## About Frontiers

Frontiers is more than just an open access publisher of scholarly articles: it is a pioneering approach to the world of academia, radically improving the way scholarly research is managed. The grand vision of Frontiers is a world where all people have an equal opportunity to seek, share and generate knowledge. Frontiers provides immediate and permanent online open access to all its publications, but this alone is not enough to realize our grand goals.

## Frontiers journal series

The Frontiers journal series is a multi-tier and interdisciplinary set of open-access, online journals, promising a paradigm shift from the current review, selection and dissemination processes in academic publishing. All Frontiers journals are driven by researchers for researchers; therefore, they constitute a service to the scholarly community. At the same time, the *Frontiers journal series* operates on a revolutionary invention, the tiered publishing system, initially addressing specific communities of scholars, and gradually climbing up to broader public understanding, thus serving the interests of the lay society, too.

## Dedication to quality

Each Frontiers article is a landmark of the highest quality, thanks to genuinely collaborative interactions between authors and review editors, who include some of the world's best academicians. Research must be certified by peers before entering a stream of knowledge that may eventually reach the public - and shape society; therefore, Frontiers only applies the most rigorous and unbiased reviews. Frontiers revolutionizes research publishing by freely delivering the most outstanding research, evaluated with no bias from both the academic and social point of view. By applying the most advanced information technologies, Frontiers is catapulting scholarly publishing into a new generation.

## What are Frontiers Research Topics?

Frontiers Research Topics are very popular trademarks of the *Frontiers journals series*: they are collections of at least ten articles, all centered on a particular subject. With their unique mix of varied contributions from Original Research to Review Articles, Frontiers Research Topics unify the most influential researchers, the latest key findings and historical advances in a hot research area.

Find out more on how to host your own Frontiers Research Topic or contribute to one as an author by contacting the Frontiers editorial office: [frontiersin.org/about/contact](https://frontiersin.org/about/contact)

# Women in cytokines and soluble mediators in immunity

## Topic editors

Diana Boraschi — Shenzhen Institute of Advanced Technology, Chinese Academy of Sciences (CAS), China

Giselle Penton-Rol — Center for Genetic Engineering and Biotechnology (CIGB), Cuba

Marita Troye Blomberg — Stockholm University, Sweden

Olukemi Amodu — University of Ibadan, Nigeria

## Citation

Boraschi, D., Penton-Rol, G., Troye Blomberg, M., Amodu, O., eds. (2024). *Women in cytokines and soluble mediators in immunity*. Lausanne: Frontiers Media SA.  
doi: 10.3389/978-2-8325-4434-1

*Dr. Penton-Rol was employed by Center for Genetic Engineering and Biotechnology.*

## Table of contents

- 12 **Editorial: Women in cytokines and soluble mediators in immunity**

Diana Boraschi, Giselle Penton-Rol, Olukemi Amodu and Marita Troye Blomberg

### A. CYTOKINES IN INVERTEBRATES

- 19 **Soluble mediators of innate immunity in annelids and bivalve mollusks: A mini-review**

Laura Canesi, Manon Auguste, Teresa Balbi and Petra Prochazkova

- 28 **Environmental stress and nanoplastics' effects on *Ciona robusta*: regulation of immune/stress-related genes and induction of innate memory in pharynx and gut**

Rita Marino, Daniela Melillo, Paola Italiani and Diana Boraschi

- 40 **Transcriptional and proteomic analysis of the innate immune response to microbial stimuli in a model invertebrate chordate**

Assunta Liberti, Carla Pollastro, Gabriella Pinto, Anna Illiano, Rita Marino, Angela Amoresano, Antonietta Spagnuolo and Paolo Sordino

### B. MAMMALIAN IMMUNITY

- 61 **IL-2 and IL-15 drive intrathymic development of distinct periphery-seeding CD4<sup>+</sup>Foxp3<sup>+</sup> regulatory T lymphocytes**

Cécile Apert, Ariel O. Galindo-Albarrán, Sarah Castan, Claire Detraves, Héloïse Michaud, Nicola McJannett, Bart Haegeman, Simon Fillatreau, Bernard Malissen, Georg Holländer, Saulius Žuklys, Jérémy C. Santamaria, Olivier P. Joffre, Paola Romagnoli and Joost P. M. van Meerwijk

- 79 **The chemokine landscape: one system multiple shades**

Valentina Cecchinato, Veronica Martini, Edisa Pirani, Elaheh Ghomeh and Mariagrazia Uguccioni

- 90 **Culture density influences the functional phenotype of human macrophages**

Adele V. Ruder, Lieve Temmerman, Joep M.A. van Dommelen, Jan Nagenborg, Chang Lu, Judith C. Sluimer, Pieter Goossens and Erik A.L. Biessen

## C. CYTOKINES/SOLUBLE FACTORS' PROFILE IN DISEASES AS DIAGNOSTIC/PROGNOSTIC MARKERS

### 1. INFECTIONS

#### 100 Time evolution of cytokine profiles associated with mortality in COVID-19 hospitalized patients

Laura Sánchez-de Prada, Óscar Gorgojo-Galindo, Inmaculada Fierro, Ana María Martínez-García, Guillermo Sarmentero-López de Quintana, Rocío Gutiérrez-Bustillo, María Teresa Pelaez-Jareño, Elisa Álvarez-Fuente, Esther Gómez-Sánchez, Eduardo Tamayo, Álvaro Tamayo-Velasco and Marta Martín-Fernández

#### 110 Immunologic and vascular biomarkers of mortality in critical COVID-19 in a South African cohort

Jane Alexandra Shaw, Maynard Meiring, Candice Snyders, Frans Everson, Lovemore Nyasha Sigwadhi, Veranyay Ngah, Gerard Tromp, Brian Allwood, Coenraad F. N. Koegelenberg, Elvis M. Irusen, Usha Lalla, Nicola Baines, Annalise E. Zemlin, Rajiv T. Erasmus, Zivanai C. Chapanduka, Tandi E. Matsha, Gerhard Walzl, Hans Strijdom, Nelita du Plessis, Alimuddin Zumla, Novel Chegou, Stephanus T. Malherbe and Peter S. Nyasulu on behalf of the COVID-19 Research Response Collaboration

#### 122 Panoramic snapshot of serum soluble mediator interplay in pregnant women with convalescent COVID-19: an exploratory study

Geraldo Magela Fernandes, Lizandra Moura Paravidine Sasaki, Gabriela Profirio Jardim-Santos, Heidi Luise Schulte, Felipe Motta, Ângelo Pereira da Silva, Aleida Oliveira de Carvalho, Yacara Ribeiro Pereira, Caroline de Oliveira Alves, David Alves de Araújo Júnior, Dayde Lane Mendonça-Silva, Karina Nascimento Costa, Maria Eduarda Canellas de Castro, Lucas Lauand, Rodrigo de Resende Nery, Rosana Tristão, Patricia Shu Kurizky, Otávio de Toledo Nóbrega, Laila Salmen Espindola, Luiz Cláudio Gonçalves de Castro, Patrícia Nessralla Alpoim, Lara Carvalho Godoi, Luci Maria Sant Ana Dusse, Jordana Graziela Alves Coelho-dos-Reis, Laurence Rodrigues do Amaral, Matheus de Souza Gomes, Pedro Luiz Lima Bertarini, Joaquim Pedro Brito-de-Sousa, Ismael Artur da Costa-Rocha, Ana Carolina Campi-Azevedo, Vanessa Peruhype-Magalhães, Andrea Teixeira-Carvalho, Alberto Moreno Zaconeta, Alexandre Anderson de Sousa Munhoz Soares, Valéria Valim, Ciro Martins Gomes, Cleandro Pires de Albuquerque, Olindo Assis Martins-Filho and Licia Maria Henrique da Mota

#### 137 Single cell meta-analysis of EndMT and EMT state in COVID-19

Lanlan Zhang, Chuang Tang, Min Zhang, Xia Tong, Yingying Xie, Ruitong Yan, Xiangjun Wang, Xin Zhang, Dan Liu and Shasha Li

- 149 **The SARS-CoV-2 Nucleoprotein Induces Innate Memory in Human Monocytes**  
Patricia Urbán, Paola Italiani, Diana Boraschi and Sabrina Gioria
- 157 **Pre-existing immunity to SARS-CoV-2 before the COVID-19 pandemic era in Cameroon: A comparative analysis according to HIV-status**  
Abba Aissatou, Joseph Fokam, Ezechiel Ngoufack Jagni Semengue, Désiré Takou, Aude Christelle Ka'e, Collins Chenwi Ambe, Alex Durand Nka, Sandrine Claire Djupsa, Grâce Beloumou, Laura Ciaffi, Michel Carlos Tommo Tchouaket, Audrey Rachel Mundo Nayang, Willy Leroi Togna Pabo, René Ghislain Essomba, Edie G. E. Halle, Marie-Claire Okomo, Anne-Cecile ZK. Bissek, Rose Leke, Yap Boum, Georges Alain Etoundi Mballa, Carla Montesano, Carlo-Federico Perno, Vittorio Colizzi and Alexis Ndjolo
- 164 **Inflammatory profile of vertically HIV-1 infected adolescents receiving ART in Cameroon: a contribution toward optimal pediatric HIV control strategies**  
Aude Christelle Ka'e, Aubin Joseph Nanfack, Georgia Ambada, Maria Mercedes Santoro, Desire Takou, Ezechiel Ngoufack Jagni Semengue, Alex Durand Nka, Marie Laure Mpouel Bala, Orphelie Ndoh Endougou, Elise Elong, Grace Beloumou, Sandrine Djupsa, Davy Hyacinthe Gouissi, Nadine Fainguem, Michel Carlos Tommo Tchouaket, Samuel Martin Sosso, Daniel Kesseng, Francis Ateba Ndongo, Nelson Sonela, Arnaud Cedric Lacmago Kamta, Hyppolite K. Tchidjou, Therese Ndomgue, Suzie Tetang Moyo Ndiang, Anne Esther Njom Nlend, Celine Nguefeu Nkenfou, Carla Montesano, Gregory Edie Halle-Ekane, Giulia Cappelli, Caroline T. Tiemessen, Vittorio Colizzi, Francesca Ceccherini-Silberstein, Carlo-Federico Perno and Joseph Fokam
- 174 **Aortic aneurysms and markers of platelet activation, hemostasis, and endothelial disruption in people living with HIV**  
Sylvester Klöcker Grønbaek, Julie Høgh, Andreas Dehlbæk Knudsen, Michael Huy Cuong Pham, Per Ejstrup Sigvardsen, Andreas Fuchs, Jørgen Tobias Kühl, Lars Køber, Jan Gerstoft, Thomas Benfield, Sisse Rye Ostrowski, Klaus Fuglsang Kofoed and Susanne Dam Nielsen
- 183 **Interferome signature dynamics during the anti-dengue immune response: a systems biology characterization**  
Júlia Nakanishi Usuda, Desirée Rodrigues Praça, Dennyson Leandro M. Fonseca, Alexandre H. C. Marques, Igor Salerno Filgueiras, Victor Gabriel Bastos Chaves, Anny Silva Adri, Amanda Torrentes-Carvalho, Mario Hiroyuki Hirata, Paula Paccielli Freire, Rusan Catar, Gustavo Cabral-Miranda, Lena F. Schimke, Guido Moll and Otavio Cabral-Marques
- 199 **Single cell transcriptomics of bone marrow derived macrophages reveals Ccl5 as a biomarker of direct IFNAR-independent responses to DNA sensing**  
Emily McCarty, Justin Yu, Van K. Ninh, David M. Calcagno, Jodi Lee and Kevin R. King

- 210 **Immunogenomic profile at baseline predicts host susceptibility to clinical malaria**  
Gillian Mbambo, Ankit Dwivedi, Olukemi O. Ifeonu, James B. Munro, Biraj Shrestha, Robin E. Bromley, Theresa Hodges, Ricky S. Adkins, Bourema Kouriba, Issa Diarra, Amadou Niangaly, Abdoulaye K. Kone, Drissa Coulibaly, Karim Traore, Amagana Dolo, Mahamadou A. Thera, Matthew B. Laurens, Ogobara K. Doumbo, Christopher V. Plowe, Andrea A. Berry, Mark Travassos, Kirsten E. Lyke and Joana C. Silva
- 224 **Is TNF alpha a mediator in the co-existence of malaria and type 2 diabetes in a malaria endemic population?**  
Subulade A. Ademola, Oluwayemi J. Bamikole and Olukemi K. Amodu
- 232 **Are IL-1 family cytokines important in management of sickle cell disease in Sub-Saharan Africa patients?**  
Liliane K. Siransy, Romuald S. Dasse, Honoré Adou, Patricia Kouacou, Sidonie Kouamenan, Yassongui Sekongo, Richard Yeboah, Charlene Memel, Aniella Assi-Sahoin, Salimata Y. Moussa, Doris Oura and Jocelyne Seri
- 242 **Clinical and immunological spectra of human cutaneous leishmaniasis in North Africa and French Guiana**  
Nasreddine Saidi, Romain Blaizot, Ghislaine Prévot, Karim Aoun, Magalie Demar, Pierre André Cazenave, Aida Bouratbine and Sylviane Pied
- 255 **Cytokine/chemokine profiles in people with recent infection by *Mycobacterium tuberculosis***  
Mariana Herrera, Yoav Keynan, Lucelly Lopez, Diana Marín, Lázaro Vélez, Paul J. McLaren and Zulma Vanessa Rueda
- 267 **Analyses of human immune responses to *Francisella tularensis* identify correlates of protection**  
Helena Lindgren, Kjell Eneslätt, Igor Golovliov, Carl Gelhaus and Anders Sjöstedt
- 281 **The osteoblast secretome in *Staphylococcus aureus* osteomyelitis**  
Valentina Granata, Valentina Possetti, Raffaella Parente, Barbara Bottazzi, Antonio Inforzato and Cristina Sobacchi
- 295 **A cytokine/PTX3 prognostic index as a predictor of mortality in sepsis**  
Sadaf Davoudian, Daniele Piovani, Antonio Desai, Sarah N. Mapelli, Roberto Leone, Marina Sironi, Sonia Valentino, Rita Silva-Gomes, Matteo Stravalaci, Fatemeh Asgari, Alessandra Madera, Daniele Piccinini, Carlo Fedeli, Denise Comina, Stefanos Bonovas, Antonio Voza, Alberto Mantovani and Barbara Bottazzi

## 2. PREGNANCY

- 313 **Pro- and anti-inflammatory cytokines and growth factors in patients undergoing *in vitro* fertilization procedure treated with prednisone**  
Karolina Piekarska, Marta Dratwa, Paweł Radwan, Michał Radwan, Katarzyna Bogunia-Kubik and Izabela Nowak

- 331 **First-Trimester Serum Cytokine Profile in Pregnancies Conceived After Assisted Reproductive Technology (ART) With Subsequent Pregnancy-Induced Hypertension**  
Xiangxin Lan, Ling Guo, Shiqin Zhu, Yongzhi Cao, Yue Niu, Shuwen Han, Zeyan Li, Yan Li and Junhao Yan
- 341 **Circulating inflammatory cytokines and hypertensive disorders of pregnancy: a two-sample Mendelian randomization study**  
Siqi Guan, Xiaoxu Bai, Jincheng Ding and Rujin Zhuang
- 353 **Comparison of EV-free fraction, EVs, and total secretome of amniotic mesenchymal stromal cells for their immunomodulatory potential: a translational perspective**  
Andrea Papait, Enrico Ragni, Anna Cargnoni, Elsa Vertua, Pietro Romele, Alice Masserdotti, Carlotta Perucca Orfei, Patrizia Bonassi Signoroni, Marta Magatti, Antonietta R. Silini, Laura De Girolamo and Ornella Parolini
- 370 **Immune-checkpoint proteins, cytokines, and microbiome impact on patients with cervical insufficiency and preterm birth**  
Seri Jeong, Won Kyong Cho, Yeonhwa Jo, Soo-Ran Choi, Nuri Lee, Kibum Jeon, Min-Jeong Park, Wonkeun Song and Keun-Young Lee
- 381 **Monocyte signature as a predictor of chronic lung disease in the preterm infant**  
Anita C. Windhorst, Motaharehsadat Heydarian, Maren Schwarz, Prajakta Oak, Kai Förster, Marion Frankenberger, Erika Gonzalez Rodriguez, Xin Zhang, Harald Ehrhardt, Christoph Hübener, Andreas W. Flemmer, Hamid Hossain, Tobias Stoeger, Christian Schulz and Anne Hilgendorff

### 3. OTHER CONDITIONS

- 390 **Systemic inflammatory markers in patients with polyneuropathies**  
Patricia García-Fernández, Klemens Höfflin, Antonia Rausch, Katharina Strommer, Astrid Neumann, Nadine Cebulla, Ann-Kristin Reinhold, Heike Rittner, Nurcan Üçeyler and Claudia Sommer
- 408 **In search of immune cellular sources of abnormal cytokines in the blood in autism spectrum disorder: A systematic review of case-control studies**  
Wared Nour-Eldine, Samia M. Ltaief, Nimshitha P. Abdul Manaph and Abeer R. Al-Shammari
- 424 **Evaluation of plasma IL-21 as a potential biomarker for type 1 diabetes progression**  
Anna-Mari Schroderus, Josh Poorbaugh, Samantha McElyea, Stephanie Beasley, Lin Zhang, Kirsti Näntö-Salonen, Reeta Rintamäki, Jussi Pihlajamäki, Mikael Knip, Riitta Veijola, Jorma Toppari, Jorma Ilonen, Robert J. Benschop and Tuure Kinnunen

- 432 **Adipokines as potential biomarkers for type 2 diabetes mellitus in cats**  
Olga Sierawska and Paulina Niedźwiedzka-Rystwej
- 443 **Prognostic analysis and validation of diagnostic marker genes in patients with osteoporosis**  
Xing Wang, Zhiwei Pei, Ting Hao, Jirigala Ariben, Siqin Li, Wanxiong He, Xiangyu Kong, Jiale Chang, Zhenqun Zhao and Baoxin Zhang
- 459 **Proteomic aptamer analysis reveals serum biomarkers associated with disease mechanisms and phenotypes of systemic sclerosis**  
Francesca Motta, Antonio Tonutti, Natasa Isailovic, Angela Ceribelli, Giovanni Costanzo, Stefano Rodolfi, Carlo Selmi and Maria De Santis
- 470 **IL-22BP production is heterogeneously distributed in Crohn's disease**  
Aurélie Fantou, Eric Lagrue, Thomas Laurent, Laurence Delbos, Stéphanie Blandin, Anne Jarry, Gaëlle Beriou, Cécile Braudeau, Nina Salabert, Eros Marin, Aurélie Moreau, Juliette Podevin, Arnaud Bourreille, Régis Josien and Jérôme C. Martin
- 482 **Differential protease content of mast cells and the processing of IL-33 in *Alternaria alternata* induced allergic airway inflammation in mice**  
Olga Krysko, Darya Korsakova, Andrea Teufelberger, Amse De Meyer, Jill Steels, Natalie De Ruyck, Judith van Ovost, Sharon Van Nevel, Gabriele Holtappels, Frauke Coppieters, Mikhail Ivanchenko, Harald Braun, Maria Vedunova, Dmitri V. Krysko and Claus Bachert

## D. CYTOKINES/SOLUBLE FACTORS IN PATHOGENIC MECHANISMS

- 497 **Cause or consequence? The role of IL-1 family cytokines and receptors in neuroinflammatory and neurodegenerative diseases**  
Diana Boraschi, Paola Italiani, Paola Migliorini and Paola Bossù
- 508 **Macrophage IL-1 $\beta$  contributes to tumorigenesis through paracrine AIM2 inflammasome activation in the tumor microenvironment**  
Zhi Huan Chew, Jianzhou Cui, Karishma Sachaphibulkij, Isabelle Tan, Shreya Kar, Kai Kiat Koh, Kritika Singh, Hong Meng Lim, Soo Chin Lee, Alan Prem Kumar, Stephan Gasser and Lina H. K. Lim
- 521 **Membrane-bound Interleukin-1 $\alpha$  mediates leukocyte adhesion during atherogenesis**  
Christina Maeder, Thimoteus Speer, Angela Wirth, Jes-Niels Boeckel, Sameen Fatima, Khurram Shahzad, Marc Freichel, Ulrich Laufs and Susanne Gaul

- 533 **Interleukin-36 $\gamma$  is causative for liver damage upon infection with Rift Valley fever virus in type I interferon receptor-deficient mice**  
Martina Anzaghe, Marc A. Niles, Eugenia Korotkova, Monica Dominguez, Stefanie Kronhart, Samira Ortega Iannazzo, Ingo Bechmann, Malte Bachmann, Heiko Mühl, Georg Kochs and Zoe Waibler
- 547 **Cytokine signaling converging on *IL11* in ILD fibroblasts provokes aberrant epithelial differentiation signatures**  
Miriam T. Kastlmeier, Erika Gonzalez-Rodriguez, Phoebe Cabanis, Eva M. Guenther, Ann-Christine König, Lianyong Han, Stefanie M. Hauck, Fenja See, Sara Asgharpour, Christina Bukas, Gerald Burgstaller, Marie Piraud, Mareike Lehmann, Rudolf A. Hatz, Jürgen Behr, Tobias Stoeger, Anne Hilgendorff and Carola Voss
- 560 **The dysregulation of leukemia inhibitory factor and its implications for endometriosis pathophysiology**  
Katherine B. Zutautas, Danielle J. Sisnett, Jessica E. Miller, Harshavardhan Lingegowda, Timothy Childs, Olga Bougie, Bruce A. Lessey and Chandrakant Tayade
- 573 **GAS6/TAM signaling pathway controls MICA expression in multiple myeloma cells**  
Andrea Kosta, Abdelilah Mekhloufi, Lorenzo Lucantonio, Alessandra Zingoni, Alessandra Soriani, Marco Cippitelli, Angela Gismondi, Francesca Fazio, Maria Teresa Petrucci, Angela Santoni, Helena Stabile and Cinzia Fionda
- 586 **Increased plasma level of terminal complement complex in AMD patients: potential functional consequences for RPE cells**  
Catharina Busch, Saskia Rau, Andjela Sekulic, Luce Perie, Christian Huber, Miranda Gehrke, Antonia M. Joussem, Peter F. Zipfel, Gerhild Wildner, Christine Skerka and Olaf Strauß
- 603 **The hyperinflammatory spectrum: from defects in cytotoxicity to cytokine control**  
Raquel Planas, Matthias Felber, Stefano Vavassori and Jana Pachlopnik Schmid
- 622 **The clinical relevance of OSM in inflammatory diseases: a comprehensive review**  
Cody L. Wolf, Clyde Pruett, Darren Lighter and Cheryl L. Jorcyk
- 646 **The role of tumor-associated macrophages and soluble mediators in pulmonary metastatic melanoma**  
Kaifen Xiong, Min Qi, Tobias Stoeger, Jianglin Zhang and Shanze Chen
- 662 **The cytokine network in acute myeloid leukemia**  
Michela Luciano, Peter W. Krenn and Jutta Horejs-Hoeck

## E. CYTOKINES AND CYTOKINE MODULATION IN THERAPY

- 676 **A natural goldmine of binding proteins and soluble receptors simplified their translation to blockbuster drugs, all in one decade**  
Daniela Novick
- 681 **Intravesical BCG in bladder cancer induces innate immune responses against SARS-CoV-2**  
Renate Pichler, Gabriel Diem, Hubert Hackl, Jiří Koutník, Laura S. Mertens, David D`Andrea, Benjamin Pradere, Francesco Soria, Andrea Mari, Ekaterina Laukhtina, Wojciech Krajewski, Jeremy Yuen-Chun Teoh, Francesco Del Guidice, Marco Moschini, Martin Thurnher and Wilfried Posch for the European Association of Urology-Young Academic Urologists (EAU-YAU): Urothelial carcinoma working group
- 694 **Immunotherapy with STING and TLR9 agonists promotes synergistic therapeutic efficacy with suppressed cancer-associated fibroblasts in colon carcinoma**  
Sare Hajiabadi, Soodeh Alidadi, Zohreh Montakhab Farahi, Mohammad M. Ghahramani Seno, Hamidreza Farzin and Alireza Haghparsat
- 709 **Modulation of innate immunity in airway epithelium for host-directed therapy**  
Iwona T. Myszor and Gudmundur Hrafn Gudmundsson
- 728 **NO–IL-6/10–IL-1 $\beta$  axis: a new pathway in steatotic and non-steatotic liver grafts from brain-dead donor rats**  
Arani Casillas-Ramírez, Marc Micó-Carnero, Alfredo Sánchez-González, Cristina Maroto-Serrat, Andrés Trostchansky and Carmen Peralta
- 755 **Modulation of intestinal IL-37 expression and its impact on the epithelial innate immune response and barrier integrity**  
Laura Kröhn, Aline Azabdaftari, Julian Heuberger, Christian Hudert, Matthias Zilbauer, Tilman Breiderhoff and Philip Bufler
- 766 **The effects of Phycocyanobilin on experimental arthritis involve the reduction in nociception and synovial neutrophil infiltration, inhibition of cytokine production, and modulation of the neuronal proteome**  
Javier Marín-Prida, Arielis Rodríguez-Ulloa, Vladimir Besada, Alexey Llopiz-Arzuaga, Nathália Vieira Batista, Ignacio Hernández-González, Nancy Pavón-Fuentes, Érica Leandro Marciano Vieira, Viviana Falcón-Cama, Emilio F. Acosta, Gillian Martínez-Donato, Majel Cervantes-Llanos, Dai Lingfeng, Luis J. González, Julio Raúl Fernández-Massó, Gerardo Guillén-Nieto, Eduardo Pentón-Arias, Flávio Almeida Amaral, Mauro Martins Teixeira and Giselle Pentón-Rol

- 784 Anti-inflammatory mechanisms and pharmacological actions of phycocyanobilin in a mouse model of experimental autoimmune encephalomyelitis: A therapeutic promise for multiple sclerosis**  
Javier Marín-Prida, Nancy Pavón-Fuentes, Nielsen Lagumersindez-Denis, Hanlet Camacho-Rodríguez, Ana Margarita García-Soca, Rocío de la Caridad Sarduy-Chávez, Érica Leandro Marciano Vieira, Juliana Carvalho-Tavares, Viviana Falcón-Cama, Julio Raúl Fernández-Massó, Ignacio Hernández-González, Gillian Martínez-Donato, Gerardo Guillén-Nieto, Eduardo Pentón-Arias, Mauro Martins Teixeira and Giselle Pentón-Rol
- 802 Targeting the chemokine receptor CXCR4 with histamine analog to reduce inflammation in juvenile arthritis**  
Nassima Bekaddour, Nikaia Smith, Benoit Beitz, Alba Llibre, Tom Dott, Anne Baudry, Anne-Sophie Korganow, Sébastien Nisole, Richard Mouy, Sylvain Breton, Brigitte Bader-Meunier, Darragh Duffy, Benjamin Terrier, Benoit Schneider, Pierre Quartier, Mathieu P. Roderio and Jean-Philippe Herbeuval
- 818 A peptide derived from HSP60 reduces proinflammatory cytokines and soluble mediators: a therapeutic approach to inflammation**  
Maria del Carmen Domínguez-Horta, Anabel Serrano-Díaz, Mabel Hernández-Cedeño, Gillian Martínez-Donato and Gerardo Guillén-Nieto
- 828 The antitumor effect induced by an IL-2 'no-alpha' mutein depends on changes in the CD8<sup>+</sup> T lymphocyte/Treg cell balance**  
Tania Carmenate, Galia Montalvo, Sum Lai Lozada, Yaretnis Rodriguez, Yaquelin Ortiz, Claudia Díaz, Janet Avellanet, Juhee Kim, Charles D. Surh, Luis Graça and Kalet León
- 837 The immunoregulatory effect of the TREM2-agonist Sulfavant A in human allogeneic mixed lymphocyte reaction**  
Giusi Barra, Carmela Gallo, Dalila Carbone, Marcello Ziaco, Mario Dell'Isola, Mario Affuso, Emiliano Manzo, Genoveffa Nuzzo, Laura Fioretto, Giuliana D'Ippolito, Raffaele De Palma and Angelo Fontana

## Editorial on the Research Topic

### Women in cytokines and soluble mediators in immunity

The Research Topic dedicated to “*Women in Cytokines and Soluble Factors in Immunity*” was launched in March 2022 by two experienced and two younger female scientists, active in four different continents. In 24 months, we have collected over 60 contributions from female scientists around the World. Most of the papers are original research studies and deal with human diseases (tumors, infections), evaluating the pathological or predictive role of cytokines, but also the importance of cytokines in invertebrate immune defense. Most of the papers list young PhD students as first author, but many very experienced female scientists have also contributed. Most of the papers come from Europe, but significant contributions were received from Asia, Americas and Africa. Impressively, almost one third of the papers are cross-continental collaborations. While much still must be done for promoting female participation to scientific research, in particular in developing countries, this Research Topic underlines an encouraging scenario of commitment and dedication to science, desire of collaboration, capacity to coach, train and support younger female scientists to engage in a scientific career.

## 1 Cytokines and soluble factors in immunity

The field of cytokines and other soluble factors in immunity encompasses many different scientific areas, from evolution of immunity to clinical diagnostic studies. This Research Topic includes several important contributions in different areas of basic and clinical research on soluble immune factors, as briefly summarized below.

## 1.1 Invertebrate immunity

Soluble immune factors are essential elements in the defensive system of invertebrate metazoans, and include enzymes such as lysozyme and phenoloxidase, complement and inflammatory cytokines such as IL-17 and TNF (1–6). A comprehensive analysis of soluble factors-mediated immunity in two different invertebrate phyla, annelids and bivalve mollusks, is reported by an excellent group of four women scientists active in two different European countries (Canesi et al.). Two studies from Italy and Italy-China analyzed the immune response of tunicates to biotic or abiotic challenges and showed that the modulation of several immune factors, including complement, cytokines, enzymes and variable chitin-binding and LPS-binding proteins, is the basis of primary and memory responses in *Ciona robusta* (Marino et al., Liberti et al.).

## 1.2 Mammalian immunity

In mammalian immunity, soluble factors have a major importance both for innate and adaptive immune response. As for invertebrates, complement is one of the key anti-bacterial effector systems (4, 7, 8). For adaptive immunity, antibodies are the highly specific and effective neutralizing tools (8). Cytokines and chemokines are soluble factors that participate to both innate and adaptive immunity, representing the natural bridge between the two systems (8). The role of soluble factors in the T cell development has been extensively examined, including at the level of intrathymic differentiation (8, 9). A very interesting study addresses the role of two such factors, IL-2 and IL-15, in driving the differentiation of distinct Treg cells in the thymus (Apert et al.). It is notable that such study is the result of a collaboration between three different European countries, France, Switzerland and UK. A comprehensive assessment of the multifaceted role of chemokines in immunity is provided by a young researcher active in one of the groups that discovered chemokines, in Switzerland (Cecchinato et al.). The ability of innate cells such as macrophages to produce cytokines and other soluble factors in response to challenges is generally assessed *in vitro* in culture systems that may not reproduce accurately the *in vivo* conditions (10, 11). This is a shortcoming that may lead to misleading results and inaccurate prediction of immune reactivities. A joint collaboration between Dutch, UK and German researchers pointed out how variations in cell density in culture can influence the function and cytokine production by human macrophages, which warrants a particular attention in the reliable design of our cell culture systems (Ruder et al.).

## 1.3 Cytokines/soluble factors' profile in diseases as diagnostic/prognostic markers

The role of cytokines and other immune soluble factors in diseases has gained increasing importance, and many studies have

pointed at the possibility of using them as diagnostic markers, able to identify the type and stage of multiple different diseases, and as prognostic tools for predicting future susceptibility or resistance to disease development.

### 1.3.1 Infections

The recent COVID-19 pandemic has produced numerous studies of cytokines as markers of disease and disease severity. Association with mortality, as well as other immune and vascular biomarkers, is reported in two studies, one in Spain (Sanchez-de Prada et al.) and one in South Africa in collaboration with UK (Shaw et al.). The soluble immune factors' profile in COVID-19 convalescent pregnant women was examined in an extensive Brazilian study encompassing ten different institutions (Fernandes et al.). The lung inflammatory conditions and the infection-dependent epithelial to mesenchymal transition was examined at the single cell level in a collaborative study between China and USA (Zhang et al.). The importance of the viral nucleoprotein in inducing anti-inflammatory innate memory was examined in a joint study between the European Commission JRC, Italy and China (Urban et al.). A very interesting study in Cameroon in collaboration with Italy highlighted the presence of antibodies reactive to SARS-CoV-2 in archive samples of HIV patients dating back to before the COVID-19 pandemic (Aissatou et al.). Inflammation-related soluble factors were examined in HIV patients both for optimizing treatment in Cameroonian adolescents in a collaborative study between Cameroon, Italy, France and South Africa (Ka'e et al.) and for predicting hematological complications and, again, optimize treatment, in a Danish study (Grønbaek et al.). Response to viruses has been further examined in a collaborative Brazil-Germany study in terms of systems biology dynamical evaluation of interferon-related signatures in Dengue infection (Usuda et al.) and single cell-based identification of the chemokine CCL5 as biomarker of macrophage response to DNA sensing in a USA work (McCarty et al.).

Several studies focused on parasitic diseases, in particular malaria. A comprehensive immunogenomic study was performed in a collaboration between USA, Mali and Portugal to identify an immune profile predictive of susceptibility to clinical malaria (Mbambo et al.). Another study from Nigeria explored the possible pathogenic role of TNF- $\alpha$  in malaria patients with type 2 diabetes (Ademola et al.). In a study from the Côte d'Ivoire, another inflammatory cytokine, IL-1 $\beta$ , and other members of the IL-1 family, were examined in sickle cell disease in Sub-Saharan Africa, in the attempt to design a better management of the disease (Siransy et al.). The immunological aspects of clinical forms of cutaneous leishmaniasis in North Africa and French Guiana were addressed in a collaborative study between France, Tunisia and French Guiana (Saidi et al.).

Focus on bacterial infections encompasses a study examining the profile of cytokines and chemokines in people recently infected with *Mycobacterium tuberculosis*, within a collaboration between Colombia and Canada (Herrera et al.), a Canadian-Swedish study reported on correlates of protection in *Francisella tularensis* infection (Lindgren et al.), a very interesting evaluation of the osteoblast

secretome in osteomyelitis induced by *Streptococcus aureus* was contributed by an Italian group (Granata et al.), and an Italian-UK collaboration provided an excellent review of the value of PTX3 as prognostic marker of mortality in sepsis (Davoudian et al.).

### 1.3.2 Pregnancy

The involvement of soluble immune factors in some pathological aspects associated with pregnancy has been the focus of a number of manuscripts. The levels of cytokines in patients undergoing procedures for *in vitro* fertilization were examined in a study from Poland (Piekarska et al.). The cytokine levels in first trimester-pregnant women developing hypertension after assisted reproductive technology were examined in a Chinese study (Lan et al.), while another Chinese study addressed the association between circulating inflammatory cytokines and pregnancy-associated hypertension (Guan et al.). Pregnancy-associated immunomodulation through extracellular vesicles and soluble factors released by amniotic mesenchymal stromal cells was investigated for possible translational applications by an Italian study (Papait et al.). The correlation between immune parameters, including cytokines, and cervical insufficiency and preterm births was addressed by a Korean study (Jeong et al.). Eventually, the association between monocyte signatures and the risk of developing chronic lung disease in preterm infants was shown in a German study (Windhorst et al.).

### 1.3.3 Other conditions

Cytokines and soluble factors can act as markers of disease, disease progression and disease severity in several diseases in which inflammation is involved. A collaborative study between Germany and Austria addressed the presence of systemic inflammation-related markers in polyneuropathies (Garcia-Fernandez et al.), while a study from Qatar has investigated the cellular sources of anomalous cytokine levels in autism (Nour-Eldine et al.). In a Finnish/USA study, circulating IL-21 was found to correlated with disease progression in type 1 diabetes (Schroderus et al.), whereas a Polish study suggested adipokines could be disease biomarkers in type 2 diabetes, demonstrated in a cat model (Sierawska and Niedźwiedzka-Rystwej et al.). Soluble prognostic and diagnostic biomarkers of osteoporosis were investigated in a Chinese study (Wang et al.). In an Italian study, soluble biomarkers of disease mechanisms and phenotypes of systemic sclerosis were identified with an aptamer-based proteomic approach (Motta et al.). The distribution of IL-22BP in Crohn's disease was the focus of a French investigation (Fantou et al.). Eventually, the contribution of mast cell proteases and IL-33 processing in the development of allergic lung inflammation was examined in a mouse model in a collaborative study between Belgium, Austria, Russia, Germany and China (Krysko et al.).

## 1.4 Cytokines and soluble factors in pathogenic mechanisms

Whether anomalies in cytokine production is a consequence of disease or may be part of the pathogenesis is still an open question.

Several studies included in this collection tackle the issue in the attempt to identify the involvement of cytokines in pathogenesis vs. pathology. Several of the studies focused on cytokines of the IL-1 family, which include highly inflammatory factors, such as IL-1 $\beta$ , that have a well-known role in many chronic inflammatory and degenerative diseases (12, 13). A manuscript from Italy and China examined the role of IL-1 family cytokines in neuroinflammatory and neurodegenerative diseases and concluded that most likely these cytokines are involved in both pathogenesis and downstream pathological symptoms (Boraschi et al.). That IL-1 $\beta$ , the best-known inflammatory cytokine of the family, can be involved in tumorigenesis is known (14, 15), but a study from Singapore and Switzerland further identified AIM2 activation as one of the factors contributing to the production of IL-1 $\beta$  in the tumor microenvironment (Chew et al.). IL-1 $\alpha$ , a cytokine mostly present as membrane bound molecule thereby acting through cell-to-cell contact (16, 17), was found responsible for activating leukocyte adhesion during atherogenesis in a German study (Maeder et al.). Another German study found that IL-36 $\gamma$ , a less known inflammatory cytokine of the IL-1 family mostly active at the tissue level, is responsible for interferon-independent liver injury caused by the Rift Valley virus (Anzaghe et al.). Other specific cases were examined: the role of IL-11 in fibrosis in interstitial lung disease, studied using human organoids by a German group (Kastlmeier et al.); the dysregulation of LIF in endometriosis, proposed by a Canadian-USA collaboration (Zutautas et al.); the role of GAS6/TAM in regulating NK cell recognition of multiple myeloma cells and degranulation studied by an Italian-USA group (Kosta et al.); and the involvement of the complement terminal complex in the inflammatory activation of retinal pigment epithelium and the associated development of age-related macular degeneration proposed by a German collaboration study (Busch et al.). Eventually, a group of studies examined the entire spectrum of cytokines and soluble factors associated with initiation vs. maintenance of different pathologies. A collaborative study between Switzerland and Spain reviewed the contribution of cytokines to the hyperinflammatory spectrum (Planas et al.). A USA group reviewed the contribution of oncostatin M, a cytokine of the IL-6 family, in inflammatory diseases (Wolf et al.). In cancer, the contribution of tumor-associated macrophages and their soluble factors in lung metastatic melanoma was addressed in a China-Germany collaborative study (Xiong et al.). Eventually, an informative review on the role of cytokines in Acute Myeloid Leukemia was contributed by an Austrian group (Luciano et al.).

## 1.5 Cytokines and cytokine modulation in therapy

Targeting cytokines for curing diseases is an approach that has turned out to be successful in several instances, see as an example the TNF- $\alpha$  or IL-1 $\beta$  inhibitory biologicals currently used in several chronic inflammatory diseases (18–21), although the efficacy is not complete and side effects can be observed [such as the tuberculosis activation in patients with latent tuberculosis treated with anti-

TNF- $\alpha$  drugs; (22)]. An historical excursus describing how several of these cytokine inhibitors were originally identified is provided by Daniela Novick, a pioneer woman scientist who accelerated substantially the development of anti-cytokine drugs (Novick et al.). Inflammation, including induction of inflammatory cytokines, has been for decades the core of cancer immunotherapy, with the use of bacteria and bacterial-derived molecules (23). The use of BCG is currently the golden standard treatment for non-invasive bladder cancer, and its effect includes the activation of an anti-tumor innate and inflammatory response (24, 25). Based on the notion that innate immunity is non-specific, a large collaborative study (involving researchers from Austria, The Netherlands, France, Italy, Russia, Poland and Hong Kong) showed that treatment of bladder cancer patients with BCG induced a systemic innate response able to counteract the SARS-CoV-2 infection (Pichler et al.). On the same line, a very interesting study from an Iranian and Canadian collaboration shows that the use of molecules that induce innate/inflammatory activation can substantially increase the therapeutic immune response against colon cancer in a preclinical model and also downregulates the pathological presence of fibroblasts in the tumor microenvironment (Hajjabadi et al.). A review of the innate immunity in the airways, contributed by an Icelandic/Swedish group, comes to similar conclusions, i.e., that activation of innate immune/inflammatory epigenetic mechanisms by bacterial products may contribute to effective response and disease resolution (Myszor and Gudmundsson).

Anti-inflammatory strategies are the most common approaches to cytokine inhibition in different diseases. In liver transplantation from brain dead donors, inflammation is largely dependent on increased IL-1 $\beta$  production and was shown, in a study from a Mexico-Spain-Uruguay collaboration, to be the main cause of rejection, as it could be mitigated by treatment with the IL-1 antagonist IL-1Ra (Casillas-Ramirez et al.). Interestingly, a German-UK study on IL-37, an anti-inflammatory cytokine of the IL-1 family that is active in the gut, showed that the IL-37 role at the level of the mucosal epithelium is minimal, suggesting an anatomically distinct and localized anti-inflammatory activity (Krohn et al.). Among anti-inflammatory strategies, the use of phycocyanobilin, a tetrapyrrole chromophore from microalgae, displays substantial anti-inflammatory properties and was found able to inhibit leukocyte infiltration and cytokine production in a rheumatoid arthritis model (Marin-Prida et al.) and in a multiple sclerosis model (Marin-Prida et al.), as reported by two Cuban studies, one in collaboration with Brazil, China, Mexico, and the other one with Brazil and Germany. A French study explored the use of a synthetic histamine analogue that binds to CXCR4 (a chemokine receptor important for leukocyte mobilization) for inhibiting inflammation in juvenile arthritis cells *in vitro* and in a mouse model *in vivo*. Using this model, they observed substantial reduction of inflammatory cytokines, immune cell infiltration and joint and bone erosion (Bekaddour et al.). Anti-inflammatory effects were also observed in a Cuban study using a modified peptide derived from HSP60 both in animal models of RA and in human patients. The treatment inhibited inflammatory cytokine production, including IL-17, and ameliorated the cytokine storm in COVID-19 patients (Dominguez-Horta et al.). Anti-inflammatory

strategies targeting T cells included the above-mentioned study, which identified an increase in Treg cells, and a collaborative study between Cuba, Korea and Portugal on a mutant of IL-2, which showed that the antitumor activity of the mutein is based on the change of the balance between CD8<sup>+</sup> and Treg cells (Carmenate et al.). Eventually, an Italian study showed that a synthetic sulfolipid can decrease IL-12 production by dendritic cells and promote T cell differentiation towards Treg (Barra et al.).

## 2 Women in cytokines and soluble factors in immunity

This Research Topic provides much more than a number of good scientific papers on the general topic of cytokines and soluble factors in immunity. Being dedicated to women immunologists active in the area of cytokines, the Research Topic aimed to be as inclusive as possible, having expert scientists who could set an inspiring example for the young students who are just approaching science, and encouraging female researchers to engage in a scientific career in every country, in particular those where research conditions are more difficult in general and for women in particular. To reflect our intention, the four editors of the Research Topic are two old and two young female immunologists, active in four different continents. We have collected 62 contributions, in which the first or the senior author are female scientists. Many are young PhD students, while others are very experienced researchers. Authors of these papers come from 40 countries across four continents (Europe, Asia and Middle East, Africa, Americas). Impressively, over 77% of the studies are collaborative studies, and 44% of these collaborations are intercontinental, as we did underline in the previous paragraphs. This reflects a very encouraging trend, i.e., that scientists (and women in particular) strongly believe that progress means collaboration without borders and without any type of bias (Figure 1).

We had in 2023 two important examples of successful women, whom are worth mentioning for their life-long commitment. Claudia Goldin, an American economist, has been awarded the Nobel Prize in Economic Sciences for her relentless engagement in understanding and making known the gap between women and man in the labor market (26). Her work and her analysis of the reasons why the majority of undergraduates in USA are women are impacting substantially on the general understanding of the female working and social conditions, well beyond her country. Another inspiring example is Katalin Karicó, a Hungarian biochemist who moved to USA when she was 30, after she lost her lab position due to lack of funding. Katalin is an expert in RNA, and in 1989, soon after having moved to the USA, she started working on mRNA and focused on mRNA-based therapeutic approaches. In the following years, she encountered huge difficulties in obtaining funding and in developing her academic career but she never abandoned her focus on therapeutic mRNA, and eventually she succeeded in dumping the RNA inflammatory activity and devising an effective delivery system. This was the basis for the first widespread human application of mRNA, as vaccine for SARS-CoV-2. She was awarded the Nobel Prize in Physiology and Medicine in October 2023. Few months earlier, her biography was published as an illustrated children book, with the compelling title “Never give up” (27).

FIGURE 1

Worldwide distribution of the contributions to “Women in Cytokines and Soluble Factors in Immunity” with their collaborative interconnections. Artwork by Denise Ruiz Castro and Maykel Pedro Penton Martinez (Design project InDi productions, Havana, Cuba) and Sheila Delgado-Lora.

The contribution of women to science is substantial, but the gaps and inequalities are still outstanding in many countries and institutions. Although there are many initiatives aiming at raising awareness and encourage women’s participation in science (for instance the International Day of Women and Girls in Science, celebrated every February 11), we, as women scientists, are those who should “never give up”, both in pursuing advancement of knowledge and in closing gaps and eliminating inequalities.

## Author contributions

DB: Writing – review & editing, Writing – original draft. GP-R: Writing – review & editing. OA: Writing – review & editing. MB: Writing – review & editing.

## Funding

The author(s) declare financial support was received for the research, authorship, and/or publication of this article. DB was supported by the EU H2020 project PANDORA (GA 671881), the China-Italy NSFC-MAECI bilateral project 82261138630, the Key Collaborative Research Program of the Alliance of International Science Organizations ANSO-CR-KP-2022-01, and the Bill & Melinda Gates Foundation grant INV-059115.

## Acknowledgments

The authors are grateful for the active collaboration and support of many colleagues, who helped in making this endeavor a success. Of the people of *Frontiers in Immunology*, we thank in particular the editor-in-chief Gigi Notarangelo and the section editor Silvano Sozzani, who always patiently answered all our queries and requests of help, Jonathan Paul, who relentlessly followed the editorial work, and Madeleine Metcalf, who has concretely supported the participation of young female scientists from developing countries. We are very grateful to Denise Ruiz Castro and Maykel Pedro Penton Martinez (Design project InDi productions, Havana, Cuba), who conceived a compelling figure for illustrating the worldwide collaboration of women immunologists, and Sheyla Delgado-Lora, a young Cuban scientist who completed the design with great sensibility. Lastly, we are happy to acknowledge many fruitful collaborations with our male colleagues and the feeling that gender is slowly becoming a non-issue in an increasing number of research labs in several countries.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Publisher's note

All claims expressed in this article are solely those of the authors and do not necessarily represent those of their affiliated

organizations, or those of the publisher, the editors and the reviewers. Any product that may be evaluated in this article, or claim that may be made by its manufacturer, is not guaranteed or endorsed by the publisher.

# Soluble mediators of innate immunity in annelids and bivalve mollusks: A mini-review

Laura Canesi<sup>1</sup>, Manon Auguste<sup>1</sup>, Teresa Balbi<sup>1</sup>  
and Petra Prochazkova<sup>2\*</sup>

<sup>1</sup>Department of Earth Environment & Life Sciences, University of Genoa, Genoa, Italy, <sup>2</sup>Laboratory of Cellular and Molecular Immunology, Institute of Microbiology of the Czech Academy of Sciences, Prague, Czechia

Annelids and mollusks, both in the superphylum of Lophotrochozoa (Bilateria), are important ecological groups, widespread in soil, freshwater, estuarine, and marine ecosystems. Like all invertebrates, they lack adaptive immunity; however, they are endowed with an effective and complex innate immune system (humoral and cellular defenses) similar to vertebrates. The lack of acquired immunity and the capacity to form antibodies does not mean a lack of specificity: invertebrates have evolved genetic mechanisms capable of producing thousands of different proteins from a small number of genes, providing high variability and diversity of immune effector molecules just like their vertebrate counterparts. This diversity allows annelids and mollusks to recognize and eliminate a wide range of pathogens and respond to environmental stressors. Effector molecules can kill invading microbes, reduce their pathogenicity, or regulate the immune response at cellular and systemic levels. Annelids and mollusks are “typical” lophotrochozoan protostome since both groups include aquatic species with trochophore larvae, which unite both taxa in a common ancestry. Moreover, despite their extensive utilization in immunological research, no model systems are available as there are with other invertebrate groups, such as *Caenorhabditis elegans* or *Drosophila melanogaster*, and thus, their immune potential is largely unexplored. In this work, we focus on two classes of key soluble mediators of immunity, i.e., antimicrobial peptides (AMPs) and cytokines, in annelids and bivalves, which are the most studied mollusks. The mediators have been of interest from their first identification to recent advances in molecular studies that clarified their role in the immune response.

## KEYWORDS

Innate immunity, invertebrate, earthworm, bivalves, antimicrobial peptides, cytokines

## Annelids

Annelids, or segmented worms, are invertebrates with a true coelom filled with coelomic fluid containing several coelomocyte populations. Annelids include polychaetes (marine worms), oligochaetes (earthworms), and leeches. All members of this group are, to some extent, segmented, i.e., they consist of segments that are made up of sub-segments partially intersecting with the body cavity. Since their body is open to the environment, the coelomic cavity is not aseptic, and therefore they had to evolve extremely effective weapons against unwanted enemies. Effector immunocytes called amoebocytes are involved in a broad range of defense functions, including phagocytosis modulated by humoral components, opsonins, which are complement-like molecules, and lectins. The coelomic fluid of annelids contains various antimicrobial factors like lysozyme, hemolytic factors that bind sphingomyelin (fetidin, lysenin, lysenin-related proteins), antimicrobial peptides (AMPs), proteases (lumbrokinase, catalase, superoxide dismutases), cytolytic proteins (coelomic cytolytic factor (CCF)), clotting and coagulation factors, and enzyme-activation-based cascades (prophenoloxidase cascade) (1). Bioactive agents in the coelomic fluid also include several metabolites, like drilodefensins, responsible for the inhibitory effects of polyphenols in the earthworm digestive tract (2), and metallothioneins, small metal-binding proteins responsible for the detoxification and regulation of heavy metals (3). Notably, the humoral defense also includes pattern recognition receptors (PRRs) (such as Toll-like receptors (TLRs) and CCF) that are frequently based on lectin-saccharide interactions designed to recognize highly conserved structures present in different

microorganisms (pathogen-associated molecular patterns (PAMPs)). Consequently, cellular and humoral pathways of the innate defense are orchestrated by cytokine-like factors (4).

## AMPs

AMPs are evolutionarily ancient molecules produced by all living organisms, including annelids. They represent the first line of defense against microbes but also regulate commensal symbionts at various anatomical sites. Although more than 2,000 AMPs have been described in a wide range of organisms, the number of AMPs described in annelids is very small (Table 1).

The first discovered AMP in annelids was lumbricin-1 from the earthworm *Lumbricus rubellus* (5). Related peptides were subsequently identified in several annelids: Hm-lumbricin from the leech *Hirudo medicinalis* (6), peptide PP-1 from the Asian earthworm *Metaphire tschiliensis* (7), lumbricin-PG from the earthworm *Pheretima guillelmi* (8), and lumbricin and lumbricin-related peptide from the earthworm *Eisenia andrei* (9). These AMPs are enriched with prolines and display a broad spectrum of antibacterial activities. However, they are not inordinately abundant and probably do not represent their primary biological function. Their mechanism of action on microorganisms remains unknown.

Macins are quite long cationic cysteine-rich AMPs with an  $\alpha$ -helix/ $\beta$ -sheet structure. In leeches, the group includes theromacin from *Theromyzon tessulatum* (6) and Hm-neuromacin and Hm-theromacin from *H. medicinalis* (10). In addition to their antimicrobial activity, these AMPs are associated with regenerating damaged nerve cords. Their

mechanism of action consists of the induction of bacteria aggregation followed by membrane permeabilization (19).

The BRICHOS-AMPs (Bri2 chondromodulin and prosurfactant protein C) are cysteine-rich AMPs only found in polychaetes. They arise from a precursor containing the BRICHOS domain, a hydrophobic region, and a cysteine-rich C-terminal region folding into a double-stranded  $\beta$ -sheet. Interestingly, the BRICHOS domain is linked to amyloid formations occurring in several major human diseases like Parkinson's and Alzheimer's (20). The first described members of the BRICHOS family were arenicin 1 and 2 in the polychaete *Arenicola marina* (11). The subsequently identified arenicin 3 differs in its primary sequence and contains an extra disulfide bond (12). A similar AMP, alvinellacin, was identified in the hydrothermal Pompeii worm *Alvinella pompejana*, a deep ocean polychaete associated with hydrothermal vents (13). By genome screening of *Capitella teleta*, another member of the BRICHOS-AMPs family called capitellacin was described (14). Nicomicin-1 and -2 were discovered in the arctic polychaete *Nicomache minor*, which lives in frigid waters (15). Except for Nicomicin-2, all BRICHOS-AMPs exhibit a broad spectrum of antimicrobial activities against Gram-negative and Gram-positive bacteria, including multi-resistant species and fungi. These AMPs have membranolytic activity, causing membrane permeabilization of microbes within minutes. Arenicins are also hemolytic and cytotoxic to mammalian cells (21).

Hedistin, characterized by a linear  $\alpha$ -helix structure, has only been described in the marine polychaete *Hediste diversicolor* (16). Hedistin contains bromotryptophan residues, making it stereochemically less susceptible to proteolysis. It is expressed by NK-like cells, suggesting its involvement in innate immune responses, which is confirmed by its comprehensive antimicrobial activity (16). Perinerin from the Asian marine clamworm *Perinereis aibuhitensis* is a hydrophobic and highly basic peptide with antimicrobial and bactericidal activity (17). It contains four cysteine residues forming disulfide bonds and acts through its pore-forming activity. Ms-hemerycin was identified in the marine lugworm *Marphysa sanguinea*, which lives in a swamp (18). This small peptide forms an unordered structure with a partial helical region. It has strong antimicrobial activity, but its mode of action is unconventional (Table 1).

## Cytokines

Most of our understanding of cytokines and their receptors in invertebrates relies on functional assays and similarities at the physicochemical level. The existence of cytokines in annelids, specifically IL-1- $\alpha$ , TNF- $\alpha$ ) and POMC-derived peptide-like molecules, is indicated by work using immunohistochemical methods for their detection (22). Flow cytometry using monoclonal antibodies against human or mouse cytokines detected TNF- $\alpha$  and tumor growth factor- $\alpha$  (TGF- $\alpha$ ) in earthworm coelomocytes (23).

Several genomic sequence analyses suggest that the innate immune system of invertebrates and vertebrates evolved independently and that invertebrate cytokine-like molecules and vertebrate cytokines do not have the same evolutionary ancestry. One of the molecules that can be considered a cytokine is coelomic cytolytic factor (CCF), which was first found in the earthworm *E. fetida* and later in other earthworm species (24, 25). CCF exists in both membrane and soluble forms and functions primarily as a PRR (4). However, some of its properties indicate that it also functions as a cytokine. Based on similar lectin-like activities, CCF shares functional analogies with mammalian tumor necrosis factor (TNF- $\alpha$ ). They both lyse the TNF-sensitive tumor cell line L929, and in African and American trypanosomes, they are secreted after LPS stimulation, have opsonizing properties, bind antigens *via* lectin-like interactions, and increase membrane conductance in mammalian cells by interacting with ion-channels or ion-channel-coupled molecules. Despite the functional analogies of CCF and TNF- $\alpha$ , they do not display any gene or amino acid sequence homology, which indicates distinct evolutionary origins and convergence of invertebrate and vertebrate cytokine molecules (26–28) (Table 2).

Endothelial monocyte-activating polypeptide II (p43/EMAP-II), a chemokine, has been described in earthworms and leeches (46, 47). Endothelial monocyte-activating polypeptide II (p43/EMAP-II), a chemokine, has been described in earthworms and leeches (46, 47). In mammals, EMAP-II is released after processing the p43 precursor and functions as a pro-inflammatory cytokine chemotactic for monocytes and granulocytes and as a marker of microglial cell reactivity induced by brain tissue inflammation or neurodegeneration, but it has more pleiotropic biological activities (48). Similarly, the medicinal leech *HmEMAP-II* is processed from the *Hmp43* precursor, which is released by apoptotic cells and serves as a monocyte chemo-attractant (49). The *HmEMAP-II* has a chemo-attractant effect on microglial cells, *e.g.*, the effect of mammalian EMAP-II on monocytes. Further, gene expression of *HmEMAP-II*, which can recruit phagocytic cells at lesion sites, is controlled by *HmTLR* (46). In earthworms, greater expression of EMAP-II is accompanied by a greater abundance of *mccEaTLR* in seminal vesicles, suggesting its involvement in signal transduction (50) (Table 2).

Interleukin 17 (IL-17), the most conserved cytokine across animal phyla, is an essential factor in innate immunity. In humans, it is produced by activated T lymphocytes and cells participating in innate immunity, *e.g.*, mucosal epithelial cells (51). IL-17 has also been described in some annelids, including the segmented worm *C. teleta*, whose genome screening identified seven genes for IL-17. However, the function of IL-17 molecules has not been identified (31). Although the innate immunity signaling pathways involving cytokine action are not well described in annelids, several pathways have been identified by analysis of the coelomic fluid transcriptome of two

TABLE 2 Cytokines in annelids and bivalve mollusks.

## Cytokines

Type	Annelids	Bivalve mollusks
TNF- $\alpha$	CCF: found in earthworms; a functional analog of mammalian TNF- $\alpha$ (27)	AbTNF- $\alpha$ : homolog of TNF- $\alpha$ in abalone <i>Haliotis discus discus</i> ; expressed in both immune and non-immune tissues; activation by pathogenic bacteria, viruses, LPS (29) CgTNF-1, CgTNF-2 in <i>C. gigas</i> hemocytes, activated by bacterial stimuli (30)
IL-17	IL-17: 7 genes for IL-17 in polychaete <i>C. teleta</i> ; function was not identified (31)	IL-17: 15 genes for IL-17 in <i>P. fucatomartensii</i> (PmIL-17), 10 in <i>C. gigas</i> (CgIL-17), 6 in <i>M. galloprovincialis</i> , 10 in scallop <i>Mizuhopecten yessoensis</i> ; mucosal immunity; upregulation after bacterial stimulation; inflammatory response; NF- $\kappa$ B signaling pathway (32–35)
AIF-1	AIF-1: detected in leech <i>H. medicinalis</i> ; chemo-attractant for macrophages that induces their migration towards an inflammation site (36)	CgAIF-1: identified in <i>C. gigas</i> ; calcium-binding cytokine associated with immune cell activation and inflammatory response; activated by multiple PAMPs; enhances mRNA levels of MIF, TNF- $\alpha$ , and IL-17 (37)
EMAP-II	EMAP-II: chemokine for microglial cells, found in earthworms and leeches (3, 4)	n/i
MIF	n/i	MgMIF: identified in <i>M. galloprovincialis</i> ; downregulated following a challenge by bacteria and fungi (38); CfMIF: identified in scallop <i>Chlamys farreri</i> ; upregulated by LPS, PGN, and $\beta$ -glucans; rCfMIF promotes migration of sheep fibroblast into scraped spaces <i>in vitro</i> (39) PoMIF: identified in oyster <i>Pinctada fucata</i> ; upregulation upon bacterial stimulation (40)
IFN- $\gamma$	n/i	CgIFNLP: identified in oyster <i>C. gigas</i> has an IFN domain; shares low sequence identities with vertebrate IFNs, but displays a similar three-dimensional structure with class II helical cytokines; promotes the apoptosis and phagocytosis of hemocytes; responds to poly (I:C) stimulation; several components of the IFN-like system, activation by virus, poly (I:C), LPS; antiviral immunity (41–44)
Prokineticins	n/i	Astakins: homologs of vertebrate prokineticins; regulates hematopoiesis and the function of immune cells; lack of the essential sequence for proper signaling and binding of the G-protein coupled receptors; different receptor-mediated mechanisms; characterized in oyster <i>C. gigas</i> with a CgATP synthase $\beta$ subunit protein involved in signaling in hemocytes (45)

AbTNF- $\alpha$ , tumor necrosis factor alpha homolog in *Haliotis*; AIF-1, allograft inflammatory factor-1; CCF, coelomic cytolytic factor; CfMIF, macrophage migration inhibitory factor in *Chlamys*; *C. gigas*, *Crassostrea gigas*; CgAIF-1, allograft inflammatory factor-1 in *Crassostrea*; CgIFNLP, interferon gamma like protein in *Crassostrea*; CgIL-17, interleukin 17 in *Crassostrea*; CgTNF-1/2, tumor necrosis factor alpha in *Crassostrea*; *C. teleta*, *Capitella teleta*; EMAP-II, endothelial monocyte-activating polypeptide II; IL-17, interleukin 17; IFN- $\gamma$ , interferon gamma; n/i, not identified; LPS, lipopolysaccharide; MgMIF, macrophage migration inhibitory factor in *Mytilus*; MIF, macrophage migration inhibitory factor; NF- $\kappa$ B, nuclear factor kappa B; PAMPs, pathogen-associated molecular patterns; PGN, peptidoglycan; *P. fucata martensii*, *Pinctada fucata martensii*; PmIL-17, interleukin 17 homolog in *Pinctada*; PoMIF, macrophage migration inhibitory factor in *Pinctada*; rCfMIF, recombinant CfMIF; TNF- $\alpha$ , tumor necrosis factor alpha.

earthworm species, *E. andrei* and *fetida*. In doing so, specific innate immune pathways were identified, such as the complement cascade, regulation of autophagy, NK-mediated cytotoxicity, chemokine-, MAPK-, mTOR-, NOD-like receptor-, and TLR- and Jak-STAT signaling (52). This suggests that many hidden molecules functioning as cytokines have not been discovered yet, and establishing their ability to build molecular networks is needed (Table 2).

Allograft inflammatory factor-1 (AIF-1) is a calcium-binding protein induced by cytokines participating in the allograft immune and inflammatory response of humans. It is expressed by monocytes/macrophages, the homolog of which was detected in the medicinal leech *H. medicinalis*, where it serves as a potent chemo-attractant for macrophages, and it induces their migration towards sites of inflammation (36) (Table 2).

## Bivalves

Among *Mollusca*, bivalves, including edible and aquacultured species (oysters, mussels, clams, etc.), are the most widely studied relative to their immune defenses. Bivalve hemocytes are

responsible for cell-mediated immunity through the combined action of phagocytic processes and humoral defense factors such as agglutinins (e.g., lectins), lysosomal enzymes (e.g., acid phosphatase, lysozyme), reactive oxygen intermediates, and cytokines and various AMPs (53). Bivalve hemolymph serum contains a wide range of secreted components that participate in agglutination, opsonization, degradation, and encapsulation of microorganisms, as well as clotting and wound healing. In general, non-self recognition (in the form of PAMP) by soluble lectins and other PRRs and opsonins in hemolymph and hemocytes, which are present in the circulation and tissues, triggers signaling transduction cascades that release several effectors from tissues and hemocytes that lead to humoral and cellular immune responses, depending on the nature and location of the immune stimuli. An overview of the most recent accomplishments in the fields of recognition, agglutination, and opsonization (lectins, fibrinogen-related domain-containing proteins, C1q domain-containing proteins, lysozymes, bactericidal/permeability-increasing proteins, and other pore-forming molecules, proteases, and protease inhibitors, cathepsins, phenoloxidase cascade) is provided by Gerdol et al. (54).

## AMPs

From the first identification (20 years ago), in the hemolymph of the mussel *Mytilus galloprovincialis*, of a peptide sharing sequence similarity with the arthropod defensin, and therefore named *Mytilus galloprovincialis* Defensin-1 (MGD-1) (55), research on bivalve AMPs has steadily increased. With advances in molecular technologies, different AMPs have been identified in several bivalve species (mussels, oysters, clams, scallops), which are generally characterized by structural differences, different activities, differential tissue/cell expression, accessory functions, and often species-specific biological properties (reviewed in (54, 56, 57).

Resilience to pollution, pathogens, and changing environmental conditions means that some bivalve species are important models for studying the role of AMPs in adaptation and immunity. The Mediterranean mussel, *M. galloprovincialis*, which is not subjected to the same massive pathogen-associated mortalities as other bivalves, represents a unique model for studying AMPs. In this species, a remarkable abundance of AMPs has been reported, with antimicrobial activity against various bivalve and vertebrate pathogens, with different AMPs (including defensins, mytilins, and myticins) sharing antibacterial and antifungal properties; mytimycin appears to be a strictly antifungal protein. *Mytilus* AMPs are highly polymorphic and have high genetic variability: the recent assembly of the *M. galloprovincialis* genome showed that, although dozens of different sequence variants were identified for each AMP family, each individual possessed a unique combination of a small number of variants (58).

Myticin C (MytC), the most expressed AMP in adult mussels, has the highest RNA polymorphism relative to other mussel AMPs (59). MytC has been shown to inhibit the replication of bacteria, fish viruses, and human herpesvirus (56) and to have chemotactic and wound healing properties (59, 60). In oyster hemocytes, treatment with mussel hemolymph, or synthetic MytC peptides, inhibits replication of OsHV-1. In addition, *in vivo* studies suggested that overexpression of MytC in hemocytes could alter the transcription of other immune-related genes (AMPs, complement proteins, lysozyme). These data suggested that MytC may also play a role as an immune system modulator with chemokine-like activities (56, 59). In *M. galloprovincialis*, the extensive repertoire of AMPs, endowed with a broad spectrum of immune functions, might have significantly contributed to the evolutionary advantage of mussels in adapting to extremely changing environments (56, 58).

Among AMPs, Big defensins (BD), the ancestors of  $\beta$ -Defensins, essential components of innate immunity in vertebrates and invertebrates, are a large family of AMPs characterized by a highly hydrophobic globular N-terminal domain, which is present in different phylogenetically distant species, including both marine and freshwater bivalves (61). Bivalves often display an expanded repertoire of BD sequences

and thus represent an excellent case for investigating the processes behind the remarkable diversity of the primary sequence, both between and within species. In contrast with human  $\beta$ -defensins, BDs are characterized by antimicrobial activities over a wide range of osmolarity. Studies in bivalves showed that the presence of the conserved hydrophobic domain confers bactericidal activity even at high salt concentrations (62). Moreover, bivalve BD displays a characteristic mechanism of action, i.e., the N-terminal domain drives bacteria-triggered peptide assembly into antimicrobial aggregates termed “nanonets,” which entrap microbes and prevent invasive pathogens from entering host cells (63). This effect has been described for the Cg-BigDef1 in *C. gigas* (62) and the ApBD1 in the scallop *Argopecten purpuratus* (64).

An exhaustive list of AMPs isolated from marine bivalves and their main characteristics (peptide sequence, length, net charge, percent hydrophobic residues, structure, antimicrobial activity), updated to 2017, is provided in an article by Zannella C, et al. Microbial diseases of bivalve mollusks: infections, immunology, and antimicrobial defense (57). As mentioned above, most data refer to *Mytilus* sp. and *Crassostrea gigas* (57). More recently, other AMPs have also been characterized, i.e., Myticusin-beta in *Mytilus coruscus* (65), Myticalin in *M. galloprovincialis* (66), and hemoglobin-derived polypeptides in *Tegillarca granosa* (67).

## Cytokines

Recent developments in the study of bivalves are based on studies first carried out on Pacific oyster *C. gigas*, one of the most widely cultivated marine species. Partly because of its commercial importance, Guofan Z. et al., using genetic and genomic techniques, sequenced the genome in 2012 (68). The sequencing led to a significant increase in studies on bivalve cytokines (roughly 70% of all publications on the subject have occurred in the last decade, according to PubMed).

Pioneering work in the early '90s shed the first light on the conservation of cytokine-like molecules in mollusks (69, 70). Subsequent studies indicated that host defense mechanisms in different invertebrate groups, including bivalves, can be modulated by a cytokine-like network like that in vertebrates (71–73). However, until the identification of the first molecules with a cytokine-like activity (24, 74), most information relied on functional assays, using heterologous cytokines and antibodies directed towards vertebrate cytokines and their receptors.

The first studies were limited to evolutionarily conserved factors identifiable by sequence similarities, such as IL-17 (32), MIF (38), AIF-1 (37), and TNF- $\alpha$  (29, 30). The functional role of these conserved cytokines was indicated by their increased expression in response to bacterial stimuli. Most current information for IL-17 comes from phylogenetic studies, identification of related signaling pathways, and effector mechanisms in models of *M.*

*galloprovincialis* and *C. gigas* (33–35). IL-17 plays a crucial role in mucosal immunity in mussels, just like in vertebrates (35), which was first identified in *C. gigas* (32) and later on in *Pinctada fucata* (75). Further genomic searching found that there were fifteen IL-17 genes in *P. fucata martensii*, ten in *C. gigas*, six in *M. galloprovincialis*, and ten in scallop *Mizuhopecten yessoensis* (31) (Table 2). At least some of these IL-17 molecules, e.g., PmIL-17-2 from *P. fucata martensii* and CgIL-17-5 from *C. gigas*, were found to be involved in the innate immune response after bacterial stimulation (31, 34). The inflammatory IL-17 cytokines are encoded by a diverse gene family leading to expanded IL-17 repertoires in various marine invertebrates. This can be seen, for example, in the study of 16 mussel genomes, which revealed 379 unique IL-17 sequences and 96 unique IL-17 receptor variants (35). Phylogenetic analysis revealed that all detected invertebrate IL-17 genes, from both annelids and mollusks, are clustered into one group, suggesting a common ancestral gene of these invertebrate IL-17s (31) (Table 2).

However, for many other divergent cytokines, their presence and function in bivalves remained elusive and can only be demonstrated indirectly; interferon- $\gamma$  is a good example. In *M. galloprovincialis* hemocytes, human recombinant IFN- $\gamma$  was shown to activate members of a STAT-like pathway; moreover, hemocyte pretreatment with IFN- $\gamma$  increased bacteria-induced STAT1-like phosphorylation, indicating that the function of mussel hemocytes may be physiologically regulated *in vivo* by endogenous IFN- $\gamma$ -like cytokines (76). Since the release of the genome of *C. gigas* and other species, several components of the IFN-like system (IFN-like molecules, IFN-like receptors, and components of related signaling pathways) have been identified (41–43). Interestingly, the IFN system of bivalves can be activated by virus or poly (I:C) challenges and further regulate the antiviral response of hemocytes; however, some components also showed a positive response to other immunostimulants, such as lipopolysaccharide (LPS) and bacteria. Unlike vertebrate IFN systems, the bivalve IFN-like system may participate in multiple biological activities, such as antibacterial immunity (reviewed in (44) (Table 2).

Other cytokines that developed independently in different invertebrate groups are now being identified. For example, Astakines, considered homologous of vertebrate prokineticins, regulate hematopoiesis and immune cell function. Astakines lack the AVITGA sequence in the N-terminus essential for proper signaling and binding of G-protein coupled receptors, indicating the presence of distinct receptor-mediated mechanisms in invertebrates. Recently, a *C. gigas* astakine was identified and characterized using a CgATP synthase  $\beta$  subunit protein, which is involved in hemocyte signaling (45).

Whatever the role of the various bivalve cytokines, transcriptomic data indicate modulation within different species in response to environmental stressors (77) and refs. therein). However, little is known about how cytokine expression is physiologically regulated. Recent studies underlined the role of

different miRNAs in the expression of TNF- $\alpha$  and IL-17 in oyster hemocytes (78, 79).

## Conclusions and perspectives

Annelids and bivalve mollusks represent important invertebrate groups for investigating innate immunity, particularly for the wide range of soluble immune mediators, which show a large diversity in structure and functions.

With regards to AMPs in annelids, three main classes have been identified so far in oligochaetes (lumbricins), polychaetes (BRICHOS-AMPs), and leeches (macines). Bivalves, in particular marine species, display a much wider repertoire of different AMPs (55), with some of them (*i.e.*, myticins, big defensins) also showing immune-related functions other than direct antibacterial activity.

Several soluble factors endowed with cytokine-like activity have been described in annelids and bivalves; however, few are structurally conserved in both groups relative to their vertebrate counterparts (*i.e.*, IL-17), which underlies their distinct evolutionary origin. From this perspective, research on invertebrate cytokines still represents an open and promising field for the identification of new immunoactive molecules.

Moreover, the properties of AMPs and cytokines in both groups of invertebrates suggest they have application potential in human health and the environment, especially given the global problem of antibiotic resistance. The increasing appearance of bacterial strains resistant to antibiotics has promoted an intense search for new anti-infective drugs that can be an effective alternative to conventional antibiotics. Invertebrate AMPs are in the spotlight as innovative drug candidates not only for the treatment of infectious diseases but also for their immunomodulatory potential.

To develop AMPs as efficient and safe new drugs, their mode of action needs to be fully understood. Despite their advantages, selecting suitable AMPs for clinical use is progressing very slowly. Pharmaceutical companies have had little interest in developing new antibiotics over the last 30 years because of high production costs and short efficacy periods (since bacterial resistance to new drugs develops rapidly). Although microorganisms can develop resistance to AMPs as a consequence of continuous selection pressure, AMPs still present several important advantages over antibiotics, e.g., they are much less stable in the environment and thus much reduced environmental impact. It was shown that cationic AMPs do not induce bacterial stress pathways and thus do not increase bacterial mutagenesis, which is not the case with antibiotics (80). Further, AMPs often use different mechanisms of action, including disruption of bacterial membranes, inhibition of metabolic pathways, and recruitment and activation of various immune cells (81).

Few annelid AMPs are currently being evaluated in clinical trials as treatments against various bacterial and fungal infections. An analog of Arenicin-3 was selected for preclinical trial by

Adenium Biotech Ltd. for its effective action in treating urinary tract infections (82), but the trial was unfortunately stopped due to the company's bankruptcy. The only molecule derived from the earthworm *L. rubellus* and successfully used in therapy, although not an AMP, is the enzyme lumbrokinase, used for its fibrinolytic properties to treat thrombus-related diseases. Similarly, since leech saliva contains large amounts of various enzymes with thrombolytic, anticoagulant, anti-inflammatory, and analgetic activity, leeches have been used to treat various diseases such as vascular disorders, cardiovascular disease, skin disorders, diabetic foot ulcers, migraine, knee osteoarthritis, and even in cosmetic surgery (83). The best-known enzyme from leeches is hirudin, which was discovered in 1884 when an extract from *H. medicinalis* was found to have anticoagulant properties (84). Recently, hirudin derivatives (e.g., lepirudin, desirudin) and hirudin analogs (e.g., bivalirudin) have been used clinically as direct bivalent thrombin inhibitors. However, despite its effectiveness, safety, and few complications, leech treatment is still controversial.

Despite the enormous potential of marine biodiversity for discovering AMPs, no bivalve AMPs have been tested in clinical trials. If, on the one hand, their resistance to high salt concentrations may represent potential advantages in medical applications (57), on the other hand, development has been hampered by many issues, such as discrepancies between *in vitro* and *in vivo* tests and susceptibility to proteases and pH, which affects AMP half-life *in vivo* (85).

Annelids and bivalves represent a vast source of AMPs that could serve as potential candidates for antibacterial drug development in human and veterinary medicine. Due to their broad spectrum of antimicrobial activities and emerging new immune modulation functions, AMPs have great potential for biotechnological applications and continue to be the subject of many molecular and functional studies. Antimicrobial peptides (AMPs) have been successfully applied in various areas of human health, including clinical medicine and drugs. However, as with AMPs from humans and other sources, high cost, poor stability, and toxicity are disadvantages that limit the clinical development of AMPs (86). In this light, a promising biotechnology field is genetically engineered microorganisms, where natural AMPs can be expressed or modified to create improved antibacterial abilities and increased stability while reducing toxicity (86).

The same applies to their cytokines, which act as natural immunomodulators with potential new biomedical applications.

However, our understanding of invertebrate cytokines is still limited compared to AMPs and hampers the development of biotechnological products. The multiple and complex immunoregulatory roles of annelid and bivalve cytokines represent a still largely unexplored field of research with substantial innovative potential. This particularly applies to those cytokines that are not structurally conserved and whose role and molecular machinery are still elusive. The application of multiple molecular and functional approaches will help to better define their biological role in immune homeostasis in health and disease.

## Author contributions

PP, MA, TB, and LC contributed to the writing of the manuscript. PP and LC provided critical review and input. All authors read and approved the final manuscript.

## Funding

This project has received funding from the European Union's Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant agreement No 671881.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

# Environmental stress and nanoplastics' effects on *Ciona robusta*: regulation of immune/stress-related genes and induction of innate memory in pharynx and gut

Rita Marino<sup>1,2</sup>, Daniela Melillo<sup>2</sup>, Paola Italiani<sup>1,2,3</sup>  
and Diana Boraschi<sup>1,2,3,4\*</sup>

<sup>1</sup>Biology and Evolution of Marine Organisms, Stazione Zoologica Anton Dohrn (SZN), Napoli, Italy, <sup>2</sup>Institute of Biochemistry and Cell Biology, National Research Council (CNR), Napoli, Italy, <sup>3</sup>China-Italy Joint Laboratory of Pharmacobiotechnology for Medical Immunomodulation (CNR, SZN, SIAT), Shenzhen, China, <sup>4</sup>Laboratory of Inflammation and Vaccines, Shenzhen Institute of Advanced Technology (SIAT), Chinese Academy of Sciences, Shenzhen, China

In addition to circulating haemocytes, the immune system of the solitary ascidian *Ciona robusta* relies on two organs, the pharynx and the gut, and encompasses a wide array of immune and stress-related genes. How the pharynx and the gut of *C. robusta* react and adapt to environmental stress was assessed upon short or long exposure to hypoxia/starvation in the absence or in the presence of polystyrene nanoplastics. We show that the immune response to stress is very different between the two organs, suggesting an organ-specific immune adaptation to the environmental changes. Notably, the presence of nanoplastics appears to alter the gene modulation induced by hypoxia/starvation in both organs, resulting in a partial increase in gene up-regulation in the pharynx and a less evident response to stress in the gut. We have also assessed whether the hypoxia/starvation stress could induce innate memory, measured as gene expression in response to a subsequent challenge with the bacterial agent LPS. Exposure to stress one week before challenge induced a substantial change in the response to LPS, with a general decrease of gene expression in the pharynx and a strong increase in the gut. Co-exposure with nanoplastics only partially modulated the stress-induced memory response to LPS, without substantially changing the stress-dependent gene expression profile in either organ. Overall, the presence of nanoplastics in the marine environment seems able to decrease the immune response of *C. robusta* to stressful conditions, hypothetically implying a reduced capacity to adapt to environmental changes, but only partially affects the stress-dependent induction of innate memory and subsequent responses to infectious challenges.

## KEYWORDS

nanoplastics, *Ciona robusta*, innate immunity, innate memory, stress

# 1 Introduction

It is well known that marine organisms ingest plastic particles, including fish (1, 2) and several invertebrate species (3–5). The major threat of plastics released into the environment is related to the degradation of these materials into micro- and nano-sized particulates that can more easily bioaccumulate (6). Across marine filter-feeding invertebrate organisms, the solitary ascidian *Ciona robusta* represents an optimal model to study the impact of sub-micron particle bioaccumulation on fundamental physiological functions (7, 8). In fact, unlike bivalves (9), *C. robusta* does not have the ability to sort particles and reject the unsuitable material (10). The impact of nanoplastics accumulation on the immune defensive functions is of particular interest because of the importance of such functions for optimal adaptation to environmental changes. To fully understand the possible impact of nanoplastics on *C. robusta* it is therefore important to assess it in conditions of environmental stress.

Major stressful environmental conditions for ascidians are starvation and hypoxia. Starvation is known to affect the ascidian metabolic profile and induce autophagy-related genes. In a metabolomic study on *Halocynthia roretzi*, a strong upregulation of defence and energy metabolites was observed in response to starvation, largely mediated by the impact on the gut associated microbiota (11).

Hypoxia is a decrease in dissolved oxygen that causes significant physiological disturbances in many marine organisms (12, 13), including increased vulnerability to diseases and parasites (14). Hypoxia threshold is species- and stage-specific (13), and its effects depend on the presence of other environmental challenges (warming, acidification, pollution). Hypoxia causes a decrease of energy supply from mitochondrial metabolism, which cells seek to compensate by undergoing a metabolic reprogramming (*i.e.*, enhanced glycolysis, glutaminolysis, fatty acid synthesis and decreased gluconeogenesis, nucleotide synthesis, fatty acids  $\beta$ -oxidation) that mostly involves the family of hypoxia-inducible transcription factors (HIFs) (15). In mammalian immune cells, hypoxia and HIF signalling influence immune cell functions in a cell-type specific manner (16). Of special interest is the cross-talk between hypoxia and inflammation. Inflammation plays a key role in the physiological response to hypoxic stress, as shown for instance by the increase of circulating inflammatory cytokines in individuals with mountain sickness (17). Conversely, tissue sites where an inflammatory reaction takes place undergo significant shifts in metabolic activity leading to O<sub>2</sub> deficiency, defined as “inflammatory hypoxia” (16, 18). In addition, HIF transcription/stabilisation can be activated by a variety of inflammation-related extracellular factors, such as bacterial products (*e.g.*, lipopolysaccharide or LPS), TNF- $\alpha$ , IL-1, reactive oxygen and nitrogen species (ROS, RNS), even in normoxic conditions.

In the present study, we have evaluated the primary response of *C. robusta* in terms of expression of immune and oxidative stress-related genes induced by exposure to a combined hypoxic and starvation stress, and how the presence of nanoplastics in the environment can interfere with the stress-induced immune adaptation response. We focused on two organs involved in immune defence, namely the

pharynx and the gut, as these organs, involved in respiration and digestion, are directly exposed to environmental stresses. We have also evaluated how a previous exposure to such combined stresses could influence the ability of the *C. robusta* immune organs to react to a subsequent bacterial challenge.

# 2 Materials and methods

## 2.1 Animals and treatments

Adults of *C. robusta* were collected in the small sea of Taranto, Italy, and maintained at the SZN in tanks with circulating aerated seawater at 18°C with proper feeding. Hypoxia/starvation (H/S) treatment was performed by starving animals in tanks for 12 h, then transferring individual animals in 200 mL millifiltered sea water (MFSW) within a 250 mL glass beaker at 18°C for 2 or 18 h (starvation plus hypoxia). Treatments with polystyrene beads (MPs) of either 0.1  $\mu$ m or 0.35  $\mu$ m (cat. 00876 and 07306; Polysciences, Inc., Warrington, PA, USA) was conducted by diluting nanoplastic beads in MFSW at the concentration of  $9.1 \times 10^8$  particles/mL and  $7.4 \times 10^7$  particles/mL, respectively, and adding them to individual animals in beaker for 2 or 18 h. The concentration of 0.1  $\mu$ m nanoplastics was selected based on previous dose-response experiments as the concentration causing the highest bioaccumulation after 2 h of exposure (8, and data not shown). The concentration of 0.35  $\mu$ m nanoplastics was selected in order to correspond to that of 0.1  $\mu$ m particles in terms of surface area. Endotoxin treatment was carried out by inoculation of 50  $\mu$ g of lipopolysaccharide (LPS, from *Escherichia coli*, serotype O55:B5; Merck Sigma-Aldrich®, St. Louis, MO, USA). LPS was inoculated in 50  $\mu$ L of marine solution (MS: NaCl 0.45 M, MgCl<sub>2</sub> 26 mM, KCl 11 mM, CaCl<sub>2</sub> 12 mM, pH 7.4), through the tunic between the two siphons.

For memory experiments, animals were first exposed to H/S stress alone or in the presence of nanoplastics for 2 or 18 h as described above, then were transferred to the aquarium, where they were kept in large aerated tanks and properly fed for additional 7 days (resting or extinction period). After the resting period, animals were injected with 50  $\mu$ L of LPS, as described above. After 24 h, animals were sacrificed and exanguinated, and gut and pharynx fragments were collected for gene expression analysis. For each condition, three animals were included.

## 2.2 RNA extraction and real-time PCR

Tissue samples were weighed and immediately homogenised with an Ultra-Turrax T25 at 0°C with 3 cycles of 30 s, then processed for total RNA extraction with commercially available kits (miRNeasy Kit; Qiagen, Hilden, Germany), according to the manufacturer's instructions. A mix of Oligo (dT) and random-primed single stranded cDNA were synthesised from 2  $\mu$ g of pharynx RNA using the QuantiTect Reverse Transcription Kit (Qiagen).

Real-time PCR experiments were carried out with a RotorGene instrument (Qiagen) with RealAmp qPCR Master mix chemistry (GeneAll Biotechnology Co., Ltd., Seoul, South Korea). Specific primers were designed, according to the nucleotide sequence, for genes encoding the *C. robusta* homologues of the complement component C3-1 (*C3-1*), the C3 receptor C3aR (*C3ar*), the two isoforms of interleukin-17 *Il17-1*, *Il17-2*, the IL-17 receptor *Il17r*, the tumour necrosis factor *Tnf*, the transforming growth factor beta *Tgfb*, the LPS binding protein *Lbp*, the Toll-like receptors *Tlr-2* and *Tlr13*, the cluster of differentiation 36 *Cd36*, the variable chitin-binding proteins *VCBP-B* and *VCBP-C*, the superoxide dismutase A *SodA*, the glutathione-S transferase *GST* and the glutathione reductase *GR* (Table 1). Gene nomenclature is designed according to previous publications (19–27) and includes the indication of the *C. robusta* gene isoforms as a number after a dash. Other isoforms of C3 (*C3-2*), IL-17 (*Il17-3*), and TLR (*Tlr-1*) could not be evaluated because their expression resulted undetectable in every condition in both gut and pharynx. Likewise, expression of the gene encoding the precursor of the enzyme phenoloxidase was not detectable. After preliminary evaluation of different housekeeping genes (*Actin*, *S27*, *Gapdh*), the glyceraldehyde 3-phosphate dehydrogenase gene *Gapdh* was selected for its consistent expression stability, and used as reference gene in all experiments. All primers produced single-band amplicons of the expected size, which were verified by DNA sequencing. Reactions were performed in triplicate, and the PCR programme included a denaturation step (95°C for 15 min) followed by 40 cycles of amplification (94°C for 15 s, 60°C for 30 s, and 72°C for 30 s), and a final extension step (72°C for 10 min). PCR amplification efficiencies, calculated for primer pairs of the

reference and target genes, were both 2. All data were normalised against *Gapdh* using the Pfaffl method (28). Real-time PCR results are reported as relative gene expression towards *Gapdh* or as the ratio between treated and control animals.

## 2.3 Statistical analysis

All values were expressed as mean  $\pm$  SEM of samples from 3 animals with the same treatment. Statistical significance of differences between treatments was assessed by using the one sample Student's *t* test followed by non-parametric Mann-Whitney U-test correction for PCR data of primary effects, and ordinary one-way ANOVA of one sample *t* test for PCR data of memory experiments, using the GraphPad Prism 6 software. *p* values <0.05 were considered statistically significant.

## 3 Results

### 3.1 Induction of immune response by hypoxia/starvation stress

The basal expression of sixteen genes was examined in *C. robusta*. Genes were selected based on three criteria, immune-related genes that are already known to be involved in the *Ciona* immune responses (*C3-1*, *C3ar*, *Il17-1*, *Il17-2*, *Il17r*, *Tnf*, *Tgfb*, *Lbp*, *Tlr-2*, *Tlr13*, *Cd36*) (19–26), pharynx- and gut-specific genes involved in mucosal immunity (*VCBP-B* and *VCBP-C*) (27) and

oxidative stress-related genes (*Sod-A*, *GST*, *GR*) (29). Gene expression was measured in the two organs that display immune reactivity, namely the pharynx and the gut. The relative contribution of haemocytes, the main circulating immune cells of *C. robusta*, was not specifically assessed, as the number of recovered cells was insufficient for RNA extraction.

Results in Table 2 show the basal expression of immune/stress-related genes in both organs in unexposed animals kept in optimal conditions of oxygenation and nutrition. Gene expression was also measured in animals treated with the bacterial agent LPS, to mimic exposure to an infectious challenge. Substantial variations in gene expression could be observed, which differ between the two organs. In the pharynx, reaction to LPS resulted in a general upregulation of the majority of the immune/stress-related genes, with a very high increase in the expression of *Tnf*, *Tgfb*, *VCBP-B* and *VCBP-C* and a significant but less substantial increase of *Il17-2* and *Tlr-2* expression. Only one gene, *GST*, was significantly down-regulated in the pharynx in response to LPS. The scenario in the gut is very different, with only one gene, *C3ar*, significantly up-regulated in response to LPS. The expression of most genes is either unchanged or down-regulated by LPS in the gut, although a statistically significant decrease was only observed for *Il17r*, *VCBP-B* and *GR*. Notably, expression of *VCBP-B*, which was increased over 4000x in the pharynx, was completely inhibited by LPS in the gut (Table 2).

We analysed whether stress conditions could induce an immune reaction similar to exposure to an infectious agent. Stress was

obtained by keeping animals in a small volume of millifiltered seawater (MFSW) for 2 or 18 hr, without oxygenation and feeding. The expression of the selected immune/stress-related genes was examined in the stressed animals as compared to control animals kept in oxygenated tanks with food. The results in Figure 1 show that the stress induced by hypoxia/starvation (H/S) has a significant effect on the expression of immune/stress-related genes, and that this effect is different depending on the organ and the duration of stress. In the pharynx, a short H/S stress induced a significant upregulation of *C3-1*, *Tnf*, *Tgfb*, *Lbp*, *VCBP-B*, *VCBP-C* and *GR* (Figure 1A). An H/S stress of 18 h induced expression of the *Il17r* gene and further increased *Tnf* expression, while upregulation of *C3-1*, *Tgfb* and *Lbp* remained sustained at the same level, and that of *VCBP-B* and *VCBP-C* returned to baseline (Figure 1B). The response of the gut to H/S stress was substantially different. The short 2 h stress induced a strong up-regulation of the *C3ar* and *VCBP-C* genes, and a significant increase of *Il17-2*, *Tgfb*, *Lbp*, *Tlr-2*, *VCBP-B* and *SodA*, while other genes were only marginally affected (Figure 1C). After 18 h of H/S stress, expression of *C3-1*, *Il17r*, *Tnf* and *Cd36* was up-regulated, up-regulation of the *C3ar*, *VCBP-B* and *VCBP-C* was sustained at the same level, while that of *Tgfb* was further increased, and that of the other genes decreased towards basal expression levels (Figure 1D). Full data (mean levels of gene expression with SEM and statistical analysis) are reported in the Supplementary Table S1. Thus, H/S stress could induce substantial variations in immune/stress gene expression both in the pharynx and in the gut, suggesting an active

immune adaptation to the environmental changes. The kinetic differences in the expression profiles underline the evolution of the adaptive changes, while the difference between the two immune organs strongly support their distinct roles in immune responses.

### 3.2 Modulation of stress-induced immune response by nanoplastics

To assess whether concomitant exposure to nanoplastics could affect the stress-induced response, animals were exposed to polystyrene beads of two different sizes (diameter 0.1 and 0.35  $\mu\text{m}$ ) in H/S conditions. After 2 or 18 h, the gene expression was assessed. As shown in [Figures 2](#) and [3](#), the presence of nanoplastics could affect the gene expression changes induced by H/S both in the pharynx and in the gut. In the pharynx, the presence of nanoplastics induced some significant changes in the gene expression induced by a 2 h exposure to H/S stress alone, *i.e.*, further up-regulation of H/S stress-induced *Tgfb* gene expression, and down-regulation of H/S stress-induced *C3-1* and *Lbp* gene expression ([Figure 2A](#)). Other changes (*e.g.*, up-regulation of the stress-induced decrease of *Il17-1*

and *Cd36* genes) were not statistically significant. After 18 h, the presence of nanoplastics induced several changes compared to H/S alone, in particular a decrease in *C3-1*, *Il17r* and *Tnf* expression and an increase of *Il17-2* ([Figure 2B](#)). In the pharynx, differences were also noted between nanoplastics of different size, with the larger particles in combination with H/S for 18 h able to up-regulate the expression of *C3ar*, *Tgfb*, *Tlr13*, *Cd36*, *VCBP-B* and *VCBP-C* (not induced by the combination of H/S and small nanoplastics).

In the gut, no substantial size-dependent effect of nanoplastics was noted on the gene modulation induced by H/S stress ([Figures 2C, D](#)). After 2 h of exposure to H/S stress in the presence of nanoplastics, gene expression was either unaffected or decreased, with a significant inhibition of *C3-1*, *C3ar*, *Tgfb*, *Lbp*, *Tlr-2*, and *VCBP-C* ([Figure 2C](#)). After 18 h of combined exposure to H/S stress and nanoplastics, gene expression changes were more evident than with the shorter exposure, showing a significant decrease in the expression of *C3-1*, *C3ar*, *Il17r*, *Tnf*, *Tgfb*, *Cd36*, *VCBP-B* and *VCBP-C* ([Figure 2D](#)). The increased expression of *Il17-1*, *SodA* and *GR* genes in the presence of nanoplastics was not statistically different from H/S stress alone.

Notably, the comparison of the gene expression profiles induced by H/S stress and by H/S stress plus nanoplastics with those of naïve

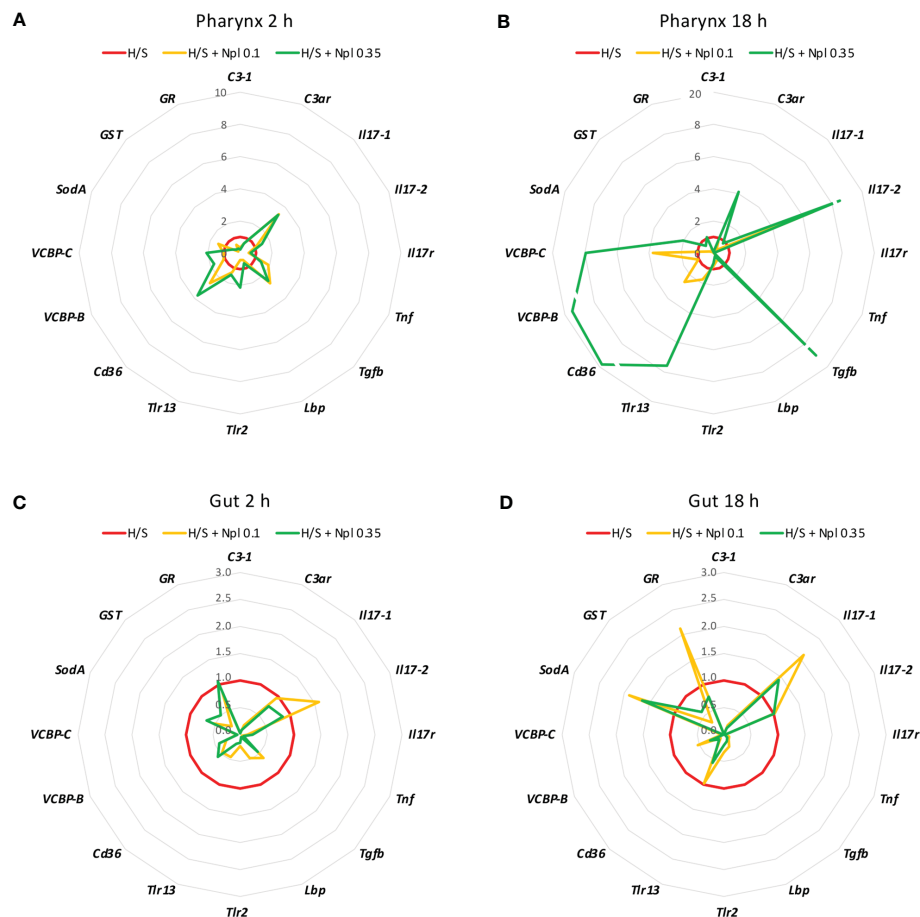

FIGURE 2

Effect of nanoplastics on the hypoxia/starvation stress-induced gene expression in the pharynx and gut of *Ciona robusta*. Gene expression was measured in the pharynx and in the gut of animals exposed to hypoxia/starvation (H/S) stress alone (red line) or combined with nanoplastics for 2 or 18 h. (A, B) gene expression in the pharynx; (C, D) gene expression in the gut. (A, C) gene expression at 2 h; (B, D) gene expression at 18 h. Nanoplastics of two different sizes were used, 0.1  $\mu\text{m}$  (yellow line) and 0.35  $\mu\text{m}$  (green line). Data are the mean of values from 3 animals and are expressed relative to gene expression in H/S-exposed animals. The mean values of gene expression relative to the housekeeping gene *Gapdh*, the SEM values and the statistical analysis are reported in the [Supplementary Table S2](#).

animals shows that the presence of nanoplastics may reduce some of the gene expression changes induced by H/S stress (Figure 3). This is particularly evident in the gut, both after a short or long exposure to stress, where exposure to nanoplastics substantially limited the up-regulation of several of the immune/stress genes induced by H/S (Figures 3C, D). Full data (mean levels of gene expression with SEM and statistical analysis) are reported in the [Supplementary Tables S2 and S3](#).

Thus, the presence of nanoplastics may dampen some of the stressful effects induced by H/S, which however may result in inadequate adaptation to the environmental changes.

### 3.3 Organ-specific modulation of immune/stress-related gene expression by stress-induced innate memory

We assessed the response to the prototypical bacterial agent LPS in the pharynx and gut of animals that were previously primed by H/S in comparison to unprimed controls. As described above for the

primary response, the “memory” response was measured as expression of immune/stress-related genes. As already mentioned, the response of naïve animals to LPS encompasses a general up-regulation of immune/stress-related genes in the pharynx, opposite to a general down-regulation in the gut (Table 2). In animals previously exposed to H/S stress (either 2 or 18 h, followed by one week in tank with proper oxygenation and nutrition) the response to LPS was significantly different, implying the establishment of a stress-induced innate memory, able to modulate the response to an infectious challenge. In the pharynx, pre-exposure to H/S stress induce a substantial decrease in the expression of several genes and the up-regulation of the *GST* gene (Figure 4A, Table S4). Notably, down-regulation exclusively occurred for genes that were up-regulated in response to LPS in naïve animals, while up-regulation occurred for the only gene that was strongly down-regulated by LPS in naïve animals. This implies that animals exposed to H/S stress have developed “tolerance” to LPS in the pharynx, as their expression profile of immune/stress-related genes is similar to the basal expression profile of untreated animals (Table S4). A similar induction of “tolerance” to LPS was observed in the gut of animals

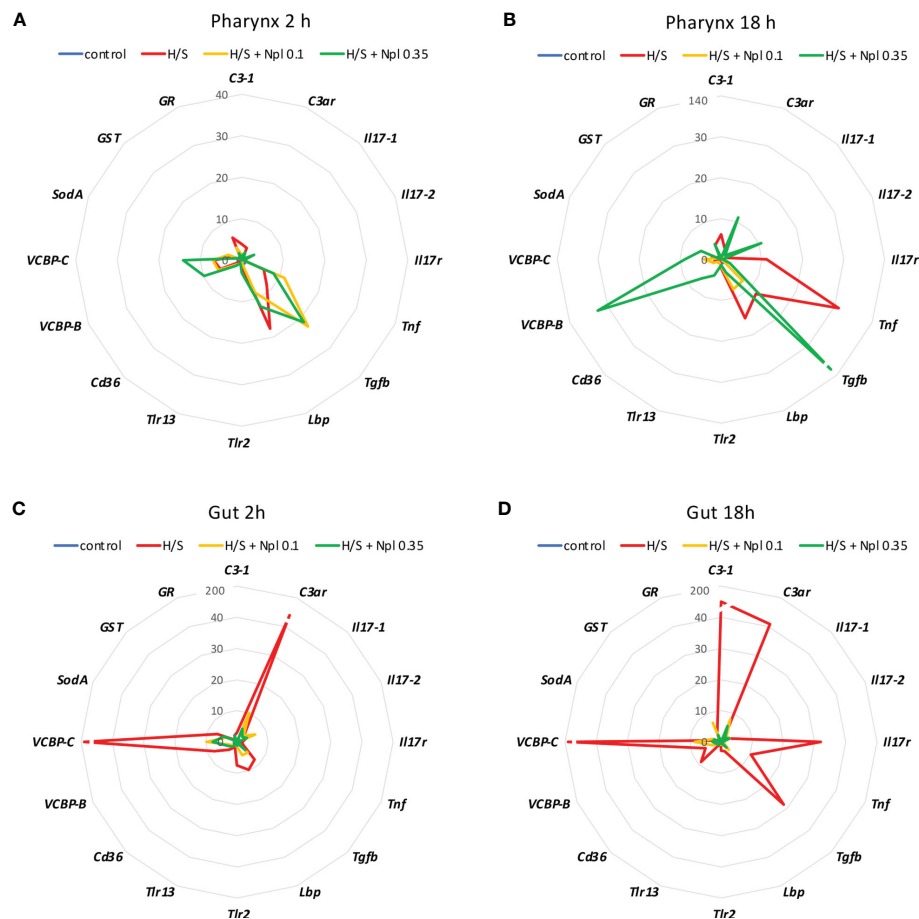

FIGURE 3

Effect of the combined exposure to hypoxia/starvation and nanoplastics on the immune/stress-related gene expression in the pharynx and gut of *Ciona robusta*. Gene expression was measured in the pharynx and in the gut of animals exposed to hypoxia/starvation (H/S) stress alone (red line) or combined with nanoplastics for 2 or 18 h. (A, B) gene expression in the pharynx; (C, D) gene expression in the gut. (A, C) gene expression at 2 h; (B, D) gene expression at 18 h. Nanoplastics of two different sizes were used, 0.1  $\mu\text{m}$  (yellow line) and 0.35  $\mu\text{m}$  particles (H/S + Npl 0.35). Data are the mean of values from 3 animals and are expressed relative to gene expression in control naïve animals (kept in tank in optimal oxygenation and nutrition conditions; blue line). The mean values of gene expression relative to the housekeeping gene *Gapdh*, the SEM values and the statistical analysis are reported in the [Supplementary Tables S2](#) (pharynx) and [S3](#) (gut).

pre-exposed to H/S stress. While the response to LPS in the gut is a general down-regulation of immune/stress gene-expression, expression of these genes in response to LPS was higher in animals pre-exposed to H/S stress ([Figure 4B](#), [Table S5](#)). Thus, as in the pharynx, pre-exposure to H/S stress induced a state of unresponsiveness to LPS in the gut, with the gene expression profile of H/S-primed animals challenge with LPS similar to that of naïve unchallenged animals ([Table S5](#)). No substantial differences were observed between 2 vs. 18 h of pre-exposure to H/S stress ([Figures 4A, B](#)).

### 3.4 Effect of nanoplastics on the organ-specific stress-induced innate memory

We examined whether the combined exposure to H/S stress and nanoplastics could affect the tolerance type of innate memory response to LPS induced by H/S stress alone. Data in [Figure 4](#) show the innate memory response to LPS of animals pre-exposed to

H/S stress alone (H/S) or in the presence of small 0.1  $\mu\text{m}$  nanoplastics (H/S + Npl 0.1) or 0.35  $\mu\text{m}$  particles (H/S + Npl 0.35), compared to unexposed animals (no priming). Notably, nanoplastics appear to reverse in some cases the gene down-regulation caused by pre-exposure to H/S stress in the pharynx (e.g., *Tnf*, *Tgfb*, *VCBP-B*) and increase the expression of genes that were either up-regulated (*GST*) or not affected (*Lbp*, *SodA*) by H/S stress ([Figure 4A](#), [Table S4](#)). Some changes were common to nanoplastics of both sizes, e.g., upregulation of *Tnf* and *Lbp* gene expression, while other were size-specific, with larger particles able to significantly upregulate *SodA* and *GST*, while small particles were inactive ([Figure 4A](#), [Table S4](#)). After 18 h, the nanoplastics effects on H/S-induced changes were essentially maintained, except for the loss of effects for small particles on H/S-induced down-regulation of *Tgfb* and the up-regulation of *GR* by large particles. Notably, up-regulation of *C3ar* was observed with larger particles (inactive at 2 h), while the effect of small particles (active at 2 h) was lost ([Figure 4A](#), [Table S4](#)). In the gut, both common and size-dependent effects of nanoplastics were observed on the gene modulation

FIGURE 4

Stress-induced memory response to LPS in *Ciona robusta*. The response to LPS was measured in naive animals (no priming) and animals pre-exposed to H/S stress alone (H/S) or with nanoplastics of 0.1  $\mu\text{m}$  (H/S + Npl 0.1) and 0.35  $\mu\text{m}$  (H/S + Npl 0.35) for 2 or 18 h. After pre-exposure, animals were then transferred in tanks and kept in optimal oxygenation and nutrition conditions for one week, before receiving 50  $\mu\text{g}$  LPS intratracheally. Gene expression in response to the LPS challenge was measured 24 h later. (A) gene expression in the pharynx; (B) gene expression in the gut. The heatmaps report the results of gene expression (mean values from 3 animals relative to gene expression in unchallenged control animals). The SEM values and the statistical analysis are reported in [Supplementary Tables S4](#) (pharynx) and [S5](#) (gut).

induced by H/S stress (Figure 4B, Table S5). After 2 h of pre-exposure to H/S stress in the presence of nanoplastics, small particles could induce a statistically significant increase of the expression of the *Tgfb* gene compared to H/S alone, an effect not shared by larger particles (Figure 4B, Table S5), while after 18 h both types of particles were active (Figure 4B, Table S5). After 18 h, smaller particles were able to further increase the H/S-induced expression of the *VCBP-B* and *VCBP-C* genes, as opposed to the lack of effect by larger particles (Figure 4B, Table S5).

## 4 Discussion

Studies of inflammatory responses to LPS in tunicates have demonstrated an up-regulation of cytokine-like genes such as *Tnf* (25) and *Il17* (22), as well as complement components (30, 31), mostly evident in haemocytes and in the pharynx. On the other hand, data concerning the stress-induced response are poorly represented. Several invertebrate species, such as oysters, are remarkably resilient to fluctuating environmental conditions, and this adaptation is based on a large repertoire of immune-related genes, many of which are greatly expanded in the genome (32). Rather than on the main circulating immune cells, the haemocytes, in our study we focused on the pharynx and the gut, two organs involved in respiration and digestion and therefore directly exposed to environmental stresses, to assess the organ-specific immune adaptation. We found that an environmental stress, represented by hypoxia and starvation (H/S),

up-regulates the expression of a variety of immune/stress-related genes, both in the pharynx and in the gut of *C. robusta*. Interestingly, beyond the up-regulation in both organs of the complement gene *C3-1*, the cytokine/cytokine receptor genes *Il17r*, *Tnf*, *Tgfb* and *Lbp*, the chitin-binding protein genes *VCBP-B* and *VCBP-C* and the stress-related gene *GR*, we could observe a gut-specific up-regulation of *C3ar*, *Tlr-2* and *CD36*. We also examined how the additional presence of another environmental stress, i.e., nanoplastics, may affect the adaptation reaction to H/S. In the pharynx, co-exposure to H/S and nanoplastics induces an enhanced up-regulation of the *Il17-2*, *Tgfb*, *VCBP-B* and *VCBP-C* genes, a substantial down-regulation of *Tnf*, and no change in the other genes. On the contrary, the effect of nanoplastics co-exposure in the gut is a general down-regulation of all the immune/stress-related genes. These data suggest two scenarios. First, while the H/S stress strongly affects the expression of immune/stress-related genes, in line with the expected adaptation to the changing environmental conditions, such effects are different between the two immune organs, stressing their different immune protective role. The second observation is that the presence of nanoplastics interferes with the stress-induced immune response, which may therefore affect the adaptation capacity of the animals.

It is interesting to examine the regulation of the *Lbp* gene in response to LPS (used as positive control) vs. stress. In mammals, LBP is induced by LPS stimulation and displays a concentration-dependent modulation of LPS activity: at low concentrations, LBP shuttles LPS to monocytes or other immune cells, whereas at high

concentration it inhibits the endotoxic activity of LPS by facilitating its elimination (33–35). Unexpectedly, in the present study we found that the *Lbp* gene in *C. robusta* is unresponsive to LPS stimulation in both organs, while it is up-regulated by H/S stress in particular in the pharynx. These results seem to suggest that *Lbp* activation is independent of LPS, but necessary in the adaptive immune reaction initiated by H/S stress. Notably, this protective effect is partially abolished in presence of nanoplastics, supporting the hypothesis that animals exposed to nanoplastics may be less able to adapt to environmental changes.

The induction of innate memory was examined in the pharynx and in the gut of animals previously exposed to H/S stress alone or together with nanoplastics. Pre-exposed animals were administered with LPS, and the expression of immune/stress-related genes was compared to that of naïve animals. Upon previous H/S and H/S nanoparticles experience, haemocytes and/or pharynx cells react to a systemic LPS challenge by turning off most immune/inflammatory response as compared to unprimed animals, a response that compatible with a tolerance type of innate memory, while only transcription of *GST* is increased in animals pre-exposed to H/S and nanoplastics. GSTs are a multigene family of isozymes that catalyse the conjugation of glutathione (GSH) to several molecules. In our animal model, we could hypothesise that immune memory in the pharynx is linked to the oxidative stress generated by hypoxic conditions, which may be exacerbated in the presence of nanoplastics. In fact, nanoplastics may amplify the oxidative and inflammatory effects of H/S by reducing the filtration rate of the animals and related O<sub>2</sub> supply, by clotting mucus and clogging the pharynx stigmata. Upon challenge with LPS, known to lower the GSH levels in vertebrate models (36), there is a strong upregulation of the *GST* gene in animals pre-exposed to H/S and nanoplastics, likely underlying a memory-dependent protective response aiming at restoring the tissue GSH pool and its detoxification effects.

In order to appropriately assess the innate memory induced by H/S and nanoplastics in the gut, it is important to keep in mind some organ-related effects. The role of starvation in the gut is twofold. As in all tissues and organs, together with hypoxia, starvation contributes in eliciting oxidative and inflammatory stress. More specifically in the gut, starvation impairs mucus production/transport to the post-branchial digestive tract, and this makes the gut epithelium more vulnerable to microorganism colonisation. Regarding the effect of size and time of exposure to nanoplastics, we expect bigger particles to accumulate more easily in the gut after being trapped by mucus in the pharynx (8), thereby depleting the external nanoplastics concentration with time. In the memory experiments, the gut from primed animals reacts to an LPS challenge by increasing the expression of *VCBP* genes. This upregulation likely occurs in newly differentiating cells of the stomach. Since the stomach is the tract of the gut system with the fastest cell-renewing rate (about 14 days from stem cells to fully mature cells) (37), we can hypothesise that the stem cells primed by H/S and nanoplastics start expressing *VCBP* genes during the LPS-induced differentiation. Previous studies on *VCBP* expression in adult animals showed that *VCBP-C* is expressed in crypts, the stem cells reservoir, and in mucous cells, located at the

junction between stomach and intestine, whereas *VCBP-B* is detected in folds, with a scattered pattern (38). Therefore, the potentiation of *VCBP-B* seems to represent a true memory-induced protective response, while the upregulation of *VCBP-C* may represent a sustained response, *i.e.*, a re-stimulation of a response already ongoing in developing stem cells.

The most striking findings in this study regard the regulation of the *VCBP* genes. Chitin-binding peptides/proteins and chitinase-like proteins are involved in constitutive and induced resistance to fungal colonisation, and are found in a number of organisms (39), including bacteria (40), plants (41), invertebrates (42, 43) and humans (44). The antifungal activity of these proteins is likely the result of their binding to nascent fungal cell wall chitin, through their chitin-binding lectin-like domain (CBD), resulting in disrupted fungal cell polarity with concomitant inhibition of growth (39). The variable region-containing chitin-binding domain proteins (VCBPs), thus far identified in two protochordates, the amphioxus *Branchiostoma floridae* (45) and the ascidian *Ciona robusta* (28), are secreted molecules expressed in stomach and gut lumen and in blood (28, 38). These proteins are thought to actively contribute to gut microbiota homeostasis *via* their IgV domains (46), while the Ig domains apparently have a structural role that allows for optimal binding to the cell walls, sporangia (spore-forming bodies) and spores of a diverse set of filamentous fungi isolated from the *Ciona* gut (47). The function of VCBPs secreted in the blood has been ascribed to their opsonising activity towards bacteria, mediated by the Ig domains with the contribution of CBD (27, 48). Since most studies focused on *VCBP* expression in the stomach and gut, there is no information about their expression and possible role in the pharynx, the filter feeding organ of the animal from which food particles entangled in mucus, secreted by the endostyle, are moved to the alimentary canal to be digested.

In our study, we have assessed the expression of *VCBP-B* and *VCBP-C* in the gut and in the pharynx of *C. robusta* in response to various stimuli, both as primary immune reaction and in immune memory responses. The *VCBP-B* gene product, expressed in the stomach of adults and in blood cells of *Ciona*, is a protein displaying one IgV domain, one Ig-like domain and one CBD. Conversely, the *VCBP-C* gene product, expressed in the stomach and gut of juvenile and adult animals and in blood cells, displays two Ig-like domains (no IgV domain) and a CBD. The differences in their expected functions are however not known (48). We observed that these genes are sensitive to every stimulus administered to animals, but in an organ-specific way. In response to systemic LPS, both genes were strongly up-regulated in the pharynx (over 4000-fold for *VCBP-B*), while in the gut the basal *VCBP-B* expression was decreased to zero in response to LPS and that of *VCBP-C* was not affected. Examining the gene expression in response to H/S stress, we observed a significant up-regulation of both genes (about 5–8-fold for *VCBP-B* and 200-fold for *VCBP-C*) upon both short and long stress. We could hypothesise that H/S stress decreases the mucus production and/or mucus transport (10) from the endostyle to the gut, and consequently the gut epithelium is less protected, resulting in an inflammatory condition similar to the experimental colitis in the mouse, which also displays a significant functional/physical impairment of the gut

barrier (49). In the mouse colitis model, the disease is associated with an overgrowth of *Candida albicans* (50). Fungal overgrowth in the gut is in turn associated with dysbiotic changes in the gut microbiota and alterations of the digestive mucosa that promote *C. albicans* translocation across the digestive intestinal barrier and its haematogenous dissemination and invasive fungal infections (51, 52). Therefore, we can hypothesise that, following a stressful event compromising the mucus production/transport, the strong up-regulation of *VCBP* genes (mostly *VCBP-C* whose tissue expression pattern involves the majority of stomach outer folds and gut) could be due to the urgency of fighting epithelium colonisation by microorganisms. When animals are exposed to nanoplastics in the same H/S conditions, the up-regulation of *VCBP-C* was lost, similar to other genes, probably because of a higher toxicity of particles for the gut cells, poorly protected by mucus.

In the pharynx, LPS was extremely potent in up-regulating the expression of *VCBP-B*. So far, this gene was known to be expressed in the stomach of adult individuals and in granular amoebocytes (28, 38), but our qPCR data could also show an expression in the pharynx. However, the systemic LPS administration implies the stimulus reaching the blood, thus it is possible that granular amoebocytes contribute to the gene up-regulation observed in the pharynx. From our previous study (27), we know that the intratunical LPS administration in *Ciona* triggers an inflammatory response, which entails blood cell composition changes as well as a transcriptomic modulation of several genes. The strong induction of *VCBP-B* expression in the pharynx of LPS-treated animals is consistent with a close relationship between *VCBPs* and inflammatory environments and bacterial burden. Such correlation is supported by data in different systems. For instance, the human chitinase-3-like protein 1 (YKL-40) is highly expressed in serum from healthy volunteers inoculated with *Escherichia coli* endotoxin (53). In *S. pneumoniae*-infected mice, the Chi3l1 protein is up-regulated and plays central roles in promoting bacterial clearance and mediating host tolerance through inhibition of macrophage pyroptosis (54).

Although the exact functions of different *VCBP* proteins are still unknown (48), our data support the hypothesis that *VCBPs* exhibits a tissue-specific protective function, with *VCBP-B* mainly involved in patrolling the pharynx/blood district, whereas *VCBP-C* is mainly involved in the control of gut homeostasis.

In conclusion, our study demonstrates that *C. robusta* mounts a potent organ-specific adaptation response to environmental changes (the combination of hypoxia and starvation) and that such response depends on the duration of stress. The adaptation response is different in the pharynx and the gut or H/S-exposed animals, underlining the different protective role of the two organs. The presence of nanoplastics, in combination with H/S stress, changes gene expression as compared to H/S alone, resulting in an anomalous expression profile in the pharynx after 18 h of exposure and in a general inhibition of the H/S-induced changes in the gut. This may result in a hampered capacity of the animals to adapt to the environmental changes. When assessing the immune response to a bacterial challenge (LPS) in animals pre-exposed to H/S with or

without nanoplastics, we could observe that the strong reaction to LPS in the pharynx was substantially decreased in animals that had previously experienced an H/S stress, whereas the low/down-regulated gene expression in the gut in response to LPS was generally abolished in previously stressed animals. Thus, animals experiencing environmental stress mount a robust adaptation response, based on changes in the expression of several immune/stress-related genes. Such adaptation (immune memory) strongly influences the immune reaction to a subsequent infectious challenge, which is less strong both in the gut and in the pharynx. We can hypothesise that the mitigation of the response to LPS (decrease in gene up-regulation in the pharynx and increase of gene down-regulation in the gut) may have a double effect, less protective capacity against infections but also less self-damage caused by an exceedingly strong reaction. It is notable that the presence of nanoplastics, which has effects on the primary adaptation response, does not have substantial effects on the H/S stress-induced memory reaction to ensuing challenges. This may be interpreted as an interference (likely due to particle accumulation in tissues) with the tissue homeostasis and functionality, *i.e.*, with adaptation to the environmental changes, which however does not substantially affect the defensive capacity (measured as memory response to an infectious challenge).

## Data availability statement

The original contributions presented in the study are included in the article/[Supplementary Material](#). Further inquiries can be directed to the corresponding author.

## Ethics statement

Studies on *Ciona robusta* do not need ethical review and approval, in accordance with the national and international legislation regulating animal experimentation. All activities were performed according to the Italian DLgs 26/2014, the European Directive 2010/63/EU and the associated “A working document on Animal Welfare Bodies and National Committees to fulfil the requirements under the Directive”. Ethical clearance was confirmed by the Animal Welfare Committee of the Stazione Zoologica Anton Dohrn (Ethical Clearance Waive request 01/2023).

## Author contributions

RM and DM planned and performed the experiments. PI and DB contributed to the experimental design. All authors contributed to writing the manuscript. PI and DB critically revised the manuscript. All authors contributed to the article and approved the submitted version.

## Funding

This work was supported by the EU Commission H2020 projects PANDORA (GA671881) and ENDONANO (GA 812661) (PI, DB), the project MIUR/PRIN-20173ZECM of the Italian Ministry of Research (PI), the China-Italy NSFC-MAECI bilateral project 82261138630 (DB) and the Key Collaborative Research Program of the Alliance of International Science Organizations ANSO-CR-KP-2022-01 (DB).

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Inflammatory response triggered by innate immunity can act to protect against microorganisms that behave as pathogens, with the aim to restore the homeostatic state between host and beneficial microbes. As a filter-feeder organism, the ascidian *Ciona robusta* is continuously exposed to external microbes that may be harmful under some conditions. In this work, we used transcriptional and proteomic approaches to investigate the inflammatory response induced by stimuli of bacterial (lipopolysaccharide -LPS- and diacylated lipopeptide - Pam2CSK4) and fungal (zymosan) origin, in *Ciona* juveniles at stage 4 of metamorphosis. We focused on receptors, co-interactors, transcription factors and cytokines belonging to the TLR and Dectin-1 pathways and on immune factors identified by homology approach (*i.e.* immunoglobulin (Ig) or C-type lectin domain containing molecules). While LPS did not induce a significant response in juvenile ascidians, Pam2CSK4 and zymosan exposure triggered the activation of specific inflammatory mechanisms. In particular, Pam2CSK4-induced inflammation was characterized by modulation of TLR and Dectin-1 pathway molecules, including receptors, transcription factors, and cytokines, while immune response to zymosan primarily involved C-type lectin receptors, co-interactors, Ig-containing molecules, and cytokines. A targeted proteomic analysis enabled to confirm transcriptional data, also highlighting a temporal delay between transcriptional induction and protein level changes. Finally, a protein-protein interaction network of *Ciona* immune molecules was rendered to provide a wide visualization and analysis platform of innate immunity. The *in vivo* inflammatory model described here reveals interconnections of innate immune pathways in specific responses to selected microbial stimuli. It also represents the starting point for studying ontogeny and regulation of inflammatory disorders in different physiological conditions.

## KEYWORDS

inflammatory response, innate immunity, *Ciona robusta*, marine invertebrates, microbial stimuli, transcriptional analysis, proteomic analysis, protein-protein interactome

# 1 Introduction

The ascidian *Ciona robusta* is a filter-feeding marine species belonging to Tunicata, the sub-phylum most closely related to Vertebrata within the phylum Chordata (1). This species commonly thrives in polluted habitats highly enriched in pathogenic and nonpathogenic bacteria, fungi and viruses, sensing either potentially infectious ones or establishing homeostatic relationships, respectively. *C. robusta* is a consolidated experimental system in a wide array of biological fields (2–5) including immunology since, like all invertebrates, it possesses only innate immunity as a defense strategy against infections (6). The absence of the adaptive immune system facilitates studies of the innate immune crosstalk with the environment and of the establishment and maintenance of homeostasis with nonpathogenic and “foreign” microorganisms. In recent years, this marine species has been exploited for studies of host-microbiome interactions within the digestive tract in relation to microbial settlement and mucus colonization, leading to the characterization of different elements of the gut environment, such as chitin-rich mucus and a subset of secreted immune effectors (7, 8). *Ciona* has also been used in the context of identifying and defining immunological memory as a consequence of sophisticated responses mediated by trained immunity after inflammatory challenges (9).

The study of inflammatory mechanisms is essential to understanding the role of the immune system in the interaction with microbiota (10), and as a sentinel in cellular and tissue homeostasis (11–13). When these conditions deviate from homeostasis, activation of inflammatory pathways can help to restore the physiological equilibrium (11). In *Ciona*, several genomic and transcriptional studies have focused on the role of the innate immune system in the inflammatory response after challenges mainly with lipopolysaccharide (LPS) (reviewed in (14)), a component of Gram-negative bacterial membrane that belongs to the category of pathogen-associated molecular patterns (PAMPs). The knowledge of the immune repertoire of *C. robusta* is based on domain sequence similarities and phylogenetic relationships with their vertebrate counterparts (14), while the immunological role was functionally confirmed at the protein level in only few cases (15–17).

Several classes of immune factors have been recognized in *C. robusta*, such as *i*) pathogen recognition receptors (PRRs) like the Toll-like receptors (TLRs) TLR1 and TLR2 (17, 18) and C-type lectin receptors (CLRs) like CD94 (19); *ii*) cytosolic lectins like galectins, collectins (i.e. mannose-binding lectins) and intelectins (14, 20–24); *iii*) molecules of the complement system like C3 and its receptor C3aR (15, 16, 25, 26); *iv*) cytokines like the three interleukin-17 family members IL17-1, IL17-2 and IL17-3, the interleukin receptor IL17-R (27), the tumor necrosis factor  $\alpha$  (TNF $\alpha$ ) (28), the transforming growth factor beta (TGF- $\beta$ ) (29) and the macrophage migration inhibitory factor (MIF) (30), *v*) defensins like the molecule against microbes A precursor (mamA) (31); and *vi*) cytokine induction mediators like the gene coding for the transcription factor nuclear factor kappa B (NF- $\kappa$ B) (17, 32). All these immune molecules are transcriptionally, and sometimes translationally, upregulated in hemocytes and pharynx following

subtunical injection of LPS in the pharyngeal wall, the first portion of the digestive tract of adult individuals of *C. robusta* (14). Moreover, C3 and C3aR have been proven to exert a chemotactic activity on ascidian hemocytes (15, 16). Here, our analyses of mRNA and protein expression patterns included most of these molecules, as well as additional genes putatively involved in the inflammatory response that were identified by homology search analysis in the current study.

An important experimental advantage of adopting *C. robusta* in comparative immunology is the capacity to perform *in vitro* fertilization and rear thousands of transparent filter-feeding juveniles. Metamorphic stage 4 of juvenile development (1<sup>st</sup> ascidian stage) is the first filter-feeding stage in the life cycle of *Ciona* (33), and can be used for investigating the inflammatory response to environmental microbial components at the early phase of immune system development and maturation. While the inflammatory response in adult ascidians usually involves stimulus injection in the body wall, stage 4 *C. robusta* juveniles can be exposed to resuspended, exogenous, and sometimes harmful compounds that can be ingested by filtration, thus reproducing a more natural physiological condition. In this work, this juvenile stage was used to explore the activation of key components of the innate immune response in the whole animal after exposure to different PAMPs.

The inflammatory molecules used in this study include components of bacterial [i.e., LPS and diacylated lipopeptide (Pam2CSK4)] and fungal (i.e., zymosan, an insoluble preparation of *Saccharomyces cerevisiae* cell wall, consisting of  $\beta$ -glucans, mannans, mannoproteins and chitin) cell walls. Of note, the effect of Pam2CSK4 [present in both Gram-positive and Gram-negative bacteria (34, 35)] on *Ciona* immune response has not been previously investigated. In mammals, these stimuli are described to be agonists of TLRs and Dectin-1. Specifically, LPS is an agonist of human TLR4 (36, 37), Pam2CSK4 is an activator of TLR2/TLR6 heterodimer (38), and zymosan is an agonist of human TLR2 and Dectin-1 (39). In a previous study conducted by Sasaki and coworkers using *Ciona* adults, activation of TLRs was induced by zymosan and not by another lipopeptide, Pam3CSK4 (17).

Here, we gathered evidence in support of specific transcriptional and translational changes induced by PAMPs, and of possible interactions between molecules and pathways involved in the immune response, specifically TLRs and Dectin-1 pathways. In summary, this study depicts *C. robusta* as a unique chordate organism for studying factors and mechanisms that modulate immune activation and homeostasis, thus supporting its use as a viable experimental system in translational research and biotechnological approaches.

## 2 Materials and methods

### 2.1 Ethics statement and animal sampling

The research described herein was performed by using *Ciona* specimens collected in the Mar Piccolo of Taranto (Taranto, Italy, ~40° 29'29"N, 17°17'55"E) and in the Fusaro lagoon (Naples, Italy, ~40° 49'10"N, 14°03'28"E), in locations that are not privately-owned nor

protected in any way, according to the authorization of Marina Mercantile (Decree of the President of the Republic (DPR) 1639/68, Sep. 19, 1980, confirmed on Jan. 10, 2000). The study did not involve mammalian or vertebrate subjects, or endangered or protected species, and was carried out in strict accordance with European (Directive 2010/63/EU) and Italian (Legislative Decree n. 26/2014) legislation for the care and use of animals for scientific purposes. *C. robusta* is considered an introduced species and is not regulated or protected by environmental agencies in Italy. The animal collection services contracted in this study maintain current permits and licenses for collection and distribution of marine invertebrates to academic institutions. No special permission was required to collect ascidians, and animal handling was in accordance with the guidelines of our academic institutions. Animals were recovered and brought to the laboratory alive and maintained in clean water with aeration, temperature control and properly fed. In accordance with general animal protocols, the least number of specimens required per experiment were utilized. Animal waste products were disposed appropriately.

## 2.2 Juvenile treatment and sample preparation for gene expression and proteomic analyses

To obtain stage 4 *Ciona* juveniles, *in vitro* fertilization was performed using eggs and spermatozoa surgically collected from the gonoducts of different animals that had been exposed to constant light to elicit gamete maturation. *In vitro* egg fertilization follows the procedure described previously (40), with the exception that 0.22  $\mu$ M filtered seawater (FSW) was used and no sterilization step was performed. After the time required for egg fertilization (about 10 minutes), fertilized eggs were diluted in FSW in 150 mm Petri dishes and raised at 18°C. Eighteen hours (hr) later, when animal have reached the non-feeding swimming tadpole larval stage, batches containing at least 90% normally developed larvae were selected for inflammatory treatments. Then, larvae were gently transferred to 6-well plates containing 4 ml FSW and 600–700 larvae per well. Animals were let to grow O/N at 18°C, and the day after the FSW was replaced with fresh one to eliminate post-metamorphic stages not attached to the dish, or unsettled larvae not properly developed. When juveniles have reached stage 4 (33), 3–4 days post fertilization, they were ready to be treated with different inflammatory stimuli, such as LPS (Sigma #L2880), Pam2CSK4 (InvivoGen #tlrl-pm2s-1) and zymosan (InvivoGen #tlrl-zyn). We referred to literature for the concentration of each inflammatory agent that best suits the activation of the immune system. LPS is usually injected in adults in the quantity of 100  $\mu$ g dissolved in marine solution (27–29), or resuspended in a cell line-based heterologous system at the concentration of 2.5 and 5  $\mu$ g/ml (17). Here, we used LPS at an intermediate concentration of 10  $\mu$ g/ml. The triacylated form Pam3CSK4 was tested on cell lines in a heterologous system at the concentration of 0.5 and 2  $\mu$ g/ml (17). Here, we used Pam2CSK4 at 1 and 10  $\mu$ g/ml concentrations. The third inflammatory agent, zymosan, was reported in *Ciona* as a modulator of TLR activation in an *in vitro* heterologous system at the concentration of 100  $\mu$ g/ml (17). Here, we used it at 10 and 100  $\mu$ g/ml concentration.

Each compound was resuspended at the appropriate concentration in 4 ml of 0.22  $\mu$ M FSW, and animals were treated with these solutions for 30 minutes (min), 2 hr and 4 hr, while control animals were exposed to normal FSW. At the end of each time treatment, samples for gene expression analysis were collected in RNAlater by replacing the FSW supplemented with the microbial stimulus with 1 ml RNAlater solution in each well. Sample storage followed the manufacturer's instruction; briefly, after O/N incubation in RNAlater at room temperature (RT), RNAlater solution was removed and samples (whole animals still attached to the bottom of 6-well plates) were frozen at -20°C for long term storage until RNA extraction. In turn, samples for proteomic analyses were processed by removing FSW supplemented with the microbial stimulus followed by fast freezing in dry ice and storage at -80°C until protein extraction.

## 2.3 Gene expression analysis

### 2.3.1 The identification of immune molecules

To search for new immunocompetent molecules, we used orthologous gene search and homology domain approaches to explore the *C. robusta* genome annotation databases ANISEED (v.2019) (41), NCBI (42) and UCSC Genome Browser (assembly ID: ci3 (43)). A combination of tools (e.g., PSI-BLAST (44), BLAST v.2.13.0 (45) and Jalview v.2.11.2.0 (46)) and resources (e.g., UniProt (47), InterPro (48) and SMART (49)) was used to compare protein functional and structural domains and to analyze the percentage of sequence identity of molecules of interest between *Ciona robusta* and *Homo sapiens*. The following protein domains were used as queries: *i*) C-type lectin (CTL) or carbohydrate-recognition domain (CRD) (CLECT); *ii*) interferon regulatory factor (IRF) domain (also known as tryptophan pentad repeat); and *iii*) immunoglobulin (Ig) and immunoglobulin-like (Ig-like) domains.

### 2.3.2 RNA extraction

Total RNA was extracted from whole-body *Ciona* juveniles using RNAqueous<sup>TM</sup>-Micro Total RNA Isolation Kit (Invitrogen #AM193) following manufacturer's instructions. Briefly, juvenile samples collected in 6-well plates as described in the previous section, were allowed to thaw slowly before proceeding to RNA extraction. After adding lysis buffer, samples were detached by scraping using flat blade cell lifter, collected, and transferred to 1.5 ml microtube, and mechanically broken using an ultra sonicator (Branson) for 15 seconds (sec) at 20% of maximum power. RNA extracted was eluted in 20  $\mu$ l elution buffer, and subsequently DNA contamination was eliminated by performing DNase step as described in the manufacturer's procedure. RNA quality and quantity were evaluated through agar gel electrophoresis and NanoDrop spectrophotometer (ThermoFisher) reading, respectively.

### 2.3.3 Quantitative reverse transcription PCR analysis

Single-stranded cDNA was synthesized from 1  $\mu$ g of total RNA employing QuantiTect Reverse Transcription kit (Qiagen #205311). Gene expression was analyzed by quantitative reverse transcription PCR (RT-qPCR) on cDNA from control juvenile

samples and juvenile samples exposed to the different microbial stimuli. Primer sequences for the genes to be examined are listed in [Supplementary Tables 1A, B](#). Actin gene was used as reference for internal standardization.

The amplification efficiency of each RT-qPCR primer set was assessed employing 10-fold serial dilution of juvenile cDNA or it was already tested in a previous work, employing 10-fold serial dilution of cDNA synthesized from *Ciona* digestive tract (50) ([Supplementary Tables 1A, B](#)). RT-qPCR was performed according to the manufacturer's recommendation with the Fast SYBR Green MasterMix (Applied Biosystems #4385612), 0.28  $\mu$ M of each primer and 5 ng of cDNA per reaction. A denaturation step at 95°C for 20 sec, 40 amplification cycles (95°C for 1 sec and 60°C for 20 sec) and a Melt Curve step (95°C for 15 sec, 60°C for 1 min and 95°C for 15 sec) were employed. Reactions for each sample were performed in triplicate on five or six biological replicates. In order to calculate mRNA expression level (mRNA RQ) relative to the control sample of each fertilization, data were analyzed with Vii<sup>TM</sup> 7 Real-Time PCR software (Life Technologies) and quantified with the comparative  $C_t$  method ( $2^{-\Delta\Delta C_t}$ ) based on  $C_t$  values. Expression level of the selected genes is indicated as fold change. Results are represented as violin plots, showing the full distribution of the data, reported as value of the fold change of each sample (biological replicate), and the median for each condition analyzed. Significance of the relative  $2^{-\Delta\Delta C_t}$  of each group (biological replicates  $n = 5$  or  $6$ ), compared to the controls, was determined using 'paired parametric t-test'. One-way ANOVA analysis, according to normality test results, performed on each gene, was employed to determine statistically significant differences between the three time points for each microbial stimulus treatment. The statistical analyses were performed using GraphPad PRISM software, version 9.3.1.

## 2.4 Targeted proteomics analysis

### 2.4.1 Protein extraction and samples preparation for mass spectrometry analysis

Total protein extraction from whole-body *C. robusta* juveniles followed the same procedure used for RNA extraction ([paragraph 2.3.2](#)) with the exception that the juveniles were lysed in 2% CHAPS buffer (100  $\mu$ l per well, Sigma #C9426) and mechanically broken using an ultra sonicator (Branson) for 30 sec at 20% of maximum power. Sample lysates were then centrifuged at 13,000 rpm for 15 min at 4°C, supernatants were collected in 1.5 ml microtubes and stored at -80°C. An aliquot of 30  $\mu$ l of each protein lysate was subjected to the *in-solution* digestion protocol by reducing with 100 mM dithiothreitol (dissolved in 50 mM ammonium bicarbonate) to a final concentration of 20 mM and incubated for 60 min at 60°C. After cooling the protein solution at RT, the protein cysteines were alkylated by adding iodoacetamide to a final concentration of 40 mM, followed by incubation in the dark for 45 min at RT. A solution of formic acid was added at a final concentration of 1% to block the alkylation reaction and proteins precipitated by a chloroform/methanol/water precipitation protocol (51). Supernatants were removed and the pellets dried. Digestion of

protein mixtures was carried out in 10 mM ammonium bicarbonate by using trypsin at 50:1 protein:enzyme mass ratio. The samples were incubated at 37°C for 16 hr, and the trypsin digestion stopped by acidification of the peptide's mixture.

The peptides were dried under vacuum and finally resuspended in 50  $\mu$ l of 0.1% HCOOH for a further desalting step using manually equipped tips with three Empore disc C18 (Merck, #66883-U) before the liquid chromatography-mass spectrometry tandem (LC-MS/MS) analysis in Multiple Reaction Monitoring ion mode (MRM).

### 2.4.2 LC-MS/MS analysis

The peptide mixture was analyzed by LC-MS/MS analysis using a Xevo TQ-S (Waters, Milford, MA, USA) equipped with an ionkey coupled to an Acquity UPLC system (Waters, Milford, MA, USA). For each run, the peptide mixture (2  $\mu$ l) was injected and separated on a BEH C18 peptide separation device (130Å, 1.7  $\mu$ m, 150  $\mu$ m X 50 mm) at 45°C with a flow rate of 3  $\mu$ l/min using an aqueous solution (LC-MS grade) containing 2% ACN as a mobile phase A and 98% ACN of an aqueous solution as a mobile phase B, both acidified with 0.2% HCOOH. The gradient for the MRM method started with 7% buffer B for 5 min, from 5 to 40 min reached 50% buffer B to 95% buffer B during the next 2 min. The column was finally re-equilibrated to initial conditions for 4 min. The parameters of the MS source were as follow: 3900 V as ion spray voltage, 150°C interface heater temperature, 150 l/h gas flow with 7 bar nebulizer pressure.

MRM mass spectrometric analyses were performed in positive ion mode for the run time with 5 points per peak and 3 min dwell times. The cone voltage was set to 35 V. A range of 300-1000 m/z was preferentially selected as precursor or product ions.

### 2.4.3 Informatics tools

The latest version of Skyline software (22.2 - 64 bit version MacCossLab Software, University of Washington, USA) (52) was used for *in silico* selection of peptides with proteotypic sequences for each selected protein. For each peptide, m/z precursor ion, m/z product ion, and relative collision energy were provided by Skyline ([Supplementary Table 2](#)). Seven and thirty amino acid-long tryptic proteotypic peptides, preferably without missed cleavages and devoid of methionine and cysteine residues, were chosen for the development of MRM assays. Sequences with a proline (P) on the C-terminal side of arginine (R) or lysine (K) or showing the NXT or NXS glycosidic consensus motif were also excluded. The six transitions of proteotypic peptides were selected for method development based on the y-fragment ions.

### 2.4.4 Statistical analysis

The areas of extracted ion chromatograms of all proteotypic peptides for each protein were averaged to get a value representative of a specific protein. Such values were uploaded on Perseus software (53) used for the statistical analysis. Expression values of each protein were log2 transformed to obtain a Perseus matrix. Finally, heatmap of cluster analysis and principal component analysis (PCA) were performed by using the obtained Perseus matrix.

## 2.5 In silico analysis of potential interactions

To increase knowledge about the landscape of molecular dynamics triggered by inflammation, a protein-protein interaction map was generated using the STRING database (54). Multiple sequence queries were followed by evaluation of protein sequence identity by means of Multiple Sequence Alignment (MSA) in Jalview (46) and BlastP (44, 45). The resulting interaction networks were modified and merged with the Cytoscape v.3.9.0 software (55) in order to build a complete protein-protein interactome in which to connect all molecules whose gene expression was analyzed in this study. Among the applications available in Cytoscape “App Manager” for functional analyses of immune-related pathways, we installed and used the STRING Enrichment application, that is based mainly on KEGG (56), SMART, COMPARTMENTS (57), Panther (58, 59), AmiGO 2 (60) and QuickGO (61), Pfam (62), InterPRO and Reactome (63) databases. This application was used to retrieve annotations about compartmentation, Gene Ontology (GO), pathway analysis and domain analysis of the selected nodes of the map. The main findings are reported in the protein-protein interaction network.

## 3 Results

### 3.1 Experimental setup: concentration and exposure time to microbial stimuli

In this study, the effect of 30 min, 2 hr and 4 hr exposure to microbial stimuli in *C. robusta* juveniles has been investigated by evaluating changes in the expression levels of immune genes and proteins in the whole-body animal (Figure 1A). Also, juveniles were exposed for 4 hr at all selected concentrations (10 µg/ml LPS, 1 and 10 µg/ml Pam2CSK4, 10 and 100 µg/ml zymosan), raised in FSW for 24 hr, and then analyzed for survival and altered gross phenotypes. In all experimental conditions, juveniles were alive and morphologically normal, suggesting that the concentrations of the microbial stimuli did not trigger a strong immune response that could be lethal for the animals (Figure 1B).

### 3.2 Immune gene mining and expression

Previous studies have identified the main molecular actors of the innate immune system of *C. robusta*, revealing high-rate conservation of PRRs, cytokines and complement system molecules, to name a few. In our work, to widen the spectrum of molecules that could be responsive to the inflammatory stimuli here tested, more counterparts of genes involved in the inflammatory response of vertebrates were included. The genes encoding the tyrosine-protein kinase SYK and Nuclear factor of activated T-cells 5 (NFAT5), respectively co-interactor and transcription factor of PRR pathways, were identified by orthologous gene search and had already been annotated (<http://www.aniseed.cnrs.fr>). Then, more

immune genes were uncovered by homology search analysis of *C. robusta* genome and proteome (Table 1). Specifically, we searched for molecules containing the CLECT and the Ig domains, since they are present in proteins with immune functions (64–67), and the IRF domain contained in the homonymous transcription factor involved in PRR pathways (68).

The CLECT domain allowed to identify the Dectin-1 CLR family 4 members M (CLEC4M) and F (CLEC4F), and Macrophage mannose receptor 1-like (MR). Ig- or Ig-like domains were found in FAM187A, fibronectin (FN), fibronectin like (FN-like), and tyrosine-protein kinase receptor 3 (TYRO3). TYRO3 is a receptor which is also characterized by FN and Tyrosine kinase catalytic domains and is involved in inflammation resolution (69, 70). FAM187A (Cirobu.g00001161) groups together with the ascidian *Botryllus schlosseri* Triggering receptor expressed on myeloid cells (TREM)-like 2 gene (TREML2) (Boschl.g00005277) in the “Gene Phylogeny” section of the ANISEED database. In human, the TREM2 pathway is expressed in various tissue macrophages, such as the microglia of the central nervous system, and increasing evidence suggests that TREM2 is involved in neuroinflammatory responses and neurodegenerative diseases like Alzheimer and Parkinson (71, 72) and contributes to mucosal inflammation in the digestive tract during the development of colitis in mice (73). The IRF domain was present in IRF-like gene. Furthermore, search for *C. robusta* NFAT5 led to the identification of FAM136A, a mitochondrial protein conserved across metazoans (74) whose human orthologue shows a correlation with Meniere’s disease, an inner ear problem with an autoimmune condition (75).

In detail, the effect of LPS, Pam2CSK4 and zymosan has been tested on the activity of the following *Ciona* factors: i) immune receptors such as TLR1, TLR2, CLEC4M, CLEC4F and MR; ii) Ig-like V-type domain-containing proteins as FAM187A, FN, FN-like and TYRO3; iii) the co-interactor SYK; iv) transcription factor coding genes NF-κB, IRF-like and NFAT5; v) FAM136A; vi) cytokines IL17-1, IL17-2, IL17-3, and their receptor IL17R, TNFα, TGFβ and MIF; vii) defensins like mamA and viii) complement system genes C3 and C3aR. The results obtained for each stimulus are described below. For sake of simplicity in the presentation, FAM136A and IL17R were included in the categories of transcription factors and cytokine signaling, respectively, besides their different roles.

#### 3.2.1 LPS: effects on TLR2 and TYRO3 genes

LPS is the inflammatory agent more widely used in *Ciona* adults (by injection). Here, 10 µg/ml LPS did not induce a significant immune response in stage 4 juveniles, as shown by lack of changes in the expression of most genes (Supplementary Figure 1) apart from the upregulation of *TLR2* and *TYRO3* after 30 min treatment (Figure 2). Thus, the modest activation of an immune response following LPS infection is rapidly resolved.

#### 3.2.2 Pam2CSK4: effects on genes encoding for PRRs, transcriptional factors, and cytokines

Unlike LPS, the inflammatory stimulus Pam2CSK4 was seen to induce transcriptional modulation of several molecules and

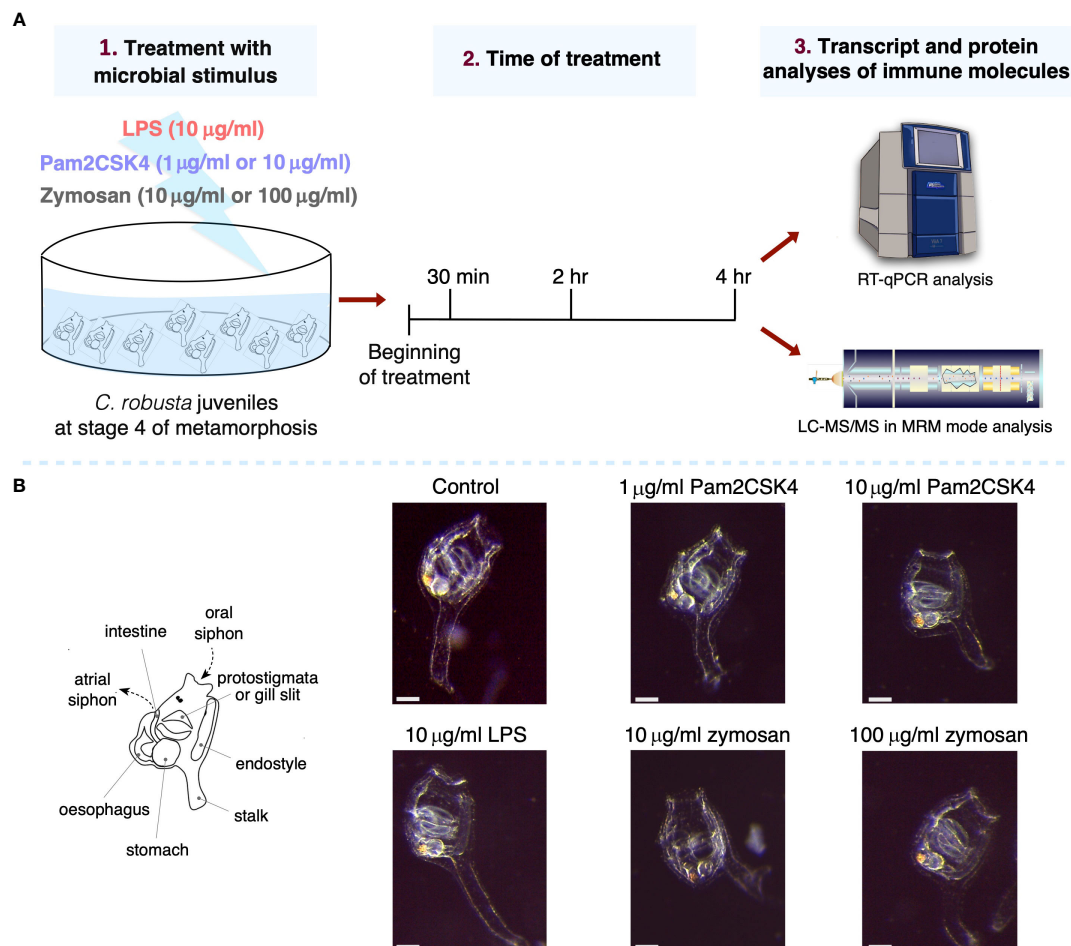

FIGURE 1

Experimental setup and effect on morphology of *C. robusta* juveniles after 24 hours from the treatment. (A) Scheme of *C. robusta* juveniles' treatment with different microbial stimuli, concentrations and duration, followed by quantification of immune molecules through gene expression (RT-qPCR technique) and protein level (LC-MRM/MC technique). (B) On the left, schematic representation of *C. robusta* juveniles at stage 4 showing the main anatomical features observed at this metamorphic stage. On the right, after 24 hours juveniles (exposed for 4 hours to diverse concentration of microbial stimuli) appear morphologically normal. Scale bar, 100  $\mu\text{m}$ .

pathways at all concentrations and time points. Following 1  $\mu\text{g/ml}$  Pam2CSK4 treatment, *TLR1* was upregulated after 30 min treatment, *TLR2* after 30 min and 2 hr, and *CLEC4F* receptor after 4 hr treatment (Figure 3). While the expression of the genes encoding the receptor, *CLEC4M*, the Ig-domain containing proteins *FAM187A*, *FN*, *FN-like* and *TYRO3*, the cofactor *SYK*, was not regulated by Pam2CSK4 exposure, the expression of *FN*, *FN-like* and *TYRO3* was significantly modulated between 30 min and 4 hr treatments (Supplementary Figure 2). The expression of the transcription factor coding gene *NF- $\kappa$ B* was affected at all time points analyzed, with upregulation at 30 min and down-regulation at 2 hr and 4 hr; *IRF-like* was upregulated at both 30 min and 2 hr, whereas *NFAT5* was downregulated at 4 hr (Figure 3). Significant upregulation of *FAM136A* was observed after 30 min exposure (Figure 3). Concerning cytokines, *IL17-3* and *TGF $\beta$*  were significantly upregulated at 30 min and 2 hr treatment, respectively (Figure 3). Upregulation of *IL17R* was also observed at both 30 min and 2 hr time points (Figure 3). Conversely,

cytokines *IL17-1*, *IL17-2*, *TNF $\alpha$*  and *MIF*, defensin *mamA*, and molecules of the complement system *C3* and *C3aR* were not affected in their transcriptional levels (Supplementary Figure 2). Statistical analysis by using one-way ANOVA test revealed that 1  $\mu\text{g/ml}$  Pam2CSK4 had a significant effect on the modulation of genes coding for receptors (*TLR2*, *CLEC4F* and *MR*), transcription factors (*NF- $\kappa$ B*, *IRF-like* and *NFAT5*) and cytokines (*IL17-3* and *TGF $\beta$* ) (Figure 3).

Pam2CSK4 at the concentration of 10  $\mu\text{g/ml}$  induced downregulation of *CLEC4M* and *CLEC4F* after both 2 and 4 hr treatment. TLR receptor coding genes were only affected after 4 hr, with downregulation of *TLR1* and upregulation of *TLR2* (Figure 4). Cytokines were upregulated following 30 min and 4 hr treatment (*IL17-1*), at all-time points (*IL17-3*) and 2 and 4 hr (*TGF $\beta$* ), while a downregulation of *MIF* was observed at 2 and 4 hr treatment (Figure 4). The highest concentration of Pam2CSK4 also induced upregulation of both defensin *mamA* and molecules of the complement system *C3* and *C3aR* after 4 hr treatment (Figure 4).

Protein names, accession numbers in NCBI and UniProtKB databases of *C. robusta* immune-related molecules are reported, together with the percentage of identity respect to human orthologs, investigated with both Protein Similarity Search (PSI-BLAST) database and Multiple Sequence Alignment Viewer application (MSA).

No change in gene expression was observed for *MR*, *FAM187A*, *FN*, *FN-like*, *TYRO3*, *SYK*, *NF-κB*, *IRF-like* and *NFAT5*, protein coding gene *FAM136A*, and cytokines *TNFα*, *IL17-2* and the receptor *IL17R* (Supplementary Figure 3). Statistical analysis by using one-way ANOVA test revealed that 10 μg/ml Pam2CSK4 induces a significant modulation in the expression of *CLEC4F*, *IL17-1*, *IL17-3* and *TGFβ* (Figure 4).

Taken together, these data show that Pam2CSK4 is able to trigger the activation of both PRR pathways investigated, modulating the transcription of receptors (*TLRs* and *CLEC4M*) and transcription factors (*NF-κB*, *IRF-like* and *NFAT5*) with concentration-dependent timing of activation. The inflammatory state induced by this bacterial stimulus is demonstrated by the activation of pro-inflammatory cytokines like *IL17-1* and *IL17-3*. Finally, the upregulation of *TGFβ* cytokine at late time point indicates a resolution of the inflammatory response.

### 3.2.3 Zymosan: effects on genes encoding for CLRs, Ig-containing molecules, cofactors, transcriptional factors, and cytokines

*Ciona* juveniles exposed for 4 hr to the lower concentration of zymosan, 10 μg/ml, showed a significant downregulation of the receptors *CLEC4M*, *MR*, *FN*, *FN-like* and the cofactor *SYK* (Figure 5). A similar effect was observed on the transcription factor coding genes *NFAT5* and *IRF-like*, the last one being downregulated also at 2 hr (Figure 5). Downregulation of the cytokine *IL17-2* (2 and 4 hr) and of the complement component *C3* (30 min and 4 hr) was also observed (Figure 5). The other genes analyzed, such as receptors (*TLR1*, *TLR2*, *CLEC4F*), Ig domain-containing proteins (*FAM187A* and *TYRO3*), transcription factor coding genes (*NF-κB*), *FAM136A*, cytokines (*IL17-1*, *IL17-3*, *IL17R*, *TGFβ*, *TNFα* and *MIF*), defensins (*mamA*) and complement system components (*C3aR*) were not affected by this inflammatory stimulus (Supplementary Figure 4).

## Receptors and Ig-domain containing molecules

FIGURE 2

Effect of 10 µg/ml LPS treatment on gene expression. *C. robusta* juveniles at stage 4 of metamorphosis treated with 10 µg/ml LPS show significant changes in gene expression of *TLR2* and *TYRO3*, detected by RT-qPCR, after 30 min treatment. Truncated violin plots represent the distribution and the density of numerical data of gene expression reported as fold changes ( $2^{-\Delta\Delta C_t}$ ) of mRNA Relative Quantification (mRNA RQ) compared to the corresponding control samples (no treated juveniles), that are reported as dotted black line. The black lines in each violin plots indicate the median of data set (n = 6, biological replicates). Statistical methods: paired samples t-test, significance indicated by black asterisk. (\*p. value < 0.05).

One-way ANOVA analysis revealed a modulation in *IRF-like*, *IL17-2* and *C3* expression (Figure 5).

Zymosan at the concentration of 100 µg/ml induced significant upregulation in the expression of genes coding for the Ig-domain containing proteins *FAM187A* (4 hr) and *TYRO3* (2 hr), cofactor *SYK* (2 hr), cytokines *IL17-3* (30 min and 4 hr), *TGFβ* (2 and 4 hr), *MIF* (30 min) and complement component *C3aR* (2 hr) (Figure 6). No effect was observed on the expression of the genes coding for receptors and Ig-domain containing proteins (*TLRs*, *CLE4M*, *CLE4F*, *MR*, *FN* and *FN-like*), transcription factors (*NF-κB*, *IRF-like* and *NFAT5*), *FAM136A*, cytokines (*IL17-1*, *IL17-2*, *IL17R*, *TNFα*), defensins (*mamA*) and complement system molecules (*C3*) (Supplementary Figure 5). One-way ANOVA analysis showed a significant modulation of *IL17-3* expression during the analyzed time points, and a significant shift in the transcriptional response of *FAM187A* between 30 min and 4 hr treatments (Figure 6).

Collectively, the immune response induced by zymosan involves CLRs (*CLE4M* and *MR*), cofactors (*SYK*) and transcription factors (*IRF-like* and *NFAT5*), suggesting an interplay of distinct PRR pathways. Among immune stimuli tested in this study, zymosan was the only one that affected the expression of Ig-containing molecules (*FAM187A*, *FN*, *FN-like* and *TYRO3*). Moreover, the activation of the inflammatory state following exposure to the higher concentration is highlighted by the modulation of the cytokine's transcripts, pro-inflammatory (*IL17-3*), and consequently anti-inflammatory (*TGFβ*), indicating again a resolution of the inflammation.

### 3.3 Targeted proteomics

To explore the effect of each stimulus treatment at protein level, the targeted proteomic approach has been conceived for detecting

changes in protein amount of the immune molecules here investigated. Indeed, A LC-MRM/MS method was developed for the detection of changes in protein abundance for the immune molecules. We first selected a panel of 1-3 proteotypic peptides for each protein and then recorded from 3 to 6 transitions (a combination of each precursor ion to several fragment ions) for each peptide. A total number of 32 peptides belonging to 16 proteins (listed in the Supplementary Table 1 and in the Figure 7B) was selected by monitoring 139 transitions displaying a good instrumental response (the same retention time for all transitions and a peak area higher than 1,000). An example of MRM chromatogram was reported for one peptide of the *NFAT5* protein (Supplementary Figure 6). After selecting the best instrumental response (see instrumental parameters in Supplementary Table 2), the relative quantification was performed by comparing the areas underlying the extracted ion chromatogram (EIC) peaks reflecting the differential expression of selected 16 proteins following the various stimulation *versus* the control sample. As an example, the EIC peak areas of two proteins, e.g. *FAM136A* and *FN*, were reported in a histogram representation (Supplementary Figure 7), displaying a similar trend in the samples. A significant downregulation was observed for the *FAM136A* and fibronectin protein along the Pam2CSK4 and zymosan treatment (independently from the stimulus kinetics) in comparison to the other samples, included the control.

The EIC peak areas were then uploaded on Perseus software to discover the response of *C. robusta* juveniles to stimulation with 10 µg/ml LPS, 1 µg/ml Pam2CSK4 and 100 µg/ml zymosan at 30 min, 2 hr and 4 hr of treatment compared to the control samples. The PCA analysis allowed to summarize and visualize the overall protein response to the microbial stimulation within a biplot where the control and treated samples were graphically

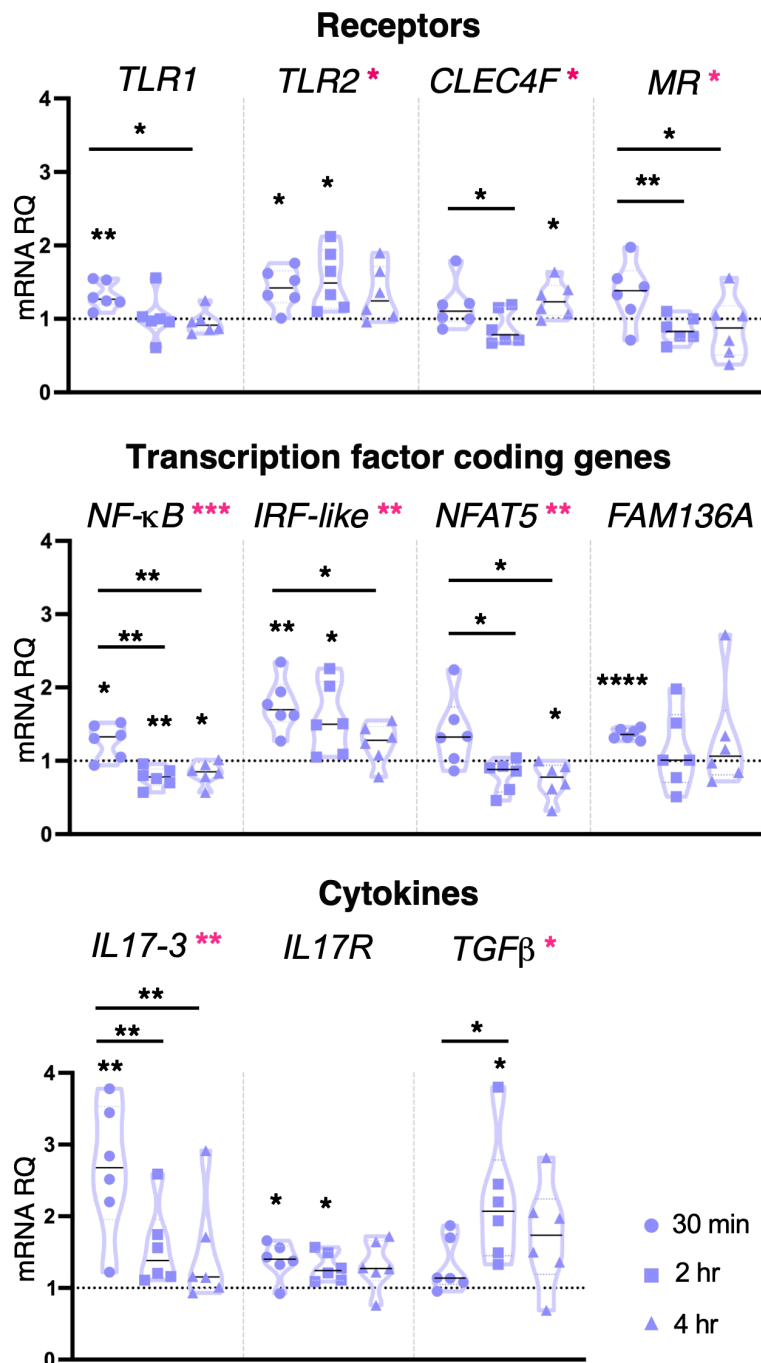

FIGURE 3

Effect of 1 µg/ml Pam2CSK4 treatment on gene expression. *C. robusta* juveniles at stage 4 of metamorphosis, treated with Pam2CSK4 at the concentration of 1 µg/ml, show significant changes in gene expression of *TLR1*, *TLR2*, *CLEC4F*, *MR*, *NF-κB*, *IRF-like*, *NFAT5*, *FAM136A*, *IL17-3*, *IL17R* and *TGFβ*, detected by RT-qPCR, after 30 min, 2 hr and 4 hr of treatment. Truncated violin plots represent the distribution and the density of numerical data of gene expression reported as fold changes ( $2^{-\Delta\Delta Ct}$ ) of mRNA Relative Quantification (mRNA RQ) compared to the corresponding control samples of juveniles (not treated) and reported as dotted black line. The black lines in violin plots indicate the median of data set ( $n = 6$ , biological replicates). Graphics shows also significant expression changes between two different time points of the treatment, indicated by horizontal black lines. Statistical methods: paired samples t-test, significance indicated by black asterisks; one-way ANOVA test, significance indicated by magenta asterisks. (\*p. value < 0.05, \*\*p. value < 0.01, \*\*\*p. value < 0.001, and \*\*\*\*p. value < 0.0001).

represented. Among all revealed components, the first two (Supplementary Table 3) resulted in a two-dimensional PCA biplot (Figure 7A). PCA reduced the dimensionality of the multivariate data to two principal components explaining almost 90% variance (79.6% for Component 1 and 9.7% for Component 2)

with minimal loss of information. The statistical analysis revealed a clear separation between a large cluster that included control, LPS (30 min, 2 hr, 4 hr), Pam2CSK4 (30 min) and zymosan (30 min, 2 hr) treatments, a small cluster consisting of 2 hr Pam2CSK4 and 4 hr zymosan treatments, and the 4 hr Pam2CSK4 treatment that was

FIGURE 4

Effect of 10 µg/ml Pam2CSK4 treatment on gene expression. *C. robusta* juveniles at stage 4 of metamorphosis, treated with Pam2CSK4 at the concentration of 10 µg/ml, show significant changes in gene expression, detected by RT-qPCR, of *TLR1*, *TLR2*, *CLEC4M*, *CLEC4F*, *IL17-1*, *IL17-3*, *TGFβ*, *MIF*, *mamA*, *C3* and *C3aR*, after 30 min, 2 hr and 4 hr. Truncated violin plots represent the distribution and the density of numerical data of gene expression reported as fold changes ( $2^{-\Delta\Delta C_t}$ ) of mRNA Relative Quantification (mRNA RQ) compared to the corresponding control samples of juveniles (not treated) and reported as dotted black line. The black lines in each violin plots indicate the median of data set ( $n = 6$ , biological replicates). Graphics shows also significant expression changes between two different treatment time points, indicated by black lines. Statistical methods: paired samples t-test, significance indicated by black asterisks; one-way ANOVA test, significance indicated by magenta asterisks. (\*p. value < 0.05, \*\*p. value < 0.01, \*\*\*p. value < 0.001 and \*\*\*\*p. value < 0.0001).

different from all other analyzed conditions (Figure 7A). This finding suggested that the stimulation of *C. robusta* juveniles with zymosan for 4 hr and Pam2CSK4 for 2 hr, and with Pam2CSK4 for 4 hr induced a significant dysregulation of protein abundance as a consequence of microbial treatment response. Even the heatmap representation enabled the visualization of *hierarchical clustering* where the aforementioned microbial stimuli displayed the greatest response of immune molecules (Figure 7B).

### 3.4 Interactome of immune molecules

A protein-protein interaction network, based on STRING output and then modified and merged in Cytoscape, has been constructed to include all the immune molecules whose gene expression has been investigated in this study (Figure 8). The interactome shows that both receptors TLR1 and TLR2 are connected with the three transcription factors NF-κB, IRF-like,

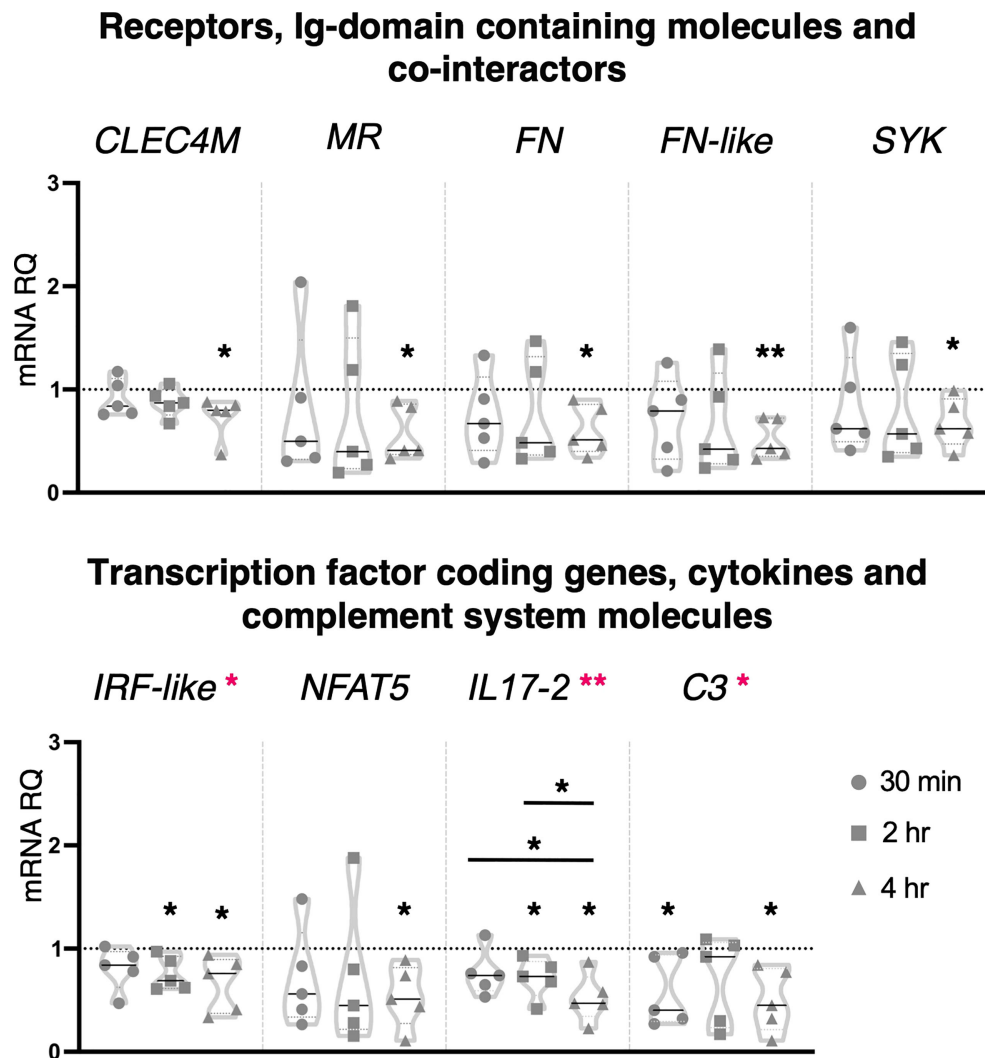

FIGURE 5

Effect of 10 µg/ml zymosan treatment on gene expression. *C. robusta* juveniles at stage 4 of metamorphosis, treated with zymosan at the concentration of 10 µg/ml, show significant changes in gene expression, detected by RT-qPCR, of *CLEC4M*, *MR*, *FN*, *FN-like*, *SYK*, *IRF-like*, *NFAT5*, *IL17-2* and *C3* after 30 min, 2 hr and 4 hr. Truncated violin plots represent the distribution and the density of numerical data of gene expression reported as fold changes ( $2^{-\Delta\Delta C_t}$ ) of mRNA Relative Quantification (mRNA RQ) compared to the corresponding control samples of juveniles (not treated) and reported as dotted black line. The black lines in each violin plots indicate the median of data set ( $n = 5$ , biological replicates). Graphics shows also significant expression changes between two different treatment time points, indicated by horizontal black lines. Statistical methods: paired samples t-test, significance indicated by black asterisks; one-way ANOVA test, significance indicated by magenta asterisks. (\* $p$ . value < 0.05, \*\* $p$ . value < 0.01).

NFAT5, and with the interleukin receptor IL17R. Notably, TLR2 is also connected with cofactor SYK, receptors MR and TYRO3, complement molecule C3, cytokine MIF and the molecule FAM136A. Although the lack of STRING annotations for IL17 gene products, possibly due to difficulties in investigating such proteins in *C. robusta*, the presence of connections with the receptor, IL17R, could provide clues about the interactions of these interleukins (Figure 8).

As reported for IL17s, lack of annotation information also affects other proteins, such as CLEC4M, CLEC4F, C3aR, mamaA and TNF $\alpha$ . However, we found connection of similar domains belonging to other proteins, as in the case of CLEC17A-like that reveals a connection with the protein SYK (Figure 8). The

interaction map shows that other main players of TLR signaling are connected, including MyD88, IRAK4, IKK, TAK1, p38, TRAF3 (13, 76, 77) and MAPKs. The genes coding for these proteins were not investigated in this work but should be future objects of similar studies. All the molecules included in the interaction map that were not investigated by transcriptional and proteomics analyses in this study, are listed in the Supplementary Table 4.

The enrichment analysis has been performed through STRING Enrichment app in Cytoscape to depict the Biological Processes, Molecular Functions and Cellular Components in which these molecules are involved. Some of the results are represented as Split Donut Chart (chosen option in the Network specific settings

## Ig-domain containing molecules and co-interactors

**FIGURE 6**

Effect of 100  $\mu\text{g/ml}$  zymosan treatment on gene expression. *C. robusta* juveniles at stage 4 of metamorphosis, treated with zymosan at the concentration of 100  $\mu\text{g/ml}$ , show significant changes in gene expression, detected by RT-qPCR, of *FAM187A*, *TYRO3*, *SYK*, *IL17-3*, *TGFβ*, *MIF* and *C3aR* after 30 min, 2 hr and 4 hr. Truncated violin plots represent the distribution and the density of numerical data of gene expression reported as fold changes ( $2^{-\Delta\Delta C_t}$ ) of mRNA Relative Quantification (mRNA RQ) compared to the corresponding control samples of juveniles (not treated) and reported as dotted black line. for STRING Enrichment table) in the protein-protein interaction network, using certain colors from the Enrichment color palette to underline specific outputs. To generate a map easier to understand, we have highlighted the biological processes that are more significant for this study. These comprise TLR signaling pathways (GO:0002224), innate immunity including inflammation and

response to external stimulus (GO:0050896, GO:0002682, GO:0050794, GO:0050778), regulation and response to cytokine production (GO:0034097, GO:0001817, GO:0001818, GO:0001819), CTL or CRD domains (SM00034), and leukocyte-mediated immunity and adhesion to endothelial cells (GO:0045785, GO:0050900, GO:0002443) (Figure 8).

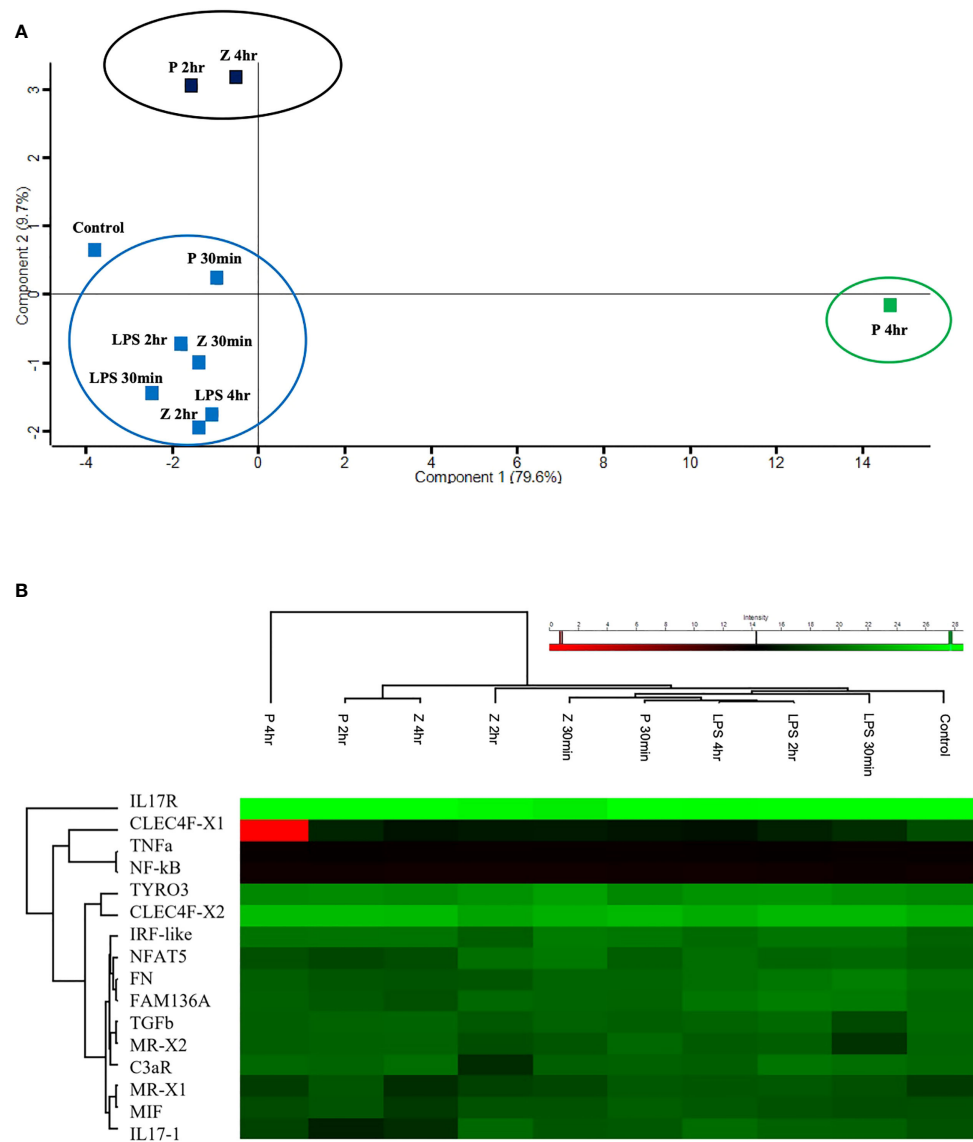

FIGURE 7

Targeted proteomic analysis of *C. robusta* juveniles expose to 10  $\mu$ g/ml LPS, 1  $\mu$ g/ml Pam2CSK4 and 100  $\mu$ g/ml zymosan. **(A)** PCA analysis, clustering overall protein level variations at each time point of animals treated with microbial stimuli, shows similar protein level among control, LPS treated-, 2 hr and 4 hr zymosan treated-, and 30 min Pam2CSK4 treated- samples. 4 hr zymosan treated- and 2 hr Pam2CSK4 treated- samples have protein levels that cluster together and differs from control samples; whereas 4 hr Pam2CSK4 treated samples have protein level that highly differ from all the other treatment conditions. **(B)** Heatmap shows both hierarchical clustering of the treatment conditions and protein levels of the analyzed immune molecules, extracted from *C. robusta* juveniles expose to 10  $\mu$ g/ml LPS, 1  $\mu$ g/ml Pam2CSK4 and 100  $\mu$ g/ml zymosan for 30 min, 2 hr and 4 hr and detected through LC-MRM/MS method. "P" and "Z" indicate Pam2CSK4 and zymosan treatments, respectively.

## 4 Discussion

The marine invertebrate *C. robusta* has recently become an excellent experimental organism for studying gut mucosal immunity, including processes mediating host mucosal-microbial associations (7, 8, 40, 78–82). In this work we used *Ciona* for investigating the inflammatory response activated by three PAMPs (LPS, Pam2CSK4 and zymosan) and for developing an invertebrate inflammatory model to use in research fields, from comparative immunology to translational biology and drug discovery.

