sub> cells ( $5 \times 10^5$  cells/well) were cultured in 12-well plate together with irradiated rat thymocytes (5000 rad,  $1.25 \times 10^7$  cells/well) in complete DMEM/1% rat serum with 10  $\mu$ g/mL MBP and 200  $\mu$ g/ $\mu$ L PCB for 3 h. Immediately after, nuclear DNA was labeled with 1  $\mu$ g/mL DAPI, the image was taken by confocal microscopy and analyzed by Fiji software. Blue and red colors indicate the presence of the cell nucleus and PCB, respectively, in two T<sub>MBP-GFP</sub> cells.

**Introduction:** Among immune cells, activated monocytes play a detrimental role in chronic and viral-induced inflammatory pathologies, particularly in Juvenile Idiopathic Arthritis (JIA), a childhood rheumatoid arthritis (RA) disease. The uncontrolled activation of monocytes and excessive production of inflammatory factors contribute to the damage of bone-cartilage joints. Despite the moderate beneficial effect of current therapies and clinical trials, there is still a need for alternative strategies targeting monocytes to treat RA.

**Methods:** To explore such an alternative strategy, we investigated the effects of targeting the CXCR4 receptor using the histamine analog clobenpropit (CB). Monocytes were isolated from the blood and synovial fluids of JIA patients to assess CB's impact on their production of key inflammatory cytokines. Additionally, we administered daily intraperitoneal CB treatment to arthritic mice to evaluate its effects on circulating inflammatory cytokine levels,

immune cell infiltrates, joints erosion, and bone resorption, as indicators of disease progression.

**Results:** Our findings demonstrated that CXCR4 targeting with CB significantly inhibited the spontaneous and induced-production of key inflammatory cytokines by monocytes isolated from JIA patients. Furthermore, CB treatment in a mouse model of collagen-induced arthritis resulted in a significant decrease in circulating inflammatory cytokine levels, immune cell infiltrates, joints erosion, and bone resorption, leading to a reduction in disease progression.

**Discussion:** In conclusion, targeting CXCR4 with the small amino compound CB shows promise as a therapeutic option for chronic and viral-induced inflammatory diseases, including RA. CB effectively regulated inflammatory cytokine production of monocytes, presenting a potential targeted approach with potential advantages over current therapies. These results warrant further research and clinical trials to explore the full therapeutic potential of targeting CXCR4 with CB-like molecules in the management of various inflammatory diseases.

#### KEYWORDS

monocytes, cytokines, arthritis, inflammation, treatment

## Introduction

Rheumatoid arthritis (RA) is a long inflammatory condition that results to the aggressive synovial hyperplasia causing destruction of articular joints. Joint inflammation is characterized by proliferation of macrophage-like (1) and fibroblast-like synoviocytes to form a pannus, which invades and destroys the cartilage (2). Juvenile Idiopathic Arthritis (JIA) is a rare and complex form of RA affects children younger than 16 years old, characterized by a multifactorial disorder with heterogeneous manifestations that include all forms of chronic arthritis (3, 4). Over-production of TNF- $\alpha$ , IL-1 $\beta$  and IL-6 is strongly involved in most forms of JIA (5, 6). The release of such inflammatory factors by monocytes depends on several highly conserved families of pattern recognition receptors (PRR), one of them being the Toll-like receptor family (TLRs). The increase in circulating TNF- $\alpha$  levels in all forms of JIA argues for a major contribution of monocytes to disease progression (7). This is supported by the observation that monocytes from systemic JIA patients produced more inflammatory cytokines than monocytes from healthy donors in response to TLR4 and TLR8 stimulation (8). Current antirheumatic drugs, including corticosteroids and antibodies-based biotherapies, target inflammatory macrophages or macrophages secreted cytokines to reduce synovial inflammation. However, not all patients respond to antibody therapy and chronic application of glucocorticoids leads to severe side effects, highlighting the need for novel therapeutic strategies.

In the context of chronic and acute inflammatory diseases, the chemokine receptor CXCR4 could emerge a potential therapeutic target. We previously showed that histamine and the histamine

analog clobenpropit (CB) through their engagement of CXCR4 exhibited a broad-spectrum inhibitory activity on the production of all subtypes of interferons (IFN) in TLR7-activated human plasmacytoid dendritic cells (pDCs) (9). Moreover, intranasal spray of CB resulted in drastic reduction of type I and III IFN secretions in broncho-alveolar lavages from Influenza A virus (IAV) infected mice (9). Of note, the anti-IFN activity of CB was not associated with histamine receptors but strictly dependent on CXCR4 (9). As CXCR4 is highly expressed by all immune cells, including monocytes and macrophages, we hypothesize that CB could also downmodulate monocyte-driven inflammation in rheumatoid arthritis.

In this study, we explored the potential of CB to decrease the production of proinflammatory cytokines by monocytes obtained from the blood and synovial fluids of individuals diagnosed with Juvenile Idiopathic Arthritis (JIA). In these monocytes, we evaluated both the spontaneous and induced cytokine production. Finally, we further probed *in vivo* whether CB treatment would attenuate inflammation and impair disease progression in a model of collagen-induced arthritic mice.

## Results

### CB down-regulates TNF- $\alpha$ , IL-1 $\beta$ , and IL-6 productions in TLR-7/8-activated monocytes

To first assess the potential anti-inflammatory properties of histamine and the histamine analog CB, we took advantage of the

monocyte-derived THP-1 NF- $\kappa$ B reporter cell line. Upon TLR7/8 activation by R848, the reporter gene SEAP is induced by activation of the NF- $\kappa$ B signaling pathway. We thus measured the production of SEAP by R848-activated THP-1 cells in the presence or absence of varying concentration of histamine (Figure 1A) or CB (Figure 1B) ranging from 1 to 100  $\mu$ M. We showed that CB, and to a lesser extent histamine, reduced in a dose-dependent manner activation of NF- $\kappa$ B in THP-1 cells, without any obvious toxicity. In addition, CB treatment (20  $\mu$ M) prevented the transcription of TNF- $\alpha$ , IL-1 $\beta$  and IL-6 encoding genes in R848-activated THP-1 cells (Figure 1C).

To extend our results obtained with THP-1 cell line, we next tested the ability of CB to control cytokine production in R848-stimulated human blood mononuclear cells (PBMCs) from healthy donors (HD). We first tested the overall effect of CB by measuring the concentrations of multiple cytokines (*i.e.* IL-1 $\beta$ , -6, -8, -10, TNF- $\alpha$ ...), chemokines (*i.e.* CCL2, CCL3, CCL4, CCL5...), growth factors (*i.e.* EGF, FGF, VEGF...) and interferons (IFN $\alpha$ / $\beta$ / $\gamma$ ) in the cell culture medium of R848-stimulated PBMCs with or without of CB (20  $\mu$ M) ( $n=5$ ) (Figure 1D). CB downmodulated the R848-induced production of chemokines, growth factors, IFN subtypes, and all proinflammatory cytokines, including TNF- $\alpha$ , IL-1 $\beta$  and IL-6 (Figures 1D, E). Mass Cytometry (CyTOF) analysis revealed that among PBMCs monocytes represented the main producers of TNF- $\alpha$ , IL-1 $\beta$  and IL-6 upon TLR7/8 stimulation by R848. CB treatment drastically reduced the production of those inflammatory factors by R848-activated monocytes (Figures 1F, G) ( $n=4$ ). To better evaluated the effect of CB on the proinflammatory cytokines, we purified monocytes from the blood of HD. Accordingly, using a multiplex bead-based assay (Figure 1H) and intracellular flow cytometry staining of TNF- $\alpha$  and IL-1 $\beta$ , we showed in monocytes purified from HD that CB inhibited the production of TNF- $\alpha$  and IL-1 $\beta$  ( $IC_{50} = 2,8 \mu$ M and  $IC_{50} = 8 \mu$ M, respectively) with no observed toxicity (Figure 1I).

## CB controls activation of monocytes from healthy individuals in a CXCR4-dependent manner

We next tested whether the anti-inflammatory properties of CB depend on CXCR4. In our initial approach, we employed the widely recognized CXCR4 antagonist AMD3100 to regulate the anti-inflammatory effects of CB on activated PBMCs. Cells were cultured with increased concentrations of AMD3100 in presence of CB (20  $\mu$ M) and R848 for 24h. The supernatants were transferred to reporter THP1-Dual cells allowing simultaneous quantification of the activity of IRF and NF- $\kappa$ B promoters. We showed that CB reduced activation of both IRF and NF- $\kappa$ B and that AMD3100 blocked the anti-inflammatory activity of CB in a concentration dependent manner (Figures 2A, B).

We further quantified TNF- $\alpha$ , IL-1 $\beta$  and IL-6 productions in R848-stimulated primary purified monocytes from HD in the presence of CB (20  $\mu$ M) and increasing concentrations of AMD3100 (up to 50  $\mu$ M) using flow cytometry. As expected, AMD3100 inhibited in a dose-dependent manner the ability of

CB to reduce intracellular TNF- $\alpha$ , IL-1 $\beta$  and IL-6 levels in monocytes without noticeable toxicity (Figures 2C, D).

To firmly establish that CB immunoregulatory activity relates to CXCR4, the expression of CXCR4 was silenced in primary monocytes using small interfering RNA (siRNA). While the transfection of a siRNA control (siControl) had no impact on the CB-induced inhibition of pro-inflammatory cytokines, CB lost its ability to inhibit TNF- $\alpha$ , IL-1 $\beta$  and IL-6 intracellular productions in CXCR4-silenced human monocytes (siCXCR4) (Figures 2E, F). Taking into account the 95% transfection efficiency in monocytes, we checked that CXCR4 expression was strongly reduced in siCXCR4-transfected monocytes compared to siControl (Figures 2G, H). These overall data show that the immunoregulatory effects of CB strictly depends on CXCR4 engagement.

## CB inhibits spontaneous proinflammatory cytokine production in JIA patients' monocytes

Our next attempt was to prob whether CB exerts an anti-inflammatory effect on immune cells isolated from JIA patients. Spontaneous inflammation is a well-known hallmark of JIA. While elevated levels of IL-6 are easily measurable in the plasma of RA patients (10), the detection of circulating TNF- $\alpha$  in these patients remains a challenge. Thus, to capture TNF- $\alpha$  in the plasma, we developed a TNF- $\alpha$  digital ELISA (Simoa) that detects TNF- $\alpha$  for concentrations as low as 1 fg/mL. Using this technology, we measured detectable levels of TNF- $\alpha$  in patients' plasma and found higher concentration of TNF- $\alpha$  in blood plasma from JIA patients than in HD (JIA patients' median = 3.4 pg/mL vs. HD' median = 1.07 pg/mL) (Figure 3A). To better capture the spontaneous inflammation in JIA patients, we conducted a gene expression analysis on a set of 579 markers associated with inflammation on purified monocytes of PBMC from HD and JAI patients. As compared to HD, the expression of 51 inflammatory genes significantly increased and 16 decreased in oligoJIA patients (Figure 3B). The results of the principal components analysis (PCA) revealed that monocytes in each group grouped together (Figure 3C). Pathway analysis using DAVID (11, 12) showed enrichment in the rheumatoid arthritis pathway (Figure 3D). Since JIA is primarily a joint-related inflammatory disease (13), this prompted us to examine the inflammatory status of synovial fluids. Using Simoa technology, we measured TNF- $\alpha$  concentrations between 3 and 26 pg/mL (median = 10.8 pg/mL) in synovial fluid (SF) from eighteen JIA patients' knees with active arthritis (Figure 3E). When comparing circulating levels of TNF- $\alpha$  in plasma and SF from six matched patients, higher levels of TNF- $\alpha$  were systematically measured in SF compared to blood plasma (Figure 3F).

We next assessed the effect of CB treatment on the spontaneous TNF- $\alpha$  production by human monocytes isolated from PBMCs (Figure 3G) and synovial fluid mononuclear cells (SFMcs) (Figure 3H) from JIA patients. CB treatment significantly decreased TNF- $\alpha$  levels in the culture medium of both SFMCs and PBMCs monocytes. We also showed that CB exerted a dose-

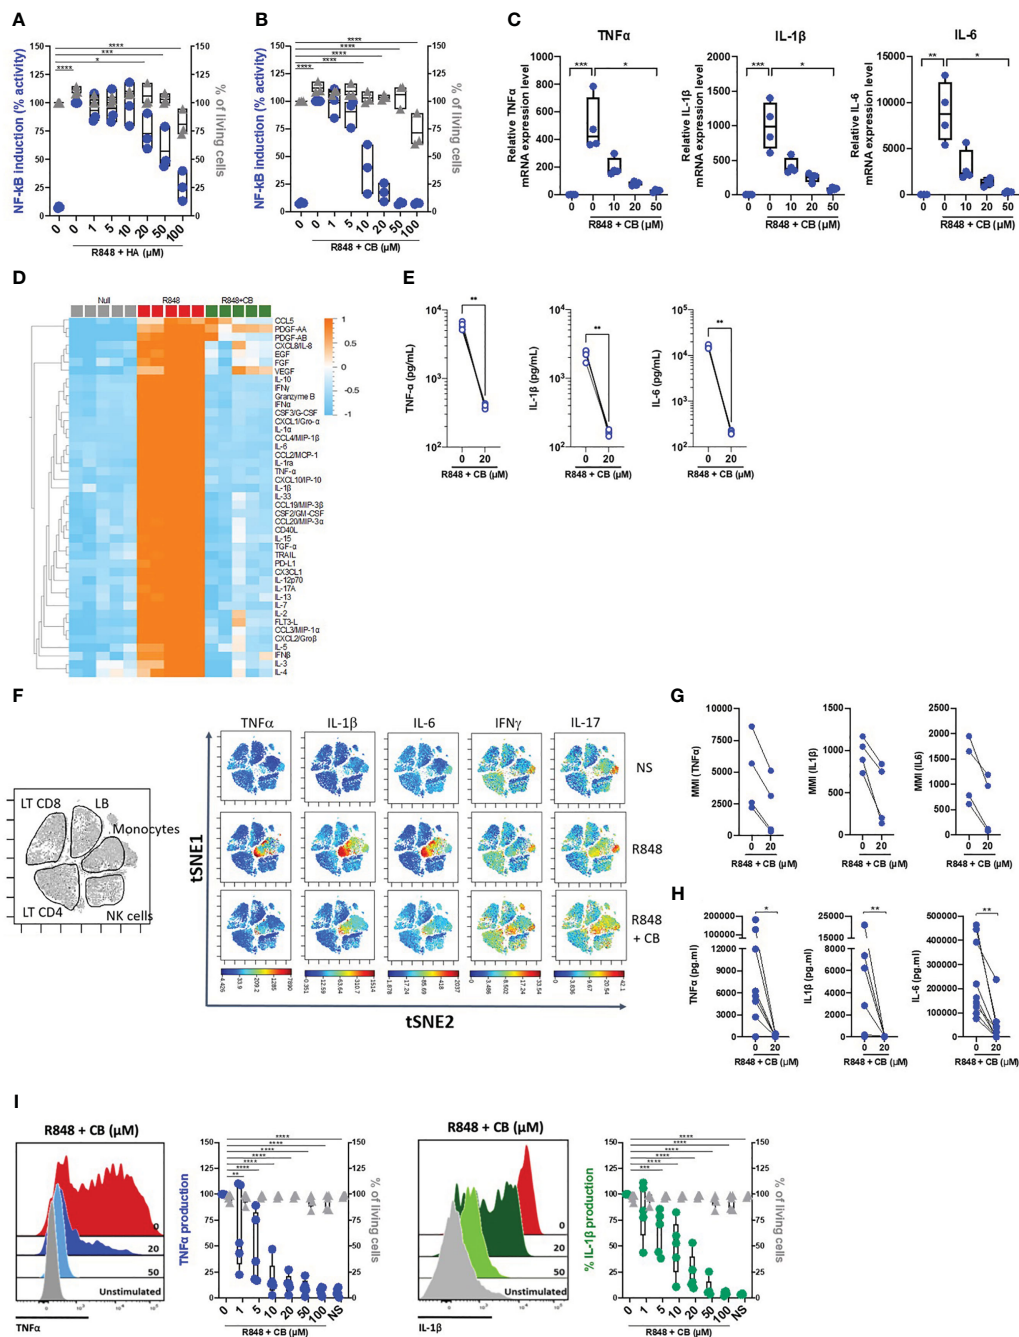

FIGURE 1

CB inhibited TLR-7/8-mediated TNF- $\alpha$ , IL-1 $\beta$  and IL-6 production by human monocytes. (A, B) THP1 NF- $\kappa$ B reporter cells were treated with increasing concentration of Histamine (A) or CB (B) ranging from 1 to 100  $\mu$ M then stimulated with R848 (5  $\mu$ g/ml) for 24 hours. NF- $\kappa$ B reporter activity was measured using QUANTI-Blue, a SEAP detection reagent. (C) mRNA levels of TNF- $\alpha$ , IL-1 $\beta$  and IL-6 from THP1-dual pre-incubated with increased doses of CB and stimulated overnight with R848 (5  $\mu$ g/ml), were measured by RT-qPCR and normalized to RPL13A. Kruskal-Wallis with Dunn's multiple comparisons test. (D–G) PBMCs from healthy donors (HD) were preincubated with CB (20  $\mu$ M) then stimulated with R848 (5  $\mu$ g/ml) overnight. (D, E) Cytokine production was measured in the supernatant using a bead-based multiplexed immunoassay system Luminex. (D) Heatmap representation of statistically different cytokines (P < 0.05) between the different conditions (Null, R848, R848+CB), ordered by hierarchical clustering. Up-regulated cytokines are shown in orange, and down-regulated in blue. P values were determined with the Kruskal-Wallis test. (E) Individual cytokines from the Luminex are represented. Mann-Whitney test. (F) PBMCs were analyzed by mass cytometry (CyTOF) and tSNE analysis were performed using CD56, CD3, CD11c, BDCA4, CD14, HLADR, CD123, CD4, CD8, and CD19 markers. Intracellular levels of TNF- $\alpha$ , IL-1 $\beta$ , IL-6, IFN $\gamma$ , and IL-17 were evaluated. (G) Mean Metal Intensity (MMI) of TNF- $\alpha$ , IL-1 $\beta$ , and IL-6 was evaluated on gated monocytes from four different donors. (H) Cytokine production was measured in the supernatants of purified monocytes from nine HD using the multiplex bead-based immunoassay LEGENDplex. Mann-Whitney test. (I) Purified monocytes from five HD were preincubated with increased doses of CB then stimulated with R848 during 5 h. Intracellular levels of TNF- $\alpha$  and IL-1 $\beta$  as well as viability were evaluated by flow cytometry. SSC-A, side scatter. FSC-A, forward scatter. 2-way ANOVA. \*\*\*\*P < 0.0001, \*\*\*P < 0.001, \*\*P < 0.01, \*P < 0.05.