### 4.1 Inflammation and the "patterns of pathogenesis" hypothesis

To interpret the inflammatory response in ascidian juveniles, it is important to recall some basic immunological concepts, such as the definition of inflammation and which factors/conditions activate it. The term "inflammation" defines the process triggered by innate immune cells when the homeostatic state is altered due to microbial infection or tissue injury (11–13). Marine organisms are continuously exposed to, and challenged by, a multitude of

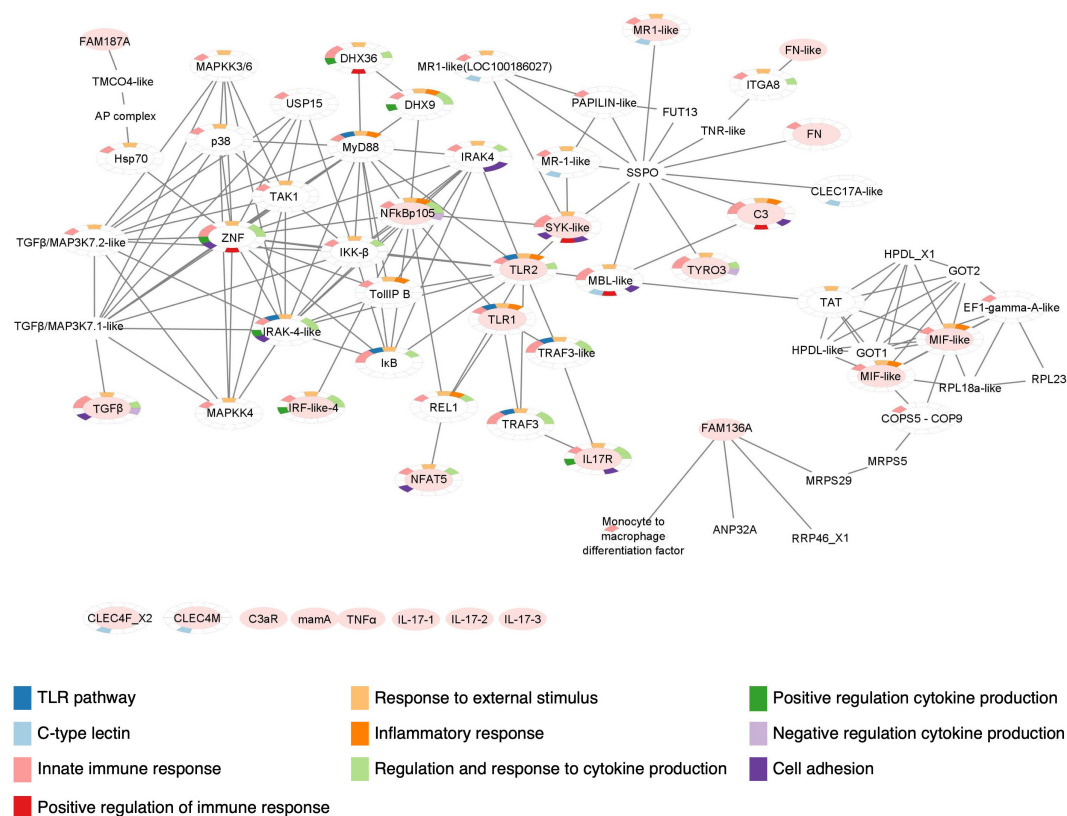

FIGURE 8

Protein-protein interaction network of *Ciona robusta* immune molecules. Protein-protein interaction map constructed with the STRING database and modified with Cytoscape, reveals the interaction between *C. robusta* immune molecules investigated through gene expression. Here, these molecules are indicated with an oval filled with light red color and those that are still not connected in the map are reported below. GO enrichment analysis is also indicated, highlighting in the color-legend some of the Biological Processes, related with immunological features, in which the molecules present in the map are involved.

microorganisms (e.g., bacteria, archaea, fungi, viruses, protozoans) inhabiting the surrounding environment (83). These microbes may be beneficial for the host by helping to shape the immune system and influencing developmental and physiological processes (84). The superorganism theory emphasizes how the concept of *self* and *non-self* has changed over time by incorporating host microbiota in the definition of *self* (84–86). During early development, the crosstalk between host and microbes is crucial to shape immune system maturation, that will allow to discriminate between *self* and *non-self*, and to establish a homeostatic state with beneficial components (86). These processes are mostly studied within the gastrointestinal tract where the symbiotic interactions mostly take place (87, 88). This equilibrium is broken when pathogenic microbes, or their components (as PAMPs), invade the host epithelial barrier and induce infection. Colonization and invasion by pathogens activate an inflammatory response that primarily involves PRRs (and their signaling pathways), the main players of the innate immune system (13, 68, 89, 90), with the aim to eliminate the infectious agents and to restore homeostasis (11, 12). PRRs have broad specificity and can recognize many PAMPs, which have a common structural motifs or patterns, thus representing a sort of pathogenicity markers (89, 91). In 2009, Vance and coauthors have proposed the “patterns of pathogenesis”, or POP hypothesis,

according to which the immune system recognizes pathogens not only by virtue of the presence of PAMPs but also by their pathogenic behaviors (92). These include growth upon host invasion, cytosolic invasion and disruption of the normal functions in the host cell cytoskeleton (92). On these grounds, a microbe can be considered pathogenic or nonpathogenic depending on the site of infection and on the immune state of the host. Hence, POP do not define a pathogen, rather a pathogenic behavior (86, 92). These new concepts may help to better understand the effect of PAMPs on the immune response, and thus on the onset of the inflammation, in different organisms and physiological states.

Based on the POP hypothesis, it is important to consider the physiological conditions at which the immune challenge is encountered. *Ciona* stage 4 juveniles are immunological naïve and probably they still do not have a stable microbiota. As they start interacting with the surrounding environment by seawater filtration, ascidian juveniles are here exposed to resuspended microbial components (8, 33, 40) and an immune response is observed if microbial components interact with the epithelial barrier. In line with *Ciona* LPS injection-based studies (14, 25, 93), the resuspension approach used herein may act differently in terms of immune activation patterns on older juveniles, like stage 8 (2<sup>nd</sup> ascidian stage) (33).

## 4.2 Stimulus-specific response of innate immunity in *C. robusta* juveniles

In this work we found that LPS, the most common inflammatory stimulus used in vertebrates (13, 68, 94, 95), ascidians and other marine invertebrates (96–99), does not significantly alter gene expression in the adopted experimental setup, that are naïve metamorphic stage 4 juveniles. In line with the transcriptional results, targeted proteomics data show that LPS treatment does not elicit protein level variations. The POP hypothesis may help to explain the lack of an immune response to LPS in *C. robusta* juveniles treated by LPS resuspension. Since these organisms inhabit a habitat rich in LPS-containing Gram-negative bacteria (78) that are continuously filtered by the organism and interact with host mucosal sites, ascidian juveniles may not recognize LPS as a PAMP and/or LPS may not cross the epithelial barrier of their gastrointestinal tract. Instead, the other two microbial components that we used as inflammatory stimuli, the bacterial Pam2CSK4 and the fungal zymosan, are apparently able to interact with the epithelial barrier and then be sensed by host immune surveillance as PAMPs, thus triggering an immune response.

Pam2CSK4, which is not commonly used as a microbial stimulus in vertebrates as well as marine organisms, has been shown to bind the heterodimer TLR1/TLR6 (38) and, in monocytes, to enhance expression and function of Fcγ, a receptor involved in phagocytosis and inflammatory cytokine production (100). In mice, *in vitro* and *in vivo* stimulation of macrophages induces the activation of MAP kinase and NF-κB pathways upon TLR2 binding (101). Also, Pam2CSK4 treatment of human platelets *in vitro* activates TLR2/TLR6 complex and initiates signaling events that stimulate increase of NF-κB protein level and interactions between platelets and endothelial cells (ECs). This event increases inflammatory cytokine production and reduces EC permeability (102). In our experiments, Pam2CSK4 was the most effective inflammatory stimulus in ascidian juveniles, featuring a concentration-dependent influence on both TLR and Dectin-1 pathways. Also, it is worth mentioning that 1 μg/ml is lower than the concentration of Pam2CSK4 used on human cell lines (10 μg/ml) (100, 102), suggesting that ascidian juveniles are highly responsive to this microbial stimulus. The immune response to Pam2CSK4 observed in *Ciona* juveniles at stage 4 include the modulation of the PRRs expression, TLRs and CLECs, and of the transcription factors just at the lower concentration tested. While expression data show that Pam2CSK4 exposure modulates both TLR and Dectin-1 pathways, the protein-protein interaction network could not confirm it, as long as CLEC4M and CLEC4F receptors are concerned.

The time of activation of each pathway depends on the amount of microbial component that interacts with host mucosal barrier. We may hypothesize a stronger, but vital, immune response induced by 10 μg/ml Pam2CSK4 that can penetrate mucus barrier (due to the higher amount of Pam2CSK4 molecules), interact with epithelial layer and affect gene expression of *Ciona* complement system components C3 and C3aR, that consequently

can activate cell adhesion, chemotaxis and phagocytosis processes in order to fight the invading microbial molecules (103, 104). Moreover, as in human platelets (102), Pam2CSK4 is able to alter transcriptional levels of cytokines (e.g., *IL17-3* and *TGFβ*) in *Ciona*. The activation of *TGFβ* following *IL17-3* modulation could be explained as a possible resolution of the inflammation induced by this microbial stimulus (105), in agreement with the observation that juveniles after 24 hr treatment are healthy (Figure 1B). That 10 μg/ml Pam2CSK4 can induce a strong inflammatory response is corroborated by the evidence of expression changes of other cytokine coding genes like *IL17-1* and *MIF*. In mammals, *MIF* has pro-inflammatory and immunoregulatory properties, and upregulates *TLR4* expression (106). In LPS-injected *Ciona* adults, a major role of *MIF* signaling pathway has been described in regulating *IL17s* and *TGFβ* expression (93). A similar effect is observed also here in the inflammatory state induced by Pam2CSK4 treatment, where a downregulation of *MIF* expression is concurrent with the upregulation of *IL17s* and *TGFβ* (after 2 and 4 hr treatment with 10 μg/ml Pam2CSK4).

Compared to Pam2CSK4 infection, zymosan modulates a smaller and diverse set of molecules and pathways in *Ciona* juveniles (Figure 9). As a cell wall preparation of yeast *S. cerevisiae*, zymosan is a mix of glucans, mannans, mannoproteins and chitin (107). These components are implicated in yeast recognition by innate immune cells, stimulating phagocytosis by macrophages (108) and cytokine production (i.e. *TNFα*, *IL1β*, *IL-10* and *TGFβ*) by monocytes, macrophages and dendritic cells (39, 109–111). In vertebrates, zymosan activates both TLR and Dectin-1 pathways (39). Moreover, a cell signaling cascade activated by the binding of β-glucan to Dectin-1 receptor can initiate both Syk-dependent and Syk-independent cascades (68, 112). In mammals, Syk is involved in cytokine transcription upon recruitment by Dectin-1 (113). However, Syk factor is involved in both PRR pathways (68, 114).

In *Ciona*, the protein-protein interaction network here generated highlights a potential connection among TLR2, SYK and MR molecules. Although activation of *Ciona* TLRs was induced by zymosan in a heterologous cellular system (17), here we did not observe changes in the expression of the two *TLR* genes investigated, but we found an alteration of *SYK* expression that does not permit us to rule out the hypothesis of an involvement of TLR pathway. The high zymosan concentration seems to induce a stronger inflammatory response that affect mainly gene transcription of cofactors involved in both TLR and Dectin-1 pathways, highlighting again an interconnection between the two pathways as observed in juveniles exposed to Pam2CSK4, although we did not observe a direct effect on the expression of the PRRs investigated. The finding that high concentration induces upregulation of the gene coding for *TYRO3*, a coreceptor involved in the resolution of inflammation, is in line with the upregulation of *TGFβ* observed after the increase of the expression of the two pro-inflammatory cytokines *IL17-3* and *MIF*. The role of *TYRO3* in the negative regulation of cytokine production has been depicted also by GO analysis of the biological process of *Ciona* protein-protein interaction map.

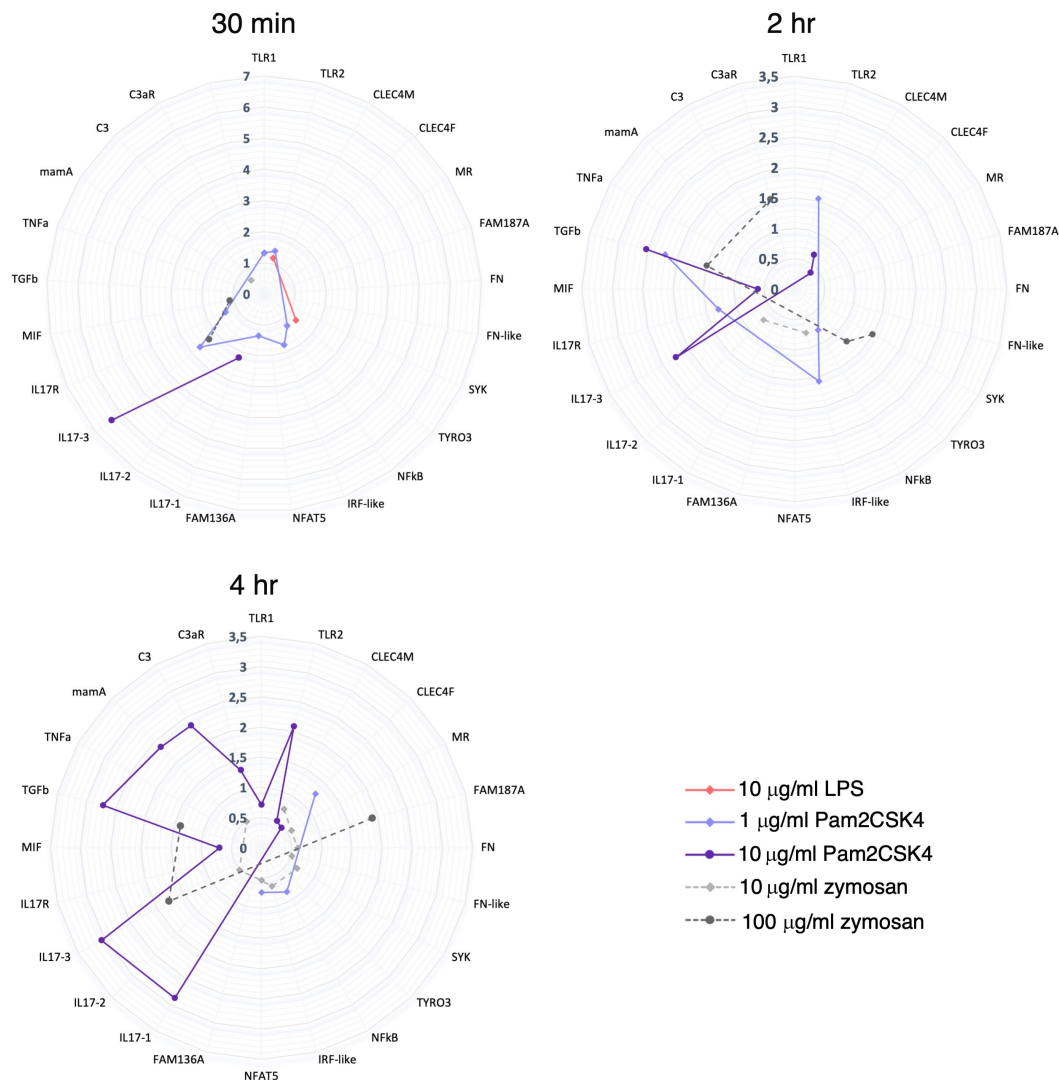

FIGURE 9

Summary of gene expression modulation at 30 min, 2 hr and 4 hr treatment. Radar plots show a summary of the genes that are (significantly) modulated at each time point treatment (30 min, 2 hr and 4 hr) by 10 µg/ml LPS, 1 and 10 µg/ml Pam2CSK4 and 10 and 100 µg/ml zymosan. 10 µg/ml LPS modulated just 2 genes at 30 min treatment. 1 µg/ml Pam2CSK4 modulate a higher number of genes at 30 min (7 genes) and 2 hr (4 genes) respect to 4 hr (3 genes) treatment. On the contrary, 10 µg/ml Pam2CSK4 has a major effect at late time points, 2 hr (5 genes) and 4 hr (11 genes), respect to the 30 min (2 genes) treatment. zymosan treatment, at both concentrations used, has an effect at the late time points, 2 hr (10 µg/ml, 2 genes; 100 µg/ml, 4 genes) and 4 hr (10 µg/ml, 9 genes; 100 µg/ml, 3 genes) respect to the 30 min treatment (10 µg/ml, 1 genes; 100 µg/ml, 2 genes).

In this study, we have observed an effect on the transcriptional levels of Ig-domain containing molecules (*FAM187A*, *FN* and *FN-like*) at both zymosan concentrations. Of note, the connection of these molecules with the Dectin-1 and TLR immune pathways was confirmed by the protein-protein interaction network. The immune role of these Ig-domain containing molecules represents an interesting starting point for future investigation in deciphering their role in the inflammatory response to fungal wall components. Moreover, the finding that *Ciona* *FAM187A* is phylogenetically related to *B. schlosseri* *TREML2* gene and that homology search analysis of *C. robusta* genome and proteome revealed the presence of genes coding for SYK (a downstream effector of the TREM2 pathway) and TYRO3, the latter binding in mammals TYRO

protein tyrosine kinase binding protein (TYROBP), also known as DNAX-activating protein of 12 kDa (DAP12) whose putative receptor is TREM2 (115), induce to hypothesize that the existence of the TREM2 signaling is an ancient trait whose origin dates back to the common chordate ancestor. It also prompts for a better understanding of the evolution of this pathway in immune function, and in particular in the response to molecules of fungal origin.

Finally, we report that zymosan affect the transcription of the *Ciona* complement system, suggesting the activation of a phagocytosis process. This has been observed also in mammals, where zymosan is phagocytosed by macrophages with or without opsonization and can activate alternative pathway of complement system (116–118).

### 4.3 Targeted proteomics supports transcriptional data and show time delay between mRNA and protein expression

Proteomic data reveal an effect on protein level modulation after 2 hr Pam2CSK4 and 4 hr zymosan treatments, and a major effect after 4 hr treatment with Pam2CSK4. Here, the targeted proteomic analysis performed on a small subset of proteins (encoded by the genes analyzed at the transcriptional level) and experimental conditions highlights that *i*) Pam2CSK4 has a major effect in the immune regulation respect to zymosan, and that *ii*) the immune response to these two PAMPs differs in the time of activation. As to the latter aspect, low concentration of Pam2CSK4 is sufficient to induce early expression changes (30 min and 2 hr) as suggested by the transcriptional modulation of a higher number of genes at these time points (Figure 9). This evidence corresponds to a significant effect in a general protein modulation at 2 hr and 4 hr of treatment (Figure 7). A similar delay is observed also in the case of zymosan, which induces a significant modulation of protein levels only at 4 hr, compared to the transcriptional response observed at 2 and 4 hr (Figures 7, 9). These analyses help draw a first consideration concerning the temporal delay observed in the synthesis of proteins with respect to mRNA expression. The initiation of protein translation occurs within minutes after mRNA export into the cytoplasm, thus justifying the lag between transcription and translation. However, we cannot exclude the involvement of mechanisms, such as translational control through RNA binding proteins, that tightly regulate the production of specific proteins, thereby helping to resolve the inflammatory response (119). In mouse dendritic cells treated with LPS, time delay between transcriptional induction and protein level increases was described, with rapid expression of immune response genes (5 hr post LPS treatment) followed by the best quantitative correlation of protein levels to the mRNA levels at 12 hr (120).

### 4.4 Concluding remarks

In our study, we have added a further tile in the use of the ascidian *C. robusta* as an experimental system in comparative immunology field. Specifically, we have *i*) developed *Ciona* as an *in vivo* inflammatory model for studying the activation of the immune response to selected microbial stimuli, showing an interconnection between different PRR pathways and indicating the upregulation of cytokines gene expression (*IL17-3* and *TGFβ*) as markers of inflammation, *ii*) constructed a first protein-protein interaction map that can help to predict potential molecular interactions, and *iii*) correlated changes observed at transcriptional and translational levels. This new marine invertebrate inflammatory model represents the starting point for future studies, that include either large-scale sequencing or other “-omics” approaches for better defining the cellular pathways or biological processes affected by microbial treatments, but also for investigating host response to PAMPs in different physiological conditions and at different stages

of maturation of the immune system. These advancements will contribute to our understanding of the crosstalk between host and microbiota and to test the POP hypothesis. As suggested by Newton and Dixit (2012), it is important to understand how, in a whole organism, innate immune cells exposed to multiple inflammatory stimuli can integrate signaling triggered by different receptors to identify critical components that can be targeted for therapeutic benefit in inflammatory disorder (13). In this framework we believe that, based on the results obtained in this study, this marine model organism could represent a proficient experimental system. Future studies can lead to the use of *C. robusta* experimental system in translation research or in any kind of approach (i.e., biotechnological or ecotoxicological) where the effect of molecules, either drugs or pollutants, on the activation and regulation of the innate immune system has to be investigated, like in large-scale screening of inflammatory modulators.

### Data availability statement

The original contributions presented in the study are included in the article/Supplementary Material. Further inquiries can be directed to the corresponding authors.

### Ethics statement

Ethical review and approval was not required for the study on animals in accordance with the local legislation and institutional requirements.

### Author contributions

AL, CP, RM, AS and PS contributed to conception and design of the study. AL and CP performed *in vivo* treatments and gene expression analysis. CP executed *in silico* analysis and wrote the corresponding sections of the manuscript. GP, AI and AA performed proteomic analysis, its data curation and wrote the corresponding sections of the manuscript. AL performed interpretation and curation of data and wrote the first full version of the manuscript. RM, AS and PS reviewed and edited the manuscript, and contributed to the discussion. AL and PS supervised the project. All authors contributed to the article and approved the submitted version.

### Funding

This work was supported by “Antitumor drugs and vaccines from the sea (ADViSE)” funded by the Regione Campania POR Campania FESR 2014/2020 Asse I. to AL, CP, PS and AS. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

## Acknowledgments

The authors thank Dr. Angelo Fontana for the meaningful discussion on the project and Dr. Larry J. Dishaw for helpful comments and valuable suggestions to improve the manuscript. The authors also wish to thank the Service of Marine Biological Resources (SZN) for providing technical assistance.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Development of Foxp3-expressing regulatory T-lymphocytes (Treg) in the thymus is controlled by signals delivered in T-cell precursors via the TCR, co-stimulatory receptors, and cytokine receptors. In absence of IL-2, IL-15 or their receptors, fewer Treg apparently develop in the thymus. However, it was recently shown that a substantial part of thymic Treg are cells that had recirculated from the periphery back to the thymus, troubling interpretation of these results. We therefore reassessed the involvement of IL-2 and IL-15 in the development of Treg, taking into account Treg-recirculation. At the age of three weeks, when in wt and IL-15-deficient (but not in IL-2-deficient) mice substantial amounts of recirculating Treg are present in the thymus, we found similarly reduced proportions of newly developed Treg in absence of IL-2 or IL-15, and in absence of both cytokines even less Treg developed. In neonates, when practically no recirculating Treg were found in the thymus, the absence of IL-2 led to substantially more reduced Treg-development than deficiency in IL-15. IL-2 but not IL-15 modulated the CD25, GITR, OX40, and CD73-phenotypes of the thymus-egress-competent and periphery-seeding Treg-population. Interestingly, IL-2 and IL-15 also modulated the TCR-repertoire expressed by developing Treg. Upon transfer into Treg-less *Foxp3<sup>sf</sup>* mice, newly developed Treg from IL-2- (and to a much lesser extent IL-15-) deficient mice suppressed immunopathology less efficiently than wt Treg. Taken together, our results firmly establish important non-redundant

quantitative and qualitative roles for IL-2 and, to a lesser extent, IL-15 in intrathymic Treg-development.

#### KEYWORDS

thymus, T lymphocyte, regulatory T cell (T reg), immunopathology, cytokines

## Introduction

Regulatory T lymphocytes expressing the forkhead/winged helix transcription factor Foxp3 (Treg) play a central role in the control of innate and adaptive immune responses (1). This is best illustrated by the observation that the absence of Treg in individuals and animals carrying mutations in the gene encoding Foxp3 leads to a rapidly lethal inflammatory autoimmune syndrome (2, 3). The thymus is the major organ where Treg development occurs, even if Treg can also differentiate from conventional T cells (Tconv) in the periphery (4). In the thymus, development of T cell precursors into either Treg or Tconv is governed by several parameters including signals transmitted by the TCR, co-stimulatory receptors, and cytokine receptors. Thus, it was shown that high affinity interactions between the precursor's TCR and MHC/peptide complexes expressed by thymic stromal cells are required for Treg development (5–7), which results in a Treg population enriched in autospecific cells (as compared to the Tconv-population) (8, 9). Several co-stimulatory molecules are selectively implicated in the development of Treg, including CD28, LFA-1, and CD27 (10–13). Finally, also cytokines appear important for Treg development (14).

Previous reports indicated roles for the cytokines IL-2 and IL-15 in the intrathymic development of Treg (15–23). Mice deficient in IL-2, IL-15, the IL-2-receptor  $\alpha$  chain CD25, the  $\beta$  chain shared between the receptors for IL-2 and IL-15 (CD122), or the “common” cytokine-receptor  $\gamma$  chain ( $\gamma_c$ , CD132), all have reduced proportions of Treg in the thymus. *In vitro*, these cytokines drive differentiation of CD25<sup>+</sup>Foxp3<sup>−</sup> Treg precursors to fully mature Treg (21). IL-2 was reported to prevent apoptotic cell death of autospecific Treg-precursors and appears to induce Foxp3-expression (22, 24). IL-15 was shown to be involved in the development of CD25<sup>−</sup>Foxp3<sup>+</sup> (but not CD25<sup>+</sup>Foxp3<sup>−</sup>) Treg precursors (19). Similar mechanisms apparently also operate in the human thymus (25, 26). However, in at least one report unaltered numbers of TCR-transgenic Treg developed in absence of IL-2 (27). Moreover, a large fraction of thymic Treg are cells that had recirculated from the periphery back to the thymus (28). Since IL-2 is required for peripheral survival of Treg (29), this recirculation-process would be expected to be strongly reduced in mice deficient in IL-2,

which would, at least in part, explain reduced Treg levels in mice carrying a null-mutation of the *Il2* locus (*Il2*<sup>0</sup>). Therefore, the roles of IL-2 and IL-15 in development of Treg remain unclear.

In the thymus, IL-2 and IL-15 appear to be produced by stromal cell-types involved in selection of the TCR-repertoire expressed by Treg, including dendritic cells (DC) and medullary epithelial cells (mTEC), as well as by T lymphocytes, but this issue remains controversial (19, 30–34). Through trans-presentation by their respective high affinity receptor  $\alpha$ -chains, IL-2 and IL-15 can have very local effects (19, 31, 35). Distinct thymic stromal cell-types have distinct phenotypes and thus apparently convey distinct signals to developing T cells (36). It is therefore conceivable that Treg developing in an IL-2 vs. IL-15-dependent manner are phenotypically and/or functionally distinct.

Mice deficient in IL-2 or its receptor develop a severe and rapidly lethal autoimmune pathology (37–40), which is at least in large part due to the requirement of this cytokine for peripheral survival and function of Treg (29). Also mice deficient in IL-15 or its trans-presenting receptor  $\alpha$ -chain develop symptoms of autoimmune-disease, though much later and much less severely. Defects in thymic negative selection of autospecific precursors of CD4<sup>+</sup> T cells may be involved in the development of these symptoms (32). It remains to be investigated if IL-2 and IL-15 modulate the selection of the TCR-repertoire expressed by Treg developing in the thymus and/or their functional potential, both of which may be involved in the development of symptoms of autoimmune-pathology.

We reassessed the involvement of IL-2 and IL-15 in Treg-development using mice in which we could distinguish newly developed from recirculating Treg. Thus, we firmly confirm that in IL-2- and, to a lesser extent, in IL-15-deficient mice substantially less Treg develop in the thymus. Our data also reveal that these cytokines drive development of thymus-egress and periphery-seeding competent Treg that are phenotypically distinct and that express partly distinct TCR-repertoires. Upon adoptive transfer into new-born Treg-deficient mice, thymus-exit-competent Treg that had developed in IL-2-deficient mice protected less efficiently from immune-pathology than Treg from wt or IL-15-deficient mice. Finally, we found that whereas the IL-2 involved in Treg development is non-redundantly produced by T cells and by DC, the IL-15

appears, at least in part, derived from DC. Based on our and previously reported data, we discuss mechanisms potentially involved in our finding that IL-2 and IL-15 apparently drive development of different Tregs.

## Materials and methods

### Mice

*Rag2-Gfp* mice (41, 42) were kindly provided by Drs. A. Liston and P. Fink; *Foxp3-Thy1<sup>a</sup>* mice (43) by Dr. A. Liston; *Il15<sup>o</sup>* mice (44) by Dr. Y. Tanriver; and CD4-Cre (45) and CD11c-Cre mice (46) by Dr. J.-C. Guéry. Kaa *Tcrb*-transgenic mice (7) and  $\beta$ 5t-Cre mice (47) were previously described. *Il2<sup>o</sup>* (B6.129P2-*Il2<sup>tm1Hor</sup>/J*) mice, *Tcr<sup>a</sup>* mice, and *Foxp3<sup>sf</sup>* mice were purchased from JAX laboratories, *Il15<sup>fl</sup>* (C57BL/6N-*Il15<sup>tm1c(EUCOMM)Hmg</sup>*/H) mice (48) from MRC Harwell Institute/Mary Lyon Centre, Oxfordshire, UK. *Il2<sup>fl</sup>* mice were generated as described in the [Supplementary Materials](#) and Methods section. All animals were on a C57BL/6 genetic background.

Rare sick animals, identified based on abnormally high proportions of CD4SP cells (>10% of total thymocytes), were excluded from analysis. *Il2<sup>fl</sup>* or *Il15<sup>fl</sup>* mice with germline recombination (as determined by PCR on tail biopsies) were excluded from analysis. Because mice were analysed before sexual maturity, we have not observed any differences between male and female mice, and all data are pools of both sexes.

### Generation of *Il2<sup>fllox</sup>* knock-in mice

The mouse *Il2* gene (ENSMUSG00000027720) was edited using a double-stranded homology-directed repair (HDR) template (targeting vector) with 3.5 and 3.3 kb-long 5' and 3' homology arms, respectively. It included a first loxP site located 173 bp upstream of exon 3, a second loxP site located 150 bp downstream of exon 3, and a frt-neo<sup>r</sup>-frt cassette. The final targeting vector was abutted to a cassette coding for the diphtheria toxin fragment A (49). JM8.F6 C57BL/6N ES cells (50) were electroporated with 20 mg of targeting vector. After selection in G418, ES cell clones were screened for proper homologous recombination by Southern blot and PCR analysis. A neomycin specific probe was used to ensure that adventitious non-homologous recombination events had not occurred in the selected ES clones. Mutant ES cells were injected into BalbC/N blastocysts. Following germline transmission, excision of the frt-neo<sup>r</sup>-frt cassette was achieved through genetic cross with transgenic mice expressing a FLP recombinase under the control of the actin promoter (51). A pair of primers (sense 5'-GCCACAGAATTGAAAGATCTTC-3' and

antisense 5'-TCTTGTGGAATTCTACTCCG-3') amplified a 418 bp-long band in the case of the wild-type *Il2* allele and a 500 bp-long band in the case of the mutant LoxP-flanked *Il2<sup>fllox</sup>* allele.

The resulting *Il2<sup>fllox</sup>* knock-in mice (official name B6-*Il2<sup>Tm1Ciphe</sup>* mice) have been established on a C57BL/6N background. When bred to mice that express tissue-specific Cre recombinase, the resulting offspring will have exon 3 removed in Cre-expressing cells, preventing them to produce IL-2. Germline-recombination was tested by tail DNA genotyping using 5'-AGATTGGAACA ATAGTCTGAACTTGTGCT-3', 5'-TTGCAGGTGATGGTA GGTGGAAAT-3', and 5'-TCAAATCCAGAACATGCCGCA-3' primers, allowing to detect 633bp, 755bp, and 245bp bands corresponding to wt, *Il2<sup>fllox</sup>* and recombined *Il2<sup>fllox</sup>* alleles, respectively. Requests for *Il2<sup>fllox</sup>* mice should be addressed to BM.

### Flow cytometry

Sample preparation and staining were performed using standard procedures. S1P1 staining was performed on ice as follows: after blocking non-specific labelling with mouse IgG (100µg/ml), cells were stained with unlabelled anti-S1P1 (50µg/ml, 90'), then stained with donkey-anti-rat IgG-biotin (1/100 diluted) in presence of mouse IgG (100 µg/ml, 30'), then blocked with rat anti-mouse FcγR antibody 2.4G2 (10 µg/ml, 15') and then incubated with streptavidin-PE (30'). Finally, staining with antibodies to indicated surface markers was performed in presence of 2.4G2 (10 µg/ml, 30'). Antibodies are listed in [Table S1A](#). For MOG (35–55)/I-A<sup>b</sup> tetramer (NIH tetramer facility) staining, after organ digestion, cells were washed, resuspended in RPMI medium, and incubated 15min on ice with an Fc block mix (2.4G2 at 10µg/ml; mouse and rat IgG at 25µg/ml) and 100nM dasatinib (Sigma-Aldrich). 6x10<sup>6</sup> cells were then incubated for 2 hours at 25°C with 1.5 µl tetramer in 100 µl RPMI medium. Labelled cells were acquired using an LSRII or a Fortessa flow cytometer (BD Biosciences, San Jose, CA) and the data analysed using FlowJo software (Tree Star, Ashland, OR). Doublets and dead cells were excluded from the analysis by using appropriate FSC/SSC gates.

### Generation of TCRseq libraries

CD4<sup>+</sup>CD8<sup>−</sup>Thy1.1<sup>+</sup>GFP<sup>+</sup> thymic Treg (105) were FACS sorted from individual three-week-old wt (n=4), *Il2<sup>o</sup>* (n=4), or *Il15<sup>o</sup>* (n=4) *Rag2-Gfp Foxp3-Thy1a Tcr<sup>a/o</sup>* Kaa TCRβ-transgenic B6 mice. RNA was extracted by Nucleospin RNA XS (Macherey-Nagel) according to the manufacturer's instructions, and was quality controlled (RIN > 8) using Agilent 2100 BioAnalyzer (Agilent technology). cDNA synthesis and library preparation were performed as previously described (52), and was adjusted to our

different conditions. In brief, cDNA synthesis was performed in a thermocycler using 1  $\mu$ M of reverse transcription oligonucleotides mixture corresponding to the TCR $\alpha$  constant region (Table S1B: TRAC\_RT\_1-9), a DNA-RNA hybrid template-switch oligonucleotide with 12 random nucleotides serving as unique molecular identifier (UMI) to tag individual mRNA molecules (Table S1B: UNIV5\_TSv2), 5 U/ $\mu$ L of SMART Scribe reverse transcriptase (Clontech), 2 U/ $\mu$ L of Recombinant RNase inhibitor (Clontech), 0.5 mM of each dNTP, Ultra low fast first strand buffer, 5mM of DTT, 1M of Betaine, 6 mM of MgCl<sub>2</sub>, incubated during 45' at 42°C, 10' at 70°C. After removal of hybrid oligonucleotide with 1U of Uracil-DNA Glycosylase (Biolabs) incubated during 40' at 37°C, the cDNA was purified using Agenecourt AMPure XP beads (Beckman Coulter) according to the manufacturer's instructions. The first PCR reaction was performed with 0.2  $\mu$ M of the oligonucleotides UNIV5\_P12v2 and TRAC3\_P1v2 (Table S1B), in the PCR-mix-solution (manufacturer's buffer with 1.5 mM MgSO<sub>4</sub>, 0.2 mM of each dNTP, and 0.02 U/ $\mu$ L Hot Start DNA Polymerase (Millipore)), with the parameters 2' at 95°C; 10 cycles of 20" at 95°C, 15" at 59°C, 45" at 70°C; and a final incubation of 3.5' at 70°C. The amplicons were then purified using Agenecourt AMPure XP beads. The second, semi-nested PCR was done using 2' at 95°C followed by 20 cycles of 20" at 95°C, 15" at 59°C, 45" at 70°C; and a final incubation of 3.5' at 70°C with UNIV5\_P12v2 and TRAC3\_P2v2 (Table S1B). In the third PCR a 3' index, P5 and P7 Illumina sequences, and read1, read2, and index sequencing sequences were added. It was performed using UNIV5\_P3v2 and TRAC3\_P3v2-index (Table S1B), as follows: 2' at 95°C, 1 cycle of 20" at 95°C, 15" at 59°C, 45" at 70°C; 5 cycles of 20" at 95°C, 15" at 75°C, 45" at 70°C; and a final incubation of 3.5' at 70°C. For the fourth amplification PCR, primers UNIV5\_P4v2 and UNIV3\_P4v2 (Table S1B) and thermocycler parameters 2' at 95°C, 5 cycles of 20" at 95°C, 15" at 60°C, 45" at 70°C; and a final incubation of 3.5' at 70°C, were used. The quality of each library was checked by using Agilent 2100 BioAnalyzer with a 640pb mean peak size. The samples were indexed and sequenced with 300pb paired end on Illumina MiSeq sequencer (Illumina).

## Processing of TCRseq data

Initially, reads were processed with the toolkit PRESTO (53) as follows. Using FilterSeq, reads with a quality higher than 20 were selected. Using MaskPrimers and PairSeq algorithms, the sequences corresponding to the *Tcr* $\alpha$  constant region (AGCAGGTTCTGGGTTCTGGA) and indicating location of the UMI (CTTGGGGG) were searched for and indexed to the head of the paired reads. Using BuildConsensus, consensus-sequences of the reads with the same UMI were constructed. Next, the forward and reverse reads were aligned to assemble the *Tcr* $\alpha$  sequences (AssemblePairs) and the UMI groups containing

at least two reads were selected. The sequenced fragments from each selected UMI were aligned to the *Tcr* $\alpha$  genomic region using the toolkit MiXCR (54), with the tools "align" and "assemble". The aligned fragments were exported as data tables "clonotype-tables" using the tool "exportClones". Using VDJtools (55) these clonotype-tables were then processed to graph with customized scripts in R. For all graphics described below, the "clonotypes" were selected according to their differences in the amino-acid sequences of the V segments, CDR3, and J segments. The Chao1 and Shannon-Wiener diversity-measures of the total *Tcr* $\alpha$  repertoires were calculated using the command CalcDiversityStats from VDJtools. The Morisita-Horn similarity measure of clonotypes represented at  $\geq 5$  UMIs in individual samples was determined using the R package "divo". "Public repertoires" were defined as the clonotypes present in all four replicates for each condition. Custom scripts used are available at [https://github.com/arielgalindoalbarra/IL2\\_IL15\\_Tregdependents](https://github.com/arielgalindoalbarra/IL2_IL15_Tregdependents).

## In vivo Treg-assays

New-born (*Foxp3<sup>sf</sup>Rag2<sup>o</sup> x Foxp3<sup>sf</sup>Tcr<sup>o</sup>*)F1 mice were i.v. injected into the temporal vein (56) with  $4 \times 10^5$  GFP<sup>+</sup>CD4<sup>+</sup>CD8<sup>-</sup>Thy1.1<sup>+</sup> Treg cells FACS-sorted from *Rag2-Gfp Foxp3-Thy1<sup>a</sup>* thymi. At three weeks of age, mice were euthanized, macroscopically analysed, and blood and organs collected for analysis.

## Determination of antibody titres and of autoantibodies

Serum antibody titres were determined using LegendPlex (BioLegend), according to the manufacturer's instructions. For tissue-immunoblots, organs/tissues were harvested from RAG2-deficient B6 mice, rinsed in PBS, and lysed with a Dounce homogenizer in RIPA buffer containing a protease inhibitor cocktail. The crude tissue extracts were centrifuged (10<sup>4</sup>G, 12 min) and the soluble protein extracts were aliquoted and stored at -80°C. The protein concentration was determined using standard Bradford Protein Assay. 35  $\mu$ g of total soluble protein-extract was run on SDS-PAGE, then blotted on a nitrocellulose membrane. Membranes were incubated in Odyssey blocking buffer (Li-Cor) for 30' at RT, then incubated o/n at 4°C with 800-fold-diluted sera from *scurfy* mice injected or not with Treg. Bound immunoglobulin was detected using IRDye<sup>®</sup> 800CW-labeled Goat-anti-Mouse IgG(1/2a/2b/3) (LiCor, 1h at RT). This antibody also reacts with IgK and IgA. Fluorescence was visualized and quantified using the Odyssey Classic Imaging System and ImageStudio software (Li-Cor).

## Data and materials availability

The TCRseq data reported in this study are available from Gene Expression Omnibus with accession code GSE153484. Mice are available upon request.

## Statistical analysis

The statistical significance of differences between groups of data was analysed using the two-tailed Mann-Whitney test or the Wilcoxon matched pairs signed rank test, as indicated.

## Results

### IL-2 and IL-15 play major non-redundant quantitative roles in intrathymic Treg development

We and others recently showed that a substantial proportion of the thymic Treg-pool is composed of cells that had recirculated from the periphery back to the thymus (28, 57–60). Thus, in young B6 adults, typically analysed in reports, 40 to 80% of thymic Treg are recirculating cells (28). This issue was not taken into account in the studies demonstrating reduced numbers of Treg in the thymus of mice deficient for IL-2, IL-15, or their receptors, and may dramatically impinge on interpretation of results. We therefore first reassessed the respective roles of IL-2 and IL-15 in intrathymic differentiation of Treg strictly focusing on newly developed Treg. To do so, we used mutant mice expressing green-fluorescent-protein (GFP) under control of the *Rag2* promoter and the allelic cell-surface marker *Thy1.1* under control of the *Foxp3* promoter (*Rag2-Gfp Foxp3-Thy1<sup>fl</sup>*). In the thymi of such mice, GFP<sup>+</sup>Thy1.1<sup>+</sup> and GFP<sup>−</sup>Thy1.1<sup>+</sup> cells are newly developed and recirculating/thymus-resident Treg, respectively (28). Initial analyses were conducted on thymi of three-week-old mice to avoid any potential confounding effects due to the thymic involution resulting from the immune-pathology developing later-on in IL-2-deficient mice. Importantly, Treg developing early in life play a central role in the prevention of lethal immunopathology (61), validating this choice. We compared IL-2- and/or IL-15-deficient (*Il2<sup>o</sup>* and *Il15<sup>o</sup>*, respectively), *Rag2-Gfp Foxp3-Thy1a* mice with *Il2<sup>wt/wt</sup>* or *Il15<sup>wt/wt</sup>* (“wt”) littermates. The absolute numbers of total thymocytes recovered from wt, *Il2<sup>o</sup>*, and *Il15<sup>o</sup>* mice were similar (Figure S1A). We determined the percentages of Foxp3<sup>+</sup> Treg among newly developed (GFP<sup>+</sup>) CD4<sup>+</sup>CD8<sup>−</sup>TCR<sup>high</sup> (CD4SP) thymocytes (Figures S1B, 1A) and thus observed that in the absence of IL-2 substantially (39 ± 14%) less Foxp3<sup>+</sup> Treg

developed in the thymus (Figure 1B). Remarkably, a similar analysis revealed that, as compared to wt littermates, also in *Il15<sup>o</sup>* mice substantially (25 ± 12%) less Treg newly developed. Mice lacking both IL-2 and IL-15 (*Il2<sup>o</sup>Il15<sup>o</sup>* mice) displayed the strongest decrease in newly developed Treg among CD4SP cells (reduction of 74 ± 11%). These effects were specific to Treg as the development of CD4SP Tconv was not much affected (Figure S1C). Further analysis of the absolute numbers of newly developed Treg in the thymi of wt and mutant mice confirmed that IL-2 and IL-15 play quantitatively non-redundant roles in intrathymic Treg development (Figure S1D).

Negative selection through induction of apoptosis can happen up to late stages of T cell development (62). To assess the involvement of IL-2 and IL-15 in Treg development up to late stages of this process, we therefore first quantified developing Treg expressing the sphingosine 1-phosphate receptor (S1P1), sufficient for thymic egress of T lymphocytes (63). As expected, a large proportion of Treg expressed S1P1 (Figure S1E). Analyses of thymocytes from wt and cytokine-mutant mice revealed substantially lower levels of Treg among newly developed GFP<sup>+</sup>S1P1<sup>+</sup>CD4<sup>+</sup>CD8<sup>−</sup> thymocytes in *Il2<sup>o</sup>* and in *Il15<sup>o</sup>* mice, as compared to wt littermates (reductions of 20 ± 11% and 31 ± 9%, respectively), with a defect that was most pronounced in *Il2<sup>o</sup>Il15<sup>o</sup>* mice (reduction of 70 ± 6%, Figure 1C). To assess involvement of IL-2 and IL-15 up to the very last stage of intrathymic Treg development, we also assessed the influx of recent thymic emigrants (RTE) Treg into the spleen of the various mutant mice. In *Rag2-Gfp* transgenic mice, these cells can be identified by their remaining low but detectable levels of GFP (Figure S1F). We found substantially less Foxp3<sup>+</sup> Treg among CD4<sup>+</sup> RTE in spleens of *Il2<sup>o</sup>*, *Il15<sup>o</sup>*, and *Il2<sup>o</sup>Il15<sup>o</sup>* mice than in wt controls (Figure 1D). Taken together, these data indicate that IL-2 and IL-15 non-redundantly and to similar extents control the thymic production of Treg that egress into the periphery.

These data suggest that IL-2 and IL-15 play quantitatively similar roles in Treg development in the thymus. However, we previously showed that Treg recirculating from the periphery inhibit *de novo* development of Treg (28). Since IL-2 plays a crucial role in the survival of Treg in the periphery (29), it would be expected that in *Il2<sup>o</sup>* mice much less recirculating Treg recirculate to the thymus. We indeed found much less recirculating Treg in thymi of *Il2<sup>o</sup>* and of *Il2<sup>o</sup>Il15<sup>o</sup>* (but not of *Il15<sup>o</sup>*) mice as compared to wt animals (reduction of 87 ± 5% and 90 ± 6%, respectively, Figures 1E, S1G). To assess the implication of IL-2 and IL-15 in Treg-development independently of their effect on recirculation of peripheral Treg to the thymus, we quantified Treg in four-day-old mice, in which the thymus only just started to produce Treg and inhibition of Treg development by recirculating cells is minimal (28). Given the consistent results we obtained when analysing Treg-proportions among

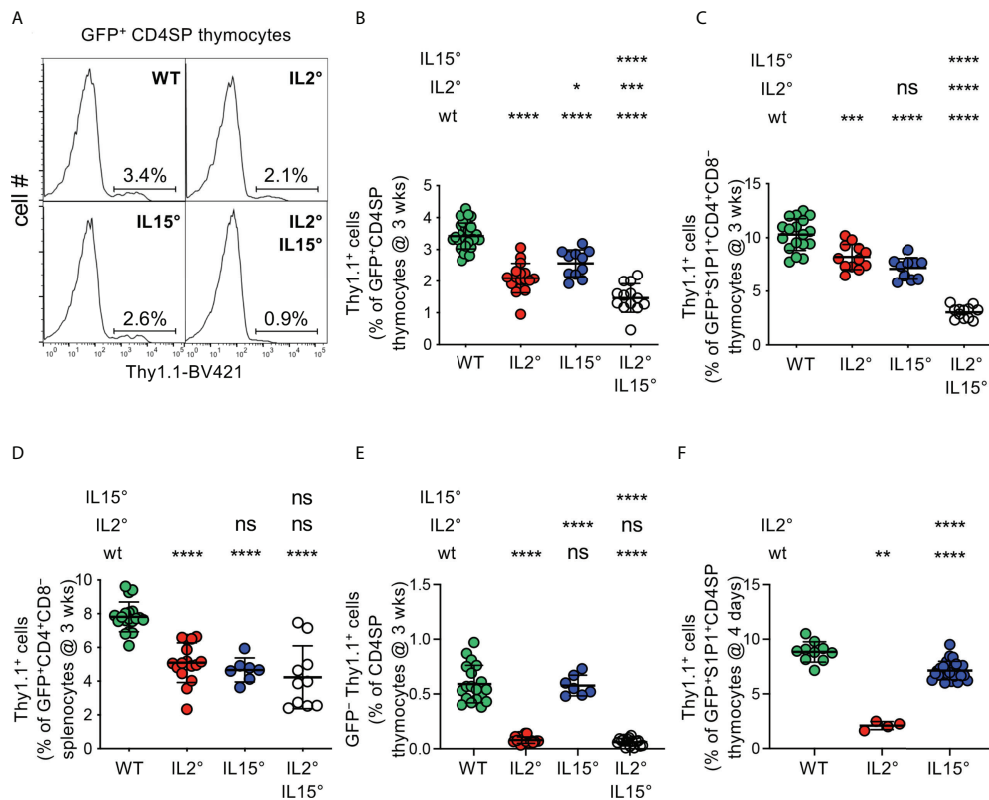

FIGURE 1

*IL-2 and IL-15 quantitatively regulate intrathymic Treg-development.* Thymocytes from (A–E) three-week-old or (F) four-day-old *Rag-Gfp* *Foxp3-<sup>Thy1</sup>* mutant, *Il2*<sup>°</sup> and/or *Il15*<sup>°</sup> mice, and *Il2*<sup>wt/wt</sup> and *Il15*<sup>wt/wt</sup> littermates (for absolute numbers see Figure S1A), were stained with fluorescent antibodies against indicated markers and analysed by flow cytometry. (A) Representative histograms of Thy1.1 expression (indicating *Foxp3*-expression) on GFP<sup>+</sup> (i.e. newly developed) CD4<sup>+</sup>CD8<sup>-</sup>TCR<sup>high</sup> (CD4SP) thymocytes (gated as in Figure S1B). Indicated gates were used for the quantification of Thy1.1<sup>+</sup> Treg. (B) Percentages of Treg among GFP<sup>+</sup> CD4SP thymocytes from indicated mice (n=31, 17, 11, and 13 wt, *Il2*<sup>°</sup>, *Il15*<sup>°</sup>, and *Il2*<sup>°</sup>/*Il15*<sup>°</sup> mice, respectively). (C) Percentages of Treg among GFP<sup>+</sup> S1P1<sup>+</sup> CD4<sup>+</sup>CD8<sup>-</sup> thymocytes (n=18, 12, 10, and 12 mice). For S1P1 gates see Figure S1E. (D) Percentages of Treg among RTE in the spleen (n=19, 16, 7, 10 mice). For RTE gates see Figure S1F. (E) Percentages of GFP<sup>+</sup> (recirculating) Treg among CD4SP thymocytes (n=19, 17, 7, and 15 mice). For recirculating Treg-gates see Figure S1G. (F) Percentages of Treg among GFP<sup>+</sup> S1P1<sup>+</sup> CD4SP thymocytes from four-day-old mice (n=10, 4, and 25 mice). For absolute numbers see Figure S1H. Dots indicate individual mice. ns, not significant; \**p* < 0.05; \*\**p* < 0.01; \*\*\**p* < 0.001; \*\*\*\**p* < 0.0001 (Mann-Whitney test). Bars indicate mean values ± SD.

GFP<sup>+</sup>CD4SP and among GFP<sup>+</sup> S1P1<sup>+</sup> CD4<sup>+</sup>CD8<sup>-</sup> thymocytes in three-week-old mice (cf. Figures 1B, C), and the observation that Treg only start to leave the thymus at four days of age and are therefore quite rare in the spleen (64), we limited these analyses to GFP<sup>+</sup> S1P1<sup>+</sup> CD4SP thymus egress-competent cells. We found substantially (76 ± 4%) less Treg among GFP<sup>+</sup> S1P1<sup>+</sup> CD4SP thymocytes in *Il2*<sup>°</sup> as compared to wt mice (Figure 1F). Absence of IL-15 led to a more modest (19 ± 10%) reduction in Treg-development. Analysis of absolute numbers of S1P1<sup>+</sup> Treg newly developed in four-day-old mice confirmed the major role for IL-2 in Treg-development (Figure S1H).

Taken together, our data unequivocally demonstrate that IL-15 and, more prominently, IL-2 play substantial and non-redundant quantitative roles in intrathymic Treg development, which directly impacts the influx of newly developed Treg into peripheral secondary lymphoid organs.

## IL-2 and IL-15 differentially drive development of thymus-exit-competent and periphery-seeding CD25<sup>+</sup> and CD25<sup>-</sup> Treg subsets.

The peripheral Treg pool consists of cells expressing or not the IL-2Rα-chain CD25, and CD25<sup>+</sup> vs. CD25<sup>-</sup> Treg have distinct properties (65). The observation that IL-2 and IL-15 quantitatively controlled intrathymic Treg development in a non-redundant manner led us therefore to assess expression of CD25 by newly developed Treg.

In *Il2*<sup>°</sup> and *Il2*<sup>°</sup>/*Il15*<sup>°</sup> mice, we found an almost complete lack of newly developed CD25<sup>high</sup> Treg, while a deficiency in IL-15 did not have a statistically significant impact on the development of this population (Figure S2A). Consistently, we found strongly reduced proportions of CD25<sup>high</sup> cells among newly developed

S1P1-expressing Treg in the thymus of *Il2*<sup>o</sup> and *Il2*<sup>o</sup>/*Il15*<sup>o</sup> mice (reductions of  $92 \pm 9\%$  and  $100 \pm 0\%$ , respectively) but unaltered percentages in *Il15*<sup>o</sup> mice (Figures 2A, B). Whereas *Il2*<sup>o</sup> and *Il2*<sup>o</sup>/*Il15*<sup>o</sup> mice also displayed a nearly complete ( $93 \pm 5\%$  and  $97 \pm 6\%$ , respectively) loss of CD25<sup>high</sup> RTE Treg in the spleen, in *Il15*<sup>o</sup> mice, we found a smaller decrease of this population ( $28 \pm 9\%$ , Figure 2C). We obtained similar results in thymi of four-day-old mice, indicating that they are due to absence of IL-2 or IL-15 and not to differences in accumulation of Treg that had recirculated back from the periphery (Figure 2D).

The total absence of newly-developed CD25<sup>high</sup> Treg in the thymus of *Il2*<sup>o</sup> mice suggested that development of CD25<sup>low</sup> Treg might be much less affected by the deficiency in IL-2. Importantly, in wt animals, thymus-exit-competent S1P1<sup>+</sup>CD25<sup>low</sup> Treg were even more abundant than S1P1<sup>+</sup>CD25<sup>high</sup> Treg (Figure S2B) and we obtained similar results for RTE in the spleen (Figure S2C). Since S1P1-expression is sufficient for thymus-egress (63), these observations indicate that Foxp3<sup>+</sup>CD25<sup>low</sup> CD4<sup>+</sup>CD8<sup>−</sup> thymocytes can leave the thymus and are not, or at least not exclusively, precursors for Foxp3<sup>+</sup>CD25<sup>high</sup> newly developing thymic Treg. As compared to three-week-old wt animals, newly developed CD25<sup>low</sup> Treg were abundant and even somewhat increased in the thymus of *Il2*<sup>o</sup> mice (Figure S2D). We also observed unaltered proportions of exit-competent (S1P1<sup>+</sup>) CD25<sup>low</sup> Treg among CD4<sup>+</sup>CD8<sup>−</sup> cells in the thymus and increased percentages among RTE in the spleen (Figures 2E, F). The increase in CD25<sup>low</sup> Treg in the thymus (Figure S2D) and among RTE (Figure 2F) in *Il2*<sup>o</sup> mice may be due to (an expected) failure in CD25-expression and/or absence of recirculating Treg. To study the implication of recirculating Treg, we analysed four-day-old *Il2*<sup>o</sup> mice. As compared to wt animals, we observed strongly ( $63 \pm 6\%$ ) reduced levels of newly developed CD25<sup>low</sup> Treg in the thymus of *Il2*<sup>o</sup> mice (Figure 2G). In absence of IL-15, we consistently found substantial reductions in the proportions of CD25<sup>low</sup> Treg among S1P1<sup>+</sup> Treg in the thymus (reduction of  $41 \pm 13\%$ ) and among RTE in the spleen (reduction of  $57 \pm 14\%$ ) of three-week-old mice, as well as in the thymi of four-day-old animals (reduction of  $24 \pm 11\%$ , Figures 2E, F, G, S2D). In thymi of *Il2*<sup>o</sup>/*Il15*<sup>o</sup> mice, we found even more reduced proportions of CD25<sup>low</sup> Treg among exit-competent S1P1<sup>+</sup> CD4<sup>+</sup>CD8<sup>−</sup> cells than in *Il15*<sup>o</sup> mice ( $54 \pm 8\%$  vs.  $41 \pm 13\%$ ), indicating non-redundant roles of IL-2 and IL-15 in the development of these cells (Figure 2E).

Combined, these data indicate that IL-2 is strictly required for the development of thymus-exit-competent CD25<sup>high</sup> Treg and, to a lesser extent, also drives that of CD25<sup>low</sup> Treg. By contrast, IL-15 modestly drives development of CD25<sup>high</sup> as well as of CD25<sup>low</sup> Treg. Since peripheral CD25<sup>−</sup> vs. CD25<sup>+</sup> Treg have distinct *in vivo* functional properties (65)(cf. discussion-section), these data suggest that IL-2 and IL-15 drive development of functionally distinct Treg.

## IL-2 but not IL-15 modulates expression of GITR, OX40 and CD73 by the newly developed Treg-population

We then searched for further phenotypic differences of Treg developing in wt, *Il2*<sup>o</sup> and *Il15*<sup>o</sup> mice. It was previously reported that GITR is expressed at distinct levels on newly developed Treg-subsets (66) and, among several markers studied, we found that OX40 and CD73 are expressed in a bi-modal manner in wt animals (Figure S3A). Moreover, in wt animals, GITR, OX40 and CD73 are expressed at higher levels on CD25<sup>high</sup> than on CD25<sup>low</sup> Treg (Figures S3A, B). As a consequence of reduced development of CD25<sup>high</sup> Treg in *Il2*<sup>o</sup> mice, average expression levels of these three markers were lower on Treg from *Il2*<sup>o</sup> than from wt and *Il15*<sup>o</sup> animals (Figures 2H, I, J, S3A). Expression of these cell-surface molecules by Treg developing in *Il15*<sup>o</sup> mice was similar to that on wt Treg (Figures 2H, I, J, S3A). Together with the data on CD25, these results indicate that IL-2 (but not IL-15) modulates the phenotype of the Treg population newly developing in the thymus and suggest that it may thus affect the functional potential of these cells.

## The TCR-repertoires expressed by Treg that developed in an IL-2 vs. IL-15-dependent manner are distinct

Very localized activity of the IL-2 vs. IL-15 produced by in part distinct thymic (stromal) cell-populations appears involved in Treg development (19, 31). Different thymic stromal cells present distinct self-peptides and thus select Treg with different specificities (33). We therefore hypothesized that the TCR-repertoires expressed by Treg that developed in an IL-2 vs. IL-15-dependent manner are dissimilar. To address this possibility, we bred *Rag2-Gfp Foxp3-Thy1<sup>a</sup>* mice expressing a transgene encoding the public TCRβ clonotype (“Kaa”) of the MOG-reactive CD4<sup>+</sup> T cell response during EAE in C57BL/6 mice (7, 67), and that were either *Il2*<sup>o</sup>, *Il15*<sup>o</sup>, or wt littermates. We analysed the development of MOG (35–55)/I-A<sup>b</sup>-specific Treg by flow-cytometry. A quite substantial proportion ( $26 \pm 6\%$ ) of newly developed Treg stained positive with the MOG (35–55)/I-A<sup>b</sup>-tetramer in Kaa TCRβ-transgenic mice, but not in non-transgenic littermates used as controls (Figures 3A, B). We did not observe a significant difference between wt and *Il2*<sup>o</sup> mice. By contrast, we found  $22 \pm 8\%$  less MOG (35–55)/I-A<sup>b</sup>-specific cells among newly developed Treg in *Il15*<sup>o</sup> than in wt mice. We conclude that IL-15 plays a significant quantitative role in the development of MOG (35–55)/I-A<sup>b</sup>-specific Treg while IL-2 appears not involved. These data therefore show different contributions of IL-2 and IL-15 to the development of Treg specific for a self-antigen.

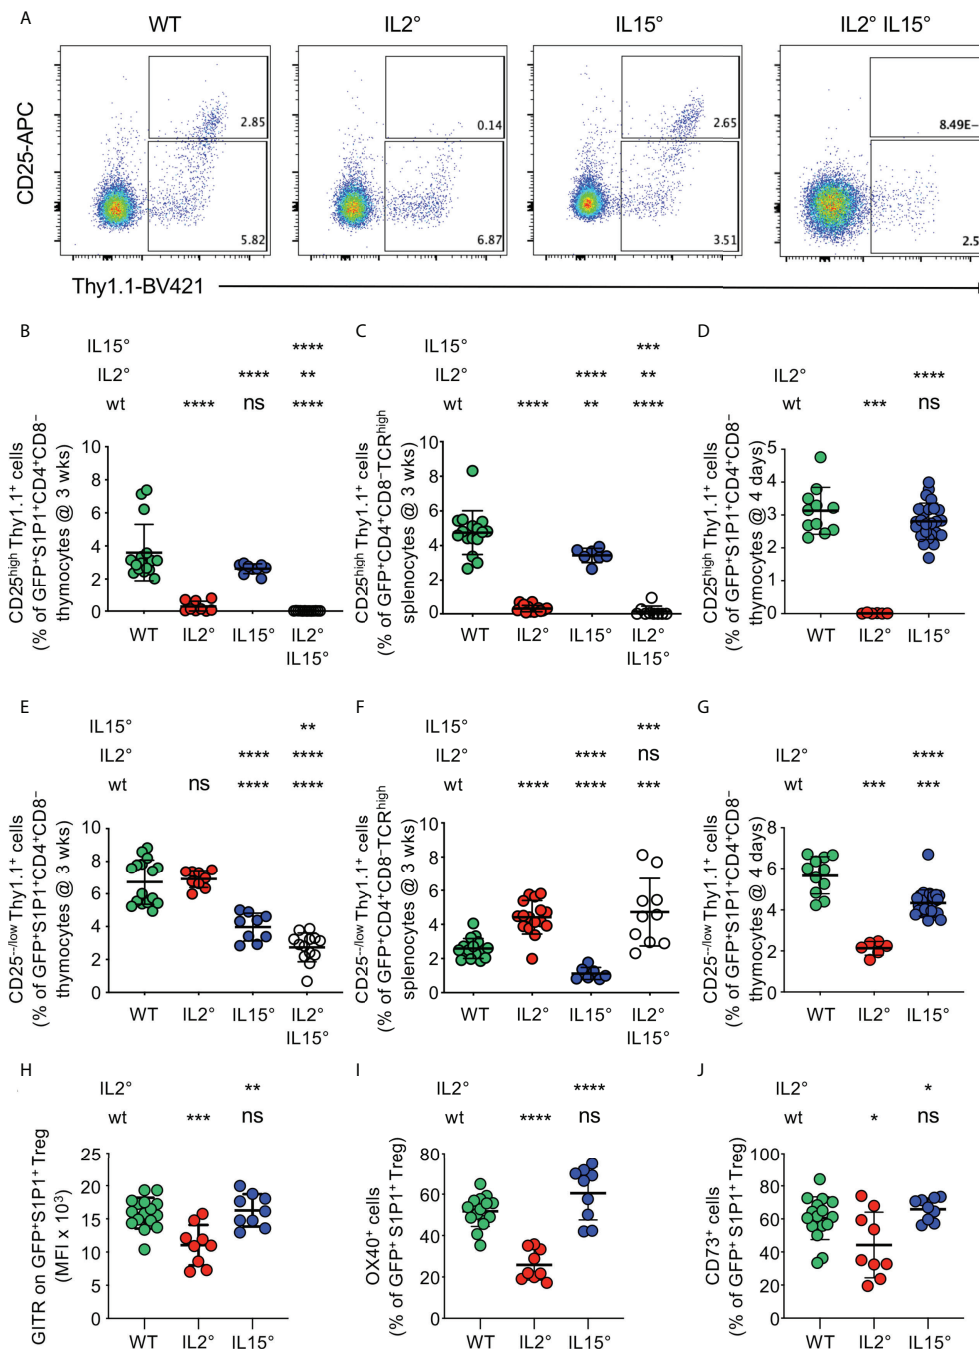

FIGURE 2

IL-2 and IL-15 differentially affect the phenotype of thymus exit-competent Treg. Thymocytes from *Rag-Gfp Foxp3-Thy1<sup>a</sup>* mutant, *IL2<sup>o</sup>* and/or *IL15<sup>o</sup>* mice, and *IL2<sup>wt/wt</sup>* and *IL15<sup>wt/wt</sup>* littermates, were stained with fluorescent antibodies against the indicated markers and analysed by flow cytometry. (A) Foxp3 vs. CD25 expression by GFP<sup>+</sup> S1P1<sup>+</sup> CD4<sup>+</sup>CD8<sup>-</sup> thymocytes from indicated mice. Depicted gates were used to quantify CD25<sup>low</sup> and CD25<sup>high</sup> Treg. Percentages of (B–D) CD25<sup>high</sup> or (E–G) CD25<sup>low</sup> Treg among (B, E) newly developed S1P1<sup>+</sup> CD4<sup>+</sup>CD8<sup>-</sup> thymocytes (n=16, 9, 9, and 13 wt, *IL2<sup>o</sup>*, *IL15<sup>o</sup>*, and *IL2<sup>o</sup>IL15<sup>o</sup>* mice, respectively) and (C, F) CD4<sup>+</sup>CD8<sup>-</sup>TCR<sup>high</sup> RTE in the spleen from three-week-old animals (n=16, 16, 7, and 9 mice), and (D, G) newly developed S1P1<sup>+</sup> CD4<sup>+</sup>CD8<sup>-</sup> thymocytes from four-day-old animals (n=11, 6, and 25 mice). (H–J) Expression (MFI, % positive cells, as indicated) of indicated markers on GFP<sup>+</sup>S1P1<sup>+</sup>CD69<sup>low</sup> CD4<sup>+</sup>CD8<sup>-</sup> thymic Treg from indicated mice (n=16, 9, and 9 mice). Typical cytometry-plots are shown in Figure S3. ns, not significant; \**p* < 0.05; \*\**p* < 0.01; \*\*\**p* < 0.001; \*\*\*\**p* < 0.0001 (Mann-Whitney test). Dots indicate individual mice. Bars indicate mean values ± SD.

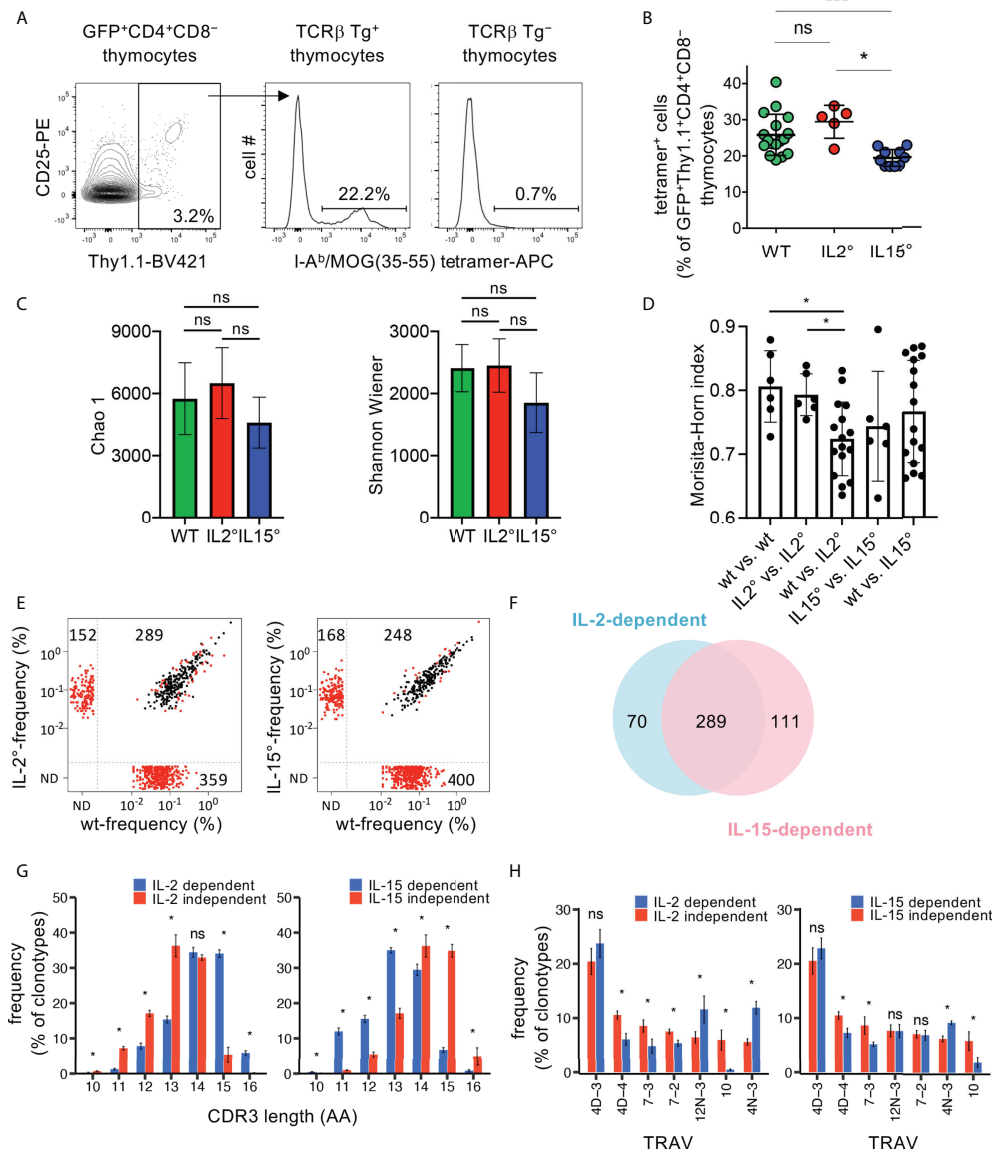

FIGURE 3

The TCR-repertoires expressed by Treg developing in an IL-2 and IL-15-dependent manner are partially distinct. (A) Flow-cytometry analysis of thymocytes from Rag2-Gfp Foxp3-Thy1<sup>a</sup> Kaa TCRβ-transgenic (Tg<sup>+</sup>) or non-transgenic (Tg<sup>-</sup>) mice. Representative I-A<sup>b</sup>/MOG (35-55) tetramer-stainings on GFP<sup>+</sup>Thy1.1<sup>+</sup>CD4<sup>+</sup>CD8<sup>-</sup> wt thymocytes (i.e. newly developed Treg) are shown. (B) Proportions of tetramer positive cells, gated as in (A), in wt (n=17), IL2<sup>o</sup> (n=5), and IL15<sup>o</sup> (n=10) mice. Dots indicate individual mice. (C–H) TCRseq analysis of TCRα repertoires expressed by newly developed Treg from Rag2-Gfp Foxp3-Thy1<sup>a</sup> Tcrα<sup>+/o</sup> Kaa TCRβ-transgenic wt (n=4), IL2<sup>o</sup> (n=4) and IL15<sup>o</sup> (n=4) mice. (C) Chao1 and Shannon-Wiener diversity of the TCR-repertoires. (D) Morisita-Horn similarity between all individual samples from indicated mice based on clonotypes with ≥ 5 UMIs. Dots indicate distinct comparisons. (E) Frequency of individual clonotypes in the public TCR-repertoire expressed by Treg from indicated mice. Red dots indicate clonotypes differentially expressed between wt and mutant Treg (p < 0.05, LIMMA test). N.D., not detected. (F) Venn diagram showing the partial overlap of the IL-2 and the IL-15-dependent public clonotypes (i.e. those within the lower-right quadrants in (E)). (G) Distribution of the TCRα CDR3-lengths of IL-2 and the IL-15-dependent and -independent public clonotypes (lower-right vs. upper-right quadrants in E, respectively). CDR3α start with conserved Cys and Ala and end with conserved Phe. See Figure S4 for average CDR3-lengths. (H) TRAV- (TCR Vα-segment-) usage in the indicated groups of TCRα clonotypes. Only TRAV represented at ≥ 5% in at least one indicated group are shown. See Figures S5, S6 for clonotypes found only in cytokine-deficient mice (upper-left quadrants in (E)). ns, not significant; \*p < 0.05; \*\*\*p < 0.001 (Mann-Whitney test). Bars indicate mean values ± SD.

To investigate the involvement of IL-2 and IL-15 in shaping of the TCR-repertoire expressed by Treg in a broader manner, we next bred *Rag2-Gfp Foxp3-Thy1<sup>a</sup>* mice that expressed the K $\alpha$  transgenic TCR $\beta$  chain, that were heterozygous for a *Tcra* null-mutation, and that were either *Il2<sup>o</sup>*, *Il15<sup>o</sup>*, or homozygous wt littermates. We analysed the TCR $\alpha$ -repertoires expressed by newly developed Treg in the thymus by high-throughput sequencing of *Tcra* mRNAs. The diversity (*i.e.* the number of clonotypes and their abundance) of the TCR $\alpha$ -repertoires expressed by Treg populations developing in wt and mutant animals appeared similar (Figure 3C). Comparison of the TCR-repertoires demonstrated higher similarities within the four wt and the four *Il2<sup>o</sup>* replicates than between the four wt and the four *Il2<sup>o</sup>* samples (Figure 3D). We did not find significant differences in the similarities between TCR-repertoires expressed by Treg from wt and *Il15<sup>o</sup>* mice (Figure 3D). These results demonstrate that IL-2 modulates the TCR-repertoire expressed by newly developing Treg. We argued that the principal differences in the TCR-repertoires are the ones reproducibly found in all mice of the same genotype, *i.e.*, the “public” TCR-repertoires. *Il2<sup>o</sup>* mice lacked a substantial part (55%) of the public TCR clonotypes we detected in wt animals (Figure 3E). Wt animals lacked 34% of the public TCRs we detected in *Il2<sup>o</sup>* mice. Similarly, *Il15<sup>o</sup>* mice lacked 62% of the public TCRs detected in wt animals and wt animals lacked 40% of the public TCRs we detected in *Il15<sup>o</sup>* mice. A quite large proportion (61%) of the public clonotypes lacking in *Il2<sup>o</sup>* or *Il15<sup>o</sup>* mice were identical, and therefore appeared to require both IL-2 and IL-15 for their development (Figure 3F). However, 19% of the IL-2-dependent and 28% of the IL-15-dependent public clonotypes appeared to specifically require these respective cytokines. Given that these data concern TCR-clonotypes reproducibly found in wt vs. *Il2<sup>o</sup>* vs. *Il15<sup>o</sup>* mice, they strongly suggest that IL-2 and IL-15 contribute to shaping of the TCR-repertoire expressed by newly developing Treg.

To obtain insight into the potentially different characteristics of the public TCR $\alpha$ -clonotypes expressed by Treg developing in an IL-2- vs. IL-15-dependent manner, we next compared their CDR3-lengths and TCR-V $\alpha$  (TRAV)-usages. The distributions of the CDR3-lengths were different between IL-2- or IL-15-dependent vs. independent clonotypes (Figure 3G). The average CDR3-sizes of the public IL-2-dependent clonotypes were somewhat greater than those of the IL-2-independent ones (Figure S4). By contrast, the average CDR3-sizes of the public IL-15-dependent clonotypes were slightly smaller than those of the IL-15-independent ones (Figure S4). Also clonotypes found in *Il2<sup>o</sup>* or *Il15<sup>o</sup>* but not in wt animals had average CDR3-size and distribution of CDR3-lengths that were significantly different from those that were cytokine-independent (Figures S5A, B). Analysis of the TRAV-usage revealed substantial differences between cytokine-dependent vs. -independent clonotypes (Figure 3H). Also clonotypes found in *Il2<sup>o</sup>* or *Il15<sup>o</sup>* but not in wt animals had TRAV-usages that were significantly different

from those that were cytokine-independent (Figure S6). Taken together, these observations indicate distinct characteristics of the public TCR $\alpha$ -chain clonotypes expressed by Treg requiring the presence or absence of IL-2 or IL-15 for their development. The reproducibility of these results in the four biological replicates for each genotype also indicated that the differences were not due to sampling randomness.

## Origins of the IL-2 and IL-15 involved in Treg development

Probably through trans-presentation by their respective high affinity receptor  $\alpha$ -chains, IL-2 and IL-15 can have very local effects (19, 31, 35, 68). Distinct thymic stromal cell-types have distinct phenotypes and thus apparently convey distinct signals to developing T cells (36). Our observation that IL-2 and IL-15 appear to qualitatively modulate Treg development may therefore be due to interactions of developing Treg with distinct stromal cell-types. We therefore sought to identify the stromal cells producing the IL-2 and IL-15 involved in Treg-development, which remains a controversial issue (19, 30–34).

In the thymus, TEC and DC appear to produce IL-15 and to express the IL-15R $\alpha$  chain required for its trans-presentation to responder cells (19, 32, 34). To assess the role of the IL-15 produced by these cells in Treg-development, we generated *Rag2-Gfp Foxp3-Thy1<sup>a</sup>* mice in which one *Il15* allele was constitutively and the other conditionally invalidated (*Il15<sup>o/fl</sup>*). The Cre recombinase required for invalidation of the *Il15* locus was expressed under control of the promoter of the gene encoding the thymus-proteasome  $\beta$ 5t-subunit, active during early stages of TEC-development (47), or that of the gene encoding CD11c, expressed by DC (46). The development of iNKT cells depends on IL-15 (69). *Il15*-invalidation in TEC or in DC led to reduced accumulation of CD4SP iNKT cells (Figures S7A, B). Interestingly, *Il15*-invalidation in TEC, but not in DC, led to reduced accumulation of CD4<sup>+</sup>CD8<sup>−</sup> iNKT cells (Figure S7C). These data thus confirm conditional invalidation of the *Il15* locus in the mice. They also suggest distinct origins of the IL-15 involved in the development of CD4<sup>−</sup>CD8<sup>−</sup> vs. CD4<sup>+</sup>CD8<sup>−</sup> iNKT cells. Unexpectedly, in  $\beta$ 5t-Cre *Il15<sup>o/fl</sup>* mice we found unaltered proportions of Treg among CD4SP thymocytes (Figure 4A). By contrast, in CD11c-Cre *Il15<sup>o/fl</sup>* mice (16.8  $\pm$  24.3%) less Treg developed than in control mice not expressing the Cre-recombinase (Figure 4A). These results suggest that the IL-15 involved in Treg-development is, at least in part, produced by DC.

Whereas T cells appear to produce IL-2 involved in Treg-development in the thymus, the role of dendritic cells (DC) remains controversial (19, 30, 31, 68). As compared to in their Cre<sup>−</sup> littermates, in CD4-Cre<sup>+</sup> *Il2<sup>o/fl</sup>* mice, in which T cells do not produce IL-2, we found very strongly (90.7  $\pm$  4.4%) reduced proportions of CD25<sup>high</sup> Treg among CD4SP (Figure 4B), which

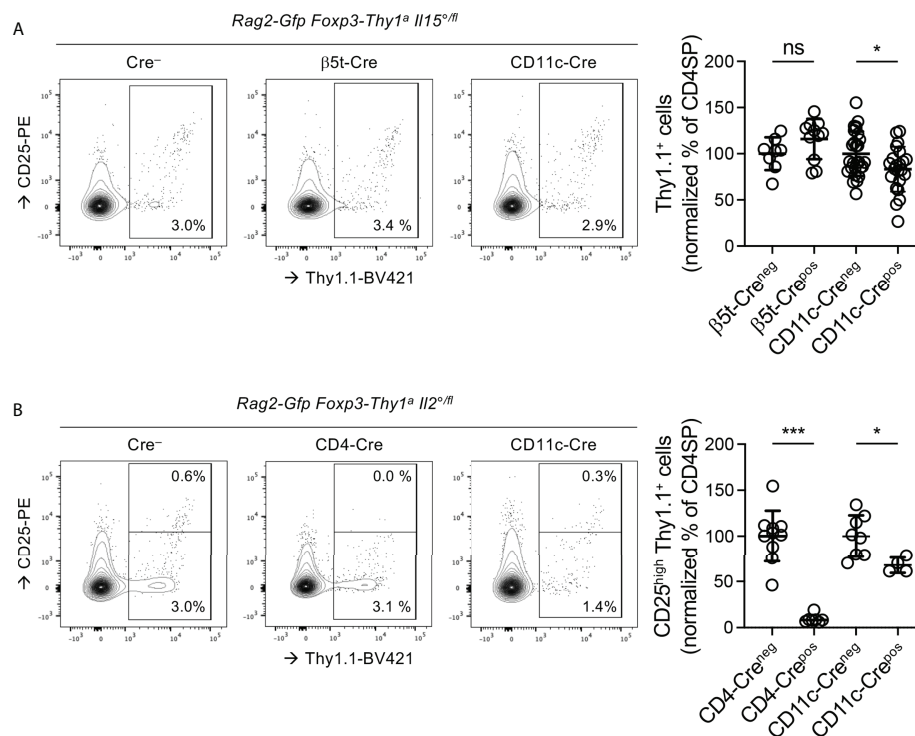

FIGURE 4

The IL15 involved in Treg development is produced by DC and the IL-2 by T cells and, to a lesser extent, by DC. Thymocytes from three-week-old Rag2-Gfp Foxp3-Thy1<sup>a</sup> mutant, (A) Il15<sup>o/fl</sup> or (B) Il2<sup>o/fl</sup> mice, expressing or not the indicated Cre-transgenes, were stained with fluorescent antibodies against indicated markers and analysed by flow cytometry. (left hand panels) Representative histograms of Thy1.1 (indicating Foxp3-expression) vs. CD25 expression on GFP<sup>+</sup> (i.e. newly developed) CD4SP thymocytes (gated as in Figure S1B). Indicated gates were used for the quantification of (CD25<sup>low</sup> and CD25<sup>high</sup>) Thy1.1<sup>+</sup> Treg among CD4SP cells. (right-hand panels) Quantification of (A) total or (B) CD25<sup>high</sup> Treg among GFP<sup>+</sup> CD4SP thymocytes. Dots indicate individual mice and values were normalized to the average percentages found in Foxp3<sup>Thy1a/wt</sup> male and Foxp3<sup>Thy1a/wt</sup> female, Cre<sup>-</sup> littermates ((A) n=8 β5t-Cre<sup>-</sup>, 11 β5t-Cre<sup>+</sup>, 27 CD11c-Cre<sup>-</sup>, 22 CD11c-Cre<sup>+</sup>, (B) 10 CD4-Cre<sup>-</sup>, 7 CD4-Cre<sup>+</sup>, 8CD11c-Cre<sup>-</sup>, and 4 CD11c-Cre<sup>+</sup> mice). ns, not significant; \*p < 0.05; \*\*\*p < 0.001 (Mann-Whitney test). Dots indicate individual mice. Bars indicate mean values ± SD.

confirms that T-cell-derived IL-2 plays an important role in Treg development. Also in CD11c-Cre Il2<sup>o/fl</sup> mice, in which DC do not produce IL-2, we found substantially (32.2 ± 8.4%) less newly developed CD25<sup>high</sup> Treg (Figure 4B). These data therefore indicate that IL-2 derived from both T and dendritic cells is involved in Treg-development.

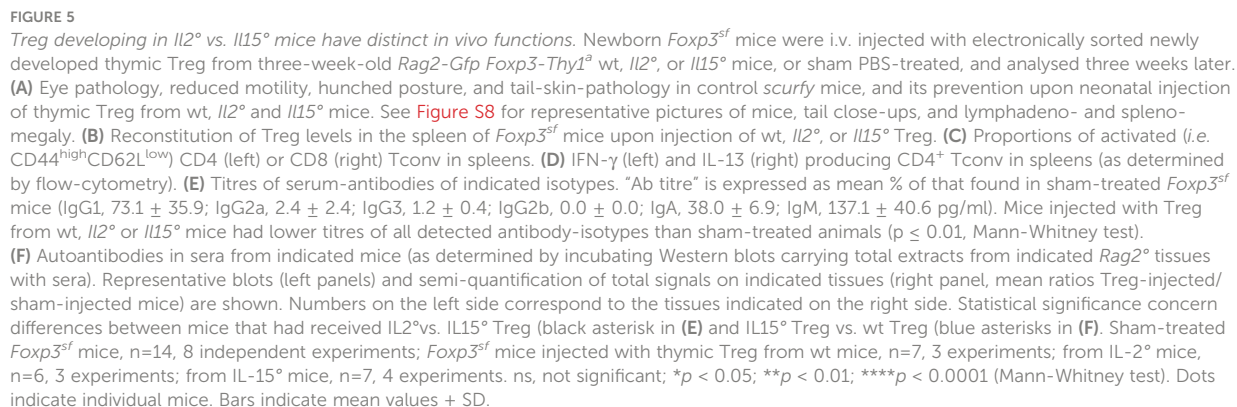

## Thymic Treg from Il2<sup>o</sup> and from Il15<sup>o</sup> mice have distinct capacities to prevent autoimmune pathology

Our results reveal that Treg developing in the thymi of wt, Il2<sup>o</sup> and Il15<sup>o</sup> mice are phenotypically distinct and that the TCR-repertoires they express are, in part, distinct. We therefore postulated that Treg from wt vs. Il2<sup>o</sup> vs. Il15<sup>o</sup> mice may have distinct capacities to prevent autoimmune pathology. To assess this possibility, we adoptively transferred (by i.v. injection) identical numbers of GFP<sup>+</sup>Thy1.1<sup>+</sup>CD4<sup>+</sup>CD8<sup>-</sup> thymic Treg,

sorted from three-week-old wt, Il2<sup>o</sup> or Il15<sup>o</sup>, Rag2-Gfp Foxp3-Thy1<sup>a</sup> mice, into new-born Treg-deficient Foxp3<sup>sf</sup> mice and analysed lymphocyte-activation, cytokine production, (auto) antibody production, and development of immunopathology three weeks later (Figures 5, S8, S9).

Injection of newly developed wt thymic Treg into Foxp3<sup>sf</sup> mice reconstituted Treg levels to 11 ± 3% and strongly reduced the symptoms of the autoimmune-pathology observed in sham-treated animals: Skin desquamation; hunched posture; spleno- and lymphadeno-megaly (Figures 5A, B, S8); activation of splenic CD4<sup>+</sup> or CD8<sup>+</sup> T cells (as indicated by a CD44<sup>high</sup>CD62L<sup>low</sup> phenotype, Figure 5C); IFN-γ or IL-13 production by splenic CD4<sup>+</sup> Tconv (Figure 5D); circulation of serum antibodies of IgM, IgG1, IgG2a, IgG3, and IgA isotypes (Figure 5E); production of circulating antibodies directed against a large array of autoantigens of all organs assessed (Figure 5F), and infiltration by mononuclear cells in pancreas, skin, and lungs, and associated bronchial- and ear-thickening (Figure S9). Newly developed Treg isolated from Il2<sup>o</sup> and from Il15<sup>o</sup> thymi

populated *Foxp3<sup>sf</sup>* mice as efficiently as wt Treg (Figure 5B). They also inhibited development of all of the symptoms, but to distinct degrees (Figures 5A, C–F, S8, S9). Thus, despite similar reconstitution, Treg from *Il2<sup>o</sup>* (but not those from *Il15<sup>o</sup>*) mice inhibited to a lesser extent than Treg from wt mice IFN- $\gamma$  and IL-13 production by CD4 Tconv (Figure 5D). Treg from *Il2<sup>o</sup>* mice prevented the production of IgG1 less efficiently than Treg from *Il15<sup>o</sup>* mice (Figure 5E). Quantification of the tissue blots hybridized with sera from *Foxp3<sup>sf</sup>* mice injected with Treg from wt, *Il2<sup>o</sup>* or *Il15<sup>o</sup>* thymi, revealed some minor differences, but all three quite efficiently prevented autoantibody production (Figure 5F). We did not find significant differences between the capacity of wt vs. *Il2<sup>o</sup>* or *Il15<sup>o</sup>* Treg to prevent infiltration by mononuclear cells in the pancreas, lungs and ears, or thickening of bronchus-walls or ears (Figure S9). Combined, these data indicate that the intrathymic availability of IL-2 is essential for the development of a fully functional Treg population. The role of IL-15 in this process appears more subtle.

## Discussion

In the study reported here, we investigated the quantitative and qualitative roles of IL-2 and IL-15 in the intrathymic generation of Treg. By focusing on newly developed Treg and by analysing young mice in which Treg development is practically uninhibited by recirculating Treg, we showed important quantitative roles of IL-2 and, to a lesser extent, IL-15 in Treg development. IL-2 and IL-15 drive the development of phenotypically distinct, thymus egress-competent and periphery-seeding Treg, and differently modulate the selection of the TCR-repertoire they express. Treg developing in absence of IL-2 (but not of IL-15) had clearly detectable, though limited, defects in the control of immune-responses *in vivo*. Combined, these data consolidate and extend the suspected quantitative roles of IL-2 and IL-15 in Treg-development in the thymus and indicate that these cytokines also play important qualitative roles in this process.

The thymi of mice deficient in the IL-2R $\alpha$  or  $\beta$  chains, in IL-2 or in IL-15 contain fewer Treg (16, 18–20, 23, 70–72). However, among thymic Treg, the proportion of cells that had recirculated from the periphery back to the thymus is very large in wt animals (28). These data therefore mostly failed to formally demonstrate a role for IL-2 and IL-15 in Treg development in the thymus. In our experimental mouse model, we could unambiguously identify newly developed Treg and found substantially less Treg in IL-2- or IL-15-deficient mice than in wt animals. Using an elegant experimental model in which T cell-development was induced through induction of ZAP70-expression, Marshall et al. showed that antibody-mediated IL-2-blockade reduced *de novo* development of Treg, which is consistent with our results (19). It now therefore appears clearly demonstrated that IL-2 affects Treg development in the thymus.

IL-2 and IL-15 do not only act on Treg-precursors but also on other cell-types (potentially) involved in Treg development in the thymus. Thus, IL-2 plays a crucial role in the peripheral survival of Treg (29). Accordingly, in IL-2-deficient mice we found almost no Treg that had recirculated from the periphery back to the thymus. Therefore, as compared to wt mice, in IL-2-deficient mice at least two parameters affecting Treg development had changed: availability of IL-2 and inhibition of Treg development by recirculating cells. To exclude this additional parameter, we analysed Treg-development four days after birth, *i.e.* when Treg just start to develop and leave the thymus, the proportion of recirculating Treg in the thymus is very low, and inhibition of Treg-development is minimal (28). We observed that in absence of IL-2 substantially fewer Treg developed than in absence of IL-15. Our results thus confirm and substantially extend an earlier report in which *de novo* development of Treg was studied through induction of ZAP70-expression (19). Interestingly, we observed a more robust decrease in Treg development in neonate than in three-week-old IL-2-deficient mice (as compared to wt animals). A hypothesis that may explain this observation is that in three-week-old (but not in neonatal) mice, Treg development is substantially inhibited by recirculating Treg, in part through limitation of the availability of IL-2 (28). Further limiting IL-2-availability through genetic invalidation of the gene encoding it would affect Treg development to a lesser extent in three-week-old mice than in neonates, in which recirculating-Treg-mediated inhibition of Treg-development is minimal. Assessing this hypothesis will require the generation of mice in which recirculating Treg do not accumulate in the thymus.

Also iNKT cells may, through production of IL-4, modulate Treg development (73). As we here confirmed, in absence of IL-15 substantially fewer iNKT cells accumulated in the thymus. It remains therefore unclear if the reduced Treg development we observed in IL-15-deficient mice was due to a direct effect on Treg precursors or on iNKT cells. It will be important to study the effect of IL-15 deficiency on Treg development in iNKT cell-deficient mice.

Deficiency in IL-2 or IL-15 will also affect differentiation and/or maintenance of other cell-types known to modulate T cell-development in the thymus but not addressed in this study. For example, IL-15 drives differentiation of CD8 memory T cells (74), reported to reduce negative selection of autospecific thymocytes through deletion of DC and mTEC (75). Therefore, it will now be important to address the involvement of other cell types potentially involved in the effects of IL-2 or IL-15-deficiency on Treg-development.

Combined, our results thus firmly demonstrate quantitatively substantial and non-redundant (direct and/or indirect) roles for IL-2 and, to a lesser extent, IL-15 in Treg development. We also found that the phenotypes of Treg developing in an IL-2- vs. IL-15-dependent manner are distinct: Whereas IL-2 is strictly required for the differentiation of CD25<sup>+</sup> Treg, IL-15 only plays a modest role,

and both cytokines play a role in the development of CD25<sup>low</sup> Treg. Our results thus support and extend an earlier report on the distinct roles of IL-2 and IL-15 in Treg development in the thymus (19). Importantly, in wt animals, the egress-competent phenotype of the thymic CD25<sup>low</sup> Treg subset and the fact that these cells were abundant among RTE in the spleen indicated that it is not (only) a precursor population for newly developing thymic CD25<sup>+</sup> Treg. The fact that we readily detected these cells among splenic RTE in IL-2-deficient mice supports our conclusion that they do not need to go through a CD25<sup>+</sup> phase to leave the thymus. Komatsu and colleagues showed that CD25<sup>+</sup> Treg have a less stable phenotype than CD25<sup>+</sup> Treg and can lose Foxp3-expression and suppressive activity and acquire the capacity to produce IL-2, IFN- $\gamma$ , IL-4, and IL-17 (65). *In vitro*, IL-2 did not stabilize Foxp3-expression of peripheral CD25<sup>+</sup> Treg, suggesting that availabilities of IL-2 in the thymus and in the periphery play non redundant roles. Our results indicate that this apparently functionally distinct CD25<sup>low</sup> Treg subset may, in part, have a thymic origin. Also the GITR, OX-40 and CD73-phenotypes were differentially affected by absence of IL-2 or IL-15. Together, these observations suggest that IL-2 and IL-15 may drive the development of potentially *in vivo* functionally distinct Treg populations.

We hypothesized that IL-2 and IL-15 may drive development of Treg expressing distinct TCR-repertoires. We found that 73% of the public clonotypes observed in wt animals required IL-2 and/or IL-15 for their development. Much smaller proportions of the public clonotypes observed in wt animals specifically required IL-2 (but not IL-15: 11%) or IL-15 (but not IL-2: 17%) for their development. Since distinct proportions of CD25<sup>+</sup> vs. CD25<sup>+</sup> Treg developed in *Il2*<sup>o</sup> vs. wt and *Il15*<sup>o</sup> mice, these observations are consistent with a recent report showing that intrathymic CD25<sup>+</sup> vs. CD25<sup>+</sup> Treg express distinct TCR-repertoires (73). The non-redundant roles of IL-2 and IL-15 may in part be due to an anti-apoptotic action of IL-2 (22) which would allow selection of Treg expressing TCRs recognizing self-MHC/peptide complexes with higher affinity. The public TCR $\alpha$ -repertoires expressed by Treg developing in an IL-2- or IL-15-dependent manner have different CDR3-lengths and TRAV-usages than those developing in wt mice. Previous work demonstrated shortening of the CDR3 $\alpha$  during T cell selection in the thymus (76). Interestingly, whereas IL-2-dependent TCR $\alpha$ -chains have larger CDR3 than IL-2-independent ones, IL-15-dependent TCR $\alpha$ -chains have smaller CDR3 than IL-15-independent ones. Distinct CDR3 $\alpha$ -lengths and TRAV usages will probably have an influence on the affinities of the TCRs for peptide/MHC complexes expressed by thymic stromal cells, suggesting an interplay between cytokine-receptors and TCR in driving development of the Treg-subsets. Whatever the precise origin(s) of these distinct characteristics may be, they also indicate that the differences in the TCR $\alpha$ -repertoires we observed are not due to sampling biases.

Intriguingly, some Treg newly developing in the thymus of *Il2*<sup>o</sup> and of *Il15*<sup>o</sup> mice expressed public TCR-clonotypes that we did not observe in wt animals. Limiting our analysis to clonotypes found in all four replicates will constrain but not entirely avoid effects of sampling randomness, which may therefore be involved in the detection of clonotypes exclusively in *Il2*<sup>o</sup> or *Il15*<sup>o</sup> mice. However, small but statistically significant differences in CDR3 lengths and in TRAV-usage of public TCR $\alpha$  found in IL-2<sup>o</sup> but not in wt mice vs. those found in wt and in IL-2<sup>o</sup> mice, indicated that a substantial proportion of Treg-clonotypes found exclusively in *Il2*<sup>o</sup> or *Il15*<sup>o</sup> mice is not due to sampling biases. By contrast, they suggested that these cells have distinct peptide/MHC-recognition characteristics. A hypothesis that may explain this observation is, again, that signals through the TCR synergize with signals through the receptors for IL-2 and IL-15 to drive differentiation and selection of Treg-precursors, *i.e.* the cytokines would act as a rheostat.

The differences in the TCR-repertoires expressed by Treg from wt, IL-2- and IL-15-deficient mice may be due to the distinct sources of these cytokines in the thymus. Consistent with this postulate, it was previously shown that Treg specific for a model-antigen expressed by mTEC do not require IL-2 for their development (27). IL-2-deficient DC supported the development of Treg less efficiently than wt cells in an *in vitro* thymus culture system (31). In agreement with this observation, we observed a reduction in newly developed Treg in mice with an IL-2-ablation targeted to DC. DC trans-presenting IL-2 *via* the IL-2R $\alpha$ -chain (35) may favour differentiation of Treg specific for ligands expressed by these stromal cells, as previously suggested (68). Whereas *Il2*-mRNA was detected in thymic DC (31), using an experimental model in which *Il2*-expression-history could be traced, Hemmers et al. did not find evidence for expression in CD90<sup>+</sup>CD19<sup>+</sup>Ly6G<sup>+</sup>Ly6C<sup>+</sup> thymic DC (30). Together with our data, these observations suggest that IL-2 expression by thymic DC is limited to a particular subset of these cells (or of other CD11c<sup>+</sup> cells). It appears rather unlikely that the reduced Treg development we observed in the *Il2*<sup>o/fl</sup> CD11c-Cre mice was due to the previously reported very limited activity of the transgenic construct in T lymphocyte-progenitors (<10%) (46). In mice with an IL-15-ablation targeted to DC, we found fewer newly developed Treg, and DC are known to express the IL-15R $\alpha$ -chain (32). It remains to be investigated if the IL-2R $\alpha$  and IL-15R $\alpha$  chains are expressed by the same or by distinct DC and if these DC present the same repertoires of MHC/peptide complexes. Similarly, mTEC trans-presenting IL-15 *via* the IL-15R $\alpha$ -chain (32) might favour differentiation of Treg specific for ligands expressed by these stromal cells. It was indeed shown that radioresistant stromal cells play an important role in the trans-presentation of the IL-15 involved in Treg development (19). However, even if the abridged development of iNKT cells indicated reduced IL-15 production in our mice with an IL-

IL-15-deficiency targeted to TEC, we have not observed a reduction in Treg development. The precise stromal origin of the IL-15 involved in Treg development will therefore require further work.

A non-mutually exclusive explanation for the differences in TCR-repertoires expressed by Treg that had newly developed in wt, IL-2 or IL-15-deficient mice is related to the indirect effects of these cytokines. Both recirculating Treg and iNKT cells (and potentially other cell-types), the presence of which is controlled by IL-2 and IL-15, respectively, appear to modulate Treg development in the thymus (28, 73), and these cells may also modulate selection of the TCR-repertoire, e.g. through affecting thymic stromal cells. This postulate would imply that also the TCR-repertoires of Tconv developing in wt vs. *Il2*<sup>o</sup> vs. *Il15*<sup>o</sup> animals may be distinct. Assessing these possibilities will require analysis of TCR-repertoires expressed by Tconv and Treg developing in mice lacking recirculating Treg and iNKT cells.

Treg developing in absence of IL-2 or IL-15 therefore are phenotypically (and potentially functionally) distinct and they express distinct TCR-repertoires. We postulated that these cells may have distinct capacities to prevent (auto)immune pathology *in vivo*. To distinguish between roles of these cytokines in the thymus vs. the periphery, we transferred Treg isolated from wt, IL-2 or IL-15-deficient thymi into *Foxp3*<sup>sf</sup> hosts sufficient for these cytokines. Upon transfer into neonatal *scurfy* mice, newly developed thymic Treg from wt, *Il2*<sup>o</sup> and *Il15*<sup>o</sup> mice equally efficiently reconstituted adoptive hosts. However, Treg from *Il2*<sup>o</sup> mice less efficiently inhibited IFN- $\gamma$  and IL-13 production by CD4 T cells than wt Treg. Consistent with their reduced capacity to inhibit production of a Th2 cytokine, they also less efficiently inhibited serum accumulation of antibodies of IgG1 isotype. Treg from *Il15*<sup>o</sup> mice had a slightly lower capacity to inhibit formation of autoantibodies to pancreas and liver. However, we did not observe differences in the capacity of newly developed Treg from wt, *Il2*<sup>o</sup> and *Il15*<sup>o</sup> mice to prevent the histological lesions observed in Treg-deficient *Foxp3*<sup>sf</sup> mice. These results indicate that IL-2 (and potentially IL-15) plays a qualitative role in the intrathymic development of Treg, a role that cannot be replaced by exposure to this cytokine in the periphery. Redundancy of Treg with distinct antigen-specificities and/or effector-functions may explain the modest nature of the defects we observed.

The reduced capacity of Treg from IL-2-deficient mice to inhibit cytokine production by T cells *in vivo* may be due to reduced stability of Foxp3-expression by these cells. In absence of IL-2, Treg precursors failed to express high levels of CD25. Komatsu and colleagues showed that CD25<sup>+</sup> Treg have a less stable phenotype than CD25<sup>+</sup> Treg: They lose Foxp3-expression and suppressive activity, and even acquire the capacity to produce IL-2, IFN- $\gamma$ , IL-4, and IL-17 (65). Taken together, these two observations suggest that, upon adoptive transfer

into IL-2-sufficient mice, (CD25<sup>+</sup>) thymic Treg from IL-2-deficient animals will have a defect in Foxp3-stability and therefore less efficiently control T cell-activation *in vivo*. Extensive (e.g. single cell transcriptomic) analysis of the similarity of the CD25<sup>+</sup>/low Treg-populations developing in wt vs. *Il2*<sup>o</sup> mice and assessment of their differentiation upon adoptive transfer into neonatal *Foxp3*<sup>sf</sup> mice will be required to assess this hypothesis. Whatever the precise explanation, IL-2 in the thymus and in the periphery apparently has non redundant effects on Treg.

The data presented here indicate a more complex role for the cytokines IL-2 and IL-15 in the intrathymic differentiation of Treg than what was previously appreciated. Rather than only quantitatively controlling this process, they appear to also qualitatively do so by guiding differentiation of Treg with distinct phenotypes and by shaping the antigen-specificity of Treg emerging from the thymus. This is, in part, potentially due to the distinct thymic cell-types known to produce and to respond to these cytokines. The relative availability of IL-2 and IL-15 in the thymus may change during life. We thus previously described that Treg recirculating from the periphery back to the thymus limit the availability of IL-2 and thus inhibit Treg development (28). It will now be important to assess how such potential changes influence the development of Treg in the thymus and the immunosuppressive activity of these cells in the periphery.

## Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: <https://www.ncbi.nlm.nih.gov/geo/>, GSE153484.

## Ethics statement

The animal study was reviewed and approved by the "Comité d'éthique en matière d'expérimentation animale" UMS006 CEEA-122, authorisation number APAFIS#4151-201602171 0481496.v6.

## Author contributions

Conceptualization: CA, OJ, PR, and JM. Methodology: SC and CD. Formal analysis: AG-A and BH. Investigation: CA, NM, SC, CD, HM, JS. Mouse model: BM. Resources: SF, GH, SZ. Writing – original draft: CA, JM; Writing – review & editing: OJ. Supervision: JM. All authors contributed to the article and approved the submitted version.

## Funding

This work was financially supported by the Fondation pour la Recherche Médicale (to JvM, DEQ20160334920); the IdEx Toulouse (to PR); the Région Midi Pyrénées (to JvM, 15/06/12.05); the Agence Nationale pour la Recherche (to PR, ANR-16-CE15-0015-01), and the Fondation ARC pour la Recherche sur le Cancer (to CA, DOC20180507201). *Il2fl* knock-in mice were generated by the Centre d'Immunophénomique (CIPHE, Marseille, France). CIPHE is supported by the Investissement d'Avenir program PHENOMIN (French National Infrastructure for Mouse Phenogenomics; ANR-10-INBS-07 to BM).

## Acknowledgements

We thank Adrian Liston and Pamela Fink for providing *Rag-Gfp Foxp3-Thy1<sup>a</sup>* mutant mice and the NIH tetramer-facility for MOG (35–55)/I-A<sup>b</sup> tetramers. We are very grateful to the following persons for excellent technical assistance: Fatima L'Faqihi, Valérie Duplan-Eche, Anne-Laure Iscache, Lidia De la Fuente, Paul Menu of the INFINITY Cytometry platform; Adrien Castinel of the GeT-PlaGE Genotoul; and the personnel of the Inserm US006 ANEXPLO/Creffre animal and experimental histopathology facilities. We thank F. Fiore for supervising the construction of the *Il2<sup>fl</sup>* mice and the members of the 'Integrative T cell Immunobiology team' and Sylvie Guerder for discussions and input in the project. JPMvM is grateful to the

staff of the Biochemistry Institute of the Lausanne University, Epalinges, Switzerland, for its hospitality. CA, AGA, SC, NM, JS, OJ, and JvM dedicate this work to the memory of their late, much respected and regretted colleague PR.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Leukocyte trafficking is mainly governed by chemokines, chemotactic cytokines, which can be concomitantly produced in tissues during homeostatic conditions or inflammation. After the discovery and characterization of the individual chemokines, we and others have shown that they present additional properties. The first discoveries demonstrated that some chemokines act as natural antagonists on chemokine receptors, and prevent infiltration of leukocyte subsets in tissues. Later on it was shown that they can exert a repulsive effect on selective cell types, or synergize with other chemokines and inflammatory mediators to enhance chemokine receptors activities. The relevance of the fine-tuning modulation has been demonstrated *in vivo* in a multitude of processes, spanning from chronic inflammation to tissue regeneration, while its role in the tumor microenvironment needs further investigation. Moreover, naturally occurring autoantibodies targeting chemokines were found in tumors and autoimmune diseases. More recently in SARS-CoV-2 infection, the presence of several autoantibodies neutralizing chemokine activities distinguished disease severity, and they were shown to be beneficial, protecting from long-term sequelae. Here, we review the additional properties of chemokines that influence cell recruitment and activities. We believe these features need to be taken into account when designing novel therapeutic strategies targeting immunological disorders.

Chemokines, Antagonism, Repulsion, Synergism, CXCL12/HMGB1 heterocomplex, Autoantibodies

## Introduction

Chemokines, chemotactic cytokines, engage in a promiscuous fashion a panel of over 20 chemokine receptors, key regulators of leukocyte migrations and functions. The chemokine system includes approximately 50 ligands, which play a fundamental role both in physiological and pathological immune responses (1).

The three-dimensional structures of all chemokines, as determined by nuclear magnetic resonance (NMR) spectroscopy or by X-ray crystallography, reveal remarkably similar protein backbones, tied together by two disulfide bonds formed among the four cysteines conserved in almost all chemokines. In all known structures, the N-terminal domain is unordered and contains two of the four cysteines. The loop region after the second cysteine, often referred to as “the N-loop”, is followed by three antiparallel  $\beta$ -strands and a C-terminal  $\alpha$ -helix, all of which are connected by short, random-coiled loops. The proximity of the cysteines in the N-loop has been used to classify chemokines in subfamilies: CC, where the cysteines are adjacent, CXC, in which one amino acid is interposed between the cysteines and CX<sub>3</sub>C, where three amino acids are present in between, while XC chemokines lack the first and the third conserved cysteine (2–4).

To mediate their activity, chemokines bind to cell surface receptors, which belong to the largest branch of the  $\gamma$  subfamily of rhodopsin-like G protein-coupled receptors (GPCRs). Today, 19 signaling receptors have been identified: 6 CXCRs, (CXCR1–6), 10 CCRs (CCR1–10), CX3CR1 and XCR1 (5). In addition, there are four “atypical” receptors (ACKR1–4) that use  $\beta$ -arrestins to elicit their functions. Atypical chemokine receptors impacts chemokine availability by scavenging and degrading the chemokine in the lysosomes, or by transporting the chemokines across different barriers *via* transcytosis (6).

Initial studies on structure-function relationships of chemokines were performed with CXCL8, using N-terminal truncations and amino acid substitutions. NMR-studies of CXCL8 in complex with peptides derived from the N-terminus of CXCR1, together with single-site mutagenesis, led to the identification of the major receptor-binding region: a positively charged groove between the N-loop and the third  $\beta$ -strand, into which the N-terminus of the receptor binds (7). Further studies of other chemokine receptor-peptide complexes corroborated this model (2).

Despite the apparent redundancy within the chemokine system, characterized by multiple chemokines binding to a single receptor and one receptor being activated by multiple chemokines, the system has been demonstrated to exhibit a high degree of specificity and complexity. Chemokine receptors are selectively expressed on specific subsets of cells, which contributes to their functional characteristics and homing abilities. Their ligands, on the other hand, can be expressed either individually or in combination within a particular tissue, both under normal and pathological conditions (8).

Studies investigating expression of chemokines in human samples from different diseases have revealed that many chemokines can be produced during the disease process (9). *In vivo* models and *in vitro* studies have highlighted the importance of chemokine binding to extracellular matrix components, and their activities as complexes (10). However, in pathological conditions, chemokine production does not always entirely account for the disease characteristics. This discrepancy might be partially explained by the additional chemokine activities and their natural regulation that we, and others, have described in the last three

TABLE 1 Modulators of chemokine activities.

Activity	Receptor	Modulator	Reference

decades (Table 1). This review aims to summarize these findings and their relevance to disease progress and treatment.

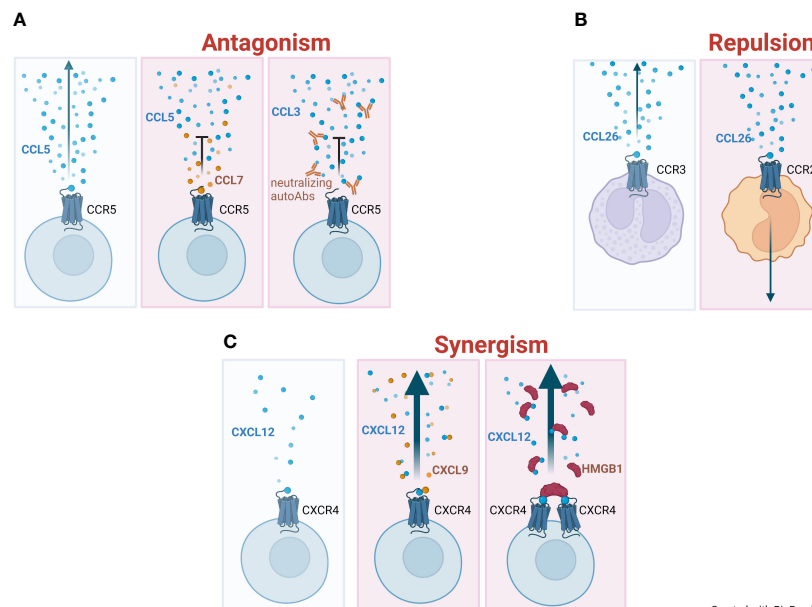

## Natural chemokine antagonists

The concomitant expression of several chemokines in inflamed tissues led us to explore the possibility that leukocyte infiltration may occur stepwise in response to gradients of different chemokines, and that chemokines can modulate, as natural antagonists, the activity of receptors that are different from their “traditional” target ones.

Chemokine receptor antagonism by unmodified naturally occurring ligands, therefore, constitutes a potentially important regulatory principle of chemokine-driven reactions.

Several reports have described that natural chemokine antagonists block the migration of inflammatory cells or provide an additional mechanism for selecting the leukocyte sub-type to be recruited at site of inflammation (Figure 1A).

A thorough pharmacological characterization of CCR5 revealed CCL7, a promiscuous agonist for CCR1, CCR2, and CCR3, as a highly potent, complete antagonist (18). An extensive study by Loetscher et al. showed CXCL11, an agonist of CXCR3, to be a highly selective and potent antagonist for CCR3, while CXCL9 and CXCL10, the other two agonists of CXCR3, were less efficient inhibitors (15). CCL18 and CXCL11 have independently been

FIGURE 1

Mechanisms of regulation of chemokine activities. **(A)** Directional migration (indicated with an arrow) of a chemokine (blue circles) on its respective receptor, and the gradient formation (left panel). Antagonistic effect and impairment of migration elicited by the co-presence of high levels of a non-agonist chemokine (CCL7, orange circles) (middle panel) or by neutralizing autoantibodies (autoAbs) targeting the chemokine (right panel). **(B)** Repulsive effect of CCL26 on monocytes that move away from the chemokine gradient (right panel) compared to eosinophils, which are attracted by it (left panel). **(C)** Absence of migration at low concentrations of the agonist (blue circles) (left panel). Enhanced migration (represented as a thick arrow) in the presence of an heterocomplex formed at low concentration of the agonist (CXCL12) and concomitant high concentration of a non-agonist chemokine (CXCL9, orange circles) (middle panel) or the alarmin High Mobility Group Box 1 (HMGB1) (red half-circles) (right panel).

confirmed as CCR3 antagonists (16, 17). We have reported on the antagonistic effects of CCL11 on CCR2 (14), while another report characterized CCL11 as a partial antagonist of CCR2 (36). Similarly, CCL4 has been described as an antagonist (11) or partial agonist (37) for CCR1, possibly depending on the cellular background. Furthermore, we have characterized CCL26 as a natural antagonist for CCR1 and CCR5 (12), and CXCL11 for CCR5 (19).

In addition, naturally occurring post-translational modifications of chemokines, such as proteolytic processing of the N-terminus domain (38), as well as synthetic N-terminal truncated forms (13) have been shown to have antagonist activity. As an example, a truncated variant of CCL2 (MCP-1 (9–76)) prevents the onset of arthritis, and reduces symptoms and cellular infiltrates in the MRL-*lpr* mouse model. Despite this important finding, clinical trials aimed at blocking CCL2/CCR2 interaction in Rheumatoid Arthritis (RA) failed to reach phase III (5), most likely due to the complexity of the disease in humans (e.g.: synovial infiltrate with predominant follicle like structure, monocyte/macrophages, or fibroblasts) and the different chemokines produced.

The unmodified natural antagonists act similarly to the truncated variants, which lack the N-terminal motif, and bind to the receptors *via* the structurally conserved N-loop and third  $\beta$ -strand, but then present the receptor with an N-terminal motif that is incapable of activating it. This notion is supported by experiments showing that a CCL11 variant, featuring the N-terminal motif of CXCL11 instead of its native one, acted as a highly potent CCR3 antagonist (39).

## Repulsive chemokines

A second feature of chemokines is their potential to exert a repulsive effect on selected cell types (Figure 1B). This feature was first described in 2000 by Poznansky and colleagues: high concentrations of CXCL12 exert a repulsive rather than an attractive effect on mature T cells (22).

While low concentrations of the chemokine attract a variety of leukocyte subpopulations, high concentrations of CXCL12 induce a repulsive effect on both naïve and memory CD4<sup>+</sup> and CD8<sup>+</sup> T cells, which move away from the source of the stimulus. The repulsive effect of CXCL12 on T cells is mediated by distinct signaling pathways as compared to those involved in chemotaxis: while the first is inhibited by cAMP agonists, the second requires tyrosine kinase activity, and they both depend on CXCR4, G $\alpha$ i protein and phosphatidylinositol 3-kinase activities. Differences in i) receptor dimerization and internalization, ii) signal transduction pathways elicited by surface or endocytosed receptor/ligand complexes, and iii) ratio between GAG-bound and free CXCL12, have been theorized as mechanisms involved in the different activity exerted by low or high chemokine concentrations, but no definitive experimental evidence has been provided to support these possibilities (40). It has been speculated that the repulsive effect exerted by CXCL12 on T cells prevents their infiltration in organs that produce abundant amounts of the chemokine, such as the bone marrow or the thymus, or can act as a limiting mechanism to avoid excessive accumulation of lymphocytes at site of inflammation to avoid self-perpetuating immune responses.

The relevance of the repulsive effect of CXCL12 on T cells in physiology has been later proven in the setting of mature thymocytes emigration from the thymus (23). Mature single positive CD4<sup>+</sup> and CD8<sup>+</sup> thymocytes, but not immature triple negative or double positive thymocytes, migrate away from thymic fragments through a *Bordetella Pertussis* toxin sensitive process, indicating that G $\alpha$ i protein-coupled receptors are responsible for the active movement of cells away from the tissue. Lack of a negative CXCL12 gradient and/or inhibition of CXCR4 prevent thymocytes emigration from thymic fragments, thus demonstrating that the repulsive effect is dependent on the presence of CXCR4 on mature thymocytes and on the high concentrations of CXCL12 produced by the thymic stroma.

Elevated levels of CXCL12 are also found in dysplastic tissues, such as primary brain tumors, melanomas, and ovarian carcinomas. Despite high concentrations of the chemokine, these tumors are rarely infiltrated by T cells. In 2006, Vianello and colleagues provided evidence that melanomas expressing elevated levels of CXCL12 can repel T cells, thereby abrogating Antigen (Ag)-specific T cell infiltration into the tumor and allowing it to escape immune control (24). Melanomas engineered to express low or high concentrations of CXCL12 display distinct levels of tumor infiltrating lymphocytes. Ag-specific T cells infiltrate tumors expressing low levels of CXCL12, but not those expressing elevated levels of the chemokine. The infiltration of Ag-specific T cells into these tumors is therefore affected by the concentration of CXCL12, with low concentrations leading to chemotactic effects and high concentrations to repulsion. These activities are mediated by CXCR4, as Ag-specific T cell pre-treatment with the antagonist AMD3100 results in decreased infiltration of low CXCL12 expressing tumors, but abrogates the repulsive effect, and restores infiltration in tumors expressing high levels of CXCL12, possibly *via* different chemokine receptors.

The ability to induce migration away from the stimulus is not an exclusive feature of CXCL12. Indeed, we showed that CCL26 actively repulses monocytes (20), a finding that was later confirmed in an independent study (21). While both the chemotactic and repulsive effects exerted by different CXCL12 concentrations are mediated by CXCR4, the repulsive effect of CCL26 does not require the expression of its cognate receptor CCR3. This repulsive effect on monocytes depends on CCR2 availability, and requires G $\alpha$ i protein and tyrosine kinase activities. Moreover, monocyte migration along a CCL2 gradient is significantly increased in the presence of an opposite CCL26 gradient, indicating that the concomitant presence of two opposite gradients in the microenvironment could enhance monocyte responses to CCL2. This effect could be relevant *in vivo* to direct monocytes from the blood stream to the site of inflammation, with CCL26 being expressed by vascular endothelial cells, during allergic reactions (41), and CCL2 by the inflamed tissue.

## Synergy-inducing chemokines

A third level of modulation in chemokine activity is their ability to interact with other chemokines or molecules in the

microenvironment, leading to synergistic effects on leukocyte functions in response to chemoattractants (Figure 1C). This can occur through direct interactions between molecules or through engagement of different receptors on the same cell. The first description of this mechanism dates to 2002 when the bovine chemokine regakine-1 was discovered to induce an enhanced neutrophil migration when combined with CXCL7, CXCL8 and C5a (42). The receptor or the mechanism of regakine-1 induced synergism were not identified. Competition with labelled C5a for binding to neutrophils or receptor transfected cell lines demonstrated that regakine-1 does not alter receptor recognition. The protein kinase inhibitors 2'-amino-3'-methoxyflavone (PD98059), wortmannin and staurosporin had no effect on the synergy between C5a and regakine-1. This first observation was followed by the description that migration of natural type I IFN-producing cells, a subpopulation of murine and human lymphocytes, to the CXCR3 agonists requires stimulation of CXCR4 by CXCL12 (29). The mechanism by which CXCL12 induces enhanced migration in response to CXCR3 agonists remains unknown. CXCL12 does not upregulate the expression of CXCR3 and does not increase the affinity of CXCR3 for its agonists. Apart from chemotaxis, the authors did not investigate other cell functions, and did not assess the signaling pathways involved. Similarly, the same enhanced migration in response to CXCR3 agonists, induced by stimulation with CXCL12, was observed by Vanbervliet et al. on human plasmacytoid dendritic cells (30). These reports undoubtedly indicated, as for natural antagonist chemokines, the necessity to further investigate the mechanisms governing concomitant expression of chemokines and cell functions, fostering research in this area.

Assessing the activity of chemokine heterocomplexes, von Hundelshausen et al. demonstrated that the complex between two chemokines, CCL5 and CXCL4, triggers the arrest of monocytes on activated endothelium (27), while concomitantly we demonstrated that the heterocomplex between CXCL13 and CCL21 or CCL19 modulates CCR7-expressing cell activities (28). Likewise, CCR4<sup>+</sup> lymphocytes migrate toward low concentrations of CCL22 in the presence of CXCL10 (26), monocytes migrate toward low concentrations of CCL7 in the presence of CCL19 or CCL21 (25), and lymphoma cells respond to the heterocomplex formed by CXCL12 and CXCL9 *via* CXCR4 (31).

Von Hundelshausen et al. extensively studied how human chemokines interact with each other and demonstrated their relevance in enhancing receptor triggering or inhibiting receptor activities (43). Several studies performed *in vivo* highlighted the importance of disrupting the heterocomplex formation to ameliorate inflammation (44–46).

Recently, a non-dissociating CXCL4–CXCL12 heterodimer was used as a new tool to further study chemokine-chemokine and chemokine heterodimer-receptor interactions in breast cancer cells (47).

Chemokine heterocomplexes might provide an amplification system, when the concentration of the agonist is too low to trigger a proper receptor response (48). On the other hand, when synergy-inducing molecules are present in an environment rich of the agonist, they could possibly dampen cellular responses, as indicated by *in vitro* migration (26, 28, 34).

Chemokine activity can also be modulated by their interaction with other molecules such as the alarmin High Mobility Group Box 1 (HMGB1) (34), as described in the next section, the  $\alpha$ -defensin HNP1 (32), or galectins (33), further supporting the relevance of the tissue microenvironment in modulating cellular recruitment and responses in inflammation.

## CXCL12/HMGB1 heterocomplex

Damage-associated molecular patterns, also known as alarmins, are danger signals released upon tissue damage to activate the inflammatory response. The alarmin HMGB1 has been shown to form a heterocomplex with CXCL12, favoring cell migration *via* CXCR4 both *in vitro* and *in vivo*. This synergistic activity, demonstrated *in vitro* using mouse fibroblasts and monocytes, was further assessed in an *in vivo* model of sterile inflammation. Moreover, this effect is blocked by glycyrrhizin, which prevents the formation of the heterocomplex, by anti-CXCL12 antibodies, or by AMD3100, inhibiting CXCR4 activation (34).

HMGB1 is characterized by two DNA binding domains, Box A and Box B, connected by a flexible linker region, and a long acidic C-terminal tail. In the tissue microenvironment, HMGB1 can be present in two different redox isoforms: reduced-HMGB1 in which the two conserved cysteines at position 23 and 45 within Box A are reduced, and oxidized-HMGB1 in which these two cysteines form a disulfide bond. Only reduced-HMGB1 synergises on CXCL12 activities (49). Results from NMR and Surface Plasmon Resonance experiments

revealed that CXCL12 interacts separately with each of the HMGB1 boxes (34). Molecular dynamics simulations and protein-protein docking calculations showed that reduced-HMGB1 can accommodate two CXCL12 molecules, while oxidized-HMGB1 tends to be more compact and displays a lower accessible surface for the chemokine. Furthermore, only when the two CXCL12 bind to the reduced-HMGB1, their N-terminal domains are oriented in the best conformation to trigger CXCR4 dimers (Figure 2A) (50). Fluorescence Resonance Energy Transfer studies investigating CXCR4 dimer formation showed that the CXCL12/HMGB1 heterocomplex induces different rearrangements of CXCR4 homodimers on the cell surface, compared to CXCL12 alone, without altering the overall number of CXCR4 homodimers formed (34). Triggering of CXCR4 by the heterocomplex, in comparison to CXCL12 alone, results in a distinctive engagement of the  $\beta$ -arrestin proteins:  $\beta$ -arrestin1 for actin polymerization and  $\beta$ -arrestin2 for directional migration. In addition, CXCR4 is preserved on the cell surface and this results in an enhanced response to the chemotactic signal (51).

## CXCL12/HMGB1 heterocomplex in inflammation

The early recruitment of mononuclear cells at the site of inflammation, also driven by the CXCL12/HMGB1 heterocomplex, is an essential step to mount a proper immune response. In such cases, it is essential that HMGB1 is maintained reduced in the microenvironment.

The heterocomplex mediated migration was first assessed in an *in vivo* model of sterile inflammation, achieved by the injection of

FIGURE 2

The CXCL12/HMGB1 heterocomplex. (A) Model of two molecules of CXCL12 (blue circle) complexed with reduced High Mobility Group Box 1 (HMGB1) (red half-circles), binding and triggering CXCR4 homodimers on the cell surfaces. (B) CXCL12/HMGB1 heterocomplex is present in rheumatoid arthritis, where it sustains inflammation in the synovial membrane (left panel). A positive effect of the CXCL12/HMGB1 heterocomplex has been shown in models of sterile inflammation, fracture healing, muscle repair and hematopoiesis after chemotherapeutic myeloablation (middle panel). The role of the heterocomplex in cancer has yet to be fully understood (right panel).

cardiotoxin into the muscle. Endogenous production of HMGB1, and subsequent heterocomplex formation with the CXCL12 expressed on endothelial cells, promotes a fast recruitment of CD11b<sup>+</sup> mononuclear cells (34). In this model, pre-treatment with glycyrrhizin, completely abolishes leukocyte infiltration.

More recently, Ferrara and colleagues, monitored HMGB1 redox status and leukocyte infiltration in tissues, demonstrating that in early inflammation HMGB1 is mainly reduced, while oxidized-HMGB1 is prevalent at later stages, possibly due to the production of Reactive Oxygen Species by infiltrating leukocytes (52).

Despite its beneficial role in early leukocyte recruitment during acute inflammation, persistent expression of the heterocomplex might be detrimental and delay resolution of inflammation.

In patients with RA, an autoimmune condition affecting the joints, monocytes are known to be recruited *via* CXCL12 (53), and HMGB1 is found overexpressed in the synovial fluid (54), where the heterocomplex can be detected (35). Monocytes from RA patients with active disease migrate towards the CXCL12/HMGB1 heterocomplex formed at lower HMGB1 concentration, compared to monocytes obtained from healthy individuals, due to the production of thioredoxin and thioredoxin reductase, enzymes implicated in maintaining HMGB1 in its reduced form (35). *In vitro* treatment of monocytes from healthy individuals with prostaglandin E2, found at high concentration in the sera of RA patients, recapitulates the response to the heterocomplex of monocytes from active RA. This effect is abolished by celecoxib, a COX2 inhibitor used in RA treatment, which restores migration patterns to normal levels. Together, this study demonstrated the pathological role of CXCL12/HMGB1 heterocomplex in the recruitment of monocytes during active disease status, where they promote tissue damage (Figure 2B).

Indirect evidence points to a role for the CXCL12/HMGB1 heterocomplex in autoimmune disorders affecting the eyes. In a model of autoimmune uveitis, adoptive transfer of uveitogenic Ag-specific T cells promotes the active secretion of HMGB1 by retinal cells, a process mediated by Fas-FasL interaction (55, 56). Yun and colleagues demonstrated that, early after adoptive transfer, retinal cells actively secrete HMGB1 and subsequently produce CXCL12 (57). In addition, CXCR4 inhibition significantly reduces ocular leukocyte infiltration and improves clinical score. Although this represents the first indication of HMGB1 and CXCL12 pathological expression in uveitis, redox status of HMGB1 and therefore heterocomplex formation remains to be proven. Local upregulation of HMGB1 has been shown in vitreous samples of diabetic patients with ongoing retinopathy, and in the retinas of diabetic rat and mice models (58–60). The presence of CXCL12/HMGB1 heterocomplex has been demonstrated after intravitreal HMGB1 injection in diabetic mice, which upregulates CXCL12 (61). Future studies should investigate heterocomplex mediated leukocytes recruitment in the retina and how best to pharmacologically impair this migration.

A potential pathological role of CXCL12/HMGB1 has also been suggested for infectious diseases.

HMGB1 is secreted locally in response to *Pseudomonas aeruginosa* lung infection (62). De Leo and colleagues have

recently demonstrated, in an *in vivo* model, that a newly discovered CXCL12/HMGB1 heterocomplex inhibitor, pamoic acid, can reduce lung neutrophil load during the acute and chronic phase of the infection (63). This is the first report highlighting neutrophil recruitment *via* the heterocomplex, and future studies are needed to validate its activity in other pathological conditions driven by this cell type.

The research on inhibitors of the CXCL12/HMGB1 heterocomplex was boosted by the results obtained in patients with RA and *in vivo* models of inflammation, in view of developing additional treatments for several pathological conditions fueled by monocyte infiltration (63–66). Currently, small molecules and computationally identified peptides have been tested for their ability to inhibit the heterocomplex *in vitro* and *in vivo*.

### CXCL12/HMGB1 heterocomplex in tissue repair

Two independent works have demonstrated that the CXCL12/HMGB1 heterocomplex enhances tissue regeneration *in vivo* after muscle injury or bone fracture, acting *via* CXCR4 (Figure 2B) (67, 68). Tirone and colleagues showed that HMGB1 accelerates tissue regeneration by acting on resident stem cells. This process requires the presence of both CXCL12 and CXCR4, indicating a role for the CXCL12/HMGB1 heterocomplex (67).

Systemically administrated exogenous HMGB1 in C57BL/6J mice accelerates hematopoietic recovery after myeloablation induced by chemotherapy (68). On the other hand, genetic deletion of HMGB1 delays fracture healing. The regenerative process is inhibited by adding glycyrrhizin or AMD3100, suggesting that HMGB1 exerted these regenerative effects by forming the heterocomplex with CXCL12 and acting *via* CXCR4. By investigating the cell cycle rate, cell dimensions, ATP concentrations, mitochondrial DNA, and mTORC1 dependence, Lee and colleagues showed that HMGB1 drives hematopoietic stem cells into the dynamic GAlert phase, defined as an intermediate active state between G0 and G1 (68).

Both groups proposed 3S-HMGB1, a synthetic non-oxidizable form of HMGB1 in which the cysteines are replaced by serines, as a potential new pharmacological tool with a broad range of medical uses, including hematopoietic recovery after chemotherapy, healing after injury or elective surgery.

### CXCL12/HMGB1 heterocomplex in cancer

While the multiple activities orchestrated by CXCL12 in the tumor microenvironment have been well documented, as well as the presence of HMGB1, little is known on the relevance of the CXCL12/HMGB1 heterocomplex in mediating tumor growth and metastasis.

CXCL12 promotes cancer development by two main mechanisms: i) directly activating signaling pathways involved in cancer cell growth, metastasis, and angiogenesis, and ii) indirectly promoting metastasis by recruitment of CXCR4<sup>+</sup> cancer cells to CXCL12-expressing organs (69).

On the other hand, HMGB1 plays paradoxical roles in cancer, depending on its localization. While nuclear HMGB1 acts as a tumor suppressor for its roles in chromosome stability and induction of tumor cell death, high extracellular HMGB1 expression has been associated with poor prognosis in patients with various type of cancers (70). Although tumor cells mainly express reduced-HMGB1, infiltrating leukocytes are responsible for the presence of oxidized-HMGB1 in tumor microenvironment (52).

Whether tumor cell migration, metastasis formation, and immune cell recruitment can be modulated by the heterocomplex is yet to be demonstrated.

## Naturally arising antibodies against chemokines

A further mechanism by which chemokine activities can be modulated is through the development of autoantibodies targeting their binding or triggering sites (Figure 1A).

Arise of anti-cytokines antibodies is well documented in pathology, where they prolong the half-life of circulating cytokines, as observed for interleukin (IL)3, IL4, IL6 and IL7 (71, 72). In addition they trigger Fcγ receptors and stimulate pro-inflammatory responses (73) or promote complement

mediated cytotoxicity (74). Similar mechanisms of action could be envisioned for anti-chemokine autoantibodies.

Few reports described the role and functions of anti-chemokine autoantibodies. They can promote or prolong chemokine activities, or be beneficial to the host, through dampening excessive inflammation, thanks to their neutralizing properties (Table 2) (78, 79).

## Anti-chemokine antibodies sustaining pathology

Acute respiratory distress syndrome (ARDS) is a life threatening pulmonary condition characterized by pulmonary infiltrates, hypoxemia and edema. Bronchoalveolar lavage fluid (BAL) of ARDS patients presents elevated levels of autoantibodies complexed with CXCL8 (82). In a study aimed at investigating the relationship between the presence of these complexes and development stages of acute lung injury, Kurdowska and colleagues demonstrated an association between elevated levels of autoantibodies bound to CXCL8 and an adverse outcome (75). CXCL8-autoantibodies complexes, isolated from BAL after acute lung injury, maintain the CXCL8 chemotactic activity on neutrophils and, in addition, can trigger superoxide release by

TABLE 2 Naturally arising antibodies against chemokines.

Anti-chemokine antibodies sustaining pathology			
Disease	Autoantibody specificity	Mode of action	Reference
Acute respiratory distress syndrome	CXCL8 (immune-complexes)	Associated to adverse outcome Chemotactic activity on neutrophil maintained Superoxide release <i>via</i> FcγRIIa	(75) (73)
Asthma	CXCL8 (immune-complexes)	Proinflammatory	(76)
Rheumatoid Arthritis	CXCL8 CCL4, CCL19, CCL25, CXCL7, CXCL8, CXCL9	Proinflammatory; Increased in patients with advanced extra-articular and clinical manifestations	(77)
			(78)
Anti-chemokine antibodies preventing adverse outcome			
Disease	Autoantibody specificity	Mode of action	Reference
Type1 Diabetes Mellitus	CCL3	Neutralizing activity; Counteract disease progression	(79)
Atopic Dermatitis	CCL3	Neutralizing activity; Counteract disease progression	(80)
Prostate Cancer	CCL2	Neutralizing activity; Limit tumor growth	(81)
COVID-19	CCL19, CCL22, CXCL17	Unknown; Increased in COVID-19 convalescents	(78)
	CXCL8, CCL25, CXCL5	Unknown; Increased in COVID-19 convalescents with mild disease	
	CCL21, CXCL13, CXCL16	Neutralizing activity (CXCL13, CXCL16); Increased in COVID-19 convalescents without long COVID	

binding to FcγRIIIa (73). Elevated levels of both IgG and IgA autoantibodies complexes with CXCL8 are also found in circulation, as well as in BAL of asthmatic patients, confirming their proinflammatory role (76). Anti-CXCL8 autoantibodies were also identified in RA patients, with high levels of IgA anti-CXCL8 present in patients with advanced extra-articular and clinical manifestations (77). The authors hypothesize that prolonged CXCL8 production leads to the arising of anti-CXCL8 antibodies, aiming at limiting the persistent inflammation; however, the presence of such antibodies complexed with CXCL8, instead, promotes Fc mediated activities, contributing to the persistent chronic inflammation. We recently confirmed elevated levels of circulating anti-CXCL8 IgG autoantibodies in RA patients together with other autoantibodies targeting CCL4, CCL19, CCL25, CXCL7 and CXCL9 (78).

## Anti-chemokine antibodies preventing adverse outcome

Type 1 (insulin-dependent) diabetes mellitus (T1DM) is a chronic autoimmune disease in which insulin-secreting cells within Langerhans islets in pancreas are eliminated by the immune system (83). Patients with T1DM develop autoantibodies against several antigens, which include insulin and islet cells, before symptoms onset. Of note, the majority of T1DM patients selectively develop anti-CCL3 antibodies, with neutralizing properties (79). Anti-CCL3 antibodies production might be specific of T1DM, since the authors did not find them in other autoimmune diseases. Interestingly, anti-CCL3 antibodies are also found in 95% of first-degree relatives of T1DM patients. Cameron and colleagues showed that in CCL3-deficient NOD mice about 60% of the pancreas islets display a normal histology. In contrast, in NOD mice expressing CCL3, 40% of pancreatic islets showed sign of moderate to severe insulinitis (84). Indeed, when NOD mice were treated with an anti-CCL3 antibody, a reduction in incidence of diabetes was observed (84). Collectively, these data suggest that, these antibodies might counteract disease progression.

Higher level of autoantibodies against CCL3 were shown in atopic dermatitis (AD), a chronic skin inflammation which leads to skin lesions (80). This is in line with previous studies on AD patients in which CCL3 was shown to be produced by PBMCs (85). The presence of these autoantibodies, if proven to neutralize CCL3 activities, might play a role in suppressing disease progression, similarly to T1DM.

In cancer, several studies highlighted the importance of CCL2 in promoting monocyte migration from the bone marrow to the circulation and ultimately to the tumor site, where they elicit immune suppressive activity and stimulate tumor growth (81, 86–89). Prostate cancer patients present high expression of CCL2 in the tumor, and elevated levels of anti-CCL2 neutralizing autoantibodies (81). Importantly, the presence of anti-CCL2 autoantibodies was exclusive in patients bearing malignant, but not benign tumors. Nevertheless, in a mouse model, CCL2 overexpression induced a sustained autoantibody production and significantly limited tumor growth, suggesting a potential beneficial role of these autoantibodies (81). The authors speculated that a therapeutic strategy aiming at

enhancing the pre-existing anti-CCL2 antibodies might be beneficial as the sera concentration of these antibodies might not be elevated enough to completely suppress monocyte infiltration and tumor cell migration.

A novel coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), emerged in December 2019, causing pneumonia outbreaks worldwide (90). Autoantibodies targeting cytokines and several immune factors have been described in patients with coronavirus disease 2019 (COVID-19) (91). In particular, autoantibodies targeting type I IFN have been found in ~ 10% of life-threatening pneumonia and in ~ 20% of deaths due to COVID-19. We have recently demonstrated that autoantibodies targeting several chemokines, including CCL19, CCL22 and CXCL17, are developed post-SARS-CoV-2 infection. Convalescent individuals who experienced mild COVID-19 have higher levels of autoantibodies targeting CXCL8, CCL25 and CXCL5 compared to those that required hospitalization. We showed that these autoantibodies have neutralizing properties, and therefore could be beneficial in dampening the inflammatory response, preventing hyper-activation of the immune system and tissue damage associated to severe COVID-19. Long-term sequelae (long COVID), spanning from neurological, to respiratory and systemic/inflammatory symptoms, have been reported after SARS-CoV-2 infection (92). We found that autoantibodies to CCL21, CXCL13 and CXCL16 are present in individuals that do not develop long COVID (78). All together these data point to a beneficial role of anti-chemokine antibodies in COVID-19, with their presence correlating with better outcome and lack of long COVID.

## Conclusions

Even though, in modern pharmacology, the γ subfamily of GPCR represents the most successful target of small molecule inhibitors for treating diseases affecting different systems, inhibitors of chemokines and chemokine receptors were unsuccessful for the treatment of inflammatory diseases, where the involvement of the chemokine system plays a key role. The extensive characterization of chemokine expression in tissues, both in physiological and pathological conditions, fostered researchers to look at the chemokine system from a distinct perspective, leading to the identification of additional functions. The complexity of the tissue microenvironment influences chemokine receptor mediated cell recruitment and activities. Natural chemokine antagonism modulates cell recruitment in response to different chemokine gradients. Chemokines can exert a repulsive effect either at different chemokine concentrations or acting on different receptors, contributing to tumor immune evasion or tissue egress. Chemokines and inflammatory molecules, concomitantly expressed, can also synergistically act on cell migration and activities. The presence of autoantibodies targeting chemokines, either neutralizing their activities or promoting Fc-mediated functions, sustain pathology or prevent adverse outcome. Therefore, we believe that all these features should be taken into account for future drug development studies and novel approaches into personalized medicine.

## Author contributions

All authors listed, have made substantial, direct and intellectual contribution to the work, and approved it for publication.

## Funding

The authors would like to thank, for the support received over the years: the Swiss National Science Foundation (3100A0-143718/1 and 141773-RM3); Innosuisse (46411.1 IP-LS); the European Union's Programs for research technological development and demonstration (INNOCHEM - LSHB-CT-2005-518167 (FP6), DEC-VAC - LSHP-CT-2005-018685 (FP6), ADITEC - 280873 (FP7), and TIMER - 281608 (FP7)); the San Salvatore Foundation; the Novartis Foundation; the Helmut Horten Foundation; the Institute for Arthritis Research; the Gottfried and Julia Bangerter-Rhyner-Foundation; the Ceschina Foundation and the Fratelli Agostino Enrico Rocca Foundation.

## Conflict of interest

VC and MU have filed a provisional patent application in connection with the work on autoantibodies targeting chemokines. MU is inventor in the patent # PCT/EP2019/057125 on peptides inhibitors of the CXCL12/HMGB1 heterocomplex.

The remaining authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Macrophages (MΦ) are commonly cultured *in vitro* as a model of their biology and functions in tissues. Recent evidence suggests MΦ to engage in quorum sensing, adapting their functions in response to cues about the proximity of neighboring cells. However, culture density is frequently overlooked in the standardization of culture protocols as well as the interpretation of results obtained *in vitro*. In this study, we investigated how the functional phenotype of MΦ was influenced by culture density. We assessed 10 core functions of human MΦ derived from the THP-1 cell line as well as primary monocyte-derived MΦ. THP-1 MΦ showed increasing phagocytic activity and proliferation with increasing density but decreasing lipid uptake, inflammasome activation, mitochondrial stress, and secretion of cytokines IL-10, IL-6, IL-1β, IL-8, and TNF-α. For THP-1 MΦ, the functional profile displayed a consistent trajectory with increasing density when exceeding a threshold (of 0.2 × 10<sup>3</sup> cells/mm<sup>2</sup>), as visualized by principal component analysis. Culture density was also found to affect monocyte-derived MΦ, with functional implications that were distinct from those observed in THP-1 MΦ, suggesting particular relevance of density effects for cell lines. With increasing density, monocyte-derived MΦ exhibited progressively increased phagocytosis, increased inflammasome activation, and decreased mitochondrial stress, whereas lipid uptake was unaffected. These different findings in THP-1 MΦ and monocyte-derived MΦ could be attributed to the colony-forming growth pattern of THP-1 MΦ. At the lowest density, the distance to the closest neighboring cells showed greater influence on THP-1 MΦ than monocyte-derived MΦ. In addition, functional differences between monocyte-derived MΦ from different donors could at least partly be attributed to differences in culture density. Our findings demonstrate the importance of culture density for MΦ function and demand for awareness of culture density when conducting and interpreting *in vitro* experiments.

## KEYWORDS

macrophage, quorum sensing, culture density, *in vitro*, macrophage function

# 1 Introduction

Macrophages (MΦ) have attracted growing interest as a therapeutic target due to their dynamic role in various pathologies, including inflammatory diseases and cancer (1–3). Cell lines like THP-1, J774 or RAW264.7, or primary MΦ derived from bone marrow cells or blood monocytes are commonly used as models of human MΦ in biological assays or screening tools *in vitro* (1). To ensure reproducibility and comparability of results obtained from MΦ cultured *in vitro*, standardized cultivation protocols optimized for each cell type and assay are essential (4, 5). However, culture density at point of observation is an often-overlooked factor and either not specified at all or insufficiently substantiated by experimental data. Even though seeding density is usually mentioned and cells are often seeded at similar densities, differences in growing protocols, experimenters, and experimental conditions may result in density differences during experimentation. This is particularly worrisome in view of the reported importance of local contact and context for MΦ viability (6) and recent growing evidence of quorum sensing by MΦ (7).

Quorum sensing, a term adopted from bacteriology, refers to the modulation of gene expression by diffusible molecular cues (autoinducers) which convey information about density between cells (8–10). Quorum sensing had originally been established for biofilm formation of bacteria (8) but has recently also been observed in MΦ (7, 9, 11). In RAW264.7 MΦ, gelsolin was identified as autoinducer of programmed cell death 4 (PDCD4) expression which increased at higher cell density (11). Moreover, a quorum sensing mechanism has been observed in mice where the inflammation-resolving effect of nitric oxide (NO) was found to be dependent on the density of NO-producing MΦ (7).

Along with quorum sensing, cell density is vital for MΦ proliferation and viability. Indeed, MΦ were found to resume exponential growth faster (12), and to exhibit a more mature phenotype (13) and improved viability (12) at lower density. At higher density on the other hand, more MΦ adopted a high activation state (9). Moreover, culture density has been shown to influence several key functions of MΦ, including cytokine secretion (9, 13), polarization (13), phagocytosis (14), accumulation of esterified cholesterol (15), formation of multinucleated giant cells (16), and inhibition of mycobacterial growth (17). However, previous studies mostly compared two densities (“high” versus “low”) for only a single function, and either focused on murine MΦ cell lines or on bone marrow-derived MΦ (BMDM). So far, a comprehensive study of the functional implications of density in human MΦ models is lacking. Failure to account for density differences may introduce bias as it remains unclear whether observed effects of a treatment agent are merely attributable to its effect on culture density, either by promoting proliferation and cell survival, or by inducing cell death.

The aim of this study was to investigate the influence of culture density on human MΦ function. Using high-throughput measurement of 10 functional parameters, we studied the phenotype of THP-1 MΦ as well as human primary monocyte-derived MΦ (MDM). Moreover, we considered the colony-forming

growth pattern of THP-1 cells, and donor-specific differences in MDM as additional modulators of culture density-related functional changes.

## 2 Materials and methods

### 2.1 THP-1 cell culture and differentiation to MΦ

THP-1 cells were seeded at increasing densities in 96-well black clear-bottom imaging microplates (Corning #353219) in RPMI medium with HEPES and GlutaMAX (Gibco #72400-021) supplemented with 10% heat-inactivated (30 minutes at 56°C) fetal bovine serum (FBS; SERANA #S-FBS-SA-015) and 1% penicillin-streptomycin (Gibco #15070-063). Seeding densities were 5,000, 12,000, 21,000, 37,000, 53,000, 69,000, or 87,000 cells/well, denoted as  $\times 10^3$  cells/mm<sup>2</sup> (0.16, 0.38, 0.66, 1.16, 1.66, 2.16, or  $2.72 \times 10^3$  cells/mm<sup>2</sup>, respectively) that were rounded to one decimal digit to improve readability (0.2, 0.4, 0.7, 1.2, 1.7, 2.2, or  $2.7 \times 10^3$  cells/mm<sup>2</sup>, respectively). THP-1 cells were differentiated into MΦ by exposure to 2000 nM phorbol 12-myristate 13-acetate (PMA; Sigma #P1585) for 48 hours at 37°C, 5% CO<sub>2</sub> after which they were rested for 24 hours in fresh culture medium before performing the functional assays.

### 2.2 PBMC isolation, monocyte isolation, and differentiation to MΦ

Peripheral blood mononuclear cells (PBMCs) were isolated from leukocyte reduction system cones, a by-product of thrombopheresis of routine blood donations from healthy volunteers collected at the University Hospital RWTH Aachen, Germany, by density centrifugation with Lymphoprep™ (STEMCELL Technologies #07861). Isolated PBMCs were cryopreserved for later use in one-third freezing medium containing 75% FBS and 25% dimethyl sulfoxide (DMSO; Merck #102950). CD14 MicroBeads (Miltenyi #130-096-052) were used to positively select CD14+ monocytes, following the manufacturer’s protocol. Monocytes of 6 donors were pooled before seeding at the respective densities in 96-well black clear-bottom imaging microplates, or kept separate and seeded in 384-well plates (Greiner Bio-One #781866) in culture medium containing RPMI medium with HEPES and GlutaMAX supplemented with 10% heat-inactivated FBS and 1% penicillin-streptomycin. Seeding densities were 30,000, 64,000, 98,000, 132,000, 166,000, or 200,000 cells/well, denoted as  $\times 10^3$  cells/mm<sup>2</sup> (0.94, 2.0, 3.06, 4.13, 5.19, or  $6.25 \times 10^3$  cells/mm<sup>2</sup>, respectively) that were rounded to integers to improve readability (1, 2, 3, 4, 5, or  $6 \times 10^3$  cells/mm<sup>2</sup>, respectively). At 384-well format, cells were plated at 13,000 cells/well. Monocytes were differentiated into MΦ with 100 ng/ml recombinant human macrophage colony-stimulating factor (M-CSF) (ImmunoTools #11343113) for 7 days at 37°C, 5% CO<sub>2</sub> with one medium change.

## 2.3 Functional high-throughput measurements

MΦ functions were assessed using the “MacroScreen” high-content analysis (HCA) platform developed in-house, a semi-automated microscale (96- to 384-well format) assay platform to perform an expanding range of fluorescence-based functional assays (18). All MacroScreen assays have been benchmarked against conventional mesoscale assays. Images were taken using the BD Pathway 855 automated fluorescent microscope (BD Biosciences) by taking 9 images per well with a 10x Olympus 0.40 NA objective (96-well format) or 20x Olympus 0.75 NA objective (384-well format). All experiments were performed in n=3-6 replicates. Images were analyzed with CellProfiler software version 4.0.4 (19) by creating a digital segmentation mask for each cell based on its nuclear staining signal using the IdentifyPrimaryObjects module followed by the ExpandOrShrinkObject module. Percentage of positive cells was measured using the MeasureObjectIntensity module followed by the ClassifyObjects module, which determines the amount of positive cells relative to the total number of segmented objects in the image. Distance to the closest neighboring cell was measured per image, for each cell, using the MeasureObjectNeighbors module in CellProfiler 4.0.4 (19).

## 2.4 Phagocytosis

Cells were incubated with 25 µl/ml pHrodo™ Red Zymosan Bioparticles™ (ThermoFisher Scientific #P35364) per well in culture medium for 1 hour at 37°C, 5% CO<sub>2</sub>. Zymosan particles taken up by cells are reflected by tetramethyl rhodamine isothiocyanate (TRITC) fluorescence signal. Nuclei were stained with Hoechst 33342 (Sigma #B2261) in culture medium for 10 minutes at 37°C, 5% CO<sub>2</sub> which was replaced by PBS before imaging.

## 2.5 Lipid uptake

Low-density lipoprotein (LDL) was isolated from serum of healthy volunteers *via* density centrifugation and oxidized using CuSO<sub>4</sub> as described previously (20). Cells were incubated with 8 µg/ml oxidized LDL (oxLDL) pre-mixed with 2 µg/ml TopFluor® Cholesterol (Avanti Polar Lipid #810255P) in culture medium for 3 hours at 37°C, 5% CO<sub>2</sub>, reflected by fluorescein isothiocyanate (FITC) fluorescence signal. Nuclei were stained with Hoechst 33342 in culture medium for 10 minutes at 37°C, 5% CO<sub>2</sub> which was replaced by PBS before imaging.

## 2.6 Inflammasome

Cells were primed with 50 ng/ml LPS from *E. coli* (Invivogen #tlrl-ebllps) for 3 hours at 37°C, 5% CO<sub>2</sub>. 10 µM nigericin (Invivogen #tlrl-nig) for 1 hour at 37°C, 5% CO<sub>2</sub> served as second signal for inflammasome activation. Fc receptor was blocked with Fc receptor binding inhibitor antibody (Invitrogen

#14-9161-73) before cells were fixed using 2% PFA with 5 mM EDTA in PBS and permeabilized using 5% FBS and 0.5% Triton X-100 in PBS for 20 minutes on ice. Next, the intracellular adapter protein apoptosis associated speck-like protein containing a CARD (ASC) was stained using PE-conjugated anti-ASC antibody (clone HASC-71; BioLegend #653904) overnight at 4°C. Nuclei were stained with Hoechst 33342 in PBS for 10 minutes on ice, and cells were washed with and imaged in PBS afterwards.

## 2.7 Mitochondrial stress

Mitochondrial stress was induced using 1200 nM staurosporine (Sigma #S4400) for 1 hour at 37°C, 5% CO<sub>2</sub>. Mitochondria and nuclei were stained simultaneously with 250 nM MitoTracker™ Deep Red FM (ThermoFisher Scientific #M22426) and Hoechst 33342, respectively, in culture medium for 30 minutes at 37°C, 5% CO<sub>2</sub> before imaging in PBS. Alexa 594 fluorescence signal reflects mitochondrial staining dependent on membrane potential.

## 2.8 Proliferation

Cells were incubated with 10 µM 5'-ethynyl-2'-deoxyuridine (EdU; ThermoFisher Scientific #A10044) for 2 hours at 37°C, 5% CO<sub>2</sub>. Next, cells were fixated with 3.7% PFA in PBS for 15 minutes and washed twice with PBS before permeabilization with 0.1% Triton X-100 in PBS for 15 minutes. After another wash with PBS, Click-iT reaction cocktail (ThermoFisher Scientific #C10269) including Alexa Fluor 594 azide (ThermoFisher Scientific, #A10270) prepared according to the manufacturer's instructions was added. After 30 minutes, cells were washed with PBS and nuclei stained with Hoechst 33342 for 15 minutes. Cells were imaged in 1:5 KI quencher (1M KI in 10 mM KH<sub>2</sub>PO<sub>4</sub>) in PBS.

## 2.9 Multiplex ELISA

THP-1-derived MΦ were stimulated with 50 ng/ml LPS from *E. coli* for 6 hours at 37°C, 5% CO<sub>2</sub>. Supernatant was collected and cytokine levels of IL-1β, IL-6, IL-8, IL-10, IL-12p70, and TNF-α were measured in a custom V-plex human cytokine ELISA (MSD Meso Scale Diagnostics) according to the manufacturer's protocol. Measured levels of IL-12p70 were close to or below the standard curve (0.1169 pg/ml), thus these data are not presented here.

## 2.10 Dimensionality reduction and visualization

We calculated the mean of the replicates for each feature of HCA functional data and cytokine data at the same density, resulting in a density-feature matrix with 7 rows (densities) and 10 columns (features/functions). The functional profile of THP-1 MΦ for the 7 different densities was analyzed in an integrated manner by two-dimensional Principal Component Analysis (PCA), where the relative contribution

of each individual function to the first (PC1) and second principal component (PC2) axes was visualized outside the X and Y axes.

## 2.11 Statistical analysis

Data are expressed as mean  $\pm$  SEM, unless stated otherwise. Normal distribution was assessed by Shapiro-Wilkes normality test, and equality of variances by Brown-Forsythe test. For normally distributed data with equal variance, significance was assessed by one-way ANOVA followed by Tukey's multiple comparisons test at a significance level of  $p < 0.05$ . For normally distributed data with unequal variance, significance was assessed by Brown-Forsythe ANOVA and Dunnett's T3 multiple comparisons test, and Kruskal-Wallis test with Dunn's multiple comparisons test was used for not normally distributed data. All statistical analyses were performed using GraphPad Prism 8 software.

## 3 Results

### 3.1 Density influences the functional phenotype of MΦ

We assessed the functional phenotype of THP-1-derived MΦ seeded at 7 different densities ranging from  $0.2$  to  $2.7 \times 10^3$  cells/mm<sup>2</sup> using the MacroScreen platform, an HCA platform based on several fluorescent imaging-based functional assays. For clarity's sake, we presented the  $p$ -values of all group comparisons for all assays in a significance matrix (Supplementary Table 1). As expected, the number of nuclei per fluorescent image increased with density in all high-content functional assays (Supplementary Figures 1A–E). No changes in the pH of the culture medium were observed. Whereas the phagocytic activity of THP-1 MΦ was found to increase with higher density (Figure 1A), uptake of oxLDL decreased (Figure 1B). MΦ seeded at  $0.2 \times 10^3$  cells/mm<sup>2</sup>, the lowest density in the tested density range, showed the highest inflammasome activation in response to LPS and nigericin (Figure 1C). Moreover, at lower densities, MΦ were found to be more resistant to staurosporine-induced mitochondrial stress (Figure 1D). Proliferation measured by EdU incorporation increased with density (Figure 1E). Secretion of the cytokines IL-10, IL-1 $\beta$ , IL-6, IL-8, and TNF- $\alpha$  in response to LPS stimulation was measured using multiplex ELISA, and was found to decrease with density, after an initial sharp increase between the two lowest densities included in the density range ( $0.2$  and  $0.4 \times 10^3$  cells/mm<sup>2</sup>) (Figures 1F–J). PCA allowed separation of THP-1 MΦ seeded at different densities based on their functional profiles (Figure 1K). A large proportion of variation (61.27%) could be explained by PC1 which loadings included mitochondrial stress, lipid uptake, proliferation and phagocytosis, suggesting these functions to be mostly influenced by density. Variation along PC2 (largely attributable to inflammasome activation and cytokine secretion) almost exclusively manifested at the lowest density ( $0.2 \times 10^3$  cells/mm<sup>2</sup>). Together, these data demonstrate the profound and variable impact of culture density on several THP-1 MΦ functions. Execution of certain functions may depend on exceeding a lower density threshold.

### 3.2 Density influences the functional phenotype of primary MΦ

We also investigated whether culture density influences the functional phenotype of human MDM, pooled from 6 healthy donors. A significance matrix with the  $p$ -values of all group comparisons can be found in Supplementary Table 2. As seen in THP-1 MΦ, the number of detected nuclei increased with increasing seeding density (Supplementary Figures 1F–I). Phagocytic activity increased in the lower densities but decreased again at seeding densities exceeding  $3 \times 10^3$  cells/mm<sup>2</sup>, possibly reflecting limited substrate (Figure 2A). Using a constant substrate-to-cell ratio, increased phagocytosis also at higher densities could be observed (Supplementary Figure 2). OxLDL uptake between MDM seeded at different densities was similar, contrary to THP-1 MΦ (Figure 2B). With increasing density, MDM demonstrated more inflammasome activation (Figure 2C) and were more susceptible to mitochondrial stress (Figure 2D). Overall, our findings show that density also affects primary MΦ and leads to changes in several functions. In MDM, these changes were less pronounced and less consistent compared to THP-1 MΦ, suggesting that the observed impact of density on MΦ function may be particularly relevant for cell lines.

### 3.3 Colony formation may contribute to density-dependent functional effects

We observed that THP-1 MΦ formed colonies in culture, especially if cultured at higher densities. Thus, we set out to study if at least part of the density-dependent functional changes may be attributed to changes in the colony-forming growth pattern of THP-1 cells. We assessed the association between the functional outcome of an index cell with its distance to the closest neighboring cell. Index cells that were close to neighboring cells had higher proliferation rates compared to MΦ in more scarcely populated niches (Figure 3A). However, at very low seeding density ( $0.2 \times 10^3$  cells/mm<sup>2</sup>), MΦ proliferation was low regardless of the index cell's distance to neighboring cells, suggesting proliferation to be linked to colony formation. Similarly, we found that at a seeding density of  $0.2 \times 10^3$  cells/mm<sup>2</sup>, MΦ with neighboring cells in close proximity had taken up fewer fluorescent beads compared to equally dense MΦ seeded at higher densities (Figure 3B), a finding that was less pronounced for the uptake of oxLDL (Figure 3C). Interestingly, a similar proximity effect on phagocytosis and lipid uptake in MDM (Figures 3D, E), in which we did not observe colony formation in culture, was not apparent. These findings suggest that MΦ only exert certain functions beyond a local cell density threshold.

### 3.4 Functional differences between MDM of different donors may arise from density differences

Inter-donor variability has previously been proposed to compromise reproducibility of *in vitro* experiments with MDM (21, 22). Therefore, we looked at functions of MDM from 6 healthy

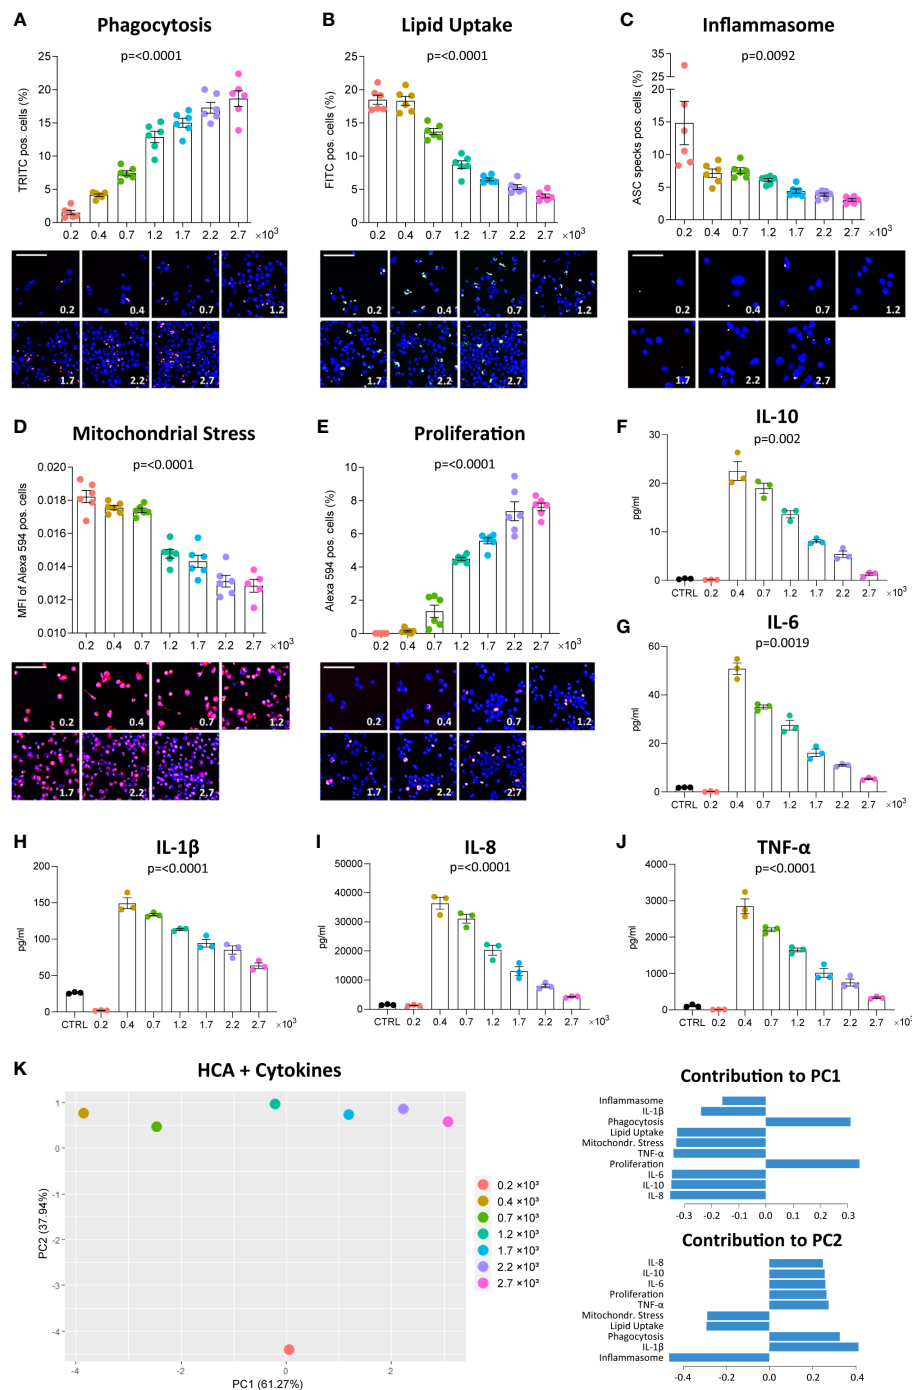

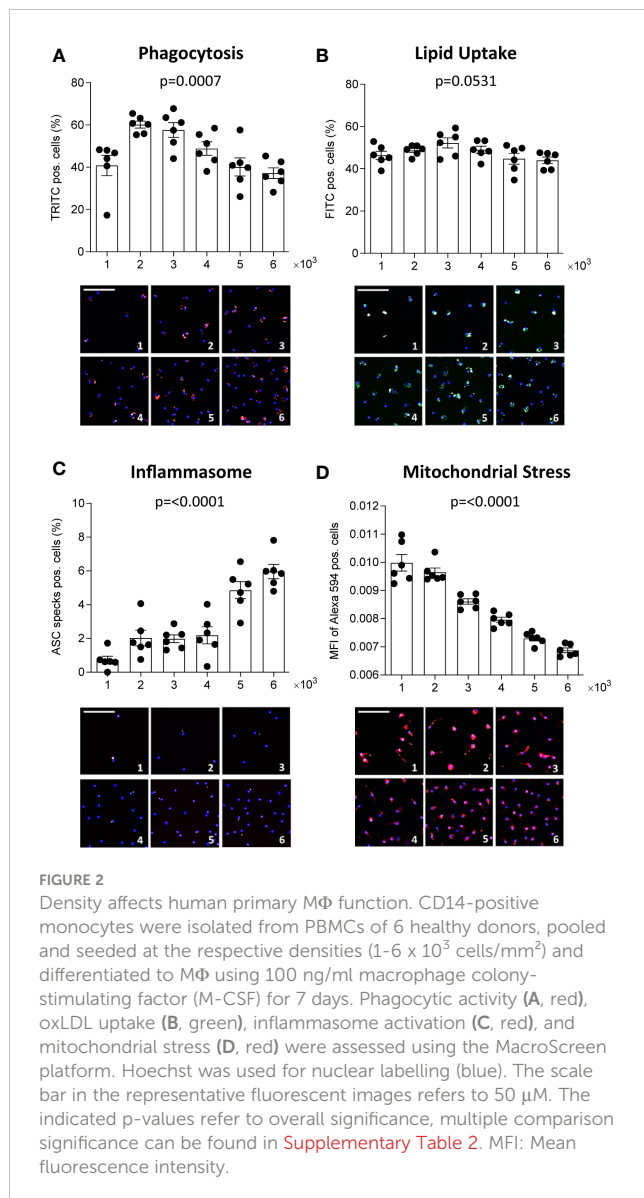

FIGURE 1

Density affects MΦ function. THP-1 cells were seeded at the respective densities ( $0.2$ – $2.7 \times 10^3$  cells/mm<sup>2</sup>) and differentiated with  $2000$  nM PMA for  $48$  hours followed by a resting period of  $24$  hours. Phagocytosis of zymosan-coated beads (A, red), uptake of fluorescently-labelled oxLDL (B, green), inflammasome activation (C, red), mitochondrial stress in response to staurosporine (D, red) and EdU incorporation in proliferating cells (E, red) were assessed using the fluorescent imaging MacroScreen platform. Hoechst was used for nuclear labelling (blue). In the representative fluorescent images, the scale bar refers to  $50 \mu\text{m}$ . In the representative images for the inflammasome assay, the scale bar refers to  $25 \mu\text{m}$ . Secretion of IL-10 (F), IL-6 (G), IL-1 $\beta$  (H), IL-8 (I), and TNF- $\alpha$  (J) in response to  $6$ -hour stimulation with  $50$  ng/ml LPS were measured by multiplex ELISA. Cells in the control (CTRL) condition were seeded at  $1.7 \times 10^3$  cells/mm<sup>2</sup> and not stimulated with LPS. The indicated p-values refer to overall significance, p-values of all group comparisons can be found in [Supplementary Table 1](#). (K) PCA plot of the high-content analysis (HCA) data and cytokine measurements with the factor loadings for PC1 and PC2. MFI: Mean fluorescence intensity.

donors (A–F) plated at the same density ( $13,000$  cells/well). A significance matrix with the p-values of all group comparisons can be found in [Supplementary Table 3](#). Differences in the number of nuclei (Figure 4A), phagocytosis (Figure 4B), oxLDL uptake

(Figure 4C), inflammasome activation (Figure 4D) and mitochondrial stress (Figure 4E) between donors were apparent. Interestingly, MDM from donors A and B, which showed higher phagocytic activity and oxLDL uptake, also had a higher number of

nuclei compared to the other donors. This suggests that functional differences between MDM obtained from different donors may well be related to inter-donor differences in density, possibly resulting from differences in adherence and survival capacity.

## 4 Discussion

*In vitro* studies are an indispensable step in the screening of genes or drugs and the safety testing of compounds, before costly and time-consuming pre-clinical *in vivo* studies may commence (23). Parameters that should be considered for robust *in vitro* testing include the culture medium and supplements such as growth factors or antibiotics, the culture dish and its coating, and culture maintenance (24). In this study, we have shown that culture density, a frequently overlooked factor, is an at least equally important parameter with major impact on MΦ assay outcome. As we show, density affects the functional phenotype of both THP-1

MΦ and primary MDM, with individual functions showing distinct density responses. Moreover, our data suggest the distance of index cells to their neighbor cells to influence functionality of THP-1 MΦ but less so of MDM, and the functional profiles and density response to vary considerably between donors.

The effect of low and high culture density on individual MΦ functions has been studied previously. In BMDM, secretion of TNF-α and other cytokines (MCP-1, RANTES, MIP-1α and MIP-1β) was found to increase with cell density (9). However, another study found BMDM at higher density to secrete less pro-inflammatory cytokines, including IL-6 and TNF-α (13). These contradicting results may be explained by differences in applied seeding densities in the two studies, as these were approximately 10 times higher in the latter study. Although our study did not look at BMDM, our THP-1 MΦ results do support a decrease of cytokine secretion with increasing density. However, at the lowest density, cytokine secretion by THP-1 MΦ was at most marginal, suggesting a defective response of sparsely seeded MΦ to toll-like receptor (TLR) activation, potentially due to quiescence or compromised viability.

Although phagocytosis and lipid uptake are both clearance mechanisms, they showed a divergent density response pattern in both THP-1 MΦ and MDM. Previously, THP-1 MΦ seeded at a lower density were found to show a 5-fold higher accumulation of esterified cholesterol after exposure to acetylated LDL (acLDL), which the authors attributed to increased scavenger receptor activity and acLDL degradation (15). Moreover, murine peritoneal IC-21 MΦ showed decreased phagocytosis of latex beads when seeded at a higher density (14), which partly concurs with our findings in human primary MDM and can be attributed to the limited availability of beads per cell. Bead concentration should be increased if cells are cultured at higher density to ensure sufficient bead availability for all actively phagocytosing cells.

Primary cells or cell lines are frequently and often interchangeably used in MΦ *in vitro* studies; the latter offering the advantages of easier availability and culture maintenance, and a uniform genetic background which may increase reproducibility (21). A serious disadvantage of cell lines is that compared to primary cells, they are to a certain degree de-differentiated and show clear transcriptional and functional differences. For example, the murine J774A.1 MΦ cell line and BMDM were found to respond differently to mycobacterial infection (25). Often myeloma-derived or immortalized cell lines have aberrant contact inhibition and growth patterns (26); indeed, we found the proximity of neighboring cells to have a greater impact on THP-1 MΦ than MDM function. In THP-1 MΦ, this may be attributed to increased proliferation at closer proximity which is absent at lower density, and suggests quorum sensing to induce functional changes locally at sites of colony formation. Comparing primary human monocytes with the monocytic cell lines U-937, HL-60, and THP-1, the latter were found to most closely resemble primary monocytes (27). Nevertheless, in contrast to primary MDM, cell line-derived MΦ do not capture inter-donor variability. This might be evaded by iPSC-derived MΦ, although Vaughan-Jackson et al. recently demonstrated density-related effects also in iPSC, including a more rounded and less elongated morphology, decreased cytokine secretion, and altered surface marker expression at higher density (28). However, it could be argued that also primary MΦ in monocultures *in vitro* do

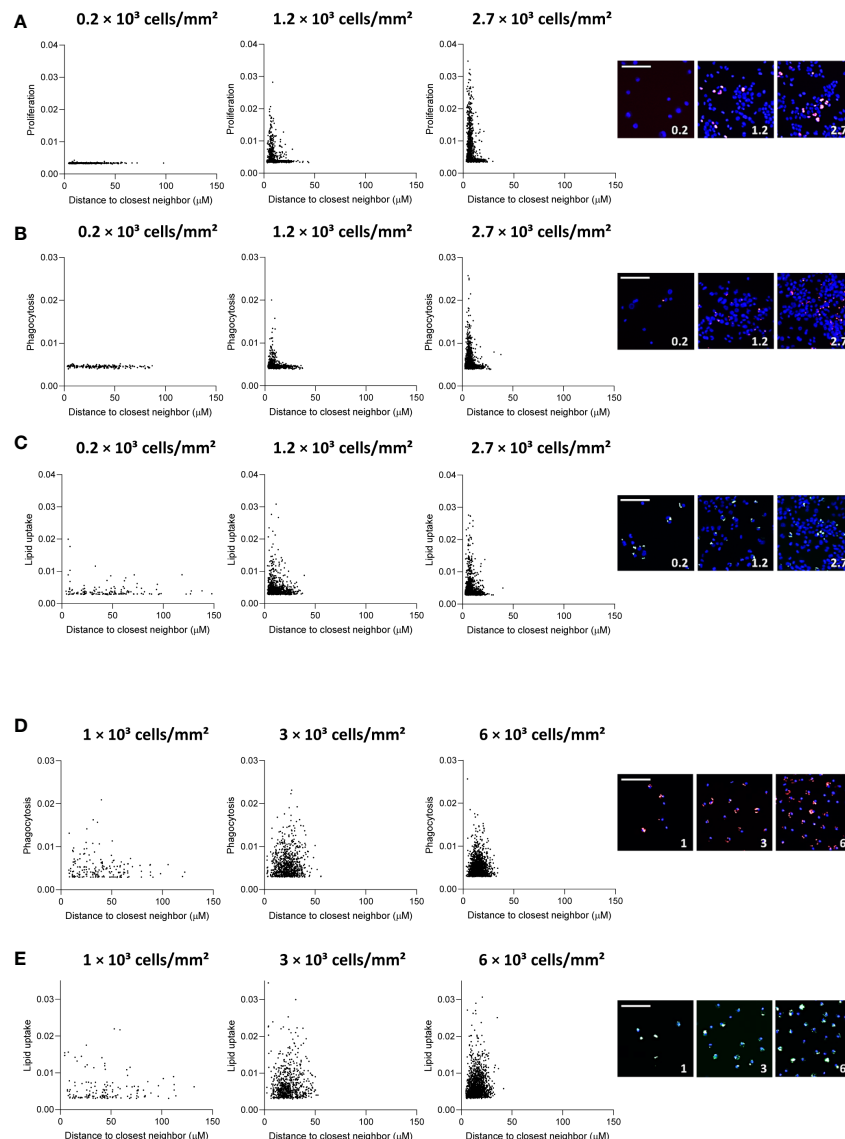

FIGURE 3

Distance to neighboring cells influences THP-1 function. Distance to closest neighbor was plotted against mean fluorescence intensity (MFI) per cell for proliferation (A), phagocytosis (B) and lipid uptake (C) assays in THP-1 MΦ, and (D) phagocytosis and (E) lipid uptake assay in primary MDM, for 3 plating densities each. The scale bar corresponds to 50 μm.

not mirror the *in vivo* conditions, where MΦ are embedded in a local heterogeneous tissue microenvironment with implications for cell function (21). The complex cellular and molecular microenvironment tissue MΦ are exposed to *in vivo* cannot be mimicked by exposure to a single or a few selected stimuli such as LPS and IFN-γ, or IL-4 and IL-10, as commonly done (29, 30).

Of note, we did not observe any indications for increased acidification of the culture medium which could explain the observed density effects and even at the highest density, the total cell number was most likely too low to deplete key nutrients. However, the comparability of our results on THP-1 MΦ and MDM may be impeded because different seeding densities had to be used due to the proliferating nature of the THP-1 cell line. In addition, the culturing process of MDM (7 days) and THP-1 MΦ (2 days PMA stimulation and 1 day resting) differs considerably. An extended resting period (5

days after 3 days PMA stimulation) has been shown to yield THP-1 MΦ with a phenotype closer to MDM (31). Moreover, the functional profile we provide here is not comprehensive as it only includes measurements of 5 cellular readouts and 5 cytokines. Future studies could reveal if the observed culture density effects also apply to other functions such as efferocytosis, susceptibility to apoptosis, production of reactive oxygen species (ROS), and metabolic differences.

In conclusion, our study highlights the importance of culture density for *in vitro* MΦ assay outcome and pleads for more awareness and closer monitoring of differences in cell density between conditions. This is particularly important for the THP-1 cell line which demonstrated more pronounced density effects compared to primary MDM, and when treatments are suspected to act pro-apoptotic or favor cell detachment or proliferation, which in turn impacts cell density. Moreover, a sufficiently large donor pool should be

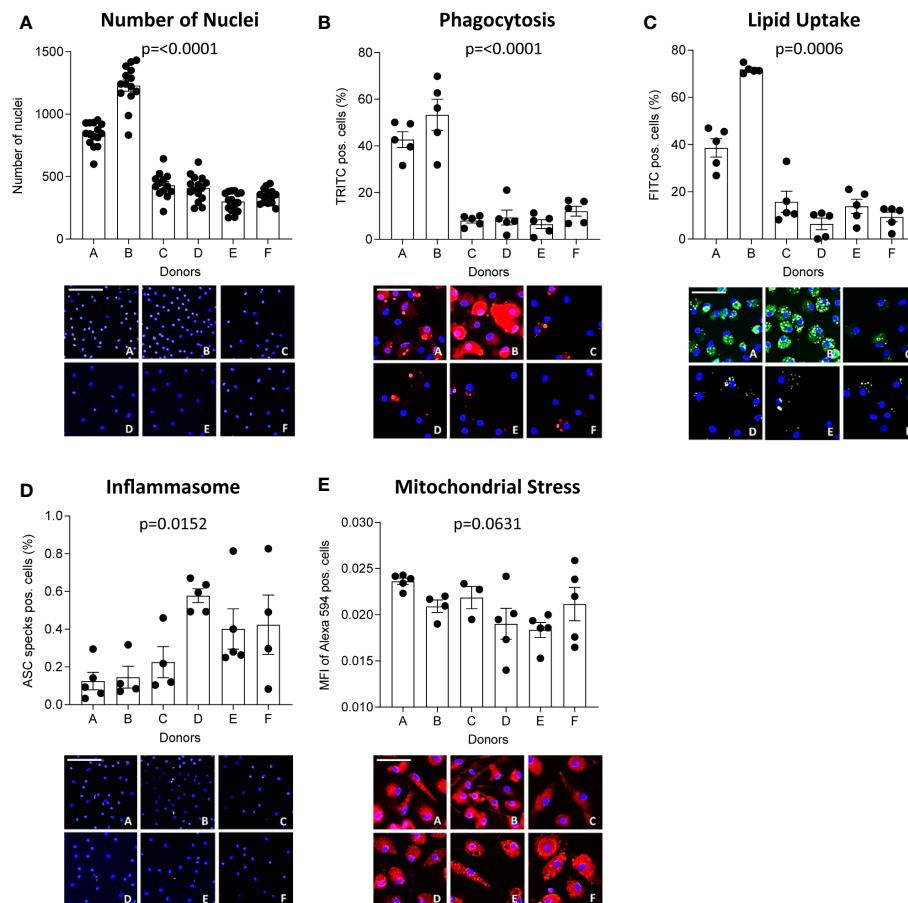

FIGURE 4

MΦ function differs between donors. CD14-positive monocytes of 6 healthy donors were seeded at 13,000 cells/well and differentiated into MΦ for 7 days using 100 ng/ml macrophage colony-stimulating factor (M-CSF). The number of nuclei per donor at experimentation (A) is given. Their functional phenotype was assessed using the MacroScreen platform: phagocytosis (B, red), lipid uptake (C, green), inflammasome activation (D, red), and mitochondrial stress (E, red). The scale bar corresponds to 25 μm. The indicated p-values refer to overall significance, multiple comparison significance can be found in [Supplementary Table 3](#). MFI: Mean fluorescence intensity.

used in experiments with primary MDM to account for inter-donor variability, as the number of cells after differentiation and culture differed between donors despite seeding at the same density. Disregarding density differences may lead to secondary effects on MΦ functions, and thus misinterpretation of findings.

## Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## Author contributions

AR, JN, LT, PG and EB contributed to the conception and design of the study. AR, JD and JN carried out the experiments. CL performed the bioinformatic analyses. PG, LT, JS and EB

contributed to the interpretation of results. AR wrote the manuscript with input from all authors. All authors contributed to the article and approved the submitted version.

## Funding

**Background:** High cytokine levels have been associated with severe COVID-19 disease. Although many cytokine studies have been performed, not many of them include combinatorial analysis of cytokine profiles through time. In this study we investigate the association of certain cytokine profiles and its evolution, and mortality in SARS-CoV2 infection in hospitalized patients.

**Methods:** Serum concentration of 45 cytokines was determined in 28 controls at day of admission and in 108 patients with COVID-19 disease at first, third and sixth day of admission. A principal component analysis (PCA) was performed to characterize cytokine profiles through time associated with mortality and survival in hospitalized patients.

**Results:** At day of admission non-survivors present significantly higher levels of IL-1 $\alpha$  and VEGFA (PC3) but not through follow up. However, the combination of HGF, MCP-1, IL-18, eotaxine, and SCF (PC2) are significantly higher in non-survivors at all three time-points presenting an increased trend in this group through time. On the other hand, BDNF, IL-12 and IL-15 (PC1) are significantly reduced in non-survivors at all time points with a decreasing trend through time, though a protective factor. The combined mortality prediction accuracy of PC3 at day 1 and PC1 and PC2 at day 6 is 89.00% ( $p < 0.001$ ).

**Conclusions:** Hypercytokinemia is a hallmark of COVID-19 but relevant differences between survivors and non-survivors can be early observed. Combinatorial analysis of serum cytokines and chemokines can contribute to mortality risk assessment and optimize therapeutic strategies. Three clusters of cytokines have been identified as independent markers or risk factors of COVID mortality.

#### KEYWORDS

COVID-19, cytokines, mortality, principal component analysis - PCA, hospitalized patients

## Introduction

Coronavirus disease 2019 (COVID-19) has emerged as a global infectious respiratory disease caused by a novel betacoronavirus: the SARS-CoV-2 (severe acute respiratory syndrome coronavirus 2) (1, 2). Since its emergence in December 2019 until December 2021, it has infected nearly 300 million people and killed more than 5 million people across the world (3). COVID-19 infection displays a wide clinical presentation ranging from asymptomatic or mild symptoms to severe pneumonia and critical respiratory failure (4). Due to its complex pathophysiology, prognosis at hospital admission remains a challenge.

Severe COVID-19 has been associated with an acute hyperimmune response known as “cytokine storm” or “cytokine release syndrome” (CRS) contributing to multiorgan failure (5). Recent studies suggest its relation to an impaired type I IFN immunity (6, 7). That hypercytokinemia, has been correlated with respiratory failure, ARDS and adverse clinical outcomes (8–10). Cytokines released by immune cells in case of uncontrolled inflammation, have been studied as markers and profiles of severity to predict outcomes (11–16). Although individual cytokine analysis can shed some light on COVID-19 pathology, the immune responses are complex, and a combinatorial analysis could better explain the relations between cytokine levels. Previous studies with principal component analysis (PCA) and transcriptomic have determined the cytokine profiles regarding COVID-19 severity and mortality (7, 17–19). However, differences between the different cytokine profiles and how they evolve through time in hospitalized patients, comparing mortality and survival has not been performed yet.

In this study, we aimed to establish the timeline of different cytokine profiles that help to predict patient outcome in order to anticipate, adapt treatment and improve survival.

## Materials and methods

### Study design

We performed a prospective study at Hospital Clínico of Valladolid (Spain). A total of 108 patients with RT-PCR-confirmed SARS-CoV2 infection and were recruited from late March to 11th April of 2020. Patients with other active infections or a terminal chronic disease were excluded. Patients were divided into two groups according to the occurrence of mortality. In addition, 28 age and gender matched healthy volunteers with a negative RT-PCR test for SARS-CoV2 infection were also recruited during routine pre-anesthetic evaluation for scheduled surgery. The present study was approved by the Valladolid Hospital's Clinical Ethics Committee (CEIm) (cod: PI 20-1717) and all subjects provided a written informed consent.

Plasma samples were collected the first, third and sixth day of hospital admission in 3.2% sodium citrate tubes and centrifuged at 2000 g for 20 minutes at room temperature. Plasma was aliquoted and stored at -80°C until used.

### Cytokine analysis

Concentration of 45 cytokines in plasma was determined by 45-plex Human XL Cytokine Luminex Performance Panel (R&D), following manufacturer instructions. The cytokines analyzed are the following ones: BDNF, EGF, eotaxin (also known as CCL11), FGF-2, GM-CSF, GRO- $\alpha$  (CXCL1), HGF, IFN- $\alpha$ , IFN- $\gamma$ , IL-1 $\alpha$ , IL-1 $\beta$ , IL-10, IL-12 p70, IL-13, IL-15, IL-17a (CTLA-18), IL-18, IL-1RA, IL-2, IL-21, IL-22, IL-23, IL-27, IL-31, IL-4, IL-5, IL-6, IL-7, IL-8 (also known as CXCL8), IL-9, IP-1 beta (CCL4), IP-10 (CXCL10), LIF, MCP-1 (CCL2), MIP-1 $\alpha$  (CCL3), NGF- $\beta$ , PDGF-BB, PIGF-1, RANTES (CCL5), SCF, SDF-1 $\alpha$ , TNF- $\alpha$ , TNF- $\beta$ , VEGF-A, and VEGF-D.

## Statistical analysis

Since most of the cytokine data did not follow a normal distribution, continuous variables were presented in terms of median (interquartile range, IQR) and compared among groups using the Mann-Whitney U-test or T-test. Categorical variables were described as count and percentages, which were compared using the  $\chi^2$  test or Fisher exact test, when appropriate.

Distributions of the cytokine values were assessed and log2 transformed to render the principal component analysis (PCA). PCA was carried out with all variables related to cytokine concentrations that showed significant differences between survivors and non-survivors in the univariate analysis, on at least one of the three analyzed days. All participants for whom the variables of interest were available were included in the final analysis and no assumptions were made for missing data. Prior to extraction of factors, Kaiser-Meyer-Olkin (KMO) measure of sampling adequacy and the Bartlett test of sphericity were checked to evaluate the fitness of the data for factor analysis. The factor solution was formed based on the eigenvalues, which represent the amount of variance captured by given components. Factors with eigenvalues  $>1.0$  were retained, according to the Kaiser-Guttman criterion and the Scree Plot. Then we optimized the factor solution using varimax rotation. A factor-based-score was calculated for each component, and we estimated the factor scores on all COVID-19 patients at the first, third and sixth day of admission.

To assess changes over time in outcome measures within each group, Friedman's repeated measures test with Dunn's multiple comparison test was used for non-parametric data and a repeated-measures analysis of variance (RM-ANOVA) with Tukey's multiple comparison test for parametric data.

A multivariable logistic regression analysis was performed to estimate the relevance of each factor obtained in the PCA analysis, differentiating the profile of the patients who survived versus those who did not survive 28 days after admission. The logistic regression model was internally validated by performing bootstrap resampling (1000 resamples). The area under the receiver operating characteristic curves (AUC ROC) shows the accuracy for the final logistic regression model and individual predictors. All statistical analyses were performed using SPSS version 28.0 for Windows (SPSS, Inc, Chicago, Ill). A p-value of less than 0.05 was regarded as statistically significant.

## Results

### Characteristics of the patients

A total of 108 hospitalized subjects admitted with clinical SARS-CoV-2 pneumonia were enrolled, of whom 20 died within 28 days after admission and composed the non-survivors' group.

The other 88 patients were included in the survivors' group. Baseline characteristics of patients are reported in [Table 1](#). The group of non-survivors was significantly older than the other group. There were no differences in terms of gender and comorbidities between groups. Considering the analytical variables, non-survivors presented higher levels of glycaemia, creatinine, leukocytes, neutrophils, procalcitonin, CRP, D-dimer and LDH. There were no significant differences in clinical outcomes referring to the percentage of patients with invasive mechanical ventilation and length of stay in hospital and intensive care unit.

### Cytokine profile

In bivariate analysis, the levels of 10 cytokines were different ( $p < 0.05$ ), at least in one of the three moments (1, 3 and 6 days) between survivors and non-survivors ([Tables S1–3](#)). On the first day of admission ([Table S1](#)), significant differences were observed regarding HGF, IL-2, IL-1 $\alpha$ , IL-15 and VEGFA levels. IL-15 and IL-2 were the only cytokines whose levels were significantly reduced by half in the group of non-survivors at 28 days. The rest of cytokines were significantly increased in this group. Specifically, IL-1 $\alpha$  and VEGFA quadrupled and doubled their levels, respectively. On the third day of admission ([Table S2](#)), differences between groups were found in the case of BDNF, eotaxin, IL-18 and again HGF and IL-15 levels. In non-survivors, levels of HGF and IL-18 were significantly higher, where HGF tripled the levels compared to survivors. On the other hand, levels of BDNF, eotaxin and IL-15 were significantly lower in this group. Finally, on the sixth day of admission ([Table S3](#)), cytokines significantly elevated in non-survivors were SCF, MCP-1, IL-18, VEGFA and HGF. The exception became again IL-15, which barely showed variation over time, and whose levels in non-survivors remained the half of those in survivors. IL-18 increased its levels compared to day 3 of admission; and VEGFA, which significantly doubled the level on the first day of admission, tripled the levels in non-survivors on the sixth day. However, HGF stands out as the only cytokine that remained significantly elevated in the group of non-survivors through all three measurement times, reaching its maximum peak and difference compared to survivors, on the sixth day of admission.

Some of these 10 cytokines and chemokines (IL-1 $\alpha$ , IL-2, IL-15, IL-18, eotaxin, HGF, MCP-1, SCF and VEGFA) have been linked to different aspects of COVID-19 disease, its severity and even mortality but a combinatorial analysis can help us to understand its complex interaction. Principal component analysis (PCA) is a technique for reducing the dimensionality of such datasets, increasing interpretability but at the same time minimizing information loss.

TABLE 1 Clinical characteristics of the patients. Data are represented as [median (IQR)] and as [% (n)].

	Non-survivors at 28 days (N=20)	Survivors (N=88)	p-value
Age in years [median (IQR)]	73.5 (14)	67 (17)	0.017

## Principal component analysis

The Kaiser-Meyer-Olkin measure of sampling adequacy (0.7) and the Bartlett test of sphericity ( $p < 0.001$ ) indicated that the factor matrix was adequate for data (Table S4).

PCA resulted in three components with eigenvalues greater than one that describe relationships between cytokines' levels in patients with COVID-19. The three components accounted for 66.09% of the total variance. PC1, PC2, and PC3 accounted for 32.63%, 19.14%, and 14.32% of the variance, respectively. PC1 is composed by IL-15, IL-2 and BDNF; PC2 by HGF, MCP-1, IL-18, eotaxin and SCF; and PC3 by IL-1 $\alpha$  and VEGFA. Figure 1 show three-dimensional score plot illustrating how cytokines were distributed on PCs.

The algorithms of the principal components were applied to all patients and calculated scores were saved as new variables PC1, PC2 and PC3 at the first, third and sixth day of admission.

## Principal components score in COVID patients vs control group

In addition, the algorithms of the principal components were applied to the control group and the PCA scores (PC1, PC2 y PC3) were compared between COVID-19 and healthy SARS-CoV-2-negative control subjects on the day of admission. The calculated scores were higher in COVID-19 patients than in controls: PC1 ( $t_{(52,26)} = 3.53$ ;  $p = 0.001$ ); PC2 ( $U = 988.00$ ;  $p =$

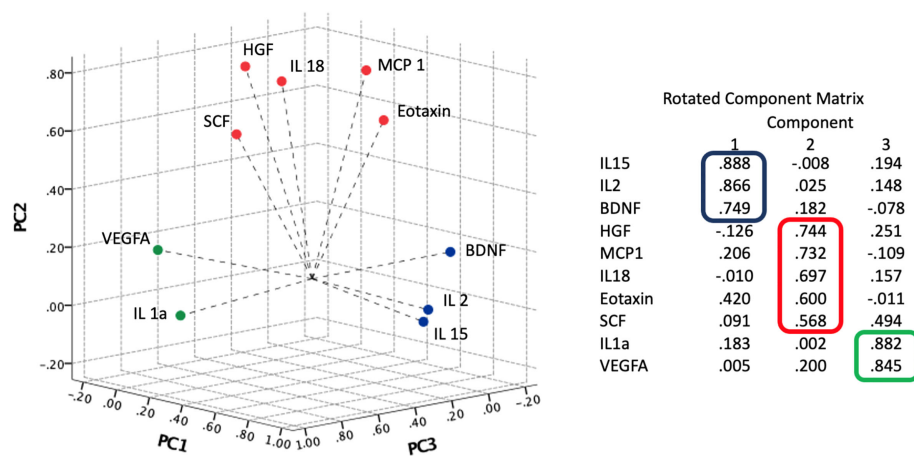

FIGURE 1

Component plot in rotated space. Results of principal component analysis (PCA) and Varimax rotation method with Kaiser normalization. The three components accounted for 66.09% of the total variance.

0.005); PC3 ( $U = 1111.00$ ;  $p = 0.031$ ). These values let us confirm that those cytokines are different between infected and healthy subjects, emphasizing the importance of these cytokines in COVID-19 infection.

## Principal components score in survivors vs non-survivors

Figure 2 shows PC1, PC2 and PC3 scores at the first, third and sixth day of admission for survivors and non-survivors. In Figure 2A, significant differences are observed between both groups. Mortality was associated with lower scores of PC1 and higher scores of PC2 and PC3. This indicates that higher scores in PC1 are protective while PC2 and PC3 represent risk factors. In contrast to PC3, which is only significantly elevated in non-survivors at day one; the differences between survivors and non-survivors in the cytokines of PC1 and PC2 intensified through time. Figure 2B shows that in the first 6 days of hospitalization, the mean score is stable and significantly lower for patients who survived than for those who died. In addition, a growing trend is observed for this marker in patients who did not survive.

## Multivariate analysis of principal components associated with mortality at 28 days

Sex and age between both groups were not significant variables in the final adjusted model. Logistic regression analysis (Table S5) showed that on the day of admission, only

the combination of cytokines defined by PC3 was significant [OR: 2.35, 95%CI: 1.09–5.06,  $p = 0.029$ ]. In contrast, PC1 and PC2 were significant on the sixth day of admission, where PC1 cytokines represented a protective factor relative to mortality at 28 days [OR: 0.273, 95%CI: 0.12–0.64,  $p = 0.003$ ] while PC2 was pointed out as the major risk factor [OR: 5.24, 95%CI: 2.03–13.48,  $p = 0.001$ ]. ROC curves of significant factors and predicted probability for final logistic regression model are shown in Figure 3. The area under the curve ( $AUC = 0.89$ , 95%CI= 0.81–0.96,  $p < 0.001$ ) shows a good discrimination ability of the model.

## Discussion

Several studies have been carried out comparing cytokine profiles in severe and moderate COVID-19 (20–23). However, there are fewer studies comparing differences in cytokine profiles between survivors and non-survivors or analyzing the relationship between the evolution of cytokines profile in COVID-19 hospitalized patients and mortality (17, 24). Severe disease is characterized by acute lung injury (ALI) that can eventually lead to highly lethal acute respiratory distress syndrome (ARDS) and a cytokine storm (25, 26). Previous studies have associated the significant elevation of many cytokines such as IL-2, IL-7, IL-10, GSCF, IP-10, MCP-1, MIP-1a and TNF- $\alpha$  in the blood of patients with severity of the disease. Particularly the level of IL-6 and IL-10 (27–30). However, we found three cytokine clusters (PC1, PC2 and PC3) that could be considered as independent risk factors. Their different contribution would be associated to a higher or lower mortality risk. On one hand, IL-2, IL-15 and BDNF levels (PC1) are significantly reduced in the group of non-survivors, which

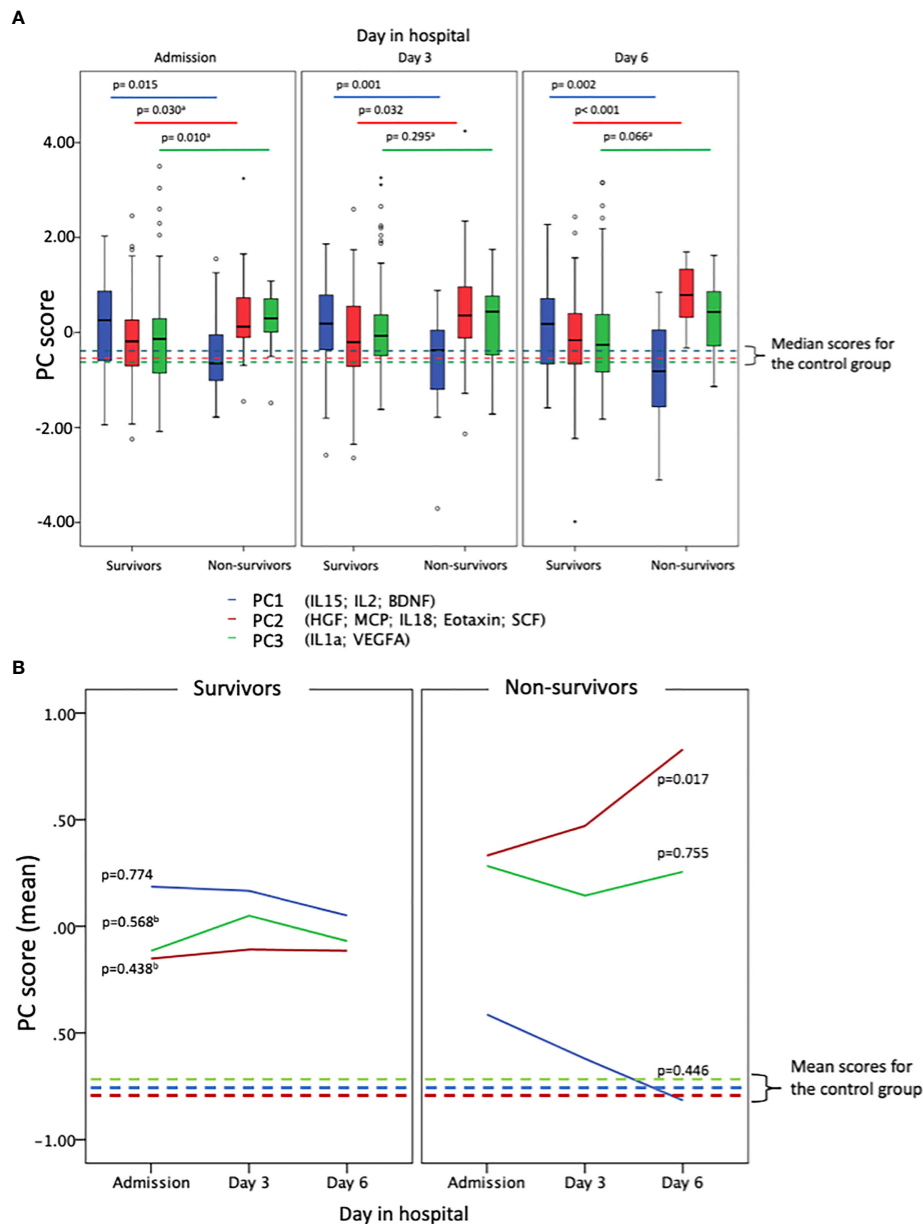

FIGURE 2

PC scores for COVID patients (survivors and non-survivors) and controls when applying PC estimators. In blue PC1 groups IL-15; IL-2 and BDNF. In red PC2 groups HGF; MCP1; IL-18; eotaxin and SCF. In green PC3 groups IL-1a and VEGFA. **(A)** Box-plots shows the different contribution of each of the factors obtained in the analysis of principal components for survivors and non-survivors, showing, in addition, three moments in the evolution of the disease (first, third and sixth days of admission of the patients). **(B)** Shows that in the first 6 days of hospitalization, the mean score is stable and significantly lower for patients who survived than for those who died. In addition, a growing trend is observed for this marker in patients who did not survive. Trends over time of the PC scores for survivors and non-survivors were calculated separately by using RM-ANOVA or Friedman test.

suggests they constitute a protective factor. In contrast, cytokines included in PC2 (HGF, SCF, IL-18, MCP-1 and eotaxin) together with the combination of PC3 (IL-1 $\alpha$  and VEGFA) are significantly increased in non-survivors representing a risk factor for mortality at 28 days. It is interesting that, while PC1

and PC2 are significantly reduced and increased, respectively, at the three stages evaluated; PC3 only showed to be significantly increased in non-survivors at the day of admission. In addition, whereas no trend is observed in PC1 or PC3, PC2 seems to display an increasing trend through time.

FIGURE 3

Receiver operating characteristic (ROC) curves for the predicted probability of the logistic regression model and significant predictors for 28-day mortality (PC3 at the day of admission, PC1 and PC2 at the sixth day after admission).

PC3, constituted by the combination of IL-1 $\alpha$  and VEGFA is only significantly increased at day of admission. The importance of this set at day 0 may be explained by its implication in the initial response to COVID-19 severe infection. Initial COVID-19 studies revealed higher levels of IL-1 $\alpha$ , which is a cytokine of initial states of the innate immune response (31). Actually, IL-1 $\alpha$  has recently been described as an early marker to predict a bad outcome in COVID-19 severe patients (23). This could be explained by the fact that the precursor of IL-1 $\alpha$ , in contrast to IL-1 $\beta$  or IL-1 $\alpha$ , does not need to be activated and is capable of triggering a powerful inflammatory response when it is released by damaged cells (32). Its main biological activities are activation of T lymphocytes, and B cell proliferation along with synthesis of immunoglobulins (31). On the other hand, VEGFA has a key role in lung development resulting in an appropriate organization of the pulmonary vascular network (33). VEGFA can be released during hypoxia, in inflammatory situations where there is damage to the endothelium. Its effect is mediated by VEGFR-1 and VEGFR-2 that contribute to hematopoiesis and monocyte chemotaxis and increased permeability, respectively. PC3 component could be interpreted as the initial expression of the existence of a severe cell damage in lungs due to macrophage infiltration produced by

SARS-CoV-2 virus (34), which would initiate the subsequent fatal pathogenesis and exacerbate the immune response observed in following stages of disease. As a matter of fact, our results support previous studies that prove the early use in severe disease of treatments with IL-1 antagonists such as anakinra, improves outcome by blocking progression of the cytokine storm (35).

Our results showed that despite cytokine levels were increased in both survivors and non-survivors, in the first group levels remain similar through time. However, there is a significant upward trend in PC2 in non-survivors through time, which could remark their importance as mortality markers, as they are particularly elevated at day 6. The cytokines of PC2 are HGF, SCF, IL-18, MCP-1 and eotaxin. The importance of PC2 is that, altogether, represent the intense and probably irretrievable damage in lung tissue due to the virus itself as well as the extreme immune response. First, IL-18, a cytokine belonging to the IL-1 family and intervening in cellular immune response it is secreted upon macrophage activation in viral infections and courses with endothelial damage in lung tissue (32). IL-18 binds in its mature form to specific receptor IL-1 receptor 5 (IL-1R5, known as IL-18 receptor alpha chain), leading to the recruitment of the coreceptor, IL-1 receptor 7 (IL-1R7, known as IL-18 receptor

beta chain). IL-18BP, a natural inhibitor of IL-18, circulates maintaining a balance between both of them. Severe COVID-19 patients have been shown to have an imbalance of IL-18/IL-18BP (36, 37). Actually, an antibody against IL-1R7 has been proposed to reduce inflammatory signalling of IL-18 in COVID-19 patients (38). SCF, HGF and eotaxin are upregulated by inflammatory processes and secreted by mast cells upon cytokine stimulation including IL-18. All of them have also been related to severe lung injury. Eotaxin and SCF play a central role in mast cell and eosinophilic infiltration and, SCF promotes the expression and release of MCP-1 from lung mast cells (39–41). In addition, HGF can promote the development of different cell lineages, including thrombocytes, as to contribute to tissue repair and modulate the adaptive immune response to control inflammation (15, 42). Worthy of remark is that HGF and eotaxin were found to be elevated in patients with severe influenza A (H1N1) virus and other viral infections and in patients with inflammatory lung injury (43–46). Finally, we have MCP-1, which has been previously described as a factor to predict severity in COVID-19 patients due to its activity in monocyte recruitment to arterial wall (47). More than 70% of the deaths related to COVID-19 are associated with deregulation of the mechanisms that control blood clotting, as a part of the innate immune response to limit pathogen spread in a process known as immunothrombosis (48, 49). Moreover, hypoxic environment due to pulmonary affection activates pro-coagulation factors that may promote thrombosis (50). In our work, both MCP-1 and D-dimer are elevated in non-survivors indicating thrombotic events were taking place. Taking together PC2, has a potential as a marker of bad prognosis due to extreme inflammation and lung injury.

According to the logistic regression model, the most contributing factor to survival in this case is a protective factor for mortality that involves high plasma levels of the cytokines IL-2, IL-15 and BDNF in survivors compared to those determined in deceased patients. The elevation of the plasmatic levels of some of these three cytokines would, therefore, increase this protective factor. BDNF has a pivotal role in neuroplasticity that is considerably affected by inflammatory states. The most common pro-inflammatory cytokines are IL-1 $\beta$ , IL-6, TNF- $\alpha$  and IFN- $\gamma$  cause a significant reduction of BDNF gene expression (51). In fact, low serum BDNF levels were correlated with severe SARS-CoV-2 infection in a recent study where BDNF levels were restored during patients' recovery. This has been linked to the lymphopenia observed in critical COVID-19 patients as lymphocytes contribute to peripheral BDNF secretion (52). IL-2 and IL-15 have several similar functions. Both cytokines stimulate the proliferation of T cells; induce the generation of cytotoxic T lymphocytes; facilitate the proliferation of B cells as well as immunoglobulin secretion; and induce generation and persistence of natural killer cells (53). On one hand, IL-15 has a pivotal role in viral clearance by long-lasting, high avidity T-cell responses to invading pathogens by

ensuring survival of memory cells. Actually, influenza and other respiratory viruses induce peripheral and local expression of IL-15, which is critical for anti-viral responses by different lymphocyte populations. Low levels of circulating IL-15 have been associated with high viremia and poor disease outcome (54). On the other hand, IL-2 is involved in maintenance of peripheral regulatory T cells and elimination of self-reactive ones (53). What is more important, both IL-2 and IL-15 can regulate cell proliferation, thus controlling excessive response (31). The progressive decrease of BDNF, IL-15 and IL-2 in plasma may be a warning factor of disease deterioration in severe patients with COVID-19 pneumonia. For that matter, IL-2 and IL-15 supplementation have been proposed as to improve the immune disorder and reduce mortality (55, 56).

The independence of the three factors suggests three possible independent therapeutic pathways of intervention. One aimed at stopping the initial proinflammatory response by blocking IL-1 and VEGFA. Other aimed at regulating the immune response by increasing IL-15 levels, IL-2 and BDNF. And other aimed at limiting lung tissue by interfering with HGF, SCF, IL-18, MCP-1 or eotaxin. As a multiphasic disease, immune monitoring and multiple targets would be a great approach to improve outcomes.

The main limitations of the study are that we only performed a plasma analysis including 45 cytokines. This means some relevant cytokines in severity of COVID-19, might not be included. However, we selected this panel as it was the most complete available for cytokine analysis and eligible for clinical implementation. As future directions, we considered it would be interesting to confirm our results, especially in relevant cytokines by a classic ELISA analysis. In addition, we consider it would be interesting to evaluate cytokine profiles in healthy population and how these levels correlate with clinical parameters and outcomes. Also, a further multicentric corroboration of our findings would be of interest.

## Conclusions

In summary our findings unravel the cytokine evolution in relation to mortality caused by COVID-19 disease. We propose the use of PC2 associated with clinical data as a marker of strong lung damage, and evolution of values of PC1 and PC3 to predict outcome thus personalize treatment. In addition, we consider early target of the markers of dysregulation of immune responses and therapies to promote tissue repair could be a better approach in severe patients as antiviral therapy could not be useful at that point.

**Introduction:** Biomarkers predicting mortality among critical Coronavirus disease 2019 (COVID-19) patients provide insight into the underlying pathophysiology of fatal disease and assist with triaging of cases in overburdened settings. However, data describing these biomarkers in Sub-Saharan African populations are sparse.

**Methods:** We collected serum samples and corresponding clinical data from 87 patients with critical COVID-19 on day 1 of admission to the intensive care unit (ICU) of a tertiary hospital in Cape Town, South Africa, during the second wave of the COVID-19 pandemic. A second sample from the same patients was collected on day 7 of ICU admission. Patients were followed up until in-hospital death or hospital discharge. A custom-designed 52 biomarker panel was performed on the Luminex® platform. Data were analyzed for any association between biomarkers and mortality based on pre-determined functional groups, and individual analytes.

**Results:** Of 87 patients, 55 (63.2%) died and 32 (36.8%) survived. We found a dysregulated cytokine response in patients who died, with elevated levels of type-1 and type-2 cytokines, chemokines, and acute phase reactants, as well as reduced levels of regulatory T cell cytokines. Interleukin (IL)-15 and IL-18 were elevated in those who died, and levels reduced over time in those who survived. Procalcitonin (PCT), C-reactive protein, Endothelin-1 and vascular cell adhesion molecule-1 were elevated in those who died.

**Discussion:** These results show the pattern of dysregulation in critical COVID-19 in a Sub-Saharan African cohort. They suggest that fatal COVID-19 involved excessive activation of cytotoxic cells and the NLRP3 (nucleotide-binding domain, leucine-rich-containing family, pyrin domain-containing-3) inflammasome. Furthermore, superinfection and endothelial dysfunction with thrombosis might have contributed to mortality. HIV infection did not affect the outcome. A clinically relevant biosignature including PCT, pH and lymphocyte percentage on differential count, had an 84.8% sensitivity for mortality, and outperformed the Luminex-derived biosignature.

#### KEYWORDS

biomarkers, cytokines, COVID-19, SARS-CoV-2, prognostic, mortality

## 1 Introduction

Understanding the mechanisms driving severe disease and causing mortality or recovery among Coronavirus disease 2019 (COVID-19) patients is crucial for developing future clinical decision support systems, planning disease control strategies, and developing host-directed therapies. Older age, obesity, diabetes, hypertension, lymphopenia, and neutrophilia have been consistently identified in many studies as predictors of mortality (1, 2). HIV has also been associated with poor outcomes from COVID-19 in multi-center prospective studies, especially in people with a low CD4 cell count (3, 4). Many immunological biomarkers of mortality have been reported, such as interleukin-1 $\alpha$  (IL-1 $\alpha$ ), IL-1 $\beta$ , IL-6, IL-10, IL-18, and tumor necrosis factor (TNF) (5, 6). Along with ferritin, D-dimer, C-reactive protein (CRP), and procalcitonin (PCT), these immunologic biomarkers are found in the group of people infected with Severe Acute Respiratory Syndrome coronavirus-2 (SARS-CoV-2) who develop hyperinflammation, known as a ‘cytokine storm’ (2). Excessive cytokine production from inflammatory cell death is associated with acute organ damage which is life-threatening. This is mediated in part by synergism between TNF and interferon gamma (IFN $\gamma$ ), which triggers the PANoptosis (pyroptosis, apoptosis, and necroptosis), a mechanistic compendium of programmed cell death pathways (7). In addition to hyperinflammation, endothelial markers such as intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and E-selectin have been associated with disease severity and death. This highlights the important role of vascular endothelial cells as targets of SARS-CoV-2, and of endothelial activation with dysfunction in the pathogenesis of severe COVID-19 (8, 9).

Despite the extraordinary number of publications on this topic during the pandemic, few data from African countries are available

in the public domain. Furthermore, Sub-Saharan African populations have a low vaccination coverage to mitigate the effects of future waves or variants which escape immunity acquired from previous infection (10). Therefore, data on the predictors of mortality in Sub-Saharan African populations are greatly needed. The second wave of COVID-19 in South Africa, which occurred between October 2020 and February 2021, was dominated by the B.1.351 Beta variant of SARS-CoV-2 (10). The rapid spread of infection in the population resulted in a high rate of admission of critically ill patients that overwhelmed the health care services. The B.1.351 Beta variant was associated with a high mortality rate among patients admitted in the Intensive Care Unit (ICU) and other healthcare environments (10).

In this study, our team examined the serum of critical COVID-19 patients in Cape Town, South Africa, for key immunological and endothelial cell biomarkers of mortality. The aim was to gain insight into the immune mechanisms underlying fatal COVID-19 and identify the biomarkers with the best predictive potential.

## 2 Materials and methods

This investigation was a sub-study of a large prospective cohort spanning the whole COVID-19 pandemic, performed in the ICU of Tygerberg Hospital, Cape Town, South Africa. Participants for this sub-study were admitted during the second wave of the COVID-19 pandemic from 9 October 2020 to 10 February 2021. All adult patients admitted to the ICU during this timeframe with laboratory-confirmed SARS-CoV-2 infection on quantitative real-time reverse transcription polymerase chain reaction (RT-qPCR) from nasopharyngeal swab testing, and COVID-19 acute respiratory distress syndrome (ARDS) according to the Berlin definition (11),

were recruited on the day of admission to ICU. They were followed until the primary endpoint of death or survival to hospital discharge. Eligibility for ICU admission was predetermined by the provincial Department of Health guidelines, based on the severity of illness, likely prognosis, and ICU bed availability (12).

Baseline demographic characteristics, comorbidities, medication history, and indicators of the severity of illness (i.e., type and intensity of respiratory support, arterial blood gas values, and evidence of other organ dysfunction) were collected and transferred by authorized study staff to an access-controlled Research Electronic Data Capture (REDCap®) database hosted by Stellenbosch University (13). Baseline laboratory measurements were retrieved from the National Health Laboratory Service (NHLS) Laboratory Information System (TrakCare® Lab Enterprise). Only results from blood taken on the day of ICU admission were used. In cases where a full panel blood test was not performed on the day of ICU admission, the results from blood taken within 48 hours of the date and time of ICU admission were used. The first arterial blood gas performed after admission to ICU was selected for the analysis, irrespective of the type of respiratory support at that time. Further data on the patient's clinical progress during admission were collected, including the primary outcome of death or discharge from the hospital, progression to mechanical ventilation, and initiation of new medications. Data were verified remotely using electronic hospital records and the TrakCare® system. Serum samples were collected from all patients on day 1 (the day of ICU admission), and a second sample was collected from those who survived to day 7, to capture the trajectory of key analytes at a time point when they were likely to differentiate between survivors and non-survivors (5).

## 2.1 Laboratory procedures

The baseline blood tests and SARS-CoV-2 RT-qPCR were performed according to the protocols of the NHLS at Tygerberg Hospital, accredited as ISO15189 compliant by the South African National Accreditation Services (SANAS), and all methods are subjected to both internal and external quality control schemes. These methods have been described in a previous publication (14).

Day 1 and day 7 serum samples were aliquoted and frozen at -80°C on the day of sampling. After a single freeze-thaw cycle, a magnetic Luminex® assay with a Luminex® MAGPIX® CCD Imager [xPONENT® software; Research and Diagnostics Systems Inc.® a Bio-technie® brand (Catalog number LXSAHM); Minneapolis, NE, USA] was used to determine the levels of a custom-designed 52-analyte panel of immune and vascular/endothelial cell biomarkers including: Arginase-1, CRP, D-dimer, Endothelin-1 (ET-1), E-Selectin, ferritin, growth differentiation factor-15 (GDF-15), granulocyte macrophage colony stimulating factor (GM-CSF), granulysin, hypoxia inducible factor 1- $\alpha$  (HIF1 $\alpha$ ), High mobility group box 1 (HMGB1), I-309/chemokine ligand 1 (I-309/CCL1), ICAM-1, Indoleamine-2,3-dioxygenase 1 (IDO-1), IFN $\beta$ , IFN $\gamma$ , IL-1a, IL-1b, IL-1Ra, IL-2, IL-4, IL-5, IL-6, IL-8, IL-10, IL-13, IL-15, IL-17, IL-18, IL-21, IL-22, IL-23, IL-33, Interferon gamma-induced protein 10/Chemokine (C-X-C motif) ligand 10 (IP-10/CXCL10), monocyte chemoattractant protein 1/chemokine (C-C motif) ligand

2 (MCP-1/CCL2), MCP-3/CCL7), MCP-4/CCL13, monokine induced by gamma interferon/Chemokine (C-X-C motif) ligand 9 (MIG/CXCL9), myeloperoxidase (MPO), plasminogen activator inhibitor-1 (PAI-1), PCT, P-selectin, S100 calcium-binding protein A8/migration inhibitory factor-related protein 8 (S100A8/MRP-8), S100 calcium-binding protein A9/migration inhibitory factor-related protein 14 (S100A9/MRP-14), growth stimulation gene-2/Interleukin-1 receptor-like-1 (ST2/IL-1RL1), transforming growth factor  $\beta$ 1 (TGF $\beta$ 1), TGF $\beta$ 2, TGF $\beta$ 3, TNF $\alpha$ , VCAM-1, vascular endothelial growth factor (VEGF), Von Willebrand Factor A2 (vWF A2). Analyte kits were supplied by Whitehead Scientific (Pty) Ltd, Cape Town, South Africa, and Merck (Pty) Ltd, Gauteng, South Africa.

## 2.2 Statistical analysis

Data were analyzed using R suite® statistical software (R version 4.2.3) (15). Selected clinical variables, NHLS-derived laboratory variables, and all Luminex®-derived variables were assessed for their effect on the primary outcome of death, or survival to hospital discharge. Pairwise comparisons were done using robust t-tests for the continuous variables, and Cochran-Armitage tests for the trends of the categorical variables. Analytes where all measured values were lower than the limit of detection were excluded from this analysis. For patients with values on both days 1 and 7, a paired Yuen's t-test with standardized winsorization was used to assess the effect of both values on the outcome. Analytes for which most of the results were lower than the limit of detection but had at least five valid entries (IL-1a, IL-4, IL-5, IL-21, IL-22, IL-23, and HMGB-1) were converted into categorical variables for the specific sample day using the minimum, maximum, and median of the measurable values, as shown in [Supplementary Table 1](#). The minimum value indicated the lowest concentration (including those extrapolated downwards), while the maximum value was the highest concentration and any values which were extrapolated upwards, and the median was simply the standard median value. The analytes were then stratified by the outcome status of death or survival, and a Cochran-Armitage test for trend was applied.

Variables with the highest impact on the outcome from day 1 and day 7 separately, as well as the difference between day 1 and day 7 values in patients who had both day 1 and day 7 values measured (hereafter the trajectory analysis), were identified using a Boruta algorithm. Boruta is an all-relevant feature-selection algorithm that makes use of a permuted random forest selection process. It was chosen for this analysis because of the rigorous method by which it identifies variables with a real impact on the outcome, without relying on assumptions about the distribution of the data or excluding all variables with incomplete data in the way that other tools would. Through multiple iterations, it provides a ranking of variables' importance to the outcome as well as a statistical interpretation of the performance based on the binomial distribution, i.e., a score of the feature importance (16). On day 1 analysis, all Luminex® analytes and the baseline clinical variables were included in the Boruta. On the day 7 analysis, and the trajectory analysis only the Luminex® analytes were included.

The variables thus identified were further subjected to correlation-based filtering, and the remaining variables were then used as predictors in two independent classification models (logistic regression and a random forest model). V-fold cross-validation (stratified by outcome, with five repeats) was applied to obtain measures of performance. A second analysis was done using predetermined ‘functional groups’ of cytokines and vascular/endothelial biomarkers (Table 1). These were analyzed together to assess their combined effect, using a robust t-test on a pooled average value for that group, obtained by scaling and centering each analyte separately (independent of the outcome state), then calculating the mean for each patient. A  $p < 0.05$  was considered significant. However, to minimize the impact of multiple testing and forgo *post-hoc* correction, those interactions which remained significant at  $p < 0.005$  are highlighted.

## 3 Results

Table 2 presents the baseline characteristics of the 87 critically ill COVID-19 patients included in the analysis, of whom 55 (63.2%) died in ICU, and 32 (36.8%) survived to hospital discharge (median

3 days after ICU discharge, range 1–48 days). All patients were receiving 8mg of intravenous dexamethasone daily, and therapeutic dose subcutaneous enoxaparin sodium from admission to ICU. None of the patients received any antiviral treatment or immunomodulatory drugs for COVID-19.

### 3.1 Clinical variables

On admission to ICU, all patients had clinically diagnosed ARDS with hypoxemia: 68 (78.2%) had a ratio of partial pressure of oxygen in arterial blood ( $\text{PaO}_2$ ) to the fraction of inspired oxygen ( $\text{FIO}_2$ ), hereafter  $\text{PaO}_2/\text{FIO}_2$ , of  $< 100$  (severe hypoxemia); 16 (18.4%) had a  $\text{PaO}_2/\text{FIO}_2$  of  $100 - 200$  (moderate hypoxemia); and 3 (3.4%) had a  $\text{PaO}_2/\text{FIO}_2 > 200$  (mild hypoxemia) (11). Most patients (59, 67.8%) required invasive mechanical ventilation during their admission. The remaining 28 (32.2%) were supported with non-invasive ventilation or high-flow nasal cannula oxygen.

All patients had at least one comorbidity, of which hypertension (51, 58.6%) was the most common. Nineteen (21.8%) patients were known to have diabetes mellitus, but 49 (56.3%) patients had an

TABLE 1 List of predetermined functional groups of analytes.

Group number	Group name	Analytes
1	Clinical markers of inflammation or infection	CRP; Ferritin; PCT; D-dimer
2	Th1	$\text{IFN}\gamma$ , $\text{TNF}\alpha$ , IL-2, IL-12, IL-15
3	Th2	IL-4, IL-13, IL-5, IL-33, ST2, IL-21
4	Treg	IL-10, TGF $\beta$
5	Th17	IL-17, IL-22, IL-23
6	Th1 activation	$\text{TNF}\alpha$ ; IL-6, IL-1b, IL-1a, IL-18; IL-15
7	Th2 activation	IL-4; IL-13; IL-5; IL-10
8	Myeloid derived suppressor cells	Arginase-1; S100A8; S100A9; TGF $\beta$ ; IL-10; IDO-1; IL-1Ra
9	Anti-inflammatory myeloid cells	IL-1Ra
10	Antiviral	$\text{IFN}\beta$
11	Chemokines	IL-8; MCP-1, MCP-3, MCP-4, MIG, IP-10; i309
12	Vascular/endothelial adhesion molecules	VCAM-1, ICAM-1
13	Growth factors	GM-CSF; VEGF
14	NK and CTL cytolytic activity	Granulysin
15*	Expanded vascular/endothelial adhesion markers	ICAM-1, E-selectin, P-selectin, VCAM-1
16*	Inflammation	MPO, $\text{TNF}\alpha$ , CRP
17*	Hemostatic factors	PAI-1, vWFA2
18*	Cell growth/death factors	GDF-15, VEGF
19*	Vascular tone	Endothelin-1

\*These groups were designed to focus on markers of relevance to the vascular endothelium.

CRP, C-reactive protein; CTL, cytotoxic T lymphocyte GDF-15, growth differentiation factor-15; GM-CSF, granulocyte macrophage colony stimulating factor; I-309, chemokine ligand 1 (CCL1); ICAM-1, intercellular adhesion molecule-1; IDO-1, Indoleamine-2,3-dioxygenase 1;  $\text{IFN}\beta$ , interferon  $\beta$ ;  $\text{IFN}\gamma$ , interferon  $\gamma$ ; IL, interleukin; IL-1Ra, Interleukin-1 receptor antagonist; IP-10, interferon  $\gamma$ -induced protein 10/Chemokine (C-X-C motif) ligand 10 (CXCL10); MCP, monocyte chemoattractant protein; MIG, monokine induced by interferon  $\gamma$ /Chemokine (C-X-C motif) ligand 9 (CXCL9); MPO, myeloperoxidase; NK, natural killer cell PAI-1, plasminogen activator inhibitor-1; PCT, procalcitonin; S100A8, S100 calcium-binding protein A8/migration inhibitory factor-related protein 8 (MRP-8); S100A9, S100 calcium-binding protein A9/MRP-14; ST2, growth stimulation gene-2/Interleukin-1 receptor-like-1 (IL-1RL1); TGF $\beta$ , transforming growth factor  $\beta$ ;  $\text{TNF}\alpha$ , tumour necrosis factor  $\alpha$ ; VCAM-1, vascular cell adhesion molecule-1; VEGF, vascular endothelial growth factor; vWF A2, Von Willebrand Factor A2.

Categorical variables are expressed as a number followed by a percentage and the continuous variables are expressed as a median followed by the interquartile range. Laboratory values refer to those obtained on the day of admission to the ICU (day 1). <sup>§</sup>Indicates an elevated glycated hemoglobin fraction, noted independent of an established diabetes diagnosis. <sup>¶</sup>A subjective opinion of the treating clinician rather than objective measurement, and as such should be interpreted with caution. <sup>‡</sup>The first arterial blood gas done on admission to ICU, whilst receiving oxygen therapy or ventilatory support. \*PaO<sub>2</sub>/FIO<sub>2</sub> is the ratio of arterial oxygen partial pressure (PaO<sub>2</sub> in mmHg) to fractional inspired oxygen (FIO<sub>2</sub> expressed as a fraction), where a value <300 indicates mild hypoxaemia, <200 moderate hypoxaemia, <100 severe hypoxaemia. <sup>†</sup>p values not corrected for multiple testing effect. In this case, variables with a p-value < 0.005 may be considered most likely to have post-test significance using the modified one-step M-estimator. ICU, intensive care unit; HIV, human immunodeficiency virus; PaCO<sub>2</sub>, partial pressure of arterial carbon dioxide; PaO<sub>2</sub>, partial pressure of arterial oxygen; eGFR, estimated glomerular filtration rate (calculated using Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formula uncorrected for ethnicity); NT-proBNP, N-terminal pro-brain natriuretic peptide. Bold values means P values which are statistically significant.

HbA1c >6.5% on admission to the ICU (including all but one of the confirmed diabetics). There were 13 people living with HIV (PLWH), with a median CD4 cell count of 238 cells/mm<sup>3</sup>, and all had suppressed viral loads on antiretroviral therapy except for three who had no data available. Four (4.6%) patients had previous tuberculosis, and four had chronic obstructive pulmonary disease. Nine (10.3%) patients reported hyperlipidemia and two (2.3%) reported ischaemic heart disease, two asthma, two hypothyroidism, previous malignancy, and chronic kidney disease, respectively. Three patients (3.4%) were pregnant on admission. Variables associated with mortality are detailed in Table 2. In addition to these, patients receiving antibiotics at any time during their ICU stay had significantly higher odds of death (Odds ratio 10.1, 99.5% C.I. 2.9–55, p < 0.001).

## 3.2 Biomarkers

The Boruta algorithm identified the following combination of clinical and Luminex® variables measured on day 1 as most influential in predicting the outcome: pH, partial pressure of carbon dioxide in arterial blood (PaCO<sub>2</sub>), lymphocytes percentage on the differential count, PCT, GDF-15, IL-15, ST2, IL-1Ra, and MPO. Only Luminex® data were considered for day 7, as all clinical data were captured on day 1. The most important day 7 variables identified by the Boruta were: IL-15, ET-1, GDF-15, IL-1a, IP-10, MCP-1, MCP-3, PCT, ST2, TGFβ2, VCAM-1, I309, and S100A8. The following variables were the most important in trajectory analysis: IL-15, GDF-15, VCAM-1, MCP-1, IL-18, and MCP-3. Several of these variables were highly correlated with each other (Figure 1).

On day 1 two selections were tested: Group 1 included variables that are readily available in a clinical setting: pH, lymphocyte percentage on the differential count, and PCT. Group 2 included IL-15, MPO, GDF-15, ST-2, and IL-1Ra. Other combinations with randomly selected day 1 variables were also tested, as well as all variables combined. The day 1 clinical biomarker group achieved a diagnostic accuracy of 72.7% on logistic regression and 73.5% on random forest, with an area under the receiver operating curve (AUC) of 85.8% and 82.8%, respectively (Figure 2). Day 1 clinical biomarkers had higher sensitivity (84.8% and 82.8%) than

specificity (60.7% and 64.1%). The day 1 Luminex® biomarker group achieved a diagnostic accuracy of 65.1% on logistic regression and 66.7% on random forest, with an AUC of 77.3% and 80.2% respectively. The sensitivities of this group were 78.0% and 80.4%, and specificities were 52.3% and 52.9%. When all the day 1 clinical and Luminex® biomarkers were included without filtering, the diagnostic accuracy was 78.1% and 75.1% on logistic regression and random forest models respectively; the AUCs were 86.2% and 88.6%; sensitivities were 83.2% and 88.8%; and specificities were 73.1% and 61.3%. The following day 7 variables were included in the

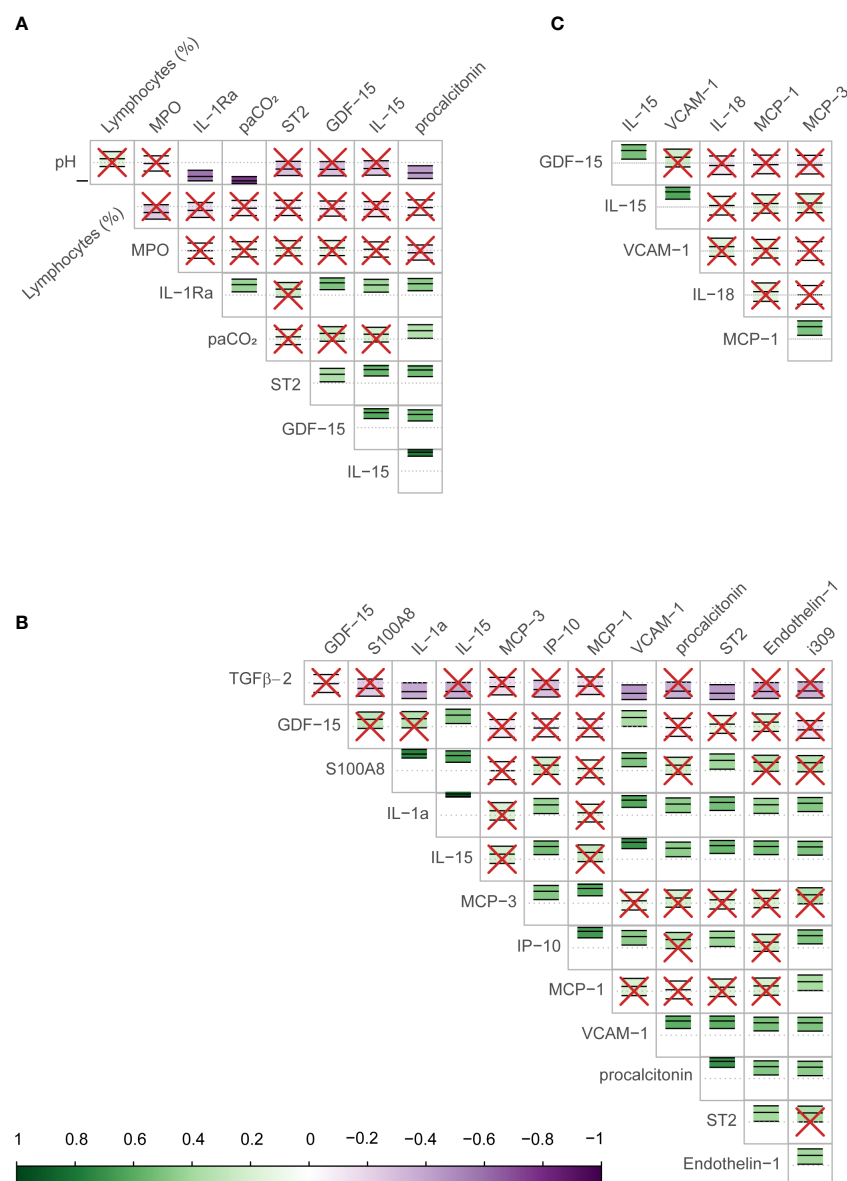

FIGURE 1

Correlation between biomarkers identified as important in predicting COVID-19 mortality in the study sample. The figure shows the correlation (Pearson) between biomarkers identified by the Boruta algorithm as important in determining the outcome (mortality) for day 1 (A), day 7 (B), and the longitudinal trajectory between days 1 and 7 (C). The scale bar on the bottom of the figure shows the strength of the correlation (closer to 1 or -1 are strongly positive or negative respectively) with a corresponding color scale. Within each cell is a central dotted line representing 0, and the green or purple annotation represents the correlation coefficient and confidence intervals for the two biomarkers interacting in that cell, as well as the direction of the interaction. The biomarker names are shown on the labels of the rows and columns. In cells with red crosses, the confidence interval crosses the 0 line and these interactions are non-significant. Those without crosses represent the significant correlations between the biomarkers, the strength of association may be judged by their color.

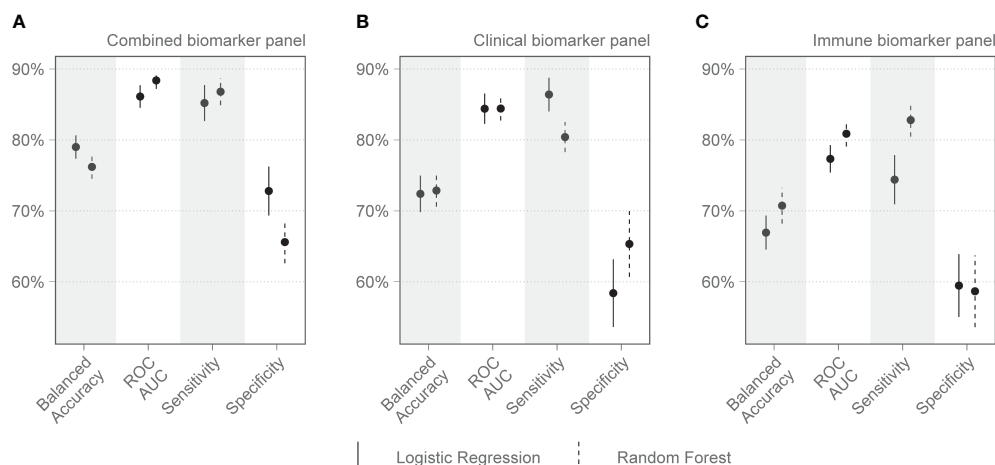

FIGURE 2

Performance metrics for models of clinical and immunologic biomarkers in predicting COVID-19 mortality on admission to the Intensive Care Unit (Day 1). (A) shows the combined performance of both clinical and immunologic biomarkers identified by the Boruta algorithm. (B) shows the performance of a clinical biomarker panel including pH, procalcitonin (PCT), and lymphocyte percentage on the differential count. (C) shows the performance of an immunologic biomarker panel including IL-15, MPO, GDF-15, ST-2, and IL-1Ra. Each dot represents the mean, with the line extending from it representing the standard error. A solid line is the logistic regression model, and a dashed line is the random forest model, both tuned to balanced accuracy. ROC, receiver operating curve; AUC, area under the curve.

modeling: IL-15, VCAM-1, and PCT. The performance metrics for the day 7 biomarkers were: diagnostic accuracy of 85.2% and 82.6% (logistic regression and random forest respectively); AUC of 91.1% and 93.0%; sensitivity of 80.1% and 86.5%; and specificity of 90.2% and 78.8% (Figure 3). When all the day 7 variables were included in the model without filtering, the metrics improved further (accuracy: 90.7% and 88.1%; AUC: 96.7% and 95.1%; sensitivity: 91.6% and 90.2%; specificity: 89.8% and 86.0%). Variables modeled from the trajectory analysis included IL-15, IL-18, and MCP-1. The biomarker trajectory analysis from day 1 to 7 performed less well than the day 7 panel, but performed well in comparison with the other models (Supplementary Figure 1). To test whether there was a

confounding effect of HIV, we ran the same analysis excluding the 13 PLWH and compared the resultant performance metrics to the results of the whole cohort using Welch's t-test. There was no difference between the whole cohort and the cohort with PLWH filtered out in the day 1 performance metrics, or in the day 7 metrics from the random forest models. The day 7 logistic regression metrics were better in the cohort without the PLWH, but this is likely because of the tendency of logistic regression to overfit in small datasets (Supplementary Figure 3).

Analysis of predetermined functional groups identified an increase in biomarkers of a pro-inflammatory/T helper cell type 1 (Th1) activating response (IL-1 $\alpha$ ,  $p = 0.008$ ; IL-1 $\beta$ , IL-6, IL-15, IL-

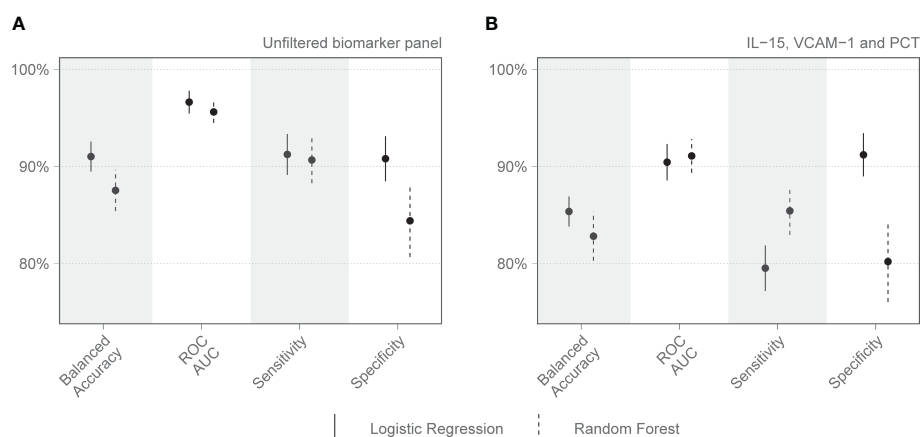

FIGURE 3

Performance metrics for models of immunologic biomarkers in predicting COVID-19 mortality on day 7 of admission to the Intensive Care Unit. (A) shows the performance of all day 7 analytes identified by the Boruta algorithm, without filtering. (B) shows the performance of the combination of analytes selected after correlation-based filtering, including IL-15, VCAM-1, and PCT. Each dot represents the mean, with the line extending from it representing the standard error. A solid line is the logistic regression model, and a dashed line is the random forest model. Models are tuned to balanced accuracy. ROC receiver operating curve, AUC area under the curve.

18, and TNF $\alpha$ ,  $p = 0.018$ , 95% C.I. 0.06–0.65) and the chemoattractants/leukocyte trafficking chemokines for both T helper cell type 2 (Th2) and Th1 (I309, IL-8, IP-10, MCP-1, MCP-3, MCP-4, and MIG,  $p = 0.034$ , 95% C.I. 0.02–0.57) on day 1 among patients who died. The anti-inflammatory IL-1Ra was also higher in these patients on day 1 ( $p = 0.003$ , 95% C.I. 0.04–0.45). On day 7, the inflammatory response on day 1 persisted, and Th2 cytokines (IL-13, IL-21, IL-33, and ST2,  $p = 0.002$ , 95% C.I. 0.23–0.89; IL4,  $p = 0.017$ ) and acute phase pro-inflammatory markers (D-dimer, ferritin, PCT,  $p = 0.024$ , 95% C.I. 0.06–0.65) were significantly increased in those who died. Markers of an anti-inflammatory/Treg response were reduced on day 7 in those who died (IL-10, TGF $\beta$ 1, and TGF $\beta$ 2,  $p = 0.005$ , 95% C.I. -0.65, -0.12). Endothelin-1 ( $p < 0.001$ , 95% C.I. 0.61–1.61) and vascular endothelial adhesion markers (ICAM-1 and VCAM-1,  $p = 0.003$ , 95% C.I. 0.30–1.15) were increased in those who died. Using a 99.5% confidence interval and assuming significance at a  $p$ -value  $< 0.005$ , those interactions which remained significant included higher IL-1Ra values on day 1 in those who died ( $p = 0.004$ , 99.5% C.I. 0.00–0.52), and higher Th2 cytokines (IL-13, IL-21, IL-33, ST2,  $p = 0.001$ , 99.5% C.I. 0.08–1.04), Endothelin-1 ( $p < 0.001$ , 99.5% C.I. 0.44–1.82) and ICAM-1 and VCAM-1 ( $p = 0.003$ , 99.5% C.I. 0.13–1.44) on day 7 in those who died (Figure 4). The results of all functional groups are shown in Supplementary Figure 2. The longitudinal trajectory analysis was significant for three variables: a reduction in the value of IL-18 and VCAM-1 from day 1 to day 7 was associated with survival ( $p = 0.002$  and  $p = 0.004$  respectively), and an increase in IL-15 from day 1 to day 7 was associated with death ( $p = 0.002$ ) (Figure 5).

A comparison between the results of the biomarkers performed on both the Luminex® and NHLS assay platforms (CRP and PCT) is included in the Supplementary Material (Supplementary Figures 4, 5).

## 4 Discussion

In this study, we present the immunologic and vascular biomarkers of mortality in 87 patients with critical COVID-19 who were admitted during the second wave of the pandemic in South Africa. Our results show that hyperinflammation was associated with death from COVID-19, as shown by the increased levels of Th1 and Th2 cytokines, Th1/Th2-related chemokines, and acute phase inflammatory proteins in those who died.

Cytokines related to hyperinflammation have been strongly associated with severe COVID-19 in other studies (5, 6). Similar to our findings, Lucas et al. (5) reported that patients with higher incidences of coagulopathy and mortality had a baseline immune signature driven by a combination of Th1 and Th2 responses, however, our study, unlike Lucas et al., did not identify Th17 responses as part of this signature. Moreover, Lucas et al. showed that patients with severe COVID-19 maintained elevated Th1 and Th17 cytokine levels throughout the course of their disease compared to patients with moderate disease and that severe disease was also associated with a rise in Th2 responses. In line with this, elevations in Th1 cytokines were associated with mortality at days 1 and 7 in our cohort of patients with severe COVID-19, and at the later time point, the Th2 cytokines also became significant. In Abers et al., elevated levels of IL-15, soluble ST2, and MCP-1, amongst others, were independently associated with mortality (6). Similar to our findings, the longitudinal trajectory of both IL-15 and MCP-1 in Abers et al. were significantly associated with the outcome (6). IL-1Ra is a competitive antagonist of the potent Th1 cytokine IL-1 $\beta$ . It rises in response to IL-1 and modulates its inductive effects on IL-6 and Th17 responses. In this study, IL-1Ra was strongly associated with mortality, providing further evidence of the presence of hyperinflammation and the body's attempt at immune regulation (17). Many of the cytokines and chemokines reported in this study

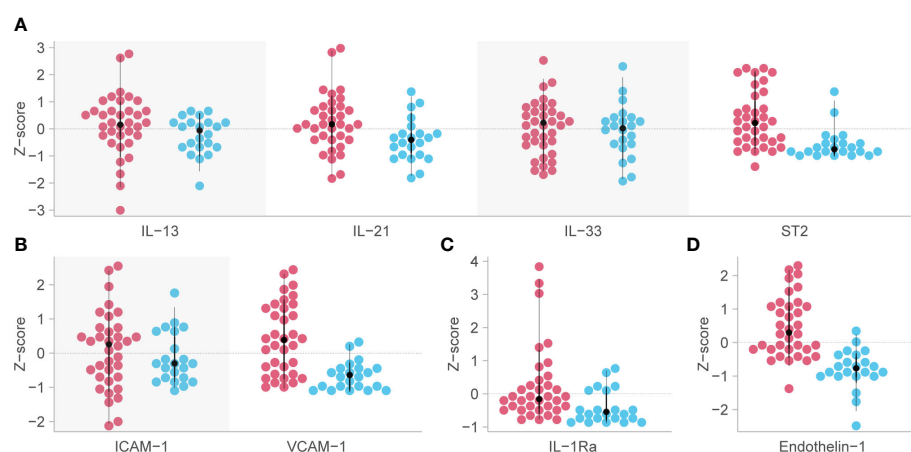

FIGURE 4

Biomarkers associated with mortality in critical COVID-19 which remained significant at the  $p < 0.005$  level. Red dots indicate the analyte levels in patients who died and blue dots are those who survived. (A) functional group 3, representing Th2 responses [except for Interleukin (IL)-4 and IL-5] on day 7 post-admission. (B) functional group 12, representing intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) on day 7 post-admission. (C) IL-1Ra or functional group 9, representing anti-inflammatory myeloid cells on day 1. (D) Endothelin-1 (ET-1) or functional group 19, representing vascular tone and endothelial dysfunction on day 7 post-admission. Analyte levels have been scaled and transformed to Z-scores for comparability, and the means were compared with a robust t-test. ST2, growth stimulation gene-2.

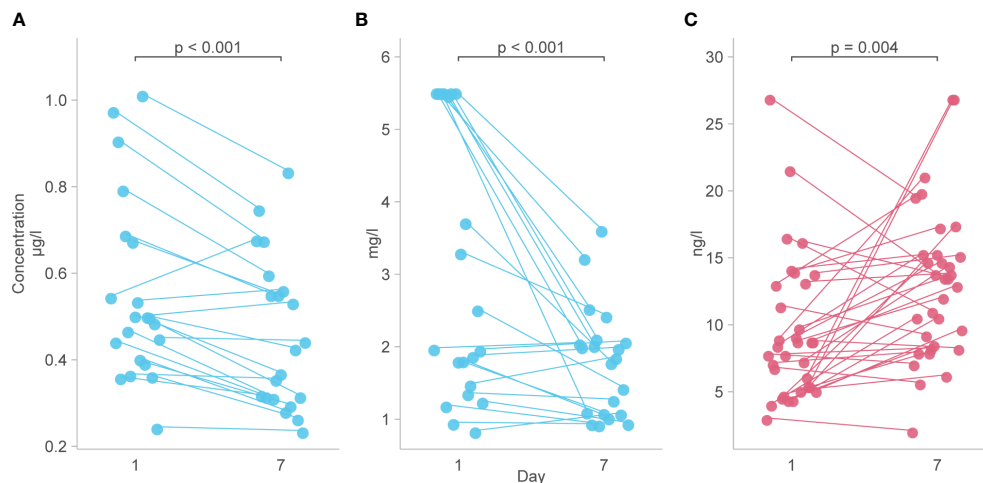

FIGURE 5

Biomarkers with a longitudinal trajectory associated with survival or death. (A) Levels of IL-18 between day 1 and day 7 in survivors. (B) Levels of VCAM-1 from day 1 to day 7 in survivors. (C) Levels of IL-15 from day 1 to day 7 in those who died. Analyte levels have been scaled and transformed to Z-scores for comparability and the means were compared with a robust t-test.

are also known to be elevated and predict mortality in other forms of ARDS and sepsis, particularly IL-6, IL-8, IL-18, TNF $\alpha$ , and IFN $\gamma$  (18–20). However, this may not represent the cytokine milieu in the lung. In one report from Saris et al., IL-6, IP-10, MCP-1, IL-10, and IFN $\alpha$  were all elevated in the plasma of critically ill COVID-19 patients (21). In the bronchoalveolar lavage fluid (BALF), however, IL-6, MCP-1, and IL-10 were significantly higher than plasma, but IP-10 was not and IFN $\alpha$  was undetectable. This demonstrates that while circulating biomarkers are useful for predicting severity, they do not reveal the full picture.

IL-15 is a pro-inflammatory cytokine with important effects on the activation and cytolytic activity of cytotoxic CD8 T lymphocytes and NK cells, particularly in short-term hypoxia (22). IL-15 was significantly associated with mortality in our panel overall. IL-18 is also pro-inflammatory, activated by the NLRP3 (nucleotide-binding domain, leucine-rich-containing family, pyrin domain-containing-3) inflammasome along with IL-1 $\beta$  and, in combination with IL-12, acts on CD4 T cells, CD8 T cells, and NK cells to induce IFN- $\gamma$  production. Higher levels of IL-18 have been associated with increased severity of COVID-19 (23). In ARDS from avian influenza virus (H5N1 and H7N9), the prolonged activation of the NLRP3 inflammasome and consequently Caspase 1, results in excess IL-18 and IL-1 $\beta$  production. This in turn causes an IFN- $\gamma$ -biased cytokine storm, pyroptosis, and lung damage (24). In the absence of IL-15, IL-18 does not induce IFN- $\gamma$  production but rather plays an important role in the differentiation of naive T cells into Th2 cells and stimulates the production of IL-4 and IL-13. In this study, we found that the survivors of COVID-19 ARDS had reduced levels of IL-15 and IL-18 over the period of ICU admission to day 7 and that the levels of these cytokines were consistently higher in those who died than those who survived. Continuous stimulation with IL-15 has been shown to cause exhaustion in certain immune cells, including NK cells (25). Together, this suggests that these pathways are involved in excessive inflammatory cell death and lung damage, and reflects the development of reduced inflammatory processes in those who survived. This may have been perpetuated by

the failure of the regulatory responses which was identified at day 7 in those who died.

The chemokines as a functional group, as well as the levels and trajectory of individual chemokines such as IP-10, MCP-1, and MCP-3, featured prominently in predicting the poor outcome in our study and also shown in other studies. This highlights the role of leukocyte chemoattractants in severe disease progression (26, 27). IP-10 and MCP-1 have also been associated with thrombosis, and it is hypothesized that this may be the underlying mechanism that precipitates an increased risk of mortality (27). Both IL-15 and IP-10 (along with IL-6 and IL-10) were shown to be raised in the serum of severe COVID-19 patients as compared to severe non-COVID-19 acute respiratory illness from another cohort in the Sub-Saharan Africa region (28).

Bacterial superinfection and venous thromboembolism are known complications of critical COVID-19 (29). Our patients who died had significantly higher routine PCT values on day 1, and higher Luminex®-derived PCT, ferritin, and D-dimer values on day 7, than those who survived. We also found that receiving antibiotics during admission was associated with mortality. In addition, there was considerable overlap between the markers identified in our study and those known to be associated with mortality from bacterial sepsis (30). In combination, these findings suggest that bacterial superinfection and venous thromboembolism played a role in mortality, although neither condition was verifiable with imaging or autopsy because of the COVID-19-related restrictions and resource constraints. Theoretically, a dysregulated immune response combined with the corticosteroids that were used to treat the hyperinflammation could have resulted in an individual patient's susceptibility to secondary infection. Bacterial superinfections occur in up to 50% of critical COVID-19 patients (29, 31). They prolong ventilation, and along with fungi are common causes of mortality in critical COVID-19 (31, 32). They generally occur later in the ICU admission than our samples were taken, but it may be that some of our patients presented late in the

evolution of their disease (29, 31). An elevated D-dimer, however, may be indicative of more than a complication of critical COVID-19. Endotheliitis and a progressive endothelial thrombo-inflammatory syndrome have been suggested as the main pathological mechanism of organ injury in severe disease, rather than hyperinflammation (30, 33). This is partly because cytokine levels in COVID-19 hyperinflammation are profoundly lower than in non-COVID-19 ARDS and associated bacterial sepsis (30).

In addition to the hypothesized role of IP-10 and MCP-1 in thrombosis discussed earlier, the prominence of vascular/endothelial markers in all our analyses supports the endotheliitis theory. ET-1 is a potent vasoconstrictor released from endothelial and smooth muscle cells, which stimulates interleukin and TNF $\alpha$  expression in monocytes, leukocyte adherence, platelet aggregation, expression of adhesion molecules including ICAM-1 and VCAM-1, production and action of growth factors, DNA and protein synthesis, and cell cycle progression (34). It is a marker of endothelial dysfunction and is higher in patients with severe COVID-19, those with respiratory failure, and those who died in hospital (35, 36). The endothelium-derived vascular adhesion molecules ICAM-1 and VCAM-1 are markers of endothelial activation, have been reported as elevated in severe COVID-19, and are associated with death among patients admitted to the ICU (9, 26, 37). In addition to this, they are critical for the recruitment of inflammatory cells from circulation into the lungs, and in this way may be mediators of lung injury in ARDS (38). Indeed, VCAM-1 has been shown to be elevated in the BALF of patients with COVID-19 ARDS (39). In our study, ET-1, ICAM-1, and VCAM-1 were significantly associated with the outcome, particularly in the day 7 analysis and the trajectory analysis, where a reduction in the level of VCAM-1 from day 1 to 7 predicted survival. ET-1 and the adhesion molecules play a critical role in the pro-atherosclerotic pathway, and it is not clear in this study whether the derangements we observed were because of pre-existing vascular disease, a new onset COVID-19 endotheliitis, or some combination of the two. GDF-15 is a stress-responsive member of the TGF $\beta$  cytokine superfamily which is produced by many cell types including activated macrophages, cardiomyocytes, adipocytes, endothelial cells, and vascular smooth muscle cells. It increases during states of tissue injury and inflammation and has a tissue-protective role in sepsis, including the regulation of injury-mediated responses in the lungs (40). GDF-15 levels have been associated with cardiovascular risk and disease, including endothelial dysfunction and atherosclerosis (41). In this particular study, a high GDF-15 was strongly associated with COVID-19 mortality. A study by Ahmed et al. found that GDF-15 was a significant marker of disease severity that correlated with IL-6 as a predictor of ICU and hospital outcomes (42). Taken together these data suggest a prominent role for endothelial dysfunction and inflammation in the pathogenesis of fatal COVID-19, possibly in the context of pre-existing vascular disease.

Our models created a clinically relevant biosignature for predicting mortality on day 1 of admission to the ICU. It only included results which should be made available within a few hours of admission: lymphocyte percentage on the differential count, pH, and PCT. With sensitivities of 82.8% and 84.8%, this signature might be worth further investigation for use as a triaging tool in

the overburdened ICU settings during pandemic times. The combination of clinical and Luminex®-derived biomarkers from day 1 performed even better, and our Luminex®-alone signature from day 7 did better on performance metrics than most other reported scoring systems. However, this finding should be regarded with caution. Our sample was from a highly selected population of critically ill COVID-19 ARDS patients from a specific geographic region. Other scoring systems may suffer the same limitations as documented in a critical appraisal of 39 prognostic models for mortality risk in COVID-19, only one model did not show a high risk of bias (1). This model, the 4C mortality score, predicted in-hospital mortality using patient age, sex, number of comorbidities, respiratory rate, peripheral oxygen saturation, level of consciousness, urea level, and CRP. The AUC was 0.79 for the derivation cohort and 0.77 for the validation cohort (43). Our clinical model for use on day 1 in the ICU has fewer variables than the 4C score and our results suggest that if there was a point-of-care assay for some of the Luminex® analytes we could provide critical care clinicians with a highly sensitive and specific prediction score which is easily available at the bedside. The biosignature we found may also be valid in ARDS of other causes considering the similarity between the biomarkers that we have shown and ARDS of other causes, and the significant association between ARDS severity (the PaO<sub>2</sub>/FIO<sub>2</sub>) and mortality.

Two of the strongest clinical markers of prognosis in this study were the pH and PaCO<sub>2</sub> on arterial blood gas. COVID-19 ARDS usually presents as a Type 1 respiratory failure with severe hypoxemia, rather than Type 2 where hypercapnia is the dominant feature. In our patients who all had severe hypoxemia, a rising PaCO<sub>2</sub> and drop in pH likely indicated a severe ventilation-perfusion mismatch (from either lung or vascular pathology), where both the transfer of O<sub>2</sub> into the alveolar capillaries and the clearance of CO<sub>2</sub> were impaired. Consistent with this, a rising PaCO<sub>2</sub> trajectory has been associated with mortality from COVID-19 in mechanically ventilated patients in a large population-based cohort study (44). The complex relationship between pH and PaCO<sub>2</sub> was further explored in the larger cohort, which included the patients in this sub-study of biomarkers of mortality (14).

PLWH made up 15.5% of the study population. Even though the proportion of PLWH was higher among those who died, the data was insufficient to determine an exposure-outcome relationship. In addition, there could have been inherent selection bias due to the fact that the PLWH who were selected for admission to the ICU, based on the local eligibility criteria, were virologically suppressed on ART. Epidemiologic evidence from South Africa has shown a significant association between HIV infection and in-hospital mortality among critical COVID-19 patients (3). In this study patients who were not on ART or virologically suppressed were more likely to die in hospital than their counterparts (3). The mechanism underlying this increased risk remains unknown. A histopathology study found no difference in the lungs, liver, heart, or rate of bacterial co-infection (other than *Mycobacterium tuberculosis*) of PLWH who died of COVID-19 and the HIV-uninfected COVID-19 deceased (45). Another study done within the African continent found no significant difference in serum or nasal lining fluid cytokine responses to moderate-severe COVID-19

between PLWH and HIV-uninfected counterparts (28). However, the study was not sufficiently powered to detect statistically significant differences.

Our study was limited by the small sample size which might have underpowered its ability to detect significant differences. Other key variables such as markers of cardiac dysfunction (Troponin T and NT-proBNP) and hypercoagulability (D-dimer) were seen to be higher in patients who died, but the observed differences were not statistically significant. Other data reported from South Africa have, however, shown these biomarkers of critical illness in COVID-19 in our population to be relevant (46). Selection bias also seems to have played a role in the study as there was no significant difference between groups in age or comorbidity, despite the fact that these have been reported to be among the most common factors associated with mortality. This may be because all our patients had already developed critical illness at the time of admission such that our study sample overall was older with a high rate of comorbidity and therefore a higher risk of death. Lastly, our analysis was limited by the inclusion of only two time points, which may not provide a true reflection of the trajectory over time. Biomarker levels may have fluctuated between the two measured time points or changed significantly after day 7.

In summary, this study has added much-needed data to the pool of biomarkers of severe COVID-19 ARDS in sub-Saharan African populations. We have shown that hyperinflammation, or a severely dysregulated cytokine response, is associated with mortality in the ICU. Our results also suggest that fatal COVID-19 ARDS involves excessive activation of cytotoxic cells and the NLRP3 inflammasome. Bacterial superinfection from immune dysregulation or treatment-induced suppression, and thrombosis from underlying endothelial dysfunction, likely contributed to death in these patients. Our models have made a biosignature of fatal COVID-19 on admission to the ICU which warrants further testing.

## Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: [https://figshare.com/projects/COVID19\\_ICU\\_immune\\_and\\_vascular\\_biomarkers\\_of\\_mortality/163708](https://figshare.com/projects/COVID19_ICU_immune_and_vascular_biomarkers_of_mortality/163708).

## Ethics statement

The studies involving human participants were reviewed and approved by Stellenbosch University Health Research Ethics Committee. Written informed consent for participation was not required for this study in accordance with the national legislation and the institutional requirements.

## Author contributions

AEZ, PN, GW, HS, BA, RE, ZC, TM, AZ and NC conceived and designed the study. CS performed the assays. CK, UL, EI, NB, LS, JS, and VN collected or contributed to the data. MM and GT

performed the analysis. GW, NdP, HS, AZ, BA, FE, JS, and SM informed the interpretation of the data. JS wrote the paper, which was critically reviewed and approved in the final draft by all authors. All authors contributed to the article and approved the submitted version.

## Funding

This work was conducted under the COVID-19 Africa Rapid Grant Fund supported under the auspices of the Science Granting Councils Initiative in Sub-Saharan Africa (SGCI) and administered by South Africa's National Research Foundation (NRF) in collaboration with Canada's International Development Research Centre (IDRC), the Swedish International Development Cooperation Agency (Sida), South Africa's Department of Science and Innovation (DSI), the Fonds de Recherche du Québec (FRQ), the United Kingdom's Department of International Development (DFID), United Kingdom Research and Innovation (UKRI) through the Newton Fund, and the SGCI participating councils across 15 countries in sub-Saharan countries. JAS is funded by the South African Medical Research Council through its Division of Research Capacity Development under the Bongani Mayosi National Health Scholars Programme for funding received from the Public Health Enhancement Fund/South African National Department of Health. The content hereof is the sole responsibility of the authors and does not necessarily represent the official views of the SGCI/NRF and the SAMRC.

## Acknowledgments

The authors wish to acknowledge Chanelle Rinkwest and Soraya Chalklen who diligently collected the data and samples for this study under exceptionally difficult circumstances.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

**Introduction:** SARS-CoV-2 infection during pregnancy can induce changes in the maternal immune response, with effects on pregnancy outcome and offspring. This is a cross-sectional observational study designed to characterize the immunological status of pregnant women with convalescent COVID-19 at distinct pregnancy trimesters. The study focused on providing a clear snapshot of the interplay among serum soluble mediators.

**Methods:** A sample of 141 pregnant women from all prenatal periods (1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> trimesters) comprised patients with convalescent SARS-CoV-2 infection at 3–20 weeks after symptoms onset (COVID, n=89) and a control group of pre-pandemic non-infected pregnant women (HC, n=52). Chemokine, pro-inflammatory/regulatory cytokine and growth factor levels were quantified by a high-throughput microbeads array.

**Results:** In the HC group, most serum soluble mediators progressively decreased towards the 2<sup>nd</sup> and 3<sup>rd</sup> trimesters of pregnancy, while higher chemokine, cytokine and growth factor levels were observed in the COVID patient group. Serum soluble mediator signatures and heatmap analysis pointed out that the major increase observed in the COVID group related to pro-inflammatory cytokines (IL-6, TNF- $\alpha$ , IL-12, IFN- $\gamma$  and IL-17). A larger set of biomarkers displayed an increased COVID/HC ratio towards the 2<sup>nd</sup> (3x increase) and the 3<sup>rd</sup> (3x to 15x increase) trimesters. Integrative network analysis demonstrated that HC pregnancy evolves with decreasing connectivity between pairs of serum soluble mediators towards the 3<sup>rd</sup> trimester. Although the COVID group exhibited a similar profile, the number of connections was remarkably lower throughout the pregnancy. Meanwhile, IL-1Ra, IL-10 and GM-CSF presented a preserved number of correlations ( $\geq 5$  strong correlations in HC and COVID), IL-17, FGF-basic and VEGF lost connectivity throughout the pregnancy. IL-6 and CXCL8 were included in a set of acquired attributes, named COVID-selective ( $\geq 5$  strong correlations in COVID and  $< 5$  in HC) observed at the 3<sup>rd</sup> pregnancy trimester.

**Discussion and conclusion:** From an overall perspective, a pronounced increase in serum levels of soluble mediators with decreased network interplay between them demonstrated an imbalanced immune response in convalescent COVID-19 infection during pregnancy that may contribute to the management of, or indeed recovery from, late complications in the post-symptomatic phase of the SARS-CoV-2 infection in pregnant women.

chemokines, cytokines, growth factors, COVID-19, pregnancy

## 1 Introduction

In March 2020, the World Health Organization (WHO) characterized the outbreak of the Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) disease (COVID-19) as a pandemic, having since confirmed more than 655 million COVID-19 cases, 6.6 million of which resulted in death (1). SARS-CoV-2 is transmitted through airborne droplets, respiratory secretions, and direct contact. The clinical symptoms relating to the COVID-19 disease were primarily respiratory, and later reported as multisystemic effects. COVID-19 illness symptoms can be

asymptomatic, mild, moderate, severe, or critical (2–4). Fever, cough, dyspnea, and myalgia were the most common mild symptoms. The pathogenesis of COVID-19 has been strongly associated with an unbalanced immune response; however, the pathophysiology of the disease remains under investigation (5–7).

Multiple studies concluded that pregnant women are a high-risk population for the COVID-19 disease. Infectious diseases in pregnancy are regularly considered a critical condition. Physiological changes during pregnancy have significant effects on the immune system, cardiopulmonary system and coagulation, and these changes may result in an altered response to COVID-19

infection (3, 8–11). Cytokine levels during pregnancy could be responsible for metabolic imprinting as cytokines are transferable from maternal to fetal circulation and are capable of modulating placental nutrient transfer. Maternal inflammation may induce metabolic reprogramming at several levels, from the periconceptional period onwards. Such processes and their consequences on the maternal and perinatal periods have not been extensively studied to date. Moreover, the maternal immune activation triggered by COVID-19 can have impacts for the mother, pregnancy outcome and offspring (12, 13). The understanding such phenomena should contribute to the proper management of children born to SARS-CoV-2-infected mothers (14).

The aim of the present study was to conduct a prospective observational study designed to characterize the immunological status of pregnant women with convalescent COVID-19, focusing on an overall snapshot of the interplay between serum soluble mediators.

## 2 Materials and methods

### 2.1 Study population

This cross-sectional observational study was conducted between July 2020 and December 2021 during the COVID-19 pandemic in the Federal District of Brazil during circulation of the SARS-CoV-2 B.1.1.28 and B.1.1.33 strains. A total of 141 participants were enrolled as non-probability convenience sampling, including pregnant women with convalescent SARS-CoV-2 infection (COVID, n=89) at 3–20 weeks after symptoms onset during the prenatal period (1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> trimesters), together with a healthy control group composed of age-matched pre-pandemic non-infected pregnant women (HC, n=52).

The COVID-19 pregnant women were recruited at two public hospitals - the University Hospital of Brasília and the Asa Norte

Regional Hospital, both public reference centers for COVID-19 in the Federal District of Brazil and participants of a large research project named PROUDEST (15). The COVID group comprised pregnant women aged 18–44 years, with a median age of 31 years. This group was further categorized into subgroups according to the pregnancy trimester, referred to as: 1<sup>st</sup> (n=7), 2<sup>nd</sup> (n=34) and 3<sup>rd</sup> (n=48). COVID-19 diagnosis was confirmed by a documented positive RT-PCR test using a nasopharyngeal swab or rapid test (Biomanguinhos, FIOCRUZ, Brazil) for IgM or IgG, during pregnancy. Most of the COVID-19 group (97%, 86 out of 89) presented the non-severe form of the disease. The most common symptoms were: Anosmia (68%), runny nose and/or nasal congestion (68%), headache (67%), ageusia (63%), myalgia (57%), cough (43%), fever (43%), dyspnea (31%), sore throat (31%), asthenia (22%), diarrhea (17%), nausea and vomiting (11%), joint pain (5%), dizziness (4%) and skin diseases (2%). SARS-CoV-2 infection during pregnancy was associated with important adverse maternal and neonatal outcomes, including gestational diabetes mellitus (37%), Apgar score at first minute  $\leq 7$  (22%), systemic arterial hypertension (18%), fetal restriction growth (11%), preterm labor (11%), acute fetal distress (8%), Apgar score at fifth minute  $\leq 7$  (5%) and preeclampsia (3%).

The HC group comprised a selected non-probability convenience sampling from a biorepository maintained at Grupo Integrado de Pesquisas em Biomarcadores, Instituto René Rachou, Fundação Oswaldo Cruz (FIOCRUZ-Minas), Belo Horizonte, Brazil. The HC group comprised pregnant women, aged 18–42 years, with a median age of 28 years. The healthy control group was composed by primiparous with no previous history or current status of obesity, systemic arterial hypertension, diabetes mellitus and without records of pre-eclampsia. The HC group was further categorized into subgroups according to pregnancy trimester, referred to as: 1<sup>st</sup> (n=21), 2<sup>nd</sup> (n=10) and 3<sup>rd</sup> (n=21).

The Table 1 summarize the major demographic and clinical features of the study population.

TABLE 1 Demographic and clinical features of the study population.

Characteristics	GROUPS	
	Healthy Controls – HC (n=52)	COVID-19 – COVID (n=89)
Age, median (min-max)	28 (18–42)	31 (18–44)
Obstetric History		
Previous Pregnancies, median (min-max)	0% (0)	2 (0–6)
Abortions, median (min-max)	0% (0)	0 (0–2)
Complications* % (n)	0% (0)	24% (21)
Current Study		
Obesity % (n)	0% (0)	11% (10)
SAH % (n)	0% (0)	18% (16)
Diabetes % (n)	0% (0)	37% (33)
Pre-eclampsia % (n)	0% (0)	3% (3)

SAH, systemic arterial hypertension. \*Obesity, SAH, diabetes, pre-eclampsia.

All study participants provided written informed consent prior to inclusion in accordance with the Helsinki Declaration and Resolution 466/2012 from the Brazilian National Health Council for research involving human subjects. This study was recorded on the Brazilian Registry of Clinical Trials Platform (ReBEC, RBR-65qxs2) and approved by the National Commission for Ethics in Research in Brazil (CONEP, CAAE 32359620.0.0000.5558). The anonymization strategy to protect the identity of participants was achieved by replacing the direct identifiers by standardized alphanumeric codes (*PRAxxxPNy* and *PRBxxxPNy*), where “PR” refer to the PROUDEST project name (15), “A” and “B” refers to the hospital unit, the “xxx” represent the sequential number of patient inclusion, “PN” refer to prenatal period and “y” the trimester of sample collection.

## 2.2 Biological samples

Whole blood sample (10 mL) were collected from each participant in vacuum tubes without anticoagulant by venipuncture at the first prenatal appointment or upon enrolment in the study. Serum samples were obtained by centrifugation (1400 x g, 10 min, 4°C) of original samples within 6 h after blood collection. The serum specimens were aliquoted and stored at -80°C until quantification of serum soluble mediators.

## 2.3 Quantification of serum soluble mediators

Serum soluble mediators were quantified by a high-throughput Luminex microbead multiplex assay (Bio-Plex Pro™ Human Cytokine 27-plex Assay, Bio-Rad Laboratories, Hercules, CA, USA). The manufacturer's instructions were followed to determine the concentrations of chemokines (CXCL8; CCL11; CCL3; CCL4; CCL2; CCL5; CXCL10), pro-inflammatory cytokines (IL-1 $\beta$ ; IL-6; TNF- $\alpha$ ; IL-12; IFN- $\gamma$ ; IL-15; IL-17), regulatory cytokines (IL-1Ra; IL-4; IL-5; IL-9; IL-10; IL-13) and growth factors (FGF-basic; VEGF; PDGF; G-CSF; GM-CSF; IL-2; IL-7). The assays were conducted in parallel batches by a trained technician at the flow cytometry facility at FIOCRUZ-Minas. The concentrations of serum soluble mediators (pg/mL) were obtained according to a 5-parameter logistic curve fit regression of standard curves.

## 2.4 Statistical analysis

Descriptive statistics were carried out using the Prism 8.0.2 software (GraphPad Software, San Diego, USA). Data normality was assessed using the Shapiro-Wilk test. Considering the nonparametric distribution of all data sets, multiple comparisons

amongst HC and COVID subgroups were carried out using the Kruskal-Wallis followed by Dunn's post-test. Additionally, comparative analysis between HC and COVID at matching trimesters was performed using the Mann-Whitney test. In all cases, statistical significance was considered at  $p < 0.05$ .

The serum soluble mediator signatures were calculated as the proportion (%) of pregnant women with serum levels above the reference values (cut-off) defined as the median Z-score of each soluble mediator detected for all HC along the 1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> trimesters (CXCL8=-0.3; CCL11=-0.3; CCL3=-0.3; CCL4=-0.3; CCL2=-0.4; CCL5=-0.2; CXCL10=-0.2; IL-1 $\beta$ =-0.3; IL-6=-0.3; TNF- $\alpha$ =-0.3; IL-12=-0.3; IFN- $\gamma$ =-0.4; IL-15=-0.5; IL-17=-0.4; IL-1Ra=-0.4; IL-4=-0.3; IL-5=-0.2; IL-9=-0.2; IL-10=-0.2; IL-13=-0.4; FGF-basic=-0.5; PDGF=-0.4; VEGF=-0.4; G-CSF=-0.2; GM-CSF=-0.4; IL-2=-0.4; IL-7=-0.3). Additionally, trimester-matching signatures were assembled, considering the reference values (cut-off) defined as the median Z-score of each soluble mediator detected for HC trimester subgroups at 1<sup>st</sup> (CXCL8 = 0.2; CCL11 = 0.1; CCL3 = 0; CCL4=-0.6; CCL2 = 0.4; CCL5=-0.2; CXCL10=-0.7; IL-1 $\beta$ =-0.2; IL-6 = 1.6; TNF- $\alpha$ =-0.1; IL-12=-0.2; IFN- $\gamma$ =0.1; IL-15=-0.5; IL-17 = 0.1; IL-1Ra=0.1; IL-4=-0.5; IL-5=-0.1; IL-9 = 0.5; IL-10=-0.2; IL-13 = 0.2; FGF-basic=0.3; PDGF=0.2; VEGF=0.1; G-CSF=-0.2; GM-CSF=0.1; IL-2=-0.4; IL-7=-0.2), 2<sup>nd</sup> (CXCL8=-0.3; CCL11=-0.2; CCL3=-0.3; CCL4=-0.2; CCL2=-0.5; CCL5=-0.1; CXCL10=-0.6; IL-1 $\beta$ =-0.3; IL-6=-0.4; TNF- $\alpha$ =-0.3; IL-12=-0.3; IFN- $\gamma$ =-0.4; IL-15 = 0.2; IL-17=-0.2; IL-1Ra=-0.5; IL-4 = 0.2; IL-5=-0.2; IL-9=-0.6; IL-10=-0.2; IL-13=-0.4; FGF-basic=-0.6; PDGF=-0.6; VEGF=-0.2; G-CSF=-0.1; GM-CSF=-0.6; IL-2=-0.1; IL-7=-0.2) and 3<sup>rd</sup> trimesters (CXCL8=-0.4; CCL11=-0.4; CCL3=-0.3; CCL4 = 0.3; CCL2=-0.5; CCL5 = 0.1; CXCL10 = 0.6; IL-1 $\beta$ =-0.4; IL-6=-0.3; TNF- $\alpha$ =-0.3; IL-12=-0.3; IFN- $\gamma$ =-0.4; IL-15=-0.5; IL-17=-0.4; IL-1Ra=-0.6; IL-4=-0.3; IL-5=-0.2; IL-9=-0.8; IL-10=-0.3; IL-13=-0.4; FGF-basic=-0.6; PDGF=-0.7; VEGF=-0.4; G-CSF=-0.2; GM-CSF=-0.7; IL-2=-0.5; IL-7=-0.3). The serum soluble mediators displaying a proportion above 50% in pregnant women were included in the set of biomarkers with increased levels.

Heatmap constructs were assembled using conditional formatting in Microsoft Excel to illustrate the overall profile of serum soluble mediator signatures of the COVID and HC subgroups along the pregnancy trimesters. The ratio between the proportion of pregnant women with serum levels above the reference values in the COVID group in relation to HC (% COVID/%HC) was also assessed by comparative analysis.

Serum-soluble mediator networks were built based on correlation analysis (Pearson and Spearman rank tests) between pairs of serum-soluble mediators. Only significant strong correlations ( $p < 0.05$  and “r” scores  $\geq |0.67|$ ) were employed to construct the comprehensive networks. The open-source Cytoscape software (available at <https://cytoscape.org>) was used to create cluster network layouts comprising the 4 categories of serum soluble mediators - chemokines, pro-inflammatory cytokines, regulatory cytokines, and growth factors. Descriptive analysis of

serum soluble mediator networks was performed by considering the ascendant number of strong correlations to identify the set of biomarkers with five or more strong correlations ( $\geq 5$ ). Venn Diagram analysis (available at (<http://bioinformatics.psb.ugent.be/webtools/Venn/>)) was performed to assess the preserved (common), lost or acquired (selective) serum soluble mediators with  $\geq 5$  strong correlations in COVID subgroups compared to trimester-matching HC.

The MATLAB software was employed for Principal Component Analysis (PCA). The PCA data was assembled to verify the ability of serum soluble mediators to cluster convalescent COVID-19 pregnant women from HC, as well as subgroups of COVID-19 as compared to trimester-matching HC. The PCA analysis enabled data dimensionality reduction.

### 3 Results

#### 3.1 Levels of serum soluble mediators in convalescent COVID-19 at distinct pregnancy trimesters

The levels of chemokines, pro-inflammatory cytokines, regulatory cytokines and growth factors were measured in serum samples from pregnant women with convalescent COVID-19 at 3–20 weeks after symptoms onset (COVID) and compared with those detected in trimester-matching pre-pandemic non-infected pregnant women as a healthy control (HC). The results are presented in **Figures 1 and 2**.

In general, healthy pregnant women presented a progressive decrease in most serum soluble mediators towards the 2<sup>nd</sup> and 3<sup>rd</sup> pregnancy trimester, including: chemokines (CXCL8, CCL11, CCL3 and CCL2); pro-inflammatory cytokines (IL-1 $\beta$ , IL-6, TNF- $\alpha$ , IL-12, IFN- $\gamma$ , and IL-17); regulatory cytokines (IL-1Ra, IL-4, IL-5, IL-9, IL-10 and IL-13), and growth factors (FGF-basic, VEGF, PDGF, GM-CSF and IL-7). Conversely, progressive increases in CCL4, CCL5, CXCL10 and G-CSF were observed in the HC group. No difference was observed in the HC group for IL-15 and IL-2 (**Figures 1, 2**).

Overall, higher levels of the most soluble mediators were observed in convalescent COVID-19 pregnant women compared to the healthy controls, especially at the 2<sup>nd</sup> and 3<sup>rd</sup> trimesters, including higher levels of CXCL8; CCL11; CCL2; CCL3; IL-1 $\beta$ ; IL-6; TNF- $\alpha$ ; IL-12; IFN- $\gamma$ ; IL-17; IL-1Ra; IL-5; IL-9; IL-10; IL-13; FGF-basic; VEGF, and GM-CSF. Conversely, lower levels of CCL4, CCL5, CXCL10, G-CSF and IL-7 were observed towards the 2<sup>nd</sup> and 3<sup>rd</sup> trimesters in the COVID group compared to the HC group (**Figures 1, 2**).

Additional analysis amongst the COVID subgroups along the pregnancy trimesters demonstrated an inverted profile of CCL3, IL-1Ra and FGF-basic towards higher levels in the 3<sup>rd</sup> trimester (**Figures 1, 2**).

**Supplementary Figure 1** summarizes the major changes observed in serum soluble mediators along the trimesters of healthy and convalescent COVID-19 pregnancy.

#### 3.2 Serum soluble mediator signatures in convalescent COVID-19 at distinct pregnancy trimesters

Serum soluble mediator signatures were assembled as the percentage of pregnant women with serum levels above the reference values defined as the median Z-score of each soluble mediator detected in all healthy controls along the pregnancy. The results are presented in **Figure 3**.

Data analysis demonstrated that the proportion of healthy pregnant women with high levels of serum soluble mediators progressively decreased towards the 2<sup>nd</sup> and 3<sup>rd</sup> pregnancy trimesters. These data further corroborated that a healthy pregnancy course has a progressive decrease in most serum soluble mediators towards the 2<sup>nd</sup> and 3<sup>rd</sup> trimesters, except for CCL4, CCL5 and CXCL10 (**Figure 3A**).

On the other hand, the proportion of pregnant women with convalescent COVID-19 presenting high serum soluble mediator levels progressively increased from the 1<sup>st</sup> to the 3<sup>rd</sup> pregnancy trimester (**Figure 3A**). Heatmap constructs further illustrated that the major increase in serum soluble mediators observed in pregnant women with convalescent COVID-19 occurred in pro-inflammatory cytokines, namely IL-6, TNF- $\alpha$ , IL-12, IFN- $\gamma$  and IL-17 (**Figure 3B**).

The profile of serum soluble mediators was further characterized as the ratio (%COVID/%HC), assessed by dividing the percentage of pregnant women with soluble mediator levels above the reference values observed in the COVID group by the percentage of trimester-matching HC patients. Using this strategy, the results confirmed that a larger set of biomarkers presented a high ratio (%COVID/%HC) towards the 2<sup>nd</sup> and 3<sup>rd</sup> trimester. In the 2<sup>nd</sup> pregnancy trimester, increased ratios were observed for IL-6, IFN- $\gamma$ , IL-5 and GM-CSF (3x increase) in the COVID-19 group. A larger set of serum soluble mediators with increased ratios was identified for COVID-19 groups at the 3<sup>rd</sup> pregnancy trimester, including CXCL8, CCL11, IL-5 and PDGF (3x increase), CCL3, IL-1 $\beta$ , IFN- $\gamma$ , IL-17 and IL-13 (4x increase), CCL2, TNF- $\alpha$  (7x) along with IL-1Ra, IL-9, GM-CSF and FGF-basic (5x, 9x, 9x, and 15x increase, respectively) (**Figure 3C**).

The signatures of serum soluble mediators were also assessed considering the reference values of trimester-matching healthy controls. The results are presented in the **Supplementary Figure 2**. Data reinforce that larger sets of serum soluble mediators with increased ratios were identified for the 2<sup>nd</sup> and 3<sup>rd</sup> pregnancy trimesters as compared with trimester-matching controls (**Supplementary Figure 2**).

#### 3.3 Serum soluble mediator networks in convalescent COVID-19 at distinct pregnancy trimesters

Aimed at assessing a panoramic snapshot of serum soluble mediator interplay in pregnant women with convalescent COVID-19 and healthy controls, integrative networks were constructed

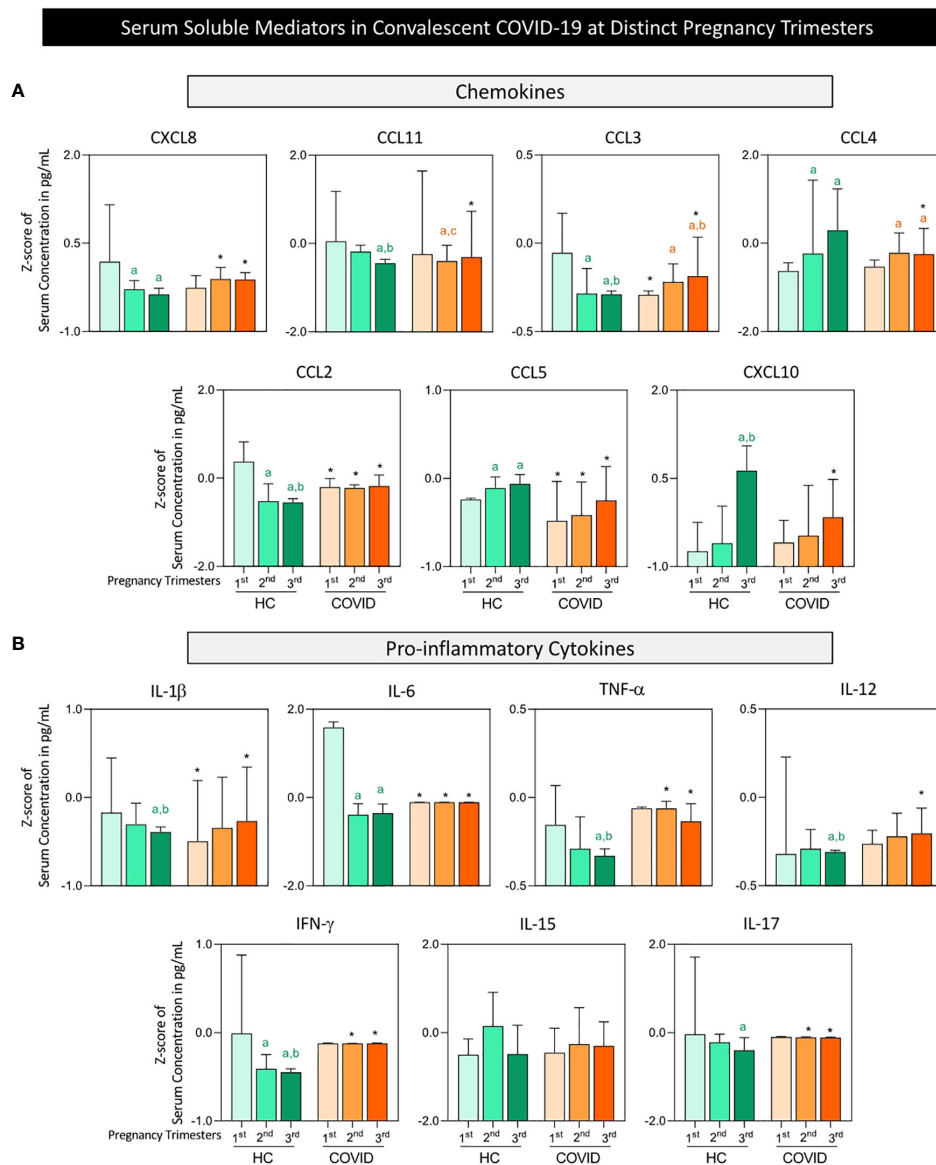

FIGURE 1

Serum and pro-inflammatory cytokines in convalescent COVID-19 patients at distinct pregnancy trimesters. The levels of: **(A)** chemokines (CXCL8, CCL11, CCL3, CCL4, CCL2, CCL5, CXCL10), and **(B)** pro-inflammatory cytokines (IL-1 $\beta$ , IL-6, TNF- $\alpha$ , IL-12, IFN- $\gamma$ , IL-15, IL-17) were measured in serum samples from pregnant women with convalescent COVID-19 at 3–20 weeks after symptoms onset (COVID,  $n=89$ ), with pre-pandemic non-infected pregnant women as a Healthy Control (HC,  $n=52$ ). The HC and COVID-19 groups were further categorized into subgroups according to pregnancy trimester, referred to as: HC 1<sup>st</sup> ( $n=21$ ), HC 2<sup>nd</sup> ( $n=10$ ), HC 3<sup>rd</sup> ( $n=21$ ), and COVID 1<sup>st</sup> ( $n=7$ ), COVID 2<sup>nd</sup> ( $n=34$ ), COVID 3<sup>rd</sup> ( $n=48$ ). The measurements were taken by high-throughput multiplex bead array as described in Material and Methods. The results are presented in bar charts of median values and interquartile ranges for Z-score of serum concentration (pg/mL). Multiple comparative analysis was performed by Kruskal–Wallis followed by Dunn's post-test and comparisons between COVID-19 and HC at matching pregnancy trimesters assessed using the Mann–Whitney test. In all cases, significance was considered at  $p<0.05$ . Intragroup differences were underscored by the letters "a", "b" and "c" for comparisons with the 1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> trimesters, respectively. Inter-group differences at matching pregnancy trimesters were highlighted denoted by an asterisk (\*).

based on the overall correlation between pairs of molecules. The results are presented in Figure 4.

Data analysis demonstrated that healthy pregnancy evolves towards the 3<sup>rd</sup> trimester with an overall decrease in network connectivity (1<sup>st</sup> = 336; 2<sup>nd</sup> = 300 and 3<sup>rd</sup> = 112 strong correlations). Although pregnant women with convalescent COVID-19 exhibited a similar continuous decrease in network

connectivity towards the 3<sup>rd</sup> trimester (1<sup>st</sup> = 146; 2<sup>nd</sup> = 78 and 3<sup>rd</sup> = 70 strong correlations), the number of connections was remarkably lower in the COVID group compared to HC group (Figure 4).

Overall, the analysis of cluster connectivity during healthy pregnancy showed that pro-inflammatory cytokines presented more connections at the 1<sup>st</sup> and 2<sup>nd</sup> trimesters (96 and 92 strong

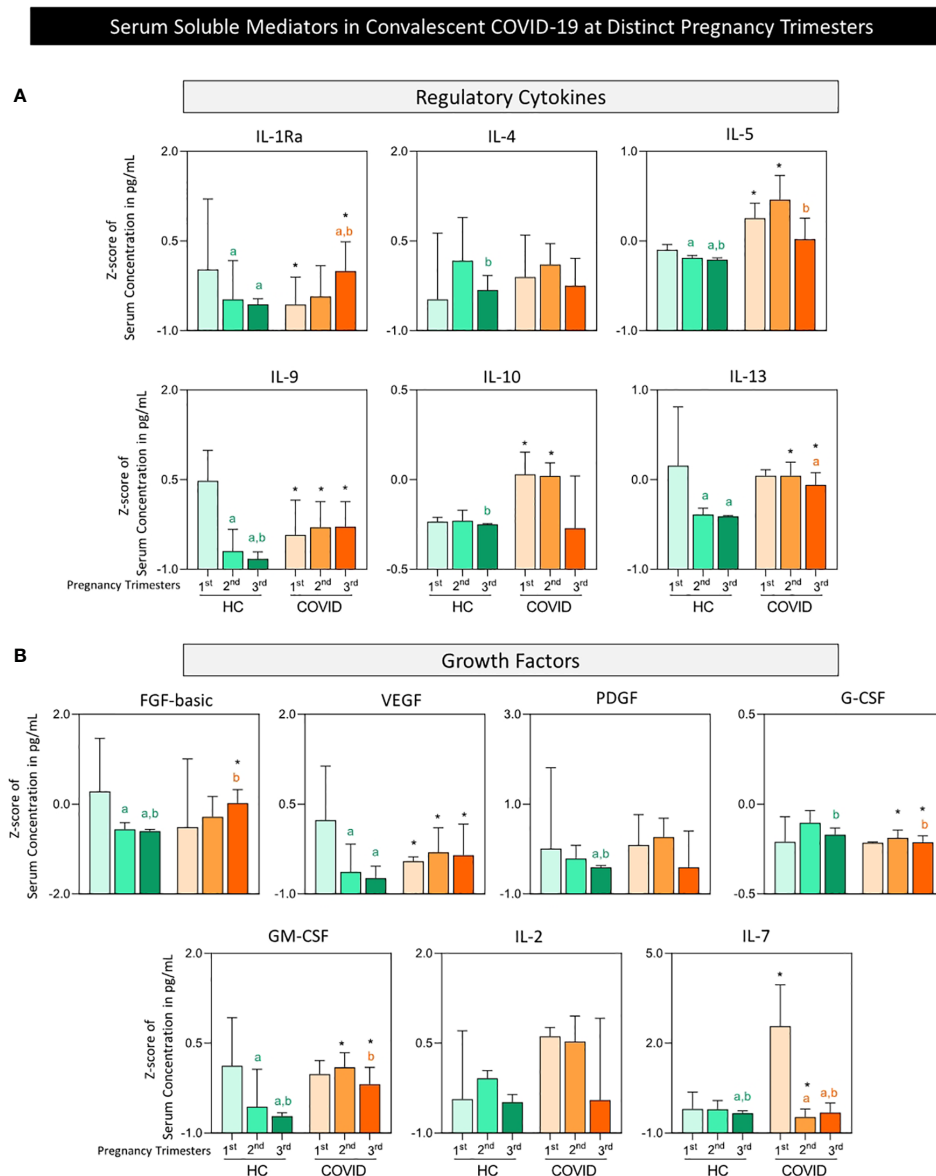

FIGURE 2

Serum regulatory cytokines and growth factors in convalescent COVID-19 patients at distinct pregnancy trimesters. The levels of: **(A)** regulatory cytokines (IL-1Ra, IL-4, IL-5, IL-9, IL-10, IL-13), and **(B)** growth factors (FGF-basic, PDGF, VEGF, G-CSF, GM-CSF, IL-2, IL-7) were measured in serum samples from pregnant women with convalescent COVID-19 at 3–20 weeks after symptoms onset (COVID,  $n=89$ ), with pre-pandemic non-infected pregnant women as a Healthy Control (HC,  $n=52$ ). The HC and COVID-19 groups were further categorized into subgroups according to pregnancy trimester, referred to as: HC 1<sup>st</sup> ( $n=21$ ), HC 2<sup>nd</sup> ( $n=10$ ), HC 3<sup>rd</sup> ( $n=21$ ), and COVID 1<sup>st</sup> ( $n=7$ ), COVID 2<sup>nd</sup> ( $n=34$ ), COVID 3<sup>rd</sup> ( $n=48$ ). The measurements were taken by high-throughput multiplex bead array as described in Material and Methods. The results are presented in bar charts of median values and interquartile ranges for Z-score of serum concentration (pg/mL). Multiple comparative analysis was performed by Kruskal-Wallis followed by Dunn's post-test, and comparisons between COVID-19 and HC at matching pregnancy trimesters assessed by the Mann-Whitney test. In all cases, significance was considered at  $p<0.05$ . Intragroup differences were underscored by the letters "a" and "b" for comparisons with the 1<sup>st</sup> and 2<sup>nd</sup> trimesters, respectively. Inter-group differences at matching pregnancy trimesters were denoted by an asterisk (\*).

correlations, respectively), with growth factor predominance at the 3<sup>rd</sup> trimester (42 strong correlations). Conversely, the COVID group displayed a predominance of regulatory cytokines in the 1<sup>st</sup> trimester (47 strong correlations) with growth factor predominance in the 2<sup>nd</sup> and 3<sup>rd</sup> trimesters (24 and 21, respectively) (Figure 4).

In general, convalescent COVID-19 infection during pregnancy leads to a loss of network connectivity, with fewer strong correlations and changes in the predominance of connectivity amongst the categories of serum soluble mediators (Figure 4).

### 3.4 Descriptive analysis of serum soluble mediator networks in convalescent COVID-19 patients at distinct pregnancy trimesters

In order to provide a more comprehensive overview of the network connectivity between serum soluble mediators in pregnant women with convalescent COVID-19 and healthy controls along the pregnancy trimesters, a descriptive Venn diagram analysis was

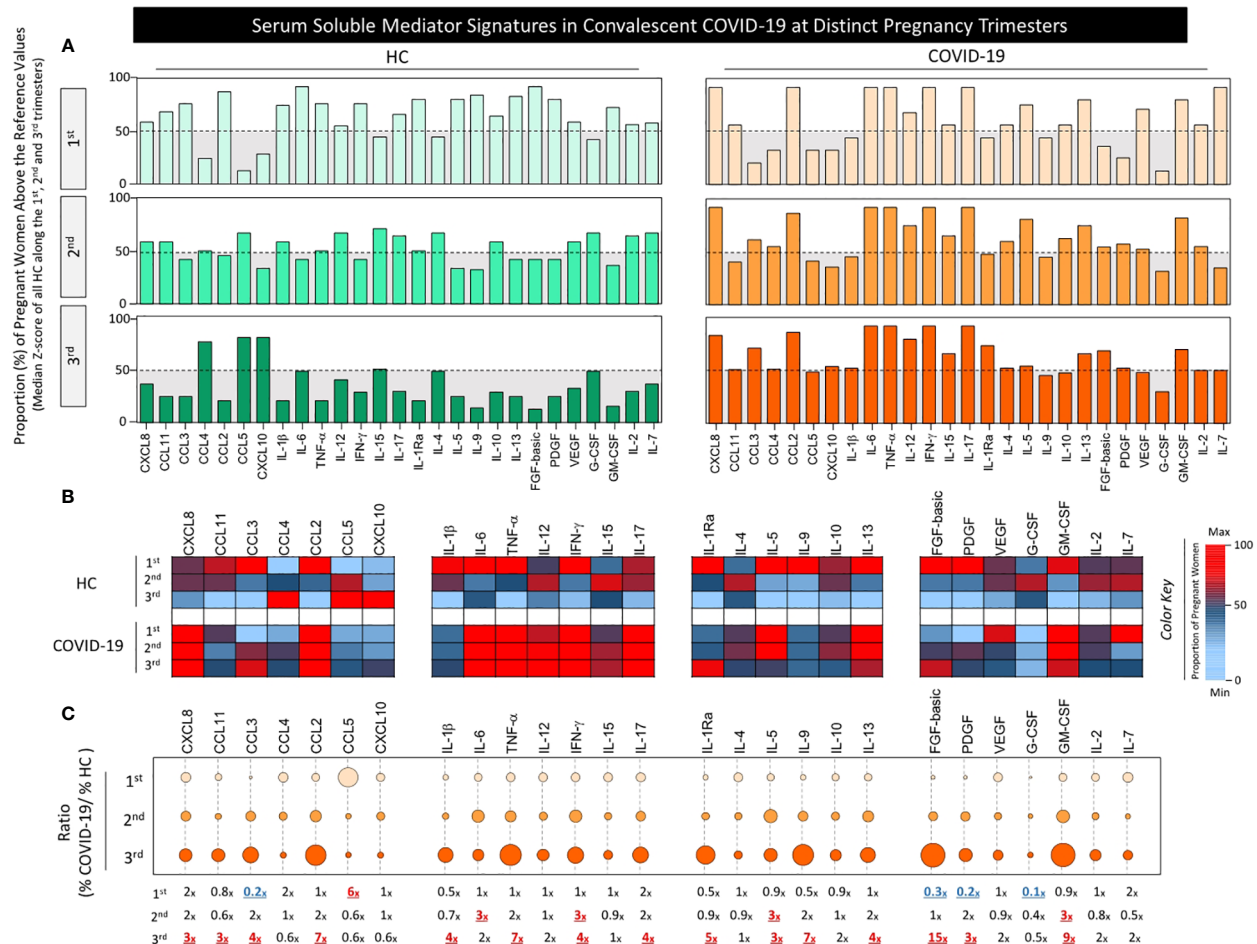

FIGURE 3

Serum soluble mediator signatures in convalescent COVID-19 patients at distinct pregnancy trimesters. Signatures of: serum chemokines (CXCL8, CCL11, CCL3, CCL4, CCL2, CCL5, and CXCL10), pro-inflammatory cytokines (IL-1 $\beta$ , IL-6, TNF- $\alpha$ , IL-12, IFN- $\gamma$ , IL-15, and IL-17), regulatory cytokines (IL-1Ra, IL-4, IL-5, IL-9, IL-10, and IL-13), and growth factors (FGF-basic, PDGF, VEGF, G-CSF, GM-CSF, IL-2, and IL-7) were assembled for pregnant women with convalescent COVID-19 at 3–20 weeks after symptoms onset (COVID,  $n=89$ ) and for pre-pandemic non-infected pregnant women as a Healthy Control (HC,  $n=52$ ). The HC and COVID-19 groups were further categorized into subgroups according to pregnancy trimester, referred to as: HC 1<sup>st</sup> ( $n=21$ ), HC 2<sup>nd</sup> ( $n=10$ ), HC 3<sup>rd</sup> ( $n=21$ ) and COVID 1<sup>st</sup> ( $n=7$ ), COVID 2<sup>nd</sup> ( $n=34$ ), COVID 3<sup>rd</sup> ( $n=48$ ). The measurements were taken by high-throughput multiplex bead array as described in Material and Methods. (A) The results are presented in bar charts showing the proportion (%) of pregnant women with serum levels above the reference values (cut-off) defined as the median Z-score of each soluble mediator detected for all HC along the 1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> trimesters, as described in Material and Methods. The serum soluble mediators displaying a proportion of pregnant women above 50% (grey zone, dashed line) were included in the set of biomarkers with increased levels. (B) Heatmap constructs were further assembled to illustrate the overall profile of serum soluble mediator signatures of COVID and HC subgroups along the pregnancy trimesters. A color key was used to underscore the serum soluble mediators with decreased (proportion <50%, towards light blue), unaltered (proportion =50%, black) or increased levels (proportion >50%, towards red). (C) The ratio between the proportion of pregnant women with serum levels above the reference values in the COVID group in relation to HC (%COVID/%HC) was further calculated and presented in orbital graphs. The ratios of each serum soluble mediator along the 1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> trimesters are provided in the figure, underscored as decreased ( $\leq 0.3x$ , blue), unaltered ( $0.4\text{--}2x$ , black) or increased ( $\geq 3x$ , red).

performed to identify the set of biomarkers with preserved (common), lost or acquired (selective) attributes with five or more ( $\geq 5$ ) strong correlations in COVID subgroups as compared to the trimester-matching HC group. The results are presented in the Figure 5.

Heatmap constructs were assembled to organize the serum soluble mediators with an ascending order of strong correlations and identify the set of biomarkers with five or more ( $\geq 5$ ) strong correlations at each pregnancy trimester in the COVID and HC groups (Figure 5A).

Data analysis demonstrated that the number of preserved attributes referred to as common in HC and COVID ( $\geq 5$  strong correlations in HC and COVID) with five or more correlations progressively decreased from the 1<sup>st</sup> ( $n=12$ ) to the 2<sup>nd</sup> ( $n=6$ ) and 3<sup>rd</sup> trimesters ( $n=4$ ). In detail: 1<sup>st</sup>: CCL11, CCL3, CCL2, IL-1 $\beta$ , IL-12, IL-15, IL-1Ra, IL-5, IL-9, IL-10, GM-CSF, and IL-2; 2<sup>nd</sup>: IL-6, TNF- $\alpha$ , IL-1Ra, IL-5, IL-10, GM-CSF and 3<sup>rd</sup>: IFN- $\gamma$ , IL-1Ra, G-CSF, and GM-CSF.

The number of lost attributes referred to as HC-selective ( $\geq 5$  strong correlations in HC and <5 strong correlations in COVID)

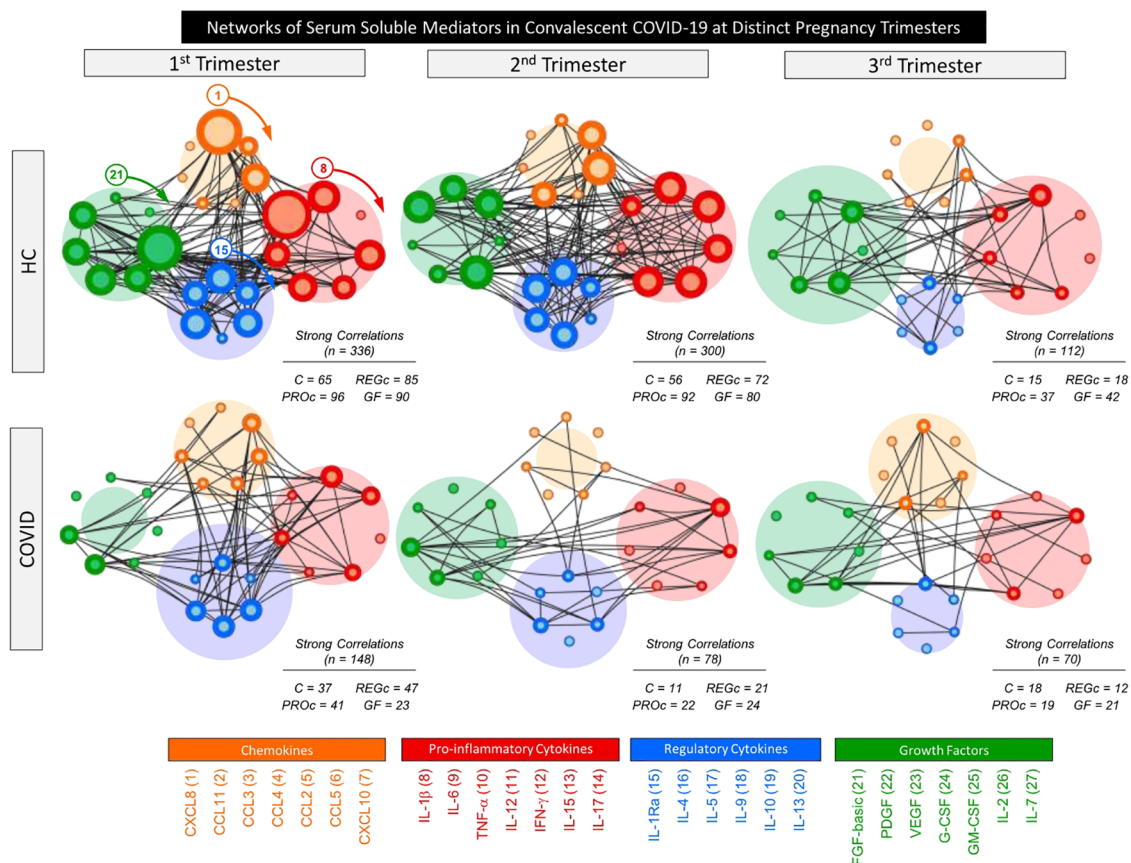

FIGURE 4

Networks of serum soluble mediators in convalescent COVID-19 patients at distinct pregnancy trimesters. Comprehensive networks were assembled for serum chemokines, pro-inflammatory cytokines, regulatory cytokines, and growth factors observed in pregnant women with convalescent COVID-19 at 3–20 weeks after symptoms onset (COVID,  $n=89$ ), with pre-pandemic non-infected pregnant women as a Healthy Control (HC,  $n=52$ ). The HC and COVID-19 groups were further categorized into subgroups according to pregnancy trimester, referred to as: 1<sup>st</sup> (HC=21 and COVID=7), 2<sup>nd</sup> (HC=18 and COVID=34) and 3<sup>rd</sup> (HC=21 and COVID=48). The measurements were taken by high-throughput multiplex bead array as described in Material and Methods. Data analyses were carried out by Pearson and Spearman rank tests with only significant strong correlations ( $p<0.05$  and “ $r$ ” scores  $\geq |0.67|$ ) employed to construct the comprehensive networks. Cluster layout networks were assembled, comprising 4 categories of serum soluble mediators as follows: - Chemokines – C (orange nodes – 1=CXCL8; 2=CCL11; 3=CCL3; 4=CCL4; 5=CCL2, 6=CCL5 and 7=CXCL10); Pro-inflammatory – PROc (red nodes – 8= IL-1 $\beta$ ; 9=IL-6; 10= TNF- $\alpha$ ; 11=IL-12; 12= IFN- $\gamma$ ; 13=IL-15 and 14=IL-17); Regulatory cytokines – REGc (blue nodes – 15=IL-1Ra; 16=IL-4; 17=IL-5; 18=IL-9; 19=IL-10 and 20=IL-13), and Growth Factors – GF (green nodes – 21=FGF-basic; 22=PDGF; 23=VEGF; 24=G-CSF; 25=GM-CSF; 26=IL-2 and 27=IL-7). Node border thickness is proportional to the number of strong correlations. Connecting edges (black lines) are used to link pairs of serum soluble mediators presenting significant correlations. The number of strong correlations (C, PROc, REGc and GF) observed for each network is provided in the figure and used for comparative analysis between COVID and HC, as well as amongst subgroups. The circular background area is proportional to the number of strong correlations of each cluster within the respective network.

was higher in the 2<sup>nd</sup> trimester ( $n=15$ ) compared to 1<sup>st</sup> ( $n=10$ ) and 3<sup>rd</sup> ( $n=9$ ). In detail: 1<sup>st</sup>: CXCL8, TNF- $\alpha$ , IFN- $\gamma$ , IL-17, IL-4, IL-13, FGF-basic, VEGF, G-CSF, and IL-7; 2<sup>nd</sup>: CXCL8, CCL11, CCL3, CCL2, IL-1 $\beta$ , IL-12, IFN- $\gamma$ , IL-17, IL-4, IL-9, IL-13, FGF-basic, VEGF, G-CSF, and IL-7; 3<sup>rd</sup>: CCL11, CCL3, IL-1 $\beta$ , IL-12, IL-15, IL-17, IL-9, FGF-basic, and VEGF. A set of acquired attributes, named COVID-selective ( $<5$  strong correlations in HC and  $\geq 5$  strong correlations in COVID) were identified in each trimester: 1<sup>st</sup> ( $n=3$ ): CCL4, CCL5, and IL-6, 2<sup>nd</sup>: ( $n=1$ ) IL-2, and 3<sup>rd</sup> ( $n=3$ ) CXCL8, CCL2 and IL-6 (Figure 5B).

From an overall perspective, a pronounced decrease in network connectivity between serum soluble mediators was observed in convalescent COVID-19 infection during pregnancy as demonstrated by the fewer number of molecules establishing strong correlations driven by an imbalance between preserved, lost and acquired attributes in the COVID group. While IL-1Ra, IL-10 and GM-CSF presented a preserved number of correlations ( $\geq 5$  strong correlations in HC and COVID), IL-17, FGF-basic and VEGF lost connectivity throughout pregnancy. IL-6 (at 1<sup>st</sup> and 3<sup>rd</sup> trimesters) and CXCL8 (at 3<sup>rd</sup> trimester) were included in a set of acquired

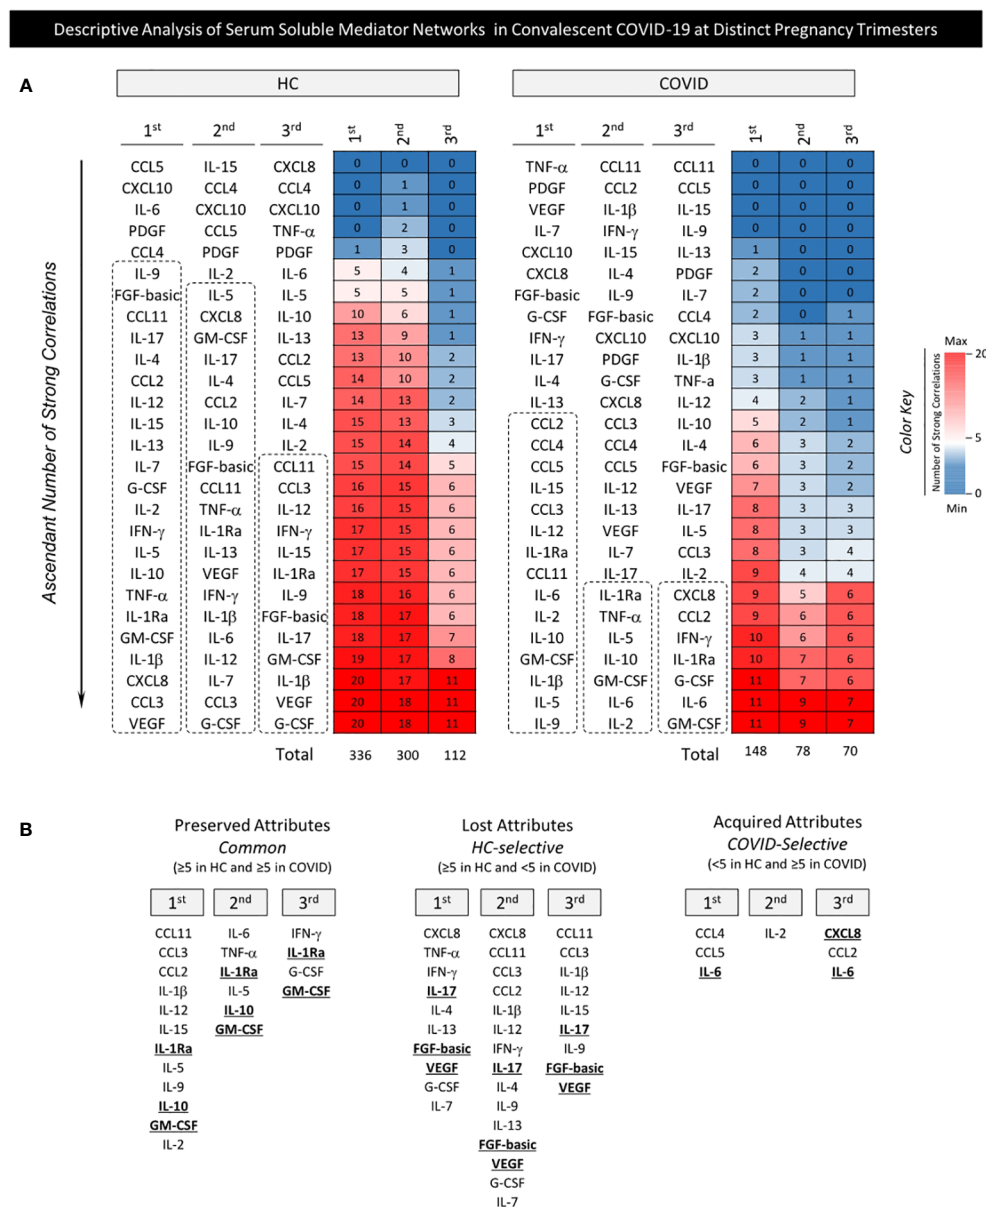

FIGURE 5

Descriptive analysis of serum soluble mediator networks in convalescent COVID-19 patients at distinct pregnancy trimesters. The overall profile of serum soluble mediator networks was assessed in pregnant women with convalescent COVID-19 at 3–20 weeks after symptoms onset (COVID, n=89) with pre-pandemic non-infected pregnant women as a Healthy Control (HC, n=52). The HC and COVID-19 groups were further categorized into subgroups according to pregnancy trimester, referred to as: 1<sup>st</sup> (HC=21 and COVID=7), 2<sup>nd</sup> (HC=10 and COVID=34), and 3<sup>rd</sup> (HC=21 and COVID=48). (A) The ascendant number of strong correlations was arranged to identify the set of biomarkers with five or more (≥ 5) strong correlations with other molecules at each pregnancy trimester in HC and COVID subgroups. Heatmap constructs were assembled to illustrate the overall profile of serum soluble mediator networks of COVID and HC subgroups along the pregnancy trimesters. A color key was used to underscore the serum soluble mediators with ≥ 5 strong correlations (towards red). (B) A summary of preserved (≥5 in HC and ≥5 in COVID), lost (≥5 in HC and <5 in COVID) or acquired (<5 in HC and ≥5 in COVID) attributes were identified by Venn diagram analysis. Attributes identified along the trimesters are highlighted by bold underline format.

attributes, named COVID-selective (≥5 strong correlations in COVID and <5 in HC) (Figure 5B, bold underline attributes).

### 3.5 Multivariate analysis of serum soluble mediators in convalescent COVID-19 patients at distinct pregnancy trimesters

Multivariate analysis of chemokines, pro-inflammatory cytokines, regulatory cytokines and growth factors was performed

using PCA to verify the ability of serum mediators to cluster convalescent COVID-19 pregnant women apart from trimester-matching pre-pandemic non-infected pregnant women as a healthy control (HC). The results are presented in Figure 6. The PCA coordinates (2<sup>nd</sup> and 3<sup>rd</sup> principal components) demonstrated that although convalescent COVID pregnant women could be clustered apart from the HC when considering all trimesters together, the segregation profile was more evident when the COVID and HC

### Multivariate Analysis of Serum Soluble Mediator Signatures in Convalescent COVID-19 at Distinct Pregnancy Trimesters

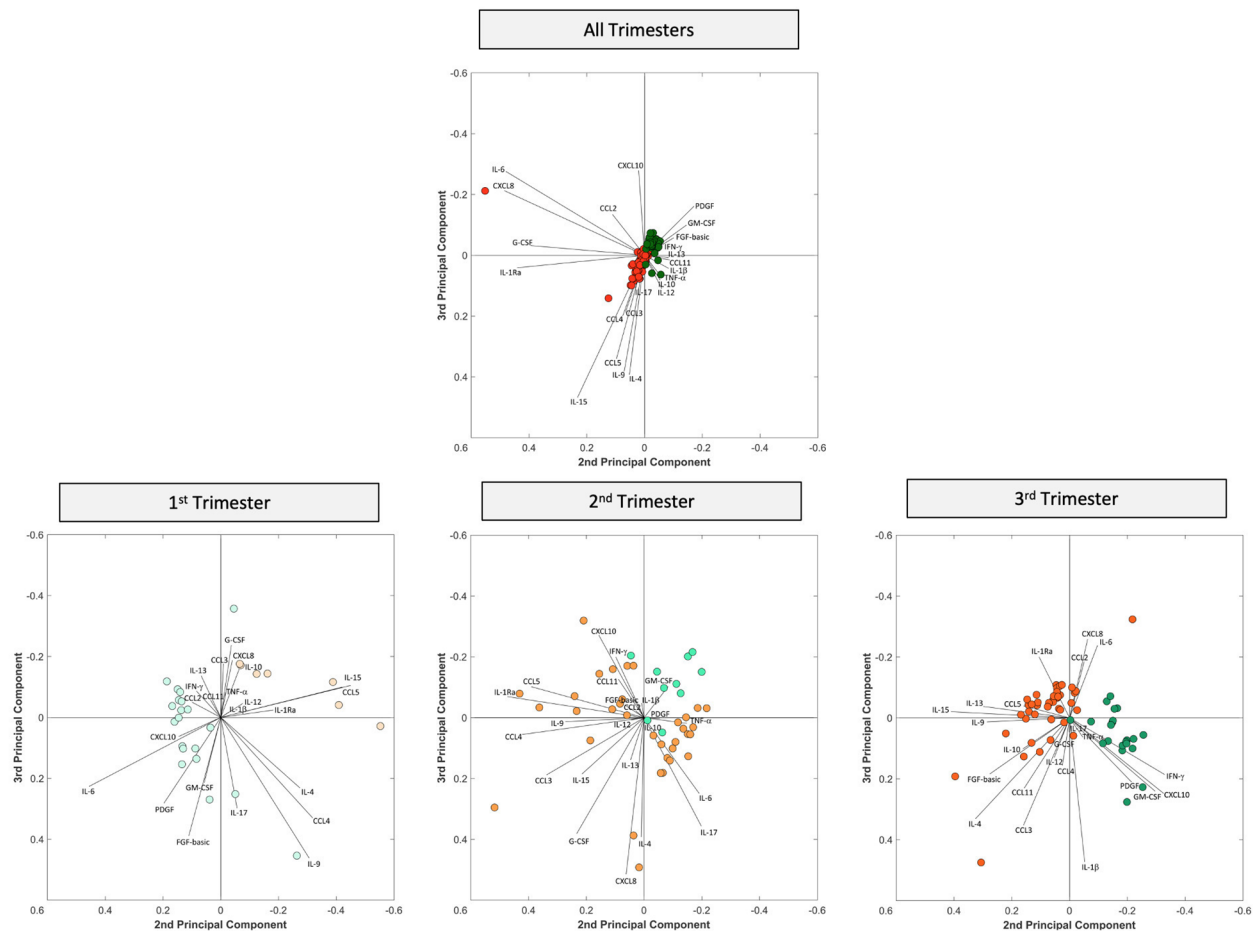

FIGURE 6

Multivariate analysis of serum soluble mediator networks in convalescent COVID-19 patients at distinct pregnancy trimesters. Multivariate analysis of serum chemokines, pro-inflammatory cytokines, regulatory cytokines and growth factors were performed to verify the ability of soluble mediators to cluster convalescent COVID-19 pregnant women at 3–20 weeks after symptoms onset (COVID,  $n=89$ ), with pre-pandemic non-infected pregnant women as a Healthy Control (HC,  $n=52$ ) as well as subgroups of COVID-19 and HC categorized according to pregnancy trimester, referred to as: HC 1<sup>st</sup> (○,  $n=21$ ), HC 2<sup>nd</sup> (●,  $n=10$ ), HC 3<sup>rd</sup> (●,  $n=21$ ) and COVID 1<sup>st</sup> (○,  $n=7$ ), COVID 2<sup>nd</sup> (●,  $n=34$ ), COVID 3<sup>rd</sup> (●,  $n=48$ ). The measurements were taken by high-throughput multiplex bead array as described in Material and Methods. Principal Component Analysis (PCA) was carried out by MATLAB software as described in Material and Methods. PCA coordinates (2<sup>nd</sup> and 3<sup>rd</sup> principal components) were used to compare and visualize the grouping of convalescent COVID-19 vs HC and subgroups according to pregnancy trimesters.

subgroups were compared at matching gestational trimesters (Figure 6). Vector analysis conducted in the 1<sup>st</sup> trimester indicated that CXCL8, CCL3, CCL5, IL-1 $\beta$ , TNF- $\alpha$ , IL-12, IL-15, IL-1Ra, IL-10, and G-CSF were associated with convalescent COVID-19 in pregnant women. Data from the 2<sup>nd</sup> trimester showed that most soluble mediators were vectors associated with differential distribution of convalescent COVID-19 in pregnant women, except for GM-CSF. Additionally, the PCA coordinates obtained from the 3<sup>rd</sup> trimester demonstrated that several soluble mediators were vectors related to convalescent COVID-19 in pregnant women, except for CXCL10, IL-1 $\beta$ , TNF- $\alpha$ , IFN- $\gamma$ , PDGF and GM-CSF (Figure 6).

## 4 Discussion

Pregnancy triggers a unique immunological status, aiming to protect the fetus from maternal rejection and guarantee fetal development until birth. Several studies have reported that the immune system plays a balancing role during pregnancy with constant changes according to maternal and fetal demands (16, 17). Physiological changes in immune status during pregnancy are often characterized by alterations in cell-mediated immunity and humoral responses, from the 1<sup>st</sup> to 3<sup>rd</sup> pregnancy trimesters. Previous studies have demonstrated that successful implantation is associated with a transient increase in systemic proinflammatory

profile followed by a switch toward an anti-inflammatory profile after blastocyst transfer when pregnancy is confirmed (18). Pregnant women are particularly susceptible to COVID-19 due to physiological changes in the immune system, which may result in an altered response to SARS-CoV-2 infection in pregnancy. Furthermore, SARS-CoV-2 infection during pregnancy can disrupt the immune response homeostasis, impacting the maternal immune activation, with effects on pregnancy outcome and offspring (12, 13, 19, 20). It has already been reported that the adverse impacts of the COVID-19 pandemic on maternal health are not limited to morbidity and mortality caused by the disease itself, but are also associated with adverse pregnancy outcomes, including preeclampsia, preterm birth and stillbirth (19).

Most of the information on the impact of SARS-CoV-2 infection in pregnancy has been derived from reports concerning acute symptomatic infection (21). However, little data is available regarding the long-term impact of SARS-CoV-2 infection on pregnancy during the convalescent phase of the disease. In view of this, we designed this study as a pioneer exploratory investigation to perform descriptive and panoramic analysis of serum soluble mediator interplay in pregnant women during the convalescent phase of SARS-CoV-2 infection throughout prenatal care. This study comprises an innovative investigation of the long-lasting impact of SARS-CoV-2 infection during pregnancy focusing on the analysis of the immune response during the convalescent phase comprising 3–20 weeks after symptoms onset.

Our results demonstrate that, in general, serum soluble mediators have different trajectories during healthy pregnancy and are disturbed in pregnant women with convalescent SARS-CoV-2 infection. Herein, healthy pregnant women presented a progressive decrease in most serum soluble mediators towards the 2<sup>nd</sup> and 3<sup>rd</sup> pregnancy trimester, including chemokines, pro-inflammatory and regulatory cytokines, in addition to growth factors. Previous studies corroborate our findings in healthy pregnancies. The levels of chemokines and pro-inflammatory cytokines usually peak in the first trimester of pregnancy and decline in the 2<sup>nd</sup> and 3<sup>rd</sup> trimesters, while regulatory cytokines and growth factors have diverse trajectories (22, 23). Our findings highlighted that higher levels of most soluble mediators were observed in the COVID group compared to HC control group. The major increase occurred in pro-inflammatory cytokines, including IL-6, TNF- $\alpha$  and IFN- $\gamma$ , a larger set of biomarkers with elevated COVID/HC ratios observed towards the 2<sup>nd</sup> (3x increase) and 3<sup>rd</sup> (3–15x increase) pregnancy trimesters. Studies of immune mediators in SARS-CoV-2 infection during pregnancy remain scarce. It has been proposed that the immunomodulation observed during pregnancy may protect pregnant COVID-19 patients from suffering from a cytokine storm (15, 24). However, no studies focusing on comparative analysis of immunological profiles of COVID-19 and healthy pregnant women at matching pregnancy trimesters have been reported. It is noteworthy that due to physiological changes in the immune response during pregnancy, the inclusion of trimester-matching healthy controls is essential to enable conclusive analysis. Therefore, our study is pioneering in terms of providing a detailed profile of long-lasting changes during convalescent

COVID-19 infection in pregnancy as it made direct comparison to trimester-matching healthy controls. Our findings did not support that an immunomodulatory profile is triggered by SARS-CoV-2 infection during pregnancy. In fact, the lower levels of soluble mediators previously reported in convalescent COVID-19 pregnant women were compared with those observed in non-pregnant women and did not consider the physiological changes triggered by pregnancy or alterations in soluble mediators inherent in trimesters (24). Moreover, other studies proposing the immunomodulatory state for acute COVID-19 infection during pregnancy in comparison to healthy pregnant women did not consider stratification by gestational trimesters (15). According to our findings, higher levels of serum soluble mediators were observed for convalescent COVID-19 infection during pregnancy, especially IL-6, TNF- $\alpha$  and IFN- $\gamma$  in comparison to healthy pregnant women at matching pregnancy trimesters.

Successful pregnancy requires finely coordinated communication between the maternal and fetal microenvironments. Cytokine signaling pathways participate as mediators of these communications to guarantee healthy pregnancy. From the existing data available, there is no consensus trend for the changes observed for IL-6, TNF- $\alpha$  and IFN- $\gamma$  during pregnancy (16). Several studies have demonstrated that IL-6, TNF- $\alpha$  and IFN- $\gamma$  concentrations significantly increased between the 1<sup>st</sup>, 2<sup>nd</sup> and 3<sup>rd</sup> trimesters of healthy pregnancy (25–30). However, corroborating our findings, other authors detected significant reductions in IL-6, TNF- $\alpha$  and IFN- $\gamma$  in maternal serum concentrations between the 1<sup>st</sup> and 3<sup>rd</sup> trimesters (31–33).

Infections or inflammatory conditions, such as COVID-19 during pregnancy, can have a detrimental impact on fetal development and also contribute to pregnancy-associated pathological conditions (34). Despite the conflicting data regarding the overall profile of IL-6, TNF- $\alpha$  and IFN- $\gamma$  during healthy pregnancy, there is a consensus that the establishment of a pro-inflammatory microenvironment is associated with the risk of developing pregnancy-associated pathological conditions, including pregnancy loss, preeclampsia, and gestational diabetes mellitus (35). In this sense, the upregulation of pro-inflammatory cytokines in pregnant women with convalescent COVID-19 may suggest that these patients are more vulnerable to developing adverse pregnancy outcomes.

Integrative network analysis demonstrated that both HC and convalescent COVID-19 pregnancies evolve with decreasing connectivity between serum soluble mediators towards the 3<sup>rd</sup> trimester. However, the COVID group exhibited a remarkably lower number of connections. Overall, IL-1Ra, IL-10 and GM-CSF presented a preserved number of correlations throughout the pregnancy.

Further research is warranted to determine the precise IL-10 profile during healthy pregnancy (14). A few studies have reported that IL-10 significantly increases from the 1<sup>st</sup> to the 2<sup>nd</sup> and 3<sup>rd</sup> trimesters in healthy pregnancy (30, 36). However, corroborating our findings, other studies have detected that IL-10 decreases between the 1<sup>st</sup> and 3<sup>rd</sup> trimesters (31, 37). Considering the critical role of IL-10 as a chief anti-inflammatory cytokine, the preserved IL-10 connectivity axis observed during the 1<sup>st</sup> and 2<sup>nd</sup> trimesters may represent a mechanism to protect the fetus from

maternal pro-inflammatory rejection and guarantee fetal development until birth.

Our data demonstrated that IL-1Ra decreased in convalescent COVID-19 pregnant women in the 1<sup>st</sup> trimester but increased in the 3<sup>rd</sup> trimester. Previous studies reported that IL-1Ra levels increased during the inflammatory response to control acute inflammation and prevent immunopathological events (38). The IL-1 receptor antagonist (IL-1Ra) is an anti-inflammatory cytokine that blocks IL-1 $\alpha$  and IL-1 $\beta$  functions and modulates their biological effects (39). It has been previously demonstrated in experimental models that high IL-1Ra levels at the beginning of pregnancy may lead to miscarriage due to impaired embryonic adhesion (40), and data from human studies showed that higher levels of circulating IL-1Ra have been reported in adverse pregnancy outcomes, including preeclampsia (41). Regarding the changes in IL-1Ra levels observed in convalescent COVID-19 along the pregnancy trimesters, our findings of preserved correlation profile between IL-1Ra and other soluble mediators throughout the pregnancy may suggest that an intricate microenvironment of soluble mediators is relevant to guarantee fetal development until birth.

Our data also demonstrated that GM-CSF presented preserved correlation with other soluble mediators throughout pregnancy. It was previously reported that after embryo implantation, GM-CSF participates in a network of cytokines and growth factors that regulate morphological and functional development of the placenta (42).

Conversely, despite increases in IL-17, FGF-basic and VEGF, loss of connectivity was observed throughout pregnancy. IL-17 up-regulates the expression of a variety of biological molecules with angiogenic properties including VEGF (43–47). VEGF plays a central role in vasculogenesis and angiogenesis, which augments vascular endothelial cell proliferation, migration, and survival. Moreover, data from previous studies have shown that IL-17 can induce placental oxidative stress and vascular dysfunction, resulting in hypertension and increased risk of preeclampsia (48). The loss of network connection of IL-17 and VEGF with other soluble mediators throughout the pregnancy may lead to intrinsic vascular dysfunction that results in impaired neonatal development. Post-natal follow-up studies may contribute to identifying impaired new-born growth and development related to altered angiogenesis.

Our data also demonstrated that IL-6 and CXCL8 were included in the set of attributes acquiring strong correlation in the 3<sup>rd</sup> pregnancy trimester, named COVID-selective correlations. Implications of IL-6 and CXCL8 in pregnancy-associated pathological conditions, such as pregnancy loss, preeclampsia, gestational diabetes mellitus, and infection/inflammation have been reported (35). These two soluble mediators are abundantly produced at the fetomaternal interface throughout pregnancy and have been shown to participate in several pregnancy-related events. Unbalanced expression/secretion of IL-6 and CXCL8 at the fetomaternal interface has been indicated in unexplained pregnancy loss (35). A study of the dynamic connections of the soluble mediator network in pre-eclampsia identified positive correlation between IL-

6 and CXCL8, suggesting that these molecules are implicated in the pathophysiology of this pregnancy-associated disease (35, 49). Moreover, a meta-analysis and systematic review suggested a role of CXCL8 in shaping the immune microenvironment in gestational diabetes mellitus (50).

The present study has some limitations. The low number of pregnant women enrolled in each pregnancy trimester re-enforce the need to further validate our findings. This work was performed during circulation of the B.1.1.28 and B.1.1.33 SARS-CoV-2 strains and therefore, the impact of other variants on the immunological profiles remains to be addressed. Despite the pioneering approach of this exploratory investigation, the observational design with multiple comparisons without corrections for co-morbidities or other confounding variables also constitutes a study limitation that may interfere in the levels of systemic soluble mediators. Moreover, regardless the relevance of nutritional aspects and the dietary inflammatory indices interfering in the immune response during pregnancy (51), we did not have the opportunity to address this issue in the present investigation.

In conclusion, the main finding of this study, a pronounced increase in serum levels of soluble mediators with decreased network interplay between them, portrayed an imbalanced immune response in convalescent COVID-19 infection during pregnancy that may contribute to the prevention or management of clinical course pregnancy complications.

## Data availability statement

The original contributions presented in the study are included in the article/[Supplementary Material](#). Further inquiries can be directed to the corresponding authors.

## Ethics statement

The studies involving human participants were reviewed and approved by National Commission for Ethics in Research in Brazil (CONEP, CAAE 32359620.0.0000.5558). The patients/participants provided their written informed consent to participate in this study.

COVID-19 prognoses suggests that a proportion of patients develop fibrosis, but there is no evidence to indicate whether patients have progression of mesenchymal transition (MT) in the lungs. The role of MT during the COVID-19 pandemic remains poorly understood. Using single-cell RNA sequencing, we profiled the transcriptomes of cells from the lungs of healthy individuals (n = 45), COVID-19 patients (n = 58), and idiopathic pulmonary fibrosis (IPF) patients (n = 64) human lungs to map the entire MT change. This analysis enabled us to map all high-resolution matrix-producing cells and identify distinct subpopulations of endothelial cells (ECs) and epithelial cells as the primary cellular sources of MT clusters during COVID-19. For the first time, we have identified early and late subgroups of endothelial mesenchymal transition (EndMT) and epithelial-mesenchymal transition (EMT) using analysis of public databases for single-cell sequencing. We assessed epithelial subgroups by age, smoking status, and gender, and the data suggest that the proportional changes in EMT in COVID-19 are statistically significant. Further enumeration of early and late EMT suggests a correlation between invasive genes and COVID-19. Finally, EndMT is upregulated in COVID-19 patients and enriched for more inflammatory cytokines. Further, by classifying EndMT as early or late stages, we found that early EndMT was positively correlated with entry factors but this was not true for late EndMT. Exploring the MT state of may help to mitigate the fibrosis impact of SARS-CoV-2 infection.

## KEYWORDS

COVID-19, endothelial-mesenchymal transition (EndMT), epithelial-mesenchymal transition (EMT), single cell RNA sequencing, endothelial cells (ECs)

**Abbreviations:** COVID-19, Coronavirus disease 2019; MT, Mesenchymal transition; EndMT, Endothelial-mesenchymal transition; EMT, Epithelial-mesenchymal transition; IPF, Idiopathic pulmonary fibrosis.

## Introduction

Alveolar epithelial type II cells (AEC2s) produce surfactants and serve as progenitors (1). Type II alveolar epithelium is reduced due to massive necrosis with SARS-COV-2 infection in patients (2). This leads to decreased barrier permeability and accumulation of proteinaceous edema fluid in the alveolar cavity, resulting in hypoxemia and even acute respiratory distress syndrome (ARDS), with a prognosis including fibrosis formation (3). Epithelial-mesenchymal transition (EMT) is the process by which epithelial cells differentiate into mesenchymal (fibroblast-like) cells expressing mesenchymal biomarkers such as  $\alpha$ -Smooth Muscle Actin ( $\alpha$ -SMA), and N-cadherin (4, 5). Therefore, we speculated that EMT might underlie the mechanism of lung fibrosis observed with ARDS in COVID-19 patients.

Early-stage and late-stage mesenchymal transition (MT) processes are considered the most critical pathogenic mechanisms of fibrosis in diseases like idiopathic pulmonary fibrosis (IPF), pulmonary hypertension, coronary artery disease, and other vascular-related disorders (6). Once endothelial cells (ECs) are damaged and the collagen and matrix are exposed, in addition to activation of the coagulation system, immune cells are recruited, leading to the release of large amounts of inflammatory factors are then released (7). Endothelial-mesenchymal transition (EndMT) occurs when ECs respond to chronic inflammation, transforming themselves into a more aggressive mesenchymal state (8, 9). In the early stages, irreversible vascular damage or EndMT, mainly presents more robust endothelial markers (e.g., vascular endothelial cadherins (VE-cadherins), *CD31* and *Tie1/2*) and expresses weaker mesenchymal markers (e.g., *N-cadherin*, *fibroblast specific protein-1* or *S100A4*, *fibronectin*, *vimentin*, *SM22- $\alpha$* , *calponin*, and  *$\alpha$ -smooth muscle actin*) (10, 11). Otherwise, late-stage EndMT presents weaker endothelial markers but with more robust mesenchymal markers.

EMT also has a similar process with the presence of EndMT as well as MT markers in the early stages (12, 13). However, in the late stage, epithelial markers are lost, and fibroblast markers are predominant (12, 13). Therefore, we hypothesized that EMT and EndMT may underlie factors implicated in the prolonged ventilator dependence and high mortality rates observed in hospitalized COVID-19 patients.

Herein, we draft EndMT and EMT by integrated analysis of 167 single-cell and single-nucleus RNA-sequencing (scRNA-seq and snRNA-seq, respectively) samples. We performed the first single-cell RNA sequencing meta-analysis associating COVID-19 with underlying contributor genes for MT. We have also identified specific gene programs enriched in MT-associated genes with fibrosis and highlight other entry factors that are significantly expressed in the lungs, which may play a role in SARS-CoV-2 infection.

## Materials and methods

### Data collection

We obtained scRNA/snRNA sequencing data from Gene Expression Omnibus database (GEO) database (<https://www.ncbi.nlm.nih.gov/geo/>). The majority of the data used in this manuscript is publicly available from previously published studies: COVID-19:GEO accession GSE171524, GSE171668, GSE149878, GSE161382 and GSE163919 (14–17). IPF: GEO accession GSE136831 and GSE135893 (18, 19). The Bulk RNA data is also available in the GEO database (accession number GSE47460) (20).

### scRNA/snRNA-seq data processing

We analyzed the scRNA and snRNA sequencing data using R(version 4.1.3) and Seurat v 4.0.2 (21). To eliminate low quality/dead cells or empty droplets, any single cells containing less than 200 genes or greater than 5,000 genes, or cells with more than 10% mitochondrial genes were removed. We next removed doublet contamination. As a result. We detected 49,795 genes in a total of 612,151 cells. Next, we performed LogNormalize() to normalize the gene expression data, used the FindVariableFeatures() function to identify genes whose expression was highly variable between cells, and used ScaleData() to scale the data. The "RunPCA" function was used for principal component analysis (PCA). Using the default parameters, Harmony package (22) was utilized to combine data and eliminate batch effect, Using the default parameters, Harmony performs de-batching by single patients. Subsequently, the top 20 statistically significant principal components were used in the "FindNeighbors" function. Cells were clustered (Cluster resolution = 0.6) by using the "FindClusters" function and visualized with the UMAP method.

### Cell type identification and data visualization

Cell type identification was mostly accomplished with the use of "FindAllMarkers," classical cell marker genes, R-packages (clustermole, singscore), and cell type annotation using a mixture of known cell marker genes. *EPCAM*<sup>+</sup> epithelial cells, *CLDN5*<sup>+</sup> endothelial cells, *PTPRC*<sup>+</sup> immune cells, and *COL1A2*<sup>+</sup> (mesenchymal cells). Cell clustering was performed using the Seurat "FindNeighbors" and "FindClusters" functions, and the final Seurat objects were created after UMAP downsampling. The heatmap was created using the R package ggplot2 in Seurat, and umap maps, violin maps, bar maps, heat maps, and point maps were created.

## Enrichment analysis

Enriched gene ontology biological (<http://geneontology.org/>) processes with a false discovery rate less than 5 percent were identified using the Gene Ontology Resource. KEGG (<http://www.kegg.jp>) enrichment analyses were carried out with the Fisher's exact test, and FDR correction for multiple testing was also performed. Gene Set Enrichment Analysis (GSEA) were performed with clusterProfile. The three methods determine whether a set of genes has statistically significant differences between two biological states (23).

## Trajectory analysis

The R package monocle3 v1.0.0 was used to construct single cell trajectory analysis. Cells marked as EndMT/EMT and their subsets information were input and constructed into a monocle object (24). The left side of the heat map, created with the R package monocle2, shows the signaling pathways enriched to the gene set. Each row of the heat map (ranging from red to blue) represents a gene; each column represents a proposed time point; and the color represents the average expression value of the gene at the current time point (from high to low expression, respectively) (25).

## Bulk RNA data

Univariate analysis was performed by using the Pearson's correlation coefficient of gene expression data and diffusing capacity of the lung for carbon monoxide (DLCO). The data is available in the Gene Expression Omnibus database (accession number GSE47460).

## Statistical analysis of functional data

The R language or the GraphPad Prism software, version 9 (San Diego, California USA, [www.graphpad.com](http://www.graphpad.com)) were used to perform all computations and analyses. T-tests were used for comparisons between groups, and one-way ANOVA was used for comparisons between multiple groups. A statistically significant difference was defined as a p value <0.05. The Wilcoxon rank sum statistical test was used to examine differentially expressed genes in each cluster. The meta package was used to perform the meta-analysis in R.

## Results

### Single-cell transcriptome sequencing reveals the presence of fibrosis-associated cell subpopulations

To investigate the contribution of EndMT in SARS-CoV-2 infection in the lungs, we analyzed existing scRNA/snRNA-seq

datasets to assess which clusters express EndMT markers. In a previously unpublished dataset consisting of COVID-19 and IPF lung tissue ( $n=167$ ), we recovered at least 14 distinct major cell types, including macrophages, monocytes, neutrophils, T cells, B cells, DCs, granulocytes, endothelial cells, fibroblasts, SMC/pericytes, goblet cells, alveolar type 1 epithelial cells (AT1), alveolar type 2 epithelial cells (AT2), ciliated cell populations, and proportional analysis of subpopulations, of whole lung tissue (Figures 1A, B). After analyzing their differentially expressed genes (DEGs), compared to controls, we found that the DEGs in COVID-19 patients were mainly concentrated in macrophages and monocytes, and the DEGs in IPF patients were mainly concentrated in the epithelium (Figure 1C). Further, we analyzed the ratio of cell subpopulations and found that the ratio of ECs and epithelial was upregulated in COVID-19 patients, while higher than in pulmonary fibrosis (Figure 1D). Using correlation analysis, we found that lymphatic ECs, SMC/pericytes, myofibroblasts, rest ECs, late EMT, proliferative fibroblast, rest fibroblasts, late EndMT, *DKK2*+ ECs, and activated ECs cells had a strong correlation. This phenomenon prompted us to question why fibroblasts and correlate strongly with ECs (Figure 1E). Therefore, we analyzed fibroblasts, and based on a literature search, we analyzed fibroblast subpopulations such as rest fibroblasts, myofibroblasts, and proliferative fibroblasts (Figures 1F, H). A comparison of COVID-19 and IPF samples revealed that the, myofibroblast proportion was significantly higher in patients with IPF compared to COVID-19 patients (Figure 1G). Interestingly, we also found that myofibroblast expression was much higher in male COVID-19 patients than male patients, but the opposite was true for rest fibroblasts (Figure 1I). We also analyzed the expression of entry factors in whole lung cells, and consistent with previous literature reports, *ACE2* was mainly concentrated in respiratory epithelium cells such as AT1 and AT2. However, *BSG*, *CTSL*, and *FURIN* were also abundantly expressed in macrophages and fibroblasts (Figure 1J). *TMPRSS2* and *ACE2* expression were upregulated in COVID-19 patients but *BSG*, *CTSL*, *FURIN* expression was higher in IPF patients, suggesting their role in increased myofibroblast expression in COVID-19 (Figure 1K). We also analyzed correlation analysis of entry factors and lung function test (%predicted DLCO) and found that lung function was negatively correlated with the normalized bulk RNA-seq gene expression of the entry factors (*CTSL*, *BSG*, *ACE2*) (Figure 1L).

### Single-cell transcriptome sequencing Atlas of EMT stage

EMT is a common type of transition, and we divided the epithelium into goblet, ciliated, EMT, AT1, and AT2 cell subgroups, in which the EMT proportion was significantly upregulated in COVID-19 and IPF patients, but there were no significant

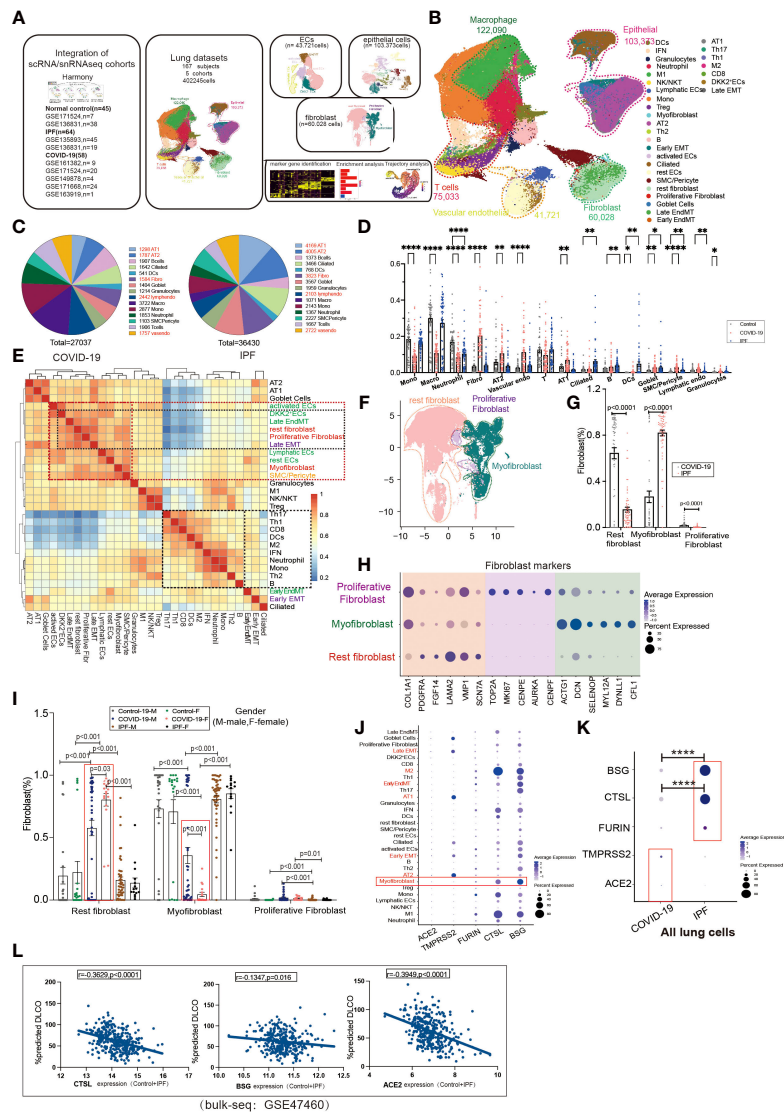

FIGURE 1

Subpopulation correlation analysis suggested a strong correlation between MT subpopulation and fibroblast subpopulation. **(A)** Scheme of this study. **(B)** Demonstration of HC, COVID-19, and IPF subgroups using UMAP, including Endothelial (vascular endothelial: rest ECs, EndMT, DKK2+ ECs, activated ECs; Lymphatic ECs); Epithelial (AT2, AT1, Goblet Cell, EMT, Ciliated); Fibroblast (Proliferative Fibroblast, Myofibroblast, Rest fibroblast, Late EndMT, Late EMT; SMC/Pericyte; T cells (Th1, Th17, Th2, Treg, NK/NKT, CD8, IFN); Macrophage (M2, M1); Granulocytes; DCs; Mono; Neutrophil. And the proportion of cell subpopulations in HC, COVID-19, IPF. Marker genes: Endothelial cells: PECAM1, VWF, CLDN5; Macrophages: MARCO, MSR1, MRC1; T cells: CD3E, CD3D, GZMH; Granulocytes: MS4A2, CPA3, TPSA1; B cells: MS4A1, BANK1, CD79A; Monocytes: CD14, FCN1; Neutrophil: S100A8, S100A9; Epithelial cells: EPCAM; Fibroblast: COL1A1, PDGFRA, ELN; SMC: SCGB1A1, RPL26). **(C)** Pie charts show the number of differentially expressed genes per cell type in COVID-19/IPF compared to controls. The DEGs of COVID-19 were mainly concentrated in macrophages and monocytes, and the DEGs of IPF were mainly concentrated in epithelium. **(D)** The proportion of cell subpopulations in HC, COVID-19, IPF. **(E)** The heat-map shows the correlation analysis for each cell subpopulation. The correlation between late-stage EMT, late-stage EndMT and fibroblast subpopulation was higher. **(F)** UMAP suggests a subpopulation distribution of fibroblasts, including Myofibroblasts, Proliferative fibroblasts and Rest fibroblast. **(G)** Ratio of fibroblast subpopulations in patients with COVID-19, IPF, showing myofibroblast ratio in IPF is higher than that in COVID-19, but Rest fibroblast ratio in IPF is lower than that in COVID-19. **(H)** Markers of fibroblast subpopulations, including Myofibroblast (ACTG1, DCN, SELENOP, MYL12A, DYNLL1, CFL1), Proliferative fibroblast (TOP2A, MKI67, CENPE, AUPKA, CENPF) and Rest fibroblast (COL1A1, PDGFRA, FGF14, LAMA2, VMP1, SCN7A). **(I)** The proportion of fibroblast subpopulations in COVID-19, IPF by female and male, showing Myofibroblast ratio in females is lower than that in males with COVID-19. **(J)** The DOT plot shows the expression of entry factors in subgroups of control, COVID-19, IPF. Subgroups including Rest fibroblast, Myofibroblast, Proliferative Fibroblast, Late EndMT, Late EMT, SMC/Pericyte; rest ECs, DKK2+ ECs, activated ECs, Lymphatic ECs, EndMT-early; AT1, AT2, Ciliated, Early EMT, Goblet Cell; Granulocytes; B, Th2, Th1, Th17, Treg, CD8, Mono, M1, M2, Neutrophil, DCs, NK/NKT. **(K)** The DOT plot shows the expression of entry factors in COVID-19, IPF. **(L)** Correlation analysis of entry factors (CTSL, BSG, ACE2) and lung function test (%predicted DLCO) showed that lung function was negatively correlated with the normalized bulk RNA-seq gene expression of the entry factors. \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\*\* $P < 0.0001$ .

differences between COVID-19 and IPF (Figures 2A, B). After excluding datasets with significant heterogeneity, we performed a meta-analysis using 3 GEO datasets with a pooled SMD of 0.99 and 95% CI (0.49; 1.49) (Figure 2C). Surprisingly, the EMT rate was much more significant in the middle-aged group than in the aged group. The middle-aged group was mainly enriched for inflammation-related signaling pathways, and then the aging adult group was enriched for more fibrosis-related signaling pathways (Figures 2D, E). Whether classified by smoking or not, we observed that EMT was higher in both COVID-19 patients than in controls, and then IPF was higher in the non-smoking group compared to samples. In COVID-19, smoking is enriched for more interferon-related signaling pathways compared to samples from non-smoking individuals (Figures 2F, G). We found that the proportion of EMT was higher in patients who smoked, while in COVID-19 patients, the proportion of EMT was more significant in non-smoking males than in females (Figures 2H, I). This phenomenon indicates that males contribute more to EMT progression. EMT is positively correlated with myofibroblasts in COVID-19 patients, and IPF patients also have the same expression trend. Males upregulated inflammation-related signaling pathways, however females were enriched for downregulated inflammatory signaling pathways (Figure 2J).

Trajectory analysis mentions early and late mesenchymal transitions, and its marker also suggests its transition status (Figure 3A). *EPCAM* expression was significantly decreased from early to late stages. *TAGLN* expression was increased in the early stages but decreased in the late stages. *COL3A1* expression was somewhat lower during the early stages but increased significantly during the late stages (Figures 3C, D, G). From early to late stages, Monocel2 displayed the primary enhanced signaling pathways concurrently (Figure 3B). *TAGLN* is a typical EMT marker gene that is elevated in COVID-19 patients. A meta-analysis of a dataset of five GEO resulted in a pooled SMD of 0.73, 95 CI% (0.30; 1.15) (Figures 3D–F). *COL3A1* is a well-characterized marker of late MT that is increased in COVID-19 patients. The dataset of five GEOs was analyzed using meta-analysis, resulting in a pooled SMD of 1.77, 95 CI% (0.82; 2.72) (Figures 3G–I). Further analysis of the correlation between invasion genes showed that the epithelial entry factor genes (*BSG*, *FURIN*, *CTSL*) were positively correlated with the ratio of early EMT in COVID-19, *TMPRSS2* was negatively correlated with the ratio of early EMT in COVID-19, and *FURIN* was positively correlated with the ratio of early EMT in IPF (Figure 3J). *TMPRSS2* was positively correlated with the ratio of late EMT in COVID-19 and *BSG* was negatively correlated with the ratio of late EMT in COVID-19 (Figure 3K).

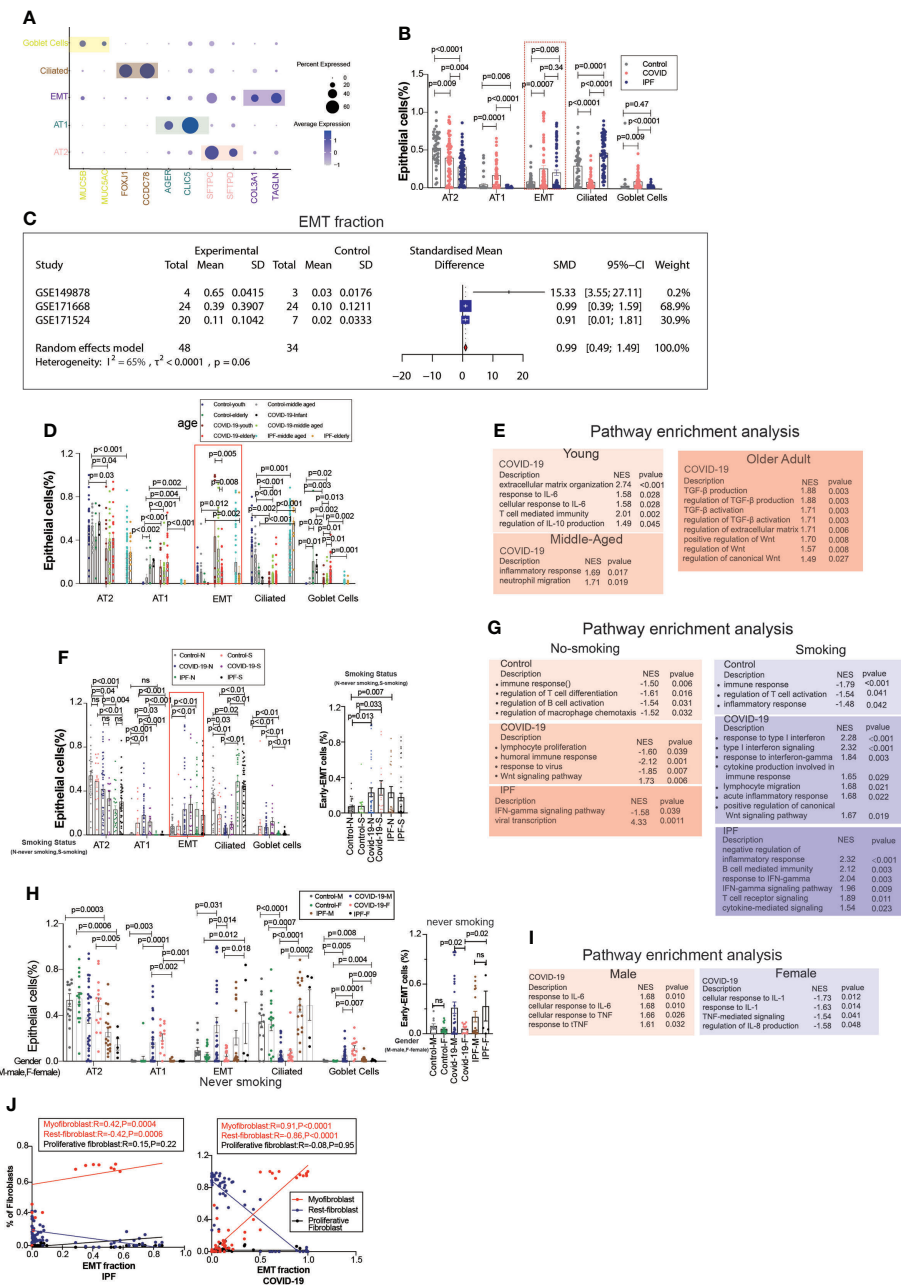

## Single-cell transcriptome sequencing Atlas of EndMT stage

A further exploration of the potential cause of elevated fibroblast expression in COVID-19, revealed subpopulations of

endothelium cells based on the high correlation between fibroblasts and endothelial cells (Figure 1D), and we found a subpopulation of endothelial cells with EndMT as in IPF (Figure 4A), which highly expresses the marker gene for subpopulations (Figure 4B). We divided the subgroups of endothelial cells into lymphatic ECs, EndMT, *DKK2*+ ECs, activated ECs, and rest ECs. Comparing the endothelium subgroup ratios in ECs, we found that the ratio of EndMT was increased in COVID-19 and higher in IPF than in the controls (Figure 4C). We showed common inflammation-associated cytokines through different subpopulations, implying an abundant expression of EndMT (Figure 4D). To exclude the effect of smoking, we selected nonsmoking patients for comparison, and the results suggested that the proportion of EndMT was also higher in males than in females in COVID-19 patients (Figure 4E). We compared the proportion of entry factor genes in Lymphatic ECs, EndMT, *DKK2*+ ECs, activated ECs, and rest ECs in COVID-19 and IPF (Figures 4F, G). The findings suggest that EndMT plays a unique function in COVID-19, and meta-analysis of data from several GEO databases indicates that the EndMT proportion in COVID-19 vs. control pooled SMD was 0.64, 95% CI [0.16; 1.12] (Figure 4H). After dividing the data into two groups, EndMT<sup>low</sup> and EndMT<sup>high</sup>, the latter group was found to have a higher proportion of myofibroblasts (Figure 4I). A hypothesis was then raised about whether EndMT led to the increase in fibroblasts. Enrichment analysis of cytokine expression in the EndMT subpopulation revealed high expression of cytokines associated with fibrosis in COVID-19 and IPF (Figure 4J). The EndMT ratio was positively correlated with myofibroblast cells and negatively correlated with rest fibroblast (Figure 4K).