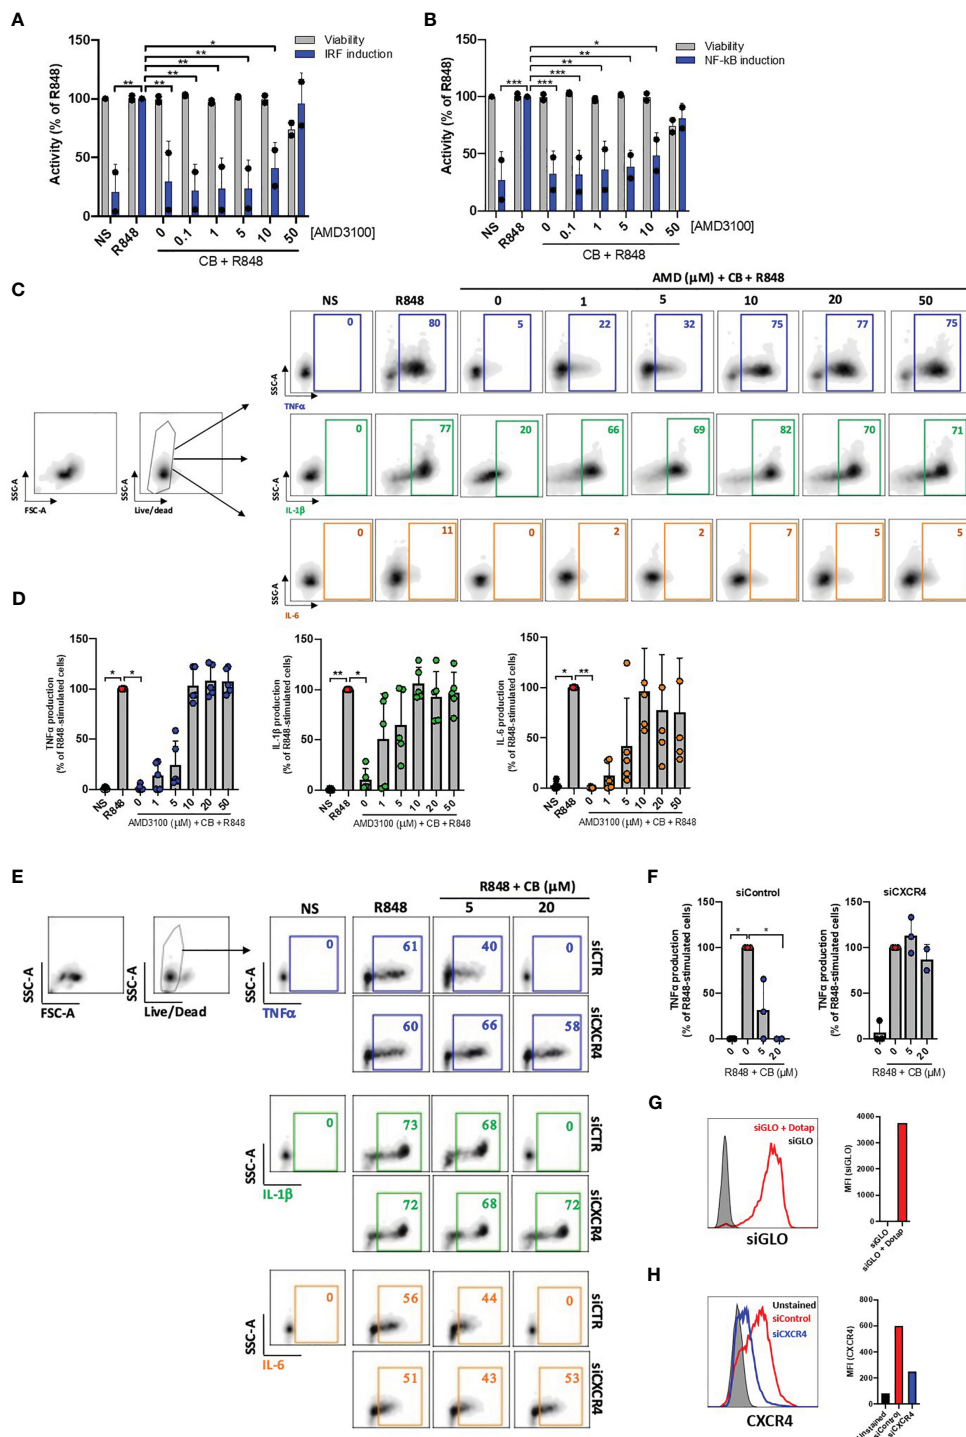

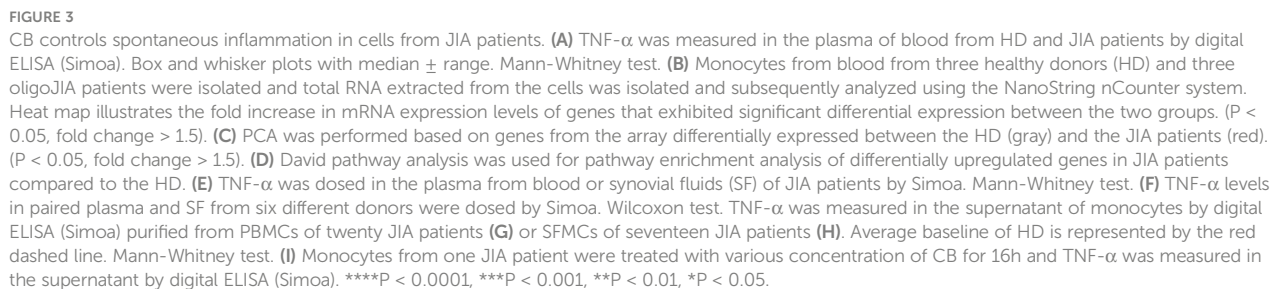

FIGURE 2

CB immunoregulatory activity on primary monocytes is CXCR4 dependent. (A) and (B) PBMCs from two healthy donors were cultured in presence of increased concentrations of AMD3100, then treated with CB (20  $\mu$ M) and activated with R848 (5  $\mu$ g/mL) for 24 hours. The level of (A) interferons and (B) inflammatory cytokines in the culture supernatants was measured using the reporter cell line THP1-dual. Two-way ANOVA with Dunnett's multiple comparisons test. (C) and (D) Isolated monocytes from five healthy donors were cultured in presence of increased concentrations of AMD3100, then treated with CB (20  $\mu$ M) and activated with R848 (1  $\mu$ g/mL) for 6 hours. Intracellular levels of TNF- $\alpha$ , IL-1 $\beta$  and IL-6 were evaluated by flow cytometry, (C) dot plot representation from a donor and (D) histogram representation from 5 donors. Friedman with Dunn's multiple comparisons test. (E, F) Monocytes were treated for 24 hours with CXCR4 siRNA (siCXCR4) or Control siRNA (siControl) at 160 nM. Cells were then pre-incubated with CB (20  $\mu$ M) and stimulated with R848 (1  $\mu$ g/mL) for 6 hours. Intracellular levels of TNF- $\alpha$ , IL-1 $\beta$  and IL-6 were evaluated by flow cytometry: (E) dot plot representation from a donor and (F) histogram representation from 3 donors. Data shown as the median  $\pm$  s.d. Kruskal-Wallis with Dunn's multiple comparisons test. (G) the efficiency of transfection with dotap on monocytes was evaluated with GLO siRNA in flow cytometry. (H) The expression of CXCR4 on monocytes treated with siControl and siCXCR4 was assessed by flow cytometry. \*\*P < 0.01, \*P < 0.05. NS, nonstimulated.

Finally, using purified SFMCs from JIA patients we showed that CB inhibited the production of the 40 soluble factors induced by R848 activation (**Figure 4D**). Overall data indicate that CB could

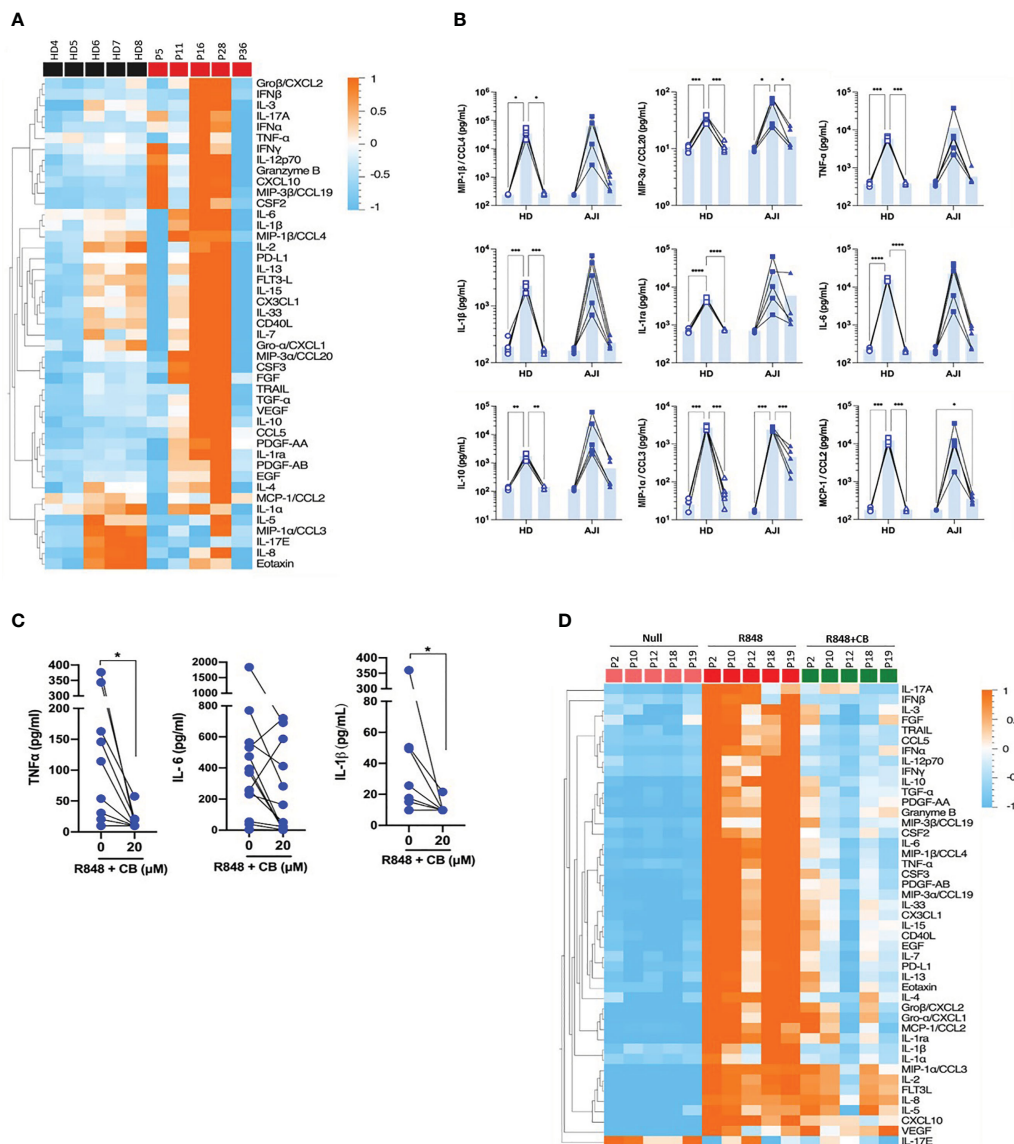

FIGURE 4

CB controls R848-induced inflammation in cells from JIA patients. **(A)** PBMCs from HD and JIA patients were incubated with R848 (5  $\mu$ g/mL) for 16h. P2 P12 P18 and P19 patients are oligoJIA, P10 is a polyJIA. Cytokine production was measured in the supernatant using a bead-based multiplexed immunoassay system Luminex. Heatmap representation of statistically different cytokines (P<0.05) in PBMCs supernatant upon R848 stimulation between HD and JIA patients, ordered by hierarchical clustering. Mann-Whitney test. **(B)** PBMCs from HD and JIA patients were pre-incubated with CB at 20  $\mu$ M and then stimulated with R848 (5  $\mu$ g/mL) for 16h. Cytokine production was measured in the supernatant using a bead-based multiplexed immunoassay system Luminex. Individual cytokines are represented. Two-way RM ANOVA with Tukey *post hoc* correction. **(C)** Monocytes from JIA patients were pre-incubated with CB at 20  $\mu$ M and then stimulated with R848 (5  $\mu$ g/mL) for 16h. reduce hyper secretion of inflammatory cytokines observed in JIA patients during flares.

## CB inhibits inflammatory cytokine and reduces disease progression in collagen-induced arthritis mouse model

The anti-inflammatory properties of CB in PBMCs, SFMCs and purified monocytes of JIA patients, suggest that CB represents a

promising therapeutic option for arthritis. Consequently, we proceeded to evaluate the potential therapeutic impact of CB in DBA/1J mice, which serve as a mouse model for arthritis-like pathology known as collagen-induced arthritis (CIA) (14). CIA mice exhibit numerous clinical, histological, and immunological similarities to human RA (15). This includes symmetric joint involvement, synovitis, cartilage, and bone erosions. Several studies reported a major role of IL-1 $\beta$  in disease development in CIA mouse model (16), as well as a pathologic role of IL-6 in the effector phase of autoimmune arthritis by promoting bone destruction (17).

CIA mice were daily intraperitoneally injected with CB (at 3 mg/kg (mpK), 10 mpK, and 30 mpK) over a two-week period. As a reference drug, the corticosteroid prednisolone (15 mpK) was also injected in CIA mice. CB treatment did not exert any effect on mouse body weight whatever the dose tested overtime (Figure 5A), indicating no major toxicity of CB in treated mice. While CIA mice displayed elevated levels of circulating IL-1 $\beta$  and IL-6 two weeks after disease onset (Figure 5B), CB treatment resulted in a profound decrease of both cytokines (Figure 5B). Of note, the highest dose of CB (30 mpK) was as efficient as the referenced corticosteroid prednisolone.

Additionally, we conducted an investigation to assess the impact of CB treatment on the progression of the disease. The daily injection of CB attenuated the progression of the disease during the 14 days of treatment (Figure 5C). Mice treated with CB had thinner paws than mice treated with PBS (Figure 5D). In arthritic mice, the histological analysis of the tissue injury revealed severe cartilage damage (yellow arrow), bone remodeling (black arrow) and tissue infiltration by immune cells (green arrow) (Figure 5E). Daily CB treatment attenuated all these pathological markers (Figure 5E). To further characterize the effect of CB treatment, individual paws were scored, reflecting the severity of the disease. CB treatment drastically reduced the terminal paw score (Figure 5F), which was associated with reduced inflammation, cartilage damage, bone remodeling on limbs and pannus (Figures 5G, H).

## Discussion

In this study, we reveal a broad-spectrum anti-inflammatory activity of the histamine analog CB. Our findings reveal a notable decrease in the production of key inflammatory cytokines when monocytes derived from the blood and synovial fluids of individuals with JIA are exposed to CB. This reduction is observed both in spontaneous and induced cytokine production. This immunomodulatory activity of CB strictly depends on the engagement of CXCR4 chemokine receptor. In addition, CB displays high efficiency *in vivo* to reduce inflammation and subsequent tissue damage in arthritic mice, leading to reduction of disease progression. In summary, our results strongly indicate that the targeting of CXCR4 using CB-like molecules holds great potential as a therapeutic approach for inflammatory diseases characterized by detrimental hyperactivation of monocytes.

The pro-inflammatory cytokines TNF- $\alpha$  and IL-6 are major contributors to JIA and RA (18, 19). The clinical benefits observed upon inhibiting TNF- $\alpha$  and IL-6 strongly support the hierarchical significance of these two pro-inflammatory factors among all the factors produced during JIA flares. While the TNF- $\alpha$  signature has been clearly identified in JIA patients (20), systemic TNF- $\alpha$  protein remains, however, difficult to detect and measure, notably because most classical ELISAs are not sensitive enough to detect TNF- $\alpha$  concentration below one pg/mL. To overcome this challenge, we developed an ultrasensitive digital TNF- $\alpha$  ELISA (Simoa) with attomolar sensitivity that permits to show that TNF- $\alpha$  concentration in plasma from JIA patients is six-fold higher than

the one in healthy donors. Through Simoa experiments, we also measured that TNF- $\alpha$  concentration in synovial fluid JIA patients is higher in their synovial fluid than that in plasma. In most forms of RA, including JIA, blood monocytes are attracted to synovial fluids where they differentiate into inflammatory macrophages (1) and produce joint-degrading mediators. These immune cells emerge as being the major sources of TNF- $\alpha$ . Accordingly, we show that purified monocytes from JIA patients spontaneously produce more TNF- $\alpha$  than monocytes from healthy donors. As previously described by Cepika et al. (1), we also confirm that monocytes from JIA patients are hyperresponsive to TLR-7/8 activation compared to healthy individuals. Our study provides evidence that CB is a powerful inhibitor of pro-inflammatory cytokine and chemokine production in inflammatory monocytes derived from the blood or synovial fluid of individuals with Juvenile Idiopathic Arthritis (JIA). Interestingly, CB anti-inflammatory activity is not restricted to TNF- $\alpha$  and IL-6, as the inflammatory signature of JIA patients is largely toned down under CB exposure. These *ex vivo* results suggest that CB potentially reduces hypersecretion of cytokines and chemokines observed in JIA patients during flares. In RA animal models, IL-6 has been shown to promote osteoclast activation, synoviocyte proliferation, and recruitment to inflammatory areas, leading to the development of synovial pannus (17). In conjunction with IL-1 $\beta$ , IL-6 enhances the production of matrix metalloproteinases, thereby contributing to the degradation of joints and cartilage (21). In collagen-induced arthritis (CIA) mice, daily treatment of CB exhibits strong anti-inflammatory properties by blocking both IL-1 $\beta$  and IL-6 secretions. According to massive reduction of cartilage damage, bone remodeling, immune cell tissue infiltration and pannus CB treatment results in reduced disease progression and paw thickness in arthritic mice similarly to the referenced corticosteroid prednisolone. These *in vivo* experiments validate the concept of the immunomodulatory activity of CB observed *in vitro* and *ex vivo* on synovial monocytes from JIA patients.

In competition assays using the CXCR4 antagonist AMD3100 or siRNA-based experiments to down-regulate CXCR4 expression, we further demonstrated that CB anti-inflammatory activity on monocytes strictly depends on CXCR4. Beyond the impact of CXCR4 signaling on regulation of the IFN pathway (9), this result highlights that CXCR4 also represents a broad spectrum regulator of inflammation in various cell types, including pDC and monocytes. The concurrent anti-IFN and anti-inflammatory effects exerted by CXCR4 can have substantial clinical advantages, particularly considering the frequent presence and functional activity of type I interferons (IFNs) in RA (22). It is worth noting that a recent study has revealed significantly elevated levels of CXCR4 and its natural ligand, CXCL12, in both the serum and joint synovial fluids of individuals with active RA when compared to a control group (23). Furthermore, the expression levels of CXCR4 and CXCL12 in the active RA group were found to be higher compared to the group in remission (23). Higher accessibility to CXCR4 in RA patients makes targeting the CXCR4 anti-inflammatory pathway a particularly promising strategy for these pathologies.

For instance, drugs that target TNF- $\alpha$ , IL-6 and IL-1 $\beta$  cytokines or their receptors have shown beneficial effects in JIA patients (18).

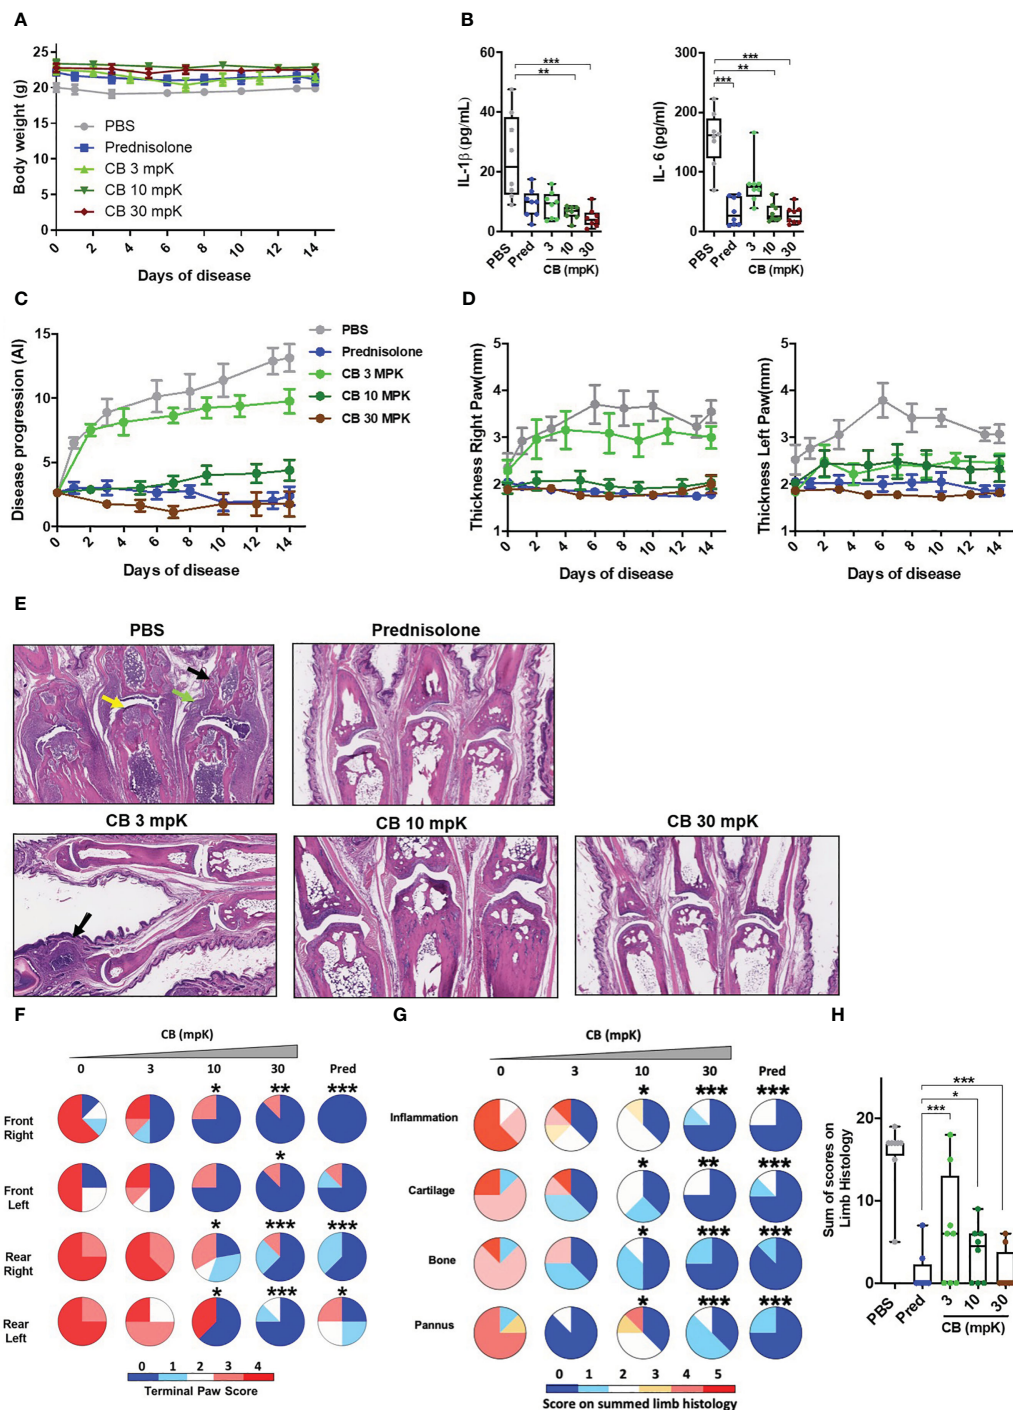

FIGURE 5

CB controls inflammation and disease onset in collagen induced arthritic mice. (A) The body weight of collagen induced arthritic mice treated with prednisolone (Pred, 15 mpK) or 3, 10, or 30 mpK of CB was measured every other day. (B) IL-1 $\beta$  and IL-6 were measured by ELISA in the serum after 2 weeks of treatment. Kruskal-Wallis test with Dunn's *post hoc* correction. (C) the progression of the disease was assessed according to several markers in the legs. (D) The thickness of the legs was measured. (E) Representative hematoxylin and eosin staining of paw sections from collagen induced arthritic mice treated with prednisolone (Pred, 15 mpK) or 3, 10, or 30 mpK of CB: joints with pannus and inflammation (green arrow), loss of articular cartilage (yellow arrow) and bone remodeling (black arrow). (F) Impact of the treatment was evaluated by a paw score, signs of arthritis in all paws according to a 0–4 scale of ascending severity, after 2 weeks of treatments. (G) Effects of the treatment on the scoring for inflammation, cartilage damage, bone remodeling, and pannus after 2 weeks of treatment. (H) Combined disease score after 2 weeks of treatment. Kruskal-Wallis test with Dunn's *post hoc* correction. All data are presented as median  $\pm$  range, \*\*\* $P$  < 0.001, \*\* $P$  < 0.01, \* $P$  < 0.05.  $n$  = 8 mice per group.

However, these treatments are often associated with highly heterogeneous responses across patients in terms of efficacy and treatment resistance. Consequently, it is not uncommon for a patient to change medication throughout the course of the disease. To some extent, this could be explained by the very high specificity of these treatments toward a single cytokine in a set of diseases characterized by a very broad inflammatory spectrum. By contrast to targeted therapies, corticosteroids have been used for decades to block overall pro-inflammation in RA patients, with, however, strong side-effects (24). In order to address these limitations, innovative approaches such as Janus kinase (JAK) inhibitors have emerged as promising strategies. These small molecules effectively inhibit the activity of JAK, and they have demonstrated reasonable success in treating the adult form of arthritis (25–27). Regarding strategies targeting JAK, our findings demonstrate that CB treatment effectively inhibits a broad range of cytokines *in vitro*, *ex vivo*, and *in vivo*.

In contrast, CB exerts its effects at an earlier stage compared to JAK inhibitors. Instead of directly targeting cytokine-mediated signaling, CB acts one step upstream by inhibiting the production of inflammatory cytokines. This approach may offer certain advantages in terms of therapy efficacy compared to JAK inhibitors. The significant suppression of disease progression observed in mice with RA following treatment with CB provides strong validation for the concept of targeting CXCR4 using CB-like molecules as a potential therapeutic strategy for arthritic conditions. Indeed, CB exhibits all the essential characteristics of a promising new drug for the treatment of rheumatoid arthritis (RA). It is a small molecule that has demonstrated an absence of side effects in *in*

*vivo* preclinical models. CB specifically targets the widely expressed immune cell receptor CXCR4, and it exerts a broad anti-inflammatory effect by modulating cytokine production. These attributes collectively highlight CB as a potential candidate for RA therapy.

In summary, the minimal cytotoxicity of CB, coupled with its wide-ranging inhibitory effects on *ex vivo* production of inflammatory cytokines and its therapeutic efficacy demonstrated *in vivo*, indicates that the use of CB-like molecules to target CXCR4 could serve as a novel and promising therapeutic strategy for chronic inflammatory diseases, including rheumatoid arthritis.

## Materials and methods

### Blood samples isolation and culture of blood leukocytes

The blood samples obtained from donors in good health were sourced from “Etablissement Français du Sang” (agreement # 07/CABANEL/106), located in Paris, France. The use of materials from JIA patients was conducted with the approval of the Comité de Protection des Personnes (N° EudraCT: 2018-A01358-47) in France. The experimental procedures involving human blood adhered to the guidelines set by the European Union and the Declaration of Helsinki. Informed consent was obtained from all donors, including both healthy individuals and patients. Table 1 provides a summary of the clinical data pertaining to the JIA patients. *In vitro* experiments were conducted using human

SF, synovial fluid; oligoJIA, oligoarticular juvenile idiopathic arthritis; ERA, enthesitis-related arthritis; polyJIA, polyarticular juvenile idiopathic arthritis; sJIA, systemic juvenile idiopathic arthritis; RF, rheumatoid factor; ANA, antinuclear factor. The Null and CB columns correspond to TNF- $\alpha$  assay data by Simoa performed on supernatants of isolated monocytes from blood or synovial fluid of JIA patients. Null: untreated monocytes, CB: monocytes treated with 20  $\mu$ M CB.

mononuclear cells obtained from peripheral blood or synovial fluid (SF) through centrifugation using density gradient medium (STEMCELL Technologies). Human monocytes were isolated by positive selection using Human CD14 microbeads (Miltenyi). SFMC (Synovial fluid mononuclear cells), PBMC (Peripheral blood mononuclear cells), and monocytes were cultured in RPMI 1640 medium (Invitrogen, Gaithersburg, MD) (R10) supplemented with 10% heat-inactivated fetal bovine serum and 1mM glutamine

(Hyclone, Logan, UT). The JIA patients were identified as P1 to P36 (refer to [Figure 2](#)).

## Cell stimulation

PBMCs were initially seeded at a concentration of 2.106 cells per milliliter (mL), while monocytes isolated from either PBMCs or

SFMCs were seeded at a concentration of  $1.10^6$  cells per mL. Prior to a 16-hour stimulation with the TLR-7/8 agonist Resiquimod – R848 at a concentration of 5  $\mu\text{g/mL}$  or as specified, the cells were pre-treated for 1 hour with AMD3100 (Sigma-Aldrich) and/or clobenpropit (CB) (Sigma Aldrich) at a concentration of 20  $\mu\text{M}$  (or other specified concentration). Subsequently, flow cytometry or mass cytometry techniques were employed to collect the cells, and supernatants were collected to detect cytokine levels. For intracellular staining, Brefeldin A (BFA) was added to the cells 30 minutes after stimulation and incubated for 5 hours.

THP1-dual cells (Invivogen) were seeded at a concentration of  $1.10^6$  cells per mL in RPMI 1640 (Invitrogen, Gaithersburg, MD) (R10) medium supplemented with 10% heat-inactivated fetal bovine serum, 2mM glutamine (Hyclone, Logan, UT), 25mM HEPES, and 1% Pen-Strep. Before a 24-hour stimulation with the TLR-7/8 agonist Resiquimod – R848 at a concentration of 5  $\mu\text{g/mL}$ , the cells were pre-treated for 1 hour with clobenpropit (CB) (Sigma Aldrich) or Histamine at concentrations ranging from 1 to 100  $\mu\text{M}$ . The activity of the NF- $\kappa\text{B}$  reporter was measured using QUANTI-Blue, a SEAP detection reagent, following the instructions provided by the supplier.

## Mass cytometry

Peripheral blood mononuclear cells (PBMCs) obtained from healthy donors were stimulated with R848 in the presence of CB. Brefeldin A was added overnight to the culture. Following stimulation, PBMCs were treated with a mixture of surface antibodies and Rh isotopes in PBS for 20 minutes at room temperature. Both commercially available and custom-conjugated antibodies were used to create a panel for phenotypic and functional analysis. Two DNA interchelators, Rhodium isotope mass 103 and Iridium isotopes mass 191 & 193, were employed to determine cell viability and gate the singlet cells during analysis. Prior to analysis, each antibody was titrated using PBMCs. Subsequently, the cells were fixed with Fix-I solution (Maxpar Fix-I buffer; Fluidigm) for 15 minutes at room temperature. After fixation, the cells were incubated with anti-cytokine antibodies and Ir isotopes in Perm-S solution for 30 minutes at room temperature (Maxpar Perm-S buffer; Fluidigm). Before CyTOF acquisition, the cells underwent three washes with highly pure water and were resuspended in water at a maximum concentration of 500,000 cells/mL (Maxpar Water; Fluidigm). Data acquisition was performed using a CyTOF2 instrument (Fluidigm) and the analysis included data cleaning using FlowJo software and the application of the viSNE algorithm in Cytobank for the primary analysis. The table (Table 2) provides the details of antibodies coupled with the respective metals.

## Flow cytometry

The cells underwent a PBS wash and were subsequently treated with a viability stain, Zombie Aqua (Biolegend), for 30 minutes at a temperature of 4°C. Following the wash, the cells were suspended in

PBS containing 2% FCS and 2mM EDTA and stained with the extracellular mix, APC Vio770 anti CD14 (clone REA599) from Miltenyi Biotec, at a dilution of 1/100. For intracellular staining of TNF- $\alpha$  and IL-1 $\beta$ , an Inside Stain kit (Miltenyi Biotec) was utilized in accordance with the manufacturer's instructions. In brief, the cells were fixed with 250  $\mu\text{L}$  of the Inside Fix solution for 20 minutes at room temperature (RT), then washed and stained with 100  $\mu\text{L}$  of the Inside Perm solution containing PE anti TNF- $\alpha$  (clone cA2, Miltenyi Biotec) and APC anti-IL-1 $\beta$  (clone REA1172, Miltenyi Biotec) antibodies at a dilution of 1/50 for 30 minutes at RT. Data acquisition was carried out using a Canto II flow cytometer and analyzed using Diva software (BD Biosciences, San Jose, CA) and FlowJo software (Treestar, Ashland, OR).

## CXCR4 knockout experiments

The experiment involved seeding monocytes at a density of 105 cells/100  $\mu\text{L}$  in 96-well plates and placing them in an incubator at 37°C. Two types of siRNA, namely control siRNA (qiagen) and CXCR4 siRNA (SMARTPool, Dharmarcon), were diluted in DOTAP (1,2-dioleoyl-3-trimethylammonium-propane; Roche Applied Sciences). The mixture was gently combined and allowed to incubate at room temperature for 15 minutes. Following the incubation period, the mixture was added to the cultured cells, achieving a final concentration of 160 nM. The cells were then further incubated at 37°C for 24 hours prior to the addition of treatments and stimulation.

## Cytokine detection

The supernatants underwent cytokine production testing through two different methods. The first method involved utilizing the LEGENDplex Antivirus Human panel bead assay (Biolegend, San Diego, USA) as per the manufacturer's instructions. Alternatively, a commercial Luminex multi-analyte assay (Biotechne, R&D systems) was also employed, following the provided instructions.

## Simoa

A novel Simoa digital ELISA specific to TNF- $\alpha$  was developed by employing a Quanterix Homebrew Assay and incorporating two commercially available antibodies (28). Initially, the 28401 antibody (R&D) clone was utilized as a capture antibody following the coating of paramagnetic beads (0.3 mg/mL). The ab9635 polyclonal antibody (Abcam) was biotinylated (biotin/Ab ratio = 30:1) and employed as the detector. To establish the standard curve, recombinant TNF- $\alpha$  (R&D) was used after conducting cross-reactivity assessments. The limit of detection was determined by calculating the average value of all blank runs  $\pm$  3 standard deviations (SDs), resulting in a detection limit of 1 fg/mL.

## RNA isolation and real-time quantitative RT-PCR analyses

The THP1-Dual monocyte cells were cultured at a density of 1.6.106 cells/mL. Prior to a 24-hour stimulation with R848 at a concentration of 10  $\mu$ g/mL, the cells were pre-treated with clobenpropit (CB) for 1 hour. To isolate the total RNA, an E.Z.N.A. kit (Omega Bio-Tek, USA) was used following the manufacturer's instructions. For the synthesis of first-strand cDNA, the Prime Script RT Master Mix kit (Takara Bio Europe, France) was employed. Quantitative real-time PCR was conducted at 60°C using the Takyon

ROX SYBR MasterMix (Eurogentec, Belgium) in the CFX384 Touch Real-Time PCR Detection System (Bio-Rad, France). The RT-qPCR analyses utilized the primers provided in the list below:

*RPL13A*: forward primer, 5'-AACAGCTCATGAGGCTACGG-3'; reverse primer, 5'-TGGGTCTTGAGGACCTCTGT-3'

*IL1B*: forward primer, 5'-CCTGTCCTGCGTGTGAAAGA-3'; reverse primer, 5'-GGGAAGTGGGCAGACTCAAA-3'

*IL6*: forward primer, 5'-GACAGCCACTCACCTCTTCA-3'; reverse primer, 5'-CCTCTTTGCTGCTTTCACAC-3'

*TNF- $\alpha$* : forward primer, 5'-CCTGCTGCACTTTGGAGTGA-3'; reverse primer, 5'-GAGGGTTTGCTACAACATGGG-3'

## Nanostring gene expression analysis

Isolated monocytes from both control subjects and patients were used to extract total RNA. The extracted RNA was diluted to a concentration of 20 ng/ $\mu$ l using ribonuclease-free water. Subsequently, 100 ng (5  $\mu$ l) of each sample was subjected to analysis utilizing the Human Immunology kit v2 and Nanostring Counter. To ensure accuracy, each sample underwent individual multiplexed reactions, consisting of eight negative probes and six serial concentrations of positive control probes. The resulting data was then imported into the nSolver analysis software (version 2.5) for quality assessment and data normalization, adhering to NanoString analysis guidelines. This normalization process involved the utilization of positive probes and housekeeping genes. Prior to hierarchical clustering using Qlucore Omics Explorer version 3.1, the mRNA expression levels were logarithmically transformed. For pathway analysis, the DAVID bioinformatics databank (<https://david.ncifcrf.gov>) was employed. Supplementary data includes the presented mRNA levels.

## Mice

Washington Biotechnology, INC conducted animal experiments in a manner that ensured unbiased results. The animals were housed in a controlled environment with regulated temperature, humidity, and 12-hour light/dark cycles. They had access to food and water without restriction. The mouse experiments conducted by Washington Biotechnology, INC were reviewed and approved by the WBI Animal Care and Use Committee under the reference IACUC NO. 17 006. The experimental procedures followed the guidelines outlined in the "Guide for the Care and Use of Laboratory Animals" and adhered to ethical standards and regulations. On Day 0, the mice were weighed, and the thickness of their hind limbs was measured using a digital caliper. They were then subcutaneously injected with a 50  $\mu$ L emulsion of collagen and Complete Freund's Adjuvant at the base of their tails. On Day 21, the mice were weighed again and received a subcutaneous injection of a 50  $\mu$ L emulsion of collagen and Incomplete Freund's Adjuvant at the base of their tails. After this, the mice were divided into five groups, each consisting of eight mice. From Day 21 to Day 35, the first group received intraperitoneal injections of PBS. The second group was administered prednisolone (Sigma, P4153) orally via daily gavage at a dosage of 10 mL/kg, which had been dissolved in 3 mL of PBS to form a 1.5 mg/mL solution. The mice in groups 3, 4, and 5 were treated with CB. Briefly, CB was dissolved in PBS and administered daily through intraperitoneal injections at dosages of 3 mg/kg, 10 mg/kg, and 30 mg/kg respectively (groups 3 to 5). On Day 35, all mice were weighed, assessed for signs of arthritis, and their hind paw volumes were recorded. The mice were anesthetized and their blood was collected in pre-chilled EDTA tubes. The blood samples were processed to obtain plasma, which was then frozen and subsequently thawed at room temperature. The plasma samples

were diluted 1:2 and analyzed using ELISA to measure levels of IL-1 $\beta$  (R&D Systems, Cat. MLB00C) and IL-6 (R&D Systems, Cat. M6000B). The limbs were individually removed and preserved in 10% neutral buffered formalin.

## Histology on mice limbs

Formalin-fixed mouse paws were processed routinely, sectioned at approximately 8 microns, and stained with hematoxylin and eosin. Glass slides were evaluated using light microscopy by a board-certified veterinary pathologist. The severity of histologic findings was scored using the following scoring criteria as adapted from Crissman et al (29).

- Inflammation

0=Normal

1=Minimal infiltration of inflammatory cells in synovium and periarticular tissue of affected joints

2=Mild infiltration, if paws, restricted to affected joints

3=Moderate infiltration with moderate edema, if paws, restricted to affected joints

4=Marked infiltration affecting most areas with marked edema

5=Severe diffuse infiltration with severe edema

- Cartilage Damage

0=Normal

1=Minimal=minimal to mild loss of toluidine blue staining with no obvious chondrocyte loss or collagen disruption in affected joints

2=Mild=mild loss of toluidine blue staining with focal mild (superficial) chondrocyte loss and/or collagen disruption in affected joints

3=Moderate=moderate loss of toluidine blue staining with multifocal moderate (depth to middle zone) chondrocyte loss and/or collagen disruption in affected joints

4=Marked=marked loss of toluidine blue staining with multifocal marked (depth to deep zone) chondrocyte loss and/or collagen disruption in most joints

5=Severe =severe diffuse loss of toluidine blue staining with multifocal severe (depth to tide mark) chondrocyte loss and/or collagen disruption in all joints

- Bone Resorption

0=Normal

1=Minimal=small areas of resorption, not readily apparent on low magnification, rare osteoclasts in affected joints

2=Mild=more numerous areas of, not readily apparent on low magnification, osteoclasts more numerous in affected joints

3=Moderate=obvious resorption of medullary trabecular and cortical bone without full thickness defects in cortex, loss of some medullary trabeculae, lesion apparent on low magnification, osteoclasts more numerous in affected joints

4=Marked=Full thickness defects in cortical bone, often with distortion of profile of remaining cortical surface, marked loss of medullary bone, numerous osteoclasts, affects most joints

5=Severe=Full thickness defects in cortical bone and destruction of joint architecture of all joints

## Statistics

Cellular data sets were analyzed by Mann-Whitney test to compare the group with CB treatment to the untreated group. Flow cytometry data were performed using FlowJo software.

Animal data are shown as median and min/max. Data sets were analyzed by ANOVA (Kruskal-Wallis) tests with Dunn's post-test for multiple comparisons with the different concentrations of CB and prednisolone treatment. Data analysis and graph preparation were performed using GraphPad Prism 8 software (GraphPad Software, San Diego, CA). Statistical significance was determined with a threshold of  $p < 0.05$ , indicating values below this threshold were considered statistically significant. Heatmaps were generated using Qlucore OMICS explore Version 3.5 (26) software.

## Data availability statement

The data presented in the study are deposited in the Gene Expression Omnibus repository, accession number GSE243512.

## Ethics statement

The blood from healthy donors was obtained from "Etablissement Français du Sang" (convention # 07/CABANEL/106), Paris, France. For JIA patients' material, the study was approved by the Comité de Protection des Personnes (N° EudraCT: 2018-A01358-47) in France. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

## Author contributions

NB, NS, MR and J-PH conceived and designed the study. NB, NS, and J-PH had complete access to all the data generated in the study and assume full responsibility for the data's integrity and the accuracy of the data analysis. NB, NS, PQ, and MR contributed to writing the paper. BS and J-PH wrote the paper. NB, NS, BB, TD, AB and J-PH performed data analysis. RM, SB, BBM, BT and PQ were involved in the clinical study and sample collection. BB, AL, TD, AB, SN, and MR performed specific experiments and/or analysis. All authors participated in the review process of the manuscript and provided their final approval for the version that is intended for publication. All authors unanimously take responsibility for all aspects of the work, ensuring that any questions concerning the accuracy or integrity of any part of the research are thoroughly investigated and appropriately resolved.

Cytokines are secretion proteins that mediate and regulate immunity and inflammation. They are crucial in the progress of acute inflammatory diseases and autoimmunity. In fact, the inhibition of proinflammatory cytokines has been widely tested in the treatment of rheumatoid arthritis (RA). Some of these inhibitors have been used in the treatment of COVID-19 patients to improve survival rates. However, controlling the extent of inflammation with cytokine inhibitors is still a challenge because these molecules are redundant and pleiotropic. Here we review a novel therapeutic approach based on the use of the HSP60-derived Altered Peptide Ligand (APL) designed for RA and repositioned for the treatment of COVID-19 patients with hyperinflammation. HSP60 is a molecular chaperone found in all cells. It is involved in a wide diversity of cellular events including protein folding and trafficking. HSP60 concentration increases during cellular stress, for example inflammation. This protein has a dual role in immunity. Some HSP60-derived soluble epitopes induce inflammation, while others are immunoregulatory. Our HSP60-derived APL decreases the concentration of cytokines and induces the increase of FOXP3+ regulatory T cells (Treg) in various experimental systems. Furthermore, it decreases several cytokines and soluble mediators that are raised in RA, as well as decreases the excessive inflammatory response induced by SARS-CoV-2. This approach can be extended to other inflammatory diseases.