We then tried to determine whether EndMT has a series of genes that can affect COVID-19 and IPF MT by trajectory analysis and classified EndMT into early, intermediate, and late stages (Figure 5A). The enrichment of genes in early and late stages demonstrates that the interferon-gamma signaling pathway is upregulated in early stages. Simultaneously, late stages exhibit increased expression of the ECM-receptor interaction signaling pathway (Figure 5B). The expression of marker genes associated with EndMT also suggested early, intermediate, and late stages (Figure 5C). *ACTA2* expression was low in the intermediate stage but rapidly increased in the late stage (Figure 5D). Calculating the fraction of *ACTA2* present throughout the early stages of the disease reveals that the expression in COVID-19 is more significant than in controls (Figure 5E). By screening the marker genes of early stage EndMT, the marker gene at the early stage was finally identified as *ACTA2* with an SMD of 0.87, 95% CI (0.23, 1.51) for COVID-19 vs. control in 5 GEO datasets following meta-analysis (Figure 5F). Subsequently, *MMP2* and *COL3A1* were used to identify the late-stage marker gene (Figure 5G, J). *COL3A1* expression was increased in COVID-19 compared to controls (Figure 5K), and although all GSE statistics of *MMP2*-

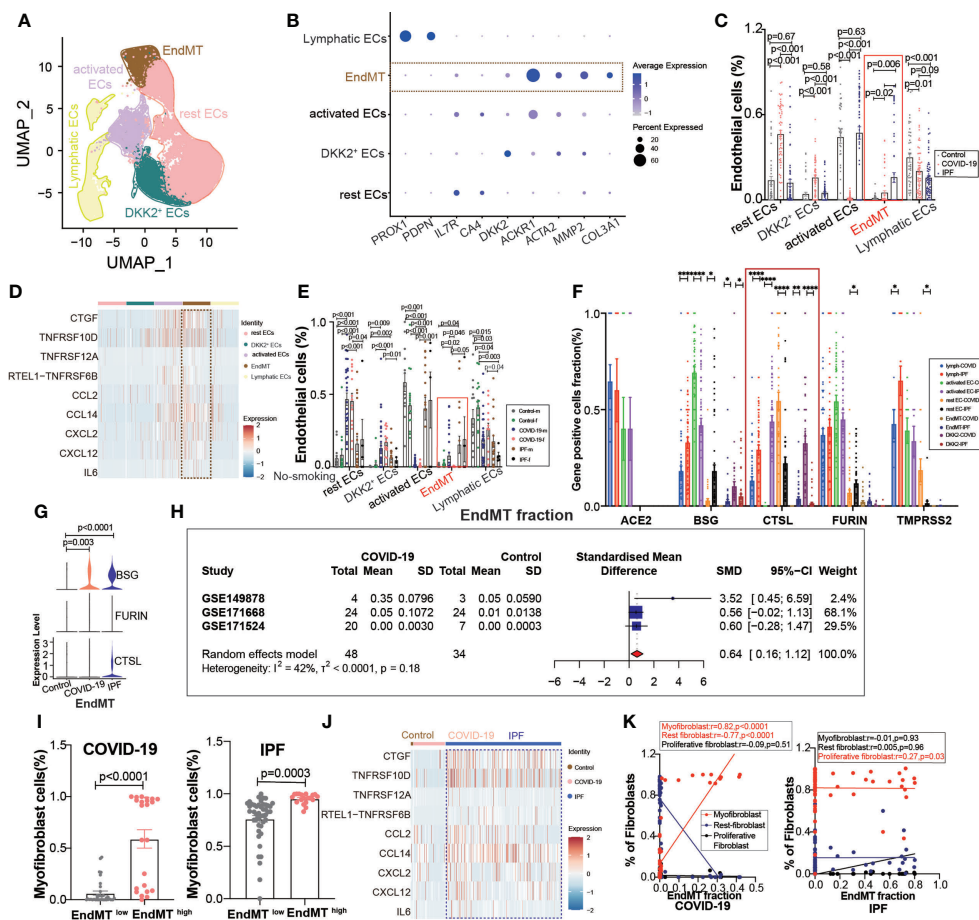

FIGURE 4

EndMT proportion is upregulated in COVID-19. (A) The expression of pulmonary ECs in patients with health control, COVID-19, IPF was demonstrated using UMAP plots with subpopulations marked by a color code. ECs subpopulations including rest ECs, EndMT, DKK2<sup>+</sup> ECs, activated ECs; Lymphatic ECs. (B) Dot chart shows the marker of EndMT, mainly focusing on ACTA2, MMP2, COL3A1; rest ECs (IL7R, CA4), DKK2<sup>+</sup> ECs (DKK2), activated ECs (ACKR1); Lymphatic ECs (PROX1, PDPN). (C) Proportion of ECs among normal control group, COVID-19 group and IPF group, the ratio of EndMT was increased in COVID-19 and IPF than controls. One-way ANOVA was used to compare multiple groups ( $p < 0.05$ ). (D) Heatmap shows a comparison of the expression of major cytokines in the cell subpopulations of ECs shows that EndMT is enriched in more cytokines compared to the other groups. (E) Comparison of the ratios of HC, COVID-19, IPF subpopulations of ECs by gender in nonsmokers. EndMT ratio in females is lower than that in males with COVID-19. (F) Comparison of entry factors (ACE2, BSG, FURIN, CTSL, TMPRSS2) positive cell fraction in ECs subtype of COVID-19 and IPF. (G) Comparison of EndMT proportion of entry factors (BSG, FURIN, CTSL) in HC, COVID-19, IPF. (H) Forest plot of studies with lung scRNA data on the COVID-19, after excluding a study with only one case and a high heterogeneity study. The analysis included data from 3 studies with a total of 48 COVID-19 and 34 controls.  $p$  value for heterogeneity was 0.18,  $I^2$  was 42%. (SD: Standard deviation). (I) Ratio of myofibroblasts in COVID-19 and IPF for EndMT<sup>low</sup> versus EndMT<sup>high</sup>, showing myofibroblast ratio in EndMT<sup>high</sup> is higher than that in EndMT<sup>low</sup>. (J) A comparison of the expression of major cytokines in the EndMT shows that COVID-19 and IPF are enriched in more profibrotic cytokines compared to HC group. (K) Correlation analysis of EndMT with myofibroblast, rest fibroblast and proliferative fibroblast in COVID-19 and IPF patients (Pearson test), showing EndMT is positively correlated with myofibroblasts in COVID-19 patients. \* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$ , \*\*\*\* $P < 0.0001$ .

positive cells were not significant (Figure 5H), MMP2-positive cells were statistically differentially upregulated in late stage of EndMT by meta-analysis of GSE data. Using meta-analysis, we demonstrated that the MMP2 pooled SMD in 5 distinct GEO datasets was 0.54, 95% CI (0.13, 0.96) (Figure 5I), and ultimately, meta-analysis revealed that the COL3A1 pooled SMD of late stages of COVID-19 was 0.84, 95% CI (0.24, 1.44) when

compared to controls (Figure 5L). Further analysis of the correlation with invasion genes showed that the entry factor genes (BSG, FURIN, and CTSL) were positively correlated with the ratio of early EndMT in COVID-19, and CTSL was positively correlated with the ratio of early EndMT in IPF (Figure 5M). ACE2 was positively correlated with the ratio of late EndMT in IPF (Figure 5N).

## Discussion

To our knowledge, this first single-cell meta-analysis that describes MT-related clusters in COVID-19 patients. When we examined the MT transition state in COVID-19 using IPF with MT and a high number of fibroblasts as a control, we identified a substantial link between fibroblasts and MT across all subpopulations. By analyzing the correlation of each subgroup, we screened the relevant subgroups of MT (i.e., EndMT and EMT). COVID-19 patients exhibited an increased MT than healthy controls, but less than IPF patients. We further found that male patients had a higher proportion of cells in EMT and EndMT. Several studies have shown a higher prevalence of pulmonary fibrosis after COVID-19 in males. This is likely because males are more exposed to fibrotic triggers, such as occupational agents (26–28).

In EMT, young people are more enriched in inflammation such as *IL-6* signaling pathways, aging adults are enriched with more fibrosis-promoting signaling pathways such as TGF- $\beta$ . Increased levels of TGF- $\beta$ , an anti-inflammatory but profibrotic cytokine, might be the leading cause of EMT in aging adults (29). Smoking COVID-19 patients showed a higher percentage of EMT, but were more enriched in the interferon signaling pathway, compared to non-smoking COVID-19 patients. Despite early reports to the opposite, there is mounting evidence that individuals with severe COVID-19 have a strong type I interferon response, as opposed to the delayed, potentially suppressed response observed early in infection (30). Through various pathways, a potent type I interferon response might increase hyperinflammation in the progression to severe COVID-19 (31). Insights into the therapeutic use of type I interferon in patients with MT will come from an improved knowledge of the functions of type I interferon at various stages of the disease and in patients who are non-smokers vs. smokers.

MT is involved in pulmonary fibrosis and vascular remodeling in the pathogenesis of IPF. Several triggers and pathways are associated with the EMT and EndMT (32). Archana et al. have shown that EndMT markers (N-cadherin, S100A4, and vimentin) are increased in the arterial layers (intima, media, and adventitia) of IPF patients (33). Similarly, during the EndMT process, active ECs express adhesion molecules, such as intercellular adhesion molecule-1 (*ICAM-1*) and vascular cell adhesion molecule-1 (*VCAM-1*), which enhance EndMT formation in our results. Moreover, *ICAM-1* is also an adhesion molecule for another virus, such as human rhinovirus (34), influenza virus (35), and HIV (36). It is reasonable to speculate that with the activation of *ICAM-1*, the risk of associated secondary infection may also increase.

The mesenchymal cells we identified are divided into early and late stage. Compared to IPF, these cells are related to the expression of entry factors such as *BSG*, *CTSL*, and *FURIN*. Sohal

et al. indicate that ILDs, especially IPF, have a higher risk of developing severe COVID-19 infection and post-COVID-19 interstitial pulmonary fibrosis. They found TGF- $\beta$ 1 and  $\alpha$ -smooth muscle actin (myofibroblast marker) are in similar areas as COVID-19 markers. They suggest that myofibroblasts and surrounding tissue secrete growth factors which could further affect COVID-19 adhesion proteins/cofactors and post-COVID-19 interstitial pulmonary fibrosis (37). Our study confirms that entry factors are negatively correlated with early EndMT cell fraction and are positively correlated with fibroblasts. This suggests that the conversion of activated ECs to EndMT is linked to mesenchymal conversion of ECs in the early phases. Therefore, this provides a strategy for the early prevention of pulmonary fibrosis in COVID-19 patients.

Improvements in patient stratification and therapeutic approaches for lung fibrosis will be contingent on the capacity to reprogram EMT (38). EMT has been hypothesized as a source of myofibroblast also in SSc (39) and EMT-related pathways (40). Early EMT leads to activation fibrosis as a result of the downregulation and/or destruction of junctional components like *TAGLN*. The late EMT mesenchymal marker *COL3A1* increases along with the slow loss of *EPCAM*, a marker of epithelial cells (41). Late EMT has been classically associated with fibrosis in organs such as the kidneys, liver, and lungs. It is interesting to note that, in consistent with our data, the EMT status of primary tumors was not consistently associated with poor patient survival (38). Our study suggests that late EMT and invasive genes are almost independent, and early EMT is associated with invasive genes. The process of EndMT can also represent a therapeutic target in the early stages of the disease (42). Early, immature stress fibers are present in the early stages of EndMT. Late stages of EndMT, however, may be identified by matured stress fibers formed by microfilaments (43). The inflammatory leukocytes engaged in the early stages of the illness trigger the EndMT, which has also been discovered in lung fibrosis (44). Therefore, late EndMT could contribute to aggravating the pro-fibrotic signaling in lung fibrosis. Late EndMT, then, could contribute to exacerbating the pro-fibrotic TGF- $\beta$  signaling in lung fibrosis. According to this principle, we chose *ACTA2* as the early marker and also *MMP2* and *COL3A1* as the late markers. *ACTA2* was only transiently displayed in the early EndMT, but *MMP2* and *COL3A1* were subsequently upregulated through further remodeling (45).

It is important to note that our study has some limitations: 1. First, we not count whole organ MT because this included all the up-regulation of the entry factor. This data will be included in our subsequent studies. Second, no in vitro or in vivo animal experiments were performed to validate the key genes. Third, we did not validate COVID-19 patient samples. Fourth, no SARS-CoV-2 positive cells were extracted for further analysis. Finally, the correlation between MT and entry factor was inadequate and required further exploration.

## Conclusion

In conclusion, for the first time, we have analyzed ECs as well as epithelial MT subpopulations in COVID-19 patients, establishing the correlation between their MT subpopulations with irreversible myofibroblasts. However, although entry factors are also highly expressed in IFP, it is not associated with the MT of IPF. Thus, we further explored the mesenchymal-associated cluster's genes and found that some genes are expressed both in COVID-19 patients and IPF patients. This suggests potent targets that could reverse MT in COVID-19 and IPF.

## Data availability statement

The original contributions presented in the study are included in the article/**Supplementary Material**. Further inquiries can be directed to the corresponding authors.

## Author contributions

LZ, XZ, and DL conceived the topic for this study. LZ, XZ, MZ, and XT performed single-cell RNA sequencing. LZ, XZ, XW, SL, RY, MZ, YX, XT, CT, and DL contributed to the writing and revising of the manuscript. DL, and CT critically revised the manuscript. All authors listed have read and approved the manuscript before submission.

The interaction of SARS-CoV-2 with the human immune system is at the basis of the positive or negative outcome of the infection. Monocytes and macrophages, which are major innate immune/inflammatory effector cells, are not directly infected by SARS-CoV-2, however they can react to the virus and mount a strong reaction. Whether this first interaction and reaction may bias innate reactivity to re-challenge, a phenomenon known as innate memory, is currently unexplored and may be part of the long-term sequelae of COVID-19. Here, we have tested the capacity of SARS-CoV-2 and some of its proteins to induce innate memory in human monocytes *in vitro*. Our preliminary results show that the Spike protein subunits S1 and S2 and the entire heat-inactivated virus have no substantial effect. Conversely, monocytes pre-exposed to the nucleocapsid N protein react to subsequent viral or bacterial challenges with an increased production of anti-inflammatory IL-1Ra, a response profile suggesting a milder response to new infections.

## INTRODUCTION

The novel coronavirus SARS-CoV-2, which suddenly emerged in December 2019, is still haunting mankind and has affected not only the healthcare systems but also the global socio-economic balances (1–3). COVID-19, the disease caused by the virus, was designated as a global pandemic by the World Health Organization, with more than 534 million confirmed cases and over 6.3 million confirmed deaths, as of June 2022 (4). Taking advantage of the recent progress in virology, molecular biology and pharmacology, and thanks to an amazing effort of the international scientific community, both in academia and industry, and a huge resource allocation, we were rapidly able to dissect and understand the SARS-CoV-2 structure, functions, lifecycle, and pathological characteristics (5–9). This led in a very short time to vaccine development and to several pharmacological approaches to treat or reduce the severity of patients' symptoms (2, 10, 11).

Despite the rapid and huge progress in understanding the interactions between the virus and the human immune system, much is still unknown to explain/predict the variability of immune responses that determines different susceptibility to severe effects, reactivity to re-infection, or response to vaccination.

Specific antiviral immunity is mainly based on the development of neutralizing antibodies and cytotoxic CD8+ T cells, while innate immune reactions encompass the activation of inflammatory

protective responses triggered by recognition of viral patterns by membrane and cytoplasmic pattern-recognition receptors (12). While vaccination strategies are currently based on the generation of specific anti-viral immune memory, much less emphasis has been dedicated to harnessing the protective potential of innate immunity and its memory capacity.

The concept of innate immune memory, i.e., a change in the non-specific reactivity to challenges of innate immune cells previously exposed to various stimuli, is well known in plants, invertebrates and also in vertebrates (13–15). Thus, it can be hypothesized that innate memory, induced by previous exposure to infections or other challenges (including vaccination), may participate to the effectiveness of subsequent defensive innate responses in a personalized fashion, which is dependent on individual history of pathogen/antigen exposure: the “immunobiography” (16).

While abundant information is available on the specific functions and kinetics of the adaptive immune response to SARS-CoV-2 (17–19), less is established regarding the balance between protective and detrimental effects of innate immune responses in COVID-19. A general increase in the circulating levels of inflammatory cytokines has been observed (possibly secondary to barrier disruption and release of bacterial products) in parallel to downregulation of myeloid cells’ markers and function (20). There is clear evidence that the variability in innate immune system components is a main contributor to the heterogeneous disease course observed for COVID-19 (20–22) and in the response to vaccination (23). Thus, it is fundamental to understand if and how interaction of innate cells with SARS-CoV-2 induces an innate memory, and whether such memory may contribute to future protection or to post-infection pathologies, as suggested by epigenetic studies (24).

Here, we provide preliminary evidence that the SARS-CoV-2 nucleocapsid protein N, as opposed to other viral components, can induce innate memory in human primary monocytes in culture. This memory is limited to a significant increase in the production of the anti-inflammatory cytokine IL-1Ra in response challenges, suggesting a less inflammatory secondary reactivity. On this basis, we hypothesize that innate memory to viral components may contribute to the overall response to subsequent challenges (viral or bacterial infections or re-infections), including response to vaccination. The large inter-individual variability suggests the needs for a personalized assessment, in order to predict the features of innate/inflammatory reactivity to future challenges in previously infected individuals.

## MATERIALS AND METHODS

### Selection of Stimuli

The human recombinant coronavirus SARS-CoV-2 nucleocapsid protein (N; ab272107) was expressed in *E. coli* with a C-terminal His tag. Expression in *E. coli* produces a non-glycosylated protein, similar to the “natural” protein. Human recombinant Spike glycoprotein subunit 1 (S1; ab 272105) and subunit 2 (S2; ab272106) were

expressed in HEK 293 cells as chimeras with a C-terminal Fc tag. Recombinant proteins were purchased from Abcam (Milan, Italy). LPS contamination was checked in-house with the chromogenic LAL assay Pyros Kinetix® Flex (Associates of Cape Cod, Inc., East Falmouth, MA, USA). The endotoxin contamination was 353 EU/mg for N, 26 EU/mg for S1 and 7 EU/mg for S2. Heat-inactivated SARS-CoV-2 (ATCC VR-1986HK) was obtained from LGC standards (Milan, Italy); LPS from *E. coli* O55:B5 was from Sigma Aldrich® (Merck KGaA, St. Louis, MO, USA); the TLR7/8 agonist Resiquimod (R848; cat. tlr-r848, purity ≥ 95% by UHPLC) was purchased from InvivoGen (San Diego, CA, USA). R848 was devoid of TLR2 (lipoproteins) and TLR4 agonist activity, tested on HEK-Blue TLR2 and TLR4 cells.

Concentration of viral stimuli to be used in culture was based on preliminary dose-response experiments, viability assessment and LAL results, while concentrations of reference stimuli (LPS and R848) were selected based on previous experience and *ad hoc* dose-response assessment (data not shown). Thus, the same concentration of 1 µg/mL was selected for N, S1 and S2, which corresponded to an endotoxin contamination of 0.35, 0.03 and 0.01 EU/mL. Since 1 EU roughly corresponds to 100 pg of LPS, the LPS contamination of N was estimated around 35 pg/mL in the assay, a concentration unable to induce monocyte activation in our hands. For the whole heat-inactivated virus,  $5 \times 10^5$  RNA genome copies were used as stimulus in culture, based on preliminary dose-response experiments (data not shown).

### Human Monocyte Isolation

Blood was obtained from anonymized healthy SARS-CoV-2 negative non-vaccinated donors, upon informed consent and in agreement with the Declaration of Helsinki. The protocol was approved by the Regional Ethics Committee for Clinical Experimentation of the Tuscany Region (Ethics Committee Register n. 14,914 of May 16, 2019). Monocytes were isolated by CD14 positive selection with magnetic microbeads (Miltenyi Biotec, Bergisch Gladbach, Germany) from peripheral blood mononuclear cells (PBMC), obtained by Ficoll-Paque gradient density separation (GE Healthcare, Bio-Sciences AB, Uppsala, Sweden). Monocyte preparations used in the experiments were > 95% viable and > 95% pure (assessed by trypan blue exclusion and cytosmeas).

Monocytes were cultured in culture medium (RPMI 1640 + Glutamax-I; GIBCO by Life Technologies, Paisley, UK) supplemented with 50 µg/mL gentamicin sulfate (GIBCO) and 5% heat-inactivated human AB serum (Sigma-Aldrich). Cells ( $1 \times 10^5$ ) were seeded in a final volume of 100 µL in 96-wells flat bottom plates (Corning® Costar®; Corning Inc. Life Sciences, Oneonta, NY, USA) at 37°C in moist air with 5% CO<sub>2</sub>. Monocyte stimulation was performed after overnight resting.

### Human Monocyte Activation and Induction of Innate Memory

For assessing the primary response to stimulation, monocytes were exposed for 24 h to culture medium alone (medium/negative control) or containing LPS (positive bacterial control, 1 ng/mL), R848 (positive viral control, 0.5 µg/mL),

heat-inactivated SARS-CoV-2 virus ( $5 \times 10^5$  RNA copies), N (1  $\mu\text{g/mL}$ ), S1 (1  $\mu\text{g/mL}$ ) or S2 (1  $\mu\text{g/mL}$ ). Cell viability, measured both as lack of LDH release (LDH-Cytotoxicity Colorimetric Assay Kit; BioVision, Inc., Milpitas, CA, USA) and as metabolic activity (reduction of MTT to formazan) (25) was unaffected by treatment (data not shown). At the end of the exposure time, all supernatants were collected. For memory experiments, cells were then washed and cultured with fresh culture medium for 7 additional days (one medium change after 4 days). During this period, after the activation induced by previous stimulation subsides, cells return to their baseline status (as determined by evaluation of inflammation-related cytokines in the supernatant; data not shown). At the end of the resting phase, the supernatant was collected and cells were challenged for 24 h with fresh medium alone or containing 5 ng/mL LPS, 2.5  $\mu\text{g/mL}$  R848, or 5  $\mu\text{g/mL}$  N (i.e., a 5x higher concentration than in the primary stimulation), according to the standard protocols for *in vitro* innate memory assessment (14, 15). All supernatants (after the first stimulation, after the resting phase and after the challenge phase) were frozen at  $-80^\circ\text{C}$  for subsequent cytokine analysis. By visual inspection, cell viability and cell number did not substantially change in response to the different treatments.

### Cytokine Analysis by Multiplex ELISA

Samples were tested for the presence of cytokines and chemokines by commercial ELISA-based microarrays that simultaneously measure multiple proteins in a single sample aliquot. Multiplex Bio-Plex Pro<sup>TM</sup> Human Cytokine 8-plex Assay (cat. M50000007A) was used for assessing the production of IL-2, IL-4, IL-6, IL-8, IL-10, TNF $\alpha$ , IFN- $\gamma$ , and GM-CSF. Singleplex for IL-1 $\beta$  (cat. 171B5001M) and IL-1Ra (cat. 171B5002M) were also included. Samples were run according to the manufacturer's instructions. Cytokines were analyzed with the Bio-Plex200 System using the Bio-Plex Manager<sup>TM</sup> software, and data were analyzed by the Bio-Plex Data Pro<sup>TM</sup> software, using five-parametric curve fitting. For each cytokine, assay ranges and LOD were provided by the manufacturer. All reagents and instruments, including Washing Station and Shaker Incubator, were from BIO-RAD Laboratories, Inc. (Hercules, CA, USA). Two repeated measurements were made for each marker for each donor. The symbols reported in the figures are the averages of such repeated measurements.

### Statistical Analysis

Data were analyzed using the GraphPad Prism 6.01 software (GraphPad Inc., La Jolla, CA, USA). For cytokine production, results are presented as ng produced cytokine/ $10^6$  plated monocytes. Results from individual donors are reported as mean values of 2-3 replicates (each tested with technical duplicates in ELISA). Average values of individual donors' data are reported as light grey columns. Statistical significance of differences is indicated by *p* values, calculated using one way ANOVA and Dunnett's Multiple Comparison.

## RESULTS

### Primary Response of Human Monocytes to Inactivated SARS-CoV-2 or Its Components

The primary response of human monocytes to different SARS-CoV-2 stimuli was assessed after exposure *in vitro* for 24 h. Monocytes are key innate immune cells responsible of inflammatory defensive responses, and their activation was evaluated in terms of production of four innate cytokines, the inflammatory factors TNF $\alpha$  and IL-6, and the anti-inflammatory cytokines IL-10 and IL-1Ra (Figure 1). As positive control, cells were exposed to LPS or R848, potent activators of human monocyte innate/inflammatory responses that mimic bacterial and viral challenges, respectively. The concentrations of LPS (1 ng/mL) and R848 (0.5  $\mu\text{g/mL}$ ) were selected in order to induce a measurable but not maximal response (data not shown). The viral agents used were the heat-inactivated SARS-CoV-2 virus ( $5 \times 10^5$  RNA genomic copies/well; 5:1 vs. monocytes), the nucleocapsid protein N (1  $\mu\text{g/mL}$ ), the S1 subunit of the Spike protein (responsible for viral binding to target cells; 1  $\mu\text{g/mL}$ ) and the S2 subunit of the Spike protein (responsible for viral entry in target cells; 1  $\mu\text{g/mL}$ ). The endotoxin contamination of the recombinant viral proteins was below monocyte activation

**FIGURE 1** | Primary innate immune primary response to inactivated SARS-CoV-2 or its proteins in human monocytes. Human monocytes isolated from blood of four individual donors (green, red, blue, and yellow symbols) were cultured for 24 h in culture medium alone or containing the inactivated SARS-CoV-2 virus ( $5 \times 10^5$  copies), or the viral proteins N, S1, S2 (all at 1  $\mu\text{g/mL}$ ). The production of TNF $\alpha$  (upper left), IL-6 (upper right), IL-10 (lower left) and IL-1Ra (lower right) was measured in the 24 h supernatants by ELISA. Medium alone was used as baseline value, LPS (1 ng/mL) and R848 (0.5  $\mu\text{g/mL}$ ) were used as positive controls. Data are presented as individual donors' values (colored symbols) and as mean of the individual values (gray columns). Statistical significance: \* *p* < 0.05; \*\* *p* < 0.01; \*\*\* *p* < 0.001; \*\*\*\* *p* < 0.0001.

threshold (see Materials and Methods). Monocytes from four SARS-CoV-2 negative non-vaccinated donors were tested.

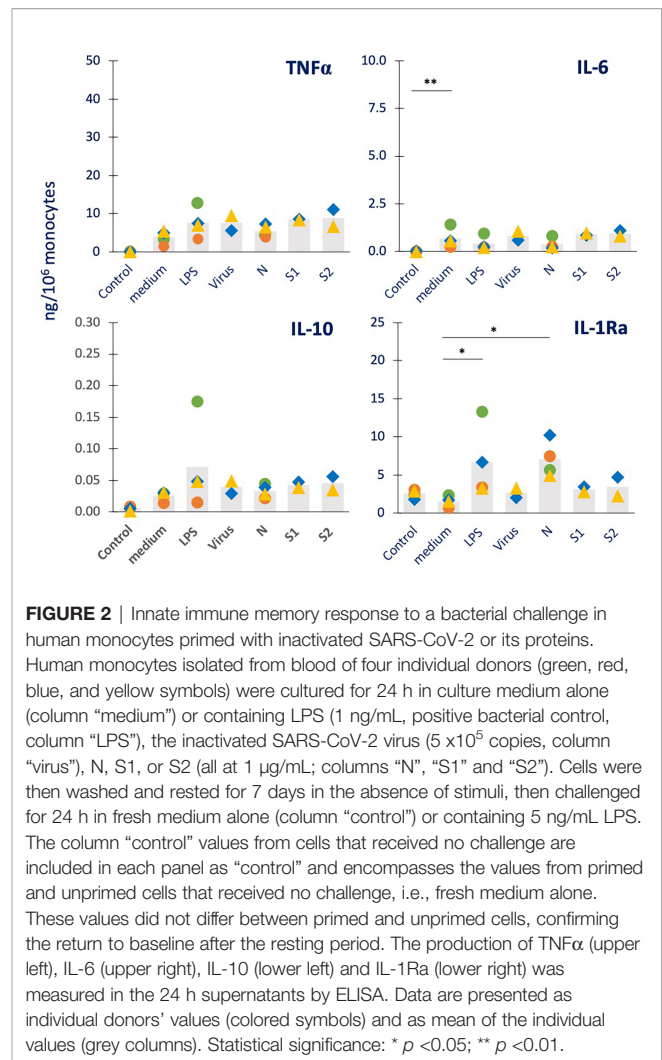

As shown in **Figure 1**, both LPS and R848 were able to induce a substantial production of the inflammatory factors TNF $\alpha$  and IL-6 and of the anti-inflammatory cytokine IL-10, although with a high inter-individual variability (which in some cases did not allow for reaching statistical significance). For the other anti-inflammatory cytokine IL-1Ra, as expected, a measurable constitutive production was evident in unstimulated cells, which was increased by exposure to LPS or R848. Among the viral agents, only N showed the capacity to stimulate monocytes (in 2/3 of 4 donors), whereas the inactivated whole virus and the two Spike proteins were essentially inactive.

The production by monocytes of other inflammation-related factors was also examined. Data for the inflammatory cytokine IL-1 $\beta$ , the chemokine IL-8, the immune interferon IFN- $\gamma$  and the growth factor GM-CSF are reported in **Supplementary Figure S1**, while the production of the T cell cytokines IL-2 and IL-4 was undetectable (data not shown). Again, N was the only viral factor able to activate monocyte responses (evident for IL-8 and GM-CSF production in 3 out of 4 donors), which were in the same range as those induced by the positive controls LPS and R848. These results partially confirm a previous report, showing that N could induce the production of IL-6 and IL-10 in human monocytes, but not TNF $\alpha$  and IL-1 $\beta$  (26). At variance with the same study, here we could not see any effect by S1. The differences in the recombinant protein constructs and in the exposure time (1 vs. 3-5 days), and the fact that the endotoxin contamination was not assessed in the other study may explain the different result.

## Secondary Memory Response of Human Monocytes Primed With Inactivated SARS-CoV-2 or Its Components

After the primary response (**Figures 1** and **S1**), cells were washed and cultured for 7 additional days in fresh culture medium to allow extinction of activation and return to baseline. The culture medium was refreshed after 4 days. The extinction of cell activation was confirmed by examining the production of cytokines released in the culture medium at the end of the resting period (representing the cytokine release in the last 3 days of resting) (data not shown). After the extinction period, cells were either exposed to medium alone (control) or challenged with 5x higher concentration of LPS (representing a bacterial challenge) or R848 (representing a viral challenge), in order to assess the development of a memory response able to react to more severe challenges. LPS priming was used as control of LPS challenge, while R848 priming was used as control of R848 challenge. As for the primary response, the memory response was assessed in terms of production of inflammatory and anti-inflammatory cytokines, and the results are reported in **Figures 2** and **3** for the major inflammatory (TNF $\alpha$ , IL-6) and anti-inflammatory (IL-10, IL-1Ra) cytokines.

As expected, LPS challenge of medium-primed cells showed a general induction of TNF $\alpha$ , IL-6 and IL-10 production, but no increase over the substantial baseline production of IL-1Ra (columns “medium” vs. “Control” in **Figure 2**). Although the

increase did not always reach statistical significance on average, this was evident at the individual donor’s level. LPS-primed cells did not show the development of a tolerance memory response (columns “LPS” vs. “medium”) relative to the inflammatory cytokine TNF $\alpha$ , while this was small but detectable in 2/4 donors for IL-6, confirming the variability in the development of LPS tolerance already observed in other subjects (15, 27, 28). A tendency to a potentiated response could be observed in LPS-primed cells in terms of production of the anti-inflammatory factor IL-10 (although not reaching statistical significance), while a significant increase in IL-1Ra was evident. Priming with the inactivated virus did not have substantial effects on the response to the LPS challenge (columns “Virus” vs. “medium”). When examining the memory-inducing capacity of viral proteins, it was observed that the S1 and S2 subunits of the Spike protein had no memory-inducing activity (columns “S1” and “S2” vs. “medium”), similar to the inactivated virus. Priming with the nucleocapsid protein N, on the other hand, induced a significant and considerable potentiation of IL-1Ra production (columns “N” vs. “medium”). When examining the memory effects of virus or viral components on other innate immune factors induced by

the bacterial challenge LPS (**Supplementary Figure S2**), we observed that neither LPS nor virus/viral components had clear effects on the production of the inflammatory cytokine IL-1 $\beta$ , the chemokine IL-8, the immune interferon IFN- $\gamma$  and the growth factor GM-CSF, again with inter-individual variability of response.

We also assessed the capacity of SARS-CoV-2 and its components to induce innate memory to a viral challenge, using R848 as prototypical viral agent (**Figure 3**). As a control, priming with R848 was included. The results show that unprimed monocytes respond to R848 challenge with a potent production of TNF $\alpha$ , IL-6 and IL-10 (in 3/4 donors), generally higher than that induced by the bacterial challenge. Conversely, the R848 challenge was completely inactive in modulating the constitutive production of IL-1Ra (columns “medium” vs. “Control”). Priming with R848 potentiated the secondary response to the R848 (columns “R848” vs. “medium”) in all donors for TNF $\alpha$ , IL-6 and IL-1Ra, and in 2/4 donors for IL-10 (although the average increase reached statistical significance only for TNF $\alpha$  and IL-1Ra). Priming with the inactivated virus had little/no effect on the secondary response to the R848 virus-like challenge (columns “virus” vs. “medium”). Priming with the

nucleocapsid protein N showed potentiation of the memory response to R848 in terms of IL-1Ra production (in all 4 donors), while having limited/no effect of the secondary production of TNF $\alpha$ , IL-6 and IL-10 (columns “N” vs. “medium”). The priming with the Spike protein subunits S1 and S2 showed no substantial variations relative to controls (columns “S1” and “S2” vs. “medium”). We have additionally examined other four cytokines (IL-1 $\beta$ , IL-8, IFN- $\gamma$ , GM-CSF; **Supplementary Figure S3**). All four factors are produced by medium-primed cells in response to R848 (columns “medium” vs. “Control”). While the production of IL-8 was never significantly modified by priming with any agent (upper right panel), priming with R848 potentiates the production of IL-1 $\beta$ , IFN- $\gamma$  and GM-CSF (columns “R848” vs. “medium” in the left and lower right panels). As in other cases, priming with the inactivated virus had no memory effect (columns “Virus” vs. “medium”). Priming with N showed a potentiation of the response to R848 in terms of IL-1 $\beta$  production in all donors and GM-CSF in 3/4 donors (columns “N” vs. “medium”).

Eventually, we investigated the possibility that exposure to N could induce a memory response in previously primed cells. Thus, we have measured the production of cytokines in response to N (5  $\mu$ g/mL) in monocytes previously primed with medium alone or containing LPS (1 ng/mL), R848 (0.5  $\mu$ g/mL) or N (1  $\mu$ g/mL). The data in **Figure 4** show that challenge with N could induce a significant production of TNF $\alpha$ , and measurable levels of IL-6, IL-10, IL-1 $\beta$ , IL-8 and GM-CSF in unprimed cells (of 3/4 donors), while unable to increase the constitutive production of IL-1Ra and IFN- $\gamma$  (columns “medium”). None of the priming agents used (LPS, R848, N) was able to induce a memory that substantially changed the secondary response (although with strong inter-individual variability), except in the case of IL-1Ra, whose production in response to challenge with N was significantly increased in cells primed with LPS, R848 or N.

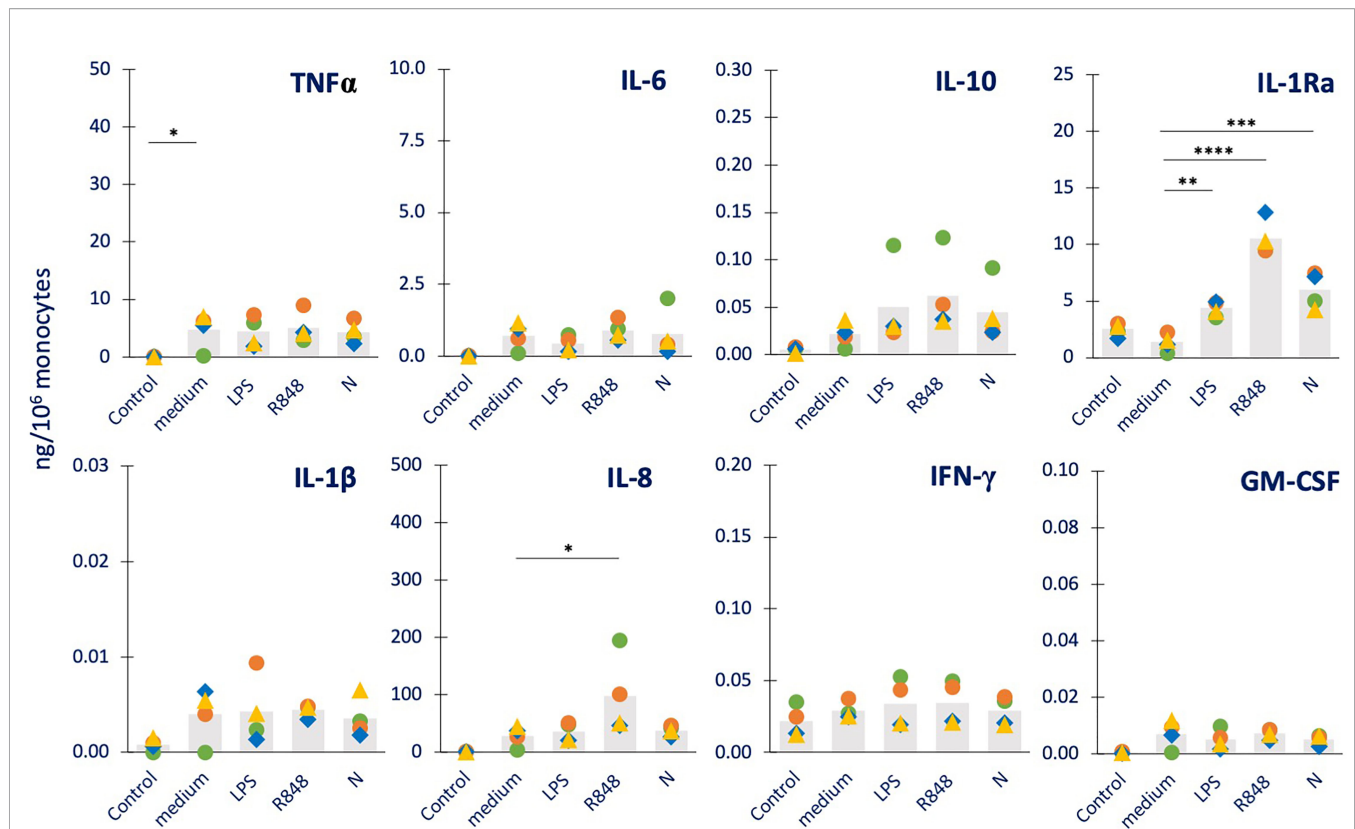

**FIGURE 3 |** Innate immune memory response to a viral challenge in human monocytes primed with inactivated SARS-CoV-2 or its proteins. Human monocytes isolated from blood of four individual donors (green, red, blue, and yellow symbols) were cultured for 24 h in culture medium alone or containing R848 (0.5  $\mu$ g/mL, positive viral control), the inactivated SARS-CoV-2 virus ( $5 \times 10^5$  copies), or the viral proteins N, S1, and S2 (all at 1  $\mu$ g/mL). Cells were then washed and rested for 7 days in the absence of stimuli, then challenged for 24 h in fresh medium alone or containing 2.5  $\mu$ g/mL R848. The production of TNF $\alpha$  (upper left), IL-6 (upper right), IL-10 (lower left) and IL-1Ra (lower right) was measured in the 24 h supernatants by ELISA. The values from cells that received no challenge are included in each panel as “control” and encompass the values obtained from primed and unprimed cells (which did not differ, confirming the return to baseline after the resting period). Data are presented as individual donors’ values (colored symbols) and as mean of the individual values (gray columns). Statistical significance: \*  $p < 0.05$ ; \*\*  $p < 0.01$ ; \*\*\*  $p < 0.001$ ; \*\*\*\*  $p < 0.0001$ .

## DISCUSSION AND CONCLUSIONS

This study provides initial evidence that the major SARS-CoV-2 structural nucleocapsid (N) protein has the ability to induce an innate memory that changes the monocyte response profile upon re-challenge. It should be noted that these results are preliminary, since only cytokine production was examined, and their interpretation is likewise limited, since only four non-vaccinated donors are included.

Several studies have pointed to a possible role of innate memory, induced by live attenuated vaccines such as BCG, for preventing the severe effects of SARS-CoV-2 infection (29, 30). On the other hand, the innate immune/memory profile of monocytes/macrophages from convalescent or vaccinated subjects revealed that both the whole infective virus and the Spike protein encoding vaccine are able to induce a transcriptional and epigenetic reprogramming suggestive of establishment of innate memory (19, 23, 24). Notably, *in vitro* challenge of blood leukocytes from convalescent individuals showed an increased production of the inflammatory/activating cytokines IL-1 $\beta$  and IL-6, based on an extensive

**FIGURE 4** | Innate immune memory response to a challenge with the N protein in human monocytes primed with bacterial or viral agents. Human monocytes isolated from blood of four individual donors (green, red, blue, and yellow symbols) were cultured for 24 h in culture medium alone (column "medium") or containing LPS (1 ng/mL, column "LPS", control bacterial agent), R848 (0.5 μg/mL, column "R848", control virus-like agent) or N (1 μg/mL, column "N"). Cells were then washed and rested for 7 days in the absence of stimuli, then challenged for 24 h in fresh medium alone or containing 5 μg/mL N. The production of TNFα, IL-6, IL-10, IL-1Ra (upper panel from right to left) and IL-1β, IL-8, IFN-γ, GM-CSF (lower panel from right to left) was measured in the 24 h supernatants by ELISA. The values from cells that received no challenge are included in each panel as "Control" and encompass the values obtained from primed and unprimed cells (which did not differ, confirming the return to baseline after the resting period). Data are presented as individual donors' values (colored symbols) and as mean of the individual values (gray columns). Statistical significance: \*  $p < 0.05$ ; \*\*  $p < 0.01$ ; \*\*\*  $p < 0.001$ ; \*\*\*\*  $p < 0.0001$ .

epigenetic reprogramming of both CD14<sup>+</sup> and CD16<sup>+</sup> monocytes (24). Indeed, inhibitors of IL-6 (e.g., the anti-IL-6 receptor Tocilizumab) and of IL-1β (Anakinra) have been used in the therapy of COVID-19. While the treatment with Tocilizumab showed contradictory results regarding its efficacy (31–33), the use of the recombinant form of the IL-1 receptor antagonist IL-1Ra Anakinra showed encouraging results in decreasing clinical parameters and reducing overall mortality (34–36).

Bearing in mind that these results are preliminary, the major finding of our study is that one of the SARS-CoV-2 proteins, the nucleocapsid protein N, can induce innate memory in human monocytes (from subjects that were not previously infected by SARS-CoV-2 or vaccinated), and that this memory was almost exclusively represented by an increased capacity to produce the IL-1 inhibitor IL-1Ra. While confirming that innate memory is non-specific (the same memory response in terms of increased IL-1Ra production is triggered by challenge with LPS, R848 or N), this finding points to the importance of the N protein in stimulating an anti-inflammatory compensatory mechanism to control the

cytokine storm and the tissue inflammation caused by the infection. Only in response to a strong viral-like challenge (R848), priming with N could also result in enhanced production of IL-1β. This suggests that the memory induced by N is preferentially active in anti-viral responses and includes the potentiation of a very important defensive effector molecule while, at the same time, being able to control unwanted inflammation through the enhanced production of anti-inflammatory IL-1Ra. Upregulation of IL-1Ra is expected to inhibit IL-1-dependent inflammation but also the entire inflammatory cascade initiated by IL-1β (37, 38). Conversely, a tendency of decreased production of the inflammatory cytokines TNFα and IL-6 was observed in cells primed with the two spike protein subunits S1 and S2 and challenged with the R848. Since only two donors could be examined for S1 and S2 priming, this tendency cannot be considered reliable. However, it may suggest that different parts of the virus can prime the innate immune system towards a milder secondary reaction by using different mechanisms (increase of anti-inflammatory reactions induced by N protein priming and a concomitant decrease of inflammatory responses induced by

**TABLE 1 |** Summary of the capacity of SARS-CoV-2 and its proteins to induce innate memory in human monocytes.

Priming and challenge/memory stimuli		Cytokine production*							
		TNF $\alpha$	IL-6	IL-10	IL-1Ra	IL-1 $\beta$	IL-8	IFN- $\gamma$	GM-CSF
Priming with SARS-CoV-2	Memory response to								
	LPS (bacteria)	no	no	no	no	no	no	no	no
	R848 (viruses)	no	no	no	no	no	no	no	no
N	LPS (bacteria)	no	no	no	↑↑	no	no	no	no

	N (SARS-CoV-2)	no	no	no	↑↑	no	no	no	no
S1	LPS (bacteria)	(↑)	no	no	no	no	no	no	no
	R848 (viruses)	(↓)	(↓)	no	no	no	no	no	(↓)
S2	LPS (bacteria)	no	no	no	no	no	no	no	no
	R848 (viruses)	(↓)	(↓)	no	no	no	no	no	(↓)
R848	R848 (viruses)	↑	↑	no	↑↑	↑	no	↑	↑
	N (SARS-CoV-2)	no	no	no	↑↑	no	↑	no	no

\*Cytokine production is expressed as increase (↑ or ↑↑), indicating increase and strong increase, respectively), decrease (↓) or no change (no) compared to medium-exposed cells. Symbols within parentheses indicate dubious results, i.e., those in which the trend was observed in 3/4 donors (for N priming) and in which only two donors could be examined (for S1 and S2 priming).

Spike protein priming). The fact that the whole virus could not induce any memory response may be explained by the cross-regulating effects of the different viral components or by changes induced by the inactivation process.

**Table 1** summarizes the findings reported in this study and highlight the strong and consistent potentiation effect of priming with the N protein on IL-1Ra production, which may underlie a less severe response to secondary infections, with a better control of innate/inflammatory effector mechanisms.

**Background:** The lower burden of COVID-19 in tropical settings may be due to preexisting cross-immunity, which might vary according to geographical locations and potential exposure to other pathogens. We sought to assess the overall prevalence of SARS-CoV-2 antibodies and determine SARS-CoV-2 seropositivity according to HIV-status before the COVID-19 pandemic era.

**Methods:** A cross-sectional and comparative study was conducted at the Chantal BIYA International Reference Centre (CIRCB) on 288 stored plasma samples (163 HIV-positive versus 125 HIV-negative); all collected in 2017–2018, before the COVID-19 pandemic era. Abbott Panbio™ COVID-19 IgG/IgM assay was used for detecting SARS-CoV-2 immunoglobulin G (IgG) and M (IgM). Among people living with HIV (PLHIV), HIV-1 viral load and TCD4 cell count

(LTCD4) were measured using Abbott Real Time PCR and BD FACSCalibur respectively. Statistical analyses were performed, with  $p < 0.05$  considered statistically significant.

**Results:** The median [IQR] age was 25 [15–38] years. Overall seropositivity to SARS-CoV-2 antibodies was 13.5% (39/288) of which 7.3% (21) was IgG, 7.3% (21) IgM and 1.0% (3) IgG/IgM. According to HIV-status in the study population, SARS-CoV-2 seropositivity was 11.0% (18/163) among HIV-positive versus 16.8% (21/125) among HIV-negative respectively,  $p = 0.21$ . Specifically, IgG was 6.1% (10/163) versus 8.8% (11/125),  $p = 0.26$ ; IgM was 5.5% (9/163) versus 9.6% (12/125),  $p = 0.13$  and IgG/IgM was 0.6% (1/163) versus 1.6% (2/125) respectively. Among PLHIV, SARS-CoV-2 seropositivity according to CD4 count was 9.2% ( $\geq 500$  cells/ $\mu$ L) versus 1.8% (200–499 cells/ $\mu$ L), (OR=3.5;  $p = 0.04$ ) and 0.6% ( $< 200$  cells/ $\mu$ L), (OR=17.7;  $p < 0.01$ ). According to viral load, SARS-CoV-2 seropositivity was 6.7% ( $\geq 40$  copies/mL) versus 4.9% ( $< 40$  copies/mL), (OR= 3.8;  $p < 0.01$ ).

**Conclusion:** Before COVID-19 in Cameroon, cross-reactive antibodies to SARS-CoV-2 were in circulation, indicating COVID-19 preexisting immunity. This preexisting immunity may contribute in attenuating disease severity in tropical settings like Cameroon. Of relevance, COVID-19 preexisting immunity is lower with HIV-infection, specifically with viral replication and poor CD4-cell count. As poor CD4-count leads to lower cross-reactive antibodies (regardless of viral load), people living with HIV appear more vulnerable to COVID-19 and should be prioritized for vaccination.

#### KEYWORDS

HIV, SARS-CoV-2, immunoglobulin G/M, T-CD4 lymphocytes, HIV viral load

## Introduction

December 2019 was marked by the appearance of the new coronavirus 2019 disease (COVID-19) in the city of Wuhan in China, which quickly became a pandemic resulting on January 30<sup>th</sup> 2020 in a Public Health Emergency of International Concern (PHEIC) (1–4). As of November 22<sup>nd</sup> 2022, 643,620,075 cases had been diagnosed worldwide with 6,628,090 deaths reported, giving a fatality rate of 1.03% three years after the beginning of the pandemic (5). Seven coronaviruses can lead to infection, but the causal agent of COVID-19 was identified as the novel severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) (3, 6, 7). Of note, SARS-CoV-2 is an enveloped virus with a linear and unsegmented positive-sense RNA genome, coding for four main structural proteins, namely: the spike (S), nucleocapsid (N), envelope (E) and membrane (M) (8). The S protein contains, the S1 subunit which is divided into an N-terminal domain (NTD) and a receptor binding domain (RBD) responsible for binding the virus to the host cell Angiotensin-Converting Enzyme 2 (ACE2) receptor binding domain (8). The N protein on the other hand is involved in the externalization of viral particles from the infected cell. Additionally, the spike glycoprotein polymer (specifically S1) mediates viral attachment, followed by membrane fusion. This glycoprotein is immunogenic and hence ideal for serosurveys

(targeting IgM and IgG humoral circulating antibodies) (3, 7, 9–11), which are one of the best approaches to appraise the extent of COVID-19 infection and disease circulation within a given community.

Surprisingly, from the overall global burden of COVID-19, a small proportion of cases were reported in Africa. On November 22<sup>nd</sup> 2022, 12,697,321 cases were reported indicating 1.97% of the global burden (5) and suggesting a much lower severity of the disease (12). Several hypotheses have been proposed to explain this low incidence of COVID-19 in Africa among which were: (i) the young population in Sub-Saharan Africa as compared to Caucasians; (ii) SARS-CoV-2 persistence and spread disadvantaged by climatic and environmental factors; (iii) social distancing favored by the lifestyle in rural/less developed areas, which limits the spread of the disease; (iv) underestimation of morbidity and mortality counts due to poor testing coverage, reflecting weak health systems; (v) a rapid activation of the natural innate non-specific immunity due to an overexposure to pathogens; and (vi) specific immune response following a previous contact with viruses sharing common antigenic profiles with SARS-CoV-2 (4, 6, 8). The potential low circulation of SARS-CoV-2 in Africa may be justified by the existence of specific pre-pandemic antibodies, responsible for cross-immunity during the pandemic (8). Furthermore, with the emergence in 2019 of SARS-CoV-2, the

world now has to face two pandemics: COVID-19 and HIV/AIDS (13). As COVID-19 pandemic continues to cause much uncertainty around the world, and especially among people living with and affected by HIV (>67% of whom residing in sub-Saharan Africa), understanding its extent as well as the determinants of induced immunogenicity is crucial to frame the response strategy within national programs and better prepare for future pandemics. We therefore sought to assess the overall prevalence of SARS-CoV-2 antibodies and determine SARS-CoV-2 seropositivity according to HIV-status during the COVID-19 pre-pandemic era in Cameroon.

## Methods

### Study design

We carried out a case-control study on archived plasma samples collected between 2017 and 2018, before the outbreak of COVID-19 in Cameroon.

### Study site

As a COVID-19 reference center for diagnostic and genomic surveillance, the “Chantal BIYA” International Reference Centre for research on HIV/AIDS prevention and management (CIRCB) is a government institution of the Cameroonian Ministry of Public Health committed to research on HIV/AIDS prevention and management. Additionally, CIRCB covers: (a) HIV early infant diagnosis in the frame of the national PMTCT program; (b) diagnosis of co-infections with HIV; (c) viral load measurement; (d) CD4 and CD8 T lymphocytes counts; (e) biochemical and hematological tests for drug follow-up; (f) genotypic HIVDR testing (GRT) at subsidized costs; with quality control programs conducted in partnership with Quality Assessment and Standardization of Indicators (QASI) and other international organizations ([http://www.circb.cm/btc\\_circb/web/](http://www.circb.cm/btc_circb/web/)).

### Sampling and eligibility criteria

We enrolled archived plasma samples previously anonymized and codified as per institutional biobanking procedures (from both HIV-positive and negative individuals). Socio-demographic and clinical data were obtained from the CIRCB database. Samples were from people residing in the Centre region of Cameroon. For HIV-positive individuals, only those with CD4-cell count, HIV-1 viral load measurements and with a complete treatment history were included; those with any co-infection or related co-morbidity were excluded.

## Clinical and laboratory procedures

### Serological assays

SARS-CoV-2 antibodies were tested using the Abbott Panbio™ COVID-19 IgG/IgM Rapid Test Device as per manufacturer's

instructions. Assay performance as reported by the manufacturer was as follows: sensitivity (97.8%); specificity (92.8%); precision (>99% both for intra-assay and inter-assay assessments) (14). Briefly, plasma samples were mixed by low-speed vortex after which 10 µL of supernatant was applied to the specimen well (S) of the test device. Two drops (approximately 60 µL) of buffer were added and a timer was started for 10 minutes. At the end of the 10 minutes the test device was read. A valid result consisted of the appearance of a red line in the Control (C) area of the reading window. A negative result consisted of the presence of the red line only in the C area whereas the presence of a red line on both C and G (IgG) areas indicated a reactivity to IgG; a red line on both C and M (IgM) areas, reactivity to IgM and a red line in C and both G and M areas of the reading window indicated a positive result for both IgG and IgM.

### T-CD4 lymphocytes phenotyping

Before storage in the biobank, CD4 cells count of PLHIV had also been performed using the BD FACSCalibur™ Flow Cytometer as per the manufacturer's instructions with results reported as the number of cells per microliter of blood (15). We therefore classified CD4 results as follows: no immunodeficiency (above or equal to 500 cell/µL); mild immunodeficiency (between 350 and 499 cell/µL); advanced immunodeficiency (between 200 and 349 cell/µL) and severe immunodeficiency (below 200 cell/µL).

### Viral load measurements

Before storage in the biobank, HIV-1 viral load measurement had also been performed using the Abbott™ *m2000rt* instrument for Real Time PCR as-per the manufacturer's instructions (16), with a lower detection threshold of 40 HIV-1 RNA copies/mL and an upper detection threshold of 10,000,000 copies/mL.

### Statistical analysis

Data collected were entered on Microsoft Excel 2021. The software IBM.SPSS® Statistics V.20 was used for statistical analysis. Association analyses were performed using Pearson Chi-Square Test with statistical significance considered at  $p < 0.05$ . All variables with  $p < 0.2$  during bivariate analyses were retained for multivariable analysis.

## Results

### Clinical characteristics of the study population

Out of a total of 288 selected samples, 163 were HIV positive (56.6%) and 125 HIV negative (43.4%). Median age [interquartile range; IQR] in the study population was 25 [15-38] years; 18 [13-41] years among HIV-positive versus 28 [23-35] years among HIV negative. Majority of our study population was of the male gender, 58.0% (159/288), with similar distribution according to HIV-status. The rest of socio-demographic and clinical parameters are summarized in Table 1.

TABLE 1 Clinical characteristics of the study population.

Variables		Effective n (%)
<b>Gender</b>		
	Female	121 (42.0)
	Male	167 (58.0)
<b>Age</b>		
	Median age	25 years
	0-19	108 (37.5)
	20-39	118 (40.9)
	40-59	54 (18.8)
	>60	8 (2.8)
<b>HIV status</b>		
	HIV positive	163 (56.6)
	HIV negative	125 (43.4)
<b>WHO clinical stages (for HIV positive) *</b>		
	I	114 (75.5)
	II	21 (13.9)
	III	14 (9.3)
	IV	2 (1.3)
	Median ART-duration (months)	24 [7-66]
<b>ART line</b>		
	First line	139 (85.3)
	Second line	24 (14.7)
<b>Most prescribed regimen</b>

<b>HIV Viral Load (copies/mL)</b>		
	< 40	50 (30.7)
	$\geq 40$	113 (69.3)

\*Data regarding WHO clinical stages were obtained for 151 participants only.

## Overall seroprevalence of SARS-CoV-2 antibodies

The global prevalence of SARS-CoV-2 antibodies was 13.5% (39/288) in the study population; 7.3% (21/288) IgG, 7.3% (21/288) IgM and 1.04% (3/288) IgG/IgM. Distribution of SARS-CoV-2 antibodies was similar according to age and HIV-status ( $p=0.07$  and  $p=0.21$  respectively); but statistically higher in men (aOR=2.54; [95%CI: 1.15-5.64];  $p=0.02$ ), as presented in [Tables 2, 3](#) below.

## Seroprevalence of SARS-CoV-2 antibodies among HIV-infected participants

Concerning HIV-infected participants, virological control (VL<40copies/mL), high CD4 cells count (>350cells/ $\mu$ L) and ART duration >23 months were all significantly associated to SARS CoV-2 seropositivity in bi-variables analyses ( $p=0.005$ ;  $p=0.01$ ;  $p<0.001$  respectively) but not in multivariable analysis ( $p=0.14$ ;  $p=0.19$ ;  $p=0.96$  respectively) as presented in [Table 4](#) below.

TABLE 2 Overall prevalence of SARS-CoV-2 antibodies (IgG and IgM) using the rapid diagnostic assay.

Variables	Overall prevalence of Ig		Prevalence of IgG		Prevalence of IgM	
	n (%)	p-value	n (%)	p-value	n (%)	p-value
Gender						
Male	29 (17.37)	0.04	17 (10.18)	0.03	14 (8.38)	0.54
Female	10 (8.26)		4 (3.31)		7 (5.79)	
Age						
<25 years	25 (17.36)	0.08	14 (9.72)	0.17	13 (9.03)	0.36

Gender (M/F)	2.54	[1.15-5.64]	0.02

## Discussion

To the best of our knowledge, no evidence clearly explains the low severity of COVID-19 in Africa, a continent that has the weakest health system and infrastructures. Indeed, the limited number of healthcare infrastructures, the poor access to specialized health services (present only in some urban areas), and the limited number of professionals trained in critical care have already been widely documented across the continent (3, 17–21); thus calling for further investigations to clarify on this low incidence of COVID-19 in Africa (12). The objective of this study was to assess the circulation of SARS-CoV-2 antibodies in a pre-pandemic era according to HIV-infection in Cameroon.

First and foremost, our findings effectively demonstrated the circulation of SARS-CoV-2 antibodies in Cameroon before the disease outbreak in 2019. This pre-existence of specific SARS-CoV-2 antibodies strongly supports the hypothesis of potential cross-immunity during the pandemic. The later could also be justified by a previous contact with other coronaviruses sharing common antigenic profiles (4, 8), which could be either HKU1, NL63, OC43 or 229E. Moreover, the circulation of these specific coronaviruses within Central Africa had never been described before the COVID-19 outbreak (22, 23). Assessing the titer and immunogenicity of these specific pre-pandemic SARS-CoV-2 antibodies through broadly neutralizing assays will help confirm this hypothesis and further characterize this cross-immunity to understand its effect on SARS-CoV-2 variants and sub-lineages circulating nowadays (24). On one hand, we observed a higher seropositivity SARS-CoV-2 antibodies among males as compared to females, likely driven by the differential level of ACE-2 receptors

among men as compared to women (8, 25). On the other hand, knowing that estrogens decrease plasma renin activity while androgens increase plasma renin activity and the expression of angiotensinogen messenger RNA, it is therefore predicted that the latter hormone would up-regulate ACE2 expression (25). In effect, the human angiotensin-converting enzyme 2 (ACE2) has been described as the functional receptor for the severe acute respiratory syndrome caused by coronaviruses (8, 26), thus facilitating recognition and infection by coronaviruses (26). Therefore, the protective role of ACE2 in chronic pathologies like hypertension, cardiovascular diseases, and acute respiratory distress syndrome (25), would be reversed in the advent of COVID-19.

With respect to HIV-status, we observed here a similar distribution of SARS-CoV-2 antibodies between HIV-infected and uninfected participants. This observation is in line with several studies conducted early in the pandemic, indicating that the clinical presentation of COVID-19 is similar in people with and without HIV, particularly if they are on ART and have achieved HIV viral suppression (13, 27–29). However, among sera of HIV-infected participants, high CD4 counts, virological control (>40copies/mL) and ART duration, seemed individually associated to the presence of SARS-CoV-2 antibodies; suggesting that people with a highly compromised immune system, an uncontrolled viral replication and/or the absence of an effective ART-regimen stand a high risk of not controlling SARS-CoV-2 replication or developing severe symptoms of COVID-19 (13). This observation therefore suggests that a closer monitoring of HIV/SARS-CoV-2 co-infection would be beneficial in order to preserve the benefits of vaccine-induced immunogenicity in this key population. Importantly, the pathogenicity associated to each virus separately and subsequent

TABLE 4 Predictors of SARS-CoV-2 seroprevalence among HIV-infected participants.

Variables	Prevalence of Ig		
	n (%)	OR [95%CI] (p-value)	aOR [95%CI] (p-value)
CD4 (cells/ $\mu$ L)			
$\geq 350$	14 (18.18)	4.55 [1.42-14.51] (0.01)	2.65 [0.62-11.26] (0.19)
$< 350$	4 (4.65)

2 <sup>nd</sup> line	5 (20.83)		

impairments to the immune system have been described; and even though vaccination of HIV-infected is essential to uphold an already weak immune system, it is important to emphasize that our findings primarily suggest there is a greater risk of COVID-19 severity among the severely immune-compromised and in those with an uncontrolled viral replication.

## Conclusion

In summary, cross-reactive antibodies to SARS-CoV-2 were in circulation in Cameroon before COVID-19, suggesting preexisting immunity, which may have contributed in limiting the spread of COVID-19 and attenuating the severity of new variants within this tropical setting. This preexisting immunity appears similar among HIV-infected versus uninfected participants. As poor CD4-count leads to lower cross-reactive antibodies (regardless of viral load), people living with HIV (especially those with poor clinical status) appear more vulnerable to COVID-19 and should be prioritized for vaccination.

## Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## Ethics statement

The studies involving human participants were reviewed and approved by National Ethics Committee for Research on Human Health, Cameroon. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

## Author contributions

JF and DT, conceptualization. AA, EN, DT, CC, ADN, AK'E, SD, and GB, formal analysis and investigation. AA, JF, EN, DT, CC, ADN, AK'E, MT, AM, and WT, data curation and methodology. Antiretroviral therapy (ART) has improved the lifespan of people living with HIV. However, their immune system remains in a state of sustained activation/inflammation, which favors viral replication and depletion of helper T-cells with varying profiles according to ART-response. We herein sought to ascertain the inflammatory profile of adolescents living with perinatal HIV-1 infection (ALPHI) receiving ART in an African context. In this cross-sectional and comparative study among ART-experienced ALPHI in Yaounde-Cameroon, HIV-1 RNA was measured by Abbott Real-time PCR; CD4 cells were enumerated using flow cytometry;

serum cytokines were measured by ELISA; HIV-1 proviral DNA was genotyped by Sanger-sequencing; and archived drug resistance mutations (ADRM) were interpreted using Stanford HIVdb.v9.0.1. Overall, 73 adolescents were enrolled (60 ALPHI and 13 HIV-1 negative peers) aged 15 (13–18) years; 60.00% were female. ART median duration was 92 (46–123) months; median viral load was 3.99 (3.17–4.66) RNA Log<sub>10</sub> (copies)/mL and median CD4 count was 326 (201–654) cells/mm<sup>3</sup>. As compared to HIV-negative adolescents, TNF $\alpha$  was highly expressed among ALPHI ( $p < 0.01$ ). Following a virological response, inflammatory cytokines (IFN $\gamma$  and IL-12), anti-inflammatory cytokines (IL-4 and IL-10) and inflammation-related cytokines (IL-6 and IL-1 $\beta$ ) were highly expressed with viral suppression (VS) vs. virological failure (VF), while the chemokine CCL3 was highly expressed with VF ( $p < 0.01$ ). Regarding the immune response, the inflammatory cytokine TNF $\alpha$  was highly expressed in those that are immunocompetent (CD4  $\geq 500$  cell/mm<sup>3</sup>) vs. immunocompromised (CD4  $< 500$  cell/mm<sup>3</sup>),  $p \leq 0.01$ ; while chemokine CCL2 was highly expressed in the immunocompromised ( $p < 0.05$ ). In the presence of ADRMs, IL-4 and CCL3 were highly expressed ( $p = 0.027$  and  $p = 0.043$  respectively). Among ART-experienced ALPHI in Cameroon, the TNF $\alpha$  cytokine was found to be an inflammatory marker of HIV infection; IFN $\gamma$ , IL-1 $\beta$ , IL-6, and IL-12 are potential immunological markers of VS and targeting these cytokines in addition to antiretroviral drugs may improve management. Moreover, CCL3 and CCL2 are possible predictors of VF and/or being immunocompromised and could serve as surrogates of poor ART response.

HIV-1, inflammation, antiretroviral therapy, adolescents, cytokines, viral load, CD4

## Introduction

Children and adolescents constitute a growing population of people living with HIV in developing countries, mainly due to ongoing mother to child transmission of HIV-1 (MTCT) and the benefits of antiretroviral therapy (ART) in sustaining the lifespan of infected children (1). Of note, sub-Saharan Africa (SSA) is paying the heaviest toll of pediatric HIV as ~85% of worldwide new pediatric infections occur in this region (2). Even though ART has substantially contributed to reducing HIV-1 MTCT (3), women in SSA settings (Cameroon included) (4) still face delayed HIV-1 diagnosis during pregnancy/breastfeeding, which leads to limited coverage in prevention of MTCT (PMTCT) and occurrence of new pediatric HIV-1 infections (5).

With more than 160,000 new cases of HIV-infection reported among children in 2021, pediatric HIV remains a major public health concern, thus calling for novel strategies to ensure optimal management of such a lifelong condition from childhood (1, 2). As in HIV-infected adults, ART increases the life expectancy of HIV-infected infants and children, allowing them to grow toward adulthood. However, the differential features in HIV pathogenesis between adults and children (i.e., faster disease progression and lower control of viral replication) require innovative approaches to optimize the outcomes with current pediatric ART in this

underserved population (6–9). Moreover, the inability of antiretrovirals to access latent reservoirs, characterized by infected long-lived memory CD4<sup>+</sup> T lymphocytes and macrophages, results in the persistent immune activation and inflammation observed in the course of HIV-1 infection (6–8).

Several cytokines have been associated with HIV-1 infection and pathogenesis (10–14). Of note, inflammatory cytokines, including interleukins (IL)-2, IL-6, IL-12, interferon gamma (IFN $\gamma$ ), and tumor necrosis factor- $\alpha$  (TNF $\alpha$ ), were reported to be essential for the clearance of HIV infection (10). Furthermore, IL-4, IL-5, IL-10, and IL-13 are known to be associated with disease progression (13, 15). However, such knowledge gaps still exist in the frame of pediatric HIV-infection, and specifically within sub-Saharan Africa (SSA) clinical settings.

An effective immune response against HIV must strike a balance between inflammatory and anti-inflammatory cytokines. Even though ART acts by trying to restore this equilibrium, it is still unclear how immunologic and virologic parameters of adolescents living with perinatal HIV-1 infection (ALPHI) influence circulating cytokine levels. In view of optimizing immunotherapeutic strategies toward HIV pediatric control, the objective of this study was to determine the cytokine profile of ALPHI in Cameroon and to assess the relationship between cytokine levels and the virologic or immunologic responses.

## Materials and methods

### Study design

A cross-sectional observational and comparative study was conducted among 73 adolescents (60 HIV-positive and 13 HIV-negative, ratio 5:1) aged 13–18 years at the Chantal BIYA International Reference Centre for research on HIV/AIDS prevention and management (CIRCB) in Yaoundé-Cameroon for the period ranging from March to July 2019.

Briefly, 60 ART-experienced ALPHI (60.00% were female) were enrolled from reference pediatric health facilities in the city of Yaoundé-Cameroon (Essos Health Centre and the Mother-Child Centre of the Chantal BIYA Foundation), as previously described within the frame of the EDCTP READY-Study cohort (16). Additionally, 13 age-matched HIV-negative adolescents, without malaria and hepatitis B/C infections, were enrolled as a control group.

### Sampling and data collection

From each participating ALPHI, the following parameters were collected: date of HIV diagnosis, age, gender, date of ART initiation, and complete ART history (duration/regimen). Then, 8 mL of whole blood was collected in EDTA tubes for immunological (CD4 count and cytokine testing) and virological (HIV-1 viral load, HIV-1 proviral DNA amplification, and sequencing) analyses.

### HIV-1 RNA measurement

A reverse transcription-polymerase chain reaction (RT-PCR) assay was performed on 700 µL of plasma samples using the Abbott RealTime (Abbott Park, IL, USA), an in vitro platform with a lower and upper detection limit of 40 and 10,000,000 copies/mL respectively. RT-PCR was then performed to quantify the HIV-1 viral RNA (plasma viral load, PVL) of each participant by RNA extraction from plasma followed by reverse-transcription/amplification of RNA extracts and simultaneous revelation as per the manufacturer's instructions ([www.molecular.abbott/int/en/products/infectious-disease/realtime-hiv-1-viral-load](http://www.molecular.abbott/int/en/products/infectious-disease/realtime-hiv-1-viral-load)). For the purpose of the study, the PVL results of each ALPHI were classified as either viral suppression ( $PVL < 1000$  copies/mL) or virological failure ( $PVL \geq 1,000$  copies/mL).

### Helper CD4+ T cells count

CD4+ T cells were enumerated by flow cytometry with a counter cytometer, using the CD4 easy count kit as per the manufacturer's instructions (Sysmex Partec GmbH) as previously described (17). For the purpose of the study, ALPHI were then classified as either immunocompetent ( $CD4 \geq 500$  cells/µL) or immunocompromised ( $CD4 < 500$  cells/µL).

### Cytokine measurement

Inflammatory (IL-1 $\beta$ , IL-6, IL-12, CCL2, CCL3, CCL4, IFN $\gamma$ , IL-17A, and TNF $\alpha$ ), anti-inflammatory (IL-4 and IL-10), and inflammation-related cytokine (IL-6 and TGF $\beta$ 1) measurement was performed on plasma using the sandwich-based enzyme-linked immunosorbent assay (ELISA) with Multi-Analyte ELISArray (Qiagen, Frederick, Maryland, 21704, USA) following the manufacturer's recommendations (<https://www.qiagen.com/us/products/discovery-and-translational-research/functional-and-cell-analysis/elisa-assays/multi-analyte-elisarray-kits>) (18). The optical density was measured at 450 nm ( $OD_{450}$ ), and the concentration in pg/mL was calculated based on the logarithmic function  $y = a \ln(x) + b$  obtained through the standard curves of samples with known concentrations.  $OD_{450}$  reads between 0 and 2.5 were considered to be within the linear range for all of the analytes as instructed (<https://www.qiagen.com/dk/resources/faq?id=c9815b21-393e-4cef-8968-5d4e67801aa1&lang=en>).

### HIV-1 DNA extraction and genotyping

HIV-1 DNA extraction was done from 200 µL of buffy coat following the protocol of the QIAamp DNA Mini Kit (Qiagen, Maryland, USA). Viral DNA extracts were directly amplified using a two-round PCR according to an in-house genotyping protocol as previously described (9). Sanger-sequencing was performed by capillary electrophoresis on ABI 3500 (Applied Biosystems) using the dye deoxy-termination chain with a set of eight sequencing primers. HIV-1 sequences were assembled and edited using Recall v.2.28 software. Edited sequences were then analyzed for the interpretation of HIV-1 archived drug resistance mutations (ADRM) using the Stanford HIV Drug Resistance Database algorithm v.9.0.1 (<https://hivdb.stanford.edu/>). Sequences with more than three mutations in the reverse transcriptase (RT) and/or two mutations in the protease (PR) known to be associated with APOBEC3G/F activity were excluded due to event of hypermutation (19).

### Statistical and phylogenetic analysis

Data were coded and recorded in an excel spreadsheet, cleaned, and double checked. The parameters of central tendency (median) and dispersion (interquartile range) were used to describe discontinuous variables. Categorical variables were described in terms of proportions and frequencies. A Mann-Whitney test was used to compare the mean of continuous variables between the following groups: i) ALPHI vs. uninfected adolescents; ii) ALPHI on viral suppression vs. virological failure; iii) immune-competent vs. immunocompromised ALPHI; iv) ALPHI with vs. without ADRMs. A Spearman correlation test was performed between the PVL/CD4 T cell and each cytokine. Any  $p$ -value  $< 0.05$  was considered statistically significant.

## Ethical and regulatory considerations

As per the Declaration of Helsinki adopted by the 18<sup>th</sup> World Medical Assembly in 1964 with respect to international regulations for ethics and good clinical practices, ethical clearance for the present study was obtained from the National Ethics Committee for research on human health (reference N° 2021/12/CE/CNERSH/SP). Administrative authorisations were obtained from the Directorate General of CIRCB and the Directors of clinical sites. Confidentiality was ensured by the use of de-identified and anonymised datasets. Written informed consent was obtained from parents or legal guardians, and written assent was provided by each participating adolescent. For the purpose of beneficence, all laboratory results (HBV, Malaria, CD4, PVL, genotypic drug resistance testing) related to the clinical management of the study participants were provided free of charge for personalized case management toward optimal HIV treatment or treatment of any reported co-infection or comorbidity.

## Results

### Socio-demographic, immuno-virological, and treatment characteristics of HIV-1 infected adolescents

Out of the 60 ALPHI, 36 (60%) were female, and the median [interquartile range, IQR] age was 15 [13-18] years. All were receiving ART and the median [IQR] duration on treatment was 92 [46-123] months; 80% were on non-nucleoside reverse transcriptase inhibitor (NNRTI)-based first-line regimens. Regarding the WHO clinical staging, the majority (70%) were categorized as clinical stage I, and 16.7% were categorized as clinical stage II. Regarding virological response, the median PVL was 3.99 [3.17-4.66] log<sub>10</sub>(copies/mL), of whom about three quarters (n=47) of participating ALPHI were experiencing virological failure (VL≥1000 copies/mL) as defined by WHO in our context. See detailed description in [Table 1](#).

### Profile of cytokines and HIV-1 status

Out of all cytokines measured, only the concentration of the inflammatory cytokine TNFα was significantly higher in HIV-1 infected participants compared to their HIV-negative peers (p<0.01), indicating its role as a marker of inflammation or immune activation ([Table 2](#)).

### Profile of cytokines and virological response

The concentration of inflammatory cytokines IL-1β, IL-12, and IFNγ; anti-inflammatory cytokine IL-4; and inflammation-related cytokine IL-6 were significantly higher in ALPHI with viral

**TABLE 1** Socio-demographic, immuno-virological, clinical, and therapeutic features of ALPHI.

Gender	Female, n (%)	36 (60.00)
	Male, n (%)	24 (40.00)
Age at enrollment, years	Median [IQR]	15 [13-18]
ART duration, months	Median [IQR]	92 [46-123]
	<60 months, n (%)	17 (28.33)
	≥60 months, n (%)	36 (60.00)
	Unknown, n (%)	7 (11.67)
ART exposition	First-line (NNRTI based regimen)	48 (80.00)
	Second line (PI based regimen)	12 (20.00)
WHO Clinical stages	I, n (%)	42 (70.00)
	II, n (%)	10 (16.67)
	III, n (%)	6 (10.00)
	IV, n (%)	2 (3.33)
	Median [IQR] (log <sub>10</sub> (copies/mL))	3.99 [3.17-4.66]

	≥500, n (%)	12 (37.5%)

ART, Antiretroviral therapy; NNRTI, non-nucleoside reverse-transcriptase inhibitors; PI/r, ritonavir-boosted protease inhibitor; CD4, cluster of differentiation.

suppression compared to those with virological failure;  $p<0.05$  ([Figure 1](#)). Additionally, the anti-inflammatory cytokine IL-10 was also highly expressed among ALPHI experiencing viral suppression, while the chemokine CCL3 was significantly expressed among ALPHI experiencing virological failure as compared to those on viral suppression;  $p<0.01$  ([Figure 1](#)). However, only cytokines IL-1β and IL-4 were negatively correlated with PVL ( $r = -0.44$ ;  $p<0.01$  and  $r = -0.27$ ;  $p=0.04$  respectively; [Figure 2](#)), suggesting that lower levels of IL-1β and IL-4 are associated with increased severity of PVL, while chemokine CCL2 alone was positively correlated with PVL;  $r = 0.36$ ;  $p<0.01$ .

### Profile of cytokines and immune response

According to the distribution of CD4 cells count in the study population, the median value [IQR] was 326 [201-654] cells/mm<sup>3</sup>, of which 20 (62.5%) participants were immunocompromised (CD4<500 cells/mm<sup>3</sup>) and 12 (37.5%) were immunocompetent (CD4≥500 cells/mm<sup>3</sup>) as per the classification of the World Health Organization ([Table 1](#)).

One inflammatory cytokine (TNFα) was highly expressed in immunocompetent ALPHI ( $p \leq 0.01$ ), while one anti-inflammatory

IL, interleukin; TGF, transformative growth factor; TNF, tumor necrosis factor.  
Bold: statistical significant.

chemokine CCL2 was highly expressed in immunocompromised ALPHI ( $p<0.05$ ), as shown in Figure 3. Interestingly, both biomarkers (TNFα and CCL2) correlated significantly with the CD4 T cell count ( $r= 0.42$ ,  $p=0.01$  and  $r= -0.43$ ,  $p=0.01$  respectively), thus confirming their clinical significance in pediatric HIV infection.

Profile of cytokines and antiretroviral therapy regimen

No significant association was found between the ART regimen (NNRTI-based versus PI/r) and the profile of studied cytokines/chemokines (data not shown), suggesting minimal (if any) effect of

FIGURE 2

Correlation between cytokines (IL-1 $\beta$  and IL-4) and viral load. IL, interleukin. This graph shows the negative correlation between cytokines IL-1 $\beta$ /IL-4 and the plasmatic viral load highlighting the decrease of such interleukins with increasing levels of viral load.

the ART regimen on the profiling and dynamics of cytokines/chemokines during the course of HIV pediatric infection.

## Profile of cytokines, HIV-1 clades, and archived drug resistance mutations

Out of 32 adolescents from whom HIV-1 genotyping was successful in proviral DNA, 22 (68.75%) were infected with CRF02\_AG, 04 (12.50%) with subtype G, 01 (3.13%) with each of the following: recombinant A1/G/K, A1/G, CRF11\_cpx,

CRF13\_cpx, CRF18\_cpx, CRF37\_cpx, and subtype H. There was no preferential pattern in cytokine profiling according to HIV-1 clade distribution (data not shown).

According to HIV-1 mutational profile in proviral DNA, 10 participants (31.25%) harbored archived drug resistance mutations (ARDMs), including 10/32 (31.25%) with NNRTI resistance-associated mutations, 8 (25.00%) with NRTI resistance-associated mutations, and only 1 (3.12%) with a ritonavir-boosted protease inhibitor (PI/r) resistance-associated mutation. The profile of cytokines according to the presence of ARDMs revealed that the levels of IL-4 cytokines and CCL3 were significantly higher in

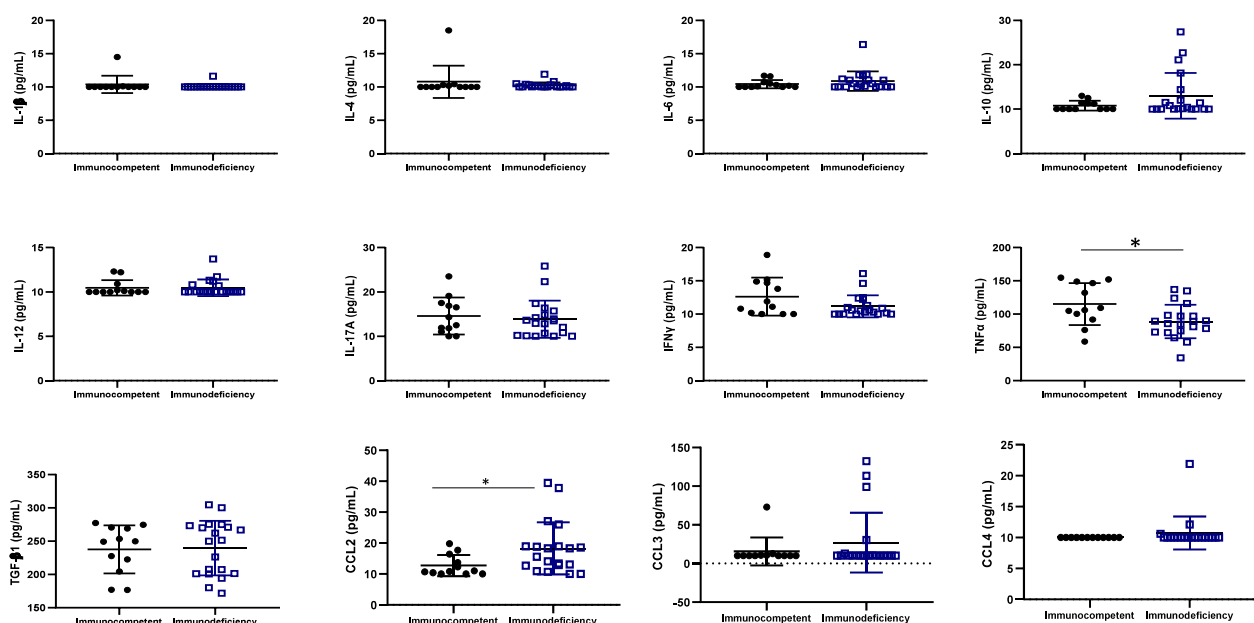

FIGURE 3

Cytokine profile according to immunocompetence. IL, interleukin; TGF, transformative growth factor; TNF, tumor necrosis factor; Immunocompetent: CD4 $\geq$ 500 cells/mm $^3$ ; immunodeficiency: CD4<500 cells/mm $^3$ ; \* ( $p < 0.05$ ); N=32. This graph shows the significant high level of the inflammatory cytokine TNF $\alpha$  in immunocompetent adolescents as compared to those with immunodeficiency while, the level of the chemokine CCL2 was high in adolescents with immunodeficiency as compared to those with good immune response.

adolescents with ADRMs;  $p < 0.05$  (Figure 4). The other cytokines/chemokines (IL-1 $\beta$ , IL-6, IL-10, IL-12, MCP1, CCL4, IFN $\gamma$ , IL-17A, TNF $\alpha$ , and TGF- $\beta$ 1) were not significantly associated to the presence of ADRMs ( $p = 0.19$ ,  $p = 0.85$ ,  $p = 0.44$ ,  $p = 0.57$ ,  $p = 0.92$ ,  $p = 0.14$ ,  $p = 0.11$ ,  $p = 0.71$ ,  $p = 0.33$ ,  $p = 0.81$  respectively).

## Discussion

With the goal to contribute to the control of pediatric HIV-infection in the era of ART and to further support the UNAIDS agenda for research into a functional HIV cure in SSA, the present study has provided new insights on the expression of inflammatory (IL-1 $\beta$ , IL-6, IL-12, CCL2, CCL3, CCL4, IFN $\gamma$ , IL-17A and TNF $\alpha$ ), anti-inflammatory (IL-4 and IL-10), and inflammation-related (IL-6 and TGF- $\beta$ 1) cytokines/chemokines in APHI in a typical SSA setting like Cameroon. Taking into consideration the ART paradigm and the high burden of pediatric HIV-infection in SSA settings like Cameroon (4, 9), this setting represents an ideal avenue for setting up baseline investigations that could pave the way for pediatric HIV cure research in this sub-region.

Among participants, the gender distribution was similar among APHI, suggesting an even distribution of the studied parameters. Moreover, the majority (4/5) of APHI were on an NNRTI-first-line ART regimen (in accordance with the proportion of national ART regimens at the time of the study implementation), and a majority (3/4) were also on a virological failure regimen. Despite the fact that the observed rate of virological response was primarily related to sampling for the purpose of our study objectives, poor ART responses among these APHI has been previously reported, driven by poor adherence and the low-genetic barrier to HIV resistance of first-generation NNRTIs that were commonly used, hence supporting transition to newer regimens (20, 21).

Regarding the profile of inflammatory cytokines, only TNF $\alpha$  was highly expressed among HIV-1-infected adolescents compared to their HIV-negative peers. This underscores the fact that TNF $\alpha$  is highly produced during HIV infection to increase antiviral immunity (22, 23) but also to induce NF- $\kappa$ B, which in turn drives proviral transcription and HIV replication (24). Although previous

studies have indicated that TNF- $\alpha$  stimulates HIV-1 replication in cultured PBMC (25, 26), recent studies have found no correlation between levels of TNF- $\alpha$  and HIV-1 replication in lymphoid tissue (26). Further, one group has demonstrated that TNF- $\alpha$  suppresses HIV-1 production in peripheral blood monocytes (PBM) (27, 28). These studies indicate that TNF- $\alpha$  may have distinct effects on the pathogenesis of HIV.

Regarding virological response, our findings underscore a decrease in inflammation-related cytokines IL-1 $\beta$  and the anti-inflammatory cytokine IL-4 with increasing levels of plasmatic viral load being observed. Although during the course of HIV-1 infection the level of IL-1 $\beta$  is increased in different anatomical compartments, particularly in lymphatic tissues, and this elevation is associated with disease progression off-ART (29), a consequence of immune depletion and chronic immune activation following HIV replication could be the progressive decrease of the cytokines over time with antiretroviral treatment. On the other hand, HIV can directly infect and deplete specific immune cells that are responsible for producing IL-4, further contributing to its reduced levels (30) as observed in Brazilian adolescents with long ART experience (31). Inflammatory cytokines such as IL-12 and IFN $\gamma$  as well as the inflammation-related cytokines IL-6 and IL-1 $\beta$  were lowly expressed among viral failure adolescents, while the expression of inflammatory cytokine CCL3 was higher among those experiencing virological failure. In fact the low level of IFN $\gamma$  observed in a context of sub-optimal virological response was similar to what have been observed in studies conducted in Brazil and Kenya where a low concentration of IFN $\gamma$  was observed in adolescents with a detectable viral load (31) and ART non-adherent people living HIV with active viral replication (32). Even though there was not significance association between TNF $\alpha$  and viral load, we have noticed a low level of this inflammation cytokine in adolescents with virological suppression, similarly to what observed in a USA children cohort where low levels of TNF $\alpha$  correlated with low levels of viral load (33). The fact that higher levels of IL-12 was observed in virally suppressed adolescents stresses the immune-stimulatory properties of this cytokine that enhances antiviral activity, thereby contributing in the control of viral replication (34). Furthermore, IL-12 is critical for promoting

FIGURE 4

Profile of IL-4 and CCL3 according to the occurrence of ADRMs. ADRMs, Archived Drug Resistance Mutations; IL, interleukin. This graph shows the significant high level of the chemokine CCL3 as well as the cytokine IL-4 among adolescents with ADRMs.

the differentiation of CD4<sup>+</sup> T cells into Th1 cells, which in turn restrains HIV-1 replication and disease progression. As IL-12 is also known to stimulate IFN $\gamma$  (35), it might be relevant to consider this biomarker in pediatric HIV control or functional cure research strategies. Although IL-10 is generally considered to be an immunosuppressive cytokine that can inhibit antiviral immune responses and promote viral replication (34, 36), we rather observed its expression in a context of viral suppression in this subset of ALPHI and correspondingly with a study conducted in Brazil (31). Thus, IL-10 might have a complex role in HIV pathogenesis, which may be either context- or age-dependent; thereby requiring further investigations to delineate the underpinning mechanism(s).

TNF $\alpha$  and CCL2 are two important cytokines that play a critical role in the immune response during HIV infection. A higher expression level of TNF $\alpha$  was found in immune-competent compared immunocompromised ALPHI, indicating its role in controlling HIV-1 replication (37). In contrast, the high expression of CCL2 in immunocompromised APHI highlights its role in the recruitment of monocytes and other cells to sites of viral replication, leading to possible immune dysfunction (38). Thus, strategies to minimize the expression of CCL2 may strengthen the pediatric immune response, which in turn would support immune normalization and better control of HIV replication.

Looking at the profile of cytokines according to ADRMs, only IL-4 and CCL3 were highly expressed in the presence of ADRMs. To the best of our knowledge, there is currently no evidence to suggest that these biomarkers (IL-4 and CCL3) can influence archiving of HIV-1 drug resistance mutations (39). While calling for further investigations, IL-4 is known to promoting survival of CD4<sup>+</sup> T cells (i.e., primary targets for HIV-1 infection) (39), either by impairing HIV-1 replication/transcription in infected cells or by limiting the viral cytopathic effect, which consequently favors viral archiving in cellular reservoirs (40). Inversely, IL-4 may also increase the expression of certain proteins (Tat) involved in HIV-1 replication, thereby enhancing the transcription of viral genes under sub-optimal ART (41). Thus, in the frame of a fully functional ART, exploring the role of IL-4 as a possible adjuvant to sustained viral control may contribute to future off-ART strategies investigational approaches in pediatrics.

## Conclusion

Among ALPHI on ART, evidence of the expression level of cytokines and chemokines shows that TNF $\alpha$  is a specific inflammatory marker contributing to chronic immune activation in the course of pediatric HIV-infection. Regarding the response to ART, IFN $\gamma$ , IL-1 $\beta$ , IL-6, and IL-12 appear as biomarkers of viral suppression, which highlights their roles as potential adjuvants (in the frame of ART success) toward the development of an optimal pediatric HIV control or functional cure strategy. Furthermore, as CCL2 and CCL3 are associated with virological failure and poor immunity, downregulating these markers may contribute to viral control strategies.

## Data availability statement

The original contributions presented in the study are included in the article/supplementary material. Further inquiries can be directed to the corresponding authors.

## Ethics statement

The studies involving humans were approved by National Ethics Committee for research on human health. The studies were conducted in accordance with the local legislation and institutional requirements. Written informed consent for participation in this study was provided by the participants' legal guardians/next of kin.

## Author contributions

AJN, JF, and GA conceived the study. ACK, MM, GB, and SD enrolled participants. DT, MM, ON, GB, and SD analyzed samples. ACK, AJN, EN, and ON performed the statistical analysis. JF, C-FP, VC, TN, FC, MS, CN, GH-E, and CT interpreted the data; ACK, JF, AJN, and GA drafted the manuscript. AJN, ADN, EN, NF, MT, SS, DK, FA, NS, AL, TN, ST, AEN, CN, CM, GH-E, CT, VC, MS, FC, C-FP, and JF revised the manuscript. AJN and JF supervised the work. All authors contributed to the article and approved the submitted version.

## Funding

This work was supported by the Chantal Biya International Reference Centre for Research on HIV/AIDS Prevention and Management (CIRCB) and the European and Developing Countries Clinical Trials Partnerships, through the following grant agreements: READY-Study (TMA2015-CDF1027); and AVIR-Study (TMA2020-CDF3228).

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

**Introduction:** People living with HIV (PLWH) are at twice the risk of developing cardiovascular diseases and have more than four times higher odds of aortic aneurysm (AA) than the uninfected population. However, biomarkers of AA in PLWH are yet to be discovered. We aimed to investigate whether circulating biomarkers reflecting platelet activation, hemostasis and endothelial disruption, i.e. sCD40L, D-dimer, syndecan-1, and thrombomodulin, were associated with AA in PLWH.

**Methods:** Five hundred seventy one PLWH from the Copenhagen Comorbidity in HIV Infection (COCOMO) study  $\geq 40$  years of age with an available contrast-enhanced CT scan as well as available biomarker analyses were included. The biomarkers were analyzed on thawed plasma. For each biomarker, we defined high level as a concentration in the upper quartile and low level as a concentration below the upper quartile. For D-dimer, the cut-off was defined as the lower limit of detection. Using unadjusted and adjusted logistic and linear regression models, we analyzed associations between AA and sCD40L, D-dimer, syndecan-1, and thrombomodulin, respectively in PLWH.

**Results:** PLWH had median (IQR) age 52 years (47–60), 88% were male, median (IQR) time since HIV diagnosis was 15 years (8–23), and 565 (99%) were currently on antiretroviral treatment. High level of sCD40L was associated with lower odds of AA in both unadjusted (odds ratio, OR, 0.23 (95% CI 0.07–0.77;  $P=0.017$ )) and adjusted models (adjusted OR, aOR, 0.23 (95% CI 0.07–0.78;  $P=0.019$ )). Detectable level of D-dimer was associated with higher odds of AA in both unadjusted (OR 2.76 (95% CI 1.34–5.67;  $P=0.006$ )) and adjusted models (aOR 2.22 (95% CI 1.02–4.85;  $P=0.045$ )).

**Conclusions:** SCD40L was associated with lower odds of AA whereas D-dimer was independently associated with higher odds of AA in PLWH. This calls for further investigations into specific biomarkers to aid early diagnosis of AA in PLWH.

#### KEYWORDS

HIV, PLWH, aortic aneurysm, sCD40L, D-dimer (DD), syndecan-1, thrombomodulin (TM)

## 1 Introduction

As the median age of people living with HIV (PLWH) increases (1), so does the burden of age-related comorbidities (2). The risk of incident cardiovascular diseases (CVD) in PLWH is twice that of uninfected individuals (3), with myocardial infarction, stroke, and coronary artery disease being the most frequent manifestations (4). In a previous study by our group, HIV infection was associated with a 4.5 increased odds ratio (OR) of having aortic aneurysms (AA) compared to uninfected controls (5). AA is a rare but potentially severe manifestation of CVD, as the mortality rate of a ruptured abdominal AA may be as high as 80% (6). The European Society of Cardiology recommends screening of populations with a high risk of abdominal AA (7), because most AA are asymptomatic and diagnosed incidentally (8).

The initial phase of the pathogenesis of AA is not fully understood, but studies have suggested endothelial cell injury to contribute (9, 10). Associations have been found between AA, in the majority of studies in patients undergoing surgery for AA, and a marker of platelet activation, soluble CD40L (sCD40L) (11, 12), a marker of hemostasis, D-dimer (13–17), and the markers of endothelial disruption, syndecan-1 (18–20) and soluble thrombomodulin (21, 22), respectively. Importantly, all of these biomarkers have been reported to be elevated in PLWH compared to uninfected controls (23–28).

Possible associations between these biomarkers and AA have yet to be established but could aid in the early identification of high-risk patients. So far, no studies on the association between AA and markers of platelet activation, hemostasis, and endothelial disruption, respectively, in PLWH have been published. Thus, we investigated whether sCD40L, D-dimer, syndecan-1, and thrombomodulin (the biomarkers) are associated with AA in a large cohort of well-treated PLWH. We hypothesized that each of the biomarkers would be independently associated with AA in PLWH.

## 2 Materials and methods

### 2.1 Study design and population

The Copenhagen Comorbidity in HIV Infection (COCOMO) study is a non-interventional cohort study that aims to assess non-

AIDS comorbidities in PLWH. Inclusion criteria were age above 18 years and a positive HIV test. Between March 2015 and December 2016, 1099 PLWH living in the greater Copenhagen area were included. Procedures for recruitment and collection of data have previously been described elsewhere (29). A combined thoracic and abdominal contrast-enhanced computed tomography (CT) scan was offered to all COCOMO participants. In this study, we included COCOMO participants who were ≥40 years of age, had a contrast-enhanced CT performed, and had biomarkers measured in plasma.

Written informed consent was obtained from all participants. Ethical approval was obtained by the Regional Ethical Committee of Copenhagen (COCOMO: H-8-2014-004). The study was carried out in accordance with the Declaration of Helsinki.

### 2.2 Clinical characteristics and self-reported outcome

A physical examination including measurement of blood pressure and anthropometrics was performed by trained clinical staff. Venous blood was collected non-fasting. Blood for plasma samples (EDTA anti-coagulated) was stored on ice until centrifugation in a cold centrifuge at 4°C, and cryovials were transferred to liquid nitrogen within 72 hours (29). Extensive questionnaires included questions regarding medication, medical history, and smoking. From medical records, HIV-specific data such as transmission mode, duration of HIV infection, type of antiretroviral therapy, and hepatitis B and C status were obtained. Hepatitis B virus co-infection was defined as positive hepatitis B virus surface-antigen and hepatitis C virus co-infection as positive hepatitis C virus RNA. Hypertension was defined as systolic blood pressure ≥140 mmHg and/or diastolic blood pressure ≥90 mmHg and/or current use of antihypertensive medication according to Joint National Committee guidelines (30).

### 2.3 CT examinations and aortic analyses

Contrast-enhanced thoracic and abdominal CT examinations including contrast-enhanced CT angiography were performed using a 320-detector CT scanner (Aquilion ONE, ViSION Edition, Canon Medical Systems, Otawara, Japan) at Rigshospitalet University Hospital, Copenhagen, Denmark.

Aortic analyses were performed by two trained examiners on contrast-enhanced CT images. Maximal and minimal inner aortic diameter was measured at seven anatomical points of the aorta, in four of which maximal outer diameter of the aorta was measured as

**Abbreviations:** PLWH, People living with HIV; CVD, Cardiovascular diseases; AA, Aortic aneurysms; sCD40L, Soluble CD40 ligand; FEU, Fibrin Equivalent Units; ET-1, Endothelin-1; OR, Odds ratio; aOR, Adjusted odds ratio; CI, Confidence interval; SD, Standard deviation.

well (5). According to the European Society of Cardiology guidelines, aortic aneurysms were defined as  $\geq 50\%$  increase in aortic diameter compared to the expected normal diameter or an infrarenal diameter of  $\geq 30$  mm (7). This resulted in the definition of AA as diameter of ascending aorta  $\geq 45$  mm and/or diameter of descending aorta  $\geq 35$  mm and/or diameter of suprarenal aorta  $\geq 30$  mm and/or diameter of the infrarenal aorta  $\geq 30$  mm (31).

## 2.4 Markers of platelet activation, hemostasis, and endothelial disruption

Plasma concentrations of sCD40L, soluble syndecan-1, and thrombomodulin, were analyzed on thawed plasma using Luminex® Human Discovery Assays (R&D Systems, UK, Europe) in a 1:2 dilution, according to the manufacturer's instructions, at the Department of Clinical Immunology, Copenhagen University Hospital, Rigshospitalet, Copenhagen, Denmark. Plasma concentrations of D-dimer were measured as routine biochemistry on fresh blood samples at Department of Clinical Biochemistry, Copenhagen University Hospital, Herlev, Copenhagen, Denmark (29).

## 2.5 Statistics

Continuous data were reported using means and standard deviations for normal deviates and medians with interquartile ranges for variables not normally distributed, as appropriate. For categorical data, frequency counts and percentages of subjects within each category were reported. Logistic regression analyses were applied where the dependent variable was binary and linear regression where the dependent variable was continuous.

As the primary outcome, we investigated the association between AA and high levels of sCD40L, syndecan-1, and thrombomodulin and detectable level of D-dimer one at a time using simple and multivariable logistic regression. For each biomarker, we created a dichotomous variable defining high level of the biomarker as a concentration in the upper quartile and low level as a concentration below the upper quartile. We used the third quartile as cut-off in the dichotomous variables for sCD40L, syndecan-1 and thrombomodulin to make the effect estimates more easily interpretable. For D-dimer, the cut-off was defined as the lower limit of detection (290 ng/mL (Fibrin Equivalent Units, FEU)), creating a dichotomous variable with detectable versus undetectable as most of the measurements were below the lower limit of detection. We created two predefined models; model 1 adjusted for age (per decade) and sex and model 2 adjusted for traditional risk factors that were significant in previous analyses on AA in PLWH (5) (age, sex, BMI category, hypertension, and smoking (current/previous/never)). Furthermore, in sensitivity analyses, we investigated the associations between AA, sCD40L, and (one at a time) use of aspirin, use of statins, weekly alcohol intake, and hypertension. As a sensitivity analysis, we included all four biomarkers into a single analysis with AA.

Additionally, continuous variables were used in pre-specified, secondary analyses to make sure any linear associations between exposure and outcome would not be overlooked. We adjusted for the same predefined models 1 and 2. Moreover, in sensitivity analyses, we investigated associations between aortic diameter (maximum outer diameter of ascending, descending, suprarenal, and infrarenal aorta) and high versus low levels of the biomarkers. Lastly, in sensitivity analyses, we examined associations between aortic wall thickness (maximal outer minus maximal inner diameter of ascending, descending, suprarenal, and infrarenal aorta) and high versus low levels of the biomarkers.

P-values  $< 0.05$  were considered statistically significant, and all P-values were two-sided. R (version 4.1.0 (2021-05-18)) was used for all statistical analyses (32).

## 3 Results

We included 571 participants aged 40 years or older with available contrast-enhanced CT and biomarker measurements. As reported previously, 43 aneurysms were found in 39 PLWH (6.8%). The median (IQR) age of PLWH was 52 years (47-60) and 88% were male (Table 1). The median (IQR) time since HIV diagnosis was 15 years (8-23) and 565 (99%) were currently on antiretroviral therapy (Table 1). Participant characteristics, HIV-specific variables, and biomarkers are listed in Table 1.

### 3.1 Aortic aneurysms and the association with markers of platelet activation, hemostasis, and endothelial disruption

We found high levels of sCD40L to be associated with lower odds of AA; univariably with OR 0.23 (95% CI 0.07-0.77;  $P=0.017$ ) and adjusted odds ratio, aOR, 0.23 (95% CI 0.07-0.78;  $P=0.019$ ) adjusted in model 2 (Table 2). In a sensitivity analysis, further adjustment of model 2 for use of aspirin did not significantly alter the association between high level of sCD40L and AA (aOR 0.25 (95% CI 0.07-0.87;  $P=0.029$ )). In other sensitivity analyses, use of statins, weekly alcohol intake, and hypertension were not associated with AA and sCD40L.

Detectable level of D-dimer was associated with higher odds of AA, both univariably (OR 2.76 (95% CI 1.34-5.67;  $P=0.006$ )) and adjusted in model 1 (aOR 2.22 (95% CI 1.02-4.85;  $P=0.045$ )). Adjusting for traditional risk factors in model 2 did not change the parameter estimate, (aOR 2.24 (95% CI 0.99-5.04;  $P=0.052$ )). There were aortic aneurysms among PLWH with undetectable D-dimer.

Syndecan-1 and thrombomodulin were not associated with AA (Table 2).

Including all four biomarkers into a single analysis did not significantly alter the associations compared to the individual associations between the biomarkers and AA.

In exploratory analyses with the biomarkers as continuous variables, a doubling in sCD40L concentration was associated with lower odds of AA; univariably with OR 0.81 (95% CI 0.66,0.98;  $P=0.028$ ) and aOR 0.76 (95% CI 0.62-0.95;  $P=0.014$ ) adjusted in model 2. A twofold increase in D-dimer concentration was associated with higher odds of AA; univariably with OR 1.51 (95% CI 1.22-1.86;  $P<0.001$ ) and aOR 1.41 (95% CI 1.08-1.84;  $P=0.010$ ) adjusted in model 2. Syndecan-1 was not significantly associated with AA. A twofold increase in thrombomodulin concentration was univariably associated with higher odds of AA (OR 1.82 (95% CI 1.02-3.26;  $P=0.043$ ) but not in adjusted models (Table 3). Analyses of high versus low levels and with continuous variables are shown in Figure 1.

### 3.2 Aortic diameter and the association with markers of platelet activation, hemostasis, and endothelial disruption

The mean (SD) aortic diameters are presented in Figure 2 and Table 4. Diameter in ascending aorta 34.54 mm (4.30); in descending aorta 26.36 mm (2.70); in suprarenal aorta 24.97 mm (2.82); and in infrarenal aorta 21.65 mm (3.17). In sensitivity analyses, high level of sCD40L was associated with smaller suprarenal aortic diameter (0.46 mm (95% CI 0.01-0.91;  $P=0.045$ )) adjusted in model 2 but not univariably (0.40 mm (95% CI 0.14-0.93;  $P=0.144$ )). Detectable level of D-dimer was associated with larger infrarenal aortic diameter; univariably 1.11 mm (95% CI 0.38-1.84;  $P=0.003$ ) and 0.97 mm (95% CI 0.30-1.63;  $P=0.004$ ) adjusted in model 2. High level of syndecan-1 was univariably associated with larger diameter of the ascending aorta (1.04 mm (95% CI 0.23-1.85;  $P=0.012$ )) and with larger infrarenal aortic diameter (0.95 mm (95% CI 0.36-1.55;  $P=0.002$ )). High level of thrombomodulin was associated with larger infrarenal aortic diameter; univariably 1.41 mm (95% CI 0.82-2.00;  $P<0.0001$ ) and 0.89 mm (95% CI 0.38-1.41;  $P<0.001$ ) adjusted in model 2. Furthermore, high level of thrombomodulin was univariably associated with larger diameter of the ascending aorta (1.12 mm (95% CI 0.30-1.92;  $P=0.007$ )) and with larger suprarenal aortic diameter (0.68 mm (95% CI 0.14-1.21;  $P=0.024$ )) (Table 4 and Figure 2).

### 3.3 Aortic wall thickness and the association with markers of platelet activation, hemostasis, and endothelial disruption

The mean (SD) aortic wall thickness was: in ascending aorta 2.28 mm (0.59); in descending aorta 2.32 mm (0.60); in suprarenal aorta 2.22 mm (0.76); and in infrarenal aorta 2.09 mm (0.81). In sensitivity analyses, high level of sCD40L was not associated with aortic wall thickness. Detectable level of D-dimer was associated with greater infrarenal aortic wall thickness; univariably 0.46 mm (95% CI 0.36-0.56;  $P<0.001$ ) and 0.41 mm (95% CI 0.30-0.51;  $P<0.001$ ) adjusted in model 2. High level of syndecan-1 was univariably associated with greater infrarenal aortic wall thickness (0.16 mm

(95% CI 0.01-0.31; *P*<0.040)). High level of thrombomodulin was associated with greater infrarenal aortic wall thickness; univariably 0.27 mm (95% CI 0.12-0.42; *P*<0.001) and 0.18 mm (95% CI 0.03-0.33; *P*=0.018) adjusted in model 2.

## 4 Discussion

In a large cohort of well-treated PLWH, we found high level of sCD40L to be associated with lower odds of AA and D-dimer above 290 ng/mL (FEU) to be associated with higher odds of AA. The same associations were found in analyses with biomarkers treated as continuous analyses.

### 4.1 sCD40L

The primary source of sCD40L is activated platelets (33). A study reported decreased platelet counts in HIV-negative AA patients compared to controls (34), and it is possible that lower platelet count in the PLWH with AA may contribute to the inverse association between AA and sCD40L, since platelets are critical for vascular endothelial integrity and health (35). Other studies have

reported aspirin to suppress (36) or block (37) the release of sCD40L from platelets. Furthermore, hypertension is associated with higher concentration of sCD40L (26), statins reduce sCD40L in CVD patients (38, 39), and alcohol is proposed to partially activate platelets (40) resulting in decreased sCD40L production. However, our analyses showed no such associations, so this cannot explain the contrast to previous reports of sCD40L being increased in plasma from HIV-negative patients with abdominal AA compared to matched controls (11) and the lacking finding of associations between sCD40L and AA (41).

In line with the emerging focus on the role of endothelial cells in AA pathogenesis (9, 10), we hypothesized that the biomarkers may be involved in the pathogenesis prior to the aortic diameter exceeding the aneurysmal limit. Therefore, we performed sensitivity analyses regarding associations between aortic diameter and the biomarkers. We found sCD40L to be negatively associated with suprarenal aortic diameter, while, at present, studies regarding associations between aortic diameter and sCD40L have not been published. Another measurement of interest is the aortic wall thickness, which studies have suggested the incorporation of into the risk analysis of AA (42, 43). Therefore, we investigated associations between wall thickness and the biomarkers but found no association with sCD40L.

## 4.2 D-dimer

D-dimer, an important marker of hemostasis, has been reported elevated in HIV-negative patients with abdominal AA compared to controls without abdominal AA (13–17). Furthermore, a study reported D-dimer to be 49% higher in PLWH on ART aged 45–76 years than in population controls (adjusted percent difference) (27). In line with these findings, our results highlight D-dimer as a possible biomarker, not only associated with abdominal AA, but all AA in PLWH. However, adjusting for known risk factors resulted in an only borderline significant parameter estimate, perhaps caused by an insufficient sample size, as plasma from 83 patients lacked measurement of D-dimer. The reported association between D-dimer and larger infrarenal aortic diameter is consistent with a previous study (44) and suggests a possible role of D-dimer as an indicator of larger infrarenal aortic diameter. Additionally, the reported associations between D-dimer and greater infrarenal aortic wall thickness may indicate increased fibrinolytic activity in the infrarenal aorta. However, as D-dimer is a general marker of fibrinolysis and not disease-specific, combination with other biomarkers may increase the specificity.

## 4.3 Syndecan-1

A previous study reported concentrations of syndecan-1, a key constituent of the endothelial glycocalyx and a regulator of inflammation, to be elevated in aortic tissue, though not in plasma, from patients with ascending AA compared to matched controls (18). Additionally, a study reported elevated syndecan-1 in PLWH compared to uninfected controls (23). Syndecan-1 is a key constituent of glycocalyx on most endothelial cells in the body, and its soluble form is generated by shedding from the endothelial glycocalyx indicative of damage to endothelial cells (45). As suggested by a previous study (18), it is possible that increased local shedding of syndecan-1 from the aneurysm is masked by the total pool of the biomarker, resulting in non-significant associations with AA in this study. Furthermore, since we only measured syndecan-1 in plasma and not aortic tissue, this may altogether explain why we do not reproduce the previously found association. Syndecan-1 being univariably associated with larger diameter in ascending and infrarenal aorta suggests an association between larger aortic diameter and endothelial disruption.

## 4.4 Thrombomodulin

Another biomarker shed from endothelial cells indicating endothelial cell injury (46), is soluble thrombomodulin, which has been reported elevated in serum from HIV-negative patients with abdominal AA compared to healthy controls (21, 22). Moreover, several studies have reported thrombomodulin to be elevated in PLWH compared to uninfected controls (24, 25). We found thrombomodulin to be univariably associated with AA when kept as a continuous variable, but not when used as a dichotomous variable. However, this finding was not significant when adjusted for known risk factors in our predefined models and we considered it

to be an incidental finding. A potential reason why we found no independent association between thrombomodulin and AA in PLWH is the above-mentioned possible masking of shedding from the aneurysm by the shedding from all endothelial cells. The reported association between thrombomodulin and larger infrarenal aortic diameter suggests thrombomodulin as a possible marker of aortic diameter, though at present, no studies regarding this association have been published. Moreover, as with syndecan-1, the association between thrombomodulin and greater infrarenal aortic diameter indicates an association between larger aortic diameter and endothelial disruption. However, further studies into these associations are required.

## 4.5 Diameter of aneurysms

The patients in the majority of the previous studies were undergoing surgery for AA, meaning that the diameters of the aneurysms were larger than those in our study, in which the vast majority of aneurysms had diameters below the surgical threshold. A study reported the size of abdominal AA to be associated with concentration of D-dimer (47), while another study suggested endothelin-1 (ET-1), which is released from endothelial cells in response to among other factors vascular injury, as a marker of aneurysm diameter (48). Though such associations have not presently been reported regarding the other biomarkers, it is possible that the smaller diameters of the aneurysms in our study precluded the use of these biomarker concentrations to identify AA, and may, thus, partly explain the negative inverse association between sCD40L and AA and the lack of associations between AA and high levels of syndecan-1 and thrombomodulin, respectively.

## 4.6 Strengths and limitations

A limitation of this study is its cross-sectional design, making it difficult to investigate causal relationships between the biomarkers and AA. Moreover, the cohort is predominantly male and in fact, all AA were found in men. Strengths include a large cohort of well-treated PLWH and the opportunity to adjust for known risk factors for AA. Lastly, the prevalence of AA is high, making it possible to investigate associations with AA.

## 5 Conclusions

In conclusion, in this large cohort of well-treated PLWH, we found high sCD40L to be associated with lower odds of AA, and we confirmed previous findings of the association between high D-dimer and higher odds of AA. Furthermore, thrombomodulin and D-dimer were associated with larger aortic diameter and sCD40L with smaller aortic diameter. These findings regarding sCD40L and AA call for further investigation into its utilization as a biomarker of AA in PLWH. D-dimer holds promise as a possible marker, though not specific of AA, why further examinations of specific biomarkers remain necessary to aid in the early diagnosis of AA in PLWH.

## Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## Ethics statement

The studies involving human participants were reviewed and approved by Regional Ethical Committee of Copenhagen. The patients/participants provided their written informed consent to participate in this study.

## Author contributions

Design of the COCOMO study was carried out by SN et.al (29). and data collection was performed by the COCOMO-team from the Viro-Immunology Research Group. SO contributed to the Luminex® analysis and interpretation of the analysed biomarkers. Statistical analysis plan and design of this sub study was written by SG under supervision by SN and JH. Statistical analyses, interpretation of data, and writing of the manuscript was performed by SKG under supervision by SN, JH and AK. Review of the manuscript was performed by MP, PS, AF, JK, LK, JG, TB, SO, and KK. All authors contributed to the article and approved the submitted version.

## Funding

This work was supported by Rigshospitalet Research Council, Region Hovedstaden, Novo Nordisk Foundation, Augustinus Foundation, Gilead Sciences and Lundbeck Foundation. The study was designed, conducted, analyzed, and written by the authors without involvement of any commercial party.

Dengue virus (DENV) infection manifests as a febrile illness with three distinct phases: early acute, late acute, and convalescent. Dengue can result in clinical manifestations with different degrees of severity, dengue fever, dengue hemorrhagic fever, and dengue shock syndrome. Interferons (IFNs) are antiviral cytokines central to the anti-DENV immune response. Notably, the distinct global signature of type I, II, and III interferon-regulated genes (the interferome) remains uncharacterized in dengue patients to date. Therefore, we performed an in-depth cross-study for the integrative analysis of transcriptome data related to DENV infection. Our systems biology analysis shows that the anti-dengue immune response is characterized by the modulation of numerous interferon-regulated genes (IRGs) enriching, for instance, cytokine-mediated signaling (e.g., type I and II IFNs) and chemotaxis, which is then followed by a transcriptional wave of genes associated with cell cycle, also regulated by the IFN cascade. The adjunct analysis of disease stratification potential, followed by a transcriptional meta-analysis of the interferome, indicated genes such as *IFI27*, *ISG15*, and *CYBRD1* as potential suitable biomarkers of disease severity. Thus, this study characterizes the landscape of the interferome signature in DENV infection, indicating that interferome dynamics are a crucial and central part of the anti-dengue immune response.

## KEYWORDS

DENV, interferon, transcriptome, interferome, dengue

## 1 Introduction

Human arboviruses, such as the dengue, Zika, and chikungunya viruses, have frequently emerged or re-emerged worldwide in recent decades, and they are among the most epidemiologically essential viruses (1). Dengue virus (DENV) is the most prevalent among these (it affects a stunning 390 million individuals annually), and DENV is considered endemic in more than 100 countries (2). Surprisingly, despite its high prevalence and substantial global health impact, it is still characterized as a neglected tropical disease.

Four different DENV serotypes (DENV1-4) are transmitted by the vector *Aedes aegypti* and *Aedes albopictus* mosquitoes (3). The course of dengue infection can be divided into phases. The acute phase is characterized by high fever with abrupt onset, lasting between 2 to 7 days, which is characterized by multiple symptoms, such as malaise, myalgia, arthralgia, rash, retro-orbital pain, and headache (3, 4).

The acute phase can be classified into two stages: 1) Early acute (day 0 to 3 from symptom onset) and 2) Late acute or defervescence (day 4 to end of acute phase) (5). The critical stage during

defervescence is characterized by increased capillary permeability and plasma leakage. This event may lead to severe shock, organ impairment, and bleeding. If the patient survives, the convalescent phase follows, where leaked fluids are reabsorbed and homeostasis is reestablished (4).

Moreover, dengue can be clinically classified by disease severity: 1) dengue fever (DF), characterized by fever and two or more dengue symptoms; 2) dengue hemorrhagic fever (DHF), marked by increased vascular permeability, plasma leakage, bleeding, and thrombocytopenia (3, 4); and 3) dengue shock syndrome (DSS), when DHF symptoms are aggravated with severe plasma leakage and circulatory compromise (6).

The DENV infection typically presents as a self-limiting febrile disease, indicating a central role of the immune system in controlling disease (7). Antigen-presenting cells can recognize viruses via pattern recognition receptors (PRRs), triggering the production of pro-inflammatory cytokines and phagocytic/microbicidal activity (8). This represents an initial step in controlling the virus spreading, followed by activation of the adaptive immune response (8, 9).

One key mechanism of the anti-viral immune response is the production of interferons (IFNs) by various cell types. IFNs are rapidly induced cytokines that respond strongly to DENV (10, 11). There are three families of IFNs: type I (mainly represented by IFN- $\alpha$  and IFN- $\beta$ ), type II (IFN- $\gamma$ ), and type III (IFN- $\lambda$ 1-4). IFNs are central mediators of innate and adaptive immunity as well as immune homeostasis.

For instance, interferon-alpha/beta (IFN- $\alpha/\beta$ )-binding to their receptor (IFNAR) triggers the activation of multiple downstream signaling pathways, including the canonical STAT1-STAT2-IFN-regulatory factor 9 (IRF9) signaling complex (12), which then binds to the IFN-stimulated response elements (ISREs) in gene

**Abbreviations:** AUC, area under the curve; BP, biological process; DEA, differential expression analysis; DENV, dengue virus; DF, dengue fever; DEG, differentially expressed gene; DHF, dengue hemorrhagic fever; DSS, dengue shock syndrome; FC, fold change; GO, gene ontology; IFN, interferon; IFNAR, Interferon- $\alpha/\beta$  receptor; IL-27, interleukin-27; IRF9, transcription 1 (STAT1)-STAT2-IFN-regulatory factor 9; IRG, interferon-regulated gene; ISRE, IFN-stimulated response elements; MDA5, melanoma differentiation-associated protein 5; OOB, out-of-bag; PCA, principal component analysis; PRR, pattern recognition receptor; RF, random forest; ROC, receiver operating characteristic; RLR, RIG-I-like receptor; RIG-I, retinoic acid-inducible gene I; TAM, Tyro3, AXL, and MerTK; TIM, T cell/transmembrane, immunoglobulin, and mucin.

promoters, leading to the induction of a large number of IFN-stimulated genes (ISGs).

Individual transcriptome studies of DENV-infected patients revealed that different IFN-associated genes are elicited in response to DENV infection (5, 6, 13–15) and that several of them are essential to promote a protective anti-viral reaction (5, 6), corroborated by linear and mechanistic approaches (16–18). In turn, DENV proteins antagonize IFN signaling (19, 20), underscoring the importance of these molecules in the response to DENV.

A comprehensive analysis of the IFN signature in the context of dengue infection has not been conducted yet. Here, we performed an integrative analysis of multiple studies of dengue patients' transcriptomes, considering the disease phases and severities, to characterize the dengue interferome [i.e., types I, II, and III interferon-regulated genes (IRGs)] (Figure 1).

## 2 Materials and methods

### 2.1 Data curation

We systematically searched the GEO database to collect publicly available gene expression data (<https://www.ncbi.nlm.nih.gov/gds>). Our search query (“dengue virus”[MeSH Terms] OR “dengue virus”[All Fields] OR “DENV”[All Fields] OR “dengue”[MeSH Terms] OR “dengue”[All Fields]) AND “Homo sapiens”[Organism] AND (Expression profiling by high throughput sequencing[DataSet Type] OR Expression profiling by array[DataSet Type]) resulted in 93 series as of 17<sup>th</sup> of August of 2021 (Figure 2A; All results in Table S1).

The inclusion criteria included: (1) *Homo sapiens* microarray or RNAseq expression data, (2) natural dengue infection, (3) blood or PBMC samples, (4) availability of convalescent-phase samples, and (5) at least one group with ten or more samples. The exclusion criteria included (1) *in vitro* samples, (2) cohorts with only infants and/or children, and (3) results from vaccine or drug trials. We included in our analysis seven datasets: GSE25001 (6, 21), GSE28405 (14, 22), GSE28988 (23), GSE28991 (24), GSE43777 (5, 25), GSE40628 (13, 26), and GSE51808 (15, 27).

The samples were categorized into three groups according to time after symptom onset: 1) Early acute (0–3 days), 2) Late acute (4–8 days), and 3) Convalescent ( $\geq 14$  days). For dataset GSE43777, the late acute phase comprised days 4–10 from disease onset. When applicable, samples were also classified according to disease severity as: 1) Dengue fever (DF), 2) Dengue hemorrhagic fever (DHF), and 3) Dengue shock syndrome (DSS), as determined by the authors when samples were collected. Information about the included series is provided in Table 1.

### 2.2 Differential expression analysis

The identification of differentially expressed genes (DEGs) was performed with the GEO2R web tool (<https://www.ncbi.nlm.nih.gov/geo/geo2r/>) (28), applying statistical tests from the *limma* R package (29). All groups were compared to the convalescent. The DEGs were determined following the cutoffs of log<sub>2</sub> fold-change (FC) > 1 (upregulated) or < -1 (downregulated) and adjusted p-value < 0.05, using R 4.0.5. DEGs and respective log<sub>2</sub> FC are displayed in Table S2.

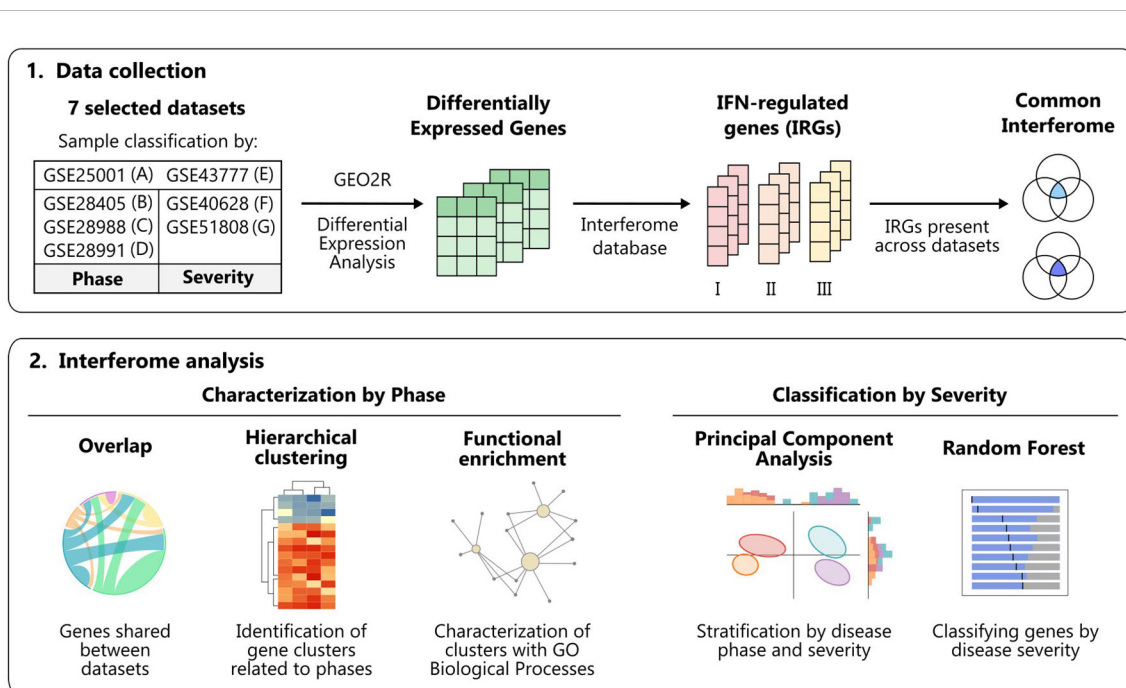

FIGURE 1

Workflow summary. Schematic overview of the data collection and analyses performed to characterize the interferome in dengue infection across disease phases and severity degrees. Figure created with Inkscape. IFN, interferon; GO, Gene Ontology.

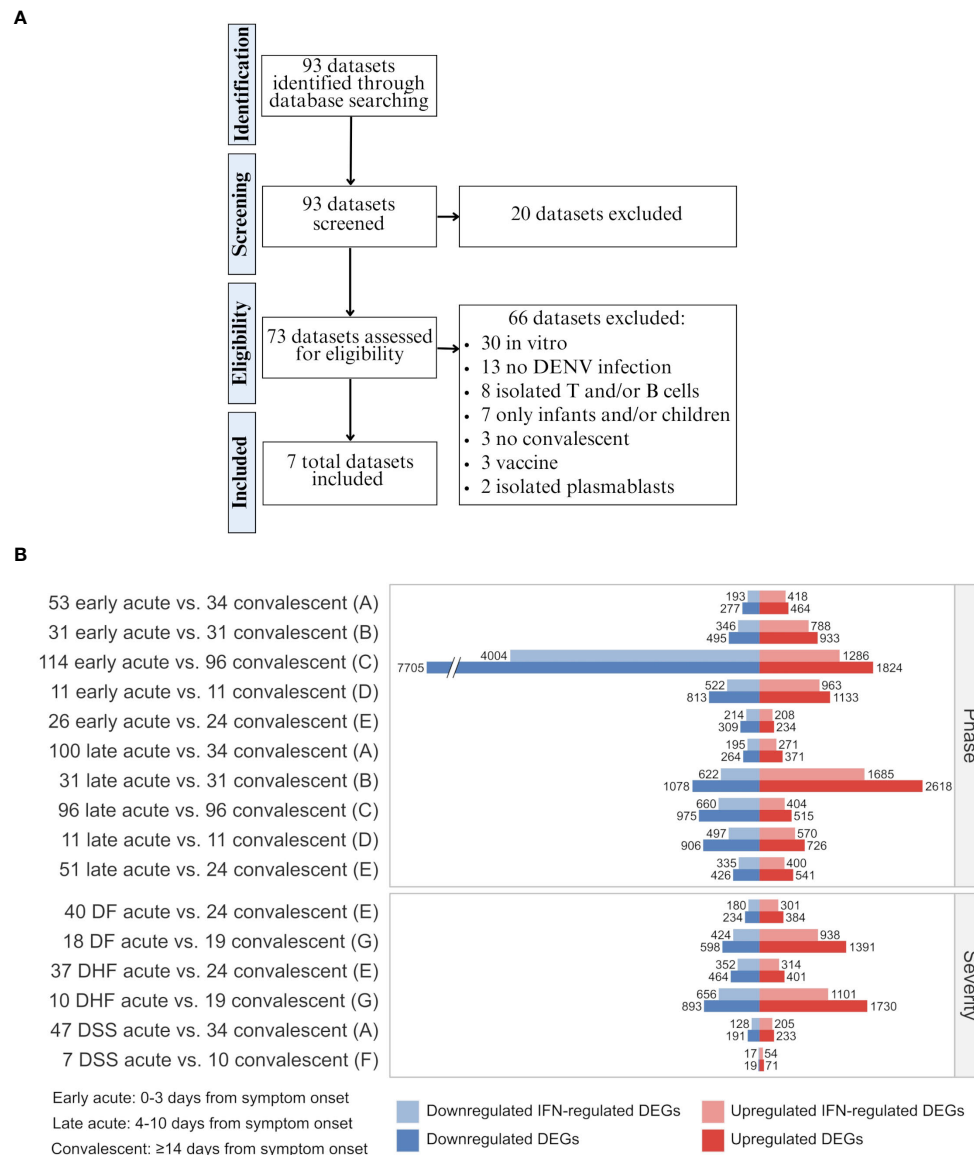

FIGURE 2

Data curation flow chart and differential expression of total genes and interferon-regulated genes across disease phases and disease severity degrees of dengue infection. **(A)** Steps of systematic search and assessment of datasets. Details of datasets and applied inclusion/exclusion criteria are available in [Table S1](#). **(B)** Barplot showing the number of up- and downregulated DEGs and IFN-regulated DEGs for each cohort comparison and dataset as denoted by letters (A, GSE25001; B, GSE28405; C, GSE28988; D, GSE28991; E, GSE43777; F, GSE40628; G, GSE51808) ([Table S3](#)). The sample size of each cohort is indicated by a whole number in front of the group name. DF, Dengue fever; DHF, Dengue hemorrhagic fever; DSS, Dengue shock syndrome; DEG, differentially expressed gene; IFN, interferon.

## 2.3 Interferome analysis

To specifically analyze the IFN network, we employed the Interferome database V2.01 (<http://www.interferome.org/interferome/home.jsp>) (30), which holds information about IFN-regulated genes (IRGs) expression after treatment with IFNs in various experimental systems. The DEGs were submitted to the database to identify IRGs and the specific regulating IFN type. The results summary and IRGs list are in [Tables S3, S4](#).

## 2.4 Data integration and hierarchical clustering

The overlap of the IFN-regulated DEGs between datasets both by IFN type and disease phase were retrieved and represented with Circos (<http://circos.ca/>) (31) and UpSet plots generated with the web tool Intervene (<https://asntech.shinyapps.io/intervene/>) (32). The data used to create the plots are provided in [Tables S5, S6](#). For each combination of IFN type and disease phase or severity, the

Datasets, sample origin, and number of samples by disease phase and/or severity. Annotations: \* 4-10 days in GSE43777. DF, Dengue fever; DHF, Dengue hemorrhagic fever; DSS, Dengue shock syndrome; DEG, differentially expressed gene; DENV, dengue virus; IFN, interferon.

genes shared by all the datasets considered were selected (Table S7). The heatmaps of the log2 fold-change of these shared genes across disease phases or severities were generated with the web tool Morpheus (<https://software.broadinstitute.org/morpheus/>) (33). The hierarchical clustering method utilized was Euclidean distance complete linkage. The data used to create the heatmaps are provided in Tables S8, S9.

## 2.5 Functional enrichment

Functional enrichment analysis based on the clusters of common genes was performed with the web tool EnrichR (<https://maayanlab.cloud/Enrichr/>) (34). The resulting enriched Gene Ontology (GO) Biological Processes (BPs) were filtered by adjusted p-value < 0.05, as well as combined scores and categories befitting the analyzed cell types. When many results from EnrichR were redundant or closely related terms, these were also filtered with Revigo (<http://revigo.irb.hr/>) (35). The most relevant BPs were represented with an alluvial plot generated with R package ggalluvial (36). The functional enrichment analysis according to disease phase and IFN type was conducted with R 4.0.5 and the ClusterProfiler (37) R package. The results were filtered by adjusted p-value < 0.05 and presented as dot plots and networks. The results from the functional enrichment analysis by cluster are available in Table S10 and by disease phase and IFN type in Table S11.

## 2.6 Principal component analysis

Datasets A and E, which had the largest number of samples per phase and severity group (i.e., DSS and DHF, respectively), were selected to analyze the power of the interferome to discriminate the disease severities. The expression values were processed on the ExpressAnalyst web tool (<https://www.expressanalyst.ca/>) (38), and log2 normalized when applicable. For each disease phase, the IRGs previously identified as commonalities were selected. As of dataset E, four samples (GSM1071100, GSM1071104, GSM1071105, GSM1071108) identified as outliers in the PCA were removed from further analyses. Principal Component Analyses (PCA) by singular value decomposition (39, 40) were performed with the log2-transformed expression values of the intersection genes (Table S12) utilizing R 4.0.5 and packages factoextra (41), ggplot2 (42), and ggExtra (43).

## 2.7 Ranking of severity-classifying genes

The samples from datasets A and E were grouped by disease severity for each phase. The log2-transformed expression values of the commonalities used in the respective PCAs were applied in the random forest (RF), a machine learning algorithm, which uses the

combination of multiple tree classifiers (44) to identify classifiers of dengue severity, using R 4.1.3 and package randomForest (45) (data used in RF available in Table S13). For cross-validation, 75% of the data was set for training and 25% for testing. A heatmap for each dataset depicting the fold change of the top 10 severity-classifying genes across disease phases was plotted using Morpheus (33) (data available in Table S14).

## 2.8 Transcriptional meta-analysis and gene annotation

The meta-significant genes were obtained by the Fisher p-value combination method using the ExpressAnalyst web tool (<https://www.expressanalyst.ca/>) (38) (results in Table S15). We used the late acute phase samples from datasets A and E to perform a meta-analysis. Briefly, the log2-transformed expression values were adjusted for batch effect with the combat function from R package sva (46) with R 4.1.3, and the differential expression analyses compared the severe dengue (DSS and DHF) samples with the non-severe dengue (non-DSS and DF) samples. We used Fisher's method to obtain combined p-values for information integration, as recently described (47). A box plot was generated using the Robust Multi-array Average (RMA)-normalized and mean-summarized expression of the putative biomarkers for predicting severe dengue clinical outcome (*IFI27*, *ISG15*, and *CYBRD1*) genes from dataset G (GSE51808) (data available in Table S16). Wilcoxon's test was applied to evaluate the statistical significance between acute DF or acute DHF and convalescent groups. The gene functions were retrieved from the NCBI Gene database (<https://www.ncbi.nlm.nih.gov/gene/>) (48) and UniProt Knowledgebase (<https://www.uniprot.org/>) (49) (Table S17).

## 3 Results

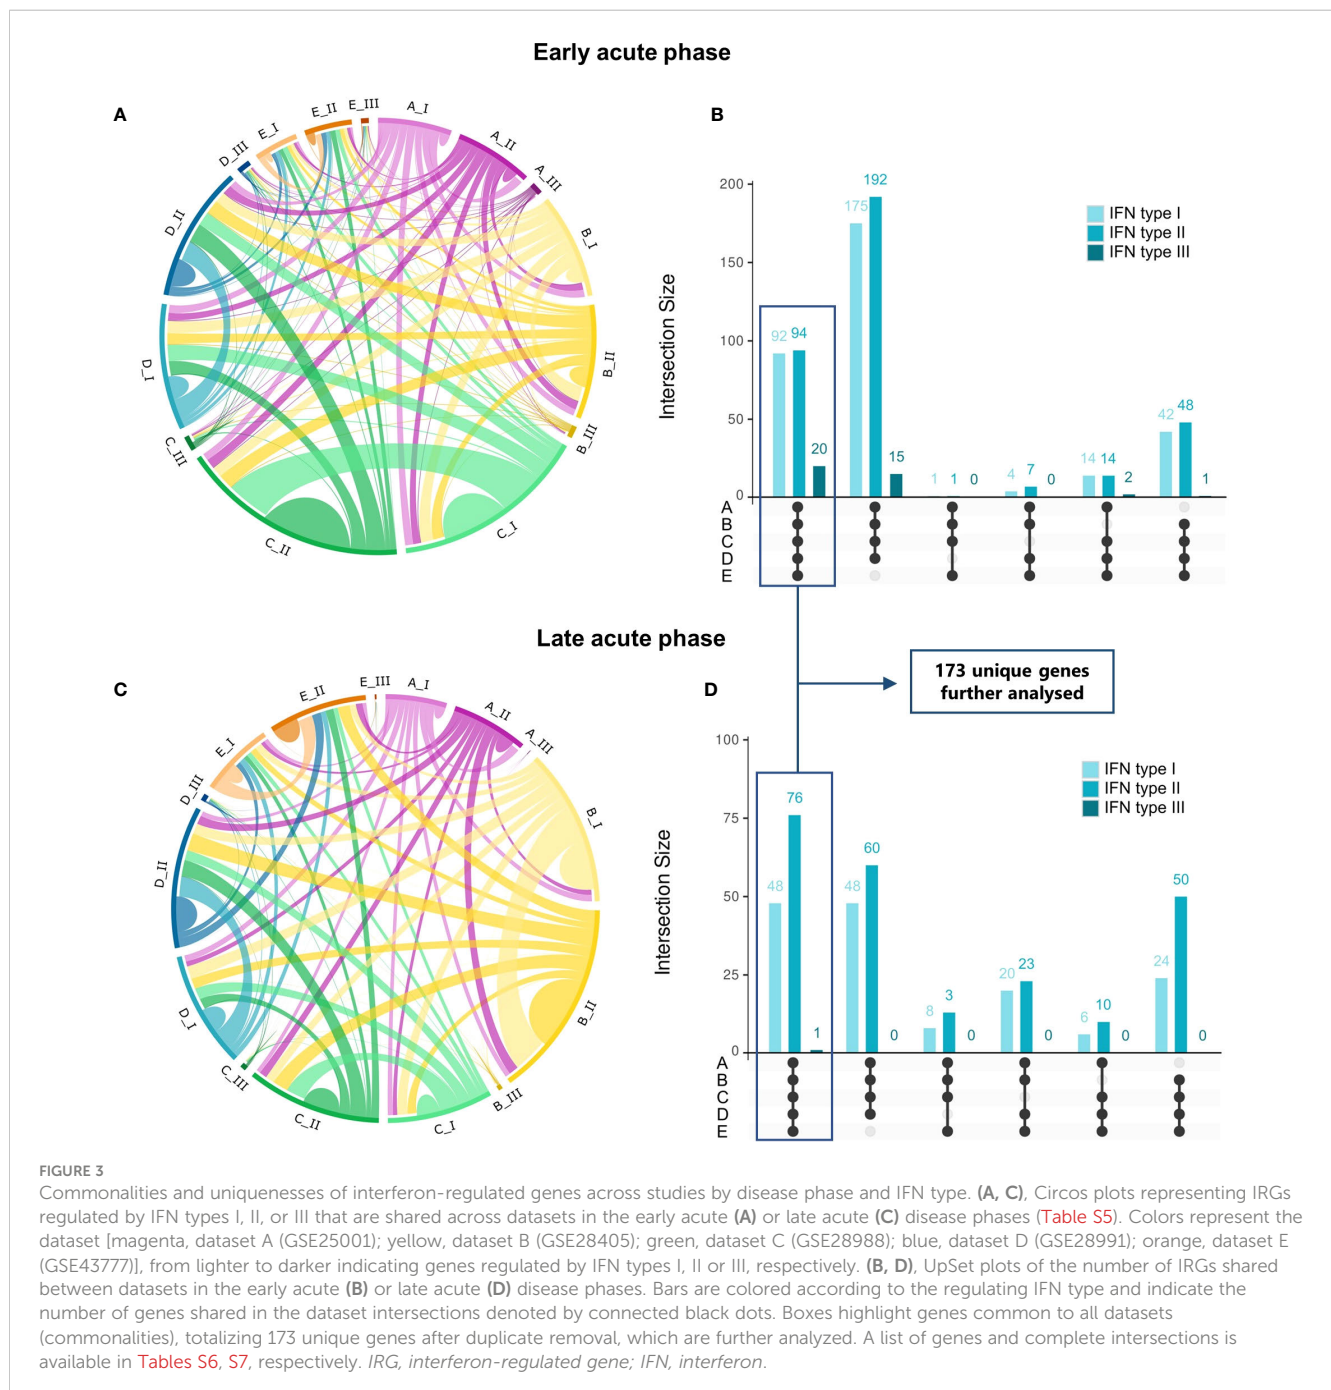

### 3.1 The interferome signature is a hallmark feature of the anti-dengue immune response

We performed a comprehensive multi-study analysis of dengue cohorts to characterize the interferome signature induced by DENV infection according to the disease phase. We obtained seven datasets of dengue fever transcriptomes according to our inclusion criteria of (1) *Homo sapiens* microarray or RNAseq expression data, (2) natural dengue infection, (3) blood or PBMC samples, (4) availability of convalescent-phase samples, and (5) at least one group with ten or more samples; and exclusion criteria of (1) *in vitro* samples, (2) cohorts with only infants and/or children, and (3) results from vaccine or drug trials. All these datasets were generated through microarray technology (GSE25001 (6, 21) (A), GSE28405 (14, 22) (B), GSE28988 (23) (C), GSE28991 (24) (D), GSE43777 (5, 25) (E), GSE40628 (13, 26) (F), and GSE51808 (15, 27) (G) (Table 1).

We compared the gene expression profiles of the different disease phases (early or late acute phases in contrast with the convalescent phase; datasets A-E) and severities (DF, DHF, or DSS acute phase in contrast with the convalescent phase; datasets A, E-G) through differential expression analyses (DEAs). Following, we identified the interferon-regulated genes (IRGs), as summarized in **Figure 2B** and **Table S3**. These results show that most DEGs induced by DENV are regulated by IFNs (On average 72% [minimum: 55%, maximum: 82%]), including a mix of downregulated and upregulated genes. These data confirm the well-established pivotal role of IFNs and the cascade of IFN-associated genes transcribed during the anti-dengue immune response.

### 3.2 Consistent IFN type I and II interferome signature during different dengue phases

We next analyzed the overlap between dengue's early and late acute phases, identifying the transcriptional intersections between studies A to E. The investigation of common IRGs found 173 common DEGs between the datasets during early and late acute phases (**Figures 3A, C**, respectively, **Table S5**), thus revealing a substantial overlap between genes regulated by IFN type I and type II. In contrast, only a few IFN type III-regulated genes were identified. Intriguingly, the distinct difference in the number of IFN type III-regulated genes may be attributed to the limited

experimental data available for IFN type III, which has been only recently characterized (50), resulting in fewer annotated genes on the database. In contrast, types I and II IFNs have been studied extensively (51).

We found a distinct interferome signature across the datasets during early and late acute phases (Figures 3B, D). This indicates that several IRGs are consistently modulated during the anti-DENV immune response. In the early acute phase, 92, 94, and 20 genes were found to be regulated by type I, II, and III IFNs, respectively, across the five datasets (commonalities). Likewise, in the late acute phase, 48, 76, and 1 gene(s) were found to be regulated by type I, II, and III IFNs, respectively. These commonalities in interferome signatures across datasets suggest a conserved response to DENV infection. A comprehensive list of these genes is provided in Table S6, and their intersection in Table S7.

### 3.3 Interferome clusterization at the early and late acute dengue phases

We characterized the interferome expression patterns across the transcriptome datasets from dengue patients at acute phases (datasets A-E) with an unsupervised hierarchical clustering analysis (Figure 4 and Table S8). The IRG expression pattern segregated patients at early acute from those at late acute phases. To further investigate whether the IRG expression pattern could also stratify the patients by disease severity, we analyzed samples from DF, DHF, and DSS patients. However, we found that the differences in the expression pattern of IRGs were not strong enough to segregate by disease severity (Figure S1 and Table S9).

Next, we characterized the clusters through gene ontology (GO) analysis to identify distinct biological processes (BPs) that are enriched by the differential expression signatures found in our gene sets (Figure 4 and Table S10). Namely, cluster 1, composed of strongly upregulated genes CCL8 and CCL2 during the early acute phase; cluster 2, comprising downregulated genes at early and late acute phases; cluster 3, including genes more upregulated in the early acute phase; and cluster 4, consisting of genes more upregulated in the late acute phase. Cluster 1 enriched BPs were related to the migration and chemotaxis of lymphocytes, granulocytes, and mononuclear cells. Cluster 2 included genes involved in phagocytosis, cellular response to catecholamine stimulus, and anion homeostasis. Cluster 3 exhibited genes enriching several processes related to the response to the virus (e.g., positive regulation of RIG-I signaling pathway, regulation of viral genome replication) and IFN-related processes (e.g., ISG15-protein conjugation, regulation of type I IFN production). Cluster 4 comprises genes enriching several cell cycle-associated processes such as phase transition, checkpoint, and DNA replication.

To assess whether GO differences depended on the particular IFN type, we further conducted a functional enrichment analysis of the 173 common IRGs by IFN type and disease phase (Table S11). In the early acute phase (Figure 5), genes regulated by IFN types I

and II robustly overlapped (86 in 100 genes). Hence, we joined these genes and carried out the enrichment analysis. For the three IFN types, we found a predominance of BPs related to host regulation and defense against the virus, analogous to the enrichment results of cluster 3. In the late acute phase (Figure 6), considering that only one common gene was regulated by IFN type III, we performed the enrichment analysis only for types I and II. We found several cell cycle-associated BPs during the late acute phase, as seen in cluster 4 (Figure 4). Hence, these findings indicate a phase-specific interferome signature.

### 3.4 Anti-DENV interferome stratifies patients according to disease phase and severity

We further examined a possible stratification power of the anti-DENV interferome with principal component analysis (PCA), considering disease phases and severities. The PCA of IRGs indicated that they stratify DF, DHF, non-DSS, and DSS dengue patients at early and late acute phases from their counterparts in convalescence (Figures 7A–D and Table S12). In the late acute phase, the interferome signature could differentiate DF patients from DHF patients and partially distinguish non-DSS from DSS patients. However, for the IRGs identified in the early acute phase, there was only minimal differentiation power based on disease severity. This fact implies that the interferome signature at the later stage of DENV infection may play a distinct role compared to early dengue stages.

To better understand the interferome's stratification power for dengue patients according to disease severity, we next applied random forest (RF), a machine learning algorithm, to identify classifiers of dengue severity (Table S13). In agreement with the PCA results, RF analysis of DF versus DHF late acute groups indicated an out-of-bag (OOB) error rate of 27.78% and area under the curve (AUC) of the receiver operating characteristic (ROC) curves of 0.952 (Figures 8A, B). Thus, IRGs are strong classifiers of DHF at the late phase. However, we did not find solid classifiers for DSS or the early acute phase. For dataset A, comparing non-DSS and DSS late acute groups, the OOB error rate was high for the non-DSS group (group 1), and the AUC of the ROC curves was 0.833 (Figures S2). When we performed RF with early acute samples from dataset E and dataset A, the OOB error rate was 31.58% and 33.33%, with AUC of 0.583 and 0.622, respectively (Figure S3).

The top ten IRGs classifying dengue severity (DF and DHF; Figure 8C) were *SULF2*, *ISG15*, *NME1*, *CYBRD1*, *GINS2*, *GAS6*, *UBE2T*, *RNASE1*, and *MKI67*, in decrescent order. We evaluated the expression patterns of these top 10 genes through DEAs within each disease phase, comparing disease severities (Figure 8D and Table S14). Only *IFI27* and *ISG15* were significantly differentially expressed between DHF and DF samples in the late acute phase. To further investigate whether these ten genes could also classify by disease

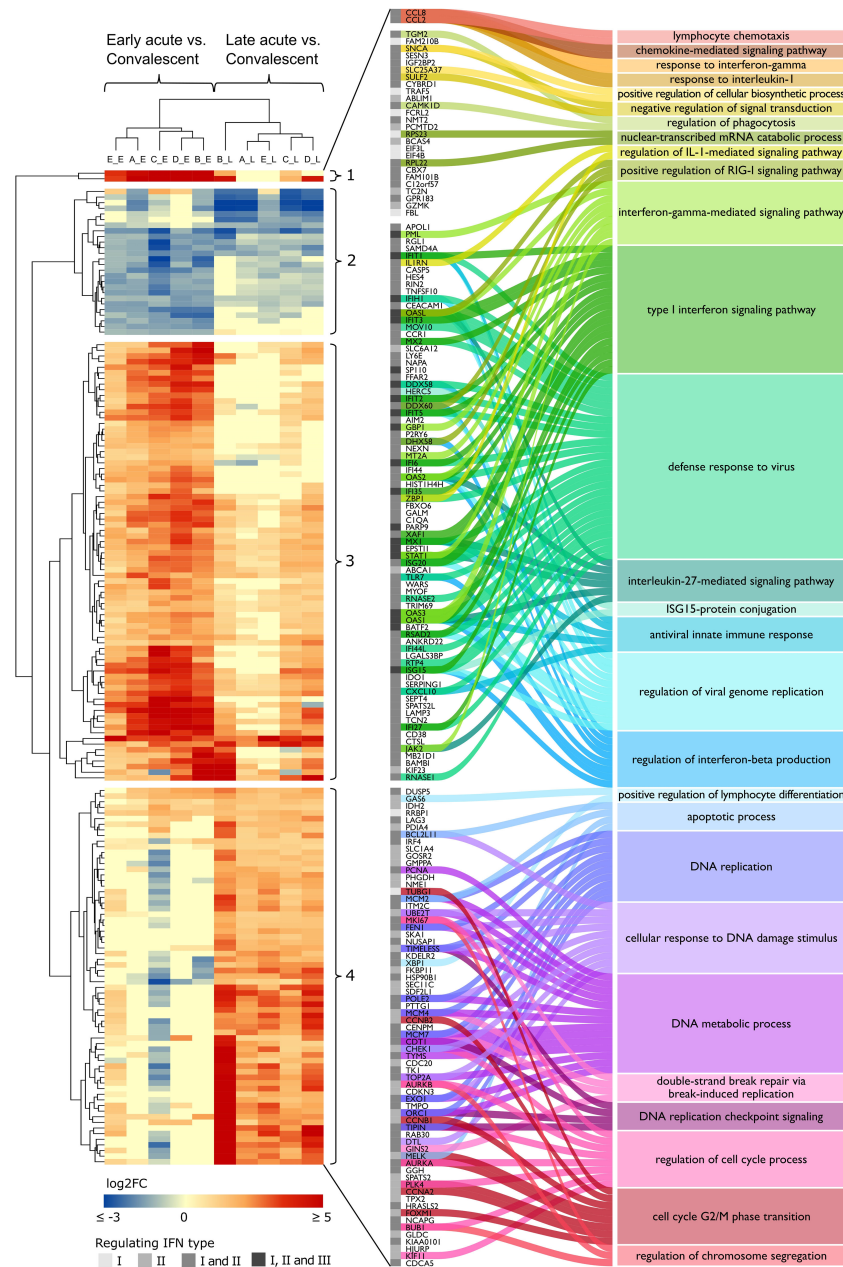

FIGURE 4

DENV infection acute phase interferome landscape. Heatmap of log2 FC of the common IRGs across the acute phases in datasets A to E (Table S8). The red color scale denotes up-regulated genes; the blue color scale denotes down-regulated genes, yellow color denotes genes not differentially expressed (FC close to zero or missing). Hierarchical clustering by Euclidean distance complete linkage metric discriminated cohorts (columns) by disease phase (early acute, late acute) and IRGs (rows) into four distinct clusters (1–4). The amplified view and alluvial plot represent the IRGs of each cluster and the main BPs associated with each cluster. The IFN types that regulate the IRGs are indicated by a grayscale column, from lighter to darker, representing IFN types I and II alone or I and II, as well as I, II, and III together. Complete functional enrichment results by cluster are available in Table S10. Heatmap columns legend: First letter indicates dataset (A, GSE25001; B, GSE28405; C, GSE28988; D, GSE28991; E, GSE43777), while second letter indicates disease phase comparisons (E, early acute vs. convalescent; L, late acute vs. convalescent). DENV, dengue virus; FC, fold change; IRG, interferon-regulated gene; BP, biological process; IFN, interferon; IL-1, interleukin-1; RIG-I, retinoic acid-inducible gene I; ISG15, ISG15 ubiquitin-like modifier.

severity, including DSS, we performed a meta-analysis with the late acute samples of datasets A and E. We found 872 meta-significant genes (Table S15). Of the top ten ranked genes, *IFI27*, *ISG15*, and *CYBRD1* were also identified among the meta-significant genes. To further validate these genes as putative biomarkers for predicting

severe dengue clinical outcome classification across disease phases, we analyzed their expression on an independent cohort (dataset G). The acute and convalescent phases were significantly different, while there was no difference between the convalescent and healthy control samples (Figure S4 and Table S16).

## 4 Discussion

The interferome is a highly complex ancient molecular system (already present in jawed vertebrates) (52), which plays a crucial and central part in the anti-DENV immune response and many other viral infections. Upon virus recognition by PRRs, the IFN system is rapidly triggered within hours from infection, initiating IFN production and a cascade of signaling pathways (53), and as shown here, the transcription of an array of IRGs. In this context, this study comprehensively characterizes the dengue interferome signature in patients, encompassing different datasets, disease

phases, and severities. The IFNs are among the oldest known cytokines (51) and the results presented here indicate that the interferome can still be explored in more detail in DENV-infected patients to provide new contextual information that may benefit these patients and result in improved treatment strategies. Our findings align with previous studies highlighting the significant role of IFN responses in the immune response to DENV infection (54–56). Indeed, we consistently observed a functional enrichment of several IFN-related functions during the acute disease phase. Thus, our integrative systems biology analysis based on seven independent datasets confirms the consistency of prior individual

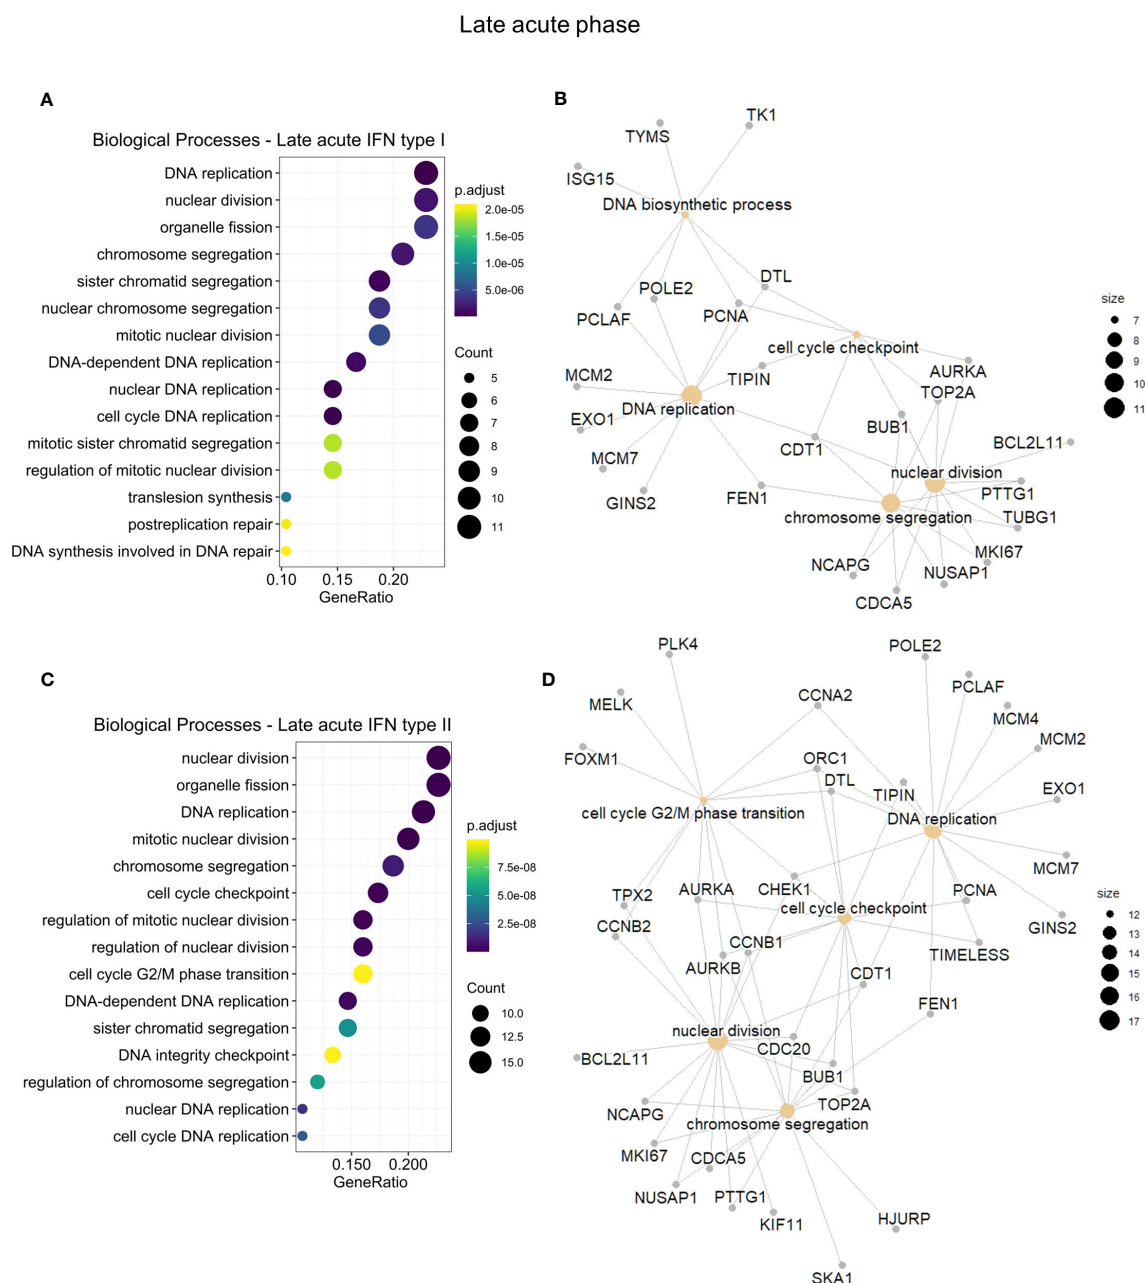

FIGURE 6

studies, such as those reported by Sun et al. (5), characterized by cytokine-mediated signaling (e.g., type I IFN) and chemotaxis, which is followed by a transcriptional wave of genes associated with the cell cycle.

Our current study emphasizes the predominance of IFN-regulated genes among DEGs, characterizing the interferome signature as an evident hallmark of the acute response to DENV. This finding agrees with the observation of high levels of type I IFN during acute dengue infection with concomitant CD4<sup>+</sup> and CD8<sup>+</sup> T

cell activation at symptom onset (57). It is already well established that the first powerful wave of type I IFNs may be an early attempt of the host to protect itself against the initiation and development of more advanced disease by employing an early acute phase. Meanwhile, the enrichment of cycle-associated BPs at the late acute phase might represent the simultaneous occurrence of leukocyte proliferation to fight against the infection, together with the manipulation of the cell cycle by the DENV (58, 59) through distinct mechanisms that remain to be explored further in future

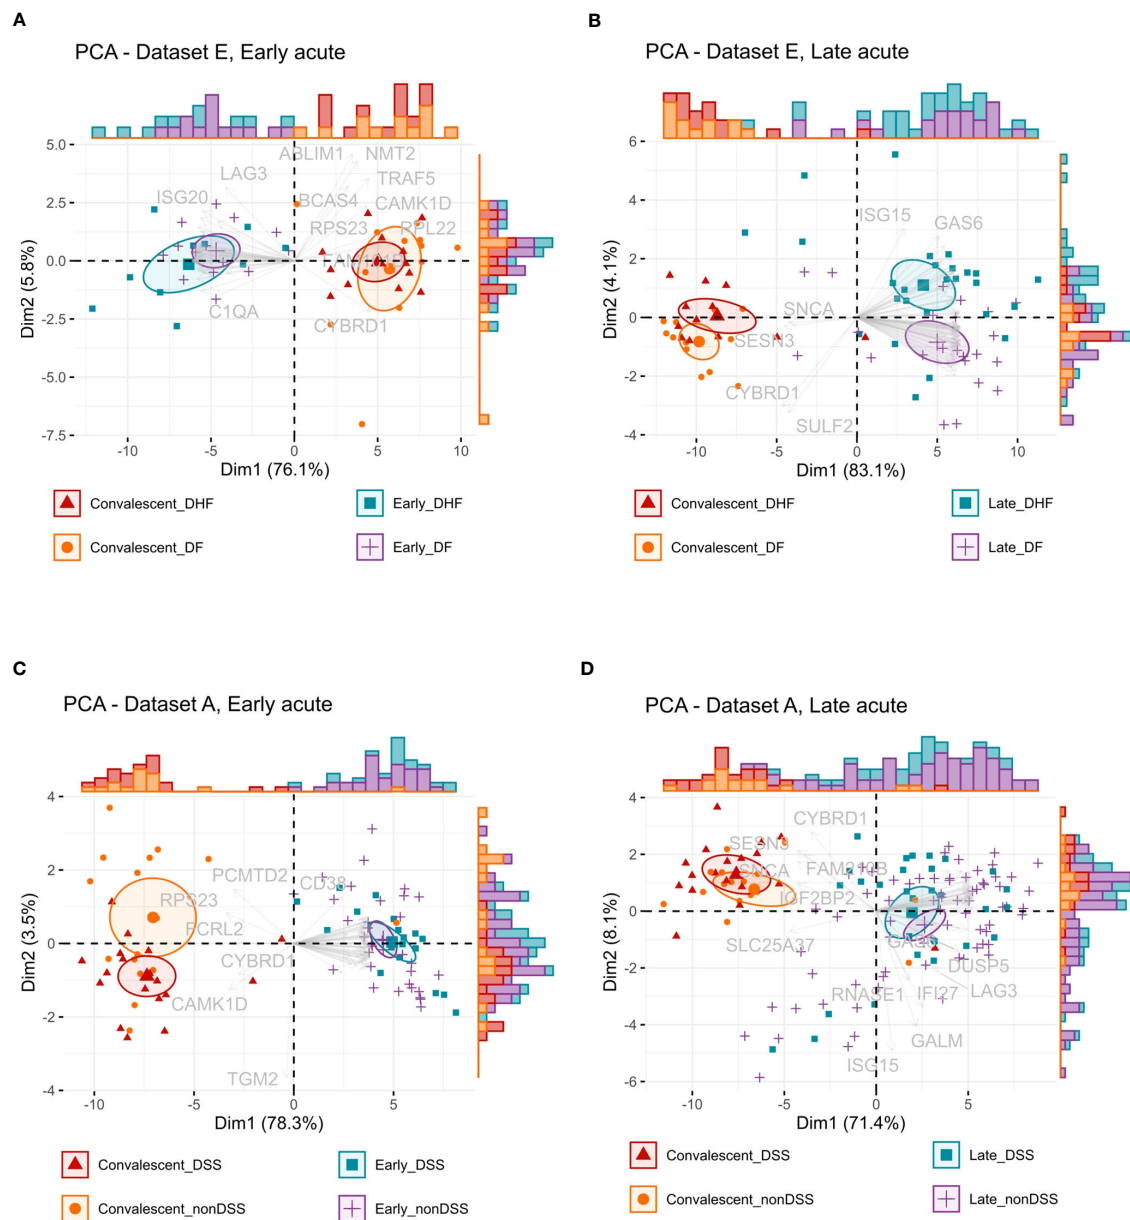

FIGURE 7

Interferon-regulated genes stratification capacity by disease phase and severity. (A, B), Principal component analysis (PCA) biplots of the log2-transformed gene expression values from dataset E of the early acute phase (A) or late acute phase (B) IRGs common across all studies. (C, D), PCA biplots of the log2-transformed gene expression values from dataset A of the early acute phase (C) or late acute phase (D) IRGs common across all studies. Data is available in [Table S12](#). Ellipses represent the concentration of samples. Vectors represent the loadings, individual contributions of the genes. Histograms represent the distribution of samples across the biplot. Color and shape identify the groups: red color and triangles represent the convalescent more severe samples (DHF or DSS), orange color and dots represent the convalescent less severe samples (DF or nonDSS), blue color and squares represent the acute phase more severe samples (DHF or DSS), purple color and positive signs represent the acute phase less severe samples (DF or nonDSS). IRG, interferon-regulated gene. DSS, Dengue shock syndrome; DF, nonDSS, non-Dengue shock syndrome; Dengue fever; DHF: Dengue hemorrhagic fever.

studies. Moreover, our work demonstrates that IRGs are still differentially expressed in the late acute phase. As a result, as IFNs may still be detected, they may also play a regulatory role in this phase of the disease. Genes upregulated at the late acute phase enriched BPs mostly related to mitosis and cell cycle, which was also reported by Sun et al. (5), suggesting this may represent a recovery of the immune cells after viremia has decreased. Thus, indicating a

long-lasting cascade effect of the interferome in the anti-DENV immune response.

Clinical investigations of dengue patients have assessed varying timeframes of IFN kinetics and levels during infection, e.g., higher IFN- $\alpha$  levels were identified in the period comprising the early acute phase (0 to 3 days after fever onset) (54, 60), but also throughout the acute phase (57). IFN- $\gamma$  was also reported to be elevated in the early

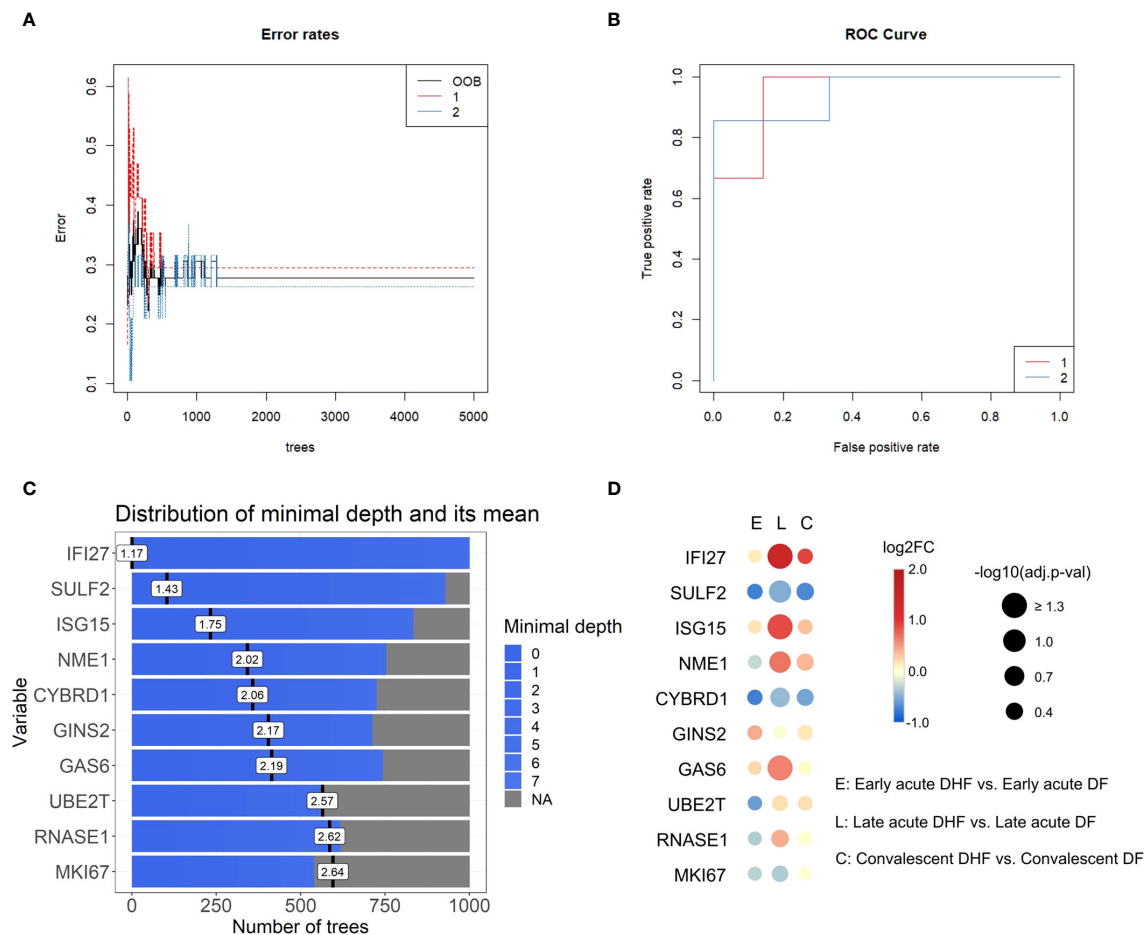

FIGURE 8

Top interferon-regulated genes for severity classification in the late acute phase ranked by random forest (Dataset E). (A), Error rates of random forest models by number of trees. (B), Receiver operating characteristic (ROC) curve of the generated classifying models. The red line corresponds to group 1 (late acute DF), blue line corresponds to group 2 (late acute DHF). (C), Bar plot of the top ten severity classifying genes ranked by the random forest model, number of trees, and distribution of the minimal depth. Blue bars represent the minimum and maximum minimal depth, and black vertical lines represent the mean minimal depth for each classifying gene. Data input of log2-transformed expression values of IRGs common across datasets A to E in the late acute phase are available in Table S13. (D), Bubble heatmap of the log2FC of IRGs resulting from the DHF vs. DF comparison for each disease phase (early acute, late acute, convalescent). The red scale indicates positive FC (up-regulated genes), blue scale indicates negative FC (down-regulated genes). Bubble size represents  $-\log_{10}$ -transformed adjusted p-value. Data is available in Table S14. IRG, interferon-regulated gene; DHF, dengue hemorrhagic fever; DF, dengue fever; FC, fold change, OOB: out-of-bag.

acute phase (57), although peaking around defervescence (61). Likewise, in the early acute phase, we observed the enrichment of BPs primarily related to antiviral defense mechanisms. These BPs included regulating typical viral processes, replication, life cycle, and signaling pathways of RLRs, as well as inflammatory cytokines. These results are consistent with the well-established functions of IFNs in innate immunity. Therefore, our integrative findings from different patient datasets confirm the consistency of the molecular dynamics of the early acute phase of dengue infection, when the viremia, innate immune responses, and IFN responses peak (52).

The observed cell-cycle-related effects of the distinct anti-DENV interferome signature should be investigated further. They may be explained by the fact that IFNs have been reported to negatively regulate the proliferation and differentiation of cell types, such as innate lymphoid type 2 cells and dendritic cells (53), as means of controlling the infection by hampering the viral replication and enhancing the elimination of infected cells (52).

On the other hand, both IFN- $\alpha$  and IFN- $\gamma$  have also been reported to enhance immune proliferation (62, 63). These apparently contradicting effects illustrate how the IFN system is highly pleiotropic, presenting extensive functions and effects (62, 64).

The stratification and classification analyses (PCA and random forest) results demonstrate effective discrimination between disease severities based on the interferome signature only in the late acute phase, indicating that the interferome has a more prominent role at this stage. The late acute phase is critical, wherein the disease course is defined as severe or non-severe dengue (4). So far, identifying early-stage biomarkers to classify which patients will progress to severe dengue is still an unsolved challenge. The random forest algorithm identified the top ten ranking genes (*IFI27*, *SULF2*, *ISG15*, *NME1*, *CYBRD1*, *GINS2*, *GAS6*, *UBE2T*, *RNASE1*, *MKI67*) for differentiation of DHF and DF in the late acute phase. Among them, *IFI27*, *ISG15*, and *CYBRD1* were also meta-significant genes. We confirmed in an independent dataset that these putative

biomarkers are differentially expressed during acute infection for both DF and DHF and return to baseline expression upon disease resolution. Further, *IFI27* and *ISG15* were significantly upregulated in the DHF late acute phase and have previously been associated with dengue severity by Zanini et al. (65).

Mechanistically, *IFI27* (interferon alpha inducible protein 27) is involved in type-I interferon-induced apoptosis (49) and was recently identified as a key ISG in DENV infection, using similar approaches (66). In addition, *IFI27* was predominantly upregulated across disease phases in DHF and DSS, being a putative late-stage biological indicator for severe dengue. In turn, *ISG15* encodes a ubiquitin-like protein with an antiviral activity that can induce NK cell proliferation, act as a chemotactic factor for neutrophils, and induce IFN- $\gamma$  (49). *ISG15* was upregulated in DHF but downregulated in DSS, representing a potential molecule differentiating patients between the two severities in the late acute phase. On the other hand, *CYBRD1* encodes a plasma membrane reductase that reduces extracellular Fe<sup>3+</sup> into Fe<sup>2+</sup>, expressed in monocytes and neutrophils (49, 67). It is a meta-significant gene, downregulated in DHF but upregulated in DSS. *CYBRD1* can potentially be a classifier between DHF and DSS in the late acute phase, and to the best of our knowledge, it has not been previously associated with dengue. *GAS6* encodes a ligand for tyrosine-protein kinase receptors, which has been shown to bind to TAM receptors, inhibiting inflammatory innate immune response. DENV exploits the apoptotic clearance function of TIM and TAM receptors, mediated by Gas6, to gain entry into cells (68). This fact highlights the interplay between *GAS6* and DENV infection, emphasizing the involvement of *GAS6* in modulating immune responses and facilitating viral entry. As this gene was upregulated in the DHF group, this enhanced viral entry may be related to the increased disease severity.

Our work has some limitations. For instance, the molecular signatures identified in this study must be investigated in longitudinal studies and verified further at the protein level. As with all transcriptomic data, it does not necessarily reflect in expressed proteins or functional effects, and possible biomarkers are only putative, with further clinical studies necessary to evaluate their applicability. Another limitation is that some samples included children and infants, whose immune response differs from that of adults (69). As expected, most severe dengue (DHF and DSS) samples were secondary infection cases (70). However, no information allowed us to consistently identify the samples regarding either reinfection or DENV serotype, which can affect the response to infection (71). Other populational factors affecting the response to DENV that could not be considered in this study are ethnicity, geographic location, nutritional status, and comorbidities (72, 73), as that information were unavailable and/or not comparable. Despite these limitations and the cohort heterogeneity, we found consistent molecular signatures across the studies, indicating our results are robust and characteristic of the overall DENV infection.

## 5 Conclusions

Our study underscores the significant involvement of IFN-regulated genes in the acute dengue response, as reflected by the

distinct interferome signature during different phases of DENV infection. Summarily, our approach focused on the expression patterns of IRGs across disease phases and severities in dengue patients. Of note, most DEGs induced by dengue infection were also regulated by IFN, which corroborates the broad modulation of the immune response by the IFN system. Moreover, this study provides valuable insights into the qualitative and quantitative aspects of the dengue interferome, highlighting the dynamic interplay between IFN signaling and gene expression modulation in the context of dengue infection. Hence, our study indicates consistent molecular signatures of disease severity in the late acute stage that can help the development of better classificatory methods and treatment to reduce morbidity and mortality of dengue patients.

## Data availability statement

Publicly available datasets were analyzed in this study. This data can be found here: GEO Datasets (<https://www.ncbi.nlm.nih.gov/gds>), accession numbers GSE25001, GSE28405, GSE28988, GSE28991, GSE43777, GSE40628, GSE51808. Codes utilized in this manuscript are available at the following link: [https://github.com/JNUsuda/dengue\\_interferome](https://github.com/JNUsuda/dengue_interferome).

## Ethics statement

Ethical approval was not required for the study involving human samples in accordance with the local legislation and institutional requirements. Written informed consent for participation in this study was provided by the participants' legal guardians/next of kin. Ethical approval was not required for the study involving animals in accordance with the local legislation and institutional requirements because publicly available datasets were used in this study.

## Author contributions

JU, DP, and OC-M conceived this study. JU performed the data analysis. DF, AM, IF, VC, AA, AT-C, MH, PF, RC, GM, GC, LS, DP, and OC-M provided scientific insights. JU, RC, GM, DP, and OC-M wrote and revised the final version of the manuscript. DP and OC-M supervised the work. All authors contributed to the article and approved the submitted version.

## Funding

We thank the São Paulo Research Foundation (FAPESP) (grants: 2021/03675-5 to JU; 2020/16246-2 to DF; 2023/03841-8 to VC; 2020/11710-2 to DP; and 2018/18886-9 to OC-M) for financial support. We acknowledge the Brazilian Federal Agency for Support and Evaluation of Graduate Education (CAPES/PROEX) (grant 88887.848413/2023-00 to AA) and the National Council for Scientific and Technological Development (CNPq) Brazil (grants: 102430/2022-5 to LS; 309482/2022-4 to OC-M). The contributions by GM were made possible by

funding from the German Federal Ministry for Education and Research (BMBF) and the German Research Foundation (DFG; project EXPAND-PD; CA2816/1-1) through the Berlin Institute of Health (BIH)-Center for Regenerative Therapies (BCRT) and the Berlin-Brandenburg School for Regenerative Therapies (BSRT, GSC203), respectively, and in part by the European Union's Horizon 2020 Research and Innovation Program under grant agreements No 733006 (PACE) and 779293 (HIPGEN) and 754995 (EU-TRAIN).

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

**Introduction:** The type I interferon (IFN) response is an innate immune program that mediates anti-viral, anti-cancer, auto-immune, auto-inflammatory, and sterile injury responses. Bone marrow derived macrophages (BMDMs) are commonly used to model macrophage type I IFN responses, but the use of bulk measurement techniques obscures underlying cellular heterogeneity. This is particularly important for the IFN response to immune stimulatory double-stranded DNA (dsDNA) because it elicits overlapping direct and indirect responses, the latter of which depend on type I IFN cytokines signaling via the IFN alpha receptor (IFNAR) to upregulate expression of interferon stimulated genes (ISGs). Single cell transcriptomics has emerged as a powerful tool for revealing functional variability within cell populations.

**Methods:** Here, we use single cell RNA-Seq to examine BMDM heterogeneity at steady state and after immune-stimulatory DNA stimulation, with or without IFNAR-dependent amplification.

**Results:** We find that many macrophages express ISGs after DNA stimulation. We also find that a subset of macrophages express ISGs even if IFNAR is inhibited, suggesting that they are direct responders. Analysis of this subset reveals *Ccl5* to be an IFNAR-independent marker gene of direct DNA sensing cells.

**Discussion:** Our studies provide a method for studying direct responders to IFN-inducing stimuli and demonstrate the importance of characterizing BMDM models of innate immune responses with single cell resolution.

## Introduction

The type I interferon (IFN) response is an innate immune program that fuels inflammation during diverse pathologic processes including infections, malignancies, sterile tissue injury, autoimmunity, and autoinflammatory diseases (1–9). In the setting of viral infections, this response is adaptive; however, in the context of sterile injuries and autoimmune diseases, this response is often overly exuberant and maladaptive. IFNs are thought to mediate pathology by signaling *via* their cell surface IFN alpha receptor (IFNAR) as detailed below. As a result, therapies based on inhibition of type I IFN signaling using neutralizing antibodies against the IFN alpha receptor (IFNAR) have been developed and were recently FDA approved for treatment of lupus (10).

The type I IFN response is shown schematically in Figure 1. It begins when molecularly conserved pathogen- and damage-associated molecular patterns (DAMPs and PAMPs) are detected by genome encoded pattern recognition receptors (PRRs), for example, when immune stimulatory double-stranded DNA (dsDNA) is sensed by the cytosolic DNA sensor intracellular cyclic GMP-AMP synthase (cGAS) or Toll Like Receptor 9 (TLR9) (7, 11, 12). Receptor engagement leads to intracellular signaling that culminates in activation of the master transcriptional regulator interferon response factor 3 (IRF3) which, once phosphorylated, dimerizes, and translocates into the nucleus where it induces expression of target genes such as type I IFN secreted cytokines (Ifn $\alpha/\beta$ ) (7, 11, 12). Beyond the cGAS, other cytosolic DNA sensors have been described but they are not known to induce type I IFN responses (13–15).