## KEYWORDS

HSP60, APL, cytokines, inflammation, rheumatoid arthritis, CIGB-814/CIGB-258, COVID-19, Jusvinza

# 1 Introduction

Cytokines are molecules with relatively low molecular weights. These proteins are secreted by several immune cells (1, 2). Some cytokines are pro-inflammatory and others are anti-inflammatory. Consequently, they act mostly as regulators of immune and inflammatory responses (3–5).

Additionally, cytokines have important functions in a diversity of biological events including cell activation, differentiation, and proliferation (6, 7). Furthermore, cytokines play a crucial role in acute and chronic inflammation, and tumor progression, as well as in the onset and chronicity of autoimmune diseases (1, 6, 8).

The inhibition of proinflammatory cytokines has been used in the treatment of autoimmune diseases such as RA (9–11). Some of these drugs were repositioned in the management of COVID-19 patients (12, 13). However, controlling hyperinflammation with cytokine inhibitors is still a challenge, because these molecules are redundant and pleiotropic (14, 15). Likewise, these drugs are immunosuppressive and they can lead to the fall of the general condition of COVID-19 patients (16–18).

In this article, we focus on an original approach to the control of inflammation using an APL derived from HSP60. This therapeutic concept is focused on the induction of peripheral tolerance using a modified autoantigen implicated in RA pathogenesis. HSP60 was the autoantigen chosen for the APL design. Interestingly, this protein plays a dual role in immunity, i.e. certain soluble HSP60-derived epitopes induce inflammation and others are immunoregulatory (19–23).

The APL designed has anti-inflammatory properties and increases Treg in preclinical models of RA (24, 25). Clinical investigations in RA patients indicate that this molecule is safe and reduces inflammation (26–28).

Based on these results we decided to investigate whether this molecule could be useful in treating the hyperinflammation that distinguishes COVID-19 patients who are progressing to severe and critical conditions. The treatment with this peptide inhibited several cytokines and soluble mediators associated with hyperinflammation in COVID-19 patients (29, 30).

Given all these results, the anti-inflammatory effects of this molecule are assessed in other experimental models of inflammation.

# 2 HSP60, autoantigen selected for APL design

Among the autoantigens involved in RA pathogenesis, we selected HSP60 for the APL design. This selection was supported by the therapeutic potential of HSP60 for autoimmune diseases. We hypothesized that an APL derived from HSP60 would enhance these therapeutic effects.

HSP60 is extremely conserved in evolution (31, 32). This protein is classified as a chaperone and is located inside the mitochondria where, together with the co-chaperonin Hsp10, it assists in protein homeostasis (33, 34).

However, under certain physiological conditions, HSP60 is located in other cellular organelles and it can even appear in the extracellular space. At these sites, HSP60 participates in pathogenic events such as inflammation, autoimmunity and carcinogenesis (35, 36).

HSP60 has an interesting connection with innate and acquired immune response, which is related to its conservation through evolution and its chaperone function.

This molecule has been described as an innate signal for macrophages and dendritic cells. Macrophages in reaction to HSP60 produce pro-inflammatory molecules (37–39). HSP60 stimulates the maturation of dendritic cells (40).

This chaperone was identified as a dominant bacterial antigen during infections or vaccination. Both biological events are characterized by the secretion of antibodies to bacterial HSP60 (41). Moreover, autoantibodies to self-HSP60 are identified in several autoimmune diseases such as RA, lupus, inflammatory bowel disease and atherosclerosis (42–46).

Furthermore, autoantibodies against HSP60 are present in healthy subjects; for example, an Ig M iso-type autoantibody against HSP60 was identified within the blood of the umbilical cord of some newborns (47), and IgM and IgG autoantibodies against HSP60 were identified in healthy human beings (48).

On the other hand, epitopes derived from mycobacterial HSP65 that are identical to the HSP60 human peptide, induced cytotoxic T cell reactivity in healthy humans (20). Besides, T cells against HSP60 self-peptides were found in the blood of the umbilical cord of healthy neonates (39). These facts indicate that it is normal to find effector T cells to self-HSP60 from birth.

Cohen hypothesized that HSP may be included in the “immunological homunculus”, which comprises several dominant antigens involved in an intricate biologic regulatory network (40).

Other authors have described that T cells to self-HSP60 are related to spontaneous remission in juvenile idiopathic arthritis (41, 42) and induce resistance to induction of experimental arthritis in Lewis rats (43–45). T cells against HSP60 that secreted IL-10 can be favorable in attenuating inflammation during autoimmune diseases and harmful in infections (42, 46, 47). In contrast, T cells vs HSP60 that produce proinflammatory cytokines can be damaging in autoimmune diseases and beneficial against pathogens (48).

Studies about HSP60 have progressively increased in recent years, mainly because of its potential as an approach for emerging therapeutic procedures in inflammatory diseases and severe chaperonopathies such as several kinds of cancer, as well as inflammatory and autoimmune diseases and neurodegenerative diseases (36, 49–52).

Particularly, since the regulatory effect of HSP60 on the immune response is well defined, several authors have proposed different approaches for its use in the treatment of autoimmune diseases (22, 23). Regardless of the potential risks of generating adverse inflammatory effects, diverse formulations of HSP60 and peptides derived from it, have been studied in experimental models without observing pathological autoimmunity (53).

Furthermore, reports show the use of the immunomodulatory properties of HSP60 and its peptides in clinical trials for

autoimmune diseases (54–57). However, none of these therapeutic candidates have become registered drugs.

We believe that there are key points in the success of the treatments based on peptides derived from HSP60 for their use in inflammation and the reduction of pro-inflammatory cytokines, i.e., the selection of a specific epitope, the biodistribution of this molecule and the frequency of its administration.

### 3 An APL designed from HSP60 as an inducer of peripheral tolerance

The identification of an epitope from HSP60 is a critical factor for induced peripheral tolerance as a possible treatment for autoimmune diseases.

The potential of the APLs as tolerance inducers has been previously reported (58–60). APLs are similar to the wild-type peptide but with one or two mutations in the essential interaction positions with the T-cell receptor (TCR) or with the HLA class II molecules that modify the pathways for the activation of T cells. These APL can modify the response of autoreactive T cells by several mechanisms (60–64).

In contrast with other authors, we selected the N-terminal sequence from human HSP60 (amino acids 90 to 109). This region is much conserved, it is 100% identical in humans, monkeys, fish, rats and mice, but the match is 50% with *Mycobacterium tuberculosis* (Mt). In this sequence, the ProPred computer algorithm (65) predicted new epitopes that would be interacting directly with the HLA class II molecule associated with RA. Aspartic acid 18 was substituted by leucine (Figure 1). This mutation increased the affinity between APL and HLA class II molecules, according to the bioinformatic prediction (24).

Furthermore, potential binding motifs (cores) of this APL and its wild type peptide (E18-3), and the affinity of both to HLA class II alleles related with RA, were analyzed by the NetMHCIIpan platform (66, 67). This algorithm indicated that APL has two possible overlapping epitopes. A notable feature is that the replacement of Asp-18 in E18-3 with a Leu raises the affinity of APL to HLA class II. Predictions using NetMHCIIpan advise that the novel peptide binds to more RA related HLA class II molecules and has a better affinity than E18-3 (68).

This novel peptide was called APL-1 or CIGB-814 in preclinical and clinical studies in RA. This peptide was renamed CIGB-258 during clinical research in COVID-19 patients. Subsequently,

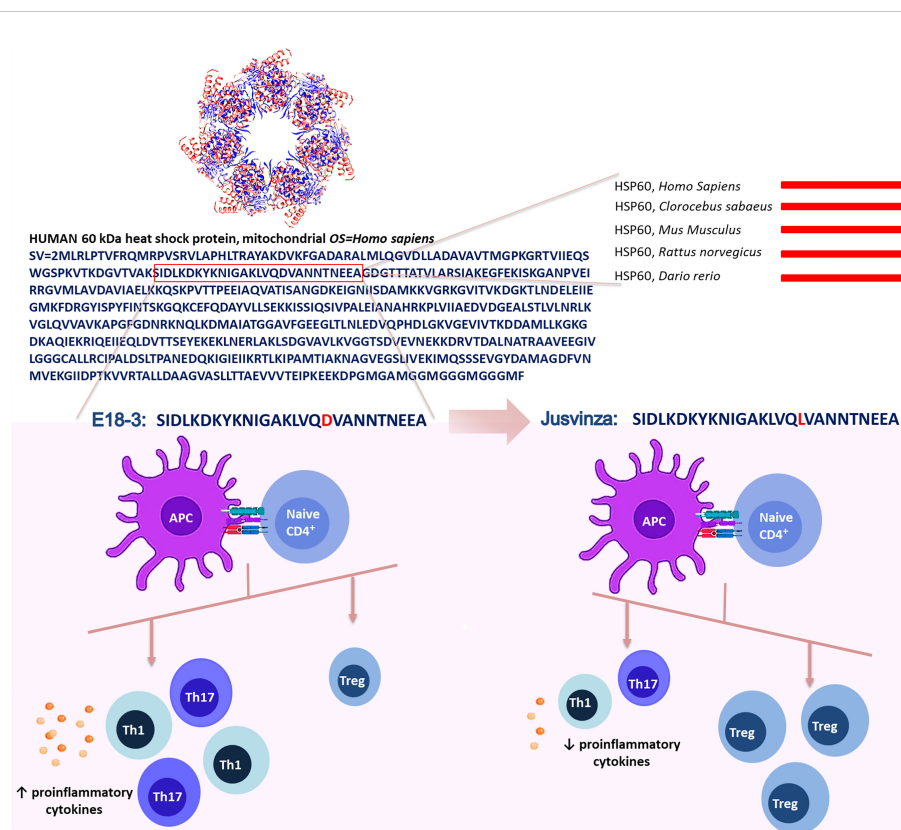

FIGURE 1

Jusvinza was designed from the N-terminal region of the human HSP60 (amino acids from 90 to 109). This sequence is 100% identical between humans, rats, mice, monkeys and Zebrafish (lines red). In this region, the aspartic acid-18 (red) involved in the interaction with the HLA class II molecule was substituted by leucine (red). This change increased the affinity between Jusvinza and HLA class II molecules. Jusvinza induces an increase of FOXP3+ regulatory T cells (Treg) and reduces proinflammatory cytokines. In contrast, the wild-type peptide did not induce Treg cells and increase proinflammatory cytokines.

CIGB-258 was granted Authorization for Emergency Use (AEU) by the Cuban Regulatory Authority for COVID-19 patients under the commercial name of Jusvinza.

## 4 Biodistribution and pharmacokinetics (PK) of Jusvinza

The biodistribution profile of a drug is essential in activating the molecular mechanisms that induced peripheral tolerance. Hence, depending on the organ where the drug is positioned, it may be able to interact with antigen-presenting cells (APC), T cells and cytokines that mediate the induction of tolerance.

The biodistribution of a peptide can be affected by the dose, as well as by the inoculation route. Jusvinza was mainly distributed in the stomach and small intestine, after being inoculated in Lewis rats. The levels of Jusvinza increased in lymph nodes (LNs) at 24 hours, compared to four hours postadministration. This peptide was likewise found in the liver, spleen, heart and lungs (Figure 2A). The biodistribution of Jusvinza was almost the same for the three routes studied (subcutaneous, intravenous and intradermal routes) (69). This biodistribution profile is interesting because the small intestine is specialized in the induction of tolerance (70).

In addition, the highest concentration of Jusvinza in the blood plasma of rats was found at 0.5 to 1 hour; and the half-life in the

blood was calculated to be of six hours. These results agree with the PK profile identified in RA patients included in the Phase I Clinical Trial (27).

Recently, we have identified that Jusvinza binds only with apolipoprotein A-I (Apo-AI) and transthyretin in human plasma. The identification of these proteins were through affinity chromatography using as the matrix a pearl-shaped resin (ChemMatrix) - coupled to Jusvinza. The eluted proteins were accurately identified by mass spectrometry (nano ESI-MS). Apo-AI and transthyretin are involved in lipid metabolism, and changes in their conformation and concentration have been associated with diseases such as type II diabetes and atherosclerosis. These results agree with those of Cho et al, who demonstrated that Jusvinza enhanced HDL stability (71).

Future research is needed to elucidate the biological significance of the binding of Jusvinza to Apo-AI and transthyretin.

## 5 Jusvinza reduces inflammation and TNF $\alpha$ in two animal models for RA

The biological effect of Jusvinza was assessed in an experimental model in rats (72). Jusvinza has an epitope that could be bound to rat MHC class II molecules (RT1.BI); according to the MHC2PRED software (73). In this animal model, the disease is induced in rats

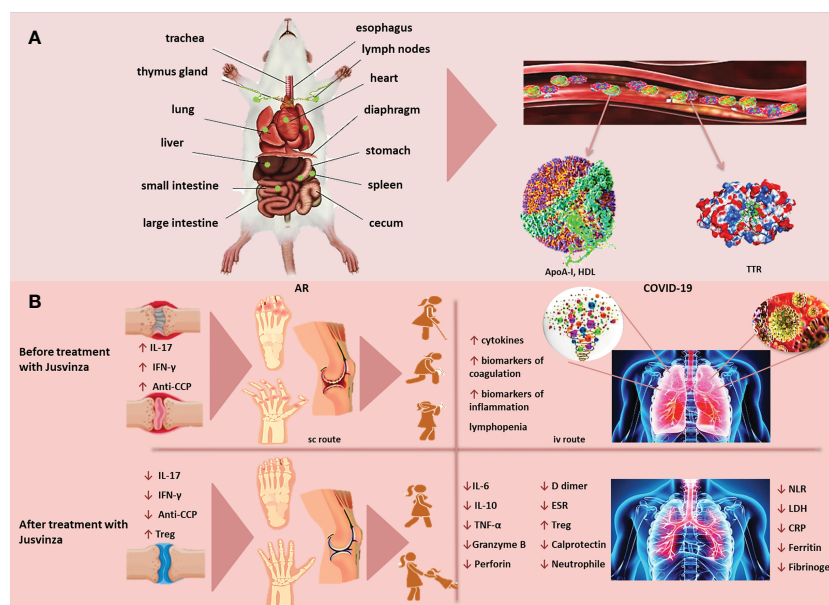

FIGURE 2

(A) Jusvinza is mainly distributed to the stomach and small intestine, as early as 4 hours post-administration. The concentration of Jusvinza increased in lymph nodes (LNs) at 24 hours post-administration. This peptide was also found in the liver, spleen, heart and lungs in Lewis rats. Jusvinza binds apolipoprotein A-I (Apo-AI) and transthyretin (TTR) in plasma. (B) Jusvinza reduces inflammation in animal models and RA patients. The processing and presentation of this APL by the antigen-presenting cells (APC) to the autoreactive T lymphocytes in the periphery could induce the expansion of Treg. These cells migrate to the swollen joints and attenuate autoreactive T cells responsible for arthritis pathogenesis. In addition, Jusvinza reduces TNF $\alpha$ , IL-17, interferon-gamma (IFN- $\gamma$ ), anti-CCP antibodies and neutrophil migration. Jusvinza reduces hyperinflammation in COVID-19 patients. Jusvinza can inhibit the activity of monocytes, macrophages and neutrophils. This inhibition may contribute to the decrease of IL-6, TNF $\alpha$  and IL-10, as well as the restoration of lymphocyte counts in patients. Additionally, this peptide can induce Treg. These activated cells migrate to inflamed sites and could cross-recognize the wild-type epitope from HSP60 expressed in the endothelial tissue and inhibit autoimmune damage induced during viral infection.

through immunization with *Mt* in incomplete Freund's adjuvant (AA). Jusvinza reduced the inflammation and pannus in these rats with arthritis.

However, the original epitope from HSP60 did not produce these therapeutic effects in rats. Besides, the treatment with Jusvinza significantly reduces TNF $\alpha$  levels in the spleen of treated animals compared to the placebo group. This clinical efficacy induced by Jusvinza was associated with an increase of Treg in the rats.

The AA model is characterized by the fact that immunization with *Mt* protects against subsequent attempts to induce this disease. This effect is due to the induction of Treg against a conserved epitope from HSP60 (aa from 256 to 270) and the secretion of regulatory cytokines (41, 74). These factors could favor the therapeutic effect of Jusvinza in the AA model. Hence, it was essential to assess the therapeutic effect of Jusvinza in another animal model, in which Treg cells are not induced against HSP60 in the course of the disease.

Consequently, the therapeutic effect of Jusvinza was evaluated in Collagen Induced Arthritis (CIA) in DBA/1 mice (75). Jusvinza monotherapy was able to reduce inflammation in these mice. The therapeutic effect was similar to mice inoculated with Jusvinza plus methotrexate (MTX) (25). Furthermore, pannus development was not detected in mice treated with Jusvinza. This indicates that the migration of macrophages and neutrophils did not take place in the joints of mice treated with this peptide.

These results were also linked to a decrease in TNF $\alpha$  levels. This cytokine is crucial for the onset and chronicity of RA. TNF $\alpha$  can stimulate proinflammatory cytokine production, increasing the expression of adhesion molecules and neutrophil activation, and enhancing antibody secretion by plasmatic cells (76–78).

Contrary to the effect in the spleen of AA rats treated with Jusvinza, Treg was not detected in CIA mice. Nevertheless, the treatment with Jusvinza plus MTX induced Treg in the spleen of CIA mice. The molecular mechanism of MTX is not associated with an induction of Treg in mice (79). But, the decrease of TNF $\alpha$  mediated by MTX can favor the induction of Treg by Jusvinza. The results suggest that MTX plus Jusvinza could have a molecular synergic effect in the CIA model.

Jusvinza reduced inflammation in AA and CIA models mediated by the expansion of Treg at the periphery. These cells could migrate to the swollen joints and decrease autoreactive T cell activity that perpetuates arthritis, blocking the production of proinflammatory cytokines and the consequent neutrophil migration.

## 6 Jusvinza induces Treg with suppression activity and reduces IL-17 secreted by Th17

Jusvinza induced Treg in draining lymph nodes and spleen from healthy BALB/c mice. At the same time, the wild-type epitope of HSP60 recruits more CD4<sup>+</sup> FoxP3<sup>+</sup> T lymphocytes, showing that the mutation of the wild-type peptide was effective in inducing Treg and reinforces the beneficial potentials of Jusvinza for the management of RA patients (24).

In addition, experiments with peripheral blood mononuclear cells (PBMC) from RA patients indicate that Jusvinza induces Treg (24, 80). In contrast, the wild-type peptide did not induce Treg (24).

Furthermore, autologous cross-over experiments showed that Jusvinza-treatment had a significant effect in reducing IL-17 levels. Jusvinza can induce Tregs and its suppressive activity against antigen-specific T lymphocytes cells, whereas the activated T effector cells produce less IL-17 (68).

The change of sequence produced in Jusvinza could increase Treg in RA patients and specifically inhibit autoreactive T cells. Treatment with Jusvinza could help restore the healthy Th17/Treg balance for patients with RA and other autoimmune diseases.

## 7 Jusvinza reduces inflammation, proinflammatory cytokines and autoantibodies against cyclic citrullinated peptides (anti-CCP) in RA patients

The safety of Jusvinza was assessed in patients with RA, during an open phase I clinical trial. Twenty patients with moderately active RA were involved in this study. Three doses (1, 2.5 and 5 mg) of Jusvinza were evaluated by the subcutaneous route. This study included the restriction of the use of non-steroidal anti-inflammatory drugs, disease-modifying anti-rheumatic drugs and corticosteroids, as of four weeks before the start of the Jusvinza treatment. Clinical response in patients was assessed following the guidelines of the American College of Rheumatology and Disease Activity Score in 28 joints. Function and health-related quality of life, quantification of inflammatory biomarkers and radiographic changes in patients were also evaluated.

Jusvinza was well tolerated at all doses. The adverse effects detected were minor and reversible, essentially irritation at the inoculation site. Treatment with this peptide diminished disease activity and magnetic resonance imaging score in patients. This treatment enhanced the health-related quality of life of all patients included in the study. Moreover, Jusvinza significantly reduced IL-17 and interferon-gamma (IFN- $\gamma$ ) in patients (26).

RA is mediated by autoreactive T lymphocytes, with TH1 and TH17 phenotypes. However, antibodies against citrullinated self-proteins have a pathogenic role in this disease. Anti-CCP antibodies are related to a fast course of RA, primary erosive damage, increased inflammation and disability in patients (80).

Jusvinza induced a significant reduction of anti-CCP antibodies in patients (28). These results suggest that Jusvinza could inhibit B lymphocytes that produce these pathogenic antibodies.

Another explanation is related to the possible induction of Treg by Jusvinza in patients. This peptide increases Tregs in some experimental models (24, 25). Tregs have different mechanisms of action that may depend on cell contact, through which they can induce apoptosis on effector T cells and plasma cells secreting anti-CCP antibodies (81). Interestingly, Jusvinza decreased the viability of PBMC isolated from RA patients by inducing apoptosis (82).

Furthermore, Jusvinza might affect the citrullination process by decreasing IL-17. Interactions with viruses or bacteria that activate NETosis are the leading sources of protein citrullination in RA (83). NETosis is a type of regulated cell death dependent on the formation of neutrophil extracellular traps. Some studies describe that HSP60 disturbs the effector functions of neutrophils, i.e. HSP60 enhances the phagocytic activity of neutrophils (84); bacterial HSP GroEL from *Staphylococcus epidermidis* biofilms promoted ADN decondensation and induced NETosis (85); inflammatory cytokines can lead to NETosis in neutrophils from RA patients (86). Specifically, IL-17 has widespread inflammatory effects on the joints, inducing bone and cartilage erosions and promoting the migration of inflammatory molecules to the synovia (87). This cytokine plays an important role in the regulation of anti-citrullinated protein antibody secretion (88).

Jusvinza decreases IL-17 and soluble mediators as anti-CCP antibodies, and it can stimulate the activation of the suppressive activity of Tregs (24, 68) (Figure 2B). Therefore, all results confirm the beneficial effect of Jusvinza and its possible medical application in the reduction of inflammation in RA and other inflammatory diseases.

## 8 Jusvinza reduces cytokines involved in the “cytokine storm” and soluble mediators of inflammation in COVID-19 patients

The clinical spectrum of COVID-19 is very widespread and complex. Patients may range from asymptomatic cases to those showing a rapid progression toward acute respiratory distress syndrome (ARDS) and death (89). Patients progressing to severe stages present an exacerbated inflammatory response, evidenced by the increase in the serum concentration of inflammation biomarkers (90). A group of these patients progresses to cardiovascular collapse, multiple organ failure, and death. Under these conditions, the treatments used for inflammatory chronic diseases have been repositioned to reduce hyperinflammation in COVID-19 patients (91, 92).

The anti-inflammatory effects of Jusvinza in several experimental models of RA are associated with TNF $\alpha$  reduction and Treg induction. At the same time, the therapeutic effect and the reduction of IL-17, IFN $\gamma$  and autoantibodies against citrullinated self-proteins in RA patients (24, 26, 28, 68, 80) were the rational bases in the proposal of this molecule for the management of hyperinflammation in COVID-19 patients. Consequently, the Cuban Regulatory Authority approved the exploratory use of this peptide for COVID-19 patients in critical and serious conditions.

Exploratory studies in COVID-19 patients revealed that this APL promotes clinical and radiological improvement linked to a decrease in systemic inflammation biomarkers and IL-6, TNF $\alpha$  and IL-10 (29, 93). The treatment with this peptide was granted the AEU by the Cuban Regulatory Authority for COVID-19 patients (94). After this AEU, Jusvinza was included in the Cuban guidelines

for the management of COVID-19 patients with signs of hyperinflammation (95).

High levels of IL-6, associated with disease severity, have been widely described in COVID-19 patients (96, 97). IL-6 is considered one of the most important cytokines in infections, along with IL-1 and TNF- $\alpha$  (98). Jusvinza reduced IL-6 levels linked to the clinical improvement of patients (29).

TNF- $\alpha$  stimulates an ongoing inflammatory response associated with autoimmune diseases (99, 100). TNF- $\alpha$  is a pro-inflammatory cytokine that can support T cell apoptosis by interacting with its receptor (101, 102). This cytokine is essential in the pathogenesis of lung fibrosis and SARS-CoV-2 infection (103). Interestingly, TNF- $\alpha$  is significantly reduced with Jusvinza therapy (29).

On the other hand, critically ill COVID-19 patients display an increase of IL-10 related to a worsening of this disease (104). IL-10 is a cytokine with many pleiotropic properties in immunoregulation and inflammation (105). The coronaviruses have intricate mechanisms that use the immunoregulatory function of IL-10 for immune evasion, helping virus replication (106). An association between a high concentration of IL-10 with the fall and functional exhaustion of CD8+ and CD4+ T cells has been found in COVID-19 patients (107), indicating that this cytokine plays a key role in SARS-CoV-2 pathogenesis. The Jusvinza treatment led to IL-10 reduction after 96 hours of therapy. This reduction was associated with the clinical improvement of patients (29). IL-10 is secreted by macrophages, monocytes and T cells. However, T cells can not contribute to the high concentration of IL-10 because these patients are characterized by a marked lymphopenia, typical of COVID-19. Jusvinza diminishes monocyte and macrophage counts under cell stress (82). This is possibly the mechanism through which IL-10 is reduced in COVID-19 patients treated with Jusvinza. Besides, the reduction of IL-6 and TNF- $\alpha$  could downregulate IL-10.

Furthermore, high concentrations of calprotectin (S100A8/A9) are associated with negative clinical results in COVID-19 patients (108). Jusvinza reduces calprotectin in sera from COVID-19 patients and this reduction was correlated with the contraction in neutrophil count. These results are interesting because calprotectin is also increased in patients with chronic inflammatory diseases, inducing cytokine production (109).

Lymphopenia, with significantly reduced numbers of T lymphocytes, has been described in severe COVID-19 patients. This lymphopenia is related to the functional activities of cytotoxic T lymphocytes in COVID-19. Natural killer cells, total T cells, as well as CD8+ T cells, are lower in patients showing severe disease than in healthy persons (110).

Likewise, Granzyme B and perforin are increased in CD8+ T cells in severely ill patients (111). Both proteins decreased in the serum 96 hours after the treatment with Jusvinza. This reduction was related to the stabilization of lymphocyte and neutrophil counts in the patients (29).

Additionally, Tregs are significantly reduced in severely ill COVID-19 patients (112, 113). Jusvinza induces Tregs in seriously ill COVID-19 patients (29). Gammazza et al. identified an epitope from HSP60 that is common with the SARS-CoV-2 replicase polyprotein 1ab. These authors suggested that post-

translational modifications during metabolic stress produced by hypertension and diabetes could disturb HSP60 localization and induce an endothelial injury (114). The beneficial result of Jusvinza in COVID-19 patients could be facilitated by the induction of Treg. These cells migrate to inflamed tissues and could cross-recognize the wild-type peptide from HSP60. This new “cross-talk” could induce regulatory mechanisms that would reduce autoimmune damage in the endothelium produced by viral infection. Moreover, Jusvinza could inhibit the activity of neutrophils, monocytes and macrophages. This inhibition may influence the decrease of several proinflammatory cytokines and soluble mediators of inflammation, as well as the increase of lymphocyte counts (Figure 2B). All these effects could resolve exacerbated inflammation and contribute to a positive outcome for the patients.

These results are the premise for the evaluation of the anti-inflammatory effect of Jusvinza in other experimental models of inflammation.

## 9 Anti-inflammatory activity of Jusvinza against acute toxicity induced by carboxy methyl lysine in Zebrafish

High levels of inflammatory cytokines have characterized severe stages of COVID-19 (113), autoimmune diseases and inflammatory chronic diseases (115). The non-enzymatic glycation of proteins and carbohydrates induces some glycation end products, related to hyperinflammation (116). The glycation of high-density lipoproteins (HDL) is associated with the dysfunctional activity of this lipoprotein (117), which could enhance inflammation. Glycated HDL were found to be toxic in different human cells (118, 119), and in Zebrafish and its embryos, producing reactive oxygen species and showing a slower development rate (120).

Zebrafish (*Danio rerio*) is a routinely used model to assess the toxicity of advanced glycation end products (120) and to evaluate the anti-inflammatory effect of therapeutic candidates.

Recently, Cho et al. studied the therapeutic effect of Jusvinza against inflammation induced by N<sup>ε</sup>-carboxymethyl lysine (CML) in Zebrafish embryos and adults (71). High concentrations of CML have been identified in the serum of patients with diabetes mellitus and atherosclerosis (121, 122). These patients also showed extremely high inflammatory cytokines, such as IL-1 and TNF $\alpha$ , indicating that a high CML concentration is linked to a pro-inflammatory condition (123). CML produced an important glycation and aggregation of HDL that disturbs the structure and function of HDL, which is linked to a reduction in apolipoprotein A-I stability (118).

Microinjection of CML in Zebrafish embryos produces high embryonic death rates, where survival is of only 18% of the fish showing developmental defects. However, Jusvinza co-injection induces a significant increase in survival and normal development of the fish. Furthermore, an intraperitoneal inoculation of CML in adult Zebrafish produced acute paralysis, sudden death, and affected its swimming capacity through hyperinflammation. But, a co-inoculation of Jusvinza caused a quicker recovery of swimming

capacity and a higher survivable rate. Interestingly, the group treated only with CML showed a survival rate of 49%, while the group treated with CML and inoculated with Jusvinza had a survival rate of 97%, with a significant decrease in liver inflammation.

On the other hand, these authors compared the efficacy of Jusvinza, Infliximab (Remsima®), and Tocilizumab (Actemra®) in the model of the acute death of Zebrafish induced by CML. The results showed that the Jusvinza group had a quicker recovery and swimming capacity, with a higher survivable rate than the Remsima® group (71).

## 10 Conclusions and perspectives

This review describes an important translational research outcome; from the design of an APL for the induction of tolerance in RA, followed by its assessment in experimental models, and finally the treatment of the inflammation that characterizes RA and COVID-19 patients.

The anti-inflammatory effect of Jusvinza constitutes an attractive therapeutic approach for an extensive variety of diseases, characterized by inflammation and high levels of proinflammatory cytokines, such as autoimmune diseases, COVID-19, atherosclerosis, diabetes and neurodegenerative diseases.

High doses of interleukin-2 (IL-2) have been used for the treatment of melanoma and renal cell carcinoma, but this therapy has limited efficacy, with a ~15% response rate. Remarkably, 7%–9% of patients achieve complete or long-lasting responses. Many patients treated with IL-2 experienced an expansion of regulatory T cells (Tregs), specifically the expansion of ICOS<sup>+</sup> highly suppressive Tregs, which correlate with worse clinical outcomes. This partial efficacy together with the high toxicity associated with the therapy has limited the use of IL-2-based therapy. Taking into account the understanding of IL-2 structure, signaling, and *in vivo* functions, some efforts to improve the cytokine properties are currently under study. In previous work, we described an IL-2 mutein with higher antitumor activity and less toxicity than wtIL-2. Mutein was *in silico* designed for losing the binding capacity to CD25 and for preferential stimulation of effector cells CD8<sup>+</sup> and NK cells but not Tregs. Mutein induces a higher anti-metastatic effect than wtIL-2, but the extent of the *in vivo* antitumor activity was still unexplored. In this work, it is shown that mutein induces a strong antitumor effect on four primary tumor models, being effective even in those models where wtIL-2 does not work. Furthermore, mutein can change the *in vivo* balance between Tregs and T CD8<sup>+</sup> memory/activated cells toward immune activation, in both healthy and tumor-bearing mice. This change reaches the tumor microenvironment and seems to be the major explanation for mutein efficacy *in vivo*.

## KEYWORDS

IL-2 mutein, treg, cancer therapy, CD8<sup>+</sup> T cells, TME

**Abbreviations:** Foxp3, forkhead box P3 transcription factor;  $\gamma_c$ , common  $\gamma$ -chain; IL-2R, IL-2 receptor; IU, international units; Tregs, regulatory T cells; wtIL-2, wild-type human IL-2.

## Introduction

IL-2 is a cytokine with a pivotal role in the control of immune system homeostasis, acting on both effector and regulatory lymphocytes (1). The IL-2 binds to the multimeric IL-2 receptor (IL-2R) expressed on different lymphocyte subsets and induces lymphocyte survival, proliferation, and activation. The heterotrimeric IL-2R is composed of three subunits: IL-2R $\alpha$  (CD25), IL-2R  $\beta$  (CD122), and IL-2R $\gamma$  (CD132). The IL-2R $\beta$  and IL-2R $\gamma$  chains are responsible for signaling and together form the dimeric intermediate affinity receptor (KD  $\sim$  1 nM) highly expressed on memory phenotype (MP) CD8<sup>+</sup>CD44<sup>hi</sup> and NK cells (2). The  $\alpha$ -chain (CD25) is expressed constitutively on CD4<sup>+</sup>Foxp3<sup>+</sup>Tregs (3) and transiently on activated CD4<sup>+</sup> and CD8<sup>+</sup> T cells (4) and together with IL-2R $\beta$  and IL-2R $\gamma$  forms the high-affinity IL-2R (KD  $\sim$  1 pM) (5, 6).

Based on its immune-stimulatory activity, IL-2 has been used in the treatment of advanced melanoma and renal cell carcinoma, but its high toxicity precludes its extended use (7). Nevertheless, it is notable that 15%–30% of treated patients experienced clinical improvements including long-lasting responses (8). However, some patients became unresponsive to the therapy, probably associated with the expansion of the highly suppressive ICOS<sup>+</sup>Tregs (9, 10). As IL-2-based therapy has not reached the expectancy, improving the IL-2 therapeutic index is still an active and important topic. Among other examples are the immunocytokine format for directing IL-2 to the tumor cells (11, 12), IL-2 fusion with the IgG-Fc region to increase the molecule half-life (13), or increasing the half-life and changing molecular properties with site-directed pegylation that has been assayed (14). Moreover, the design and evaluation of different muteins seem to be reasonable to increase therapy efficacy (15, 16). One of the ideas is to change the IL-2 distribution among different lymphocyte populations, based on the differential expression of IL-2R $\alpha\beta\gamma$  or IL-2R $\beta\gamma$ . We previously described a mutein, named no-alpha, with a severe decrease in affinity to CD25 (16). No-alpha mutein behaves as an agonist with higher antitumor activity but lower toxicity than wtIL-2. In the present work, we extended the demonstration of the antitumor capacity of no-alpha mutein to four primary tumor models and survival induction in two spontaneous metastases models. Mutein was originally designed to induce preferentially CD8<sup>+</sup> and NK *in vivo* expansion and activation, but this issue remained to be fully demonstrated *in vivo*. Here we demonstrate that mutein can change the CD8<sup>+</sup>MP/Treg balance *in vivo* in both healthy and tumor-bearing mice. This change toward immunity reaches the tumor microenvironment, and it is mainly due to the specific increment in CD8<sup>+</sup> T-cell proliferation without any important change in Treg accumulation or activation.

## Methods

### Mice

Seven- to eight-week-old female C57BL/6 and BALB/c mice were obtained from The National Center for Laboratory Animal Breeding (Havana, Cuba), Animal Resources Centre, IBS Pohang Institute of Basic Science (Pohang, Korea), or Instituto Gulbenkian de Ciencia (Oeiras, Portugal). Food and water were administered *ad libitum*. The experiments were performed according to the International Guidelines for the Care and Use of Laboratory Animals, using standardized procedures of the three institutes.

### Production and purification of hIL-2 no-alpha mutein from insoluble material

The hIL-2 no-alpha mutein was produced in *Escherichia coli*, and the isolation of inclusion bodies and purification of the protein were performed as previously described (16). Briefly, the frozen pellets were suspended in 10 mM of Tris and 1 mM of EDTA (pH 8) (TE) and sonicated using an ultrasonic cell disrupter (IKA, Wilmington, NC, USA). The insoluble material was harvested by centrifugation (18,000  $\times$ g) and washed successively with 4 M of urea-TE and 1% Triton X-100-TE using an Ultra Turrax T8 homogenizer. For further purification, a GE AKTA explorer system was used; the protein was extracted with 6 M of guanidinium hydrochloride-TE at 0.1 g/ml (wet weight), and renaturation was carried out by dialysis. For further purification, protein was applied to a reverse-phase C4 column (Vydac). In this final chromatography, the recombinant polypeptides were purified using an H<sub>2</sub>O-acetonitrile-trifluoroacetic acid system, with a linear gradient (30%–85% of acetonitrile) and 0.6 ml/min flow. Finally, the proteins were dialyzed against 10 mM of acetate (pH 4), filtered through 0.2- $\mu$ m filters, and stored at 4°C. The molecule was tested for low endotoxin levels, and the biological activity was evaluated using the CTLL-2 cell proliferation assay.

### *In vivo* effect on T-cell populations

Healthy mice were treated with wtIL-2 (20,000 or 40,000 international units (IU)) or no-alpha mutein (200 or 400 IU) for 6 days twice a day. After the treatments, the spleens were harvested, and the cell suspension was obtained, stained, and analyzed by flow cytometry. For assessing BrdU incorporation, mice were fed with BrdU in the water 3 days before sacrifice. The BrdU staining was performed with the specific kit from BD Biosciences (San Jose, CA, USA) following the fabricant instructions.

## Antibodies and flow cytometry

All fluorochrome-conjugated mAbs used for flow cytometry measurement were from Thermo Fisher (Waltham, MA, USA) unless otherwise stated: fluorescein isothiocyanate (FITC) or BV-conjugated anti-CD3 (145-2C11), PE or APC-conjugated anti-CD4 (L3T4), PB or FITC-conjugated anti-Foxp3 (NRRF-30), PE-Cy7-conjugated anti-CD25(3C7), APC-Cy7-conjugated anti-CD8 (eBio H35-17.2), BV605 or APC anti-CD44 (IM7), PE-conjugated anti-CD122(5H4), and APC-conjugated anti-CD45(30-F11). Intracellular Foxp3 staining sets were purchased from eBioscience (San Diego, CA, USA). Live/dead fixable near IR dye from Thermo Fisher Scientific was used for dead cell discrimination. Samples were measured using a flow cytometer Gallios (Beckman Coulter, Brea, CA, USA) or LSR Fortessa (Becton Dickinson, Franklin Lakes, NJ, USA) and analyzed using Kaluza software or FlowJo software (TreeStar, Inc., San Carlos, CA, USA).

## Tumor challenges and treatments

Mouse transplantable tumor cell lines used melanoma MB16, colon CT26, mammary tumor 4T1, lung carcinoma 3LL-D122, and lung carcinoma TC1 cells maintained in Dulbecco's modified Eagle medium (DMEM) F12 (GIBCO, Grand Island, NY, USA) supplemented with 10% heat-inactivated fetal bovine serum, 2 mM of L-glutamine, 50 U/ml of penicillin, 50 µg/ml of streptomycin. All cells were maintained at 37°C under a humidified 5% CO<sub>2</sub> atmosphere. Tumor cells were harvested using trypsin/EDTA and resuspended in phosphate-buffered saline (PBS) for *in vivo* experiments. All the tumor cells were inoculated in the right flank s.c., except the 4T1 cells that were inoculated in the mammary gland and the 3LL-D122 cells that were inoculated in the footpad. For the 3LL-D122 spontaneous metastasis model, the primary tumors were eliminated by surgery when they reached a diameter of 9 mm. Treatments consisted of two cycles of five daily i.p. injections of PBS, wtIL-2 (30,000 IU), or no-alpha mutein (300 IU) twice a day, and the cycle was repeated after one resting week. Tumor size was assessed using a microcaliper every 3 days, and the tumor volume was calculated using the following formula: (width<sup>2</sup> × length)/2. For the spontaneous metastases models with 3LL-D122 and 4T1 cells, the mouse survival was also monitored periodically for 80 days. For tumor-infiltrating lymphocyte evaluation, tumors were mechanically dissociated. First, the tumors were cut into small pieces and then meshed through a 70-µm cell strainer using a syringe plunger. The obtained cell suspensions were centrifuged, stained, and analyzed by flow cytometry.

## Data and statistical analysis

For statistical analysis, the Graph Pad Prism 4.0 software was used. For comparison of the CD8/Treg ratios, and BrdU incorporation levels in healthy mice parametric ANOVA followed by Tukey's multiple comparison test were applied. In the antitumor assays, a two-way ANOVA followed by Bonferroni's test was applied for comparison of the tumor curves; for survival analysis, the log-rank test was used. In the case of CD8/Treg ratio in tumor-bearing mice, the Kruskal-Wallis test followed by Dunn's test for multiple comparisons was used.