Type I IFNs are diffusible extracellular cytokines that spread responses from directly-stimulated cells to neighboring cells by binding to cell surface interferon alpha receptors (IFNAR1 and IFNAR2, hereafter IFNAR) (Figure 1). Autocrine signaling is also possible if the directly-stimulated cells express IFNAR. Ligand binding of IFNAR leads to intracellular signaling that activates a heterotrimeric transcriptional regulatory complex composed of STAT1, STAT2, and IRF9, called ISGF3. Within the nucleus, ISGF3 upregulates hundreds of genes that are collectively referred to as interferon stimulated genes (ISGs). Some ISGs are thought to be directly inducible by IRF3, independent of IFNAR, while others are IFNAR-dependent, but it is challenging to separate and quantify direct and indirect effects using bulk measurement techniques (16–18). Most experimental studies of the type I IFN response to immune stimulatory DNA rely on bulk measurement techniques that average responses over large numbers of cells. It is therefore difficult to separate, characterize, and quantify the responses of direct DNA-sensing cells amidst secondary IFNAR-dependent cells. Even when IFNAR Abs are used to block secondary signaling, the primary response is averaged across all cells and is thus severely diluted.

Here, we utilize single cell RNA-Seq to characterize bone marrow derived macrophages (BMDMs), a commonly used *in vitro* model of tissue macrophages, at steady state and after exposure to immune stimulatory dsDNA with or without simultaneous IFNAR Ab treatment or genetic deficiency of IFNAR (19). This enables dissection of IFNAR-dependent and IFNAR-independent responses with single cell resolution, even when cells derive from the same culture well and thus share a

FIGURE 1

Overview of Direct and Secondary Type I IFN response to Immune-stimulatory dsDNA. When double-stranded DNA (dsDNA) is complexed with a polyelectrolyte transfection reagent and added to cells in culture, it activates an innate immune response. Some cells internalize the particulate material, allowing dsDNA to be sensed by the cytosolic pattern recognition receptor cGAS, which catalyzes synthesis of the second messenger, cGAMP that signals *via* the adaptor STING and the TBK1 kinase to promote phosphorylation, dimerization, and nuclear translocation of the master transcriptional regulator IRF3. Once inside the nucleus, IRF3 binds to the promoters of IRF3-dependent genes such as the type I interferon cytokines, IFN $\alpha$  and IFN $\beta$ . Secreted type I IFN cytokines can diffuse to neighboring cells and bind to their cognate surface receptor, interferon alpha receptor (IFNAR), leading to JAK/STAT signaling and assembly of a heterotrimeric transcriptional regulatory complex known as ISGF3, composed of Stat1, Stat2, and Irf9. ISGF3 binds to ISRE consensus sequences and upregulates hundreds of effector genes, which are collectively known as interferon stimulated genes (ISGs). By performing experiments in the presence or absence of an IFNAR neutralizing antibody, one can dissect the "Direct" IFNAR-independent and "Indirect" IFNAR-dependent elements of the type I IFN response.

microenvironment. Our results point to *Ccl5*, a proinflammatory chemokine, as a marker of direct DNA sensing cells which is inducible independent of IFNAR-mediated amplification.

## Results

### Single cell analysis of bone marrow derived macrophage subsets

To dissect direct and indirect responses to transfected immunogenic DNA stimulation with single cell resolution, we designed the following experiment. We used single cell RNA-Seq to define the heterogeneity of cultured BMDMs (i) at steady state, (ii) in response to dsDNA alone, or (iii) in response to dsDNA + IFNAR Ab inhibition of secondary signaling, or (iv) in dsDNA-treated IFNAR KO (Figure 2A). BMDMs were derived by flushing hematopoietic cells from the femurs of adult C57BL6 mice and differentiating them into macrophages in culture using monocyte colony stimulating factor (m-CSF) as we previously described (20). We then subjected the cultures to 24 hours of stimulation with the conditions above, after which BMDMs were collected, stained with DAPI, purified by flow cytometry, and subjected to droplet-based microfluidic single cell barcoding (Chromium, 10X Genomics), library preparation, and next generation sequencing (NovaSeq, Illumina). After demultiplexing and mapping to a reference murine genome, we performed shared nearest neighbor (SNN) clustering on the integrated data from all three treatment groups to define a universal embedding of shared BMDM subtypes (Figure 2B). Unbiased clustering revealed 6 coarse BMDM clusters, 2 of which were interpreted to be proliferating based on expression of canonical cell replication marker genes and labeled them Repl(G2/G1) and Repl(S/G1) (Supplementary Figure S1). Proliferating BMDMs were stratified by cell cycle phase cell based on their expression of *Mcm6* and *Mcm5* (S phase), *Top2a* and *Cenpa* (G1 phase), *Birc5* and *Nusap1* (G2 phase) (Figures 2C, D). Non-proliferating BMDMs were also readily stratified into 3 clusters based on their expression of *Fabp4* and *Fabp5* and MHCII genes such as *H2-Aa* and *H2-Ab1* (Figures 2C, D). We labeled the non-proliferating BMDM subsets (*Fabp4*-, MHCII-), (*Fabp4*+, MHCII-), and (*Fabp4*+, MHCII+). The final cluster was defined as a monocyte-like BMDM Progenitor characterized by expression of *S100a4* and *S100a6*.

### Single cell analysis of cytosolic DNA-induced ISG expression in BMDMs

Having defined the BMDM subtypes at steady state, we turned our attention to the response to dsDNA. Experiments based on bulk measurement techniques (e.g., qPCR) have firmly established that dsDNA complexed with a transfection reagent, when delivered to macrophages in culture, induces expression of type I IFNs and ISGs (21). However, underlying single cell heterogeneity remains

incompletely defined. Consistent with results from bulk experiments, single cell RNA-Seq profiling of dsDNA-stimulated BMDMs markedly induced expression of ISGs (*Irf7*, *Ifit2*, *Oasl2*, *Rsad2*, *Isg15*) compared to unstimulated controls as well as compared to dsDNA in the context of IFNAR Ab, thus demonstrating successful inhibition of secondary amplification (Figure 3A). Violin plots confirmed dsDNA-dependent and IFNAR-dependent induction of ISGs at the single gene level while broader macrophage marker genes such as *Ms4a7* remained highly expressed across all three conditions (Figure 3B). To evaluate dsDNA responses independent of clustering, we created an ISG Score based on the summed expression of a collection of ISGs derived from previously published studies (Table 1). dsDNA-treated BMDMs had the highest ISG Scores, which were almost completely abrogated by IFNAR Ab inhibition (Figure 3C). Interestingly, we did not find that dsDNA induced ISGs preferentially expressed by one or more of the BMDM subtypes. Instead, they were uniformly elevated across all proliferative and non-proliferative subsets compared to control (Figure 3D). Although we included IFNAR KO BMDMs, they were found to have significant ISG expression in scattered cells with or without DNA stimulation, which limited their utility for identifying direct DNA-stimulated cells (Supplementary Figure S2). Taken together, these data demonstrated that dsDNA stimulation induces ISG expression in both proliferating and non-proliferating BMDMs, and that secondary amplification of the response *via* type I IFN secretion plays a dominant role in the ISG response since it is markedly abrogated by simultaneous blockade with a neutralizing IFNAR Ab.

### Direct IFNAR-independent responses to immune stimulatory DNA

Since IFNAR Ab treatment markedly inhibited secondary amplification of DNA-induced IFN responses, we reasoned that any residual ISG expression must result from IFNAR-independent responses to DNA. To identify direct DNA-sensing cells, we bioinformatically combined BMDMs from control and IFNAR Ab treated cells and reclustered (Figure 4A, Supplementary Figure S3). This revealed a small group of BMDMs with high ISG scores despite inhibition of IFNAR-dependent amplification (Figure 4B). We interpreted these ISG-expressing BMDMs to be direct responders to dsDNA stimulation. Unbiased clustering of IFNAR Ab-treated Condition 3 cells revealed 8 distinct clusters including one expressing ISGs embedded within the broader *Fabp4*+MHCII-cluster, as illustrated in a feature plot (Figure 4C) and heatmap of top marker genes expressed by each cluster (Figure 4C). The top marker genes for directly DNA-stimulated BMDMs were *Ccl5*, *Irf7*, *Ifit1*, *Isg15*, *Rsad2*, *Oasl2*, *Bst2*, and *Ifi204* (Figure 4D). To confirm the result independent of clustering, we plotted the ISG Score for each DNA- and IFNAR-Ab-treated BMDM of Condition 3 and identified the same small population of *Fabp4*+MHCII-ISG+ cells (Figure 4E). Together, these results suggest that direct DNA-sensing BMDMs are preferentially *Fabp4*+MHCII- macrophages.

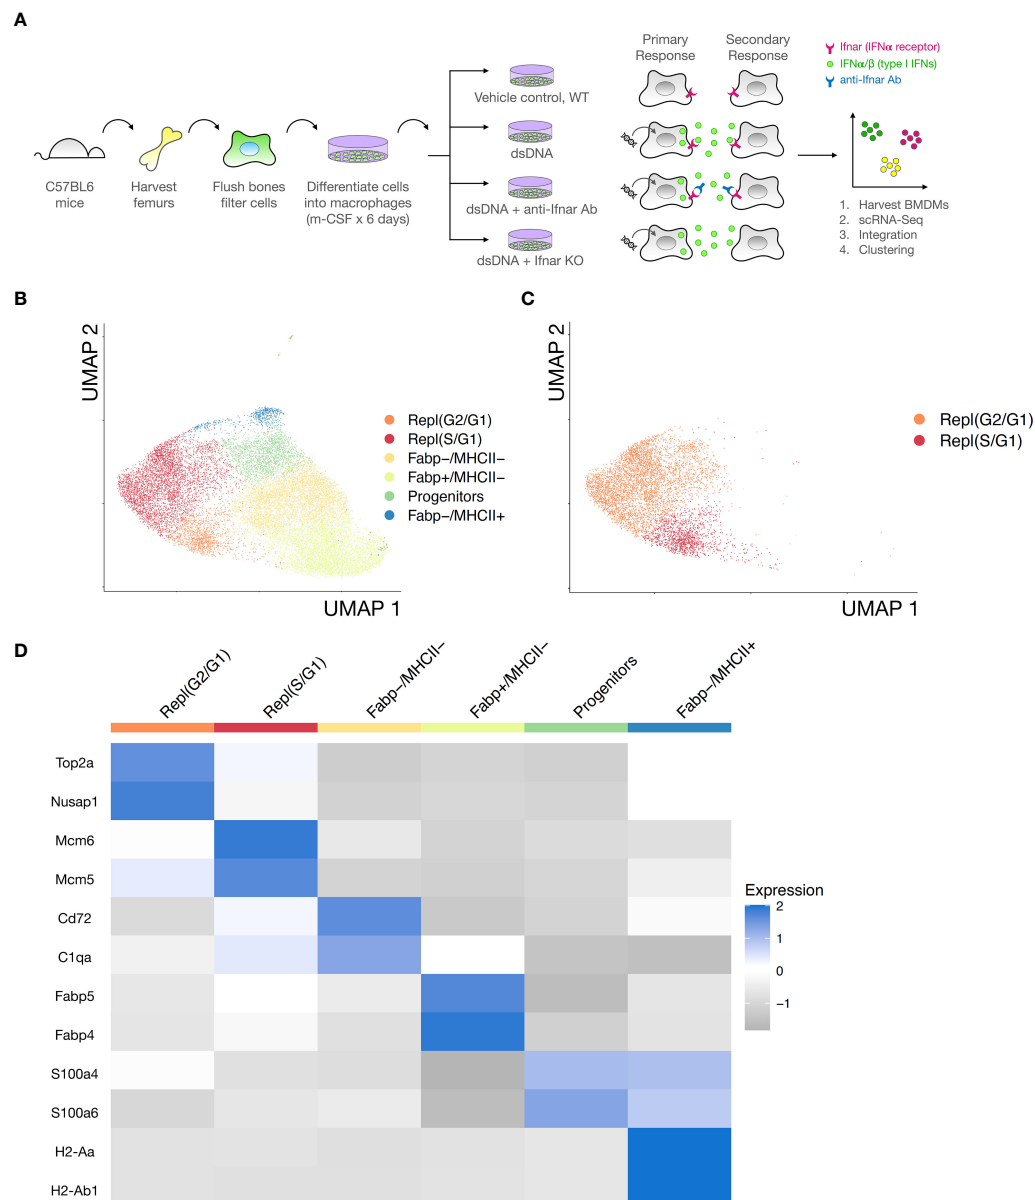

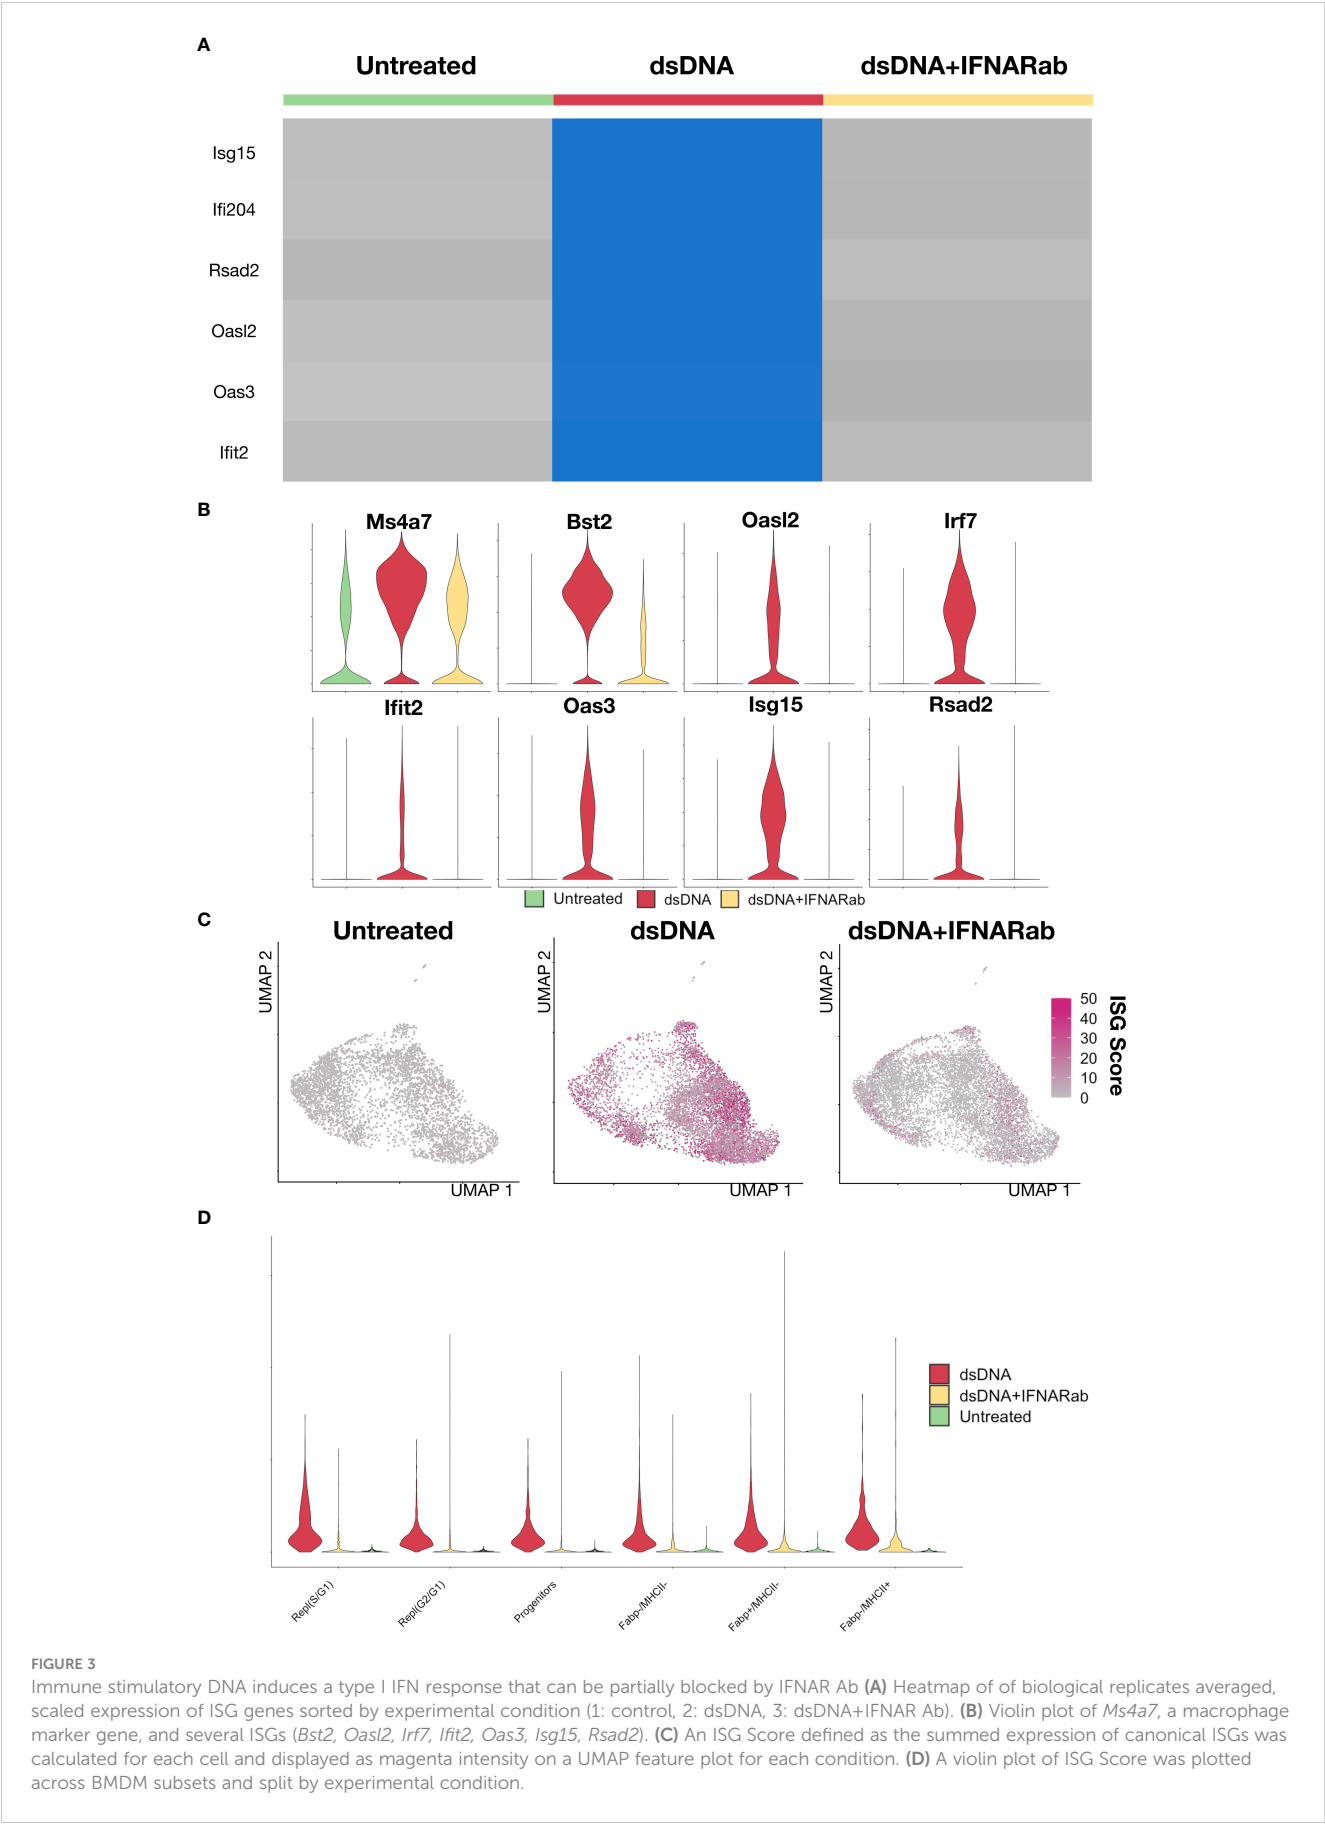

FIGURE 2

Integrated single cell transcriptomes reveal cell-cycling and non-cycling BMDM subsets. **(A)** Bone marrow derived macrophages (BMDMs) were isolated from adult male C57BL/6 and IFNAR KO mice and differentiated in culture with m-CSF. BMDM were stimulated for 24 hours with one of the following i) vehicle control, ii) dsDNA complexed to LTX transfection reagent, or iii) dsDNA + IFNAR Ab, or iv) dsDNA-transfected IFNAR KO. Cells were then collected, stained with DAPI, FACS sorted to isolate live single cells, and processed for single cell RNA-Seq barcoding and sequencing using established 10X Genomics protocols. Condition 1 was designed to define the transcriptional heterogeneity and BMDM subsets in the unstimulated state. Condition 2 was designed to define the transcriptional response of BMDM subsets to dsDNA, an inducer of primary and secondary type I IFN responses. Condition 3 was designed to block IFN-dependent secondary responses and isolate the direct effects of dsDNA. **(B)** Data from all three experimental conditions, excluding the IFNAR KO due to strain differences, was integrated and clustered. Unsupervised clustering of integrated data ( $n = 19,343$  cells) revealed at least 6 distinct BMDM subsets. Data is dimensionally reduced using UMAP and displayed on a 2D plot to communicate relative similarities in transcriptional profiles between BMDM subsets. **(C)** Identification of replicating BMDMs from clusters based on cell cycle phase (color-coded legend) using cell cycle sorting. **(D)** Heatmap of biological replicates averaged, scaled expression defining differentially expressed genes for each BMDM subset. Cell cycling subsets (clusters 1-2, red & orange) and non-cycling subsets (clusters 3-6, yellow, green, and blue) are annotated.

## Gene expression signatures of direct Ifnar-independent DNA-induced macrophages

Bulk measurement techniques do not allow separation of direct DNA-sensing cells from the more abundant secondary IFNAR-dependent cells. This limits separation of cell-specific

roles in initiation and amplification of IFN responses *in vivo*. To identify genes that may discriminate direct and indirect cells, we identified the most highly differentially expressed genes between direct DNA responsive cells and secondary IFNAR-dependent cells. First, we isolated Fabp4+MHCII- macrophages, which contained the majority of directly responding cells. We

reclustered them, which revealed an ISG+ and ISG- population. Next, we combined the direct macrophages from condition 3 (dsDNA + IFNAR Ab) with the Fabp4+MHCII- macrophages from condition 2 (dsDNA Alone) and reclustered (Figure 5A, Supplementary Figure S4). We displayed expression of 45 ISGs as a heatmap. This revealed *Ccl5* to be the most differentially expressed between the direct cells from condition 3 and combined indirect and direct cells from condition 2 (Figure 5B). Feature plots show the cells colored by ISG Score compared to the more stringent by Direct DNA-sensing Score (Figure 5C). We selected the top 4 genes and created a Direct Score (*Ccl5*, *Cdk8*, *Cxcl2*, and *Cd74*) (Figure 5D). Based on these results, we propose that the top gene, *Ccl5*, may represent a useful marker gene for identifying direct DNA sensing cells.

## Discussion

BMDMs are a widely used experimental tool used across diverse innate immune studies, but they are typically analyzed using bulk measurement techniques that obscure population heterogeneity (19). In this study we applied single cell RNA-seq to reveal functional heterogeneity within cultured BMDMs. Using single cell RNA-Seq, we show that immune stimulatory DNA induces ISG expression across all proliferating and non-proliferating BMDM subsets; however, in the context of anti-IFNAR Ab blockade, DNA was only able to induce a small non-proliferative Fabp4+MHCII- population of macrophages.

These cells, which do not benefit from secondary signaling *via* IFNAR, were interpreted as directly-stimulated cells. Using this population, we identified *Ccl5*, also known as RANTES, as a transcriptional biomarker that discriminates directly from indirectly DNA-stimulated cells. *Ccl5* is a secreted proinflammatory chemokine capable of recruiting diverse immune cell types (17, 22, 23). However, independent of its functional role, we propose that *Ccl5* may be useful transcriptional biomarker for identifying direct DNA-stimulated cells *in vivo* using single cell RNA-Seq.

BMDMs are a ubiquitous part of an innate immunologist's experimental toolkit, owing to the ease of harvesting and differentiating them in cell culture. However, an often-overlooked assumption of this model is that all cells in the culture are assumed to represent the response of a prototypical macrophage (19). Single cell transcriptomics has emerged as a powerful tool for revealing cellular heterogeneity *in vitro* and *in vivo* within population previously assumed to be homogeneous. *In vivo*, this technology is informing the growing appreciation of macrophage diversity within the bone marrow and at sites of tissue injury (3, 24). Here, we apply single cell transcriptomics to the commonly used BMDM model experimental system. At baseline, transcriptional profiling of BMDMs divides cultured macrophages into proliferative and non-proliferative subsets, each with additional substructure. Our data suggests that when BMDMs are stimulated with immune stimulatory DNA, it is the non-proliferating BMDMs that are directly stimulated, which then broadly recruit both proliferative and non-proliferative cells *via* secreted type I IFN cytokines signaling *via* the IFNAR cell surface receptor to express secondary ISGs (25, 26).

Limitations of our study include the small biological sample size; however, this is somewhat mitigated by the large number of total single cell transcriptomes analyzed (20,000+). An alternative explanation for the directly stimulated cells that we observed is that there is a population of cells that are resistant to IFNAR Ab blockade. While this cannot be disproven, it seems unlikely since the resistant population would have to also have to uniquely respond to DNA stimulation with overexpression of *Ccl5* compared to other ISGs when compared to all IFN-induced cells.

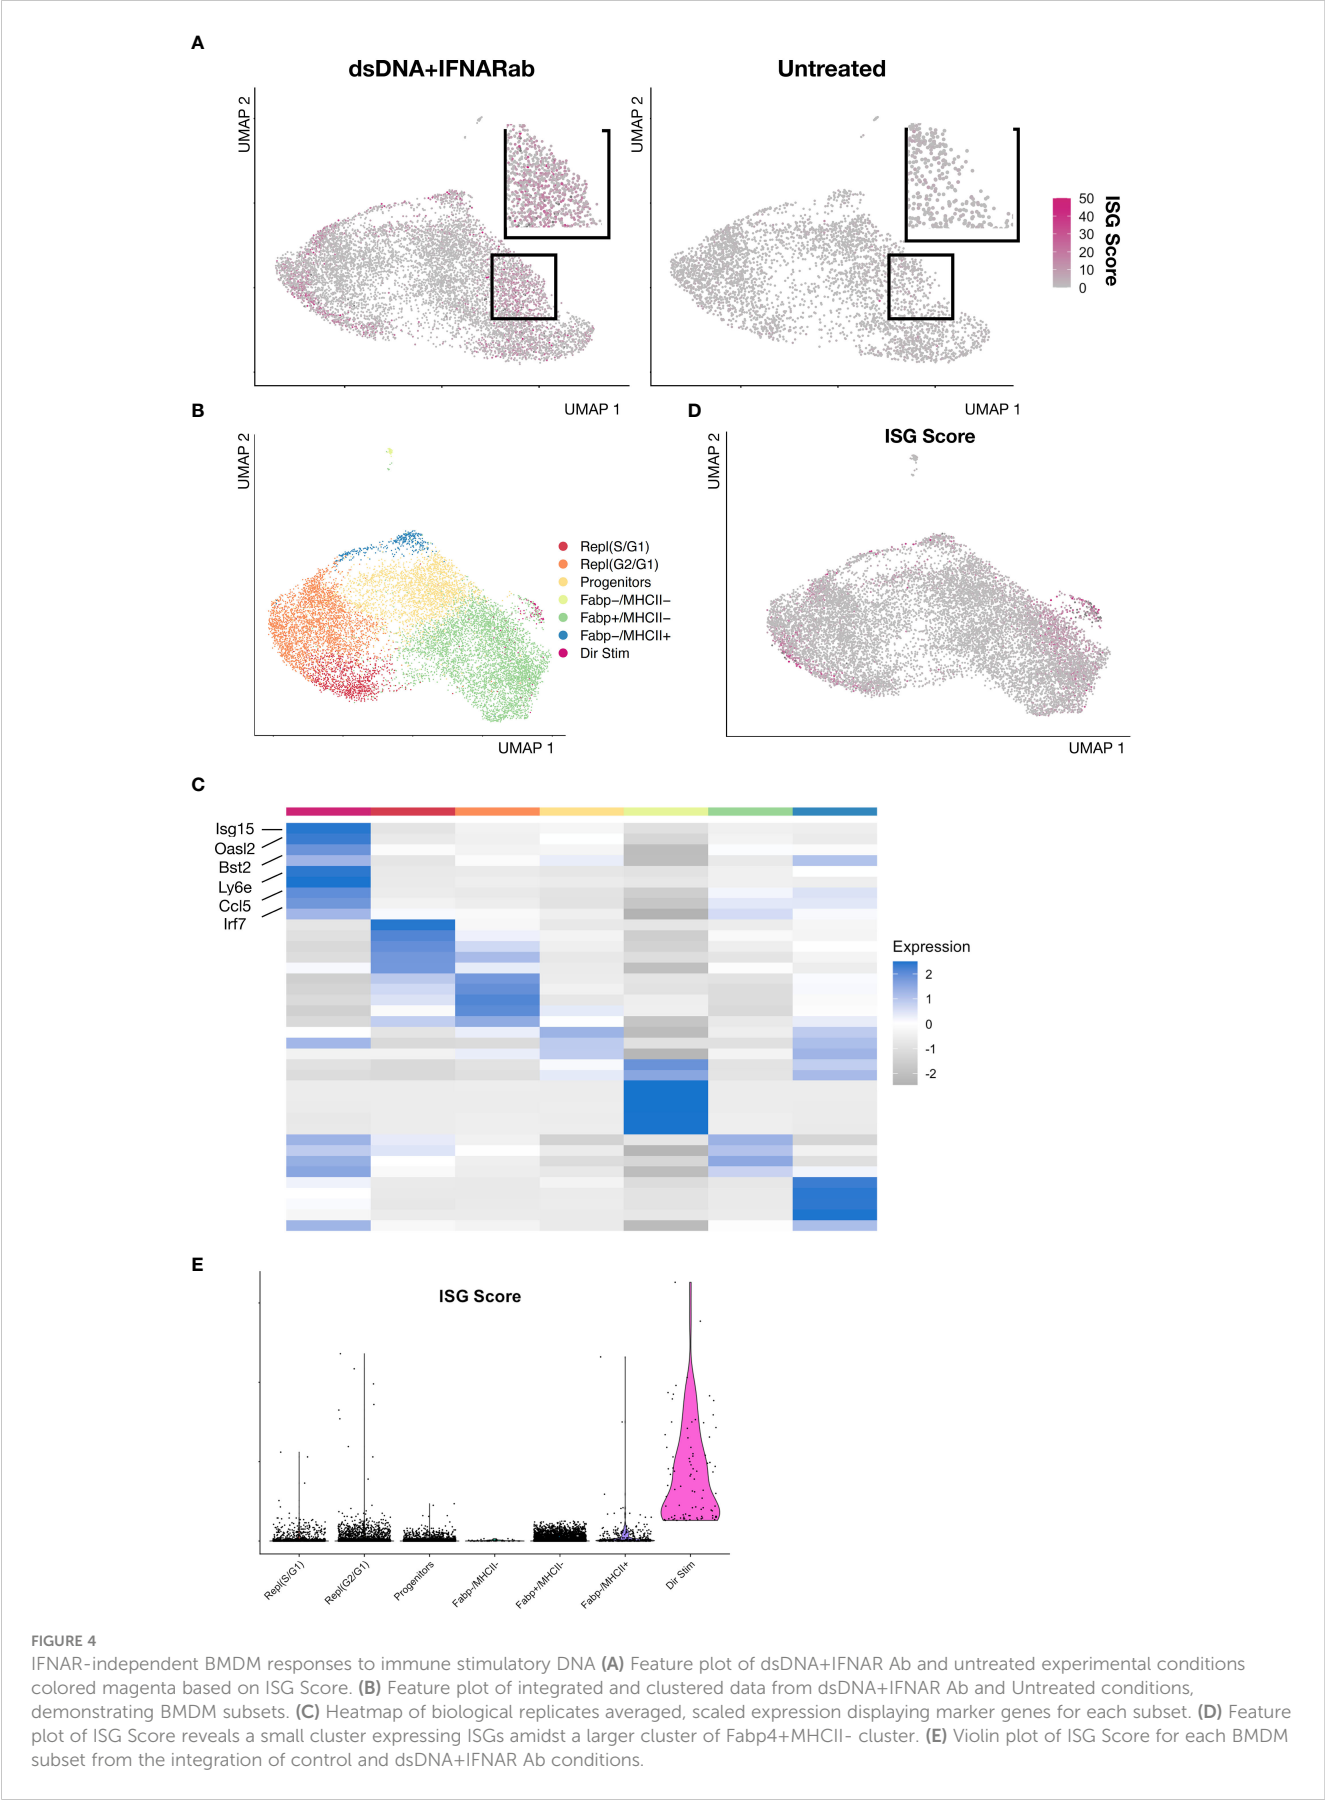

## Conclusion

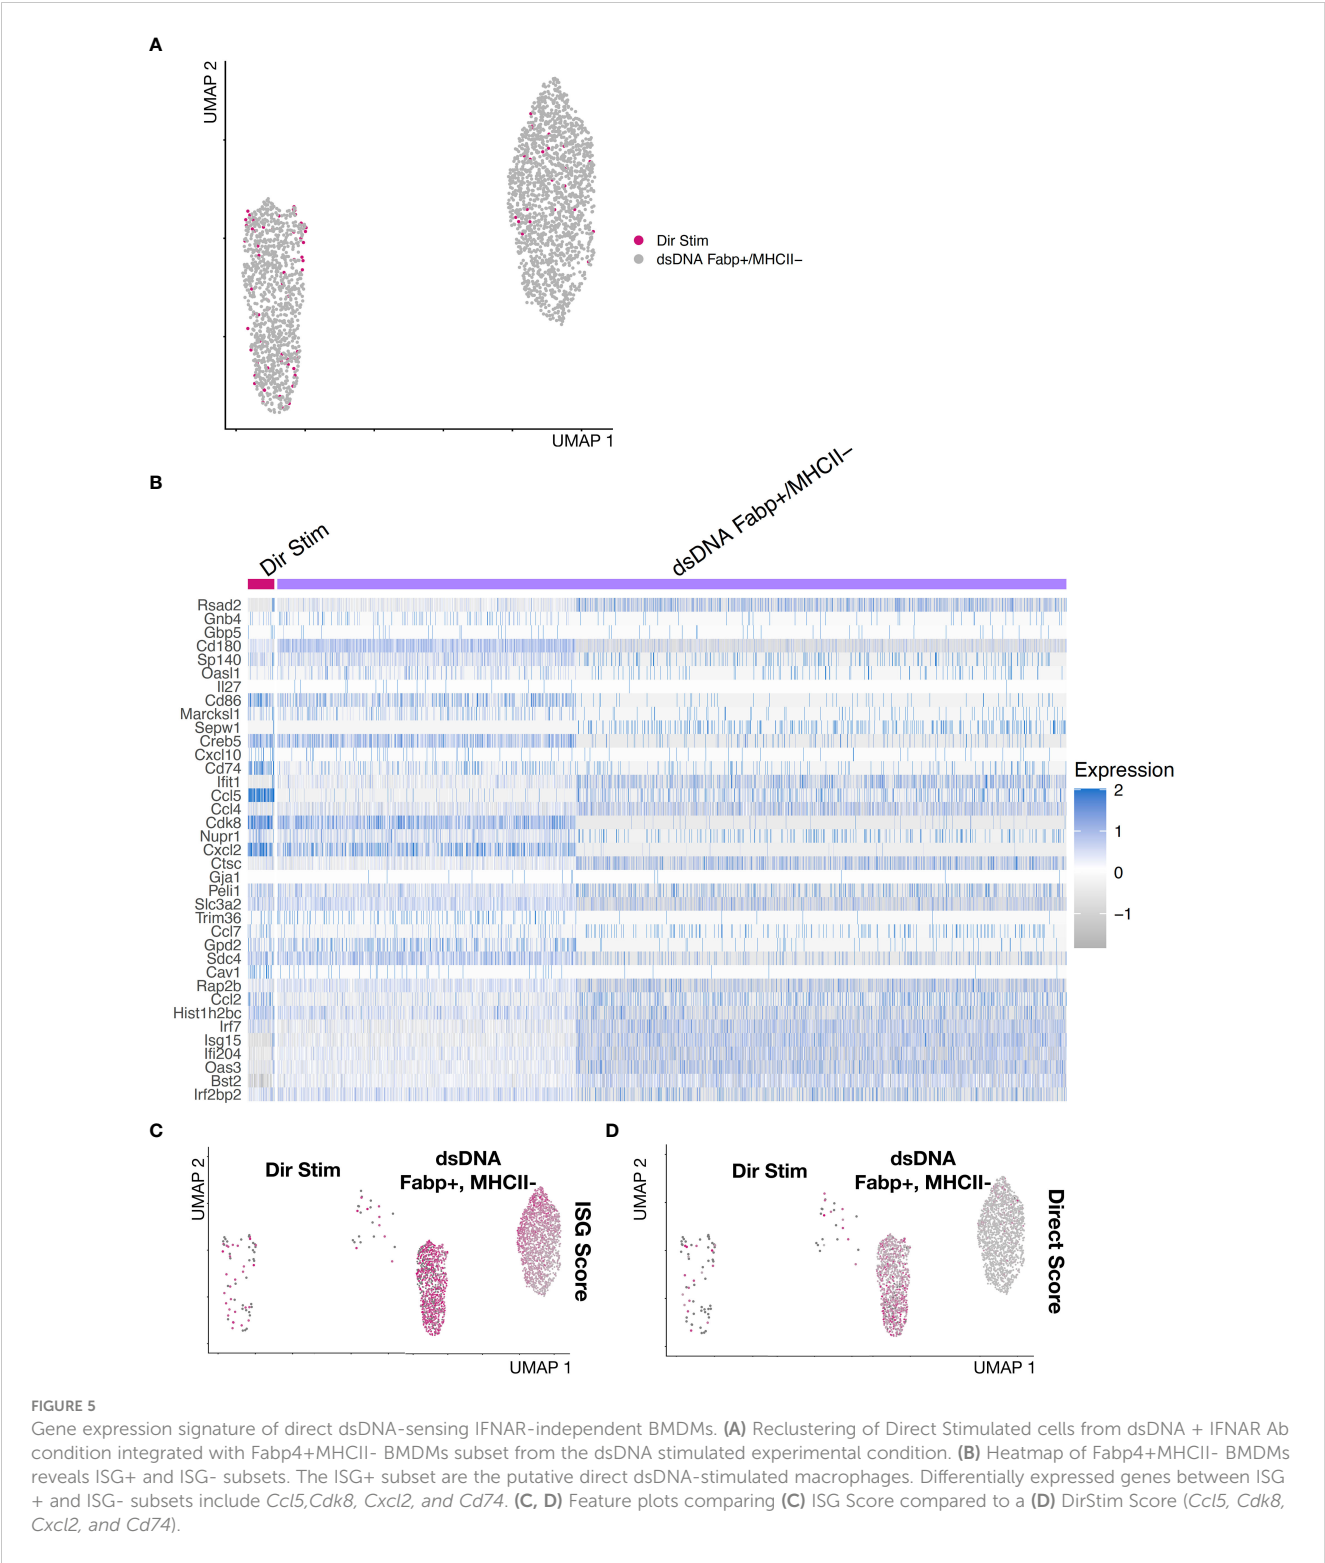

In summary, we have used single cell RNA-Seq to define the heterogeneity of macrophages in culture, both at steady state and in response to immune stimulatory DNA, with and without blockade of secondary IFNAR-dependent amplification, revealing *Ccl5* as an IFNAR-independent marker of direct DNA-sensing cells.

## Methods

### Animals and tissue processing

Mouse experiments were approved and conducted under the oversight of University of California San Diego Institutional

**FIGURE 5** Gene expression signature of direct dsDNA-sensing IFNAR-independent BMDMs. **(A)** Reclustering of Direct Stimulated cells from dsDNA + IFNAR Ab condition integrated with Fabp4+MHCII- BMDMs subset from the dsDNA stimulated experimental condition. **(B)** Heatmap of Fabp4+MHCII- BMDMs reveals ISG+ and ISG- subsets. Animal Care and Use Committee (IACUC #17144) using Adult C57BL/6J (3 WT mice, stock 000664, and 2 IFNAR -/- mice, stock 028288). All experiments were performed with 10 to 14-week-old animals and were carried out using age and gender matched groups without randomization. All mice were maintained in a pathogen-free environment of UC San Diego.

### Cell culture

Bone marrow derived macrophages (BMDMs) were isolated by flushing femurs of adult mice and culturing the resulting cells in 10% FBS 1% Pen/Strep-containing DMEM supplemented with 10ng/mL recombinant m-CSF (Peprotech) for 7 days. 5μg of immunogenic HT

DNA (*In vivogen*) was complexed with a Lipofectamine transfection agent (ThermoFisher) at a ratio of 1:1.5 in serum free-media and added to 1 million BMDMs in a 6-well multi-well plate with serum- and mCSF-containing media for each experiment. Two independent experiments were performed, yielding  $n = 5$  for each condition. For inhibition of secondary signaling *via* the IFNAR receptor, cells were treated with 20  $\mu\text{g}/\text{ml}$  of MARI-5A3 IFNAR neutralizing antibody or isotype control (BioXCell).

## Flow cytometry

Isolated cells were stained at 4°C in FACS buffer (PBS supplemented with 2.5% bovine serum albumin). Cell suspensions were labeled with DAPI just prior to flow cytometric analysis to allow exclusion of dead cells. Doublets and dead cells were excluded by forward scatter and Dapi. Data was acquired by Sony sorter MA900 at UCSD and analyzed with FlowJo software.

## Single cell RNA-seq

Single cell RNA-Seq was performed by microfluidic droplet-based encapsulation, barcoding, and library preparation (10X Genomics) as previously described (27). Paired end sequencing was performed on an Illumina NovaSeq instrument. Low level analysis, including demultiplexing, mapping to a reference transcriptome (Ensembl Release 85 - GRCm38.p5), and eliminating redundant UMIs, was performed with the CellRanger pipeline.

## Single-cell RNA-seq data quality control, normalization and integration

To account for variations in sequencing depth, total transcript count for each cell was scaled to 10,000 molecules, and raw counts for each gene were normalized to the total transcript count associated with that cell and then natural log transformed. Cells with between 200 and 2,000 uniquely expressed genes and < 1% mitochondrial counts were retained for further analysis. Highly variable genes across individual datasets were identified with the *FindVariableFeatures* method from the Seurat R package (version 3.0) by selecting 3,000 genes with the highest feature variance after variance-stabilizing transformation. Integration of multiple single-cell RNA-seq datasets was performed in Seurat to enable harmonized clustering and downstream comparative analyses across conditions (28–30). Anchoring cell pairs between datasets were identified by Canonical Correlation Analysis (CCA) and the mutual nearest neighbors (MNN) method using the Seurat *FindIntegrationAnchors* function.

## Dimensional reduction, unsupervised clustering, sub-clustering

After scaling and centering expression values for each variable gene, linear dimensionality reduction was performed on integrated

data using principal component analysis (PCA). Clustering was performed using the shared nearest neighbor (SNN) clustering algorithm with the Louvain method for modularity optimization, as implemented in the Seurat *FindNeighbors* and *FindClusters* functions. To visualize data in two-dimensional space, Uniform Manifold Approximation and Projection (UMAP) dimensional reduction was performed. Differentially expressed genes (DEGs) between clusters were determined using a Wilcoxon Rank Sum test. Where specified, subsets of cells were isolated and reclustered to identify new DEGs.

## Quantification of ISG score and direct score

ISG Scores were measured as the sum of the raw reads for the ISGs: Ifi204, Isg15, Irf7, Ifit1, Rsad2, Oasl2, Oas3, Gpb5, Bst2, Ifit2, Ifit3, Oas2, Isg20, Cxcl10, Oasl1, Gpb2, Ccl5, Ccl3. Direct Scores were measured as the sum of the raw reads for: Ccl5, Cdk8, Cxcl2, and Cd74. ISG and Direct Scores were normalized to reads per cell and scaled by  $10^4$ .

## Statistics

Statistical analysis was performed using GraphPad Prism software. All data are represented as mean values  $\pm$  standard error of mean (S.E.M.) unless indicated otherwise. A statistical method was not used to predetermine sample size. All analyses were unpaired. *P* values are indicated by *P* values less than 0.05 were considered significant and are indicated by asterisks as follows: \* $p < 0.05$ , \*\* $p < 0.01$ , \*\*\* $p < 0.001$ , \*\*\*\* $p < 0.0001$ .

## Data availability statement

The single cell RNA-Seq datasets presented in this study have been deposited to the Gene Expression Omnibus under accession no. GSE229311 (GEO). The code used to process this data is publicly available at Zenodo (<https://zenodo.org/record/7874451>).

## Ethics statement

The animal study was reviewed and approved by University of California San Diego Institutional Animal Care and Use Committee (IACUC #17144).

## Author contributions

EM, JY, VN, and KK designed the study, performed analysis, and wrote the initial manuscript. VN conducted experiments. EM, JY, and DC performed analysis. KK directed the project. All authors contributed to the article and approved the submitted version.

## Funding

The work was funded by the following National Institutes of Health (NIH) grants, NIH T32HL007444 (VN), NIH T32HL105373 (DC), NIH R00HL129168 (KK), and NIH DP2AR075321 (KK).

## Acknowledgments

We thank Richard Ng, Avinash Toomu, and Nika Taghdiri for technical assistance. This publication includes data generated at the UC San Diego IGM Genomics Center utilizing an Illumina NovaSeq 6000 that was purchased with funding from a National Institutes of Health SIG grant (#S10 OD026929).

### SUPPLEMENTARY FIGURE 1

Integrated single cell transcriptomes reveal cell-cycling and non-cycling BMDM subsets. (A) Data from all experimental conditions was integrated and clustered. Unsupervised clustering of integrated data (n= 24,377 cells) revealed at least 6 distinct BMDM subsets. Data is dimensionally reduced using UMAP and displayed on a 2D plot to communicate relative similarities in transcriptional profiles between BMDM subsets. (B) Identification of replicating BMDMs from clusters based on cell cycle phase (color-coded legend) using cell cycle sorting. (C) Heatmap of biological replicates averaged, scaled expression of defining 1065 differentially expressed genes for each BMDM subset. Cell cycling subsets (clusters 1-2, red & orange) and non-cycling subsets (clusters 3-6, yellow, green, and blue) are annotated.

### SUPPLEMENTARY FIGURE 2

Immune stimulatory DNA induces a type I IFN response that can be partially blocked by IFNAR Ab. (A) Heatmap of biological replicates averaged, scaled expression of ISG genes sorted by experimental condition (1: control, 2: IFNAR KO control, 3: dsDNA, 4: dsDNA+IFNAR Ab, 5: dsDNA+IFNAR KO). (B) Violin plot of *Ms4a7*, a macrophage marker gene, and several ISGs (*Bst2*, *Oas1*, *Irf7*, *Irf2*, *Oas3*, *Isg15*, *Rsd2*). (C) An ISG Score defined as the summed expression of canonical ISGs was calculated for each cell and displayed as magenta intensity on a UMAP feature plot for each condition. (D) A violin plot of ISG Score was plotted across BMDM subsets and split by experimental condition.

### SUPPLEMENTARY FIGURE 3

IFNAR-independent BMDM responses to immune stimulatory DNA. (A) Feature plot of dsDNA+IFNAR Ab, dsDNA+IFNAR KO, and untreated experimental conditions colored magenta based on ISG Score. (B) Feature plot of integrated and clustered data from dsDNA+IFNAR Ab, dsDNA+IFNAR KO, and Untreated conditions, demonstrating BMDM subsets. (C) Heatmap of biological replicates averaged, scaled expression displaying marker genes for each subset. (D) Feature plot of ISG Score reveals a small cluster expressing ISGs amidst a larger cluster of *Fabp4*+*MHCII*- cluster. (E) Violin plot of ISG Score for each BMDM subset from the integration of control and dsDNA +IFNAR Ab conditions.

### SUPPLEMENTARY FIGURE 4

Gene expression signature of direct dsDNA-sensing IFNAR-independent BMDMs. (A) Reclustering of Direct Stimulated cells from dsDNA + IFNAR Ab and dsDNA+IFNAR KO conditions integrated with *Fabp4*+*MHCII*- BMDMs subset from the dsDNA stimulated experimental condition. (B) Heatmap of *Fabp4*+*MHCII*- BMDMs reveals ISG+ and ISG- subsets. The ISG+ subset are the putative direct dsDNA-stimulated macrophages. Differentially expressed genes between ISG+ and ISG- subsets include *Ccl5*, *Cdk8*, *Cxcl2*, and *Cd74*. (C-D) Feature plots comparing (C) ISG Score compared to a (D) DirStim Score (*Ccl5*, *Cdk8*, *Cxcl2*, and *Cd74*).

**Introduction:** Host gene and protein expression impact susceptibility to clinical malaria, but the balance of immune cell populations, cytokines and genes that contributes to protection, remains incompletely understood. Little is known about the determinants of host susceptibility to clinical malaria at a time when acquired immunity is developing.

**Methods:** We analyzed peripheral blood mononuclear cells (PBMCs) collected from children who differed in susceptibility to clinical malaria, all from a small town in Mali. PBMCs were collected from children aged 4–6 years at the start, peak and end of the malaria season. We characterized the immune cell composition and cytokine secretion for a subset of 20 children per timepoint (10 children with no symptomatic malaria age-matched to 10 children with >2 symptomatic malarial illnesses), and gene expression patterns for six children (three per cohort) per timepoint.

**Results:** We observed differences between the two groups of children in the expression of genes related to cell death and inflammation; in particular, inflammatory genes such as CXCL10 and STAT1 and apoptotic genes such as XAF1 were upregulated in susceptible children before the transmission season began. We also noted higher frequency of HLA-DR+ CD4 T cells in protected children during the peak of the malaria season and comparable levels cytokine secretion after stimulation with malaria schizonts across all three time points.

**Conclusion:** This study highlights the importance of baseline immune signatures in determining disease outcome. Our data suggests that differences in apoptotic and inflammatory gene expression patterns can serve as predictive markers of susceptibility to clinical malaria.

## Introduction

Malaria remains a major global health concern that impacts over 200 million people annually, causing an estimated 619,000 deaths in 2021 (1). Despite its global distribution throughout the tropical and subtropical regions, 95% of malaria cases occur in sub-Saharan Africa, and are caused primarily by *Plasmodium falciparum* (1). Individuals in malaria-endemic regions with high transmission are repeatedly exposed to diverse *P. falciparum* strains and their associated antigens; these successive exposures can lead to acquired immunity to clinical malaria (2). However, children with similar levels of malaria exposure can vary in susceptibility to clinical disease. Several host factors, including those related to red blood cell disorders (HbS, HbC, G6PD and alpha-thalassemia), are known to be associated with protection, while some HLA alleles are associated with increased susceptibility to malaria infection (3, 4). Nevertheless, much remains to be understood, particularly regarding differences in the host response to infection (5).

Previous studies have implicated the activation of the type 1 interferon pathway in mitigating severe disease to mild malaria and interferon-gamma (IFN $\gamma$ ) secretion with protection from clinical disease (6). However, other studies suggest a role for IFN $\gamma$  in exacerbating severe malaria episodes (cerebral malaria), implying that a delicate balance of inflammatory cytokines is critical to regulate malarial disease and pathogenesis (7). T cell-mediated immune responses play an important role in controlling pro- and anti-inflammatory immune responses during blood stage malaria (8). Type 1 helper CD4 T cells (Th1) produce inflammatory cytokines such as IFN $\gamma$  and TNF $\alpha$  that shape the early adaptive immune response to *Plasmodium* infection. These inflammatory responses are controlled by regulatory T cells (Tregs) that produce cytokines such as IL-10 and TGF $\beta$  (9). Later in infection, Type 2 helper CD4 T cells (Th2) dominate and aid in antibody production, which is characteristic of a protective response to blood stage *Plasmodium* infection (10).

Transcriptomic analysis from whole blood cells has shown that naïve individuals >13 years old have a higher pro-inflammatory cytokine response when compared to their malaria-experienced counterparts upon infection with *P. falciparum* (11). This may indicate a dampened immune response in individuals with pre-existing immunity to malaria, which could impact the clinical presentation of the disease. Some studies suggest exhausted B and

T cells play a role in the lack of robust immune responses in individuals with recurrent exposure to *P. falciparum* (12). However, it remains to be determined how molecular pathways correlate with malaria exposure history in children with distinct levels of susceptibility to clinical malaria, and which immunoprofiles characterize a protective response. Gene expression studies are increasingly used to decipher molecular mechanisms and pathways associated with malaria infection using either peripheral blood mononuclear cells (PBMCs) or whole blood (11, 13), and to analyze gene expression patterns in immune cells during malaria infection only (11, 14). Here, we compare the longitudinal transcriptional profiles of two cohorts of location and age-matched children, ages 4 to 6 years old, who differ in the degree of malaria susceptibility, to better understand the protective immune response to malaria at a time when acquired immunity is developing. We hypothesize that in an area of high malaria transmission, children who do not manifest clinical disease throughout an entire transmission season can control infection better than those who experience two or more symptomatic malaria episodes during the same period (either by preventing erythrocytic infection or by controlling symptoms), and that this difference is reflected in their PBMC transcriptomic profiles. To address this hypothesis, we compared PBMC gene expression profiles derived from a subset of children categorized as “susceptible” versus “non-susceptible/protected” to malaria, and who were part of the control arm of a malaria vaccine trial in Mali (15). An improved understanding of the host immune response to malaria, and in particular the identification of immune cell subpopulations that may play a role in a protective immune response, may identify those at increased risk and inform preventative treatment.

## Methods and sample collection

### Ethics

Sample processing was conducted with review and oversight by the University of Maryland, Baltimore’s Human Research Protection Office. The primary study was reviewed and approved by the Institutional Review Boards of the University of Maryland, Baltimore and the University of Bamako, Mali. Village permission to conduct research was obtained from village chiefs, government

officials, and traditional healers prior to study initiation. Individual written informed consent was obtained from the parent or legal guardian of each child prior to screening and enrollment in accordance with the Declaration of Helsinki. Child assent was also obtained prior to study conduct.

## Study design

After obtaining informed parental consent, PBMCs from children who were part of a randomized, controlled, double-blind Apical Membrane Antigen 1 (AMA1) malaria vaccine trial in Bandiagara, Mali, West Africa, were cryopreserved on site using standardized procedures and transported to the University of Maryland, Baltimore (UMB), utilizing a tightly controlled cold chain. Registration on ClinicalTrials.gov (NCT00460525) and full study details have been previously described (15). Bandiagara, Mali, is a Sahelian town of approximately 14,000 inhabitants with highly prevalent and seasonal malaria transmission (June to December) (16, 17). There is no significant variability in the socio-economic state in this remote community. The prevalence of HIV is extremely low, and previous screening of children aged 3 months to 14 years revealed no concomitant infections with filaria. While *S. haematobium* is endemic, prevalence is typically low for children aged 2–6 years. At the time of the study conduct, children under 6 years of age routinely acquired 1–4 symptomatic malaria infections per season. All children were provided government-issued, insecticide-treated bed nets with 61% of control participants reporting use (15). Participants were continuously monitored through passive case detection and the rate of loss to follow-up was less than 7%. The Bandiagara research center served as the primary source of western medical care for most children in the village, and few had access to pharmaceuticals for intermittent malarial therapy. A subset of children ( $n = 25$ ) ages 4–6 was selected from the control arm (three doses of human diploid-cell rabies vaccine (RabAvert, Chiron Vaccines)) based on age, number of clinical malaria episodes, and availability of sample across all three timepoints (15). We examined PBMCs from this cohort (Supplementary Table 1). The original study followed children during a single malaria transmission season (6 months) and PBMCs were collected at day 0 (beginning of transmission season), day 90 (peak transmission season), and day 150 (end of transmission season) (Supplementary Figure 1A). For this analysis, children with at least two clinical malaria episodes throughout the transmission season were classified as “susceptible” and were age-matched to children with no clinical malaria episodes throughout the same transmission season; the latter were classified as “protected” (Supplementary Figure 1B). Malaria episodes were acquired by susceptible participants between day 8 and 146. The timing of illness varied among participants, with the majority experiencing their first episode before the day 90 timepoint, except for one participant (Supplementary Figure 1C). Clinical malaria was defined as a symptomatic infection consistent with malaria (e.g., fever, headache, malaise) and evidence of parasitemia in the absence of an alternative clinical diagnosis. None of the

children met the definition of severe malaria. Only children with PBMC available at all three time points were eligible for analysis. Serum samples were collected for each child at the same timepoints and kept at  $-80^{\circ}\text{C}$ .

## Peripheral blood mononuclear cells stimulation

Cryopreserved PBMCs were thawed with fetal bovine serum (FBS) enriched media (RPMI, Gibco, Grand Island, New York) and incubated at  $37^{\circ}\text{C}/5\% \text{CO}_2$  overnight. After incubation, PBMCs were washed and partitioned into three  $1 \times 10^6$  cell aliquots. One aliquot was stimulated with *P. falciparum* schizonts (Pfsz; derived from a Malawian source and cultured *in vitro* at UMB) at a 3:1 ratio (3 schizonts/cell) and incubated at  $37^{\circ}\text{C}/5\% \text{CO}_2$  for 4 hours. The other two aliquots served as negative (media) and positive (stimulation with 10 mg/ml *Staphylococcus* enterotoxin B (SEB); Sigma, St. Louis, MO) controls and incubated at  $37^{\circ}\text{C}/5\% \text{CO}_2$  for 2 hours. Golgi blockade (BD Pharmingen) was added at 0.5 mL/tube and incubated overnight (16 hours) at  $37^{\circ}\text{C}/5\% \text{CO}_2$ . As the addition of Golgi blockade compromised RNA integrity, a finding not previously noted in the literature, samples from 6 unique randomly selected children that met the age and malaria episode criteria were immediately extracted after stimulation for RNA sequencing without the addition of Golgi blockade.

## Regulatory T cell (Tregs) depletion

PBMCs were thawed as described above. A portion of the cells were partitioned to serve as negative and positive controls. The remaining PBMCs were split into two aliquots that were either mock depleted or depleted of CD25 cells using Dynabeads Pan Mouse IgG or CD25 magnetic beads, respectively (Invitrogen, Carlsbad, California) at a bead to PBMC ratio of 5:1 as described (18). PBMCs were stimulated with media, schizonts and SEB as described above.

## Staining protocol

PBMCs were stained with viability marker, Cisplatin ( $\text{Pb}^{194/195}$ ) (Sigma Aldrich, Indianapolis) at 1.25 mL per 500 mL for a final concentration of 25 mM. After a 1-minute incubation, PBMCs were washed with PBS supplemented with 10% fetal calf serum (FCS) then incubated with one of two optimized (13–21 cell surface markers) panels (Supplementary Tables 2, 3) for 20 minutes. Cells were then fixed using IC fixation buffer (eBioscience) and permeabilized using Caltag Reagent B (Invitrogen, Oregon) along with an intracellular staining cocktail (Supplementary Tables 2, 3), followed by the addition of DNA intercalator Iridium 191 (Ir-191 intercalator, NA). Cells were then washed 2x with cell staining media (0.2 mg/mL sodium azide in low-barium PBS supplemented with 2% FCS) and resuspended in Milli-Q water for assessment by

mass cytometry. Before analysis, a viability dye, Cisplatin (19) and the DNA metalointercalator  $^{191/193}\text{Ir}$  to identify individual cells, was used to complete the panel.

## Generation of RNAseq data

Immediately after PBMC stimulation, Roche Protector RNase inhibitor (3335399001; MilliporeSigma, Burlington, Massachusetts, USA) was added to each sample. RNA was isolated using QIAzol (Qiagen 79306; Hilden, Germany) and the Direct-zol RNA Mini Prep Plus Kit (Zymo Research, Irvine, California, USA) per manufacturer's instructions. RNA quality was assessed using the Agilent Bioanalyzer 2100, and only samples with RNA integrity numbers (RIN) greater than 7 or total RNA concentration greater than 100 ng were selected for RNA sequencing (Supplementary Table 4). PolyA-enriched, strand-specific RNA libraries were constructed and 100bp paired-end reads were sequenced on an Illumina NovaSeq 6000 platform. Reads were assessed for quality, trimmed if PHRED scores fell below 20, and any remaining adapter sequences were removed. These processed paired-end reads were aligned to human reference genome GRCh38 using HISAT2, and counts were generated using the HTseq analysis package (20–22). Reads that successfully mapped to the reference genome were used for downstream analyses. The data are available under bio-project ID (PRJNA603324).

## Differential gene expression analyses

To perform differential gene expression analyses, we used DEseq, EdgeR and Cuffdiff R packages (21, 23). Any genes with counts per million (CPM) values of less than 10 in 86% of the samples (or 45 of all 53 samples analyzed) were excluded from the analyses. Hemoglobin genes (the most expressed genes after those encoding rRNAs) were removed to improve power. This cutoff was selected to account for the low sample size and to ensure that each group had at least two samples present for differential expression analyses. For visualization of differentially expressed genes, normalized read counts generated by DEseq were input for the software gEAR ([https://umgear.org/multigene\\_curator.html](https://umgear.org/multigene_curator.html)) to create volcano plots, implemented using the Dash Bio suite of bioinformatics components (v0.6.1 - <https://github.com/plotly/dash-bio>). Welch's t-test was used to determine significance (24), and was computed using the python package diffxpy (v0.7.4 - <https://github.com/theislabs/diffxpy>).

## Pathway and functional analysis

Pathway enrichment analysis was conducted with the output from deseq2. Differentially expressed genes with a false discovery rate (FDR) <0.05, and a log fold change (LFC) >1, were used. Genes that passed these cutoffs were submitted to DAVID web-based tool (<https://david.ncifcrf.gov/tools.jsp>) (25, 26). Bar plots were created with GraphPad Prism v9. Further functional analyses were

performed using GSEA (27), using normalized expression values from all genes as the input.

## Mass cytometry data processing

FlowJo v.10.8.0 Software (BD Life sciences, Ashland, Oregon, USA) was used to select intact ( $\text{Ir}191^+$ ,  $\text{Ir}193^+$ ), live ( $\text{PT}195^-$ ), singlet,  $\text{CD}14/\text{CD}19^-$  and  $\text{CD}3^+$  cells. Specimens were included in the analysis if (i) the cell viability was >80% after thawing and (ii) cells were shown to be functionally active as determined by the production of IFN $\gamma$  by at least 0.2%  $\text{CD}3^+$  cells after stimulation with SEB. A response was considered specific if (i) the differential in the number of positive events in the stimulant pool compared to the media control was significantly increased by Chi-square analyses; and (ii) the net percentage of cytokine producing cells was >0.1% in stimulant pool as compared to the media control. A response was considered positive if the production of one or more cytokines, meeting the pre-defined criteria, was measured in response to antigen stimulation of PBMCs. A mean of ~200,000 cells per sample were analyzed by the CyTOF<sup>®</sup> Mass Cytometer, with 71%–98% of the cells intact. After gating,  $\text{CD}3^+$  populations were exported via FlowJo to create new FCS files containing only the intact, live,  $\text{CD}3^+$  cell populations. FCS files were further analyzed in R version 2021.09.2 + 384 using flowCore (28) and CATALYST (29, 30) packages. FlowCore package was used to read the FCS files into R and CATALYST package was used to create a single cell experiment and transform the data with arcsinh cofactor 5. FlowSOM (31) and ConsensusClusterPlus (32) packages were used to perform high dimension clustering and generate 20 clusters using the cell surface marker panel (Supplementary Table 2). UMAP was used to perform high dimension reduction to visualize the clusters generated. Clusters were manually annotated based on cell surface marker expression.

## Differential analysis of mass cytometry data

Differential analysis was performed using *diffcyt* (<https://bioconductor.org/packages/3.15/bioc/html/diffcyt.html>), an R package that utilizes *edgeR*, *limma* and *voom* methods as part of the workflow (33). We used the *diffcyt* differential abundance (DA) method to test for differences in cell type abundance between our two study groups and the *diffcyt* differential states (DS) method to test for differences in intracellular marker expression within each identified cell population between protected and susceptible individuals. We used an FDR cutoff of <0.05 to identify differentially expressed cell types and cytokines.

## Differential antibody responses to PfEMP1 microarray

A protein microarray featuring 257 PfEMP1 protein fragments from reference and clinical infections was probed with sera collected before the malaria transmission season (day 0), from 19

children in the same cohort. Samples were randomly selected to include children whose PBMCs were processed *via* RNA sequencing and mass cytometry. Nine serum samples were from protected children while 10 serum samples were from susceptible children. Sera from a pool of North American malaria-naïve adults was used as a negative control while sera from Malian adults from the same study site collected under a different study protocol were used as positive control (34). Slide preparation and serum probing were performed as described elsewhere (35–37). Fluorescence intensity was defined as the raw signal intensity reduced by the mean for the no-DNA negative controls for each serum sample. For each protein fragment, we compared the distribution of fluorescence intensities between sera of susceptible and protected children with a two-tailed Wilcoxon rank-sum test.

## Results

### Quality control of data and experimental samples

PBMCs were processed from 26 Malian children. Cells from 6 individuals were processed through RNA sequencing and cells from 20 distinct children were profiled *via* mass cytometry. Study groups were assigned based on the number of clinical malaria episodes experienced during a single malaria transmission season.

RNAseq data was generated for six children for each of the three timepoints, and for each of the three stimulation conditions (media, schizonts and SEB), for a total of 54 samples. One SEB stimulated sample from day 150 did not pass QC and was not included in the analyses. For each sample, an average of 30 million Illumina reads were generated (Supplementary Table 5).

Mass cytometry data was generated for 20 different children from the same cohort. For each of the three time points, and each of the three conditions, an average of 200,000 cells were processed. Samples were functionally active if SEB stimulated controls had at least a 0.2% increase in IFN $\gamma$  production relative to unstimulated cells.

### Gene expression differences exist between susceptible and protected groups at baseline

To assess if gene expression differences are present between malaria-protected and malaria-susceptible children, we performed a pair-wise comparison of bulk RNA sequence data to identify genes that were either significantly up-regulated or down-regulated at day 0 (start of malaria transmission season) before and after PBMC stimulation with malaria antigen. At baseline, we observed 78 genes significantly differentially expressed based on our analysis parameters (Figure 1A). We observed 74 downregulated and 4 upregulated genes in protected relative to susceptible children. Baseline differences in gene expression at the beginning of the malaria season suggest that differences already exist between children who later develop clinical malaria episodes and those

who do not. Of interest, genes upregulated in susceptible children compared to protected children included CXCL10, STAT1, STAT2, IRF1, XAF1 and GZMB. CXCL10, STAT1 and STAT2, all genes that are downstream of interferon signaling, and IRF1, XAF1 and GZMB, which participate in apoptotic processes. Next, we evaluated gene expression patterns in Pfsz-stimulated PBMCs and observed 11 differentially expressed genes, of which 9 were downregulated and 2 upregulated in protected children relative to susceptible children. We observed some overlap in upregulated genes in susceptible children before and after antigen stimulation (Figure 1B and Supplementary Figure 2A). One gene, DDX11, was upregulated in protected children before and after Pfsz stimulation (Figures 1A, B and Supplementary Figure 2B). DDX11 encodes a helicase and plays a role in DNA repair (38). However, the direct role of this gene in regulating immune responses is not known.

To determine if the expression patterns observed were restricted to individual genes or whether, instead, they reflect broader differences at the pathway level, we searched for enriched biological, functional, and immunological pathways at day 0, with DAVID, using genes upregulated in susceptible children (FDR < 0.05; LFC >1) as input. Relative to protected children, we observed enrichment in “Type I interferon signaling,” “interferon-gamma signaling,” and “apoptotic” pathways in susceptible children (Figures 1C, D). Further analysis using gene set enrichment analysis (GSEA) showed enrichment in IFN $\gamma$  and apoptotic pathways (Supplementary Figure 3).

To determine whether the observed differences in gene and pathway expression were based on different levels of pre-existing immunity to malaria between the susceptible and protected groups, we probed a protein microarray populated with 257 fragments of *P. falciparum* erythrocyte membrane protein-1s (PfEMP1s) with sera from day 0 timepoint. Increased responses to PfEMP1 have been associated with recent malaria exposure (39–41). We compared the PfEMP1 serologic responses between the two groups and observed no differences in antibody responses to 99.2% of the fragments (255/257 PfEMP1 fragments; Supplementary Figure 4B). Additionally, we compared the proportion of individuals within each group with serorecognition of each protein fragment (defined as a fluorescence intensity greater than the mean plus two standard deviations for a serum panel from 10 malaria-naïve North American adults probed on the microarray). We observed that across extracellular PfEMP1 fragments, there was a trend towards greater proportions of protected children with serorecognition of these fragments than susceptible children [68.1% of extracellular PfEMP1 fragments(65/204)]. Interestingly, for 19 of the 20 intracellular PfEMP1 fragments on the microarray, a higher proportion of the susceptible group had serorecognition of the intracellular PfEMP1 fragment than the protected group (Supplementary Figure 4C). Our group previously found that serologic responses to the intracellular region of PfEMP1s is associated with greater malaria exposure (40), suggesting that the susceptible group may have had more malaria exposure than the protected group. In addition, we analyzed previously published ELISA data for Apical Membrane Antigen 1 (AMA1), another

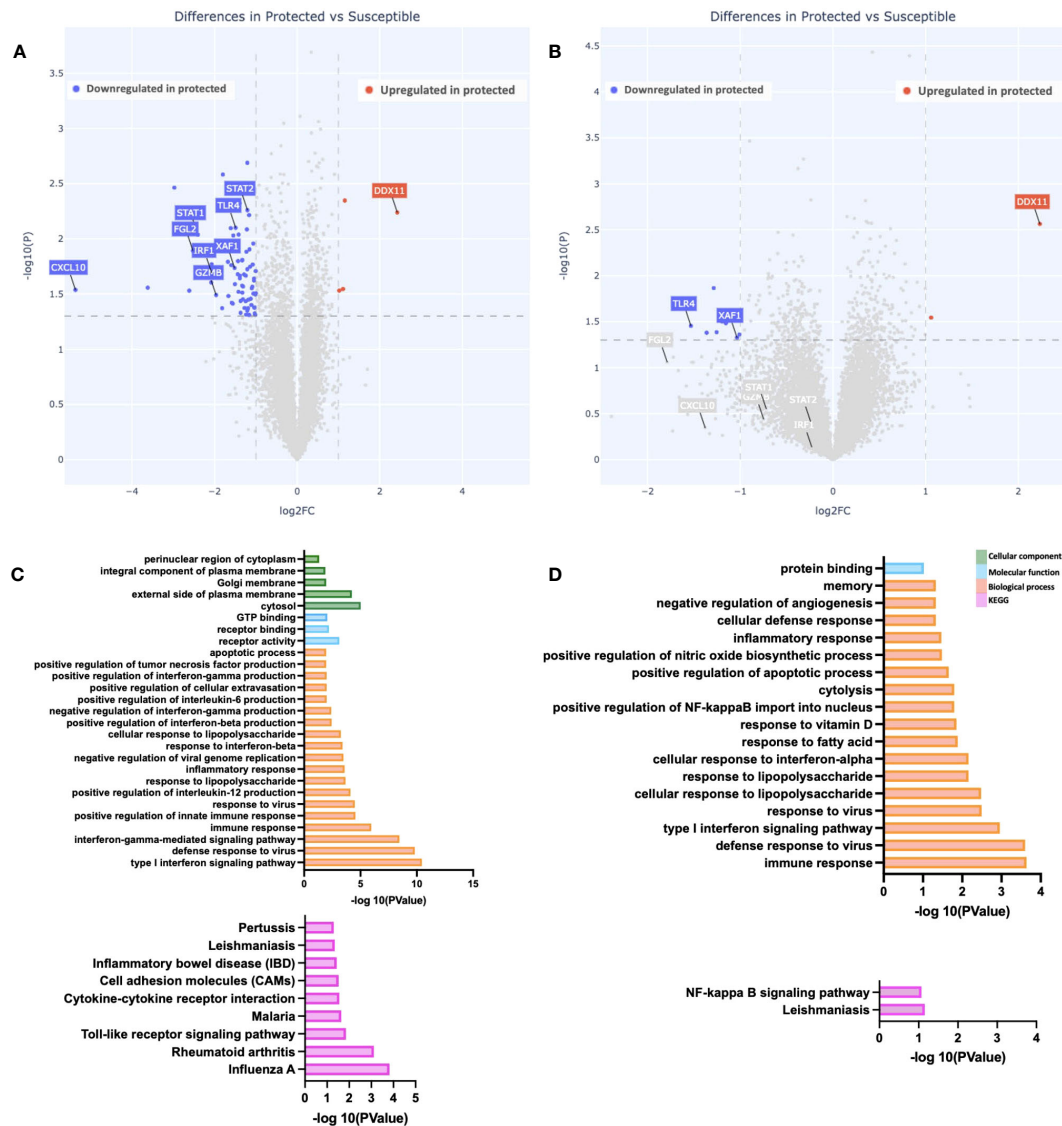

FIGURE 1

Differences in gene expression and immune pathways exist at baseline. (A) Unstimulated PBMCs. (B) PBMCs stimulated with malaria antigen (*P. falciparum* schizont, PfSz). (C, D) Pathway enrichment analysis on differentially expressed genes (False discovery rate,  $\text{FDR} < 0.05$ ; gene expression log-fold change,  $\text{LFC} > 1$ ), using pathway enrichment software DAVID (26). (C) Pathways enriched in susceptible children before antigen stimulation. (D) Pathways enriched in susceptible children after PfSz stimulation. Enrichment analyses were performed on differentially expressed genes that met the  $\text{FDR}$  and  $\text{LFC}$  thresholds; no genes overexpressed in protected children met this threshold.

important blood stage *P. falciparum* antigen, the responses to which decrease over time since a previous clinical malaria episode (42), for individuals in the same study. A comparative analysis of 25 samples for which data was available, twelve of which were from protected and 13 of which were from susceptible children, showed no significant differences in the baseline AMA1 antibodies present in the serum collected from the children in either cohort (Supplementary Figure 5). The lack of differences in antibody responses to PfEMP1 and AMA1, two major blood stage malaria antigens, suggest that the differences in gene and pathway expression between groups are not due to differences in malaria

exposure between the two groups. Finally, we investigated the possibility of ongoing subclinical malaria infections in susceptible children at baseline. To this effect, we analyzed previously generated data on a screen to detect the presence of parasites based on PCR amplification of the AMA1 gene from the day 0 timepoint (15). Although 2/12 individuals from the protected group were asymptotically positive at baseline compared to 0/13 individuals from the susceptible group, we observed no statistically significant differences (Fisher's exact test) in the percent of individuals testing positive for malaria for each study group (Supplementary Figures 6A, B), consistent with the

hypothesis that the observed patterns are not caused by differences in ongoing or recent malaria exposure.

## Gene expression at peak malaria transmission

To evaluate how increased natural exposure to malaria impacts the differences observed at baseline, we evaluated gene expression differences between the two groups at day 90 (peak malaria transmission). At this time point, we identified 73 differentially expressed genes in the unstimulated PBMCs; 61 were downregulated while 12 were upregulated in PBMCs from

protected children relative to susceptible children (Figures 2A, B). Pathway enrichment analyses revealed significantly enriched “inflammatory response” among biological processes, in susceptible children (Figures 2C, D). We also observed enrichment in other biological processes in this group, including “chemotaxis” and “response to IFN $\gamma$ ,” as well as enrichment in molecular functions including “chemokine activity” and “receptor activity” (Figures 2C, D). KEGG pathway analysis revealed multiple enriched pathways in susceptible children, including the “malaria” pathway (Figures 2C, D). Consistent with pre-stimulation observations, the biological process “inflammatory response” was significantly enriched, after Pf $\dot{z}$ -stimulation, in susceptible children compared to protected children (Figure 2D).

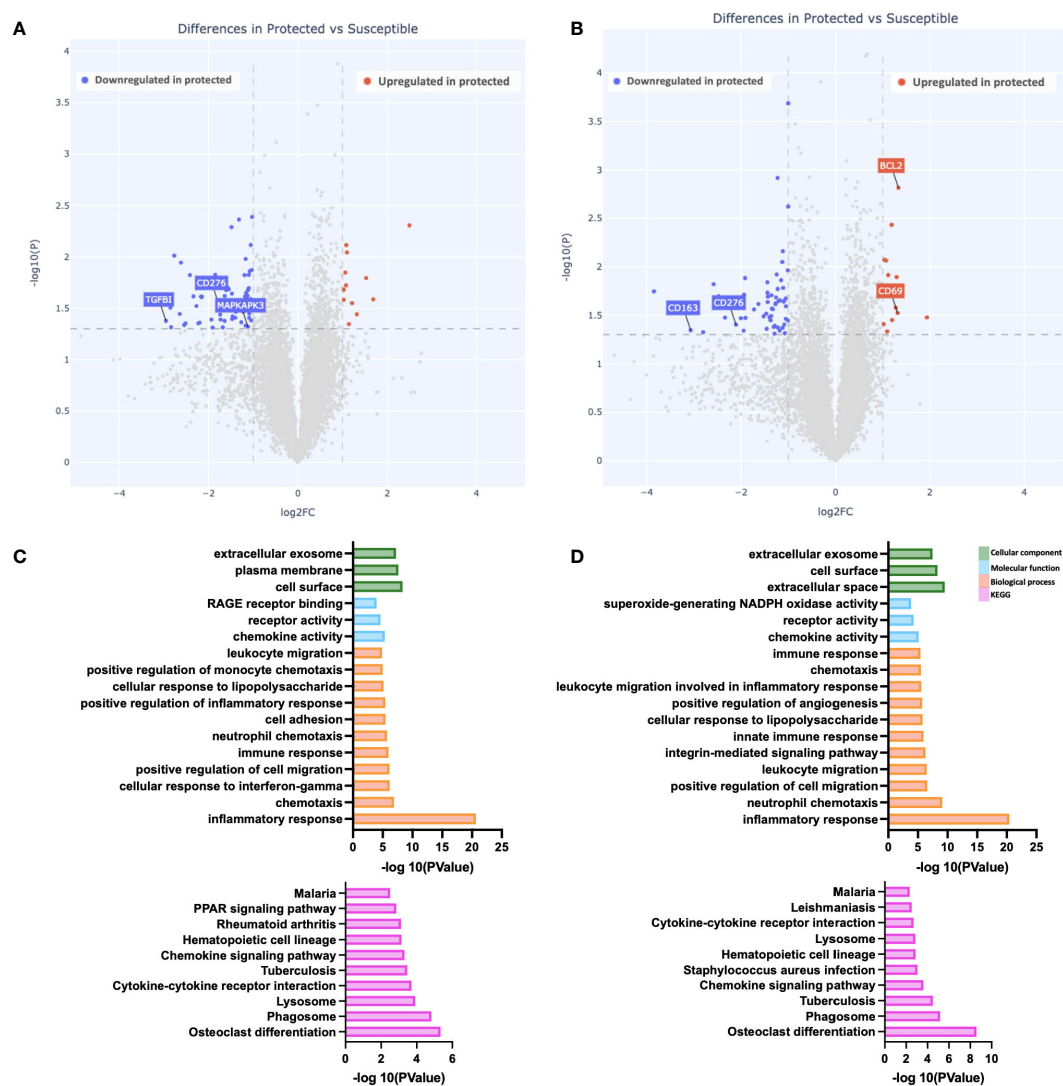

FIGURE 2

(C) Pathways enriched in susceptible children before antigen stimulation. (D) Pathways enriched in susceptible children after Pf $\dot{z}$  stimulation. Enrichment analyses were performed on differentially expressed genes that met the FDR and LFC thresholds.

## Reduced gene expression differences at the end of the malaria transmission season

We evaluated gene expression differences between the two groups at day 150 (end of the transmission season). We observed the fewest differences at this time point, with a total of 11 genes differentially expressed between the two groups. Six genes were downregulated compared to five genes upregulated in protected versus susceptible children (Figure 3A). Upregulated genes include the chemokine ligand CCL24 (Figures 3A, B), while downregulated genes included STAT1 and CD163 (Figures 3A). Pathway enrichment analysis revealed increased chemokine activity in susceptible children compared to protected children (Figures 3C, D). Chemokines play

an important role during the host immune response to infection, as they recruit immune cells to the site of infection by binding chemokine receptors on the surface of immune cells (43). In malaria, high serum chemokine levels are associated with high parasite density and in some cases, severe malaria (44, 45).

## Similar immune cell population clustering patterns between protected and susceptible children

To identify additional distinguishing properties between children with varying malaria susceptibility, we also investigated

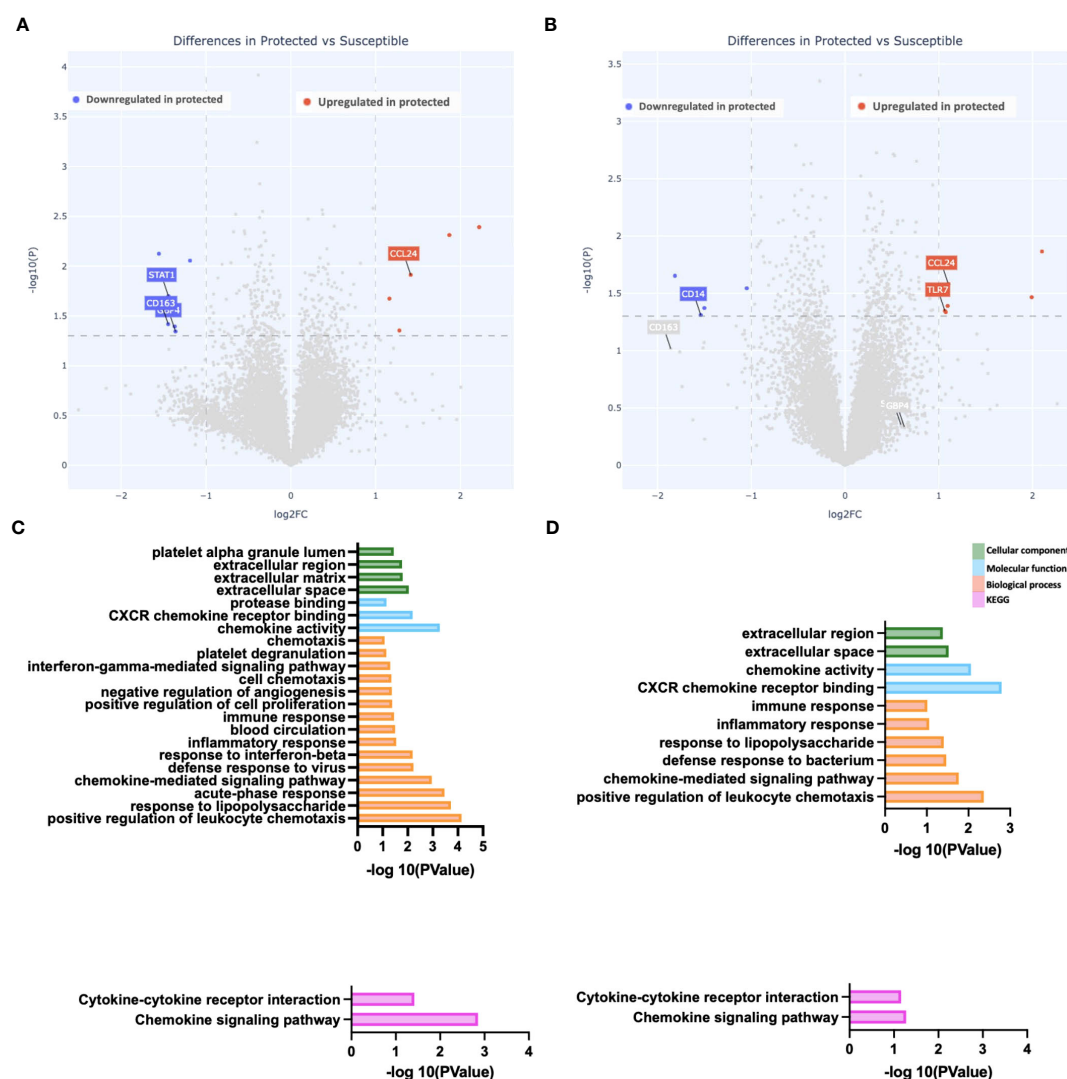

FIGURE 3

Reduced gene expression differences at the end of the malaria transmission season. (A, B) Depicted is a volcano plot of differential gene expression, with significant differences shown (blue, red), based on Welch's Test ( $\log_{10}(p\text{val})$  is plotted against the  $\log_2$  foldchange; significance:  $P$  value  $< 0.05$ ). (A) Unstimulated PBMCs. (B) PBMCs stimulated with malaria antigen (*P. falciparum* schizont, PfSz). the phenotypes of immune cell populations. PBMCs were stimulated and analyzed *via* mass cytometry (see Methods). Using a panel specific for effector function CD4<sup>+</sup> T cell profiling (Supplementary Table 2), we performed high dimensional clustering on CD3<sup>+</sup> PBMCs collected at each timepoint and identified distinct cell populations (Figures 4A-C). Across all three timepoints, we were able to successfully identify CD8<sup>+</sup>, gd and naïve and memory CD4<sup>+</sup> T cell populations, as well as a cluster annotated as “T cells” for cells that were not positive for either CD4<sup>+</sup>, CD8<sup>+</sup> or gd TCR antibodies. Memory cell populations became more defined as the transmission season progressed. By day 150, we identified distinct memory CD4<sup>+</sup> T cell populations, including central memory (T<sub>CM</sub>) (CD4<sup>+</sup>CD45RA<sup>-</sup>CCR7<sup>+</sup>), effector memory (T<sub>EM</sub>) (CD4<sup>+</sup>CD45RA<sup>+</sup>CCR7<sup>+</sup>), and CD45RA<sup>+</sup> effector memory populations (T<sub>EMRA</sub>) in both protected and susceptible individuals (Figures 4B, C). For each identified cluster, we performed both differential cell type abundance and differential state analyses using *diffcyt* package. We observed variable cell type abundances across all individuals regardless of protected or susceptible status (Figures 4D-F and Supplementary Figures 7A-F). Differential state analysis did not detect any significant differences in intracellular marker abundance between protected and susceptible children; however, we observed slightly elevated levels of Programmed Cell Death 1 (PD-1) at day 0 and day 90 (Figures 5A, B), elevated IL-4 across all three timepoints (Figures 5A-C) and elevated IL-6 at day 150 within all PBMCs in susceptible children compared to protected children (Figure 5C).

Within this small subset, we did not observe significant differences in cytokine production within CD4<sup>+</sup> or CD8<sup>+</sup> T cells alone (Supplementary Figure 8).

The presence of slightly elevated levels of PD1 in the mass cytometry data along with the enrichment of cell death pathways in susceptible children prompted us to investigate the role of regulatory T cells at baseline and across the transmission season. Previous studies show that the presence of Tregs may promote increased *P. falciparum* parasitemia due to a reduction in host responses to infection, and that these effects are reversed under CD25 depleted conditions (18, 46). To probe how regulatory T cells from protected and susceptible children behave as exposure to *P. falciparum* increases, we stained stimulated PBMCs with a regulatory T cell panel (Supplementary Table 3). We assessed cell composition and cytokine secretion patterns of stimulated CD3<sup>+</sup> cells in the presence and absence of Tregs (CD4<sup>+</sup>CD25<sup>+</sup>). We were able to successfully identify a small subset of Tregs (200-1200 cells) at all three timepoints and, as expected, these cells were absent under the CD25 depleted conditions (Figures 6A-F). Additionally, we identified an HLA-DR<sup>+</sup> CD4<sup>+</sup> population across all three timepoints in both CD25<sup>+</sup> present and depleted conditions (Figures 6A-F). HLA-DR is a human MHC class II molecule that is expressed on a variety of lymphocytes, including activated T cells (47). Differential abundance and state analyses for PBMCs stained with the regulatory panel revealed differences in the frequency of HLA-DR<sup>+</sup> CD4<sup>+</sup> T cells at day 90, when protected children had a higher frequency of this population relative to susceptible children

(D–F) UMAP plots displaying immune cell populations identified through unsupervised clustering of CD25-depleted PBMC stained with the regulatory panel. (D) Day 0, (E) Day 90, and (F) Day 150. (G–I) Heatmap showing cell type frequencies of CD3<sup>+</sup> T cell populations present in children from each of two conditions (protected, teal; susceptible, purple). High frequency populations are displayed in dark red and lowest frequencies are in dark blue. Population frequencies that are significantly different (FDR < 0.05) between protected and susceptible children are marked with a green bar (to the right of heat map). (G) Day 0, (H) Day 90, and (I) Day 150.

(Figures 6G-I). We did not observe significant differences in intracellular marker expression between the two groups (Supplementary Figure 9). Comparison of intracellular cytokine production in PBMCs before and after CD25 depletion revealed individual-specific changes, with no significant trend noted within the entire group (Supplementary Figures 10 A-F). Some individuals, patients 4, 6, 9, and 10 experienced slight increase in IFN $\gamma$  and IL-2 levels at day 0 while patients 2, 3, and 13 experienced decrease in these cytokines at the same time point (Supplementary Figures 10A, D). These data demonstrate inter-individual variation present in samples collected from individuals in an endemic setting.

## Discussion

In this study, we used both bulk RNA sequencing and mass cytometry to identify host immune gene and protein expression patterns associated with varying susceptibility to clinical malaria disease. We used samples from a cohort of children who have high exposure to malaria, but who are early in the trajectory of acquiring immunity to malaria. We performed RNA sequencing on PBMCs to characterize gene expression patterns of children with different levels of malaria susceptibility. Through gene expression analyses, we identified higher baseline expression of CXCL10, STAT1, STAT2, GZMB, XAF1 and IRF1 in susceptible children relative to protected children. Our findings suggest that existing differences in gene expression, already in place before a malaria transmission season may impact susceptibility to subsequent infection. However, a new study with a larger cohort is needed to enable a study design with stronger statistical power and establish definitive conclusions. Furthermore, utilizing a regression approach can help determine the association between the number of malaria events and the enrichment of specific pathways.

Interferon gamma-induced protein 10 (CXCL10), a pro-inflammatory chemokine induced by multiple cytokines including IFN $\gamma$ , has been previously identified as a marker of malaria disease severity (48–50). A study of CXCL10 wildtype (WT) and Knockout (KO) mice showed efficient parasite control in KO mice while WT mice progressed to cerebral malaria (48). Additionally, a field study in Ghana found higher CXCL10 levels from postmortem cerebral spinal fluid (CSF) in cerebral malaria patients (51). Another gene downstream of IFN $\gamma$  signaling, STAT1, was also significantly overexpressed in the susceptible group relative to the protected group. STAT1 is a transcription factor activated by multiple interferons, and it regulates various cellular processes including cell proliferation and differentiation (52, 53). Although we did not see differential expression between groups with IFN $\gamma$  cytokine expression, we found evidence of gene expression differences for molecules downstream of IFN signaling, suggesting that gene expression studies may detect changes that are missed by cytokine studies.

Our pathway-level analyses revealed an enrichment of the apoptotic pathway in susceptible children. These observations are consistent with previous studies that have demonstrated increased apoptosis of immune cells (lymphopenia) in individuals with malaria infection (54, 55). Additional studies have found that

malaria infection increases apoptotic processes, mediated through FAS, FASL and Tumor Necrosis Factor (TNF) (56–58). Although we did not observe increased expression of these specific genes, we observed higher expression of pro-apoptotic genes XAF1 and IRF1 in susceptible children at baseline. XAF1 is a transcriptional co-activator of IRF1, a protein that negatively regulates anti-apoptotic genes and promotes FASL expression in immune cells (59–62). The RNA-seq data were supported by mass cytometry results of slightly higher levels of PD-1 in susceptible children.

High dimension reduction and differential analysis of mass cytometry data identified higher frequencies of HLA-DR<sup>+</sup>CD4<sup>+</sup> T cells in protected children when compared to susceptible children. HLA-DR is a late activation marker that is upregulated on the surface of either memory or naïve T cells after antigen encounter. Although the function of HLA-DR on the surface of T cells is poorly understood, studies on infectious pathogens including *Mycobacterium tuberculosis* (the causative agent of tuberculosis, or TB) and Human Immunodeficiency Virus (HIV), show that HLA-DR<sup>+</sup>CD4<sup>+</sup> T cells have the ability to persist longer in the periphery and are more resistant to suppression mechanisms initiated by regulatory T cells (63–65).

Our data shows that inherent differences in inflammatory and apoptotic gene expression already exist at baseline between children who will go on to have two or more malaria episodes throughout a malaria season and those who will not experience clinical malaria. Recent studies report on the importance of baseline immune signatures on the subsequent response to disease progression, vaccine efficacy, and treatment failure or success (66). Tsang et al. showed a correlation between the extent of an immune response to influenza vaccination and the pre-vaccination status of an individual (67). Additionally, the importance of baseline immunity has been noted in cancer, where studies show that the presence of certain immune genes influences the activity of some immunotherapies as well as cancer metastasis (68). These studies also emphasize the importance of a systems approach to understanding overall immune signatures (66, 69).

Our current study corroborates and extends previous findings. We compared children with two or more episodes of clinical malaria (susceptible cohort) to age- and location-matched children without clinical malaria (protected cohort). Although the cohorts had similar risk of malaria exposure, we identified differences in gene expression patterns assessed before the onset of the malaria transmission season between the cohorts. This study emphasizes the importance of understanding the initial gene expression repertoire to accurately interpret clinical and immunological implications of field studies with human subjects. In conclusion, this study identifies potential genes and cell populations associated with, and which may play a causal role in, predicting malaria susceptibility.

## Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession

number(s) can be found below: PRJNA603324 (Bioproject- Genbank) and GEO Accession GSE234970.

## Ethics statement

The studies involving human participants were reviewed and approved by Institutional Review Board for Human Subject Research at University of Maryland Baltimore. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

## Author contributions

GM, JS, and KL were involved in study design and execution of current study. KL, ML, CP, and MAT were involved in the execution of the primary study. GM, KL, and RB contributed to protocol optimization. GM, AnD, and OOI contributed to bioinformatics analysis. TH and RA contributed to software optimization and training. MAT, OKD, AK, DC, and AB were responsible for study management in Mali. BS, AB, and MT contributed to microarray data generation and analysis. GM, JS, and KL contributed to interpretation and writing of the article. All authors participated in editing and approved the submitted version.

## Funding

This project was funded in part by federal funds from the National Institute of Allergy and Infectious Diseases, National Institutes of Health, Department of Health and Human Services under grant number U19AI110820. Site development and the conduct of the original clinical trial were supported by contract N01AI85346 and cooperative agreement U19AI065683 from the National Institute of Allergy and Infectious Diseases, grant D43TW001589 from the Fogarty International Center, National Institutes of Health and contract W81XWH-06-1-0427 from the United States Department of Defense and the United States Agency for International Development for site development and the conduct of the trial.

# Is TNF alpha a mediator in the co-existence of malaria and type 2 diabetes in a malaria endemic population?

Subulade A. Ademola\*, Oluwayemi J. Bamikole  
and Olukemi K. Amodu

Molecular Genetics Unit, Institute of Child Health, College of Medicine, University of Ibadan, Ibadan, Nigeria

Malaria remains a disease of public health importance globally, especially in sub-Saharan Africa. Malaria deaths reduced globally steadily between 2000-2019, however there was a 10% increase in 2020 due to disruptions in medical service during the COVID-19 pandemic. Globally, about 96% of malaria deaths occurred in 29 countries; out of which, four countries (Nigeria, the Democratic Republic of the Congo, the Niger, and the United Republic of Tanzania) accounted for just over half of the malaria deaths. Nigeria leads the four countries with the highest malaria deaths (accounting for 31% globally). Parallely, sub-Saharan Africa is faced with a rise in the incidence of Type 2 diabetes (T2D). Until recently, T2D was a disease of adulthood and old age. However, this is changing as T2D in children and adolescents is becoming an increasingly important public health problem. Nigeria has been reported to have the highest burden of diabetes in Africa with a prevalence of 5.77% in the country. Several studies conducted in the last decade investigating the interaction between malaria and T2D in developing countries have led to the emergence of the intra-uterine hypothesis. The hypothesis has arisen as a possible explanation for the rise of T2D in malaria endemic areas; malaria in pregnancy could lead to intra-uterine stress which could contribute to low birth weight and may be a potential cause of T2D later in life. Hence, previous, and continuous exposure to malaria infection leads to a higher risk of T2D. Current and emerging evidence suggests that an inflammation-mediated link exists between malaria and eventual T2D emergence. The inflammatory process thus, is an important link for the co-existence of malaria and T2D because these two diseases are inflammatory-related. A key feature of T2D is systemic inflammation, characterized by the upregulation of inflammatory cytokines such as tumor necrosis factor alpha (TNF- $\alpha$ ) which leads to impaired insulin signaling. Malaria infection is an inflammatory disease in which TNF- $\alpha$  also plays a major role. TNF- $\alpha$  plays an important role in the pathogenesis and development of malaria and T2D. We therefore hypothesize that TNF- $\alpha$  is an important link in the increasing co-existence of T2D.

## KEYWORDS

malaria, type 2 diabetes (T2D), TNF- $\alpha$ , malaria-endemic population, inflammation, cytokine, hypothesis, TCF7L2 gene

## Introduction: the hypothesis

Type 2 diabetes is a non-communicable disease of serious public health importance globally. It is the most common type of diabetes mellitus, accounting for 90–95% of all diagnosed diabetes cases (1, 2). Worldwide, an estimated 537 million adults aged 20–79 years are currently living with diabetes (3, 4). The development of type 2 diabetes is mainly caused by two factors; impaired insulin secretion by pancreatic  $\beta$ -cells and the inability of insulin-sensitive tissues to respond to insulin (1, 5). Type 2 diabetes develops when the pancreas cannot produce enough insulin or when the insulin-sensitive tissues become resistant to insulin. Symptoms of T2D include excessive thirst and dry mouth, frequent urination, lack of energy, tiredness, slow healing wounds, recurrent infections in the skin, blurred vision, tingling or numbness in hands and feet (6). However, these symptoms can be mild or absent, making it possible for people with type 2 diabetes to live several years with the condition before being diagnosed.

Malaria is one of the most severe diseases of public health importance globally. With 247 million cases reported in 84 malaria endemic countries in 2021 (2), malaria remains a major cause of morbidity and mortality in many developing countries. The causative agent, the protozoan *Plasmodium*, malaria is transmitted to humans by infected female *Anopheles* mosquitoes. The human *Plasmodium* species include *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*, *Plasmodium falciparum* and *P. knowlesi* (2). The most dangerous of the plasmodia infecting humans is *P. falciparum* (7), and it is one of the most important causes of child mortality worldwide. The *P. falciparum* life cycle comprise a non-pathogenic symptomless extraerythrocytic stage, which is followed by the invasion of mature red blood cells by the infective forms (merozoites) and the initiation of pathogenic intraerythrocytic stages. Most of the clinical signs of malaria are caused by the parasite at stages in which it multiplies asexually in red blood cells. The most common clinical symptoms of severe malaria are high fever, progressing anemia, multi-organ dysfunction and unconsciousness or coma, which is one of the causes of death (7). The stages of the *P. falciparum* life cycle are complex, and this allows for the use of various evasion strategies by the malaria parasite. The immune response triggered against the malaria parasite is also complex and stage specific (8). Both the innate and adaptive immune responses are activated by the malaria parasite during malaria infection. The host immune responses play a key role in determining the efficiency of parasite clearance, resulting in immunological phenotype of individuals that are resistant or susceptible to malaria infection.

Several studies in recent times have reported the co-existence of malaria and type 2 diabetes in developing countries. However, most of the evidence reported in literature have been based on the effect of malaria on the risk of diabetes (9); the effect of diabetes on malaria outcome (10–12); and the effect of malaria on glycemic presentation (6). These findings have resulted in the emergence of hypotheses and pathways that have provided explanations for the co-existence of malaria and type 2 diabetes (13). The most popular of the hypotheses that has emerged to explain the co-existence of malaria and type 2 diabetes is the intra-uterine hypothesis. Summarily, the intra-uterine hypothesis is based on the effect of

the malaria-induced inflammation which occurs during exposure to malaria *in utero* on the development of type 2 diabetes later in life.

The intra-uterine hypothesis arose as a plausible explanation for the increase in the burden of type 2 diabetes in malaria endemic populations. Low birth weight arising from of intra uterine stress has been linked with changes in skeletal muscle and pancreatic morphology function (14), leading to increased skeletal muscle insulin resistance and future risk of type 2 diabetes. Exposure to malaria *in utero* is associated with increased risk of preterm and low birthweight births (15) and may be a potential cause for later development of type 2 diabetes in life. A recent study reported subtle elevations of plasma glucose levels in young adult offspring of pregnancies affected by malaria which may be an early marker for the risk of later developing type 2 if these individuals are exposed to an obesogenic environment (16). Furthermore, malaria has been positively associated with insulin resistance (17) mediated by inflammation (18); which is an important risk factor for the development of type 2 diabetes (19). These findings give indirect evidence that inflammation is an important link for the co-existence of malaria and diabetes.

Cytokines are important mediators in the pathogenesis of malaria and T2D. Interestingly, the pro-inflammatory cytokines implicated in the pathogenesis of malaria such as IL-1 $\beta$ , IL-6, IL-8 and IL-12 (20, 21) have also been linked with the pathogenesis of T2D (22, 23). However, TNF- $\alpha$  is distinct among the main cytokines involved in the pathogenesis of malaria and T2D. TNF- $\alpha$  is a proinflammatory cytokine with pleiotropic properties (24). It is a multipotent cytokine produced by a wide range of immune cells such as B cells, T cells and macrophages. TNF- $\alpha$  is involved in various steps of immune responses and can initiate host defense, both innate and adaptive immune responses (25). TNF- $\alpha$  plays an important role in the pathogenesis of malaria (18, 26) and has also been implicated in the development of insulin resistance which contributes to the development of type 2 diabetes (27). In malaria infection, TNF- $\alpha$  is also involved in anti-*Plasmodium* responses that lead to intra-erythrocytic parasite killing and parasitemia reduction and it also plays a central role in the progression of malaria to cerebral malaria (21, 28). TNF- $\alpha$  upregulates the expression of adhesion receptors on endothelial cells, leading to an increase in the sequestration of parasite-infected RBCs on the endothelial cells in the brain. Furthermore, TNF- $\alpha$  is a major adipocyte cytokine; it interferes with insulin signaling after binding to its cognate receptor on muscle cells, thereby impairing insulin action (29–32). TNF- $\alpha$  has also been shown to increase leukocyte adhesion to endothelium, which results in endothelial dysfunction pathogenesis (33). *In vitro*, TNF- $\alpha$  has been shown to increase the transcriptional activity of TCF7L2 (a gene that has consistently been associated with type 2 diabetes) leading to reduced adipogenesis (34).

## Functional studies

TNF- $\alpha$  is an important human cytokine that is implicated in malaria pathogenicity (35). Malaria infected individuals produce varying levels of TNF- $\alpha$ ; the level of TNF- $\alpha$  production is directly

proportional to malaria severity (36). A high TNF production is associated with accelerated parasite clearance, while excessive TNF levels are associated with complications such as cerebral malaria or severe anemia (37). The pathway to TNF- $\alpha$  production in malaria infection begins at the pre-erythrocytic phase after the entry of *Plasmodium falciparum* parasite into the human host, sporozoite antigen stimulates the release of TNF- $\alpha$  before sporozoite invasion into the liver (38).

Following the release of merozoites from the liver, the merozoites infect red blood cells. In the red blood cells, molecular interactions occur between the merozoite and the red blood cell surface. Eventually, the merozoites develop into fully matured trophozoites which rupture to release merozoites, hemozoin and toxins such as *P. falciparum* glycosylphosphatidyl inositol into the bloodstream. This stimulates macrophages to produce TNF- $\alpha$  alongside other pro-inflammatory cytokines such as IFN- $\gamma$  and IL-12 (39, 40), which coincides with the clinical manifestation of malaria. However, TNF- $\alpha$  is the main cytokine that has been associated with the severe forms of malaria, cerebral malaria (41–43).

Recent report shows that TNF- $\alpha$  plays dual role (which includes protective and pathogenic) in malaria physiopathology; as at higher levels, it promotes pathogenicity in cerebral malaria while it is protective against severe malaria at lower levels (44–46). This corroborates Clark et al. (47) findings, who reported that increased TNF- $\alpha$  production induces the cytoadherence of parasite-infected red blood cells to the endothelial cells lining blood vessels in the brain, a phenomenon known as sequestration which is characteristic of cerebral malaria.

Tumor necrosis factor (TNF)- $\alpha$  was the first proinflammatory cytokine to be implicated in the pathogenesis of insulin resistance and type 2 diabetes (48, 49). Several studies have demonstrated high levels of TNF- $\alpha$  in patients with type 2 diabetes. The major organs involved in the development of type 2 diabetes include the pancreas ( $\beta$ -cells and  $\alpha$ -cells), liver, skeletal muscle, kidneys, brain, small intestine, and adipose tissue (50). TNF- $\alpha$  has been shown to reduce the expression of insulin-regulated glucose transporter type 4 (GLUT4), which is located mainly on adipocytes, and skeletal and cardiac muscles (48). The consequence of this is a reduction in insulin receptor substrate-1 (IRS-1) which results in impaired insulin sensitivity. Furthermore, TNF- $\alpha$  can act as an inhibitor of peripheral insulin action by inducing serine phosphorylation of insulin receptor substrate-1 which leads to insulin resistance (48).

Obesity is a major risk factor for type 2 diabetes (51). The level of mRNA of TNF- $\alpha$  and its protein has been shown to increase in the adipose tissues of diabetic individuals (52, 53). TNF- $\alpha$  impairs insulin sensitivity in adipose tissues is *via* the downregulation of protein level of insulin receptor substrate1 (IRS-1) and glucose transporter 4 (GLUT4) (53). The expression of TNF- $\alpha$  is increased in human adipose tissues with insulin resistance (27). In adipose tissues, TNF- $\alpha$  activates enhanced lipolysis leading to increased secretion of free fatty acids from adipose tissue into the circulation (49, 54). TNF- $\alpha$  mediates its biological effect in adipose tissues *via* the two receptors, TNFR1 and TNFR2. The TNFR1 is widely expressed on all cell types, while TNFR2 is expressed predominantly on leukocytes and endothelial cells. The two

TNFRs have been shown to mediate distinct biological effects. The binding of TNF- $\alpha$  to TNFR1 mostly triggers pro-inflammatory pathways (55). The action of TNF- $\alpha$  on adipose tissues can also alter the production of many adipokines. This is relevant to the systemic effects of this TNF- $\alpha$  on insulin sensitivity and whole-body energy homeostasis (56). On the other hand, TNF- $\alpha$  upregulates the expression of genes like vascular cell adhesion molecule-1, plasminogen activator inhibitor-1, IL-6, IL-1b, angiotensinogen, resistin and leptin (57).

In obese individuals, TNF- $\alpha$  is over-expressed in adipose and muscle tissue (58). In obese type 2 diabetes patients, the TNF- $\alpha$  plasma level is related to the amount of visceral fat and is not instantly affected in poorly controlled diabetic patients by acute lowering of blood glucose level (59). Moreover, the levels of TNF- $\alpha$  expression strongly correlate with hyperinsulinemia and decreased insulin sensitivity (60). TNF- $\alpha$  also plays a vital role in the pathogenesis and development of obesity-induced insulin resistance as demonstrated by the augmented levels of TNF- $\alpha$  in systemic circulation, liver, and adipocytes (61–63). Impairment of normal functioning of the  $\beta$ -cells of pancreatic islets is one of the major causative factors for the suppression of insulin secretion. TNF- $\alpha$  can also induce the inflammation in pancreatic islets which lead to the induction of apoptosis in  $\beta$ -cells of pancreatic islets (64).

## TNF- $\alpha$ in genetic studies

Genetic variations in the promoter region of the TNF- $\alpha$  gene may regulate TNF- $\alpha$  production, transcription and affect susceptibility to or protection from inflammatory-related diseases such as malaria and type 2 diabetes (26, 65, 66). Many studies have been carried out to determine whether the TNF- $\alpha$  polymorphisms are associated with levels of TNF- $\alpha$  production, disease susceptibility and or disease severity (67–69). The polymorphisms at positions -238 (rs361525), -308 (rs1800629), -857 (rs1799724), -863 (rs1800630) and -1031(rs1799964) have been associated with increased transcriptional activity and production of TNF- $\alpha$  in several studies (20, 70). The polymorphism at the -308G/A has been linked with various inflammatory and autoimmune diseases (71–74). The -238 G/A polymorphism has been associated with insulin resistance syndrome and obesity (75). The polymorphisms at positions -857, -863 and -1031 have been associated with both increased luciferase activity and increased concanavalin-A stimulated TNF- $\alpha$  production from peripheral blood mononuclear cells (76). In malaria, the aforementioned SNPs have been associated with control of parasitemia levels and increased anti-*P. falciparum* IgG levels (77, 78); suggesting that the TNF- $\alpha$  SNPs may play a role in the effectiveness of anti-parasite responses. However, the control of TNF- $\alpha$  gene expression by these polymorphisms seems to be context-dependent based on secreting cell types, cell activation status, and action of other inflammatory mediators such as IL-6 and CRP (79).

A previous study by McGuire et al. (80) associated the A allele of TNF- $\alpha$  -308 with cerebral malaria. Gimenez et al. (36) also reported that TNF- $\alpha$  and TNF- $\alpha$  receptors are involved in the

pathogenesis of cerebral malaria. Mohamedahmed and Abakar (81) implicated high TNF- $\alpha$  plasma levels with susceptibility to severe malaria, and this was corroborated with previous reports (26, 82, 83) that showed that TNF - 238G/A, a TNF- $\alpha$  SNP was associated with severe malaria and/or progression from uncomplicated malaria infection to severe malaria.

Single nucleotide variations in the TNF- $\alpha$  gene have also been implicated in increased insulin resistance typical of type 2 diabetes. The most widely studied of the TNF- $\alpha$  promoter variants are the TNF- $\alpha$  -308G/A and -238G/A polymorphisms. These TNF- $\alpha$  variants have been studied in association with the outcome of type 2 diabetes. Although several studies have focused on these associations, their conclusions have been controversial (84–86). An earlier meta-analysis on the association between TNF- $\alpha$  -308G/A and type 2 diabetes did not find any significant association (87). A more recent meta-analysis however, found the TNF- $\alpha$  -308G/A variant to be associated with susceptibility to type 2 diabetes (88). On other hand, the TNF- $\alpha$  -238G/A was not associated with type 2 diabetes in most of the previous meta-analyses carried out on the variant (87, 89). Generally, the association of 308G/A and 238G/A polymorphisms have been associated with insulin resistance, obesity and T2DM has been demonstrated in some ethnic groups (90–93).

## Discussion: TNF- $\alpha$ , an important link in the co-existence of malaria and type 2 diabetes

Malaria has long been associated with inflammation (94). Tumor necrosis factor (TNF)- $\alpha$  is an important pro-inflammatory cytokine involved in immune responses to malaria infection. It plays an important role in both the innate and adaptive immune responses to malaria parasites during malaria infection. Although inflammation is a major host defense mechanism against pathogens such as the *Plasmodium* parasite, inflammation can be harmful to the host with resultant acute or chronic pathology if dysregulated (20). As discussed earlier, TNF- $\alpha$  promotes pathogenicity in cerebral malaria at higher levels, while it is protective against severe malaria at lower levels (44–46). This is evident in malaria infection as increased serum levels of TNF- $\alpha$  is characteristic of malaria episodes and elevated levels correlates with faster parasite clearance with the resolution of malaria episodes (95, 96). On the other hand, increased TNF serum levels were repeatedly found in children with severe malaria (94, 97), establishing the important role that TNF- $\alpha$  plays in malaria pathogenesis. Interestingly, the TNF- $\alpha$ -induced inflammation seen in malaria infection is similar to that observed in type 2 diabetes (98). Studies have demonstrated high levels of TNF- $\alpha$  in patients with type 2 diabetes. TNF- $\alpha$  reduces the expression of insulin-regulated glucose transporter type 4 (48), resulting in impaired insulin sensitivity. Also, increased levels of TNF- $\alpha$  expression is strongly correlated with hyperinsulinemia and decreased insulin sensitivity (60).

The inflammation link between malaria and type 2 diabetes is not direct due to the complex nature of the inflammatory process in the two diseases. Nevertheless, previous studies have associated malaria-induced inflammation with critical risk factors of T2DM. A good example is the malaria-induced inflammation in placental malaria that has been associated with low birth weight, which is an important risk factor for the development of type 2 diabetes later in life (19, 99). Similarly, malaria has been positively associated with insulin resistance mediated by inflammation (17, 18), which is a key risk factor for the development of type 2 diabetes (19). One of the most important inflammatory mediators that has been implicated in the development of insulin resistance (which is central to the development of type 2 diabetes) is TNF- $\alpha$  which is also involved in the pathogenesis of malaria (18, 100). These observations affirm inflammation *via* TNF- $\alpha$  as a mechanism which contributes to the co-existence of malaria and type 2 diabetes in malaria endemic regions.

The pertinent question then, is, how does TNF- $\alpha$  connect malaria and type 2 diabetes? The answer lies in the well-known type 2 diabetes marker, TCF4 also known as TCF7L2 (transcription factor 7-like 2). The transcription factor 7-like 2 (TCF7L2) is the most potent locus for type 2 diabetes; as the association of TCF7L2 with type 2 diabetes has been consistently replicated in multiple populations with diverse genetic origins (101). TNF- $\alpha$  has been shown to enhance the transcriptional activity of TCF7L2 *in vitro*, leading to reduced adipogenesis (54). The transcriptional effects of TNF- $\alpha$  promote oxidative stress and mitochondrial dysfunction, lipolysis and altered adipokine expression, thereby compromising insulin signaling and adipocyte lipid metabolism (56). Cawthorn et al. (54), found that TNF- $\alpha$  enhanced TCF4-dependent transcriptional activity during early anti-adipogenesis suggesting that TNF- $\alpha$  and Wnt signaling pathways may converge to inhibit adipocyte development at the level of TCF4-dependent gene transcription. TCF7L2 is a transcription factor that forms a basic part of the Wnt signaling pathway (101). This evidence further strengthens the possibility of a link between TNF- $\alpha$  and TCF7L2 which may play an important role in the co-existence of malaria and type 2 diabetes.

In order to test this hypothesis, we genotyped a TCF7L2 gene variant (rs7903146) in Nigerian children with malaria in a pilot study and found the gene to be present in the population. The study was carried out among under-five children in Ibadan, southwest Nigeria, an area that is holoendemic for malaria. The children were categorized into, asymptomatic, uncomplicated and severe malaria groups as defined by World Health Organization. Genotyping was done using PCR-RFLP, we found the TCF7L2 gene variant, rs7903146 in the population with a minor allelic frequency of 0.139. We also found the TCF7L2 variant, rs7903146 to be associated with susceptibility to developing severe malaria in children from Ibadan southwest Nigeria. These results suggest an association between the type 2 diabetes gene (TCF7L2) and malaria in Ibadan, Nigeria, a population that is malaria endemic.

This evidence suggests a probable pathway that links TNF- $\alpha$  and TCF7L2 in the co-existence of malaria and type 2 diabetes. During malaria infection, infected erythrocytes lead to the activation of macrophages and natural killer cells which lead to

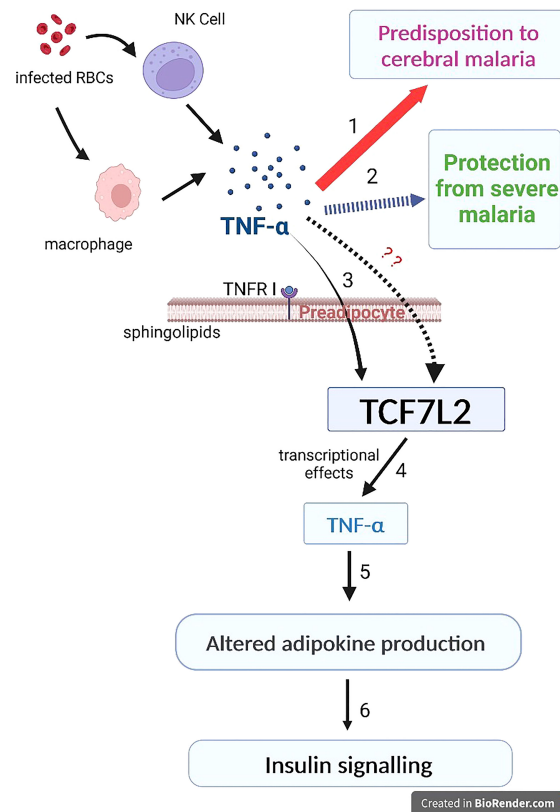

FIGURE 1

The inflammation link between malaria and type 2 diabetes. During malaria infection, infected erythrocytes lead to the activation of macrophages and natural killer cells which lead to the production of TNF- $\alpha$ . Varying levels of TNF- $\alpha$  determine the outcome of clinical malaria; the thick red arrow indicates high levels of TNF- $\alpha$  that promote cerebral malaria (1) while the dashed blue arrow indicates reduced levels of TNF- $\alpha$  that protects against severe malaria (2). 3-6: in type 2 diabetes, TNF- $\alpha$  mediates its biological effect in adipose tissues through its receptor, TNFR1. TNF- $\alpha$  binds to TNFR1, leading to the production of soluble forms of TNF- $\alpha$ . In preadipocytes, TNF- $\alpha$  can stimulate transcription via the type 2 diabetes gene, TCF7L2, leading to altered adipokine production, thereby compromising insulin signaling and adipocyte lipid metabolism (4-6; Figure 1). However, the effect(s) of varying levels of TNF- $\alpha$  on the transcriptional activity of TCF7L2 remains unknown (this is indicated by the red question marks).

the production of TNF- $\alpha$ . However, varying levels of TNF- $\alpha$  determine the outcome of clinical malaria; high levels of TNF- $\alpha$  promote cerebral malaria while reduced levels of TNF- $\alpha$  protects against severe malaria (1-3; Figure 1). In type 2 diabetes, TNF- $\alpha$  can mediate its biological effect in adipose tissues through its receptor, TNFR1. TNF- $\alpha$  binds to its receptor, TNFR1, leading to the production of soluble forms of TNF- $\alpha$ . In preadipocytes, TNF- $\alpha$  can stimulate transcription *via* the type 2 diabetes gene, TCF7L2, leading to altered adipokine production, thereby compromising insulin signaling and adipocyte lipid metabolism (4-6; Figure 1). However, the effect(s) of varying levels of TNF- $\alpha$  on the transcriptional activity of TCF7L2 remains unknown (7; Figure 1). Studies are needed to investigate the effect of varying levels of TNF- $\alpha$  on the transcription of TCF7L2.

There are critical knowledge gaps which requires further studies. One of these is the effect of the varying levels of TNF- $\alpha$  on the transcriptional activity of TCF7L2. This is important because TNF $\alpha$  is known to have differential effects depending on its level of production *in vivo*. However, the effect(s) of its elevated or reduced levels on the transcriptional activity of the type 2 diabetes gene, TCF7L2 remains unknown. Another knowledge gap is the dearth of studies on malaria

and type 2 diabetes in children and adolescents. Most of the research that has been carried out on the co-existence of malaria with diabetes has been conducted using the adult population with little or no studies on children. This is important mainly because malaria is most severe in children and the incidence of type 2 diabetes is becoming more common in children and adolescents.

## Data availability statement

The original contributions presented in the study are included in the article/Supplementary Material. Further inquiries can be directed to the corresponding author.

## Ethics statement

The studies involving human participants were reviewed and approved by Oyo State Ministry of Health Ethics Review Board. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

## Author contributions

SA and OA conceived and designed the idea behind the paper, OB analyzed the data and participated in the manuscript drafting and revision. All authors contributed to the article and approved the submitted version.

## Acknowledgments

The authors sincerely appreciate the efforts of the doctoral students; Babajide Adedeji, Taiwo Olajide and Noah Bukoye for their assistance in proof reading the article.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Publisher's note

All claims expressed in this article are solely those of the authors and do not necessarily represent those of their affiliated organizations, or those of the publisher, the editors and the reviewers. Any product that may be evaluated in this article, or claim that may be made by its manufacturer, is not guaranteed or endorsed by the publisher.

**Introduction:** Sickle cell disease (SCD) is the most common genetic disease found in Africa and throughout the world. It is responsible for a high rate of hemolysis, systemic inflammation, and modulation of the immune system with the involvement of immunological molecules, such as cytokines. IL-1 $\beta$  is a major inflammatory cytokine. IL-18 and IL-33, members of IL-1 family, also exhibit characteristics of inflammation-related cytokines. Thus, in order to contribute to the evaluation of the severity and prognosis of SCD in Africa, this study aimed to estimate the cytokine response, in particular the levels of cytokines of the IL-1 family, in sickle cell patients living in a Sub-Saharan country.

**Methods:** Ninety patients with a diagnosis of SCD were recruited with different hemoglobin types. Samples were assessed for cytokine levels using the Human Inflammation Panel assay from BioLegend. The assay allows the simultaneous quantification of 13 human inflammatory cytokines/chemokines, i.e., IL-1 $\beta$ , IFN- $\alpha$ 2, IFN- $\gamma$ , TNF $\alpha$ , MCP-1 (CCL2), IL-6, IL-8 (CXCL8), IL-10, IL-12p70, IL-17A, IL-18, IL-23, and IL-33.

**Results and discussion:** the assessment of plasma cytokines in SCD patients revealed significantly increased levels of IL-1 family cytokines in crisis compared to steady state, suggesting a substantial involvement of these cytokines in clinical exacerbation. This suggests the possibility of a causal effect in the SCD pathology and can open the way to define better care, pointing toward new therapeutic avenues for sickle disease in Sub-Saharan Africa.

sickle cell disease, cytokines, IL-1, IL-18, IL-33, Africa, chemokines

# 1 Introduction

Sickle cell disease (SCD) is the most common genetic disease in Africa, more than 23 countries in West and central Africa and throughout the world (1). Increasing global migration has introduced SCD into many areas where they were not originally endemic (1, 2), so that the disease has been designated by the World Health Organization (WHO) and United Nations as a global public health problem (1, 3). SCD is characterized by the formation of a particular hemoglobin called hemoglobin S (HbS), generated a single point mutation in the  $\beta$  globin chain of hemoglobin (Hb) that causes the substitution of the glutamate at position 6 with a valine (4). People who inherit the abnormal gene from both parents are homozygotes (SS or SSFA2) and develop SCD (5).

Other types of abnormal hemoglobin are frequently associated with HbS, e.g., hemoglobin C (HbC). Individuals with both HbS and HbC are heterozygotes HbSC (SC). Although the clinical complications of hemoglobin C disease are not severe, inheritance with other abnormal hemoglobin such as hemoglobin S may have significant consequences (6). Another frequent association described (SFA2) is the inheritance a thalassemia defect on one  $\beta$  gene that reduces the production of hemoglobin associated with the  $\beta$  S gene. Despite our understanding of the molecular basis and pathophysiology of these diseases, the burden is still heavy, particularly in countries that have medical settings with limited resources (4, 7).

The sickle cell gene is present in 10–45% of the population in many countries, resulting in an estimated prevalence of at least 2% (1). Clinical manifestations of SCD are of three main categories: chronic hemolytic anemia, vaso-occlusive phenomena and extreme susceptibility to infections that varies greatly from one individual to another. Deaths from SCD complications occur mostly in children under five, adolescents and pregnant women (1). Infant morbidity and mortality associated with SS homozygosity is very high among African children (50–90%) (8) and, under the age of five, it is related to acute, chronic and severe complications (9–11).

Inflammation is a fundamental component in SCD. HbS polymerization under deoxygenation conditions causes the red blood cells to adopt their characteristic sickle shape. This predisposes red cells to numerous intracellular and membrane alterations that make them more adhesive. Therefore, they interact with endothelial cells, activated neutrophils and platelets. Sickled red cells also release heme, which is highly inflammatory, and numerous other molecules with inflammatory potential, such as ATP, Cyclophilin A, and extracellular DNA (12). These molecules act as damage-associated molecular patterns (DAMPs) and participate in the activation of the innate immune system and the coagulation system. All these events participate in the chronic inflammatory processes in the SCD leading to numerous complications.

A very serious and dramatic complication is stroke, which causes severe motor and neurocognitive sequelae. The cerebrovascular accident exists in all forms of SCD (SS, SC, SFA2) ranging from 1.2 to 12% of prevalence according to the age of the patient and the country (13). By the age of 45, about 25% of patients have suffered an apparent stroke even with chronic transfusion

therapy or a normal transcranial doppler (TCD) (13–15). In addition, after a first stroke, silent cerebral infarcts can occur despite regular blood transfusions (14). Although in SCD the incidence of first clinical stroke has fallen over the past decades in the USA and Europe, this is still a highly prevalent matter of concern in Africa, where the majority of people with this condition live. Prevention and care of stroke as well as other complications have been largely neglected in Africa. To improve quality of life, prevention and early recognition *via* cytokines may be a key to decrease morbidity and mortality in SCD. The involvement of immune reactions and their effector molecules, such as the cytokine response in SCD, are of increasing interest, due to cytokines' capacity to drive acute and chronic inflammatory states, thereby contributing to the pathology of SCD (16–18). Several cytokines and chemokines are involved in the chronic inflammatory state in SCD patients. Increased IL-1 $\alpha$  and IL-1 $\beta$  are reported in SCD, which trigger inflammatory reactions leading to primary leukocyte recruitment, endothelial cell activation and production of other many inflammatory mediators, in particular IL-8. IL-8 is a very important chemokine, which facilitates the recruitment of leukocytes, such as neutrophils and eosinophils, to blood vessel walls (19, 20). The increased production of inflammatory cytokines could contribute to the pathophysiology of the disease and can be responsible for the damage to the different organs and the occurrence of common cyclic events in sickle cell patients (17, 21). Insightful understanding of the correlation between inflammatory mediators, such as cytokines, and stroke or other organ damage may provide new biomarkers or therapeutic approaches for SCD management.

Cytokines of the IL-1 family have multiple local and systemic effects, which regulate both innate and adaptive immune responses. Many IL-1 family cytokines have inflammatory activity (IL-1 $\alpha$ , IL-1 $\beta$ , IL-18, IL-36 $\alpha$ , IL-36 $\beta$ , IL-36 $\gamma$ ), while others are mainly anti-inflammatory (IL-1Ra, IL-33, IL-36Ra, IL-37, IL-38) (22). IL-1 $\beta$  is a major inflammatory cytokine that has been associated with exacerbation of injury in stroke, but that was shown to exert both deleterious and protective functions in stroke (19).

Most studies involving cytokines have been conducted in high income countries. Unfortunately, in West Africa, access to such analysis is not possible due to lack of well-equipped infrastructures, absence of standardized management and too few skilled immunologists.

To our knowledge, very few studies have investigated the cytokines association with SCD in our area. This study is the first one done in sickle cells patients in Côte d'Ivoire and will help the evaluation of the significance of cytokines, in particularly those belonging to the IL-1 family, in the management, severity and prognosis of SCD in Sub-Saharan Africa.

## 2 Material and methods

### 2.1 Study population

This is a prospective case-control study of a population of 90 patients with SCD, aged 4 to 55 years, and followed at the

Therapeutic and Research Unit of the National Blood Transfusion Center in Abidjan, Côte d'Ivoire. It was conducted after approval by the national ethics committee (n°44\_2018-SIHOTS). Informed consents were obtained from the patients' parents or legal guardians before patients were enrolled in this study.

Patients were divided into two groups: patients admitted for crisis for and steady state patients.

Steady state was defined as a state without pain, illness, or infection during the last three months before the study; this group represents our control group compared with the crisis group.

The profile of homozygous or heterozygous sickle cell patients was determined by hemoglobin electrophoresis on cellulose acetate strips (pH 9.2).

Patients with crisis were admitted to the Unit, while those who were asymptomatic, i.e., at steady state, were present to the Unit of Therapeutic Transfusion for routine monitoring. Crisis was defined as an episode of acute diffuse pain with infection or anemia, requiring hospitalization and/or analgesic administration. Clinical investigations were evaluated by a specialist in hematology. Cytokine levels were compared in steady-state and crisis patients according to the type of hemoglobin and the complications. All subjects were from West African countries: Côte d'Ivoire, Ghana, Guinea, Mali, Nigeria and Togo.

## 2.2 Cytokine analysis

Blood samples were collected by venipuncture in EDTA tubes for basic determination of hematological indices and for cytokine dosage.

The blood count was obtained with an automated hematological cell count machine (Sysmex XN 550). Plasma was extracted by centrifugation at 1000xg at 4°C for 10 min and stored at -30°C for cytokine assays.

Before assay, samples were thawed, mixed and centrifuged, then assessed for cytokine levels using the BioLegend LEGENDplex™ Human Inflammation Panel assay (Cat. N°740118), an immunoassay based on immunofluorescent beads. The assay allows the simultaneous quantification of 13 human inflammatory cytokines/chemokines, i.e., IL-1β, IFN-α2, IFN-γ, TNFα, MCP-1 (CCL2), IL-6, IL-8 (CXCL8), IL-10, IL-12p70, IL-17A, IL-18, IL-23, and IL-33. The assay was performed in the BioLegend laboratory in San Diego, CA, USA.

All samples were processed and analyzed on the same day of thawing. A minimum of cytokine-specific 3000 beads were acquired with a BD FACSCalibur™ cytometer. Controls provided by the manufacturer were used. Data analysis was performed using LEGENDplex™ Data Analysis Software.

## 2.3 Statistical analysis

All results are expressed as mean ± SD. Data were analyzed using the SPSS version 22.0 program (SPSS Inc., Chicago, IL, USA). Statistical results with a *p* value ≤ 0.05 were significant.

For the comparison of cytokine means, we first used the Levene test to determine the equality of variances: if the Levene test was not significant (*p* > 0.05), we had an equality of variances and used the Student *t*-test for the 2-modality variables and the ANOVA test for the more than 2-modality variables. If the Levene test was significant (*p* ≤ 0.05), we had a variance inequality and in this case we use nonparametric tests such as the Mann-Whitney U test for the 2-modality variables and the Kruskal-Wallis for variables with more than 2 modalities.

## 3 Results

### 3.1 Biometric and epidemiological characteristics of sickle cell patients by clinical status

Ninety (90) patients with a diagnosis of SCD, comprising 48 women (53.3%) and 42 men (42.70%) were recruited.

Among the sickle cell patients, 34 (37.8%) were in steady state phase and represented our stable controls, while 56 (62.2%) were in crisis and represented the cases.

Our SCD patients show in general a low body mass index BMI (Table 1). We find an average BMI of  $20.74 \text{ kg/m}^2 \pm 2.82$  in SCD patients in crisis versus  $20.24 \text{ kg/m}^2 \pm 5.63$  in SCD patients in steady state phase. Few patients were overweight, and none was obese.

Cerebral stroke was found in 45.95% followed by leg ulcer (27.03%) and osteonecrosis (10.81%). Other complications such as heart disease, splenomegaly and hyperviscosity were found in patients in our study with prevalence of 5.41% (Figure 1). The minimum age for stroke patients was 7 years, with an average of 21 years and a maximum of 37 years.

### 3.2 Biological characteristics

#### 3.2.1 Type and levels of hemoglobin and white blood cells

Regarding hemoglobin type, 46 were homozygous Hb SS (SSFA2) (51.1%), 28 were heterozygous SFA2 (31.1%) and 16 were Hb SC (17.8%) (Table 1).

SCD was associated with a decrease in the hemoglobin level in the 2 groups, steady state and crisis ( $8.7 \pm 2$  and  $8.5 \pm 2.1 \text{ g/l}$ , respectively), compared to the normal blood level of hemoglobin but showing a non-significant difference (*p* = 0.64) (Table 1).

No significant difference was observed for white blood cells and leukocyte subpopulations for SCD in steady state phase or during crisis.

#### 3.2.2 Cytokines in steady state and crisis

Thirteen cytokines were measured in our SCD patients. Three cytokines of the IL-1 family were assessed, i.e., IL-1β, IL-18 and IL-33. We have compared their levels to those of the most studied cytokines in SCD, i.e., TNFα, IL-6, IL-8 and IL-10. They were all increased in the crisis group except IL-10 and IL-33, with TNFα and

\*\*Mean percentage of hemoglobin types among all SCD patients (steady state and crisis) were: SSFA2, 51.1%; SFA2, 31.1%; SC, 17.8%.

IL-10 not reaching statistical significance (Table 2). By contrast, anti-inflammatory IL-33 and IL-10 were decreased in the crisis group, with significant difference for IL-33 (Table 2). Other cytokines (IFN- $\alpha$ 2, IFN- $\gamma$ , MCP-1, IL-12p70 and IL-17A, IL-23) were detected, which however did not differ between groups (Supplementary Table 1).

We also compared the mean levels of circulating cytokines in patients during crisis with those in steady state relative to the type of hemoglobin (Table 3).

In SSFA2 patients, a significantly lower level was measured for IL-33 ( $p=0.000096$ ) during crisis. In SFA2 patients, a higher level was observed for IL-1 $\beta$  ( $p=0.02$ ) during crisis. In SC patients, higher

level of IL-18 ( $p=0.01$ ) and lower values for IL-33 ( $p=0.000029$ ) were observed during crisis.

### 3.2.3 Cytokines in SCD complications

Complications have been observed in our SCD patients. Stroke was the most important (46%), followed by leg ulcer (27%) and osteonecrosis (10.8%) (Figure 1).

IL 1 $\beta$  and IL-18 were increased in stroke ( $p<0.001$  stroke vs. steady state), while IL-33 was decreased ( $p<0.05$  stroke vs. steady state) (Figure 2). In patients with osteonecrosis there was a tendency towards decreased levels of all three cytokines compared to steady state, which however did not reach statistical significance (Figure 2). In patients with leg ulcers the three cytokine levels did not significantly differ from those in steady state, although there was

FIGURE 2

Comparison of IL-1 cytokine levels according to the 3 most common complications. Cytokines levels were assessed in steady state SCD patients (34 patients; yellow columns), in crisis patients with stroke (17 patients; blue columns), in leg ulcers (10 patients; orange columns) and in osteonecrosis (4 patients; grey columns). Data are presented as mean pg/ml  $\pm$  SD of IL-1 $\beta$  (left panel), IL-18 (center panel) and IL-33 (right panel). Statistical significances for complications vs. steady state were found for IL-1 $\beta$  (stroke vs. steady state, stroke vs. osteonecrosis), IL-18 (steady state vs. stroke, stroke vs. leg ulcer, stroke vs. osteonecrosis) and IL-33 (steady state vs. stroke). \*  $p < 0.05$ ; \*\*\*  $p < 0.001$ .

a tendency towards decrease (Figure 2). For the other cytokines, no significant difference was found (Supplementary Figure 1).

We also compared cytokines by type of crisis (hemolytic anemia, HA; vaso-occlusive crisis, VOC).

Among the crisis, HA accounted for 55%, followed by VOC (45%). A tendency (not statistically significant) towards higher levels of IL-1 $\beta$ , IL-6, IL-8, and TNF $\alpha$  and lower levels of IL-10 were observed in HA, compared to steady state, while IL-18 tended to be higher in VOC (Figure 3).

## Discussion

In the present study, assessment of plasma cytokines in SCD patients revealed measurable circulating levels of the IL-1 family cytokines in both clinical presentations, crisis, and steady state

(Table 2). We consider the cytokine levels in plasma of SCD patients in steady state as a benchmark, in order to assess the variations during crisis or with complications. How much these values compare to cytokine levels of healthy subjects is currently unknown (study ongoing), although from previously published data steady state SCD patients seem to have increased levels of IL-6, IL-8 and IL-18 (which in normal subjects are  $\leq 10$  pg/ml for IL-6 and IL-8, and around 200 pg/ml for IL-18), suggesting a partially upregulated inflammatory level in steady state SCD. Variability of conditions in different geographical settings and differences in detection assays makes impossible any quantitative comparison with data from other studies (23).

Patients in crisis showed higher levels of the inflammatory cytokines IL-1 $\beta$ , IL-6, IL-8 and IL-18 compared to those in steady state conditions and decreased levels of the anti-inflammatory factor IL-33 (Table 2). Differences were not statistically significant for IL-10 and TNF $\alpha$ .

FIGURE 3

Comparison of IL-1 family cytokines according to the type of crisis in SCD patients. The levels of IL-1 $\beta$  (left), IL-18 (center) and IL-33 (right) in SCD patients were compared between steady state (34 patients; yellow boxes), vaso-occlusive crisis (VOC; 24 patients; green boxes) and hemolytic anemia (HA; 32 patients; brown boxes). Data are presented as median values and interquartile range in pg/ml. Statistical analysis was performed using Kruskal-Wallis. \*\*  $p < 0.01$ . VOC, vaso-occlusive crisis; HA, hemolytic anemia.

IL-1 $\beta$  is a key mediator of the inflammatory response and shows a huge complexity. In addition to being essential for host response and resistance to pathogens, it also exacerbates the damage caused by chronic disease and acute tissue injury, as is the case in SCD (16, 24). Our study shows a significant increase of IL-1 $\beta$  levels in crisis subjects ( $p=0.03$ ). The values found in sickle cell patients in crisis were 10 times greater compared with the steady state, suggesting an involvement of this cytokine in SCD crisis. Our values are similar to those observed by Pitanga et al., who found low IL-1 $\beta$  levels (below 10 pg/ml) both in normal children and in steady state SCD patients (18). The substantial increase in crisis patients that we have observed is in contrast to the data of Pathare et al., who found no change between steady state and crisis levels (24). It should be noted that the circulating IL-1 $\beta$  levels in healthy subjects reported in that study are exceedingly high and different from the low-undetectable levels commonly observed in healthy people (18, 25, 26), thus posing some questions on the reliability of the detection assay.

Although IL-1 $\beta$  has been well characterized, IL-18 and other members of the IL-1 family are less so (27, 28). In our study, IL-18 was detected at high levels both in steady state and, at even higher levels, during crisis. A study suggested a possible role for IL-18 in the physiopathology of crisis in SCD (29). High levels of IL-18 have been associated with high levels of LDH and uric acid, and patients with these indicators have poor prognosis (29). It should be noted that IL-18 is not an exclusively inflammatory cytokine (28). Its circulating levels are well detectable in healthy subjects and increase in essentially all inflammatory conditions (25, 28). IL-18 is an established biomarker of heart failure, so that it has been proposed that anti-IL-18 treatment may have therapeutic effects in patients with SCD at risk for cardiac arrhythmias and adverse outcomes (30).

Interleukin-33 (IL-33), another member of the IL-1 cytokine family, is widely expressed by various tissues, such as smooth muscle cells, epithelial cells, fibroblasts, and keratinocytes. IL-33 is mainly involved in type 2 inflammation, alternative to classical type 1 inflammation, and has anti-inflammatory protective effects in many diseases (31–33). In our study, IL-33 was significantly higher in steady state (Table 2). IL-33 has been proposed as a novel contributor to anemia in inflammatory disease through its effects on differentiation of erythroid cells and as a therapeutic target for this type of patients (34). This cytokine has been rarely investigated in SCD. A link between hemolysis and IL-33 has been proposed, although results might be biased by the fact that the evaluation was performed on stored red blood cells (35). In our study, IL-33 seems to behave as an anti-inflammatory cytokine. This may be due to the heterogeneity of patient genotypes, treatment, environmental impact, socio-economic status, nutrition, the presence of other associated inflammatory factors such as infections or other inflammatory stress and genetic polymorphism (36, 37).

SCD is characterized by common acute and chronic complications. In our study, five types of complications have been identified: stroke (46%), leg ulcer (27%), osteonecrosis (10.8%), hyperviscosity (5.4%), heart disease (5.4%), and splenomegaly (5.4%) and no patient has no more than one complication.

Stroke was the most important complication in our study and in other regions of the world (13) as it is a devastating complication and an important cause of death in SCD. Between 5 and 17% of SCD

patients will suffer a first stroke during childhood or adolescence in the absence of screening and prophylactic treatment (10, 11, 13). The minimum age of stroke of our patients in our study was 7 years, a quite young age, and this could be explained by the precariousness of the management, lack of access to care, and inadequate plans for the management of sickle cell children (1). IL-1 $\beta$  has been associated with exacerbation of injury in stroke and has been implicated in the pathogenic processes associated with a number of central nervous system disorders (38–40), while IL-6 and IL-10 have been found to be neuroprotective (38). The mechanism by which IL-1 $\beta$  affects seizure is unknown. It is known that IL-1 $\beta$  administered with the excitatory neurotransmitter AMPA ( $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) produces a widespread cortical cell death (38). Also, recent work in a murine model with SCD has shown that Interleukin-1 receptor inhibition reduced the size of stroke (41). Although there are indications of a detrimental role of IL-1 $\beta$ , a study showed that an increased IL-1 $\beta$  concentration was linked with protection from stroke development in HbSS children with abnormal transcranial doppler (TCD) (19). IL-1 $\beta$  has been therefore qualified as both beneficial and deleterious in cerebral ischemia depending on its plasma levels. Protective concentration ranges should be well identified to benefit from this predictive biomarker in the management of cerebrovascular events in SCD (19). This suggests that plasma IL-1 $\beta$  levels in combination with TCD measurements may be used to improve evaluation of stroke risk in HbSS patients, by early identification of those needing intensive prophylactic interventions, especially as these strokes can be asymptomatic or silent.

Sickle cell leg ulcers came in second position in our study (27.03%). It is the most important common cutaneous complication in SCD, severe, chronic, and disabling with intense and continuing pain (42). There is no official recommendations for treatment and a high rate of relapse (42). No significant differences was found for IL-1 $\beta$  or for any other cytokine, suggesting that these cytokines are not useful predictors for poor outcomes (Supplementary Figure 1) (43).

Osteonecrosis was the third most frequent complications in our study, with a prevalence of 10.81%. It is a form of ischemic bone injury that leads to degenerative joint disease, and SCD is an important cause of its occurrence (44). An estimated 50% of adults will develop an osteonecrosis by age 35 years old (45). The circulating IL-33 concentration is considered a biomarker of avascular necrosis of the femoral head in patients without SCD, since increased IL-33 levels correlate with osteonecrosis of the femoral head (46, 47). In our study, the IL-33 values in patients with osteonecrosis were very low, thus discounting this marker as an element of early diagnosis and progression of osteonecrosis. Our findings are consistent with those of Agrawal et al. in India (46), in which IL-33 plasma levels did not correlate with osteonecrosis of the femoral head in patients with SCD.

We also presented the results according to the hemoglobin type and the clinical status at the time of the blood sampling, to find a correlation between the hemoglobin type, the level of cytokines and the crisis (Table 3). Relative to the cytokines of the IL-1 family, significant differences between crisis and non-crisis states were found for phenotypes SFA2 (IL-1 $\beta$ ), SSFA2 (IL-33) and SC (IL-18, IL-33). It is however difficult to determine an influence or a cause-effect correlation.

The clinical manifestations of SCD are multifaceted but we investigated the major features: vaso-occlusive (VOC) and hemolytic anemia (HA). In our study, HA was the most common with 55% followed by the VOC (45%). The lower frequency of VOC compared to other studies (48, 49) may be explained by the fact that VOC are mostly managed at home by patients and often not reported (50). We noted a tendency towards higher levels of IL-1 $\beta$ , IL-6, IL-8 and TNF $\alpha$  in HA compared to VOC, which however did not reach statistical significance, while IL-18 and IL-10 are significantly higher in VOC. None of them was however statistically different from the steady state levels. Since hemolysis triggers inflammation and participates in numerous multisystemic complications of SCD (51), and red blood cells could play a role in cytokine signaling (52), this could explain why inflammation-related cytokines are higher in HA. Conversely, the anti-inflammatory cytokine IL-10 was significantly increased in VOC compared to HA, in agreement with other studies (53, 54). The fact that IL-18 was also higher in VOC underlines the notion that this is not a classically inflammatory cytokine and supports previous indirect data hypothesizing the involvement of IL-18 in vascular occlusion in SCD (28). Furthermore, data in SCD mice showed that IL-18 is strongly involved in the entire process of leucocyte recruitment in VOC, while IL-1 $\beta$  is only involved in the late steps of the process (55).

Therapeutic options for SCD are limited to hematopoietic stem cell transplantation, which is a curative option but not available for our countries due to its high cost and the lack of resources. Therefore, anti-inflammatory drugs are important for us because they can neutralize key players in the SCD inflammatory scenario. Many are currently under investigation as potential therapeutics, and agents such as antibodies to anti-IL-1 $\beta$ , the IL-1 receptor antagonist or the IL-18 binding protein are expected to provide benefits for these patients (12).

In conclusion, few studies in Sub-Saharan countries describe the cytokine levels in SCD patients. Our data emphasize the role of inflammation in SCD in crisis, suggesting an important involvement of inflammation-related cytokines in the dynamics of SCD.

IL-1 family members are poorly studied in SCD, even though these cytokines are key mediators of the inflammatory response that enhances the damage caused by SCD. IL-1 family cytokines deserve further consideration with larger cohorts, as they can be useful predictors of poor or favourable outcome, depending on the circumstances. A better knowledge of these cytokines in the evolution of SCD in African countries, considering the specific aspects of patients' management due to extrinsic factors (such as the environment, access to care, socio-economic status), will improve survival and increase the quality of life of these patients in low-income countries.

## Data availability statement

The original contributions presented in the study are included in the article/Supplementary Material. Further inquiries can be directed to the corresponding author.

## Ethics statement

The studies involving human participants were reviewed and approved by Ethic Committee of Faculty of Medecine-SIHIOTS 044\_2018-sihiots. Written informed consent to participate in this study was provided by the participants' legal guardian/next of kin.

## Author contributions

LS conceived and designed the experiments, conducted all the experiments, analyzed, and interpreted the data, assembled all the figures, supervised the study, and wrote the manuscript. RD co-supervised the study, contributed to the scientific discussion, and wrote the manuscript. HA contributed to the scientific concept, revised the manuscript, contributed to data interpretation, and performed the statistical analysis. YS, SK, AA-S, SM, DO and JS contributed to obtaining clinical data, and organized and implemented sample management. PK, RY and CM analyzed data and critically revised the manuscript. All authors contributed to the article and approved the submitted version.

## Acknowledgments

We would like to thank all sickle cell patients who agreed to participate in this study. We acknowledge the help from the Immunology Department of Abidjan, Bouake, and the Therapeutic Unit of the National Blood Transfusion Center. We are particularly grateful to the staff of the BioLegend HQ facility in San Diego for help and assistance for immunocytometry evaluations, especially Drs Shaoquan Ji and Binggang Sun.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Cutaneous leishmaniasis (CL) caused by infection with the parasite *Leishmania* exhibits a large spectrum of clinical manifestations ranging from single healing to severe chronic lesions with the manifestation of resistance or not to treatment. Depending on the specie and multiple environmental parameters, the evolution of lesions is determined by a complex interaction between parasite factors and the early immune responses triggered, including innate and adaptive mechanisms. Moreover, lesion resolution requires parasite control as well as modulation of the pathologic local inflammation responses and the initiation of wound healing responses. Here, we have summarized recent advances in understanding the *in situ* immune response to cutaneous leishmaniasis: *i)* in North Africa caused by *Leishmania (L.) major*, *L. tropica*, and *L. infantum*, which caused in most cases localized autoresolutive forms, and *ii)* in French Guiana resulting from *L. guyanensis* and *L. braziliensis*, two of the most prevalent strains that may induce potentially mucosal forms of the disease. This review will allow a better understanding of local immune parameters, including cellular and cytokines release in the lesion, that controls infection and/or protect against the pathogenesis in new world compared to old world CL.

## KEYWORDS

*L. major*, *L. infantum*, *L. tropica*, *L. guyanensis*, *L. braziliensis*, cutaneous leishmaniasis (CL), clinical manifestation, local immune response

## Introduction

Leishmaniasis is a parasitic disease caused by a vector-borne protozoan parasite belonging to the *Leishmania* genus. It is transmitted as a flagellated promastigote via the bite of an infected sandfly (1, 2). Following its inoculation, promastigotes are ingested by innate cells mainly macrophages, neutrophils, and dendritic cells, where they evolve into amastigotes. *Leishmania* parasites are distributed in more than 98 countries, with 350 million people exposed and 12 million infected (3, 4). The cutaneous form is the most frequent, with an estimation of 600 000 to 1 million new cutaneous leishmaniasis (CL) cases per year. This disease is also responsible for significant psychosocial impacts due to the scars that persist after recovery and the associated social stigma (5). In the Old World, specifically in North Africa (NA), CL is caused by three species: *L. major*, *L. tropica*, and *L. infantum*. Cutaneous leishmaniasis is highly prevalent in Morocco, Algeria, and Tunisia. In the New World (NW), CL is widely distributed in South and Central America. It is mainly caused by *L. amazonensis*, *L. guyanensis*, *L. panamensis*, *L. peruviana*, *L. mexicana*, and *L. braziliensis* (6). These species can cause cutaneous and sometimes mucosal leishmaniasis (ML), with only a small potential for self-healing. French Guiana (FG) is a good example of an endemic South American country, where numerous works have been published on CL. The disease is basically divided into four clinical phenotypes (1): Localized CL (LCL) (2), mucocutaneous leishmaniasis, and (3) diffuse and (4) disseminated CL (7–9). Skin lesions result from a deregulated immune response which is unable to eliminate the intracellular parasites. This could explain the high number of parasites in the inflammatory infected zone for some forms of CL (10). Unbalanced T helper (Th)1/Th2 responses has been associated with an increased tissue destruction and a worsening of skin lesions. Moreover, in a susceptible murine model of *L. major* infection, improved resistance to infection was linked to the production of cytokines in lymph nodes. In most mouse strains, Th1 cells bring resistance through the secretion of IFN- $\gamma$ . In contrast, susceptible mice generate a Th2 cell response characterized by the production of IL-4 and IL-13, which hampers the ability of IFN- $\gamma$  to trigger toxic metabolites (11). The evolution of lesions is determined by a complex interaction between many factors triggered by the early immune responses, including innate and acquired immune mechanisms (10). However, there is a significant lack of information on the cutaneous immune response within CL lesions determining the evolution of the disease both in NA and FG. A better knowledge of the pattern of immune mechanisms and related factors involved in lesion progression or healing might provide helpful information for identifying new immunotherapeutic targets and new drugs.

In this review, we will sum up the current knowledge on clinical manifestations, lesion evolution and local immune response associated with *L. infantum*, *L. major* and *L. tropica* in NA and *L. guyanensis* and *L. braziliensis* CL in FG. We will also discuss similarities and divergences in immune mechanisms induced in NA and FG.

## Comparison of clinical manifestations and disease outcome between North Africa and French Guiana

The clinical presentation and the outcome of CL depend on multiple factors, including species involved, lesion location, sandfly infectivity, comorbidities, treatment modalities, skin microbiota and host immune responses against *Leishmania* (Figure 1) (23–25). The clinical appearance of CL is initially characterized by an erythematous, non-specific papule or patch following an incubation period after the bite of the *Leishmania* infected sandfly. This sub-clinical or early CL has the potential for self-healing; it then evolves into ulcerated (85%) or non-ulcerated (nodules, papules, plaques 15%) specific lesions. Some lesions have a very small potential for self-healing, especially those in the New World, and almost always require a treatment; the median incubation of CL in French Guiana is 25 days. Hypopigmented, hyperpigmented or atrophic scars can persist after treatment, depending on the skin phototype (26–31). In some cases, the lesions can persist for more than one year and become a chronic non-healing form (32, 33). Therefore, some infected patients leading to disfigured (34–36). However, the disease outcome also depends on the parasite species (Table 1).

Concerning *L. major*, this species is the most frequent in NA countries, where it remains a major public health problem, with more than 1000 to 8 000 cases yearly in Tunisia and 10,000 to 25,000 in Algeria (9, 40, 51, 52). Lesion can be single or multiple, usually with ulcerative nodules. These primary lesions can give birth to secondary peripheral lesions “satellite” (Figure 2) (9, 58). The most common type of ulcer is the ulcero-crusted form (59), also known as the “wet” or “rural” type. It is characterized by a painless ulcer with a clear raised border and a brownish scab covering it, commonly affecting the upper and lower limbs. CL caused by *L. major* has a wide range of clinical presentations, so it should be considered as a possibility in many skin diseases, including actinomycetoma, pyoderma gangrenosum, and various types of skin cancer. In Tunisia, about 11 uncommon clinical forms of CL due to *L. major* have been reported in zoonotic foci in Central and South regions of the country (60–62). This diversity may be due to the combination of the parasite’s genetics and the host’s immune response.

*L. tropica*, is responsible for chronic CL (CCL). Among the different countries of NA, Morocco presents the widest endemic areas and the highest incidence for this species (9). Compared with *L. major*, cutaneous lesions are distinguished by their chronicity; their appearance is dry and slightly inflamed. Therefore, this makes *L. tropica* CL more difficult to diagnose, which causes a delay in patient care (9, 63–66). Lesions in CCL are drier than in *L. major*, with papules, nodules, or crusty ulcers. Also, they are different in location and size compared to other species, as it mainly appears on the face and are typically smaller, with a diameter of less than 2 cm (41, 51, 67, 68).

The third CL causative species in NA is *L. infantum*, the primary responsible agent of visceral leishmaniasis (VL) (69).

FIGURE 1

The pathogenesis of CL and the evolution of lesions are multifactorial; it depends on the complex interactions between the *Leishmania* parasite, the immune system, and the skin environment, including the vector-injected particles and the microbial skin communities. Sandfly saliva contains potent vasodilators, maxadilan, and adenosine, described respectively in *Lutzomyia longipalpis* and *P. papatasi*, that prevent clotting at the biting site (12), in addition of proteins that trigger a host immune response (13–15). As clearly demonstrated by several investigators, sandfly saliva contains immunomodulatory molecules that have been shown to enhance disease progression (16–18). Some of them, such as the parasite secretory gel (PSG), afford *Leishmania* protection from a hostile pro-inflammatory environment. They may directly regulate macrophages activation in dampening the early pro-inflammatory response and orchestrating wound repair and re-epithelialization (19). In fresh wounds, a robust pro-inflammatory response is required to sterilize the damaged tissue of potentially pathogenic bacteria. The skin microbiota plays a fundamental role in the host immune system's induction, education, and function. In turn, the host immune system has evolved multiple means to maintain its homeostatic relationship with the microbiota. It has been shown that *Staphylococcus* spp., *Streptococcus* spp., *Enterococcus* spp., *Pseudomonas* spp., and other opportunistic bacteria are present in CL lesions (20–22). It was proven using a *Leishmania*-infected mouse with dysbiotic skin microbiota that naturally acquired dysbiosis can cause a change in inflammatory responses and disease progression. It has been demonstrated that the skin microbiome could modulate the skin's immune response by enhancing IL17 production, which is essential in mediating inflammation in CL. While Th17 cells are a source of IL-17, it is possible that IL-17 produced by innate lymphoid cells present in the skin could contribute to disease progression. In effect, Scoot's team has suggested that following infection by *L. major*, RORγt+ILCs produced IL-17 in the skin may contribute to disease progression.

Between 50 and 150 cases are reported annually in Tunisia; few data are available for other countries (9). Compared to the previous two, the clinical appearance of wounds is more significant (58, 70). The duration between the bite of the infective sandfly and the onset of symptoms may vary between several weeks to 1 year (average 3–6

months) (51, 71). Another characteristic is that lesions may last longer than those with *L. major*, persisting for several months or years; such lesions are often slow to heal and may leave large, disfiguring, or disabling scars. Clinically, *L. infantum* lesions may present as papules or nodules, typically on the extremities and

TABLE 1 Summary of the different *Leishmania* species, clinical presentations, vector and transmission cycles in North African countries (Old World) and French Guiana (New World).

<i>Leishmania</i> species	Clinical presentation	Vectors	Transmission cycle	References

bordered by a large zone of infiltration (9, 37). Plaque is the most frequent clinical manifestation of cutaneous *L. infantum* involvement, followed by ulcers, nodules, and papules (72). The clinical presentation is a single small plaque on the face (9). Cases of mucosal involvement have recently been reported in travelers returning to Europe but are seldom described by North African teams (73).

In French Guiana, CL is caused by certain species belonging to the *Leishmania Viannia* subgenus, which is endemic to Central and

South America (74). *L. guyanensis* represents more than 80% of cases in FG, while *L. braziliensis* has emerged in the 2000s and represents about 10-15% of cases (75). Other species, such as *L. lainsoni*, *L. naiffi*, and *L. amazonensis* can also be found but remain rare and are not part of this review (76). Though a complex clinical classification has not been proposed in FG, a very wide spectrum of clinical lesions can be observed, including impetigo-like, lupoid-like, sporotrichoid, crusted ulcers, patches, plaques, nodules, papules, or even extensive sores (Figure 2). These atypical forms

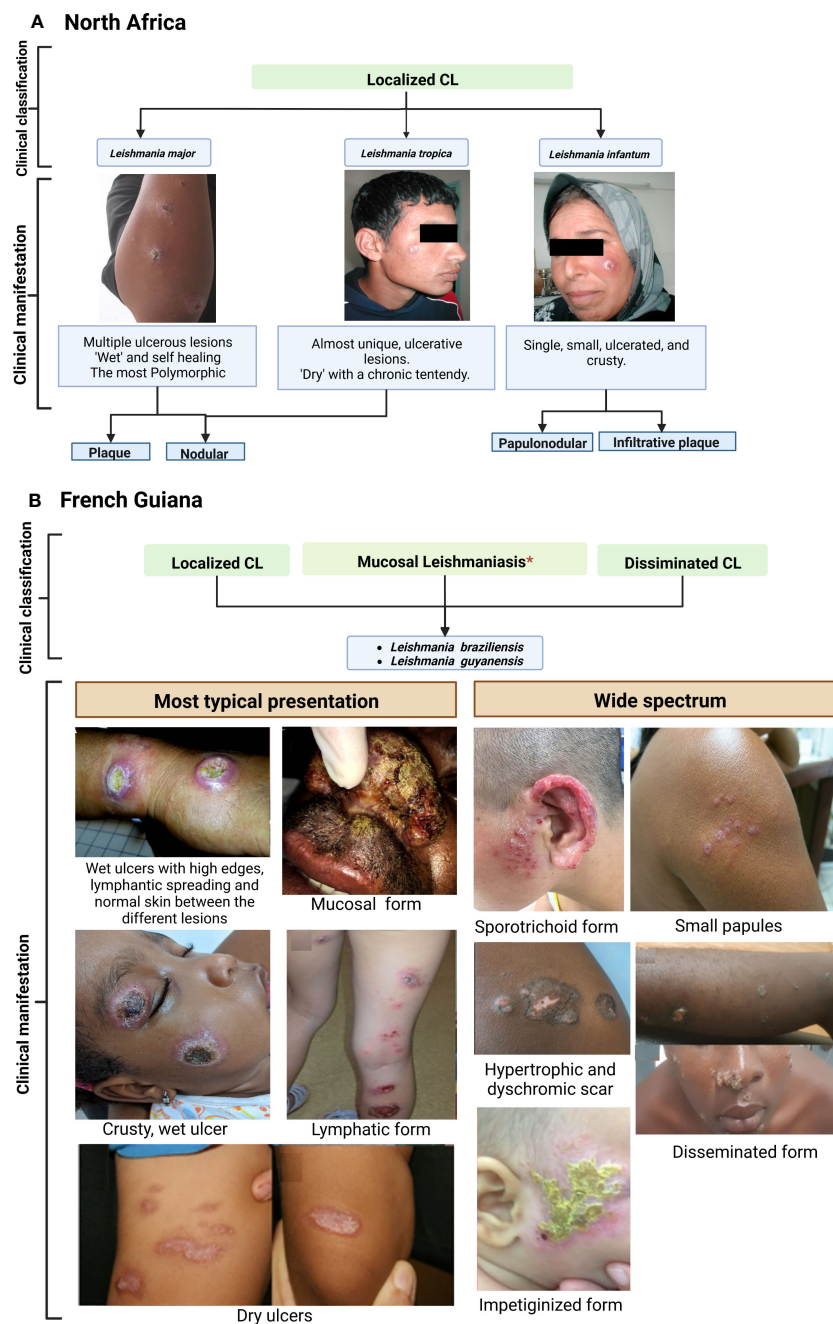

FIGURE 2

Clinical features of cutaneous leishmaniasis caused by *L. major*, *L. tropica* and *L. infantum* (Old world) (A) compared to *L. braziliensis* and *L. guyanensis* (New World) (B). Case photos were provided by the laboratory of Medical Parasitology and Mycology, Institute Pasteur of Tunis, and Dermatology Department, Centre Hospitalier de Cayenne, French Guiana. \*Risk for mucosal involvement is about 6% for *L. braziliensis* and 1% for *L. guyanensis*. Reference: North Africa; French Guiana (9, 53–57).

have also been described in other countries of South America, notably Brazil (77, 78). However, the typical form of CL in French Guiana and the rest of the Amazon basin consists of a wet, acute ulcer which is slightly painful and usually without secondary bacterial infection (44). Several lesions can be found, particularly when *L. guyanensis* is involved. The skin between the lesions is normal, without erythema. A lymphangitis with or without parasitic nodules can be observed. Compared to Old World (OW) leishmaniasis, New World (NW) forms are known for a greater tendency to disseminate systemically in the skin (6, 79).

In addition, a great number of lesions with lymphatic involvement are observed for *L. guyanensis* CL in FG (42, 43) (Figure 2). This species is known to occasionally cause mucosal issues, but it is less common than mucosal disease caused by *L. braziliensis* (44, 80–82). Indeed, less than 1% of *L. guyanensis* cases in FG display a mucosal involvement (81, 83). *L. braziliensis* CL can manifest in different ways, from a single ulcer on the skin, which is often associated with satellite adenomegaly, to the less frequently disseminated form (82, 84). Potentially severe mucosal involvement of the upper airways are typically described with this species (47, 82, 85–87). Single lesions are more frequent than with *L. guyanensis* (44, 83).

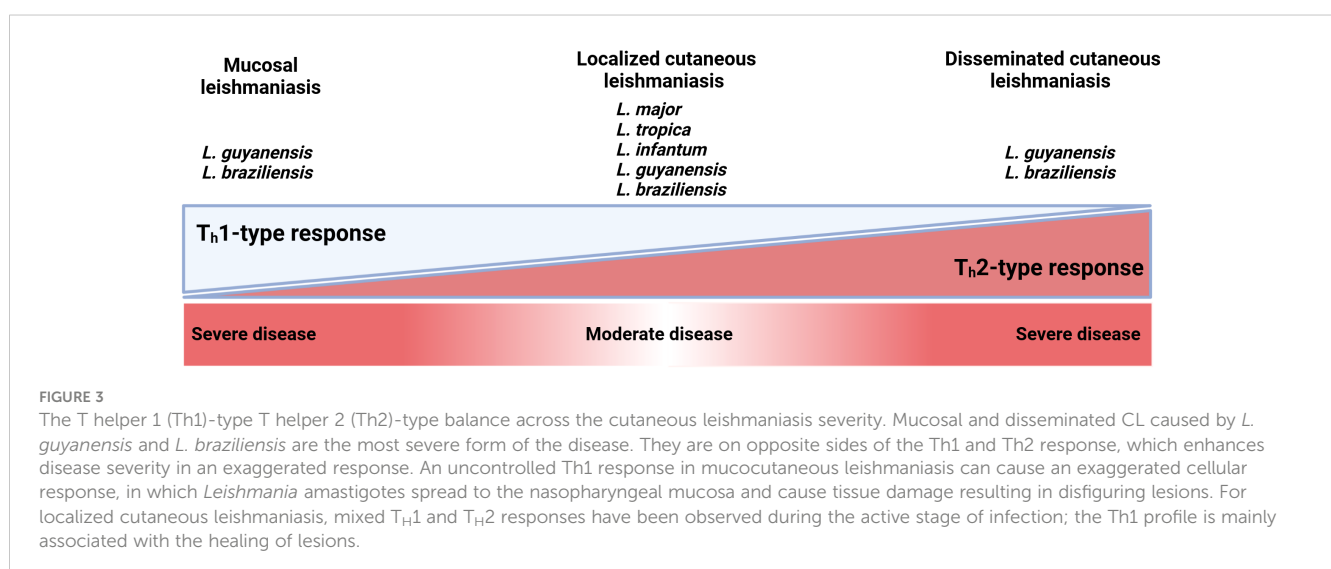

## Cell-mediated immune responses associated with protection in the skin of CL patients

CL in NA and FG is characterized by various immunological features (Figure 3) (44, 47, 58, 74, 88–90). Once the *Leishmania* infected sandfly bites, the infection starts with an asymptomatic “silent phase” of variable duration, characterized by an inflammatory wave of poly morpho nuclear (PMN), dendritic cells (DC), and monocyte-derived macrophages which harbour a proliferation of amastigotes intracellular parasites (10, 91, 92). Then, a massive recruitment of CD4<sup>+</sup> and CD8<sup>+</sup> T lymphocytes,

with enhanced pro-inflammatory responses participate in granuloma formation and parasite control. As a result, few parasites remain in the lesions and promote a delayed-type hypersensitivity (DTH) (Figure 4) (10, 93, 94). However, differences in intralesional immune profiles between the different CL forms are not well documented. Still, the infection outcome is clearly the consequence of a balance between pro and anti-inflammatory responses.

## In *L. major* infection

During *L. major* infection, promastigotes deposition in the skin promotes neutrophils and dendritic cells (DCs) recruitment during the earliest stage of infection (95). In this stage, Chaves et al. demonstrated the anti-inflammatory functions of dermal tissue-resident macrophages, which was supported by the reduced parasite burdens observed in mice (96). The clearance and control of *L. major* multiplication involved mainly cytotoxic CD8<sup>+</sup> T cells and CD4<sup>+</sup> helper T cells and the production of IFN- $\gamma$  (90, 97); in fact, non-healing lesions in mice are associated with a small number of TCD4<sup>+</sup> (98, 99). However, PWK mice strain develops prolonged but self-healing lesions, with an immune response characterized by a mixed Th1-plus-Th2 pattern acquiring resistance to a secondary challenge (100). Formaglio et al. recently showed the implication of the resident memory CD4<sup>+</sup> T cells in delayed-hypersensitivity response, without the involvement of circulating T cells but with the recruitment of activated inflammatory monocytes. These monocytes produce reactive oxygen species (ROS) and nitric oxide (NO) that play a role in the inhibition of *L. major* development in the mice (101). These findings underscore the central role of skin-resident CD4<sup>+</sup> T cells' in enhancing the protective immune response against *L. major* (102). Independently of the T resident memory cells, the acute availability of circulating CD4<sup>+</sup> T helper 1 effector cells (Th1EFF) at the time of secondary infection is critical for the Th1 immune response. Th1EFF cell-phagocyte interactions proved crucial in

FIGURE 4

Immune responses and skin cytokine profile during cutaneous leishmaniasis infection. Pro-inflammatory cytokines are produced primarily to amplify the immune response to *Leishmania* infection. The major proinflammatory cytokines include TNF- $\alpha$ , IFN- $\gamma$ , IL-1, IL-8, IL-12, IL-17 and Granzyme  $\beta$ . In contrast, anti-inflammatory cytokines are immunoregulatory molecules that counteract the effects of pro-inflammatory cytokines to limit the inflammation. These major anti-inflammatory cytokines include IL-5, IL-6, IL-4, IL-10, IL-13, and TGF- $\beta$ . It has been proposed that the existence of Tregs in infected tissues could be an immune response from the host to maintain the balance to control *Leishmania* infection and reduce excessive inflammation that supports parasite survival. This is achieved by Tregs inhibiting Th17 cells through the production of IL-10. The role of the local humoral response to amastigote spreading and tissue destruction is still incompletely understood.

preventing the establishment of a permissive *L. major* niche in lesions (103). However, if NK cells may play several roles in developing an effective T cell response against *Leishmania*, their contributions to the response to CL in humans are less clear. For instance, it has been shown that NK-cell-derived IFN- $\gamma$ , in mice, is essential for activating the dendritic cells that mediate the T-cell-dependent protection against *L. major* infection (104). Another mechanism associated with Human skin lesions protection is granzyme B-dependent CD8 T-cell cytotoxicity, as it participates in controlling parasite multiplication through a cytotoxic process (88, 105). On the other hand, in mice, a negative regulatory role for IL-4 was identified in limiting the recruitment of Th1 cells to *L. major* infected tissues, which alters the *Leishmania* clearance (89, 106). Therefore, the study of the impact of IL-4 on lesion evolution could provide hints for a therapeutic trial (107–109). In addition, the cytokine balance IL-4/IFN- $\gamma$  has also been demonstrated to participate in the commitment of local immune response. Indeed, IL-4 secretion at the site of *L. major* infection rather than low IFN- $\gamma$  production may play a role in the prolongation of disease during acute and chronic CL lesions. A moderate increase of CD4 Tregs would be observed in chronic lesions. However, few studies have suggested the role of Tregs during human CL; Belkaid et al. demonstrated that Tregs are rapidly accumulated at sites of *L. major* infection, favoring the early parasite expansion, contributing to the maintenance of immunological self-tolerance, and coinciding with the expression of effective immune responses (98, 110). In a group of *L. major* infected patients, Hoseini et al. observed a significantly higher expression of Foxp3 in chronic lesions

compared to acute lesions; The moderate increase of T reg in chronic lesions and their function in persistent infection is still not apparent (111).

## In *L. infantum* infection

*L. infantum* is mostly responsible for visceral leishmaniasis (LV) but can also cause CL; little is known about the pathogenesis of this form. Recently, the level of IFN- $\gamma$  was evaluated for sporadic CL and zoonotic CL and was found to be significantly higher in *L. infantum* lesions than due to *L. major* (90). As mentioned above, for CL caused by *L. major*, CD8<sup>+</sup> T cells are an essential part of the defense mechanisms against the parasite; however, for *L. infantum* infection, IFN- $\gamma$  has a long-range effect inducing skin tissue destruction and keratinocyte apoptosis (10, 112, 113). In addition, it has been shown that increased IL4 production in skin lesions of *L. infantum*-infected dogs is associated with severe clinical signs and a high parasite burden (114). Although the role of IL4 was little described for *L. major* infection, no data was found for *L. infantum* human cutaneous Leishmaniasis. Furthermore, there is still much to be learned regarding the role of T reg cells on skin lesions in human CL caused by *L. infantum*; authors have suggested that T reg cells and the regulatory cytokines, especially TGF- $\beta$ , play an essential role in the immunopathogenesis of non-typical ulcerated leishmaniasis (NUCL), modulating the cellular immune response in the skin, avoiding tissue damage, and leading to low parasitic persistence in the skin (115, 116). These factors could play a role in

regulating the cellular immune response balance, resulting in the maintenance of a low tissue parasitism that avoids lesion growth.

## In *L. tropica* infection

Although little is known about the *in situ* immune status of *L. tropica*-infected patients, cases develop a chronic CL with a strong delayed-type hypersensitivity (117). It has been recently shown that *L. tropica* has an enhanced capacity to reduce NO production by macrophages *in vitro*, which could help to understand why *L. tropica* infection could induce chronic lesions (118). In a study by Ajdary et al., evaluating T-cell responses to *Leishmania* antigen *in vitro*, Th2 cell response was dominant in active CL cases, and Th1 characterized the group of healed patients (119). The level of specific cytokine was evaluated *in vitro* in the PBMC but not in the skin, and high levels of IFN- $\gamma$ , IL-5, and IL-13 in non-healing patients were observed, suggesting a mixed Th1/Th2 response with chronic lesions. In contrast, patients with acute lesions respond to infection *via* a Th1-type response (119). However, such a result must be confirmed locally in skin lesions or animal models. It has been discovered that in the early stages of *L. tropica* infection, the amount of IL-4 is upregulated and linked to a higher parasite burden. This may play a role in the development of CL by inhibiting the protective immune response. These findings indicate that the parasites may rapidly multiply at the beginning of the infection, leading to a Th2-type immune response (120). Information on regulatory immune responses is lacking for *L. tropica* CL. However, *L. tropica*-infected lesions from Indian patients, the analysis of localized immune response reveals the presence of Th17 and T reg cells (121). Because of the difficulties in establishing infection *in vivo*, published data using animal models for leishmaniasis caused by *L. tropica* is limited (122). Nevertheless, it was suggested that the presence of Tregs in infected tissues may be a possible host immune response or homeostatic mechanism to control *L. tropica* infection and to reduce the excessive inflammation supporting parasite survival through IL-10. Still, additional investigations are needed to clarify this response.

## In *L. braziliensis* infection

The severity of lesions that develop in patients infected by *L. braziliensis* is mainly associated with a highly inflammatory cutaneous environment. In fact, patients with *L. braziliensis* infection exhibit a strong T-helper 1 (Th1) immune response, which leads to excessive inflammation and tissue damage (123). High levels of both IFN- $\gamma$  and TNF- $\alpha$  are observed in CL caused by this species. Still, while IFN- $\gamma$  may have a protective function (124), there is strong evidence to support the role of TNF- $\alpha$  in the pathology of cutaneous and mucosal lesions (125–130). Thiago Cardoso and colleagues (2014) studied the protective and pathological functions of CD8<sup>+</sup> T Cells in *L. braziliensis* infection. The frequency of CD8<sup>+</sup> T cells expressing granzyme in the lesions of severe CL patients is more significant than that in patients during early stage of CL (131). However, cytotoxic CD8 T cells are harmful

to both *L. braziliensis* and infected host cells because cytotoxicity is higher in mucocutaneous leishmaniasis than in the localized form (132, 133). Recently, it has been observed a high proportion of senescent T cells (Tsen) with high inflammatory profiles in *L. braziliensis* lesions with mucosal involvement (134, 135), which is linked to the severity and tissue damage (136). Therefore, *in vivo*, senescent CD8<sup>+</sup> T cells appear to be the most important cell populations mediating skin pathology (137). Other cells, particularly Treg cells, accumulate in lesions caused by *L. braziliensis*, and contribute to the local control of effector T-cell functions (138). Campanelli et al. research suggests that Treg accumulated at the sites of *L. braziliensis* infection may contribute to the local control of effector T cell functions. Still, a direct correlation with the pathogenesis is yet to be detected (138).

## In *L. guyanensis* infection

Little is known about the immune responses induced during human infection with *L. guyanensis*, which generally generates a mixed Th1/Th2/Th17 immune response. IL-13 is the main Th2 cytokine found in *L. guyanensis* LCL lesions, according to research by Bourreau and colleagues. As IL-13 has many similar effects with IL-4 (139), patients with *L. guyanensis* LCL are likely to have a Th2 response that includes the production of either IL-4 or IL-13. However, IL-13 plays a key role in maintaining the Th2 response in Human leishmaniasis by making certain cells resistant to IL-12 (140). In *L. guyanensis* infection, the levels of Foxp3 in the lesions were superior in chronic patients than in acute ones demonstrating the regulatory role of T reg. Furthermore, Tregs isolated from skin biopsy of *L. guyanensis* patients with acute CL had a suppressive effect on CD4<sup>+</sup>T effector (eff) cells. Also, Foxp3 expressions were higher in skin biopsies than in peripheral blood mononuclear cells (PBMC), confirming the recruitment of Tregs to the infection site (141, 142). *L. guyanensis* shows unique characteristics with a mixed immune response (Figures 5, 6), which warrants further investigation to uncover the mechanisms that regulate immune responses and control inflammation caused by this parasite. Recently, a proposed relationship between *Leishmania* RNA Virus (LRV) and the severity of leishmaniasis has been suggested, as various factors are linked to the pathogenicity of the disease (146). Zabala-Peñafiel and colleagues demonstrated that *L. guyanensis* metastatic strains had a higher rate of LRV1 positivity than non-metastatic strains (147). During macrophage infection, it caused over-expression of pro-inflammatory mediators such as TNF- $\alpha$  and IL-6. Ginouvès and colleagues found that 74% of the *Leishmania* (*Viannia*) subgenus clinical isolates in French Guiana contain LRV1, with the majority being *L. braziliensis* and *L. guyanensis*. Patients infected with LRV1-positive *L. guyanensis* have a high ratio of IL-17A and IFN $\gamma$  in their skin lesions (146) (Figure 5). This is accompanied by higher levels of IL-17A in blood cell cultures after stimulation with live parasites, compared to those infected with LRV1-free *L. guyanensis* (148). This demonstrates that virus infection can exacerbate atypical tegumentary leishmaniasis caused by *L. guyanensis*. These findings suggest that the presence of LRV1 in the parasites not only increases the risk of developing

**FIGURE 5**  
The *in situ* immune response against *L. guyanensis* contains a dsRNA virus called (LRV-1). The response to the virus is mediated by TLR 3 in the endosomal macrophage compartment, where the parasite lives and divides. A hypothesis is that after the infection, the viral RNA is released after parasite death and binds to TLR-3 (143), promoting pro-inflammatory cytokines and chemokines production such as IL-6, TNF-α, CXCL-10, and CCL-5 and controlling the severity of the disease (144). Generally, *L. guyanensis* infection induces a mixed Th1/Th2/Th17 immune response. Th-17 cells appear to predominate in lesions in the presence of *Leishmania* RNA with high production of IL17-A. TGF-β is essential for establishing infection and, together with IL-10, leads to therapeutic failures and increased disease severity. The stimulation of TLR3 results in the downregulating of IFN-γ receptor expression, reducing macrophage activation, which explains the high level of IFN-γ observed in lesions produced by Th-1. Indeed, via Akt (Protein kinase B) signaling, TLR3 activation by LRV1 promoted parasite persistence (145). Altogether, it enhances inflammation and thus exacerbates disease.

Comparison between the *in situ* immune profiles in lesions of patients infected with the five *Leishmania* species (*L. major*, *L. infantum*, *L. tropica*, *L. guyanensis*, *L. braziliensis*) and the implication for pathogenesis and the control of the diseases.

ML but also causes complications in CL. Contradictorily, in a study conducted by Ginouvès et al., no correlation was found between the presence of LRV1 or its genotypes in *L. guyanensis* parasites and treatment failure, either after the first or second course of treatment of pentamidine (149). Additional research is required to assess a possible link between LRV1-infected parasites and their clinical symptoms.