## Results

### IL-2 no-alpha mutein is able to modify the CD8<sup>+</sup>MP/Treg balance in healthy mice

The IL-2-derived no-alpha mutein was previously characterized by its capacity to stimulate *in vitro* cells with different forms of IL-2R. To evaluate the effect of the IL-2 no-alpha mutein on CD8<sup>+</sup>MP and Treg balance *in vivo*, B6 mice were treated with both molecules, and the accumulation and proliferation of both populations on the spleens of treated mice were measured. Mice were treated with 20,000 IU of wtIL-2 or 200 IU of mutein, and the selected doses expressed as protein mass correspond to 20 µg of wtIL-2 and 20 µg of no-alpha mutein and are equivalent for cells expressing the IL-2Rβγc, for which the two molecules induce similar levels of proliferation *in vitro* (16). **Figure 1A** shows representative results obtained in the experiments. As expected, the mice treated with mutein showed higher percentages of CD8<sup>+</sup>MP cells, reaching 38.8%, and the wtIL-2 induced a lower accumulation level of 15.25% still above the value of 10.7% in the control group. On the contrary, the wtIL-2 was the only molecule able to increase the percentage of Tregs among the CD4<sup>+</sup> T lymphocytes, reaching approximately 15% in comparison with the typical 10% observed in the control group and the group treated with mutein. To test the overall impact on the balance effector/regulatory cell, mice were treated with two different doses of each molecule: 20,000 or 40,000 IU for wtIL-2 and 200 or 400 IU for mutein. Total CD8<sup>+</sup>CD44<sup>hi</sup>CD122<sup>+</sup> T cells and CD4<sup>+</sup>CD25<sup>+</sup>Foxp3<sup>+</sup> cells on the spleens were quantified. The mice treated with mutein showed a higher CD8<sup>+</sup>MP/Treg ratio than the mice treated with wtIL-2 in both dose levels. The results show that regardless of the dose, mutein is always able to expand CD8<sup>+</sup>MP T cells preferentially (**Figure 1B**). To define if the observed accumulation was related to an increment in proliferation, the incorporation of BrdU by the cells in treated mice was measured. **Figure 1C** shows representative histograms, and **Figures 1D, E**

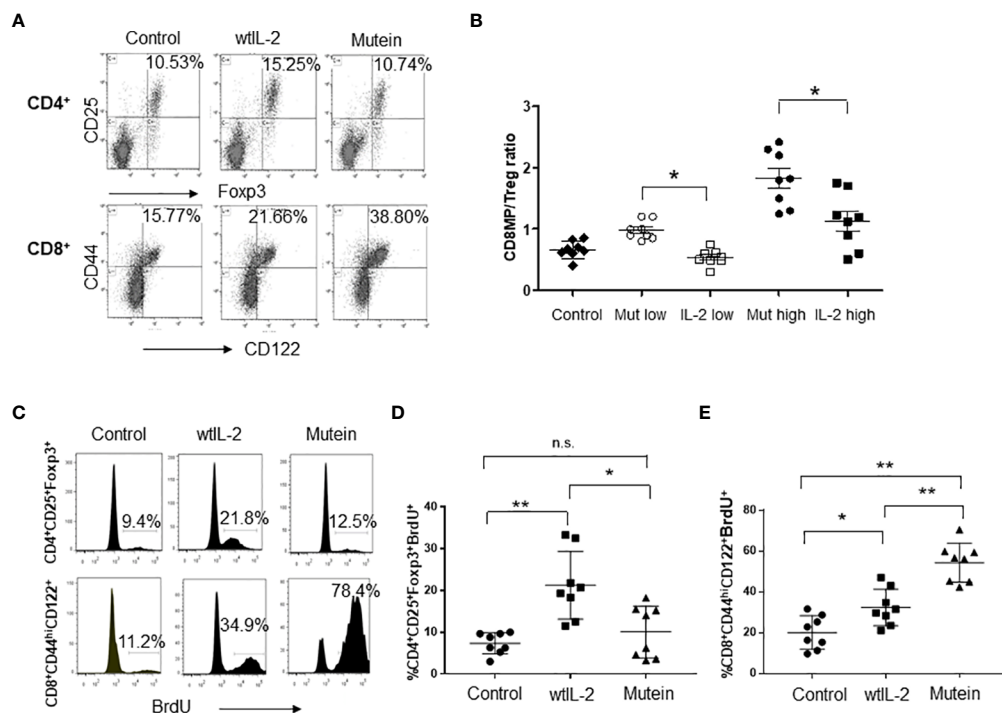

FIGURE 1

No- $\alpha$  mutein induces accumulation and proliferation of CD8<sup>+</sup>MP cells but not Tregs. Mice were treated i.p. with 20,000 IU of wtIL-2 or 200 IU of mutein during a week, and the percentages and numbers of CD8<sup>+</sup>MP and Tregs on the spleens of treated mice were determined. **(A)** Representative dot plots. **(B)** CD8<sup>+</sup>MP/Treg cell ratio measured on mice treated with two different doses of wtIL-2 and no- $\alpha$  mutein: low doses, 20,000 IU of wtIL-2 or 200 IU of mutein; high doses 40,000 IU of wtIL-2 or 400 IU of mutein. The experiment was performed three times; representative data are presented,  $n = 8$  per treatment,  $p < 0.05$ , Bonferroni test. For BrdU incorporation, mice were treated with 20,000 IU of wtIL-2 or 200 IU of mutein and fed with BrdU in the water for the last 3 days of treatments. **(C)** Representative histograms of BrdU incorporation. **(D, E)** Cumulative data from two independent experiments,  $n = 8$ , Tukey's test was used for multiple comparisons ( $p < 0.001$  \*\*;  $p < 0.05$  \*). n.s., non significant.

show cumulative data from two independent experiments. Mutein induced an outstanding increment on BrdU<sup>+</sup> CD8<sup>+</sup>MP cells, in a range from 40% to almost 80% of CD8<sup>+</sup>MP cells in the S phase of the cell cycle. The wtIL-2, on the contrary, induced a higher accumulation of Tregs, with an increment in the percentages of BrdU positive Tregs, in a range from 11% to 32% being statistically different from the average level observed in the control group 7.4% (Figure 1D).

## IL-2 no- $\alpha$ mutein reduces primary tumor growth and is able to modify the CD8/Treg balance in tumor-bearing mice

It was previously demonstrated that no- $\alpha$  mutein induces an important anti-metastatic effect in the MB16 and 3LL-D122 experimental metastasis tumor models (16). Now we extended the study of the antitumor activity to other models with tumor cell lines from different origins. In the models for

primary tumor growth studied (CT26, MB16, TC1, and 4T1), mutein was able to delay tumor growth (Figure 2A). The most important finding was that in two models (MB16 and 4T1) in which the wtIL-2 did not show any effect, mutein was highly effective in delaying the primary tumor growth, and the difference between mutein and the wtIL-2 was statistically significant for both tumor models ( $p < 0.05$ \*,  $p < 0.001$ \*\*).

Next, we evaluated the capacity of the IL-2 mutein to change the balance of CD8<sup>+</sup>MP/Tregs in tumor-bearing mice. Although different tumors induce different suppressive mechanisms (17), we have previously studied that all the tumors used in the present work expand Tregs on mouse spleens above the normal levels, even when other suppressive populations can also be expanded. We focused on the balance of CD8/Tregs because of the well-known function of IL-2 stimulating these populations. Furthermore, the results confirm our hypothesis about the mechanism of action of mutein.

We evaluated the accumulation of CD8<sup>+</sup>MP and Tregs on the spleens of tumor-bearing mice treated with IL-2 or mutein on day 21 after tumor implant. First, we selected the MB16

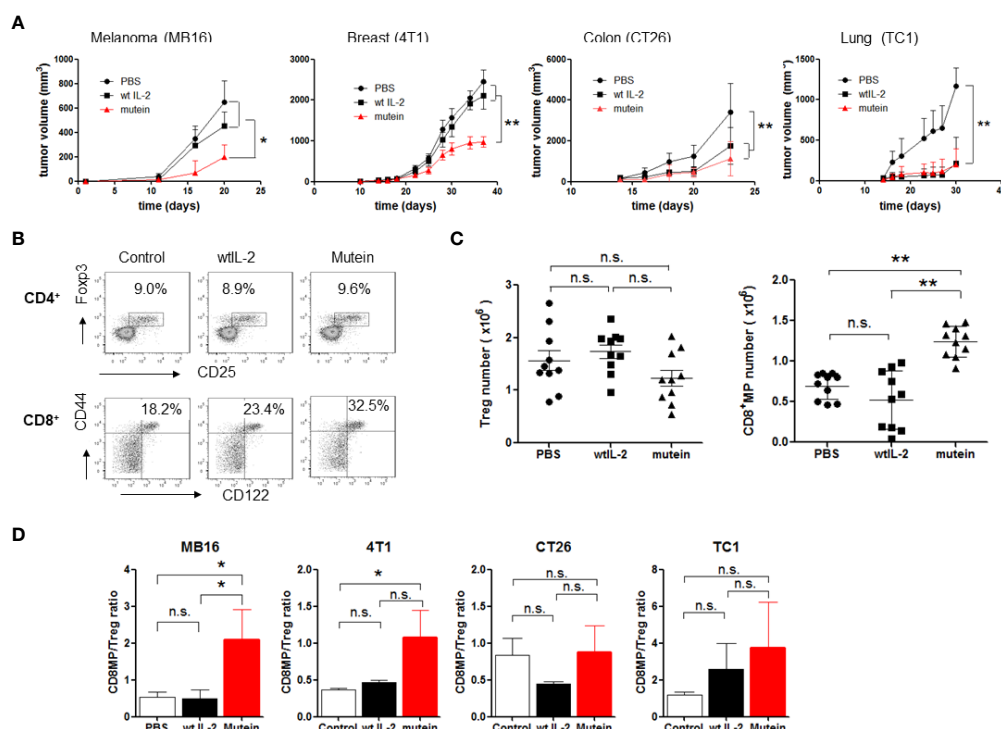

FIGURE 2

No- $\alpha$  munein induces a potent antitumor effect in four different tumor models and is able to change CD8<sup>+</sup>MP/Treg balance in tumor-bearing mice in the spleens. Mice were inoculated with tumor cells and received 300 IU of munein or 30,000 IU wtIL-2, twice a day, for 2 weeks separated by a resting week. MB16, CT26, and TC-1 cells were inoculated s.c. on the right flank; 4T1 cells were inoculated on mammary glands. (A) Tumor growth curves. (B) Representative dot plots from spleen of MB16-bearing mice. (C) CD8<sup>+</sup>MP and Treg number from spleens of MB16-bearing mice. (D) CD8<sup>+</sup>MP/Treg ratios on spleens of mice inoculated with the different tumor cell lines. Cumulative data from three experiments,  $n = 9$  per treatment. Statistical differences in tumor growth were determined by two-way ANOVA test, using GraphPad software ( $p < 0.001$  \*\*;  $p < 0.05$  \*). n.s., non significant.

tumor model because it is one of the tumor models where munein showed a higher antitumor effect than the wtIL-2. Figure 2B shows representative results of CD8<sup>+</sup>MP and Treg measurement on melanoma-bearing mice treated with the different molecules, and Figure 2C shows cumulative data of cell number. There were no statistical differences in Tregs number among the groups treated with wtIL-2, munein, or PBS as control. However, the percentage and number of CD8<sup>+</sup>MP cells increased notably in the mice treated with no- $\alpha$  munein, reaching 32% of CD8<sup>+</sup> cells and more than  $1 \times 10^6$  cells, while the mice treated with the wtIL-2 only showed a discreet increase in the percentages reaching 23% of CD8<sup>+</sup>MP cells close to the value of the control group (18%); nevertheless, the number of activated CD8<sup>+</sup> cells was similar for the group treated with the wtIL-2 and the control group. The increment on CD8<sup>+</sup>MP cells but not in Tregs results in a change in the CD8<sup>+</sup>MP/Treg balance toward immune activation (Figure 2D). This change on CD8<sup>+</sup>MP/Treg balance was also observed for the 4T1 model and, to a less extent, not statistically different for CT26 and TC1 models. Interestingly, the two models where munein induced the highest effect on primary tumor growth

(MB16 and 4T1) were those with statistical differences in the CD8<sup>+</sup>MP/Tregs ratio between the groups treated with munein and the wtIL-2.

## IL-2 no- $\alpha$ munein increases the survival of tumor-bearing mice and changes the CD8<sup>+</sup>/Treg balance in the tumor microenvironment

No- $\alpha$  munein effect on survival of tumor-bearing mice was also tested. The experimental tumor models 4T1 and 3LL-D122 were selected due to their capacity for inducing spontaneous metastases. Mice were treated with 30,000 IU of wtIL-2 or 300 IU of munein; these doses are equivalent in the ability to stimulate effector cells, both CD8<sup>+</sup> activated and NK cells expressing the dimeric IL-2 receptor ( $\beta\gamma\epsilon$ ). Similar to the traditional treatment used in humans, the molecules were administered twice a day for 5 days, and the same treatments were repeated a week apart (Figure 3A). In both cases, the mice treated with munein showed a higher survival ratio than the mice treated with the wtIL-2 ( $p <$

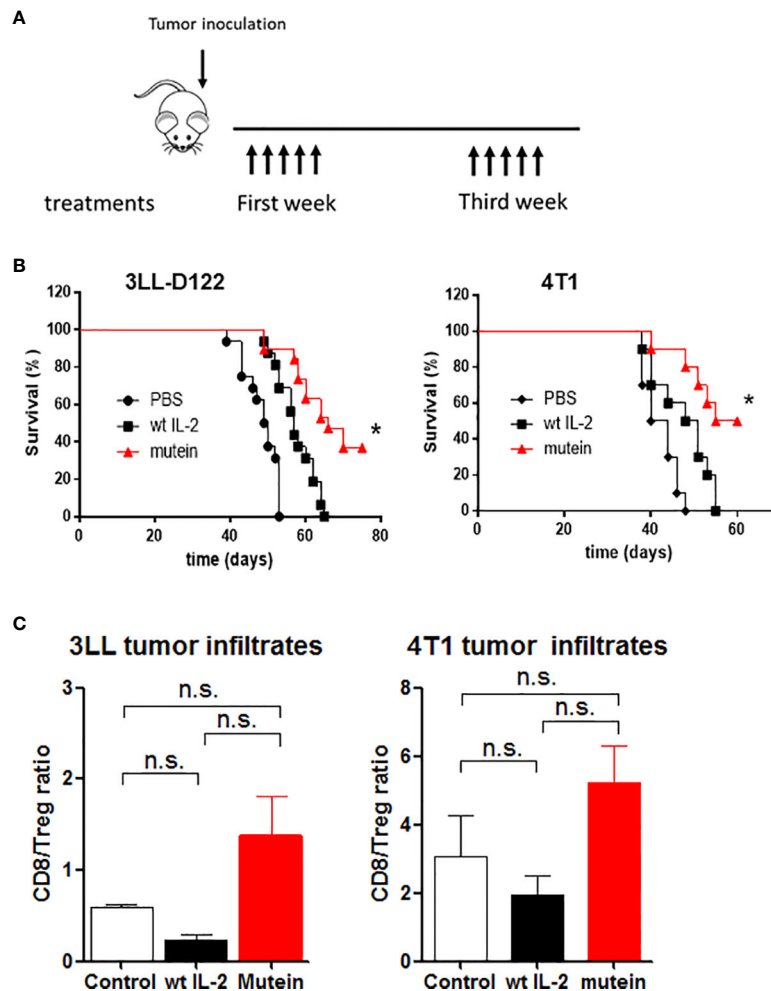

FIGURE 3

No-alpha mutein induces higher survival than wtIL-2 and induces changes in the tumor microenvironment. Mice were inoculated with 4T1 cells in the mammary gland or with 3LL-D122 on the foot pad; in the case of 3LL-D122, the primary tumors were eliminated by surgery when the control reached 9 mm; mice were treated with 30,000 IU wtIL-2 and 300 IU of no-alpha mutein or phosphate-buffered saline (PBS), and survival was observed. (A) Treatment schedule. (B) 3LL-D122 and 4T1 survival curves from spontaneous metastasis development. Survival curves were compared by log-rank test. (C) For tumor infiltrate measurement, mice were sacrificed when tumors reached 5–6 mm diameter and analyzed by flow cytometry. The graph represents the ratio between percentages of CD8<sup>+</sup>T lymphocytes and Treg referred to as total CD45<sup>+</sup> cells. n.s., non significant. \* $p < 0.05$ .

0.05), and both groups showed better survival than the control group treated with PBS (Figure 3B).

To study if the effect on immune balance reaches the tumor microenvironment, mice inoculated with 4T1 and 3LLD-122 cells were treated as described above. After the primary tumors were 6–7 mm in diameter, the mice were sacrificed, and the tumors were collected and analyzed by flow cytometry. TILs were evaluated as percentages of CD8<sup>+</sup> or CD4<sup>+</sup>CD25<sup>+</sup>Foxp3<sup>+</sup> T lymphocytes from the total number of CD45<sup>+</sup> cells, and the ratio between percentages is shown (Figure 3C). The tumors treated with mutein showed a higher level of CD8<sup>+</sup>T lymphocytes than the tumors treated with the wtIL-2, inducing a desired increment in the balance CD8<sup>+</sup>/Tregs in the tumor microenvironment.

## Discussion

IL-2 is a pleiotropic cytokine with a central role in the control of the immune response (1). Due to its effect on both effector and regulatory T cells, IL-2 has been evaluated as a therapeutic tool in a wide range of diseases related to cancer and autoimmunity (8, 18). After several years of using high-dose IL-2 therapy for cancer treatment, many approaches are under study aiming to improve the therapeutic index of the cytokine.

We have previously described the design and evaluation of an IL-2 mutein with a reduced binding capacity to the alpha chain of the IL-2R, named 'no-alpha mutein'; mutein shows a higher anti-metastatic effect and less toxicity than wtIL-2, opening the

opportunity to a better IL-2-based tumor therapy (16). Now the evaluation of the antitumor effect of mutein was expanded to other tumor cell lines and experimental settings. Mutein showed a strong effect in delaying primary tumor growth and inducing a better survival ratio in the models of spontaneous metastases induced by 4T1 and 3LL-D122 cell lines. Moreover, the effect on activated CD8<sup>+</sup>MP cells vs Tregs balance in the spleens was measured in healthy and tumor-bearing mice. Mutein was able to increase CD8<sup>+</sup>MP/Treg ratio in both settings, validating the hypothesis that it is enough to eliminate the interaction of the IL-2 molecule with the receptor alpha chain to achieve a preferential expansion of IL-2Rβγc-expressing cells. The effect of mutein was also measured in the tumor microenvironment of 4T1 and 3LL-D12 models, and a change in the CD8<sup>+</sup>/Treg balance was found.

The selection of the appropriate dose to compare the *in vivo* effect was an important choice. Usually, the IL-2 dose used in humans corresponds to 600,000 IU/kg, and it is considered a high dose treatment; in most tumor experiments in mice, an equivalent dose of 30,000 IU is used, corresponding with 1–3 μg of wtIL-2 per dose. For mutein, as well as for the wtIL-2, the biological activity is determined in the cell proliferation assay for the CTLL-2 cell line expressing the IL-2Rαβγc. As mutein only binds to the dimeric receptor, more molecules are needed to achieve the same level of CTLL-2 proliferation. We considered the 100-fold difference in the affinity of the IL-2Rαβγc vs the IL-2Rβγc and chose 300 IU as the equivalent dose for mutein; this dose corresponds with 10 to 30 μg of mutein depending on the specific activity of the production batch. Mutein has shown lower toxicity than wtIL-2; consequently, it is possible to use 30 μg or higher doses without inducing severe toxic effects on treated mice.

When the selected doses were evaluated *in vivo*, the activated CD8<sup>+</sup>CD44<sup>hi</sup>CD122<sup>+</sup>T cells accumulated to higher levels in the healthy mice treated with mutein than in the mice treated with wtIL-2. To study the CD8<sup>+</sup>MP/Treg ratio in healthy mice, two dose levels were evaluated; mutein showed a significant change toward immune activation rather than suppressive condition. Taking into account the CD8<sup>+</sup> preferential expansion demonstrated *in vivo*, we can speculate that when different lymphocyte populations are present and compete for the cytokine, mutein is captured preferentially by the CD8<sup>+</sup> cells, which express a high level of the dimeric βγc IL-2R form.

In this work, we explored how general could be the advantage of no-alpha mutein over wtIL-2 and used several tumor models regardless of whether Treg expansion is the main suppressive mechanism or not. We demonstrated that in the models with higher Treg expansion, such as MB16 and 4T1, the differences in the antitumor activity between mutein and the wtIL-2 were higher as well as the changes induced on CD8<sup>+</sup>MP/Treg ratio. Consequently, mutein should be advantageous in the treatment of those cancer diseases where the Treg expansion is relevant; in these settings, we expect better efficacy and lower percentages of non-responder patients due to lower levels of ICOS<sup>+</sup>Treg proliferation. A phase I clinical trial evaluating mutein safety is already in progress.

Expansion of Tregs in lymphoid organs and the tumor microenvironment is one of the tumor mechanisms to escape from immune surveillance (19). In humans, Treg increment is related to worse outcomes in many tumor diseases, and the expansion of ICOS-positive Tregs is related to IL-2 therapy unresponsiveness (9). Several examples are attempting to target Tregs in order to achieve significant antitumor responses; antibodies against CTLA-4, GITR, CXCR4, ICOS, and CD25 have been used for this purpose (20–24), although the restricted expression of the target molecules on Tregs can be sometimes questioned. Vargas *et al.* provided an elegant demonstration of specific CD25<sup>+</sup> expression on Tregs in both mice and human tumor infiltrates. They demonstrated that increasing the CD25 mAb PC-61 affinity to activating FcγRs was sufficient to specifically deplete Tregs in the tumor microenvironment and to improve the antitumor effect of mAb alone or in combination with PD-1 mAb (25). Another outstanding finding was the induction of systemic antitumor response after intratumor Treg depletion with a mAb targeting CTLA-4 molecule, underscoring the relevance of Tregs as immunosuppressive mechanisms in tumor settings (22). Also, there is the work from Cheung *et al.*, which improved the old concept of the ONTAK molecule, with the production of a second-generation IL-2 diphtheria toxin fusion protein with higher activity and better formulation than the previous one, and the demonstration of Treg depletion in spleens and LN together with a potent antitumor activity (26).

In the present work, not Treg depletion but changes in the balance of CD8/Tregs were achieved, treating the mice with no-alpha mutein. The goal was to abolish Treg expansion mediated by IL-2 while conserving the immunostimulatory properties of the cytokine-activating effector cells. Recently a similar idea was accomplished through a different approach (14). Charych *et al.* developed a modified IL-2, with a site-directed PEG attachment on the alpha surface of the molecule; the modified IL-2 (NKTR-214) also increased the CD8<sup>+</sup>/Tregs ratio and has a higher half-life, which could be an advantage for treatment schedule but also a problem considering the toxic effects associated with the IL-2 molecule. NKTR-214 shows a potent antitumor effect both alone and in combination with a PD-1 mAb. Also, the first phase I clinical trial was conducted by assaying safety and dose regimen for the NKTR-214 molecule; moderate responses were observed together with several adverse events associated with the treatment. Levin *et al.* also described an IL-2 mutein with agonistic properties (15); H-9 has an increased affinity for the β chain of IL-2R, and although it conserves the capacity to induce Treg proliferation, also induced an outstanding effect on CD8<sup>+</sup> cells and induces higher antitumor activity than wtIL-2.

In conclusion, our results extend previous studies from our group and other laboratories showing that IL-2 muteins can lead to an antitumor effect *in vivo* by expanding effector CD8<sup>+</sup> T cells while restricting the expansion of Treg cells. The benefit of this approach for cancer treatment will now be assessed under clinical trials that have been already initiated.

## Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## Ethics statement

This study was reviewed and approved by Ethic Committees for laboratory animal care and use at the CIM, Havana; Postech, Korea and at the IMM, Lisbon.

## Author contributions

TC, GM, YO designed and performed *in vivo* antitumor experiments. TC, JK, JA, YO, design and performed *in vivo* experiments for lymphocytes changes. CD, JA, TC, performed tumor microenvironment measurements. SLL, YR purified wtIL-2 and IL-2 mutein. TC wrote the document, CHDS, LG and KL design experiments, generated ideas and discuss the experiment designs and results. All authors contributed to the article and approved the submitted version.

**Introduction:** Sulfavant A (SULF A) is a synthetic derivative of naturally occurring sulfolipids. The molecule triggers TREM2-related maturation of dendritic cells (DCs) and has shown promising adjuvant activity in a cancer vaccine model.

**Methods:** the immunomodulatory activity of SULF A is tested in an allogeneic mixed lymphocyte reaction (MLR) assay based on monocyte-derived dendritic cells and naïve T lymphocytes from human donors. Flow cytometry multiparametric analyses and ELISA assays were performed to characterize the immune populations, T cell proliferation, and to quantify key cytokines.

**Results:** Supplementation of 10 µg/mL SULF A to the co-cultures induced DCs to expose the costimulatory molecules ICOSL and OX40L and to reduce release of the pro-inflammatory cytokine IL-12. After 7 days of SULF A treatment, T lymphocytes proliferated more and showed increased IL-4 synthesis along with downregulation of Th1 signals such as IFN $\gamma$ , T-bet and CXCR3. Consistent with these findings, naïve T cells polarized toward a regulatory phenotype with up-regulation of FOXP3 expression and IL-10 synthesis. Flow cytometry analysis also supported the priming of a CD127-/CD4+/CD25+ subpopulation positive for ICOS, the inhibitory molecule CTLA-4, and the activation marker CD69.

**Discussion:** These results prove that SULF A can modulate DC–T cell synapse and stimulate lymphocyte proliferation and activation. In the hyperresponsive and uncontrolled context of the allogeneic MLR, the effect is associated to differentiation of regulatory T cell subsets and dampening of inflammatory signals.

## Introduction

Dendritic cells (DCs) are innate immune cells which uniquely trigger naïve T cell activation and differentiation by providing T-cell-receptor ligands and co-stimulatory molecules (1). The interaction between DC and T cell, named the immune synapse, has a great functional plasticity that allows to modulate the activation of immunogenic or tolerogenic response (2) (3). The exchange of signals and the microenvironment established during the immune synapse helps to control the magnitude, type, and efficacy of the immune response (1). However, the mechanisms by which DCs are able to transduce the environmental stimuli and prime an effective T cell response are the result of inhibitory and stimulatory signals that are only partly understood. These signals are neither consequential nor accessory but are all part of a finely regulated bidirectional process orchestrating the dialogue between DCs and T cells. Notably, in the absence of an adequate apposition of effector and accessory molecules, T cells become anergic (1) (4). In this context, a great interest has recently arisen for new drugs capable of triggering and controlling activation and proliferation of T cells by modulating the immune synapse (5).

The mixed lymphocyte reaction (MLR) constitutes an effective tool to test activation, inhibition, or functional alteration of proliferating T cells in a model of immune microenvironment. In

the classical allogeneic MLR experiments, T cells and monocyte derived DCs (MoDCs) from distinct individuals are co-cultured. The allogeneic forms of major histocompatibility complex (MHC) molecules on MoDCs stimulate proliferation and activation of T cells more strongly than conventional exposure to antigens. The technique provides a model for the study of the immune synapse (6) and, over the time, the assay has been widely employed for the preclinical tests of immunomodulatory molecules with applications in immunology, autoimmunity, inflammation, vaccine development (7) (8).

Sulfavant A (SULF A) is a synthetic sulfolipid derived from naturally occurring sulfoquinovosides that are essential components of the chloroplast membranes in the photosynthetic organisms (9). The molecule primes an unconventional maturation of MoDCs through a toll like receptor (TLR)-independent mechanism leading to up-regulation of the costimulatory and MHC molecules along with hypoproduction of cytokines (10) (11) (12) (13). The molecule has been proposed as a vaccine adjuvant (EU Patent n. EP3007725B1) and despite the divergence from the inflammatory mechanisms of conventional adjuvants, retains the ability to activate immune protection in an experimental model of a prophylactic vaccine against melanoma in B16F10 mice (11). Very recently, we showed that SULF A can bind the triggering receptor expressed on myeloid cells (TREM2) which helps explain the unusual mechanism of action of the sulfolipid and the ability to trigger *in vitro* the differentiation of a homeostasis-inducing DC subpopulation that we named *homeDC* (14).

In the current study, we investigate the effect of SULF A in an experimental model of allogeneic MLR with MoDCs isolated from a human donor that were co-cultured with naïve T cells of another individual at 1:10 ratio. The sulfolipid was tested at a concentration of 10  $\mu$ g/mL that corresponds to the active dose used in previous experiments to stimulate *in vitro* DC maturation (10). The aim of the study was to evaluate whether SULF A affects T cell activation and proliferation in the context of allogeneic MLR, as well as to gain more insight into the effects of SULF A on adaptive immunity and the mechanisms of immune homeostasis.

## Materials and methods

### Isolation and culture of human primary cells

Monocyte-derived dendritic cells (MoDCs) were differentiated from human peripheral blood of healthy volunteers collected from Umberto I Hospital of Nocera Inferiore, Salerno (Italy). No identifying information on the donors was retained.

After density gradient isolation of Peripheral blood mononuclear cells (PBMCs) by routine Ficoll (Ficoll Paque Plus, GE Healthcare, USA), monocytes were separated by CD14 microBeads (Miltenyi Biotec, Auburn, CA, USA). Cell purity was verified by flow cytometer (FACS) analysis using human monoclonal antibodies: CD3 Percp (SK7) (Becton Dickinson), CD14 Vioblue (REA599), and CD45 FITC (REA747) (Miltenyi Biotec, Auburn, CA, USA). The CD14+/CD3-/CD45+ cells had always a purity higher than 98%. Monocytes were cultured for 6 days in RPMI medium supplemented with 10% FBS and 1% pen/strep in the presence of IL-4 (5 ng/mL) and GM-CSF (100 ng/mL) to obtain immature dendritic cells (iMoDCs). On day 6, iMoDCs were harvested, centrifuged (10 min, 300 g) and stained with CD3 Percp (SK7) (Becton Dickinson), CD14 Vioblue (REA599), CD11c FITC (REA618), CD80 PE (2D10), CD83 APC (REA714), antibodies (Miltenyi Biotec, Auburn, CA, USA) to verify cells differentiation by flow cytometry. The CD3-/CD14-/CD83-/CD80low/CD11c+ population was always higher than 95%. Naïve T cells were obtained from different buffy coats. After PBMCs separation, cells were isolated by naïve pan T cells isolation kit (Miltenyi Biotec, Auburn, CA, USA) according to manufacturer instructions. The purity of the population was verified by FACS using the human monoclonal antibodies CD3 Percp (SK7) (Becton Dickinson), CD45RA FITC (REA562), CD45RO PE (REA611), and CCR7 PeVio770 (REA108) (Miltenyi Biotec, Auburn, CA, USA). The CD3+/CD45RA+/CD45RO-/CCR7+ population had always a purity higher than 96%.

### Allogeneic mixed lymphocyte reaction assay

MoDCs (stimulators) and naïve CD3+ T lymphocytes (responders) deriving from six different donors were cultured in a ratio of 1:10 (10.000 stimulators:100.000 responders) in round-bottomed 96-well plates with RPMI medium completed with 10% human AB serum in the presence of 10 µg/mL SULF A in PBS (MLR +SULF A). The concentration of SULF A used was established on the basis of previous dose-response experiments (10) (14). Untreated co-cultures were used as control (MLR). For the analysis of MoDCs, co-cultures were harvested and analyzed by flow cytometry after 48h. The analysis was carried out by antibody staining with CD86 PEVio 615 (REA968), CD11c FITC (REA618), CD14 Vioblue (REA599), (Miltenyi Biotec, Auburn, CA, USA) ICOSL APC (2D3), and OX40L PE (11C3.1) (Sony Biotechnology). For the analysis of T cells, co-cultures were analyzed by flow cytometry after 7 days. Functional surface markers were stained by anti CD3 Percp (SK7) (Becton Dickinson), CD4 PEVio 615 (REA623) or PE (SK3) (Becton Dickinson), CD8 APCvio770 (REA734), CD25 FITC (REA570) or PE (REA570), CD127 PEVio615 (MB15-18C9), CTLA-4 PEVio770

(REA1003), CD69 APCVio770 (REA824), (Miltenyi Biotec) OX40 FITC (ACT35), ICOS Alexa fluor 700 (C398.4A) (Biolegend). For detection of intracellular cytokines, cells were treated for 6 hours at 37°C with 10 ng/mL phorbol 12-myristate 13-acetate (PMA), 500 ng/mL ionomycin, and 10 µg/mL brefeldin A (BFA) (Sigma Aldrich, Milan, Italy) and then stained with, IL-4 APC (BD4-8) (Sony Biotechnologies), IFNγ Vioblue (REA600), TNFα APC (REA656) and IL-17 PE (CZ8-23G) (Miltenyi Biotec, Auburn, CA, USA).

### Lymphocyte proliferation assay

T cell proliferation was analyzed by flow cytometry using Cell Trace™ CFSE Cell Proliferation Kit (Thermo Fisher, Waltham, MA, USA). Naïve T cells (at least  $2 \times 10^6$ ) were suspended in PBS 5% AB serum and labeled with 5µM carboxyfluorescein succinimidyl ester (CFSE). Cells were washed 3 times with 5% AB serum in PBS, suspended in the co-culture medium again and an aliquot was immediately acquired by flow cytometry to set the initial fluorescence (time zero). After addition to stimulators MoDCs, dilution of the CFSE signal was measured every day to establish the experimental conditions for cell number and proliferation rate. The 7-day endpoint was selected because T cells showed a consistent proliferation rate and their number in the well did not exceed  $1.5 \times 10^6$ /mL. CFSE dilution was recorded by flow cytometry as loss of fluorescence within 7 days from the addition of 10 µg/mL of SULF A (MLR+SULF A). Untreated co-cultures were used as blank (MLR) whereas co-cultures with 1 µg/mL phytohemagglutinin (PHA) were used as a positive control of proliferation. Gating strategies are shown in [Supplementary Figure 1](#). The CFSE is reported as percentage of CFSE negative cells.

### Flow cytometry

Flow cytometry was performed by FACSaria™ (BD Bioscience) or MACSQUANT 16® Analyzer (Miltenyi Biotec). For surface staining, cells were washed in PBS and stained with Viability™ 405/520 Fixable Dye (Miltenyi Biotec, Auburn, CA, USA) for live cell discrimination. After washing in the staining buffer (SB) (2% FBS and 0.1% sodium azide in PBS), cells were incubated at 4°C with the mixture of antibodies and isotype controls according to incubation time and quantity suggested by the manufacturers. After two additional washes, cells were acquired for the FACS analysis. For the detection of intracellular cytokines, surface markers of live cells were stained as described above. Cells were then fixed and permeabilized by BD Cytofix/Cytoperm™ kit (BD Bioscience, Franklin Lake, NJ, USA) and incubated at 4°C for 20 minutes. After two washes in BD Perm/Wash™ buffer (diluted 1:10), cells were stained with the different intracellular antibodies, according to manufacturer instructions. Cells were washed in BD Perm/Wash™ and suspended in SB for the analysis. Flow cytometry was performed on 5000 events for each population of interest according to the instrument recommendations. Isotypic and FMO controls were performed to exclude nonspecific fluorescence and set the plot axis position. Control in FITC channel and back gating strategies were used to exclude cell autofluorescence.

## Real-time PCR

Total RNA was isolated using Trizol Reagent (Thermo Fisher, Waltham, MA, USA) according to manufacturer instructions. RNA quantity and purity were measured by a NanoDrop 2000 spectrophotometer (Thermo Fisher Scientific). Sample purity was checked at A260/A280 ratio between 1.80 and 2.00. Gene expression was measured by RT-qPCR by using validated primers for *T-bet*, *RORγT*, *GATA3*, *FOXP3*, *IL-10*, *IL-21* and *TGFβ* after 7 days from addition of SULF A to MLR test. 18S Ribosomal RNA (rRNA) was used as a housekeeping gene to normalize sample-to-sample systematic variation in RT-qPCR. ΔCt method was used to calculate the relative gene expression.

## ELISA

IL-12p70, TNFα, and IL-10 were measured in the supernatants of the co-cultures at 48h and 7 days using commercially available kits (Thermo Fisher Scientific, Waltham, MA, USA) following the manufacturer instructions. Each sample was tested in duplicate and the colorimetric reaction (absorbance at 450 nm) was quantified by EZ Read 2000 (Biochrom Ltd, Harvard bioscience) spectrophotometer. Absorbance was converted to pg/mL according to the standard curve generated with a five-parameter logistic curve fit.

## Statistical analysis

Gates between 0.5 and 1% positive events were set for isotype controls in flow cytometry. Flow Jo v10 (BD Biosciences) or MACS Quantify (Miltenyi Biotec) software were used for the measurements. Statistical analysis between the mean values for two groups were performed by non-parametric (two-sample) T test. The paired version of the test was used when replicates were matched in the two conditions. A *P* value less than 0.05 was considered statistically significant. Graphics were drawn by GraphPad Prism 8 (GraphPad Software, San Diego California, USA).

## Results

### Effect of SULF A on T cell proliferation in the MLR assay

DCs are potent inducers of lymphocytes activation in allogeneic MLR. The expression of high levels of MHC and the exposition of costimulatory molecules, make them particularly suitable to elicit a strong T cell response (6). Starting from this assumption, we used the MLR model to study the effect of SULF A on naïve T lymphocytes proliferation. The MLR condition led to proliferation of about 40% of T CD3+ population after 7 days. The addition of SULF A to the co-cultures was associated to a further increase of 20%, overall reaching a mean proliferation of 60% (Figures 1A–E). In order to investigate whether this activation concerned T helper or cytotoxic T cells, we analysed CFSE dilution in T CD4+ and TCD8+ subsets according to

the gate strategy reported in [Supplementary Figure 1](#). The T CD4+ subset showed a basal proliferation of 30% reaching 50% when SULF A was added to the co-culture (Figures 1F–J). Slight changes were registered for the T CD8+ subset for which the baseline proliferation of 10% increased by only 5% with the addition of the sulfolipid (Figures 1K–O). Minor differences of proliferation were observed among the three compartments when naïve T cells were cultured in the presence of antiCD3/antiCD28 beads used as stimulus (not shown).

### DC phenotype in the MLR assay after addition of SULF A

To better understand the effect of SULF A on T cell response developing in the MLR context, we decided to study cytokine production along with DC phenotype. After 48 h from the treatment with SULF A, we observed that IL-12, a prototypic proinflammatory cytokine, was significantly reduced. The levels of IL-10, the main cytokine involved in the down-regulation of inflammatory processes, increased but did not reach formal statistical significance (*P* = 0.0625) (Figures 2A–B); no change was detectable for the TNFα production ([Supplementary Figure 2](#)). According to the gating strategy described in [Supplementary Figure 3](#), flow cytometry showed upregulation of the surface expression of the OX40L and ICOSL of DCs after SULF A addition to the co-cultures (Figures 2C–D). OX40L and ICOSL belong to the group of costimulatory molecules which are not constitutively expressed by resting DCs but are secondary exposed on the cell surface especially in the course of tolerogenic or regulatory immune response (1) (15) (16). The binding of OX40L with OX40 promotes T cells autocrine production of IL-4 and Th2 polarization (16). Molecules able to induce OX40L upregulation on DCs are of interest for clinical treatments of atopic dermatitis and asthma (17) (18). ICOSL is mainly involved in follicular T cells polarization, adaptive tolerance, and the maintenance of effector/regulatory T cells balance (19) (20). In experimental models of allergic encephalomyelitis (EAE) and autoimmune type 1 diabetes, blockade of ICOS/ICOSL is associated to severe worsening of the diseases (21).

### Gene and protein expression by CD4<sup>+</sup> T cells in the presence of SULF A

In order to characterize priming of naïve CD4+ T cell, we considered the effect of SULF A on the hallmarks of Th1 and Th2 response in co-cultures at day 7. SULF A significantly downregulated the gene expression of the transcription factor *T-bet* (Figure 3A) and surface expression of CXCR3 marker (Figure 3B), while gating analysis of flow cytometry data ([Supplementary Figure 4](#)) revealed a consistent reduction of the intracellular level of IFNγ (Figure 3C) but no change of TNFα (*P* = 0.062) (Figure 3D). In agreement with the down-regulated production of IL-12 at 48h, these data supported the attenuation of Th1 differentiation by SULF A. Pro-inflammatory markers related to Th17 response, such as IL-17 ([Supplementary Figure 4](#)) or the transcription factor *RORγT* ([Supplementary Figure 5A](#)), as well as the pleiotropic cytokine *TGFβ*

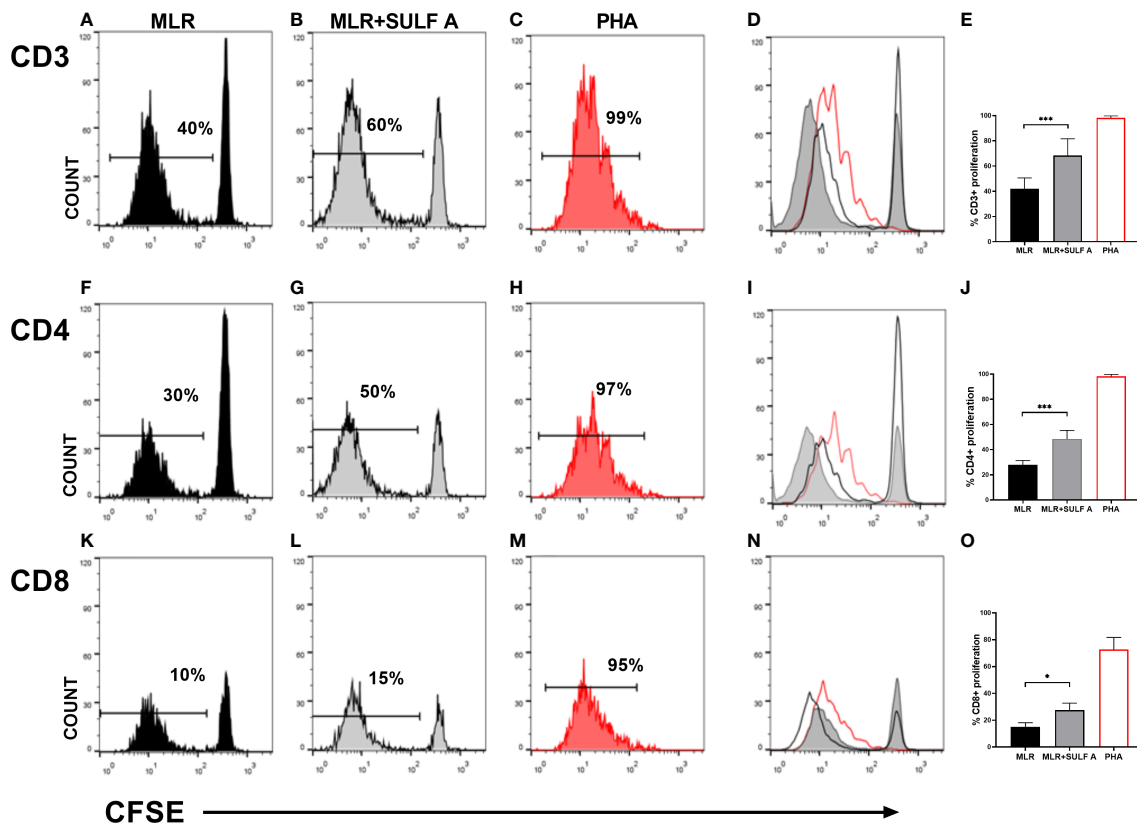

FIGURE 1

T cells proliferation induced by SULF A. Naïve T cells proliferation was assessed by CFSE dilution after 7 days of co-culture. The analysis was performed on 5000 live/T CD3+ cells. Histogram plots relative to one representative experiment are shown for CD3+ panels (A–D), for CD4+ panels (F–I) and for T CD8+ panels (K–N). Numbers in the plots indicate the percentage of proliferating cells. Panels (D) (T CD3+), (I) (T CD4+), (N) (T CD8+) show the overlay of the three experimental conditions for each subset. The bar graphs (E, J, O) represent the mean of 6 experiments. Gate strategy is reported in [Supplementary Figure 1](#). MLR = untreated cocultures; MLR+SULF A = cocultures treated with 10  $\mu$ g/mL SULF A; PHA = cocultures treated with 1  $\mu$ g/mL phytohemagglutinin (positive control). Statistical analysis was performed by one-way Anova non parametric test. \* $P < 0.05$ ; \*\*\* $P < 0.001$ .