## Conclusion

The outcome of *Leishmania* infection relies on the intricate equilibrium of pro- and anti-inflammatory immune responses generated by the host. Both innate and adaptive immunity are inextricably linked to each other as the cytokines produced by cells of the innate system determine the outcome and magnitude of the adaptive immune response. Therefore, the immune responses need to be tightly regulated to avoid immune-mediated pathology to host tissue. Here, we have highlighted recent progress made in understanding the immune response to cutaneous leishmaniasis caused by *Leishmania major*, *L. tropica*, and *L. infantum* in North Africa on the one hand, and by *L. guyanensis* and *L. braziliensis* in French Guiana on the other hand. If cellular and cytokines are released in the lesion during OW-CL, much remains to be known in NW-CL. Indeed, this review could significantly contribute to understanding local immune parameters that control and protect the pathogenesis during *Leishmania* infection. However, a better knowledge of the local immune response in Human CL may help to identify new mechanisms and targets to develop new and more adapted treatments. New local therapies for cutaneous leishmaniasis in NA, French Guiana, and all endemic countries are urgently needed. Drug development is considered a priority, as most current treatments are based on expensive drugs or potential side effects. The cost of anti-Leishmanial drugs is a crucial issue in low-income countries. Besides, therapeutic failures remain frequent, and cases of unresolved CL are often reported, possibly because all current drugs only target the parasite, not the host responses. This review demonstrates how these responses can shape the clinical lesions and lead to different forms. Research efforts should focus on testing immunotherapies that could reduce the severity of pathology seen in some cases of cutaneous leishmaniasis, which could consecutively lessen the duration of antiparasitic courses and their toxicity. In the last decade, several drugs have been developed for other skin inflammatory diseases or as immunotherapy for skin cancers. Some of these drugs inhibit IL-4 or cytotoxicity and might be helpful in combination with existing anti-parasitic drugs. Anti-IL 4 drugs could be useful for all species of *Leishmania*, while specific inhibitors of IL-13 and IL-17 could be used to dampen tissue damage in *L. guyanensis* infections (Figure 6). Dupilumab is currently used in atopic dermatitis both for its IL-4 and IL-13 effects and could be tested in association

with antiparasitic drugs. Other candidates could include anti-IL17 used for inflammatory skin diseases, such as secukinumab, brodalimumab or ixekizumab. Furthermore, skin dysbiosis has been shown to drive the inflammatory response in *L. major* infected germ-free mice model (150). These observations emphasize the need to explore mechanisms by which skin microbiota is involved in the physiopathology of CL. In our opinion, it is essential that these advances in the role of microbiota should be included in the research for the development of new drugs and vaccines against CL.

## Author contributions

SP designed, revised, and supervised the work. NS reviewed the literature, created the figures, and wrote the manuscript. RB, GP, KA, MD, PC, AB participated in the manuscript's analysis, drafting, and revising. All authors revised and approved the manuscript's final version.

## Funding

This work was supported by LabEx PARAFRAP ANR-11-LABX-0024i and MALTOX FEDER CTG Guyane.

## Acknowledgments

We wish to thank all the authors who have participated in this Research Topic and the reviewers for their insightful comments and suggestions. NS was funded by the Federation of African Immunological Societies (FAIS) Legacy Project (FLP), 2019, and the High-level scientific stays (SSHN) grant from the Minister of Europe and foreign affairs France, 2020.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

**Introduction:** The risk of progression to tuberculosis disease is highest within the first year after *M. tuberculosis* infection (TBI). We hypothesize that people with newly acquired TBI have a unique cytokine/chemokine profile that could be used as a potential biomarker.

**Methods:** We evaluated socio-demographic variables and 18 cytokines/chemokines in plasma samples from a cohort of people deprived of liberty (PDL) in two Colombian prisons: 47 people diagnosed with pulmonary TB, 24 with new TBI, and 47 non-infected individuals. We performed a multinomial regression to identify the immune parameters that differentiate the groups.

**Results:** The concentration of immune parameters changed over time and was affected by the time of incarceration. The concentration of sCD14, IL-18 and IP-10 differed between individuals with new TBI and short and long times of incarceration. Among people with short incarceration, high concentrations of MIP-3 $\alpha$  were associated with a higher risk of a new TBI, and higher concentrations of Eotaxin were associated with a lower risk of a new TBI. Higher concentrations of sCD14 and TNF- $\alpha$  were associated with a higher risk of TB disease, and higher concentrations of IL-18 and MCP-1 were associated with a lower risk of TB disease.

**Conclusions:** There were cytokines/chemokines associated with new TBI and TB disease. However, the concentration of immune mediators varies by the time of incarceration among people with new TBI. Further studies should evaluate the changes of these and other cytokines/chemokines over time to understand the immune mechanisms across the spectrum of TB.

## KEYWORDS

tuberculosis infection, TST conversion, *Mycobacterium tuberculosis*, cytokines, chemokines, tuberculosis

# 1 Introduction

To reduce the burden of Tuberculosis (TB) worldwide, two key components will be necessary: 1) prevention of new TB infection (TBI) and 2) prevention of the progression from TBI to TB disease (1). The global prevalence of TBI is 24.8% (95% CI: 19.7–30.0%) and 21.2% (95% CI: 17.9–24.4%) based on the results of the interferon-gamma release assays (IGRAs) and tuberculin skin test (TST), respectively (2). Prevalence among people who are at higher risk for TBI, including people deprived of liberty (PDL), is generally higher than the community at large in the same geographic location and can be as high as 88.8% (3).

Control of the progression to TB disease relies on accurate TBI diagnosis. However, this is one of the significant challenges in the path toward TB elimination. The main limitations of current tests (TST and IGRAs) are their inability to distinguish between TBI and TB disease or to predict TB progression to active disease (4–8). Despite numerous articles reporting immune markers associated with TBI and TB disease, there is high heterogeneity in the design, participant selection, sample processing (including the stimulation protocols), measured markers and analysis that limits comparing study results (9).

TB disease occurs most frequently among people newly infected with TB, mainly within the first year of acquiring mycobacterial infection (10). Identifying and prioritizing those with new TBI within the first year of mycobacterial infection to offer TBI treatment could be an effective measure to decrease TB transmission.

This study focused on incarcerated population because of the high risk of exposure to TB and progress to TB disease (11). We analyzed data and samples collected from two prisons where we have previously shown high rates of TB infection and disease (12, 13). This study aimed to determine the plasma concentration of 18 cytokines/chemokines associated with the presence of new *Mycobacterium tuberculosis* (MTB) infection and compare it with the concentration among people with pulmonary TB diagnosis and exposed but uninfected people.

# 2 Methods

## 2.1 Ethics statement

Approval for the study was obtained from the Ethics Committees of the Universidad Pontificia Bolivariana and the University of Manitoba. The Instituto Nacional Penitenciario y Carcelario (INPEC) and the director of each prison approved the project. In all cases, written consent forms were explained and signed in the presence of two witnesses (always people deprived of liberty -PDL).

## 2.2 Study design, settings, and population

This cohort study was conducted in Colombia between September 2016 and December 2018 in two medium and high-security men's prisons. According to the inclusion criteria, the cohort included 124 PDL with a negative two-step TST at

enrolment (Supplementary Material 1). Complete information related to the protocol, procedures, eligibility, recruitment, follow-up and epidemiological data for this cohort study has been published elsewhere (13).

During the cohort study, the TBI incidence rates varied between 2,402.88 cases per 100,000 person-months (95% CI 1,364.62 - 4,231.10) in PDL with short time of incarceration to 419.66 issues per 100,000 person-months (95% CI 225.80 - 779.95) in individuals with a long time of incarceration (13). For this reason, the cohort was divided into two subgroups: 64 “PDL with short incarceration” for those who were enrolled in follow-up upon incarceration or within the first three months of incarceration, and 60 “PDL with long incarceration” for people who started their follow-up after one year or more of imprisonment.

The primary outcome in the cohort was a new TBI (documented TST conversion). In the end, there were 25 new TBIs among 124 people with a negative two-step TST at enrolment. Thirteen out of 25 were people with short incarceration, and 12/25 new TBIs were people with long incarceration. Ninety-nine individuals remained TST negative after the follow-up. Supplementary Material 1 has information about the new TBI diagnosis criteria.

In addition, we included 51 of 88 (57.95%) people with a new pulmonary TB diagnosis during the study period. The prison healthcare system performed the microbiological diagnoses, and we also collected sputum samples to confirm *Mycobacterium tuberculosis*. People were invited to participate in the study after the TB diagnosis. Supplementary Material 1 describes the eligibility criteria and the TB diagnosis.

## 2.3 Procedures

### 2.3.1 Data collection

The socio-demographic data were collected from all individuals at baseline: age; history and time of prior incarceration; use of drugs (inhaled, injected, or smoked), smoking, and alcohol consumption; comorbidities (chronic obstructive pulmonary disease, diabetes, chronic kidney disease, HIV, and any other immunosuppressive condition); contact with a person diagnosed with TB disease (outside and inside the prison); history of prior TB, including date of the last episode, and outcome; weight and height. To determine previous exposure to the BCG vaccine, the field team sought the presence of the BCG scar.

### 2.3.2 Blood sample collection

All PDL included in the study provided blood samples at baseline and every three months during their follow-up. The samples were collected in sodium heparin tubes, and plasma was separated and stored at -80°C until processing.

We processed 148 samples as follows: a) 58 samples of PDL with a new TBI (21 samples at baseline, 18 at pre-conversion [3 months before TST conversion], and 19 at the time of TST conversion); b) 43 samples of PDL of the last follow-up available among people that remain TST negative and had the longest follow-ups; c) and 47 samples at baseline of people diagnosed with TB disease (Figure 1).

We excluded 4/51 participants diagnosed with TB because 3 had HIV co-infection, and one did not have a plasma sample at baseline.

### 2.3.3 Cytokines and chemokine selection and detection

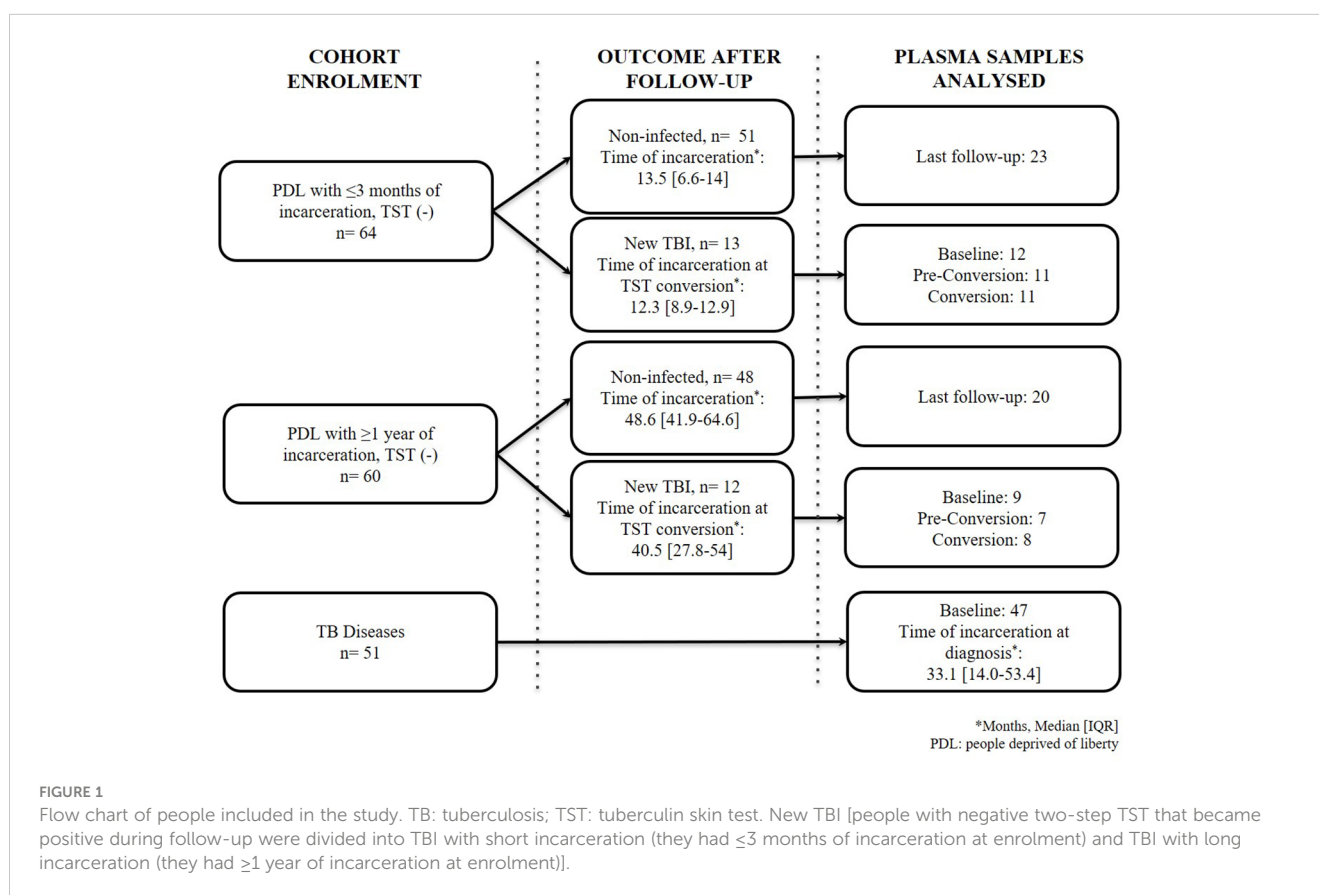

The cytokines/chemokines quantified in the study were selected based on: 1) a systematic review we conducted to identify the relevant cytokines/chemokines associated with TBI (14), 2) published reviews about the pathophysiology of *M. tuberculosis* infection (15–17), 3) results from animal models (guinea pig, macaques and mice) (15, 16, 18–20), 4) immune response to intracellular bacteria (21, 22), 5) *M. tuberculosis* pathway (23) (available at: <http://www.genome.jp/kegg/pathway.html>) and 6) our previous results among people diagnosed with TB disease (24).

Commercial multiplex and single bead-based fluorescent assay kits were used to quantify 18 cytokines/chemokines of interest from plasma samples as follows: Macrophage Inflammatory Protein 3 $\alpha$  (MIP-3 $\alpha$ /CCL20), Human Cytokine/Chemokine magnetic Panel III, Milliplex<sup>®</sup> Map kit; Interleukin 18 (IL-18), Human IL-18 Singleplex Magnetic Bead kit, Milliplex<sup>®</sup> Map kit; soluble CD14 (sCD14), Human Cardiovascular Disease (CVD) Panel 6 Magnetic Bead kit, Milliplex<sup>®</sup> Map kit; Eotaxin 1 (CCL11), Interferon gamma (INF- $\gamma$ ), Interleukin 5 (IL-5), Interleukin 6 (IL-6), Interleukin 10 (IL-10), Interleukin IL-12 p40 homodimer (IL-12[p40]), Interleukin

13 (IL-13), Interleukin 15 (IL-15), Interleukin (IL-17), Interleukin-1 receptor antagonist (IL-1RA), human interferon-inducible protein 10 (CXCL10/IP-10), monocyte chemoattractant protein-1 (CCL2/MCP-1), macrophage inflammatory protein 1 $\alpha$  (CCL3/MIP-1 $\alpha$ ), macrophage inflammatory protein 1 $\beta$  (CCL4/MIP-1 $\beta$ ), Tumor necrosis factor alpha (TNF- $\alpha$ ), Human Cytokine/Chemokine magnetic Bead Panel, Milliplex<sup>®</sup> Map kit, Millipore Corporation, Billerica, MA, USA.

The assays were performed according to the manufacturer's instructions, using 25  $\mu$ l of plasma per sample (5  $\mu$ l to run the sCD14 assay) and overnight incubation. Standards were reconstituted and serially diluted to generate standard curves. Two controls with low and high concentrations, provided by the commercial kit, were included in each assay and considered positive controls for the experiment. Results were analyzed in the BioPlex-200 instrument (Bio-Rad, Mississauga, Canada), reported as mean fluorescence intensity, and converted to pg/ml or ng/ml using the BioPlex<sup>®</sup> Manager version 6.0 (Bio-Rad, Mississauga, ON).

To control for potential biases, all specimens were analyzed, blinded to the clinical status, and longitudinal samples were performed by the same person and analyzed on the same plate. Samples with values outside the standard curve range were assigned a value of one-half of the lower limit of detection (LOD divided by 2) in pg/mL.

## 2.4 Analysis

We used descriptive statistics (median [IQR] and *n* [%]) to report cytokines/chemokines and socio-demographic variables, and chi-squared and Kruskal Wallis tests to evaluate differences between groups. The primary outcome of this study was a new TBI stratified by short and long incarceration.

In individuals with new TBI, we compared the concentration of the immune mediators at baseline, three months before the TST conversion (pre-conversion point) and TST conversion. Wilcoxon test was used to compare the changes in cytokines/chemokines over time. In addition, we used the Mann-Whitney test to compare each follow-up between individuals with a new TBI with short and long times of incarceration.

Then, we compared plasma concentration of cytokines/chemokines in people with new TBI with short and long incarceration to non-infected individuals and people diagnosed with pulmonary TB using the Kruskal-Wallis test. We used multinomial logistic regression to determine the association between each cytokine/chemokine and new TBI with short or long incarceration compared to TB disease and non-infected groups. All cytokines/chemokines were log-transformed to adjust for skewness before the multivariable analysis. Variables included in the final regression model were selected using the biological plausibility criteria, a manual backward elimination method. We adjusted the model by age, BCG scar, contact with a person diagnosed with TB and drug use. All models were adjusted by cluster effect (15 different courtyards in the two prisons).

All analyses were done using STATA® version 14. A two-tailed *p*-value <0.05 was considered significant. Considering the multiple comparisons were made when we evaluated the cytokine concentration between the groups, a *p*-value <0.01 was considered significant, applying the Bonferroni correction.

## 3 Results

### 3.1 Study participants

The median time of TST conversion (new TBI) among the short incarceration group was 12.3 months, and in the new TBI with long incarceration group was 40.5 months (Figure 1). The majority of new TBIs occurred in one prison (75%).

There was no significant difference between groups regarding the mean age (Table 1). Ten individuals in the study had a body mass index  $\leq 18.5$  kg/m<sup>2</sup>, and 9 of them had a TB diagnosis. Individuals diagnosed with TB reported higher consumption of smoked drugs (61.7%) and inhaled drugs (34%) compared to the other groups (*p*  $\leq$  0.001). There was no difference in the frequency of alcohol consumption and tobacco use (*p* > 0.051) (Table 1). Having contact with a person diagnosed with TB was reported in 8.3% of the new TBI group, 34% of people diagnosed with TB, and 19.2% in the non-infected group. Table 1 reports socio-demographic information at baseline.

IL-10, IL-12, IL-13, IL-15, IL-17A, IL-1RA, IL-5, IL-6 and MIP-1 $\alpha$  had more than 40% of the results below the lower detection

limit. We did not see consistent trends of these results within and between groups or by the follow-up time. Therefore, these cytokines/chemokines were excluded from the analysis and results.

### 3.2 The concentration of cytokines/chemokines among the new TBI group is affected by the time of incarceration

Supplementary Material S2 reports the median concentrations of all immune parameters at baseline, pre-conversion and TST conversion by short and long incarceration among the new TBI group.

Our results showed that there were no differences in the concentrations of MIP-3 $\alpha$  (Figure 2A), Eotaxin (Figure 2B), INF- $\gamma$  (Figure 2D) and MIP-1 $\beta$  (Figure 2F). We found higher concentrations of sCD14 at baseline compared to pre-conversion and TST conversion points; the change was more evident in PDL with long incarceration (Figure 2C). PDL with short incarceration showed increased plasma levels of IL-18 at baseline and pre-conversion, compared to the time of TST conversion (Figure 2E). MCP-1 showed an increased concentration over time, with a higher concentration at the time of TST conversion (Figure 2G). We also found that in PDL with short incarceration, IP-10 decreased three months before TST conversion (Figure 2H).

The concentrations of sCD14 (Figure 2C) and IL-18 (Figure 2E) were higher among people with new TBI and short incarceration compared to those with long incarceration (*p* < 0.05). The concentration of IP-10 (Figure 2H) was higher in people with long incarceration.

### 3.3 Cytokines/chemokines concentrations are different between groups

We found higher concentrations of sCD14 and TNF- $\alpha$  among people diagnosed with TB, MIP-3 $\alpha$  among people with new TBI and short incarceration, and IL-18 and MCP-1 among people with new TBI and long incarceration (Table 2). We did not find differences in the concentration of Eotaxin, INF- $\gamma$ , MIP-1 $\beta$ , and IP-10 among the groups (Figures 3B, 3D, 3F, 3H).

The concentration of sCD14 was higher in the TB disease group compared to non-infected individuals and new TBI with long incarceration group (Figure 3C). TNF- $\alpha$  was higher in the TB disease group compared to non-infected individuals (Figure 3I). MIP-3 $\alpha$  was higher in the new TBI with short incarceration compared to the TB disease group (Figure 3A). MCP-1 was higher in the new TBI with long incarceration compared to the TB disease group (Figure 3G). IL-18 (Figure 3E) and MCP-1 (Figure 3G) concentrations were lower in the TB disease group compared to non-infected individuals.

### 3.4 There are cytokines/chemokines associated with a new TBI and TB disease

In the multivariable analysis, only having a BCG scar was associated with decreased risk of a new TBI in people with short

incarceration. The other socio-demographic variables (age, history of having contact with a person diagnosed with TB, and drug use) were not associated with new TBI or TB disease. Although having a BMI of less than 18 kg/m<sup>2</sup> and alcohol consumption were significant factors, the multinomial model did not converge when we included those variables due to the low number of outcomes in the 'yes' category.

In the final multinomial model (Table 3), we identified that higher concentrations of MIP-3 $\alpha$  were associated with a higher risk of a new TBI. The presence of a BCG scar and higher concentrations of Eotaxin were associated with a lower risk of a new TBI among people with short incarceration compared to non-infected individuals.

Higher plasma concentrations of sCD14 and TNF- $\alpha$  were associated with an increased risk of TB disease. Finally, we found that higher concentrations of IL-18 and MCP-1 were associated with

a lower risk of TB disease compared to non-infected individuals (Table 3).

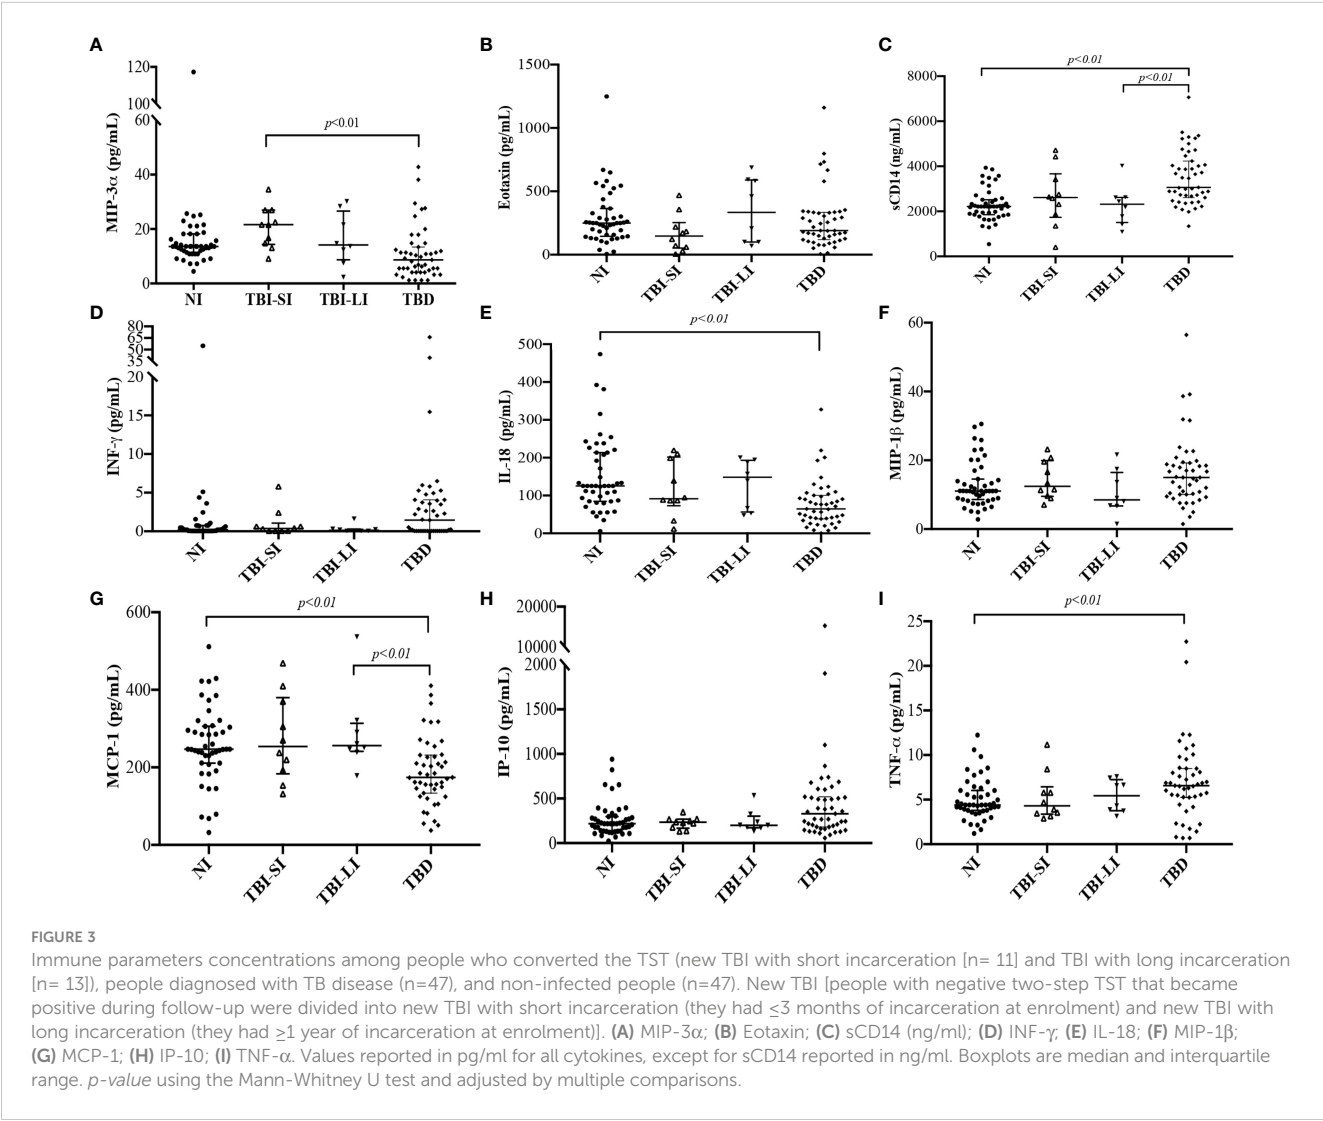

## 4 Discussion

The main results of our study were: 1) the concentration of immune mediators in persons with a new TBI varies according to the time of incarceration (short or long incarceration); and 2) Among people with short incarceration, high concentrations of MIP-3 $\alpha$  were associated with a higher risk of a new TBI, and higher concentrations of Eotaxin was associated with a lower risk of a new TBI. Higher concentrations of sCD14 and TNF- $\alpha$  were associated with a higher risk of TB disease, and higher concentrations of IL-18 and MCP-1 were associated with a lower risk of TB disease.

cRR, crude relative risk \*aRR: adjusted relative risk based on multinomial logistic regression analysis; TB, tuberculosis. New TBI [people with negative two-step TST that became positive during follow-up were divided into TBI with short incarceration (they had  $\leq 3$  months of incarceration at enrolment) and TBI with long incarceration (they had  $\geq 1$  year of incarceration at enrolment)]. All variables included in the multinomial regression model were selected through a manual backward elimination method. \*The bivariable and multivariate models are adjusted by cluster effect (15 courtyards). Variables with statistical significance are shown in bold.

In this study, immune mediators' concentration varied among people newly infected by the time of incarceration. Levels of sCD14 and IL-18 were increased in individuals with short incarceration and IP-10 in those with long incarceration. These variations between people could occur for several reasons: 1) early exposure to *M. tuberculosis* can induce increased macrophage activation, leading to elevated sCD14 concentration. 2) Continuously exposed individuals ( $\geq 1$  year in prison) could eliminate the bacteria repeatedly, owing to an effective immune response. 3) Other factors associated with prison entry include stress, physical activity, or dietary patterns. Several studies have documented changes in the production of pro-inflammatory cytokines when people are under a chronic stressful situation (25), variable levels of physical activity/exercise (26), or when a stress-generating situation is compounded by an infectious process, such as influenza vaccination (27). People deprived of liberty are exposed to acute and chronic stressors, given the social and safety conditions that prevail in prisons in which they live or the changes associated with freedom deprivation (28). In other words- the inflammatory milieu induced by environmental factors related to imprisonment may alter the immune response, thereby increasing the risk of MTB infection (29).

We found that increased circulating levels of MIP-3 $\alpha$  were associated with a higher risk of having new TBI after short incarceration. The MIP-3 $\alpha$ /CCL20 is a dendritic cell, T cell, B cell and monocyte chemoattractant involved in lymphocyte homeostasis and trafficking, cell proliferation and activation (21, 30, 31). Rivero-Lezcano et al. reported that the expression of MIP-3 $\alpha$  increased up to 39-fold when monocytes from healthy donors were infected with *M. tuberculosis* (32), and Lee et al. showed that

MIP-3 $\alpha$  was up-regulated in PBMC and bronchoalveolar lavage fluids from people diagnosed with TB compared to healthy controls after *in vitro* stimulation with the 30 kDa antigen (Ag) of *M. tuberculosis* (33). MIP-3 $\alpha$  concentration in serum/plasma samples is an attractive target for further evaluation in newly acquired MTB infection studies among people with documented recent exposure. In our research, PDL with a new TBI and with short incarceration had lower circulating levels of Eotaxin. Eotaxin has been reported as inhibited after *in vitro* infection by *M. tuberculosis* (34), decreased in people diagnosed with TB disease, and with increasing levels after anti-TB treatment (35).

After adjusting for the other co-variables, individuals with elevated concentrations of MCP-1, a potent chemotactic factor for monocytes (36), had a lower risk of TB disease. In a model of macaques previously vaccinated with BCG, the production of  $\beta$ -chemokine MCP-1 increased in lung lesions of animals after five weeks of infection with MTB (37). These immune molecules are mainly associated with the recruitment of monocytes/macrophages, in keeping with the observation that animals had a higher frequency of macrophages (CD14+ CD68+) in peripheral blood three weeks post-infection with MTB (37). In this case, the increase in cells and  $\beta$ -chemokines may be a sign of the recruitment of these cells from peripheral blood to the site of infection in the lung. Our results show that the concentrations of MCP-1 were lower among the TB disease group compared to non-infected individuals; however, most reports about this chemokine have shown increased concentration among people diagnosed with TB (38, 39). Results may be different because of stimulation with mycobacterial antigens or the absence of stimulation in whole blood samples. Increased concentrations of MCP-1 have been reported in stimulated samples from individuals

diagnosed with active TB, but higher concentrations in unstimulated samples among non-infected individuals compared to individuals diagnosed with TB (40). Some additional explanations for those differences between the studies are the ancestry of the population, the specimen (serum, whole blood, or supernatants of cultured PBMC), and the presence of genetic polymorphisms regulating IL-18 or MCP-1 production (41) in the populations, which could alter the final structure, concentration, or function of the protein.

We also found that higher concentrations of sCD14 and TNF- $\alpha$  were associated with a higher risk of TB disease. These immune mediators are highly involved in monocyte/macrophage activation and trafficking pathways (42, 43). Macrophages are the main niche for the growth and survival of *M. tuberculosis* (44); likewise, macrophages are the most important cells for infection control in animal and human models and critical cells in the host response during active disease (44–46) trying to limit the systemic spread of mycobacteria (47). Soluble CD14, whose membrane-bound portion is highly expressed in these cells, is a mediator of macrophage activation and serves as a receptor for mycobacterial lipoarabinomannan (43). It has been reported among people diagnosed with TB disease (48, 49), with or without concurrent HIV infection (47, 50), and individuals with diabetes mellitus (51). A published article by Lawn SD et al. suggests that sCD14 might increase the concentration of TNF- $\alpha$  due to the high load of mycobacterial antigens among people living with HIV and co-infected with TB disease (47). In our study, people diagnosed with TB had higher plasma concentrations of TNF- $\alpha$ , presumably contributing to cell recruitment, the production of other pro-inflammatory cytokines, and apoptosis of MTB-infected cells (52). Similar to our study, TNF- $\alpha$  has been reported to be increased in adults (49, 53–56) and children (57) diagnosed with TB disease.

Our findings show lower concentrations of IL-18 and MCP-1 among the TB group compared to non-infected individuals. Other researchers have shown that *M. tuberculosis*-stimulated culture supernatants from people diagnosed with TB have lower concentrations of IL-18 compared to those from healthy TST converters (58). IL-18 has an important function in TB as a pro-inflammatory cytokine (59); it plays an important role in the T-cell-helper type 1 (Th1) response, primarily by its ability to induce IFN- $\gamma$  production in T cells and natural killer (NK) cells (60) and in combination with IL-12 triggers the antimicrobial protein cathelicidin and autophagy, resulting in inhibition of intracellular mycobacteria in macrophages and lung epithelial cells (61). Still, studies in humans are not conclusive. For example, Yamada G et al. (62) showed that increased serum IL-18 concentrations were associated with TB disease compared to healthy individuals (including TST converters).

Future studies are needed to validate and complement our cytokine and chemokine findings.

We did not find associations between IP-10, IL-17, IL-10, and a new TBI (the first one was not different between groups, and the latter two had concentrations below the lower detection limit), contrary to other publications (63, 64). This discrepancy may be attributed to the measurement of immune mediators after mycobacterial antigen and mitogen stimulation in prior studies

(53, 56, 65–75), in contrast to the unstimulated measurements in our study. In the case of IL-17, there are six members in the IL-17 family, including IL-17A, IL-17B, IL-17C, IL-17D, IL-17E, and IL-17F (76, 77). Our study only measured IL-17A. Therefore, it is possible that other not measured subunits, such as IL-17F, were increased in plasma samples. In the same way, IL-17 is described as essential in the lung during recent infection (60). Still, perhaps blood sampling in the context of recent infection may have contributed to the reduced systemic level of IL-17.

Another reason for discrepant results may be that individuals included in other longitudinal studies were evaluated with only one TST administration, and those with a negative TST may represent a false negative result (61). In our previous studies, a second administration of TST identified an additional 11.6% positive TST individuals (78).

Our study's most crucial distinguishing feature is the study design (cohort). In cross-sectional studies, the duration an individual has had TBI cannot be quantified. The main limitation of a cross-sectional approach is that human and primate studies have demonstrated there is a spectrum of TB stages (5, 6, 79, 80), on which there is little published work (4, 6), and that potentially could alter the concentration of the immune parameters according to the stage of the infection. The cohort design allowed us to quantify the concentration of cytokines at a temporal point close to the time of infection (new infection) and identify individuals in whom infection occurred recently. Borgstrom WE et al., using mathematical models and CD4+ T-cell flow-cytometry data, showed that the most specific prediction of recent TBI was a high proliferative CD4+ response to CFP-10 and PPD, and a low response to ESAT-6 at  $\leq 1$  month after exposure (81).

Our study has other strengths: rigorous selection criteria among people diagnosed with TB, including only those with microbiological confirmation and with less than 15 days of treatment, rule out of booster effect, and rigorous monitoring and follow-up every three months to all uninfected participants.

The main limitation of this study is that some bacterial factors may modify the response to cytokines, such as the virulence of some strains; however, in people with TBI, it is not feasible to isolate the mycobacterium, and therefore the role of MTB strain cannot be assessed yet.

## 5 Conclusion

Our study found that immune markers vary according to the time of incarceration. Among people with short incarceration, high concentrations of MIP-3 $\alpha$  were associated with a higher risk of a new TBI, and higher concentrations of Eotaxin were associated with a lower risk of a new TBI. Higher concentrations of sCD14 and TNF- $\alpha$  were associated with a higher risk of TB disease, and higher concentrations of IL-18 and MCP-1 were associated with a lower risk of TB disease. It is necessary to have more cohort studies that evaluate the changes over time of these and other cytokines/chemokines to understand the immune mechanisms across the spectrum of TB.

## Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## Ethics statement

The studies involving human participants were reviewed and approved by Ethics Committees of the Universidad Pontificia Bolivariana and the University of Manitoba. The patients/participants provided their written informed consent to participate in this study.

## Author contributions

Substantial contributions to the conception or design of the work: MH, YK, ZR. Acquisition of data: MH. Analysis and interpretation of data: MH, YK, LL, DM, ZR. Drafting the article and revising it critically for important intellectual content: MH, YK, LV, PM, ZR. Final approval of the version to be published: MH, YK, LV, LL, DM, PM, ZR. Agreement to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved: MH, YK, LL, DM, LV, PM, ZR. Principal investigator and funding acquisition: ZVR. All authors contributed to the article and approved the submitted version.

## Funding

This article (the design of the study, the collection, analysis, and interpretation of data) was funded by The Administrative Department of Science, Technology and Innovation (Colciencias), as part of the research project entitled “Host gene expression profile used to identify latent TB infection and the transition to active disease - Perfil de la expresión génica del hospedero para identificar tuberculosis latente y la transición a enfermedad activa”, grant number: 121071249878. And the project “Pro-inflammatory patterns of cytokine/chemokine associated with latent tuberculosis

in people deprived of liberty (PDL),” grant number: 639B-06/16-55, funded by Universidad Pontificia Bolivariana. The Administrative Department of Science, Technology and Innovation (Colciencias), scholarship program #647 in Colombia, and Emerging Leaders of Americas Program, 2018, a scholarship from the Government of Canada support the Ph.D. student. This manuscript was also supported, in part, by the Canada Research Chairs Program for ZR. Award number: 950-232963.

## Acknowledgments

The authors are grateful to all of the PDL who accepted to participate in the study, to INPEC (Instituto Nacional Penitenciario y Carcelario de Colombia), and to the director of each prison and all personnel working there for their support in performing the study.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Publisher's note

All claims expressed in this article are solely those of the authors and do not necessarily represent those of their affiliated organizations, or those of the publisher, the editors and the reviewers. Any product that may be evaluated in this article, or claim that may be made by its manufacturer, is not guaranteed or endorsed by the publisher.

## Supplementary material

The Supplementary Material for this article can be found online at: <https://www.frontiersin.org/articles/10.3389/fimmu.2023.1129398/full#supplementary-material>

*Francisella tularensis* is the etiological agent of the potentially severe infection tularemia. An existing *F. tularensis* vaccine, the live vaccine strain (LVS), has been used to protect at-risk personnel, but it is not licensed in any country and it has limited efficacy. Therefore, there is a need of a new, efficacious vaccine. The aim of the study was to perform a detailed analysis of the characteristics of the human immune response to *F. tularensis*, since this will generate crucial knowledge required to develop new vaccine candidates. Nine individuals were administered the LVS vaccine and peripheral blood mononuclear cells (PBMC) were collected before and at four time points up to one year after vaccination. The properties of the PBMC were characterized by flow cytometry analysis of surface markers and intracellular cytokine staining. In addition, the cytokine content of supernatants from *F. tularensis*-infected PBMC cultures was determined and the protective properties of the supernatants investigated by adding them to cultures with infected monocyte-derived macrophages (MDM). Unlike before vaccination, PBMC collected at all four time points after vaccination demonstrated *F. tularensis*-specific cell proliferation, cytokine secretion and cytokine-expressing memory cells. A majority of 17 cytokines were secreted at higher levels by PBMC collected at all time points after vaccination than before vaccination. A discriminative analysis based on IFN- $\gamma$  and IL-13 secretion correctly classified samples obtained before and after vaccination. Increased expression of IFN- $\gamma$ , IL-2, and MIP-1 $\beta$  were observed at all time points after vaccination vs. before vaccination and the most significant changes occurred among the CD4 transient memory, CD8 effector memory, and CD8 transient memory T-cell populations. Growth restriction of the highly virulent *F. tularensis* strain SCHU S4 in MDM was conferred by supernatants and protection correlated to levels of IFN- $\gamma$ , IL-2, TNF, and IL-17. The findings demonstrate that *F. tularensis* vaccination induces long-term T-cell reactivity, including T<sub>EM</sub> and T<sub>TM</sub> cell populations. Individual cytokine levels correlated with the degree of protection conferred by the supernatants. Identification of such memory T cells and effector mechanisms provide an improved understanding of the protective mechanisms against *F. tularensis*.

## KEYWORDS

*F. tularensis*, vaccination, immune response, memory cells, human correlates of protection

## Introduction

Tularemia is a disease caused by *Francisella tularensis* that affects many animal species as well as humans. The most severe form of tularemia in humans, with high mortality if untreated, is due to inhalation of *F. tularensis* subspecies *tularensis* (type A) (1). The vaccine against *F. tularensis*, a live vaccine of the less virulent subspecies *holarctica* (LVS), offers limited protection against this form of tularemia (2). Moreover, since the knowledge regarding the attenuation of LVS is incomplete, the vaccine is not licensed in any country. Tularemia is widespread over the Northern Hemisphere with local, unpredictable outbreaks, although rather uncommon in many countries (1). The highest total number of cases has been reported in Sweden, Finland, Turkey, Hungary, and Czech Republic. In these countries, as well as in other European countries, there are very marked annual and seasonal variations (3, 4). Although not a threat to the public health in most countries, there are endemic areas in, for example, Sweden and Finland with persistent high incidences, and in these areas, an efficacious vaccine would be of much value. In addition, there are at-risk groups that would benefit from vaccination, for example, clinical laboratory personnel and individuals regularly working outdoors, such as farmers.

*F. tularensis* is classified as a Category A Select Agent, due to its ease of spread by aerosol, extremely low infectious dose, and potential to cause severe morbidity and mortality, therefore considered to have the potential to pose a severe threat to public health and safety (1). The high virulence of *F. tularensis* relies on its ability to proliferate in many different cell types, including macrophages (5). As a consequence, a Th1-dependent cellular immune response is evoked to protect against the bacterium (6, 7). Detailed analysis of the characteristics of the immune response to *F. tularensis* has been performed by *in vivo* and *in vitro* studies, mostly using mice and rats, but also *ex vivo* studies using human cells (8–14). The efficacy of new vaccine candidates has been tested in mice, rats, and non-human primates, but human clinical trials are unlikely due to the low incidence and unpredictability of tularemia (7, 15). Thus, our knowledge regarding the human immune response to *F. tularensis* is based mostly on *ex vivo* studies of peripheral blood mononuclear cells (PBMCs) derived from immune individuals.

Studies of vaccine-mediated immune responses have demonstrated that there is an initial phase of rapid proliferation and expansion of antigen-specific T-cell clones and a majority of circulating T cells are antigen-specific. Subsequently, the responding cells contract and form a much smaller memory immune population (16). Experimental models have also demonstrated that the specificities of the T-cell responses are complex and composed of distinct epitope specificities with hierarchies of dominant, subdominant, and cryptic responses (17). The immunospecific T cells are characterized by their expression of surface receptors and markers, which are believed to identify the T-cell differentiation stage. However, the division of T-cell subpopulations into naïve, memory effector, and memory immunity T cells may not be unequivocal, since there is evidence that the expression of surface receptors and markers and their

correlation to effector properties may vary between different infections and vaccinations (18, 19). This indicates that studies of specific infection models are necessary to identify the pathogen-specific T cells that constitute the long-term memory as well as those that effectuate the anti-microbial responses. By combining data on the specificities of responding T cells with characterization of their phenotypes, it will be possible to delineate the responsible subpopulations and to determine their reactivity.

In addition to vaccine-specific variations in the memory immune responses, there is always heterogeneity due to individual variation and some individuals may not mount an effective immune response to certain vaccines (18). Such differences can be utilized to understand what best protects against a given pathogen. The present study analyzed development of memory T cells and cytokine responses before and after *F. tularensis* vaccination. Furthermore, it was assessed how such variation affected the protective efficacy by analyzing the ability of supernatants collected from recall-stimulated PBMC to provide control of *F. tularensis* in monocyte cultures. Thereby, it was possible to identify cytokines and memory cells of importance for protection against highly virulent strains of *F. tularensis*.

## Materials and methods

### Vaccination

All individuals were vaccinated the same day with a variant of LVS designated NDBR 101, lot no. 11 (National Drug Company, Philadelphia, PA). The lyophilized material was dissolved in 2.0 ml of sterile H<sub>2</sub>O to a concentration of  $2.4 \times 10^9$  CFU/ml and 20  $\mu$ l was inoculated by scarification in the skin of the upper arm. Ethical approvals for the study were received from the Swedish Ethical Review Authority, 2019-01567 and 2020-01860.

### Preparation of PBMCs from blood

Venous blood was drawn from healthy individuals, five women and four men (22–53 years old at time of vaccination, mean age  $36.3 \pm 12.2$  years) before vaccination and 2, 4, 12, 52, and 104 weeks after vaccination. The blood, approximately 100 ml, was collected in CPT-tubes (BD Biosciences NJ USA) and PBMCs were prepared according to the manufacturer's protocol. Purified PBMC was suspended in human serum (HS) (Innovative research, MI, USA) containing 10% DMSO (Sigma Aldrich, MO, USA) and aliquoted into cryovials, which was placed in a Cryo 1°C Freezing Container (NALGENE, NY, USA) at  $-80^\circ\text{C}$  overnight before transferred into liquid nitrogen.

### Recall stimulation PBMC

Cryovials with PBMC were thawed in a  $37^\circ\text{C}$  water bath and transferred to 20 ml of RPMI medium 1640 + GlutaMAX (RPMI), (Gibco, MA USA). The PBMC was collected by centrifugation at  $200 \times g$  for 10 min, washed with 40 ml of RPMI, and suspended in 1 ml

of RPMI + 10% HS + 10 µg/ml Gentamicin (complete RPMI). After resting at 37°C in 5% CO<sub>2</sub> for 2 h, the PBMCs were counted and diluted in complete RPMI. For FACS analysis,  $8 \times 10^5$  cells were seeded per well in a round-bottom 96-well plate (Sarstedt, Nümbrecht, Germany). For the Lymphocyte proliferation assay (LPA),  $2 \times 10^5$  cells were seeded per well. To some wells, *Ft* antigen (2.5 µg/ml), prepared from *F. tularensis* LVS as described previously (20) or Concanavalin A (ConA) (2.5 µg/ml), was added (stimulated cells) whereas other wells contained complete RPMI only (resting cells). After 3 days of incubation, 300,000–500,000 cells per sample were collected and analyzed by FACS. From separate wells, supernatants were transferred to a 96-well plate and stored at –80°C until analyzed for cytokine content by multiplex cytokine analysis. For LPA, tritium-thymidine (0.003 mCi/ml) (Perkin Elmer MA USA) was added to the cells, and after 6 h, incorporated thymidine was measured using a 1450 microbeta liquid scintillation & luminescence counter (Trilux Chelmsford UK). All time points from two to three individuals were included in each experiment.

## Flow cytometry analysis of surface markers and intracellular cytokine staining

Cells were collected after 72 h of recall stimulation and treated with 5 µg/ml of Brefeldin A and 5 µg/ml of Monensin for 4 h. Then, cells were centrifuged for 3 min at 500 × g and supernatants were removed. Cells were stained with Aqua Viability Dye (Molecular Probes/Invitrogen) for 20 min in RT and thereafter labeled with conjugated monoclonal antibodies (mAbs) against cell surface markers for 30 min at 4°C. After wash and treatment with perm/wash buffer (BD Biosciences) for 20 min at 4°C, the cells were stained for intracellular cytokines for 30 min at 4°C. The following mAb conjugates were used (BD Biosciences): CD3-APCH7 (clone SK7), CD4-FITC (clone RPA-T4), CD8-PerCPy5.5 (clone SK1), CD45RO-APC (clone UCHL-1), CCR7-PECF594 (clone 2-L1-A), CD28-PE (clone CD28.2), CD95-BUV395 (clone DX2), IFNγ-PeCY7 (clone B27), MIP-1β-AF700 (clone D21-1351), IL2-BV711 (clone 5344.111), and TNF-BV421 (clone MAb11). CD14-V500 (clone M5E2) and CD19-V500 (clone H1B19) were included in the dump channel. PBMCs were acquired using a ZE5 flow cytometer (Bio-Rad) with Everest software (Bio-Rad). Results were analyzed using FlowJo software (BD Biosciences).

## Multiplex cytokine analysis

Supernatants, 50 µl/well, were collected from cultures after 72 h of incubation. The supernatants were stored at –80°C until analyzed using a 17-plex kit (Bio-Rad Laboratories Inc., Hercules, CA, USA, M5000031YV) according to the manufacturer's instructions using a Bio-Plex 200 system (Bio-Rad Laboratories Inc., Hercules, CA, USA).

## Isolation of monocytes and generation of monocyte-derived macrophages

PBMCs,  $15 \times 10^6$  cells, prepared from buffy coat, were seeded in a 9-cm petri dish in 15 ml of complete RPMI. After 2 h, medium

containing non-adherent cells was removed and the adherent cells were washed with 20 ml of 37°C RPMI. The adherent cells were detached by scraping and thereafter transferred to a 50-ml tube, which was centrifuged at 200 × g for 10 min. The cells were suspended in complete RPMI, viable cells were determined using trypan blue exclusion in a TC20 cell counter (Bio-Rad Laboratories Inc, Hercules, CA, USA), and  $1 \times 10^5$  cells were seeded per well in a flat-bottom 96-well culture plate. After overnight incubation at 37°C in 5% of CO<sub>2</sub>, cells were washed and thereafter complete RPMI with 40 ng/ml of GM-CSF was added. After 48 h incubation at 37°C in 5% CO<sub>2</sub>, cells were washed and complete RPMI with 40 ng/ml of GM-CSF was added. Complete RPMI (100 µl) was added to each well after an additional 48 h of incubation.

## Infection of MDMs

SCHU S4, grown overnight on Gc-agar plates, were resuspended in complete RPMI and added to the MDM monolayer at an MOI of 50. After 1 h, cells were washed and complete RPMI with 10 µg/ml of gentamicin was added for 30 min. To some wells, 20-fold diluted supernatant, collected from *Ft*-stimulated PBMCs from respective donor, was added to separate cultures. Complete RPMI was used as diluent. The number of intracellular bacteria was determined after 24 h lysis of the monolayers with 0.1% deoxycholate and spreading of 10-fold serial dilutions of the lysate in PBS on agar plates. Colonies were counted after 3 days of incubation of the plates at 37°C in 5% CO<sub>2</sub>.

## Data analysis and statistical methods

Two-tailed Student's *t*-test was used to identify significant differences ( $p < 0.05$ ) between data sets. To analyze correlations between data sets, Spearman's rank correlation test was used. Cytokine data were used to derive a classifier that enables prediction of vaccination status, i.e., to predict if PBMCs were derived from individuals before vaccination with LVS or derived at 2, 4, 12, or 52 weeks after vaccination. Linear discriminant analysis (LDA), assuming homoscedasticity and no prior, was used to build the classifiers and cross-validation was used to predict the posterior probabilities (21). The LDA analyses were performed using the settings discriminant analysis and stepwise method (Wilks' Lambda) with the criteria of F to enter 3.84 and F to remove 2.71 in the program SPSS version 28. SPSS was also used to perform two-tailed Student's *t*-test and Spearman's rank correlation test.

## Results

### Proliferative responses of PBMCs

PBMCs isolated from nine individuals before vaccination with LVS and 2, 4, 12, and 52 weeks after vaccination were stimulated with *Ft* antigen, ConA, or sham for 3 days. As expected, PBMCs responded to ConA with robust proliferation, whereas non-

stimulated PBMCs showed minor proliferation (Figure 1). The average *Ft*-specific proliferative responses of PBMCs isolated from the nine individuals after vaccination, regardless of time point, were significantly higher than that of PBMCs isolated prior to vaccination ( $p < 0.05$ – $p < 0.001$ , Figure 1). The magnitude of the *Ft*-specific proliferative responses varied among individuals (Figure S1).

In summary, the PBMCs showed robust proliferation to ConA, whereas only PBMCs collected after vaccination proliferated in response to the *Ft* antigen.

## Detection of intracellular cytokines

PBMCs stimulated with the *Ft* antigen for 3 days, or sham-stimulated PBMCs, were analyzed by FACS for intracellular expression of IFN- $\gamma$ , IL-2, MIP-1 $\beta$ , or TNF. In previous studies, these cytokines have been identified to discriminate responses of immune vs. naïve individuals (12, 22). The cells were also stained for cell surface markers, which enabled identification of CD4 and CD8 lymphocytes and of various memory populations thereof (Figures 2, S2, S3 illustrate the gating strategies).

The number of CD4 T cells expressing IFN- $\gamma$  was higher among PBMCs collected 2, 4, 12, and 52 weeks after vaccination, compared to PBMCs collected prior to vaccination ( $p < 0.05$ – $p < 0.01$ , Figure 3A). For the other cytokines, there were no significant differences among the CD4 T cells at any of the time points (Figure 3A). The number of CD8 T cells expressing IFN- $\gamma$ , IL-2, or MIP-1 $\beta$  was higher among PBMCs collected 2, 4, 12, and 52 weeks after vaccination, compared to PBMCs collected prior to vaccination ( $p < 0.01$  or  $p < 0.001$ , Figure 3B). The number of CD4 or CD8 T cells expressing TNF was unchanged before and after

vaccination (Figures 3A, B). When comparing various time points after vaccination, the sole difference identified was a lower number of IFN- $\gamma$ -expressing CD8 T cells at the 52-week time point compared to the 4- and 12-week time points ( $p < 0.01$ , Figure 3B).

Cytokine expression by various T cell memory subpopulations was also analyzed. The most significantly increased expression of cytokines among CD4 T cells was identified in the transient memory ( $T_{TM}$ ) population; IFN- $\gamma$ , IL-2-, and MIP-1 $\beta$ -expressing cells were increased at all time points after vaccination compared to prior to vaccination ( $p < 0.05$ – $p < 0.001$ , Figure 4D). In the CD4 T-cell effector memory ( $T_{EM}$ ) population, cells expressing MIP-1 $\beta$  were increased at all time points after vaccination and cells expressing IFN- $\gamma$  were increased at the 52-week time point after vaccination ( $p < 0.05$ , Figure 4B). The number of CD4 central memory ( $T_{CM}$ ) cells expressing IFN- $\gamma$  or MIP-1 $\beta$  was higher in PBMCs collected 52 weeks after vaccination, but not at the other time points, compared to PBMCs collected prior to vaccination ( $p < 0.05$ , Figure 4A). The number of TNF-positive CD4 T cells was similar before and after vaccination, regardless of memory population (Figures 4A–E). Among the naïve and  $T_{SCM}$  CD4 T cells, the number of cytokine-expressing cells was similar before and after vaccination ( $p > 0.05$ , Figures 4A, E).

In the CD8 T-cell populations, the most significant expression of cytokines was identified in the  $T_{TM}$  and  $T_{EM}$  population; IFN- $\gamma$ , IL-2-, and MIP-1 $\beta$ -expressing cells were increased at all time points after vaccination compared to prior to vaccination ( $p < 0.05$ – $p < 0.001$ , Figures 5B, D). In addition, the number of MIP-1 $\beta$  expressing cells was increased at all time points after vaccination in the  $T_{CM}$  and  $T_{EMRA}$  population, and IFN- $\gamma$ - and IL-2-expressing cells were increased at various time points after vaccination in the  $T_{CM}$  population ( $p < 0.05$ – $p < 0.01$ , Figures 5C, F). The number of TNF-positive CD8 T cells was similar before and after vaccination, regardless of memory population (Figures 5A–F). Among the naïve and  $T_{SCM}$  CD8 T cells, the number of cytokine-expressing cells was similar before and after vaccination ( $p > 0.05$ , Figures 5A, E).

To verify the longevity of the memory cell populations, PBMCs from six individuals were collected 2 years after vaccination and cytokine expression by the T-cell subpopulations was analyzed. As observed at the other four time points after vaccination, CD4  $T_{TM}$ , CD8  $T_{TM}$ , and CD8  $T_{EM}$  cell populations showed increased expression of IFN- $\gamma$ , IL-2, and MIP-1 $\beta$  ( $p < 0.05$ – $p < 0.001$ , Figures S4, S5).

In summary, the CD4  $T_{TM}$ , CD8  $T_{TM}$ , and CD8  $T_{EM}$  populations showed prominently increased expression of IFN- $\gamma$ , IL-2, and MIP-1 $\beta$  in response to vaccination for a period of at least 2 years. Increased TNF expression was not detected in any of the memory populations.

## Analysis of multifunctional cells

The FACS data were subjected to further analysis for the presence of multifunctional cells, i.e., cells simultaneously expressing more than one of the investigated cytokines IL-2, IFN- $\gamma$ , MIP-1 $\beta$ , or TNF. Since their individual expression was significantly increased in the CD8  $T_{TM}$  and CD8  $T_{EM}$  populations, these were the focus of the analysis. Samples collected before vaccination and 2, 4, 12, and 52 weeks after

**FIGURE 1**  
Proliferative responses of PBMCs after recall stimulation with *Ft* antigen. PBMCs collected from nine individuals before vaccination (0) and 2, 4, 12, and 52 weeks after vaccination were cultured in the presence or absence of *Ft* antigen for 3 days. Six hours after addition of tritium-thymidine, incorporation was measured. The proliferative responses of the sham, ConA-stimulated, or *Ft*-stimulated cells are expressed as CPM for each time point. The mean  $\pm$  SEM of triplicate samples from nine individuals are shown for each time point. Asterisks indicate significant differences of the *Ft*-stimulated groups compared to *Ft*-stimulated cells obtained before vaccination, denoted week 0 (\* $P < 0.05$ ; \*\*\* $P < 0.001$ ). There were no significant differences between the time points after vaccination for each of the stimuli.

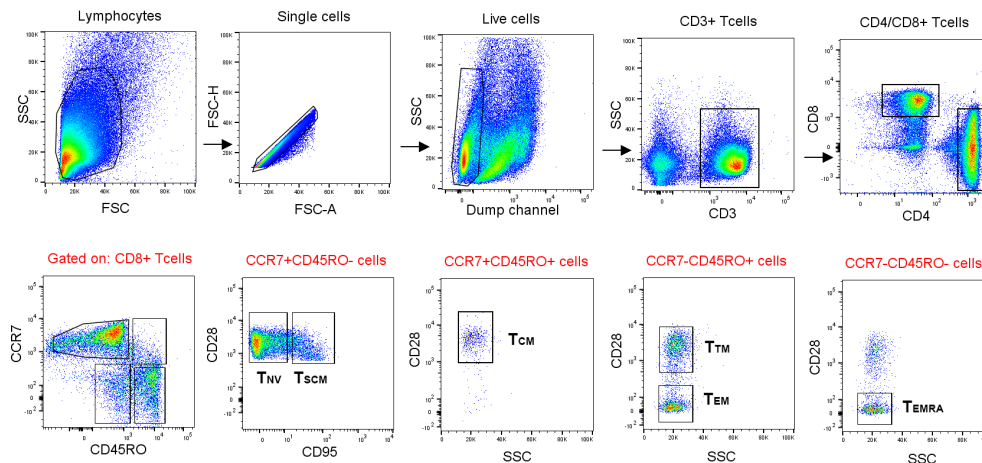

FIGURE 2

Gating strategy used for FACS analysis of memory populations. Lymphocytes were gated based on morphology detected with forward and side scatter, FSC and SSC. After gating for singlets, a gate for CD14<sup>-</sup> and CD19<sup>-</sup> live cells was created. CD4<sup>+</sup> and CD8<sup>+</sup> T cells were gated from CD3<sup>+</sup> T cells. The CD45RO<sup>+</sup>CCR7<sup>+</sup> population were gated into naïve (T<sub>NV</sub>) and stem cell-like memory T cells (T<sub>SCM</sub>) by the expression of CD95. Memory populations [central memory (T<sub>CM</sub>), transitional memory (T<sub>TM</sub>), effector memory (T<sub>EM</sub>), and effector memory RA<sup>+</sup> (T<sub>EMRA</sub>) cells] were further gated according to the positive or negative expression of CD45RO, CCR7, and CD28. Finally, IFN- $\gamma$ , TNF-, MIP-1 $\beta$ -, and IL-2-expressing cells were gated from the naïve and memory populations, respectively.

vaccination were analyzed. There were significant differences for several of the groups with the highest significances ( $p \leq 0.001$ ) among cells expressing IFN- $\gamma$  and MIP-1 $\beta$ , or IFN- $\gamma$ , MIP-1 $\beta$ , and IL-2 (Table S1). These groups were subjected to a *post-hoc* analysis using the Bonferroni *post-hoc* test to identify differences between each of the time points (Table S2). The numbers of CD8 T<sub>TM</sub> and CD8 T<sub>EM</sub> cells expressing IFN- $\gamma$  and MIP-1 $\beta$  were increased at all time points after vaccination compared to before vaccination ( $p < 0.05$ – $p < 0.001$ , Figures 6A, B). CD8 T<sub>EM</sub> cells expressing IFN- $\gamma$ , MIP-1 $\beta$ , and IL-2 were increased up to 12 weeks ( $p < 0.05$ – $0.001$ , Figure 6A). CD8 T<sub>TM</sub> cells expressing IFN- $\gamma$ , MIP-1 $\beta$ , and IL-2 were increased at some of the time points after vaccination ( $p < 0.05$ – $p < 0.001$ , Figure 6B). At the 2-year time point, CD8 T<sub>EM</sub> cells expressing IFN- $\gamma$  and MIP-1 $\beta$ , IL-2 and MIP-1 $\beta$ , or IL-2, IFN- $\gamma$ , and IL-2 were present in higher numbers than in samples collected before vaccination ( $p < 0.001$ , Figure S6).

In summary, CD8 T<sub>TM</sub> and CD8 T<sub>EM</sub> cells co-expressing various combinations of cytokines were increased post vaccination. CD8 T<sub>TM</sub> and CD8 T<sub>EM</sub> cells expressing IFN- $\gamma$  and MIP-1 $\beta$  showed the most consistent increases of cytokine expression. Multifunctional CD8 T<sub>EM</sub> cells were detected up to 2 years after vaccination.

## Detection of secreted cytokines and chemokines by LUMINEX

Supernatants from the *Ft* antigen-stimulated PBMCs collected prior to and after vaccination were analyzed for 17 cytokines, IL-1 $\beta$ , IL-2, IL-4, IL-5, IL-6, IL-7, IL-8, IL-10, IL-12p70, IL-13, IL-17, G-CSF, GM-CSF, IFN- $\gamma$ , MCP-1, MIP-1 $\beta$ , and TNF. As aforementioned, the T<sub>EM</sub> and T<sub>TM</sub> cell populations demonstrated high intracellular expression of IFN- $\gamma$ , IL-2, and MIP-1 $\beta$ , and levels of these cytokines were also high in supernatants from cultures with PBMCs collected at any of the four time points after vaccination ( $p <$

0.01 or  $< 0.001$ , Table 1). In addition, TNF was secreted at high levels in the same cultures ( $p < 0.01$ ). All other cytokines measured, except for IL-10, were secreted at higher levels from PBMCs collected at 52 weeks after vaccination compared to PBMCs collected before vaccination ( $p < 0.05$  or  $p < 0.01$ , Table 1). Most of these cytokines were also secreted at higher levels in cultures with PBMCs collected 2, 4, and 12 weeks after vaccination ( $p < 0.05$  or  $p < 0.01$ , Table 1).

## Determination of vaccination status based on cytokine patterns

Linear discriminant analysis was used to determine whether individual cytokines, or sets of cytokines, could differentiate between each of the five groups: PBMCs collected before vaccination, or collected 2, 4, 12, or 52 weeks after vaccination. Two canonical discriminant functions, based on IL-13 and IFN- $\gamma$ , were used in the analysis (Wilks' Lambda 0.222,  $p < 0.001$ ) and 99.9% of the variance was explained by function 1 (F1). The standardized canonical discriminant function coefficients for IFN- $\gamma$  and IL-13 were 0.804 and 0.787 in F1, respectively, indicating that the two variables contributed similarly to the model. To further illustrate the discriminative ability of the model, the data were plotted by discriminant loading using functions 1 and 2 (Figure 7). The results demonstrate that non-vaccinated individuals were correctly classified in 100% of the cases and therefore visualized as a distinct group in the plot. Importantly, none of the vaccinated individuals was classified as non-vaccinated (Table 2). However, the resolution among the post-vaccination groups was poor (Table 2 and Figure 7). As an example, the profiles of 64.3% of individuals sampled at 52 weeks overlapped with the profiles of individuals sampled at 2 weeks and there was no distinction between individuals sampled at 4 or 12 weeks (Table 2).

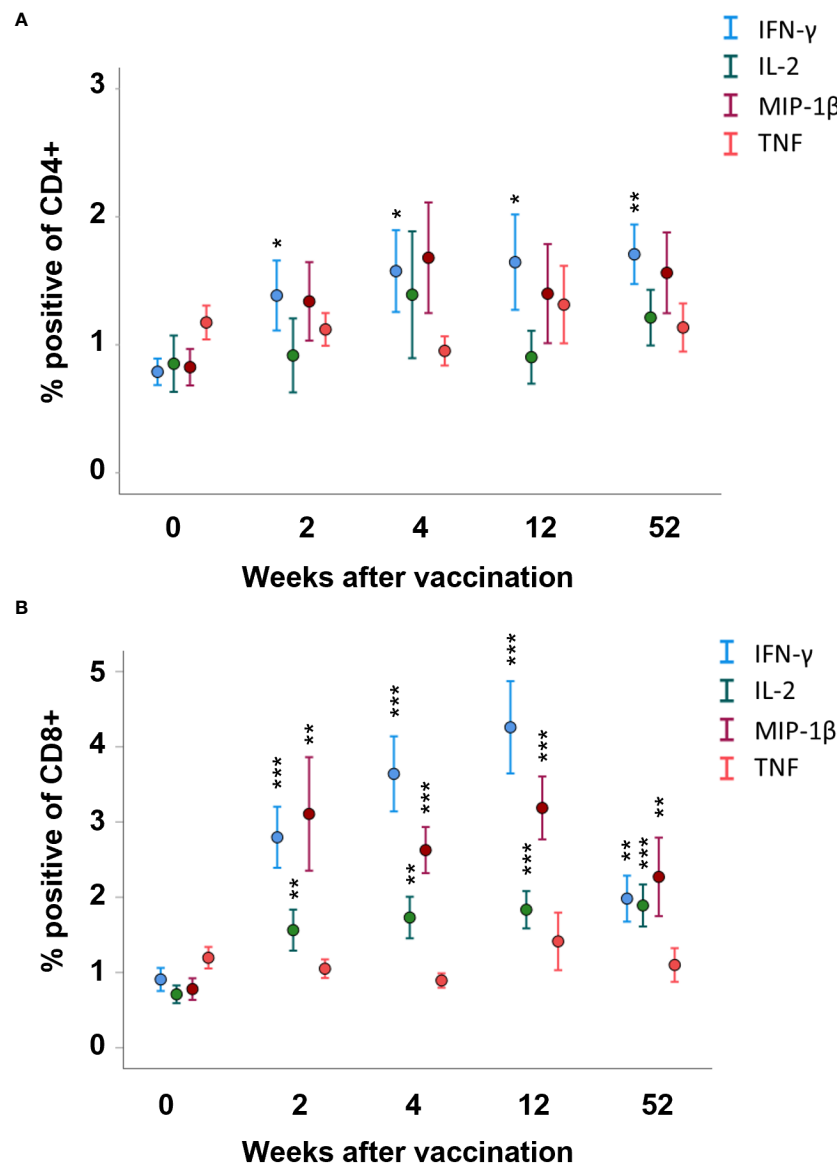

FIGURE 3

FACS analysis of intracellular cytokine expression of the CD4 and CD8 memory populations. PBMCs collected from nine individuals before vaccination (0) and 2, 4, 12, and 52 weeks after vaccination were recall-stimulated with *Ft* antigen for 3 days. The cells were analyzed to identify (A) CD4 and (B) CD8 memory populations for expression of IFN- $\gamma$ , IL-2, MIP-1 $\beta$ , or TNF. The mean  $\pm$  SEM of triplicate samples from nine individuals are shown for each time point and cytokine. Asterisks indicate significant differences of intracellular cytokine expression compared to time point 0. (\* $P < 0.05$ ; \*\* $P < 0.01$ ; \*\*\* $P < 0.001$ ).

In summary, using linear discriminant analysis, a model based on IL-13 and IFN- $\gamma$  correctly predicted if an individual had been vaccinated or not, but failed to separate groups sampled at various time points after vaccination.

## Capacity of supernatants collected from *Ft*-stimulated cells to confer protection

It was tested if the supernatants of stimulated cell cultures could activate monocyte-derived macrophages (MDMs) to control intracellular SCHU S4. Supernatants collected from *Ft*-stimulated cells from individual donors were added at a 20-fold dilution to

cultures at the time of infection with SCHU S4. Concentration of the 17 cytokines in the 20-fold diluted supernatants varied among the individuals (Table S3). After 24 h, growth of SCHU S4 was reduced in all cultures supplemented with supernatants from *Ft* antigen-stimulated PBMCs compared to cultures with supernatants from sham-stimulated PBMCs (Figure 8A). The weakest growth inhibition of SCHU S4, 5-fold, was observed in cultures supplemented with supernatants from donor D129 ( $p < 0.05$ ), and the strongest inhibition, 230-fold, was observed in cultures supplemented with supernatants from donor D135 ( $p < 0.001$ ) (Figure 8A). Supernatants from all donors elicited a significantly better control of SCHU S4 in MDMs compared to recombinant IFN- $\gamma$  ( $p < 0.05$  for 136,  $p < 0.01$  for 129, and  $p < 0.001$  for all other donors, Figure 8A). The

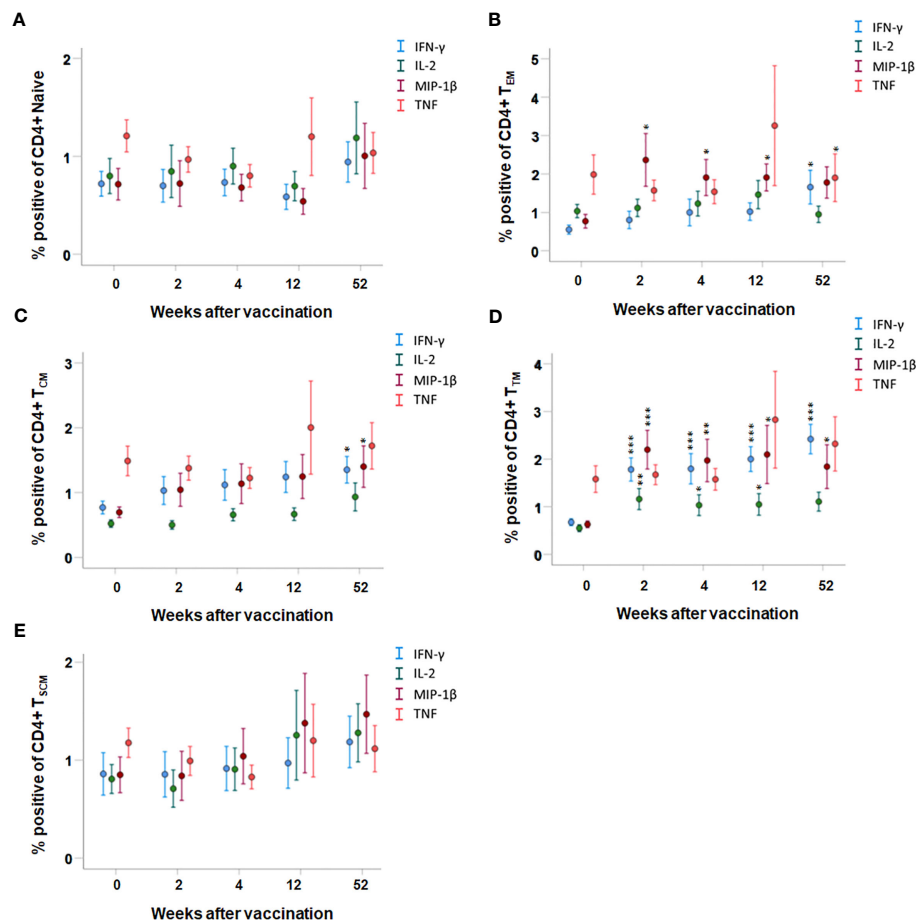

FIGURE 4

FACS analysis of intracellular cytokine expression of CD4 memory subpopulations. PBMCs collected from nine individuals before vaccination (0) and 2, 4, 12, and 52 weeks after vaccination were recall stimulated with *Ft* antigen for 3 days. The cells were stained to detect the following CD4 memory populations: (A) T<sub>Naive</sub>, (B) T<sub>EM</sub>, (C) T<sub>CM</sub>, (D) T<sub>TH1</sub>, and (E) T<sub>TH17</sub> and their expression of IFN- $\gamma$ , IL-2, MIP-1 $\beta$ , or TNF. The mean  $\pm$  SEM of triplicate samples from nine individuals are shown for each time point and cytokine. Asterisks indicate significant differences of intracellular cytokine expression compared to time point 0 (\* $P$  < 0.05; \*\* $P$  < 0.01; \*\*\* $P$  < 0.001). The T<sub>EMRA</sub> subpopulation was not detected in the CD4<sup>+</sup> population.

concentration of recombinant IFN- $\gamma$ , 15 ng/ml, was at least 5-fold higher than the concentration of IFN- $\gamma$  in any of the 20-fold diluted supernatants (Figure 8B). This suggested that the anti-*F. tularensis* effect elicited by IFN- $\gamma$  was potentiated by other cytokines present in the supernatant. Potential candidates were IL-2, IL-7, MIP-1B, and TNF, the levels of which, as of IFN- $\gamma$ , displayed a negative correlation to the number of bacteria in the cultures, i.e., higher concentrations correlated to lower bacterial numbers ( $p$  < 0.05, Table 3). Levels of IL-13 and G-CSF showed a positive correlation to the number of bacteria in the cultures ( $p$  < 0.05, Table 3).

Collectively, cells from vaccinated donors produced a mixture of cytokines in response to stimulation with *Ft* antigen that activated MDMs to control intracellular SCHU S4. The control elicited was significantly better than that conferred by recombinant IFN- $\gamma$ .

## Discussion

T-cell-mediated memory immunity is dependent on a pool of memory cells. The half-life of vaccine-induced immunity is one or

several decades; however, most evidence indicates that individual memory cells may be comparatively short-lived, in the order of months, and therefore the only logical explanation for the persistence of cell-mediated immunity for decades is the sustainability of clonal populations of memory cells (23). This is achieved by balancing proliferation, death, and differentiation rates of the populations. Thus, the cells within the populations confer long-lived memory rather than being long-lived memory cells. The longevity of these clonal populations is generally ill-defined and possibly distinct for a given T-cell population. An improved understanding of how long-term memory immunity is sustained is critical to improve efficacy of vaccines that rely on cell-mediated immunity.

Previously, we demonstrated that T-cell-mediated immune responses to *F. tularensis* may persist many decades after natural infection or vaccination (24). Herein, we elaborate on this finding and describe the cell-mediated immune responses quantitatively and qualitatively during a 1-year period after vaccination with the live vaccine strain of *F. tularensis*. Importantly, the experimental system used is devoid of antibodies; thus, any influence of humoral

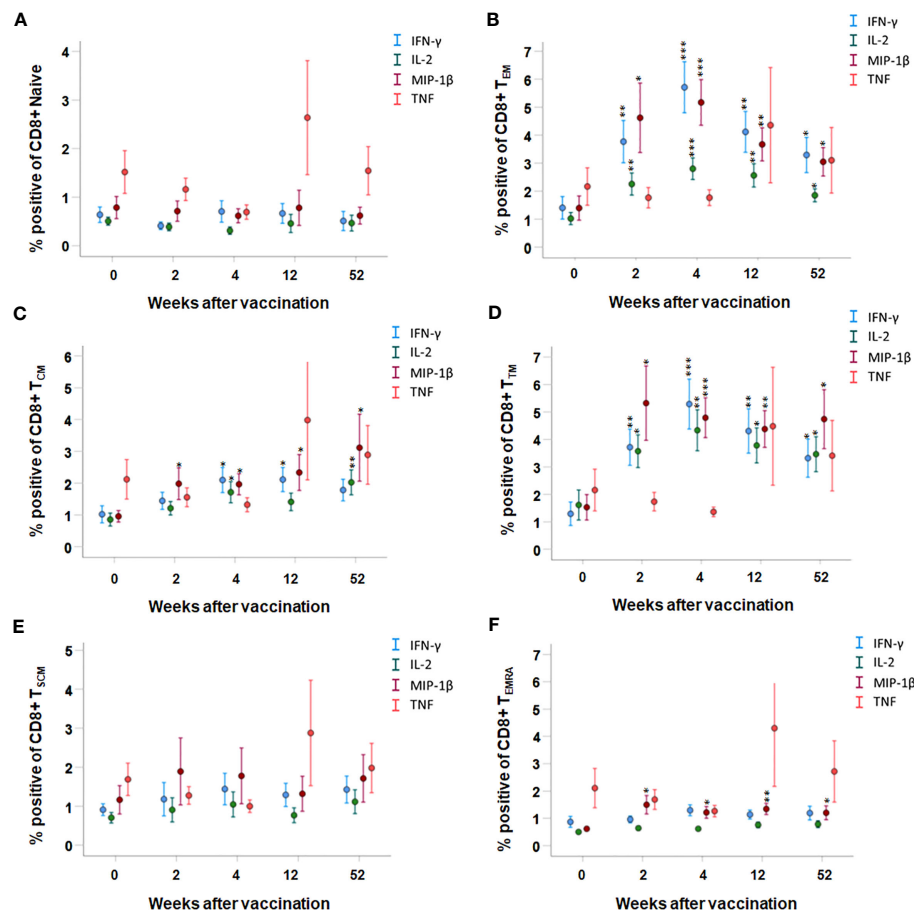

FIGURE 5

FACS analysis of the intracellular cytokine expression of CD8 memory subpopulations. PBMCs collected from nine individuals before vaccination (0) and 2, 4, 12, and 52 weeks after vaccination were recall-stimulated with *Ft* antigen for 3 days. The cells were stained to detect the following CD8 memory populations: (A)  $T_{Naive}$ , (B)  $T_{EM}$ , (C)  $T_{CM}$ , (D)  $T_{TM}$ , and (E)  $T_{SCM}$  and (F)  $T_{TEMRA}$  for their expression of IFN- $\gamma$ , IL-2, MIP-1 $\beta$ , or TNF. The mean  $\pm$  SEM of triplicate samples from nine individuals are shown for each time point and cytokine. Asterisks indicate significant differences of intracellular cytokine expression compared to time point 0. (\* $P < 0.05$ ; \*\* $P < 0.01$ ; \*\*\* $P < 0.001$ ).

immunity can be excluded. Proliferative responses, cytokine secretion, and the intracellular cytokine profiles of CD4 and CD8 cells and memory cell populations were mostly indistinguishable when PBMCs were analyzed at the three early time points after vaccination. However, absolute levels somewhat decreased thereafter, although still significantly increased compared to the responses of the PBMC obtained before vaccination. Antigenic cross-reactivity is unlikely to sustain the longevity since *F. tularensis* is not closely related to other human pathogens (25). Moreover, since tularemia is a rare disease in most regions of the world (26), reexposure is an unlikely reason for the extremely long-lived cell-mediated immunity and, therefore, the data support the notion that natural infection, or vaccination, may result in very long-lasting, persisting for many decades. The narrow immunoreactivity to *F. tularensis* is distinct from that to many other infections due to its antigenic uniqueness and rare occurrence of tularemia. In the case of *F. tularensis*, there is no direct evidence that the long-lasting cell-mediated immunity confers protection against subsequent challenge; however, indirect evidence strongly indicates that this may be the case, since tularemia has been very

rarely recorded in vaccinated individuals and only a handful of cases of reinfection have been reported during the last century (27, 28).

Beyond the characterization of the longevity of the cell-mediated immune responses, we also identified the cytokine profiles indicative of the vaccine-induced immune responses by intracellular staining of the PBMC T-cell populations. A more detailed analysis of subpopulations revealed that CD4 cell expression of intracellular IFN- $\gamma$  was increased after vaccination and sustained for the whole period of 1 year. CD8 cells expressed increased levels of IFN- $\gamma$ , IL-2, and MIP-1 $\beta$  after vaccination. All three cytokines have been identified in our previous studies of human vaccine-mediated immune responses (12, 22). When memory T-cell subpopulations were analyzed, the most nuanced cytokine expression was detected in the CD4  $T_{EM}$  subpopulation with regard to MIP-1 $\beta$  and in the CD4  $T_{TM}$  subpopulation with regard to IFN- $\gamma$ , IL-2, and MIP-1 $\beta$ , since the expression of each of the cytokines was increased at all time points after vaccination. Also, the CD8  $T_{EM}$  and  $T_{TM}$  subpopulations showed increased expression of IFN- $\gamma$ , IL-2, and MIP-1 $\beta$  at all time points. Thus, the

FIGURE 6

Multifunctional memory cell populations. Data were subjected to Boolean gating in order to detect multifunctional memory cell populations. The mean  $\pm$  SEM of triplicate samples from nine individuals are shown for each time point and cytokine combination. Asterisks indicate significant differences of number of cells positive for intracellular cytokine expression compared to time point 0. (\* $P$  < 0.05; \*\* $P$  < 0.01; \*\*\* $P$  < 0.001).

findings corroborate previously published data regarding the relevance of these cytokines in the memory immune response against *F. tularensis* after vaccination and demonstrate that the T<sub>EM</sub> and T<sub>TM</sub> populations exhibit the most diversified cytokine expression.

The identification of the CD4 T<sub>TM</sub> and CD8 T<sub>EM</sub> and T<sub>TM</sub> subpopulations as the predominant reservoirs for cytokine secretion was not entirely surprising. The T<sub>EM</sub> subpopulation is known to rapidly upregulate effector functions and to also express homing receptors for migration to nonlymphoid sites of inflammation and to possess high levels of gut-homing molecules and chemokine receptors (29). T<sub>TM</sub> cells display an intermediate phenotype between T<sub>EM</sub> and T<sub>CM</sub> subpopulations, since some transcript expression levels closely align with those of T<sub>EM</sub> cells, e.g., *CD62L* and *PIM2*, whereas others with those of T<sub>CM</sub> cells, e.g., *FasL* and *IFN- $\gamma$*  (30). Thus, the T<sub>EM</sub> and T<sub>TM</sub> subpopulations represent potential effector populations and the identification of their potent upregulation of multiple cytokines is therefore logical and identify them as important for the effective protective responses present after tularemia vaccination. In contrast, we did not detect the same broadly increased cytokine secretion by the T<sub>CM</sub> and T<sub>EMRA</sub> subpopulations. This reinforces

the general concept that the T<sub>CM</sub> subpopulation constitutes quiescent cells that require very strong stimulation and costimulation to respond to the cognate antigens (31). Their most important role with regard to protection against tularemia may be to serve as a reservoir that can be clonally expanded and differentiated into the T<sub>EM</sub> and T<sub>TM</sub> subpopulations. In fact, it cannot be ruled out that the *in vitro* antigen stimulation utilized in the present study led to differentiation of some T<sub>CM</sub> cells to T<sub>EM</sub> or T<sub>TM</sub> cells. As for the T<sub>CM</sub> subpopulation, the T<sub>SCM</sub> subpopulation may also serve as a reservoir of cells for subsequent differentiation to effector memory cells. This would be in line with previous observations regarding the T<sub>SCM</sub> subpopulation (32). The relevance of the T<sub>EMRA</sub> subpopulation appears to be infection-dependent; e.g., HIV-specific T cells predominantly belong to the T<sub>EM</sub> subpopulation, while CMV-specific T cells are mainly of the T<sub>EMRA</sub> phenotype (33). Our findings indicate a rather modest role for the T<sub>EMRA</sub> subpopulation after tularemia vaccination.

Linear discriminant analysis of patterns of secreted cytokines was utilized and a model was created based on the levels of IFN- $\gamma$  and IL-13. This analysis revealed that discrimination between non-vaccination and vaccination was 100%, but that resolution between the groups after vaccination was low. This indicates that the

qualitative and quantitative responses observed after vaccination did not change during the observation period of 1 year. This finding agrees with our previous studies demonstrating that recall responses are sustained for three decades without evidence of decline (22). Various types of logistical modeling, similar to the linear discriminant analysis used herein, have been used in previous studies on tularemia secreted cytokines, cytokine gene expression, and lymphocyte stimulation indices, and these have been linked to protective capacity or immune status (12, 13, 22, 24, 34). Also in the mouse model, similar modeling has been utilized and combined results from *in vivo* gene expression and a co-culture method (35). Such results from animal and human models of tularemia are highly relevant with regard to the FDA Animal Rule (36). The rule stipulates that vaccine efficacy and approval can be assessed based on data from animal models only, provided that protective mechanisms are well characterized and the animal data therefore can be extrapolated to the human situation. Thus, the aforementioned data fulfill the criteria and will form an important basis for the approval of new tularemia vaccines. The identification of IL-13 in the context is intriguing since it was long ago demonstrated that the cytokine inhibits nitric oxide production by activated macrophages and thereby most likely will also mitigate the protective responses to *F. tularensis* (37).

TABLE 2 Prediction of individuals according to vaccination using LDA<sup>1</sup>.

Predicted	Time after vaccination				
	Before	2 weeks	4 weeks	12 weeks	52 weeks

findings identified IFN- $\gamma$  as a key cytokine being expressed at high levels after vaccination by both CD4 and CD8 T cells. This finding was not unexpected, since the crucial role of the cytokine for protection against tularemia was first identified more than 30 years ago using various animal models (38–45). Moreover, we have previously used a human co-culture model and demonstrated the protective ability of IFN- $\gamma$  (12). In animal models, mechanisms dependent on guanylate-binding proteins GBP2 and GBP5 are crucial to effectuate the IFN- $\gamma$ -mediated control (46, 47). This was first demonstrated for the closely related bacterium *F. novicida* and subsequently also for the LVS strain using infection of mononuclear cells; however, control of the highly virulent SCHU S4 strain was not observed in the model (48). Later, it was demonstrated that control of infection with each of the three *F. tularensis* strains occurred in a mouse co-culture model, but, again, control was critically dependent on GBPs (49). Thus, the evidence from animal models indicate that the control of highly virulent strains is distinct from that of attenuated *F. tularensis* strains and demonstrates that the use of such strains in the models is necessary to identify relevant correlates of immunity and protection.

The strategy used in the present study, to directly assess the protective ability of supernatants elicited during *F. tularensis*-specific immune responses allowed identification of cytokines that correlated to protection in the model. The supernatants demonstrated protective capability even at a 20-fold dilution. However, there were distinct individual differences and the inhibitory effects varied from 5-fold to 230-fold, but this was still as efficacious, or superior to the effect mediated by high levels of recombinant IFN- $\gamma$ , despite the fact that this concentration of IFN- $\gamma$  was at least 5-fold higher than the concentrations in the supernatants. Thus, the supernatants provided additional, strongly protective effects besides that of IFN- $\gamma$ . Of relevance, the levels of several other cytokines were found to correlate to the degree of protection observed. Specifically, IL-2, MIP-1 $\beta$ , TNF, and IL-7 all fulfilled the criterion and the former three of these cytokines have previously been observed to correlate the control of infection in a human co-culture model and also in an animal models of tularemia (12, 34, 50, 51). The strategy was found to be useful and can later be combined with direct assessment of the contribution of individual cytokines, e.g., by depletion of one or several together with the assessment of the protective ability or by supplementation of combinations of recombinant cytokines.

The findings herein serve to identify both correlates of immunity and protection. In fact, even correlates of immunity are very challenging to identify with regard to cell-mediated

immune responses. In the case of the most common global infection, tuberculosis, the identification of potential immune correlates is challenging, e.g., the relevance of multifunctional cytokine-producing T cells as correlates has been questioned (52), although there are still considerable efforts trying to identify such correlates (53). With regard to tularemia, most work to identify correlates has been based on animal models, particularly the mouse model. A general finding has been the identification of Th1-related cytokines in these models; e.g., the demonstration of increased levels of IFN- $\gamma$ , TNF, and MCP-1 has been consistent. Moreover, the levels of these cytokines correlated to protection after vaccination with attenuated *F. tularensis* mutants (34, 35). Studies on immunity after tularemia vaccination, or natural infection of humans, have identified multifunctional T cells similar to findings described for tuberculosis patients (22, 52, 54). When a human co-culture system was used, correlations between levels of IFN- $\gamma$ , TNF, and MIP-1 $\beta$  and protection were observed (12). Thus, there is substantial indirect evidence that levels of Th1 cytokines, such as IFN- $\gamma$ , TNF, and MIP-1 $\beta$ , are correlates of protection in various animal and human tularemia models, thereby in much agreement with the present findings (12, 22, 34, 35, 54). Of note, none of the studies on *F. tularensis* has included neutralization of cytokines as a direct demonstration of their contribution to protection.

The present study exclusively utilized PBMCs, and this may affect the results, since memory immunity expressed by this cell type is sometimes distinct compared to that of tissue-resident immune cells. For example, it has been demonstrated that mouse lung T cells require repeated antigen stimulation to sustain memory immunity for 1 year, whereas memory immunity among circulating T cells was preserved during the same time without restimulation (55). Also, with regard to tularemia, evidence indicates that systemic and organ-specific cell-mediated immunity is distinct, e.g., an attenuated mutant of *F. tularensis* conferred superior protection after intranasal vs. intradermal vaccination (35). It was hypothesized that there are organ-specific differences between immune cells and therefore certain routes of immunization confer optimal protection. If memory immunity to some extent will be cell-specific, this may be a caveat when characterizing human protective immunity since cell sources other than peripheral blood will be severely limited. It should be noted that although intranasal vaccination can confer immunological benefits, there may be an increased risk of adverse events with this route as shown for certain vaccines (56).

Collectively, the findings herein identify characteristics of long-term immunospecific T cells, including T<sub>EM</sub> and T<sub>TM</sub>

subpopulations secreting an array of cytokines, following vaccination against *F. tularensis*. Moreover, individual cytokines were identified, the levels of which correlated with the degree of protection. Thus, the data provide important information about memory T cells and effector mechanisms that form the basis for the protective mechanisms operative against *F. tularensis*.

## Data availability statement

The original contributions presented in the study are included in the article/Supplementary Material. Further inquiries can be directed to the corresponding author.

## Ethics statement

The studies involving humans were approved by Swedish Ethical Review Authority, permits 2019-01567 and 2020-01860. The studies were conducted in accordance with the local legislation and institutional requirements. The participants provided their written informed consent to participate in this study.

## Author contributions

HL, KE, and IG performed the experiments. AS and HL designed the study. HL, KE, and AS analyzed the data and wrote the manuscript. HL, KE, IG, CG, and AS reviewed the manuscript. All authors contributed to the article and approved the submitted version.

Osteomyelitis (OM) is an infectious disease of the bone predominantly caused by the opportunistic bacterium *Staphylococcus aureus* (*S. aureus*). Typically established upon hematogenous spread of the pathogen to the musculoskeletal system or contamination of the bone after fracture or surgery, osteomyelitis has a complex pathogenesis with a critical involvement of both osteal and immune components. Colonization of the bone by *S. aureus* is traditionally proposed to induce functional inhibition and/or apoptosis of osteoblasts, alteration of the RANKL/OPG ratio in the bone microenvironment and activation of osteoclasts; all together, these events locally subvert tissue homeostasis causing pathological bone loss. However, this paradigm has been challenged in recent years, in fact osteoblasts are emerging as active players in the induction and orientation of the immune reaction that mounts in the bone during an infection. The interaction with immune cells has been mostly ascribed to osteoblast-derived soluble mediators that add on and synergize with those contributed by professional immune cells. In this respect, several preclinical and clinical observations indicate that osteomyelitis is accompanied by alterations in the local and (sometimes) systemic levels of both pro-inflammatory (e.g., IL-6, IL-1 $\alpha$ , TNF- $\alpha$ , IL-1 $\beta$ ) and anti-inflammatory (e.g., TGF- $\beta$ 1) cytokines. Here we revisit the role of osteoblasts in bacterial OM, with a focus on their secretome and its crosstalk with cellular and molecular components of the bone microenvironment and immune system.

## KEYWORDS

osteomyelitis, infection, bone, osteoblast, staphylococcus aureus, cytokines, chemokines

## Introduction

Osteomyelitis is a severe bone infection arising from hematogenous spread of pathogens, mainly in pediatric patients (1), or direct contamination of the bone after fracture or surgery, more commonly in adults (2). Typically associated with comorbidities, osteomyelitis has a relatively high incidence amongst diabetics, where it develops secondary to vascular and neuropathic complications of hyperglycemia, and may require extreme clinical measures (i.e., limb amputation) (3). Osteomyelitis occurs also in the absence of known risk factors for invasive infections, which underlines the complexity of its etiopathogenesis. Several pathogens, including bacteria, fungi, and viruses, can cause bone infections, but the most common etiologic agent of the disease is the Gram-positive bacterium *Staphylococcus aureus* (*S. aureus*), which is responsible for up to 60% of the cases (4). Different classification schemes have been proposed for osteomyelitis, based on a range of clinical and microbiological characteristics (5). Most commonly, the disease is classified as either acute or chronic, according to its duration, and either hematogenous or contiguous, according to the origin of infection. During a bone infection, the serum levels of several cytokines [e.g., IL-6, IL-8, IL-1 $\beta$ , IL-12(p70)], angiogenic factors (e.g., VEGF), and acute phase proteins (e.g., C reactive protein, CRP) increase, which is of diagnostic value in the clinical handling of the disease; nevertheless, specific infection markers with diagnostic value are still sought for (6, 7).

The first line of defense against invading pathogens, including *S. aureus*, is represented by cells of the innate immune system (neutrophils, monocytes, macrophages), which detect the pathogens through germline-encoded pattern-recognition receptors (PRRs), including Toll-like receptors (TLRs) and cytoplasmic receptors. PRRs recognize specific microbial components known as pathogen-associated molecular patterns (PAMPs), such as LPS, lipoteichoic acid, lipoproteins, and peptidoglycans, and convey the biochemical signals that are ultimately responsible for activation of the immune cells (8). PRRs are also made by non-immune cells, including cells of the osteoclast and osteoblast lineage in the bone. All TLRs but TLR2 and TLR4 are downregulated during osteoclast differentiation, and relative timing of TLR and RANKL/MCSF stimulation of osteoclast precursors elicit opposite effect on osteoclast formation (9). Very recently it has been reported that TLR2 and TLR9 signaling contributes marginally to the inflammatory bone loss and enhanced osteoclast formation that accompany *S. aureus*-dependent osteomyelitis (see *Osteoclasts and their progenitors*) (10). However, it is generally accepted that osteoblasts use TLRs and NODs to recognize and respond to *S. aureus*, which leads to secretion of the master osteoclastogenic cytokine RANKL as well as other factors (11), as discussed below.

In line with the general paradigm of immunological activation upon PRR engagement, in the context of a bone infection, polymorphonuclear leukocytes (PMNs) and macrophages migrate into the bone microenvironment and therein release several diverse inflammatory mediators, including cytokines, chemokines (e.g., IL-1 $\beta$ , IL-6, and TNF- $\alpha$ , CCL3 and CXCL2), and other factors. The immune reaction that mounts in the bone alters the local homeostasis profoundly, which adds on the direct effects of *S. aureus* on skeletal cells (8). Proinflammatory mediators promote formation and activation of osteoclasts, thus enhancing bone resorption; in parallel, new, poorly structured bone is deposited at the periosteum (periosteal bone reaction) by osteoblasts to confine the infection. These opposing processes collectively result into progressive disruption of the bone microarchitecture. The crosstalk between immune and skeletal cells in the context of bone infections sustained by *S. aureus* (a paradigmatic example of osteoimmunology) is schematically depicted in Figure 1.

Besides their function in bone homeostasis, both osteoclasts and osteoblasts exert immune regulatory functions by orchestrating synthesis and release of various inflammatory molecules (12). In the present review, we present and discuss the roles of osteoblasts in the pathogenesis of osteomyelitis, with a focus on osteoblast-derived soluble factors and their contribution to the long-term fate of bone infections (Figure 2).

## Mainstays in bone biology and basic microbiology of *S. aureus* osteomyelitis

Bone is a dynamic tissue that undergoes constant remodeling throughout life (13). Osteoclasts and osteoblasts are the two cell types primarily involved in bone remodeling, responsible for bone resorption and bone formation, respectively. Osteoclasts are of hematopoietic origin, and unique in their ability to degrade the inorganic (hydroxyapatite) and organic (mostly collagen) matrix of the bone (14) through acidification of the resorption lacuna and release of hydrolytic enzymes (e.g., cathepsin K). Conversely, osteoblasts arise from cells of the mesenchymal lineage, and produce the whole set of components of the mineralized extracellular matrix of the bone, which comprises collagen, proteoglycans and several non-collagenous proteins, and an extremely dense hydroxyapatite-based mineral (15). As the matrix grows, some osteoblasts are enclosed in it and become osteocytes. These are terminally differentiated cells that communicate with each other and other cell types by means of cellular processes that penetrate the canaliculi in the bone extracellular matrix.

FIGURE 1

Schematic representation of bone cell regulation by the main soluble factors produced by immune cells during *S. aureus*-induced osteomyelitis. Upon infection, immune cells migrate into the bone microenvironment and release cytokines (IL-17, IL-10, IL-1, IL-1β, IL-6, IL-7, IL-18, IL-4, IL-8), chemokines (CCL3), growth factors (M-CSF, G-CSF) and other several inflammatory mediators (TNF-α, PGE<sub>2</sub>, TGFβ, INF-γ, OSM) that influence osteoblast and osteoclast activity. The result is massive disruption of the normal bone architecture. The Figure was created with [BioRender.com](https://www.biorender.com).

The crosstalk between osteoclasts and osteoblasts shapes the extracellular matrix. Their mutual interaction relies on a series of membrane-bound molecules and soluble factors (e.g., EFNB2-EPHB4, FASL-FAS and SEMA3A-NRP1). Among the latter, M-CSF and RANKL, produced by osteoblasts and acting on their specific receptors on the osteoclast surface (C-FMS and RANK, respectively), have a pivotal role in bone homeostasis (14). In addition, osteoblasts release OPG, the decoy receptor for RANKL that hinders RANK-RANKL interaction, reducing osteoclast formation and bone resorption. In fact, RANKL/OPG ratio is commonly used as an indicator of the balance between bone formation and resorption (16).

*S. aureus* can invade, colonize, and thrive in the bone. Microbial surface components recognizing adhesive matrix molecules (MSCRAMMs), such as fibronectin-binding protein A and B (FnBPA and B), collagen adhesin (Cna) and Staphylococcus protein A (SpA) (17), initiate adhesion to the bone extracellular matrix. Once bound to the matrix, *S. aureus* can activate diverse mechanisms to escape the host immune response, survive in the bone microenvironment, and establish chronic infection. A primary strategy of immune evasion is biofilm formation, a complex process that involves synthesis and release of extracellular polymeric substances (i.e., polysaccharides and extracellular DNA) and is controlled both by microbial (i.e., the

Agr quorum-sensing system) (18) and host factors (i.e., mineral components of the bone matrix, such as Mg<sup>2+</sup> and Ca<sup>2+</sup>, oxygen and nutrient availability) (18). Biofilms reduce osteoblast viability and increase RANKL production, thus promoting bone resorption (19). Moreover, in an *in vitro* dynamic model of biofilm deposition, the supernatant of TNFα-treated osteoblasts was found to affect *S. aureus* adhesion and biofilm formation (20). Abscess formation is another survival strategy for *S. aureus*, whereby following upon the engagement of fibrinogen by the bacterial clumping factors A and B (ClfA and B) and its conversion to fibrin (by coagulase, CoA, and von Willebrand factor-binding protein, vWbp), a fibrous pseudocapsule is formed that encases a core of staphylococcal abscess communities (SACs) and is surrounded by a layer of necrotic leukocytes (mostly, neutrophils) (2). Furthermore, *S. aureus* is able to invade the osteocyte lacunocanalicular network through bacteria deformation (whereby a key role has been proposed for the transpeptidases penicillin-binding proteins 3 and 4), entry and migration into the canaliculi *via* asymmetric binary fission at the leading edge (21, 22); these mechanisms are particularly relevant to long term bacterial persistence and eradication. Finally, intracellular infection and survival is a bacterial strategy to evade immune surveillance; of note, all skeletal cells are potential targets, as discussed in the following section.

FIGURE 2

Schematic representation of osteoblast response to *S. aureus* infection. After osteoblast infection (1), *S. aureus* can grow and spread further in the bone (2) and induce synthesis and release of different inflammatory mediators (IL-12, IL-27, IL-6, CCL3, CCL5, CXCL2, CXCL10, CXCL9, CXCL12, TGFβ, G-CSF, M-CSF, GM-CSF, PTX3, RANKL, PGE<sub>2</sub>) (3) that act both on skeletal and immune cells. This leads to enhanced bone remodeling and immune response. See the main text for more details. The Figure was created with [BioRender.com](https://www.biorender.com).

## Skeletal cell infection in the context of *S. aureus* osteomyelitis

### Osteoclasts and their progenitors

A growing body of evidence supports the concept of osteoclasts working as the innate immune cells of the bone (23, 24); accordingly, it is expected that they play a role in the framework of osteomyelitis. Bacterial infection has the potential to influence osteoclast formation directly, through receptor ligation on progenitor cells (9), and indirectly, through enhanced cytokine release from neighboring cells (8). In particular, *in vitro* *S. aureus* infection of murine bone marrow-derived osteoclast precursors has been shown to induce their differentiation into activated macrophages that actively secrete proinflammatory cytokines, such as CCL5, MIP-1α, MIP-1β, G-CSF, IL-12p40, and MCP-1 (25). These cytokines enhance the bone resorption capacity of uninfected mature osteoclasts and differentiation of uninfected precursors. Moreover, infection of mature osteoclasts directly promotes cell fusion, which contributes to enhance their ability to resorb bone (25). A

similar effect has been also demonstrated upon exposure of human monocyte-derived osteoclasts to Staphylococcal superantigen TSST-1, while the Pantone-Valentine leukocidin, known as one of the most powerful pore-forming toxins, and hemolysin-α induced osteoclast death, indicating that the clinical presentation and outcome of bone and joint infection could be related, at least partly, to the toxin profile of the *S. aureus* isolate involved (26). The osteoclast intracellular infection, which has been demonstrated also *in vivo* (27), has been recently studied exploiting fluorescently labelled bacterial strains visualized by confocal and time-lapse microscopy (28). Intracellular penetration of bacteria occurred *in vitro* in a short timeframe; bacterial proliferation started two-four hours post-infection, but the bacterial load in the intracellular compartment of infected osteoclasts did not change over time (28). Osteoclast colonization was accompanied by reduced bactericidal potential compared to non-infected osteoclast precursors (29). Moreover, the proliferative capacity of *S. aureus* within osteoclasts was dependent on the signaling cascade activated by the osteoclastogenic master transcription factor NFATc1, and varied to some extent amongst individual osteoclasts (29).

## Osteoblasts and their progeny

*S. aureus* has been shown to infect osteoblasts and downstream mature cells (osteocytes) both in *in vitro* and *in vivo* animal models and clinical biopsies (21, 30–33). The interaction of osteoblasts with *S. aureus* involves several pathogen-derived factors and components of the osteoblast plasma membrane. For example, a major virulence factor of *S. aureus*, SpA, interacts directly with osteoblasts via TNFR1, and activates intracellular signaling cascades that result into reduced proliferation, enhanced apoptosis, and impaired mineralizing potential of cultured osteoblasts (34). The binding of *S. aureus* FnBPA and FnBPB to the extracellular matrix protein fibronectin is recognized as another important process in osteoblast infection. Indeed, fibronectin is believed to act as a “molecular bridge” in linking osteoblasts to the pathogen through  $\alpha 5 \beta 1$  integrin (35). In this respect, the supramolecular structure of fibronectin in the bone extracellular matrix has been recently shown to play an essential role in bacterial uptake by osteoblasts (36).

Whether bacteria internalization in osteoblasts is achieved passively or through an active process has been debated. It is likely that in fact both mechanisms are in place (37, 38). Intracellular infection has been proposed to occur very rapidly upon exposure to *S. aureus*. Indeed, bacteria have been detected by immunofluorescence microscopy inside murine calvaria osteoblast-like MC3T3-E1 cells as early as 15 minutes after infection, and the rate of bacteria internalization was found to increase over time (39). Invasion likely requires actin rearrangement at the cell surface; in fact, treatment with the actin depolymerization agent Cytochalasin D significantly reduced *S. aureus* invasion (40).

Mouton and colleagues recently demonstrated that *S. aureus* internalization (assessed *in vitro* through a gentamycin/lysostaphin protection assay that allows eliminating adherent and non-adherent bacteria, while sparing intracellular pathogen) induced an impairment in early osteoblast differentiation by interfering with  $\beta 1$  integrin signaling, leading to decreased expression of RUNX2 and COL1 $\alpha 1$  and ALP activity. Accordingly, an internalization defective *S. aureus* strain lacking *fnbpA* expression did not elicit this effect (41). Consistent with this, *in vivo* infection with the *S. aureus* strain capable of cell internalization altered some bone histomorphometric parameters, supporting the hypothesis that osteoblast functions are impaired upon intracellular bacterial infection (41).

Osteoblast colonization by *S. aureus* stimulates the focal adhesion kinase (FAK)/epidermal growth factor receptor (EGFR) and c-Src signaling pathways by enhancing their phosphorylation in a time-dependent fashion; on the contrary, inhibition of the EGFR/FAK or c-Src signaling pathways significantly reduces the rate of pathogen internalization (39). Consequently, these pathways could be targeted in parallel to standard antibiotic therapy of chronic *S. aureus* osteomyelitis.

Osteoblast infection by *S. aureus* has been confirmed also in the presence of invasive MRSA infection of the human MG-63 osteosarcoma cell line, using imaging flow cytometry (IFC) which is more sensitive and reproducible than conventional cell culture methods (42). Pathogen uptake is known to vary depending on the strain irrespectively of antibiotic resistance (43). Statistical analysis of results obtained by IFC assays demonstrated that intracellular persistence capacity of several different MRSA strains over a 24 hour-timeframe was correlated with the total number of infected cells at 24 hour-post-infection and not with the number of bacteria that managed to enter/replicate in each single cell, defined by spot counting after cell transient permeabilization and pathogen staining with a membrane-impermeable green-fluorochrome vancomycin analogue (42). This would suggest that other factors besides the specific clone define the bacteria ability to internalize and persist inside osteoblasts. Future research is needed on this point that is relevant to chronicization of infection.

The encounter of the pathogen with osteoblasts results into release of cytokines and chemokines (as discussed later on) that recruit and activate immune cells; increased RANKL production that sustains osteoclast activity; impaired bone matrix production and mineralization; and ultimately osteoblast death through upregulation of the cell death signal transducer TRAIL and its cell surface death receptors, and concomitant decrease of the decoy receptor OPG (44, 45). All these events contribute to bone loss. Progression from acute to chronic bone and joint infections is accompanied by phenotypic adaptation of the pathogen to a less virulent form, called “small colony variant”. This is characterized by increased intracellular persistence and antibiotics resistance, and reduced cytokine release induction and immune system stimulation (46, 47). In particular, osteocytes have been recently demonstrated to constitute a reservoir for silent or persistent infection owing to reduced antimicrobial capacity to eliminate intracellular bacteria, and higher pathogen survival in the form of small colony variants (11, 48). Moreover, infected osteocytes can also elicit an inflammatory response that contributes to communication with other skeletal cells, immune cell recruitment and bone disruption (11).

The mechanisms described above are specific for *S. aureus* and not shared by other opportunistic bacteria involved in orthopedic infections, which points to the evolution of bacterial species-specific ways of interaction with eukaryotic cells that need to be further elucidated.

## Osteoblasts as inflammatory cells

### The osteoblast secretome in a non-infected setting

The secretory function is highly relevant in the framework of osteoblast activities. It comprises the release of the diverse

components of the extracellular matrix, essentially calcium-deficient apatite and trace elements, for the inorganic part; type I collagen and other types of collagens, and non-collagenous proteins ( $\gamma$ -carboxyglutamate-containing proteins, proteoglycans, glycoproteins, and small integrin-binding ligands N-linked glycoproteins), for the organic part (49). Osteoblasts also release a variety of cytokines, chemokines, and growth factors (i.e., the osteoblast secretome) that regulate osteoclast formation and resorptive activity (e.g., M-CSF, RANKL, OPG, WNT5A, WNT16, IL-6, GM-CSF) (14), enhance the osteoblast anabolic function (e.g., IGFs and IGFBPs) (50), support hematopoiesis (e.g., G-CSF, osteopontin, thrombopoietin, angiopoietin 1, CXCL12, SCF and IL-7) (51) and act as immune modulators (e.g., IL-6, GM-CSF, CCL5) (52). In this respect, an intimate crosstalk takes place in the bone between skeletal cells and the immune system, which also involves the release of cytokines and chemokines in diverse pathophysiological contexts (53). Systemic and local factors such as inflammation and infection elicit marked changes in bone cell functions, as further described in the following sections.

## The osteoblast secretome in *S. aureus* osteomyelitis: Cytokines and growth factors

At sites of infection, soluble factors deriving from activated immune and skeletal cells make up an inflammatory milieu that mediates reciprocal regulation of the osteal and immune components and provides host defense against pathogens. In this regard, osteoblasts play an active role, and cannot be regarded as inert niches for bacterial colonization. In fact, not only do they strive to kill intracellular bacteria by increasing the production of reactive oxygen species and oxidative stress, but they also take part in the immune response orchestrated by professional innate immune cells through production of antimicrobial peptides (beta-defensins), as shown in *in vitro* and *in vivo* models and *ex vivo* in human specimens (54, 55). In addition, the osteoblast secretome further boosts the inflammatory response and affect the behavior of skeletal cells (see Figure 2).

Cytokine synthesis and release involve several intracellular signaling pathways including the NF- $\kappa$ B pathway, which regulates the secretion of IL-6 and MCP1 (CCL2; see below) (56), and the JNK pathway, which is activated downstream of *S. aureus* SpA binding to TNFR1 on the osteoblast plasma membrane and leads to increased TLR2 and RANKL protein levels and TNF- $\alpha$  and IL-6 secretion (56).

The transcriptomic profile of infected osteoblasts has been recently comprehensively investigated by RNAseq analysis of FACS-sorted *S. aureus*-bearing MG-63 cells, and compared to that of non-infected cells and of a mixed cell population

comprising both infected and not-infected MG-63 cells (57). Specifically, this work indicated enhanced immune and inflammatory responses in a model of long-term infection, taking advantage of engineered bacterial strains expressing a fluorescent reporter gene that allowed isolation of infected cells 6 days after infection. Top up-regulated genes included several cytokines such as IL-33, IL-32, IL-6, IL-1 $\beta$ , IL-1 $\alpha$ , IL-24, G-CSF, TRAIL and TNFSF14, with higher protein levels in culture supernatants. Accordingly, in the Gene Set Enrichment Analysis, several pathways enriched in FACS-sorted infected MG-63 were related to the immune response, including functional categories such as antigen processing and presentation (of note, CD44 and HLA-DR expression has been reported in cultured human osteoblasts) (58) complement and coagulation cascade, platelet activation, Th17 cell differentiation, IL-17 pathway, NOD-like and TLR signal cascades (known to be involved in bacteria recognition), and cytokine signaling (57).

At the protein level, IL-6 has been found to be upregulated in infected murine osteoblasts (in various experimental settings) and human bone tissues (59, 60). Increased IL-6 induces COX-2 and thereby PGE2 and RANKL, which modulate osteoclast recruitment and differentiation, contributing to progressive inflammatory damage and bone loss (61). Enhanced RANKL production by osteoblasts, without concomitant significant change in OPG expression, occurs also downstream of TLR2 recognition of *S. aureus*; accordingly, RANKL increase is abrogated in osteoblasts from Tlr2 knockout mice. This mechanism would support pronounced bone resorption and periosteal osteoclast formation in *S. aureus*-infected bones (62).

IL-12 also is secreted by osteoblasts in *S. aureus*-induced osteomyelitis (59). It has been proposed to strengthen Th1 immune responses and favor elimination of intracellular bacteria (63), a mechanism that could be potentially used to develop novel strategies for infection prevention (64, 65). Since IL-12 in the bone microenvironment promotes myeloid-derived suppressor cell recruitment, it is plausible that osteoblasts contribute to this mechanism (66).

Expression of the highly conserved anti-inflammatory cytokine TGF $\beta$ 1 has been reported to change in MG-63 cells infected with four different clinically isolated *S. aureus* strains (43), with 2 of them causing downregulation in the short and one upregulation in the long timeframe (3 and 24 hours post infection, respectively). Among other functions, TGF $\beta$ 1 stimulates type I collagen production (67), therefore an increase of this factor might explain the abnormal matrix deposition that occurs in the periosteum during an infection.

IL-1 $\beta$  and TNF- $\alpha$  increased in the bone of animals with *S. aureus*-induced OM (43, 68, 69), and both cytokines stimulated osteoclast maturation and function. However, some findings regarding to IL-1 $\beta$  are contradictory: *in vitro* infection of murine primary osteoblasts with *S. aureus* resulted in increased transcription, but not in increased protein synthesis or secretion. Of note, the same was observed for IL-18 (70), a

potent inflammatory molecule, structurally and functionally closely related to IL-1 $\beta$ : in fact, it favors osteoclast differentiation by expanding the inflammatory response and inhibits the osteogenic function (71). Owing to the fine line between intense or exaggerated immune response, it is reasonable that IL-1 $\beta$  and IL-18 production is strictly controlled (70), however their regulation deserves further investigation. In parallel, the specific IL-18 inhibitor *IL-18BP* was upregulated *in vitro* in human primary osteoblasts 2 hours after *S. aureus* infection (<https://www.ebi.ac.uk/arrayexpress/E-MTAB-6700>), while no data are available regarding IL-18BP protein production by osteoblasts in this specific context, to the best of our knowledge. Therefore, at present, activated immune cells, not osteoblasts, are the most likely source of these ILs in the bone microenvironment during bone infections.

Also, while low levels of TNF- $\alpha$  were detected in *in vitro* differentiated human osteoblasts and in the MG-63 cell line in basal conditions (72), a marked increase was observed in MG-63 upon infection (43, 73). A recent study described a novel signaling cascade comprising TNF- $\alpha$ /miR-129-5p/endothelial nitric oxide synthase (eNOS) in the pathogenesis of osteomyelitis (74). Briefly, TNF- $\alpha$  and miR-129-5p were upregulated while eNOS was downregulated in *S. aureus*-infected MC3T3-E1 cells and in osteomyelitis patients' blood. Accordingly, a TNF- $\alpha$  blocker inhibited miR-129-5p and elevated eNOS expression, likely contributing to rescue the mineralization defect caused by *S. aureus* infection in MC3T3-E1 cells (74).

IL-27 expression has been recently demonstrated to be induced early (on day 1) in the infected bone in a transtibial model of *S. aureus*-induced osteomyelitis and upon *in vitro* infection of MC3T3-E1 cells and primary osteoblasts (75). This cytokine likely contributes to host innate immune response in the early phases of the infection by stimulating local neutrophil recruitment and activation.

Finally, there is preliminary evidence of IFN- $\beta$  secretion by mature murine osteoblasts in response to *S. aureus* infection (76). This type I interferon has been reported to be a negative regulator of RANKL-mediated osteoclastogenesis by inhibiting the translation of the critical signaling component c-Fos (77). Based on these data, *S. aureus* would stimulate osteoblasts to release factors with opposing effects on osteoclastogenesis (78); it can be speculated that the production of IFN- $\beta$  represents a compensatory response to restore bone homeostasis.

Cytokine production from infected osteoblasts has been shown also in the framework of three-dimensional (3D) models of *S. aureus*-induced osteomyelitis, which more closely reproduce composition and structure of the natural bone compared to conventional 2D culture systems. For example, in a 3D model of osteomyelitis based on the coculture of MC3T3-E1 cells and *S. aureus* on magnesium-doped hydroxyapatite/collagen I scaffolds, *Tnf- $\alpha$*  expression increased over time during

infection. The same was observed for the long pentraxin *Ptx3*, a key pattern recognition molecule with emerging roles in bone pathophysiology, known to be induced by TNF- $\alpha$ . On the contrary, *Tgf- $\beta$*  (a reported repressor of *Ptx3* transcription) decreased over time. In the conditioned medium of the 3D cocultures, TNF- $\alpha$  was not detected, while PTX3 and OPG levels were stable over time (79). Importantly, the expression of selected osteogenic (*Bmp2*, *Alp*, *Spp1*), and antioxidant (*Nrf-2*, *Ho-1*) genes were substantially affected by the applied 3D setting, indicating matrix-dependent effects on osteoblasts during an *S. aureus* infection (79).

In *S. aureus* osteomyelitis, mRNA and serum protein levels of G-CSF significantly increase in infected patients, contributing to bone loss through suppression of osteoblast function in favor of osteoclast formation (80), and to enhanced phagocytic activity of immune cells. G-CSF is also released directly by osteoblasts upon *S. aureus* infection, as well as GM-CSF and M-CSF. In fact, GM-CSF and G-CSF mRNA expression and protein secretion were substantially upregulated in cultured mouse and human osteoblasts following interaction with *S. aureus* (81). Furthermore, these cytokines were induced in unexposed osteoblasts separated from infected osteoblasts by means of a transwell system, thus pointing to a paracrine-autocrine regulatory mechanism. On the contrary, M-CSF secretion increased only in cultures of infected human osteoblasts (81). These CSFs allow osteoblasts to modulate the cellular composition of the bone microenvironment, favoring differentiation of myeloid progenitors towards osteoclasts and various innate immune cell fates (66).

## The osteoblast secretome: Chemokines

In response to *S. aureus* infection, osteoblasts also produce chemokines, members of the C-X-C-motif chemokine ligand (CXCL) and CC-motif (CCL) families, such as CCL2, CCL5, CCL7, CCL8, CCL10, CCL11, CCL13, CCL20, CCL26, and CXCL1, CXCL2, CXCL3, CXCL5, CXCL6 and CX3CL1 (57). Chemokines are traditionally known to act as immune cell chemoattractants, recruiting and activating components of the innate and adaptive immunity, however skeletal cells also are endowed with autocrine and paracrine chemokine signaling, which modulates bone turnover (82).

CCL3 and CXCL2 are known inflammatory mediators enhancing osteoclast formation and osteolysis (83). Their expression was documented in samples from osteolytic sites of patients with implant-associated infection (83). *In vitro* experiments showed that human primary osteoblasts released CCL3 and CXCL2 upon *S. aureus* infection (83). This indicates that, besides monocytes, also osteoblasts contribute to the sustained local production of these factors and the related enhanced RANKL-dependent bone resorption (82), in line with previous evidence in a mouse model (84) of *S. aureus*-

induced osteomyelitis. Overexpression of CXCL2 would also result into inhibition of osteoblast formation through downmodulation of the ERK1/2 signaling upstream of RUNX2 (85). In accordance with a role of the CCL2-CCR2 axis in *S. aureus*-induced osteomyelitis, Ccr2-deficient mice had a higher bacterial load than wild type mice in a model of implant-associated *S. aureus* infection in which a bioluminescent bacterial strain was inoculated directly into the knee joint after implantation of an orthopedic-grade titanium pin. The infection was monitored *in vivo* by means of bioluminescence and *ex vivo* by colony-forming unit counting in the infected joint tissue (86). While the specific contribution of osteoblast-derived CCR2 could not be established in this model, the higher bacterial burden in Ccr2-deficient mice was ascribed to lower T cell and myeloid cell infiltration and overall reduced host defense against the pathogen in the absence of a functional CCR2/CCL2 axis.

*In vitro* *S. aureus* infection of human primary osteoblasts also causes a strong upregulation and release of CCL5 (also known as RANTES) compared to other cell types, such as endothelial and epithelial cells (87). The levels of this chemokine influence osteoclast and osteoblast formation and function, as highlighted in the CCL5-deficient mouse (88), besides acting as chemoattractant for monocytes/macrophages and T lymphocytes (89).

Additionally, in a mouse model of implant-associated osteomyelitis, CXCL10 and CXCL9 were up-regulated in the infected femurs versus controls at 3- and 14-days post-infection (90), suggesting a possible role of these chemokines (produced also by osteoblasts through TLR4 activation (91, 92)) in the pathological bone turnover occurring during Osteomyelitis. Of note, in clinical samples from *S. aureus*-infected patients and from a mouse model of MRSA skin infection, CXCL10 and CXCL9 have also been found to enhance the spontaneous release of the virulence factor SpA, however the underlying mechanism and the biological significance of this process are yet to be defined (93). In this regard, there is evidence that extracellular SpA contributes to biofilm formation by *S. aureus* (39), therefore the ability of certain chemokines to induce its release could paradoxically help the pathogen skip immune recognition *via* encasing in a protective layer of biofilm (94). A similar process could occur in principle in bone infections, further increasing the complexity of molecular interactions that underpin osteomyelitis.

Moreover, in a mouse model of endodontic infection-induced inflammation that mimics osteomyelitis of the jaw, the chemokines *Cxcl5*, *Cxcl2*, and *Cxcl13* were among the top upregulated genes in bone lesions (95).

Furthermore, osteoblasts express both CXCL12 (also known as SDF-1) and its receptor CXCR4. This signaling axis has been extensively studied in relation to the bone marrow niche (96) and implicated in skeletal homeostasis (97). Its involvement in bone remodeling during Osteomyelitis is quite likely, though not specifically investigated thus far, to the best of our knowledge.

Finally, the neutrophil chemoattractants CCL5, CXCL1, and CXCL8 and the chemokines related to T cell activation CXCL9, CXCL10, and CXCL11, were strongly upregulated in human-osteocyte-like cells in response to *S. aureus* invasion, in *ex vivo* infected human bone and in bone specimens from the infected acetabulum site of patients suffering from periprosthetic joint infection (48). CCL5 and CXCL10 proteins, but not CXCL8 were also confirmed to be secreted by infected osteocyte-like cells.

## Limitations of *in vitro* and *in vivo* models

Dissection of the mechanisms underlying bone infection is hindered by the involvement of a variety of cells within a complex, not easily accessible microenvironment. *In vivo* models have contributed significantly to our understanding of osteomyelitis and remain a valuable tool, even though they have inherent limitations (e.g., difficulties related to joint dimension and surgery procedures in small animals; different cortical bone composition and structure), as recently reviewed (98, 99).

Conventional *in vitro* 2D models and advanced microfluidics systems allow addressing specific hypotheses in a simplified environment (2, 100, 101), however, they also present some drawbacks: for instance, the effort to simplify the model may overlook molecules and/or cellular populations that are of pathogenetic relevance. Moreover, results achieved using cell lines may present inconsistencies with respect data obtained using primary cells. For example, *S. aureus* internalization has been shown to be 30-fold lower in human primary osteoblasts than in the human osteoblast cell line hFOB. On the other hand, human primary osteoblasts displayed significantly lower cell death and higher cytokine and chemokine production (87). These findings indicate that immortalized cell lines, though widely used, do not (always) faithfully reflect post-invasion and post-infection events occurring in primary cells and raise some doubts on the physiological relevance of cell line-based *in vitro* infection models. Conversely, the use of primary cells has drawbacks due to limited availability of material and inter-donor variability.

3D models that closely resemble the *in vivo* conditions have been implemented (79, 102, 103). In this regard, manufacturing of bioactive bone mimetic scaffolds that recapitulate texture and chemistry of the natural bone matrix provide unique experimental tools to study the interface between pathogens (including *S. aureus*) and both skeletal and immune cells in a tightly controlled setting. Yet, it is problematic to reproduce in 3D models the cellular and molecular complexity of the bone microenvironment.

Overall, consistency and translation of findings from both *in vivo* and *in vitro* settings is often problematic, and integration of different models and expertise is warranted.

## Conclusions and perspectives

In conclusion, our concise overview shows that osteoblasts are actively involved in the response to infection in *S. aureus* osteomyelitis. In this framework, they are engaged in complex osteoimmunological interactions. This implies the release of a variety of factors collectively described as the osteoblast secretome, which, on one hand, recruit and activate immune cells, on the other modulate skeletal cell function. The major source of most inflammatory mediators in the bone marrow are professional innate and adaptive immune cells enrolled from the periphery or differentiated locally in the infected bone (8) (see Figure 1), as cell subsets specifically endowed with this function. Nevertheless, osteoblasts have turned out to be partners in defense (and crime) in *S. aureus* osteomyelitis through an arsenal of diverse factors (see Figure 2). Based on the established osteoblast-osteoclast bidirectional communication occurring in pathophysiological conditions (14), we would expect bone resorbing cells in turn impact on osteoblast function during infection. This aspect would be worth investigating, also considering the increasing heterogeneity recognized within the osteoclast lineage and its possible translational implications (24, 104).

The osteoblast secretome appears to be specific to the infectious agent, but whether any of its components or combinations of them can be used as specific biomarkers of the bone infection in the clinic remains to be evaluated. The possibility to manipulate the arsenal represented by the OB secretome for therapeutic purposes in addition to standard antibiotics treatments should also be considered. The double-faced nature of several cytokines and chemokines, which foster professional immune cells but sustain bone metabolism overbalance, makes this putative strategy challenging, though worth investigating, as prompted by an unmet medical need.

## Author contributions

GV and SC drafted the manuscript. GV and SC generated the figures. All authors contributed to the article and approved the submitted version.

## Funding

This work was partially supported by Fondazione Beppe e Nuccy Angiolini Onlus.

## Acknowledgments

GV and PV are supported by Fondazione Beppe e Nuccy Angiolini Onlus. We gratefully acknowledge their generous contribution to our research.

## Conflict of interest

BB receives royalties for reagents related to innate immunity and is inventor of patents related to PTX3 and other innate immunity molecules.

The remaining authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Glossary

IL-6	Interleukin 6
IL-8	Interleukin 8
IL-1 $\beta$	Interleukin-1 beta
IL-12	Interleukin 12
VEGF	Vascular-Endothelial Growth Factor
CRP	C reactive protein
PRRs	Pattern-Recognition Receptors
TLRs	Toll-Like Receptors
PAMPs	Pathogen-Associated Molecular Patterns
LPS	Lipopolysaccharides
TLR2	Toll-like Receptor 2
TLR4	Toll-like Receptor 4
RANKL	Receptor Activator of Nuclear Factor kappa B Ligand
M-CSF	Macrophage Colony-Stimulating Factor
NOD	Nucleotide oligomerization domain
PMNs	Polymorphonuclear leukocytes
TNF- $\alpha$	Tumor Necrosis Factor-alfa
CCL3	Chemokine (C-C motif) ligand 3
CXCL2	Chemokine (C-X-C motif) ligand 2
EFNB2	Membrane-bound ligand Ephrin B2
EPHB4	Ephrin receptor B4
FASL	Fas cell surface death receptor-ligand
FAS	Fas cell surface death receptor
SEMA3A	Semaphorin 3A
NRP1	Neuropilin-1
C-FMS	Colony-stimulating factor-1 receptor
RANK	Receptor Activator of Nuclear Factor kappa B
OPG	Osteoprotegerin
MSCRAMs	Microbial Surface Components Recognizing Adhesive Matrix Molecules
FnBPA and B	Fibronectin-Binding Protein A and B
Cna	Collagen adhesin
SpA	Staphylococcus protein A
ClfA and B	clamping factor A and B
vWbp	von Willebrand factor-binding protein
SACs	Staphylococcal abscess communities
CCL5	Chemokine (C-C motif) ligand 5
MIP-1 $\alpha$	Macrophage Inflammatory Protein-1 alpha
MIP-1 $\beta$	Macrophage Inflammatory Protein-1 beta
G-CSF	Granulocyte Colony-Stimulating Factor
MCP1	Monocyte Chemoattractant Protein-1
TSST-1	Toxic Shock Syndrome Toxin 1
NFATc1	Nuclear Factor Of Activated T Cells 1
TNFR1	Tumor Necrosis Factor Receptor 1
RUNX2	Runt-related transcription factor 2
COL1a1	Collagen type I alpha 1 chain
ALP	Alkaline phosphates

(Continued)

## Continued

FAK	Focal Adhesion Kinase
EGFR	Epidermal Growth Factor Receptor
c-Src	Proto-oncogene
cellular Src	
MRSA	Methicillin-Resistant Staphylococcus aureus
IFC	imaging flow cytometry
TRAIL	Tumor Necrosis Factor-Related Apoptosis-Inducing Ligand
WNT5A	WNT family member 5A
WNT16	WNT family member 16
GM-CSF	Granulocyte-Macrophage Colony-Stimulating Factor
IGF	insulin growth factor
IGFBP	insulin growth factor-binding protein
CXCL12	Chemokine (C-X-C motif) ligand 12
SCF	Stem cell factor
IL-7	Interleukin 7
NF-kB	Nuclear factor kappa-light-chain-enhancer of activated B cells
JNK	c-Jun N-terminal kinase
IL-33	Interleukin 33
IL-32	Interleukin 32
IL-1 $\alpha$	Interleukin 1 alfa

**Background:** Early prognostic stratification of patients with sepsis is a difficult clinical challenge. Aim of this study was to evaluate novel molecules in association with clinical parameters as predictors of 90-days mortality in patients admitted with sepsis at Humanitas Research Hospital.

**Methods:** Plasma samples were collected from 178 patients, diagnosed based on Sepsis-3 criteria, at admission to the Emergency Department and after 5 days of hospitalization. Levels of pentraxin 3 (PTX3), soluble IL-1 type 2 receptor (sIL-1R2), and of a panel of pro- and anti-inflammatory cytokines were measured by ELISA. Cox proportional-hazard models were used to evaluate predictors of 90-days mortality.

**Results:** Circulating levels of PTX3, sIL-1R2, IL-1 $\beta$ , IL-6, IL-8, IL-10, IL-18, IL-1ra, TNF- $\alpha$  increased significantly in sepsis patients on admission, with the highest levels measured in shock patients, and correlated with SOFA score (PTX3:  $r=0.44$ ,  $p<0.0001$ ; sIL-1R2:  $r=0.35$ ,  $p<0.0001$ ), as well as with 90-days mortality. After 5 days of hospitalization, PTX3 and cytokines, but not sIL-1R2 levels, decreased significantly, in parallel with a general improvement of clinical parameters. The combination of age, blood urea nitrogen, PTX3, IL-6 and IL-18, defined a prognostic index predicting 90-days mortality in Sepsis-3 patients and showing better apparent discrimination capacity than the SOFA score (AUC=0.863, 95% CI: 0.780–0.945 vs. AUC=0.727, 95% CI: 0.613–0.840;  $p=0.021$  respectively).

**Conclusion:** These data suggest that a prognostic index based on selected cytokines, PTX3 and clinical parameters, and hence easily adoptable in clinical

practice, performs in predicting 90-days mortality better than SOFA. An independent validation is required.

#### KEYWORDS

sepsis, biomarkers, cytokines, PTX3, disease severity

## Introduction

Sepsis is a life-threatening condition due to a dysregulated response to infection which can lead to shock, multiple organ failure, and death. The estimated number of incident cases of sepsis increased to almost 50 million worldwide (1–4) and, despite massive efforts, the mortality rate has not improved over time. Early diagnosis of sepsis and prognostic assessment are crucial to prevent progression to severe disease and to make use of timely and appropriate treatments to reduce mortality (1–4).

Despite the recent revision of the definition of sepsis, diagnosis is still challenging for clinicians, in particular in the identification of patients at early stages (5). Alongside the diagnostic question, also important is the need to have early prognostic indications allowing clinicians to activate the most appropriate therapies based on the mortality risk of each individual patient (2, 6–10). A recent review collected 5367 studies identifying 258 different biomarkers of sepsis with potential diagnostic and/or prognostic functions (11). Among the different molecules, procalcitonin (PCT) and C-reactive protein (CRP) resulted as the most studied candidate biomarkers. However, the clinical implication and molecular involvement of these proteins still needs to be clarified and currently there is not a single molecule validated as the “gold standard” biomarker for sepsis (11). In particular the comprehensive analysis of the literature reported by Pierrakos et al. underlined the limited value of studies evaluating a single biomarker as a prognostic factor, given that mortality in septic patients is related to multiple pathophysiological processes. Therefore, investigation on multiple sepsis-related molecules is strongly suggested as a strategy to develop a validated prognostic model (12–18).

Here we focused on two proteins of the innate immune system, the long pentraxin 3 (PTX3) and the soluble form of the Interleukin-1 type 2 receptor (sIL-1R2). PTX3 is a distant relative of CRP (19, 20) and a key component of the innate immunity. The molecule is expressed by different cell types, at highest levels by phagocytes (monocytes/macrophages and myeloid dendritic cells), in response to primary pro-inflammatory signals, TLR engagement, microbial recognition and tissue damage (21–23). sIL-1R2 is generated by enzymatic

cleavage of membrane-bound IL-1R2 and is released from neutrophils and macrophages in response to both pro- and anti-inflammatory signals, acting as a “decoy receptor” which negatively regulates the IL-1 signaling pathway (24–28).

Increased levels of PTX3 have been associated with infectious disorders, including sepsis and septic shock, tuberculosis, dengue and meningitis (29–33). In all these conditions, PTX3 plasma levels correlated with severity and had prognostic value. In sepsis, available data were mainly obtained in ICU patients and indicated that PTX3 is associated with disease severity, organ dysfunction and 28-days or 90-days mortality (29, 31, 34–39). Only few reports were obtained in patients enrolled in emergency rooms, such as the work by Uusitalo-Seppälä et al., underlining the role of PTX3 as a prognostic biomarker of 28-days mortality (40) in that setting.

Similarly, circulating levels of sIL-1R2 are documented to increase in many inflammatory disorders, correlating with disease severity (41–45). Early studies also reported increased levels of sIL-1R2 in small cohorts of sepsis patients or in experimental endotoxemia models (46–48). Elevated levels of sIL-1R2 were measured in patients with clinically defined sepsis (45, 49), and in a group of ICU patients with systemic infections categorized according with Sepsis-1 criteria (44). Despite the correlation with severity, contrasting results were reported in terms of prediction of mortality: Van Der Poll et al. showed higher levels of sIL-1R2 in non-survivors compared to survivors (45), while Muller et al. reported no difference of sIL-1R2 levels in relation to mortality (44).

Reflecting the co-occurrence of inflammation and immunosuppressive mechanisms, both pro- and anti-inflammatory cytokines increase concurrently in the plasma of septic patients. Tumor necrosis factor (TNF- $\alpha$ ) and Interleukin 1 beta (IL-1 $\beta$ ), the most important primary pro-inflammatory mediators, are the cytokines most extensively studied in sepsis patients (50–52). Other pro-inflammatory cytokines in sepsis response include IL-6, IL-8, IL-12, interferon (INF)- $\gamma$ , granulocyte-colony stimulating factor (G-CSF), IL-12, IL-17 and IL-18 (50, 53, 54). Among the specific anti-inflammatory mediators enriched in sepsis, IL-1ra, IL-4 and IL-10 are the most studied (47, 53, 55, 56). So far, data showed a complex network of interactions between different cytokines in sepsis. While some

patients are characterized by rapid production of both pro and anti-inflammatory cytokines (57, 58), other septic individuals release predominantly anti-inflammatory mediators or show reduction of both types of molecules (59–62). Therefore, the available literature does not provide conclusive results. Of note, the circulating levels of cytokines differ massively from subject to subject and even within the same patient during the evolution of the disease. Hence it might be relevant to screen a set of different cytokines for monitoring sepsis patients (63, 64).

Due to the complexity of sepsis, the measurement of a set of markers related to different pathways may be more beneficial than relying on a single biomarker (11, 16–18). Thus, the aim of this study was to evaluate the prognostic value of a selection of promising innate immunity molecules, namely PTX3 and sIL-1R2, in combination with a set of pro- and anti-inflammatory cytokines. Circulating biomarkers will be integrated with clinical parameters, in order to improve the early prognostic assessment of sepsis patients in ED setting.

## Materials and methods

### Ethics approval

This study complied with the provisions of the Declaration of Helsinki and was approved by the Institutional Review Board of Humanitas Research Hospital (Approval n° 820/18). Patients were enrolled only after the signature of a written informed consent. In the case the patient was unable to provide consent, this was obtained from their relatives. Confidentiality of patient data was preserved and no patient identifiers were used in the dataset.

### Study design

We conducted a single center prospective observational study enrolling patients with suspected sepsis admitted to the Emergency Department (ED) of Humanitas Research Hospital (from now on referred as Humanitas Hospital) between October 2017 and February 2020. Patients presenting at the Emergency Department were evaluated based on the Sepsis-3 criteria defined by the Third International Consensus Definitions for Sepsis and Septic Shock (65). Sepsis-3 criteria are based on the following recommendations: i) presence of an infection; ii) presence of organ dysfunction, represented by an increase in the Sequential [Sepsis-related] Organ Failure Assessment (SOFA) score of 2 points or more; iii) presence of at least two of the following clinical criteria, that together constitute a new bedside clinical score termed quick SOFA (qSOFA): altered mentation, a respiratory rate of 22/min or greater, and systolic blood pressure of 100 mm Hg or less. Septic shock is defined as a subset of sepsis patients clinically identified by a vasopressor requirement to

maintain a mean arterial pressure of 65 mm Hg or greater, serum lactate levels greater than 2 mmol/L (>18 mg/dL) in the absence of hypovolemia or altered mentation (Glasgow coma scale score < 15). All non-sepsis patients had a proof of infectious disease.

A cohort of 178 patients aged 35–98 years old was enrolled in this study (Figure 1), representing approximately 25% of the individuals presenting at the ED of Humanitas Hospital with suspected sepsis during the recruitment period. Six patients were excluded due to missing data. The remaining population of 172 patients was stratified according to Sepsis-3 criteria as detailed above (65). Based on these criteria, the population was divided as follows: 37 patients with SOFA score < 2 were assigned to the “non-sepsis” group diagnosed with infections; 135 patients with SOFA ≥ 2 were divided into two groups: sepsis, (n=99), and septic shock (n=36). The SOFA score was also used to determine the levels of organ dysfunction and mortality risk.

A group of healthy controls (HC) was enrolled among volunteers with age higher than 50 years (n=70). Median age and 25% and 75% quartiles (Q1–Q3) were 63 years (58–67); 56% were males and 43% were females.

### Sample collection and preparation

Blood samples were collected in EDTA tubes on the day of arrival at ED or when, within 24–72 hours of observation in ED, the patient was diagnosed as sepsis or septic shock. The day of first blood withdrawal was considered as day1. For those patients admitted to Humanitas Hospital, a second collection was done on day 5 ± 1. Blood samples were centrifuged at 1800 rpm for 10 minutes, then plasma was aliquoted and stored at -20°C until analysis. To ensure the reproducible quality of samples, blood tubes were processed within 2 hours after collection.

### Data collection

Demographic information (age, sex, prior medical history), ED stay, hospital stay, ICU admission and blood pressure were collected and documented. In addition, the progression of sepsis and survival outcome at 90 days were recorded. Routine laboratory tests were performed by methods applied in the Clinical Laboratory of Humanitas Hospital.

### Biomarker measurement

PTX3 and sIL-1R2 levels were measured using sandwich enzyme-linked immunosorbent assay (ELISA). PTX3 was measured by an in-house assay based on original reagents developed at Humanitas Hospital (detection limit 100 pg/ml; inter-assay and intra-assay variability ranges from 8 to 10%), as

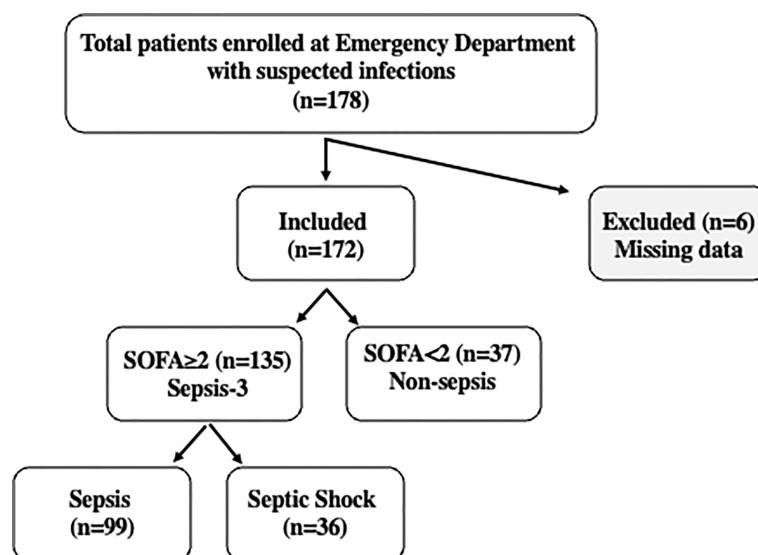

FIGURE 1

Flowchart of the study. A cohort of 178 patients was enrolled at the Emergency Department of Humanitas Research Hospital with suspected sepsis. 172 patients were included in the study and stratified based on Sepsis-3 criteria. Patients with SOFA < 2 were classified as “non-sepsis” (n=37), while the 135 patients with SOFA ≥ 2, were classified as “sepsis” (n=99) or “septic shock” (n=36) according to clinical evaluation. Septic shock patients were characterized by vasopressor requirement to maintain a mean arterial blood pressure of 65 mmHg or greater and serum lactate levels > 2 mmol/L in the absence of hypovolemia or altered mentation (Glasgow coma scale score < 15).

previously described (66). sIL-1R2 levels were measured using a commercial ELISA (Human sIL-1R2 Quantikine ELISA Kit, BioTechne; detection limit: less than 10 pg/ml) following the recommended protocol of the supplier. PCT and CRP concentrations were measured in the Clinical Laboratory of Humanitas Hospital.

A set of pro and anti-inflammatory cytokines, including IL-10, IL-6, IL-1 $\beta$ , TNF- $\alpha$ , IL-18, IL-8 and IL-1ra was measured using a customized assay in the ELLA Automated Immunoassay System (ProteinSimple, San Jose, CA, USA). The assay was performed following instructions provided by the manufacturer; concentrations of the different cytokines were directly provided by the software of the ELLA instrument. The lower limits of detection were: 0.46 pg/ml for IL-10; 0.41 pg/ml for IL-6; 0.16 pg/ml for IL-1 $\beta$ ; 0.30 pg/ml for TNF- $\alpha$ ; 0.96 pg/ml for IL-18; 0.19 pg/ml for IL-8; 3.39 pg/ml for IL-1ra.

## Statistical analysis

All statistical tests were two-sided. Stata 16.1 (StataCorp LLC, College Station, TX, USA), R software and GraphPad Prism 7.0 (GraphPad Software Inc., CA) were used for statistical analyses and graphics. All significant *P* values are reported in figures and tables legends.

Quantitative data were presented as means  $\pm$  standard deviations (SD) or medians and interquartile ranges (Q1-Q3)

according to normality (analyzed by the D’Agostino-Pearson test). Qualitative data were summarized as frequency (percentage). Parametric (Student’s *t*-test and one-way analysis of variance [ANOVA]) and non-parametric methods (two-sample Wilcoxon rank-sum [Mann-Whitney] test; Kruskal-Wallis [two-sample Wilcoxon rank-sum [Mann-Whitney] test; Kruskal-Wallis [equality-of-populations] rank test; Pearson’s chi-squared; and Fisher’s exact test) were used to detect differences between groups. Correlations were assessed by the Spearman’s rank correlation coefficient and the respective *p*-value. For hypothesis testing, a probability level lower than 0.05 was considered as statistically significant.

## Multivariable model and prognostic index development

The outcome considered for model development was 90-days mortality. We used time-to-event (survival) methods for censored observations. Time to event was defined as the time from the baseline visit (admission to emergency department) until the date of event or censoring. Kaplan–Meier estimates were used to draw cumulative incidence curves, compared by log-rank tests, as well as by univariable Cox proportional hazards (PH) analysis.

Candidate predictors for the multivariable model included the following variables at baseline: age, gender, SOFA and qSOFA scores, white blood cells, lymphocytes, neutrophils, platelets, C-reactive protein, capillary refill time, hemoglobin, hematocrit,

sodium, vitamin K, fasting blood sugars, prothrombin time, partial thromboplastin time, body temperature, heart rate, systolic and diastolic blood pressure, blood urea nitrogen,  $\text{paO}_2$ ,  $\text{spO}_2$ , ratio of  $\text{paO}_2/\text{fiO}_2$ , biomarkers of inflammation (pentraxin-3, soluble IL-1R2, IL-1 $\beta$ , IL-1ra, IL-6, IL-8, IL-10, IL-18, TNF $\alpha$ ), presence of cardiovascular disease, hypertension, malignancy, neurological disorders, diabetes type 2, chronic obstructive pulmonary disease, chronic kidney disease and other comorbidities. As the distribution of inflammatory biomarkers levels was severely positively skewed, we applied a log10-transformation prior to any analysis.

To avoid extreme collinearity, we first inspected pair-wise correlations among continuous predictors. In a few cases (e.g. hemoglobin and hematocrit) variables showed substantial collinearity ( $\rho$ -Spearman  $\geq 0.80$ ). In these cases, the variable most associated with mortality (highest likelihood ratio chi-squared test) was further considered for multivariable modelling. To assess associations between each candidate predictor and 90-days survival, we conducted explorative univariable Cox PH analysis. Except for the biomarkers of inflammation, candidate predictors showing a p-value  $< 0.20$  were considered for multivariable modelling. Given that the focus of the study was an in-depth screening of biomarkers of inflammation as potential predictors of mortality in septic patients, we explored systematically every potential interaction, also considering non-linearity through fractional polynomial terms (67). Potential interactions were screened across the other predictors at the final stage of model selection. The best fitting model was initially selected according to the lowest Akaike information criterion (68). Given the high number of candidate predictors relative to the limited sample size and number of events, we further simplified the resulting model through a backward selection procedure and eliminated variables not significant at a strict significance level of  $p < 0.005$ . This process was deemed necessary to ensure a parsimonious multivariable model and avoid substantial overfitting of the data. The proportionality of hazard assumption was tested based on Schoenfeld residuals. Model fit was assessed through the Groennessby and Borgan test (69).

We assessed model discrimination using the Harrell's c-statistic, which quantifies the ability to identify correctly those patients who will die over the study period (68). Each variable entering the final multivariable model was also assessed in terms of individual discrimination capacity (continuous), and sensitivity and specificity (dichotomous) in predicting mortality at 90 days of follow-up. The optimal cut-point for each predictor was determined through the maximally selected rank statistics, providing a threshold value corresponding to the most significant association with mortality (70). To estimate sensitivity and specificity at 90 days of follow-up, we used time-dependent receiver operating characteristic (ROC) curve analysis by means of inverse probability of censoring weighting (71). In time-dependent ROC-curve analysis, the status of an individual is observed and updated at each time point taking into account censored observations.

A preliminary prognostic index was built by multiplying the multivariable model beta coefficients (including interactions) by each patient's characteristics (age, blood urea nitrogen, and the log10-transformed PTX3, IL-6 and IL-18 levels) (68). Internal calibration was evaluated by plotting the observed proportion vs. predicted survival probability and reporting the calibration slope (which should equal one for a perfectly calibrated model) (68). We also performed a test for calibration intercept equals 0 and slope equals 1, as appropriate (68). The area under the curve of our preliminary prognostic index at 90-days were formally compared with those of SOFA and qSOFA scores, which represent the current gold standards for prediction of mortality in septic patients in different clinical settings.

A nomogram plot was produced to transform all possible total point scores into individual risks of death. We calculated the optimal cut-point of the continuous index by maximally selected rank statistics. This allowed estimating the sensitivity and specificity of this classification rule (i.e. patients scoring less points than the threshold are classified as "alive", those scoring more or equal to the threshold are classified as "dead") in predicting the 90-days risk of death.

## Results

### Patient demographics

Figure 1 reports the flowchart of the population analyzed in this study: 178 patients with suspected sepsis were enrolled during admission to the ED of Humanitas Hospital. Six patients were excluded due to missing data. Following evaluation by clinicians, the remaining population of 172 patients included 135 patients with  $\text{SOFA} \geq 2$ , 99 patients with sepsis and 36 with septic shock, while 37 patients with  $\text{SOFA} < 2$  did not meet the Sepsis-3 criteria, despite the presence of infections. These patients were categorized as "non-sepsis".

Table 1 summarizes the clinical characteristics of the overall population. The mean age was significantly increased with the severity, while no differences between males and females in the three subgroups of patients were observed. Most frequent infections were at the urinary tract (24% in non-sepsis and 41% in septic shock groups) and the respiratory tract (44% in sepsis group). Almost all the patients with sepsis and septic shock had at least one comorbidity. The most frequent comorbidity in non-sepsis and sepsis groups is represented by hypertension (40% and 34% respectively), while cardiovascular disease was the most frequent comorbidity in septic shock patients (50%). Among the laboratory and clinical results, SOFA score and levels of lactate, PCT, creatinine, d-dimer, potassium and urea were higher in septic shock patients than in the other groups of patients. Also, vasopressor need and hypotension increased significantly in septic shock patients.

TABLE 1 Demographic, laboratory and clinical characteristics of the entire patients population on day 1.

Variables	Non-sepsis (n=37)	Sepsis (n=99)	Septic shock (n=36)	<i>p</i> value
<b>Demographic Characteristics</b>

Data are reported as median [Q1-Q3] or n (%). Kruskal-Wallis equality-of-populations rank test was used for the comparisons of the different variables across the three groups of patients. Statistically significant values are in bold character. Abbreviations: COPD, Chronic obstructive pulmonary disease; DBP, diastolic blood pressure; GCS, Glasgow coma scale; ICU, intensive care unit; INR, international normalized ratio; MAP, mean arterial pressure; PCT, procalcitonin; PT, prothrombin time; PTT, partial thromboplastin time; SBP, systolic blood pressure; SOFA, Sequential Organ Failure Assessment; qSOFA, quick Sequential Organ Failure Assessment; WBC, white blood cells.

## PTX3 and sIL-1R2 levels in sepsis and association with severity

The levels of PTX3 and sIL-1R2 in HC and in non-sepsis, sepsis and septic shock patients on day 1 of ED admission are reported in [Figure 2](#) and [Table 1](#). PTX3 levels were significantly increased in all the three groups of patients compared to HC ([Figure 2A](#); PTX3 levels in HC: 2.52 [1.88-3.6], median ng/ml [Q1-Q3]). In the same cohort, sIL-1R2 levels were also increased in sepsis and septic shock patients compared to HC (median and Q1-Q3] 16.29 ng/ml [13.52-20.25]), while normal levels of sIL-1R2 were observed in non-sepsis patients ([Figure 2B](#)). The increased severity among the three groups of patients is supported by the upregulated levels of several clinical parameters, which are indicative of sepsis severity ([Table 1](#)). In parallel, both PTX3 and sIL-1R2 are increased with the increasing of severity from non-sepsis to sepsis and septic shock ([Figure 2](#) and [Table 1](#)).

For the patients admitted to wards we collected a second blood sample after 5 days of hospitalization (non-sepsis n=23, sepsis n=62, septic shock n=17). In most of the patients with matched samples at day 1 and 5 we observed a significant decrease of PTX3 after 5 days of hospitalization, while sIL-1R2 levels did not change ([Table 2](#)). PCT and CRP, two molecules widely used as biomarkers indicative of sepsis severity ([72](#), [73](#)), were also elevated in our cohort of patients compared to levels in healthy population [CRP<0.5 mg/dl; PCT 0.05-0.5 ng/ml ([74-76](#))], and were higher in Sepsis-3 patients compared to non-sepsis individuals (CRP:  $p=0.04$ ; PCT:  $p<0.0001$ , Mann-Whitney

test). In addition, a decrease was observed from day 1 to day 5 (not shown).

Univariable Spearman's rank correlation analysis of PTX3 and sIL-1R2 with SOFA score showed a positive correlation (PTX3:  $r=0.44$ ,  $p<0.0001$ ; sIL-1R2:  $r=0.35$ ,  $p<0.0001$ , [Table S1](#)). In addition, PTX3 and sIL-1R2 correlated with different clinical parameters evaluated at enrollment in ED (e.g. creatinine and D-dimer, [Table S1](#)) as well as with PCT and CRP. Finally, a correlation was observed between PTX3 and sIL-1R2 evaluated on day 1.

## Cytokine levels in Sepsis-3 population

In the same samples we measured a panel of pro-inflammatory (IL-6, IL-1 $\beta$ , TNF- $\alpha$ , IL-18 and IL-8) and anti-inflammatory cytokines (IL-10, IL-1ra). On day 1 all the cytokines were highly increased in patients compared to HC, with a gradual trend of progressively higher levels from non-sepsis to sepsis and septic shock patients ([Table 3](#)). In particular, there was approximately a 2-fold increase of all cytokines except IL-18 in septic shock patients compared to sepsis patients on day 1. When we limited the analysis to those patients admitted to wards, circulating levels of all cytokines decreased from day 1 to day 5, with the only exception of IL-1 $\beta$  in septic shock patients and IL-18 in sepsis patients ([Table S2](#)).

PTX3 and sIL-1R2 showed a positive correlation with all the pro- and anti-inflammatory cytokines considered in the present analysis, except IL-18 and IL-1 $\beta$  ([Table 4](#)). The strongest correlations were observed between the C-X-C chemokine IL-8, a main chemotactic

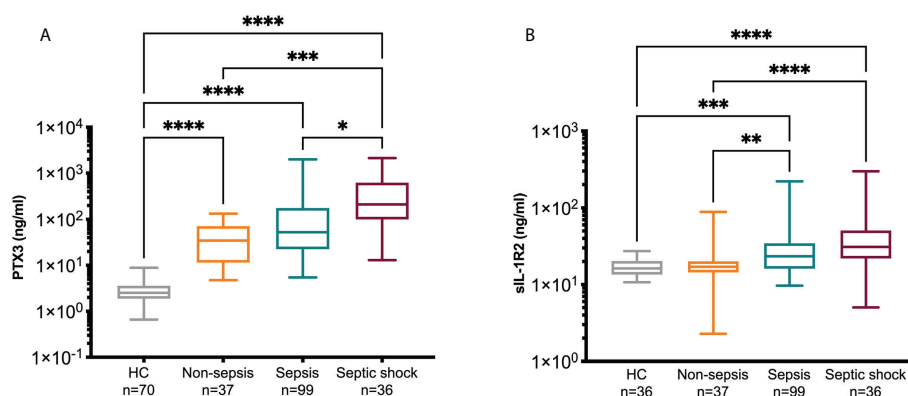

FIGURE 2

PTX3 and sIL-1R2 levels on day 1. PTX3 (A) and sIL-1R2 (B) plasma concentration were measured in non-sepsis, sepsis and septic shock patients admitted to ED. A group of healthy controls (HC) was also included. Kruskal-Wallis equality-of-populations rank test was used for the comparisons, \*  $p \leq 0.05$ ; \*\*  $p \leq 0.01$ ; \*\*\*  $p \leq 0.001$ ; \*\*\*\*  $p \leq 0.0001$ .

factor for neutrophils, and PTX3 ( $r=0.62$ ,  $p<0.0001$ ) or sIL-1R2 ( $r=0.50$ ,  $p<0.0001$ ) respectively. In addition, both pro and anti-inflammatory cytokines were positively correlated with SOFA score on day 1 of admission. Among them, TNF- $\alpha$  showed the strongest correlation ( $r=0.60$ ,  $p<0.0001$ , Table 4).

## Distribution of PTX3, sIL-1R2 and cytokines between survivors and non-survivors in Sepsis-3 patients

The 90-days survival analysis in the total Sepsis-3 population showed 99 survivors (73%) and 36 non-survivors (27%). Mortality rate was 20% among sepsis patients and 44% among septic shock patients. Of note, among the non-sepsis patients, four subjects (11%) did not survive following the 90-days follow up.

Clinical data, PTX3, sIL-1R2 and cytokines levels among survivors and non-survivors are summarized in Table 5. SOFA score, lactate, CRP, creatinine, d-dimer and urea on day 1 were remarkably higher in non-survivors compared to survivors. Similarly, PTX3 and sIL-1R2 levels at enrollment were

significantly higher in patients who died within 90 days from ED admission compared to those who survived. In addition, both pro- and anti-inflammatory cytokines levels were upregulated in non-survivors. Additional data are reported in Table S3.

## Multivariable model development

The association between candidate predictors measured at the arrival at the ED, and 90-days mortality was first explored by univariable Cox proportional analysis. Variables not associated with mortality in this cohort of patients are reported in Table S4, while predictors with a significant hazard ratio are listed in Table 6. According to the analysis, PTX3 and sIL-1R2 emerged as strong predictors of mortality, with a hazard ratio respectively of 3.09 [1.80-5.30] and 5.31 [2.05-13.74] and  $p \leq 0.001$  (Table 6). Combinations including the different biomarkers and clinical variables were then investigated. The most parsimonious multivariable Cox proportional hazard model comprising independent predictors of 90-days mortality included five variables: age, blood urea nitrogen, PTX3, IL-6 and IL-18 as

TABLE 2 PTX3 and sIL-1R2 levels at day 1 and day 5 in non-sepsis, sepsis and septic shock patients.

	PTX3 Day 1	PTX3 Day 5	p value	sIL-1R2 Day 1	sIL-1R2 Day 5	p value
<b>Non-sepsis</b> (n=23)	48.9 [28.1-82.5]	16.6 [10.0-30.7]	<b>0.001</b>	17.0 [12.0-20.0]	18.1 [13.1-21.1]	0.66
<b>Sepsis</b> (n=62)	69.4 [34.1-220.6]	17.6 [10.2-28.9]	<b>&lt;0.0001</b>	23.9 [17.9-35.1]	25.0 [17.28-35.6]	0.69
<b>Septic shock</b> (n=17)	219.8 [69.9-832.0]	30.31 [10.0-48.7]	<b>0.0001</b>	34.37 [21.3-72.2]	41.6 [15.9-82.4]	0.54

Data are reported as median ng/ml and [Q1-Q3], and refer only to those patients with available samples for both the time points. Number of patients is indicated for each group. The Wilcoxon signed-ranks test was used for the comparisons of PTX3 and sIL-1R2 levels on day 1 and day 5 in the different groups of patients. Statistically significant values are in bold character.

TABLE 3 Cytokine levels in healthy controls, non-sepsis, sepsis and septic shock patients on day 1 of admission to Emergency Department.

Cytokine	Healthy control (n=20)	Non-sepsis (n=37)	Sepsis (n=99)	Septic shock (n=36)	p value
IL-10	1.0 [0.7-1.4]	11.4 [5.8-29.0]	16.3 [8.3-41.0]	46.5 [15.2-333.5]	<b>0.0001</b>
IL-1 $\beta$	0.1 [0.0-0.3]	0.8 [0.5-1.4]	0.8 [0.5-1.3]	1.3 [0.7-2.9]	<b>0.0001</b>
IL-6	1.6 [1.0-2.9]	82.0 [30.6-128.2]	112.9 [35.2-230.3]	342.7 [125.7-8450.4]	<b>0.0001</b>
TNF- $\alpha$	4.9 [4.2-6.0]	14.9 [11.1-20.8]	23.1 [14.0-37.1]	45.5 [21.4-164.7]	<b>0.0001</b>
IL-18	138.9 [87.9-203.5]	262.6 [201.7-387.8]	328.8 [226.9-525.7]	376.3 [256.6-625.2]	<b>0.0001</b>
IL-1ra	183.5 [141.4-259.9]	2218.8 [1206.0-3258.2]	4005.4 [1418.5-9393.3]	15527.6 [4123.4-46700.6]	<b>0.0001</b>
IL-8	5.2 [4.1-8.5]	16.1 [10.9-27.5]	29.6 [15.1-73.0]	74.7 [42.2-352.3]	<b>0.0001</b>

Data are reported as median pg/ml and [Q1-Q3]; Kruskal-Wallis equality-of-population test was used for the comparison of cytokines levels among the non-sepsis, sepsis and septic shock groups of patients. Number of subjects with available data is indicated for each group. Statistically significant values are in bold character.

continuous predictors. The three biomarkers of inflammation were log10-transformed. The model included a strong positive interaction (synergistic effect) between IL-6 and IL-18 (i.e. due to this strong interaction term, despite their negative coefficients, IL-6 and IL-18 should be interpreted as positively associated with 90-days mortality, though in a non-linear fashion). All variables were significant at the conservative threshold of  $p < 0.005$ . For each predictor we calculated a threshold from the maximally selected rank statistics. The biomarkers threshold included: age (87 years), blood urea nitrogen (117 mg/dL), PTX3 (240 ng/ml), IL-6 (175 pg/ml), IL-18 (526 pg/ml). According to these thresholds, patients were categorized in two groups (i.e. high vs. low). In Figure 3 are reported the Kaplan-Meier curves for each predictor included in the final multivariable model.

The c-statistics, sensitivity and specificity of each of these predictors are reported in Table 7. PTX3 showed the highest apparent c-statistic (0.716; 95% CI: 0.636–0.796) and sensitivity and specificity (threshold: 240 ng/ml; sensitivity: 48.4%, 95% CI: 31.9–64.9; specificity: 89.9%, 95% CI: 82.7–97.0) in our cohort of patients.

Multivariable model specifications, including the baseline hazard at 90 days, are reported in Table 8. There was no evidence of violation of the proportionality of hazard assumption ( $p = 0.192$ ) and the Groennesby and Borgan test showed a reasonable model fit ( $p = 0.783$ ). The calibration plot showed good internal calibration (Figure S1), as indicated by a calibration slope equal to 1.146 (95% CI: 0.605–1.687) with an intercept not significantly different than zero ( $p = 0.876$ ). The Harrel c-statistic was 0.808 (95% CI: 0.734–0.882), indicating good discrimination performance.

We built a preliminary prognostic index by multiplying the multivariable model beta coefficients (including the interaction) by each patient's characteristics:

#### Prognostic Index

$$= 0.066 \times \text{Age} + 1.343 \times \log_{10}(\text{PTX3}) - 4.961 \\ \times \log_{10}(\text{IL} - 6) - 3.437 \times \log_{10}(\text{IL} - 18) + 0.008 \times \text{Urea} \\ + 1.903 \times \log_{10}(\text{IL} - 18) \times \log_{10}(\text{IL} - 6)$$

TABLE 4 Univariable correlations of PTX3, sIL-1R2 and SOFA score with cytokines in the Sepsis-3 population (n=135).

Data are reported as median and [Q1-Q3]; Mann-Whitney test was used for the comparisons. Only variables statistically significant are reported in the table. Abbreviations: DBP, diastolic blood pressure; FiO<sub>2</sub>, fraction of inspired oxygen; GCS, Glasgow coma scale; MAP, mean arterial pressure; SOFA, Sequential Organ Failure Assessment; qSOFA, quick Sequential Organ Failure Assessment. Statistically significant values are in bold character.

A nomogram plot associating each possible score with the individual 90-days risk of death is provided in **Figure S2**. The index was then dichotomized by applying the optimal threshold

derived by maximally selected rank-statistics (threshold value = 0.112, corresponding to a predicted 90-days risk of death of 35.3%). This allowed patient stratification into high vs. low 90-

TABLE 6 Univariable Cox proportional hazard analysis of candidate predictors of 90-days mortality.

<sup>1</sup>  $H_0 = 0.3894$  (90-days baseline hazard). Values of PTX3, IL-6 and IL-18 were log10 transformed before analysis. Abbreviations: CI, confidence interval. Statistically significant values are in bold character.

specificity (91.2%; 95% CI: 84.4–97.9) associated with this threshold showed a good performance of this classification rule in our sample of patients.

## Comparison of the prognostic index with SOFA and qSOFA

SOFA and qSOFA scores were used to identify patients with sepsis according with the Sepsis-3 criteria, however it is well known that this scoring system is also useful in predicting the clinical outcomes of critically ill patients (77, 78). We thus compared formally the AUC of our preliminary prognostic index with that of SOFA and qSOFA scores. The 90-days AUC of our preliminary index was 0.863 (95% CI: 0.780–0.945). The 90-days AUC of SOFA score was 0.727 (95% CI: 0.613–0.840), while the AUC for qSOFA at the same time-point was 0.660 (95% CI: 0.558–0.762). The AUC of our preliminary index was significantly greater than both SOFA ( $p=0.021$ ) and qSOFA scores ( $p<0.001$ ) in our cohort of patients, meaning that it was able to discriminate between patients dying from those surviving more accurately than the current gold standards.

## Discussion

Aim of this study was to evaluate the prognostic value of molecules of the innate immune response, namely PTX3 and sIL-1R2, in association with a set of pro- and anti-inflammatory cytokines (IL-1 $\beta$ , IL-6, IL-8, IL-10, IL-18, TNF- $\alpha$  and IL-1ra) and clinical parameters, in patients presenting at the Emergency Department with a suspicious or diagnosis of sepsis defined according to the Sepsis-3 criteria (65). At ED arrival, a progressive increase in the circulating levels of PTX3, sIL-1R2 and both pro- and anti-inflammatory cytokines was observed from non-sepsis to sepsis and septic shock patients. In univariable Cox analysis, PTX3, sIL-1R2 and all the cytokines analyzed in this study, except IL-18, were significant predictors of 90-days mortality. The combination of circulating levels of PTX3, IL-6 and IL-18, with age and blood urea nitrogen, constituted a preliminary prognostic index of 90-days

mortality with high sensitivity and specificity, and more efficient than the gold standards SOFA and qSOFA scores, providing a useful tool to stratify sepsis patients on arrival at the ED.

The emergency department plays a pivotal role in the prompt recognition of septic status and activation of optimal therapeutic approaches (79–81). Biomarkers predicting mortality risk would represent invaluable tools to quickly provide patients with the most appropriate hospital care (82, 83). The biomarkers described here are in principle amenable to evolution to rapid point-of-care tests better addressing emergency department needs. Different platforms are available or under development, potentially useful in this context, including the ELLA microfluidic immunoassay system used in our work or multiplexed label-free biosensors (84–86).

Several reports addressed the role of PTX3 as a biomarker of sepsis (29, 31, 33–40), while scanty and contrasting data are available on sIL-1R2 (44–49), and a general consensus on its role in sepsis has not yet been reached. The present work has the merit to analyze patients arriving at the ED and diagnosed according to the latest Sepsis-3 definition, without excluding any pre-existing comorbidity, including cancer. The model developed can be used for the early prediction of 90-days mortality risk, a timing no longer affected by the different therapies. PTX3 and sIL-1R2 circulating levels were increased, reflecting the augmented tissue damage and inflammation associated with the increased severity. In addition, both molecules strongly correlated with SOFA score in sepsis and septic shock patients (PTX3:  $r=0.44$ ,  $p<0.0001$ ; sIL-1R2:  $r=0.35$ ,  $p<0.0001$ ), confirming data obtained in earlier studies (31, 44), as well as with PCT, CRP and clinical parameters of severity. These data demonstrated that PTX3 and sIL-1R2 could be useful in monitoring the severity of disease in early hours of admission to ED.

The role of the immune system in sepsis is generally recognized and involves multiple processes, ranging from activation of pro-inflammatory mechanisms to immunosuppression, often occurring simultaneously (87–89). Early activation of the inflammatory response is involved in the pathogenesis of sepsis, and the altered levels of several cytokines observed in septic patients compared to healthy controls are likely involved in the organ injury observed in

FIGURE 4

Kaplan-Meier survival curve of the prognostic index once dichotomized by maximally selected rank statistics. Patients were categorized in high and low mortality risk groups based on the threshold value of the prognostic index. Survival in the two groups was analyzed by Log-rank test ( $p < 0.0001$ ).

sepsis (9, 90). In our cohort of patients, we observed significant changes in the levels of the panel of pro-inflammatory (IL-1 $\beta$ , IL-6, IL-8, IL-18, TNF- $\alpha$ ) and anti-inflammatory (IL-10, IL-1ra) cytokines. All the molecules were augmented in patients compared to HC and correlated with SOFA score, evidencing, as for PTX3 and sIL-1R2, the progressive increase of their circulating levels with the severity of disease. The concomitant upregulation of PTX3, CRP and pro-inflammatory cytokines (IL-6, IL-8, TNF- $\alpha$ ) on one side, and of the anti-inflammatory molecules sIL-1R2, IL-10 and IL-1ra on the other side, further supports the coexistence of pro-inflammatory and immunosuppressive mechanisms throughout the host response to sepsis.

After 5 days of hospitalization, a general decrease of PTX3 circulating levels was observed, in parallel with an improvement of patients' conditions and a reduction of the inflammation and/or infection burden. In parallel, a reduction of CRP, PCT and cytokines levels was observed in the cohort of patients, together with the general improvement of clinical parameters. On the contrary, no significant changes were recorded in circulating levels of sIL-1R2 in this time frame. Considering that sIL-1R2 is a key negative regulator of the IL-1 system, the maintenance of high levels of the molecule could tightly regulate the responses to IL-1 family members, contributing to protect from an exaggerated inflammatory response (26).

PTX3, sIL-1R2 and all cytokines investigated in our study were significantly higher in non-survivors compared to 90-days survivors, and were strong predictors of mortality. These results are in agreement with several studies reporting the association of cytokines such as IL-6 or IL-18 with poor outcome in septic patients (91, 92). In another study of a small cohort of sepsis,

severe sepsis and shock patient admitted to ICU, the levels of IL-6, IL-8 and IL-18 resulted higher in non-survivors compared to survivors, although following multivariable logistic regression analysis only IL-18 remained related to mortality (93). In addition, a positive synergistic effect has been observed between IL-18 and IL-6 that likely contributes to the association of these molecules with mortality, despite IL-18 not being a significant predictor of mortality by Cox proportional analysis. Our study was limited to a selected number of soluble mediators, and we are aware that other molecules could also play relevant roles. Growing interest has been observed for circulating antagonists of the IL-1 pathway, such as IL-18 binding protein (IL-18BP) and IL-1R4, also known as ST2 (94, 95), even for possible therapeutic implications (96). In a sub-group of patients, we measured both IL-18BP and IL-1R4: the two molecules were mildly increased in patients compared to healthy controls (data not shown). Although an increasing trend was seen from non-sepsis to sepsis and shock patients, IL-18BP and IL-1R4 were not significantly associated with mortality, in contrast to what reported by others (93, 96–98). A future comprehensive analysis of all the different molecules belonging to the IL-1 pathway would be helpful to fully define the strength of this essential family of inflammatory mediators in assessing sepsis patients.

Overall, the literature shows that none of the cytokines is a robust biomarker of mortality by itself (6, 11, 99). For this reason, the most recent investigations have mainly focused on the analysis of a combination of multiple biomarkers to predict outcome in sepsis patients (12–18). In a recent prospective observational analysis on septic patients arriving at the ED,

Song et al. showed that the combination of PTX3, IL-6, PCT and lactate was effective in predicting 28-days mortality with a good performance and better than SOFA score (100, 101). IL-6 alone, in combination with other molecules (102–104) or with neutrophil-to-lymphocyte ratio can be a marker of mortality in sepsis patients (74). Similarly, Matsumoto et al. suggested the involvement of a cytokine network including IL-6, IL-8, MCP-1 and IL-10 in the acute phase of sepsis and proposed the development of a combined score including IL-6 which is significantly correlated with prognosis (90). On the same line, our data argue in favor of the usefulness of testing a combination of multiple biomarkers to improve the prognostic capacity.

In multivariable Cox regression analysis, the combination of PTX3, urea, IL-6 and IL-18 levels with age showed the best prognostic value. Since this study includes a relatively low number of patients and death events, we ensured to select a parsimonious model with a very conservative threshold for significance ( $p < 0.005$ ). This model showed good internal calibration properties and could predict 90-days death significantly better than the SOFA score in our sample of patients, though these findings should be externally validated in an independent cohort in order to be generalizable.

Despite these limitations, these results could help to generate new hypotheses on the prognostic, but also etiological, role of IL-6 and IL-18 in sepsis. Similar to the study by Mierzchala-Pasierb et al. (105), we did not observe significant differences of IL-18 levels in survivors vs. non-survivors. However, both IL-18 and IL-6 were significant predictors of mortality in the full model. Additionally, when PTX3, urea levels and age were left unchanged, there was a highly significant interaction (positive synergistic effect) between IL-6 and IL-18, meaning there was a non-linear association between these two variables and 90-days mortality. This suggests that, although at low levels, IL-6 and IL-18 do not significantly affect the risk of mortality, thus, after a certain threshold, each increase becomes very importantly associated with the predicted mortality. This could perhaps be explained by the fact that IL-18 can induce the production of huge quantities of IL-6 from a variety of cell types through the activation of the NLRP3 inflammasome and caspase 1, effectively amplifying other pro-inflammatory signals (106). In our study, the variance of IL-18 values in sepsis patients was much lower (range from 6 pg/ml to about 2000 pg/ml) than what was observed for IL-6 (from 6 pg/ml to almost 1 million pg/ml). This may point toward a different magnitude of production of IL-6 in certain high-risk septic patients, in presence of relatively similar levels of IL-18. Further studies are necessary to characterize the physio-pathological role of these cytokines in sepsis patients.

Besides the aforementioned low number of participants, its monocentric nature, and the need for external validation, this study has other limitations. Patient demographics in our study

cohort differed from other sepsis studies, including enrollment of patients at ED admission instead of later in the ICU setting. This adds novelty to our study, but also adds heterogeneity to our results. Some clinical data are missing for a fraction of patients, such as lactate and PCT levels, and we did not have other clinical scores, such as Simplified Acute Physiology Score (SAPS) II, SAPS III, and/or Acute Physiology and Chronic Health Evaluation II (APACHE II) scores. In our cohort, 31% of sepsis patients and 39% of septic shock patients had a malignancy as comorbidity, whereas many studies exclude malignancy-linked sepsis. However, we believe that considering all sepsis cases regardless of comorbidities could have added diagnostic value in the ED setting. Given the different comorbidities in our cohort of patients, the inflammatory markers such as CRP and PCT may be also influenced, potentially affecting the results; however, the reduction observed in patients after 5 days of hospitalization suggested that comorbidities had a limited impact on the overall inflammatory status of the patients. These preliminary results need to be confirmed with multicentric studies involving larger cohorts of patients. Overall, the increasing development of point-of-care testing systems for the rapid and accurate measurement of circulating molecules makes the evaluation of multiple soluble mediators feasible even in the emergency room (85, 86).

In conclusion, we concur with other reports that a combination of inflammatory mediators and clinical parameters can improve risk stratification of sepsis patients. Our data indicate that high levels of PTX3 in plasma of patients with suspected sepsis admitted to the emergency room can be used as a prognostic marker for risk stratification. In addition, measurement of PTX3 in combination with cytokine levels (IL-6 and IL-18), and other routine clinical parameters rapidly available in ED (e.g., age, urea), can provide a promising approach for 90-days mortality prediction for sepsis patients, better than the use of a single biomarker.

## Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## Ethics statement

The studies involving human participants were reviewed and approved by the Institutional Review Board of Humanitas Hospital (Approval n° 820/18). The patients/participants provided their written informed consent to participate in this study.

## Author contributions

SD, AV, AlbM, and BB made substantial contributions to the conception and design of the study; AD, AleM, DPv, CF, and DC collected patient samples and clinical data; SD, RL, MSi, SV and RS-G performed the experiments; SD, DP, SM, MSt and SB performed the data analyses; SD, DP, AD, SB, AV, AlbM, MSt and BB interpreted the results; SD, DP, AlbM, and BB wrote the paper. All authors were involved in the analysis and interpretation of data, drafting the manuscript and revising it critically, and approved the final version.

## Funding

SD was supported by European Sepsis Academy/Innovative Training Networks (ESA/ITN) from the European Commission (H2020-MSCA-ITN-2015, Grant agreement Number: 676129). RS-G acknowledge financial support from Fundação para a Ciência e a Tecnologia (FCT) for Ph.D. grant PD/BD/114138/2016. This study has received funding from Associazione Italiana Ricerca sul Cancro (AIRC) [Special Program Metastatic disease: the key unmet need in oncology AIRC 5X1000 grant n° 21147 and “Regulatory pathways of myeloid cells, inflammation and cancer” grant IG-2019 N. 23465].

## Acknowledgments

We thank all the physicians, nurses, and laboratory personnel of the Emergency Department and wards of

Humanitas Research Hospital for their active collaboration. Also, a special thanks to all the patients who participated in this study.

## Conflict of interest

AlbM and BB are inventors of a patent (EP20182181) on PTX3 and obtain royalties on related reagents.

The remaining authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Embryo implantation is a key moment in pregnancy. Abnormal production of pro- and anti-inflammatory cytokines, their receptors and other immune factors may result in embryo implantation failure and pregnancy loss. The aim of this study was to determine the profile of selected pro- and anti-inflammatory factors in the blood plasma of patients undergoing *in vitro* fertilization (IVF) and control women who achieved pregnancy after natural conception. The examined patients were administered steroid prednisone. We present results concern the plasma levels of IFN- $\gamma$ , BDNF, LIF, VEGF-A, sTNFR1 and IL-10. We found that IVF patients receiving steroids differed significantly from patients who were not administered such treatment in terms of IFN- $\gamma$  and IL-10 levels. Moreover, IVF patients differed in secretion of all tested factors with the fertile controls. Our results indicated that women who secrete at least 1409 pg/ml of sTNFR1 have a chance to become pregnant naturally and give birth to a child, while patients after IVF must achieve a concentration of 962.3 pg/ml sTNFR1 in blood plasma for successful pregnancy. In addition, IVF patients secreting VEGF-A above 43.28 pg/ml have a greater risk of miscarriage or a failed transfer in comparison to women secreting below this value. In conclusion, fertile women present a different profile of pro- and anti-inflammatory cytokines, and growth factors compared to patients with recurrent implantation failure (RIF).