([Supplementary Figure 5](#)) were unaffected in the allogeneic MLR and were unresponsive to SULF A addition. On the other hand, the sulfolipid increased the expression of the transcription factor *GATA3* ([Figure 3E](#)) and significantly increased the intracellular production of IL-4 ([Figure 3F](#)), both signature of type 2 immunity. Expression of *IL-21*, also implicated in the development of humoral responses, responses was found up-regulated ([Supplementary Figure 5C](#)) *IL-4* is as multifunctional, immunoregulatory cytokine mostly associated with the suppression of pro-inflammatory signals, the dampening of the excessive immune response, and the stimulation of tissue repair and homeostasis ([22](#)).

## T cell differentiation in the MLR assay after addition of SULF A

After 7 days, the co-cultures treated with SULF A showed a high expression of the transcription factor *FOXP3* fork head box Protein 3 (FoxP3) ([Figure 4A](#)) and a significant increase of IL-10 synthesis ([Figures 4B–C](#)). In these samples, flow cytometry gating of T cells ([Supplementary Figure 6](#)) revealed a consistent expansion of CD127-/

CD4+/CD25+ subpopulation after addition of SULF A ([Figure 4D–J](#)). CD127 is a marker typically expressed on effector T cells, instead T CD4+ cells negative or low-level expressing this marker but positive for CD25 are generally associated to immunoregulation ([23](#)). In this population, SULF A also up-regulated the immune checkpoint receptor CTLA-4 ([Figure 4K](#)), and the inducible T-cell costimulatory receptor ICOS ([Figure 4L](#)). While CTLA-4 is constitutively expressed on FOXP3+/CD25+/CD4+Treg cells and is up-regulated in conventional T cells only after activation, ICOS is an indicator of T cell-mediated immune response. Notably, the initiation of the ICOS pathway is triggered by binding to ICOSL whose exposure is significantly increased on the DC surface 48h after the addition of SULF A to the MLR. According to these results, this population matched with the portion of proliferating T cells and were fully positive for the early activation marker CD69 ([Figure 4M](#)).

## Discussion

DCs are key players in activation and control of the immune response by presentation of the antigen to T cells in the context of

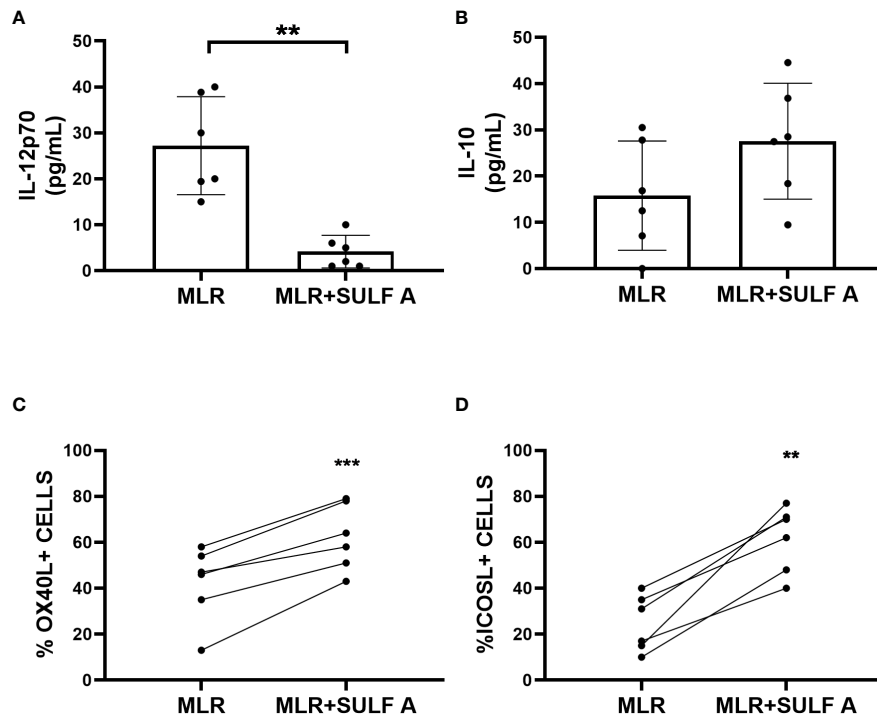

FIGURE 2

Response of cultured MoDCs with naïve T lymphocytes 48h after addition of SULF A. (A–B) Levels of cytokines IL-12 and IL-10 in supernatants measured by ELISA assay; (C–D) Surface expression of the costimulatory molecules OX40L and ICOSL of live CD11c+/CD3- DCs measured by FACS. The gating strategy used for these markers is reported in [Supplementary Figure 3](#). MLR= untreated co-cultures; MLR+SULF A= co-cultures treated with 10  $\mu$ g/mL SULF A. Statistical analysis (n = 6) was performed by paired non parametric two tailed T test. \* $P$  < 0.05; \*\*\* $P$  < 0.001.

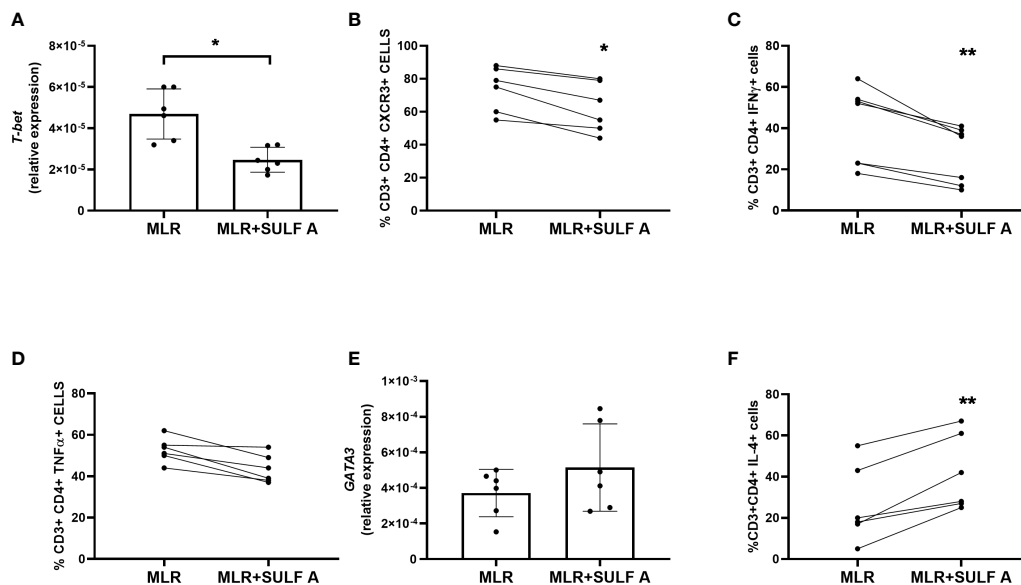

FIGURE 3

Effect of SULF A on Th1 and Th2 markers in the allogeneic MLR experiment. (A) RNA Expression of the transcription factor *T-bet* measured by qPCR after 7 day from the addition of SULF A to the co-cultures; (B–D) Surface expression of CXCR3, intracellular levels of IFNγ and TNFα measured by FACS; (E) RNA expression of the transcription factor GATA-3 measured by qPCR; (F) Intracellular level of IL-4 measured by FACS. All qPCR results (mean ± s.d) were normalized to 18S mRNA and analyzed by  $\Delta$ Ct method. Flow cytometry was performed on live CD3+/CD4+ cells (5000 events acquired) according to the gating strategy reported in [Supplementary Figure 4](#). The intracellular cytokines were detected after a treatment of 6 hours with PMA, ionomycin and BFA. MLR = untreated co-cultures; MLR+SULF A = co-cultures treated with 10  $\mu$ g/mL SULF A. Statistical analysis (n = 6) was performed by paired non parametric Two-tailed T-test. \* $P$  < 0.05; \*\* $P$  < 0.01.

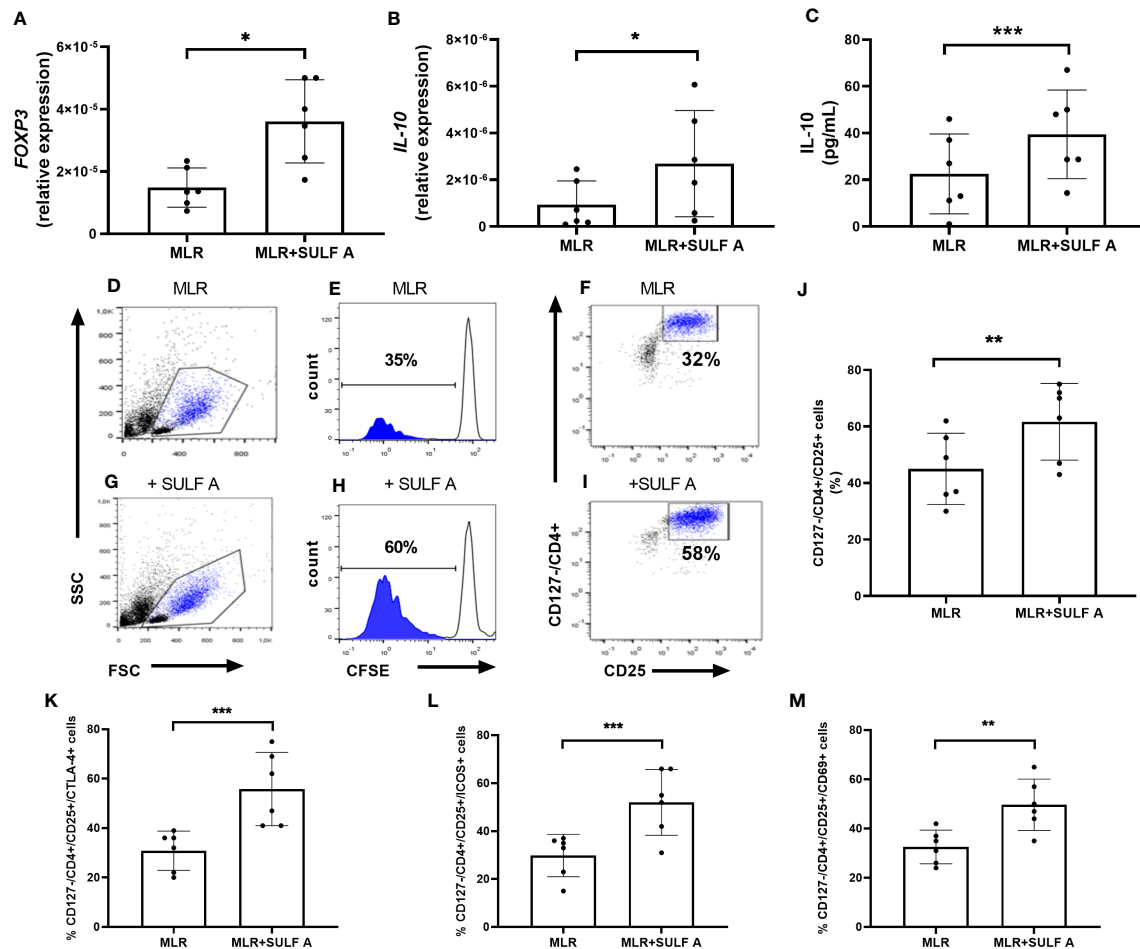

FIGURE 4

SULF A-dependent expansion of T cells in the allogeneic MLR experiment. RNA Expression of *FOXP3* (A) and IL-10 (B) measured by qPCR. Results were normalized to 18S mRNA and analyzed by  $\Delta\Delta C_t$  method. Values on y-axis represent the relative expression of mRNA levels compared to control. (C) IL-10 concentration in the MLR supernatants measured by ELISA assay. (D–I) Representative flow cytometry analysis of proliferating and CFSE-negative populations corresponding to the CD127-/CD4+/CD25+ subset. Analysis gated 5000 live cells. (J) SULF A-dependent expansion of CD127-/CD4+/CD25+ T cells (mean  $\pm$  s.d) on 6 different experiments. The analysis was carried out acquiring 5000 live cells according to the gate strategy reported in [Supplementary Figure 5](#); (K–M) Levels of cells positive for CTLA-4, ICOS and CD69 measured by flow cytometry within CD127-/CD4+/CD25+ population. MLR = untreated co-cultures; MLR+SULF A = co-cultures treated with 10  $\mu$ g/mL SULF A. Statistical analysis was performed by paired non parametric two tailed T test. \* $P < 0.05$ ; \*\* $P < 0.01$ ; \*\*\* $P < 0.001$ .

major histocompatibility (MHC) molecules and delivery of additional input in the form of costimulatory surface ligands and cytokines (1) (4). The bidirectional DC-T cell synapse is a cornerstone of adaptive immunity and has been the subject of many studies although the DC response has received less attention than T cell activation and differentiation (24). The effective tuning of the immune synapse requires combination of stimulatory and inhibitory signals to provide adequate protection and prevent aberrant response leading to pathological progression. One of the best-known examples of these mechanisms is the interaction of the costimulatory molecule CD28 and the inhibitory counterpart CTLA-4 along with their ligands CD80 and CD86 (25) (26).

SULF A is a small organic molecule suitable for pharmaceutical applications due to the property of triggering an unconventional maturation of DCs and initiating an effective immune response *in vivo* (11) (14). In this study we showed that SULF A can modulate

DC-T cell synapse in the context of the allogeneic MLR. According to the previous reports (14), addition of SULF A to MLR determined DC maturation after 48h with increased expression of the costimulatory molecules ICOSL and OX40L in conjunction with down-regulation of cytokine IL-12 and up-regulation of IL-10. This condition led to additional T cell proliferation and, although T CD4+ and T CD8+ subsets were both promoted, it was skewed towards T CD4+ proliferation. The whole CD4+ T cell subset also expressed high levels of *GATA3*, the main transcription factor involved in Th2 polarization (27), along with increased IL-4 production and down-regulated levels of IFN $\gamma$  and CXCR3 in comparison to control. In addition to the upregulation of *FOXP3* of the CD4+ T cells, gated analysis on the proliferating subset also indicated the selection of a CD127-CD4+CD25+CD69+ population by SULF A. This finding correlates with the release of high level of IL-10 and up-regulation of ICOS and CTLA-4 expression, and suggested the priming of

FIGURE 5

Graphic representation of the proposed mechanism of action of SULF A in MLR. After activation of DCs by TREM2, SULF A affects the stimulatory and inhibitory signalling of immune synapse. The glycolipid induces homeostasis restoration by promoting the release of IL-10, reduction of IL-12 and exposure of OX40L and ICOSL on DC membranes. The overall response is a robust T cell stimulation associated to a regulatory mechanism aimed at restoring homeostasis after the allogeneic immune reaction (image created with [Biorender.com](https://www.biorender.com)).

regulatory subpopulations functionally committed to maintain immune tolerance (23) (28). Moreover, ICOS is an activation marker that cooperates to maximize and sustain CD4+ and CD8+ T cell responses (29) but ICOS+ Tregs have stronger abilities of suppression and survival than ICOS- Tregs (30) (31) (32). It is worth noting that this response of the T cell compartment after 7 days was coherent with the early differentiation of tolerogenic DCs at 48h (Figure 5).

SULF A binds to TREM2, an immune receptor of the immunoglobulin superfamily, more effectively than other ligands so far reported. We put forward that the engagement of TREM2 correlates with the maturation of DCs committed to maintain homeostasis (14). The selection of this DC subset can also contribute to the regulatory response observed in the allogeneic MLR after the addition of the sulfolipid. This hypothesis agrees with the immunomodulatory properties of TREM2 that acts as a homeostasis effector in the central nervous system (33) and antagonizes the pro-inflammatory pathways originating from TLRs in DCs (34). The role of TREM2 in the immune response is still debated and could vary in relation to tissue- or organ-specific factors. However, recent studies on T CD8+ cancer infiltration indicate that the deficiency of tumor associated macrophages (TAMs) positive for TREM2 is associated with a stronger cytotoxic T cell activity and a higher responsiveness to anti PD-1 immunotherapy (35) (36). In tumor microenvironment, TREM2 expressed on TAMs is also directly involved in FOXP3 Treg cells recruitment and T CD8+ suppression, and Colonna et al., reported that anti-TREM2 mAb treatment could reduce the infiltration of immunosuppressive macrophages and expand the presence of cells expressing immunostimulatory molecules (36) (37) (38).

In conclusion, our results suggest that the immunomodulatory sulfolipid SULF A promotes a regulatory response in allogeneic MLR. Notably, the molecule triggers a negative modulation of the immune

synapse by expression of co-inhibitory molecules on DCs and T cells, along with the release of cytokines, such as IL-4 and IL-10, favoring the dampening of inflammation. In the hyperresponsive and inflammatory context of the allogeneic MLR, the overall outcome is a tolerogenic effect that is likely aimed to restoration of homeostasis. However, it is possible that SULF A could elicit inhibitory or stimulatory immune responses in a context-dependent manner. This hypothesis may explain the effective activation of antigen-induced immune protection that SULF A has shown *in vivo* (11) and agrees with recent findings on the different modulation of immune cells by TREM2 and PRRs in relation to different microenvironments and physiopathological disorders (39) (40).

## Data availability statement

The original contributions presented in the study are included in the article/[Supplementary Material](#). Further inquiries can be directed to the corresponding authors.

## Author contributions

GB and CG prepared and performed the experiments. DC, MA, MD supported the experimental work and analysis; GB, MA, DC, MD collected the data. GB and CG analyzed the results. GB performed the statistical analysis. EM, LF, MZ prepared SULF A; GN and Gd'I carried out the chemical analysis. RP contributed to the interpretation of the results and, together AF, conceived the study. AF planned the experiments, analyzed the results and, together with GB, drafted the manuscript. All authors contributed to the article and approved the submitted version.

## Funding

This research was supported by the project “Antitumor Drugs and Vaccines from the Sea (ADViSE)” (CUP B43D18000240007–SURF 17061BP000000011; PG/2018/0494374) funded by POR Campania FESR 2014–2020 “Technology Platform for Therapeutic Strategies against Cancer” Action 1.1.2 and 1.2.2. and by the project “Development of therapeutic agents for COVID and LONG COVID from natural small molecules” (n. 15, PG/2022/370426 of 18/07/2022) funded by POR FESR CAMPANIA 2014–2020 – “Implementation of research and development services for the fight against Covid-19”, DD n. 19/2022. AF also acknowledges the support of the project “Implementation of new immunomodulatory small molecules for the prophylaxis and treatment of severe symptoms of COVID-19 (IMO4CoV)”, Ident. n. FISIR2020IP\_04530, funded by Fondo Integrativo Speciale per la Ricerca (FISR) 2020.

## Acknowledgments

Authors are grateful to Dr. Carmine Oricchio and Dr. Caterina Del Gaudio of Presidio Ospedaliero Umberto I of Nocera Inferiore, Salerno (Italy) for providing the human blood samples. We acknowledge BioSEArch SRL for the permission to

use Sulfavant A. The authors also thank Dr. Lucio Caso for the technical support.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.