## KEYWORDS

*in vitro* fertilization embryo transfer, recurrent implantation failure, cytokines, proinflammatory, anti-inflammatory

# 1 Introduction

Embryo implantation is a crucial process in the development and maintenance of a pregnancy. It begins with blastocyst adhesion to the surface of the uterus. Trophoblast cells, derived from the trophoderm, form columns of anchoring villi and differentiate into syncytiotrophoblast and extravillous trophoblast (EVT). Furthermore, extravillous trophoblast migrate to the maternal uterus and develop into a placenta (1, 2). Implantation failure may occur during early stages of embryo development. Inability to naturally conceive is the primary reason behind couples using assisted reproductive techniques (ART). Despite significant advances in ART, such as *in vitro* fertilization (IVF), women undergoing these procedures experience recurrent implantation failure (RIF) (3, 4). The exact definition of RIF is difficult to determine, but most clinicians define RIF as a failure to achieve a pregnancy after three subsequent IVF cycles in which four good-quality embryos are transferred into women under the age 40 years (4–6). The pathogenesis of recurrent embryo implantation failure is ambiguous. There are many risk factors that may contribute to RIF, with the primary causes being maternal, male or embryo factors (4). During pregnancy the immune system has the dual purpose to protect the mother and the developing fetus against pathogens while also allowing tolerance for the semi-allogenic fetus, which expresses antigens from both the mother and the father. During trophoblast invasion and at birth, the decidua is dominated by pro-inflammatory factors, while anti-inflammatory factors are dominant in the second and third trimesters of pregnancy to facilitate fetal growth (7, 8).

Cytokines mediate signals between the endometrium during embryo implantation and throughout pregnancy. They may promote trophoblast invasion and placental formation. Maintaining the right balance between pro-inflammatory and anti-inflammatory cytokines is essential for pregnancy development and disorders or infections can alter cytokine expression (9). Cytokines can be secreted by endometrial cells and by immune system cells recruited into the uterus to the site of implantation. They are mostly uterine natural killer cells, macrophages, and dendritic cells (10–14). T cells also exhibit complex and variable cytokine production. Th1 cells are mainly involved in the elimination of cells infected with viruses and intracellular pathogens. Th1 cytokines (considered as pro-inflammatory) include interferon- $\gamma$  (IFN- $\gamma$ ), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and the interleukins: IL-1, IL-2, IL-12, IL-15, IL-18 (15, 16). Th1 cytokines predominate during the early stages of implantation and are thought to promote trophoblast invasion. Higher levels of TNF- $\alpha$  before embryo transfer have been shown to be associated with clinical pregnancy in RIF patients, emphasizing that pro-inflammatory factors are needed for embryo implantation (17, 18). However, studies concerning TNF- $\alpha$  are ambiguous because a meta-analysis performed by Zhang et al. showed an increased level of this cytokine in patients with recurrent spontaneous miscarriage in comparison to the controls (19). TNF- $\alpha$  works by binding to the TNF- $\alpha$  receptors (TNFR1 and TNFR2). Moreover, TNF receptors (TNFR1 and also TNFR2) expressed on trophoblasts may play a role in regulating

development of fetus in pregnancy (20–22). After embryo implantation, in the second trimester of pregnancy, a noticeable shift occurs and the Th2 (anti-inflammatory) cytokines begin to predominate in the uterus, these include: IL-4, IL-5, IL-10, IL-13 and granulocyte-macrophage colony-stimulating factor (GM-CSF). Th2 cytokines are responsible for fetal growth and maintenance of the pregnancy. The prevalence of the Th1 response over Th2 may be associated with various complications of pregnancy, for example recurrent miscarriages, pre-eclampsia and embryo implantation failure after *in vitro* fertilization (9, 23–25). In the third trimester of pregnancy, the Th1 inflammatory response returns. Of great importance in this phase is the infiltration of immune cells into the myometrium, which supports uterine contractions, labor and placental separation (10, 26).

Cytokines may have an effect on endometrial decidualization. This is the process of endometrial stromal cell differentiation into specialized decidual cells that create the lining for the implanting embryo. Cytokines promote blood vessel formation and increase blood flow in the decidua. Uterine NK cells (uNK) are capable of secreting angiogenic factors such as vascular endothelial growth factor (VEGF) and placental growth factor (PlGF) (27). PlGF may have both a pro-angiogenic or anti-angiogenic effect, therefore effective decidualization requires the appropriate expression levels of this factor (28). VEGF can regulate the proliferation and survival of endothelial cells and increases the permeability of blood vessels. Therefore, VEGF supports the differentiation of trophoblast cells and is responsible for angiogenesis in the decidua (28, 29). It is reported that VEGF-A is the most important and potent factor in angiogenesis (30). Brain-derived neurotrophic factor (BDNF), which belongs to the neurotrophin family, is involved in the proliferation, differentiation and survival of neuronal cells. BDNF also plays a role in placental development, differentiation and proliferation of trophoblasts (31). Reduced circulating levels of BDNF in the sera of women undergoing IVF were probably associated with adverse peri- and/or post-implantation events and subsequent pregnancy failure (32).

A significant role in embryo implantation may also be played by leukemia inhibitory factor (LIF). It is expressed in the endometrium at the time of implantation by uNK cells and its receptor is located both in the endometrium and on the trophoblast (33, 34). By regulating prostaglandin synthesis, LIF may affect embryo implantation and decidualization. Studies have shown that LIF can enhance the expression of human leukocyte antigen (HLA-G) in choriocarcinoma cell line JEG3, used as a model for trophoblasts (35). This induction occurred in the presence of endoplasmic reticulum aminopeptidase-1 (ERAP1), which is involved in HLA class I antigenic peptide presentation through the trimming peptides to their optimal length.

Pro-inflammatory and anti-inflammatory cytokines and cytokine receptor profiles may change in the plasma of patients before and after the *in vitro* fertilization procedure. Abnormal production of cytokines and other immune factors may result in embryo implantation failure and pregnancy loss. Measurement of the level of these factors in the plasma of patients undergoing IVF before and after the procedure may potentially be useful and have

prognostic value in the diagnosis of RIF. Therefore, the aim of this study was to determine the immunological profile of pro- and anti-inflammatory cytokines in the blood plasma of patients undergoing *in vitro* fertilization before and after embryo transfer and control women who achieved pregnancy after natural conception. We investigated plasma levels of IFN- $\gamma$ , GM-CSF, TNF- $\alpha$ , PlGF, BDNF, LIF, VEGF-A, VEGF-D, TNFR1 and interleukins: IL-10, IL-4, IL-6. The patients under examination were administered the steroid prednisone, which prompted our novel investigation into the influence of steroids on the secretion of specific cytokines.

## 2 Materials and methods

### 2.1 Study design

One hundred eighty-seven patients were involved in this study (age range: 22–46), all underwent *in vitro* fertilization embryo transfer. Patients were enrolled into the study in years 2015 to 2020. They were qualified at the Gameta Assisted Reproduction Clinic in Rzgów, a centre certified by the European Society for Human Reproduction and Embryology (ESHRE ART Centre Certification for good clinical practice) and at the Department of Surgical, Endoscopic and Oncologic Gynecology, Department of Gynecology and Gynecologic Oncology, Polish Mothers' Memorial Hospital–Research Institute. Patients underwent an average 3 unsuccessful transfers and each had 3 good quality embryos transferred. In 67 patients (35.82%) IVF was indicated due to male only fertility factors, while female factors accounted for 45 patients (24.06%). Twenty-eight patients (14.97%) were infertile due to male and female factors, while idiopathic infertility was found in 47 patients (25.13%).

Eighty-seven percent of all patients (164 women) were administered prednisone. In the standard IVF procedure, patients

were instructed to take 5 mg of prednisone on a routine basis (Encorton, Adamed, Poland) once a day in the morning orally, starting from the day of embryo transfer (ET/frozen ET). Patients with RIF received higher doses of prednisone (10–20 mg) for 2–3 weeks before ET and up to 8 weeks if pregnancy developed after transfer. Among those patients taking prednisone, 85 women achieved clinical pregnancy, 42 women experienced a miscarriage and in the case of 37 patients the embryo transfer resulted in a lack of pregnancy.

In order to supplement the luteal phase, all patients were intravaginally administered 2  $\times$  200 mg micronized progesterone (Luteina, Adamed, Poland) and oral dydrogesterone 3  $\times$  10 mg (Duphaston, Solvay Pharmaceuticals, Netherlands) until 12 weeks of gestation. Detailed information on the preparation of patients for IVF [ovarian stimulation, fertilization procedure, assessment of endometrial thickness for initiation progesterone supplementation and frozen ET (FET)] has been described in an earlier by Nowak et al. (36).

The fertile control group was recruited from the Institute of Immunology and Experimental Therapy of the Polish Academy of Sciences in the years 2018–2020. This group consisted of 67 healthy women (age range: 19–68) with at least 1 healthy-born child after natural conception and no history of miscarriage or endocrinological or immunological diseases, except five women, who had hypothyroidism. Among fertile control, we had samples from 27 pregnant women from natural conception. The gestational age of these women was from 6 to 37 weeks at the moment of blood donation. None of the fertile control patients were administered any steroid treatment.

All tested patients were of Polish origin. Experiments were carried out after obtaining the approval of the Ethics Committee of the Polish Mothers' Memorial Hospital–Research Institute in Łódź (No: 25/2019). The necessary consent was obtained from all individual participants. IVF patients differed significantly in mean

TABLE 1 Characteristics of patients and the fertile control groups.

Parameter		IVF	Fertile control	Fertile pregnant control
Number of women		N = 187	N = 40	N = 27
Age of women	Mean $\pm$ SD	32.99 $\pm$ 4.15	32.93 $\pm$ 6.03	31.69 $\pm$ 5.13
	Range	22–46	22–68	19–42
Indications for IVF-ET (%)	Male only factor	67 (35.82)	–	–
	Female only factor	45 (24.06)	–	–
	Both factors	28 (14.97)	–	–
	Unknown factor	47 (25.13)	–	–
Number of IVF-ET in all cycles	Mean $\pm$ SD	3.08 $\pm$ 0.15	–	–

	Range	1–13	–	–

age from fertile women ( $p = 0.0414$ ). The clinical characteristics of patients and fertile women are described in [Table 1](#).

## 2.2 Measurement of pro- and anti-inflammatory cytokines and growth factors levels in plasma

Plasma samples from patients were taken before and after IVF-ET [at the moment of testing for beta-subunit of human chorionic gonadotropin ( $\beta$ -hCG)] between 11 and 15 days following the ET date) and also from fertile women. Samples were stored at  $-80^{\circ}\text{C}$  until the time of assay. Plasma levels of GM-CSF, IFN- $\gamma$ , IL-10, IL-4, TNF- $\alpha$  (pg/ml) were detected by Human ProcartaPlex High Sensitivity assay (Thermo Fisher Scientific, USA) using the Luminex 200 system (Luminex Corp., USA). Concentrations of BDNF, IL-6, PlGF, LIF, TNF-R1, VEGF-A, VEGF-D (pg/ml) were measured by the commercial Human ProcartaPlex assay (Thermo Fisher Scientific, USA) also using the Luminex 200 system (Luminex Corp., USA). All measurements were performed following the protocol of the manufacturer. Luminex technology is based on colored magnetic microspheres coated with antibodies that capture specific analytes in a multiplex ELISA. The median fluorescence intensity was compared to the standard curve to calculate the analyte concentration in pg/mL with xPonent 4.2 software. Standard curves for each analyte were generated using the premixed lyophilized standards provided in the kits. Serial 4-fold dilutions of the standards were run to generate a 7-standard concentration set, and the diluent alone was used as a blank. The analyte concentrations in the samples were determined from the standard curve using a 5-parameter logistic fit curve to transform the mean fluorescence intensities into concentrations. There is a different detection range for each analyte. Standard curves measured the concentration were: for IFN- $\gamma$  from 1.44 to 5900 pg/ml, for IL-10 from 0.19 to 765 pg/ml, for BDNF from 1.71 to 7000 pg/ml, for LIF from 11.06 to 45300 pg/ml, for TNFR1 from 158.96 to 651100 pg/ml, for VEGF-A from 5.49 to 22500 pg/ml.

## 2.3 Statistical analysis

To assess the differences in the concentration of the selected cytokines and growth factors in patient plasma before and after ET, the Mann-Whitney test was performed (GraphPad Prism 5 software). The normality of the data distributions was assessed by the D'Agostino-Pearson test. Statistical significance was considered as  $p$  value  $< 0.05$ . All parameters of statistical analyses (numbers, medians, means, standard deviation and errors, min, max and 25-75% percentiles) are part of [Supplementary Tables 1-12](#). Results of the statistical analysis referring to cytokines and growth factors such as GM-CSF, IL-4, TNF- $\alpha$ , IL-6, PlGF and VEGF-D failed to yield any conclusions due to undetectable levels of cytokines. The median fluorescence intensities of tested analytes were not intensive enough to calculate their concentration. Therefore they were omitted from this manuscript.

## 3 Results

### 3.1 Secretion of IFN- $\gamma$ in patients and the fertile control groups

We found that IVF patients who were prescribed steroids differed significantly from patients who were not. IVF patients without steroid treatment had higher levels of IFN- $\gamma$  before and after ET in comparison to patients receiving steroid treatment ( $p = 0.0005$ , median 0.28 vs. 0.00 pg/ml and  $p < 0.0001$ , median 0.26 vs. 0.00 pg/ml, respectively; [Figure 1A](#); [Supplementary Table 1](#)). Fertile women who had given birth in the past and women who were pregnant at the time of blood collection differed in terms of IFN- $\gamma$  concentrations compared to IVF patients taking prednisone before and after ET ( $p < 0.0001$  for comparisons with IVF steroid treatment patients, median 0.29 vs. 0.00 pg/ml before and after ET, median 0.28 vs. 0.00 pg/ml before and after ET). IVF women untreated with steroid secreted less IFN- $\gamma$  after ET than fertile women and fertile pregnant women ( $p = 0.0041$ , median 0.26 vs. 0.29 pg/ml and  $p = 0.0148$ , median 0.26 vs. 0.28 pg/ml, respectively).

IVF patients taking prednisone, the overwhelming majority, did not secrete IFN- $\gamma$  (all medians 0.000 pg/ml), therefore we only found statistically significant differences between those patients and women from control groups (median 0.29 and 0.28 pg/ml). The concentration of IFN- $\gamma$  measured before and after ET differed in patients who became pregnant and fertile women who had given birth in the past and pregnant control ( $p < 0.0001$  for both patient groups before and after ET; [Figure 1B](#); [Supplementary Table 2](#)). We observed the same differences ( $p < 0.0001$  or  $p = 0.0002$ ) in the analysis of patients who experienced a lack of pregnancy or had miscarriages and women from the control groups.

### 3.2 IL-10 secretion in IVF patients and the fertile control groups

We observed that patients undergoing steroid treatment secreted significantly more IL-10 into plasma than patients without steroid treatment ( $p = 0.0063$ , median 0.31 vs. 0.05 pg/ml before ET;  $p = 0.0007$ , median 0.34 vs. 0.04 pg/ml after ET; [Figure 2A](#); [Supplementary Table 3](#)). Most fertile women did not secrete IL-10 (median 0.00 pg/ml) and they differed to IVF patients receiving steroid treatment and those without in terms of IL-10 plasma levels (for patients with steroid treatment:  $p = 0.0027$ , median 0.00 vs. 0.05 pg/ml before ET,  $p = 0.009$ , median 0.00 vs. 0.04 pg/ml after ET; for patients without steroid treatment:  $p < 0.0001$ , median 0.00 vs. 0.31 pg/ml before ET;  $p < 0.0001$ , median 0.00 vs. 0.34 pg/ml after ET).

The concentration of IL-10 measured before and after ET did not differ in IVF women using steroid and achieved pregnancy (median 0.34 pg/ml before and 0.35 pg/ml after ET) and patients who experienced a lack of pregnancy (median 0.24 pg/ml before and 0.50 pg/ml after ET) or patients who experienced a miscarriage (median 0.30 pg/ml before and 0.24 pg/ml after ET) ([Figure 2B](#);

Supplementary Table 4). However, we noticed a decreased level of IL-10 in women who conceived naturally and gave birth to a child (median 0.00 pg/ml). The difference in concentrations between the fertile controls and all these patients was  $p < 0.0001$ , both before and after embryo transfer (Figure 2B; Supplementary Table 4).

### 3.3 Secretion of BDNF in IVF patients and the fertile control groups

We found no significant differences between patients who received steroid treatment and patients who did not in terms of

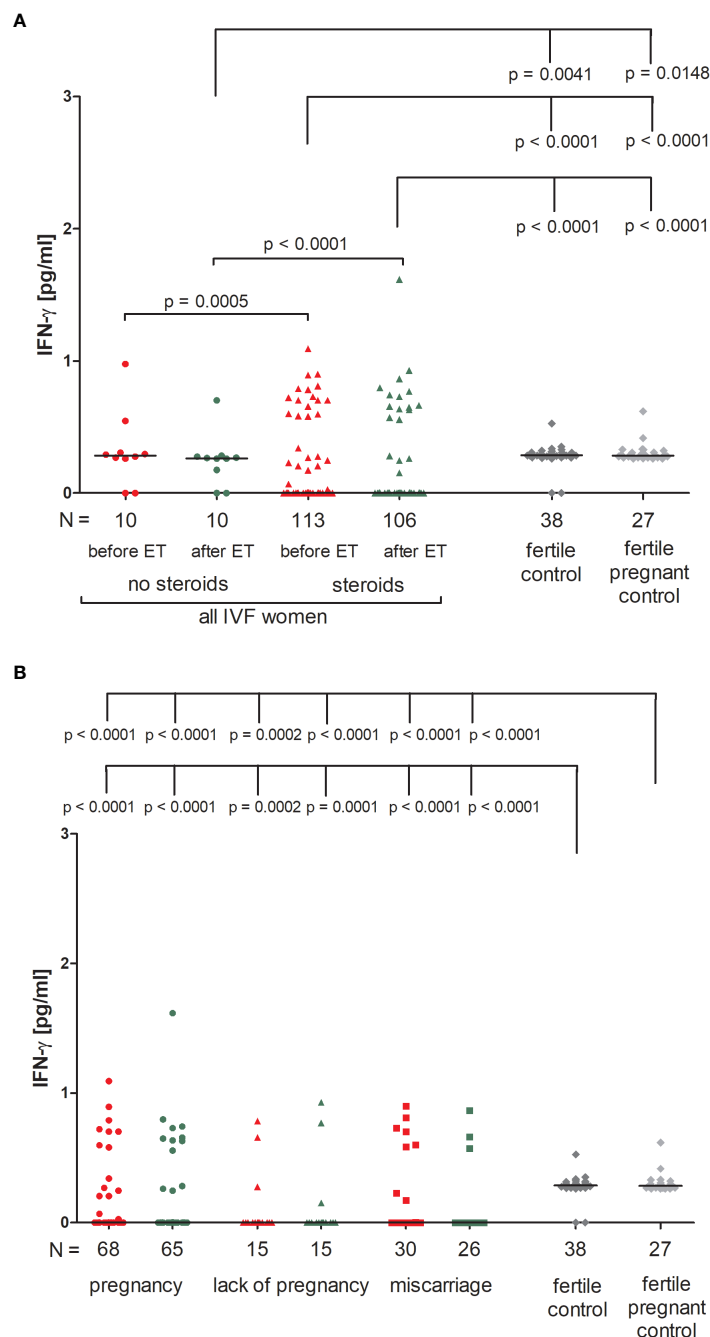

FIGURE 1

Concentration of plasma IFN- $\gamma$  measured before and after embryo transfer in all patients and fertile controls. (A) Concentration of IFN- $\gamma$  (pg/ml) measured before and after embryo transfer in patients receiving steroid or no steroid treatment and in fertile controls (without steroid treatment); (B) Concentration of IFN- $\gamma$  (pg/ml) measured before and after embryo transfer in steroid treatment patients who achieved clinical pregnancy, experienced a lack of pregnancy or miscarriage and in fertile controls (without steroid treatment). Red points indicate measurement before embryo transfer; green, after embryo transfer; dark grey points, fertile control; light grey points, fertile pregnant control. N is the number of women. Black horizontal lines represent medians. P values are calculated by Mann-Whitney test.

BDNF secretion into plasma (Figure 3A; Supplementary Table 5). On the other hand, fertile women who were pregnant at the moment of blood collection had the lowest level of BDNF (median 0.00 pg/ml). Therefore, this group of women differed in

secretion of BDNF with patients receiving steroid treatment ( $p = 0.0047$ , median 6.52 pg/ml before ET) and patients without steroid treatment ( $p = 0.0062$ , median 0.00 pg/ml before ET;  $p = 0.0006$ , median 5.38 pg/ml after ET). Women with a current natural

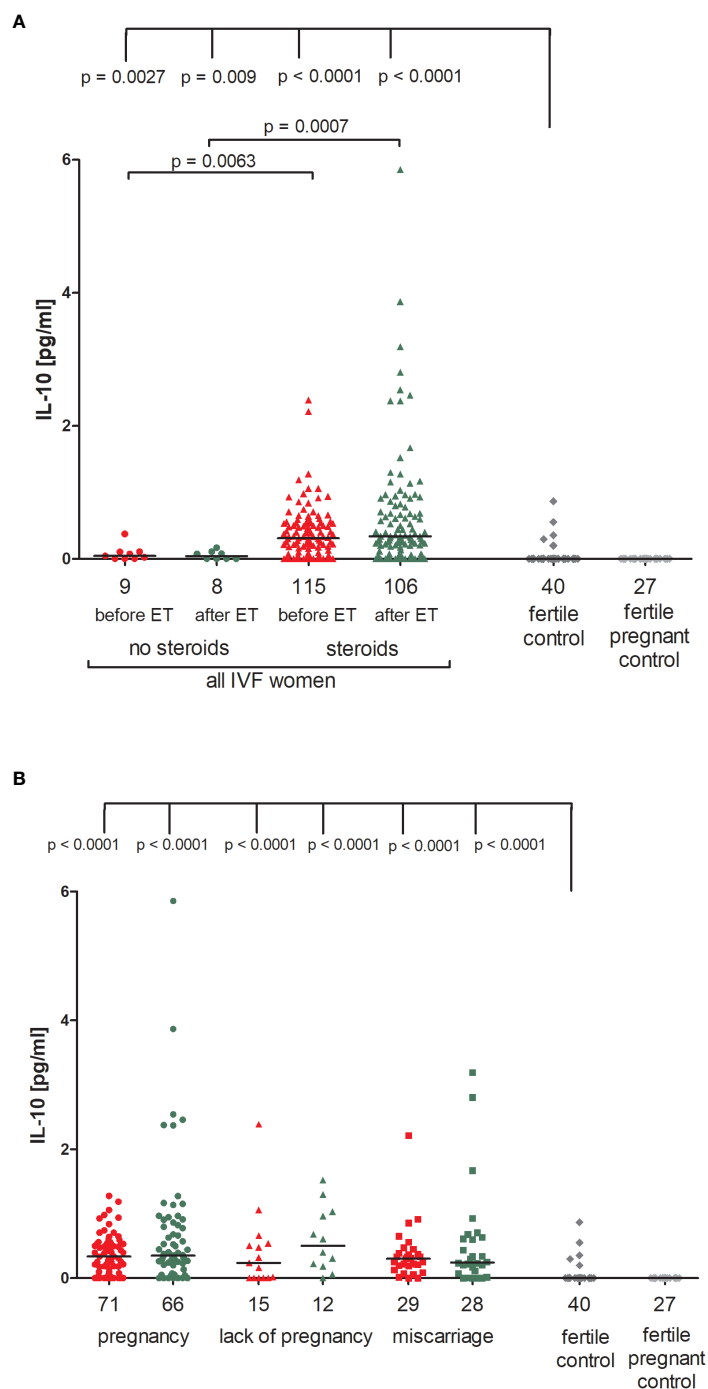

FIGURE 2

Concentration of plasma IL-10 measured before and after embryo transfer in all patients and fertile controls. **(A)** Concentration of IL-10 (pg/ml) measured before and after embryo transfer in patients receiving steroid or no steroid treatment and in fertile controls (without steroid treatment); **(B)** Concentration of IL-10 (pg/ml) measured before and after embryo transfer in steroid treatment patients who achieved clinical pregnancy, experienced a lack of pregnancy or miscarriage and in fertile controls (without steroid treatment). Red points indicate measurement before embryo transfer; green, after embryo transfer; dark grey points, fertile control; light grey points, fertile pregnant control.  $N$  is the number of women. Black horizontal lines represent medians.  $P$  values are calculated by Mann-Whitney test.

pregnancy also had a lower level of BDNF than women who had given birth in the past previously from natural conception ( $p = 0.0106$ , median 0.00 vs. 0.30 pg/ml).

When we divided patients receiving steroid treatment according to their pregnancy outcome after embryo transfer, we observed significant differences between all patients and the fertile pregnant controls (Figure 3B; Supplementary Table 6). The most striking

difference in concentration of BDNF was observed in fertile pregnant women and patients for whom the embryo transfer did not result in a pregnancy ( $p = 0.0011$ , median 0.00 vs. 13.53 pg/ml after ET, respectively). Furthermore, the level of BDNF before ET in patients with a lack of pregnancy was higher than in the fertile pregnant controls ( $p = 0.0047$ , median 0.11 vs. 0.00 pg/ml, respectively). When embryo transfer resulted in pregnancy, we

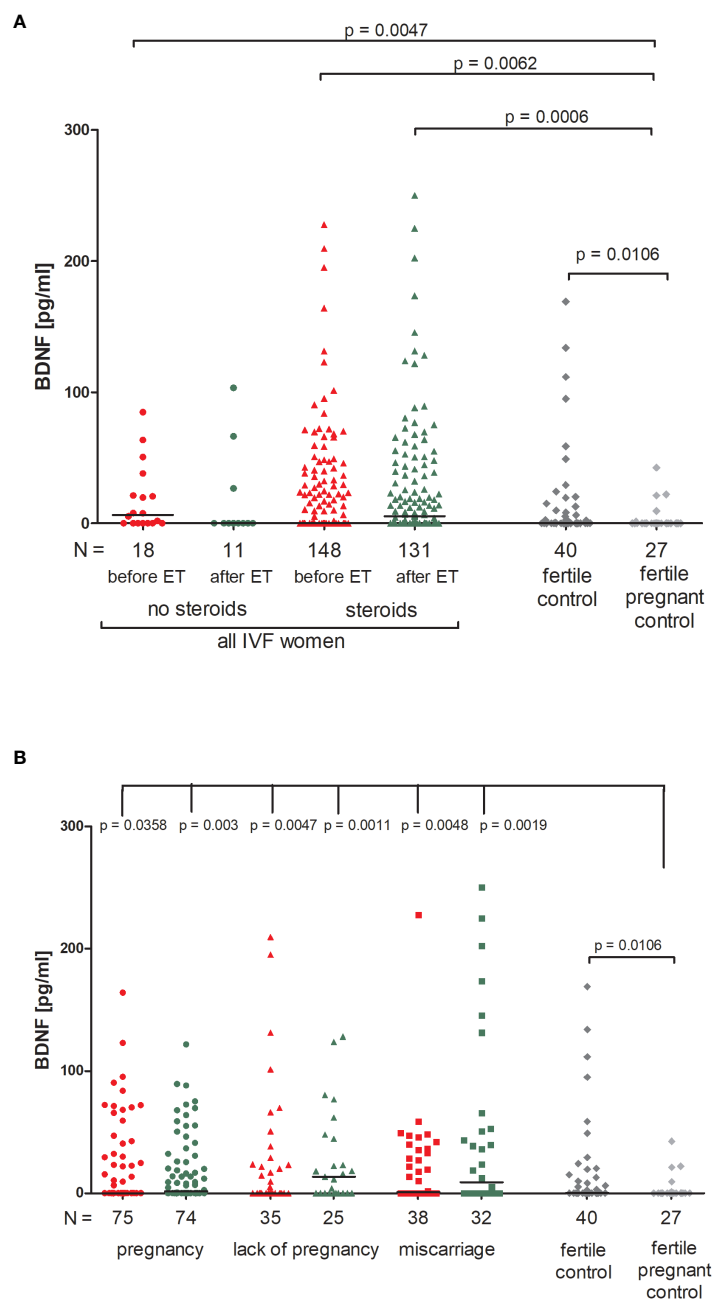

FIGURE 3

Concentration of plasma BDNF measured before and after embryo transfer in all patients and fertile controls. (A) Concentration of BDNF (pg/ml) measured before and after embryo transfer in patients receiving steroid or no steroid treatment and in fertile controls (without steroid treatment); (B) Concentration of BDNF (pg/ml) measured before and after embryo transfer in steroid treatment patients who achieved clinical pregnancy, experienced a lack of pregnancy or miscarriage and in fertile controls (without steroid treatment). Red points indicate measurement before embryo transfer; green, after embryo transfer; dark grey points, fertile control; light grey points, fertile pregnant control.  $N$  is the number of women. Black horizontal lines represent medians.  $P$  values are calculated by Mann-Whitney test.

also observed statistically significant differences between patients and the fertile pregnant controls ( $p = 0.0358$ , median 0.00 before ET vs. 0.00 pg/ml,  $p = 0.003$ , median 1.63 vs. 0.00 pg/ml, respectively). Additionally, patients who experienced a miscarriage had a higher secretion of BDNF than in the fertile pregnant controls ( $p = 0.0048$ , median 0.94 before ET vs. 0.00 pg/ml;  $p = 0.0019$ , median 8.93 vs. 0.00 pg/ml).

### 3.4 LIF secretion in IVF patients and fertile groups

Patients who were not receiving steroid treatment had higher LIF values both before and after ET, but the differences compared to patients using prednisone were not significant (Figure 4A; Supplementary Table 7). All patients had a higher concentration

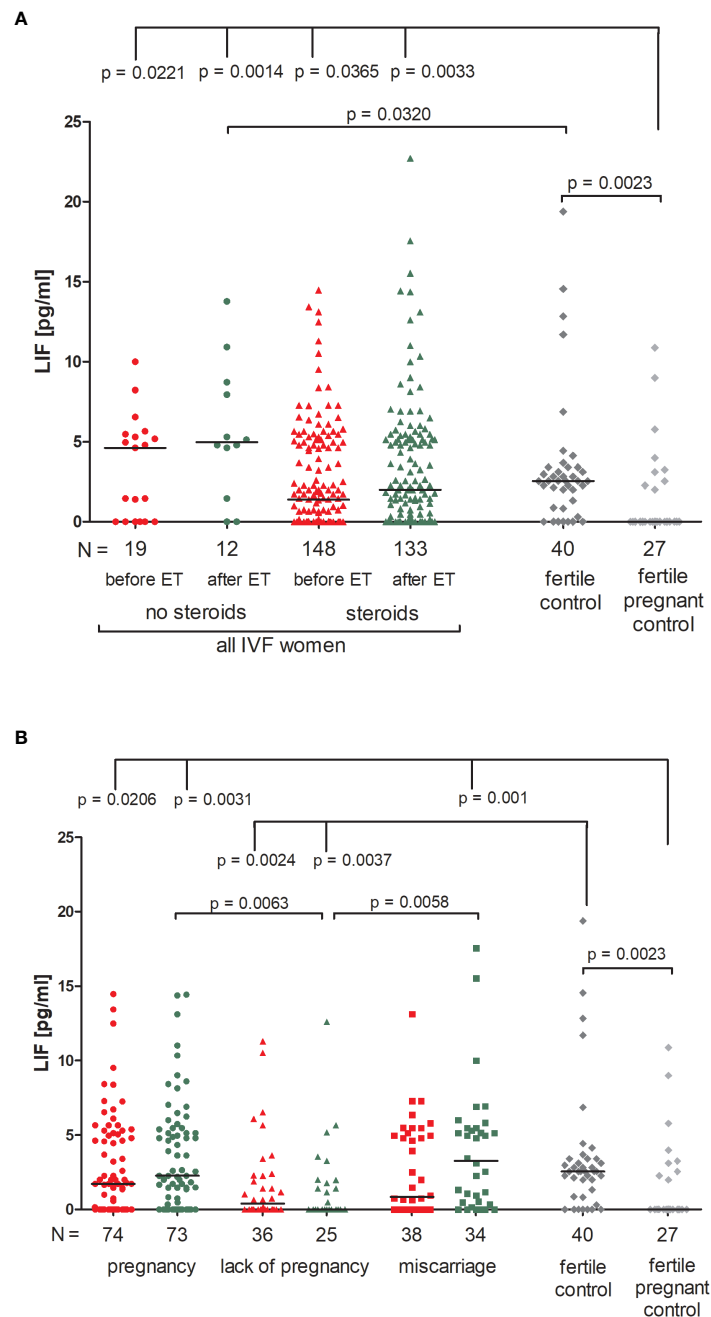

FIGURE 4

Concentration of plasma LIF measured before and after embryo transfer in all patients and fertile controls. (A) Concentration of LIF (pg/ml) measured before and after embryo transfer in patients receiving steroid or no steroid treatment and in fertile controls (without steroid treatment); (B) Concentration of LIF (pg/ml) measured before and after embryo transfer in steroid treatment patients who achieved clinical pregnancy, experienced a lack of pregnancy or miscarriage and in fertile controls (without steroids treatment). Red points mean measurement before embryo transfer; green, after embryo transfer; dark grey points, fertile control; light grey points, fertile pregnant control. N is the number of women. Black horizontal lines represent medians. P values are calculated by Mann-Whitney test.

of LIF than in the fertile pregnant controls ( $p = 0.0221$ , median 4.62 before ET vs. 0.00 pg/ml and  $p = 0.0014$ , median 4.94 after ET vs. 0.00 pg/ml for patients not receiving steroid treatment;  $p = 0.0365$ , median 1.38 before ET vs. 0.00 pg/ml and  $p = 0.0033$ , median 2.00 after ET vs. 0.00 pg/ml for patients receiving steroid treatment). In addition, patients with no steroid treatment had a higher level of LIF after ET in comparison to the fertile controls ( $p = 0.0320$ , median 4.96 vs. 2.55 pg/ml, respectively). We also observed different secretion levels of LIF in fertile women and fertile pregnant women ( $p = 0.0023$ , median 2.55 vs. 0.00 pg/ml, respectively; [Figure 4A](#); [Supplementary Table 7](#)).

When we compared patients according to various pregnancy outcomes, we observed that the lowest level of LIF in plasma was found in those patients who experienced a lack of pregnancy, in particular there was a concentration decrease after embryo transfer ([Figure 4B](#); [Supplementary Table 8](#)). Comparison between patients who experienced a lack of pregnancy and patients who achieved pregnancy after ET ( $p = 0.0063$ , median 0.00 vs. 2.27 pg/ml after ET) and also between patients who had a miscarriage ( $p = 0.0058$ , median 0.00 vs. 3.27 pg/ml after ET) was significant. P values were also significant in comparison of the LIF secretion between patients with a lack of pregnancy and fertile women ( $p = 0.0024$ , median 0.40 before ET vs. 2.55 pg/ml;  $p = 0.0037$ , median 0.00 after ET vs. 2.55 pg/ml). Moreover, patients who achieved pregnancy after ET and also patients who experienced a miscarriage had higher levels of LIF than the fertile pregnant controls ( $p = 0.0206$ , median 1.73 before ET vs. 0.00 pg/ml;  $p = 0.0031$ , median 2.27 after ET vs. 0.00 pg/ml and  $p = 0.001$ , median 3.27 after ET vs. 0.00 pg/ml; respectively; [Figure 4B](#); [Supplementary Table 8](#)).

### 3.5 Secretion of soluble TNFR1 in IVF patients and the fertile control groups

There were no significant differences between patients receiving steroid treatment and those that did not in terms of the secretion of soluble TNFR1 (sTNFR1) ([Figure 5A](#); [Supplementary Table 9](#)). The highest amount of soluble TNFR1 was excreted by fertile women who gave birth in the past (median 1843 pg/ml). These women differed in their plasma concentration of sTNFR1 to IVF patients not receiving steroid treatment ( $p = 0.0069$ , median 1843 vs. 962.80 pg/ml before ET) and also with patients who did receive steroid treatment ( $p < 0.0001$ , median 1843 vs. 676.50 pg/ml before ET;  $p = 0.0007$ , median 1843 vs. 998.70 pg/ml after ET).

Among those patients receiving steroid treatment, the lowest levels of sTNFR1 were observed in patients experiencing a lack of pregnancy (median 0.00 and 143.30 pg/ml, before and after ET, respectively; [Figure 5B](#); [Supplementary Table 10](#)). Patients who achieved pregnancy secreted higher levels of sTNFR1 than those with a lack of pregnancy ( $p < 0.0001$ , median 1134 vs. 0.00 pg/ml before ET;  $p = 0.0015$ , median 1207.00 vs. 143.30 pg/ml after ET) the same was observed in the case of patients who experienced miscarriage in comparison to patients with a lack of pregnancy ( $p = 0.0420$ , median 414.70 vs. 0.00 pg/ml before ET). When embryo

transfer resulted in pregnancy, patients had higher levels of sTNFR1 than those who had miscarried ( $p = 0.0066$ , median 1134.00 vs. 414.70 pg/ml before ET and  $p = 0.0504$ , median 1207.00 vs. 721.30 pg/ml after ET). All patients differed to the fertile controls in terms of the concentration of sTNFR1, but the most significant distinction was between patients with a lack pregnancy and the fertile controls ( $p < 0.0001$ , median 0.00 before ET vs. 1843 pg/ml and  $p < 0.0001$ , median 143.30 after ET vs. 1843 pg/ml). These patients also secreted less sTNFR1 than the fertile pregnant controls ( $p = 0.0005$ , median 0.00 pg/ml before ET vs. 523.80 pg/ml and  $p = 0.0162$ , median 143.30 pg/ml after ET vs. 523.80 pg/ml).

### 3.6 VEGF-A secretion in IVF patients and fertile control groups

Patients receiving steroid treatment and patients without steroid treatment had a similar concentration of VEGF-A in blood plasma ([Figure 6A](#); [Supplementary Table 11](#)). The lowest quantities of VEGF-A were detected in the fertile pregnant controls (median 22.62 pg/ml). Significant differences between fertile pregnant control women and patients receiving steroid treatment ( $p < 0.0001$ , median 22.62 vs. 62.73 pg/ml before ET and  $p < 0.0001$ , median 22.62 vs. 66.30 pg/ml after ET) and patients with no steroid treatment were observed ( $p = 0.0023$ , median 22.62 vs. 58.44 pg/ml before ET and  $p = 0.0102$ , median 22.62 vs. 67.48 pg/ml after ET). Fertile women who gave birth in the past secreted more VEGF-A than fertile pregnant women ( $p = 0.0204$ , median 36.80 vs. 22.62 pg/ml) but less than patients receiving steroid treatment ( $p = 0.0003$ , median 36.80 vs. 62.73 pg/ml before ET and  $p = 0.0072$ , median 36.80 vs. 66.30 pg/ml after ET).

Patients divided according to their pregnancy outcome had higher levels of VEGF-A than fertile pregnant control women ([Figure 6B](#); [Supplementary Table 12](#)). The most striking difference was found between fertile pregnant women and patients who did not achieve pregnancy ( $p < 0.0001$ , median 22.62 vs. 143.10 pg/ml before ET and  $p = 0.0005$ , median 22.62 vs. 78.41 pg/ml after ET). We also observed a higher level of VEGF-A in patients who experienced a lack of pregnancy in comparison to patients who became pregnant after IVF-ET ( $p = 0.003$ , median 143.10 vs. 57.19 pg/ml before ET) and those who miscarried ( $p = 0.003$ , median 143.10 vs. 52.72 pg/ml before ET).

### 3.7 ROC analyses for secretion of soluble TNFR1 and VEGF-A

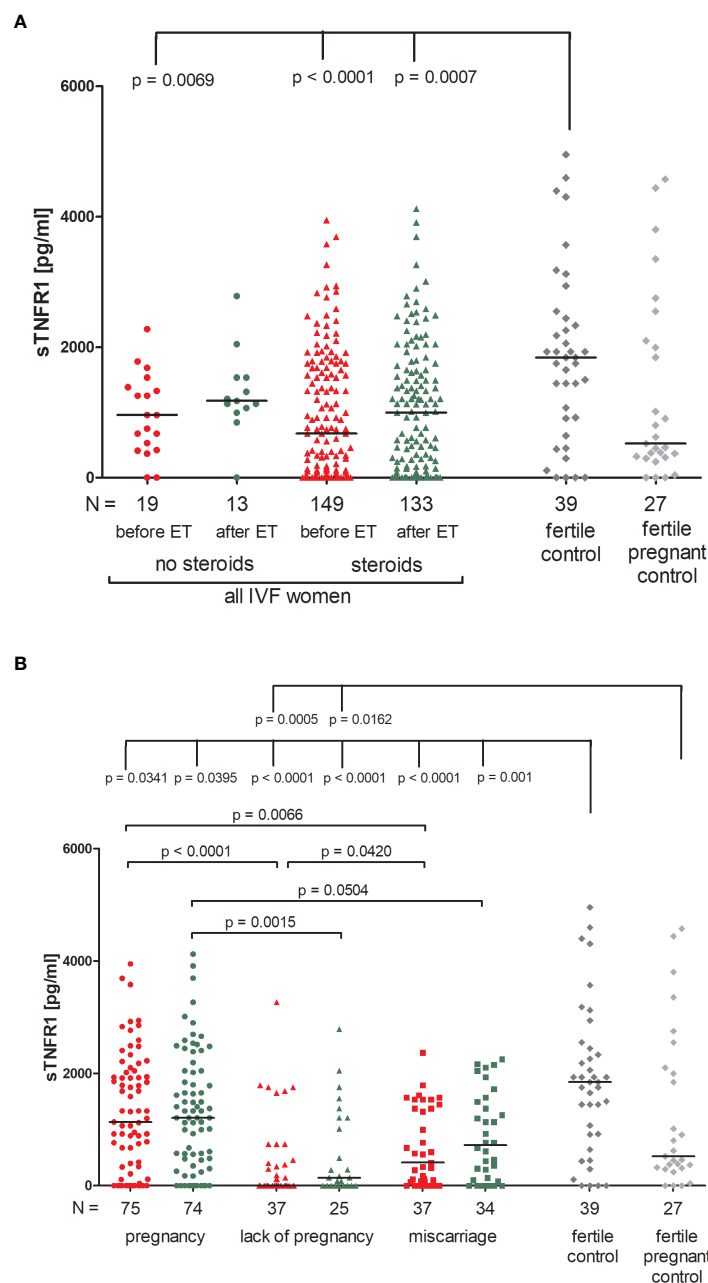

We also performed a receiver-operator curve (ROC) analyses on the secretion of all the examined cytokines, but only in the case of sTNFR1 and VEGF-A did we find statistical significance. We determined the threshold value of sTNFR1 to be 962.3 pg/ml, which allowed us to distinguish IVF patients who achieved and maintained pregnancy from those who did not get pregnant or had a miscarriage (area under the curve (AUC) = 0.66,  $p = 0.00186$ ,

sensitivity 62.71%, specificity 62.16%, and likelihood ratio (LR) = 1.66; **Figure 7A**). When we compared fertile women who gave birth in the past to those who experienced a lack of pregnancy or had miscarriage, the threshold value was 1409 pg/ml (AUC = 0.76,  $p < 0.0001$ , sensitivity 77.97%, specificity 69.23%, LR = 2.53; **Figure 7B**).

ROC analysis for IVF patients indicated only the lack of significant differences in reproductive success. But the threshold value 48.04 pg/ml was the value differentiating fertile women who gave birth in the past with patients who did not achieve pregnancy

or miscarried after IVF-ET (AUC = 0.69,  $p = 0.0016$ , sensitivity 65.52%, specificity 65.79%, LR = 1.92; **Figure 8A**). Patients who secreted VEGF-A above this value had a greater risk of miscarriage or failed transfer than women secreting below this value. Additionally, when we compared the fertile pregnant controls with patients who experienced a lack of pregnancy or miscarriage, we achieved a threshold value of 43.28 pg/ml, but the ROC analysis was stronger (AUC = 0.78,  $p < 0.0001$ , sensitivity 74.14%, specificity 81.48%, LR = 4.00; **Figure 8B**).

## 4 Discussion

In successful embryo implantation and maintenance of pregnancy, the proper interaction between the embryo and endometrium is needed. Secretion of pro- and anti-inflammatory cytokines and their changing profile is one of the most crucial factors during embryo implantation and throughout the various

stages of pregnancy (37, 38). In this study we investigated cytokine and growth factor levels measured in plasma before and after embryo transfer of patients undergoing IVF and also in the fertile controls. Patients being administered the steroid prednisone were compared in terms of the secretion of cytokines with patients who received no treatment with steroid, which may give a new insight into research on recurrent implantation failure and steroid

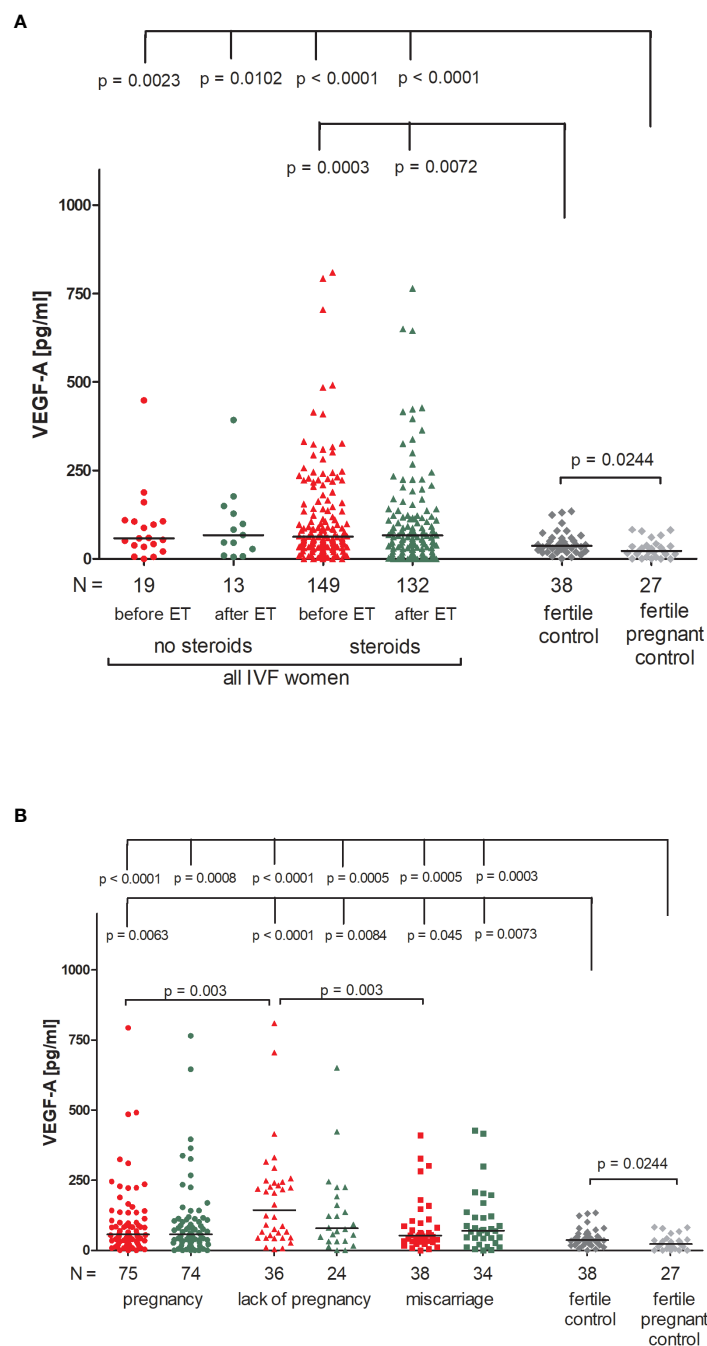

FIGURE 6

treatment during *in vitro* fertilization. We wanted also to examine whether an individual cytokine level could serve as an indicator of pregnancy outcome after embryo transfer. In addition, comparison with fertile controls identified those factors that may be associated with susceptibility to infertility.

Our study on the plasma level of IFN- $\gamma$  indicates that taking prednisone reduces secretion of this cytokine in patients undergoing IVF-ET. Fertile controls, who did not use this steroid, had a similar level of IFN- $\gamma$  as patients without steroid treatment. It indicates that approximately 0.28 pg/ml of IFN- $\gamma$  must be detectable in women planning pregnancy. The role of IFN- $\gamma$  in pregnancy has been confirmed in other studies (16, 39). IFN- $\gamma$ , which is found in the human endometrium, plays a role in the maintenance of a pregnancy via up-regulating the expression of IL-6, monocyte chemotactic protein (MCP)-1, and macrophage colony stimulating factor (M-CSF) by endometrial stromal cells (40, 41). However, as previously mentioned, during implantation and early pregnancy, there are rapid changes in the immune response in decidua that affect the embryo implantation and pregnancy (42). It

is believed that Th1 cytokines like IFN- $\gamma$  and TNF- $\alpha$  are unfavorable to a pregnancy, while Th2 cytokines as IL-4 and IL-10 are significant in the successful development of a fetus. It follows that an increase in the Th1/Th2 ratio may lead to increased cytotoxicity against the embryo and subsequently to implantation failure (43). When a Th1 environment is dominant in the endometrium, uterine NK cells may become killer cells acting upon trophoblast cells and destroying them as a consequence. Thus, proper immune balance is required for embryo implantation (44). Liang et al. reported that both the concentration of IFN- $\gamma$  in blood plasma and also the ratios of pro- and anti-inflammatory cytokines were higher in patients with RIF compared to the control group (45). Most studies have shown that IFN- $\gamma$  expression is increased in spontaneous abortion or recurrent pregnancy loss patients (46–48). Higher levels of IFN- $\gamma$  were found in serum samples of women in first trimester of pregnancy who have experienced preeclampsia and fetal growth restriction (49). Therefore, it is considered that inhibiting and regulation of the immune system by immunomodulators or

AUC (Area under curve), T (red point) - limit value, LR - likelihood ratio. (B) Comparison of patients who did not become pregnant after IVF-ET to fertile women who gave birth in the past. AUC (Area under curve), T (red point) - limit value, LR - likelihood ratio.

immunosuppressive agents could be an effective treatment strategy to resolve RIF (50, 51). Corticosteroids are often used as immunotherapy for patients suffering from RIF or recurrent miscarriage because of their anti-inflammatory and immune-suppressive properties (52). However, the effect of prednisone on the IFN- $\gamma$  level did not change in reproductive success of our patients. There were no differences in its secretion in patients achieving pregnancy after ET, patients without pregnancy after ET and also patients experiencing miscarriage.

In the case of IL-10, prednisone treatment increased its concentration in the blood plasma of the patients, while in both the non-treated non-pregnant fertile women and pregnant fertile women, its level was mostly undetectable. Other studies by Dibble et al. and Holmes et al. have reported higher levels of IL-10 in the plasma of pregnant women in comparison to non-pregnant women at different stages of pregnancy and postpartum (53, 54). However, the association between IL-10 concentration in peripheral blood during pregnancy and gestational period is inconclusive. Some studies showed no association (54, 55), while others, for example, by Dibble et al. and Allswede et al. found that plasma IL-10 levels

increased with advanced gestational weeks throughout normal pregnancy (53, 56). On the other hand, our pregnant control women were mainly at 25 weeks of gestation and we were not able to detect this cytokine in their plasma. Furthermore, decreased IL-10 levels were associated with pregnancy losses, preeclampsia, and preterm delivery (48, 53, 57, 58). An elegant study was presented by Zhao et al., 2022, who determined the level of anti-inflammatory cytokines and chemokines in the period before and after embryo implantation in patients after IVF (59). During the peri-implantation period (ET+0 to ET+9 days), the serum cytokine profiles were similar between pregnancies which miscarried or did not miscarry. Yet, the profiles from day ET+16 indicated a significant difference concerning an increase of the pro-inflammatory cytokines IL-17, IFN- $\gamma$  and TNF- $\alpha$  in the miscarriage group, but a sustained increase of anti-inflammatory cytokines IL-10 and TGF- $\beta$ 1 in the live birth group. Moreover, a change in the anti-inflammatory response at 3–6 days after ET occurred in all pregnancies whether they resulted in live birth or miscarriage. Therefore, the researchers concluded that the most exact day for measurement of pro- and anti-inflammatory cytokines

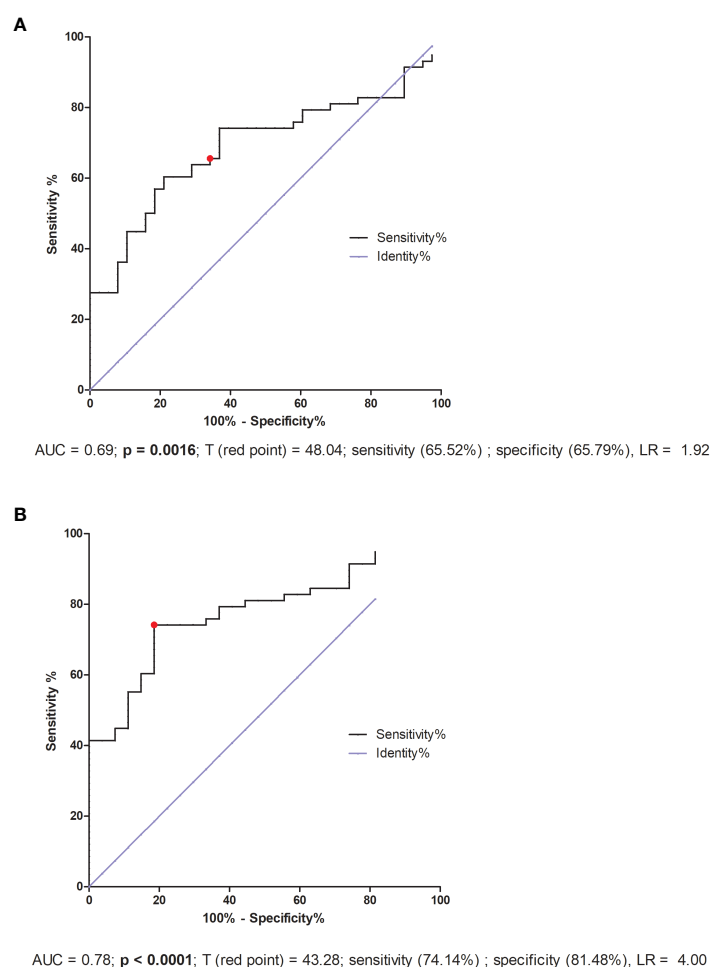

FIGURE 8

monitoring the pregnancy outcome was ET+16. In our study, plasma was collected between 11 to 15 days after embryo transfer. Probably, the differences between our study and the one quoted resulted from the day of material collection for testing, as well as from prednisone treatment. In addition, we did not detect differences in the concentration of all tested cytokines and growth factors between plasma collected before and after embryo transfer. It should also be emphasized that some measurements could not be evaluated, e.g., TNF- $\alpha$ , GM-CSF, IL-4, IL-6, PlGF and VEGF-D. Glucocorticoids acting on antigen presenting cells (APCs) inhibit the production of IL-12, the main inducer of the Th1 response, resulting in a change in the Th1/Th2 balance. IL-12 stimulates IFN- $\gamma$  production and inhibits IL-4 synthesis by T cells (60). Moreover, glucocorticoid-treated monocytes/macrophages produce significantly less IL-12, leading to a decreased capacity of these cells to induce IFN- $\gamma$  production by antigen-primed CD4+ T cells (61). In addition, glucocorticoids downregulate the expression of IL-12 receptors on T and NK cells. It has been shown that lymphocyte-derived IL-10 production appears to be upregulated by glucocorticoids. In multiple sclerosis patients with an acute relapse, treatment with glucocorticoids was associated with increased plasma IL-10 secretion (62). A similar steroidal effect was observed in our patients.

Neutrophins like BDNF ensure the survival, differentiation or death of neurons at the embryonic and postnatal stages of development. They also maintain the viability of neurons at a later age (31, 63). Moreover, BDNF and its receptors are expressed in different regions of the human placenta, indicating the diverse functions of BDNF signaling in placental development (64, 65). Our findings point out that fertile pregnant women differ in BDNF secretion in peripheral blood from IVF patients. Moreover, they also differ from fertile women who gave birth in the past. Prednisone administration did not influence the level of BDNF in the plasma of IVF patients. Among our IVF patients, we did not find differences in pregnancy outcome, although the median concentration of BDNF was 8.93 pg/ml in patients experiencing miscarriage and 13.53 pg/ml in patients without a pregnancy. During pregnancy, this level decreased to 0.00 pg/ml for the control group and IVF patients (measured in plasma collected before embryo transfer; [Supplementary Table 6](#)). A similar observation was found in a study performed by Garces et al. (66). BDNF levels have been reported to be higher in non-pregnant women than in pregnant women. Moreover, they did not vary during menstrual cycle phases and were lowest in pregnant women during the 1<sup>st</sup> trimester and similar during the 2<sup>nd</sup> and 3<sup>rd</sup> trimesters (66). The question arises: Is BDNF taken up from peripheral blood and directed to the uterus when a woman becomes pregnant to fulfill its function in the development of fetus and thus is undetectable in blood of pregnant women? However, a study by Ramer does not support our results (32). Diminished circulating BDNF early in an IVF cycle was associated with implantation and subsequent pregnancy failure (32). The primary difference between our study and their study was the lack of prednisone administration and the time frame for serum collection.

LIF, an IL-6 cytokine family member, is expressed by the endometrium during the menstrual cycle in healthy women, with

a remarkable increase during the mid-secretory to late-secretory phase (67–69). It initiates multiple factors and signaling pathways in the luminal epithelium for uterine receptivity and successful implantation (70–72). In our IVF patients, a lack of pregnancy was associated with a decreased level of LIF measured in plasma. Women achieving a pregnancy after IVF secreted LIF at a median concentration over 2 pg/ml. Surprisingly, the median LIF of our pregnant control group was 0.0 pg/ml, and that of women who gave birth in the past was over 2.5 pg/ml. However, we do not have information concerning in which phase of the menstrual cycle were women giving birth in the past. Perhaps LIF levels decline with gestational age. The pregnant women in our study were on average 25 weeks pregnant. Elevated levels of LIF have been observed in the development and progression of tumors (73). Undoubtedly, at the beginning of a pregnancy when trophoblast invasion occurs, elevated levels of LIF are required. Meanwhile, in a study by Basatvat et al., there was no reported difference in LIF gene expression level from the endometrial biopsies of healthy women and IVF-failure patients (74). In another study, a low concentration of LIF in uterine flushing fluid at day 26 was predictive of subsequent implantation and the LIF concentration was significantly lower in the pregnant group (75). Prednisolone treatment reduced the expression of human endometrial stromal fibroblasts (hESFs) cytokines (IL-6, IL-11, IL-18, LIF, and LIFR), however it had no effect on classic decidualization marker gene expression (prolactin or insulin like growth factor binding protein 1) or secretion by decidualized hESF (76).

TNFR1, also known as tumor necrosis factor receptor 1A superfamily member and CD120a, is a ubiquitous membrane receptor that binds tumor necrosis factor alpha (TNF- $\alpha$ ). Membrane TNF $\alpha$ , as well as its receptors TNFR1 and TNFR2, after cleavage by the proteinase TACE (TNF- $\alpha$  converting enzyme), occur in a soluble form (sTNFR) in many body fluids. Elevated levels of sTNFR have been observed in serum, plasma and urine and are often found to be in connection with endotoxemia, infections and malignancies, as well as chronic autoimmune diseases. The shedding of TNF receptors may lead to a transiently reduced cellular response to TNF- $\alpha$ . Depending on the sTNFR concentration, it has been suggested that sTNFRs block the binding of TNF- $\alpha$  to transmembrane TNFR and thus delay biological responses (77). However, it is also possible that shedding of TNFR in inflammation may initiate direct signaling effects through the binding of sTNFR to transmembrane TNF- $\alpha$  (mTNF- $\alpha$ ) (78, 79). Therefore, the higher the concentration of circulating sTNFR, the lower the bioavailability of TNF- $\alpha$ , which may reduce the inflammatory response. Thus, it seems reasonable to ask whether it makes sense to administer steroids to patients who have a higher level of sTNFR1? TNFR1 can fulfill its function by either blocking membrane TNF- $\alpha$  on cells or capturing TNF- $\alpha$  circulating in peripheral blood. The role of sTNFR1 has been described in pre-eclampsia and pregnancy-induced hypertension in several studies (80–85) alongside early miscarriage (86, 87). Our study shows the secretion of sTNFR1 into the plasma tested before embryo transfer and at a very early stage of pregnancy (2–3 weeks after embryo transfer to the uterus) in patients who have undergone an IVF procedure. The lowest sTNFR1 concentration was observed

in women who did not become pregnant after ET, and the highest in fertile controls who gave birth in the past. It should be noted that fertile pregnant women secreted sTNFR1 at an intermediate level (median 523.80 pg/ml). These women had an average of 25 weeks of gestation. There is a study showing that sTNFR1 expression decreases with gestational age. In the first trimester, secretion of sTNFR1 and sTNFR2 by placental macrophages were 46- and 260-fold higher than TNF- $\alpha$  concentration, respectively, whereas in the third trimester, a 15- and 1.7-fold excess was observed (88). Our results also indicate that women who secrete at least 1409 pg/ml sTNFR1 have a chance to become pregnant naturally and give birth to a child, while patients after IVF-ET with simultaneous support of the luteal phase and prednisone administration must achieve a concentration of 962.3 pg/ml sTNFR1 in the blood plasma.

VEGF-A (also called VEGF) is a multi-functional factor engaged in the regulation of proliferation, differentiation and survival of endothelial cells and it is also involved in blood vessel permeability. VEGF participates in embryonic vasculogenesis and angiogenesis during pregnancy (27). Progesterone and estrogen significantly promote VEGF production (89, 90). Therefore, in our study IVF patients, who were taking micronized progesterone, secreted more VEGF-A than in our control group. In general, we observed higher VEGF concentrations in IVF patients compared to fertile women, regardless of whether the patients were receiving steroid treatment or not. Moreover, the highest concentrations were observed in women who did not become pregnant after IVF-ET. Similar to our study, Bansal et al. showed that VEGF-A levels were significantly increased in women with RIF compared to healthy controls, however there was no correlation between VEGF-A or VEGF-R1 and the absolute levels of circulating NK cells, CD69 activated NK cells or NK cytotoxicity (91). In contrast to our research, Benkhalifa et al. reported decreased concentration of VEGF in RIF women compared to women with a successful IVF-ET with an AUC of 0.742 in ROC curve analysis and a cut-off at 55.80 pg/ml (92). The threshold value 43.28 pg/ml of our ROC analysis differentiated fertile pregnant women from IVF patients who did not become pregnant or who miscarried. Our study differs from those previously mentioned not only in the fact that patients took prednisone and progesterone alongside differences in group size but also in that they did not compare the IVF patients with a healthy fertile control group. Thus, the analysis of VEGF levels should take into consideration the impact of estrogen, progesterone and other potential influential factors to understand the role of VEGF during embryo implantation.

One of the beneficial effects of prednisolone might be its suppressive impact on uterine NK cells. A study by Cooper et al. showed a relatively high prevalence of increased uNK cells in women with recurrent reproductive failure and confirmed the role of prednisolone in reducing uNK cell concentrations (93). Nevertheless, they did not find any evidence for a significant beneficial effect of prednisolone therapy on pregnancy outcomes. In turn, Giulini et al. suggest the advantage of prednisone and antibiotic treatment on the live birth rate in a subsequent IVF cycle (94).

Indeed, the reported effectiveness of prednisolone/prednisone in prevention of miscarriage/recurrent implantation failure is highly variable between studies (93, 95–100). Therefore, the Practice Committee of the American Society for Reproductive Medicine since 2018 has not recommended the routine use of corticosteroids during ovarian stimulation to improve the outcome of live birth in ART cycles in the general population (101). ASRM has also not recommended the routine use of corticosteroids during the implantation window to improve the outcome of live births in ART cycles in the general population. In addition, the latest recommendations of the European Society of Human Reproduction and Embryology concerning recurrent implantation failure treatment do not contain guidelines for steroid treatment (102). According to the latest European recommendations (strong quality evidence), corticosteroids should be administered to women at a gestational age between 24 + 0 and 33 + 6 weeks, when preterm birth is expected in the next seven days. This treatment reduced neonatal mortality and morbidity by approximately 20% and neonatal respiratory distress syndrome by approximately 30% (103).

However, our research has limitations. Firstly, we tested only selected immunological factors that did not give a full picture of the immunological condition of the women studied. One of the weaknesses of our study was also the lack of information about the day of the menstrual cycle of the tested women who gave birth in the past, which may have influenced the results obtained. However, these were women of reproductive age (except for 1). Therefore, we added a control who was naturally pregnant at the time of blood sampling to compare the women in terms of conception method. Moreover, the group of women not treated with the steroid (N = 19 before ET) seems small compared to that treated. Despite the use of modern Luminex technology, we were unable to obtain unequivocal conclusions for all analytes tested. Panels of tested analytes need to be more refined.

## Conclusions

- i. Fertile women present a different profile of pro- and anti-inflammatory cytokines and growth factors from patients with RIF.
- ii. Women who secrete at least 1409 pg/ml sTNFR1 have a chance to become pregnant naturally and give birth to a child, while patients after IVF-ET with simultaneous luteal phase support and receiving steroid treatment must achieve a concentration of 962.3 pg/ml sTNFR1 in the blood plasma.
- iii. IVF patients secreting VEGF-A above 43.28 pg/ml have a greater risk of miscarriage or failed transfer than women secreting below this value.
- iv. The use of steroid treatment by infertile patients should be carefully considered due to the changes they cause in the immune environment of the uterus and in the peripheral blood.

## Data availability statement

The original contributions presented in the study are included in the article/**Supplementary Materials**, further inquiries can be directed to the corresponding author.

## Ethics statement

The studies involving humans were approved by Ethics Committee of the Polish Mothers' Memorial Hospital–Research Institute in Łódź (No: 25/2019). The studies were conducted in accordance with the local legislation and institutional requirements. The participants provided their written informed consent to participate in this study.

## Author contributions

KP, IN conceived and designed the experiments. KP, MD performed the experiments. KP, MD, IN, PR analyzed the data. PR, MR contributed to patient and control recruitment. KP and IN wrote the paper. KB-K contributed to the research methodology, provided equipment for the study and critically reviewed the manuscript. All authors contributed to the article and approved the submitted version.

## Funding

This study was funded by the National Science Centre, grant number 2018/29/N/NZ5/00940. Open access was covered by Hirsfeld Institute of Immunology and Experimental Therapy,

Polish Academy of Sciences, Wrocław and Gameta Hospital in Rzgów.

## Acknowledgments

We would like to thank all patients and controls who participated in this study.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

University, Suzhou, China

Pregnancy-induced hypertension (PIH) is one of the most common pregnancy complications that seriously affects the mother and fetus. The incidence of PIH is higher in pregnancies conceived after assisted reproductive technology (ART) than in spontaneous pregnancies; thus, exploring potential serum biomarkers before PIH onset is of great significance for effective early prediction and prevention of PIH in the ART population. Cytokines are involved in the inflammatory response and immune regulation, which play an essential role in the pathogenesis of PIH. A description of the cytokine profile in the first trimester of pregnancy could help identify new diagnostic tools and develop targeted therapies for PIH in the ART population. The concentrations of classical predictive markers for PIH and another 48 cytokines were measured in the first-trimester pregnancy serum samples from 33 PIH patients and 33 matched normotensive controls (NC), both of whom conceived after ART treatment. The measured values were compared and analyzed between NC and PIH, followed by comprehensive bioinformatic analysis and logistic regression analysis. There was no significant difference in classical predictive markers, including Activin A, PlGF, sFLT1 (VEGFR), and sFLT1/PlGF, between the PIH and NC groups ( $P > 0.05$ ), while 29 cytokines were significantly lower in the PIH group than in the NC group ( $P < 0.05$ ). Logistic regression analysis revealed that 17 cytokines (IL-2R $\alpha$ , M-CSF, IL-6, IL-2,  $\beta$ -NGF, IL-7, IL-12 (p70), SCF, IL-10, IL-9, MIG, GM-CSF, LIF, IL-1 $\alpha$ , MCP-3, IL-4, and HGF) in the first-trimester pregnancy serum were significantly negatively correlated with the subsequent onset of PIH. With the top 3 cytokines (IL-7, MIG, and SCF) of receiver operating characteristic (ROC) analysis, we constructed an efficient multifactor combined detection and prediction model for PIH in ART pregnancy. Classical early predictors for

hypertensive disorder complicating pregnancy cannot distinguish PIH from their normal peers in ART pregnancy. In comparison, the description of the cytokine profile in the first trimester of pregnancy enables us to distinguish high-risk ART pregnancy for PIH, permitting enough time for PIH prevention therapy. The cytokine profile we described also provides immunological insight into the further mechanistic exploration of PIH.

## INTRODUCTION

Pregnancy-induced hypertension (PIH) is one of the most common pregnancy complications, affecting 6% to 10% of pregnancies (1, 2). It is defined as a new onset of hypertension (systolic pressure  $\geq 140$  mmHg and/or diastolic pressure  $\geq 90$  mmHg) with or without proteinuria after the 20th week of gestation, which includes preeclampsia (3). PIH is characterized by maternal hypertension and multiorgan involvement resulting from systemic endothelial dysfunction, and it is also a major cause of maternal and fetal morbidity and mortality (4, 5). However, the clinical intervention of PIH stagnates in passive treatment after symptoms appear, resulting in poor prognosis. Hence, early prediction markers for PIH are of great significance for presymptomatic prophylaxis.

To date, there are several well-studied molecular markers related to placental hypoperfusion, such as placental growth factor (PlGF), soluble Fms-like tyrosine kinase-1 (sFlt-1) or vascular endothelial growth factor receptor (VEGFR) and Activin A. Although a high sFlt-1:PlGF ratio (6–8), high Activin A serum level (9) and low PlGF serum level (8) have been proven to be able to separate PIH from normotensive pregnant women, they all share low predictive accuracy in the first trimester of pregnancy (10, 11). Unfortunately, it has recently been found that the incidence of PIH in the ART population is higher than that in spontaneous pregnancy (12). Guidelines suggest that oral aspirin should be started at 11–14<sup>+</sup><sub>6</sub> gestational weeks in high-risk populations to achieve effective prevention (13). Therefore, it is urgent to explore biomarkers for the first-trimester prediction of PIH in the ART population.

The pathophysiological mechanisms of the development of PIH remain unclear. One of the more deeply studied mechanisms is fetal-maternal immunity (14). There is increasing evidence that PIH may originate from poor maternal immune tolerance and abnormal interactions between immune cells, trophoblast cells, and decidual stromal cells after embryo implantation. Immune cells such as natural killer cells, dendritic cells, and T regulatory lymphocytes in the decidua have impaired immune tolerance to spiral artery remodeling and the emergence of fetal trophoblasts, leading to increased placental shedding, exaggerated systemic inflammation, and subsequent endothelial dysfunction (15).

Cytokines are a family of small soluble proteins expressed by various cell and tissue types that serve as immune mediators. Their expression profiles have been used to classify immune responses and functional states of the immune system. Evidence suggests that cytokines play a crucial role in ovulation,

implantation, placentation, and parturition during pregnancy (16, 17). Recent research indicates that PIH is related to immune dysregulation and that components of the immune system may interact with angiogenic and antiangiogenic factors (12). In this study, the cytokine profiles were characterized in paired PIH and normotensive women following ART treatment to determine the specific cytokine signature involved, which would be of great value to explain the occurrence of PIH after ART and provide new avenues for early diagnosis, monitoring, and intervention.

## MATERIALS AND METHODS

### Participants

In this study, 33 women diagnosed with PIH and 33 controls were selected from patients who underwent *in vitro* fertilization (IVF)/intracytoplasmic sperm injection (ICSI) cycles based on a large prospective cohort conducted at the Research Center of the Reproductive Hospital Affiliated to Shandong University from January 2018 to June 2019. All patients were < 40 years and achieved singleton pregnancy by assisted reproductive technology in this pregnancy. Patients diagnosed with chronic autoimmune disease (such as systemic lupus erythematosus, thyroid autoimmunity, or antiphospholipid syndrome), preexisting secondary/essential hypertension, gestational diabetes mellitus, and other diseases that may affect the inflammatory process were excluded. Pregnancies after embryo transfer were followed by periodic reviews of electronic medical records until delivery. PIH was defined as a new onset of hypertension (systolic pressure  $\geq 140$  mmHg and/or diastolic pressure  $\geq 90$  mmHg) with or without proteinuria after the 20th week of gestation. According to clinical and laboratory evaluations, 33 patients diagnosed with PIH were included in the PIH group. To achieve a balanced baseline characteristics, propensity score matching (PSM) was applied to control for potential confounders, including age, BMI, cause of infertility, fertilization method, and embryo transfer proposal, which were weighted equally. The NC group included 33 healthy women who were matched in a 1:1 ratio to PIH based on the propensity score with a standard caliper width of 0.1. This study protocol was approved by the Ethical Committee of Reproductive Medicine of Shandong University, and all participants signed informed consent forms.

### Sample Collection

At 11–13 gestational weeks following IVF/ICSI, 6 ml fasting blood samples of the participants were collected by venipuncture.

After centrifugation at  $1300 \times g$  for 10 minutes, serum samples were separated and stored at  $-80^{\circ}\text{C}$  until measurement.

## ELISA Analysis

The serum levels of Activin A, PlGF and sFLT1 were measured using commercial ELISA kits (R&D, Cat # DAC00B, Human/Mouse/Rat Activin A Quantikine ELISA Kit; Cat # DPG00, Human PlGF Quantikine ELISA Kit; Cat # DVR100C, Human VEGFR1/Flt-1 Quantikine ELISA Kit).

## Cytokine Profiling

Individual serum samples were subjected to cytokine profile measurement by the Bio-Plex Pro Human Cytokine Screening Panel, 48-plex (BioRad). The protocol of the kit was followed for the analysis of a total of 48 cytokines, chemokines or growth factors. These included interleukin-1 $\beta$  (IL-1 $\beta$ ), IL-1 $\alpha$ , IL-1ra, IL-2, IL-2R $\alpha$ , IL-3, IL-4, IL-5, IL-6, IL-7, IL-8, IL-9, IL-10, IL-12 (p40), IL-12 (p70), IL-13, IL-15, IL-16, IL-17A, IL-18, interferon- $\alpha$ 2 (IFN- $\alpha$ 2), interferon- $\gamma$  (IFN- $\gamma$ ), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), tumor necrosis factor- $\beta$  (TNF- $\beta$ ), granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), leukemia inhibitory factor (LIF), stem cell factor (SCF), vascular endothelial growth factor (VEGF), Eotaxin, macrophage inflammatory protein-1 $\alpha$  (MIP-1 $\alpha$ ), macrophage inflammatory protein-1 $\beta$  (MIP-1 $\beta$ ), basic fibroblast growth factor (FGF basic), monocyte chemotactic protein-1 (MCP-1) or monocyte chemoattractant activating factor (MCAF), monocyte chemotactic protein-3 (MCP-3), nerve growth factor- $\beta$  ( $\beta$ -NGF), RANTES, stromal cell derived factor-1 $\alpha$  (SDF-1 $\alpha$ ), platelet-derived growth factor-BB (PDGF-BB), growth related oncogene- $\alpha$  (GRO- $\alpha$ ), hepatocyte growth factor (HGF), interferon inducible protein-10 (IP-10), cutaneous T-cell attracting chemokine (CTACK), mifepristone (MIF), gamma-interferon-induced monokine (MIG), stem cell growth factor- $\beta$  (SCGF- $\beta$ ), and TNF-related apoptosis-inducing ligand (TRAIL).

## Statistical Analysis

Statistical analysis and graphical representations were completed in IBM SPSS Statistics 21 and GraphPad Prism. Normality was assessed by Kolmogorov-Smirnov tests. Normally distributed data are presented as the mean  $\pm$  SEM, and the *t* test was used to compare the significant differences between groups. For data with a nonnormal distribution, the median with interquartile range was applied, and the Mann-Whitney U test was used for data comparison. Values of  $P < 0.05$  were considered statistically significant. Principal component analysis (PCA), heatmap and cluster analysis, forest map, and half-violin plots were conducted using the website [www.bioinformatics.com.cn](http://www.bioinformatics.com.cn). Univariate logistic regression analysis was performed to assess the longitudinal association between first-trimester serum cytokine levels and the occurrence of PIH. OR  $> 1$  indicates a risk factor, and OR  $< 1$  indicates a protective factor. Cytokines with  $P < 0.05$  were considered to be related to the occurrence of PIH and included in Receiver operating characteristic (ROC) analysis. ROC curves were drawn to analyze the independent predictive

value of specific cytokines for PIH. Additionally, IL-7, MIG, and SCF were selected to build a combined prediction model, and the combined diagnostic value of the prediction model for PIH was analyzed.

## RESULTS

### Baseline Characteristics and Perinatal Outcomes of the Participants

**Table 1** displays the baseline characteristics and perinatal outcomes of 33 women who developed PIH in later pregnancy and their 33 matched normotensive controls (NC). The systolic pressure (NC  $115.48 \pm 2.15$  vs. PIH  $127.07 \pm 2.17$ ,  $P < 0.01$ ) and mean arterial pressure (NC  $85.30 \pm 1.86$  vs. PIH  $92.66 \pm 1.83$ ,  $P = 0.01$ ) before pregnancy were higher in the PIH group than in the NC group. There were no significant differences between the two groups in other prepregnancy baseline characteristics. The incidence of cesarean section was significantly higher in the PIH group than in the NC group (NC 66.70% vs. PIH 96.97%,  $P < 0.01$ ). The gestational age at delivery was lower in the PIH group than in the NC group (NC 275 days vs. PIH 269 days,  $P = 0.02$ ). Lower gestational age and higher cesarean section rate are related to each other and exactly reflect the characteristics of PIH.

### Classical Serum Biomarker Levels in Pregnancy After Assisted Reproductive Technology

First, we wanted to verify whether classical serum biomarkers can distinguish PIH from NC in ART pregnancy. Activin A, PlGF and sFLT1 levels tested by ELISA and accordingly calculated sFlt1/PlGF are shown in **Table 2**. In the first-trimester serum of ART pregnancy, classical biomarkers appeared to have no predictive validity with no significant difference between NC and the women who developed PIH later in pregnancy.

### Cytokine Profile in First-Trimester Serum in ART Pregnancy

To explore serum markers with potential predictive/diagnostic value for PIH in the first trimester of ART pregnancy, 48 cytokine expression levels were detected in patients with PIH and NC. PCA showed that the NC and PIH groups could be well distinguished by the first principal component (PC1), and a variety of cytokines contributed to PC1 and served as the main reason for the variation (**Figure 1A**). Heatmap and cluster analysis showed that the expression level of first-trimester serum cytokines in the PIH group was lower than that in the NC group (**Figure 1B**). In total, we found 29 differentially expressed cytokines between the two groups: IL-1 $\beta$ , IL-1 $\alpha$ , IL-2, IL-2R $\alpha$ , IL-4, IL-5, IL-6, IL-7, IL-9, IL-12 (p40), IL-12 (p70), IL-16, IL-17A, TNF- $\alpha$ , M-CSF, GM-CSF, LIF, SCF, Eotaxin, MIP-1 $\beta$ , FGF basic, MCP-1 (MCAF),  $\beta$ -NGF, SDF-1 $\alpha$ , PDGF-BB, GRO- $\alpha$ , HGF, MIG, and TRAIL (**Figure 1C** and **Table 3**). Notably, compared with the NC group, the expression levels of all these cytokines were significantly lower in the PIH group ( $P < 0.05$ ). In addition, we generated ROC curves for every cytokine that showed a significant difference (**Supplementary Figure 1**).

**TABLE 1 |** Baseline characteristics and perinatal outcomes of the participants.

	NC (N = 33)	PIH (N = 33)	P Value
<b>Prepregnancy baseline characteristics</b>			
Age (yr)-Mean $\pm$ SD	30.21 $\pm$ 4.29	29.94 $\pm$ 3.75	0.78
BMI (kg/m <sup>2</sup> )-Mean $\pm$ SD	25.17 $\pm$ 3.92	25.21 $\pm$ 3.94	0.97
Blood pressure (mmHg)-Mean $\pm$ SD			
Systolic pressure	115.48 $\pm$ 2.15	127.07 $\pm$ 2.17	< 0.01*
Diastolic pressure	70.21 $\pm$ 1.90	75.45 $\pm$ 1.87	0.06

Mode of fertilization-no. (%)			0.60
IVF	21 (63.64)	23 (69.70)	
ICSI	12 (36.36)	10 (30.30)	
<b>Perinatal outcomes</b>			
Delivery mode-no. (%)			< 0.01*
Vaginal delivery	11 (33.33)	1 (3.03)	
Cesarean delivery	22 (66.67)	32 (96.97)	
Gestational age at delivery (day)-Median (P25, P75)	275.00 (269.00,279.50)	269.00 (263.50, 273.00)	0.02*
Delivery at <37 wk-no. (%)	4 (12.12)	5 (15.15)	> 0.99
Neonatal birth weight (g)-Mean $\pm$ SD	3319.09 $\pm$ 107.72	3137.19 $\pm$ 93.48	0.21
Low birth weight infants (<2500 g)-no. (%)	3 (9.09)	2 (6.06)	0.64

Values are the mean  $\pm$  SD/median (P25, P75) or n. (%). BMI, body mass index; PCOS, polycystic ovarian syndrome; IVF, in vitro fertilization; ICSI, intracytoplasmic sperm injection. Significant difference ( $P < 0.05$ , marked by \*).

**TABLE 2 |** Classical serum biomarker levels in pregnancy after assisted reproductive technology.

Cytokine	NC (N = 33)	PIH (N = 33)	P Value
Activin A (pg/mL)	2168.54 (1247.21, 3105.89)	1917.64 (1340.23, 2754.65)	0.621
PlGF (pg/mL)	56.43 (43.23, 71.14)	44.48 (36.06, 71.30)	0.221
sFlt1 (VEGFR) (pg/mL)	14401.52 (9859.96, 19593.74)	11592.32 (7951.62, 14677.62)	0.052
sFlt1/PlGF	243.43 (178.763, 315.70)	229.72 (163.65, 314.83)	0.485

Values are median (P25, P75). PlGF, placental growth factor; sFlt1, soluble fms-like tyrosine kinase-1. Significant difference ( $P < 0.05$ ).

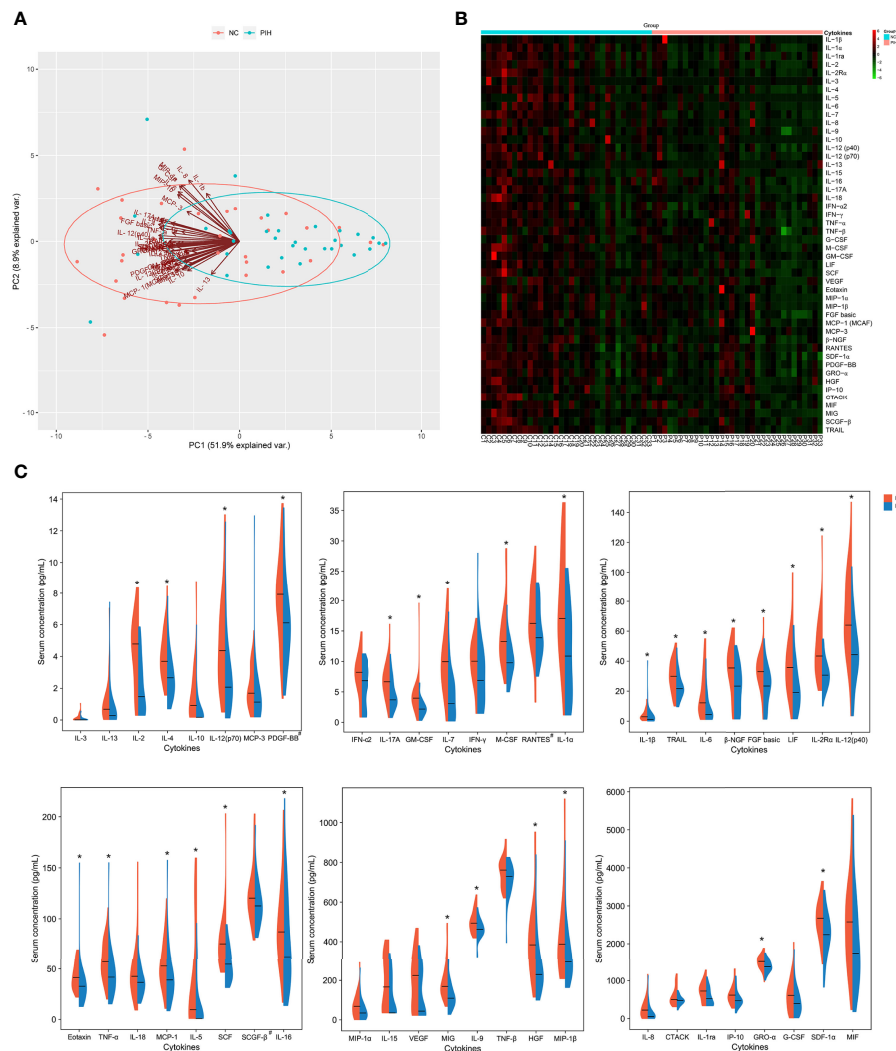

## Relationship Between the First-Trimester Serum Cytokine Profile and Subsequent PIH

We further analyzed the relationship between serum cytokine levels in the first trimester of pregnancy and the occurrence of PIH in later pregnancy by logistic regression analysis. Univariate logistic regression analysis showed that 35 cytokines were associated with subsequent PIH (**Figure 2A**). After adjusting for the influence of prepregnancy mean arterial pressure, 17 cytokines in early pregnancy serum were found to be negatively associated with an increased risk of PIH in later pregnancy, including IL-2R $\alpha$ , M-CSF, IL-6, IL-2,  $\beta$ -NGF, IL-7, IL-12 (p70), SCF, IL-10, IL-9, MIG, GM-CSF, LIF, IL-1 $\alpha$ , MCP-3, IL-4, and HGF (**Figure 2B**).

## Predictive Value of Serum Cytokines in Early Pregnancy for PIH in ART Pregnancy

We selected the above 17 cytokines related to PIH and further explored their predictive value as potential target molecules for PIH. The ROC curve analysis results are shown in **Table 4**. Among the

above 17 PIH-related cytokines, IL-7, MIG and SCF are the top three cytokines with pronounced predictive values for PIH. We then selected IL-7, MIG, and SCF to construct a combined prediction model, which was found to have good predictive value for PIH. (AUC 0.821, 95% CI: 0.718-0.924,  $P < 0.001$ ) (**Figure 3**). The AUC of the combination of IL-7, MIG, and SCF was larger than that of every single cytokine, which proved that the combined prediction model had a better ability to predict PIH than other individual indicators. The sensitivity (true-positive rate) was 81.8%, and the specificity (true-negative rate) was 72.7%. Other analyses for variable selection and the suboptimal combined prediction model are graphically represented in **Supplementary Table 1** and **Supplementary Figure 2**. In addition, we evaluated the predictive value of decreased cytokine levels on pregnancy outcome, including delivery mode, delivery at <37wk, and low birth weight infants. We found IL-2R $\alpha$ , M-CSF, SCF, and MIG are individual risk factors for cesarean delivery, and a combination of these four risk factors provide a good predictive value (AUC=0.722,  $P = 0.004$ ) for cesarean delivery mode (**Supplementary Figure 3**).

**FIGURE 1** | Analysis of 48 cytokine profiles in the first-trimester pregnancy serum of the NC group vs. the PIH group. **(A)**, PCA of 48 cytokine profiles in the first-trimester pregnancy serum. The points in the diagram represent the samples, red for the NC group and blue for the PIH group. The arrows represent the contribution and correlation of the corresponding original variables to the principal component. **(B)**, Heatmap analysis of 48 cytokine profiles in the first-trimester pregnancy serum. The row displays the cytokines, and the column represents the sample number. The color key represents the deviation of global median concentrations for each cytokine. These median values (homogenized to 0 and displayed in dark) were calculated after homogenization treatment and used as a cut-off to separate high and low cytokine concentrations. Color gradation from red to green indicates high to low cytokine concentrations, respectively, with homogenized values ranging from 6 to -6. **(C)**, Half-violin plots showing the expression distributions of 48 cytokines in the first-trimester pregnancy serum between the NC group and the PIH group. Six boxes were plotted according to general cytokine concentrations. The ordinate indicates the serum concentration of cytokines, with pg/mL as the concentration unit, except for the concentration units of PDGF-BB, RANTES, and SCGF- $\beta$  (marked by #) being ng/mL. Every different cytokine is shown as density (violin shape) and median value (horizontal lines) for NC vs. PIH. The left half (red) of each plot represents the NC group, and the right half (blue) represents the PIH group. Asterisk (\*) represents a significant difference in cytokine expression in the first-trimester pregnancy serum between the two groups.

## DISCUSSION

PIH is a common pregnancy-specific complication that threatens both maternal and fetal safety (18–20). As a result of the lack of definitive therapies except for early delivery of the fetoplacental unit once PIH occurs, in recent years, guidelines have placed greater emphasis on early warning, early detection and early intervention (21–23). Low-dose aspirin (LDA) is suggested to be used beginning from 11 gestational weeks for better prevention

efficacy in high-risk women (13, 23–25). In regard to ART pregnancy, the evaluation and prediction methods of PIH remain to be elucidated. In this study, we brought forward the serum cytokine testing time to as early as 11–13 gestational weeks for a potential timely prediction for PIH after ART. It is worth noting that even the routinely used predictive parameters, such as Activin A, PlGF, sFlt1 and sFlt1/PlGF, were not able to differ PIH from controls in ART women, which is in line with another recent study targeting the IVF population, reporting no

significant difference in first-trimester serum Activin A between normotensive controls and pregnancies with subsequent PE/PIH (26). This is possibly ascribed to the potentially undefined population specificity, emphasizing the importance of exploring novel biomarkers for PIH in the ART population. Our results show that the cytokine profile in the first trimester of ART pregnancy demonstrated a significantly downregulated trend in ART women destined to develop PIH. We found 17 cytokines in the serum of first-trimester pregnancy related to the increased risk of PIH, including 10 interleukins (IL): IL-1 $\alpha$ , IL-2R $\alpha$ , IL-2, IL-4, IL-6, LIF, IL-7, IL-9, IL-10, and IL-12 (p70); three colony stimulating factors (CSF): M-CSF, GM-CSF, and SCF; two chemokines: MIG and MCP-3; and two growth factors (GF):  $\beta$ -NGF and HGF. Moreover, we constructed a first-trimester prediction model using IL-7, MIG, and SCF for screening out the cases at high risk of developing PIH preceding clinical manifestations in ART pregnancy.

With increasing knowledge, the antecedents of poor placentation of PIH are considered to be immunological in origin (14, 27, 28). At the maternal-fetal interface during early pregnancy, the adaptive regulation of maternal immunity is

mainly characterized by the transformation of T helper type 1 (Th1) cytokines to Th2 cytokines (29, 30). Studies have shown that the shift toward Th2 may be hindered in PIH, with the cytokine profile in peripheral blood being mainly Th1 (31, 32). Our results support this theory; that is, IL-4, IL-9 and IL-10, which are related to Th2 in the serum of PIH patients during early pregnancy, are significantly downregulated.

The cytokine profile of PIH in previous studies was usually demonstrated during middle and late pregnancy, which is generally characterized by a pro-inflammatory state, showing a higher level of proinflammatory cytokines, such as IL-1, IL-6, IL-8, IL-17, and TNF- $\alpha$ , and a lower level of anti-inflammatory interleukins, especially IL-10, IL-33, and IL-35 (15, 33–35). Compared to the pro-inflammatory state in middle and late pregnancy, our assay in the ART population showed that proinflammatory factors such as IL-6 and IL-12 were downregulated in the first-trimester serum of PIH patients. A study in rats indicated that IL-6-mediated arterial pressure elevation is due to a response to chronic reductions in uterine perfusion pressure during pregnancy (36). Therefore, we hypothesized that in ART pregnancy, the shift toward a

**FIGURE 2 |** Correlation analysis of early pregnancy serum cytokines and PIH. **(A)**, The relationship between the expression level of 48 cytokines in early pregnancy serum and the occurrence of PIH in later pregnancy was analyzed by univariate logistic regression analysis and visualized as a forest map. **(B)**, After correcting the mean arterial pressure before pregnancy, the relationship between the expression level of 48 serum cytokines in early pregnancy and the occurrence of PIH in later pregnancy was analyzed by logistic regression analysis. OR > 1 indicates a risk factor, and OR < 1 indicates a protective factor.

proinflammatory phenotype in PIH probably does not occur in the very early stages of the disease. Similarly, the association of IL-12 serum levels with the development of PIH has been assessed in various studies, drawing no certain conclusions because of conflicting evidence (37–41). In fact, a proinflammatory phenotype is the result of compensation for insufficient immune activation and early placental establishment in the first trimester. Therefore, most studies devoted to finding biomarkers in middle and late pregnancy to predict PIH failed to achieve good clinical application effects (42). The difference in serum proinflammatory factors in PIH patients at different pregnancy stages and the dynamic changes need to be further explored.

In spontaneous pregnancy, semen exposure between coitus and conception primes innate and adaptive immune cells for prepared maternal immune tolerance in advance of potential implantation (43–45). In contrast, ART pregnancy tends to directly transfer embryos under the premise of prohibiting sexual intercourse in the transfer cycle. This may at least partially explain why ART is associated with an increased risk of PIH and at the same time support our results that the PIH

**FIGURE 3 |** ROC analysis of the combined prediction model for the prediction of PIH in ART pregnancy. ROC curves show the results of ROC analysis for differentiation between PIH and NC in ART pregnancy. ROC curve analysis revealed that IL-7, MIG, and SCF appeared to be potential biomarkers for the separation between PIH and NC in the first trimester of pregnancy (AUC = 0.821, 95% CI: 0.718–0.924,  $P < 0.001$ ), with a sensitivity of 81.8% and a specificity of 72.7%.

group showed lower serum cytokine levels than the normotensive group at 11–13 weeks gestation. In other words, inadequate tolerance induction before embryo transfer results in a universally low level of serum cytokines in the first trimester of pregnancy, which may disrupt the inflammatory process of embryo implantation and is in turn involved in the shallow invasion of trophoblasts in early PIH (46).

The present study is based on the human biobank of our large-scale assisted reproductive cohort platform and is the first to delineate the first-trimester serum cytokine profile of PIH, especially for the ART population. We found that maternal serum concentrations of multiple immune-related cytokines were significantly decreased in the first trimester of ART pregnancy with subsequent PIH. With conjoint analysis of serum IL-7, MIG and SCF, we demonstrated a first-trimester prediction model before PIH onset and subsequent compensatory response. Admittedly, the number of participants included in the current study is still limited and further research with a large sample size is needed to support our findings.

The establishment and maintenance of pregnancy poses great challenges to the maternal immune system. Uncoordinated maternal immunization, especially in the first trimester of pregnancy, will be a potential cause of a series of pregnancy complications (47, 48). Currently, immunotherapy has been applied to the treatment of a variety of reproductive diseases, such as recurrent spontaneous abortion (RSA) and recurrent implantation failure (RIF) (49), while the immunotherapy against PIH still needs a long way to go. Our study described the first-trimester serum cytokine profile in pregnancies conceived after ART and provided a better understanding of the immunological etiology and pathophysiology of PIH in the specific population. Additionally, the first-trimester immune

disturbance enables early prediction, which guarantees enough time for low-dose aspirin (LDA) prevention before the appearance of hypertension symptom and hopefully may also promote novel therapeutic strategies on immune regulation and shed light on the clinical management of PIH in the ART population.

## DATA AVAILABILITY STATEMENT

The original contributions presented in the study are included in the article/**Supplementary Material**. Further inquiries can be directed to the corresponding authors.

## ETHICS STATEMENT

The studies involving human participants were reviewed and approved by Ethical Committee of Reproductive Medicine of Shandong University. The patients/participants provided their written informed consent to participate in this study. Written informed consent was obtained from the individual(s) for the publication of any potentially identifiable images or data included in this article.

## AUTHOR CONTRIBUTIONS

YL conceived and designed the project. XL, LG, and SZ performed the experiments and analyzed the data. XL, YC, and YN collected the clinical serum samples and information. XL, LG, SZ, SH, and ZL wrote the manuscript. YL and JY critically revised the manuscript. All authors have been involved in interpreting the data and approved the final version.

## FUNDING

This study was supported by grants from the National Key Research and Development Program of China (2021YFC2700604), the National Natural Science Foundation of China (82101784, 82171648), the Key Research and Development Program of Shandong Province (2021LCZX02), the Natural Science Foundation of Shandong Province (ZR2020QH051), the Natural Science Foundation of Jiangsu Province (BK20200223), Taishan Scholars Program for Young Experts of Shandong Province (tsqn201812154) and the Young Scholars Program of Shandong University.

# Circulating inflammatory cytokines and hypertensive disorders of pregnancy: a two-sample Mendelian randomization study

Siqi Guan, Xiaoxu Bai, Jincheng Ding and Rujin Zhuang\*

Department of Obstetrics and Gynecology, The Second Affiliated Hospital of Harbin Medical University, Harbin, China

**Background:** Hypertensive disorders of pregnancy (HDP) pose a significant risk to maternal and fetal well-being; however, the etiology and pathogenesis of HDP remain ambiguous. It is now widely acknowledged that inflammatory response and the immune system are closely related to HDP. Previous research has identified several inflammatory cytokines are associated with HDP. This study applied Mendelian randomization (MR) analysis to further assess causality.

**Methods:** Patients with HDP who participated in the MR analysis presented with four types of HDP: pre-eclampsia or eclampsia (PE); gestational hypertension (GH); pre-existing hypertension complicating pregnancy, childbirth and the puerperium (EH); and pre-eclampsia or poor fetal growth (PF). A two-sample MR analysis was used to analyze the data in the study. The causal relationship between exposure and outcome was analyzed with inverse variance weighting (IVW), MR Egger, weighted median, weighted mode, and simple mode methods, where IVW was the primary method employed.

**Results:** Our MR analysis demonstrated a reliable causative effect of Interleukin-9 (IL-9) and macrophage migration inhibitory factor (MIF) on reducing HDP risk, while macrophage inflammatory protein 1-beta (MIP1b), Interleukin-13 (IL-13), and Interleukin-16 (IL-16) were associated with promoting HDP risk.

**Conclusions:** This study demonstrated that IL-9, MIF, MIP1b, IL-13, and IL-16 may be cytokines associated with the etiology of HDP, and that a number of inflammatory cytokines are probably involved in the progression of HDP. Additionally, our study revealed that these inflammatory cytokines have causal associations with HDP and may likely be potential therapeutic targets for HDP.

## KEYWORDS

hypertensive disorders of pregnancy, pre-eclampsia, inflammatory cytokine, Mendelian randomization, genome-wide association study

# 1 Introduction

Hypertensive disorders of pregnancy (HDP)—including pre-eclampsia/eclampsia, gestational hypertension, chronic hypertension, and pre-eclampsia superimposed on chronic hypertension (1)—is ranked as the second leading cause of maternal death globally, after maternal hemorrhage (2). Apart from causing harm to the mother, HDP is also associated with adverse fetal outcomes, such as preterm labor and fetal growth restriction (3). The exact pathogenesis of HDP is unclear, and current studies have found that endothelial dysfunction, insufficient trophoblastic invasion, abnormal angiogenesis, and aberrant uterine artery remodeling are considered to be key elements in its development (4–6). Among women in the gestational state, inappropriate immune activation and subsequent inflammation may result in maternal vasculopathy or placental dysfunction, thereby contributing to HDP (7). Previous studies have revealed that certain inflammatory cytokines are strongly correlated with HDP, such as macrophage inflammatory protein 1-beta (MIP1b) and interleukin-18 (IL-18) (8, 9). However, the causal link of various cytokines and HDP is difficult to establish through observational studies because of interference from confounding variables and reverse causations (10).

Mendelian randomization (MR) is an instrumental variable (IV) analysis which utilizes genetic variation as the IV to assess the causality for exposure and outcome (11). The advantages of MR analysis are as follows: first, genetic variations are distributed at random during meiosis and, thus, the likelihood of correlation with environmental confounders is rare (12); second, genotype distribution precedes acquired exposure in time and the two are not impacted by reverse causality; third, exposure-related genetic variation generally accompanies individuals from birth to adulthood, thereby avoiding attenuation due to error in causal inference (regression dilution bias) (13). Additionally, Mendel's laws of inheritance are universal in the population, thereby avoiding the problem of representativeness in randomized controlled experiments. A two-sample MR analysis enables assessment of the relation between exposure and outcome in two independent populations, thereby expanding the scope of application and improving validity. MR analysis was performed on the basis of the following three hypotheses related to IVs. The first hypothesis is that the selected IVs are genetic variants highly correlated to the exposure. The second hypothesis is that IVs have no association with confounding factors between exposure and outcome. The third hypothesis is that IVs make no difference to outcome directly and merely affect outcome through exposure (14).

The aim of this study is to investigate the causal association between HDP and 41 inflammatory cytokines by using MR analysis and to identify inflammatory cytokines that can serve as potential biomarkers to facilitate early detection and treatment strategies for HDP.

# 2 Materials and methods

## 2.1 Study design

We used published summarized genome-wide association studies (GWAS) data for 41 circulating inflammatory cytokines and 4 types

of HDP. In our study, a two-sample MR analysis was carried out in order to investigate bidirectional causality between inflammatory cytokines and HDP. This MR study was in accordance with the guidelines of Strengthening the Reporting of Observational Studies in Epidemiology using Mendelian Randomization (STROBE-MR) (15). The study design overview is presented in Figure 1.

## 2.2 Data sources

Data on inflammatory cytokines was taken from a GWAS meta-analysis that provided genomic variants in 8293 Finnish individuals (16). This study was conducted in three cohorts including The Cardiovascular Risk in Young Finns Study (YFS) and FINRISK surveys of the 1997 and 2002, which have already been completed. The average age of the participants in the YFS study was 37 years and that in the FINRISK survey was 60 years. The GWAS data of inflammatory cytokines used in this MR analysis were after adjusting for age, sex, and body-mass index (BMI). HDP-summarized GWAS data were retrieved from FinnGen database (<https://www.finnngen.fi/en>) R9 version. According to the definition of HDP we included two cohorts of gestational hypertension; and pre-eclampsia/eclampsia. However, since the GWAS data for chronic hypertension were not available and the pre-eclampsia superimposed on chronic hypertension cohort had only 154 case samples, these two categories under the HDP definition were unable to be included in this MR study. In addition, we found two cohorts with larger sample sizes, pre-existing hypertension complicating pregnancy, childbirth and the puerperium and pre-eclampsia or poor fetal growth, which were thus included in the study. Finally, we selected four cohorts for inclusion in this MR analysis, including pre-eclampsia or eclampsia (PE); gestational hypertension (GH); pre-existing hypertension complicating pregnancy, childbirth and the puerperium (EH); and pre-eclampsia or poor fetal growth (PF). No overlap existed between the exposure and outcome groups in the population. Table S1 lists details of the four types of HDP.

## 2.3 Instrumental variable selection

First, we applied a genome-wide significance threshold of  $p < 5 \times 10^{-8}$  so as to filter out single nucleotide polymorphisms (SNP) that were closely associated with HDP and inflammatory cytokines. A few inflammatory cytokines were found under this criterion that did not have a sufficient number of SNPs to perform MR analysis; thus, a higher cutoff value ( $p < 5 \times 10^{-6}$ ) was selected. Second, when inflammatory cytokines were used as exposure, we clumped SNPs ( $kb = 10000$ ,  $r^2 = 0.01$ ), which implies that SNPs with  $r^2 > 0.01$  in the 10000 kb range with the most significant SNPs were eliminated, thereby avoiding linkage disequilibrium (LD). Whereas for HDP as exposure, the number of SNPs was sufficient and, hence, a higher criterion for eliminating LD was set— $kb = 10000$ ,  $r^2 = 0.001$ . As we could not determine whether the palindromic SNPs were oriented in a consistent direction between exposure and outcome, these SNPs were not involved in MR analysis. Third, the  $R^2$  value was calculated for each SNP, which indicates the extent of exposure

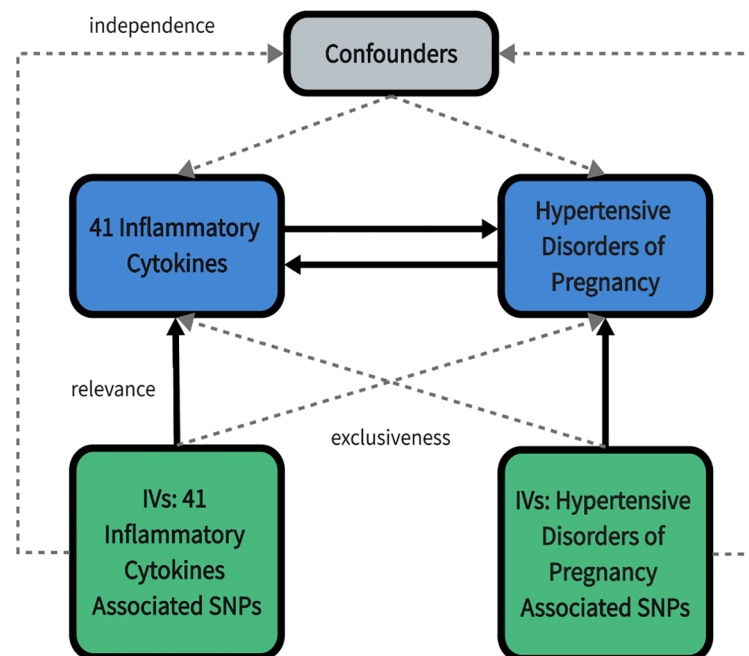

FIGURE 1

An overall design of the present study. IV, Instrumental variable; SNP, Single nucleotide polymorphism.

explained by IVs; moreover, to avoid weak instrumental bias, we evaluated the strength of the IV correlations by calculating the F-statistic and selected SNPs with F-statistic >10 for inclusion in this MR analysis. Finally, whenever unavailable SNPs are found, we use the LDlink Website (<https://ldlink.nci.nih.gov/>) to search for proxy SNPs ( $r^2 > 0.8$ ) to replace them.

## 2.4 Statistical analysis

MR analysis is conducted utilizing the “TwoSampleMR” R package (Version 0.5.6) of the RStudio (version 4.2.3), which includes five MR analysis methods. Of these five methods, inverse variance weighting (IVW) was employed as the main method, with MR Egger regression, weighted median, simple mode, and weighted mode as complementary methods. The IVW method, which ignores the presence of the intercept term in the regression and takes the inverse of the result variance (quadratic of se) as the weight for the fit, assumes that all of the SNPs turned out to be valid instrumental variables and are completely independent of each other (17). MR Egger regression accounts for the existence of an intercept term. It assumes that the instrument-exposure and instrument-outcome associations are independent—that is, the instrument strength independent of the assumption of direct effect (18). The weighted median method requires a minimum of 50% of the IVs to be valid to obtain a robust estimate; this method tolerates more invalid IVs (19). Further, inflammatory cytokines that were ultimately identified as statistically significant were subject to the following conditions: The IVW results revealed that the 95% confidence intervals (CI) did not cross over with

1 (or 0),  $p < 0.05$ , and met the consistent trend of inflammatory cytokine effects derived from the five MR analyses.

We employed three sensitivity analysis methods to assess the sensitivity of MR results, including the heterogeneity test, pleiotropy test, and leave-one-out sensitivity test. Cochran’s Q test and Rucker’s Q test were used to detect the heterogeneity, and  $p > 0.05$  was regarded as no heterogeneity. The intercept of the MR Egger analysis results were used for testing the horizontal pleiotropy, with  $p > 0.05$  considered as no pleiotropy (20). Additionally, the MR PRESSO method is capable of outlier identification and horizontal pleiotropy detection simultaneously (21). When applying MR PRESSO analysis, the NbDistribution parameter refers to the number of simulations calculated, and we set this parameter to 1000. Leave-one-out sensitivity was used to investigate whether the causal association was influenced by an SNP between exposure and outcome (22). Further, this study was not pre-registered on any platform.

## 3 Results

In this two-sample MR study, we investigated the correlation of each of the 4 types of HDP with 41 biomarkers—including interleukins, growth factors, and chemokines—thereby demonstrating that the inflammatory cytokines variably impact each disease type. Interleukin-9 (IL-9), macrophage migration inhibitory factor (MIF), MIP1b, interleukin-13 (IL-13), interleukin-16 (IL-16), and tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) in PE; MIF and vascular

endothelial growth factor (VEGF) in GH; interleukin-18 (IL-18), TRAIL, and MIP1b in EH; and IL-9, MIP1b, IL-13 and IL-16 in PF may serve as potential upstream factors for disease when inflammatory cytokines are used as exposures and disease is used as an outcome. In addition, VEGF, interleukin-12p70 (IL-12p70), interleukin-1 beta (IL-1b), interleukin-1 receptor antagonist (IL-1ra), interleukin-4 (IL-4), interleukin-7 (IL-7), interleukin-8 (IL-8), macrophage colony stimulating factor (MCSF) in PE and macrophage inflammatory protein 1-alpha (MIP1a), hepatocyte growth factor (HGF), IL-18, IL-8 in GH might cause alterations in the expression levels of these cytokines through the pathogenic pathway if the disease type is used as exposure. Further, there is no reciprocal causal association between individual biomarkers and diseases under each disease type. The results of bidirectional MR

analysis among the four types of HDP and inflammatory cytokines are presented in Figures 2–5.

### 3.1 Bidirectional interactions between 41 inflammatory cytokines and PE

The results of bidirectional MR analysis of inflammatory cytokines correlated with PE are depicted in Figure 2. When 41 inflammatory cytokines were used as exposures, 6 inflammatory factors were causally associated with the pathogenesis of PE disease, including IL9 (odds ratio (OR) = 1.168, 95%CI = 1.027–1.327,  $p = 0.018$ ) and MIF (OR = 1.120, 95% CI = 1.021–1.228,  $p = 0.016$ ) as facilitators, MIP1b (OR = 0.957, 95% CI = 0.917–0.998,  $p = 0.042$ ), IL13 (OR = 0.947, 95% CI = 0.898–

0.997,  $p = 0.039$ ), IL16 (OR = 0.916, 95% CI = 0.843–0.996,  $p = 0.039$ ), and TRAIL (OR = 0.913, 95% CI = 0.850–0.981,  $p = 0.013$ ) playing inhibitory roles. Scatter plots were used to demonstrate the trends of inflammatory cytokines under the five MR methods (Figure S1).

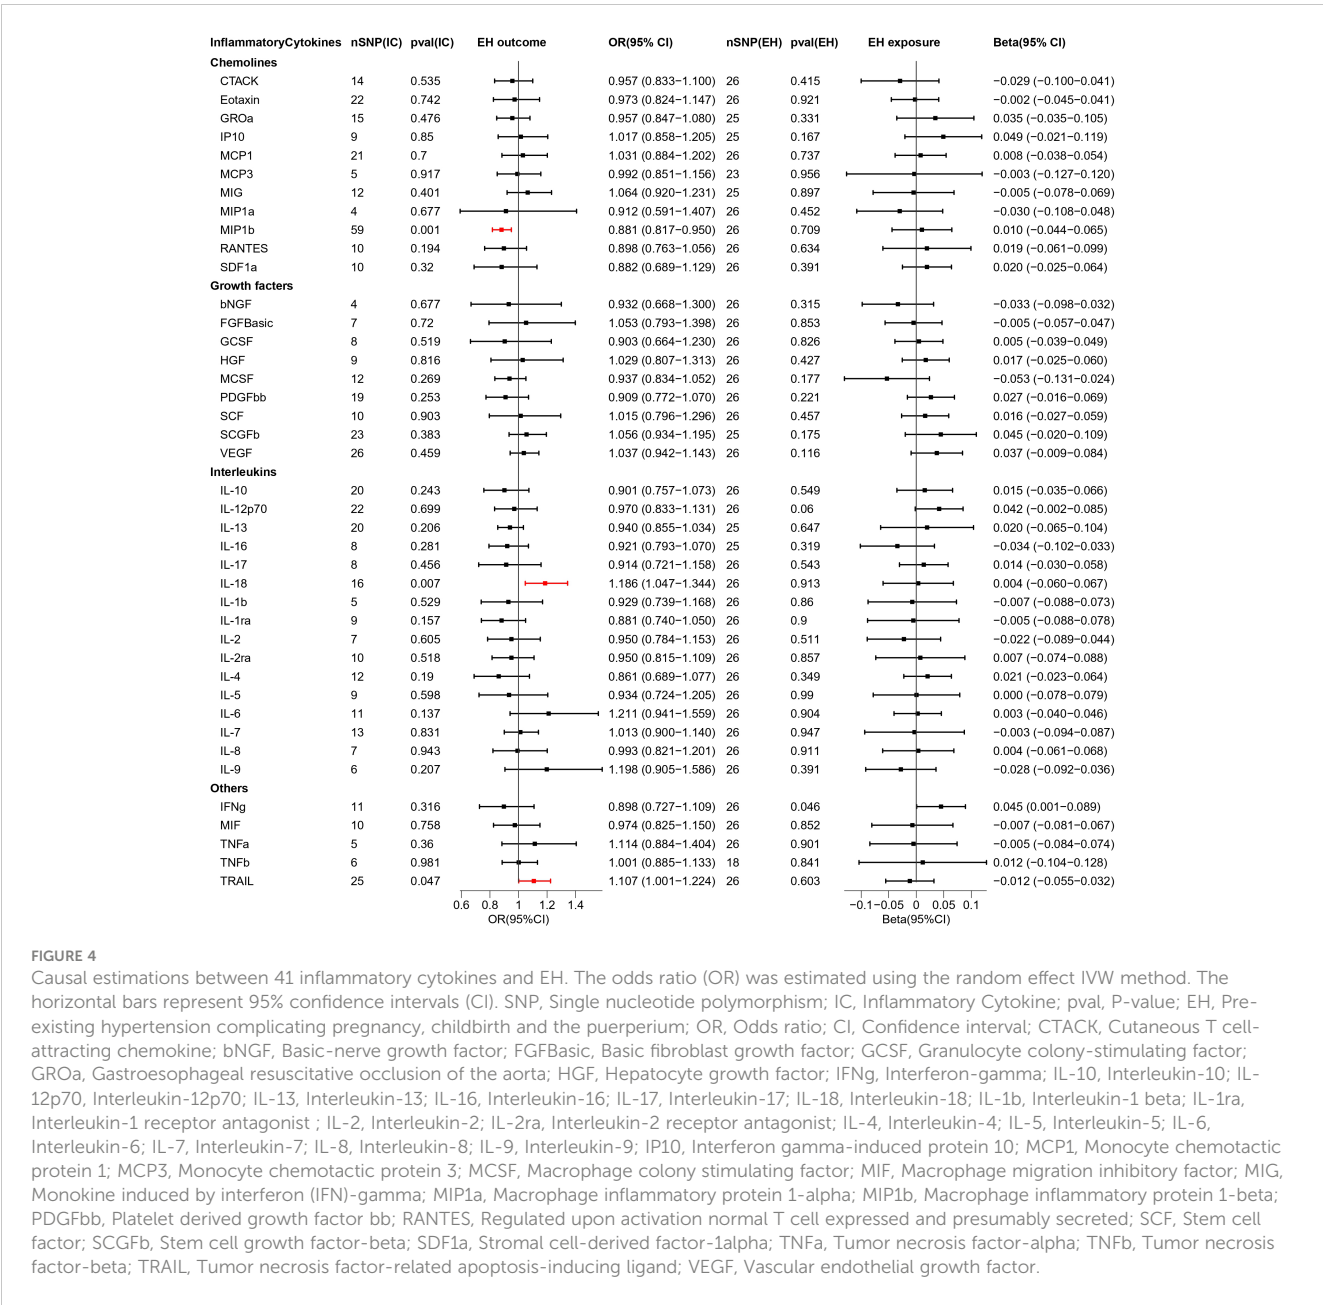

When PE was used as exposure, the remaining 33 SNPs were involved in the MR analysis. The results are depicted in Figure 2. Eight inflammatory cytokines were affected by PE, among which the growth factor MCSF (Beta = -0.159, 95% CI = -0.280–0.037,  $p = 0.01$ ) was negatively regulated, while the others were positively regulated. The remaining seven inflammatory factors were VEGF (Beta = 0.098, 95% CI = 0.026–0.170,  $p = 0.008$ ), IL12p70 (Beta = 0.076, 95% CI = 0.009–0.143,  $p = 0.027$ ), IL1b (Beta = 0.137, 95% CI = 0.032–0.243,  $p = 0.011$ ), IL1ra (Beta = 0.131, 95% CI = 0.018–0.245,  $p = 0.023$ ), IL4 (Beta = 0.086, 95% CI = 0.015–0.156,  $p = 0.017$ ), IL7 (Beta = 0.109, 95% CI = 0.006–0.213,  $p = 0.039$ ), IL8

(Beta = 0.125, 95% CI = 0.017–0.232,  $p = 0.023$ ). The scatter plot of the above inflammatory cytokines is presented in Figure S2.

### 3.2 Bidirectional interactions between 41 inflammatory cytokines and GH

As 41 inflammatory cytokines were used for MR analysis as exposure, MIF (OR = 1.142, 95% CI = 1.029–1.267,  $p = 0.012$ ), which acted as a promoter, and VEGF (OR = 0.904–0.9995,  $p = 0.048$ ), which acted as an inhibitor, were identified. The scatter plot is depicted in Figure S3.

Next, we reversed the exposure and outcome. MR analysis revealed that four inflammatory cytokines were screened out and all of them had increased expression under the influence of GH. The four

**FIGURE 4**  
Causal estimations between 41 inflammatory cytokines and EH. The odds ratio (OR) was estimated using the random effect IVW method. The horizontal bars represent 95% confidence intervals (CI). SNP, Single nucleotide polymorphism; IC, Inflammatory Cytokine; pval, P-value; EH, Pre-existing hypertension complicating pregnancy, childbirth and the puerperium; OR, Odds ratio; CI, Confidence interval; CTACK, Cutaneous T cell-attracting chemokine; bNGF, Basic-nerve growth factor; FGFBasic, Basic fibroblast growth factor; GCSF, Granulocyte colony-stimulating factor; GROa, Gastroesophageal resuscitative occlusion of the aorta; HGF, Hepatocyte growth factor; IFNg, Interferon-gamma; IL-10, Interleukin-10; IL-12p70, Interleukin-12p70; IL-13, Interleukin-13; IL-16, Interleukin-16; IL-17, Interleukin-17; IL-18, Interleukin-18; IL-1b, Interleukin-1 beta; IL-1ra, Interleukin-1 receptor antagonist; IL-2, Interleukin-2; IL-2ra, Interleukin-2 receptor antagonist; IL-4, Interleukin-4; IL-5, Interleukin-5; IL-6, Interleukin-6; IL-7, Interleukin-7; IL-8, Interleukin-8; IL-9, Interleukin-9; IP10, Interferon gamma-induced protein 10; MCP1, Monocyte chemotactic protein 1; MCP3, Monocyte chemotactic protein 3; MCSF, Macrophage colony stimulating factor; MIF, Macrophage migration inhibitory factor; MIG, Monokine induced by interferon (IFN)-gamma; MIP1a, Macrophage inflammatory protein 1-alpha; MIP1b, Macrophage inflammatory protein 1-beta; PDGFBb, Platelet derived growth factor bb; RANTES, Regulated upon activation normal T cell expressed and presumably secreted; SCF, Stem cell factor; SCGFb, Stem cell growth factor-beta; SDF1a, Stromal cell-derived factor-1alpha; TNFa, Tumor necrosis factor-alpha; TNFB, Tumor necrosis factor-beta; TRAIL, Tumor necrosis factor-related apoptosis-inducing ligand; VEGF, Vascular endothelial growth factor.

cytokines are MIP1a (Beta = 0.122, 95% CI = 0.024–0.219,  $p = 0.015$ ) HGF (Beta = 0.070, 95% CI = 0.006–0.134,  $p = 0.032$ ), IL-18 (Beta = 0.136, 95% CI = 0.030–0.241,  $p = 0.012$ ), and IL-8 (Beta = 0.116, 95% CI = 0.018–0.213,  $p = 0.02$ ). The scatter plot is depicted in [Figure S4](#). In addition, the 95% CIs for GROa and SCGFb did not pass through 0 ([Figure 3](#)). The beta values for MR Eggar were in the opposite direction as that of IVW; thus, GROa (IVW beta = 0.106, MR Eggar beta = -0.143) and SCGFb (IVW beta = 0.129, MR Eggar Beta = -0.263) were not considered as statistically significant cytokines.

### 3.3 Bidirectional interactions between 41 inflammatory cytokines and EH

We explored the causal association of 41 inflammatory cytokines with EH as outcome and obtained three inflammatory

cytokines with causal potential—IL-18 (OR = 1.186, 95% CI = 1.047–1.344,  $p = 0.007$ ) and TRAIL (OR = 1.107, 95% CI = 1.001–1.224,  $p = 0.047$ ) factors produced positive regulatory effects, while MIP1b (OR = 0.881, 95% CI = 0.817–0.950,  $p = 0.001$ ) factor exerted negative effects. The scatter plot is depicted in [Figure S5](#).

When exploring the MR analysis of the role of EH as exposure, only the IFNg was revealed as a statistically significant responder by the IVW method. However, the MR Eggar method obtained results with the opposite trend to that of the former; thus, the IFNg (IVW beta = 0.045, MR Eggar beta = -0.004) was eliminated.

### 3.4 Bidirectional interactions between 41 inflammatory cytokines and PF

When MR analysis was performed with 41 inflammatory cytokines as exposure and PF as outcome, one facilitator, IL-9

FIGURE 5

SNP, Single nucleotide polymorphism; IC, Inflammatory Cytokine; pval, P-value; PF, Pre-eclampsia or poor fetal growth; OR, Odds ratio; CI, Confidence interval; CTACK, Cutaneous T cell-attracting chemokine; bNGF, Basic-nerve growth factor; FGFBasic, Basic fibroblast growth factor; GCSF, Granulocyte colony-stimulating factor; GROa, Gastroesophageal resuscitative occlusion of the aorta; HGF, Hepatocyte growth factor; IFNg, Interferon-gamma; IL-10, Interleukin-10; IL-12p70, Interleukin-12p70; IL-13, Interleukin-13; IL-16, Interleukin-16; IL-17, Interleukin-17; IL-18, Interleukin-18; IL-1b, Interleukin-1 beta; IL-1ra, Interleukin-1 receptor antagonist; IL-2, Interleukin-2; IL-2ra, Interleukin-2 receptor antagonist; IL-4, Interleukin-4; IL-5, Interleukin-5; IL-6, Interleukin-6; IL-7, Interleukin-7; IL-8, Interleukin-8; IL-9, Interleukin-9; IP10, Interferon gamma-induced protein 10; MCP1, Monocyte chemotactic protein 1; MCP3, Monocyte chemotactic protein 3; MCSF, Macrophage colony stimulating factor; MIF, Macrophage migration inhibitory factor; MIG, Monokine induced by interferon (IFN)-gamma; MIP1a, Macrophage inflammatory protein 1-alpha; MIP1b, Macrophage inflammatory protein 1-beta; PDGFbb, Platelet derived growth factor bb; RANTES, Regulated upon activation normal T cell expressed and presumably secreted; SCF, Stem cell factor; SCGFb, Stem cell growth factor-beta; SDF1a, Stromal cell-derived factor-1alpha; TNFa, Tumor necrosis factor-alpha; TNFb, Tumor necrosis factor-beta; TRAIL, Tumor necrosis factor-related apoptosis-inducing ligand; VEGF, Vascular endothelial growth factor.

(OR = 1.118, 95% CI = 1.004–1.246,  $p = 0.043$ ), and three inhibitory factors, MIP1b (OR = 0.949, 95% CI = 0.916–0.984,  $p = 0.004$ ), IL-13 (OR = 0.949, 95% CI = 0.908–0.992,  $p = 0.02$ ), and IL-16 (OR = 0.930, 95% CI = 0.867–0.998,  $p = 0.043$ ) were found. The scatterplot is presented in Figure S6.

Reversing exposure and outcome, no significant inflammatory cytokines were found.

### 3.5 Sensitivity analysis

The results of the tests for heterogeneity and pleiotropy when inflammatory cytokines were used as exposures are presented in Table S2. The results of the tests for heterogeneity and pleiotropy when inflammatory cytokines were used as outcomes are presented

in Table S4. In addition, the leave-one-out analysis results are presented in Figure S7–12. Details of SNPs when inflammatory cytokines were used as exposures are presented in Table S3. Details of SNPs when inflammatory cytokines were used as outcomes are presented in Table S5.

## 4 Discussion

Recently, numerous studies that explore the association of HDP with the immune system and the inflammatory cytokines produced by immune cells have been published. For example, TH17 cells and their secreted interleukin-17 (IL-17) levels are found to be increased in PE patients; TH17 cells induce pre-eclampsia by participating in placental ischemia, oxidative stress, and other pathways (23). It has

also been suggested that VEGF may be an important biomarker for pre-eclampsia and has significant value in predicting its severity (24, 25). Despite the rich results of previous observational studies, the causal association among numerous important inflammatory cytokines with HDP has not been established due to the limitations of traditional epidemiology (26). Observational studies often provide biased associations due to the presence of confounding factors or reverse causality, thereby making it difficult to obtain credible conclusions using this method (27). In terms of pregnancy disorders, it is difficult to identify the causes of changes in inflammatory cytokine levels in patients with HDP through general observational studies. The presence of the disease itself, side effects caused by therapeutic drugs, underlying pathological immune response, the state of hidden infection, and harmful lifestyle habits (such as alcohol abuse and smoking) can cause changes in the levels of inflammatory cytokines (28–30). Recently, it has been reported that cytokine storms are highlighted as a common feature in pre-eclampsia and severe forms of coronavirus disease 2019 disease (31).

Our study found that more inflammatory cytokines exhibited significant changes in the initiation and progression of PE compared to GH. Among the four types of HDP, the inflammatory cytokines that recurrently appear upstream of the disease are IL-9, MIF, MIP1b, IL-13, IL-16, and TRAIL. The IL-9/IL-9R pathway is involved in regulating trophoblast function, and increased IL-9 levels were found to result in increased tissue proliferation and invasiveness (32). IL-9 and IL-9R increase fibroblast proliferation as well as induce pro-inflammatory cytokines and metalloproteinases, which are key pathological processes that promote the formation of vascular opacities (33). Prior studies have suggested that Th9 cells may be involved in immune-mediated diseases such as allergy and autoimmune inflammatory diseases (34). Th1 or Th17 cells can induce CD4+IL-9+ T cell differentiation by promoting factors such as IL-1b and IL-12 (35). Under condition of TGF- $\beta$  presence, Th-17 cells can produce IL-9 to participate in pro-inflammatory response (36). At present, research on Th9 cells in human pregnancy is limited, and the possible role of Th9 cells in preeclampsia needs to be further investigated. In addition, MIF is involved in multiple biophysiological processes that contribute to cell proliferation and differentiation, innate immune responses, and angiogenic biological activities (37). Previous studies have confirmed that large amounts of pro-inflammatory mediators are produced by MIF stimulation, including cytokines tumor necrosis factor- $\alpha$  (TNF $\alpha$ ), IL-1b, interleukin-6 (IL-6), interferon- $\gamma$  (IFN $\gamma$ ), matrix metalloproteinases, and nitric oxide (38, 39). Circulating concentrations of MIF are elevated in infected patients, inflammatory conditions, and autoimmune diseases (40). Therefore, MIF is recognized as a biomarker or pharmacological target for different diseases (41, 42), and MIF inhibitors might have considerable therapeutic benefit for numerous inflammatory and autoimmune diseases (43–46). Similar conditions have been found in mothers with pathological pregnancies (preterm birth (47) and pre-eclampsia (48)). MIP1b was revealed to have the potential to recruit macrophages and dendritic cells (49, 50), which have the ability to secrete a range of cytokines/chemokines and enzymes

implicated in angiogenesis and tissue remodeling (51). Furthermore, it has been demonstrated that macrophages promote trophoblastic invasion in pregnant mice (52). IL-13 exerts its anti-inflammatory effects by binding to IL-4 receptor  $\alpha$  (IL-4ra) (53). In addition, IL-13 can downregulate the expression of IL-1b, IL-8, TNF $\alpha$ , and MIP1a (54–56). The anti-inflammatory potential of IL-13 has been therapeutically investigated in a variety of pathologies, including psoriasis, arthritis, and Alzheimer's disease (57–59). Therefore, IL13 may be a key therapeutic target in pre-eclampsia. Currently, there are very few studies that investigate the correlation between IL-16 and HDP. It has been shown that IL-16 can initiate and amplify inflammatory responses through the release of cell signaling molecules that bind to CD4+ T cells (60). It is worth noting that Andrea L et al. found a noticeable decrease of IL-16 expression in hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome (61). Due to the lack of clarity regarding how IL-16 is implicated in the etiopathogenesis of pre-eclampsia suggests, it is noteworthy that future research on IL-16 in such disorders is necessary. Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) is part of the TNF ligand family, and TRAIL and its receptor play essential roles in trophoblastic immunity and invasion during early pregnancy (62, 63). TRAIL induces apoptosis in vascular endothelial cells and vascular smooth muscle cells during the process of remodeling the uterine spiral arteries (64). It has recently been demonstrated that pregnant women who subsequently develop HDP have reduced plasma levels of TRAIL prior to 20 weeks gestation (65), thereby suggesting that TRAIL could serve as a new predictive, noninvasive biomarker for pregnant women with HDP.

Further, previous studies have revealed that IL-12p70, IL-1ra, IL-1b, IL-8, and IL-18 are considerably higher in PE group than in normal pregnant women (66, 67), which supports our findings. IL-1ra is elevated in PE, and elevated circulating IL-1ra reflect increased activity of the pro-inflammatory cytokines IL-1a and IL-1b, both of which are difficult to identify in serum levels because of their short circulating half-lives (68, 69). Moreover, it has been revealed that IL-1b and TNF $\alpha$  can significantly increase MCSF expression in early pregnancy decidual cells (70). IL-7 cytokine is necessary for the proliferation and survival of pathogenic Th17 cells, and has a promotional role in autoimmune diseases such as experimental autoimmune encephalomyelitis (71, 72). In addition, previous evidence suggests that Th17 cells are observed to be increased in the decidual cells of patients with pre-eclampsia (73). IL-17 is a major effector molecule of Th17 cells, which plays an important role in inflammatory response, and IL-17 also induces the production of factors such as IL-6 and IL-8. However, IL-17 was not a statistically significant factor in the results of this MR analysis. In a meta-analysis published in 2020, the authors found no evidence that circulating IL-17 levels differed between pre-eclampsia and controls (74). Furthermore, Brewster et al. found that IL-17 levels were lower in patients with early-onset pre-eclampsia and higher in patients with late-onset compared to controls (75). Consequently, we consider that the role of IL-17 in pre-eclampsia needs to be approached with caution and further studies are still needed. Karol

Charkiewicz et al. demonstrated that HGF was expressed in the plasma of patients with PE at a higher level than that in healthy pregnant women (76).

Currently, the most effective way to deal with pre-eclampsia is the prompt delivery of the fetus and placenta (77). Symptoms of pre-eclampsia and eclampsia are usually greatly relieved when the fetus and placental tissue are delivered from the mother. In our study, circulating inflammatory cytokines were also no longer active in patients after delivery. Moreover, we found that IL-9, MIP1b, IL-13, and IL-16 might be associated with fetal dysplasia. Previous researches have suggested that IL-9 induces immune tolerance during pregnancy; if abnormalities occur, the fetus is no longer tolerated by the mother and has adverse outcomes for both the mother and fetus (78). MIP1b affects cytotoxicity and causes tissue damage in the developing fetal brain and is a potential mechanism for intrauterine fetal dysplasia (79). Fetal growth restriction (FGR) maternal IL-13 levels are lower than those in normal pregnancies (80). IL-13 is a Th2 cytokine with anti-inflammatory characteristics. IL-13 inhibits the production of IL-6, IL-8, TNF $\alpha$ , and IL-12 as well as suppresses cytotoxicity and blocks pathologic inflammation (81). Lower levels of IL13 in FGR may indicate a more pronounced Th1 bias or pro-inflammatory cytokine bias. Denihan et al. investigated that IL-16 participated in the process of fetal brain injury and that its level associated with the long-term prognosis of neonatal hypoxic-ischemic encephalopathy (82).

For the first time, we adopted bidirectional two-sample MR analysis to explore the causal association between circulating inflammatory cytokines and the four types of HDP. Additionally, attention has been focused on inflammatory cytokines in pre-eclampsia that may contribute to poor fetal growth and development. Prior literature reviewed upstream and downstream inflammatory cytokines in HDP, thereby providing strong evidence for our results. Our study obtained different inflammatory cytokine profiles for both the incidence and progression of the disease, which offers new directions in the prevention, surveillance, and treatment of HDP. The pathogenesis and pathophysiology of HDP, represented by pre-eclampsia, are very complex and multifactorial. This includes endothelial dysfunction, oxidative stress, angiogenesis, neutrophil activation, anti-angiogenic factors, and syncytiotrophoblast microparticles, which are all involved in the pathophysiologic process of pre-eclampsia. Inflammatory cytokines play an important role in disease progression, but not all. This study only included 41 inflammatory cytokines, which is obviously a limitation. With in-depth study of HDP, more cytokines will be explored by researchers in the future and bring new perspectives and insights for early detection and therapeutic strategies of HDP.

There are several strengths of this study. First, genetic variation is randomly distributed during gamete formation and conception; thus, MR analysis avoids the limitations of observational studies (confounding, regression dilution, and reverse causation bias) (11). Second, we used separate samples for the circulating inflammatory cytokines and HDP data, and two-sample data avoided bias from weak instrumental variables. Third, we included two large-scale cohorts were included for MR analysis, thereby applying a sufficiently large sample size to ensure generalizability of causality. Moreover, two sets of data were treated as exposure and

outcome to perform bidirectional MR analysis, respectively. Finally, so as to test the validity of the IV hypotheses, we performed sensitivity analyses, which included heterogeneity, pleiotropy, and leave-one-out analyses.

Nevertheless, there are also a few limitations of this study that must be discussed. First, the number of IVs as exposure varied for each inflammatory cytokine. During our analysis, a few IVs were discarded after screening; thus, the final MR analysis results could be influenced by the limited number of IVs. Despite this, we calculated statistical efficacy for each IV and excluded IVs with low efficacies in order to ensure that the results presented in this study remain reliable. Second, HDP occurs only in the female population, whereas circulating inflammatory cytokine GWASs are found in both male and female populations; thus, the presence of gender differences could potentially impact MR results. Third, this research data pertains to European populations; therefore, it needs to be treated with caution when generalizing to other populations. Finally, the immune system in pregnancy is complex and variable, with multiple changes in inflammatory cytokines influenced by a variety of factors, whereas it is difficult to dynamically monitor such a complex process in our study. Early-onset preeclampsia (onset < 34 weeks of gestation) and late-onset preeclampsia (onset  $\geq$  34 weeks of gestation), have different pathophysiological and immunopathological origins. However, limited by the availability of GWAS data, this study did not conduct subgroup analyses. With regard to the causal association of circulating inflammatory cytokines with HDP, deeper and more extensive studies are required in the future.

## Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found in the article/[Supplementary Material](#).

## Author contributions

SG: Data curation, Formal Analysis, Investigation, Methodology, Project administration, Resources, Visualization, Writing – original draft, Writing – review & editing. XB: Conceptualization, Investigation, Methodology, Project administration, Resources, Supervision, Visualization, Writing – original draft, Writing – review & editing. JD: Formal Analysis, Investigation, Validation, Visualization, Writing – original draft, Writing – review & editing. RZ: Conceptualization, Investigation, Project administration, Resources, Supervision, Writing – original draft, Writing – review & editing.

## Funding

The author(s) declare financial support was received for the research, authorship, and/or publication of this article. This study

was funded by Wu Jieping Medical Foundation (Grant No. 320.6750.2020-06-83).

## Acknowledgments

We sincerely thank the FinnGen database and Ari V. Aholai et al. and other related researchers for providing GWASs summary data.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Amniotic mesenchymal stromal cells (hAMSCs) have unique immunomodulatory properties demonstrated *in vitro* and *in vivo* in various diseases in which the dysregulated immune system plays a major role. The immunomodulatory and pro-regenerative effects of MSCs, among which hAMSCs lie in the bioactive factors they secrete and in their paracrine activity, is well known. The mix of these factors (i.e., secretome) can be either freely secreted or conveyed by extracellular vesicles (EV), thus identifying two components in the cell secretome: EV-free and EV fractions. This study aimed to discern the relative impact of the individual components on the immunomodulatory action of the hAMSC secretome in order to obtain useful information for implementing future therapeutic approaches using immunomodulatory therapies based on the MSC secretome. To this aim, we isolated EVs from the hAMSC secretome (hAMSC-CM) by ultracentrifugation and validated the vesicular product according to the International Society for Extracellular Vesicles (ISEV) criteria. EVs were re-diluted in serum-free medium to maintain the EV concentration initially present in the original CM. We compared the effects of the EV-free and EV fractions with those exerted by hAMSC-CM *in toto* on the activation and differentiation of immune cell subpopulations belonging to both the innate and adaptive immune systems.

We observed that the EV-free fraction, similar to hAMSC-CM *in toto*, a) decreases the proliferation of activated peripheral blood mononuclear cells (PBMC), b) reduces the polarization of T cells toward inflammatory Th subsets, and induces the induction of regulatory T cells; c) affects monocyte

polarization to antigen-presenting cells fostering the acquisition of anti-inflammatory macrophage (M2) markers; and d) reduces the activation of B lymphocytes and their maturation to plasma cells. We observed instead that all investigated EV fractions, when used in the original concentrations, failed to exert any immunomodulatory effect, even though we show that EVs are internalized by various immune cells within PBMC. These findings suggest that the active component able to induce immune regulation, tested at original concentrations, of the hAMSC secretome resides in factors not conveyed in EVs. However, EVs isolated from hAMSC could exert actions on other cell types, as reported by others.

amniotic secretome/conditioned medium, extracellular vesicles, mesenchymal stem/stromal cells, immune modulation

## Introduction

Human amniotic mesenchymal stromal cells (hAMSCs) have attracted great attention thanks to their immunomodulatory properties (1, 2) that determine significant advantages for their application in the treatment of inflammatory or immune-mediated diseases (3). Indeed, hAMSCs exert strong antiproliferative and immunomodulatory actions on different immune cells. Several *in vitro* studies demonstrated that hAMSCs and their secretome inhibit the proliferation of T cells when activated through TCR stimulation. As a matter of fact, we previously reported that hAMSCs and their secretome prevent/reduce the development of cytotoxic T cells and the polarization toward inflammatory T helper subsets and enhance instead the polarization toward regulatory T cells (4, 5). Furthermore, they suppress the *in vitro* differentiation of monocytes toward inflammatory antigen-presenting cells, triggering instead the acquisition of phenotypical and functional features typical of M2 anti-inflammatory macrophages (5–8). We have also recently

demonstrated that hAMSCs and their secretome are able to suppress the proliferation and differentiation of B lymphocytes to plasma cells (9).

The immunomodulatory properties of hAMSCs and their secretome have been shown to contribute to their ability to foster tissue regeneration and induce therapeutic effects in preclinical disease models. As a matter of fact, hAMSCs and their secretome have been successfully used to treat different inflammatory-related diseases including lung (10, 11) and liver fibrosis (12), wound healing (7, 13), collagen-induced arthritis (14), tendon-to-bone healing (15), bone defects (16), multiple sclerosis (14), inflammatory bowel disease (14), colitis (14, 17), sepsis (14), traumatic brain injury (18), and Huntington's disease (19). All these studies strongly indicate that hAMSCs provide immunoregulatory actions through paracrine signaling triggered by factors present in their secretome, which include both freely secreted factors and factors conveyed by extracellular vesicles (EVs).

EVs are a heterogeneous family of bilayer membrane vesicles that, according to their size and biogenesis, are classified into exosomes (40–200 nm; generated within the endosomal system) and microvesicles (50–1,000 nm; produced by outward budding of the plasma membrane). EVs carry molecules such as proteins, lipids, and coding and non-coding RNAs, which can contribute to the function of the cells of origin from which they are released (20, 21). Some studies suggest that EVs released from MSCs may have a therapeutic action comparable to that of parental cells and their derived secretomes, thus representing an enormous therapeutic potential for applications in regenerative medicine due to their easier management/storage and higher safety (i.e., lack of tumorigenicity) compared to cell-based therapy (22). Our previous studies evidence that the hAMSC secretome (hereinafter defined as hAMSC-conditioned medium: hAMSC-CM) contains free, soluble molecules and EV-conveyed miRNAs

**Abbreviations:** ANOVA, analysis of variance; AT, adipose tissue; BM, bone marrow; CFSE, carboxyfluorescein succinimidyl ester; CM, conditioned medium; DC, dendritic cell; Edu, 5-ethynyl-2'-deoxyuridine; EV, extracellular vesicles; GM-CSF, granulocyte-macrophage colony-stimulating factor; hAMSC, mesenchymal stromal cells derived from amniotic membrane; IFN- $\gamma$ , interferon gamma; IL-4, interleukin-4; LPS, lipopolysaccharide; mAB, monoclonal antibody; mDC, mature dendritic cell; MFI, mean fluorescence intensity; Mo, monocyte; ns, not significant; NTA, nanoparticle tracking analysis; PBMC, peripheral blood mononuclear cells; PBS, phosphate buffered saline; P/S, penicillin/streptomycin; RPMI, Roswell Park Memorial Institute 1640 medium; RT, room temperature; Th, T helper cell; Treg, T regulatory cell; TEM, transmission electron microscopy; UC, umbilical cord.

with regulatory functions on different types of inflammatory cells (23). It is now crucial to define whether the EV fraction can exert biological activities comparable to those of the CM in toto. To this end, we compared the immunomodulatory potential of the different hAMSC secretome fractions. Indeed, no study has yet to specifically address the contribution that EVs and the freely secreted fraction have to the multifaceted immunomodulatory effects of hAMSC-CM. As a matter of fact, in this comparative study we aimed to discern the relative impact of the individual components of the hAMSC secretome, maintaining for each secretome fraction (EV-free and EV) the quantitative proportions in which they are represented in the secretome of origin.

Thus, herein for the first time we compared the immunomodulatory properties of the hAMSC secretome in toto with those of the different fractions (EV-free and EV fractions) to draw upon useful information for implementing future therapeutic approaches using immunomodulatory therapies (EV vs. secretome in toto) based on the MSC secretome.

## Material and methods

### Ethics statements

The collection of human peripheral blood mononuclear cells (PBMCs) for research purposes was approved by the Regional Departments of Transfusion Medicine (Rif. 523, July 7, 2016). PBMCs were obtained from healthy adult donors after informed consent and provided by the Center of Immune Transfusion of Spedali Civili of Brescia, Italy.

Human term placentae were collected from healthy women after vaginal delivery or caesarean section at term, after obtaining informed written consent, according to the guidelines set by the local ethical committee “Comitato Etico Provinciale di Brescia,” Italy (number NP 2243, 19 January 2016).

### Isolation of mesenchymal stromal cells from human amniotic membrane and CM preparation

Cells were isolated as previously described (24). The amniotic membrane was cut in fragments and digested at 37°C for 9 min with 2.5 U/ml dispase (VWR, Radnor, PA, USA). The digestion was then blocked by washing the amniotic fragments in RPMI complete medium composed of RPMI 1640 medium supplemented with 10% heat-inactivated fetal bovine serum (FBS), 1% penicillin/streptomycin (P/S), and 1% L-glutamine (all from Sigma-Aldrich, St. Louis, MO, USA). Enzymatic

digestion continued with fragment incubation in the presence of 0.94 mg/ml collagenase and DNase I (both from Roche, Basel, Switzerland) for approximately 2.5–3 h at 37°C. The cell suspension obtained was centrifuged at low g, and the supernatant was filtered (100-µm cell strainer) (BD Falcon, Bedford, MA, USA), and the cells were collected by centrifugation. After isolation, hAMSCs (p0) were phenotypically characterized as previously reported (24). Cells with >80% expression of mesenchymal markers CD13 and CD90 and <10% expression of the hematopoietic marker CD45 and of the epithelial marker CD324 were used in this study.

Freshly isolated cells were expanded until passage 1 (p1) by plating at a density of  $10^4$  cells/cm<sup>2</sup> in Chang Medium C (Irvine Scientific, Santa Ana, CA, USA) supplemented with 2 mM L-glutamine at 37°C in the incubator at 5% CO<sub>2</sub>. To produce conditioned medium (CM), hAMSC p1 cells were seeded for 5 days in 24-well plates (Corning, NY, USA) at a density of  $5 \times 10^5$  cells/well in 0.5 ml of DMEM-F12 medium (Sigma-Aldrich) without serum, supplemented with 2 mM L-glutamine (Sigma-Aldrich) and 1% P/S as described (25).

At the end of the 5-day culture, CM was collected, centrifuged at 300×g, and filtered through a 0.2-µm sterile filter (Sartorius Stedim, Florence, Italy). An aliquot of 5 ml was kept frozen at –80°C until use (CM in toto for comparison with other fractions), while the remaining CM volume (15–20 ml) was used for EV isolation. After EV isolation, the EV-free fraction was maintained for comparison studies. Six placentas were used to obtain six different hAMSC-CM preparations. The number of CMs used for each experiment is indicated in the figure legends.

### CM fractionation by ultracentrifugation

CM was centrifuged at  $100,000 \times g$  for 1, 3, 9, or 24 h at 4°C in a 70.1 Ti rotor (Beckman Coulter, Fullerton, CA, USA). To ensure optimal EV recovery, tubes were filled up to half nominal volume. After centrifugation, supernatants (EV-free fraction) were recovered and pellets (EV fraction) were suspended in a small volume of PBS or in a volume equivalent to the starting volume of CM used to isolate EVs (for example, EVs isolated from 12 ml of CM were resuspended in 12 ml of fresh medium without serum). Both EV-free and EV fractions were stored at 4°C and utilized within 24 h from isolation.

### EV detection by nanoparticle tracking analysis

EVs in the CM in toto, EV-free fractions, or EV fractions were visualized by the NanoSight NS300 system (NanoSight

Ltd., Amesbury, UK). Dilutions with PBS were performed to ensure sample readings between 20 and 120 particles per frame. Pump flow was set to 30. Three to five recordings of 60 s were executed for each sample. Collected data were analyzed by the Nanoparticle Tracking Analysis (NTA) software, providing concentration measurements and high-resolution particle size distribution profiles.

## EV characterization by flow cytometry

For analysis of EV integrity, an identical number of EVs in both CM in toto and EV fraction samples calculated from NTA data were supplemented with carboxyfluorescein succinimidyl ester (CFSE; Sigma-Aldrich, St Louis, MO, USA) (10  $\mu$ M final) and incubated in the dark at 37°C for 30 min. CFSE-positive events were detected and counted using the FITC channel up to a maximum value of 10,000 events per second with a 10- $\mu$ l/min flow rate using a CytoFLEX flow cytometer (Beckman Coulter). Unstained CM in toto and EV fraction samples were used as negative controls to set CFSE positivity. Integrity was calculated as the ratio of FITC+ events between the EV fraction and CM in toto. Before analysis, flow cytometer performance in the nanometer range was set with reference Megamix-Plus SSC beads (Biotec, Marseille, France) composed of FITC fluorescent spheres (160, 200, 240, and 500 nm).

For EV marker detection, CM in toto and EV fraction samples were stained with CFSE as previously described. Afterward, one-seventh of the labeled samples were stored at 4°C, whereas the rest was divided into six aliquots and each stained for 30 min at 4°C in the dark with 1  $\mu$ l of the following APC-conjugated Ab: anti-CD9 (312107, BioLegend, San Diego, CA, USA), CD63 (353007, BioLegend), CD81 (349509, BioLegend), CD44 (338805, BioLegend), CD73 (344005, BioLegend), and CD90 (328113, BioLegend). Antibodies were used singularly. A maximum value of 10,000 events per second were acquired with a 10- $\mu$ l/min flow rate using a CytoFLEX flow cytometer, and APC-positive events were detected after FITC gating as previously described. Unstained samples were used as negative controls to set APC positivity.

## EV characterization by transmission electron microscopy

EV fraction samples were suspended in PBS (100  $\mu$ l per initial 5-ml volume). Five microliters was absorbed for 10 min at RT on formvar carbon-coated grids and drops blotted with filter paper. Two percent of uranyl acetate aqueous suspension was used to perform negative staining for 10 min, and excess was removed by filter paper. The grid was dried at RT. Samples were examined with a TALOS L120C transmission electron

microscope (Thermo Fisher Scientific, Waltham, MA, USA) at 120 kV.

## Protein quantification in purified EVs

After centrifugation, samples from EV fractions were analyzed with a NanoDrop ND-1000 spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA) with the Protein A280 protocol. The concentration was related with NTA data to obtain the number of EVs/ $\mu$ g protein value.

## Analysis of T-cell proliferation

T-cell proliferation was induced by stimulating peripheral blood mononuclear cells (PBMCs) with an anti-CD3 monoclonal antibody. Human PBMCs were obtained from heparinized whole blood samples using density gradient centrifugation (Histopaque-1077, Sigma-Aldrich, St. Louis, MO, USA). PBMCs ( $1 \times 10^5$ /well in a 96-well-plate) were activated with 125 ng/ml (final concentration) anti-CD3 (Orthoclone OKT3, Janssen-Cilag, Cologno Monzese, Italy). Activated PBMCs (PBMC + anti-CD3) were cultured in the presence of different volumes of CM or of its fractions (EV-free or EVs) (10, 25, 50, or 100  $\mu$ l/well of CM 5%, 12.5%, 25%, or 50%, respectively, of the final volume), for 3 days. The final volume of each well was 200  $\mu$ l. In all experiments, activated PBMCs cultured alone were used as controls. All conditions were performed in triplicate in RPMI 1640 medium (Cambrex, Verviers, Belgium) supplemented with 10% heat-inactivated FBS, 2 mM L-glutamine, and P/S.

T-cell proliferation was assessed by 5-ethynyl-2'-deoxyuridine (EdU) incorporation as previously described (26). Briefly, 10  $\mu$ M EdU (Life Technologies, Carlsbad, CA, USA) was added to PBMCs at day 3 post-stimulation. After 16–18 h, cells were harvested and EdU incorporation was evaluated by adding 2.5  $\mu$ M 3-azido-7-hydroxycoumarin (Jena Biosciences, Jena, Germany) in buffer solution (100 mM Tris-HCl pH 8.0, 10 mM L-ascorbic acid, 2 mM CuSO<sub>4</sub>) at RT for 30 min. Cells were acquired using a FACSsymphony A3 (BD Biosciences), and the percentage of proliferating EdU-positive cells was analyzed with FlowJo V10 (BD Biosciences). Cells were also stained with eFluor 780 (Thermo Fisher) for the exclusion of dead cells.

## Analysis of CD4<sup>+</sup> T helper subsets and Treg subset polarization

Phenotypes were assessed by flow cytometry analysis of the expression of specific cell surface markers and transcription factors

to identify T helper subsets (Th1, Th2, and Th17) and Treg. After 5 days of coculture in the presence of CM, PBMCs stimulated with anti-CD3 were collected and centrifuged at 300g for 5 min. Cells were stained with eFluor 780 for the exclusion of dead cells. The staining was performed using antibodies for CD3 (clone UCHT1), CD4 (clone VIT-4), CD45RA (clone HI100), CD196 (clone 11A9), CD183 (clone 1C6/CXCR3), CD25 (clone M-A25), and FoxP3 (clone 259D/C7) which all came from BD Biosciences and CD194 (clone REA279) from Miltenyi. Intracellular staining for FoxP3 was performed after fixation and permeabilization using BD Cytofix/Cytoperm (BD Biosciences), followed by staining with anti-FoxP3 antibody. Samples were acquired using a FACSymphony A3 and analyzed with FlowJo V10. T-cell subsets were identified by a sequential gating strategy. T effector cells were first identified by gating CD4-positive and CD45RA-negative cell populations ( $CD4^+CD45RA^-$  cells), and different T helper (Th) subsets were identified as follows: Th1 as  $CD196^-CD183^+$ , Th17/Th1 as  $CD196^+CD183^+$ , and Th2 as  $CD196^-CD183^-CD194^+$  (27). Furthermore, to investigate the ability of hAMSC-CM and its fraction to induce Treg polarization, we performed a mixed lymphocyte reaction (MLR-T) by coculturing T lymphocytes ( $1 \times 10^5$ ), previously isolated from PBMCs using the Pan T cell Isolation Kit (Miltenyi Biotec), with  $1 \times 10^5$  gamma-irradiated allogeneic PBMCs. Activated T lymphocytes (MLR-T) were cultured in the presence of different volumes of CM or of its fractions (EV-free or EVs) (10, 25, 50, or 100  $\mu$ l/well of CM (5%, 12.5%, 25%, or 50%, respectively, of the final volume), for 6 days. Tregs were evaluated as previously reported in the aforementioned gating strategy, and the % of Treg cells was evaluated as CD25 High and FoxP3-positive cells.

## Analysis of monocyte differentiation toward antigen-presenting cells

Monocyte-derived M1 macrophages were differentiated starting from  $5 \times 10^5$  PBMCs cultured or not (control condition) in the presence of CM or its fractions, in 24-well plates (Corning) for 4 days in the presence of 5 ng/ml GM-CSF (Miltenyi Biotec) in 0.5 ml RPMI 1640 complete medium. Cells were activated by adding 20 ng/ml interferon gamma (IFN- $\gamma$ ) (Miltenyi Biotec) for 1 h after which 0.1  $\mu$ g/ml LPS (Sigma-Aldrich) was added and left for 2 days. For dendritic cell (DC) differentiation,  $2.5 \times 10^5$  PBMCs were cultured in 48-well plates (Corning) for 4 days in the presence of 50 ng/ml recombinant human IL-4 (R&D Systems, Minneapolis, MN, USA) and 50 ng/ml GM-CSF in 0.5 ml RPMI 1640 complete medium. Complete maturation was reached by adding 0.1  $\mu$ g/ml LPS for 2 days.

M1 macrophages, as well as DC, were collected after 6 days of differentiation in the absence or presence of 10, 25, 50, or 100  $\mu$ l/well of CM or its fractions (EV-free or EVs) (2%, 5%, 10%, or 20%, respectively, of the final volume). Different CM products were added at day 0, concomitantly with the start of the

differentiation protocol. Phenotype was investigated by flow cytometry. Prior to surface marker staining, cells were stained with eFluor 780 for the exclusion of dead cells. Cells stained with CD3 were excluded; CD11b (clone ICRF44)-positive cells were analyzed for the expression of CD163 (clone GHI/61), CD197 (clone 3D12), CD86 (clone 2331 (FUN-1)), and CD14 (clone M $\Phi$ P9) to distinguish M1/M2 macrophage polarization. For mDC differentiation, the same protocol aforementioned for the macrophages was used and staining was performed for CD197 (clone 3D12), CD209 (clone DCN46), CD14 (clone M $\Phi$ P9), CD83 (clone HB15e), and CD1a (clone HI149). All antibodies were purchased from BD Biosciences.

## Analysis of B-cell proliferation and differentiation

To evaluate B lymphocyte proliferation, PBMCs were labeled with CFSE to monitor cell division (9). Stained PBMCs ( $1 \times 10^5$  cells) were seeded in 96-well tissue culture plates in 50% RPMI complete medium and 50% UltraCULTURE™ serum-free culture medium (Lonza, Basel, Switzerland). B-cell proliferation was induced by stimulating cells for 6 days with 2.5  $\mu$ g/ml CpG-ODN 2006 (Aurogene s.r.l., Rome, Italy). Activated PBMCs were cultured in the presence of CM-hAMSC or its fractions, EV-free, or EVs (10, 25, 50, or 100  $\mu$ l/well of CM 5%, 12.5%, 25%, or 50%, respectively, of the final volume).

Cells were stained with eFluor 780 for the exclusion of dead cells. The staining was performed using antibodies for CD3 (clone UCHT1), CD19 (clone SJ25C1), CD14 (clone M $\Phi$ P9), CD27 (clone M-T271), CD24 (clone ML5), CD38 (clone HB7), and IgM (clone G20-127) which all came from BD Biosciences and CD138 (clone 44F9) from Miltenyi. Samples were acquired using a FACSymphony A3 and analyzed with FlowJo V10. B-cell subsets were identified by a sequential gating strategy. Plasmablasts were identified as  $CD19^+CD27^{hi}CD38^{hi}CD138^-$  cells; plasma cells (PC) were identified by the co-expression of the CD138 marker ( $CD19^+CD27^{hi}CD38^{hi}CD138^+$ ).

## Quantification of hAMSC-EV uptake by PBMC

The spontaneous uptake of EVs by PBMC was analyzed by culturing unstimulated PBMC for 18 h with  $5 \times 10^9$  vesicles stained with CFSE, as previously reported in the section entitled “EV characterization by flow cytometry”. After incubation, the PBMCs were collected, extensively washed, and analyzed by flow cytometry for uptake. To evaluate the uptake ability of the different immune cell subsets, we stained the PBMCs with the following antibodies: CD3 (clone UCHT1), CD19 (clone

SJ25C1), and CD14 (clone MΦP9). The amount of immune cells positive for the expression of CFSE and indicative of the EV uptake was assessed with FACSsymphony A3 and analyzed with FlowJo V10. The comparison was performed using untreated PBMC as baseline for basal autofluorescence.

## Statistical analysis

The data are shown as violin-truncated plots with Tukey variations. The parameters were compared using one-way and two-way analyses of variance (ANOVA). Data are representative of at least three independent experiments. Statistical analysis was performed using Prism 8 (GraphPad Software, La Jolla, CA, USA). A *p* value lower than 0.05 was considered statistically significant.

## Results

### hAMSC-CM fractionation

In order to efficiently isolate EVs from the hAMSC-CM and obtain the EV-depleted counterpart, a tailored protocol was fine-tuned relying on a centrifugal force of  $100,000 \times g$ , as widely reported in the ISEV guidelines as an efficient method for EV isolation from CM (28). This was followed by several quality controls (Figure 1A). On a pilot hAMSC-CM lot ( $15.3 \times 10^9 \pm 0.4$  EVs/ml), different centrifugation times were scored to identify via NTA technology the experimental condition coupling the highest EV removal and recovery with the most reduced operative time to avoid EV damage by long-lasting *g*-force (Figure 1B). The combination of  $100,000 \times g$  and 3-h centrifugation resulted in the best protocol with EV recovery up to  $77.9\% \pm 4.2$  (Figure 1C). Notably, increasing the centrifugation times did not allow for higher recovery ( $80.4\% \pm 0.8$  and  $72.6\% \pm 2.8$ , 9 and 24 h, respectively), whereas a shorter time (1 h) did not lead to efficient separation of particles from the supernatant that resulted to be contaminated ( $44.0\% \pm 4.0$  of the initial EVs input with  $46.6\% \pm 7.9$  recovery). Moreover, the selected 3-h protocol led to the isolation of particles of comparable size with respect to EVs in the CM ( $133 \text{ nm} \pm 8$  vs.  $127 \text{ nm} \pm 7$ , CM vs. EVs, no significant (*p* < 0.05) difference) (Figure 1D), as scored by NTA data, while 1-h centrifugation resulted in particles of smaller size ( $96 \text{ nm} \pm 5$ ), possibly due to the selection of a subpopulation as clearly evidenced in NTA plots where larger particles are mainly detected in the supernatant. NTA graphs also showed the absence of larger (>300 nm) events both before and after EV isolation, emphasizing that the procedure does not lead to particle aggregates or clumps, even after 24 h of centrifugation. Size was substantiated by transmission electron microscopy (TEM) analysis of isolated EVs, showing their typical cup-shaped morphology, with the majority of particles below 200 nm and few large ones (>250 nm) as reported

by NTA (Figure 1E). The isolation of particles with dimensional parameters similar to those in the CM suggests the conservation of EV integrity after processing, a crucial step in order to subsequently attribute a biological effect. By flow cytometry analysis of CFSE-stained particles, compared to those in the unpurified CM, and by direct comparison with fluorescent nanobeads of predetermined size (160, 200, 240, and 500 nm), the dimensional range previously obtained with NTA technology was further confirmed to be around 150 nm (Figure 1F) both before and after purification of another parameter that confirmed the absence of major particle disruption or aggregation. Finally, we reported that EV integrity after centrifugation showed  $76.4\% \pm 2.0$  (Figure 1G). Flow cytometry also showed the low and high presence of CD9 and CD63/CD81 EV markers, respectively, as well as both the abundance of CD73/90 and the whole population shift of CD44 hAMSC markers (Supplementary Figure 1), as previously published by our group (23). Comparable data before and after centrifugation were a further support of absence of detrimental effects or isolation of subpopulation given by the isolation procedure. As a final quality control, the purity of isolated EVs was calculated and resulted to be  $0.468 \times 10^9 \pm 0.095$  EVs/ $\mu\text{g}$  protein, a value falling within the range ( $10^8$  to  $10^{10}$ ) reported for EV preparations from cell culture supernatants (29).

### Characterization of EVs from hAMSC-CM

To try to discriminate the impact of the different components of the secretome, we compared the results obtained from the secretome in toto (hAMSC-CM) with those of the same secretome depleted from EVs (EV-free) and with the EV fraction resuspended in an equivalent volume of fresh medium. Specifically, in order to evaluate the effect due to EVs alone and discern it from that of soluble bioactive molecules contained in the EV-depleted secretome, we suspended EVs in the equivalent volume of fresh medium (DMEM-F12) (for example, EVs isolated from 12 ml of CM were resuspended in 12 ml of fresh medium). The products obtained were subsequently characterized as previously described (Table 1). The average EV concentration per ml resulted to be  $12.0 \times 10^9 \pm 7.6$  in CM,  $2.0 \times 10^9 \pm 2.9$  in EV-free, and  $9.9 \times 10^9 \pm 5.5$  in EV fractions.

Overall, the recovery rate was similar to the values previously observed during protocol optimization resulting to be  $85.8\% \pm 12.8$ . Mean EV size was calculated in  $149 \text{ nm} \pm 21$  and  $147 \text{ nm} \pm 17$  for CM and EV samples, respectively, with no significant (*p* < 0.05) difference between conditions. On three random EV samples, we monitored the presence of EV and hAMSC markers obtaining results almost identical to those previously observed with a very weak presence of CD9 ( $5\% \pm 1$ ), abundant signal for CD63 ( $88\% \pm 1$ ), CD81 ( $87\% \pm 2$ ), CD73 ( $90\% \pm 2$ ), and CD90 ( $81\% \pm 1$ ), and weaker staining albeit with a whole

FIGURE 1

Definition of hAMSC-CM fractionation protocol and EV characterization. (A) Workflow of the protocol used to identify and validate the most efficient centrifugation procedure to obtain EV-depleted and EV-enriched fractions from hAMSC-CM. (B) Particle size and concentration profiles from NTA data for both fractions (EV free and EVs) after centrifugation for the indicated times (1, 3, 9, and 24 h). CM and PBS were used as starting condition and background, respectively (N = 3, values indicated as mean  $\pm$  SD). (C) EV recovery or contamination in the EV-free fraction for the tested centrifugation times (1, 3, 9, and 24 h) calculated from the NTA data with respect to EVs in the CM set as 100% (N = 3, mean  $\pm$  SD). (D) Size analysis from NTA data for the EVs identified in the CM, EVs, or EV-free fractions obtained after centrifugation for the indicated times (1, 3, 9, and 24 h) (N = 3, mean  $\pm$  SD). (E) Transmission electron micrographs of EVs in the 3-h centrifugation pellets showing characteristic cup-shaped morphology and size compatible with NTA data. Black arrows indicate the EVs. (F) Visualization of EVs (in the unprocessed CM or in EV-fraction) after a 3-h centrifugation, after CFSE staining and comparison with nanometric FITC-fluorescent beads of indicated sizes. A representative cytogram is presented. (G) % of EVs recovery after 3 h of centrifugation.

population shift for CD44 (40%  $\pm$  9). Also, purity on four samples resulted to be  $0.178 \times 10^9 \pm 0.060$  EVs/ $\mu$ g protein. Analysis on a single sample showed 78% EV integrity. Given the reliability of the procedure, in all experimental conditions discussed in the following paragraphs, with exception when indicated, we compared the effect of a range of comparable doses of hAMSC-CM and EV-free and EV fractions (100, 50, 25, and 10  $\mu$ l).

## Ability of hAMSC-CM and EV-free and EV fractions to modulate T-cell proliferation

First, we evaluated and compared the effects of different doses of hAMSC-CM in toto and fractions obtained thereof (EV-free and EV fractions) on the proliferation of T lymphocytes stimulated with anti-CD3. The results obtained confirmed that CM in toto was able to inhibit the proliferation of T lymphocytes

TABLE 1 Summary table for concentration, recovery, size, and marker expression of EVs isolated from hAMSC-CM.

in a dose-dependent manner (from  $59.4 \pm 6.6\%$  to  $15.2 \pm 8.3\%$  of proliferating T cells in control and in activated PBMCs treated with 100  $\mu\text{l}$  of CM, respectively;  $p < 0.001$ ) and that only at the lowest dose (10  $\mu\text{l}$ ) was this effect partially lost (Figure 2). A similar trend was appreciable for the EV-free fraction ( $15.9 \pm 7.5\%$  proliferating cells in activated PBMCs treated with 100  $\mu\text{l}$  of EV-free fraction,  $p < 0.001$ ) (Figure 1), whereas no appreciable effect was observed for EVs at any dose used ( $52.1 \pm 13.1\%$  proliferating cells in activated PBMCs treated with 100  $\mu\text{l}$  of EVs,  $p=\text{ns}$ ).

Ability of hAMSC-CM and EV-free and EV fractions to modulate Th subsets and Treg polarization

Given that EVs are carriers of miRNAs and given the importance that miRNAs have on modulating the cell differentiation process (30), we investigated the impact of hAMSC-CM and its fractions on the differentiation of effector T cells toward various Th subsets. This study was performed, as done

FIGURE 2 Effects of hAMSC-CM and its fractions (EV-free and EVs) on PBMC proliferation. Allogeneic PBMC ( $1 \times 10^5$ ) were stimulated with anti-CD3 antibody in the presence of 100, 50, 25, or 10  $\mu\text{l}$  of hAMSC-CM *in toto* or with the same volume of the EV-free or EV fractions. Results are expressed as percentage of EdU+ cells representative of the proliferating cells. PBMCs stimulated with anti-CD3 mAb constitute the positive control. Results are displayed as violin plots showing median (thick line) and 25th and 75th quartiles ( $***p < 0.001$  versus control (PBMC + anti-CD3),  $N \geq 3$ ).

for T-cell proliferation analysis, by stimulating PBMCs with anti-CD3 monoclonal antibody in the presence of hAMSC-CM in toto or of its two fractions (EV-free or EVs). The commitment toward the different Th subsets was evaluated by flow cytometry, and the results were expressed as % of CD4-positive cells expressing specific markers identifying Th1, Th2, or Th1/Th17 subsets. As shown in **Figure 3**, hAMSC-CM decreased the median percentage of Th1 in PBMC stimulated with anti-CD3 with respect to control without CM treatment ( $40.0 \pm 12.3\%$  vs.  $66.5 \pm 5.7\%$  in activated PBMC treated with 100  $\mu\text{l}$  CM and in control activated PBMCs, respectively;  $p < 0.05$ ). A similar trend was observed for the EV-free fraction ( $39.3 \pm 6.3\%$  in activated PBMCs treated with 100  $\mu\text{l}$  of EV-free fraction,  $p < 0.05$ ). When anti-CD3 stimulated PBMCs were cocultured in the presence of the EV fraction, we observed a

slight reduction in Th1 median percentage ( $58.6 \pm 6.6\%$  in activated PBMCs treated with 100  $\mu\text{l}$  EV fraction,  $p = \text{ns}$ ), but this reduction was not statistically significant.

No significant differences were observed for Th2 polarization or the generation of Th1/Th17 subsets, for either hAMSC-CM in toto or the different fractions tested.

In addition, we investigated the effects of the hAMSC-CM in toto or its fractions (EV-free or EVs) on Treg subset polarization (**Figure 3** lower panel). As previously reported, we confirmed that CM-hAMSC triggers the induction of Treg cells at the highest concentration ( $1.08 \pm 0.46\%$  vs.  $3.34 \pm 1.04\%$ , respectively). Similar results were also obtained by the EV-free fraction at the intermediate and lowest concentrations (50 and 10  $\mu\text{l}$ :  $3.046 \pm 1.03\%$  and  $3.094 \pm 1.14\%$ , respectively). Also in

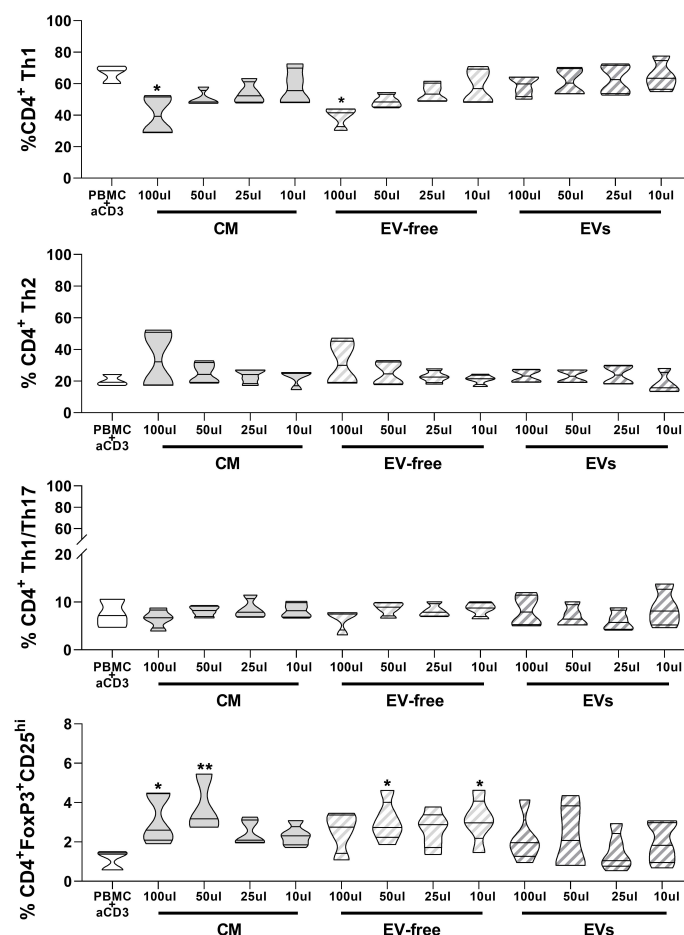

FIGURE 3

Effects of hAMSC-CM and its fractions (EV-free and EVs) on the differentiation of T lymphocytes toward Th1, Th2, Th1/Th17, and Treg subtypes. Allogeneic PBMCs were incubated with anti-CD3 mAb in the presence of 100, 50, 25, or 10  $\mu\text{l}$  of hAMSC-CM in toto or with the same volumes of the EV-free or EV fractions. Samples were collected after 5 days of culture. Results are expressed as percentage of the different Th subsets investigated: Th1 (CD183<sup>+</sup>CD196<sup>-</sup>), Th2 (CD183<sup>+</sup>CD196<sup>-</sup>CD194<sup>+</sup>), Th1/Th17 (CD183<sup>+</sup>CD196<sup>+</sup>), and Treg (CD4<sup>+</sup>CD25<sup>hi</sup>FoxP3<sup>+</sup>). Results are displayed as violin plots showing median (thick line) and 25th and 75th quartiles (\* $p < 0.05$ , \*\* $p < 0.01$ ,  $N \geq 3$  individual experiments).

this case, the EV fraction seems to be able to induce only a slight increase in the Treg subset polarization at the highest concentration used ( $2.14 \pm 1.20\%$ ).

## Ability of hAMSC-CM and EV-free and EV fractions to modulate monocyte differentiation to antigen-presenting cells

Our group previously demonstrated that hAMSC-CM hampers monocyte (Mo) differentiation toward M1-type macrophages and instead triggers the acquisition of anti-inflammatory M2 macrophage features (6). Here we wanted to clarify the impact that the EV-free fraction and EVs have on Mo-M1 differentiation comparing the results with those obtained with hAMSC-CM in toto.

Both hAMSC-CM as well as the EV-free fraction reduced monocyte differentiation toward M1 macrophages, both by

maintaining the expression of the undifferentiated monocytic marker CD14 ( $11.2 \pm 7.2\%$  control Mo-M1 macrophages vs.  $87.8 \pm 8.85\%$  hAMSC-CM 100  $\mu\text{l}$  and  $90.9 \pm 3.34\%$  EV-free fraction 100  $\mu\text{l}$ ) (Figure 4A) and by reducing the expression of markers associated with M1 differentiation, such as CD197 (chemokine receptor CCR7) ( $70.8 \pm 18.2\%$  control Mo-M1 macrophages vs.  $43.7 \pm 4.30\%$  hAMSC-CM 100  $\mu\text{l}$  and  $41.6 \pm 20.5\%$  EV-free fraction 100  $\mu\text{l}$ ) and the co-stimulatory molecule CD86 (MFI 384.8  $\pm$  122.8 control Mo-M1 macrophages vs. 133.7  $\pm$  80.2 hAMSC-CM 100  $\mu\text{l}$  and 171.4  $\pm$  78.5% EV-free fraction 100  $\mu\text{l}$ ) (Figure 4A). In parallel, they promoted monocyte skewing toward alternatively activated (M2) macrophages, as indicated by the significant increase in the percentage of macrophages expressing the M2 marker CD163 (all the results refer to the 100- $\mu\text{l}$  concentration:  $2.29 \pm 2.64\%$  control Mo-M1 macrophages vs.  $75.3 \pm 15.4\%$  hAMSC-CM and  $73.8 \pm 13.4\%$  EV-free fraction). On the other hand, the EV fraction did not affect monocyte differentiation toward M1 macrophages. Indeed, no differences vs. control Mo-M1 macrophages were observed with the administration of EVs regardless of the concentration used (all the

FIGURE 4

Effects of hAMSC-CM and its fractions (EV-free and EVs) on monocyte differentiation toward antigen-presenting cells (A) M1 macrophages were obtained by incubating PBMCs with GM-CSF for 4 days, followed by IFN- $\gamma$  + LPS for other 2 days. At the end of the culture period, the expression of CD197 and of the co-stimulatory molecule CD86, together with the pro-monocytic marker CD14, was evaluated by flow cytometry for M1 macrophages. The M2 polarization was assessed by analyzing the expression of the CD163 marker. (B) mDC differentiation was carried out by incubating PBMCs with GM-CSF + IL-4 for 4 days followed by 2 days of LPS treatment. At the end of the culture period, expressions of CD1a, CD197, CD209, CD14, and the co-stimulatory molecule CD83 were evaluated by flow cytometry for mDC differentiation. Results are presented as a percentage of expression or mean fluorescence intensity (MFI) ratio (between MFI control and MFI treated samples) and are shown as violin plots with median (thick line) and 25th and 75th quartiles (\* $P < 0.05$ , \*\* $P < 0.01$ , \*\*\* $P < 0.001$ , \*\*\*\* $P < 0.0001$  versus control M1 (A) or mDC (B),  $N \geq 3$  individual experiments).

results refer to the 100- $\mu$ l concentration: CD14 ( $16.76 \pm 7.21\%$ ), CD197 ( $72.2 \pm 12.65\%$ ), CD86 (MFI  $341.97 \pm 131.4$ ), and CD163 ( $9.6 \pm 7.14\%$ ) (Figure 4A).

In parallel, we investigated the ability of CM-hAMSC in toto and the two fractions to impact monocyte differentiation toward myeloid dendritic cells (mDC) (Figure 4B), while both the CM in toto and the EV-free fraction were able to impact monocyte-derived mDC (Mo-mDC) differentiation by lowering the expression of the maturation marker CD1a ( $56.5 \pm 18.01\%$  control Mo-mDC vs.  $11.8 \pm 8.45\%$  hAMSC-CM 100  $\mu$ l and  $10.9 \pm 8.3\%$  EV-free fraction 100  $\mu$ l) and of the costimulatory molecule CD83 (MFI  $18.8 \pm 4.14$  control Mo-mDC vs.  $6.5 \pm 2.67$  hAMSC-CM 100  $\mu$ l and  $7.2 \pm 3.77$  EV-free fraction 100  $\mu$ l), with a slight effect on CD197 expression ( $86.4 \pm 6.6\%$  control Mo-mDC vs.  $76.5 \pm 18.3\%$  hAMSC-CM 100  $\mu$ l and  $84.87 \pm 12.14\%$  EV-free fraction 100  $\mu$ l). No differences were observed in the expression of the dendritic marker CD209 ( $76.6 \pm 6.87\%$  control Mo-mDC vs.  $90.12 \pm 12.5\%$  hAMSC-CM 100  $\mu$ l and  $88.75 \pm 14.25\%$  EV-free fraction 100  $\mu$ l). Furthermore, we confirmed the ability of CM-hAMSC to impair the monocyte differentiation fostering instead the maintenance of the promonocytic marker CD14 ( $20.5 \pm 15.9\%$  control Mo-mDC vs.  $82.8 \pm 14.76\%$  hAMSC-CM 100  $\mu$ l and  $84.3 \pm 13.02\%$  EV-free fraction 100  $\mu$ l). On the other hand, also for this subset no differences were attributable to the exogenous administration of the EVs regardless of the concentration used (all the results refer to the 100- $\mu$ l concentration: CD1a ( $58.5 \pm 25.7\%$ ), CD83 (MFI  $15.03 \pm 3.07$ ), CD197 ( $91.6 \pm 7.82\%$ ), CD209 ( $9.6 \pm 7.14\%$ ), and CD14 ( $31.17 \pm 11.76\%$ ) (Figure 4B).

## Ability of hAMSC-CM and EV-free and EV fractions to modulate B lymphocyte proliferation and differentiation toward antibody-secreting cells

In order to provide a comprehensive analysis of the immunomodulatory properties of hAMSC-CM and its fractions, we also evaluated their effects on B lymphocyte proliferation induced by PBMC stimulation with CpG.

B-cell proliferation and differentiation were evaluated by flow cytometry, and specifically by the percentage of CD19<sup>+</sup>-proliferating cells, and the expression of markers specific for B-cell differentiation toward antibody-secreting cells and specifically plasmablasts (CD19<sup>+</sup>CD27<sup>High</sup>CD38<sup>High</sup>CD138<sup>-</sup> cells) and plasmacells (CD19<sup>+</sup>CD27<sup>High</sup>CD38<sup>High</sup>CD138<sup>+</sup> cells).

As shown in Figure 5, upper panel, the percentage of proliferating CD19<sup>+</sup> cells in the control condition represented by untreated PBMC activated with CpG (PBMC+CpG) was strongly reduced in the presence of hAMSC-CM (100  $\mu$ l) ( $66.8 \pm 10.74\%$  to  $38.6 \pm 20.36\%$ , respectively). When we analyzed the effect of the EV-free fraction, we observed results similar to those obtained with hAMSC-CM. The EV-free fraction (100  $\mu$ l) indeed decreased the

percentage of CD19<sup>+</sup>-proliferating cells to  $39.4 \pm 19.9\%$ . Finally, EVs induced a slight reduction of CD19<sup>+</sup>-proliferating cells in comparison to hAMSC-CM and the EV-free fraction ( $62.2 \pm 8.9\%$ ).

Moreover, we observed a higher percentage of plasmablasts (Figure 5, middle panel) in the presence of hAMSC-CM (and consequently a lower percentage of plasma cells), with respect to that observed in the control PBMCs stimulated in the absence of hAMSC-CM ( $48.4 \pm 1.27\%$  vs.  $75.75 \pm 1.06\%$ , respectively). We obtained comparable results when stimulated PBMCs were exposed to the EV-free fraction ( $75.45 \pm 0.2\%$ ), while no differences were observed when we performed the test in the presence of EVs.

Conversely, we observed that the percentage of plasma cells was strongly increased in the control condition with respect to the PBMCs activated in the presence of hAMSC-CM and the EV-free fraction ( $51.9 \pm 0.8\%$  to  $24.2 \pm 1.06\%$  and  $24.5 \pm 0.2\%$ , respectively), while only small differences were appreciable in the presence of EVs ( $42.3 \pm 4.94\%$ ) (Figure 5 lower panel).

## Uptake of hAMSC-EVs by immune cells

In an effort to exclude the lack of uptake by PBMCs as a possible mechanism responsible for the negligible immunomodulatory effect of EVs, we performed an uptake experiment by labeling EVs with CFSE. The CFSE-labeled vesicles were added to the unstimulated PBMC. We chose to evaluate fluorescence-labeled exosome uptake under a condition that could be considered similar for all immune PBMC cell types, and thus we considered the quiescent condition since activation conditions can vary between different types of immune cells. After 18 h, whole PBMC and major immune populations were analyzed by flow-cytometry to evaluate CFSE-positive cells. We observed that PBMCs were 99.8% positive for CFSE staining (Figure 6), indicating that EVs were taken up by immune cells. Furthermore, we observed that among the different immune populations, CD14<sup>+</sup> cells, representative of the monocyte compartment, were highly positive for CFSE expression in comparison to the lymphocyte compartment, considering both T and the B lymphocytes ((CD3<sup>-</sup>CD19<sup>+</sup> cells), respectively).

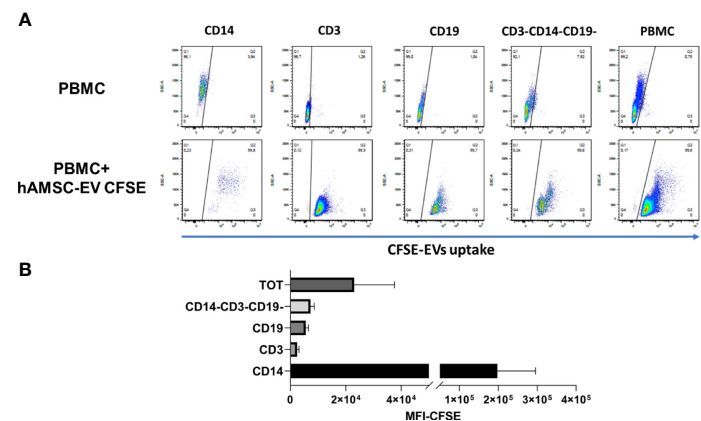

## Discussion

Our previous studies evidenced the strong immunomodulatory activities of mesenchymal stromal cells derived from amniotic membrane (hAMSC) and the essential role of the secreted bioactive factors in mediating these activities.

Given that these factors can be directly secreted as free molecules or conveyed in EVs, in this study we explored the contribution of all these components to the immunomodulatory activity of the hAMSC secretome. To this end, we compared the

**FIGURE 5**  
Effects of hAMSC-CM and its fractions (EV-free and EVs) on B lymphocyte proliferation and maturation. Allogeneic PBMCs ( $1 \times 10^5$ ) were stimulated with CpG in the presence of 100, 50, 25, or 10  $\mu$ l of hAMSC-CM or with the same volume of the EV-free or EV fractions. B-cell proliferation was measured by the analysis of CFSE dilution and calculated as percentage of CD19+ -proliferating cells. The impact that hAMSC-CM and its fractions have on B lymphocyte differentiation was evaluated analyzing the total amount of plasmablasts (CD19<sup>+</sup>CD27<sup>hi</sup>CD38<sup>hi</sup>CD138<sup>-</sup>) and plasma cells (CD19<sup>+</sup>CD27<sup>hi</sup>CD38<sup>hi</sup>CD138<sup>+</sup>) obtained from the different culture conditions and compared with the control condition. Results are presented as a percentage of expression and are shown as violin plots with median (thick line) and 25th and 75th quartiles versus control PBMC+CpG,  $N \geq 2$  individual experiments.

**FIGURE 6**  
Flow cytometry analysis of hAMSC EV uptake by PBMC (A) PBMC were cultured without stimulation in presence or absence of  $5 \times 10^9$  EVs loaded with CFSE to evaluate uptake. A staining for the different immune subsets was performed to evaluate differences in the uptake capability. (B) Mean fluorescence analysis of the different immune subpopulations normalized on the negative fraction.

ability of the secretome in toto versus EV-free and EV fractions to affect immune cell subsets *in vitro*.

Our study deeply investigated the effects of the hAMSC secretome and its fractions on immune cells and was not limited to selected immune populations (31, 32) but included immune cells belonging to both innate and adaptive immune systems.

For the first time, EV and EV-free fractions were compared with the secretome in toto by maintaining the quantitative proportions as the secretome of origin. These study conditions allowed us to depict a reliable representation of the relative immunomodulatory potency of each secretome component.

Our data evidenced that the ability of the hAMSC secretome to modulate the immune cell response is mainly mediated by factors non-conveyed by EVs. In fact, the EV-free fraction, comparable to the secretome in toto, inhibited T-cell proliferation, reduced T-cell polarization toward the Th1 subset, and promoted the induction of Treg. In addition, the EV-free fraction, similar to the secretome in toto, maintained the ability to shift monocyte differentiation toward M2 instead of M1 macrophages, to reduce the maturation of dendritic cells and to reduce the CpG-induced B-cell proliferation and differentiation toward plasmablasts and plasmacells. The EV fraction instead did not affect any of these immune parameters despite that hAMSC EVs are taken up by all types of immune cells investigated.

Our results are in line with those published by Lange-Consiglio and colleagues (33) that showed that EVs derived from equine amniotic MSCs were not able to affect PBMC proliferation. However, no other study except ours has investigated the effects of EVs from hAMSC on a wide spectrum of immune cells.

EVs from other types of MSCs, including MSCs from the bone marrow (BM), umbilical cord (UC), and adipose tissue (AT), were investigated for their ability to control the proliferation of different immune cells among which are T cells, B cells, and NK cells, but with controversial results (31, 32, 34–37). For example, some studies have shown an immunosuppressive action of EVs on T cells (34, 38); other studies instead found lower effects of EVs in relation to parental MSC (31, 32, 36), while some demonstrated no effect at all of EVs (35, 39). Controversial results were also obtained by studies focusing on the effect of MSC-derived EVs on B cells (31, 37, 40).

These different findings can potentially derive from some methodological limitations that make the various studies incomparable. For example, different methods of EV quantification were applied, such as protein concentration or EV absolute counts by NanoSight, making it difficult to identify the possible effective dose. To this regard, we explored the effects of three increasing doses of EVs (10, 50, and 100  $\mu$ l) corresponding to a wide range of EV absolute number (from  $1.8 \times 10^8$  to  $2.0 \times 10^9$  vesicles). This range covers and even exceeds the EV doses used in most of the reported studies: 5–100  $\times 10^6$  EVs (33),  $3 \times 10^6$  EVs/ $10^4$  immune cells (31), and 0.75 and  $3 \times 10^9$  particles/ml (41) and  $10^9$

particles (34). Furthermore, to exclude the possibility that the lack of effect observed for hAMSC-EVs was due to a low concentration of EVs, we repeated the immunomodulatory tests using twice the concentration of EVs used in the tests (i.e., 200  $\mu$ l instead of 100  $\mu$ l); however, we still did not observe any effect on the different immune populations tested (data not shown). Although the EV-free fraction contained a residual amount of EVs, which represents an unavoidable compromise to obtain the highest EV removal avoiding EV damage, it is very unlikely that the residual EV amount can be responsible for the immunomodulatory activities observed for the EV-free fraction; otherwise, we would have observed some of these activities also for the EV fraction.

Another important factor that could heavily impact functions of MSC-derived EVs is the MSC culture conditions used to produce CM from which EVs are isolated. The extracellular microenvironment indeed affects the composition of EVs and the consequent biological activities (42). Likewise, different methodologies have been used to isolate EVs with different impact on EV biological functions (43, 44). For example, it has been recently reported (45) that contaminating soluble factors can increase the apparent bioactivity of EV even if the specific role on immunomodulatory properties has not been elucidated.

Moreover, it is to be considered that a given type of cell (i.e., MSC) may secrete heterogeneous types of EVs characterized by differential exosome content and different subsets of exosomes with distinct proteomic profiles suggesting distinct biological functions (46–48). Thus, a specific function cannot be generalized to all MSCs and to all EVs/exosomes secreted from these cells.

Although we found that hAMSC EVs play a negligible role in determining the immunomodulatory properties of the hAMSC secretome, others have demonstrated that they exert *in vivo* beneficial effects on animal models of inflammation-driven diseases such as chronic endometritis (49), liver fibrosis, non-alcoholic steatohepatitis (50), and osteoarthritis (51). Furthermore, *in vitro* studies demonstrated that hAMSC EVs are able to reduce injury/activation in endometrial cells (52), in hepatic stellate cells (50), and in tenocytes (33). These findings, together with our recent unpublished results, that demonstrate the ability of hAMSC EVs to promote the expansion and the differentiation of dystrophic progenitor muscle cells suggest that hAMSC EVs might preferentially target injured organ/tissue specific cells by directly promoting their integrity and survival and differentiation.

## Conclusion

Our study demonstrates that EVs are not responsible for the immunomodulatory activity of the hAMSC secretome. For the

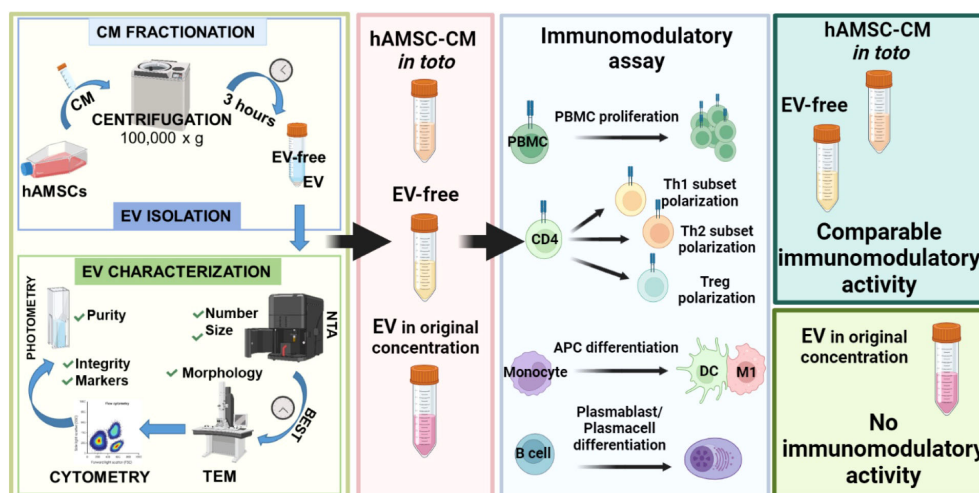

FIGURE 7

Summary figure hAMSC secreted factors able to modulate the immune system. This study demonstrates that the EV fraction of the hAMSC secretome has a negligible immunomodulatory effect while the EV-free fraction is the active component.

first time, we compare EV-enriched and EV-depleted fractions obtained from the hAMSC secretome and demonstrate that the immunomodulatory effect is exerted by secreted factors not conveyed by EVs (Figure 7). Many factors have been reported to contribute to the immunomodulatory properties of MSC, such as the TNF- $\alpha$ -induced gene/protein 6 (TSG-6) (53), IL-10 (54), indoleamine 2,3-dioxygenase (IDO) (55), and inducible nitric-oxide (NO)-synthase (iNOS) (56). Also, hepatocyte growth factor (HGF) (57, 58), transforming growth factor  $\beta$  (TGF- $\beta$ ) (59, 60), and prostaglandin E2 (PGE2) (25, 61) are some of the most studied. However, the secretome represents a repertoire of cytokines, chemokines, and growth factors that combined together can act synergistically to contribute to the immunomodulatory activity of MSC not only *in vitro* but also *in vivo*. Indeed, many studies report the ability of MSC to contribute to regenerative processes in inflammatory-mediated diseases by modulating the immune response (62). Furthermore, MSCs are now being used in numerous clinical trials to treat diseases where a dysregulated immune system plays a major role in pathogenesis (63).

Finally, our findings suggest the utilization of the hAMSC secretome *in toto* when a modulation of immune response is desired. In addition, these data open a new possible scenario for the clinical application of the hAMSC secretome *in toto* that indeed contains two fractions that target either inflammatory immune cells or also other cell types involved in tissue regeneration, a combination of potentially synergistic effects that are highly desirable for an effective regenerative medicine strategy. A further not secondary advantage of hAMSC secretome *in toto* is the use of a less manipulated product which could contain costs and variability

## Data availability statement

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation. The datasets generated for this study can be found in the OSF Repository ([https://osf.io/3ejxs/?view\\_only=40b9a42079ff43059d9236c56f61d465](https://osf.io/3ejxs/?view_only=40b9a42079ff43059d9236c56f61d465)).

## Author contributions

Designing research study: AP, ER, LDG, and OP. Conducting experiments and acquiring data: EV, PR, AM, CPO, PBS. Analyzing data: AP, ER, AC, MM. Result interpretation: AP, ER, AC, MM, ARS. Writing and reviewing the manuscript: AP, ER, AC, ARS, LDG, OP. Financial support: LDG, OP. Final approval of the manuscript: LDG, OP. All authors contributed to the article and approved the submitted version.

## Funding

This work was supported by Ministero della Salute (Ricerca Corrente), Italian Ministry of Research and University (MIUR, 5x1000), PRIN 2017 program of the Italian Ministry of Research and University (MIUR, grant no. 2017RSAFK7), and Contributi per il funzionamento degli Enti privati che svolgono attività di ricerca - C.E.P.R. (2020-2021). Italian Ministry of Health, RCR-2021-23671217 project, under the The Italian Musculoskeletal Apparatus Network RAMS.

## Acknowledgments

The authors thank the physicians and midwives of the Department of Obstetrics and Gynecology of Fondazione Poliambulanza, Brescia, Italy, and all of the mothers who donated placenta. This work contributes to the COST Action CA17116 International Network for Translating Research on Perinatal Derivatives into Therapeutic Approaches (SPRINT), supported by COST (European Cooperation in Science and Technology).

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

**Background:** Microenvironmental factors, including microbe-induced inflammation and immune-checkpoint proteins that modulate immune cells have been associated with both cervical insufficiency and preterm delivery. These factors are incompletely understood. This study aimed to explore and compare interactions among microbiome and inflammatory factors, such as cytokines and immune-checkpoint proteins, in patients with cervical insufficiency and preterm birth. In particular, factors related to predicting preterm birth were identified and the performance of the combination of these factors was evaluated.

**Methods:** A total of 220 swab samples from 110 pregnant women, prospectively recruited at the High-Risk Maternal Neonatal Intensive Care Center, were collected between February 2020 and March 2021. This study included 63 patients with cervical insufficiency receiving cerclage and 47 control participants. Endo- and exocervical swabs and fluids were collected simultaneously. Shotgun metagenomic sequencing for the microbiome and the measurement of 34 immune-checkpoint proteins and inflammatory cytokines were performed.

**Results:** First, we demonstrated that immune-checkpoint proteins, the key immune-regulatory molecules, could be measured in endocervical and exocervical samples. Secondly, we identified significantly different microenvironments in cervical insufficiency and preterm birth, with precise cervical locations, to provide information about practically useful cervical locations in clinical settings. Finally, the presence of *Moraxella osloensis* (odds ratio = 14.785;  $P = 0.037$ ) and chemokine CC motif ligand 2 levels higher than 73 pg/mL (odds ratio = 40.049;  $P = 0.005$ ) in endocervical samples were associated with preterm birth. Combining *M. osloensis* and chemokine CC motif ligand 2 yielded excellent performance for predicting preterm birth (area under the receiver operating characteristic curve = 0.846, 95% confidence interval = 0.733-0.925).

**Conclusion:** Multiple relationships between microbiomes, immune-checkpoint proteins, and inflammatory cytokines in the cervical microenvironment were identified. We focus on these factors to aid in the comprehensive understanding and therapeutic modulation of local microbial and immunologic compositions for the management of cervical insufficiency and preterm birth.

#### KEYWORDS

cervix, cervical insufficiency, cytokines, immune-checkpoint proteins, inflammation, microbiome, preterm birth

## 1 Introduction

Preterm birth (before 37 completed weeks of gestation) occurs in approximately 15 million cases annually worldwide (1) and is the leading cause of neonatal death (2). Approximately 1.1 million babies die from complications of prematurity. Cervical insufficiency, defined as painless cervical dilation in the second trimester (3), has traditionally been associated with preterm birth (4). If cervical insufficiency is left untreated, most patients deliver within two to three weeks (5), resulting in miscarriage or extremely early preterm birth. Cervical cerclage has been used to treat cervical insufficiency to reduce perinatal mortality and recurrent preterm delivery (6). In particular, emergency cerclage is indicated when visible cervical dilatation or an unexpected finding of a shortened cervix on routine examination is present (7).

The cervix, located between the microbe-rich vaginal environment and the presumably sterile intrauterine space, provides a mechanical barrier for preventing ascending infection by remaining closed during pregnancy (8). The cervix has both innate and adaptive immune functions, mediated by diverse cell types and molecules (9, 10). Patients with cervical insufficiency are therefore vulnerable to ascending infection caused by the disruption of these barriers (8). Microenvironmental factors have been associated with disease pathogenesis and preterm delivery (11, 12). However, our understanding of the interactions among microbial composition, inflammatory factors, immune-checkpoint proteins, and the modulation of immunity in patients with cervical insufficiency and preterm birth is incomplete. Accordingly, we have studied these factors in patients with cervical insufficiency and preterm

conditions, stratified by cervical location (endocervix and exocervix), to identify clinical diagnostic and therapeutic targets, particularly their predictive utility.

## 2 Materials and methods

### 2.1 Study design and sample collection

Subjects were pregnant women prospectively recruited at the High-Risk Maternal Neonatal Intensive Care Center in Kangnam Sacred Heart Hospital. Samples were collected between February 2020 and March 2021. All participants provided written informed consent and the study protocol was approved by the Institutional Review Board of Kangnam Sacred Heart Hospital (HKS 2019-11-024 and 2022-06-010). The inclusion criteria for patients with cervical insufficiency undergoing cerclage were as follows: length < 25 mm or internal os dilation of at least 1 cm, effacement of at least 50%, membranes visible at or beyond the external os, and gestational age between 16 and 24 weeks. The exclusion criteria were less than 18 years of age, multifetal gestations, major fetal malformations, ruptured membranes, vaginal bleeding, clinical chorioamnionitis, or persistent, regular contractions. Outpatients visiting our clinical center for the observation of normal pregnancy or for prophylactic cerclage due to history of previous preterm birth during the study period were included. For normal pregnant women as a control group, only gentle swab sampling without cerclage was performed during routine colposcopic examinations. Endo- and exocervical swabs and fluids were collected simultaneously and stored for analysis. The location of the endocervix is around the internal cervical os and the exocervix is near the vaginal fornix. A uniconcave balloon was used for cerclage (13, 14). After identification of the bulging fetal membranes, the cervix was retracted with two atraumatic forceps, and a sufficiently inflated balloon (Supplementary Figure S1) was used to push fetal membranes back into the uterus. Sutures were placed as high as possible using the McDonald technique with a 5-mm polyester tape. After deflating the balloon, a purse-string suture was placed and the instrument was withdrawn from the cervix. A physician working under the Maternal-Fetal Medicine division conducted all procedures using the same technique.

**Abbreviations:** sCD28, soluble cluster of differentiation 28; sTIM-3, soluble T-cell immunoglobulin and mucin-domain containing-3; sHVEM, soluble herpes virus entry mediator; sPD-L1, soluble programmed death-ligand 1; sCTLA-4, soluble cytotoxic T-lymphocyte-associated protein 4; sPD-1, soluble programmed cell death protein 1; sICOS, soluble B- and T-lymphocyte attenuator; CCL2, chemokine CC motif ligand 2; CXCL10, C-X-C motif chemokine ligand; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; TNF, tumor necrosis factor; PCA, principal component analysis; ROC, receiver operating characteristic; AUC, area under the curve; PC, principal components; OR, odds ratio.

## 2.2 Shotgun metagenomic sequencing for microbiome

The OMNIgene OMR-130 kit (DNA Genotek Inc., Ottawa, Canada) was used to analyze swab samples. DNA extraction was performed using the Maxwell 16 LEV Blood DNA Purification Kit (Promega, Madison, WI, USA) within four weeks of sampling, based on the manufacturer's instructions. After assessing DNA quality using PCR and electrophoresis, libraries were prepared as per standard Illumina protocols. The TruSeq Nano DNA Library Prep kit was used for library preparation, and the quality of the sample pool was confirmed. Libraries were paired-end sequenced ( $2 \times 150$  bp) using the Illumina HiSeqXten platform (Illumina, San Diego, CA, USA). After trimming, reads aligned to the human reference genome (GRCh38) were removed using BBDuk software. Finally, clean reads mostly derived from microorganisms were used for metagenomic analyses using Kraken2 (15).

## 2.3 Immune-checkpoint proteins and inflammatory cytokines

Sterile Dacron swabs (Puritan Medical Products, Guilford, ME) were used to take samples from the endo- or exocervix. Soluble immune-checkpoint proteins were quantified using the MILLIPLEX Human Immuno-Oncology Checkpoint Protein Premixed 17-plex Panel (Merck, Darmstadt, Germany). The measured immune-checkpoint proteins were soluble cluster of differentiation 28 (sCD28), soluble T-cell immunoglobulin and mucin-domain containing-3 (sTIM-3), soluble herpes virus entry mediator (sHVEM), sCD40, lymphocyte activation gene 3 (sLAG-3), soluble Toll-like receptor 2 (sTLR-2), soluble programmed death-ligand 1 (sPD-L1), soluble cytotoxic T-lymphocyte-associated protein 4 (sCTLA-4), sCD80/B7-1, sCD86/B7-1, soluble programmed cell death protein 1 (sPD-1), sPD-L2, and soluble B- and T-lymphocyte attenuator (sICOS). Inflammatory cytokines were assayed using the Human XL Cytokine Luminex Performance Panel Premixed Kit (R&D Systems, Minneapolis, MN). The measured cytokines were chemokine CC motif ligand 2 (CCL2), CCL3, CCL4, C-X-C motif chemokine ligand (CXCL10), granulocyte-macrophage colony-stimulating factor (GM-CSF), interferon (IFN)- $\alpha$ , IFN- $\gamma$ , interleukin (IL)-1 $\alpha$ , IL-1 $\beta$ , IL-4, IL-6, IL-8, IL-10, IL-12, IL-13, IL-17A, and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ). All assays were conducted using Luminex-based multiplex technology according to the manufacturer's protocols on a Bio-Plex 200 instrument (Bio-Rad, Hercules, CA).

## 2.4 Statistical analyses

Principal component analysis (PCA) was conducted to reduce the number of observed variables to a smaller number of principal components accounting for most of the variance in the observed variables. For pre-processing data, the *pcaMethods* R package was utilized for row scaling (16). The values were divided by standard

deviations using the unit variance scaling method. The utilized default method for calculating principal components was singular value decomposition with imputation. The distribution of continuous variables, including mean, mean standard error, standard deviation, skewness, kurtosis, 1st quartile, median, 3rd quartile, and *P*-values for normality, are presented in [Supplementary Table S1](#). The Anderson-Darling test was used for normality. For descriptive statistics for comparisons, the Chi-square test was applied to categorical variables and the Wilcoxon test was utilized for paired groups. The Mann-Whitney and Kruskal-Wallis tests were applied to two unpaired groups and three unmatched groups, respectively. For multiple comparisons, nonparametric multiple comparisons for relative effects were performed using the *moonBook* and *nparcomp* packages in R for the correction of *P*-values. Multivariate logistic regression analysis was performed, using the factors having a *P* value less than 0.05 in the univariate analysis as co-variables. A receiver operating characteristic (ROC) analysis was conducted to assess the performance of combined factors found to be significant in multivariate analyses to predict preterm birth. The area under the curve (AUC) of combined markers was classified as follows: acceptable (between 0.7 and 0.8), excellent (between 0.8 and 0.9), and outstanding (over 0.9) (17). Spearman's rank correlation analyses were performed to assess the associations of the microbiome with clinical significance, immune-checkpoint proteins, and inflammatory cytokines. Statistical analyses were performed using *ClustVis* (a web tool for visualizing clustering of multivariate data) (18); *Analyse-it* Method Evaluation Edition software, version 2.26 (*Analyse-it* Software Ltd., Leeds, UK); *MedCalc* software, version 19.8 (*MedCalc* Software Ltd., Ostend, Belgium); and the *moonBook* package in R (<http://web-r.org/>).

## 3 Results

### 3.1 Clinical and demographic information

A total of 220 samples ( $n = 110$  for endocervix and  $n = 110$  for exocervix) from pregnant women were analyzed ([Supplementary Table S2](#)). The study population consisted of 63 patients with cervical insufficiency receiving cerclage, 21 undergoing prophylactic cerclage, and 26 women with normal pregnancies. Membrane bulging was observed in 41 (37.3%) patients and the median gestational age at cerclage was 22.0 weeks (interquartile range = 5.0 weeks). Among participants with complete clinical information on their outcomes ( $n = 84$ ; 76.4%), 13 (15.5%) of them exhibited preterm birth. Patients outcomes are presented in [Supplementary Table S3](#).

### 3.2 Principal component analysis (PCA)

To investigate the overall profiles, including soluble immune-checkpoint proteins and inflammatory cytokines, according to clinical information such as sampling location, cervical insufficiency, and preterm birth, PCA was performed ([Figure 1](#)). The X and Y axes of the PCA plot for the endocervix samples show

principal components (PC) 1 and 2, respectively, which explain 37.9% and 14.6% of the total variance, respectively (Figure 1A). Meanwhile, PCA of the exocervix samples showed that PC1 accounted for 43.9% of the variance and PC2 accounted for 12.9% of the variance in the dataset (Figure 1B). Samples from patients exhibiting preterm birth varied more than those who did not and had a similar pattern to those for cervical insufficiency. These patterns were distinct in exocervical samples. PCA loading values for soluble immune-checkpoint proteins and inflammatory cytokines are presented in Supplementary Table S4 (endocervix) and Table S5 (exocervix).

### 3.3 Microbiomes, immune-checkpoint proteins, and cytokines according to sampling location

Comparisons between endocervix and exocervix samples were conducted (Supplementary Table S6). After taxonomic profiling of the microbiomes, clinically significant bacteria in the cervical environment, such as *Lactobacillus* spp., *Gardnerella vaginalis*, *Moraxella osloensis*, *Veillonella atypica*, *V. parvula*, *Streptococcus dysgalactiae*, *Ureaplasma urealyticum*, *U. parvum*, *Fusobacterium nucleatum*, *Mycoplasma hominis*, *Sneathia amnii*, *Prevotella enoeca*, *P. fusca*, *P. scopos*, *P. jejuni*, *Megasphaera elsdenii*, and *Megasphaera stantonii* were included in analyses. The median total microbiome reads (68577.5 versus 32169.0) and *Lactobacillus* spp. (41178.5 versus 21109.5) in exocervix samples were two-fold greater than in endocervix samples (Figure 2A). However, there were no significant differences at the species level. Among immune-checkpoint proteins, CD 28, TIM-3, LAG-3, PD-1, and PD-L2 showed significantly increased levels in the endocervix than the exocervix. Meanwhile, HVEM and CD40 were present at lower levels in the endocervix (Figures 2B–H). Regarding inflammatory cytokines, the endocervix had significantly increased median levels of CCL2, CCL3, CCL4, IL-6, and TNF- $\alpha$  but significantly decreased IL-1 $\alpha$  levels (Supplementary Table S6). Taken together, the endo- and exocervical microenvironments showed significant differences

in their microbiomes, soluble immune-checkpoint proteins, and inflammatory cytokines.

### 3.4 Immune-checkpoint proteins and cytokines in patients with cervical insufficiency

Significant differences were not observed among the endocervical microbiomes of patients undergoing cerclage and prophylactic, cerclage and normal individuals (Supplementary Table S7). The levels of five immune-checkpoint proteins, TIM-3, LAG-3, TLR2, PD-L2, and ICOS revealed significant differences. Among them, TIM-3 and LAG-3 with *P*-values less than 0.001 are illustrated in Figures 3A, B. For inflammatory cytokines in endocervix, the CCL2, CCL3, CCL4, GM-CSF, IFN- $\gamma$ , IL-1 $\beta$ , IL-4, IL-6, and IL-13 were significantly different among included groups (Supplementary Table S7).

For exocervical samples, the highest total microbiome reads were observed in patients with cervical insufficiency undergoing cerclages (75822.0; *P* = 0.002). Four immune-checkpoint proteins, TIM-3, LAG-3, PD-1, and CD86/B7-2, showed differences. For the inflammatory cytokines, CCL2, CCL3, CCL4, GM-CSF, IFN- $\gamma$ , IL-4, IL-6, IL-13, and TNF- $\alpha$  were significantly different (Supplementary Table S8).

### 3.5 Microbiomes, immune-checkpoint proteins, and cytokines in patients with preterm birth

Among clinical characteristics, membrane bulging was significantly different between patients with preterm birth and term participants (*P* = 0.015). Age, gestational age at sampling, and body mass index did not reveal differences. The outcomes for normal participants and patients receiving cerclages with uniconcave balloons were not different (Supplementary Table S9). In the microbiomes, *Moraxella osloensis*, *Veillonella atypica*, and *V.*

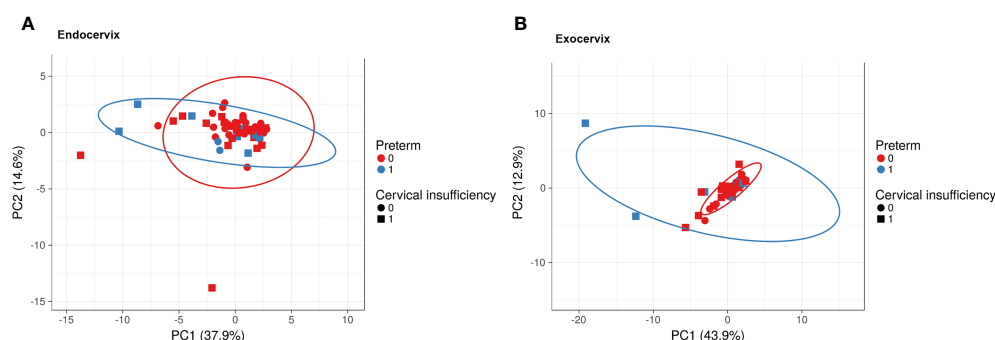

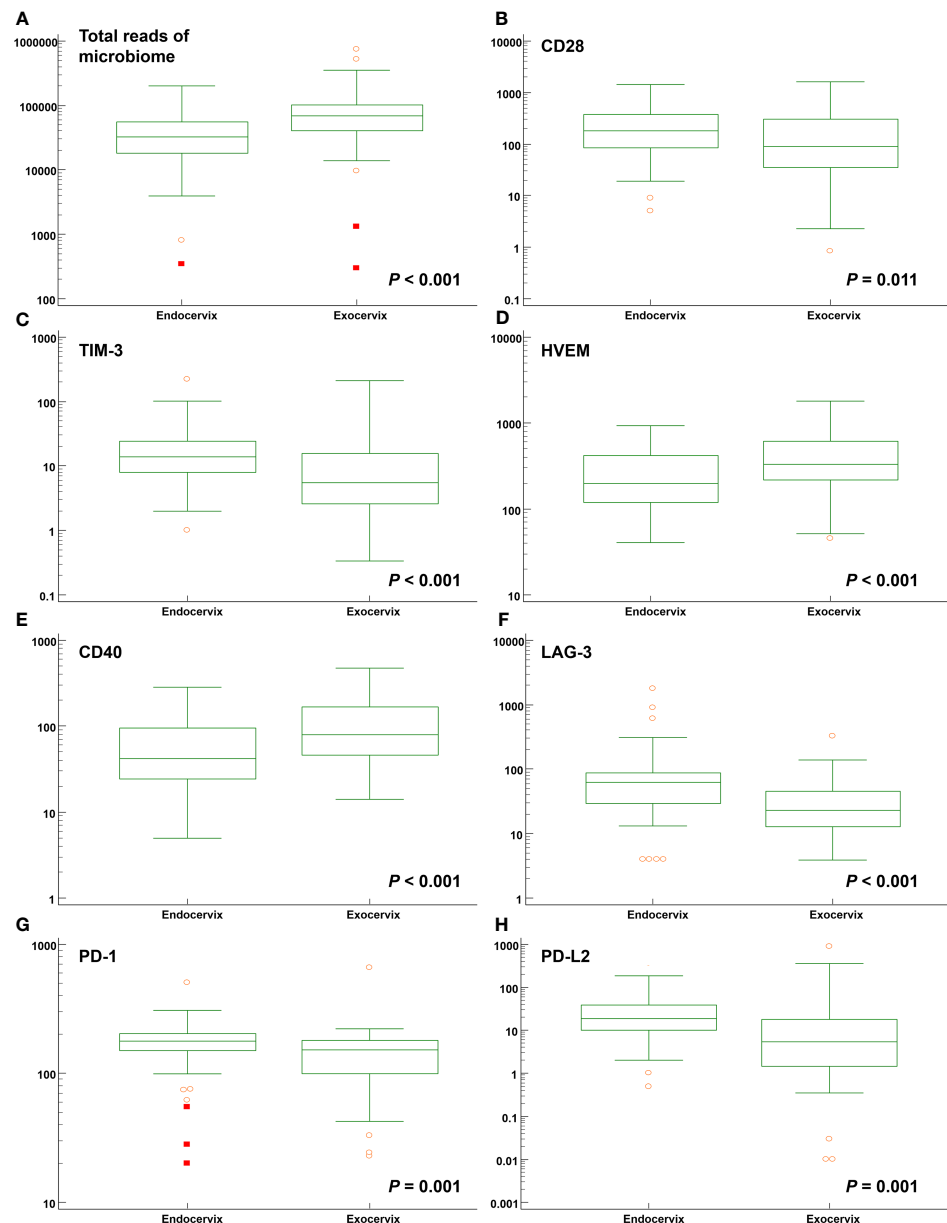

FIGURE 1

Principal component analysis plots for soluble immune-checkpoint proteins and inflammatory cytokines according to sampling location, cervical insufficiency, and preterm birth. (A) Endocervical samples; (B) Exocervical samples. Prediction ellipses illustrated as red and blue lines represent probabilities of 0.95.

**FIGURE 2**  
Distribution of total microbiome reads and levels of soluble immune-checkpoint proteins according to sampling locations such as the endocervix and exocervix. Plots for (A) total reads; (B) CD28; (C) TIM-3; (D) HVEM; (E) CD40; (F) LAG-3; (G) PD-1; and (H) PD-L2.

*parvula* were significantly increased in patients with preterm birth. The median levels of the TIM-3 immune-checkpoint protein as well as the cytokines CCL2, IL-6, and IL-17A were increased in the preterm group compared to the term group (Figures 4A–C and Supplementary Table S10). For exocervical samples, the median levels of CD80/B7-1, PD-L2, and IL-6 (Figures 4D–F and Supplementary Table S11) were significantly raised in women with preterm birth. In addition, analyses for patients undergoing cerclage were performed. For the endocervical samples, *V. atypica*, *V. parvula*, and *S. dysgalactiae* were significantly found in patients with preterm birth (Supplementary Table S12). Among them, only *S. dysgalactiae* showed significant association with preterm birth (odds ratio [OR] = 14.571;  $P = 0.029$ ). In terms of exocervical

samples, *V. atypica* and CD80/B7-1 revealed significant differences (Supplementary Table S13).

Both univariate and multivariate binary logistic regression analyses were applied to identify variables that correlated independently with the preterm state (Table 1). After univariate analyses, variables significantly associated with preterm birth were included in multivariate analyses. The presence of membrane bulging, *Moraxella osloensis*, TIM-3, CCL2, and IL-6 from endocervix were used as predictors. For exocervix, CD80/B7-1, PD-L2, and IL-6 were included as confounding variables for the multivariate analysis. The presence of *M. osloensis* (OR = 14.785;  $P = 0.037$ ) and CCL2 levels higher than 73 pg/mL (OR = 40.049;  $P = 0.005$ ) in the endocervical samples were associated with preterm birth. When factors

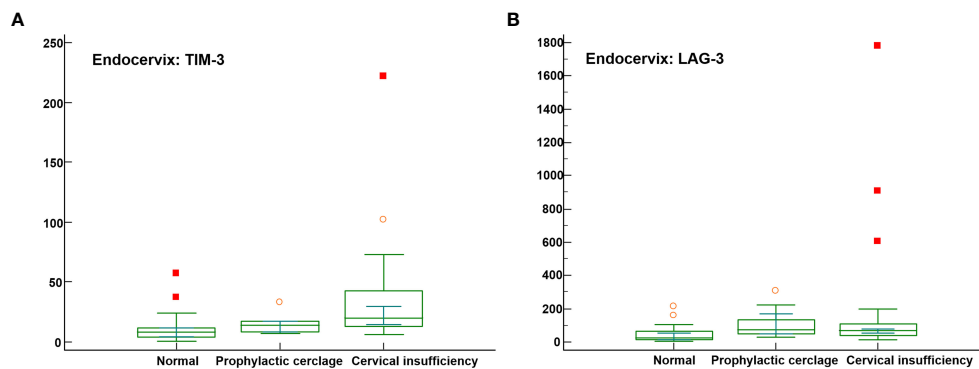

FIGURE 3

Distribution of soluble immune-checkpoint protein levels in the cervical insufficiency, prophylactic cerclage, and normal pregnant women groups. Plots for (A) Endocervical TIM-3; and (B) Endocervical LAG-3.

independently related to preterm birth after multivariate analyses were subjected to ROC analysis, the AUC was 0.846 (95% confidence interval [CI] = 0.733-0.925) (Figure 5).

### 3.6 Correlations of immune-checkpoint proteins with microbiomes and cytokines

Using Spearman's correlation coefficients, we focused on markers associated with preterm birth. For endocervix, *M. osloensis* was negatively correlated with TIM-3, CD80/B7-1, and PD-L2 (Figure 6A, Supplementary Table S14). Among the immune-checkpoint proteins, PD-L2 showed strong correlation with TIM-3 and CD80/B7-1. Among inflammatory cytokines, CCL2 and IL-6

showed no significant correlation with immune-checkpoint proteins (Figure 6B, Supplementary Table S15). In exocervical samples, CD80/B7-1 was positively correlated with CD28 and PD-1 (Figure 6C, Supplementary Table S16). PD-L2 also showed positive correlation with TIM-3. Similar to the endocervix, IL-6 in exocervical samples did not show significant correlation with any immune-checkpoint proteins (Figure 6D, Supplementary Table S17).

## 4 Discussion

We have shown that cervical immune-checkpoint proteins can be measured indicating the presence of their soluble forms in the cervical microenvironment. For cervical locations, total microbiome and

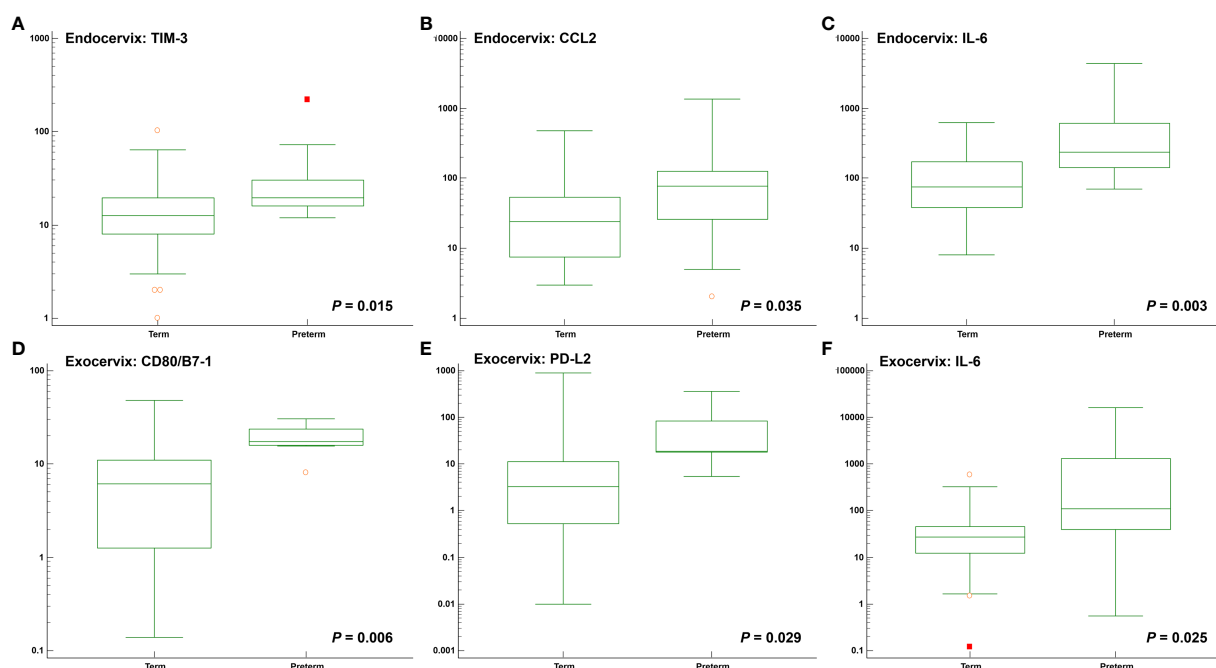

FIGURE 4

<sup>b</sup> Cutoffs for continuous values for the immune-checkpoint proteins and inflammatory cytokines were estimated using the Youden index.  
OR, odds ratio; CI, confidence interval.

*Lactobacillus* reads, seven immune-checkpoint proteins, and six inflammatory cytokines were different between endo- and exocervical samples. No significant differences were found in microbiome distributions among patients undergoing cerclage, patients undergoing prophylactic cerclage, and normal individuals for endocervical samples. Meanwhile, five immune-checkpoint proteins and nine inflammatory cytokines were different. For exocervical samples, total microbiome reads, four immune-checkpoint proteins, and nine inflammatory cytokines showed differences. For patients with preterm birth, two species, one immune-checkpoint protein, and three inflammatory cytokines from endocervical samples, as well as two immune-checkpoint proteins and one inflammatory cytokine from exocervical samples, were significantly different. The area under the ROC curve for the combined presence of *M. osloensis* and CCL2 was 0.846, suggesting excellent performance for predicting preterm birth.

Soluble immune-checkpoint proteins, which may function differently from their membrane-bound forms, have been measured in serum (19) and cervicovaginal lavages (20). However, their role in cervical insufficiency has not been examined. We found that they can be measured using minimally invasive procedures. Furthermore, our

data showed differences between endocervix and exocervix in patients with cervical insufficiency. Other microbiome comparisons between vagina and cervical canal have been conducted in women with endometriosis (21) and pregnant women (22). However, there were no data for the comparison between endo- and exocervical samples in cervical insufficiency providing information about precise sampling locations. The locations evidently had an effect on microbiomes because only the exocervix, which is nearer to cervical canal and vagina, showed differences between cervical insufficiency and normal pregnancy.

Microbiome studies on patients with cervical insufficiency are rare. Our data showed non-significant differences in microbiomes, except for exocervical samples. A previous study reported no bacterial composition differences between vagina and cervical canal in patients with cervical insufficiency, suggesting that cervical incompetence enhances exchange between these communities (22). Another study has shown differences between these communities owing to cervical obstruction in normal pregnancies (23).

Inflammatory cytokines were measured in cervicovaginal fluid in a previous study on cervical insufficiency (24). The study

FIGURE 5

Receiver operating characteristic analysis for the performance of combined variables (*Moraxella osloensis* and CCL2 from endocervical samples) for predicting preterm delivery.

reported higher levels of IL-6, in agreement with our data from both the endo- and exocervical samples. Vaginal levels of IL-6 have been reported to be predictive (24, 25), consistent with our results. Data for immune-checkpoint proteins in cervical insufficiency have yet to be reported, to the best of our knowledge.

Preterm delivery is an important complication associated with cervical insufficiency (3, 24). Reduced abundance of *Lactobacillus* spp. has been correlated with premature cervical dilation, whereas *G. vaginalis* has been associated with unsuccessful rescue cerclage (3). The dominance of *L. iners* with *Lactobacillus* depletion was observed in women with cervical shortening, which often precedes preterm delivery (26). A network meta-analysis showed that women with low *Lactobacillus* spp. abundance were at increased risk (OR = 1.69) for preterm birth when compared to those with *L. crispatus* dominance (27). There are multiple reports of dysbiotic conditions in the vaginal microbiome, such as the emergence of *F. nucleatum*, *M. hominis*, *Ureaplasma* spp., *Sneathia* spp., *Prevotella* spp., and *Megasphaera* spp (20, 28, 29). With respect to the association of *M. osloensis* with preterm birth in our study, it has also been detected in the uterine microbiome in amniotic fluid (30, 31), which is close to the endocervix. In addition, septicemia in a preterm infant, neonatal early-onset sepsis, and ophthalmia caused by *M. osloensis* have been reported (32–34). Considering we used detection through sequencing and a relatively low study population, further studies to validate this species as a predictor of preterm birth are necessary because few studies on the uterine and cervical microbiome have been conducted (28).

Immune-checkpoint proteins are involved in the modulation of T cells (35). Regulatory T cells promote maternal-fetal tolerance, as well as fetal development, throughout gestation (36). Moreover, regulatory T cells express diverse immune-checkpoint molecules involved in immunosuppression, which is critical for effective immune

intervention. Several immune-checkpoint proteins, including PD-1, TIM-3, and LAG-3, influence both decidual and peripheral regulatory T cells during pregnancy. According to our data, TIM-3 from endocervical samples was associated with preterm birth. The expression of TIM-3 downregulates signals inhibiting Th1 responses and apoptosis of antigen-specific cells (37). TIM-3 expression dysregulation has been associated with excessive or inhibited inflammatory responses, leading to autoimmune disease and pregnancy complications, including both preterm birth and recurrent spontaneous abortion (38). Thus, the TIM-3 pathway may serve as a potential target for immunotherapeutic approaches (39).

CD80, as a ligand of CTLA-4, is involved in regulating T-cell proliferation and differentiation (40). It was associated with preterm delivery in our exocervical samples. Consistent with our results, alterations in the maternal immune system, such as CD80, have been associated with preterm delivery (41). PD-L2, also associated with preterm delivery in exocervical samples, is another ligand for PD-1; innate immune activators and signaling downstream of cytokine receptors modulate its expression. PD-L2 mainly plays a role in the induction of Th2-driven T-cell immunity (42). Our understanding of PD-L2 is limited, necessitating more studies on this molecule. In addition, the strong correlation among microbiome and immune-checkpoint proteins found in our data has been consistently reported in other diseases (20, 43, 44).

Vaginal levels of the inflammatory cytokine IL-6 have been reported to be predictive in patients with cervical insufficiency (24, 25, 45), consistent with our results. CCL2 is a pro-inflammatory cytokine that is upregulated in the myometrium during labor (46). Abnormal levels of CCL2 have been associated with adverse outcomes such as spontaneous abortion, preeclampsia, and preterm labor (47). A previous study demonstrated that respondents with recurrent pregnancy loss expressed higher level

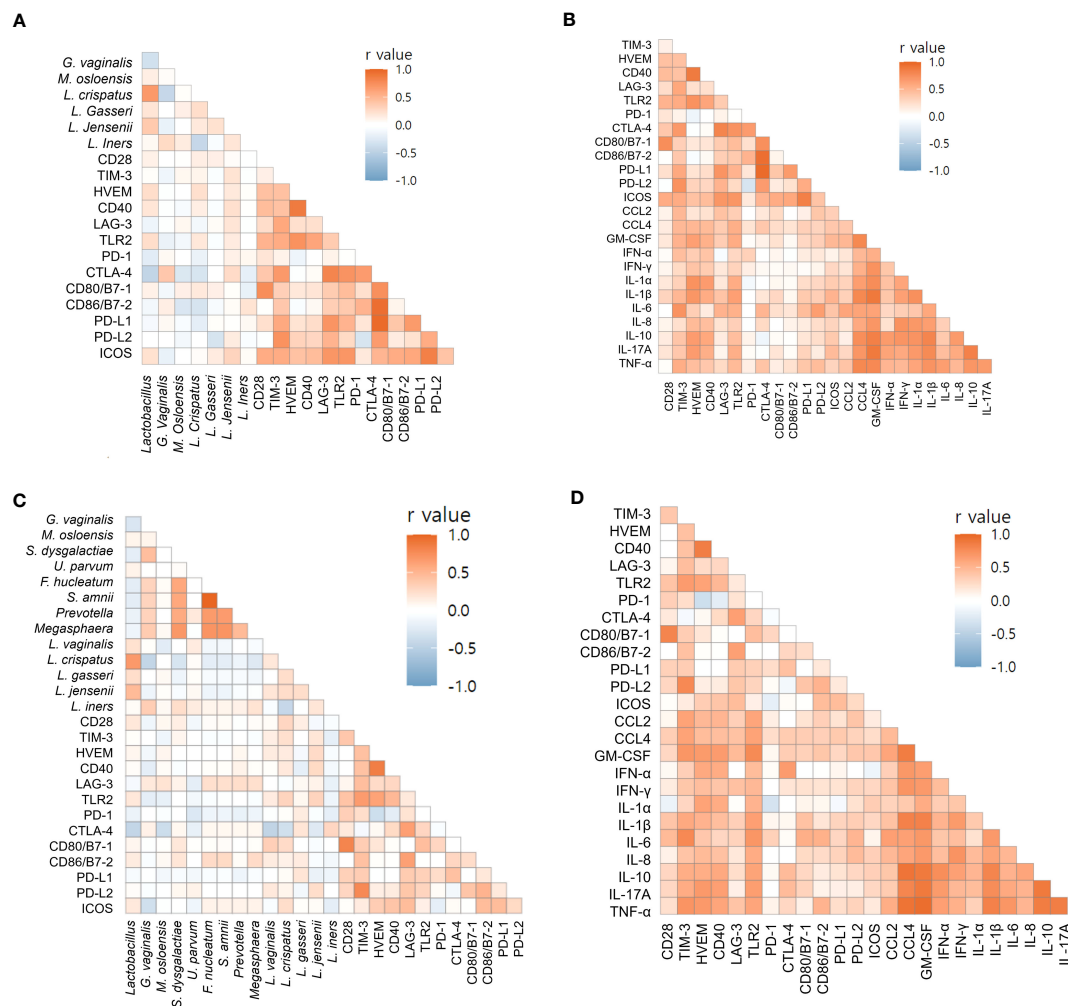

FIGURE 6

Correlations of soluble immune-checkpoint proteins with microbiomes and inflammatory cytokines based on Spearman's rank correlation analyses. (A) Soluble immune-checkpoint proteins with microbiomes in endocervical samples; (B) Soluble immune-checkpoint proteins with inflammatory cytokines in endocervical samples. (C) Soluble immune-checkpoint proteins with microbiome in exocervical samples; (D) Soluble immune-checkpoint proteins with inflammatory cytokines in exocervical samples.

of CCL2 than normal pregnant women (48). CCL2 levels were well above the normal range in plasma and placenta samples from patients with preeclampsia (49). CCL2 also integrates both mechanical and endocrine signals that influence preterm delivery, showing promise as a potential target for therapeutic prevention of preterm birth. Exploring and combining microbiomes, immune-checkpoint proteins, and inflammatory cytokines exhibited excellent performance for predicting preterm birth, supporting comprehensive approaches.

To the best of our knowledge, data for immune-checkpoint proteins in cervical insufficiency and preterm birth have yet to be reported. We found that immune-checkpoint proteins could be measured in both endo- and exocervical microenvironments and showed differences. Potential biomarkers for predicting preterm birth with precise sampling locations were identified for clinical settings. In addition, measuring soluble markers is beneficial because of easy accessibility and non-invasiveness. Limitations of our study include its relatively small sample size. Future studies with

larger study populations are needed to validate and extend our findings. Furthermore, we were not able to measure the membrane-bound forms of studied markers, as tissues from normal participants and pregnant patients with cervical insufficiency were not available.

In conclusion, we showed that soluble immune-checkpoint proteins and inflammatory cytokines, as well as microbiomes, can be detected in the endo- and exocervical microenvironments, especially in patients with cervical insufficiency. Their distributions revealed differences between endo- and exocervical microenvironments. Significantly different levels of these markers were found in cervical insufficiency. These patterns were also observed in patients with preterm deliveries. For predicting preterm birth, combining *M. osloensis* and CCL2 from endocervical samples exhibited excellent performance, showing potential as a prognostic biomarker. Understanding the relationships among microbiomes, immune-checkpoint proteins, and inflammatory cytokines has potential in the development of

novel strategies for the management of cervical insufficiency and preterm states based on risk stratification.

## Data availability statement

The data presented in the study are deposited in the NCBI Sequence Read Archive, accession number PRJNA836344 and HARVARD Dataverse, accession number <https://doi.org/10.7910/DVN/4YF2FU>.

## Ethics statement

The studies involving human participants were reviewed and approved by Institutional Review Board of Kangnam Sacred Heart Hospital (HKS 2019-11-024 and 2022-06-010). The patients/participants provided their written informed consent to participate in this study.

## Author contributions

SJ and K-YL conceived the study. WC and YJ analyzed the microbiome data. SC and K-YL led the sampling and clinical data generation. SJ, NL, and KJ generated immunologic data and performed the analyses. SJ wrote the manuscript. M-JP, WS, and K-YL reviewed and edited the manuscript. All authors contributed to the manuscript and approved the submitted version.

## Funding

This research was funded by a National Research Foundation of Korea (NRF) grant (grant number NRF-2022R1A2C1003503). The funding source had no involvement in the study design, the

collection, analysis, and interpretation of data, the writing of the report, and the decision to submit the article for publication.

## Acknowledgments

The authors appreciate the staff at MacroGen, Inc. for performing experiments for DNA shotgun sequencing and Jin Hyun Ju for sample collection and coordinating metadata. We would like to thank Editage ([www.editage.co.kr](http://www.editage.co.kr)) for English language editing.

## Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

## Publisher's note

**Introduction:** Inflammation is a key driver of morbidity in the vulnerable preterm infant exposed to pre- and postnatal hazards and significantly contributes to chronic lung disease, i.e. bronchopulmonary dysplasia (BPD). However, the early changes in innate immunity associated with BPD development are incompletely understood.

**Methods:** In very immature preterm infants below 32 weeks gestational age (GA; n=30 infants), monocyte subtypes were identified by Flow Cytometry at birth and throughout the postnatal course including intracellular TNF expression upon LPS stimulation. Complementing these measurements, cytokine and growth factor expression profiles (Luminex<sup>®</sup> xMAP<sup>®</sup>; n=110 infants) as well as gene expression profiles (CodeLink<sup>™</sup> Human I Bioarray; n=22) were characterized at birth.

**Results:** The abundance of monocyte subtypes differed between preterm and term neonates at birth. Specifically, CD14<sup>++</sup>CD16<sup>+</sup> (intermediate) monocytes demonstrated a dependency on PMA and elevated levels of nonclassical (CD14<sup>+</sup>CD16<sup>++</sup>) monocytes characterized preterm infants with developing BPD. Postnatally, lung injury was associated with an increase in intermediate monocytes, while high levels of nonclassical monocytes persisted. Both subtypes were revealed as the main source of intracellular TNF- $\alpha$  expression in the preterm infant. We identified a cytokine and growth factor expression profile in cord blood specimen of preterm infants with developing BPD that corresponded to the disease-dependent regulation of monocyte abundances. Multivariate modeling of protein profiles revealed FGF2, sIL-2 R $\alpha$ , MCP-1, MIP1a, and TNF- $\alpha$  as predictors of BPD when

considering GA. Transcriptome analysis demonstrated genes predicting BPD to be overrepresented in inflammatory pathways with increased disease severity characterized by the regulation of immune and defense response pathways and upstream regulator analysis confirmed TNF- $\alpha$ , interleukin (IL) -6, and interferon  $\alpha$  as the highest activated cytokines in more severe disease. Whereas all BPD cases showed downstream activation of chemotaxis and activation of *inflammatory response pathways*, more severe cases were characterized by an additional activation of *reactive oxygen species (ROS) synthesis*.

**Discussion:** In the present study, we identified the early postnatal presence of nonclassical (CD14<sup>+</sup>CD16<sup>++</sup>) and intermediate (CD14<sup>++</sup>CD16<sup>+</sup>) monocytes as a critical characteristic of BPD development including a specific response pattern of monocyte subtypes to lung injury. Pathophysiological insight was provided by the protein and transcriptome signature identified at birth, centered around monocyte and corresponding granulocyte activation and highlighting TNF $\alpha$  as a critical regulator in infants with developing BPD. The disease severity-dependent expression patterns could inform future diagnostic and treatment strategies targeting the monocytic cell and its progeny.

bronchopulmonary dysplasia, monocytes, cytokines, preterm infants, prenatal injury, chronic lung disease

## Introduction

Organ injury provoked by sustained inflammation is especially detrimental in the developing organism. Perinatal inflammation is linked to increased mortality and long-term morbidity in preterm infants (1). One of the most prevalent morbidities bearing significant long-term consequences is the development of neonatal chronic lung disease (CLD), known as bronchopulmonary dysplasia (BPD) with different severities ranging from mild to moderate and severe disease (2). BPD affects more than 30% of all very preterm infants (3, 4) and determines the lung's capacity to undergo structural and functional maturation as well as its potential to cope with second and third hit injury (5, 6).

The dysregulation of developmentally relevant growth factor signaling underlies the incomplete formation of the gas exchange area that is subsequently dominated by apoptotic changes and fibrotic remodeling. These processes are substantially driven by a sustained inflammatory response observed in the BPD lung (7). Despite several attempts to characterize these immune phenomena in the context of different pre- and postnatal risk factors driving BPD, comprehensive knowledge that informs diagnostic and therapeutic strategies at an early disease stage is missing. In the injured neonatal lung, both clinical and experimental studies have confirmed the presence of lung macrophages (M $\Phi$ ) and their respective signaling molecules (8, 9). These key players of innate immunity undergo a complex process of maturation and are in neonates characterized by shared and distinct functions when compared to adult M $\Phi$  including lipopolysaccharide-induced

activation, Fc receptor-dependent phagocytosis, and differences in polarization with interferon-gamma (IFN $\gamma$ ) or interleukin (IL)-10 (10, 11).

To understand early changes in the neonatal immune response that likely drive sustained inflammation related to BPD development on a cellular level and beyond, we characterized monocyte subtypes at birth and in the first week of life when undergoing postnatal treatments, delineated the corresponding cytokine and growth factor expression profile, and analyzed the immune network by transcriptome analysis in preterm infants with and without BPD.

## Material and methods

### Patient characteristics

Preterm infants <32 weeks gestational age (GA) with and without BPD were prospectively included in the study cohorts, following identical in- and exclusion (congenital malformations, metabolic disorders) criteria (12). Patient monitoring comprised an extensive set of clinical and laboratory variables from birth to discharge, including the variables displayed in Table 1 (for definitions see table legend) (15). Specifically, BPD was diagnosed according to the NIH consensus statement (4) referring to oxygen requirement and/or ventilatory support at 36 weeks postmenstrual age (PMA) for disease severity. Incidences for BPD severity (no, mild, moderate and severe) are provided in each method section as well as in Table 1 and Supplemental Tables 1, 2.

TABLE 1 Description of cohorts used for transcriptome, protein, and monocyte analysis.

	Monocyte analysis		Protein analysis		Transcriptome analysis	
	no BPD	BPD	no BPD	BPD	no BPD	BPD
<b>Number of patients</b>	15	15	55	45	13	9
<b>GA (weeks)</b>	30.14 (25.43-31.57)	25.86 (23.57-29.57)	30.6 (24.1-31.9)	26.6 (23.6 - 31.6)	30.3 (28.4-31.1)	24.7 (24.3 - 30.3)
<b>Birth weight (g)</b>	1160 (750-1760)	590 (510-1510)	1310 (510-2240)	760 (315-1550)	1400 (900-1760)	830 (590-1390)
<b>Sex (female)</b>	8 (53%)	7 (47%)	27 (49%)	15 (33%)	6 (46%)	7 (78%)
<b>ANCS</b>	12 (80%)	12 (80%)	36 (67%)	27 (60%)	9 (69%)	7 (78%)
<b>AIS</b>	5 (33%)	11 (73%)	32 (64%)	30 (67%)	1 (8%)	5 (56%)
<b>RDS</b>	11 (79%)	15 (100%)	42 (42%)	43 (96%)	12 (92%)	9 (100%)
<b>EOI</b>	1 (9.1%)	5 (33%)	4 (7%)	16 (36%)	6 (46%)	9 (100%)
<b>Mechanical ventilation</b>	7 (47%)	15 (100%)	20 (36%)	39 (87%)	6 (46%)	9 (100%)
<b>Invasive ventilation (days)</b>	0 (0-9)	19 (3-42)	2 (1-53)	16 (1-40)	7 (2-9)	6 (1-44)
<b>CPAP/NIPPV (days)</b>	6.5 (2-50)	40.5 (34-59)	9 (1-48)	50 (0-119)	2 (1-13)	11 (3-45)
<b>Oxygen supplementation (days)</b>	0 (0-1)	63 (30-176)	5 (0-97)	63 (0-138)	4 (1-18)	46 (28-138)
<b>Surfactant therapy</b>	5 (33%)	13 (87%)	18 (33%)	37 (67%)	6 (46%)	9 (100%)

Data are given as median and range or frequencies (percent of total in group).

BPD was defined according to the NICHD/NHLBI/ORD workshop (4) based on the need for oxygen supplementation ( $> \text{FiO}_2$  0.21) for at least 28 days, followed by a final assessment at 36 weeks postmenstrual age (PMA) or at discharge, whichever came first in preterm infants born  $< 32$  weeks GA.

AIS, amniotic infection syndrome; ANCS, antenatal corticosteroids; CPAP, continuous positive airway pressure; EOI, presence of early postnatal systemic infections/early-onset infection [diagnosis: one or more clinical and laboratory signs of infection according to Sherman et al. (13)]; GA, gestational age; NIPPV, non-invasive positive pressure ventilation; RDS, respiratory distress syndrome [diagnosis and severity: assessment of anterior-posterior chest radiographs according to Couchard et al. (14)].

The study was approved by the local ethic committees at LMU Munich (ethic vote #195-07) and JLU Giessen (ethic vote #file-79/01).

For monocyte subtype analysis by FACS samples of  $n=30$  infants were available for analysis. Protein analysis included samples from  $n=110$  preterm infants, and samples from  $n=22$  preterm infants were available for transcriptome analysis.

## Sample analysis

### Flow cytometry (FACS)

In order to identify monocyte subtypes (16, 17) in volume limited (20-50  $\mu\text{l}$ ) fresh, whole blood EDTA specimen of preterm infants with ( $n=15$ ) and without ( $n=15$ ) BPD, samples were incubated with CD45-APC (#IM2473), CD14(My4)-FITC (#6603511), CD16(3G8)-PE (#A07766) and HLA-DR-PC5 (#A07793) antibodies (Beckman Coulter, Germany) before adding blood volume equal amounts of counting beads (#7547053, Beckman Coulter, Germany). Data were analyzed on a four laser LSRII flow cytometer (Becton Dickinson, Germany). Monocyte subtypes were identified by gating on CD14/HLA-DR positive cells out of all CD45 positive leukocytes (Supplemental Figure 6). Further analysis for CD14 vs CD16 allowed us to define classical monocytes with high CD14 expression ( $\text{CD14}^{++}\text{CD16}^{-}$ ), nonclassical monocytes with lower CD14 and high CD16 expression ( $\text{CD14}^{+}\text{CD16}^{++}$ ), and intermediate monocytes with

high CD14 and lower CD16 expression ( $\text{CD14}^{++}\text{CD16}^{+}$ ) (18, 19). Data were analyzed by FlowJo® version 10.8.1. Intracellular TNF staining was performed in whole blood samples (PerFix -nc, Beckman Coulter # B10826) according to the manufactures' instructions. In brief, 50  $\mu\text{l}$  of whole EDTA-blood and 10  $\mu\text{g}/\text{ml}$  Brefeldin A (Sigma #B-6542) were incubated with 100 ng/ml LPS (Lipopolysaccharide, Sigma #L6261) at 37°C for 4 hours or left without stimulus. Aliquots were stained after adding 2.5  $\mu\text{l}$  Fixative Reagent 1 (15 min, RT) using 150  $\mu\text{l}$  Permeabilizing Reagent 2 and monoclonal antibodies CD14-PC5 (Beckmann Coulter #A07765), CD16(3G8)-FITC (Becton Dickinson #555406) and TNF-PE (Beckman Coulter #IM3279) or TNF-PE + rTNF in a 10-fold molar excess as an isotype control (incubation for 20 min at RT). After adding 800  $\mu\text{l}$  1:10 diluted Final Reagent B, cells were analyzed using a LSR II flow cytometer. Monocyte subtypes were identified while gating on CD14-PE versus CD16-FITC. Corresponding iTNF expression was calculated while subtracting the mean fluorescence intensity of TNF-PE minus TNF-PE/rTNF for the respective monocyte subtypes and then calculating the delta mean fluorescence intensity after stimulation with LPS for the three analyzed monocyte subpopulations.

### Protein analysis

For protein analysis, venous umbilical cord blood (CB) of 110 preterm infants (no BPD  $n=55$ , BPD (mild/moderate/severe)  $n=45$ ) was centrifuged (1,000 rpm, 5 min) and stored ( $-20^{\circ}\text{C}$ ). All samples were analyzed using the 21-plex premixed human cytokine

milliplex panel (HPANLXM 2, Luminex® xMAP®, Luminex, TX, US) according to the manufacturer's instructions.

## Transcriptome analysis

For transcriptome analysis, venous umbilical CB specimens of 22 preterm infants (no BPD  $n=13$ , BPD  $n=9$ ), were stabilized using the PAXgene Blood RNA System (PreAnalytiX, Germany) before RNA extraction (PreAnalytiX) and quantification (NanoDrop Technologies, US). From a total of 61 array images for analysis, spot signals of CodeLink™ Human I Bioarrays (GE Healthcare/Amersham Biosciences) were quantified according to the manufacturer's instructions (12) (CodeLink System Software (Batch Submission (V2.2.27), Expression Analysis (V2.2.25), GE Healthcare, Germany). Two to three technical replicates were prepared per sample. Microarrays were background corrected by subtracting and intra-slide normalized using Median normalization as recommended by the manufacturer. The 9945 transcripts were filtered for missingness (threshold  $\geq 50\%$  missing data per group), low expression (threshold  $\geq 50\%$  of values expressed below the detection threshold as defined by the manufacturer), and outliers per transcript probe and group over all microarrays (values deviating from the group median by more than 3). The remaining missing values were imputed by Bayesian Principal Component Analysis imputation in R ('pcaMethods' (20)). Subsequently, data were inter-slide normalized using Quantile normalization. The average expression of technical replicates was used for analysis. Transcriptome data were archived in Gene Expression Omnibus (GEO, Accession number: GSE225881).

## Data analysis

Data analysis was conducted in R (Version 4.1.1) (21).

*Monocyte subtypes* were analyzed using a linear mixed-effects model (R-Package *nlme* (22) that was fitted by maximizing restricted log-likelihood in order to model log-transformed monocyte levels dependent on clinical conditions, i.e., BPD, preterm or term birth, PMA, status of invasive positive pressure ventilation (timepoints: birth, before IPPV, start of IPPV, during and 2 weeks after IPPV). To analyze the development of monocyte levels over time, random effects were added to the statistical model.

*Protein expression* was analyzed by the Wilcoxon test; orthogonal partial least squares discriminant analysis (OPLS-DA) (22) for multivariate data sets using the Bioconductor packages 'ropls' (version 1.24.0), gestational age was included in the analysis. Variable influences on projection (VIP) were calculated to explain intergroup variation, i.e., BPD and no BPD. Orthogonal VIPs were calculated to facilitate the interpretation and detection of latent variables in the protein assay explaining intragroup variation. VIPs greater than 1 are considered most relevant, VIPs smaller than 0.5 are considered irrelevant (23).

*Transcriptome expression* analysis included prediction [PAM; Bioconductor packages 'pamr' (version 1.56.1)] (24, 25) and differential expression analysis (linear modeling, limma open source software, Bioconductor release 3.14) (26). Predictive analysis for microarray data used a multivariate approach to differentiate

between BPD and BPD severity grades (no BPD  $n=13$ , mild BPD  $n=6$ , moderate or severe BPD  $n=3$ ), while differential analysis for microarray data focused on differences in single transcripts in a univariate approach. The significance level was adjusted for multiple testing using the False Discovery Rate (FDR) (27). Cut-off FDR for differential expression was set at  $FDR < 0.05$  and a minimum absolute fold change of 2 between at least two groups.

## Results

### Characteristic monocyte signature in infants with BPD at birth

In order to identify early postnatal immune cell characteristics that indicate or drive morbidity development, we characterized monocyte subtypes in volume-limited CB and follow-up samples from  $n=30$  preterm infants with and without BPD. Supporting a GA specific pattern of innate immune capacities, each monocyte subpopulation showed individual trajectories ( $p < 0.05$ , two-way Analysis of Variance). Whereas levels of intermediates and nonclassical monocytes at birth decreased with increasing PMA towards stable expression levels exhibited by term newborns, classical ( $CD14^{++}CD16^{-}$ ) monocytes showed PMA independent abundances at birth (Figure 1A). The abundance of  $CD14^{++}CD16^{+}$  (intermediate) monocyte subtypes differed between preterm and term neonates at birth ( $p\text{-value}=0.067$ ) and demonstrated a dependency on PMA ( $p\text{-value}=0.003$ ) (Figure 1A). When considering disease, our analysis revealed elevated levels of nonclassical  $CD14^{+}CD16^{++}$  monocytes in preterm infants with developing BPD at birth ( $p\text{-value}=0.004$ ) (Figure 1B and Table 2). In the postnatal course, lung injury, i.e., exposure to oxygen and invasive positive pressure ventilation (IPPV) was associated with an increase of  $CD14^{+}CD16^{+}$  (intermediate) monocytes ( $p\text{-value} < 0.001$ ), while high levels of  $CD14^{+}CD16^{++}$  monocytes persisted (Figure 1B and Table 2). A peak of all monocyte subtypes can be observed when preterm infants with developing BPD are exposed to oxygen and IPPV in contrast to infants without the disease (Figure 1B and Table 2). With regard to cellular function, intermediate  $CD14^{+}CD16^{+}$  and nonclassical  $CD14^{+}CD16^{++}$  monocytes from preterm infants were revealed as the main source of intracellular TNF- $\alpha$  expression upon LPS stimulation (Figure 1C). The capacity of  $CD14^{+}CD16^{+}$  for TNF- $\alpha$  expression upon stimulation increased with PMA (Figure 1C).

Next, we identified a cytokine and growth factor expression profile by multiplexed protein analysis in CB EDTA plasma from  $n=110$  infants that corresponded to the disease dependent regulation of monocyte abundances in preterm infants with developing BPD. Protein profiling demonstrated the upregulation of IL-6, IL-8, MCP-1, MIP1a, IL-1R $\alpha$ , sIL-2 R $\alpha$ , EGF, and FGF2 levels in preterm infants with BPD when compared to infants without the disease. Multivariate modeling revealed FGF2, sIL-2 R $\alpha$ , MCP-1, MIP1a, and TNF- $\alpha$  as predictors of BPD when considering GA as a strong influencing factor (VIP). Further, TNF- $\alpha$ , IL1b, IL6, IL8, and IL-1R $\alpha$  were identified as top mediators for protein abundance (Table 3, oVIPs). In line with these findings, transcriptome analysis in CB EDTA

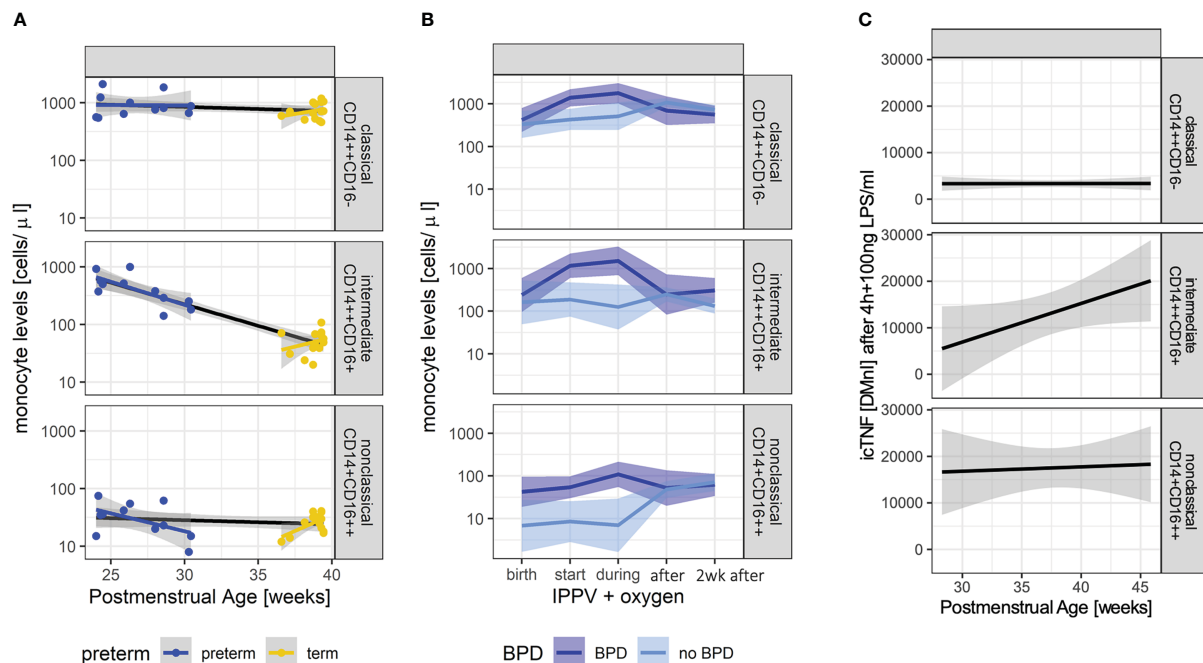

FIGURE 1

Characteristic monocyte subtypes at birth in infants developing BPD. (A): Monocyte levels (upper panel: classical (CD14<sup>++</sup>CD16<sup>-</sup>), middle panel: intermediate (CD14<sup>++</sup>CD16<sup>+</sup>), lower panel: nonclassical CD14<sup>+</sup>CD16<sup>++</sup>) of preterm (n=11, blue) and term (n=14, yellow) infants at the day of birth (+72h if not done immediately). Overall trend dependent on PMA indicated by black lines. Group comparisons: abundance preterm vs. term 0.695, p-value=0.067; development with PMA (slope): -0.017, p-value= 0.003. (B): Monocyte levels (upper panel: classical (CD14<sup>++</sup>CD16<sup>-</sup>), middle panel: intermediate (CD14<sup>++</sup>CD16<sup>+</sup>), lower panel: nonclassical CD14<sup>+</sup>CD16<sup>++</sup>) in preterm infants with (n=15, dark blue) and without BPD (n=15, light blue) at birth up until 2 weeks after the start of invasive positive pressure ventilation (IPPV) and oxygen therapy. Linear mixed effect models take PMA into account. Levels of nonclassical monocytes are elevated at birth (pairwise comparison, p-value=0.004); nonclassical (BPD vs. no BPD p-value < 0.001), intermediate (BPD vs. no BPD p-value=0.011) and classical (BPD vs. no BPD p-value=0.004) differ during IPPV. (C): Intracellular TNFα (icTNF) expression in response to LPS stimulation (4 hours after) in monocytes of preterm infants (n=9) (upper panel: classical (CD14<sup>++</sup>CD16<sup>-</sup>), middle panel: intermediate (CD14<sup>++</sup>CD16<sup>+</sup>), lower panel: nonclassical CD14<sup>+</sup>CD16<sup>++</sup>). Increases in icTNF are statistically significant in intermediate (p-value = 0.005) and nonclassical monocytes (p-value = 0.033). Levels of icTNF are displayed as delta mean intensities (DMn).

samples of 22 very preterm infants identified a cluster of 28 transcripts differentiating between BPD and no BPD cases (Supplementary Figure 1 and Supplementary Table 1) with a cluster of 71 transcripts differentiating between disease severities (Supplementary Figure 2 and Supplementary Table 2). Genes predicting BPD are significantly overrepresented in *inflammatory* and *Galanin/GMAP prepropeptide* pathways (Supplementary Table 3) and increased disease severity is characterized by the

regulation of immune and defense response pathways (Supplementary Table 4) including activated *chemotaxis of cells*, increased biological functions associated with *apoptosis*, *accumulation of leukocytes*, and decreased *phagocytosis by immune cells* (Supplementary Table 5). Differential gene expression analysis revealed 238 differentially expressed genes (DEG) out of 7,529 transcripts (FDR <0.05, and |FC|>2) when comparing cases with and without BPD (Supplementary Table 6). Upstream regulator

Univariate analysis for protein values obtained by Wilcoxon tests and multivariate analysis using orthogonal partial least squares discriminant analysis (OPLSDA). Multivariate analysis considered also gestational age (GA). Median and upper and lower quartile are presented for continuous variables, n is the number of non-missing values. VIP, Variable influence on projection; oVIP, orthogonal Variable influence on projection from the orthogonal partial least squares discriminant analysis modeling BPD. GA, gestational age; protein names according to 21-plex preterm human cytokine multiplex panel.

analysis indicated TNF-α, interleukin (IL)-2, -6, -10, and interferons as the highest activated cytokines in moderate/severe BPD patients (Supplementary Table 7).

### Mechanistic insight into BPD immune signature by transcriptome analysis at birth

Regulator effect networks consisting of upstream cytokines and downstream biological function demonstrated the activation of IL-6, TNF-α, and TNFRSF1A (tumor necrosis factor receptor superfamily, member 1a) together with the regulation of *CXCL9*, *LGALS3*, *MMP7*, *TLR3*, *IL-10*, as well as *TCR* and *LAT* in infants with BPD, indicating immune cell activation, cell-matrix interaction and remodeling at the same time. Prediction analysis revealed the activation of TNF-α as a possible regulator for the differentially regulated genes *CXCL9*, *IL10*, *LGALS3*, *MMP7*, *TLR3*, *TNFRSF1A* (Figure 2A), and also *BID*, *CAT*, *CDH13*, *TF*, *ZFP36* (Supplementary Figure 3), with functional analysis confirming the activation of *leukocyte chemotaxis*, increased neutrophil number, increased *apoptosis and necrosis* and the deactivation of the

*accumulation of eosinophils* together with the regulation of *TNF-α homeostasis* (*ZFP36*, *TNFRSF1A*). Increased disease severity was characterized by *reactive oxygen species (ROS) synthesis*, whereas all BPD cases independent of disease severity showed downstream activation of chemotaxis and activation of inflammatory response pathways (Figure 2B and Supplemental Figure 4). The transcriptome signature that was dominated by immune system activation in upstream analysis, indicated the upregulation of IL-2, TNF-α IL-6, IL-10, Interferon (IF) alpha/beta, and IFNG in mild BPD, next to the involvement of interferons from the alpha group, IL27, EBI3 in moderate/severe BPD. When comparing mild and moderate/severe BPD, differences included the activation of IL-5 (upregulation in moderate/severe BPD), and WNT1 (Supplementary Table 8).

### Discussion

There is a paucity of data providing insight into the immune cell characteristics that indicate or drive pulmonary morbidity in preterm infants early after birth.

The disease-characteristic immune response aligns with the maturational effects observed in the monocyte subtypes studied, as intermediate and nonclassical monocyte levels both demonstrated an association with PMA and specifically intermediate (CD14<sup>++</sup>CD16<sup>+</sup>) monocytes were increased in premature infants at birth. The capacity of these cells to express TNF- $\alpha$  upon stimulation, however, increased with maturation.

Closing the knowledge gap or early drivers in chronic lung disease development, we successfully identified distinct signatures of monocyte subtypes in volume-limited CB specimen and follow-up samples in preterm infants with BPD, complemented by comprehensive protein and transcriptome profiling.

The identified immune response in preterm infants with developing BPD at birth holds potential for the design of diagnostic and therapeutic strategies but warrants future studies engaging large patient collectives to delineate the differential impact of prenatal complications as well as genetic background on these disease characteristic profiles.

## Data availability statement

The data presented in the study are deposited in the GEO repository (<https://www.ncbi.nlm.nih.gov/geo/>), accession number GSE225881.

## Ethics statement

This study was confirmed by the local ethic committees at LMU Munich (ethic vote #195-07) and JLU Giessen (ethic vote #file-79/01), following the same in- and exclusion (congenital malformations, metabolic disorders) criteria. The patients/participants provided their written informed consent to participate in this study.

## Author contributions

AH, HH, TS, and CS designed the study. PO, CH, KF, MF, AF, EG, and XZ acquired the data. AH, AW, MH, PO, HE, MS, MF, and HH analyzed and interpreted the data. AH, AW, MH, TS, and CS drafted the manuscript for important intellectual content. All authors contributed to the article and approved the submitted version.

**Introduction:** In patients with peripheral neuropathies (PNP), neuropathic pain is present in 50% of the cases, independent of the etiology. The pathophysiology of pain is poorly understood, and inflammatory processes have been found to be involved in neuro-degeneration, -regeneration and pain. While previous studies have found a local upregulation of inflammatory mediators in patients with PNP, there is a high variability described in the cytokines present systemically in sera and cerebrospinal fluid (CSF). We hypothesized that the development of PNP and neuropathic pain is associated with enhanced systemic inflammation.

**Methods:** To test our hypothesis, we performed a comprehensive analysis of the protein, lipid and gene expression of different pro- and anti-inflammatory markers in blood and CSF from patients with PNP and controls.

**Results:** While we found differences between PNP and controls in specific cytokines or lipids, such as CCL2 or oleoylcarnitine, PNP patients and controls did not present major differences in systemic inflammatory markers in general. IL-10 and CCL2 levels were related to measures of axonal damage and neuropathic pain. Lastly, we describe a strong interaction between inflammation and neurodegeneration at the nerve roots in a specific subgroup of PNP patients with blood-CSF barrier dysfunction.

**Conclusion:** In patients with PNP systemic inflammatory markers in blood or CSF do not differ from controls in general, but specific cytokines or lipids do. Our findings further highlight the importance of CSF analysis in patients with peripheral neuropathies.

## KEYWORDS

cytokines, polyneuropathy, cerebrospinal fluid, neurofilament light chain, blood CSF barrier

## Introduction

Polyneuropathy (PNP) is a term to describe a group of diseases with peripheral nerve dysfunction of various etiologies. Symptoms may affect the motor, sensory and/or autonomic system, and in 50% of the cases, patients experience neuropathic pain. Why some patients with PNP have pain and others not, is unknown, and even PNPs with the same etiology may be painful or painless (1). The available treatments have modest efficacy in reducing pain and present considerable side effects (2, 3). One approach toward better symptom control and potentially causative treatment might be to find common pathophysiologic pathways in PNP of different etiologies.

Although merely 14%–20% of PNP have a definite immune-related cause (4), inflammatory processes have been found to be involved in neuro-degeneration, -regeneration and pain in neuropathies of different origin (5–7). One of the main pro-inflammatory pathways that are activated upon damage is toll-like receptor (TLR) 4 mediated. Stimulation of TLR4 results in the activation of the nuclear factor  $\kappa$  B (NF $\kappa$ B) pathway and the release of inflammatory cytokines, including tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin (IL)-1 $\beta$ , IL-6, IL-8, IL-10, or chemokines such as the CC-chemokine ligand (CCL) 2 (8). This pathway can in turn be regulated by other mediators. For instance, the NAD-dependent deacetylase sirtuin 1 (SIRT1) has been suggested to be able to inhibit the pro-inflammatory cascade by deacetylating the p65 subunit of NF $\kappa$ B (9). Fractalkine (Cx3CL1) is an algesic chemokine which is cleaved from neurons and activates glial cells (10). Furthermore, small fragments of RNA, or microRNAs (miR), can regulate the expression of genes coding for pro- and anti-inflammatory proteins and have been found altered in different neuropathies of the central or peripheral nervous system, nociception and pain (11). While many miRs might be involved in the development of neuropathic pain, miR-146a-5p, miR-132-3p and miR-155-5p participate in the regulation of the NF $\kappa$ B pathway and have been described altered in patients with painful PNP (12–14). In addition, alterations in ion channels such as voltage gated sodium channels or those of the transient receptor potential cation channel subfamily like TRPV1 might lead to enhanced excitatory responses in nociceptors and promote axonal degeneration and the release of pro-inflammatory mediators, exacerbating the immune response (15). Furthermore, TRPV1 is expressed in blood mononuclear cells, and a direct role in cytokine production and immune responses has been proposed (16, 17).

Several lipid compounds, such as prostaglandins (PGs) or thromboxanes, are known to be involved in inflammation and pain, and can in turn be upregulated upon inflammation or tissue injury. Moreover, high levels of PGs have been described in serum from patients with peripheral neuropathies, as well as in the spinal cord of animal models with peripheral injury (18, 19). In fact, non-steroidal anti-inflammatory drugs (NSAIDs), a very common treatment against pain, have anti-inflammatory and analgesic properties mediated by blocking the synthesis of PGs and thromboxanes (18, 20, 21). Short-chain and long-chain acylcarnitines can be found upstream their synthesis pathway and have been reported upregulated in sera, nerve and spinal cord in animal models of

neurodegeneration, in particular, palmitoylcarnitine (C16:0) and oleoylcarnitine (C18:1) (20, 22–24).

In PNP, signs and symptoms are typically length-dependent and thus more severe in the distal extremities of the body, such as feet and hands, than in the proximal regions or in the torso. Previous studies found a local upregulation of inflammatory mediators such as IL-2, IL-6, IL-8 or IL-10 in skin or nerve from patients with PNP (5, 25). The study of local inflammation, especially in the nerve, is difficult in humans, since it implies an invasive nerve biopsy, while systemic samples, such as blood and cerebrospinal fluid (CSF), are drawn and analyzed routinely. Since several inflammatory cytokines have been seen upregulated locally in patients with PNP, we studied whether some of these markers might be found systemically in sera or CSF. Different studies have shown a high variability in the cytokines present in serum from patients with PNP or nerve root compression, associated with the severity and symptoms of the neuropathy (26–31). Furthermore, extensive studies have shown that the CSF is directly altered by diseases of the central nervous system, while in diseases of the peripheral nervous system (PNS), differences in the levels of cytokines in CSF have yet to be explained. A factor that can influence these levels is the integrity of the barrier between blood and CSF, also called blood-CSF-barrier (B-CSF barrier) (32–34) or blood brain barrier (BBB) (35).

We hypothesized that PNP is associated with enhanced systemic inflammation that may correlate with the severity of the disease and the development of neuropathic pain. To test our hypothesis, we performed a comprehensive analysis of the protein, lipid, and gene expression of selected pro- and anti-inflammatory markers in blood and CSF from patients with PNP and controls. Furthermore, we measured the levels of neurofilament light-chain (NFL), as a cytoskeletal protein expressed by neurons and released upon cell damage, to assess the level of neurodegeneration present in patients with PNP (36), and to correlate NFL levels with the degree of inflammation. We also aimed to identify new systemic markers that might be important in the pursuit of a more accurate diagnosis and the prediction of neuropathic pain.

## Materials and methods

### Patient recruitment and diagnostic assessment

Between 2019 and 2021, 28 patients with PNP were prospectively recruited at the Department of Neurology, University of Würzburg, Germany, where they were seen for diagnostic work-up. In addition, 10 patients with acute headaches of unclear etiology were used as disease controls for the CSF analysis, and serum data from twelve healthy volunteers were included in the analysis to determine the inflammatory state of the headache group. Our study was approved by the Würzburg Medical Faculty Ethics Committee (# 15/19 and # 242/17) and all participants gave written informed consent prior to inclusion.

Diagnoses were based on history taking and neurological examination, laboratory studies, and nerve conduction examinations. All patients underwent laboratory tests including full

blood count, electrolytes, kidney and liver function tests, C-reactive protein, thyroid stimulating hormone, vitamin B12, HbA1c, oral glucose tolerance test (OGTT), screening for autoimmune antibodies (i.e., ANA, ENA, ANCA, anti-ganglioside antibodies), and lumbar puncture. Electrophysiological assessment with nerve conduction studies of the affected nerves including tibial motor nerve and sural sensory nerve was performed in all PNP patients.

To rate the severity of the neuropathy, we used standardized scales, including the modified Toronto clinical neuropathy score (mTCNS), the overall disability sum score (ODSS) and the Medical Research Council-sumscore (MRC-sumscore). Depression was assessed with the “Allgemeine Depressionsskala” (ADS) (37). Pain was evaluated by a numerical rating scale (NRS) from 0 (no pain) to 10 (worst pain), the neuropathic pain symptom inventory (NPSI) and the graded chronic pain scale (GCPS). After the diagnostic work-up, the examining neurologists categorized the neuropathies into a mild (1), moderate (2) or severe (3) clinical phenotype.

## Sample collection

From each patient, venous blood was drawn in the morning between 8 a.m. and 9 a.m. into S-Monovette<sup>®</sup> Serum-Gel Tubes (Sarstedt, Nümbrecht, Germany) and Tempus<sup>™</sup> Blood RNA Tubes (Thermo Fisher Scientific, Waltham, MA, USA). For the collection of sera, whole blood was left to clot for 30 min at room temperature and later centrifuged for 10 min at 1200 g. Supernatant was aliquoted and stored at -20°C until further analysis. Tempus<sup>™</sup> Blood RNA Tubes were immediately shaken for 30 s to lyse the cells and stabilize the RNA and stored at -80°C until extraction.

CSF samples were obtained after a lumbar puncture at the L4/5 level. The amount of CSF taken varied between 10–15 ml. Samples of 2 ml were aliquoted and subsequently stored at -20 °C.

## Gene expression analysis

RNA was extracted from Tempus<sup>™</sup> Blood RNA Tubes following the manufacturer's protocol (38, 39) from the MagMAX<sup>™</sup> for Stabilized Blood Tubes RNA Isolation Kit (Thermo Fisher Scientific, Waltham, MA, USA). RNA quality and quantity were assessed with a NanoDrop<sup>™</sup> One (Thermo Fisher Scientific, Waltham, MA, USA), and RNA was stored at -80°C.

For cDNA synthesis from mRNA, TaqMan Reverse Transcription reagents (Thermo Fisher Scientific, Waltham, MA, USA) were used. 250 ng mRNA of each sample were pre-incubated with 5 µl random hexamer at 85°C for 3 min. Next, 10 µl 10× PCR buffer, 22 µl MgCl<sub>2</sub>, 20 µl deoxyribonucleoside triphosphate, 6.25 µl multiscribe reverse transcriptase and 2 µl RNase inhibitor were added per sample. Lastly, reaction was performed under these conditions: annealing (25°C, 10 min), reverse transcription (48°C, 60 min), and enzyme inactivation (95°C, 5 min).

For miRNA, reverse transcription was carried out with the miRCURY LNA RT Kit (Qiagen, Hilden, Germany). 10 ng of RNA were mixed with 2 µl of 5× reaction buffer, 5 µl of nuclease free water and 1 µl of enzyme mix, per sample. Reaction was performed using the following program: reverse transcription (42°C, 60 min) and enzyme deactivation (95°C, 5 min).

Reactions were carried out on a PRISM 7700 Cyclor (Applied Biosystems, Waltham, MA, USA) and transcribed cDNA was stored at -20°C until further analysis.

Real time qPCR of mRNA and miRNA targets was performed to analyze gene expression using the StepOnePlus Real-Time PCR System (Thermo Fisher Scientific, Waltham, MA, USA). For mRNA, RT-qPCR was carried out with TaqMan qRT-PCR reagents (all Thermo Fisher Scientific, Waltham, MA, USA) and pre-designed assays. For target normalization, different endogenous controls were used: ribosomal protein L13a (RPL13A), actin beta (ACTb), Hydroxymethylbilane Synthase (HMBS) and TATA-Box binding protein (TBP) were tested. TBP was the most stable across groups, and thus selected as suitable endogenous control. For each reaction, 3.5 µl cDNA (8.75 ng cDNA) was mixed with 0.5 µl nuclease free water, 5 µl Fast Advanced Mastermix and 0.5 µl TBP primer and 0.5 µl target primer (see list of primers in Table 1).

For miRNA, the miRCURY LNA SYBR Green PCR Kit (Qiagen, Hilden, Germany) and pre-designed miRCURY LNA miR PCR assays (Qiagen, Hilden, Germany) were used. Based on previous experience from our group (12, 13) and on the recommendations by TaqMan Advanced miRNA Assays (<https://assets.thermofisher.com/TFS-Assets/GSD/Reference-Materials/identifying-mirna-normalizers-white-paper.pdf>), the ribosomal RNA 5s and hsa-miR-16 were tested as endogenous controls. Due to differences found in the expression of 5s between groups, hsa-miR-16 was selected as suitable endogenous control, based on its comparability and standard deviation across groups and samples. Each miRNA was run adding 5 µl 2× miRCURY SYBR Green Master Mix with 1 µl ROX per 50 µl and 1 µl primer (see list of primers in Table 1) to 4 µl of 1:80 diluted cDNA.

Each mRNA and miRNA was amplified in triplicates and relative quantitation (RQ) values were obtained by the StepOnePlus<sup>™</sup> Software v2.3 (Thermo Fisher Scientific, Waltham, MA, USA) using interpolate calibrators through the 2-ΔΔCt method.

## Protein analysis

Cytokine levels were measured in serum and CSF using the Ella<sup>™</sup> technology (ProteinSimple, San Jose, Cal, USA). Ella<sup>™</sup> is a fully automated cartridge-based system that allows you to perform multiple sample, multi-analyte immunoassays with the specificity of a traditional single-plex ELISA (enzyme-linked immunosorbent assay). Samples were thawed on ice and more than two freeze-thaw cycles were avoided. Samples were diluted 1:1 in the appropriate sample diluent from each kit and 50 µl were added to each sample well of the Simple Plex<sup>™</sup> cartridge, after 1 ml of washing buffer was added to their corresponding wells. Each sample was measured in triplicates, and the levels of each cytokine were displayed in pg/ml.

## Lipid analysis

Serum and CSF samples were quantitatively analyzed for their levels of the endogenous metabolites carnitine (CAR), palmitoylcarnitine (PC) and oleoylcarnitine (OC) by LC-MS/MS (liquid chromatography coupled with tandem mass spectrometry).

All samples were thawed on ice for the first time for this analysis, in order to avoid freeze-thaw cycles, and processed within two years upon collection. Serum samples were analyzed at a neat dilution and after applying a 1:10 dilution step in 70% (v/v) ethanol. For sample

\*Taqman Primers were purchased from Thermo Fisher Scientific, Waltham, MA, USA.

<sup>#</sup>SYBR Green Primers were purchased from Qiagen, Hilden, Germany.

TRPV1, transient receptor potential cation channel subfamily V member 1; TLR4, toll-like receptor 4; SIRT1, sirtuin 1; TNF $\alpha$ , tumor necrosis factor  $\alpha$ ; IL, interleukin; CCL2, CC-chemokine ligand 2; TBP, TATA-Box binding protein; miR, microRNA, rRNA, ribosomalRNA.

preparation, 50  $\mu$ l of serum or CSF samples were mixed with 150  $\mu$ l internal standard solution (100 ng/ml acetylcarnitine-d3 in acetonitrile). Samples were centrifuged (13000 rpm, 1.5 min) and the supernatant was used for analysis.

Chromatographic separation was performed with a UHPLC System (1290 Infinity series, Agilent) using a Waters Acquity UHPL CSH<sup>TM</sup> Fluoro-Phenyl (75  $\times$  2.1 mm, 1.7  $\mu$ m) column. The injection volume was 2  $\mu$ l and the flow rate was set to 0.3 mL/min. For the chromatographic separation a gradient was run using 0.1% formic acid in water (solvent A) and 0.1% formic acid in acetonitrile (solvent B). Detection was performed by means of a triple quadrupole mass spectrometer (API 4000<sup>®</sup>, Sciex) in multiple reaction monitoring (MRM) mode. Measurements were carried out in the positive electrospray ionization (ESI) mode. The LC-MS/MS system was operated with the Software Analyst<sup>®</sup>, Version 1.7.1 (Sciex).

Calibration samples were prepared in 30% acetonitrile and covered calibration ranges of 5 - 500 ng/ml for PC and OC and 5 - 1500 ng/ml for CAR. To verify method performance at medium analyte concentrations, QC samples with a concentration of 50.00 ng/ml CAR, OC and PC were prepared in 30% acetonitrile or in a surrogate matrix comparable to the analyzed biological samples (2% bovine serum albumin (BSA) or PBS buffer pH 7.4 diluted 1:10 in 30% acetonitrile were used to mimic serum or CSF, respectively).

Correlation coefficients of 0.9996 (CAR, OC) and 0.9992 (PC) were obtained. Accuracies of the calibration samples were found within +/-15% or within +/-20% for the lowest calibration level, respectively. Mean accuracies for all QC samples were found between

87.07% and 109.77% with CVs < 15%, indicating an acceptable method performance for all matrices investigated.

Further analytical information can be found in the **Supplementary Material**.

## Statistical analysis and visualization

Statistical analysis was performed in SPSS 27 (IBM, Armonk, NY, USA), where the Shapiro-Wilk test was used to determine the normal distribution of the data. For parametric data, a T-test was used for comparison between two groups and a Pearson test was performed for correlations. In non-parametric data, the Mann-Whitney U Test was applied for comparison of two groups, and the Spearman test was used for correlations. Data results were plotted in GraphPad Prism 9 (GraphPad Software, Inc., La Jolla, CA, USA) for visualization. Graphical images were incorporated from Smart Servier Medical Art, <https://smart.servier.com/>, under the Creative common Attribution 3.0 Unported Licence.

## Results

### Clinical characteristics of patient cohort

Baseline characteristics of the study group and the diagnostic subgroups are summarized in **Table 2**. Patients were included if they presented for diagnostic work-up for their PNP, including lumbar puncture. To be included, they further needed to have either no pain (NRS = 0) or pain  $\geq$  4 at the time of admission. Patients with an NRS between one and three were excluded from the cohort. After applying the exclusion criteria, twenty-eight patients with PNP of different etiologies were included [median body max index (BMI) 28.3, range 19.2-35.1; median age 54.5 years, range 20-80]. The median disease duration was 2.5 years (range 0.02-29 years). Nine patients were diagnosed with an inflammatory neuropathy including non-systemic vasculitis (six patients), chronic inflammatory demyelinating polyneuropathy (CIDP) (two patients) and multifocal motor neuropathy (MMN) (one patient). Nineteen patients were classified as non-inflammatory, including idiopathic neuropathy (nine patients), hereditary neuropathy (five patients), a neuropathy caused by vitamin B deficiency (three patients) or diabetic neuropathy (two patients).

Patients were classified as painless when they presented an NRS = 0 (fourteen patients; 50%), and as painful with an NRS  $\geq$  4 (fourteen patients; 50%). From the full cohort of PNP patients, at the time of inclusion fifteen patients had been treated for their neuropathy with either an immunosuppressive/immunomodulatory drug (six patients) and/or pain treatment (twelve patients), while thirteen received no treatment.

Further laboratory and electrophysiological data are given in **Table 3**. The median CRP value in serum was 0.24 mg/dl (range 0-2.37 mg/dl). In CSF, patients presented a median of 2 leukocytes/ $\mu$ l (range 0-6 cells/ $\mu$ l) and a median total protein of 46.3 mg/dl (range 19.3-194.6 mg/dl). Nerve conduction studies showed a median sural nerve sensory nerve action potential (SNAP) of 4.9  $\mu$ V (range 2.5-12.6  $\mu$ V) with a median nerve conduction velocity (NCV) of 45.9 m/s

(range 32.4-57.3 m/s), and in the tibial nerve a median compound motor action potential (CMAP) upon stimulation at the ankle of 5.4 mV (range 0.1-23.4 mV) and a median nerve conduction velocity (NCV) of 38.3 m/s (range 26.8-52.2 m/s).

## Control group

Patients that presented with acute headaches of unclear etiology (AH) and had a lumbar puncture to exclude meningitis or a subarachnoid bleed were used as controls for the CSF data. Only patients that had less than four leukocytes/ $\mu$ l in their CSF and normal protein values were included. After full clinical work-up, five of these patients had some signs of inflammation (elevated CRP,  $n = 3$ ; sinusitis,  $n = 1$ ; or elevated ANA and ANCA titers,  $n = 1$ ). Thus, the AH group was divided into two groups (unclear headache, UH, and inflammatory headache, IH), and only patients with UH were further used as controls for inflammatory markers (Table 4, Figure 1A). Twelve healthy volunteers (HC) were included as controls for NFL and inflammatory markers in serum. HC and AH did not differ in age or NFL levels in pg/ml in serum (Figures 1B, C), and in both groups a positive correlation between age and NFL was present (HC,  $p < 0.05$ ; AH,  $p < 0.01$ ) (Figure 1D). When separating AH into UH and IH, NFL levels did not differ between groups, but IL-6 was higher in IH in comparison to HC ( $p < 0.001$ ) (Figure 1E).

These results supported our decision to continue the study on inflammatory markers with the UH exclusively, while the whole cohort (AH) was used for the NFL analysis.

## NFL levels in serum and CSF from PNP patients

NFL was measured in serum and CSF in twenty-eight patients with PNP in comparison to ten age-matched AH (Figures 2A, B). PNP patients had higher serum levels of NFL than AH ( $p < 0.01$ ) (Figure 2C). There was a positive correlation between age and NFL levels in AH ( $p < 0.01$ ) but not in PNP patients (Figure 2D). NFL levels correlated negatively to sural nerve SNAP in PNP patients (Figure 2E), which translated into higher levels of NFL in patients with abnormal SNAP values ( $< 5 \mu$ V) in comparison to those with normal SNAP ( $\geq 5 \mu$ V) ( $p < 0.01$ ) (Figure 2F).

The same analysis was performed with CSF samples (Figure 3A) and we observed higher levels of NFL in PNP patients in comparison to AH ( $p < 0.001$ ) (Figure 3B). Again, a correlation between age and NFL was present in AH ( $p < 0.001$ ) but not in PNP patients (Figure 3C). Furthermore, our results showed a negative correlation between the levels of NFL in CSF and the MRC sumscore (Figure 3D), therefore suggesting an involvement of NFL release in the severity of the neuropathy.

TABLE 3 Clinical findings in PNP patients versus controls.

## Gene expression of pro- and anti-inflammatory markers in whole blood

In twenty-seven out of twenty-eight PNP patients and five UH, we analyzed the gene expression of the receptors TRPV1 and TLR4; the deacetylase SIRT1; the pro-inflammatory cytokines TNF $\alpha$ , IL-1 $\beta$ , IL-6 and IL-8, and chemokine CCL2; the anti-inflammatory cytokine IL-10; and the microRNAs miR-146a-5p, miR-132-3p and miR-155-5p in whole blood (Figure 4A). The expression results of PNP patients, with painful and painless PNP, and inflammatory and non-inflammatory PNP are displayed as fold change in comparison to UH in Table 5. Comparisons between PNP patients and controls, as well as between painful and painless PNP subgroups, and inflammatory and non-inflammatory did not show any differences in the expression of these components.

Interestingly, PNP patients were next grouped into patients with and without systemic inflammation based on increased CRP levels in the serum (cut-off 0.5 mg/dl). Patients with systemic inflammation had a higher expression of IL-10 in comparison to those with normal CRP levels ( $\leq 0.5$  mg/dl) ( $p < 0.001$ ) (Figure 4B) and a positive correlation was found between CRP levels and IL-10 expression ( $p < 0.01$ ) (Figure 4E). Furthermore, PNP patients with high CSF total protein ( $> 50$  mg/dl) also presented lower expression of TNF $\alpha$  (Figure 4C) and

higher expression of miR-155 (Figure 4D) than those with normal levels ( $\leq 50$  mg/dl). Moreover, a multivariate correlation analysis (Figure 4E) showed that CCL2 correlated positively with the duration of the disease ( $p < 0.001$ ) while negatively with several neuropathy scores such as sural nerve SNAP amplitudes ( $p < 0.01$ ) or GCPS, indicating a relation between inflammation and axonal degeneration.

## Cytokine protein levels in sera

As indicators of systemic inflammation, we analyzed the levels of the pro-inflammatory cytokines TNF $\alpha$ , IL-1 $\beta$ , IL-6 and IL-8, the chemokine CCL2, and the anti-inflammatory cytokine IL-10 in sera from twenty-eight patients with PNP and five UH (Figure 5A). Furthermore, we measured the levels of nerve growth factor beta (NGF- $\beta$ ) in sera, since it is involved in nociceptive processing and a target of novel analgesics (40). The CSF from the same cohort was available and we measured the levels of the pro-inflammatory cytokines IL-6 and IL-8, and the chemokines CCL2 and fractalkine (CX3CL1). TNF $\alpha$ , IL-1 $\beta$  and IL-10 were not detected in these samples (data not shown). All results are detailed in Table 6.

CCL2 was present in higher levels in serum in PNP in comparison to UH, while no differences were discovered for the other analyzed

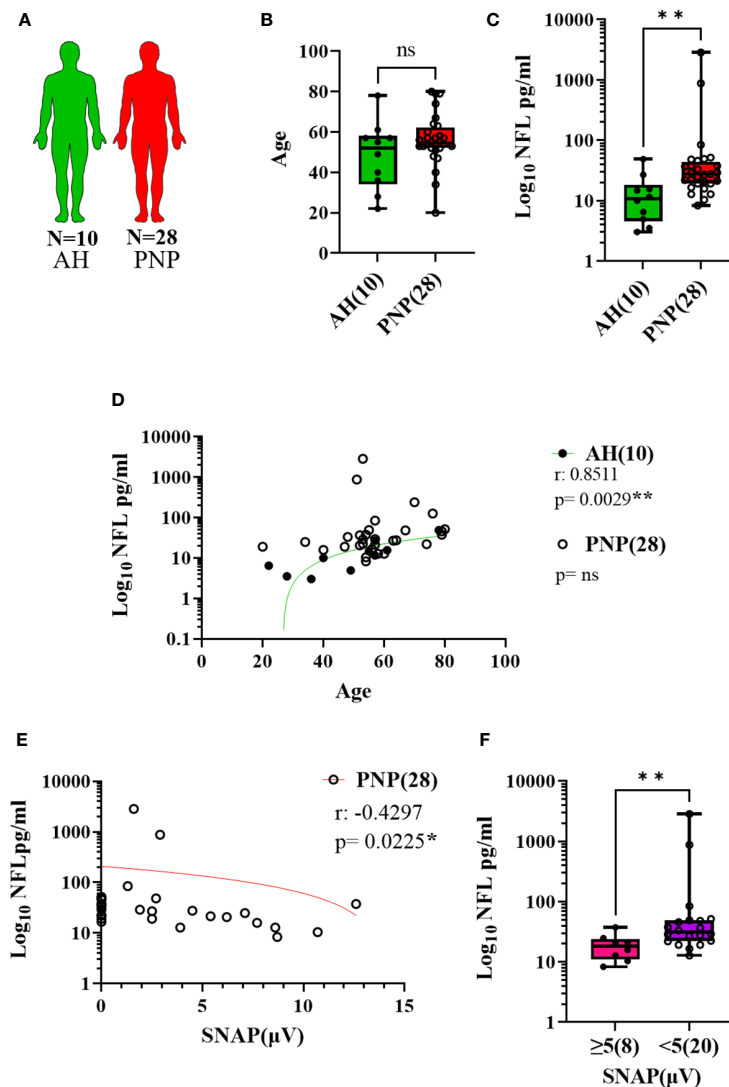

FIGURE 2

NFL levels in serum from patients with PNP. (A) Visual representation of the analyzed 10 AH (green) and 28 PNP patients (red). (B) Age values in AH and PNP. (C) Log<sub>10</sub> of NFL levels in pg/ml between AH and PNP. (D) Correlation between age and log<sub>10</sub> of NFL levels in pg/ml in AH and PNP. (E) Correlation between log<sub>10</sub> of NFL levels in pg/ml and SNAP. (F) Log<sub>10</sub> of NFL levels in pg/ml between PNP patients with normal ( $\geq 5\mu\text{V}$ ) and abnormal ( $< 5\mu\text{V}$ ) sural nerve SNAP. ns, not significant; \*,  $p < 0.05$ ; \*\*,  $p < 0.01$ . All graphical images were incorporated from Smart Servier Medical Art, <https://smart.servier.com/>, under the Creative common Attribution 3.0 Unported Licence.

markers. CCL2 was specifically upregulated in PNP patients under analgesic treatment ( $p < 0.05$ , Figure 5B). No differences were discovered between the PNP subgroups inflammatory and non-inflammatory. On the other hand, patients with a painful PNP had higher levels of IL-10 in sera than those with no pain ( $p < 0.01$ , Figure 5C). A multivariate analysis showed that the levels of IL-10 positively correlated with the pain scores in NRS ( $p < 0.01$ ), NPSI ( $p < 0.05$ ) and GCPS ( $p < 0.05$ ) (Figure 5D).

## Analysis of the relation of proteins between sera and CSF in PNP patients

The proteins present in CSF, such as NFL or inflammatory components, may be intrathecally produced or have infiltrated from the blood vessels due to a permeabilization of the B-CSF barrier. In

order to study the origin of NFL and cytokines in CSF, we compared the levels of albumin between CSF and serum (albumin ratio in CSF/ in serum:  $Q_{\text{Alb}}$ ) and divided the patients in subgroups according to the B-CSF barrier integrity: Normal B-CSF barrier integrity ( $Q_{\text{Alb}} < 0.007$ ) and mild ( $0.007 < Q_{\text{Alb}} < 0.01$ ), moderate ( $0.01 < Q_{\text{Alb}} < 0.02$ ) and severe ( $Q_{\text{Alb}} > 0.02$ ) B-CSF barrier dysfunction (Figure S1A) (41). Due to a low number of patients with severe B-CSF barrier dysfunction (2), moderate and severe groups were analyzed together. A moderate/severe B-CSF barrier dysfunction was present more often in inflammatory neuropathies than normal or mild dysfunction (Figure S1B). Furthermore, the albumin ratio ( $Q_{\text{Alb}}$ ) correlated with the severity of the clinical phenotype (Figure S1C). As expected, the levels of total protein in CSF increased as the B-CSF barrier dysfunction became more severe (Figure S1D), thus indicating a higher permeabilization or a relation between an intrathecal production and a B-CSF barrier dysfunction.

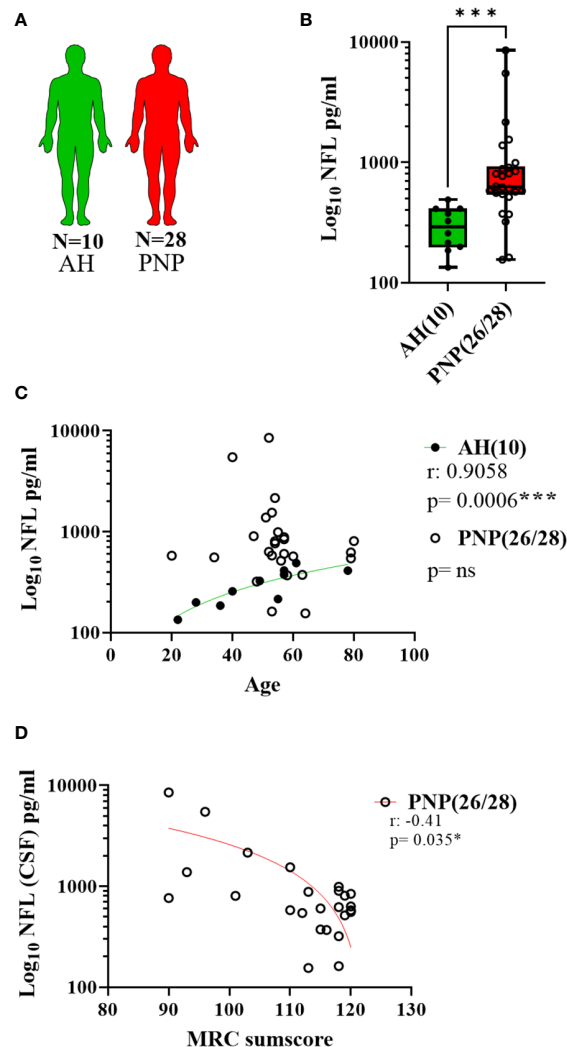

FIGURE 3

NFL levels in CSF from patients with PNP. (A) Visual representation of the analyzed 10 AH (green) and 28 PNP patients (red). (B) Log 10 of NFL levels in pg/ml between AH and PNP. (C) Correlation between age and log 10 of NFL levels in pg/ml in AH and PNP. (D) Correlation between the levels of NFL levels in pg/ml (Log10) and the MRC sumscore in PNP patients. ns, not significant; \*,  $p < 0.05$ ; \*\*\*,  $p < 0.001$ . All graphical images were incorporated from Smart Servier Medical Art, <https://smart.servier.com/>, under the Creative common Attribution 3.0 Unported Licence.

NFL measurements in serum and CSF in the different subgroups of twenty-eight PNP patients and ten AH (Figure 6A) showed higher levels in those patients with moderate/severe B-CSF barrier dysfunction in comparison to those with a normal B-CSF barrier integrity and to AH (Figures 6B, C). This resulted in a constant  $Q_{NFL}$  (NFL ratio in CSF/serum) among subgroups and between PNP and AH (Figure 6D). Furthermore, NFL in serum and CSF correlated positively with the severity of the clinical phenotype (Figure 6E), suggesting that the release of NFL might be a consequence of the severe neurodegeneration.

Interestingly, we found a correlation between the levels of NFL and IL-8 in CSF (Figure 6F), thus indicating a relation between neurodegeneration and inflammation. With this discovery, we decided to study the levels of cytokines between CSF and serum, in order to determine their origin, in the different subgroups of twenty-eight PNP patients and five UH (Figure 7A). This analysis showed that PNP patients with a moderate/severe B-CSF barrier dysfunction present higher levels of IL-6 and IL-8 in CSF and a higher  $Q_{IL-6}$  and

$Q_{CCL2}$  (cytokine ratio in CSF/in serum), than those with a normal B-CSF barrier integrity (Figure 7B). A multivariate analysis showed that the levels of IL-6 in CSF correlated with the overall severity, thus indicating a relation between the production or release of IL-6 and severe PNP (Figure 7C). Interestingly, a second multivariate analysis showed that the levels of most cytokines analyzed in CSF correlated with each other (Figure 7D), therefore suggesting a common stimulus triggering their production, or their involvement in a common pathway

## Acyl-carnitine levels in serum and CSF from PNP patients

In order to complete our study with the analysis of lipid compounds involved in pro-inflammatory pathways, we performed LC-MS to measure the levels of carnitine, palmitoylcarnitine and oleoylcarnitine in serum and CSF from twenty-three PNP patients and five UH (Figure 8A). While carnitine and palmitoylcarnitine in

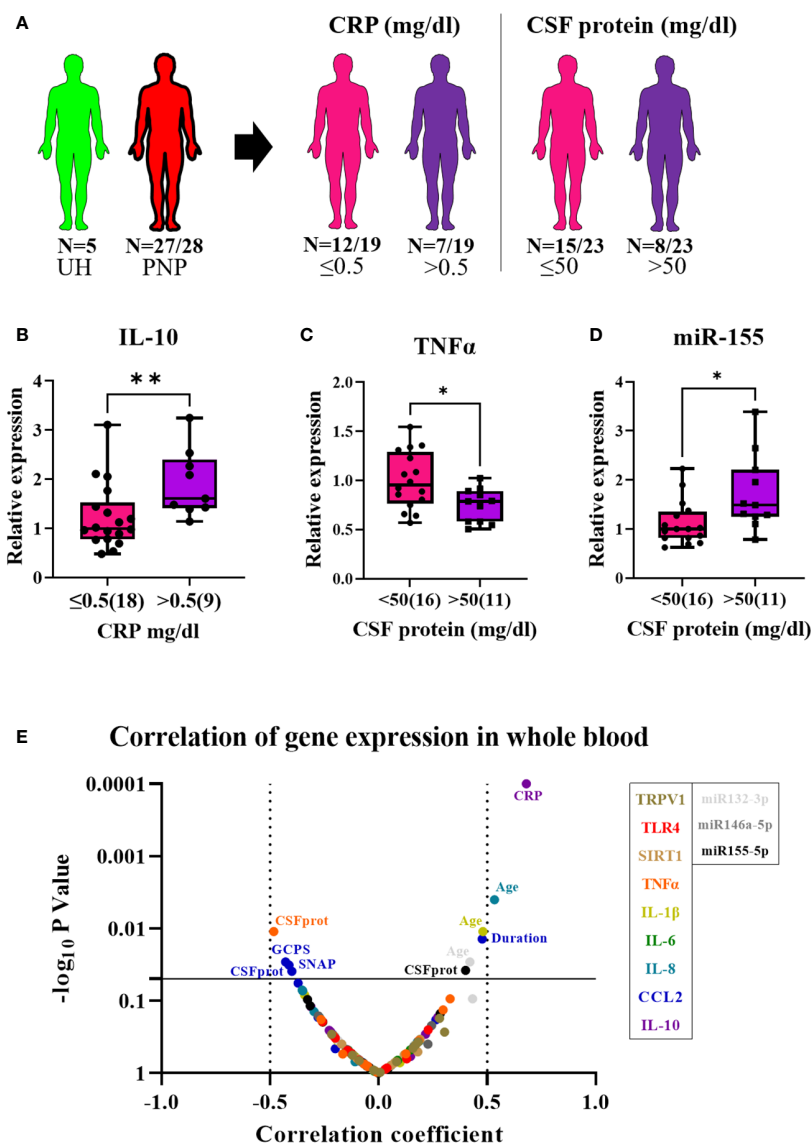

FIGURE 4

Relative gene expression of pro- and anti-inflammatory markers in whole blood from patients with PNP. (A) Visual representation of the analyzed 5 UH (light green) and 27 out of 28 PNP patients (red), further divided into 18 PNP patients with normal ( $\leq 0.5$  mg/dl, pink) and seven with increased ( $> 0.5$  mg/dl, purple) CRP levels in serum, and into 16 PNP patients with normal ( $\leq 50$  mg/dl, pink) and seven with abnormal ( $> 50$  mg/dl, purple) protein levels in CSF. (B) Relative expression of IL-10 in PNP patients with increased CRP in comparison to those with normal values. Relative expression of TNFα (C) and miR-155 (D) in PNP patients with normal and abnormal protein levels in CSF. (E) Volcano plot of the Spearman multivariate correlations between each studied target and the neuropathy scores. \*,  $p < 0.05$ ; \*\*,  $p < 0.01$ . All graphical images were incorporated from Smart Servier Medical Art, <https://smart.servier.com/>, under the Creative common Attribution 3.0 Unported Licence.

serum did not differ between PNP and UH, oleoylcarnitine was found in higher levels in patients with PNP in comparison to UH (Figure 8B). Carnitine was also not different in CSF between PNP patients and UH (Figure 8C). Palmitoylcarnitine and oleoylcarnitine were not detected in CSF samples (data not shown).

Our results also showed that PNP patients with high CSF protein ( $> 50$  mg/dl) had higher levels of carnitine in CSF and a lower serum/CSF ratio than those with normal protein levels ( $p < 0.001$ ) (Figure 8D).

Furthermore, we observed that the levels of palmitoylcarnitine and oleoylcarnitine in serum positively correlated in patients with PNP ( $p < 0.0001$ ) and in UH ( $p < 0.001$ ) (Figure 8E). Interestingly, a multivariate analysis found a positive correlation between the levels of

carnitine in serum and the mTCNS ( $p < 0.001$ ) as well as between the levels of carnitine in serum and the overall severity (Figure 8F).

## Discussion

In this study, we investigated the gene expression, protein and lipid levels of different pro-inflammatory markers in blood and CSF from patients with PNP, in comparison to a control group of patients with acute headaches of unclear etiology.

Our results showed that, contrary to our initial hypothesis of PNP being associated with enhanced systemic inflammation, PNP patients and disease controls did not present major differences in systemic

inflammatory markers. Receptors of great interest in the fields of inflammation and pain, TLR4 and TRPV1, were not informative in our cohort. While only CCL2 and oleoylcarnitine were present in higher levels in sera from PNP patients than in controls, the levels of CCL2 were associated to pain treatment.

Oleoylcarnitine, as one of the long-chain acylcarnitines found upstream of the synthesis of prostaglandins and thromboxanes, has been described upregulated in patients with systemic inflammation, as well as in different neuronal tissues in models of neurodegeneration (20, 22, 24). This suggests that the levels of oleoylcarnitine indicate an inflammatory process or neurodegeneration taking place in patients with PNP. Since it did not correlate with any neuropathy scores, we postulate that oleoylcarnitine is upregulated in all patients with PNP, and it might be of interest to explore as a potential early diagnostic marker in larger groups of different types of PNP versus controls.

Secondly, we hypothesized that a systemic inflammation may correlate with the severity of the disease and the development of neuropathic pain. Our study showed that IL-10 was the only inflammatory mediator consistently upregulated at the gene and protein level in patients with severe pain, in comparison to those without pain. IL-10 is understood as an anti-inflammatory cytokine, mainly produced by anti-inflammatory macrophages, and secreted to suppress pro-inflammatory responses and maintain tissue homeostasis (42). In patients with different neuropathies, levels of IL-10 have been described downregulated in serum and CSF and negatively correlating with pain scores, therefore suggesting an increased systemic inflammation (26–30). Our study, on the other hand, showed a positive correlation between IL-10 and CRP, confirming the involvement of IL-10 in inflammatory responses, potentially in a counter-regulatory function. Our results are in accordance with previous studies where higher levels of IL-10 were reported in serum from patients with neuropathies (27, 43, 44). This suggests that the higher expression of IL-10 might act as a

compensatory mechanism against the inflammation triggered by neuropathy-specific processes. However, high levels of IL-10 as well as of IL-10 expressing blood mononuclear cells have been found related to large nerve fiber sensory and motor axonal damage, as well as motor nerve demyelination (28, 45). Therefore, we cannot exclude the option that the overexpression of IL-10 might also play a direct role in the pathogenesis of nerve fiber damage.

Severe neuropathy indicated by a low SNAP correlated with high gene expression of CCL2. CCL2 and its receptor CCR2 can cause hyperalgesia through the upregulation of cation channels (46–48). In addition, CCL2, also named monocyte chemoattractant protein-1 (MCP-1), is directly involved in the migration and infiltration of monocytes, memory T lymphocytes, and natural killer (NK) cells, therefore also promoting local inflammatory processes (49). High systemic levels of CCL2 might thus correlate with the development of neuropathic symptoms and could serve as a severity marker of the neuropathy. Furthermore, the high levels of CCL2 might also be due to the treatment of pain as previously mentioned. More specifically, PNP patients with the highest levels of CCL2 were those that had been treated with opioids. This could either be indicate of a molecular interaction or simply support that severe neuropathy is more likely to be painful and therefore being properly treated. Kaminski et al. provided evidence for a molecular interaction because inhibition of opioid receptors led to a downregulation of CCL2 (50). On the other hand, high levels of CCL2 can inhibit the activation of opioid receptors, thus attenuating analgesia (51, 52). This suggests that the high CCL2 levels might be a compensatory effect from the opioid treatment. Further studies need to elucidate the role of CCL2 in the development of PNP and its symptoms.

Interestingly, we found that patients with a severe B-CSF barrier dysfunction, determined by the CSF/serum albumin ratio (41), also presented higher levels of NFL in serum and CSF, as well as higher levels of IL-6 and IL-8 in CSF. NFL constitutes one of the subunits of

the neurofilament that forms the cytoskeleton in neurons. Neurofilaments are especially abundant in large myelinated axons, while relatively scarce in dendrites, and their release has been described as a marker of neurodegeneration or upon neuroaxonal damage (36, 53–59). As expected, NFL levels in CSF and serum of our PNP group were increased in comparison to the controls, indicating neurodegeneration. This increase seemed to be present especially in those PNP patients with B-CSF barrier dysfunction, both in serum and CSF, while no difference was found in PNP patients with a

normal B-CSF barrier and controls. The correlation we found between the albumin ratio ( $Q_{Alb}$ ) and the severity of the neuropathy may indicate that patients with a moderate to severe B-CSF barrier dysfunction also present more severe neuropathy and thus, more neurodegeneration, explaining the higher levels of NFL in these patients. Furthermore, while a break of the B-CSF barrier would allow the exchange of proteins between serum and CSF, the levels of NFL were consistently higher in CSF than in sera, thus indicating an intrathecal production. Since we found higher NFL levels in serum

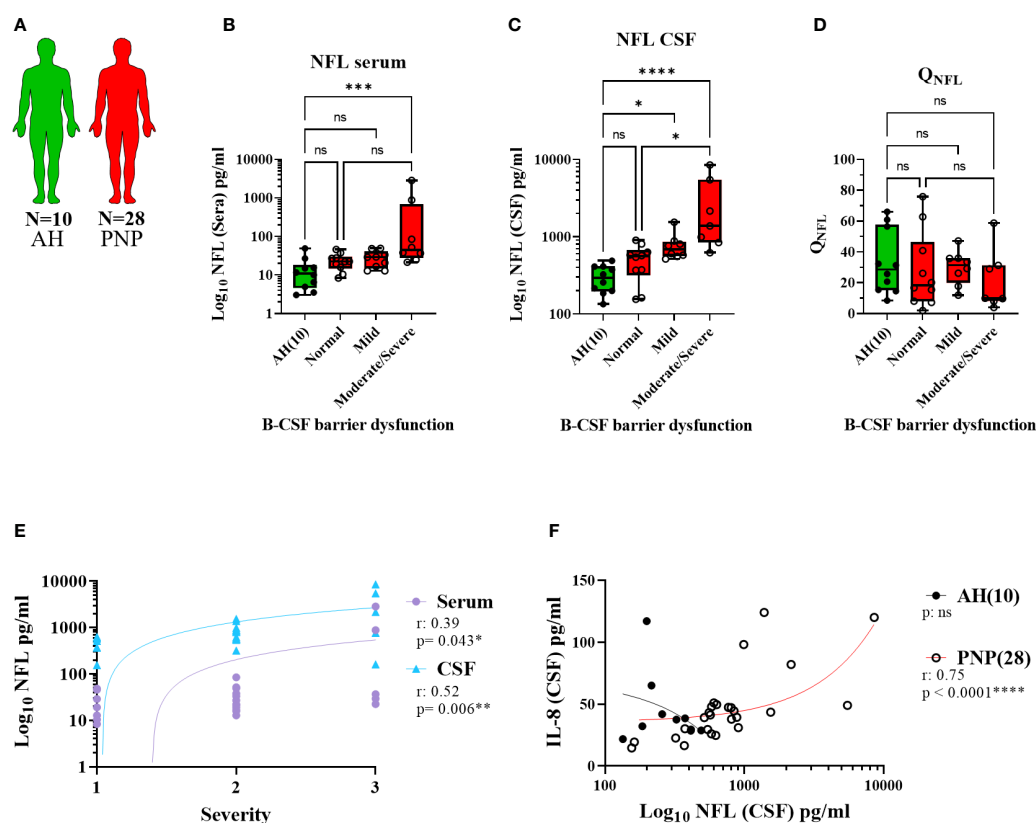

FIGURE 6

Levels of NFL between CSF and serum from patients with PNP. (A) Visual representation of the analyzed 5 AH (green) and 28 PNP patients (red). Levels of NFL in serum (B) and CSF (C) in patients with normal B-CSF barrier function, or mild, moderate and severe B-CSF barrier dysfunction. (D). NFL ratio between CSF and serum ( $Q_{NFL}$ ) in AH and the subgroups of PNP patients according to their B-CSF barrier dysfunction. (E) Correlation between the levels of NFL in serum (●) and CSF (▲) and the subjective severity. (F) Correlations between the levels of IL-8 and NFL in CSF in pg/ml. ns, not significant; \*,  $p < 0.05$ ; \*\*,  $p < 0.01$ ; \*\*\*,  $p < 0.001$ ; \*\*\*\*,  $p < 0.0001$ . Interestingly, patients with a severe B-CSF barrier dysfunction also presented higher levels of IL-6 and IL-8 in CSF, while the levels in sera remained constant, therefore causing an increment of their CSF/serum ratio. Since 1993, high levels of IL-6 and IL-8 have been reported in CSF of patients with GBS and CIDP. This study as well as more recent ones suggest a prominent intrathecal activation of cells of the monocyte/macrophage lineage, leading to the intrathecal production of the cytokines (66–68). Following a similar line of thought, we postulate that inflammation is present at the level of the nerve roots and leads to the release of pro-inflammatory cytokines directly to the CSF. Furthermore, this inflammation may cause neuronal damage and disruption of the axonal cell membrane, inducing the releases of NFL into the CSF compartment (69). The finding of a strong correlation between the levels of IL-8 and NFL in CSF supports this assumption and leads to the question whether they are simultaneously released from the same cell type, or whether they consecutively induce each other's release. Moreover, the levels of IL-6 in CSF correlated with the severity of neuropathy, thus indicating that the inflammation at the nerve roots might be the cause or consequence of the

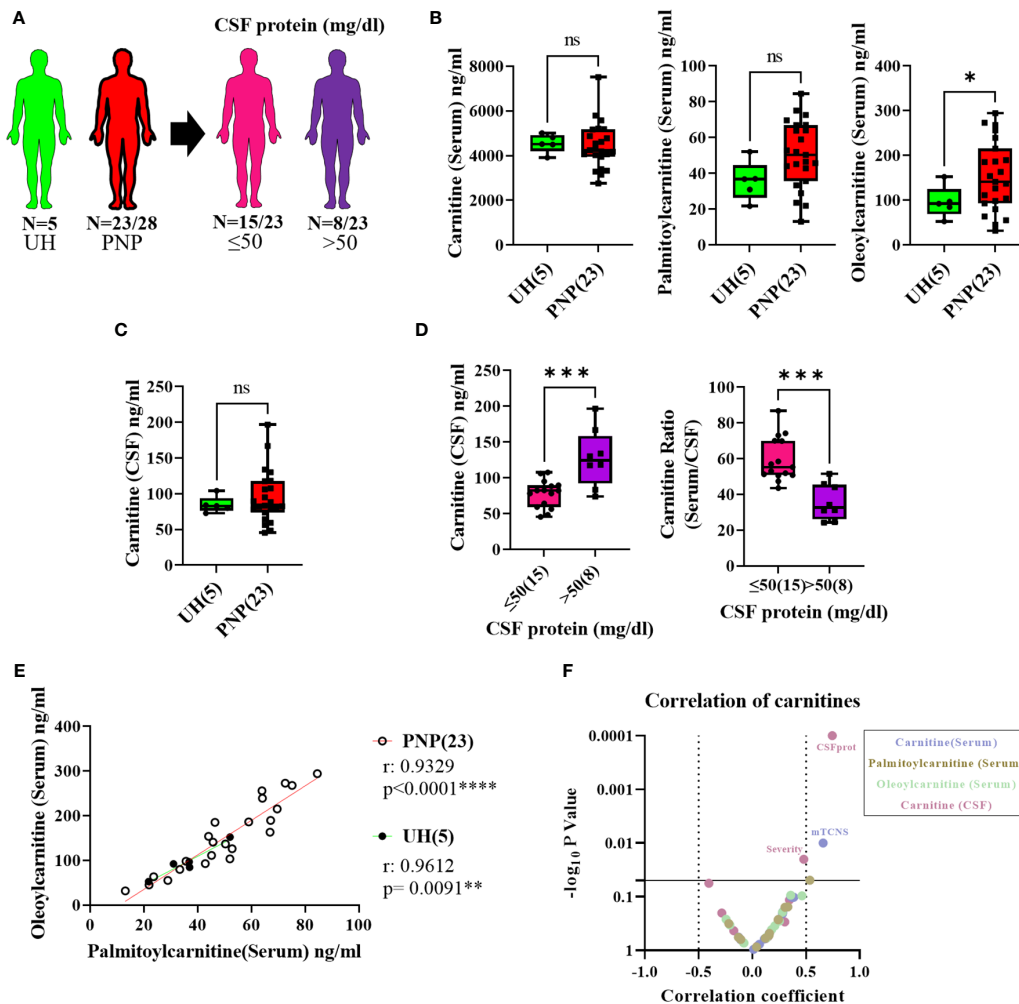

FIGURE 8

Levels of pro-inflammatory lipids in serum and CSF from patients with PNP. (A) Visual representation of the analyzed 5 UH (light green) and 23 out of 28 PNP patients (red), further divided into 15 PNP patients with normal ( $\leq 50$  mg/dl) (pink) and 8 with an abnormal ( $> 50$  mg/dl) (purple) CSF total protein. (B) Levels of carnitine, palmitoylecarnitine and oleoylecarnitine in ng/ml in serum from UH and PNP patients. (C) Levels of carnitine in ng/ml in CSF from UH and PNP patients. (D) Levels of carnitine in ng/ml in CSF (left) and its ratio (serum/CSF) (right) in PNP patients with normal and abnormal CSF total protein. Correlations can be found between oleoylecarnitine and palmitoylecarnitine (ng/ml) in serum from UH and PNP patients (E). (F) Volcano plot of the Spearman multivariate correlations between each carnitine and the neuropathy scores. \*  $p < 0.05$ ; \*\*,  $p < 0.01$ ; \*\*\*,  $p < 0.001$ ; \*\*\*\*,  $p < 0.0001$ . neurodegeneration. This would indicate that patients with more severe neuropathic symptoms would present an affection of the nerve roots and a break of the B-CSF barrier, supporting the importance of CSF analysis as a diagnostic tool for patients with PNP (70). Being an invasive procedure, lumbar puncture to obtain CSF is not without risks, and patients need to sign informed consent, however, the risk of headache, the most frequent adverse effect of lumbar puncture, can be markedly reduced by that use of an atraumatic needle (71). Other adverse effects are extremely rare when the lumbar puncture is properly performed.

Although our study includes the analysis of a large number of pro- and anti-inflammatory markers, non-biased omics-based analysis might be necessary to identify all involved markers and elucidate the specific pathways taking place in PNP. Furthermore, our results are limited by the very well characterized but low number of

recruited patients and the variance in etiologies. A larger cohort might help separating the patients into males and females and into diagnostic subgroups that could lead to clearer results.

We conclude that in patients with PNP systemic inflammatory markers in blood or CSF do not differ from controls in general, but specific cytokines or lipids do. Nevertheless, we found several indications of a correlation between inflammation and the neuropathy severity and symptoms. In particular, we described a strong interaction between inflammation and neurodegeneration at the nerve roots in a specific subgroup of PNP patients with B-CSF barrier dysfunction, which highlights the importance of CSF analysis in patients with peripheral neuropathies. We believe that the diagnostic marker panel provided in our study may help improving patient stratification not only to increase diagnostic validity, but also to guide treatment decisions.

## Data availability statement

The original contributions presented in the study are included in the article/**Supplementary Material**. Further inquiries can be directed to the corresponding author.

## Ethics statement

The studies involving human participants were reviewed and approved by Würzburg Medical Faculty Ethics Committee (# 15/19 and # 242/17). The patients/participants provided their written informed consent to participate in this study.

## Author contributions

PG-F, NÜ and CS contributed to conception and design of the study. AR performed the gene expression analysis. KH and NC performed the protein analysis. KS and AN performed the lipid analysis. KH, NC, A-KR, HR, NÜ and CS contributed to recruitment of patients and collection of clinical data. A-KR and HR provided samples from healthy controls. PG-F organized the database and performed the statistical analysis. PG-F wrote the first draft of the manuscript. KS and AN wrote a section of the manuscript. All authors contributed to the article and approved the submitted version.

## Funding

This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie Grant Agreement No. 764860. This publication was supported by the Open Access Publication Fund of the University of Würzburg

# In search of immune cellular sources of abnormal cytokines in the blood in autism spectrum disorder: A systematic review of case-control studies

Wared Nour-Eldine, Samia M. Ltaief,  
Nimshitha P. Abdul Manaph and Abeer R. Al-Shammari\*

Neurological Disorders Research Center, Qatar Biomedical Research Institute, Hamad Bin Khalifa University, Qatar Foundation, Doha, Qatar

Abnormal cytokine levels in circulating blood have been repeatedly reported in autism; however, the underlying cause remains unclear. This systematic review aimed to investigate cytokine levels in peripheral blood compartments and identify their potential immune cellular sources in subjects with autism through comparison with controls. We conducted an electronic database search (PubMed, Scopus, ProQuest Central, Ovid, SAGE Journals, and Wiley Online Library) from inception (no time limits) to July 9, 2020, and identified 75 relevant articles. Our qualitative data synthesis focused on results consistently described in at least three independent studies, and we reported the results according to the PRISMA protocol. We found that compared with controls, in subjects with autism, cytokines IL-6, IL-17, TNF- $\alpha$ , and IL-1 $\beta$  increased in the plasma and serum. We also identified monocytes, neutrophils, and CD4+ T cells as potential sources of these elevated cytokines in autism. Cytokines IFN- $\gamma$ , TGF- $\beta$ , RANTES, and IL-8 were increased in the plasma/serum of subjects with autism, and IFN- $\gamma$  was likely produced by CD4+ T cells and natural killer (NK) cells, although conflicting evidence is present for IFN- $\gamma$  and TGF- $\beta$ . Other cytokines—IL-13, IL-10, IL-5, and IL-4—were found to be unaltered in the plasma/serum and post-stimulated blood immune cells in autistic individuals as compared with controls. The frequencies of T cells, monocytes, B cells, and NK cells were unchanged in subjects with autism as opposed to controls, suggesting that abnormal cytokines were unlikely due to altered cell numbers but might be due to altered functioning of these cells in autism. Our results support existing studies of abnormal cytokines in autism and provide comprehensive evidence of potential cellular sources of these altered cytokines in the context of autism.

## KEYWORDS

immune cells, cytokines, blood, autism, systematic review, case-control

## Introduction

Autism spectrum disorder (ASD) is a heterogeneous neurodevelopmental disorder characterized by stereotyped behaviors and interests, impaired communication skills, and difficulties in social interactions. Autism is present in early childhood and affects approximately 1 in 100 children (1), according to World Health Organization epidemiological data (2022). Despite the high prevalence of autism, the etiologies and pathogenesis are still not clearly defined but are known to involve genetic and environmental factors and complex interactions between them.

Emerging evidence supports the link between immune disruption and autism. Epidemiological studies indicate that maternal infection during pregnancy is associated with an increased risk of autism development in the offspring (2–4). These correlation studies are also supported by animal models of maternal immune activation; these models give rise to offspring that exhibit behavioral and neuropathological deficits relevant to autism (3). In addition, a family history of autoimmunity and autoantibodies is also associated with an increased risk of autism (5, 6). An increased number of autoantibodies are produced by mothers with a family history of autoimmunity; these autoantibodies may target specific proteins in the fetal brain that affect neurodevelopment, which might lead to autism-related behaviors in the offspring (5, 6). In contrast, neonatal studies have shown that immune dysregulation has been detected at birth in children who later develop autism. For example, several studies have identified a correlation between abnormal levels of several cytokines in neonatal bloodspots, such as IL-1 $\beta$ , IL-6, IL-8, and RANTES, and increased risk of developing autism (7–11). Together, these studies indicate that abnormal immune factors are present during early development, before the onset of autism symptoms, and accordingly suggest that immune dysfunction is more likely to be a contributing cause of autism rather than an outcome (12).

Remarkably, immune dysregulation persists postnatally, and ongoing inflammation has been observed in individuals with autism. Several studies have revealed abnormal cytokine levels in the peripheral blood of subjects with autism, which were also associated with increased severity of autism symptoms (13, 14). Similarly, there is evidence of increased inflammatory cytokines in brain tissues and cerebrospinal fluid, as well as active neuroinflammation in the brains of individuals with autism (13–15). Cytokines play a substantial role in the brain by signaling other cells to remove dead and damaged neurons and conducting physiological and neuroprotective functions. Increased levels of inflammatory cytokines in the peripheral immune system are also correlated with increased expression of these cytokines in brain neurogenic niches, which could lead to disrupted synaptic plasticity and impaired behavioral outcomes in autism (6, 16, 17). Therefore, persistent abnormalities in

peripheral cytokine levels in subjects with autism might reflect changes in cytokine levels in the brain, which are correlated with behavioral deficits in autism.

In this review, we focus on studies that investigated immune profiles in the peripheral blood of subjects with autism compared with controls. Various studies have addressed the implications of peripheral cytokines in the pathophysiology of autism, as reported in previous systematic reviews and meta-analyses (18, 19). However, these reviews focused on the peripheral levels of cytokines in autism without considering their potential cells of origin. This is important for targeted therapies for autism. The objective of this systematic review is to provide an update on the dysregulation of cytokine levels in autism and associate these altered cytokines with their cellular immune sources. To our knowledge, this is the first review to integrate altered cytokines and their specific cellular sources in autism.

## Methods

This study was designed, reported, and executed based on the Preferred Requirements for Systematic Reviews and Meta-Analyses (PRISMA) (20). The review protocol was registered in the International Prospective Register of Systematic Reviews (registration number CRD42020205224) (21). The registered protocol was amended twice to correct a minor typing error and update the current status of the review by adding more details to the protocol sections without changing the original protocol. The PRISMA checklist used in this study is presented in Table S1.

## Inclusion and exclusion criteria

This review focused on studies of immune cells and cytokines in the blood of subjects with autism compared with their matching controls. The inclusion criteria were the following: (1) original articles; (2) case-control studies; (3) sample type: peripheral blood, plasma, or serum; (4) analysis of immune cell percentages; (5) analysis of cytokine levels in plasma, serum, or bloodspot; (6) analysis of cytokine levels in immune cells at baseline or after *in vitro* stimulation; and (7) analysis of protein or gene expression. The exclusion criteria were as follows: (1) animal work; (2) sample type: cerebrospinal fluid, tissues, brain, or cell lines; (3) cases without controls; (4) subjects under medication; (5) analysis of treatment or intervention; (6) analysis of immune cell receptors, transcription factors, or activation markers; and (7) genetic (DNA) analysis.

## Search strategy

We performed electronic searches of six different databases (PubMed, Scopus, ProQuest Central, Ovid, SAGE Journals, and

Wiley Online Library) using consistent terms. We applied a search filter to the English language results and original journal articles. No other limits were applied. The search was conducted from inception to July 9, 2020, which means no time limits were applied at the time of our database search on July 9, 2020. The search terms used in the PubMed database are as follows: (autism OR autistic OR ASD) AND (human OR subject OR child OR participant OR patient OR volunteer) AND (blood OR plasma OR serum OR immune OR peripheral OR circulating) AND ((cytokine OR chemokine OR “growth factor” OR interferon OR “tumor necrosis factor” OR “colony stimulating factor” OR interleukin) OR (lymphocyte OR monocyte OR “B cell” OR “T cell” OR “natural killer” OR “dendritic cell” OR neutrophil OR basophil OR eosinophil OR myeloid)). The search terms for the remaining databases are listed in [Table S2](#).

After removing duplicates, we screened the records for relevance based on title and abstract. The full texts of potentially relevant records were retrieved and assessed for eligibility according to our pre-defined inclusion and exclusion criteria, as detailed above. We then assessed the quality and risk of bias of each eligible study using the NIH Quality Assessment Tool of Case-Control Studies (available at: <https://www.nhlbi.nih.gov/health-topics/study-quality-assessment-tools>), which includes 12 evaluation criteria, and a final rating for each study was given based on the following criteria: 7–12 (good), 4–6 (fair), or 0–3 (poor). Studies with good or fair quality ratings were included in the qualitative synthesis of this review. All steps in the identification, screening, eligibility, and selection of records were performed by two authors independently, followed by discussion and consensus between the two authors, and any disagreement was resolved through discussion with a third author. A PRISMA flow diagram is shown in [Figure 1](#).

## Data extraction

We extracted data from the included studies and separated them into two tables in Word documents. These tables list the main outcome (increase, decrease, or no change) in autism compared with controls for either immune cell percentage or cytokine release from immune cells ([Table S3](#)) and cytokine levels in plasma, serum, or bloodspot ([Table S4](#)). Other data, such as sample size, age range, sample type, and analysis technique, are also included in [Tables S3](#) and [S4](#). From these two tables, we identified results that were consistently reported in at least three studies and placed these data into three sub-tables ([Tables 1, 2, and 3](#)), which formed the basis of this review. Data were extracted by two authors, and all data were re-checked by at least two independent authors to verify accuracy.

## Results

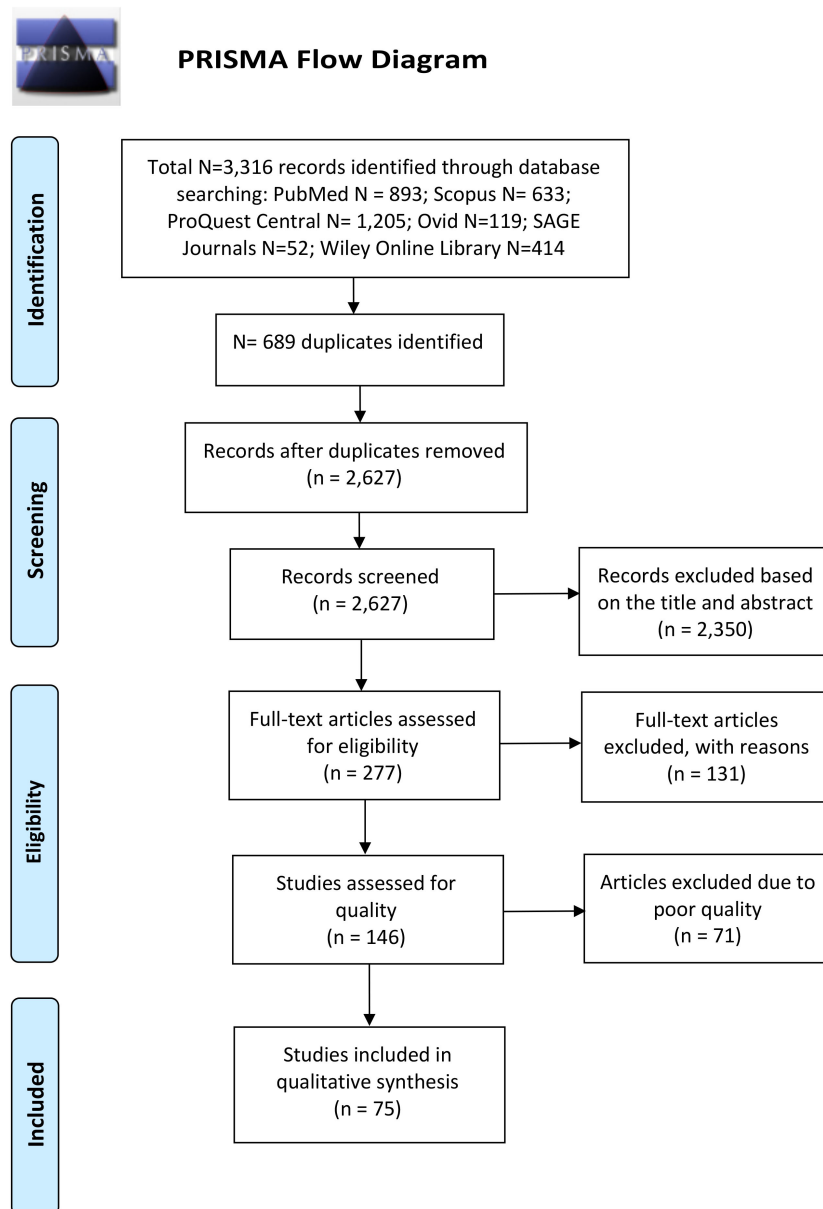

### Study characteristics

We identified a total of 3316 records in our search of six electronic databases: PubMed (N = 893), Scopus (N = 633), ProQuest Central (N = 1205), Ovid (N = 119), SAGE Journals (N = 52), and Wiley Online Library (N = 414), as illustrated in the PRISMA flow diagram in [Figure 1](#). We screened the titles and abstracts of 2627 records after duplicate removal and identified 277 potentially relevant records. We retrieved the full-text articles of 277 records to assess eligibility according to our pre-defined inclusion and exclusion criteria. A total of 131 studies were excluded for the following reasons: non-original article (N = 11); non-autism subjects (N = 5); full-text articles not found (N = 2); non-English articles (N = 1); studies not pertaining to immune cells or cytokines or only on genetic DNA (N = 74); sample type not blood, plasma, or serum (N = 6); autism cases without controls (N = 16); studies on immune-related receptors, transcription factors, or activation markers (N = 5); and studies involving treatment or intervention (N = 11). The results of the quality assessments of the 146 eligible studies are listed in [Table S5](#). Seventy-five studies had an overall rating of at least fair quality and were thus included in the qualitative data synthesis of this review.

### Data synthesis

We generated two comprehensive tables that summarize the reported findings from all 75 studies included in this review ([Table S3](#) and [S4](#)). Data related to immune cell percentages and cytokine production in immune cells are listed in [Table S3](#), whereas data related to cytokine levels in the plasma, serum, or neonatal bloodspot are included in [Table S4](#).

Of note, we did not include results from studies that were unrelated to cell quantification, such as activation markers, transcription factors, and immune cell receptors (e.g., IL-1Ra, CXCR3, CCR6, and IL-6sR). We also excluded results that were not related to cytokines, such as adhesion molecules (e.g., sPECAM-1, sVCAM-1, sP-selectin, and ICAM-1), and enzymes or enzyme inhibitors (e.g., thioredoxin, TIMP-1, and TIMP-2). Growth factors that are not cytokines, such as BDNF, GDNF, EGF, FGF2, NT-3, VEGF, PDGF-BB, and hepatocyte growth factor (HGH), were excluded from this review. Although we included “growth factor” in the search terms, this, in fact, refers to “transforming growth factor” (e.g., TGF- $\beta$ ) and “hematopoietic growth factors” (e.g., GM-CSF, G-CSF, IL-3), which are also cytokines. One study investigated immune responses in autism compared with controls and included

**FIGURE 1**  
PRISMA flow diagram displaying the different stages of this systematic review and the number of records identified in each stage.

other subgroups with and without gastrointestinal complications (66). As we were interested in results on autism as compared with controls in this review, we excluded results from the subgroups that included gastrointestinal complications (66).

Based on the results from Tables S3 and S4, we identified findings that were consistently reported in at least three references. We generated three tables that focused on basal cytokine levels (Table 1), levels of cytokines produced by immune cells (Table 2), and the percentage of the immune cell population (Table 3) in autism relative to controls. A final list of

the 62 studies, which formed the basis of this review, is included in Tables 1–3 and described in the data summary section.

## Study population and sample analysis methods

We have included a detailed description of the study population and analysis methods in Tables 1–3, based on the data extracted from individual studies in Supplementary Tables S3 and S4. Data

TABLE 1 Baseline levels of cytokines in the blood of individuals with autism compared with controls.

Cytokine affected	Sample type	No. of studies	Age range (in years) (mean $\pm$ SD)		Total sample size		% Males	Reported findings in autism compared with controls (in at least N = 3 references)		
			Autism	Controls	Autism	Controls		$\uparrow$	$\downarrow$	$\approx$
IL-6	Plasma and serum	12	2 to 21 (6.85 $\pm$ 2.21)	2 to 21 (7.04 $\pm$ 2.08)	540	470	86;75	(22–28)		(29–33)
	Plasma	4	3 to 8 (6.78 $\pm$ 2.73)	3 to 8 (6.36 $\pm$ 2.43)	134	122	85;73			(29–32)
	Serum	5	2 to 21 (5.91 $\pm$ 1.82)	2 to 21 (6.60 $\pm$ 1.97)	244	202	86;74	(22–26)		
IL-17	Plasma	5	2.1 to 11.8 (7.11 $\pm$ 2.35)	2.6 to 12 (6.83 $\pm$ 2.41)	200	168	82;71			(29–31, 34, 35)
	Serum	3	3 to 14.5 (6.70 $\pm$ 1.86)	3 to 11 (7.06 $\pm$ 1.56)	127	98	89;83	(22, 33, 36)		
TNF- $\alpha$	Plasma and serum	13	2 to 21 (6.18 $\pm$ 2.29)	2 to 21 (7.03 $\pm$ 2.17)	615	446	84;70	(24, 29, 33, 37–40)		(25, 27, 30–32, 41)
	Plasma	3	3 to 8 (6.67 $\pm$ 2.34)	3 to 8 (6.23 $\pm$ 1.92)	94	87	89;77			(30–32)
	Serum	5	2 to 21 (5.23 $\pm$ 2.11)	2 to 21 (7.33 $\pm$ 2.51)	156	142	84;64	(24, 33, 37, 38, 40)		
IL-1 $\beta$	Plasma and serum	15	2 to 21 (6.43 $\pm$ 2.63)	2 to 21 (7.08 $\pm$ 2.31)	659	496	85;73	(23–25, 27, 33, 37, 42, 43)		(22, 29, 30, 32, 40, 41, 44)
	Plasma	4	NR (8.08 $\pm$ 3.80)	NR (7.43 $\pm$ 2.93)	119	102	83;80			(29, 30, 32, 44)
	Serum	6	2 to 21 (5.25 $\pm$ 1.95)	2 to 21 (5.76 $\pm$ 1.81)	243	202	84;70	(24, 25, 33, 37, 42, 43)		
IFN- $\gamma$	Plasma and serum	11	1.58 to 14.5 (6.02 $\pm$ 2.21)	2.3 to 12 (7.00 $\pm$ 2.08)	564	374	88;73			(22, 25, 27, 29–31, 33, 39–41, 45)
	Plasma	10	2.2 to 16 (6.98 $\pm$ 2.51)	2.3 to 16 (6.61 $\pm$ 2.30)	474	344	85;77	(32, 46, 47)		(27, 29–31, 39, 41, 45)
	Serum	4	2 to 14.5 (5.17 $\pm$ 1.87)	3 to 16 (7.55 $\pm$ 1.63)	154	92	93;71			(22, 25, 33, 40)

Symbols: ↑, increased; ↓, decreased; ≈, unchanged; in autism compared with controls. CD, cluster of differentiation; NK, natural killer.

related to the study population include age, total sample size, and sex, whereas data related to the analysis methods include sample type, *in vitro* stimulus, and analysis technique.

Overall, the mean age and age range of the study population in this review were comparable between the autism and control groups. The mean age  $\pm$  standard deviation (SD) was  $7.06 \pm 0.70$  and  $7.17 \pm 0.46$  years for the autism and control groups, respectively. In Table 1, the age of subjects ranged from 2 to 12 years, apart from seven studies in which subjects reached 13, 14, 16, 21, and 28 years (22–24, 40, 46, 48, 49). Studies on MCP-1 and MIP-1 $\alpha$  bloodspots were performed using neonatal samples (7, 8, 10, 11). In Tables 2 and 3, the age of subjects ranged from 2 to 12 years, except in a few studies in which the subjects' ages reached 15, 17, and 56 years (Table 2) (55, 68, 72) and 14.5 and 56 years (Table 3) (22, 72). Regarding gender distribution, most of the studies in Tables 1–3 involved the recruitment of male subjects (at least 70% of total subjects), which was similar between the autism and control groups. However, in a few studies, the overall percentage of male subjects only reached 67%, 64%, 59%, and 32% in the control group (Tables 1 and 2).

Meanwhile, the sample type was either plasma or serum for all cytokines included in Table 1, except the bloodspot samples used in the MCP-1 and MIP-1 $\alpha$  analyses. The sample types were blood immune cells, including peripheral blood mononuclear cells (PBMCs), neutrophils, monocytes, T cells, and natural killer (NK) cells in Table 2 and T cells, monocytes, B cells, and NK cells in Table 3. The techniques used in the analysis of the samples in Table 1 were either ELISA or cytokine multiplex, as listed in

Supplementary Table S4. The analysis techniques for samples in Tables 2–3 include flow cytometry, ELISA, cytokine multiplex, qPCR, and western blot, as illustrated in Supplementary Table S3.

The stimuli used in the *in vitro* poststimulation studies are shown in Table 2. Different types of stimuli were used to assess cytokine production from various immune cells in autism, as compared with the control group. Studies on PBMCs and CD4+ T cells consistently showed differential responses from these cells in autism when stimulated with PMA/ionomycin and anti-CD3/CD28, respectively, as compared with the control group (61, 63, 69, 70). However, studies that used LPS, PHA, PGN or tetanus toxoid to stimulate PBMCs showed conflicting results, which might be due to differences in the type of cytokines analyzed in these studies (42, 64, 66, 67, 70, 71, 74). Therefore, the use of PMA/Ionomycin and anti-CD3/CD28 to stimulate PBMCs and CD4+ T cells, respectively, may represent a good model for studying cytokine production in autism. However, it should be noted that PMA/Ionomycin is a potent stimulant that bypasses receptor-mediated signal transduction mechanisms and directly activates intracellular signaling pathways that result in the production of various cytokines. Meanwhile, monocytes stimulated with LTA, neutrophils stimulated with IL-17A, and NK cells stimulated with IL-12/IL-18 or K562 cells showed differential responses in each of these cell types in autism, as compared with the controls (45, 56, 72, 73). However, the number of studies on these cell types is still limited, which makes it difficult to predict whether these stimuli can be effectively used for studying cytokine production in these cell types in autism.

## Data summary

In this review, we found that IL-6, IL-17, TNF- $\alpha$ , and IL-1 $\beta$  were increased in the serum but unchanged in the plasma in subjects with autism (Table 1). Interestingly, the increase in IL-6, IL-17, TNF- $\alpha$ , and IL-1 $\beta$  in the serum was in accordance with the elevated levels of these cytokines in *in vitro* stimulated neutrophils, monocytes, and CD4+ T cells in individuals with autism, as compared with controls (Table 2). Additionally, the levels of IL-6 and IL-17, but not TNF- $\alpha$  and IL-1 $\beta$ , were consistently higher in the unstimulated neutrophils, monocytes, and CD4+ T cells in autism subjects, as opposed to the controls (Table 2).

Meanwhile, studies have shown conflicting results for IFN- $\gamma$ , as it is not only reported to be both increased and unchanged in plasma but also unchanged in the serum of subjects with autism (Table 1). This discrepancy in IFN- $\gamma$  levels is also found in the response of blood immune cells after *in vitro* challenge, in which studies have delineated both increased and decreased IFN- $\gamma$  levels in post-stimulated NK cells and CD4+ T cells, in addition to consistently increased levels in NK cells under baseline conditions (Table 2).

Likewise, reports on TGF- $\beta$  are also conflicting, whereby it was found to be both increased and decreased in the plasma of autism subjects (Table 1), and little or no data pertaining to its cell of origin for autism are available. The two isoforms of TGF- $\beta$  ( $\beta$ 1 and  $\beta$ 2) as well as the functional forms of TGF- $\beta$  were treated equally during our data synthesis, which might have accounted for the variability observed in the TGF- $\beta$  results (Table 1).

Studies have indicated an increase in the cytokine levels of RANTES and IL-8 relative to controls in subjects with autism (Table 1). In addition, reports consistently delineate unchanged IL-13, IL-10, IL-5, and IL-4 levels in the plasma/serum and post-stimulated blood immune cells in individuals with autism as compared with controls (Tables 1 and 2). Other cytokines, IL-12, IL-2, MCP-1, MIP-1 $\alpha$ , GM-CSF, and eotaxin, were unchanged in the plasma of subjects with autism (Table 1).

Interestingly, the overall reported outcomes described above are unlikely to be caused by changes in the percentage of immune cells in subjects with autism compared with controls. As shown in Table 3, the frequency of CD3+ T cells and their subsets, CD4+ and CD8+ cells, as well as the frequency of monocytes, B cells, and NK cells were comparable between subjects with autism and controls. This might indicate that increased cytokine levels are not due to differences in immune cell numbers but rather due to the abnormal functional responses of these immune cells in individuals with autism as compared with controls. Based on the results in Tables 1 and 2, we present a schematic diagram illustrating our proposed model for the immune cells of origin of the altered cytokines in autism (Figure 2).

## Discussion

This systematic review was undertaken to investigate alterations in peripheral blood cytokines in autism and

identify the immune cells contributing to abnormal cytokine profiles in individuals with this disorder. We focused on findings that showed a difference between autism and control subjects. Remarkably, we identified a list of specific cytokines that were altered in both plasma and serum, as well as in *in vitro* stimulated blood immune cells in autism. Collectively, we found increased levels of IL-6, IL-17, TNF- $\alpha$ , IL-1 $\beta$ , IFN- $\gamma$ , RANTES, and IL-8 in the plasma/serum in autism, which is overall consistent with the findings from previous systematic reviews (18, 19). We reviewed autism studies that investigated cytokine production by *in vitro* stimulated blood immune cells and identified monocytes, neutrophils, CD4+ T cells, and NK cells as the major cellular sources of these altered cytokines. Conversely, we found TGF- $\beta$  to be both increased and decreased in the plasma of patients with autism relative to controls, and there is as yet no conclusive evidence concerning its cellular sources. Interestingly, the immune cells identified in our review that produce certain cytokines in autism are also known to produce these cytokines. In this review, we also found that the percentage of the immune cell population is consistently unaltered in autism, suggesting that abnormal cytokine levels might be due to changes in the functionality or activation status of these cells rather than their numbers in autism.

In this review, we found elevated levels of IL-6, TNF- $\alpha$ , and IL-1 $\beta$  in the plasma/serum of individuals with autism. IL-6, TNF- $\alpha$ , and IL-1 $\beta$  are early proinflammatory cytokines released from immune cells in response to inflammatory stimuli. Importantly, these cytokines can cross from the peripheral blood into the brain, where they directly affect brain function and behavior (6, 16, 17). Previous studies have shown that high levels of IL-6, TNF- $\alpha$ , and IL-1 $\beta$  are correlated with the severity of autism symptoms, which include stereotypical behaviors and impaired communication skills (27, 33, 43, 45, 52). Interestingly, we found some evidence in our review for the potential cellular sources of these cytokines in autism. Elevated IL-6 levels have been described in monocytes and neutrophils at both baseline (56, 60) and after *in vitro* stimulation (45, 56) in autism, whereas augmented TNF- $\alpha$  levels have been described only in the post-stimulated monocytes of individuals with autism (45). In addition, IL-1 $\beta$  levels are markedly increased in post-stimulated monocytes and CD4+ T cells in autism (45, 70). Altogether, we suggest that monocytes are the predominant cells contributing to the elevated cytokine levels of IL-6, TNF- $\alpha$ , and IL-1 $\beta$  in autism, along with CD4+ T cells, which act as another source of IL-1 $\beta$ , whereas neutrophils are another source of IL-6. Previous studies have shown that TNF- $\alpha$  enhances T cell proliferation, augments IL-2R (interleukin-2 receptor) on T cells, and sustains T cell survival during the initiation of T cell responses (81). Similarly, IL-1 $\beta$  acts synergistically with IL-2 to promote the expansion of CD4 and CD8 T cells (82) and induces a robust and durable primary and secondary CD4 response (83). Therefore, we suggest that elevated TNF- $\alpha$  and IL-1 $\beta$  levels would promote naïve

FIGURE 2

Schematic representation of our proposed model of peripheral immune dysregulation in autism. Activated monocytes produce high amounts of the triad of proinflammatory cytokines, TNF- $\alpha$ , IL-1 $\beta$ , and IL-6. Accordingly, TNF- $\alpha$  and IL-1 $\beta$  promote the activation, priming, and proliferation of naive and effector T cells, whereas IL-6, in the presence of dysregulated levels of TGF- $\beta$ , drives the polarization of naive T helper (Th0) cells into effector Th17 subsets. The latter produces its signature cytokine IL-17, which initiates several events that result in neutrophil recruitment and activation (80). Neutrophils in individuals with autism produce IL-17 and IL-6, which add to the observed large pool of IL-17 and IL-6. In addition, naive T helper (Th0) cells under the influence of cytokines in the milieu differentiate into Th1 cells, which impart high IFN- $\gamma$  levels and enrich the IL-1 $\beta$  pool. Natural killer (NK) cells, on the other hand, tend to be dysfunctional in autism and chronically produce IFN- $\gamma$ , which augments the IFN- $\gamma$  pool. Furthermore, the high levels of the chemotactic factor RANTES might be derived from activated monocytes, T cells, or NK cells, whereas IL-8 might be produced by monocytes and neutrophils, and function to recruit cells to the scene. The solid arrows represent confirmed findings in the tables we formulated, whereas the dashed arrows are based on well-known facts in the literature that we suggest occur in the context of autism. Created using [BioRender.com](https://www.biorender.com)

T helper (Th0) cell proliferation and expansion in the context of autism, as illustrated in our proposed model in [Figure 2](#).

However, results for TGF- $\beta$  are conflicting, whereby it is reported to be both increased (39, 46, 48) and decreased (35, 50, 51) in the plasma of individuals with autism, and there is scarce evidence concerning its cell of origin in autism. This discrepancy in TGF- $\beta$  results might be due to differences between the studies in the isoforms or functional forms being assessed. TGF- $\beta$  exists in three isoforms ( $\beta$ 1,  $\beta$ 2, and  $\beta$ 3), which are structurally similar and share approximately 71%–79% sequence identity (84, 85). Although the three isoforms show similar functions *in vitro*, isoform-specific knockout mice show phenotypic differences, suggesting distinctive functions for these isoforms *in vivo* (84, 85). Unlike other cytokines that are produced in their active forms, TGF- $\beta$  is secreted in an inactive form and stored in the extracellular matrix as a latent complex with its prodomain, which can then be converted into the active form through multiple mechanisms (86). In this review, studies showing decreased TGF- $\beta$  levels specifically involved the TGF- $\beta$ 1 isoform (35, 50, 51), whereas increased levels of TGF- $\beta$  were

found for either the TGF- $\beta$ 2 or TGF- $\beta$ 1 isoform (39, 46, 48). Among these studies, only the functional form of TGF- $\beta$  was reported in some studies, in which the activated form of TGF- $\beta$  was specifically analyzed (35, 46, 50). Based on this evidence, we speculate that the activated TGF- $\beta$ 1 isoform is decreased, whereas the activated TGF- $\beta$ 2 isoform is increased in autism, which needs to be further investigated in future studies.

Given the dysregulated levels of TGF- $\beta$  in autism, we speculate that this dysregulation may disrupt several immune processes in autism. TGF- $\beta$  is an immunosuppressive cytokine produced by the immune system guardian-regulatory T (Treg) cells, which maintain immune homeostasis (49, 50) and are involved in diverse cellular functions, including the promotion of cell growth, proliferation, and differentiation (18). Alternatively, TGF- $\beta$  can empower naive T cell differentiation into effector T helper 17 (Th17) cells (87, 88), which are important for host defense and associated with inflammation and autoimmune conditions (89). This highly dynamic function of TGF- $\beta$  is contextual; when it is produced in the presence of IL-6, TGF- $\beta$  directs Th17 cell development and differentiation (90, 91) whereas when it is produced in the presence of IL-2, TGF- $\beta$  promotes the

development of induced regulatory T cells (92). Therefore, we suggest that dysregulated TGF- $\beta$  levels, together with elevated IL-6 levels, may disrupt immune homeostasis in autism and affect Th17 cells, as shown in our proposed model in [Figure 2](#).

In this review, we found evidence of increased IL-17 levels in the serum of subjects with autism (22, 33, 36). Interestingly, previous studies have shown that IL-17 signaling is responsible for autism-like symptoms in the offspring of maternal immune-activated mice (93, 94). From the studies we included, we identified neutrophils (56) and CD4+ T cells (62) as potential sources of IL-17 in the steady state of autism, in addition to IL-17 production by stimulated CD4+ T cells (62–64). IL-17 exerts important functions on T cells and neutrophils, including priming T cells and acting on neutrophils to promote the production of the proinflammatory cytokines IL-1, IL-6, and TNF- $\alpha$  (95). Although neutrophils are recruited to inflammatory sites under the influence of chemokines induced by IL-17 (80), they can become the main producers of IL-17 under certain circumstances, as in the case of kidney ischemia-reperfusion injury (96). The biological activity of IL-17 relies on the formation of multimeric receptors composed of IL-17RA and IL-17RC subunits (80). Interestingly, neutrophils of individuals with autism were found to express the IL-17RC subunit, which was absent in the neutrophils of control subjects. This enabled neutrophils to potently respond to IL-17A/IL-17R signaling and release IL-6 (56), leading to increased IL-17 production in autism. Taken together, these results suggest that Th17 cells and neutrophils are potential sources of upregulated IL-17 levels in autism ([Figure 2](#)).

Furthermore, we found increased levels of RANTES, IL-8, and IFN- $\gamma$  in the plasma/serum of subjects with autism. However, there is still no clear evidence concerning the cellular sources of RANTES and IL-8 in our review. Given that RANTES is mainly produced by T cells, monocytes, and NK cells (97), we suggest that these cells also produce RANTES in autism ([Figure 2](#)), which does not exclude the possibility of the presence of other sources. Meanwhile, IL-8 is produced by monocytes and neutrophils, and we propose that these cell types in the circulating blood might also be potential sources of IL-8 in autism ([Figure 2](#)). In contrast, our review identified elevated production of IFN- $\gamma$  in *in vitro* stimulated CD4+ T cells (70) and NK cells in the basal state in autism (72, 73). However, reduced levels of IFN- $\gamma$  were observed in NK cells in autism after introducing an external stimulus, such as IL-12/IL-18 or K562 target cells (72, 73). These observations suggest that NK cells in autism are persistently activated and produce abnormal amounts of IFN- $\gamma$  under baseline conditions; however, they tend to be hypofunctional (exhausted) after an *in vitro* immune challenge. Interestingly, the same NK cell phenotype has also been reported in other psychiatric disorders, including obsessive-compulsive disorder, chronic stress, and depression (98, 99). Future studies are needed to further investigate the exhausted NK cell phenotype in autism, where this phenotype might be representative of a subpopulation of subjects with autism.

It is worth mentioning that the studies presented in this review suggest the prevalence of T helper 1 (Th1) and Th17 phenotypes rather than the Th2 phenotype in autism. CD4+ T helper (Th) cells are subdivided into different subsets distinguished by their unique transcription factors and cytokine production. These subsets include IFN- $\gamma$ -producing Th1 cells, IL-4-producing Th2 cells, IL-17-producing Th17 cells, and Foxp3-expressing Treg cells. Importantly, T helper cell differentiation toward a specific subset actively inhibits the transcriptional program of the other subset and its ability to produce characteristic cytokines (100). Therefore, our findings indicate that increased production of Th1 cytokines (IFN- $\gamma$ ) and Th17 cytokines (IL-17), along with no change in Th2 cytokines (IL-4, IL-5, and IL-13), might suggest a skewing toward the Th1/Th17 phenotype and dampening of the Th2 phenotype in the context of autism ([Figure 2](#)). Interestingly, Th1 cytokines were shown to be associated with autism severity and impaired behavior, whereas Th2 cytokines were correlated with better behavioral and developmental scores (67).

In addition, there are some limitations that should be considered in our systematic review. We restricted our search to articles written in English only and, thus, may have neglected results from articles in other languages. Other limitations include differences in the age range of subjects among the different studies, in addition to technical variations, such as the use of different analysis methods, sample types, and *in vitro* stimuli, which together might have contributed to the variability in the observed results across studies. The overall age range of subjects from the studies included in this review was between 2 and 12 years; however, it is important to emphasize that the immune system undergoes dynamic changes during this developmental period from early childhood to adolescence (101), which might introduce some variability when combining results from different studies. Therefore, future studies should consider restricting the age range of subjects for a more comprehensive understanding of immune changes in autism.

In our review, we also observed differences in some cytokines when measured in serum versus plasma samples, which is also supported by previous studies (102–104). This inconsistency in the results between plasma and serum might be attributed to differences in the preparation methods for these sample types. Serum samples are obtained after blood coagulation, whereas the preparation of plasma samples involves the use of various anticoagulants that affect cytokine measurement (102–104). Although the studies included in this review have used standard methods for cytokine detection, such as ELISA, cytokine multiplex, or flow cytometry, significant differences might still exist regarding sample handling and processing methods, the analysis platforms used, and the sensitivity and specificity of the antibodies used across different studies. In addition, there are variations in the type of *in vitro* stimuli, such as LPS, PHA, or PGN, used in PBMCs culture models, which could lead to variations in cell responses.

Currently, there are a limited number of studies investigating cytokine production at the level of a specific immune cell type in autism, and much of the present evidence pertains to total PBMCs.

Although we found consistent results regarding the type of altered cytokines produced by blood immune cells in autism, these results were not representative of a specific immune cell type and may include results from PBMCs. In addition, the results presented in this review and the proposed model are based on currently available evidence from the autism literature; therefore, it does not exclude the fact that other cellular sources, such as innate lymphoid cells and NK T cells, although present in very small numbers in the circulating blood, might also contribute to the production of IL-17, IFN- $\gamma$ , and other T cell cytokines, which have yet to be investigated. Furthermore, endothelial cells and tissue-resident cells are other potential sources for cytokine production, however we focused in our review on peripheral immune cells in the circulating blood in autism, which are less invasive and have current evidence in the literature. Finally, most of the studies included in this review were cross-sectional in nature and lacked details of the clinical features and comorbid conditions of autism subjects, which can be considered other limitations of the current studies in the field. These highlight the need for more longitudinal analyses in future studies in a well-characterized study population for more accurate detection of time-dependent changes in immune phenotypes in autism and their correlation with clinical and behavioral changes in autism.

## Conclusions

This systematic review supports the existing evidence of abnormal cytokine levels in the peripheral blood of individuals with autism. Given that cytokines are ubiquitous molecules circulating in the bloodstream, determining their cellular sources is crucial for targeted therapeutics. To our knowledge, this is the first review to identify the potential immune cells of origin of the altered cytokines in autism, and we propose a network model that integrates these altered cytokines and their specific cellular sources in autism. Although certain areas presented in this review still lack solid evidence, this review summarizes the current knowledge in the field and highlights the gaps that need to be considered in future studies. Most current studies on autism have focused on cytokine levels in the blood or analyzed cytokine production from a population of PBMCs. We emphasize the importance of future studies on autism to further elucidate immune sources of altered cytokines at the single-cell level and combine multi-omics approaches, such as proteomics, cell phenotyping, and single-cell transcriptomic analyses, which may reveal cell-specific immune pathways underlying autism. Since autism is a heterogeneous condition, immune phenotypes may vary widely within a group of subjects with autism. Future studies should consider the utilization of advanced bioinformatics and machine learning techniques to segregate autism groups into different subgroups based on their exhibited immune and clinical phenotypes, which might also lead to the identification of novel characteristics of subclusters of subjects with autism for a better understanding of the pathophysiology of autism.

## Data availability statement

The original contributions presented in the study are included in the article/[Supplementary Material](#). Further inquiries can be directed to the corresponding author.

## Author contributions

AA-S conceived the review. WN-E, SL, NM, and AA-S collected and summarized the review data. WN-E and AA-S wrote the manuscript. All authors contributed to the article and approved the submitted version.

## Funding

This publication was made possible by ECRA Award number ECRA01-001-3-001 from the Qatar National Research Fund (a member of Qatar Foundation), and start-up fund from Qatar Biomedical Research Institute (Grant code VR03).

## Acknowledgments
